Phytophthorols–Novel Lipids Produced by *Phytophthora cactorum*

W. David Nes*
Plant and Fungal Lipid Group, Plant Development and Productivity Research Unit, USDA, ARS, Western Regional Research Center, Albany, CA 94710

Lipid-phytophthorols are a series of saturated and unsaturated odd chain fatty alcohols (C_{17}-C_{21}) esterified to myristic acid (14:0) with each possessing two hydroxyl functions in a 1,2-diol relationship centered toward the ester terminus. They have been identified, and their biosynthetic relationship to other fatty acid and alcohols produced by *Phytophthora cactorum* have been determined. Because phytophthorols are crystalline materials and elute in TLC and HPLC with sterols, an architectural function is implied. In the absence of cholesterol, dietary phytophthorol failed to induce reproduction.
***Lipids 23,* 9–16 (1988).**

There are cogent reasons to believe that fatty acids play multiple roles: structural and reserve energy components of mycelia and spore, and in developmental regulation of the Oomycetes life cycle (1–3). However, the physiological importance of accumulating select acyl lipids, or producing additional end products derived from the pathway, e.g. very-long chain fatty alcohols (VLFA) and prostaglandins, is not clear. We have considered the possibility that the genes that control fatty acids, alcohol biosynthesis and metabolism are distributed generally throughout the oomycetous fungi. However, their expression is developmentally and compartmentally regulated so that the fitness (structure and amount) for one or more acids and alcohols to act functionally is temporally coordinated and selected by the different taxa as a result of Darwinian evolution. In order to pass through one life cycle or switch from one developmental stage into another, the organism must utilize specific fatty acids and alcohols with each one (or groups) occurring at some threshhold level in an appropriate architectural fraction and at a proper time in relation to other compounds, e.g. sterols.

In our studies with the Oomycetes, we earlier observed that the mycelia of *Phytophthora cactorum* produced a range of fatty acids and alcohols (4–6). The utility of some of these lipids in mediating growth and reproduction is presented in the present communication. Previously, [2-^{14}C]acetate supplied to *P. cactorum* was shown to be incorporated into acyl polar lipids, i.e. phospholipids and sphingolipids, triglycerides, VLFA and what appeared to be a steroidal compound based on its chromatographic behavior (4–6). However, we also had shown that the fungus lacked a completed sterol pathway (7,8). The results reported here describe the identification, biosynthesis and possible function of this unknown compound(s), which is(are) shown to be lipid but nonsteroidal. The physiological significance and biosynthetic interrelationships of the unknown lipids with other lipids produced by Oomycetes also is discussed.

MATERIALS AND METHODS

Organism. P. cactorum (University of California, Berkeley strain 51–22) was grown on a completely defined media (9). Growth was initiated by seeding the flasks with mycelia previously cultured on lipid-free media. For studies on reproduction, agar was added to solidify the media (10). Agar, which is derived from algae, retains after industrial processing, sterol (7) and unsaturated fatty acids (Nes, unpublished). The cultures routinely were monitored visually for fungal and bacterial contamination. Had a fungal spore been introduced into the cultures, ergosterol would have been detected; none was observed.

Chemicals. [1-^{14}C]Palmitic acid (55 mCi/mMol) was purchased from Amersham, Searle, Arlington Heights, IL. Methyl ester fatty acid standards were purchased from Supelco, Bellefonte, PA. Sterol and VLFA standards previously were prepared in this laboratory (11). Solvents were either redistilled reagent-grade or high-performance liquid chromatography-(HPLC) grade.

Lipid extraction and analysis. Mycelia were cultured at 20 C in the dark in 250 ml flasks supplemented with 50 ml media for two to three wk without shaking as previously described (10). For reproductive studies, agar-solidified media were dispensed into petri dishes (7). The wet mycelia were harvested and then ground with sea sand and acetone, and the material was extracted in a Soxhlet apparatus overnight with refluxing acetone. The acetone extract was applied as a band onto a thin layer chromatography (TLC) plate (developed in benzene-ether, 9:1) and bands matching the origin (polar lipids: phospholipids, glycosides and free acids), ester or front region, and R_f: 0.3 to 0.4 (cholesterol standard), 0.4 to 0.45 (lophenol standard) and 0.48 to 0.56 (lanosterol and triacontanol standards) were eluted from the plate with a series of solvents-chloroform/methanol, hexane, ether and benzene. The TLC bands were made visible by spraying the plates with an aqueous solution of H_2SO_4 followed by charring. When radioactive material was used in the incubations, the eluted zones were transferred to scintillation vials, and the solvent was removed by a stream of nitrogen. Diphenyloxanzole-benzene (POPOP) cocktail (5 ml) was added to the vial and the radioactivity determined using a scintillation counter at 90% efficiency for ^{14}C (11). The media was extracted three times with diethyl ether; the combined ether extracts were analyzed immediately by TLC and gas liquid chromatography (GLC).

To determine the fatty acid content, each of the materials eluted from the five TLC zones was reacted with BF_3 in methanol and the resultant methyl esters chromatographed on packed (Hi-Eff and carbowax columns) and

Abbreviations: AA, [1-^{14}C]arachidonic acid; CI, chemical ionization; EI-MS, electron impact-mass spectra; EPA, eicosapentaenoic acid; FT, Fourier transform; GC-MS, gas chromatography-mass spectrometry; GLC, gas liquid chromatography; HPLC, high performance liquid chromatography; LAH, lithium aluminum hydride; OH, hydroxyl; POPOP, diphenyloxanzole-benzene; RP-HPLC, reversed-phase-high performance liquid chromatography; TLC, thin layer chromatography; VLFA, very long chain fatty alcohols.

capillary (DB5-30 m) columns. The elution times of the samples on the various columns were compared with the times of transmethylated fatty acid standards. Molecular weights were verified by gas chromatography-mass spectrometry (GC-MS). Packed columns were operated isothermally at 180 C; for the capillary column, a temperature program run was employed; column temperature was programmed at a linear rate of 5 C/min from 175–225. The configuration of the double bands of oleic acid, 18:1 (Δ^9-*cis*); linolenic acid, 18:2 ($\Delta^{9,12}$*cis,cis*) α-vs-γ-linoleic acid 18:3 ($\Delta^{9,12,15}$ vs $\Delta^{6,9,12}$); and arachidonic acid, 20:4 ($\Delta^{5,8,11,14}$ all *cis*) were determined by co-chromatography of the methyl esters on $AgNO_3$ TLC plates with authentic standards (10% Ag^{++} impregnated into silica developed with hexane-benzene or chloroform) and then by GLC of the eluted bands using carbowax and capillary columns.

The TLC bands at R_f–0.3 to 0.5 also were examined by GLC without saponification, using 3% SE-30 and 3% OV-17 packed columns in which the columns were operated isothermally or in the same temperature program mode (240 to 280 C at 0.5 C/min); retention times (at 245 C) were relative to cholesterol, RRT_c.

GC-MS and direct probe-MS were carried out with a VG-micromass 70/70-HS mass spectrometer equipped with a Hewlett Packard 5880 GC. Electron ionization (EI) spectra were determined at 70 electron volts with the ion source temperature at 150 C. Chemical ionization spectra were obtained using isobutane. A Nicolet 200 operating in the Fourier transform (FT) mode at 200 MHz was used to obtain the ^{1}HNMR spectra of samples dissolved in deuterated chloroform. Acetate (acetic anhydride/pyridine or via diazomethane) and trimethyl silyl ether (Me_3Si) derivatives were prepared by standard methods. Reversed-phase HPLC was performed using a C_{18} column eluted with 4% aqueous methanol. The pump speed was set at 1.6 ml/min and the detector set at 205 nm. Fractions were collected every min, cholesterol elutes in 24 min and docosanol (C_{22}) elutes in 19 min. Sitosterol and higher long-chain fatty alcohol homologues (C_{24} and C_{26}) eluted in the 26 and 40 min fractions.

RESULTS

Phytophthorol identification. The mycelial acetone extract of *P. cactorum* yielded five major TLC zones at R_f: 0.00, 0.35, 0.41, 0.53 and 0.96. When the acetone extract was hydrolyzed with 10% methanolic KOH the TLC zones at R_f 0.35 and 0.41 disappeared. This immediately suggested that the material at R_f 0.35 and 0.41 was neither a triterpenoid nor a steroid. The combined materials at R_f 0.35–0.43 were crystalline rather than oily and possessed a broad melting point ca. 75–80 C. The unsaponified materials that migrated at R_f 0.43 were examined further by GLC. Two major peaks were evident in a chromatogram that ran substantially after sterols and triterpenoids, viz. RRT_c – 3.77 and 6.20 on OV-17 packed columns operated at 245 C. In the temperature program mode, multiple peaks were detected (Fig. 1). The GLC peaks appeared successively by C_2H_4 homologues as indicated by comparison of semilogarithmic plots constructed on the unknowns profile (C-length vs retention time) with similar plots constructed using VLFA. GC-MS of the three major peaks (ms obtained at center of peak) produced spectra with M^+ – 494, 522 and 550, respectively. High-resolution mass measurements of the three compounds indicated formulas of $C_{31}H_{60}O_4$, $C_{33}H_{64}O_4$ and $C_{35}H_{68}O_4$, respectively. Hydrolysis of the unknowns followed by acidification (6 N HCl) of the aqueous extract and then esterification (BF_3-methanol) of the heptane extractable material produced a single compound that co-chromatographed with myristic acid (14:0) in GLC. At this point, the unknowns at R_f 0.35 and 0.46 were believed to be a series of fatty acid derived compounds that possessed an acid and alcohol portion with an ester linkage. Since we found only a single fatty acid, the homologation presumedly was due to changes in the alcohol rather than the acid portion. We assumed the polar TLC-mobility was due to OH-groupings in the alcohol portion. If it was an ester compound, the material would have run to the front of the TLC.

In an earlier study, we observed that radioactivity from a [2-^{14}C]acetate feed to *P. cactorum* was incorporated into unknown materials that co-chromatographed with sterols in TLC (4) and reversed-phase high-performance liquid chromatography (RP-HPLC) (Nes, unpublished). When the material, which chromatographed at R_f–0.4, was injected into the HPLC and the fractions collected where sterols normally elute (24 to 28 min), only one principal homologue was detected by GLC (M^+-494). Its electron impact-mass spectra (EI-MS) is shown in Figure 2. The GC-MS of this material using the capillary column indicated a minor compound eluting in the tail with M^+-492. This compound was not evident readily, using the packed columns in GC-MS (EI-MS of the Me_3Si derivative of the minor compound is shown in Figure 3). ^{1}HNMR, with assignment of the first major Phytophthorol eluting in GLC) now referred to as Phytophthorol-1; compound having M^+-494), exhibited chemical shifts at 0.87 (t,J = 6.0 Hz, terminal methyl on an aliphatic chain), 1.24 (S, internal aliphatic chain of CH_2), 2.36 (t,J = 6.5 Hz, CH_2 alpha to a carbonyl group), 4.14 (m,J = 9 Hz, CH_2 alpha to oxygen, thereby implicating an ester function), 5.09

and 5.36 (m,J = 3 Hz each, two hydroxyl groups in a 1,2-relationship) ppm. Although this phytophthorol failed to be acetylated by the acetic anhydride in pyridine method, it was acetylated with diazomethane. The spectra of the acetate showed the inclusion of an acetoxy group (2.04 ppm) and loss of the OH group by the absence of the chemical shift at 5.09 ppm. A TMS-derivative also was obtained, and the mass spectra supported the molecule having two acetylable hydroxyl groups (m^+-638). ^{1}HNMR of the Me_3Si-derivative—0.87

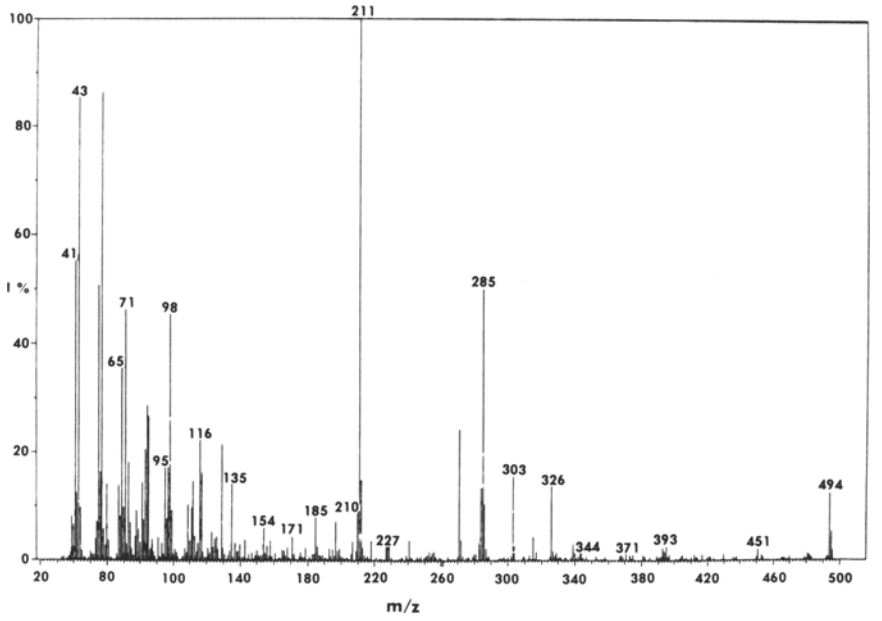

FIG. 2. EI-MS of the underivatized phytophthorol-1.

(t,J = 6 Hz), 1.24 (S), 2.43 (t,J = 4 Hz) and 4.76 (S). The peak at 4.76 ppm integrated to two protons, while the multiplet present at 4.15 ppm in the spectra of the free alcohol disappeared. These facts indicate the 2-OH groups are located close to the ester terminus. With only this information, the exact location and geometry of the two hydroxyl groups in the alcohol portion still was equivocal. The EI-MS of Phytophthorol-1 lacked any diagonistic fragments for the OH-groups. When Phytophthorol-1 was reduced with lithium aluminum hydride (LAH) and then chromatographed on reversed-phase TLC developed with methanol/H_2O (19:1), the alcohol portion (triol) migrated to R_f − 0.3. ^{1}HNMR of the sample showed a full proton (multiplet centered at 0.365 ppm, which represented the terminal OH). This material then was acetylated with diazomethane and a CI-probe obtained on the resultant derivative. Prominent fragments at m/z 403 (42%), 343 (5%), 283 (20%), 257 (20%), 227 (5%), 211 (2%), 199 (23%) and 171 (80%) characterized the hydrocarbon chain having three OH-groups. With the additional knowledge of the CI-probe data, the fragmentation pattern for the EI-MS of Phytophthorol-1 was assigned as shown in Figure 4. Phytophthorol-2 and 3 represent peaks 2 and 3 in the GLC (Fig. 1), which may be considered to be higher homologues based on the mass spectral data. Phytophthorol-4(C_{31}), 5(C_{33}) and 6(C_{35}) appear in the GLC tails of peaks 1, 2 and 3; they may be considered the unsaturated phytophthorols with the double bond located (site unknown) in the alcohol portion. Had it been in the acid portion of the esterified molecule, myristoleic acid (14:1Δ^9 *cis*) or some other suitable unsaturated fatty acid should have been detected by GLC of the transmethylated acid portion. The chromatographic and spectral data unambiquously show that the unknowns at R_f 0.46 are a homologous series of saturated and unsaturated odd-chain fatty alcohols (C_{17}-C_{21}) esterified to myristic acid (14:0), each possessing two hydroxy functions in a 1,2-diol relationship centered towards the ester terminals. These compounds (phytophthorols) are not waxy substances, and they lack interesterification common to estolide formation; therefore, a mycelial surface wax function seems unlikely. The unknowns at R_f 0.35 were found to be more highly hydroxylated phytophthorols; the location of the OH-groups currently are under investigation.

Biosynthesis of phytophthorol. When an aqueous suspension of 1 × 10^8 cpm [1-^{14}C]palmitic acid was distributed equally into two culture flasks, the growth of 18-day cultures was inhibited significantly (ca. 50% of the control cultures just entering into growth arrest). The acetone extract of the mycelia produced a radioactive sample having a specific activity per flask, 18 mg/2 × 10^7 cpm. The acetone extract was spread onto TLC plates and scanned for radioactivity as shown in Figure 5. The lack of an active incorporation of exogenous palmitate into the acetone extract and acyl lipids was not unexpected since the fungus synthesized this lipid as an end product. Similarly, in the sterol field we (12) and others (13,14) have shown dietary ergosterol (sterol end product) was not accumulated actively by Ascomycetes unless the more-advanced fungi were induced to become sterol auxotrophs. As shown in Figure 5, the [1-^{14}C]palmitate incubation produced only four radioactive zones: R_f 0.0, 0.35, 0.46 and 0.96, which sharply contrasted with the [2-^{14}C]acetate incubation to the fungus (4). The triacontanol band at R_f − 0.5, which in the earlier study was heavily labeled from [2-^{14}C]acetate, failed to incorporate

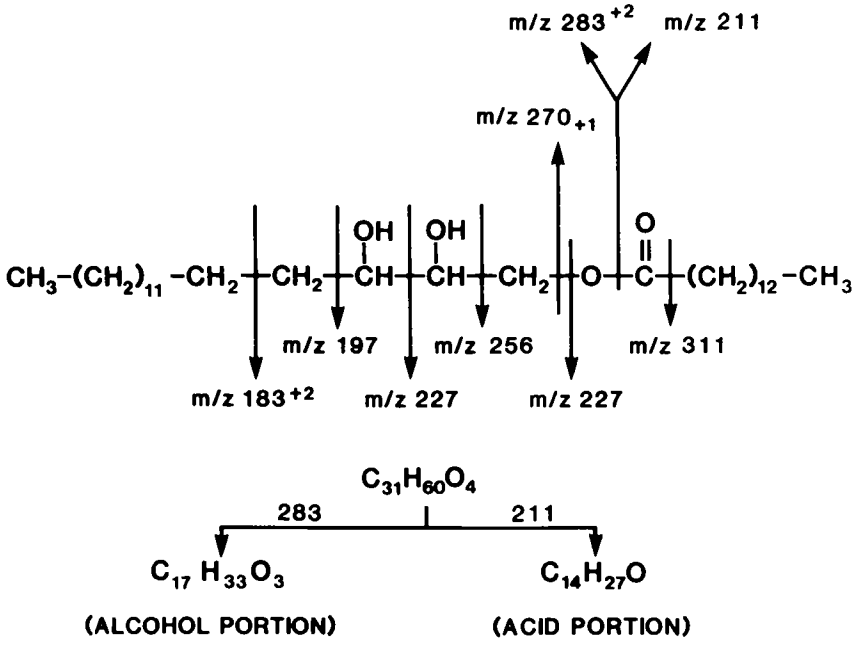

FIG. 4. Structure and mass spectral fragmentation assignment of phytophthorol-1.

detectable levels of ^{14}C from [1-^{14}C]palmitate. In order to be sure that a lower homologue in the VLFA series had not been radiolabeled (11), the material at R_f 0.4 was eluted from the plate and an aliquot reduced with LAH. Approximately 95% of the radioactivity remained at the origin when the reduced sample was chromatographed on TLC developed with benzene-ether. Both the myristic acid and alcohol fragments were converted to the monoalcohol by LAH reduction.

Since the acid fragment, now as the alcohol, moved off the origin to R_f − 0.3, leaving the triol alcohol fragment of phytophthorol at the origin, the radioactivity must be associated with the alcohol rather than the acid fragment. The material at the origin was eluted from the plate and converted to the TMS derivative. This derivatized sample together with all the radioactivity moved to the front of the TLC plate. ^{1}HNMR and GC-MS verified the chemical purity of the TLC sample as a mixture of the fatty alcohol homologues C_{17}-C_{21}. Another aliquot of the starting material at R_f 0.4 was injected into the HPLC; fractions were collected every minute for 40 min. No radioactivity appeared in the fraction corresponding to docosanol (a 19 min fraction). However, significant radioactivity appeared in the 24–28 min fractions corresponding to phytophthorol-1, followed by a few fractions in which the level of radioactivity was background. Radioactivity then appeared in subsequent fractions corresponding to the higher homologues. We have observed that docosanol can migrate into the R_f 0.4 zone under certain conditions (11). The absence of ^{14}C in the HPLC fractions corresponding to docosanol and the absence of radioactivity in the TLC-R_f 0.5 clearly show that [1-^{14}C]palmitate acid did not enter into the compartment for VLFA biosynthesis. These results differ from our other findings in which [^{14}C]palmitic acid was incorporated into VLFA produced by insects (15) and its conversion to VLFA by cell-free preparations of vascular plants (16,17).

Since [1-^{14}C]palmitic acid was incorporated into the C_{17}-alcohol, it must have been chain-elongated and then decarboxylated rather than decarboxylated before elongation. Otherwise, the radioactivity would have been lost; it was not. The media was extracted with diethylether, and the total transmethylated fatty acid composition and radioactivity was determined by GLC and TLC-radio scanning (Fig. 5). The fatty acids in the media were primarily C_{16}- and C_{18}-acids with zero and one double bond. The radioactive peak at the solvent front of the TLC plate presumably was a mixture of free acid and perhaps a trace as acyl polar lipids and prostaglandin-like materials. No labeled phytophthorols remained intact in the media, even if they were expelled with other acyl ester derivatives. A proposed biosynthetic scheme for phytophthorol-1 production from the dietary palmitic acid is shown in Figure 6.

Fatty acid esters produced by Phytophthora. Phytophthorols represent one form of fatty acid esters; other forms include acyl polar lipids and glycerides. Without sterol supplementation, logarithmically growing cultures produce ca. 0.1% dry wt phytophthorols. The total fatty acid content was approximately two orders of magnitude greater than the phytophthorol content, which was ca. 7% dry wt. The polar acyl lipids-phospholipids and sphingolipids (Nes, unpublished and [5]) and triglyceride content changed dramatically during the culture period; the fatty acids composition also changed. Triglycerides may have contained as much as 50–90% of the total esterified fatty acids, sphingolipids contained a predominance of 20:4 acid; triglycerides contain the range of acids and phytophthorols possessed a single acid, 14:0. When sterols were added to the fungus, steryl esters

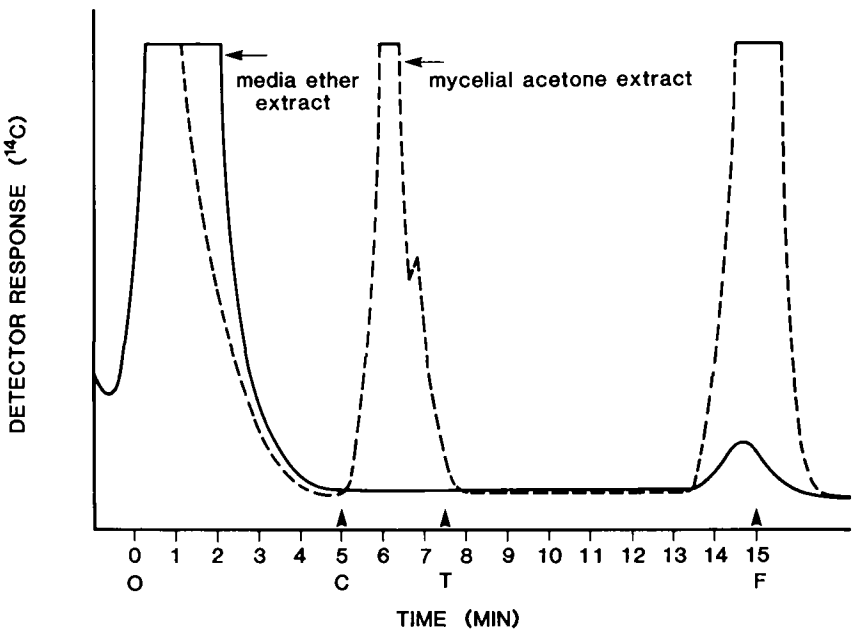

FIG. 5. TLC-radioscan of the mycelial acetone and media extracts of *P. cactorum* incubated for 18 days with [1-^{14}C]palmitate: O, origin; C, cholesterol band; T, triacontanol and lanosterol bands; F, front. TLC solvent system was benzene-ether, 9:1. Plates moved at 1 cm per min.

and acylated steryl glycosides were formed (18). The fatty acids esterified to these molecules were primarily C_{14} to C_{18} in length (19,20). In two studies on a related species of *Phytophthora* (infestans), high levels of C_{20} unsaturated acids were found to be associated with a TLC zone corresponding to steryl esters (21,22). Since the fungus was cultured under conditions in which sterol supplementation was not necessary, it was not clear whether sterol had been added to the media. If sterol had not been added, the identity of the sterol portion of the fatty acid of the sterol ester in the latter investigations would be suspect. The total fatty acid content of *P. cactorum* mycelia cultured on a completely defined media was as follows: 12:0 (tr), 14:0 (13%), 16:0 (6%), 18:0 (tr), 16:1 (tr), 18:1 (21%), 18:2 (18%), 18:3 6,9,12 (7%), 20:1 (1%), 20:2 (5%), 20:3 (10%), 20:4 5,8,11,14 (17%) and unknown (1%). When the fungus was cultured on an agar media supplemented with 10 ppm cholesterol, additional C_{20} unsaturated acids appeared in significant quantities, e.g. eicosapentaenoic acid, 20:5 $\Delta^{5,8,11,14,17}$.

Physiology of fatty acid compounds. When 1, 10, 100 or 1,000 ppm of triacontanol (C_{30}) phytophthorol-1, palmitic acid or oleic acid was incubated with *P. cactorum* in liquid or agar, solidified media growth was inhibited and reproduction was not turned on. Addition of Tween 80 and soybean lecithin (Sigma Chemical Co., St. Louis, MO) stimulated growth in a manner analogous to sterols (data not shown) and induced variable amounts of oospores, especially soybean lecithin added at high concentrations when the fungus was cultured on the Ko-media (23).

Trace levels of sterol (0.5 ppm) were sufficient to spark growth (24). This level also induced oosporogenesis. However, the number of spores produced was proportional to the dietary sterol concentrations (0.5 to 10 ppm). Thus, the stimulatory growth response was due to the sterol, not the fatty acid, supplement. Alternatively, the positive effect of certain fatty acids on reproduction may be due to the combination of having both a sterol contaminant and an unsaturated fatty acid that the fungus may require but fails to produce (cf. Discussion). When the soybean lecithin was passed through an alumina column eluted with a graded series of hexane in ether followed by chloroform/methanol (1:1) and chloroform to separate the contaminant sterol from the phospholipids, the stimulatory effect of the column purified phospholipid on growth and reproduction was substantially diminished (100% and 90%, respectively). Thus, the phospholipid alone was not responsible for growth stimulation as previously observed (25–28) or as Ko has stated for reproduction (23,29).

DISCUSSION

The total fatty acid and alcohol composition of *P. cactorum* has been elucidated in this and our earlier studies (4–6). While we have not been concerned until recently with fatty acid metabolism to prostaglandins (30–33), all Oomycetes may perform this metabolism in order to reproduce. A proposal for the biosynthetic and functional relationships of lipids produced by *P. cactorum* is shown in Figure 7. The origin of all the lipids but eicosapentaenoic acid (EPA) has been demonstrated in *P. cactorum* by incubation with appropriate labeled precursors, e.g. [2-^{14}C]acetate, [1-^{14}C]palmitate and [1-^{14}C]stearate (5 and Nes, unpublished). There are reports that [1-^{14}C]arachidonic acid (AA) is metabolized to EPA by *Achlya* (34) and *Saprolegnia* (35). However, in neither study was the starting material nor its biochemical metabolite radiochemically purified. In fact in one study (34), the AA, which

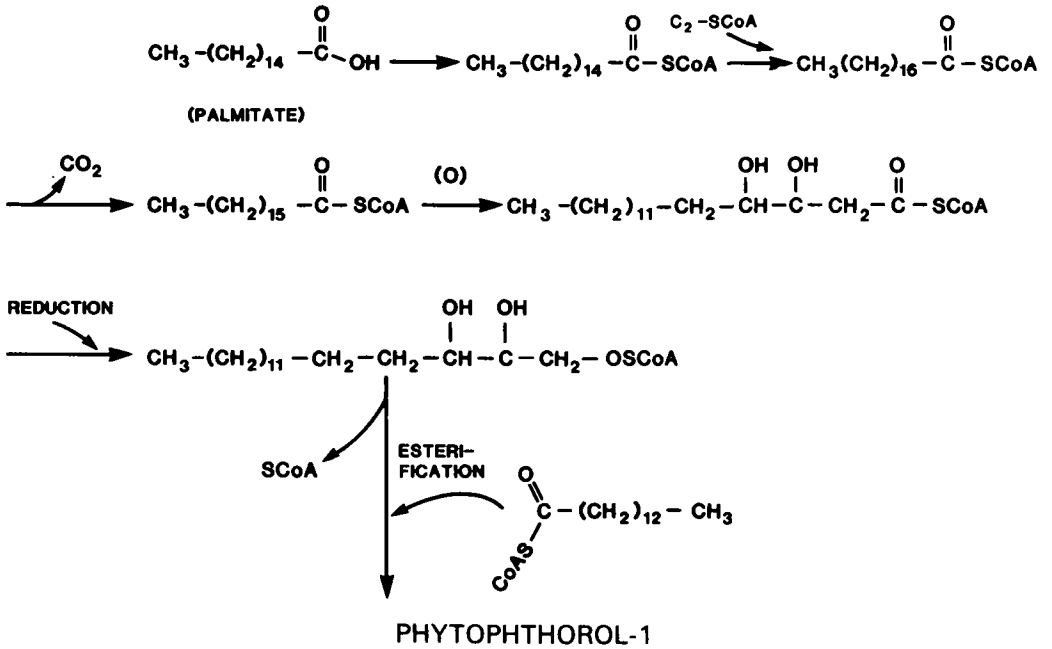

FIG. 6. Proposed biosynthetic scheme of phytophthorol-1 formation from palmitate.

was produced by biochemical rather than chemical methods, contained 4% of the 20:4 (n-3) acid. Thus, the preferential formation of EPA from 20:4(n-3) could not be ruled out. These same authors also claimed the 20:4(n-3 or $\Delta^{8,11,14,17}$) was formed following incubation with labeled stearate (18:0). The concurrent biosynthesis of C-20 isomeric unsaturated fatty acids 20:4 $\Delta^{5,8,11,14}$ and 20:4 $\Delta^{8,11,14,17}$ was difficult to accept on biosynthetic grounds (cf. Fig. 5), unless 20:3 $\Delta^{8,11,14}$ is the substrate for 20:4 $\Delta^{8,11,14,17}$. But if $\Delta^{8,11,14}$ is transformed into $\Delta^{8,11,14,17}$, why prefer using arachidonic acid as the precursor to EPA?

In a search for prostaglandins in Oomycetes, it was observed that AA was converted to metabolites of AA but not EPA (32,33). Since the desaturase cleft is assumed to fail to perform a Δ^{17}-desaturation for mechanistic reasons (36), the likelihood of a precursor-product relationship of AA with EPA seems remote. Of course, EPA could be formed by Δ^{15}-desaturation of linoleic acid; but, then a Δ^{15}-desaturase would be implicated for enzyme activity. Interestingly, Kerwin has observed the presence of α-linolenic acid and the absence of γ-linolenic acid in *Lagenidium giganteum* (a sterol-less Oomycetes [8]) in mycelia cultured with dietary phospholipids and triglycerides (38). This implies that the fungus either fails to produce γ-linolenic acid or the addition of dietary α-linolenic acid feeds back on the Δ^6-desaturase activity following its accumulation by the mycelia. To date, the cooccurrence of a Δ^6 and Δ^{15}-desaturase in nature has not been shown, although the more advanced fungi can desaturate linoleic acid to α-linolenic acid ($\Delta^{9,12,15}$) (3). If the Δ^6 and the Δ^{15}-desaturase enzymes are genetically predisposed, the oomycetous fungi temporarily may regulate the gene for Δ^{15}-desaturation until the onset of reproduction, when Δ^6-desaturase is repressed. The delayed expression of certain sterolic enzymes has been observed in fungi (12) and vascular plants (37). Another possibility is that Oomycetes do not synthesize EPA de novo and, in analogy to mammals, possess an essential dietary requirement for the acid for hormonal purposes, e.g. reproduction.

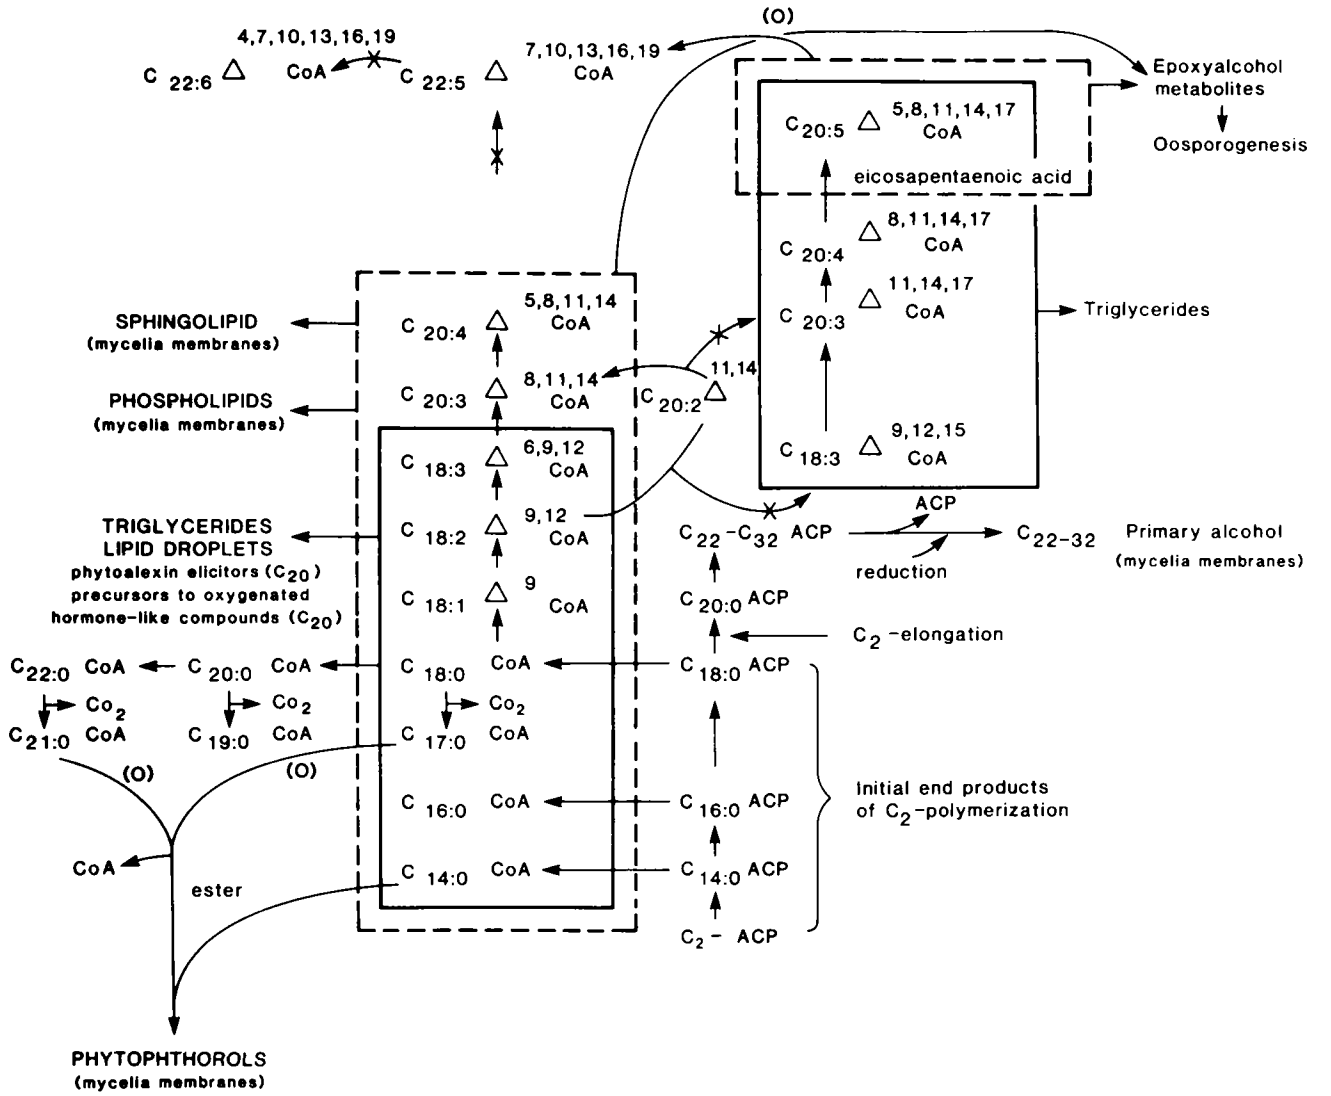

FIG. 7. Proposed biosynthetic relationships and functions of lipids produced by *P. cactorum*. X represents proposed blocks in fatty acid pathway.

The ability of Ko to induce reproduction with commercial soybean and egg lecithins in *Phytophthora* is relevant to the proposed essential fatty acid requirement by the Oomycetes (23,29). In order to stimulate oospore formation, Ko added the commercial phospholipids at 1 g/1:a; two orders of magnitude lower level, 10 mg/l (10 ppm), failed to induce oosporogenesis. It should be remembered that 10 ppm sterol induces maximal sexual sporulation (1). However, as has been shown, *Phytophthora* has the biosynthetic capacity to synthesize the head groups and dominant fatty acids that are present in the dietary phospholipid preparations. Clearly, the commercial phospholipids are not essential dietary requirements for reproduction, since these same lipids are produced by *Phytophthora*. It may be that a trace contaminant of an EPA (or other prostaglandin) precursor, e.g. α-linoleic acid, together with a contaminant sterol is present in the commercial samples, which include agar. The results of this study imply that oosporogenesis may require a dual lipid nutritional supplement: one for a select sterol and another for a select unsaturated fatty acid. If either of the two lipids are provided alone, growth, not reproduction, is affected. If the two lipids are provided together, reproduction is turned on; the number of spores produced will depend on their respective levels in the media. Presumably, the phytophthorols and VLFA replace sterols in mycelial membranes during vegetative growth. VLFA, but not phytophthorols, are present in the sterol-producing Oomycetes, *Saprolegnia ferax* (Nes, unpublished). Addition of sterols fails to change the total fatty acid composition of *P. cactorum*, although following cholesterol-induced sparking of growth the amount of fatty acid increases, and individual fatty acids associated with key ester linkages change dramatically (Nes, unpublished). This coupled with our observation that VLFA biosynthesis is compartmentalized from the fatty acid pathway leading to neutral and polar acyl lipids indicates that regulation of the fatty acid biosynthetic pathway, e.g. by use of desaturase and cyclooxygenase inhibitors, may be an approach to control pathogenesis. There are preliminary data to support this view (30,31). Interestingly, AA and EPA have been implicated in disease resistance as sesquiterpene phytoalexin elicitors (39). In conclusion, fatty acids and alcohols play multiple physiological and ecological roles, some of which are interchangeable, in *P. cactorum*. A determination of their relative importance with sterols as developmental triggers (cell-cycle mediated process [24]) vs fluidity modulators of mycelial membranes to initiate and then sustain growth and govern reproduction is under active investigation.

Neutral Lipid Transfer Protein Does Not Regulate α-Tocopherol Transfer Between Human Plasma Lipoproteins

Esther Granot[a,*], **Israel Tamir**[a] and **Richard J. Deckelbaum**[b]

Vitamin E has no known plasma carrier protein and is transported by plasma lipoproteins. The site of association of vitamin E in the lipoprotein particle and the mode of transfer of vitamin E between plasma lipoproteins have not been ascertained. Since neutral lipids (triglycerides and cholesterol esters) exchange between plasma lipoproteins by processes mediated by neutral lipid transfer protein, we questioned that if vitamin E, a hydrophobic molecule, is carried in the core of the lipoprotein particle then its transfer between plasma lipoproteins may be mediated by neutral lipid transfer protein. Transfer of D-α(5-methyl-^{3}H)tocopherol from in vitro-labeled human plasma lipoprotein fractions to other plasma lipoproteins was measured under incubation conditions that were designed to yield markedly differing degrees of neutral lipid exchange. Despite the presence of the d > 1.21 g/ml lipoprotein-poor plasma fraction or purified lipid transfer protein that resulted in up to a 10-fold increase in neutral lipid transfer, vitamin E transfer between very low density lipoproteins, low density and high density lipoproteins remained constant. Even excess amounts of lipid transfer protein, which caused triglyceride transfer between very low density and high density lipoproteins to reach saturation, failed to affect significantly vitamin E transfer. Vitamin E distribution between lipoprotein fractions did correlate with lipoprotein mass ratios. Vitamin E transfer was higher as the protein ratio of acceptor lipoproteins to donor lipoproteins increased. We conclude that vitamin E transfer between lipoproteins is not dependent primarily on neutral lipid transfer protein and is not mediated via neutral lipid transfer.
Lipids 23, 17-21 (1988).

α-Tocopherol is a lipid soluble vitamin that has no known plasma carrier protein and is transported by plasma lipoproteins (1,2). There is disagreement concerning the relative amounts of α-tocopherol in the different lipoprotein fractions. Various studies (3,4) have concluded that the low density lipoproteins (LDL) are the major carriers of tocopherol, and only when high levels of plasma tocopherol are present do the other lipoproteins carry proportionally increased amounts (5). Bjornson et al. (4) have observed that vitamin E is associated primarily with the lipoprotein class that contains the largest amount of total lipid. Yet, others have reported that vitamin E is transported mainly in high density lipoproteins (HDL) (6,7), and tocopherol levels correlate with HDL protein levels, suggesting that the apoproteins in HDL also may bind the vitamin (2).

Abbreviations: VLDL, very low density lipoprotein; LDL, low density lipoproteins; HDL, high density lipoproteins; TG, triglyceride; CE, cholesterol ester; LTP, neutral lipid transfer protein.

Vitamin E is exchanged readily among lipoproteins (8) and between lipoproteins, red blood cells (9) and tissue membranes (10). Transfer of lipoprotein components among lipoproteins and cellular compartments is determined, at least in part, by their relative hydrophobicity. Cholesterol spontaneously transfers by a aqueous diffusion mechanism (11). α-Tocopherol, another amphiphilic compound, has been shown to transfer both spontaneously between liposomes (12) and by a factor present in rat liver cytosol that enhances its transfer between membranes (10,13). Cholesterol ester and triglyceride, which are more hydrophobic, require specific plasma proteins to mediate transfer.

The exchange protein that transfers cholesterol esters (CE) and triglyceride (TG) according to the relative mass of these lipids in the different lipoproteins particles recently has been isolated and characterized (14-16). This neutral lipid transfer protein is present in the d > 1.21 g/ml lipoprotein-poor plasma fraction. A reversible mass transfer of TG and CE, mediated by neutral lipid transfer protein, has been observed to occur between very low density lipoproteins (VLDL) and either LDL or HDL, both in vivo and in vitro (17-20), resulting in transfer of TG from the triglyceride-rich lipoproteins (VLDL) to LDL or HDL with a concomitant loss of CE from the cholesterol ester-rich lipoproteins and enrichment of VLDL with cholesterol ester. No such specific transfer protein has been observed yet for the transfer of α-tocopherol between plasma lipoproteins.

Tocopherol equilibrates between lipoproteins at a rate that is 2-3 times slower than that of cholesterol and its distribution correlates best with the total lipid mass of the lipoproteins (8), suggesting an association of vitamin E with the non-polar triglyceride/cholesterol ester particle core. We hypothesized that if vitamin E is carried mainly in the core of the lipoprotein particle, then the transfer of tocopherol between plasma lipoproteins may be mediated by neutral lipid transfer protein. Therefore, to better understand the association of vitamin E with lipoprotein particles and further characterize the partitioning of tocopherol between plasma lipoproteins we have studied the role of neutral lipid transfer protein in the transfer of tocopherol among human plasma lipoproteins.

MATERIALS AND METHODS

Vitamin E. D-α(5-methyl-^{3}H)tocopherol at a specific radioactivity of 20.2 mCi/mg and radiochemical concentration of 1.0 mCi/ml, was obtained from Amersham International (Bucks., England) and purified by thin layer chromatography on silica gel plates using benzene-absolute ethanol 99:1. The vitamin was stored at −20 C and rechecked periodically by thin layer chromatography to maintain purity >95%.

Preparation of plasma lipoproteins labeled with vitamin E. Plasma lipoproteins were labeled as described by

Bjornson et al. (9): 25 ml flasks were silanized using silicone coating Sigmacote from Sigma Chemical Co. (St. Louis, MO). The flasks were dried under nitrogen. Radioactive tocopherol (2 μl; 1.6×10^6 dpm ^{3}H/1 μl) was added to the silanized flask in 0.5 ml of benzene and evaporated to a thin film by rotating the flask under nitrogen at room temperature. Five ml of fresh human plasma containing 1 mg/ml ethylenediaminetetraacetic acid (obtained from healthy, fasting donors) was added and incubated at 37 C for 12 hr in a shaking water bath. Vitamin E-labeled plasma lipoproteins then were separated from this plasma by sequential salt density ultracentrifugation (21). Individual lipoprotein fractions (separated from human plasma by sequential salt density ultracentrifugation VLDL at d < 1.019, LDL at d < 1.063, HDL at d < 1.21 g/ml) similarly were labeled with radioactive vitamin E. Incorporation of the isotope into the lipoprotein fractions using either one of the above methods of labeling ranged from 30–45% of the initial amount of radioactivity. The method of labeling did not affect the results obtained.

Lipid transfer protein (LTP) was prepared as described by Albers et al. (15), using a modification of the method of Pattnaik et al. (14). In brief, the d = 1.21–1.25 g/ml plasma fraction was placed on a phenyl-Sepharose column. The fraction containing transfer activity was further purified by diethylaminoethyl anion exchange chromatography. Lipid transfer activity was assayed by measuring the transfer of [^{3}H]cholesterol ester from [^{3}H]cholesterol ester-labeled HDL to the d < 1.019 g/ml plasma fraction.

The following incubation systems were studied (the fraction marked with an asterisk is labeled with vitamin E): VLDL* + LDL; VLDL + LDL*; VLDL* + HDL; VLDL + HDL*; LDL* + HDL; LDL + HDL*. Incubations were performed under the following conditions in the presence of either human d > 1.21 g/ml lipoprotein-poor plasma, purified neutral lipid transfer protein, rat d > 1.21 g/ml lipoprotein poor plasma (rat plasma is devoid of neutral lipid transfer activity), albumin (fatty acid-free, Sigma bovine albumin), or 50 mM Tris, 0.15 M NaCl, 0.05% EDTA, pH 7.4. The concentration of albumin or of the protein in the lipoprotein-poor plasma fraction was adjusted to a concentration of 4–5 g% in each system. Most incubations were performed at 37 C for 18 hr. Individual experiments were performed at 4 C. LTP-mediated CE-TG exchange previously has been shown by us to be minimal at 4 C (19).

Incubations of VLDL + HDL* also were performed using VLDL labeled with ^{14}C-triglyceride. (^{14}C-triglyceride)VLDL was prepared by incubation of ^{14}C-triolein Intralipid 4 Ci/ml with human VLDL at 37 C for 18 hr in the presence of d > 1.21 g/ml lipoprotein-poor plasma. Prior to the incubation, Intralipid was washed in order to rid Intralipid of excess phospholipid. Washed Intralipid was prepared by repeated centrifugation of Intralipid suspended in 0.15 M NaCl, 0.05% EDTA as described (22). This procedure resulted in a decrease from 12.5% to 3.4% in the relative weight composition of phospholipid in Intralipid. ^{14}C-triglyceride labeled VLDL was separated by ultracentrifugation at d < 1.019 g/ml after flotation of the Intralipid at d = 1.006 g/ml by swinging bucket ultracentrifugation at 25,000 rpm for 15 min. The lipoprotein fraction ratios in the incubations usually were adjusted so that the triglyceride in the triglyceride-rich lipoprotein was five-fold greater than the cholesterol ester in the cholesterol ester-rich lipoprotein (a ratio of 5:1 previously has been shown to be practical for monitoring neutral lipid mass transfer processes [19]). In addition, some incubations were performed at different protein ratios. Following each incubation, sequential salt density ultracentrifugation was used to separate the fractions corresponding to d < 1.019 g/ml-modified, "M"-VLDL; d = 1.019–1.063 g/ml-modified, "M"-LDL; d = 1.063–1.21 g/ml-modified, "M"-HDL. "M" denotes the modified lipoprotein fraction in terms of TG/CE composition following mass transfer.

In some incubations of LDL + HDL, separation of lipoprotein fractions was performed by precipitation with $MnCl_2$ and heparin, as described by Burstein et al. (23).

The total radioactivity in each fraction was calculated and, accordingly, the net transfer of radiolabeled vitamin E between the lipoprotein fractions determined.

Chemical analysis. Total and free cholesterol were assayed using the Test Combination Cholesterol Kit of Boehringer Mannheim (Mannheim, Germany). Triglycerides were assayed by the RapidChem enzymatic triglycerides reagent kit of Macomb Biotechnology Inc. (Mt. Clemens, MI). Protein was measured by the method of Lowry et al. (24) with bovine serum albumin as a standard.

RESULTS

In all incubation systems studied, vitamin E transfer from one lipoprotein fraction to another did not correlate with transfer of neutral lipids. Although in each system incubation conditions varied so that neutral lipid transfer increased up to 10-fold, vitamin E transfer showed no real changes. Figure 1 depicts experiments designed to obtain widely differing neutral lipid exchange. Although neutral lipid transfer varied considerably, the transfer of radiolabeled vitamin E from LDL to VLDL remained relatively constant in incubations of LDL with VLDL (VLDL-TG:LDL-CE 5:1) under five different conditions: in the presence of saline, d > 1.21 g/ml lipoprotein-poor plasma, purified lipid transfer protein and either albumin or rat

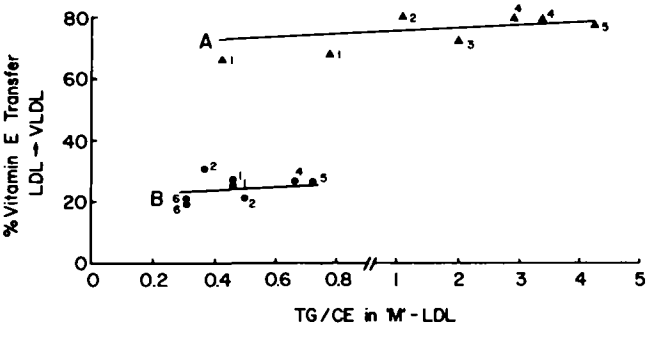

FIG. 1. Vitamin E transfer from LDL to VLDL at different ratios of neutral lipid exchange. VLDL and LDL (^{3}H-tocopherol) were incubated at VLDL:LDL protein ratios of A, 1.5:1 (▲) and B, 0.3:1 (●). Each set of incubations was performed in the presence of albumin (1), saline (2), d > 1.21 g/ml lipoprotein-poor plasma at 4 C (3) and at 37 C (5), neutral lipid transfer protein at 4 C (6) and 37 C (4). Neutral lipid exchange is measured by TG/CE ratios in "M"-LDL. Each point represents the mean of two separate sets of experiments.

lipoprotein-poor plasma. Specifically in the presence of either d > 1.21 g/ml lipoprotein-poor plasma or purified LTP, neutral lipid transfer resulted in an 8-11-fold increase in the TG/CE ratios in LDL after incubations. In contrast, in incubations in the presence of saline, albumin or rat lipoprotein-poor plasma little or no neutral lipid transfer occurred; the TG/CE ratio in post-incubation LDL remained relatively low, close to native LDL. Under all the above conditions, the transfer of vitamin E from LDL to VLDL was 60-80% of the initial amount of vitamin E in VLDL. In a similar set of incubations in which the ratio of VLDL-TG to LDL-CE was 1:1 (protein ratio 0.3:1), vitamin E transfer from LDL to VLDL was 20-30% (Fig. 1) and similarly was independent of the degree of triglyceride and cholesterol ester transfer in the system.

In incubation systems in which VLDL was the lipoprotein fraction labeled with vitamin E, transfer of vitamin E from VLDL to LDL was approximately 10% in the presence of either saline or d > 1.21 g/ml lipoprotein poor plasma although neutral lipid transfer was almost threefold higher in the presence of the lipoprotein-poor plasma fraction (Fig. 2).

To determine if excess amounts of transfer protein might affect vitamin E transfer, incubations were performed with amounts of transfer protein that produced no further increase in TG/CE exchange. The transfer of [^{3}H]α-tocopherol and [^{14}C]triglyceride between vitamin E-labeled HDL and triglyceride-labeled VLDL were measured. Vitamin E transfer did not correlate significantly with neutral lipid transfer. With increasing concentrations of purified lipid transfer protein, transfer of vitamin E remained relatively constant (40-55%) even when the increase in triglyceride transfer (from 20% to 80%) reached saturation at the higher lipid transfer protein concentrations (Fig. 3).

Vitamin E transfer between lipoprotein fractions was found to correlate with mass ratios of the donor lipoprotein to acceptor lipoprotein. This was observed in all the incubation systems studied. Vitamin E transfer from VLDL to HDL increased with rising HDL protein to VLDL protein ratios with a correlation coefficient of r = 0.87 (Fig. 4). A similar effect was demonstrated with VLDL and LDL (data not shown).

An especially high affinity of vitamin E to HDL was shown in incubations of HDL and LDL (Fig. 5). Despite conditions in which LDL lipid mass was up to 10-fold that of HDL, most of the vitamin E remained associated with HDL. Only at LDL/HDL lipid ratios 15-16:1 did most of the vitamin E associate with LDL. This implies that factors other than simple lipid mass ratios influence partitioning of vitamin E between plasma lipoproteins.

The effect of LTP on transfer of vitamin E between lipoproteins was studied following 18-hr incubations, a time period previously shown (19) to be necessary for achieving substantial changes in lipid mass and for reaching an equilibrium of mass transfer. To ascertain that an earlier effect of LTP was not being masked by measurements at 18 hr, we performed incubations at increasing time intervals (Fig. 6). There was no consistent difference in vitamin E transfer between lipoproteins with or without LTP, even at very short incubation periods.

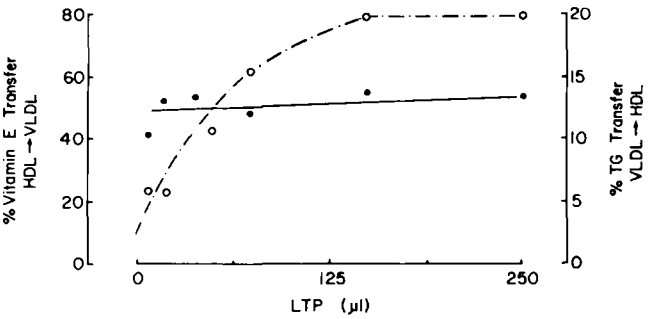

FIG. 3. The effect of neutral lipid transfer protein on vitamin E and triglyceride transfer between VLDL and HDL. VLDL (^{14}C-triglyceride) and HDL (^{3}H-tocopherol) were incubated in the presence of increased concentrations of neutral lipid transfer protein. Each point represents the mean of two separate sets of experiments. ●—●, ^{3}H-tocopherol transfer. ○—○, ^{14}C-triglyceride transfer.

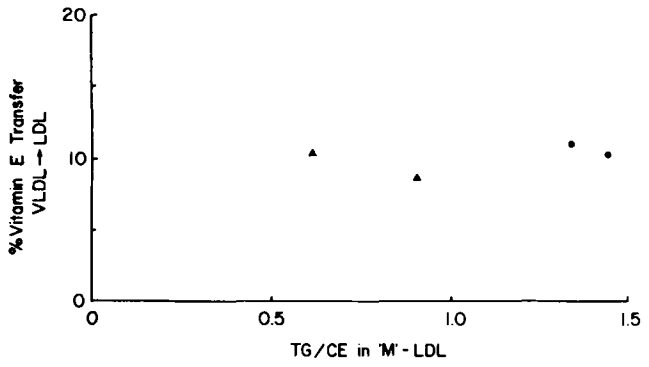

FIG. 2. Vitamin E transfer from VLDL to LDL at different ratios of neutral lipid exchange. VLDL (^{3}H-tocopherol) and LDL were incubated at VLDL:LDL protein ratio of 1.5:1. Incubations were performed in the presence of d > 1.21 g/ml lipoprotein-poor plasma (●) and saline (▲). Neutral lipid exchange is measured by TG/CE ratios in "M"-LDL. Each point represents the mean of two separate sets of experiments.

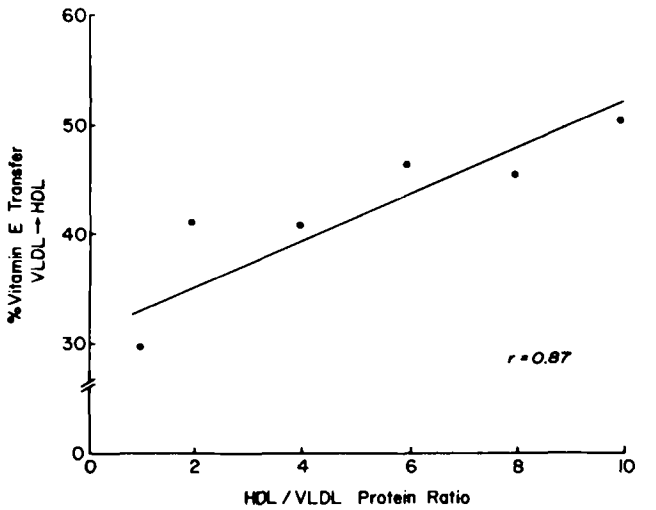

FIG. 4. The effect of lipoprotein mass ratios on vitamin E transfer between VLDL and HDL. VLDL (^{3}H-tocopherol) and HDL were incubated at increasing HDL:VLDL protein ratios. Incubations were performed in the presence of d > 1.21 g/ml lipoprotein-poor plasma. Each point represents the mean of two separate sets of experiments.

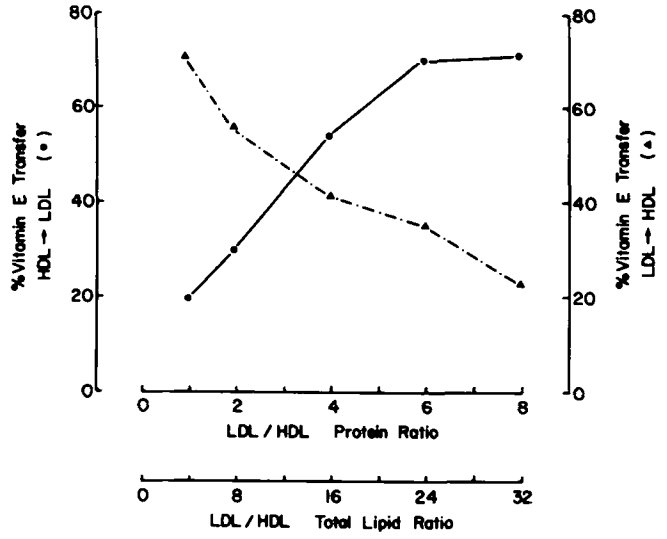

FIG. 5. The effect of lipoprotein mass ratios on vitamin E transfer between HDL and LDL. Incubations of HDL (^{3}H-tocopherol) and LDL; (●) or LDL (^{3}H-tocopherol) and HDL; (▲) were performed at varying LDL:HDL mass ratios. Incubations were performed in the presence of d > 1.21 g/ml lipoprotein-poor plasma. Each point represents the mean of two separate sets of experiments.

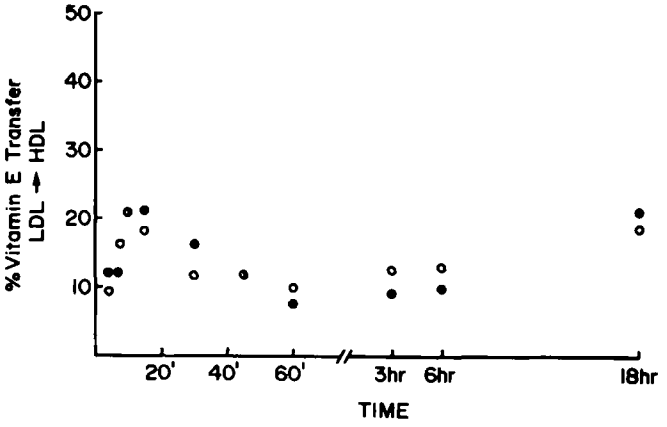

FIG. 6. Time course of vitamin E transfer between LDL and HDL with and without LTP. Incubations of LDL (^{3}H-tocopherol) and HDL (LDL:HDL protein ration 1:1) were performed at increasing time intervals in the absence of and presence of d > 1.21 g/ml lipoprotein-poor plasma. Each point represents the mean of two separate sets of experiments.

DISCUSSION

α-Tocopherol, a lipid-soluble vitamin, is transported in plasma primarily by the lipoprotein class that contains the largest amount of total lipid. α-Tocopherol levels in each lipoprotein fraction have been shown to correlate better with the amount of free cholesterol in the lipoprotein particle than with any other individual lipid (4). Earlier work on the partitioning of free cholesterol in plasma lipoproteins has suggested that most free cholesterol is associated with surface components rather than core lipids (25). But tocopherol equilibrates between lipoproteins at a rate that is slower than that of cholesterol; on isolated surface components of VLDL, two-thirds of the associated free cholesterol but only one-third of the tocopherol are separated with the surface phases (9). This suggests that up to 2/3 of lipoprotein vitamin E is associated with core lipids and, if so, may be expected to participate in exchange processes similar to those of cholesterol ester and triglyceride. Lipoprotein lipase has been shown by Traber et al. (26) to mediate the binding of vitamin E from chylomicrons to cell membranes. Lipoprotein lipase similarly enhances binding and possibly uptake of CE from lipoproteins to cells (27). The fact that CE and vitamin E may share a common mechanism of cellular uptake further suggested a close association of vitamin E with CE in the lipoprotein particle. CE transfer between lipoproteins is mediated by LTP and additionally, LTP recently has been shown to enhance the uptake of HDL-CE into liver and smooth muscle cells (28). Therefore, ascertaining a role for LTP in the transfer of vitamin E between lipoproteins also might have contributed to our understanding of the mechanism of uptake of plasma vitamin E by tissues.

Despite the evidence that substantial amounts of tocopherol are associated with the core of the lipoprotein particle, we have failed to demonstrate that tocopherol transfers between lipoproteins in conjunction with the transfer of the major core lipids, triglycerides and cholesterol esters. Under conditions leading to a wide range of cholesterol ester-triglyceride transfers, vitamin E transfer remained relatively constant. In the presence of lipoprotein-poor plasma or purified lipid transfer protein, up to a 10-fold change in the ratio of TG/CE in modified lipoproteins was achieved as compared to incubations in the presence of saline, albumin or rat plasma, which has no neutral lipid transfer activity. Yet vitamin E transfer was similar under all these conditions (Figs. 1-3). A possible cause for the lack of effect of LTP on vitamin E transfer may be a spontaneous rapid vitamin E exchange between lipoproteins that overshadows the slower transfer due to LTP. This could occur by rapid core-surface partitioning of the vitamin followed by equilibration between lipoproteins of the vitamin E partitioned in the particle surface.

Vitamin E distribution between lipoprotein fractions did correlate with lipoprotein:lipid and/or protein ratios. This was shown in incubation systems of VLDL-LDL, VLDL-HDL and LDL-HDL. Nevertheless, we noted that vitamin E transfer does not behave solely or primarily in accordance with lipoprotein total lipid mass in view of results observed in incubations of LDL with HDL. At LDL:HDL protein ratios of 2:1, the lipid ratio is approximately 8:1 but despite this high LDL total lipid mass, vitamin E was distributed so that it was predominantly associated with HDL (Fig. 5). This partitioning was observed irrespective of which lipoprotein fraction was the one initially labeled with vitamin E. These results are of interest in light of Behrens' (29) recent observations on the distribution of tocopherol in plasma lipoproteins, noting a high correlation between α-tocopherol and HDL-protein but such correlations were not observed for LDL. Thus, the factors determining partitioning of vitamin E between lipoproteins and in the lipoprotein particle itself are complex and do not depend only on total lipid mass ratios. Structural properties and specific lipid-protein interactions may prove important. Further studies will

clarify the precise partitioning of vitamin E in the lipoprotein particle and its mechanisms of transfer between human plasma lipoproteins.

[Received April 6, 1987; Revision accepted July 29, 1987]

A Novel Method to Administer Radiolabeled Lipid to Juvenile Oysters

Marilyn C. Erickson[1] and **Daniel P. Selivonchick***
Department of Food Science and Technology, Oregon State University, Corvallis, OR 97331

Particles prepared from egg yolk were shown to encapsulate protein and to be in a size range that would be filtered by the oyster. A radiotracer study involving the addition of radiolabeled phosphatidylcholine to egg yolk demonstrated that the egg yolk particles were taken up and metabolized by juvenile oysters *(Crassostrea gigas).* Catabolism of the radiolabeled lipid and subsequent resynthesis into non-lipid components occurred to a slight extent. The main factor responsible for the distribution of radioactivity amongst the lipids in the stomach tissue was believed to be transacylation.
***Lipids 23,* 22–27 (1988).**

Lipids play an important role in the diet and physiology of marine bivalves (1–4). While the lipid composition of bivalves has been detailed extensively (5), few experiments have been made to determine their metabolic pathways.

Several methods have been used to deliver radiolabeled lipids or lipid precursors to bivalves. Trider and Castell (3) incubated oyster gill and mantle tissue in a solution containing ^{14}C-acetate. Allen and Conley (6) administered 1-^{14}C-palmitate to oysters by means of a blunted hypodermic needle placed in the stomach. Lubet et al. (7) injected the mussle foot with 1-^{3}H-glycerol. Lipid metabolism measured using these means of incorporation may differ from the metabolism that occurs in bivalves in their natural habitat.

In the natural habitat, the majority of lipid and lipid precursors for bivalves are obtained by filtering and ingesting algae. Taking this into account, to monitor the fate of labeled linolenic acid and higher homologues clams have been fed a culture of *Phaeodactylum tricornutum* previously incubated with 1-^{14}C linolenic acid (8). In addition, juvenile oysters were fed either *Tetraselmis suecia* or *Dunaliella tertiolecta* that were grown in the presence of ^{14}C-sodium bicarbonate for 24 hr (4). However, the main limitation of using radiolabeled algae is the difficulty of following the metabolism of one specific lipid component.

Like algae, liposomes prepared from purified lipid are particulate and are filtered and ingested by the oysters. The metabolism of ^{14}C-dipalmityl phosphatidylcholine was followed in oysters fed liposomes that contained the radiolabeled lipid (9). Other nutritional components such as protein or carbohydrate, which are lacking in liposomes, may modify the metabolism of ingested lipid. A suitable alternative for the source material of liposomes is to use egg yolk. With one of the key components in egg yolk being lipid, the idea was generated that vesicles that would be similar to liposomes could be prepared. This paper describes the metabolic fate of phosphatidylcholine, L-α-1-palmitoyl-2-arachidonyl [arachidonyl-1-^{14}C] (^{14}C-PAPC) when the radiolabeled lipid is incorporated into egg yolk particles and fed to oysters.

MATERIALS AND METHODS

Preparation of fluorescent liposomes. Fluorescent liposomes were prepared with 10.5 mg of egg phosphatidylcholine (PC)/cholesterol/stearylamine, 87:5:8 (P-L Biochemicals, Inc., Milwaukee, WI). The material was evaporated from chloroform to a thin film on the wall of a round-bottom flask. Five ml of a solution of 30 ppt synthetic seawater, Instant Ocean from Aquarium Systems (Mentor, OH), containing 1 mg fluorescein isothiocyanate bovine serum albumin (FITC-BSA) and several glass beads were added, and the flask swirled for one hour. Unentrapped FITC-BSA was removed by centrifuging the liposomes in an IEC International clinical centrifuge (315 × g) and replacing the supernatant with Instant Ocean from Aquarium Systems Inc. (Eastlake, OH). All solutions of Instant Ocean used in this study were at 30 g Instant Ocean/l of deionized water. After several repetitions, no fluorescence was observed in the filtrate. The vesicles were diluted to 200 ml with Instant Ocean.

Preparation of fluorescent egg yolk particles. Fluorescent egg yolk particles were prepared by placing 0.20 gm of fresh egg yolk (containing 9.7% phospholipids) in a 30 ml homogenizing tube and adding 20 ml of a solution of 30 ppt Instant Ocean containing FITC-BSA (10 mg), corn starch (96 mg), thiamin-HCl (3.9 μg), riboflavin (5.8 μg), niacin (39 μg), D-biotin (0.4 μg), Na-pantothenate (9.7 μg), pyridoxine (3.9 μg), folic acid (1.9 μg), vitamin B_{12} (0.04 μg), myo-inositol (80 μg) and ascorbic acid (29 μg). All chemicals were purchased from Sigma Chemical Co. (St. Louis, MO). The materials were mixed with a high speed tissue homogenizer for 10 to 20 seconds. Unentrapped FITC-BSA was removed by centrifuging (315 × g) the egg yolk particles in an IEC International clinical centrifuge and replacing the supernatant with Instant Ocean. After several repetitions, no fluorescence was observed in the filtrate, and the final volume was brought to 200 ml with Instant Ocean. Since it was beyond the scope of this study to determine the physical nature of the lipid material formed, we will refer to the material as particles. However, it is probable that due to the high triacylglycerol content of egg yolk, the material is a mixture of vesicles and micelles containing triacylglycerol.

Preparation of radiolabeled egg yolk particles. Radiolabeled egg yolk particles were prepared by placing 0.21 g of fresh egg yolk and 10 μC of ^{14}C-PAPC (New England Nuclear, Boston, MA) in a 30 ml homogenizing tube. After adding 21.0 ml of Instant Ocean containing 0.105 g starch, the solution was mixed for one min with a high speed tissue homogenizer. The solution then was diluted with Instant Ocean to a final volume of 210 ml.

Feeding and rearing of oysters. Juvenile Pacific oysters, *C. gigas*, weighing 1.5 to 2.0 g, were obtained from Ted

Kuiper in Eureka, CA. The oysters were placed on a screen mesh two inches above the bottom of a large bucket containing 20 l of Instant Ocean solution at 19 C. Once a day for a month the oysters were fed unlabeled egg yolk particles.

For the radiotracer study, 80 oysters were starved for 24 hr and were placed on a plastic tray (1.0 mm mesh) suspended one inch above the bottom of a dish pan (26 cm × 36 cm) that contained seven liters of Instant Ocean. The water was maintained at 19 C in a temperature-controlled room. An airlift pump and three airstones attached to a Whisper 800 air pump were used to aerate and circulate the water. Oysters were fed the radiolabeled egg yolk particles twice a day for three days. After transfer to fresh Instant Ocean, the oysters were fed unlabeled egg yolk particles twice a day for five days.

Analysis of radiolabeled tissue and egg yolk. Analysis of oysters consisted of removing 24 oysters from the container after zero, one, three and eight days. Assuming equal access of oysters to the radiolabeled food, each oyster from day 1 had been exposed to 1.53×10^5 dpm, and each oyster from days 3 and 8 had been exposed to 3.71×10^5 dpm. Each set of 24 oysters was divided into two groups. After each oyster was weighed, it was dissected. The mantle, muscle and gills of each group were pooled and weighed. In addition, the digestive tissues of each group were pooled and weighed. Moisture content was determined by lyophilization of the pooled tissues.

Lipid extraction of the lyophilized tissue and radiolabeled egg yolk particles was performed according to the method of Folch et al. (10). Material insoluble in the chloroform-methanol phase was collected on a column packed with glass wool, digested in NCS solubilizer (Amersham, Arlington Heights, IL) and counted for radioactivity using Bray's scintillation solvent system (11). Samples of both aqueous phase and lipid extract also were measured for radioactivity using the liquid scintillation medium 3a70B (Research Products International Corp., Mount Prospect, IL).

Two-dimensional thin layer chromatograph (TLC) was used to separate individual phospholipids on Silica Gel H plates (0.25 mm thickness). The first dimension solvent system consisted of chloroform/methanol/ammonia (65:25:4, v/v/v). The second dimension solvent system consisted of chloroform/methanol/ammonia (100:50:12, v/v/v). Exposure to iodine revealed the location of neutral lipids (NL) and each phospholipid. All phospholipids with the exception of phosphonolipid (PPL) were identified by comparing to purified phospholipid standards subjected to the same solvent systems. The PPL spot tentatively was identified by the procedure of Stillway and Harmon (12).

Quantitation of individual phospholipids from the day 0 samples was accomplished by the phosphorus assay of Bartlett (13). Individual phospholipids from radiolabeled lipid samples were scraped into vials, hydrated with water and counted for radioactivity in 3a70B.

Neutral lipids from radiolabeled samples were separated on Silica Gel H plates (0.25 mm thickness) by one-dimensional TLC. The solvent system employed was hexane/ethyl ether/glacial acetic acid (80:20:1, v/v/v). Bands 0.5 cm in width were scraped into vials, hydrated with water and counted for radioactivity in 3a70B.

Quantitation of triacylglycerols from the 0 day samples was accomplished by applying each lipid sample to Silica Gel H plates prepared with 0.05% sodium fluorescein. After running the plate in the neutral solvent system described above, the triacylglycerol spot was detected under fluorescent light and scraped into a test tube. After eluting the triacylglycerols from the silica gel with chloroform, the samples were evaporated to dryness and then quantified according to the procedure of Van Handel and Zilversmit (14).

Total lipid from the mantle, gill and muscle tissue and total lipid from the digestive tissues were analyzed for distribution of radioactivity between the acyl portion and the glycerol-base backbone. A portion of each lipid sample was hydrolyzed with 4% H_2SO_4, and the solution was extracted with hexane. Samples of both the aqueous and organic phases were taken for liquid scintillation counting.

The fatty acid compositions of NL and of each phospholipid from the digestive tissues and from the gill, mantle and muscle tissues were determined for day 0 oysters. After separation in two dimensions on fluorescent silica gel plates, the lipids were subjected to methanolysis for 90 min in 4% H_2SO_4 in methanol (90 C). The methyl esters formed were extracted with hexane and dried over anhydrous sodium sulfate. The fractions were purified and the dimethyl acetals separated from the methyl esters on thin-layer plates (Silica Gel H) developed in benzene (15).

Gas liquid chromatography of the esterified fatty acids was done with a Varian Aerograph Model 1200 gas chromatograph equipped with a Hewlett-Packard 3380A computing integrator. The column was packed with 10% SP-2330 on 100/120 Chromosorb W AW (Supelco, Inc., Bellefonte, PA). Chromatographic peaks were identified by comparison of their relative retention times with those of standards subjected to the same conditions.

RESULTS AND DISCUSSION

Ingestion of fluorescent egg yolk particles. FITC-BSA-containing liposomes shown in Figure 1A resembled those of liposomes prepared by Parker and Selivonchick (9). Egg yolk particles (Fig. 1B) prepared with FITC-BSA were similar in shape and size to these liposomes. Most of the fluorescence appeared to be intravesicular, indicating that the protein was encapsulated within the particle. Absorption of protein to the outside of the vesicle may have occurred slightly. However, the high ionic strength of the synthetic seawater should have reduced the absorption of protein (16).

Analysis of lipids from oyster tissue. Initial analysis of oyster tissues revealed that approximately 81% of the weight was water (Table 1). These values corresponded to those obtained with pre-starved *C. gigas* (17). The recovery of lipid from the total oyster agreed closely to recoveries obtained by Watanabe and Ackman (18) for *Crassostrea virginica* and *Ostrea edulis.*

Less than 10% of the total lipid from the oysters was found in the triacylglycerol fraction. In contrast, *C. virginica* and *O. edulis* have been reported to contain at least 20% of their lipid as triacylglycerol (18). For *C. gigas,* Allen and Conley (6) reported almost 27% of the total lipid as triacylglycerols. As oysters showed decreased triacylglycerol levels when under physiological stress (1), the low content of triacylglycerol found in this study would suggest that the nutritional state of the

oysters was poor. On the other hand, species differences may have been responsible for the altered lipid distribution.

The phospholipid distribution in lipids of oyster tissues is shown in Table 2. The major phospholipids were choline phospholipids (CP) and ethanolamine phospholipids (EP) followed by serine phospholipids (SP). The percentage of PPL in the total oyster was less than the PPL content measured for *C. virginica* (19). The findings by Swift suggested that the PPL content in tissues would increase when oysters were starved. If this were the case for *C. gigas*, the data indicated that these oysters were not starved.

The major fatty acids found in the lipid of oyster tissue is shown in Table 3. Compared to the fatty acid composition found for *C. gigas* by Langdon and Waldock (20), the data agreed fairly well for C16 and C22 fatty acids. The large amounts of C18 fatty acids found in this study may be due to the high amounts of these acids in egg yolk (21). Oysters had been maintained on an egg yolk diet for one month. After this, the triacylglycerol components would have been modified. The fatty acid composition of this lipid has been shown to reflect that of the diet (20).

Incorporation of radioactivity from egg yolk particles. Lipid from egg yolk particles prepared with ^{14}C-PAPC was subjected to two-dimensional TLC to establish the distribution of the radiolabeled lipid into egg yolk particles. More than 97% of the radioactivity was found in CP, indicating very little degradation of the radiolabel during the preparation of particles.

Oysters killed after one day recovered 12.7% of the dpm from the radiolabeled food compared to a recovery of 22.8% by oysters fed ^{14}C-DPPC-containing liposomes for one day (9). A slightly greater recovery of radiolabel was shown after three days when oysters were fed the ^{14}C-PAPC containing egg yolk particles (12.8%) than when they had been fed di[1-^{14}C] palmitoyl phosphatidylcholine (^{14}C-DPPC)-containing liposomes (10.6%). Oysters from day 8 were found to contain 16% of the exposed dose.

Seventy-seven percent of the label fed to oysters was unaccounted for in oyster tissue or the culture vessel water. This unaccounted label could have been in expired $^{14}CO_2$ or in settled matter. Langdon and Siegfried (22) reported that aeration was not satisfactory always as a means of agitation because the turbulence produced tended to be localized around the bubble source, and food settlement occurred in less disturbed areas of the culture vessel. In addition, particle clumping would have led to increased amounts of label in settled matter. Before feeding, egg yolk particles were found to be 5 to 30 μm in diameter. While these particle diameters were capable of being filtered and ingested, clumping of particles may have prevented their ingestion. The production of bacterial films would have increased particle clumping and adherence of particles to surfaces (23).

The radiolabel was distributed in approximately equal portions between the stomach tissue and that of the gill, mantle and muscle tissue. Transport of the radiolabel from the stomach to the other tissues probably occurred via the blood. Allen and Conley (6) found that after ingestion of 1-^{14}C-palmitate, the specific activities of plasma and hemocyte lipids rose over a period of 10 hr and then maintained roughly steady levels. In addition, they found radioactivity in several lipid classes having only blood contact with the digestive tract, thus supporting the premise of transport of lipid through the hemolymph.

Metabolism of radiolabeled phosphatidylcholine. The distribution of radioactivity after lipid extraction of oyster tissue is shown in Table 4. The majority of radioactivity was found in the lipid phase. However, recovery of radioactivity in the aqueous and insoluble phase implied that metabolism of the ^{14}C-PAPC had occurred, and the metabolites were shunted into non-lipid components.

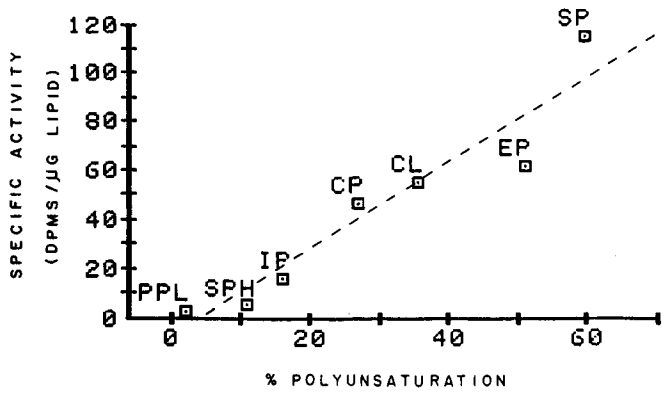

FIG. 2. Relationship between polyunsaturated fatty acids (%) and the specific activity in individual phospholipids.

This type of activity appeared to have occurred to a much greater extent in the gill, mantle and muscle tissue than in the stomach tissue.

Analysis of lipids from radiolabeled oyster tissue. After separation by two-dimensional TLC, the distribution of radioactivity among the phospholipids was determined (Table 5). The results were first expressed in terms of specific activity, dpm/μg lipid. The lipid in stomach tissue having the highest selectivity for the radiolabel was SP, followed by triacylglycerol, EP and cardiolipin (CL). The higher specific activity of SP than CP after eight days may reflect the smaller pool size of SP. In gill, mantle and muscle tissue, CL was shown to have the highest selectivity for the radiolabel, followed by CP for days 1 and 3.

By considering the total amount of radiolabel present in the lipids of each tissue, it was shown that after one day only 27% of the radiolabel remained in stomach CP. SP, EP and triacylglycerol were the other lipids in stomach tissue that had a major portion of the radiolabel. In gill, mantle and muscle tissue, 40–50% of the radiolabel remained in CP while EP and SP also had a large percentage of the radioacativity.

Analysis of radiolabeled transesterified lipid. To provide information about the routes by which radioactivity was incorporated into oyster lipids, the total lipid in each tissue was examined for intramolecular distribution of the label. In the stomach tissue, 60–75% of the radiolabel was found in the hexane soluble portion or fatty acid moiety (Table 6) compared to 100% found when oysters were fed ^{14}C-DPPC-containing liposomes (9). Transacylation could have been the main process used to transfer the radiolabeled fatty acid from CP to the other lipids in stomach tissue.

As the radiolabel was originally in arachidonic acid (AA), it was possible that the acyltransferases were acting to distribute this fatty acid for conversion into prostaglandins. Substances resembling prostaglandins have been found in scallops' tissues (24). In addition, binding sites for prostaglandins have been observed in the gill tissue of the bivalve *Modiolus demissus* (25). Therefore, one could hypothesize that the specific activity of a lipid would reflect its content of AA and its ability to serve as a precursor for prostaglandins. In this study, a correlation coefficient of 0.935 was found between the content of AA in the phospholipids and the specific activities of the individual lipids (Table 7).

An even higher correlation coefficient ($r = 0.953$) was determined for the polyunsaturated content and the specific activity of the phospholipids in stomach tissue from oysters analyzed after eight days (Figure 2). It is suggested that the fluidity of the tissue membranes regulated the activity of the acyltransferases in their transfer of the radiolabeled fatty acid (26).

For the gill, mantle and muscle tissue, 47 to 54% of the radioactivity was found in the fatty acid moiety (Table 6). Since a large portion of the radioactivity was found in the aqueous phase, in which the glycerol backbone partitions, it was not possible to correlate the specific activities observed in these tissues with the AA or polyunsaturated fatty acid content of the lipid (Table 8).

ACKNOWLEDGMENTS

The authors gratefully acknowledge the valuable assistance of J. D. Hendricks and Toshiko Morita in the histological preparations. Oysters were donated by Ted Kuiper of Eureka, CA. D. P. Selivonchick, one of the authors, also is grateful to the University of Washington, Friday Harbor Laboratory for the time and space to continue this work during the summer of 1985. This work was supported by Grant #417 from the Oregon Agricultural Experiment Station to Selivonchick.

Time Course of Dolichol and Dolichyl Phosphate in Regenerating Rat Liver

Kouji Yamada*, Manabu Murakami, Kouichi Katayama and Tadashi Sato
Tsukuba Research Laboratories, Eisai Co., Ltd., 1-3, Tokodai-5-chome, Toyosato-machi, Tsukuba-gun, Ibaragi 300-26, Japan

By using novel high performance liquid chromatographic methods, the time course of dolichol and dolichyl phosphate in regenerating rat liver was investigated and compared with that for cholesterol. The cholesterol level in the liver increased more rapidly than the level of dolichyl phosphate (Dol-P). HMG-CoA reductase activity correlated well with cholesterol concentration. The level of Dol-P at day 1 was lower than that in normal liver, but was increased at three to five days after hepatectomy, which correlates well with mannosyl transferase activity. Dolichol decreased for three days, and thereafter increased until 11 days after hepatectomy. The compositions of dolichol and Dol-P homologues did not change during the experimental period. The results indicate that the cholesterol content in regenerating rat liver increased first, followed by Dol-P, and finally dolichol.
Lipids 23, 28–31 (1988).

Dolichol consists of a group of polyisoprenols with 16 to 22 isoprene units. Dolichols occur widely in tissues and biological fluids as free alcohols, phosphate esters and fatty acid esters (1). In many mammals and yeasts, dolichyl phosphate (Dol-P) serves as a carrier of saccharide moieties in the transfer of sugars to asparagine residues of polypeptides (2–6). The function of free dolichol and dolichyl esters, however, has not been established. Since dolichol, cholesterol and ubiquinone are synthesized by a branched pathway in mevalonate metabolism or through the major branch-point of farnesyl pyrophosphate, many investigators have been interested in the regulation of dolichol biosynthesis. Dolichol synthesis has been studied in the developing sea urchin embryo (7), erythropoietic spleen (8) and the developing mouse brain (9).

Because the biosynthesis of glycoproteins in regenerating rat liver after partial hepatectomy is altered (10–12), it is anticipated that dolichol content of regenerating liver also may be altered. Thus, dolichol in liver, liver microsomes and plasma, and Dol-P in liver were determined in regenerating rat liver by the methods previously described. This paper presents the results and the time course of HMG CoA reductase activity, which is the major regulatory enzyme of cholesterol and dolichol biosynthesis, and mannosyl transferase activity, which may be supported by Dol-P endogenous to the enzyme preparation.

MATERIALS AND METHODS

Chemicals and reagents. Dolichol and Dol-P homologs used were the preparations described previously (13). Didecaprenylethanol used as an internal standard for dolichol and 2,2-didecaprenylethyl phosphate as an internal standard for Dol-P were synthesized in our laboratories (13,14). Anthracene-9-carboxylic acid was purchased from Aldrich Chemical Company (Milwaukee, WI). 3-(9-Anthryl)-diazo-2-propene was prepared from 3-(9-anthryl)-propenal by the method of Nakaya et al. (15). The standard dolichol, Dol-P and internal standards were dissolved in ethyl ether and stored at −20 C. GDP-[^{14}C]mannose and DL-[3-^{14}C]HMG CoA were purchased from Amersham International (Buckinghamshire, UK). All other reagents were analytical grade.

Animals. Male Sprague-Dawley rats weighing ca. 240 g were used. Partial hepatectomy of about 70% of the liver was performed under diethyl ether anesthesia by the method of Higgins and Anderson (16), and control rats were subjected to a sham operation. The animals were killed at the appropriate time after the operation, and the regenerating livers were separated from the nonregenerated portion and stored frozen at −80 C until analysis.

Preparation of rat liver microsomes. The liver was homogenized in 0.25 M sucrose aqueous solution. The homogenates were centrifuged at 10,000 × g for 20 min, and the supernatants were centrifuged at 100,000 × g for 60 min. The microsomes thus pelleted were washed by suspension in 0.15 M Tris-HCl buffer (pH 7.9) and centrifuged at 100,000 × g for 60 min. The washed microsomes were resuspended in 0.25 M sucrose.

Determination of dolichol and Dol-P. For the measurement of dolichol, the liver (ca. 100 mg) was homogenized in 2 ml of distilled water. First, 0.25 ml of 50% KOH aqueous solution and 3 ml of 1% pyrogallol in methanol were added successively to 2 ml of the sample. This mixture was heated at 70 C for 60 min and then cooled to room temperature. The saponified mixture was extracted with n-hexane, evaporated to dryness and analyzed by HPLC with UV detection using 2,2-didecaprenylethanol as an internal standard. The rat plasma and liver microsomes were subjected to alkaline hydrolysis, extracted with n-hexane, derivatized with anthracene-9-carboxylic acid and analyzed by HPLC with fluorescence detection. For measurement of Dol-P homologs, the livers (ca. 100 mg) were homogenized in 2 ml of distilled water. First, 1 ml of 1 N HCl aqueous solution was added to the homogenate, and the mixture was allowed to stand at room temperature for 45 min. This mixture was heated at 70 C for 45 min and then cooled to room temperature. The hydrolyzed mixture was extracted with diethyl ether, derivatized with 3-(9-anthryl)-diazo-2-propene and then determined by HPLC with fluorescence detection using 2,2-didecaprenylethyl phosphate as an internal standard. The HPLC methods have been reported in detail elsewhere (13,14).

Determination of cholesterol in rat liver. Approximately 100 mg of rat liver was homogenized in 1 ml of distilled water. The homogenate was extracted twice with four volumes of chloroform/methanol (2:1). The organic phase was evaporated to dryness under N_2 gas, and the residue was dissolved in 1 ml of chloroform/methanol (2:1). A 100 μl aliquot of the solution was evaporated to dryness, and the residue was dissolved in 100 μl of isopropyl

Abbreviation: Dol-P, dolichyl phosphate.

alcohol. Cholesterol in the isopropyl alcohol solution was measured by using Iatro Lipo TC (Iatro Inc., Tokyo, Japan), a reagent kit for the assay of cholesterol by a cholesterol oxidase method.

Assay for transfer of [^{14}C]mannose from GDP-[^{14}C]mannose to lipid intermediates. One ml of the reaction mixture consisted of 30 mM Tris-HCl buffer (pH 7.8), 1 mM $MnCl_2$, 12.5 mM mercaptoethanol, 2 mM AMP, 0.5 μCi of GDP-[^{14}C]mannose and microsomes (1.2 mg protein). The reaction was started by adding the radioactive substrate, and incubation was performed at 30 C for 15 min. After incubation, dolichyl mannosyl phosphate was extracted with chloroform/methanol (2:1) and analyzed by thin layer chromatography (17).

Assay for HMG CoA reductase activity. The reaction mixture consisted of 200 mM phosphate buffer (pH 7.4), 100 mM EDTA, 100 mM dithiothreitol, 50 mM NADPH, 1 mM DL-[3-^{14}C]HMG CoA, and microsomes (0.12 mg protein). The reaction was started by addition of microsomes and continued at 37 C for 20 min. The reaction was terminated by adding 10 μl of 2 N HCl, and the resulting mixture was further incubated at 37 C for 15 min. Then, the mixture was analyzed by thin layer chromatography (18).

RESULTS AND DISCUSSION

Time course of liver weight after partial hepatectomy. Wet weight of rat liver after partial hepatectomy was measured during the first 20 days, and the regenerative ratio of the liver was calculated (16) (Fig. 1). Regeneration proceeded rapidly during the first five days, reached 90% by day 11 and was completed by day 13.

Concentration of dolichol and Dol-P in regenerating liver. Dolichol and Dol-P in regenerating liver were analyzed by HPLC; the results are shown in Figure 2. The concentration of dolichol in the liver decreased gradually during the first three days, and at day 3 was significantly lower than that of normal liver, 13.6 + 1.34 μg/g vs 21.2 + 1.01 μg/g. From day 3, the concentration of dolichol increased gradually, and on day 11 reached a peak that was 1.5 times higher than that in normal liver. The dolichol concentration of normal liver described here agrees with the data of Keller et al. (19) and Eggens et al. (20). However, the time course of Dol-P was different from that of dolichol. The Dol-P level on day 1 was lower than that of the normal rat liver but increased rapidly during the next three days. The Dol-P level on day 5 was significantly higher than that of normal liver, 5.2 + 0.32 μg/g vs 3.0 + 0.22 μg/g. On the other hand, the concentration of dolichol and Dol-P in the control liver did not change at all in the course of the experiments. The observed normal liver level of Dol-P is in good agreement with the data of Chaudhary et al. (21). Keller et al. (19) have reported the total Dol-P (free and chemically bound Dol-P) levels in rat liver but their values are eight times higher than the control Dol-P levels presented here. This difference may be attributable to the different hydrolysis methods used. We confirmed that our assay could determine the concentrations of free Dol-P and Dol-P monosaccharides in rat liver. These results indicate that the synthesis of Dol-P might precede that of dolichol in the regenerating liver.

Figure 3 shows the mannosyl transferase activity in the regeneraing liver microsomes. The activity was lower on day 1 but was significantly higher on days 3 and 5 than that of the normal liver microsomes. The time course of mannosyl transferase activity coincided with that of Dol-P level in the regenerating liver (Fig. 2). This result suggests that Dol-P levels may regulate mannosyl transferase activity. Figure 4 shows chromatograms of dolichol and Dol-P in the regenerating rat liver on day 5. As can be seen from the chromatograms, changes of the composition of dolichol or of Dol-P were observed during the experimental period.

Concentration of dolichol in microsomes and plasma. Figure 5 shows the time course of the dolichol concentration in the liver microsomes and plasma of partially hepatectomized rats. The time course of the concentration of microsomal dolichol was in good agreement with

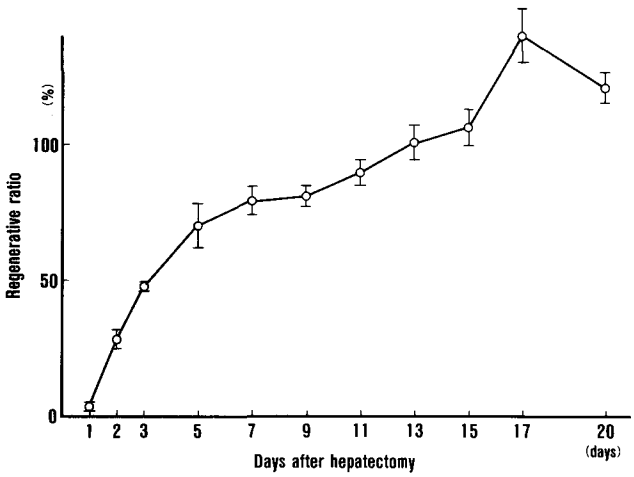

FIG. 1. Time course of liver weight after partial hepatectomy in terms of the regenerative ratio of the liver, calculated by the method of Higgins and Anderson (16). Vertical bars denote SE of the means of three separate experiments.

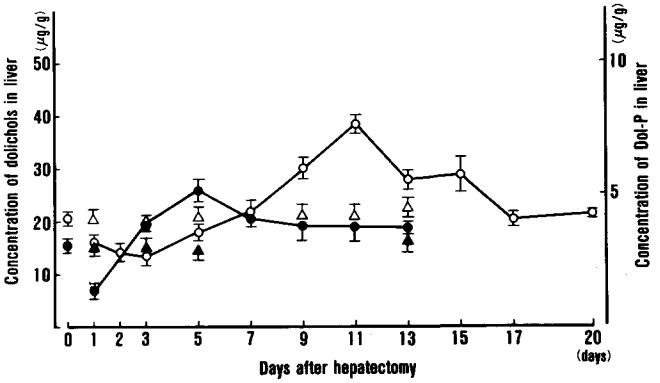

FIG. 2. Time course of the concentrations of dolichol and Dol-P in the regenerating liver. The concentration of dolichol (—○—) and Dol-P (— ● —) in the regenerating liver and the control value of dolichols (—△—) and Dol-P (—▲—) were analyzed as described in Materials and Methods. Vertical bars denote SE of the means of three separate experiments.

that of liver dolichol (Fig. 2). In contrast, the plasma level of dolichol did not decrease but was increased on day 3 when the liver dolichol concentration was lowest during the experimental period. The concentration of microsomal and plasma dolichol in the control did not change at all during the course of experiments. This result suggests that dolichol in plasma might not have originated from the liver. However, it is possible that plasma dolichol originated from liver since dolichol might be released to the plasma as a result of the hepatectomy.

Concentration of total cholesterol and HMG CoA reductase activity in regenerating liver. Figure 6 shows the time course of total cholesterol in the regenerating rat liver and that of HMG CoA reductase activity in the liver microsomes. The cholesterol level in regenerating liver was increased one and three days after hepatectomy,

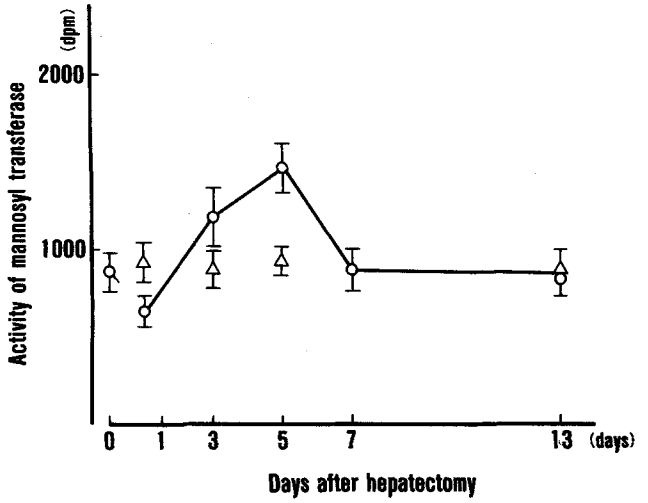

FIG. 3. Time course of mannosyl transferase activity in the regenerating liver microsomes (—○—) and the control activity (—△—). The assay condition were as described under Materials and Methods. Vertical bars denote SE of the means of three separate experiments.

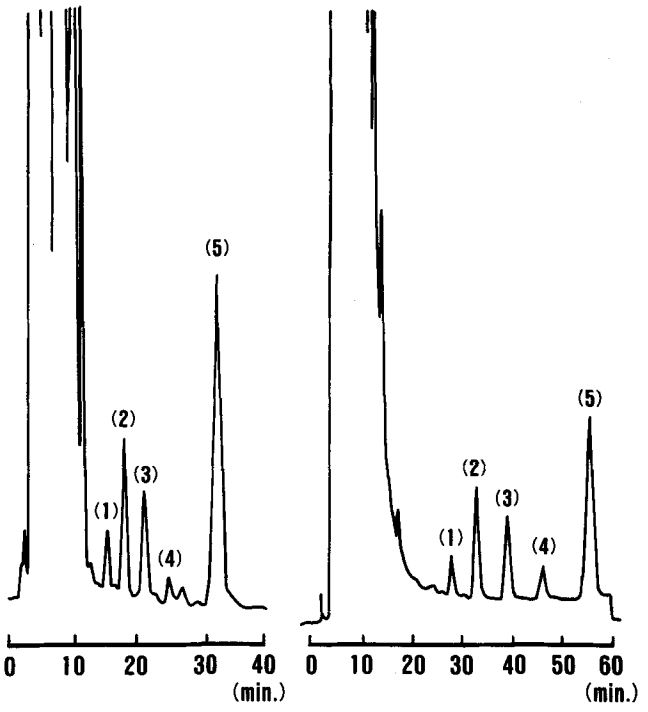

FIG. 4. Chromatograms of dolichol (left) and Dol-P (right) in the regenerating rat liver on day 5. Dolichol and Dol-P were extracted as described in Materials and Methods. Peaks were identified as follows: left: (1) dolichol-17; (2) dolichol-18; (3) dolichol-19; (4) dolichol-20; (5) 2,2-didecaprenyl ethanol (internal standard); right: (1) Dol-P-17; (2) Dol-P-18; (3) Dol-P-19; (4) Dol-P-20; (5) 2,2-didecaprenylethyl phosphate (internal standard).

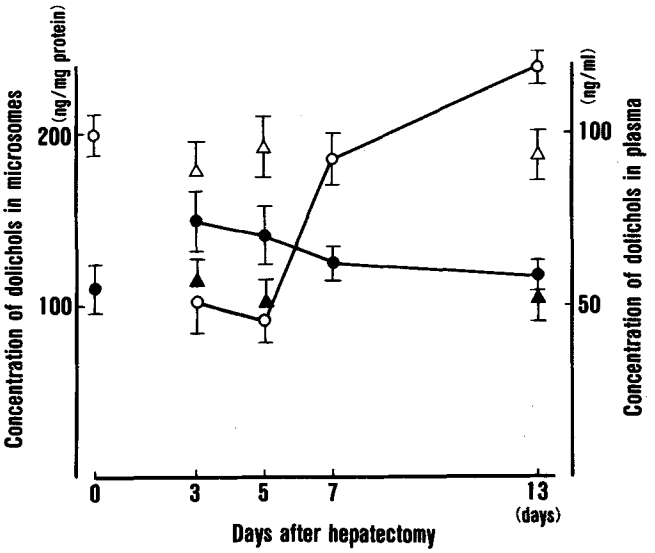

FIG. 5. Time course of the concentration of dolichol in regenerating liver microsomes (—○—) and plasma (— ● —) and the control value of dolichol in microsomes (—△—) and plasma (—▲—). Rat liver microsomes (1 mg protein) or plasma (1 ml) was extracted as described in Materials and Methods. Vertical bars denote SE of the means of three separate experiments.

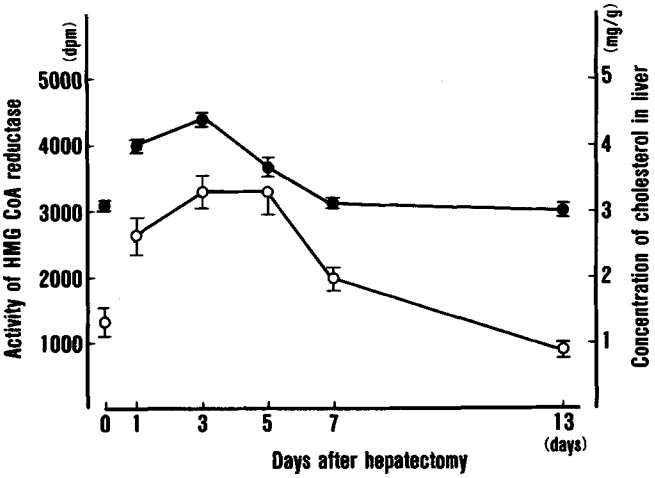

FIG. 6. Time course of the concentration of total cholesterol (— ● —) and HMG CoA reductase activity (—○—) in regenerating liver. The assay conditions were as described under Materials and Methods. Vertical bars denote SE of the means of three separate experiments.

reaching a maximum of 1.5 times that of normal liver, 3.10 + 0.09 mg/g. Subsequently, the level rapidly returned to normal. The time course of HMG CoA reductase activity in the regenerating liver microsomes was similar to that of the total cholesterol in the regenerating liver. The results clearly indicate that in the regenerating liver cholesterol increases first, followed by Dol-P and then dolichol.

James and Kandutsch (20) and Sakakihara and Volpe (9) have studied the regulation of dolichol and cholesterol synthesis in developing brain, and they found that the synthesis of cholesterol preceded that of dolichol. Their observations are in good agreement with our results in regenerating rat liver but they did not examine the synthesis of Dol-P. Since Dol-P serves as the carrier of saccharide moieties in the synthesis of asparagine-linked glycoproteins, the synthesis of Dol-P is quite important (23-25). Marino et al. (12) have recently studied the synthesis of dolichol and Dol-P in the earlier stage (16 hr after partial hepatectomy) of rat liver regeneration. These authors showed that the dolichol content and its synthesis from mevalonate were increased but no variation in Dol-P was observed. The data obtained for the dolichol and Dol-P concentrations on day 1 were different. This may be attributable to somewhat different experimental conditions. We believe that our results have clarified the relationship between dolichol and Dol-P in the regenerating liver, and our data suggest that the synthesis of Dol-P precedes the synthesis of dolichol.

Lysophosphatidylcholine Accumulation in the Ischemic Canine Heart

Anne A.A. Kinnaird, Patrick C. Choy and Ricky Y.K. Man*
Department of Pharmacology and Therapeutics and Department of Biochemistry, Faculty of Medicine, University of Manitoba, Winnipeg, Manitoba, Canada R3E OW3

The production of cardiac arrhythmias and the elevation of lysophosphatidylcholine level in the ischemic myocardium have been well-documented in a number of studies. However, the relationship between the production arrhythmias and the elevation of tissue lysophosphatidylcholine level was not reported. In this study, the lysophosphatidylcholine level and the occurrence of cardiac arrhythmias in the ischemic canine heart were monitored. A temporal relationship between the accumulation of lysophosphatidylcholine and the occurrence of arrhythmias was established after five hr of ischemia. A significant elevation of lysophosphatidylcholine was detected at three hr of ischemia without the occurrence of arrhythmias. The results indicate that cardiac arrhythmias did not cause the elevation of lysophosphatidylcholine and if lysophospholipids are causally related to the arrhythmias that a critical level of the lysophospholipid must accumulate in order to elicit electrophysiological alterations.
Lipids 23, 32-35 (1988).

The development of ventricular arrhythmias after the onset of myocardial ischemia is well-documented (1,2). However, the exact biochemical cause for the production of arrhythmias remains largely unknown. In the last decade, the accumulation of lysophospholipids in the ischemic myocardium has been suggested as one of the biochemical factors in the generation of arrhythmias (3,4). Exogenous addition of lysophospholipids have been shown to cause the depression of action potential in isolated cardiac fibers (5) and to decrease the membrane excitability in Purkinje fibers (6). Higher concentrations of lysophospholipids in the superfusate were found to produce inexcitability and sustained rhythmic activity (6). Addition of lysophosphatidylcholine in the perfusate was shown to cause the production of cardiac arrhythmias in the isolated heart (7,8).

Although the ability of exogenous lysophospholipid to cause arrhythmias is irrefutable, a direct relationship between the development of arrhythmias and the accumulation of lysophospholipids in the ischemic myocardium had not been established. In addition, there had been difficulties in the quantitation of lysophospholipids in the heart.

Lysophosphatidylcholine is the major lysophospholipid in the mammalian heart. We reported in our earlier study that there was an accumulation of lysophosphatidylcholine in the canine myocardium after 24 hr of coronary artery occlusion (9). Since arrhythmias are produced by this model after different periods of ischemia, the objective of this study was to examine the relationship between lysophosphatidylcholine accumulation and the occurrence of cardiac arrhythmias.

Abbreviation: PVC's, premature ventricular contractions.

MATERIALS AND METHODS

Materials. Lysophosphatidylcholine prepared from egg yolk was obtained from Sigma Chemical Co. (St. Louis, MO). Phosphatidylcholine and lysophosphatidylcholine standards were products of Serdary Research Labs. (London, Ontario, Canada). Thin layer chromatographic plates (SIL-G25) were obtained from Brinkmann (Rexdale, Ontario, Canada). All other chemicals were of reagent grade and were obtained from Fisher Chemical Co. (Edmonton, Alberta, Canada).

Methods. Mongrel dogs of either sex, weighing 8-15 kg, were used for this study. The dogs were anesthetized by IV injection of sodium pentobarbital (30 mg/kg). Respiration was maintained by a Harvard pump. The lead II electrocardiogram and blood pressure were monitored continuously throughout the experiment. The heart was exposed by a left thoracotomy. The left anterior descending coronary artery was isolated at a site proximal to the first branch (1-1.5 cm from the origin of the artery). The artery was occluded by the Harris two-stage procedure (10). A total of 34 dogs underwent the occlusion procedure. Four dogs developed ventricular fibrillation and subsequently died (2 in the 1-hr group and 1 each in the 3 and 5-hr group). In the remaining animals, hearts were removed at the end of 1, 3, 5, 8 and 12 hr of ischemia (7, 6, 6, 6 and 5 animals in each group respectively). Tissue samples were taken from the ischemic and nonischemic areas of the left ventricle as described previously (9). After weighing, the samples were used immediately for lipid extraction.

The electrocardiograms were later analyzed over a period of three to five min. The average number of premature ventricular contractions (PVC's) per minute was determined for comparison over the various time periods of ischemia. The number of PVC's/min was used as a measure of the frequency of cardiac arrhythmias.

Lipid analysis. Lipids were extracted from the tissue using a neutral solvent system (11). The tissue was homogenized in 10 vol (w/v) of chloroform/methanol (1:2, v/v) and extracted twice with the same solvent. The extracts were pooled and a biphasic mixture was obtained by the addition of 0.1 M KCl to provide a solvent mixture of $CHCl_3/CH_3OH/H_2O$ (2:1:0.8, v/v/v). The lower phase was evaporated under reduced pressure. The lipid extract was reconstituted in a small volume of chloroform/methanol (2:1) and was used immediately for lipid analysis. The phospholipids in the lipid extract were separated by thin layer chromatography in a solvent containing chloroform/methanol/water/acetic acid (75:60:8:10, v/v/v/v) (11). The phospholipid fractions on the thin layer chromatographic plates were visualized by iodine vapor and identified by phospholipid standards. Quantitation of lipid phosphorus was performed by the method of Bartlett (12).

The dry wt of the tissue was determined by complete dehydration in an oven at 100 C under reduced pressure. Total phospholipid content was assessed by the method

of Raheja (13). Quantitation of total cholesterol was performed by enzymatic assay with cholesterol oxidase (14).

Statistical analysis. Values were expressed as mean ± standard deviation. Analysis of variance and Student's t-test for paired or unpaired data were used where appropriate. A p-value <0.05 was considered significant.

RESULTS

The alterations of lysophosphatidylcholine concentration in the ischemic and non-ischemic areas of canine hearts after 1, 3, 5, 8 and 12 hr of coronary artery occlusion are summarized in Table 1. The results were expressed as dry wt instead of wet wt since edema, as indicated by a significant increase in tissue water in the ischemic area, was evident after 8 and 12 hr of coronary artery occlusion (Table 2). Hence, all subsequent data were calculated as per g dry wt to correct for the increase in tissue water after ischemia. There was no significant change in lysophosphatidylcholine content after one hr of ischemia. The increase in lysophosphatidylcholine in the ischemic areas as compared to the nonischemic areas of the same hearts (9) was significant after three hr of ischemia (Table 1). The percentage increases in lysophosphatidylcholine content of the ischemic area compared with the nonischemic area after 3, 5, 8 and 12 hr of ischemia were 28, 53, 104 and 171% respectively. At 12 hr of coronary artery occlusion, the increase in lysophosphatidylcholine in the ischemic area was significantly higher than the increases observed at one, three, five or eight hr.

Cardiac arrhythmias occurred during the initial phase after the occlusion of the coronary artery. The arrhythmias usually subsided over the next 30 min. Subsequently, the number of PVC's/min increased with the duration of ischemia. Significant increases in PVC's/min were observed after 8 and 12 hr of coronary artery occlusion. The relationship between the percentage increase of lysophosphatidylcholine in the ischemic area and the occurrence of PVC is depicted in Figure 1. It is evident that the time course of lysophosphatidylcholine accumulation appears to precede the increase in the number of PVC's/min.

The total phospholipid, phosphatidylcholine and total cholesterol in the nonischemic and ischemic areas after various time periods are presented in Table 3. There was no significant change in any of these lipids.

TABLE 1

Lysophosphatidylcholine Content in Nonischemic and Ischemic Regions of Canine Hearts

		Lysophosphatidylcholine concentration μmol/g dry wt

DISCUSSION

The arrhythmogenic (3,4) and cytolytic (15) actions of lysophosphatidylcholine have put a definite focus on the need to quantitate this lysophospholipid in the cardiac

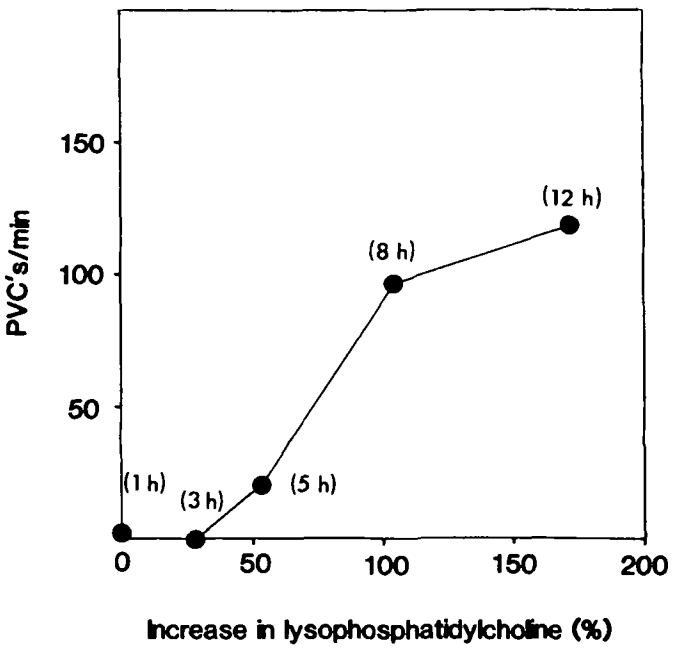

FIG. 1. The relationship between the accumulation of lysophosphatidylcholine and the frequency of cardiac arrhythmias during myocardial ischemia. Ischemia in the left ventricle of the canine heart was produced by the occlusion of the left anterior descending coronary artery. The number of premature ventricular contractions (PVC's) and the lysophosphatidylcholine content in the ischemic and nonischemic tissues were determined at different periods after the occlusion. The percentage increase of lysophosphatidylcholine in the ischemic tissue was calculated by comparison with the corresponding nonischemic tissue. The numbers in parentheses are the time points after the occlusion of the left anterior descending coronary artery.

tissue. The use of acidic extraction medium that caused the hydrolysis of phospholipid plasmalogens has been shown to produce a high lysophospholipid content (16). In this study, a neutral extraction medium that was shown to provide an accurate assessment of cellular lysophosphatidylcholine content was used (11,16). In addition, the lysophosphatidylcholine levels in the control and ischemic tissues subsequently were confirmed by a radiolabeled procedure developed in our laboratory (17).

It is clear from this study that lysophosphatidylcholine level significantly was increased after three hr of ischemia. The increase reached a maximum at 12 hr of ischemia, and no further increase was observed at 24 hr of ischemia (9). The results are expressed on the basis of the tissue dry wt since edema was apparent after prolonged period of ischemia. No significant change in total phospholipid, total cholesterol or phosphatidylcholine was detected at all time points. Although the increase in lysophosphatidylcholine probably arose from the catabolism of phosphatidylcholine, we were not able to detect such small changes in phosphatidylcholine due to its relatively large pool in comparison with lysophosphatidylcholine.

Elevated levels of lysophosphatidylcholine in the ischemic tissues were reported in a number of studies using a variety of animal models. In all cases, a significant increase in lysophosphatidylcholine levels (50% or more) was found in the ischemic myocardium (9,16,18,19). A recent report by Steenbergen and Jennings (19) noted that significant elevation of tissue lysophosphatidylcholine was not detected in the canine myocardium until after 2.5 hr using a model of in vitro ischemia. This was in contrast to previous reports that lysophosphatidylcholine level was increased in much shorter periods in porcine (16) or feline (18) hearts. A difference in species has been suggested as a reason for these apparent discrepancies (4). The result obtained from this study qualitatively and quantitatively is comparable to those reported by Steenbergen and Jennings (19). This is not surprising since canine heart was used in both studies.

The production of arrhythmias and the elevation of lysophosphatidylcholine level in the ischemic heart have been well-documented separately in various studies. However, the relationship between arrhythmia production and elevation of lysophosphatidylcholine level was not clear. It also is not known if the accumulation of

lysophosphatidylcholine may be related causally to the occurrence of cardiac arrhythmias. In this study, the monitoring of the premature ventricular contraction provided us with a facile and quantitative approach to determine the occurrence of arrhythmias. Our results clearly demonstrate a temporal relationship between the lysophosphatidylcholine level and the frequency of arrhythmias after five hr of coronary artery occlusion. It should be noted that a significant elevation of lysophosphatidylcholine level was observed at three hr of ischemia without the occurrence of arrhythmias. If lysophosphatidylcholine is a biochemical factor in the production of arrhythmias, it appears that a critical quantity of lysophosphatidylcholine (a two-fold increase) must accumulate in order to elicite electrophysiological alterations. We conclude that elevation of the lysophospholipid cannot be a consequence of cardiac arrhythmias.

Free Fatty Acid Inhibition of the Insulin Induction of Glucose-6-Phosphate Dehydrogenase in Rat Hepatocyte Monolayers

Lisa M. Salati, Bonnie Adkins-Finke and Steven D. Clarke*
Graduate Program in Nutrition, University of Minnesota, 1334 Eckles Ave., St. Paul, MN 55108

Rat hepatocytes in monolayer culture were utilized to determine if the decrease in glucose-6-phosphate dehydrogenase (G6PD) activity resulting from the ingestion of fat can be mimicked by the addition of fatty acids to a chemically, hormonally defined medium. G6PD activity in cultured hepatocytes was induced several-fold by insulin. Dexamethasone or T3 did not amplify the insulin induction of G6PD. Glucose alone increased G6PD activity in cultured hepatocytes from fasted donors by nearly 500%. Insulin in combination with glucose induced G6PD an additional two-fold. The increase in G6PD activity caused by glucose was greater in hepatocytes isolated from 72 hr-fasted rats as compared to fed donor rats. Such a response was reminiscent of the "overshoot" phenomenon in which G6PD activity is induced well above the normal level by fasting-refeeding rats a high glucose diet. Addition of linoleate to the medium resulted in a significant suppression of insulin's ability to induce G6PD, but linoleate had no effect on the induction of G6PD activity by glucose alone. A shift to the right in the insulin-response curve for the induction of G6PD also was detected for the induction of malic enzyme and acetyl-CoA carboxylase. Arachidonate (0.25 mM) was a significantly more effective inhibitor of the insulin action than linoleate was. Apparently rat hepatocytes in monolayer culture can be utilized as a model to investigate the molecular mechanism by which fatty acids inhibit the production of lipogenic enzymes. In part, this mechanism of fatty acid inhibition involves desensitization of hepatocytes to the lipogenic action of insulin.
***Lipids 23,* 36–41 (1988).**

Glucose-6-phosphate dehydrogenase (G6PD, EC 1.1.1.4.9), the rate-determining enzyme of the hexose monophosphate shunt, is a source of reduced nicotinamide adenine dinucleotide phosphate (NADPH) for cellular lipogenesis. The activity and synthesis of hepatic G6PD in vivo is affected by changes in insulin, glucocorticoid and thyroid hormone availability (1–7). Diabetes mellitus results in a pronounced loss of hepatic G6PD activity, which is restored by insulin administration (1). Adrenalectomy prevents the overshoot response of G6PD in fasted-refed rats (5), and thyroidectomy attenuates the stimulation of G6PD by dietary carbohydrate (6,7). The role of specific hormones in the modulation of G6PD synthesis has been identified utilizing cultured hepatocytes in a defined hormonal environment. Insulin and glucocorticoids are key regulatory hormones that enhance both G6PD synthesis and mRNA concentration (8–12). Thyroid hormone, in contrast to its purported stimulatory action in vivo (3,6,7), has no affect on the level of G6PD in isolated hepatocytes (8,9).

Abbreviations: G6PD, glucose-6-phosphate dehydrogenase; NADPH, reduced nicotinamide adenine dinucleotide phosphate.

Dietary fat is one of many factors that alter the hepatic content of G6PD. The induction of G6PD by dietary carbohydrate is impaired by the addition of fat, specifically polyenoic fatty acids to the diet (2,4,13). Similarly the fast-refeed overshoot of G6PD is attenuated by dietary corn oil (14). The inhibitory effect of dietary fats may be a direct regulation of hepatic gene expression. Alternatively, dietary fats may alter the concentration or modulate the action of key lipogenic hormones. Primary hepatocyte cultures provide a model to study the interaction of fatty acids with hormones on the induction of G6PD. In this communication, we report that the unique stimulatory action of insulin on G6PD is attenuated by the addition of fatty acids to the culture medium.

MATERIALS AND METHODS

Materials. Collagenase (EC 3.4.99.5) type IV was obtained from Sigma Chemical Co. (St. Louis, MO). Insulin was provided generously by Walter N. Shaw, Lilly Research Laboratories (Indianapolis, IN). Waymouth MB 752/1 medium containing glutamine and no bicarbonate and the newborn calf serum were purchased from Grand Island Biological Co. (Grand Island, NY). Tissue culture plates were obtained from Falcon Plastics (Oxnard, CA). Fatty acids were obtained from NuChek Prep (Elysian, MN). Dexamethasone-hexadrol phosphate was obtained from Organon (West Orange, NJ). Triiodothyronine (T3) and all other chemicals were purchased from Sigma Chemical Co. Collagen for coating tissue culture plates was isolated from rat tails as recommended by Michalopolous and Pitot (15). Sprague-Dawley rats were purchased from Harlan Laboratories (Madison, WI).

Liver cell isolation and culture. Liver cells were isolated and cultured as previously described (16). The hepatocyte donors were rats that had been fasted for 72 hr or rats fed laboratory chow. Fasted donors were compared to fed donors in order to ascertain if fatty acid suppression of the G6PD induction that occurs with refeeding in vivo was reproducible in vitro, if G6PD induction was less variable and more pronounced in fasted rats, and if a shorter prehormone culture period could be employed in order to shorten the time of cell culture. The isolated hepatocytes were washed into cold, well-oxygenated culture Hi/Wo/Ba medium (16) and plated onto dry collagen-coated tissue culture plates at a density of 3×10^6 cells per 60 mm plate and in a total volume of 3 ml of medium. The cells were allowed to attach to the plates for four hr in the presence of 4% newborn calf serum (v/v). After the attachment period, cells were maintained for an additional 24 hr (fasted donors) or 48 hr (fed donors) in a serum- and hormone-free medium prior to hormonal additions. The hepatocytes were maintained in culture for 96–120 hr with media changes occurring at 24 hr-intervals. The concentrations of hormones and fatty acids are indicated in the Results section. The Hi/Wo/Ba medium utilized in our studies consists of Waymouth MB 752/1 containing 28 mM glucose, glutamine (6.8 mM),

alanine (0.4 mM), serine (0.5 mM), $NaHCO_3$ (26 mM), bovine serum albumin (0.2%). Thus, a glucose stimulus for enzymatic induction was present during the 24 or 48 hr hormone-free period, except in the experiments of Figure 2 in which the inducing action of glucose alone was investigated. In these studies, glucose was absent during the 24 hr hormone-free period.

The viability of freshly isolated liver cells and cultured hepatocytes was ascertained by ATP measurements (17) and trypan-blue exclusion. Freshly isolated liver cells were 95% viable as determined by trypan-blue exclusion. ATP concentration was routinely between 0.8 and 1.2 μmol/mg DNA in the freshly isolated and cultured cells.

The cultured cells were harvested by scraping the hepatocytes from the plates with 1 ml of cold-buffered digitonin solution: Mops, pH 7.0 (20 mM), dithiothreitol (1 mM), ethylenediamine tetraacetic acid (EDTA) (2.5 mM), mannitol (250 mM) and digitonin (5 mg/ml). After a five min incubation on ice, the cell digitonin mixture was microfuged for five min. The supernate was utilized for G6PD measurements, and the cell pellets analyzed for DNA (18).

Glucose-6-phosphate dehydrogenase activity. Enzyme activity was determined in cell supernatants. NADP reduction was followed fluorimetrically in an assay system that consisted of Tris-acetate, pH 7.0 (50 mM), dithiothreitol (0.5 mM), NADP (0.5 mM) and glucose-6-phosphate (2 mM). One unit of enzyme activity is defined as the formation of 1 μmol of NADPH per min at 30 C. This assay assumes that under our conditions, 6-phosphogluconate dehydrogenase activity was not rate-limiting in the reaction. In support of such an assumption, Kelley et al. (19) reported that hepatocytes prepared from rat donors in a metabolic state comparable to that of the rats in our studies possessed 6-phosphogluconate dehydrogenase activity that significantly exceeded the activity of G6PD. Therefore, it is unlikely that 6-phosphogluconate dehydrogenase activity affected our G6PD activity determinations. Furthermore, this means that 2 μmol of NADPH are assumed to be produced per μmol of glucose-6-phosphate utilized.

Other assays. Free fatty acids were bound to bovine serum albumin as previously described (16). The albumin had been washed previously with charcoal and florisil to remove residual lipid. Cultured cells not receiving fatty acids received an equivalent amount of albumin.

RESULTS

Induction of G6PD in hepatocyte monolayers prepared from fed and fasted donor rats. Insulin in the presence of 28 mM glucose markedly enhanced G6PD activity in cultured rat hepatocytes prepared from fed or fasted donors (Fig. 1). Dexamethasone did not amplify the insulin induction of G6PD (Fig. 1). Furthermore, T_3 alone or in combination with insulin or insulin plus dexamethasone did not increase G6PD activity regardless of the nutritional status of the hepatocyte donor (data not shown).

Much of the apparent insulin response in liver cells was due to glucose per se (Fig. 1). As an example, hepatocytes from fasted donor rats cultured for 72 hr with 28 mM glucose and without hormones possessed G6PD activity

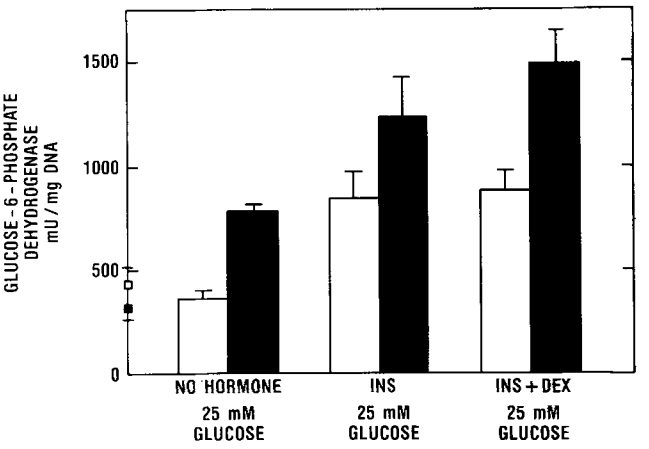

FIG. 1. Induction of G6PD activity in rat hepatocyte monolayers from fed and fasted donors. Hepatocyte monolayers were prepared from fed or 72 hr-fasted rats and maintained in culture as described in the Methods section. The medium contained 28 mM glucose during the 24 hr and 48 hr prehormone treatment culture period for the cells from fasted and fed donors, respectively. The initial G6PD activity at the time of cell isolation is depicted by the open (fed donors) and solid (fasted donors) squares on the vertical axis. The concentration of insulin and dexamethasone was 10^{-6} M. The period of hormone treatment was 72 hr. Open and solid bars represent hepatocytes from fed and fasted donor rats, respectively. Each value represents the mean of three to seven separate culture preparations with three to four plates/culture. Statistical analysis using two-way analysis of variance and F-test revealed significant ($P < 0.05$) effects of hormone and fasting but no hormone × fasting interaction (38).

that was 190% greater than the activity in freshly isolated cells (Fig. 1).

An increase of G6PD activity during culture did not occur when hepatocyte monolayers were maintained in glucose-free medium, and in fact G6PD activity declined from 191 mU/mg DNA in freshly isolated cells to 48 mU/mg DNA after 96 hr in culture (Fig. 2). Glucose induction of G6PD was nearly maximal with a glucose concentration of 5 mM, which approximately is equivalent to the level of circulating blood glucose. The glucose increment accounted for 40 to 50% of the apparent insulin-stimulated rise of G6PD activity in the hepatocytes from fasted donors. In contrast, G6PD activity was not induced by glucose in hepatocytes prepared from fed donors (Fig. 1, compare the vertical axis value with the column for no hormone-fed rat). Consequently, when the insulin induction was corrected for G6PD activity in the absence of hormones, the insulin increment was the same in hepatocytes from both fed and fasted donors, 484 mU/mg DNA vs 456 mU/mg DNA, respectively.

The glucose induction of G6PD apparently was greater in hepatocytes from fasted as compared to fed donors (Fig. 1). However, this conclusion is equivocal because the 24 hr longer prehormone culture period for cells from the fed donor may have been a factor in the apparent responsive difference between fed and fasted donors.

Fatty acid inhibition of the hormonal induction of G6PD. Dietary fatty acids are effective inhibitors of G6PD activity in vivo (2,4,13,14). Therefore, we hypothesized that the induction of G6PD in hepatocyte cultures would be attenuated by the addition of free fatty acids to the culture medium.

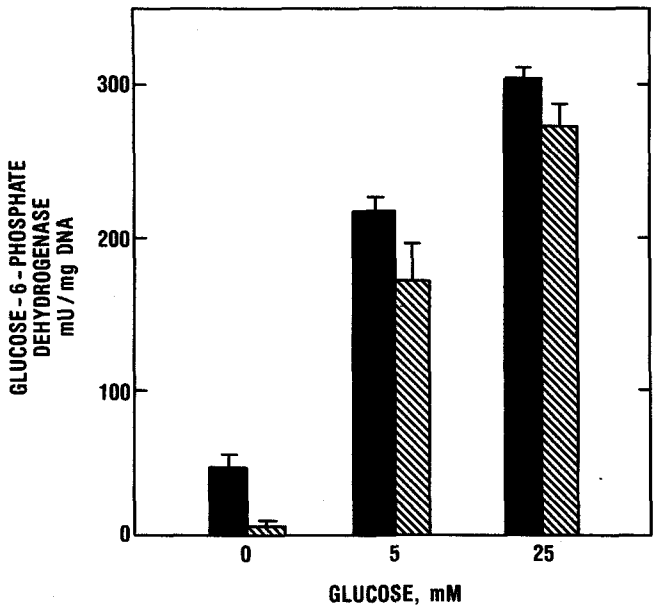

FIG. 2. Induction of G6PD by glucose in hepatocyte monolayers prepared from 72 hr-fasted rats. Hepatocyte monolayers were prepared from 72 hr-fasted rats and maintained in culture as described in the Methods section. The medium contained no glucose during the 24 hr prelinoleate treatment culture period. The concentration of glucose during the linoleate treatment phase is depicted in the figure. Hepatocytes were maintained in a media containing no fatty acid (solid bars) or 0.25 mM albumin-bound linoleate (hatched bars). Hepatocytes were harvested 72 hr after glucose addition. G6PD activity in freshly isolated hepatocytes was 191 mU/mg DNA. Each bar represents the mean of three determinations. Two-way analysis of variance and F-test (38) revealed a significant ($P < 0.05$) induction by glucose but no effect of fat.

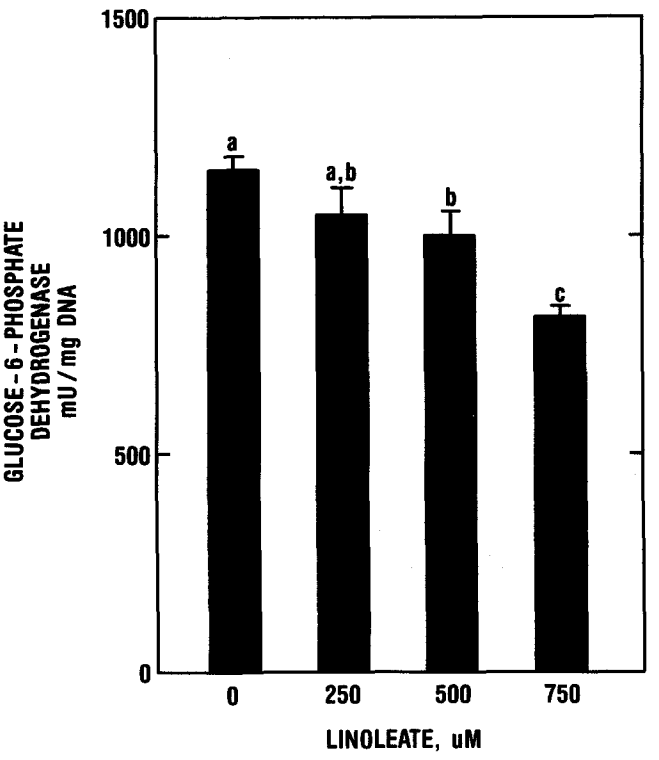

FIG. 3. Influence of linoleate on the induction of G6PD activity by insulin plus dexamethasone. Hepatocyte monolayers were prepared from 72 hr-fasted rats and maintained in culture as described in the Methods section after the hepatocytes had been maintained in culture for 24 hr in a medium containing 28 mM glucose and free of serum or hormones. After this 24 hr period, 10^{-6} M insulin/dexamethasone and the indicated concentrations of albumin-bound linoleate were added to the medium. Hepatocytes were maintained an additional 72 hr. Each bar represents the mean of three determinations from a representative cell preparation. Values with different letters are significantly different ($P < 0.05$) as evaluated by one-way analysis of variance and Tukey's t-test (38).

Hepatocytes from fasted donors were utilized in order to investigate the effect of fatty acids on G6PD response to both glucose and hormones. Linoleate was chosen as the fatty acid for primary investigation because it is not cytotoxic (16), maintains the linoleate content of the hepatocyte membrane (unpublished data) and more effectively suppresses the synthesis of lipogenic enzymes in the intact rat (2,13). The initial studies suggested fatty acids did not inhibit G6PD induction, i.e. glucose induction of G6PD was not significantly suppressed by the inclusion of linoleate (250 μM) in the culture medium (Fig. 2). Further, the induction of G6PD by 10^{-6} M insulin plus dexamethasone was not significantly decreased by 250 μM linoleate (Fig. 3). Palmitate, oleate, arachidonate, eicosapentaenoate or docosahexaenoate (250 μM) similarly were ineffective (1587, 1317, 1244, 1502 and 1361 mU/mg DNA, respectively vs 1159 mU/mg DNA without fatty acid). The induction of G6PD activity by insulin/dexamethasone was attenuated by levels of fatty acid in excess of 250 μM, but the extent of suppression was only 13% and 30% for 500 and 750 μM linoleate, respectively (Fig. 3). This inhibition was not a toxic effect of fatty acid on hepatocyte viability. Cellular ATP concentration was not lowered significantly by linoleate (Table 1).

It is possible that with 10^{-6} M insulin plus 10^{-6} M dexamethasone, the stimulatory action of the hormones overwhelmed the inhibitory mechanism of the free fatty acids. Therefore, the influence of free fatty acid on the insulin response curve for the induction of G6PD activity was examined in the absence and presence of dexamethasone (Figs. 4, 5 and 6). In the presence of 10^{-6} M dexamethasone, free fatty acid had no effect on the insulin-dependent induction of hepatocyte G6PD activity (Fig. 4). However,

TABLE 1

Influence of Linoleate on Hepatocyte ATP Concentration

Linoleate, μM	ATP, nmol/mg DNA
0	1.26 ± 0.11
250	0.96 ± 0.01
500	1.11 ± 0.04
750	0.86 ± 0.03

After the hepatocytes (isolated from fasted donors) were maintained in culture for 24 hr in the absence of hormone or serum (Hi/Wo/Ba, 28 mM glucose), the medium was changed to one containing 1 μM insulin and albumin-bound linoleate at the concentrations indicated. Each value is the average of three observations ± S.E. Fatty acid did not affect significantly the cellular ATP concentration as determined by one-way analysis of variance and F-test (38).

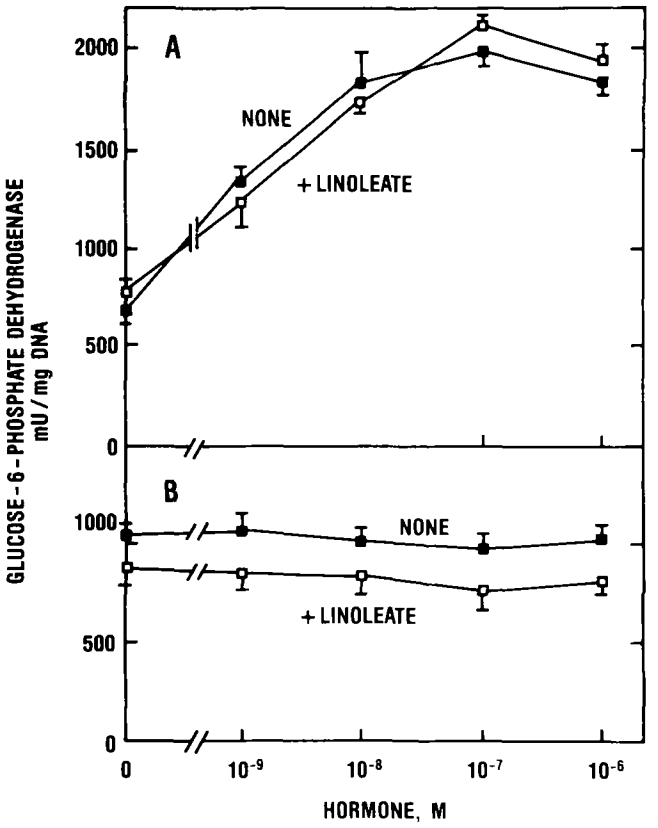

FIG. 4. Failure of linoleate to suppress G6PD induction in hepatocyte monolayers when the media contains 10^{-6} M dexamethasone (A) or insulin (B). Hepatocyte monolayers were prepared from 72 hr-fasted rats and maintained in culture as described in the Methods section. After the hepatocytes had been maintained in culture for 24 hr in a medium containing 28 mM glucose and no serum or hormones, insulin and dexamethasone were added to the medium. Figure 4A (Experiment 1) represents the response to varying insulin concentrations at a constant concentration of 10^{-6} M dexamethasone, and Figure 4B (Experiment 2) represents the response of G6PD to varying dexamethasone concentrations in the presence of 10^{-6} M insulin. Hepatocytes were harvested 72 hr after the addition of the hormone/linoleate supplements. Open squares and closed squares represent the induction of G6PD activity in the presence and absence of 0.25 mM albumin-bound linoleate. The initial activity of G6PD, i.e. 24 hr without serum or hormones, was 384 mU/mg DNA. Two-way analysis of variance indicated a significant effect of insulin ($P < 0.05$).

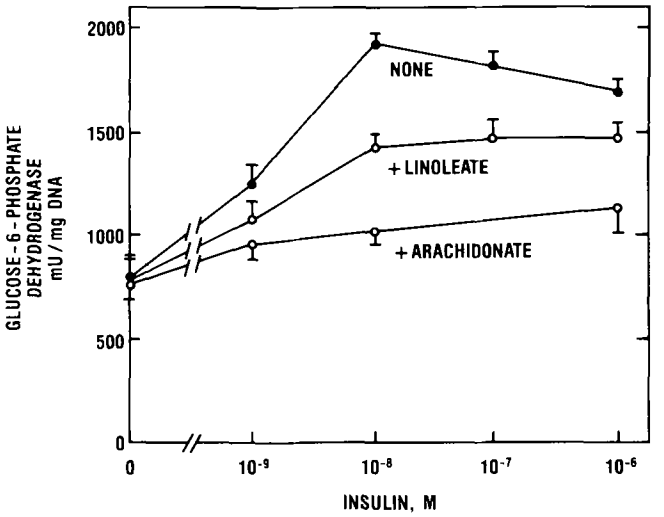

FIG. 5. Fatty acids impaired the insulin induction of hepatocyte G6PD when dexamethasone was deleted from the medium. Hepatocyte monolayers were prepared from 72 hr-fasted rats and maintained in culture as described in the Methods section. After the hepatocytes had been maintained in culture for 24 hr in a medium containing 28 mM glucose and no serum or hormone, insulin and fatty acids were supplemented to the media. Hepatocytes were harvested after being maintained an additional 72 hr. The concentration of albumin-bound linoleate and arachidonate was 0.25 mM. Each value represents the mean of three determinations. The induction of G6PD by insulin and the inhibition by fatty acid were significant ($P < 0.05$) as evaluated by a two-way analysis of variance and F-test. Arachidonate was significantly more inhibitory than linoleate ($P < 0.05$).

when dexamethasone was omitted from the media 250 μM albumin-bound linoleate significantly ($P < 0.05$) decreased the insulin-dependent induction of G6PD activity (Fig. 5). The shift of the insulin response curve to the right, which resulted from the supplementation of linoleate to the media, implies that linoleate decreased insulin sensitivity in cultured hepatocytes. A significant shift to the right in the response curve for insulin also was observed for the activities of acetyl-CoA carboxylase and malic enzyme (Figs. 6A and 6B). Arachidonate, the elongation and desaturation product of linoleate, was a significantly more effective inhibitor of G6PD induction than was linoleate (Fig. 5).

DISCUSSION

The hyperlipogenic condition induced by insulin in hepatocyte monolayers is accompanied by an increase in G6PD activity and in acetyl-CoA carboxylase (16) and malic enzyme activities (20,21). G6PD is uniquely sensitive to insulin in a manner generally unaffected by glucocorticoids (Figs. 1 and 4). The enhancement of G6PD activity by insulin is potentially via an increase in both pre- and post-translational events (22). In this regard, insulin enhancement of G6PD synthetic rate in primary rat hepatocyte monolayers was accompanied by an increase in G6PD-mRNA concentration (10,11).

While insulin is essential to maximizing the induction of lipogenic enzymes in cultured hepatocytes, glucose also appears to play a key role in this process, particularly in hepatocytes from fasted donors (Figs. 1 and 2). The fact that the glucose induction of G6PD activity was near maximum at the physiological concentration of glucose, i.e. 5 mM, indicates that glucose may play a significant role as a determinant of G6PD activity in vivo. In addition, the inductive effect of glucose in hepatocytes from fasted rats suggests that glucose per se is an important factor in the enzyme "overshoot" phenomenon of G6PD associated with fasting and refeeding carbohydrate (5,13). This effect of glucose may be at the level of transcription (23) and translation (24). Glucose treatment of hepatocytes was reported to increase the expression of several mRNAs (23) while accelerating the synthesis of G6PD (24). The stimulus for glucose induction of G6PD may be related to the undefined carbohydrate signal proposed by Mariash and Oppenheimer (20). Alternatively, the glucose mechanism may be nonspecific in the sense that it is serving as a source of energy or glycosylation substrate rather than being a specific regulator of gene expression. Nevertheless, a role for glucose as a hormone-independent

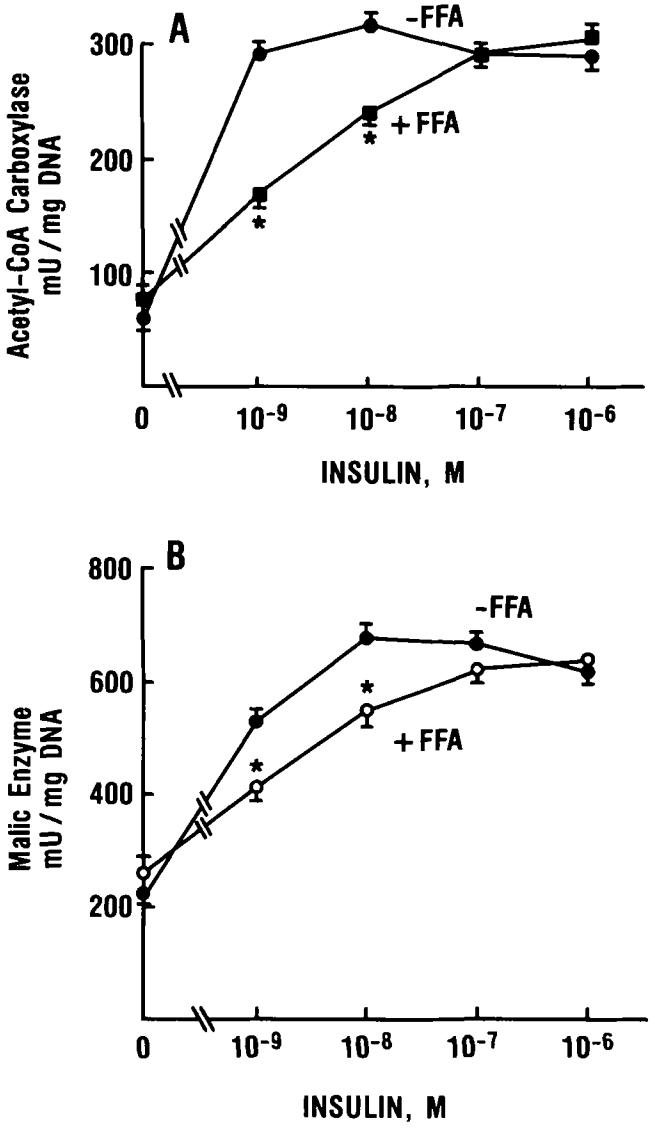

FIG. 6. Linoleate impairment of the insulin induction of hepatocyte acetyl-CoA carboxylase (A) and malic enzyme (B). Hepatocyte monolayers were prepared and maintained as described in the legend for Figure 5 except that the media of hepatocytes used to determine the activity of acetyl-CoA carboxylase contained 10^{-6} M dexamethasone. The concentration of linoleate was 0.25 mM. Each value represents the mean of three determinations. The asterisk indicates values are significantly ($P < 0.05$) lower than the activity in the absence of fatty acid.

inducer of G6PD may be teleologically advantageous because of the need for pentoses in cellular RNA/DNA synthesis.

In addition to a need for carbohydrate, adrenalcorticoids reportedly are necessary for the hyperinduction of G6PD activity in the intact animal (5). However, our studies with hepatocyte monolayers indicate that the G6PD induction primarily is a response to glucose and insulin (Figs. 1 and 2). Inclusion of dexamethasone in the media did not further increase the induction of G6PD. In contrast, dexamethasone has been reported to amplify the insulin induction of G6PD by increasing hepatocyte content of G6PD-mRNA without enhancing G6PD-mRNA translation (10). Our inability to detect an amplification of the insulin action may be the consequence of differences in culturing techniques. Specifically, our method for culturing hepatocytes utilizes a four-hr attachment period in a media containing 4% newborn calf serum.

Possibly the serum contains sufficient glucocorticoids or other stimulatory factors to eliminate the dexamethasone amplication of the insulin effect on G6PD expression. However, neither our hepatocyte model nor that of Stumpo and Kletzien (10) has defined completely the optimum conditions for G6PD expression in hepatocyte monolayers because maximal G6PD activity in cultured hepatocytes (Figs. 1 and 4; [8–10]) does not reach the level achieved in vivo (5). Apparently, additional stimuli (25), e.g. epidermal growth factor (25), are necessary for optimum hepatic G6PD induction.

Although rat hepatocytes in monolayer culture have limitations, they have provided a model in which to pursue the mechanism by which dietary fats inhibit the induction of lipogenic enzymes. One of the apparent mechanisms involves a fatty acid suppression of insulin action (Figs. 5 and 6). Free fatty acid, i.e. linoleate, reduced the sensitivity of hepatocytes to insulin as judged by the expression of G6PD, acetyl-CoA carboxylase, and malic enzyme activities. This effect occurred at physiological fatty acid concentrations and was not due to hepatocellular toxicity of the linoleate (Table 1). The linoleate/insulin interaction in the hepatocyte monolayers appears to be in disagreement with our recent report (26) that suppression of lipogenesis by dietary fat is independent of insulin. The explanation for this difference may reside in the fact that while linoleate continued to be a more effective inhibitor of lipogenesis in severely diabetic rats fed fructose, complete B-cell ablation may not have been achieved in our in vivo study (26). Mariash and Oppenheimer (20) have stated that the metabolism of fructose and its induction of lipogenic enzymes is not insulin-independent and does not occur in rats in whom serum insulin levels are undetectable. Hepatocytes in primary culture may provide a superior model for defining nutrient/hormone interactions because of the difficulties encountered with in vivo hormone ablation-replacement approaches.

Arachidonic acid was significantly more effective than linoleate (Fig. 5), which suggests the inhibitory action of linoleate may be a consequence of its conversion to arachidonate. In this regard, an inhibitor of linoleate elongation and desaturation prevented the dietary linoleate inhibition of lipogenic enzymes (27,28). However, supplementation of arachidonate to the diet reinstated the suppression of lipogenic enzymes (28). Although prostaglandins have been proposed as mediators of the linoleate/arachidonate inhibition, their role is equivocal because polyenoic fatty acids that are not prostanoid precursors, e.g. ω-3 fatty acids, also reduce the hepatic content of lipogenic enzymes (4).

It is possible that the fatty acid inhibition of the insulin induction of G6PD may have been the consequence of direct inhibition of transcription or translation or an indirect mechanism involving interference with the transduction of the insulin signal. The observation that fatty acids only interfered with insulin function as evaluated by the activities of G6PD, acetyl-CoA carboxylase and malic enzyme suggests that the mechanism of fatty acid inhibition may be indirect, i.e. reduced insulin binding and/or impaired transduction of insulin events

through the plasma membrane. In this respect, liver plasma membranes isolated from rats fed a high-fat diet bind less insulin bind insulin and generate less of the putative insulin second message (29,30). Such insulin insensitivity is attributed to altered membrane glycoprotein caused by reduced activity of several hepatic glycosyltransferases (31,32). Long-term culturing of hepatocytes with linoleate or arachidonate may be speculated to elicit a similar reduction in glycoprotein metabolism.

If fatty acids impaired the production of the insulin second message, a consequence could be reduced pyruvate dehydrogenase activation and subsequently less synthesis of the purported glucose signal that stimulates synthesis of lipogenic enzymes (30,33). Alternatively, impaired insulin binding and/or decreased transduction of the insulin signal hepatocytes cultured with fatty acids could lead to reduced insulin-receptor tyrosine kinase activity and decreased insulin mediated phosphorylation of S6-ribosomal protein (34), i.e. decreased translation rate. Such mechanisms are purely speculative but are consistent with the reported specific inhibition of fatty acid synthetase synthesis (35) and malic enzyme-mRNA translation by dietary linoleate (36). Furthermore, these hypotheses provide testable theories for the investigation of the mechanism by which dietary polyunsaturated fats suppress the synthesis of lipogenic enzymes (2).

Finally, an explanation for the alleviation of the fatty acid inhibition of G6PD-induction by dexamethasone may be that the effective intracellular free fatty acid concentration is decreased by dexamethasone as a result of phosphatidate phosphohydrolase induction (37). The consequence of this would be diversion of fatty acids into triglyceride and phospholipid (37) and a decrease in pool size of the putative fatty acid inhibitor. This effect of dexamethasone likely explains why in our previous studies, a suppression of acetyl-CoA carboxylase by free fatty acids was not discernible (16). Alternatively, dexamethasone simply may have increased the amount of G6PD-mRNA as a result of enhanced G6PD-mRNA transcription (10,11). Elucidation of the mechanism by which dexamethasone interferes with the fatty acid inhibition of lipogenic enzymes will require quantifying the level of mRNAs and rates of transcription. Certainly, our ability to develop a hepatocyte model that responds to the intact rat will greatly facilitate elucidation of the mechanism by which fatty acids suppress the production of lipogenic enzymes.

Metabolism of Sitosteryl β-D-Glucoside and Its Nutritional Effects in Rats

Nikolaus Weber
Bundesanstalt für Fettforschung, Institut für Biochemie und Technologie, H. P. Kaufmann-Institut, Piusallee 68, D-4400 Münster, Federal Republic of Germany

[4-^{14}C]Sitosteryl β-D-glucoside, intragastrically administered to rats, was not absorbed by the intestinal mucosa. At three hr after the application, radioactivity was concentrated almost exclusively in the digesta of stomach, small intestine as well as cecum and colon, whereas only low proportions of radioactively labeled compounds were found in the various tissues of the gastrointestinal tract. Minor proportions of labeled metabolites of [4-^{14}C]sitosteryl β-D-glucoside, such as sitosterol and sitosteryl esters, were formed in the small intestine in vivo and in slices of small intestine in vitro. In the tissues of cecum and colon as well as the digesta derived from them, high proportions of labeled coprositostanol, i.e. 24α-ethyl-5β-cholestan-3β-ol, that obviously had been formed by bacterial degradation of the substrate were detected.

The feeding of sitosteryl β-D-glucoside (0.5 g/kg body weight × day) over a period of four weeks did not alter significantly body weights or organ weights of rats. Analyses of steryl lipids of the various organs and tissues confirmed the findings obtained with the radioactive substrate: neither sitosteryl β-D-glucoside nor sitosterol or sitosteryl esters derived therefrom had been transported in appreciable amounts to organs and tissues outside the alimentary canal during the feeding period. Minor proportions of unmetabolized sitosteryl β-D-glucoside were detected in the tissues of stomach and intestine, whereas large proportions of the substrate were found in feces of rats that had received the sitosteryl β-D-glucoside-containing diet; coprositostanol was found in feces of these animals in high proportions as well. Thus, the use of sitosteryl β-D-glucoside as emulsifier or preservative in food and feed does not appear to involve any risk. ***Lipids 23,*** **42-47 (1988).**

β-Glycosides of sitosterol and of other phytosterols as well as acylated steryl β-glycosides are ubiquitous lipid constituents of higher plants (1). Steryl β-glycosides are also detected in algae (2), bacteria (3), yeasts (4) and, more recently, in the epidermis of chickens (5). Obviously, these substances are ingested daily with human food.

The steryl glycolipids show desirable amphiphilic and antioxidative properties (6,7) and, therefore, they appear to be potentially useful as emulsifiers and preservatives in a great variety of foodstuffs. Little is known, so far, on the intestinal absorption, metabolism and nutritional effects of steryl β-glycosides. This study records the metabolic fate and nutritional properties of sitosteryl β-D-glucoside, the most abundant steryl glycolipid in various vegetables.

Abbreviations: GLC, gas liquid chromatography; ip, intraperitoneally; TLC, thin layer chromatography. The systematic nomenclature of the sterols referred to by trivial names is, cholest-5-en-3β-ol (cholesterol); 5α-cholestan-3β-ol (5α-cholestanol); 5β-cholestan-3β-ol (5β-cholestanol, coprostanol); 24α-methylcholest-5-en-3β-ol (campesterol); 24α-methyl-5α-cholestan-3β-ol (5α-campestanol); 24α-methyl-5β-cholestan-3β-ol (5β-campestanol, coprocampestanol); 24α-methyl-cholesta-5,22-dien-3β-ol (brassicasterol); 24α-ethylcholest-5-en-3β-ol (sitosterol, β-sitosterol); 24α-ethyl-5α-cholestan-3β-ol (5α-sitostanol); 24α-ethyl-5β-cholestan-3β-cholestan-3β-ol (5β-sitostanol, coprositostanol); 24α-ethylcholesta-5,22-dien-3β-ol (stigmasterol).

MATERIALS AND METHODS

Chemicals. Sitosterol was obtained from E. Merck (Darmstadt, FRG) and pentaacetyl β-D-glucose from Sigma Chemie (Deisenhofen, FRG). Dihydrositosterols were prepared by catalytic hydrogenation of sitosterol with PtO_2 in ethyl acetate. The resulting mixture of 5α-dihydrositosterol (5α-sitostan-3β-ol) and small amounts of 5β-dihydrositosterol (5β-sitostan-3β-ol, coprositostanol) was separated twice by thin layer chromatography (TLC) on silica gel with hexane/ethyl acetate (85:15, v/v), and the components were isolated. Aliquots of sitosterol and 5α-sitostan-3β-ol were converted enzymatically to sitost-4-en-3-one and 5α-sitostan-3-one, respectively, using cholesterol oxidase (E.C. 1.1.3.6) from *Nocardia erythropolis* (Boehringer-Mannheim, Mannheim, FRG). [4-^{14}C]Sitosterol, 2.13 GBq/mmol, was purchased from Amersham Buchler (Braunschweig, FRG).

Preparation of substrates. Sitosteryl β-D-(2,3,4,6-tetraacetyl)glucoside was synthesized by the reaction of sitosterol with acetobromoglucose (8) in the presence of mercury(II)cyanide (9). The reaction product was purified by column chromatography on silica gel with diethyl ether. Traces of mercuric ions were removed by filtration of a methanolic solution of sitosteryl β-D-(2,3,4,6-tetraacetyl)glucoside through "Chelex 100" ion exchange resin (Sigma Chemie). Alkaline hydrolysis of the peracetylated reaction product yielded sitosteryl β-D-glucoside that was crystallized from methanol. The composition of steryl moieties in the substrate was determined by GLC after acid hydrolysis (16%, campesterol; 4%, stigmasterol; 65%, sitosterol; 5%, other sterols; and 10%, 5α-stanols).

[4-^{14}C]Sitosteryl β-D-glucoside, 1.11 GBq/mmol, for in vitro incubations as well as [4-^{14}C]sitosteryl β-D-glucoside, 37 MBq/mmol, for in vivo experiments were synthesized in a similar manner from [4-^{14}C]sitosterol and purified by repeated TLC on silica gel with dichloromethane/methanol (9:1, v/v). The radiochemical purity of the labeled sitosteryl β-D-glucoside was better than 98%.

Animals. Female WISW rats (Winkelmann Versuchstierzucht, Borchen, FRG) weighing 170-190 g were maintained at 22 C and 60% humidity and given Altromin standard diet (Altromin International, Lage, FRG) containing per 1 g 0.3 mg sterols (10% cholesterol, 19% campesterol, 7% stigmasterol, 5% other sterols, and 8% 5α-stanols) and 0.07 mg steryl β-D-glycosides (18% campesterol, 8% stigmasterol, 65% sitosterol, 5% other sterols and 4% 5α-stanols). Water was given ad libitum throughout the experiment.

In vivo administration of [4-^{14}C]sitosteryl β-D-glucoside. Radioactive sitosteryl β-D-glucoside (37 MBq/mmol; 148 kBq/animal) in 0.2 ml of a vegetable oil was administered

intragastrically to three animals that had been fasted for 12 hr and then fasted for another three hr. Distilled water, 5 ml/animal, was injected intraperitoneally (ip) one hr after administration of the radioactive substrate in order to get larger volumes of urine. The animals were maintained in metabolic cages throughout the experiment. The cages were flushed with synthetic air, and the carbon dioxide formed by oxidative degradation of feed was removed from the gas flux by absorption in triethanolamine. Aliquots of this solution were used for the determination of radioactivity by liquid scintillation counting.

In vitro incubations with [4-^{14}C]sitosteryl β-D-glucoside. Slices of small intestine (10) and liver snips (11), 0.7 g fresh weight each, were incubated for six hr at 30 C with 37 kBq (1.11 GBq/mmol) [4-^{14}C]sitosteryl β-D-glucoside in 4 ml TCM 199 medium (Seromed, München, FRG) that was supplemented with 1 g $NaHCO_3$/l and 10 mg amphotericin B/l and 10×10^6 I.U. streptomycin/l. The incubations were stopped by the addition of 15 ml dichloromethane/methanol (1:2, v/v) followed by homogenization using an Ultra-Turrax blender (IKA-Werke, Staufen, FRG). Lipids were extracted from the incubation mixtures and separated by TLC on silica gel as described below.

Feeding experiment. The rats were weighed and divided into two groups of eight animals, each. Group 1 was given 1 ml of a vegetable oil/animal × day for four wk using a pharynx tube, group 2 received 0.1 g synthetic sitosteryl β-D-glucoside/animal × day that was emulsified by sonication in 1 ml vegetable oil containing around 6 mg sterols (33% campesterol, 9% brassicasterol, 48% sitosterol, 8% other sterols, and 2% 5α-stanols). Every week, the total feed consumption and the weight gain of each group were determined. Feces of the two groups were collected over a period of 24 hr every week.

Extraction of lipids. The animals of the metabolic study were killed by cervical dislocation three hr after administration of the radioactive substrate. They were exsanguinated by section of the aorta. Organs and tissues (stomach, intestine, liver, kidneys, heart, lungs, spleen, brain, femoral muscle tissue and adipose tissue from the perirenal region) of three animals quickly were removed from the carcasses and weighed; digesta were removed from the stomach and various parts of the intestine. Each type of tissue and digesta was pooled and homogenized; the total lipids were extracted according to an established procedure (12). Radioactivity was determined in the various fractions by liquid scintillation counting in a Tri Carb C 2425 instrument (Packard Instruments, Downers Grove, IL).

At the end of the feeding period, the animals of the nutritional experiment were killed, and organs and tissues rapidly were dissected as described above. Subsequently, the total lipids were extracted according to an established procedure (12).

Analysis of radioactive lipids. The total lipids of each tissue as well as of digesta of the various parts of the gastrointestinal tract were fractionated on layers of silica gel using hexane/diethyl ether (4:1, v/v) followed by hexane/ethyl acetate (1:1, v/v) up to two-thirds of the plates from the origin, and the distribution of radioactivity in the various fractions was determined with a Berthold Automatic TLC Analyzer LB 2832 (BF-Vertriebsgesellschaft, Wildbad, FRG). The fractions of radioactively labeled lipids each were isolated and eluted from the adsorbent with water-saturated diethyl ether. The rather polar lipids were further fractionated on layers of silica gel using dichloromethane/methanol (9:1, v/v), and the distribution of radioactivity in the various classes of polar lipids was determined. The radioactive lipid fractions that were tentatively identified by cochromatography with standards were isolated as described above.

Aliquots of the fractions of ^{14}C-labeled steryl glycosides were acetylated and the resulting peracetylated derivatives were identified by cochromatography with synthetic sitosteryl β-D-tetraacetylglucoside on layers of silica gel using dichloromethane/methanol (98:2, v/v). Alternatively, these fractions were subjected to acid hydrolysis (5), yielding radioactive sterols that were identified by cochromatography with sterol standards on layers of silica gel using hexane/diethyl ether (3:2, v/v).

Radioactive sterol fractions were acetylated; the resulting steryl acetates were purified by TLC on silica gel with hexane/diethyl ether (4:1, v/v) and isolated as described above.

The fractions containing ^{14}C-labeled steryl esters of long-chain fatty acids were subjected to alkaline hydrolysis. The resulting radioactive sterols were purified by TLC and isolated. The various fractions of radioactive sterols and steryl acetates were analyzed by gas liquid chromatography (GLC) as described below using the Packard Gas Proportional Counter 894 for detection of radioactivity.

The fraction of radioactively labeled 5β-stanols (R_f 0.32) isolated from the digesta of cecum and colon (13) was separated twice by TLC on silica gel with hexane/ethyl acetate (85:15, v/v) from Δ^5-sterols plus 5α-stanols (R_f 0.25) and tentatively identified by cochromatography with coprostanol. The fraction of 5β-stanols containing ^{14}C-labeled coprositostanol was isolated from the adsorbent and acetylated. Identification of radioactive coprositostanyl acetate was carried out by $AgNO_3$-TLC twice using hexane/benzene (5:2, v/v) as solvent system (14) followed by radio-GLC using the conditions described below.

Aliquots of radioactive Δ^5-sterols plus 5α-stanols from the digesta of cecum and colon were converted to the corresponding Δ^4-en-3-oxo- (R_f 0.37) and 5α-dihydro-3-oxo compounds (R_f 0.53), respectively, by incubation with cholesterol oxidase and identified by cochromatography with standards on silica gel layers with hexane/ethyl acetate (7:3, v/v).

Analysis of lipid samples from the feeding experiment. The total lipids extracted from organs and tissues of rats from groups 1 and 2 of the feeding experiment were isolated as described above. Aliquots of total lipids of the various organs and tissues were separated by TLC on silica gel with hexane/diethyl ether (4:1, v/v) followed by dichloromethane/methanol (9:1, v/v). The fractions containing steryl β-glycosides, sterols and sterol esters that tentatively had been identified by cochromatography with standards were isolated and converted to the various derivatives as described for the radioactive steroid fractions.

The various fractions of Δ^5-sterols, 5β-stanols, steryl acetates and 5α-dihydro-3-oxo steroids were analyzed by GLC on a Perkin Elmer F 22 instrument (Perkin Elmer Bodenseewerk, Überlingen, FRG) equipped with flame ionization detectors. Peaks were assigned on the basis of

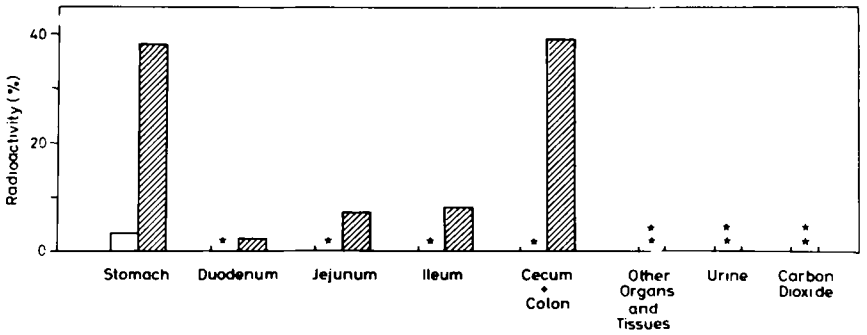

FIG. 1. Distribution of radioactivity from [4-^{14}C]sitosteryl β-D-glucoside in various organs and tissues as well as in excretion products of rats at three hr after intragastric application of the substrate. *, trace (<2%); ‡, not detected. For the stomach and the various parts of the intestinal tract, left: radioactivity in the tissues; right: radioactivity in the contents. Average from three animals.

retention times using reference compounds. Peak areas and retention times were determined using a Spectra Physics SP 4270 integrator (Spectra Physics, Darmstadt, FRG). The various sterol fractions were separated isothermically at 275 C (Δ^5-sterols, 5β-stanols) or 285 C (steryl acetates, 5α-dihydro-3-oxo steroids) on a glass column, 1.8 m × 3 mm, packed with OV-101 on Gas Chrom Q, 100–120 mesh (Applied Science Laboratories, State College, PA) with nitrogen as the carrier gas at a flow of 40 ml/min.

Statistical analysis. Statistical evaluation of differences between the values of body weights and organ weights of the control group and the group of animals that had received the diet containing sitosteryl β-D-glucoside was carried out using the Student's t-test for unpaired values.

RESULTS AND DISCUSSION

Intestinal absorption and metabolism of [4-^{14}C]sitosteryl β-D-glucoside. Initial studies were concerned with the intestinal uptake and metabolism of [4-^{124}C]sitosteryl β-D-glucoside that had been administered intragastrically to rats.

Figure 1 shows the distribution of radioactivity from [4-^{14}C]sitosteryl β-D-glucoside in various organs and tissues as well as in digesta of rats at three hr after application of this substrate. It is evident from these results that in all samples examined the radioactivity was detected predominantly in the contents of stomach and intestine. At three hr after stomach intubation, large proportions of radioactivity already had passed through the small intestine and were concentrated in the contents of cecum and colon. It is striking that only small proportions of radioactivity were associated with the intestinal tissues. Moreover, other organs and tissues such as liver, kidneys, heart, lungs, spleen, muscle, brain and adipose tissue as well as blood, obviously did not contain appreciable amounts of labeled substances.

The above findings indicate that minor proportions of the labeled substrate nonspecifically were adsorbed by the intestinal mucosa, whereas the major portion of the radioactive material passed without absorption through the alimentary canal. The virtual absence of radioactivity in organs and tissues other than gastrointestinal tissues may be attributed to a lack of transport of sitosteryl β-D-glucoside and its metabolites through the intestinal wall. In contrast, the structurally similar alkyl β-glycosides were found to be absorbed by the intestinal mucosa and, in part, transported as intact compounds to several other organs and tissues (15). Carbon dioxide formed by expiration as well as urine also are devoid of radioactivity.

The metabolism of sitosteryl β-D-glucoside was studied by examining the radioactive metabolites from extracts and digesta from various intestinal tissues of rats that had been given the radioactive substrate by stomach tube. These experiments were complemented by in vitro studies that involved incubations of [4-^{14}C]sitosteryl β-D-glucoside with slices of small intestine and liver snips. Analyses of radioactive reaction products revealed that large amounts of the labeled sitosteryl β-D-glucoside supplied as substrate remained unchanged both in the tissues of the gastro-intestinal tract, except cecum and colon, and in the in vitro incubations. Low proportions of radioactive metabolites of sitosteryl β-D-glucoside, mainly sitosterol and sitosteryl esters, were detected in the tissues of duodenum, jejunum, ileum and stomach (<0.5% of total radioactivity) as well as in the contents of the various parts of the small intestine (<1% of total radioactivity). These results are in good agreement with recent findings of investigators who tested the hemostatic effects of sitosteryl β-D-glucoside (16).

In addition, [4-^{14}C]sitosteryl β-D-glucoside was hydrolyzed by in vitro incubation with slices of small intestine at a rate of 0.8 nmol/g tissue × hr; small proportions of the resulting [4-^{14}C]sitosterol were acylated to the corresponding sitosteryl esters. However, only traces of radioactive sitosterol arose from the substrate in experiments with liver snips in vitro. It is evident from these data that the radioactive substrate is metabolized in both the in vivo and in vitro experiments at low rates.

From the data presented, it is obvious that the following reactions are involved in the metabolism of sitosteryl β-D-glucoside in the small intestine and liver of rats. Radioactive sitosterol is liberated by hydrolytic cleavage from [4-^{14}C]sitosteryl β-D-glucoside catalyzed by β-glucosidases that are present in the small intestine and liver (17–19). Substrate specificity of these enzymes for the steryl β-glycoside used seems to be rather low as compared to alkyl β-glycosides, e.g. (15). This is evident from the low proportions of radioactive sitosterol formed

during the experiments in vivo and in vitro. Moreover, the apparent absence of radioactive sitosterol in rat tissues other than those of the gastrointestinal tract is consistent with recent findings that the intestinal absorption of sitosterol and other plant sterols including 5α-stanols is limited compared to the fairly high absorbability of cholesterol (20–24).

In slices of the small intestine but not in liver snips, ^{14}C-labeled sitosterol is found to be further acylated, most probably by pancreatic cholesterol esterase and/or acyl-CoA:cholesterol acyltransferase (ACAT), yielding sitosteryl esters (22,25–27). The low rate of formation of sitosteryl esters from sitosterol (Table 1) is in good agreement with reports that esterification rate of cholesterol catalyzed by ACAT is by far higher than that of sitosterol (22).

Acyl transfer to position 6 of the sugar moiety of the substrate yielding sitosteryl (6-*O*-acyl)-β-D-glucoside obviously does not occur. Yet, 6-*O*-acylated steryl β-glycosides are common constituents of higher plants (1); they also are present in the epidermis of chickens (5). In addition, appreciable proportions of 1-*O*-alkyl-(6-*O*-acyl)-β-D-glucosides are formed in various tissues of mice from alkyl β-D-glucosides if these are used as subtrates (15).

However, in extracts from the tissues of cecum and colon as well as the corresponding digesta large proportions of radioactive metabolites of [4-^{14}C]sitosteryl β-D-glucoside that obviously had been formed by degradation of the substrate by microorganisms of the intestinal flora were detected. The main metabolites identified in the digesta of cecum and colon were coprositostanol, i.e. 24α-ethyl-5β-cholestan-3β-ol (8% of total radioactivity), and sitosterol (2% of total radioactivity). The radioactive tissue lipids of cecum and colon (<2% of total radioactivity) consisted about half of coprositostanol. This metabolite was identified by TLC and GLC as well as by its poor conversion to the corresponding 3-oxo steroids using cholesterol oxidase (28,29).

The formation of dihydrosterols is a well-known reaction occurring during the degradation of cholesterol and plant sterols such as sitosterol in mammals and microorganisms. Thus, 5α-stanols are synthesized in the liver of man and animals, whereas 5β-stanols such as coprostanol and coprositostanol are typical products of sterol metabolism in enteric microorganisms (13,30). The presence of small proportions of radioactive sitosterol and the obvious absence of radioactive sitost-4-en-3-one, which is a key intermediate in bacterial formation of 5β-stanols, reveals that this reaction is rate-limiting in the conversion of sitosterol to 5β-sitostanol. Similar results have been obtained for the transformation of sitosterol to 5α-sitostanol via sitost-4-en-3-one in rat liver (31).

The apparent absence of radioactive carbon dioxide in the expired air and of radioactive metabolites in the urine again show convincingly that [4-^{14}C]sitosteryl β-D-glucoside, given as substrate, virtually is not affected by oxidative degradation in the cells of rat organs and tissues.

Nutritional effects of sitosteryl β-D-glucoside. Steryl β-glycosides and acylated steryl β-glycosides occur in various vegetables such as potatoes and carrots at a level of about 2–8% of total lipids (32,33). Sitosteryl β-D-glucoside is found to be the most abundant steryl β-glycoside of higher plants. Absorption, transport and metabolism in animals (20–27,31,34–37) as well as pharmacological (31,38–40) and nutritional effects (23,37,41) of sitosterol are discussed in many publications, whereas little information is available on the corresponding properties of sitosteryl β-D-glycosides (16,42–44).

We have given 0.1 g sitosteryl β-D-glucoside/day to rats, i.e. 0.5 g/day × kg body weight, in order to study its nutritional effects. The intake of steryl β-D-glycosides from standard diet was around 1 mg/day × animal.

Figure 2 shows the effects of 0.1 g sitosteryl β-D-glucoside/day × animal on feed intake and weight gain of rats over a period of four wk. The average feed consumption of both groups of animals was 13–16 g per rat and day; the feed intake of the two groups of animals was quite similar. The results given in Figure 2 also show that the body weight of rats that had received sitosteryl β-D-glucoside statistically was not different ($P > 0.2$) from the body weight of animals in the control group.

The effects of sitosteryl β-D-glucoside on the weights of spleen, heart, kidneys and liver of rats are demonstrated in Figure 3. It is obvious that the weights of the various organs of the group of animals that had received the standard diet statistically was not different ($P > 0.2$) from the organ weights of animals that had been fed sitosteryl β-D-glucoside.

The proportions of sitosteryl β-D-glucoside and its metabolites, such as sitosterol and sitosteryl esters, in the lipids from the organs and tissues and from the feces of rats were determined by GLC. It was found that sterol fractions of various tissues of rats that had received the sitosteryl β-D-glucoside-containing diet and standard diet, respectively, have almost the same composition (approximately 95% cholesterol, 2–3% campesterol, 1–2% sitosterol and traces of other phytosterols). A similar

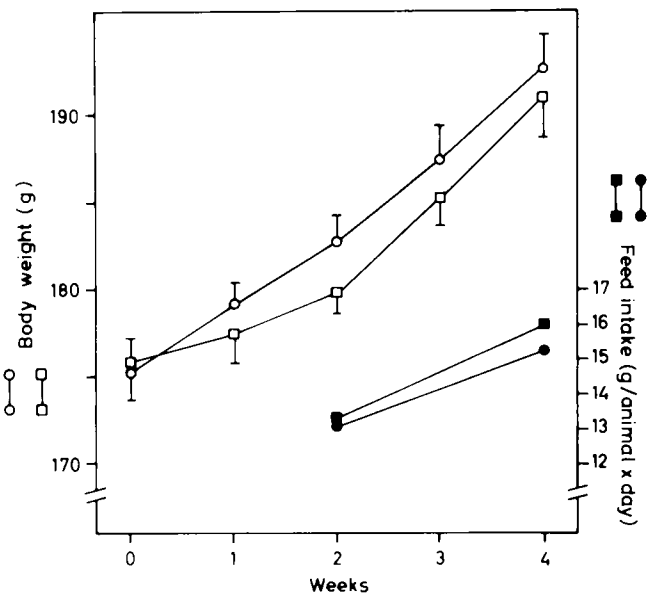

FIG. 2. Effects of standard diet or a diet containing sitosteryl β-D-glucoside administered for four wk on body weight and feed intake of rats. Values of body weight are mean ± SEM, n = 8; there are no statistically different values, $P > 0.2$; values of feed intake are mean. Standard diet, (○—○, ●—●); sitosteryl β-D-glucoside-containing diet, (□—□, ■—■).

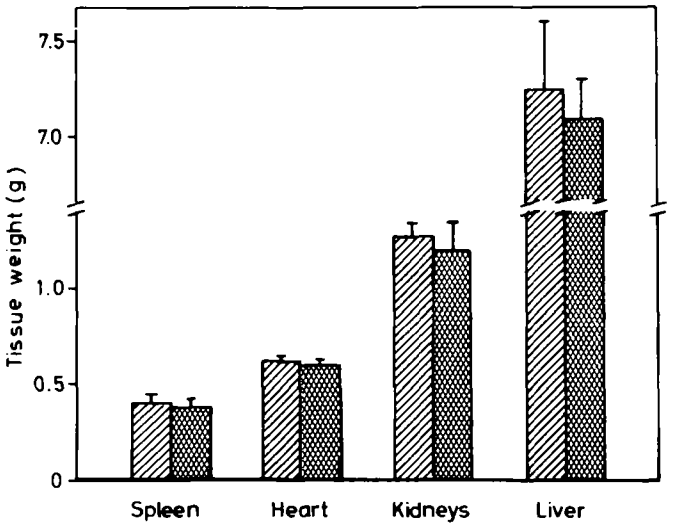

FIG. 3. Effects of standard diet or a diet containing sitosteryl β-D-glucoside administered for four wk on weights of various organs of rats. Values are mean ± SEM, n = 8; there are no statistically different values, P > 0.2. Standard diet, left column; sitosteryl β-D-glucoside-containing diet, right column.

composition of steryl moieties also was found in steryl esters isolated from various tissues of both groups of animals.

The content of Δ^5-sterols and 5α- and 5β-stanols of feces was quite similar in both groups of animals: feces of rats that had received the sitosteryl β-D-glucoside-containing diet were found to contain per 1 g: 1.1 mg Δ^5-sterols; 0.25 mg 5α-stanols; and 1.85 mg 5β-stanols, whereas 1.0 mg Δ^5-sterols, 0.25 mg 5α-stanols, and 1.75 mg 5β-stanols were detected in feces of the control group. Yet, the proportions of cholesterol and 5β-cholestanol decreased in fecal sterols of animals that had received the sitosteryl β-D-glucoside-containing diet and a concomitant increase of sitosterol and 5β-sitostanol was observed (Table 1). These findings are in good agreement with our observation that [4-^{14}C]sitosteryl β-D-glucoside was cleaved by highly active β-glycosidases of fecal microorganisms followed by hydrogen transfer to the resulting sitosterol, yielding 5β-sitostanol. The various 5α-stanols found in feces are derived predominantly from the feed (cf. sterol analyses given in the Materials and Methods section).

In the tissue lipids of the gastrointestinal tract of rats that had received the sitosteryl β-D-glucoside-containing diet, minor proportions (stomach 120 μg/g tissue; small intestine 1 μg/g tissue) of the unmetabolized substrate were found, whereas the lipids of other organs and tissues contain, if at all, only traces (<1 μg/g tissue) of steryl β-D-glycosides. In feces, major proportions of sitosteryl β-D-glucoside (around 1,300 μg/g feces dry weight) were detected at 20 hr after the last application of the substrate, whereas around 50 μg steryl β-D-glycosides derived from the standard diet were found per 1 g feces of the control group.

To summarize, it was found that [4-^{14}C]sitosteryl β-D-glucoside virtually is not absorbed in the gastrointestinal tract of rats. Yet, the substrate is cleaved at a low rate to ^{14}C-labeled sitosterol and glucose by the action of β-glycosidases of the small intestine. Remarkably, high proportions of radioactive coprositostanol derived from the substrate, which is caused most probably by bacterial transformation, are found in the tissues of cecum and colon and the corresponding digesta.

Sitosteryl β-D-glucoside, fed to rats at a level of 0.5 g/d × kg body weight for four wk, does not show results different from those of the control group with respect to feed intake, weight gain and organ weights. No ill effects are observed during this time and no abnormalities are detected in feces (color, blood, consistency) or urine (color, blood). Therefore, sitosteryl β-D-glucoside and other plant steryl β-glycosides may be of interest as potential emulsifiers and preservatives in food processing. An appreciable increase in fecal excretion of neutral steroids as found for various saponins (45,46) was not observed for sitosteryl β-D-glucoside.

TABLE 1

Composition of Sterols in Feces of Rats that had Received Sitosteryl β-D-Glucoside-containing Diet or Standard Diet

Sterols[a]		Composition (%) of various sterol fractions isolated from feces of rats that had received different diets	
		SG[b]	Standard
Cholesterol	Δ^5	6	9
Cholestanol	5α	<1	<1
	5β	11	19
Campesterol	Δ^5	7	7
Campestanol	5α	2	3
	5β	12	9
Sitosterol	Δ^5	19	15
Sitostanol	5α	5	4
	5β	32	27
Other sterols	Δ^5	3	3
	5α	<1	<1
	5β	3	3
Total sterols	Δ^5	35	34
	5α	8	8
	5β	57	58

[a] Δ^5, unsaturated sterols having a double bond at position 5; 5α, 5α-dihydrosterols (5α-stanols); 5β, 5β-dihydrosterols (5β-stanols, "coprostanols").

[b] SG, sitosteryl β-D-glucoside-containing diet.

[Received May 20, 1987; Revision accepted August 24, 1987]

Genetic Variations in Serum Lipid Levels of Inbred Mice and Response to Hypercholesterolemic Diet

Roberte Aubert[a], Dominique Perdereau[b], Micheline Roubiscoul[a], Jeannine Herzog[a] and Daniel Lemonnier[a]

[a]Unite de Recherches sur la Nutrition et l'Alimentation, Unite 1 de l'I.N.S.E.R.M., Hopital Bichat, 170 boulevard Ney, 75877 Paris Cedex 18, France; and [b]Centre de Selection et d'Elevage d'Animaux de Laboratoire, C.N.R.S., 3B rue de la Ferollerie, 45071 Orleans Cedex 2, France

The serum lipid contents of a number of inbred and congenic strains of mice were measured. There were interstrain variations in each of the lipid fractions in mice fed a normal diet. Male and female C3H mice had the highest total cholesterol level; AKR mice showed the lowest values. Serum phospholipids were correlated well with cholesterolemia. The greatest variations between strains were in the triglyceride levels. There also was significant variation in the high density lipoprotein cholesterol serum levels (from 73–88% of the total cholesterol). The response to a hypercholesterolemic diet (1% cholesterol) was tested in seven inbred strains. All strains showed changes in serum cholesterol and in the proportions of the lipoproteins fractions. There was a large increase in the low density lipoprotein + very low density lipoprotein fractions. Feeding the diet revealed marked interstrain differences in the responses of the serum cholesterol and electrophoretic lipoprotein profiles. The C57BL/6 and B10.D2 strains were hyperresponders to the hypercholesterolemic diet with 71% and 63% of their serum cholesterol in the low density lipoprotein plus very low density lipoprotein fractions, respectively.
Lipids 23, 48–54 (1988).

Epidemiological studies in humans have demonstrated an association between elevated levels of serum cholesterol and risk of atherosclerosis. The major factors controlling cholesterol levels in man have been studied; environmental and particularly dietary factors were shown to be significant but during the last few years the importance of genetic factors has become increasingly apparent.

Normocholesterolemic rats and mice probably are inappropriate experimental animals because, contrary to humans, cholesterol is mainly carried in them in high density lipoproteins (HDL) and to a lesser extent by a fraction associated with low density lipoproteins (LDL) (1). However, the availability of inbred strains of mice has provided a number of new alternatives. A variety of inbred strains of mice currently are available for genetic experimentation.

The blood cholesterol levels of different strains of mice have been reported by Bruell et al. (2) and Yamamoto et al. (3). They also showed sex-dependent differences; the cholesterol level was higher in males than in females.

The pattern of inheritance governing the blood cholesterol level has been demonstrated by Bruell (4) and Yamamoto et al. (3) in inbred strains and by Weibust (5) by selecting high and low cholesterol lines on a normal low fat, low cholesterol diet.

Abbreivations: ASAT, abdominal subcutaneous adipose tissue; EAT, epididymal adipose tissue; HDL, high density lipoproteins; HDL-C, high density lipoprotein cholesterol; LDL, low density lipoproteins; PAT, perirenal adipose tissue; VLDL, very low density lipoproteins.

Dietary factors, particularly a high fat and high cholesterol diet, were found to produce atheromatous lesions in C57BL/6J inbred mice (6).

Inbred strains exhibited marked differences in their reaction to a high fat and high cholesterol diet. The C57BR/CdJ strain appeared to be particularly susceptible, whereas CBA/J mice proved to be resistant to atherosclerosis (7); this work examined the relationship between the serum total cholesterol level and the size of atheromatous lesions in the wall of the aortic sinus.

However, recent studies have shown that the evaluation of coronary risk by total serum cholesterol levels alone was too restrictive. Triglyceride, LDL and apoprotein (Apo-B) also are risk factors while HDL and Apo-AI appear to have a protective role against coronary heart disease.

However, C57BR mice are not available in France, and no quantitative data are available on the values of circulating lipids in the males and females of inbred strains of mice. Therefore, the present study was undertaken to provide these parameters for those strains that are available in France.

The second experiment was performed to determine the lipoprotein profile in males of seven inbred strains and their susceptibility to hypercholesterolemic diet.

MATERIALS AND METHODS

Animals and diets. In experiment 1, ten male and 10 female mice from each of 11 different inbred and two congenic strains were obtained from three different colonies (Table 1).

Animals were received at four wk of age and acclimated for one wk before the study began. Males and females were housed separately in sibling groups of five animals in polypropylene cages. The temperature (22 ± 1 C), relative humidity (50 ± 10%) and light cycle (12 hr dark/light) of the room were controlled. All mice had free access to water and a normal chow diet (Table 2).

In experiment 2, male mice (4 wk old) of the inbred strains AKR/JOrl, BALB/cJOrl, CBA/JOrl, C3H/HeJOrl, C57BL/6JOrl, DBA/2JOrl, B10.D2Orl were obtained from the CSEAL-CNRS, Orléans, France. Mice were fed ad libitum normal diet (N) (Table 2) and water.

After one week, mice were matched for weight and half of them fed a hypercholesterolemic diet (C) formulated in our laboratory (Table 2). The mice were weighed weekly and killed after they had been on the experimental diet for four weeks. Food was withdrawn four hr before the mice were killed.

Animals were bled from the retroorbital venous sinus between 10–12 a.m., and blood was alllowed to clot for two hr at ambient temperature before centrifugation at 4500 tr/min for 20 min to obtain serum.

In experiment 2, the blood from three mice were pooled and clotted. Sera were drawn and aliquoted into tubes chilled on ice. Analyses were made on fresh sera within 48 hr after sacrifice. The heart, spleen, kidney and gonad were removed and weighed, as were the epididymal (EAT), perirenal (PAT) and abdominal subcutaneous (ASAT) adipose tissues.

Chemical analyses. Triglycerides were assayed using a Boehringer-Mannheim kit based on the enzymatic method developed by Wahlefeld (9). Phospholipids were assayed with the Wako phospholipid B Test kit (Biolyon, 69570, Dardilly, France). Total and free cholesterol levels were assayed by the enzymatic method of Röschlau et al. (10) with Boehringer-Mannheim kits. Esterified cholesterol was calculated by multiplying the difference between total and free cholesterol by 1.67; this figure corresponds to the ratio of the average molecular weight of human cholesteryl ester to that of free cholesterol.

Serum high density lipoprotein cholesterol (HDL-C) was measured in the supernate obtained after precipitation of very low density lipoproteins (VLDL) and LDL with phosphotungstic acid/MgC12 (Bio Merieux kit no. 61531) by the method of Burnstein et al. (11).

Lipoproteins were separated by agarose gel electrophoresis using agarose universal electrophoresis film (Corning Medical and Scientific, Palo Alto, CA). The buffer was 0.05 M barbital (Universal PHAB Corning).

After electrophoresis for 35 min at 90 v, the film was dried and then stained with Fat Red (Corning).

Lipoproteins also were separated by polyacrylamide gel electrophoresis. Five μl samples of serum were prestained with Sudan Black (v/v) and then electrophoresed on polyacrylamide gel slabs (Lipofilm Sebia) for one hr at 8 mA/slab.

Statistical analysis. In experiment 1, all results were analyzed by Tukey's test (12). The means were ranked and adjacent means were tested using the Student's t-test at an unadjusted significant level of 5%. Any groups of results separated by this percentage then were treated separately, the group mean was calculated and the greatest difference from all means of the group obtained. Finally, the individual variance ratio was estimated. All groups separated by this method are significantly different ($P < 0.05$). A Duncan's test (13) was used for statistical evaluation of sex differences.

In experiment 2, all results are expressed as mean ± SEM. Statistical differences between strains and diets were estimated by Duncan's test (13).

TABLE 2

Composition of Normal Diet (N) and Hypercholesterolemic Diet (C)

	g/100 g	
	N	C
Cellulose	3.7	5.0

[a,b]Mineral mixture and vitamin mixture as described elsewhere (8).

RESULTS

Experiment 1. Body weights. The total range body weights between strains at nine wk of age was small in males (21.6–27.8 g) and in females (18.44–24.1 g). The growth of the mice was identical in all strains. The differences observed in body weights between strains at the end of the experiment were due to differences at weaning, with the daily weight increases being similar in all strains.

Serum cholesterol levels. The distribution of total cholesterol varied with strain in male mice (Fig. 1). Total cholesterol levels were highest in the C3H strains and lowest in the AKR mice, irrespective of supplier. All female C3H mice, irrespective of supplier and substrain, had total cholesterol levels, which placed them in the same group with high levels of cholesterol. In males, the C3H mice were ranked into two groups and showed the highest values. Conversely, AKR mice had a low level of total cholesterol. For free cholesterol, all females were ranked in the same group even though the range of values was 16.1 for AKR and 30.1 mg/dl for C3H/ouJIco. The values for males varied from 42 mg/dl for DBA/2CrIBR to 15.1 mg/dl for AKR. Differences in esterified cholesterol levels accounted for the increased values of total cholesterol in C3H strains. There was no sex-dependent difference in the serum cholesterol of five strains (C57BL/6CrIBR, C3H/HeCrIBR, C3H/HeJOrl, BALB/cJOrl, AKR/JOrl).

Serum triglyceride levels. There were great variations in serum triglyceride concentrations of male mice between

strains; DBA/2 male mice were hypertriglyceridemic (300 mg/dl for DBA/2JOrl, 303 mg/dl for DBA/2JIco, and 375 mg/dl for DBA/2CrIBR) compared to 97 mg/dl for AKR mice. The differences between strains were smaller in females (254 mg/dl for DBA/2JIco vs 99 mg/dl for C57B//CrIBR), and only two groups were separated by Tukey's test. Comparisons of male and female means within each strain showed contradictory results. In two strains, the female means were higher than those of the males (B6D2F1/JIco and C3H/HeCrIBR). No difference between sexes was observed in any of the C3H and BALB strains or in the DBA/2JIco, CBA/JOrl and C57BL/6CrIBR strains. In the other strains, male mice had significantly higher serum triglyceride levels than did the females. As a result, the distribution of serum triglyceride levels was identical in males and females.

Serum phospholipid levels. In male mice, four groups were separated by statistical analysis. Levels varied from 184 mg/dl in male AKR mice to 31 mg/dl in male C3H/He mice. Except in four strains (C3H/HeCrIBR, BALB/cJOrl, AKR/JOrl and C57BL/6JIco), the means for males consistently were higher than those of females. In females, only two groups were identified. Serum phospholipids were correlated well (r = 0.859) with serum total cholesterol.

Experiment 2. Body and organ weights. Regular growth curves were observed in all the strains fed the normal diet. Body weight was unaffected by the hypercholesterolemic diet. The significant differences between the strains were due solely to the specific body weight of each strain at weaning. Differences in organ weights observed between the strains were related to the normal weight variations regardless of the type of diet.

Serum parameters. Figures 2 and 3 show the serum total cholesterol, triglyceride, and phospholipid levels of the different strains of mice maintained on the normal diet (N) and the hypercholesterolemic diet (C). On normal diet, the C3H/He mouse strain was hypercholesterolemic and hyperphospholipidemic. The AKR mice were hypocholesterolemic and the DBA/2 mice were hypertriglyceridemic.

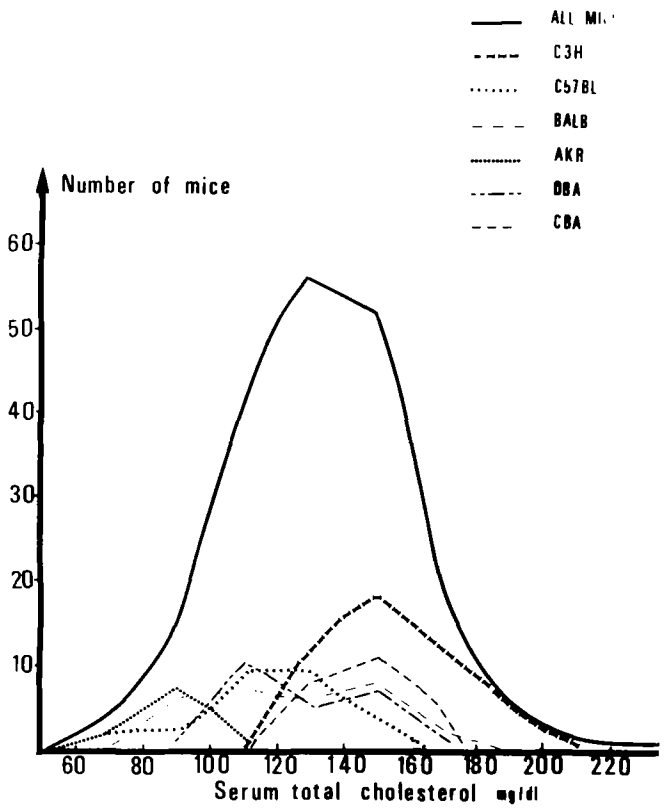

FIG. 1. Distribution of total cholesterol levels in male mice of different inbred and congenic strains.

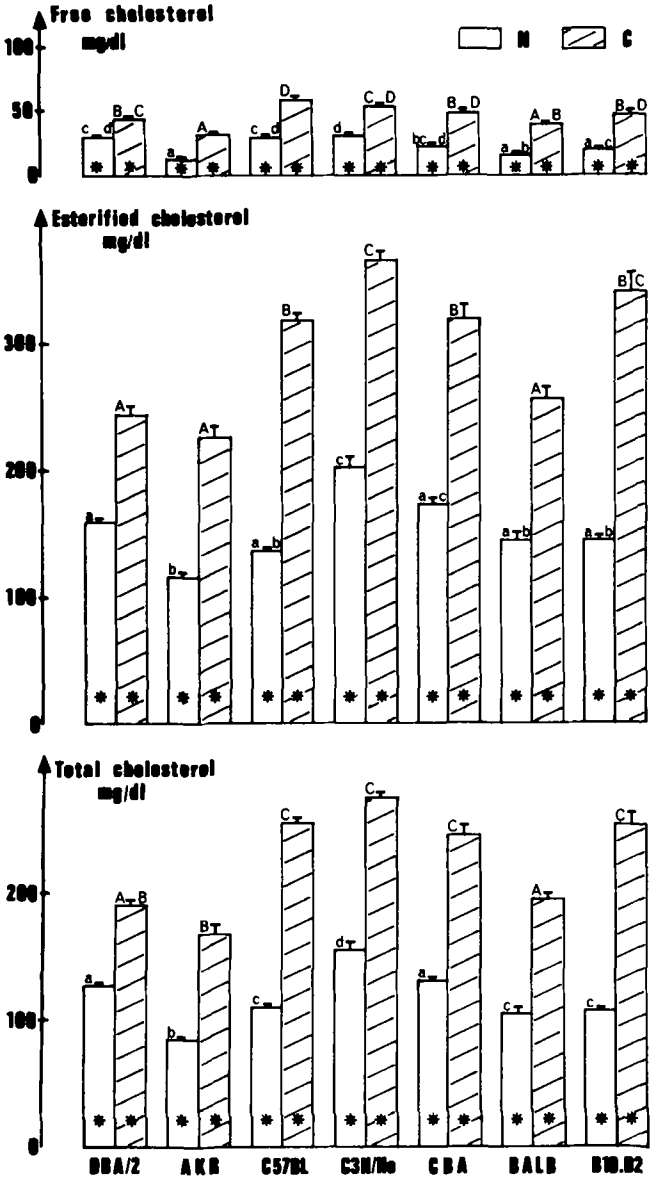

FIG. 2. Total, esterified and free cholesterol concentrations in the serum of male inbred mouse strains fed either a normal diet (N) or a hypercholesterolemic diet (C). Mice were killed in a fasted state at nine weeks of age. Each bar represents the mean and SEM of data from 10 pools of three mice, except for B10.D2 (5 pools). For comparison between strains, on the diet N, bars not sharing a common small letter are significantly different $p < 0.05$; on diet C, bars not sharing a common capital letter are significantly different $p < 0.05$. For comparison between diets for one strain, *, a significant difference $p \leq 0.05$; **, a highly significant difference $p \leq 0.01$.

On diet C, all the strains exhibited very significantly higher levels of free, esterified and total cholesterol but the increases differed from strain to strain. Serum cholesterol levels were more than doubled in C57BL/6 and B10.D2 strains; the lowest increase was observed in DBA/2 strain. The C3H/He mice had the highest cholesterol level when fed diet N, whereas on diet C this parameter was not different significantly from those of the other strains. The strains fed diet C were divided into two groups: similar high cholesterol levels (>250 mg/dl) in C57BL/6, C3H/He, CBA and B10.D2 strains; lowest cholesterol levels in DBA/2, AKR, and BALB/c strains (<200 mg/dl).

Administration of diet C induced a very significant increase in the phospholipid levels only in AKR and BALB/c strains; in contrast, the triglyceride levels decreased significantly except in the BALB/c and B10.D2 mice. Table 3 gives the distribution of cholesterol in the lipoproteins. The high density lipoproteins carried ca. 80% of the serum cholesterol in all strains fed the normal diet. In C3H mice, the HDL cholesterol level was different significantly from that of all other strains except CBA mice, with these two strains showing the highest values.

DBA/2 and C57BL/6 mice had greater cholesterol concentrations in the LDL and VLDL fractions. Cholesterol feeding promoted a rise in the HDL-C level except in C57BL/6, BALB/c and B10.D2 strains. But the HDL cholesterol/total cholesterol ratio dropped markedly in all strains after feeding the high cholesterol diet; the decrease was more pronounced in the C57BL/6 and B10.D2 strains. The level of (LDL + VLDL) cholesterol rose after cholesterol feeding in all strains. The most striking increase was observed in B10.D2 mice and the least increase in DBA/2 mice. On diet C, very significant differences were observed between strains; C57BL/6 and B10.D2 mice had the highest values.

On the normal diet, DBA/2 and C57BL/6 mice, had the largest (LDL + VLDL) cholesterol/total cholesterol ratio. Diet C induced a rise in this ratio in all strains except DBA2 mice; the highest ratio was observed in C57BL/6 and B10.D2 mice. The LDL + VLDL/HDL cholesterol ratio increased with cholesterol feeding; this ratio was very high in B10.D2 and C57BL/6 mice as compared to other strains.

Electrophoretic patterns of lipoproteins. On the normal diet, the sera of fasted mice exhibited a major α-band (HDL) on agarose gels. A pre-β band (VLDL) and a β-band (LDL) were seen in C57BL/6, B10.D2 and DBA/2 strains. This separation was more distinct on polyacrylamide gels. Administration of diet C induced a marked increase in the pre-β band masking the appearance of β-VLDL in all strains, with a greater increase in the C57BL/6 and B10.D2 strains.

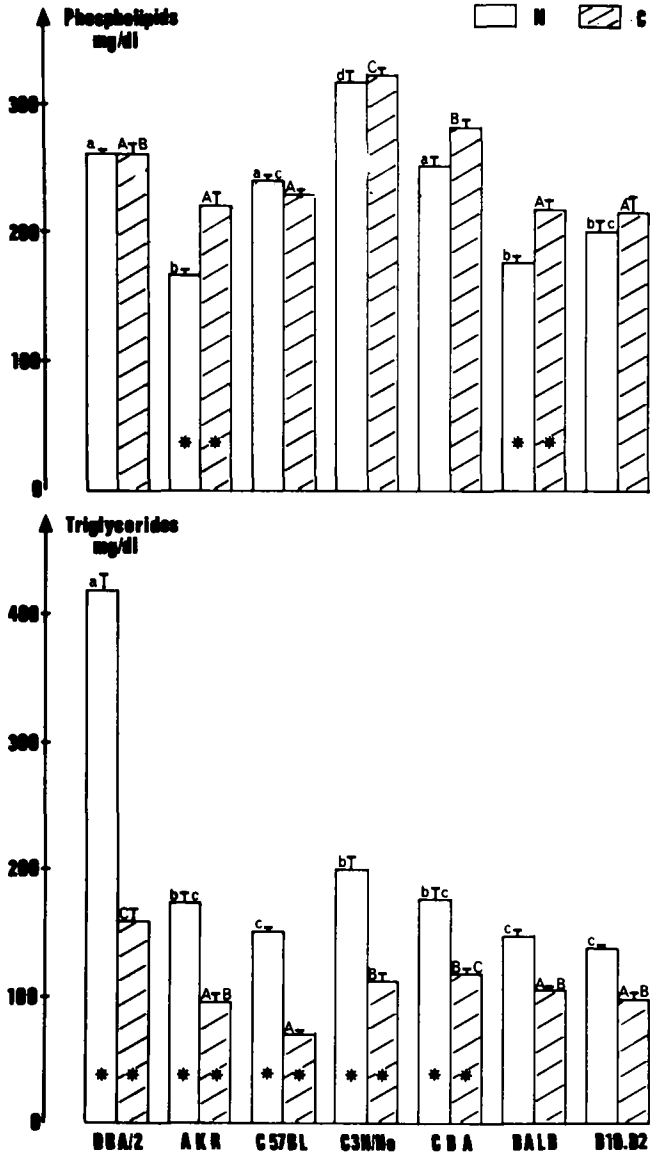

FIG. 3. Triglyceride and phospholipid concentrations in the serum of male inbred mouse strains fed either a normal diet (N) or a hypercholesterolemic diet (C). Animals were killed in a fasted state at nine wk of age. See Figure 2 for legends.

DISCUSSION

Additive inheritance of plasma cholesterol level in mice was established by Bruell (2,4) and Yamamoto et al. (3), using inbred strains and their hybrids. This was confirmed by Weibust (5) by selective breeding of mice with high or low cholesterol levels. The present study demonstrates that all serum lipid levels vary with the strain in mice. Bruell (2,4) and Weibust (5) observed significant sex differences in serum cholesterol level in inbred strains, hybrids and selected lines. In this study and as observed by Yamamoto et al. (3) in the STR/1N strain, the levels of circulating lipids in males were not higher than in females in all strains. Differences in the age of the mice could not be invoked to explain the differences between this study and other studies (2,4,5) because previous investigations have indicated that serum cholesterol levels do not vary with age in mice (2,3) in contrast with observations in humans (14).

A control diet was used to determine whether there were genetic differences between the circulating lipids of a great number of inbred mouse strains of both sexes. The greatest variations among strains was in their triglyceride levels. In males, the mean was increased by 285% in the hypertriglyceridemic strain (DBA/2CrIBR) as compared

Values in the same line not sharing the same common superscript letter are highly significantly different ($P \leq 0.01$). Effect of hypercholesterolemic diet: *, significantly ($P \leq 0.05$), **, highly significantly ($P \leq 0.01$) different from normal diet.

to AKR mice, and in females by 193% in DBA/2JIco as compared to C57BL/6JOrl.

Thompson (6) and Paigen et al. (15) have stated that C57BL/6 mice can be defined as susceptible to atheromata. In our study and as observed by Morrisett et al. (16), the susceptible strain of mice consistently maintained a lower triglyceride level on the control diet than did resistant mice (CBA) in both sexes.

Variations in phospholipid level between strains were lower than for triglyceride and more elevated for males than for females (71% increase for male C3H/HeJOrl vs AKR, 46% increase for female C3H/HeCrIBR vs DBA/2JIco). As observed by Bruell et al. (2) and Paigen et al. (15), the highest values of serum cholesterol were found in both sexes of C3H mice, whatever the substrain. In contrast, AKR male mice showed the lowest values not only for choiesterol but for all circulating lipids. The variations were less pronounced in females. If we compare our results with those of Morrisett et al. (16) and Breckenridge et al. (17), we observe that the susceptible strain of mice maintained a somewhat lower level of serum cholesterol than did the resistant strain on control diet. In contrast to their results, we found an average serum cholesterol of 117 mg/dl in C57BL/6 mice and 142 mg/dl in CBA mice. This could be in agreement with the experiment of Paigen (15) who observed that there is a low correlation between cholesterol levels and lesion formation on atherogenic diet.

In contrast to results reported by Breckenridge et al. (17) indicating that the susceptible strain of mice (C57BR) gained less weight than the resistant one (CBA), all the inbred lines showed similar growth rates in our second experiment, and the differences in body weight at weaning accounted for variations in weight observed at the end of the experiment. While differences in organ weights were observed between strains, the organ/body weight ratios were similar in all strains, except for adipose tissues where two strains of mice, DBA/2 and CBA, seem to be fatter than the others, regardless of the diet consumed. These results confirm earlier observations (18–20) of differences in fat accumulation by different mouse strains, an effect related to inefficient food utilization by the strains with lower ability to store energy as fat (21).

Morbidity and mortality were not observed in response to a high cholesterol diet, as in previous studies (6,7). The diet was tolerated well by all strains, and body weight was unaffected by diet at nine weeks of age after four weeks of ad libitum administration, as observed previously in rats (22). There is now little doubt that the quantity and type of fatty acids in the diet profoundly can influence the level of circulating cholesterol in most species, including man. In the C57BR/cdJ mouse, serum total cholesterol responded to change in P/S ratio only when cholesterol was added to the diet (23); this also is observed in man (24). Most of the apolipoproteins seem to increase when high saturated fat diets are consumed (24–26). A high carbohydrate consumption leads to high plasma cholesterol in the mouse (27).

Feeding our hypercholesterolemic diet, which is rich in saturated fatty acids, carbohydrate and cholesterol, to mice resulted in an increase of about 70–140 mg of cholesterol over that of animals maintained on the normal diet. The cholesterol levels measured in any of the strains were not as high as the level observed by Roberts and Thompson (7) in C57BR strain. This may be due to strain differences or to our diet being moderately enriched in cholesterol. Our results are more similar to those obtained by Paigen et al. (15) who examined female mice of different inbred lines fed an atherogenic diet containing 1.25% cholesterol. However, in this study, DBA/2 mice had the lowest increase in serum cholesterol level, whereas Paigen et al. (15) found that this strain had the highest one. The main effect induced by hypercholesterolemic diet was observed in the C57BL/6 and

B10.D2 strains in which serum cholesterol levels were more than doubled. CBA mice have been described as being resistant to diet-induced elevation of serum cholesterol. When fed a high cholesterol diet (7), this strain could not be differentiated from the other strains in this experiment, mean values were increased by 93%. In rats, the effect of feeding a cholesterol-enriched diet upon serum triglyceride levels led to contradictory results (22,28,29). In this study, the enriched cholesterol diet induced a decrease in serum triglyceride levels in all strains, the main effect being observed in the hypertriglyceridemic strain (DBA/2), which had a decrease of 62%.

Cholesterol feeding reduces plasma triglycerides, whereas it increases the liver triglycerides (30). The changes probably are due to a shift of hepatic lipoprotein secretory mechanisms for triglyceride-rich particles of lipoprotein towards cholesteryl esters-enriched particles in response to excess cholesterol deposition in the liver.

Recent studies demonstrate that elevated LDL levels are correlated positively with coronary heart disease in humans (31), whereas HDL appear to protect against atherosclerosis disease (32-34). Genetic variations in the structure and quantities of lipoproteins and structural variations of apolipoproteins have been demonstrated in various mouse strains (16,17,35-37). In this study, 70-80% of the cholesterol is associated with HDL, which is in agreement with results obtained by other investigators with different strains, using ultracentrifugal procedures (37-39). On the normal diet, the HDL of C3H/He and CBA mice displayed an elevated cholesterol content; in contrast, in the hypertriglyceridemic DBA/2 mice the HDL fraction had a lower cholesterol content compared to other strains. An inverse correlation between HDL cholesterol and the level of serum triglyceride has been demonstrated in humans (40).

The administration of cholesterol-enriched diet to rats induced a rise in lipoproteins corresponding to β-VLDL (41). In this study, the electrophoretic profiles of lipoproteins from mice fed a cholesterol-rich diet indicate an increase of VLDL fraction in all strains. This is in agreement with the precipitating method where a dramatic increase in LDL + VLDL cholesterol was observed in all strains fed diet C (× 2 to 9 in DBA/2 and B10.D2, respectively). It is remarkable that 38 (DBA/2) to 71% (C57BL/6) of the serum cholesterol was found in the LDL + VLDL fraction. More detailed studies are needed to establish which of the two fractions is more affected. Terpstra and Beynen (39) in Swiss mice and Tsuda et al. (42) in ICR mice noted a rise in HDL cholesterol during administration of an atherogenic diet. In our experiment, mice could be divided into two groups: HDL cholesterol increased in DBA/2, AKR, C3H/He and CBA, whereas this parameter was not altered for the other strains.

The (LDL-C + VLDL-C) to HDL-C ratio was increased markedly in all the animals fed the hypercholesterolemic diet because of the large effect of diet C on the other lipoprotein fraction.

These results indicate that the C57BL/6 and the B10.D2 mice are very susceptible to hypercholesterolemic diet but no resistant strain could be identified. The availability of inbred strains of mice with different cholesterolemic responses to change in diet may be of importance. As demonstrated by Paigen et al. (15) and Morrisett et al. (16), atherosclerotic lesions can be produced experimentally in inbred mice, and these mouse strains may prove useful in studying genetic influences on the development of atherosclerosis.

ACKNOWLEDGMENTS

The authors are grateful to Charles River France (76140 St. Aubin les Elbeuf), CSEAL-CNRS (45045 Orleans), IFFA-CREDO (69210 l'Arbresle) for kindly providing animals. We are indebted to J. Dupont (Iowa State University, Ames, IA) for helpful discussion. We wish to thank G. Mathon, A. N'Diaye, M. Lemoine and A. Portal for the preparation of diets and for care of animals. We acknowledge the excellent secretarial assistance of J. Laignel and N. Kaniewski.

Subcellular Distribution of Disaturated Phosphatidylcholine in Developing Rabbit Lung

M. Oulton* and **M. Dolphin**
Departments of Obstetrics and Gynecology and Physiology and Biophysics, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4H7

To determine the subcellular distribution of disaturated phosphatidylcholine (DSPC) in lung tissue during perinatal development, fetal rabbits at 24, 26, 28 and 31 (term) days gestation and newborns were studied. Following alveolar lavage, fractions enriched in nuclei-cellular debris, mitochondria, microsomes, surfactant (lamellar bodies) and cytosol were prepared from the residual tissue homogenate, and their DSPC content was determined. The DSPC content of the unfractionated residual lung tissue homogenate progressively and significantly increased during fetal development, rising from 9.09 ± 0.91 to 17.45 ± 2.88 mg/g dry lung between 24 days gestation, and term. Between 24 and 26 days gestation the overall increase in tissue DSPC was due to a two-fold increase in the mitochondrial, microsomal and cytosolic pools. Lamellar bodies were first isolable at 26 days gestation. The DSPC content of this fraction increased six-fold (from 0.10 ± 0.02 to 0.67 ± 0.15 mg/g dry lung) between 26 and 28 days gestation and a further seven-fold (to 4.63 ± 1.06 mg/g dry lung) by term, accounting for the overall increase in the tissue homogenate value during this time period. By the first postnatal day, microsomal and cytosolic DSPC increased another two-fold, but no significant change occurred in the other subcellular fractions. Alveolar lavage DSPC progressively increased over the time period studied. While there was no change in the lamellar body DSPC/total PC ratio during fetal development, each of the mitochondrial, microsomal and cytosolic ratios decreased between days 26 and 28 of gestation and then increased at term. Our results indicate that in addition to the pulmonary surfactant, for which DSPC is often used as a marker, other subcellular organelles contain significant DSPC pools that undergo dynamic changes in size during perinatal development.
Lipids 23, 55–61 (1988).

Lung surfactant, the phospholipid-rich material that lines the mammalian lung and prevents atelactasis by reducing the surface tension at the air-alveolar interface (1), is produced by the fetal lung in increased quantity toward the end of gestation (2,3). Surfactant is synthesized in the Type II alveolar cell and stored in intracellular lamellar inclusion bodies prior to release to alveoli (4).

Phosphatidylcholine represents the major surfactant constituent (5,6), and the disaturated species, dipalmitoyl phosphatidylcholine, is the major component responsible for its surface tension-reducing properties (1,5,6). As the lung is particularly enriched in this phospholipid, its measurement in whole lung tissue is often used as a marker for the surfactant complex (7–10). It has been shown, however, that the disaturated species of DSPC is not uniquely localized in the surfactant complex (11–14). For example, in the adult, less than half of the total lung DSPC has been identified as being surfactant-associated (12,13) and even lower values have been found for fetal and newborn lung (15). The subcellular locale of the nonsurfactant DSPC has never been fully explored. Such a study would be of particular interest to pursue over the period of time in which the surfactant pool sizes undergo dramatic changes, i.e., during late fetal and early postnatal development (2,3). In our laboratory, we have recently developed methods for the quantitative isolation of surfactant pools from fetal and newborn rabbit lung (16). In the present study, we report on the distribution of lung DSPC over these and other subcellular fractions obtained during this time period.

MATERIALS AND METHODS

New Zealand white rabbits whose time of conception was known to within 1 hr were purchased from Rieman's Fur Ranch, St. Agatha, Ontario. The does were anesthetized with intravenous sodium pentobarbital, and the fetuses were delivered by cesarean section and immediately killed by intraperitoneal injection of sodium pentobarbital. Spontaneously delivered newborns were similarly killed in their first postnatal day.

Lungs were lavaged in situ with a total of seven 0.5–1.5 ml aliquots of 0.85% NaCl. We have previously shown that this technique recovers better than 90% of the total phospholipids recovered in 12 consecutive lavages (16). For each experiment, alveolar lavage returns obtained from either 5–8 fetuses or 2–3 newborns were pooled for lipid extraction and analysis as described below.

Following the lavage procedure, the residual lung tissue obtained in each experiment was pooled and finely minced, aliquots were removed for drying to constant weight and the remainder was fractionated as follows:

A 10% homogenate (w/v) in 0.01 M Tris buffer, containing 0.145 M NaCl and 0.001 M EDTA (pH 7.4), was prepared using a polytron homogenizer (Brinkman Instruments, Rexdale, Ontario) at a speed setting of 5.0 for 10–30 sec (in 10 sec bursts). Aliquots of

the tissue homogenate were removed for lipid extraction and analysis, and the remainder was centrifuged for 5 min at 140 × g. The resultant pellet, designated as the nuclear-cellular debris fraction, was saved for lipid extraction and analysis, while the resultant supernatant was further centrifuged for 30 min at 10,000 × g. The supernatant obtained from this centrifugation step was then centrifuged for 60 min at 100,000 × g to yield a microsomal-enriched pellet and cell cytosol fractions. Mitochondrial and lamellar body-enriched fractions were prepared from the 10,000 × g pellet material as follows: the pellet was suspended in the Tris buffer, and 2.0 ml aliquots were layered over discontinuous density gradients consisting of 5.0 ml each of 0.68 M and 0.25 M sucrose (prepared in the Tris buffer). The gradients were then centrifuged for 60 min at 65,000 × g in an SB-283 swinging bucket rotor (Damon/IEC Division, Needham Heights, MA), and the surfactant (lamellar body) fraction (which formed a discrete band at the interface between the sucrose layers) and the mitochondrial-enriched pellet were removed for lipid extraction and analysis. In a previous study in our laboratory in which we developed this technique for isolating surfactant from fetal and newborn lung tissue homogenates, we found better than 85% recovery of a pure radioactive-labeled lamellar body preparation added to homogenized lung. Of the 15% loss, 5% was present in the 140 × g pellet fraction, another 5% in the 10,000 × g supernatant and the remaining 5% spread over all the other fractions obtained in the isolation procedure. The details of this isolation scheme are described in a separate report (16).

Prior to lipid extraction and/or enzymatic analysis, all particulate fractions were washed once with 0.25 M sucrose. Lipids were extracted with chloroform/methanol (2:1, v/v) as previously described (17). Aliquots of the lipid extracts were removed for separation and analysis of the individual phospholipids by two-dimensional thin layer chromatography as described elsewhere (18). Further aliquots were removed, and the DSPC was isolated by column chromatography following osmium tetroxide oxidation as described by Mason et al. (19). The DSPC content of the recovered eluates was determined by phosphorus analysis (17). In some experiments, the purity of the isolated DSPC was assessed by phospholipid and fatty acid analysis of the recovered eluates according to previously described procedures (16). For each fraction and at each gestational age, the sample contained ca. 95% DSPC, of which almost 99% of the esterified fatty acids were saturated. Palmitic acid accounted for at least 80% of the total saturates. Corrections were not made for these values. For routine analysis, ^{14}C-dipalmitoylphosphatidylcholine (DPPC) containing 10,000 dpm was run through the column to assess the recovery in each individual run. At least 90% of the radioactivity was consistently recovered. In a preliminary study, we found that reproducible recoveries could be achieved in the range of 10–1000 μg DPPC.

Aliquots of each fraction were removed for analysis of the following marker enzymes: succinate dehydrogenase (EC 1.3.99.1) according to Pennington (20), NADPH-cytochrome c reductase (EC 1.6.2.4) as described by Omura and Takesue (21), lactate dehydrogenase (EC 1.1.1.27) using a commercial kit as described in Sigma Technical Bulletin No. 500 (Sigma Chemical Co., St. Louis, MO), 5′-nucleotidase (EC 3.1.3.5) according to Avruch and Wallach (22), UDP-galactose galactosyltransferase (EC 2.4.1.38) by the procedure of Beaufay et al. (23) as modified by Jobe et al. (24), and arylsulfatase (EC 3.1.6.1) as described by Chang et al. (25). At least one analysis was performed (in duplicate) on all the fractions obtained at each gestational age. Protein was determined according to Lowry et al. (26) and DNA as described by West et al. (27). A purified plasma membrane preparation was obtained by the method of Maeda et al. (28).

RESULTS

For each gestational age and in each experiment, ca. 70% of the total tissue homogenate DNA was recovered in the fraction designated as nuclear-cellular debris, indicating that the bulk of the cell nuclei were, in fact, recovered in this fraction. Marker enzyme analysis (Table 1) indicated the presence of each of the other subcellular organelles as well. Marker enzymes for mitochondria (succinate dehydrogenase), microsomes (NADPH cytochrome c reductase) and cytosol (lactate dehydrogenase) were appropriately enriched in the fractions so designated. Each of these fractions also contained some amount of plasma membranes, golgi and lysosomes, as evidenced by the presence of 5′-nucleotidase, UDP galactosyltransferase and arylsulfatase activities, respectively. The lamellar body fraction appeared to be reasonably devoid of contamination by other subcellular organelles. Using the data in Table 1, it can be estimated that this fraction is ca. 1% contaminated with mitochondria, 3.8% with microsomes and, using the value of 111.6 nmol/min/mg protein as the specific activity of a purified preparation of plasma membranes from adult lung tissue, 3.9% with this component. None of the other marker enzymes were analyzed on the isolated surfactant fractions.

The overall phospholipid composition was determined on each fraction at each gestational age. With the exception of total tissue homogenate and isolated lamellar bodies, there was little change in the relative proportion of total phosphatidylcholine over the development period studied. Tissue homogenate phosphatidylcholine increased from 51.1 ± 1.9% (n = 3) of total phospholipids on the 24th day of gestation to 57.4 ± 0.6% (n = 3) at term; it decreased slightly on the first postnatal day to 52.7 ± 1.7% (n = 3) and changed little thereafter. A lamellar body fraction was first isolable from the tissues on the 26th day of gestation. At this stage of development, phosphatidylcholine represented ca. 50% of the total lipid phosphorus. This value increased to almost 80% by the 28th day and changed little after that. Representative overall phospholipid compositions for each subcellular fraction, obtained from the fetus at term, are shown in Table 2. As indicated, phosphatidylcholine is the major phospholipid in each fraction but is particularly enriched in the alveolar lavage and isolated surfactant fractions.

TABLE 1

Representative Distribution of Marker Enzyme Activities in Rabbit Lung Subcellular Fractions

	Tissue homogenate	Nuclear-cellular debris	Mitochondrial-enriched	Lamellar body-enriched	Microsomal-enriched	Cytosol
			units/mg protein			
Succinate dehydrogenase[a]	2.4 ± 0.4	2.8 ± 0.4 (20.5)	49.4 ± 7.5 (68.6)	0.5 ± 0.2 (0.1)	3.4 ± 0.9 (0.7)	0.7 ± 0.0 (10.1)

Results are expressed as the mean ± 1 S.D. for a total of two to four determinations.

Values shown for succinate dehydrogenase, lactate dehydrogenase and arylsulfatase were obtained on newborn preparations and for NADPH-cytochrome$_c$ reductase, 5′-nucleotidase and UDP galactosyltransferase from adult. Value in parentheses represent the percentage of total activity recovered in each fraction. Fractions were prepared as described in the text.

[a]One unit, 1 nmol/min.
[b]N.D., not determined.
[c]Specific activity obtained for a purified plasma membrane preparation, 111.6 nmol/min/mg/protein (n=3).
[d]One unit, 1 pmol/min.

Fractions were prepared from fetal lung obtained at 31 days (term) gestation. Each value represents the mean ± 1 S.D. for a total of three to five determinations on each fraction.

Abbreviations: PC, phosphatidylcholine; LPC, lysophosphatidylcholine; SM, sphingomyelin; PS, phosphatidylserine; PI, phosphatidylinositol; PG, phosphatidylglycerol; PE, phosphatidylethanolamine; X, unidentified phospholipid.

[a]N.D., not detectable.

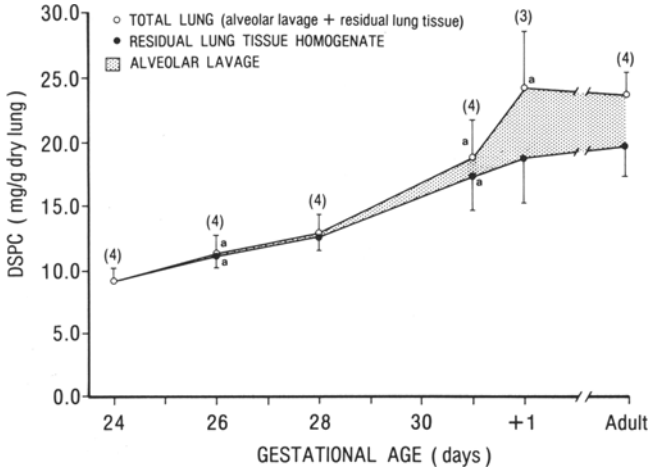

FIG. 1. DSPC content of alveolar lavage and unfractionated postlavaged lung tissue homogenate during perinatal development. Each value represents the mean ± 1 S.D. for the number of determinations shown in parentheses. (a) Significantly different from the value obtained at the previous gestational age ($p < 0.05$ by student's t-test).

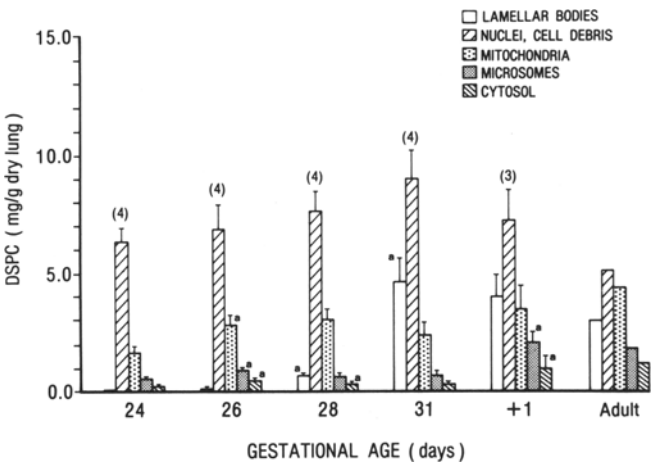

FIG. 2. DSPC content of subcellular fractions obtained from postlavaged lung tissue homogenate during perinatal development. Data representation and statistical analysis as in Figure 1.

The DSPC content of alveolar lavage and the unfractionated postlavaged lung tissue homogenate is illustrated in Figure 1. As shown, tissue homogenate DSPC progressively increased throughout fetal development, rising from 0.09 ± 0.91 to 17.45 ± 2.88 mg/g dry lung between 24 days gestation and term. Little change occurred following birth. Alveolar lavage DSPC also progressively increased during fetal development, rising from 0.02 ± 0.00 to 1.34 ± 0.36 mg/g dry lung between 26 days gestation and term. There was a further four-fold increase on the first postnatal day but no change thereafter. Total lung DSPC was calculated by summation of alveolar lavage and post-lavaged lung tissue homogenate values. The validity of this summation was established in a preliminary experiment in which the DSPC content was determined on unlavaged lung preparations. As indicated in the diagram (Fig. 1), the bulk of the total lung DSPC was recovered in the postlavaged lung tissue homogenate.

The DSPC content of the individual lung tissue fractions is shown in Figure 2. Significant developmental changes were observed for each fraction. On the 24th day of gestation, there was no isolable surfactant, and the bulk of the DSPC was recovered in the nuclear-cellular debris fraction. Between the 24th and 26th day of gestation, there was about a two-fold increase in mitochondrial, microsomal and cytosolic DSPC, with no change in the nuclear-cellular debris fraction. Surfactant was first isolable at 26 days gestation but contained less DSPC than the other subcellular fractions at this stage of development. From 26 days gestation to term, the DSPC content of the lamellar body fraction progressively and significantly increased, rising ca. six-fold (from 0.10 ± 0.02 to 0.67 ± 0.15 mg/g dry lung) between 26 and 28 days gestation and a further seven-fold (to 4.63 ± 1.06 mg/g dry lung) by term. There was little change in the DSPC content of the other subcellular fractions during this time. By the first postnatal day, both microsomal and cytosolic DSPC had again increased, but no significant change occurred in the other subcellular fractions.

TABLE 3

DSPC/Total PC Ratios of Rabbit Lung Subcellular Fractions During Perinatal Development

	DSPC/PC					
	24(4)[a]	26(4)	28(4)	31(4)	+1(3)	Adult (1)
Tissue homogenate	0.387 ± 0.030	0.401 ± 0.025	0.384 ± 0.028	0.436 ± 0.012	0.427 ± 0.026	0.427
Nuclei, cell debris	0.349 ± 0.012	0.383 ± 0.020	0.378 ± 0.027	0.399 ± 0.017	0.386 ± 0.031	0.333
Mitochondria	0.371 ± 0.014	0.390 ± 0.012	0.344 ± 0.010	0.384 ± 0.014	0.372 ± 0.008	0.347
Microsomes	0.504 ± 0.012	0.487 ± 0.029	0.385 ± 0.021	0.440 ± 0.014	0.492 ± 0.026	0.507
Cytosol	0.354 ± 0.018	0.390 ± 0.061	0.324 ± 0.011	0.357 ± 0.005	0.329 ± 0.034	0.310
Lamellar bodies	N.P.[b]	0.515 ± 0.072	0.579 ± 0.056	0.584 ± 0.015	0.505 ± 0.034	0.571
Alveolar lavage	N.D.[c]	0.459 ± 0.069	0.426 ± 0.048	0.570 ± 0.012	0.567 ± 0.018	0.572

Each value represents the mean ± 1 S.D. for the number of determinations shown.
Values underscored by a common line are significantly different ($p < 0.05$ by Student's t-test).

[a]Gestational age in days; number of determinations at each age in parentheses.
[b]N.P., none present.
[c]N.D., not determined.

Developmental changes were also found in the DSPC/total PC ratios of the individual subcellular fractions (Table 3). Each of the mitochondrial, microsomal and cytosolic ratios decreased on the 28th day of gestation and then increased. This trend was also observed in the unfractionated tissue homogenate. At each gestational age the largest DSPC/PC ratio was found in the lamellar body fraction. This ratio did not significantly change during fetal development but decreased (from 0.584 ± 0.015 to 0.505 ± 0.034) during the first postnatal day. The high value observed with the fetus was also observed in the adult. Alveolar lavage DSPC/PC ratios significantly increased between 28 days gestation and term, at which time the ratio was comparable to that obtained from the tissue-stored lamellar bodies.

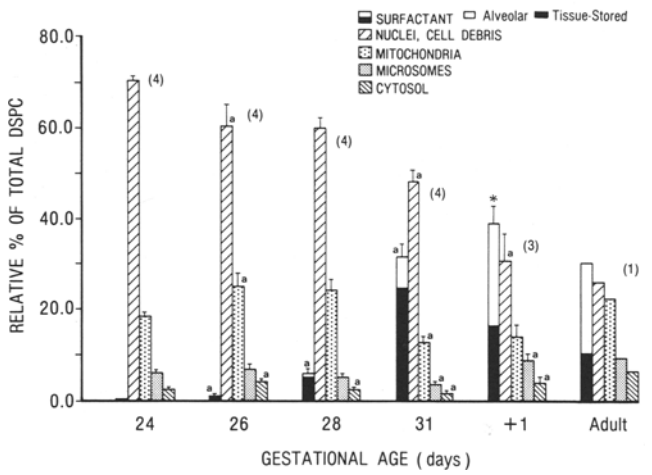

FIG. 3. Relative distribution of total lung DSPC over individual lung fractions during perinatal development. Total lung DSPC was calculated as the sum of alveolar lavage and postlavaged lung tissue DSPC. Data representation and statistical analysis as in Figure 1.

Using the data in Figures 1 and 2, the relative distribution of the total lung DSPC over the individual lung fractions was determined. Developmental changes were observed for each fraction (Fig. 3). While there was little change in the absolute content of DSPC in the nuclear-cellular debris fraction (Fig. 2), the relative proportion of total lung DSPC recovered in this fraction progressively decreased, falling from nearly 70% at 24 days gestation to about 30% by the first postnatal day. The relative proportion of total lung DSPC recovered in a surfactant pathway (tissue-stored plus alveolar) steadily increased so that by the first postnatal day this pathway contained the greatest proportion (almost 40%) of the total. At each gestational age, the mitochondrial-enriched fraction contained relatively more of the total DSPC than either the microsomes or cytosol. Developmental fluctuations were nevertheless observed in each of these subcellular fractions.

DISCUSSION

Compared to other tissues, the lung is particularly enriched in DSPC, a species of phosphatidylcholine in which both esterified fatty acids are saturated (29). Within the lung itself, this phospholipid represents the major constituent of the pulmonary surfactant, comprising up to 40–50% of the total phospholipids of this material (30). The surface tension-lowering properties of this unique material can largely be attributed to the presence of this phospholipid (1,5,6). Yet it has been shown that not all of the DSPC present in lung is associated with the surfactant complex (11–15). In the adult, for example, it has been shown that less than 50% of the total lung DSPC can be identified as being in a surfactant pathway (12–13).

In the developing fetus, surfactant production is initiated in the latter part of gestation and progressively increases toward term (2,3). The progressive accumulation of phospholipids (including DSPC) that has been observed during this time period (31–33) has generally been attributed to increased surfactant production. However, large quantities of DSPC appear to accumulate in lung tissue well before the normal onset of surfactant production (15,31–34), suggesting that, like the adult lung, the fetal lung contains considerable DSPC that is unrelated to the surfactant system.

In the fetal rabbit, surfactant synthesis is initiated on or about the 24th day of gestation (2,3), a fact that accounts for our inability to isolate a surfactant band at this gestational stage. In agreement with studies on both the rat (15,34) and rabbit (32), we did find large quantities of DSPC in the lung at this stage of development. While the bulk was recovered in the fraction designated as nuclear-cellular debris, significant levels were nevertheless recovered in the mitochondrial- and microsomal-enriched fractions as well as the cell cytosol.

At each gestational age, the largest proportion of the tissue homogenate DSPC was recovered in the nuclear-cellular debris fraction. While our present study indicates that this fraction contains not only the bulk of the cellular nuclei but other cellular constituents as well, previous studies in our laboratory have shown that very little surfactant becomes entrapped in this low-speed pellet fraction (16). In fact, it is for this reason that this very low centrifugal force has been adopted for our routine lamellar body isolation procedure. Furthermore, as large quantities of DSPC are recovered in the low-speed pellet fraction even before surfactant synthesis is initiated, it is reasonable to conclude that the bulk of the DSPC in this fraction is of nonsurfactant origin.

In agreement with others (15,31–34), we found that total tissue homogenate DSPC significantly increased during late fetal development. In addition, we have shown that not only the surfactant but the other subcellular fractions as well undergo dynamic changes in DSPC pool size during this critical stage of development. Prior to the onset of surfactant production, the overall increase in tissue homogenate DSPC appeared to be due to significant increases in the mitochondrial, microsomal and cytosolic pools. Once surfactant appears, then further increases in tissue homogenate DSPC can be attributed to increases in the surfactant pools. Following birth, on the other hand, the microsomal and cytosolic DSPC pools increase once more.

Individual surfactant constituents are synthesized in the endoplasmic reticulum of the alveolar Type II cell and transported via the Golgi apparatus for storage in the intracellular lamellar bodies, which are ultimately released to the alveolar space (4). The increased microsomal DSPC observed in the newborn could possibly represent newly synthesized material required for replenishment of the intracellular stores released to the airways following birth (2,3). Another mechanism by which depleted intracellular stores are replenished is via the uptake and reutilization of secreted surfactant constituents which are reprocessed by the Type II cell into new lamellar bodies (35). The increased cytosolic DSPC pool observed following birth could be due to this process. In considering either of these two possibilities, however, it is important to emphasize that, while the isolated surfactant originates from a single cell type, the other subcellular fractions no doubt originate from each of the more than 40 cell types present in lung (36). It is therefore difficult to determine whether the changes in DSPC pool size of these fractions are indeed a reflection of events occurring in the Type II cell or a more generalized effect. Studies with isolated Type II cells would be useful to clarify this issue.

It is interesting to note that while there was a dramatic release of DSPC to the alveoli following birth, there was not a concomitant decrease in the levels present in the intracellular surfactant stores. This suggests that the Type II cell may be still actively synthesizing and replenishing the intracellular stores. The decreased DSPC/PC ratio found in the intracellular stores also suggests that the newly synthesized material has not yet attained its full complement of the disaturated species. The newborns in the present study were killed less than 12 hr following birth. In a previous study (16) we found that it took at least 24 hr following birth to observe a depletion of intracellular stores, which were once more replenished in the next 24-hr period. While we did not determine DSPC levels in our previous study, results of our present study indicate that, at least in the adult, the high ratio observed in the late gestation fetus is once more attained. When this occurs in the postnatal period is not presently known.

Next to the tissue-stored surfactant, the mitochondrial-enriched fraction represents a major source of lung tissue DSPC. While this fraction is obviously contaminated by other subcellular organelles, we have previously shown that, like the nuclear-cellular debris fraction, negligible surfactant material is entrapped in this fraction (16). Also, considerable DSPC is recovered in this fraction prior to the onset of surfactant synthesis. As with the nuclear-cellular debris fraction, it is felt that the DSPC recovered in the mitochondrial-enriched fraction is not due to lamellar body contamination. Since this fraction is also enriched in Golgi, it could be argued that its high DSPC levels could be due to Golgi that are in the process of transferring surfactant constituents to the intracellular lamellar bodies. This may, in fact, be so for the late gestation fetus and early neonate but is unlikely to be the case in the 24-day gestation fetus.

DSPC is produced both by de novo synthesis and through remodeling of the monounsaturated phosphatidylcholine synthesized de novo (37-40). The latter mechanism occurs via two enzymatically catalyzed steps, the first involving a deacylation at the 2-position and the second involving a reacylation by an activated fatty acid (37-40). The first step is catalyzed by a phospholipase A_2, and the latter predominantly by a lysophosphatidylcholine acyltransferase. The former reaction appears to be the rate-limiting step. Phospholipase A_2 activity has been demonstrated in both purified lung microsomes and mitochondria (39), suggesting that both subcellular organelles are involved in the biosynthesis of DSPC. While it is reasonable to consider the translocation of microsomal DSPC to the intracellular lamellar bodies, this would not be likely for the mitochondrial pools. The possibility that the lamellar body itself is involved in its own DSPC production has been raised (38) but never fully established.

In conclusion, our results show that, in addition to the pulmonary surfactant, other lung subcellular fractions contain large DSPC pools that undergo dynamic changes in size during perinatal development. As DSPC is resistant to peroxidation, it may be that as well as performing its surface tension-lowering function as a major constituent of the pulmonary surfactant, it also represents a structural component for other subcellular organelles in a tissue such as lung that is exposed to high O_2 concentrations. While it is tempting to speculate that all subcellular fractions, including the lamellar bodies, are capable of their own DSPC production, further study would be necessary to clarify this point.

Differential Utilization of Long Chain Fatty Acids During Triacylglycerol Depletion. I. Rat Heart After Ischemic Perfusion[1]

S.C. Cunnane[*,a,2] and **M. Karmazyn**[b]

[a]Efamol Research Institute, Kentville, and [b]Department of Pharmacology, Dalhousie University, Halifax, Nova Scotia, Canada

Rat hearts were perfused with Krebs-Henseleit buffer for 90 min according to the Langendorff procedure. Normoxic perfusion for 90 min resulted in minor changes in fatty acid composition and a decrease in residual heart triacylglycerol to 60% of preperfusion values. When the protocol included 30 min of slow perfusion-induced ischemia, the hearts were observed to be depleted of 89% of their initial triacylglycerol content. The triacylglycerol fatty acid composition (mg %) remained similar after compared to before perfusion except for a 121 mg % increase in stearic acid and a 225 mg % increase in arachidonic acid. The percentage composition of both fatty acids was significantly inversely correlated with the amount of triacylglycerol remaining in the heart after perfusion. Postperfusion, arachidonic acid and stearic acids were present at nearly 1:1 in the residual heart triacylglycerol, suggesting that a common mechanism may be involved in the selective retention of these fatty acids by the heart.
***Lipids 23,* 62–64 (1988).**

Arachidonic acid (20:4n-6) in both liver and plasma triacylglycerol (TG) previously has been shown to be unique among other 16–20 carbon fatty acids in having a significant inverse correlation with the quantitative amount of TG in various species (1–3). Thus, when total liver TG is increased, e.g. after carbon tetrachloride injection or in essential fatty acid deficiency, the percentage composition of 20:4n-6 is lower but when total liver TG is significantly decreased, e.g. in starvation, 20:4n-6 is increased (4). While the percentage composition of 20:4n-6 varies inversely according to the total TG present, the quantitative amount of 20:4n-6 (μg/g) in TG is, except in extreme circumstances, very stable (2,3). Hence, the normal variability of the percentage composition of 20:4n-6 is attributable largely to the variability in the TG content of the major fatty acids in TG (palmitic-16:0, oleic-18:1n-9 and linoleic-18:2n-6). The marked decrease in total TG in the rat heart after perfusion in vitro with a glucose-free buffer (5) provided a different model in which the relation between 20:4n-6 and TG could be studied further.

Abbreviations: 20:4n-6, arachidonic acid; GLC, gas liquid chromatography; 18:2n-6, linoleic acid; 18:1n-9, oleic acid; 16:0, palmitic acid; 16:1n-7, palmitoleic acid; 18:0, stearic acid; TG, triacylglycerol.

EXPERIMENTAL

Male Sprague-Dawley rats (200–250 g) were obtained from Charles River Canada (Montreal, Quebec) and were fed a semisynthetic diet of the following composition (g/kg); sucrose (555), casein (200), cellulose (100), corn oil (100), minerals (35) and vitamins (10) as recommended by the American Institute of Nutrition (6). After 10 weeks, the rats were decapitated and the hearts removed immediately and perfused retrograde in vitro using the Langendorff technique (7). The perfusion medium was oxygenated Krebs-Henseleit buffer containing glucose (7), which was pumped peristaltically through a cannula inserted into the base of the aorta and into the coronary arteries. Two perfusion protocols each were used for 90 min; normoxic (10 ml/min) or normoxic plus an ischemic episode (10 ml/min-30 min, followed by 1 ml/min-30 min, followed by 10 ml/min-30 min). For the first protocol (normoxic perfusion), six hearts were perfused, whereas in the second protocol (ischemic perfusion) 18 hearts were perfused. Fresh (unperfused) hearts and perfused hearts were homogenized in chloroform/methanol (2:1, v/v) containing 0.02% butylated hydroxytoluene as antioxidant. Total TG were separated from the total lipid extract by thin layer chromatography as previously described (8). Fatty acids were transmethylated with boron trifluoride-methanol and analyzed by GLC using a Hewlett-Packard 5880 under the column conditions previously described (8). TG were quantitated by GLC by the addition of an internal standard (triheptadecanoin) to the tissue homogenates prior to lipid separation.

RESULTS

Normoxic perfusion for 90 min led to 40% less residual TG ($p < 0.01$) and 50% higher 20:4n-6 ($p < 0.05$) in the heart compared to preperfusion values and 55% higher 20:4n-6 (Table 1). There was no significant correlation between the 20:4n-6 present in the heart TG before or after perfusion and the amount of TG present before or after perfusion.

The fatty acid composition (mg % and μg/g, wet weight) of rat heart TG before and after perfusion including 30 min ischemia is shown in Table 2. Proportionally, 16:0, 18:1n-9 and 18:2n-6 were not significantly different in the hearts before and after perfusion. Palmitoleic acid (16:1n-7) was significantly lower but stearic acid (18:0) and 20:4n-6 were significantly higher in the residual heart TG after perfusion (2.21 and 3.25 times, respectively, $p < 0.01$). N-3 fatty acids were not detected in heart TG before or after perfusion. Quantitatively, since the total TG was decreased by 89% in the hearts perfused with a 30-min ischemic episode, all the TG fatty acids were significantly lower after perfusion (Table 2). However, the quantitative fatty acid changes (μg/g) could be differentiated into two groups: A) 16:0, 16:1n-7, 18:1n-9 and 18:2n-6, which were

**p < 0.01, Student's t-test.

decreased 89–95%; B) 18:0 and 20:4n-6, which were decreased 80% and 70%, respectively. Hence, compared to the net decrease of 89% in the TG fatty acids as a whole, 18:0 and 20:4n-6 selectively were retained in the residual TG remaining in the heart after ischemic perfusion.

A significant inverse correlation was observed between the mg % 20:4n-6 in TG and total heart TG (mg/g) in both fresh (unperfused) hearts and in hearts after perfusion using the ischemic episode. This correlation was also evident for 18:0 (Fig. 1). Whereas 100 μg/g 18:0 and 76 μg/g 20:4n-6 (ratio—1.32) were present in the heart TG before perfusion, after perfusion 20 μg/g 18:0 and 23 μg/g 20:4n-6 (ratio—0.89) were present. In unperfused hearts, there was no correlation between 18:0 and 20:4n-6 in heart TG ($r = -0.03$) but after perfusion (including 30 min ischemia), the correlation coefficient was $r = +0.70$ ($p < 0.01$, Fig. 2). Thus, the residual TG in the heart contained almost equal amounts of 18:0 and 20:4n-6 after ischemic perfusion, and in individual hearts (postperfusion), the two fatty acids were highly correlated. Comparison of the

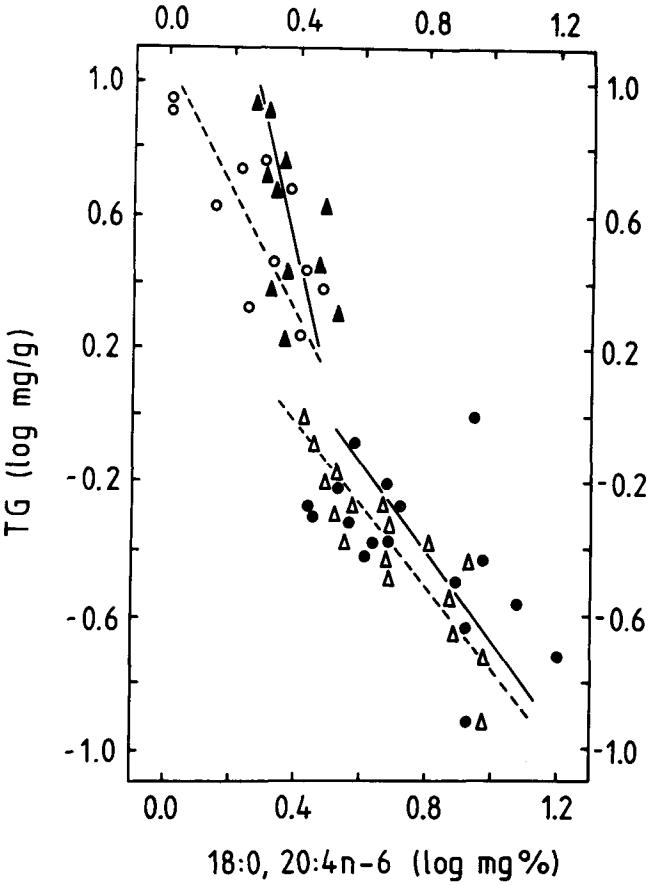

FIG. 1. Linear regression analysis of the relation between the proportional composition of arachidonic acid (20:4n-6, log mg %) and stearic acid (18:0, log mg %) of TG and total TG in rat hearts before (unperfused) and after perfusion in vitro (including 30 min ischemia). Correlation coefficients, regression equations and number of samples, before perfusion: (20:4n-6—○— — —, $r = -0.75$; $y = -0.48X + 0.55$, $p < 0.001$; $n = 11$; 18:0—▲——, $r = -0.58$, $y = -0.20X + 0.49$, $p < 0.01$, $n = 11$); after perfusion: (20:4n-6—●——; $r = 0.57$; $y = -0.56X + 0.53$; $p < 0.001$; $n = 17$; 18:0—△— — —; $r = -0.89$; $y = -0.72X + 0.40$; $p < 0.001$; $n = 17$).

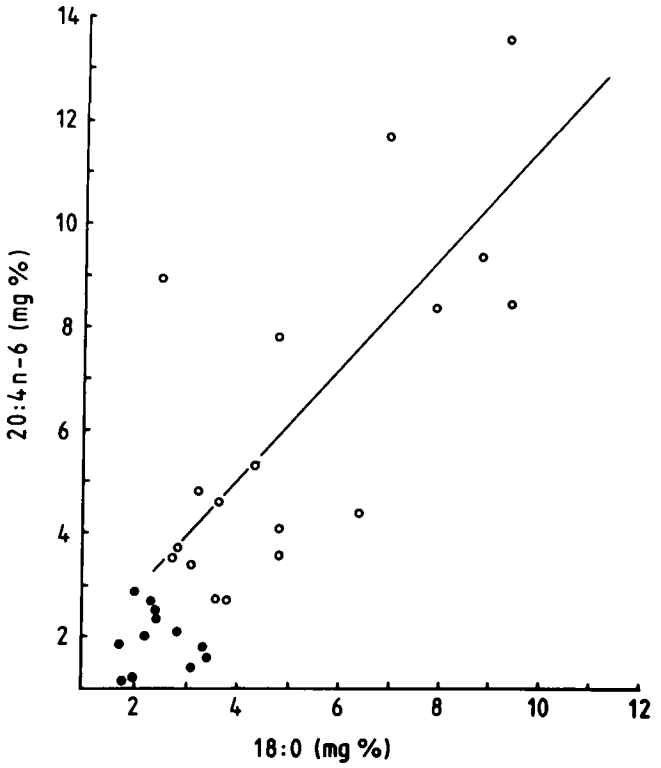

FIG. 2. Linear regression analysis of the relation between the proportional composition of arachidonic acid (20:4n-6) and stearic acid (18:0) in rat heart TG (●) before (unperfused, n = 12) and (○) after (n = 18) in vitro perfusion of the hearts (including 30 min ischemia). Correlation coefficients and regression equations: Before—($r = -0.03$, not significant). After—($r = +0.70$, $y = 0.55X + 0.27$, $p < 0.001$).

TG levels and composition of 20:4n-6 and 18:0 after perfusion in hearts perfused with or without the ischemic episode showed that the mg % of 20:4n-6 and 18:0 was significantly higher ($p < 0.01$) and the TG (mg/g) was significantly lower in hearts perfused with the ischemic episode compared to those perfused without ischemia.

DISCUSSION

These results confirm the previously reported significant inverse correlation between the mg % of 20:4n-6 in TG and total TG in plasma and liver (1-3) and extend the relationship to include the rat heart perfused in vitro. Because of the marked TG depletion, which occurs within 90 min of perfusion (only in the protocol that included 30 min of ischemic perfusion), this model appears ideal to investigate the utilization of long chain fatty acids from TG species in the heart. That ischemia is responsible for the markedly lower residual heart TG levels after 90-min perfusion is suggested by the significantly higher residual TG levels and the lack of significant changes in the fatty acid composition (except 20:4n-6) of heart TG after normoxic perfusion (Table 1). Glucose in the perfusion medium was the only exogenous energy source for the heart. By providing only 10% of the medium/min compared to normoxic perfusion, ischemic perfusion presumably required the heart to utilize endogenous energy sources, e.g. TG, more than during normoxic perfusion, hence depleting heart TG significantly more than in normoxic perfusion (Tables 1 and 2).

The retention of 20% of the original 18:0 and 30% of the original 20:4n-6 such that nearly equal amounts remained in the residual heart TG after ischemic perfusion suggests that at least two pools of 20:4n-6 may exist in rat heart TG, one of which is more readily hydrolyzed along with fatty acids such as 16:0, 18:1n-9 and 18:2n-6 during in vitro perfusion. The other 20:4n-6 pool appears to be retained more avidly possibly in combination with 18:0. That the retention of 20:4n-6 and 18:0 in rat heart TG after perfusion, including a 30 min ischemic episode, may be interrelated is suggested by the similar amount of these two fatty acids remaining in the residual TG and the significant positive correlation between these two fatty acids in the heart TG after perfusion (Fig. 2).

TG previously have been shown to be an important endogenous energy source for heart metabolism (9). Long-chain fatty acids within the total TG pool previously have not been distinguished according to their availability for hydrolysis for energy utilization by the heart. However, previous data have indicated that part of the total TG in heart is unavailable for energy metabolism (5,10). The present data support this view and suggest that, especially in the rat heart perfused in vitro using a protocol that includes a 30-min ischemic episode, a proportion of 20:4n-6 and 18:0 (20-30%) may be unavailable for hydrolysis. This may be because they are hydrolyzed differentially by TG lipases in comparison with those containing 16:0, 18:1n-9, 18:2n-6 or 16:1n-7. Alternatively, some areas of heart tissue may not be accessible for TG hydrolysis, thus causing a shift in fatty acid composition after perfusion with a medium not supplying exogenous fatty acids. Future research will address this issue.

[Received April 16, 1987; Revision accepted August 31, 1987]

Fluorescence Formation from Hydroperoxide of Phosphatidylcholine with Amino Compound

Toshihiro Iio and **Kazuaki Yoden***
Showa College of Pharmaceutical Sciences 1-8, Tsurumaki 5-chome, Setagaya-ku, Tokyo, Japan

The hydroperoxides of methyl linoleate, 1-palmitoyl-2-linoleoyl-phosphatidylcholine and trilinolein each produced similar fluorescent substances through reaction with amino compounds after decomposition by heme methyl ester. Fluorescent substances formed from methyl linoleate with 1-aminopentane revealed characteristic fluorescence peaks on HPLC, while those obtained from 1-palmitoyl-2-linoleoyl-phosphatidylcholine and trilinolein were not eluted under the same conditions. However, when both of these fluorescent substances were transesterified to methyl ester, the same fluorescence peaks were observed. This result suggests that fluorescent substances formed from oxidized membrane lipids with amino compounds remain attached to phospholipids without being released from their glycerol backbone.
***Lipids* 23, 65–67 (1988).**

Polyunsaturated fatty acids (PUFA) initially are oxidized to produce hydroperoxides (HPO) by both enzymic and nonenzymic oxidations and then the HPO produced are degraded further into secondary oxidation products (SP), including many functional aldehydes or malondialdehyde, during the oxidation process (1,2). These lipid peroxides and/or their secondary decomposition products are known to react with various amino compounds, bringing about many forms of biological damage (3). Fluorescent lipofuscin pigments associated with aging in animal tissues also have been assumed to be derived from the reaction of lipid peroxides with amino compounds (4). Fujimoto et al. recently reported that the degradation of HPO prepared from methyl linoleate (ML) in the presence of metals, hemin or ascorbic acid is involved closely in fluorescence formation through reaction with DNA (5). They also suggested that the important structural feature associated with the fluorescence formation appears to be conjugated diene HPO and not unconjugated diene isomers produced during photosensitized oxidation. Therefore, HPO derived from PUFA substituted at the 2-glycerol position of phospholipids in biological membranes (6,7) may play an important role in the formation of fluorescent substances under physiological conditions.

We recently have demonstrated that SP prepared from autoxidized methyl linolenate and ML are involved in the formation of fluorescent substances through reaction with amino compounds (8,9). The high-resolution mass spectrum of the fluorescent substance (FS-II) formed from the SP with 1-aminopentane (1-AP) as a model system showed the empirical formula to be $C_{24}H_{41}NO_4$ with a molecular weight of 407 and the presence of a methyl ester group originating from ML in the structure of the fluorescent substance (Iio, unpublished data). These results suggest that the precursor available for the fluorescence formation may be a 19-carbon length compound having a methyl ester group originating from ML without breakdown into low molecular weight compounds. Fukuzawa et al. also recently have reported that a new type of fluorescent substance was produced during oxidation in the presence of amino compounds through reaction of 12-keto-oleic acid produced from oleic acid without breakdown into low molecular weight compounds (10). In the present study, we demonstrated the formation of fluorescent substances through reaction of HPO prepared from ML, 1-palmitoyl-2-linoleoyl-phosphatidylcholine (PLPC) and trilinolein (TL) with 1-AP after decomposition by heme methyl ester (HM) as a model system.

MATERIALS AND METHODS

Materials. Linoleic acid, PLPC, TL, hemin (type I) and lipoxygenase (type I) were purchased from Sigma Chemical Co. (St. Louis, MO). 1-AP and 5% methanolic *m*-trifluoromethylpheny-trimethyl ammonium hydroxide were purchased from Tokyo Kasei Kogyo Co., Ltd. (Tokyo). High performance liquid chromatography (HPLC) grade solvents from Kanto Kagaku Co., Ltd. (Tokyo) were used for HPLC separations throughout all experiments. HM was prepared by the method of Ortiz de Montellano et al. (11).

Preparation of HPO from ML, PLPC and TL. Two mg of PLPC or TL suspended in 1 ml of 100 mM deoxycholate solution was incubated with 9 ml of 0.1 M borate buffer (pH 9.0) containing 2 mg of lipoxygenase at 30 C for 30 min (12). The products were extracted with chloroform/methanol (2:1), and each HPO was purified by HPLC or thin layer chromatography (TLC). The purification of HPO from oxidized PLPC was carried out on a μ-Bondapak FAA (3.9 × 300 mm, Waters Associates, Milford, MA), using methanol/water (9:1) at a flow rate of 1 ml/min (13). HPO of TL was subjected to TLC (kieselgel 60, Merck, Darmstadt, FRG) developed with petroleum ether/ethyl ether/28% ammonia (55:45:2) (14). 13-Hydroperoxylinoleic acid was prepared from linoleic acid using soybean lipoxygenase in 0.1 M borate buffer (pH 9.0) (15). The products were methylated with diazomethane and purified by TLC using hexane/ethyl ether/acetic acid (60:40:1) as a solvent system. SP of ML were prepared from autoxidized ML by silica gel column chromatography according to the method of Terao and Matsushita (16). Each purified HPO was estimated using molar absorbance values of 24,500 at 233 nm (17).

Formation of fluorescent substances. Each HPO (100 nmol) prepared from ML, PLPC or TL was preincubated with or without HM (1 nmol) in 2 ml of methanol at 37 C for 45 min, and then 1 ml of 1-AP (1 μmol) in methanol solution was added to the preincubation mixtures. SP also were incubated with 1-AP in 3 ml of methanol. Fluorescence developed at 37 C during 20 hr. Fluorescence spectra were measured with a Hitachi

Abbreviations: HM, heme methyl ester; HPLC, high performance liquid chromatography; HPO, hydroperoxides; ML, methyl linoleate; PLPC, 1-palmitoyl-2-linoleoyl-phosphatidylcholine; PUFA, polyunsaturated fatty acids; SP, secondary oxidation products; TL, trilinolein; TLC, thin layer chromatography.

MPF-3 fluorescence spectrophotometer, and the intensity was expressed as a percentage of that of a quinine sulfate standard (0.1 μg/ml in 0.1 N H_2SO_4). HPLC was performed on a μ-Bondasphere phenyl column (3.9 × 150 mm, Waters) using acetonitrile/water (50:50) as the mobile phase at a flow rate of 0.7 ml/min. Fluorescence peaks were monitored with a Hitachi 650-10LC fluorescence spectrophotometer with excitation and emission maxima at 350 nm and 420 nm, respectively. All of the fluorescent substances also were subjected to TLC and developed with chloroform/methanol (9:1).

Transesterification of fluorescent material. To 0.1 ml of fluorescent material, 0.85 ml of methanol and 0.05 ml of 5% methanolic *m*-trifluoromethylphenyltrimethyl ammonium hydroxide were added, and this mixture was allowed to stand at 20 C (18). Transesterification usually was completed within 45 min. The mixture was evaporated under a nitrogen stream and redissolved in 1 ml of chloroform. This chloroform solution was applied to a Sep-pak Si cartridge (Waters), and the cartridge was washed out with 8 ml of chloroform to remove the transesterification reagent. The fluorescent substance was eluted with 4 ml of chloroform/methanol (9:1) and subjected to reversed-phase HPLC under the same conditions.

RESULTS AND DISCUSSION

When purified HPO prepared from ML, PLPC and TL were incubated separately with 1-AP in methanol solution at 37 C for 20 hr after decomposition by HM, marked formation of fluorescent substances was observed. These fluorescent substances showed the same fluorescence spectra with excitation and emission maxima at 340–350 nm and 410–420 nm, respectively, consistent with that observed for SP prepared from autoxidized ML (Fig. 1). None of the HPO preincubated without HM produced any fluorescent substances. This result suggests that HPO from the unsaturated esterified fatty acids in PLPC and TL are related equally to the formation of fluorescent substances through reaction with amino compounds in the presence of HM.

However, HPLC analysis of each fluorescent product showed independent elution profiles, as shown in Figure 2A. The fluorescent substances formed from HPO of ML with 1-AP after decomposition by HM revealed two major fluorescence peaks at retention times of 5.0 min (FS-I) and 10.5 min (FS-II), respectively. On the other

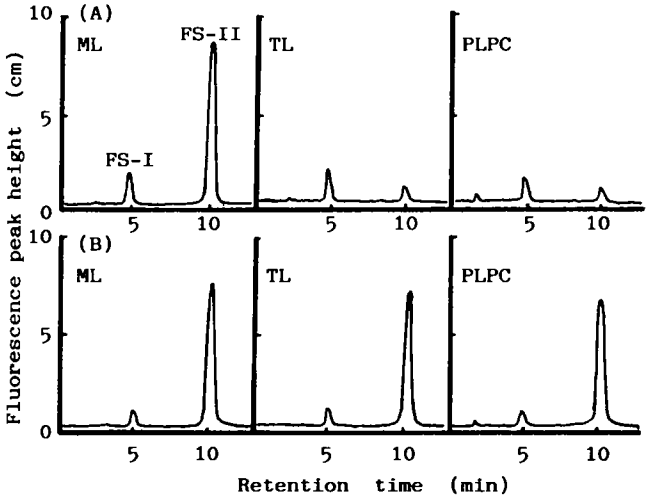

FIG. 2. HPLC of fluorescent substances formed from HPO of ML, PLPC and TL with 1-AP. HPLC was performed on a μ-Bondasphere phenyl column, and elution was carried out with acetonitrile/water (50:50) at a flow rate of 0.7 ml/min. Aliquots of the fluorescent substances were subjected to HPLC before (A) and after (B) transesterification using the procedures described in Materials and Methods.

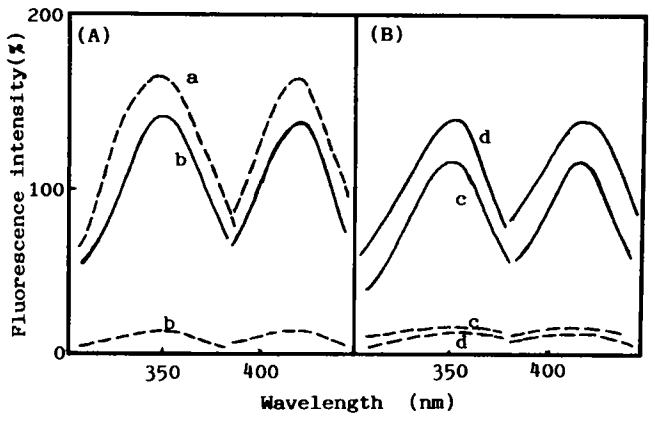

FIG. 1. Fluorescence spectra of fluorescent substances formed from SP or HPO of ML, PLPC and TL with 1-AP. HPO of ML (A-b), PLPC (B-c) and TL (B-d) were incubated with 1-AP at 37 C for 20 hr after preincubation with (——) or without (···) HM. SP prepared from autoxidized ML by silica gel column chromatography also was incubated with 1-AP at 37 C for 20 hr (A-a).

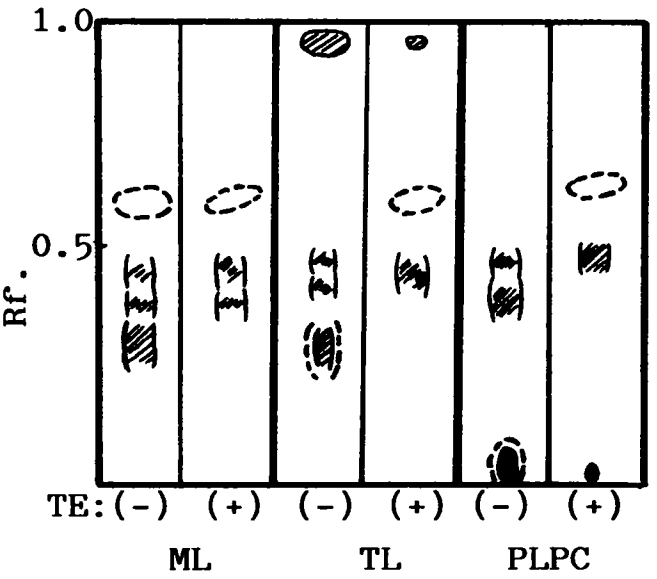

FIG. 3. TLC of flurescent substances produced from HPO of ML, PLPC and TL with 1-AP. Aliquots of fluorescent substances were subjected to TLC before (−) and after (+) transesterification (TE) and developed with chloroform/methanol (9:1). Fluorescent spots (broken circle) were detected by excitation at around 360 nm, while other spots (hatched circle) were detected using iodine vapor.

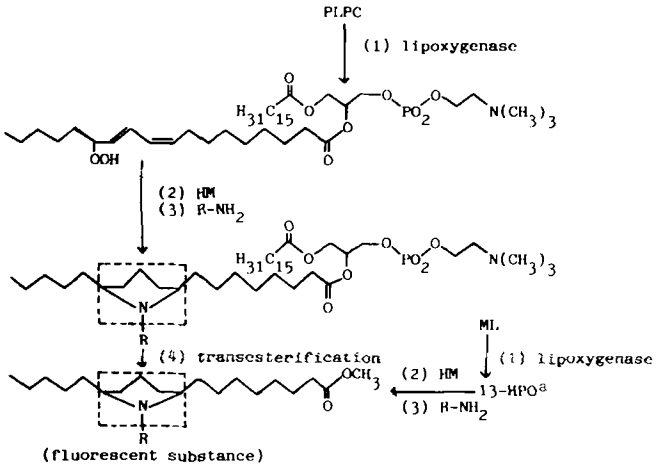

FIG. 4. Proposed mechanism for formation of fluorescent substances formed from PLPC with amino compound. The procedures (1-4) for fluorescence formation are described in Materials and Methods. The chromophobic structure enclosed with a dotted line is at present obscure. 13-HPO[a], 13-hydroperoxy methyl linoleate.

hand, the fluorescent substances derived from HPO of PLPC and TL with 1-AP showed only small fluorescence peaks at these retention times, even though samples with the same fluorescence intensities as that of ML were used for HPLC analysis and the major fluorescence peak was eluted with methanol (data not shown).

Therefore, these fluorescent substances produced from HPO of ML, PLPC and TL were transesterified to methyl esters in methanol solution and subjected to HPLC under the same conditions as those described above. Both fluorescent substances produced from HPO of PLPC and TL also were eluted at similar retention times of 10.5 min as that of FS-II obtained from HPO of ML (Fig. 2B). However, a negligible amount of FS-I was detected on HPLC after transesterification because FS-I was unstable.

TLC analysis of both the fluorescent substances produced from the HPO of PLPC and TL after transesterification to methyl ester revealed one major fluorescence spot (Rf 0.60) corresponding to FS-II formed from HPO of ML with 1-AP, while the two native fluorescent substances present before transesterification showed fluorescence spots distinct from that of FS-II on TLC (Fig. 3). The appearance of this fluorescent substance (FS-II) from the two fluorescent substances after transesterification strongly supports the possibility that HPO produced from unsaturated esterified fatty acids in phospholipids or triglycerides are involved in the fluorescence formation without being released from their glycerol backbone.

It is well known that phosphatidylcholine and phosphatidylethanolamine are the most common types of membrane lipids and that linoleic acid and arachidonic acid are abundant PUFA constituents of these phospholipids (19,20). Therefore, HPO produced from these PUFA in phospholipids by lipoxygenase or autoxidation (6,7) seem to be a primary cause of accumulation of fluorescent substances in biomembranes under physiological conditions. Nielsen reported that peroxidized phospholipid (cardiolipin) produced the fluorescent substance through reaction with albumin (21). Moreover, Shimasaki et al. have reported that the fluorescent chromolipids formed during lipid peroxidation of liposomes by ferrous ions and ascorbic acid remain in liposomal membranes (22). These reports, in addition to the results here, suggest that the hydrolytic release of unsaturated esterified fatty acids that usually are substituted at the 2-glycerol position in phospholipids is not essential for the fluorescence formation occurring in biomembranes. We recently demonstrated that both 9-hydroperoxy ML and 13-hydroperoxy ML, which are the major conjugated diene HPO produced during autoxidation of ML, formed the same fluorescent substances through reaction with 1-AP after preincubation with HM (23).

Based on the above results and the structural information mentioned above, we propose a possible mechanism for the fluorescence formation occurring during oxidation of unsaturated phospholipids in biomembranes using 13-hydroperoxides of PLPC and ML as a model compound, as shown in Figure 4. It seems likely that the precursor available for fluorescence formation keeps the original 18-carbon length of linoleic acid substituted onto phospholipids, but the structure of this precursor has not been established in detail yet.

Although fluorescent chromolipids accumulating with age in animal tissues are suggested to be produced in biomembranes, our results may support the view that fluorescent substances produced from oxidized membrane phospholipids are localized in biomembranes and accumulated without release from biomembranes.

Regulation of Squalene Epoxidase Activity by Membrane Fatty Acid Composition in Yeast

T.M. Buttke*,[1], S.L. Brint and M.R. Lowe[1]
Department of Microbiology, University of Mississippi Medical Center, 2500 N. State St., Jackson, MS 39216

Depriving *Saccharomyces cerevisiae* strain GL7 of exogenous unsaturated fatty acid supplements causes this sterol biosynthetic mutant to accumulate squalene at the expense of squalene epoxide and squalene diepoxide. To further characterize the apparent relationship between squalene epoxidase activity and membrane fatty acid composition, a variety of unsaturated fatty acids differing in their chain lengths and in the positions and orientation (*cis* or *trans*) of their double bonds were tested for their ability to promote turnover of endogenous squalene in cells previously deprived of olefinic supplements. All of the unsaturated fatty acids tested were found to restore squalene epoxidase activity but there were marked differences in their efficacies that best were correlated with the extent to which they reduced the medium chain (C-10 + C-12) saturated fatty acid content of cellular phospholipids. Additional studies demonstrated that de novo protein synthesis was required for the restoration of squalene epoxidase activity in unsaturated fatty acid-deprived cells.
***Lipids* 23, 68-71 (1988).**

Sterols such as cholesterol and ergosterol are ubiquitous components of animal and fungal membranes, respectively; they are thought to play an important role in modulating bilayer fluidity (1). In animal cells, the regulation of cholesterol biosynthesis is complex and resides primarily at the level of 3-hydroxy-3-methylglutaryl-coenzyme A reductase [HMG-CoA reductase] (2), although other enzymes also may serve as regulatory elements (3). Modulation of HMG-CoA reductase activity seems to occur via a variety of molecular mechanisms, including changes in enzyme synthesis, enzyme degradation and phosphorylation-dephosphorylation (4). A direct regulation of enzyme activity via changes in membrane fluidity also has been proposed (5) but the data regarding such a mechanism are conflicting (6). In contrast to the situation in animal cells, much less is known regarding the regulation of sterol synthesis in yeast and fungi.

Due to two different mutations, *Saccharomyces cerevisiae* strain GL7 is unable to synthesize either ergosterol or unsaturated fatty acids and requires exogenous lipid supplements for long-term growth (7). Nevertheless, the mutant can grow for extended periods of time in the absence of unsaturated fatty acids (8); strain GL7 appears to compensate for the lack of olefinic fatty acid supplements by replacing most of its membrane unsaturated fatty acids with medium chain (C-10 and C-12) saturated fatty acids (8). Under such conditions, strain GL7 grows more slowly, demonstrates a marked "clumpiness" and synthesizes squalene rather than the squalene epoxide [2,3-oxidosqualene] and squalene diepoxide [2,3;22,23-dioxidosqualene] lipids that normally accumulate due to the mutant's deficiency in 2,3-oxidosqualene-lanosterol cyclase activity (7,9). Conversely, short-term cholesterol deprivation favored the synthesis of squalene diepoxide (9). These data suggested that sterol synthesis in yeast also may be regulated by changes in membrane fluidity.

To further characterize the relationship between membrane lipid composition and squalene epoxidase activity in yeast, we now have compared various olefinic fatty acids for their ability to restore squalene epoxidase activity in strain GL7 cells, which previously had been deprived of unsaturated fatty acid supplements. Our results demonstrate that an inverse relationship exists between squalene epoxidase activity and the proportion of phospholipids containing C-10 + C-12 fatty acids in yeast cell membranes.

MATERIALS AND METHODS

Culture conditions. Saccharomyces cerevisiae strain GL7 (MAT a *gal2/erg*12-1/*heme*3-6 [7]) was grown at 30 C with shaking in a defined medium supplemented with methionine and detergent-solubilized cholesterol and unsaturated fatty acid supplements (9). The pulse-chase protocol used to compare the ability of various unsaturated fatty acids to restore squalene epoxidase activity was described previously (9). Briefly, log phase cells grown in the presence of cholesterol (10 μg/ml) and oleic acid (18:1Δ^9; 20 μg/ml) were washed twice with media and resuspended to the desired density in media containing cholesterol but lacking unsaturated fatty acid supplements. The cells were incubated under these deprivation conditions for 12 hr, after which 50 ml aliquots were pulsed for one to three hr with 10 μCi of [1-^{14}C] acetate (55 mCi/mmol; New England Nuclear, Boston, MA). The pulse was terminated with 1 M sodium acetate, and the cells were collected by centrifugation and washed twice prior to being resuspended to the same cell density in cholesterol-supplemented media either lacking unsaturated fatty acid supplements or containing one of a variety of unsaturated fatty acids (final concentration 20 μg/ml). At this point (designated as time 0), >90% of the [^{14}C] acetate incorporated into nonsaponifiable lipids was associated with squalene (9).

In vivo assay of squalene epoxidase activity. Yeast cells containing endogenously synthesized ^{14}C-labeled squalene were incubated in the absence or presence of unsaturated fatty acid supplements, and either at two-hr intervals or after a total incubation time of six hr cells were harvested and their cellular lipids were isolated and analyzed by thin layer chromatography (TLC; see below) to determine the amount of ^{14}C-labeled squalene that had been converted to squalene epoxide and squalene diepoxide. In most cases, the level of squalene epoxidase activity in vivo is reported as the percent of ^{14}C-labeled squalene present at time 0 that was converted to squalene epoxide + squalene diepoxide during the chase.

Lipid analyses. Total cellular lipids were extracted from lyophilized yeast cells and separated by TLC as described

*To whom correspondence should be addressed.
[1]Present address: Department of Microbiology and Immunology, East Carolina University, School of Medicine, Greenville, NC 27858.

previously (9). ^{14}C-Labeled lipids were localized by either autoradiography using Kodak XAR-5 film, or by the use of a linear radioactivity detector (Bioscan, Washington, DC), and quantitated by either liquid scintillation counting or by use of the Bioscan instrument.

Following separation of cellular lipids by TLC, phospholipids remaining at the origin were treated with BF_3-MeOH at 100 C for five min, and the fatty acyl methyl esters were extracted into pentane. Fatty acyl methyl esters were analyzed by gas liquid chromatography (GLC) using a Perkin-Elmer Sigma 3B gas chromatograph equipped with a six-ft glass column packed with SP2330 (Supelco) and a program having an initial time of 0 min, a ramp rate of 5 C/min, a final time of 11 min, initial temperature of 135 C and a final temperature of 175 C.

RESULTS AND DISCUSSION

Using the pulse-chase protocol described previously (9), a variety of unsaturated fatty acids were compared for their ability to restore squalene epoxidase activity in vivo. As shown in Figure 1, all of the unsaturated fatty acids tested promoted the conversion of squalene to squalene epoxide and squalene diepoxide but there were marked differences in their efficacies. Cetoleic acid (20:1) only was effective marginally in restoring squalene epoxidase activity, while linoleic acid (18:2) was the most effective of the unsaturated fatty acids tested. The other unsaturated fatty acids tested (myristoleic acid, 14:1; palmitoleic acid, 16:1; oleic acid, 18:1Δ^9; petroselenic acid, 18:1Δ^6; and elaidic acid, *trans*-18:1Δ^9) were found to be intermediate in their effectiveness. Thus, while squalene epoxidase appears to require unsaturated fatty acids for activity, the requirement is nonspecific in that it can be satisfied by unsaturated fatty acids differing in their chain lengths as well as in the position, number and orientation of their unsaturations.

One possibility for the differing efficacies of the unsaturated fatty acids is that during the six-hr chase period, they were incorporated to varying extents reflecting differences in their suitabilities as substrates for fatty acid transport or phospholipid biosynthesis. To examine this possibility, the phospholipid fatty acid profiles of the cells shown in Figure 1 and the cells of three additional experiments were determined by GLC. When the unsaturated fatty acid compositions of cellular phospholipids were plotted as a function of the amount of ^{14}C-labeled squalene converted to squalene epoxide and squalene diepoxide during the six-hr chase period (Fig. 2A), a positive correlation (r = 0.743) was observed consistent with unsaturated fatty acids being required for squalene epoxidase activity. From the best-fit line shown in Figure 2A, values for the amounts of phospholipid unsaturated fatty acids that would support minimal and maximal squalene epoxidase activity were determined to be ca. 20% and 70%, respectively. Conversely, if the medium-chain (C-10 + C-12) saturated fatty acid content of the same cells was plotted as a function of squalene

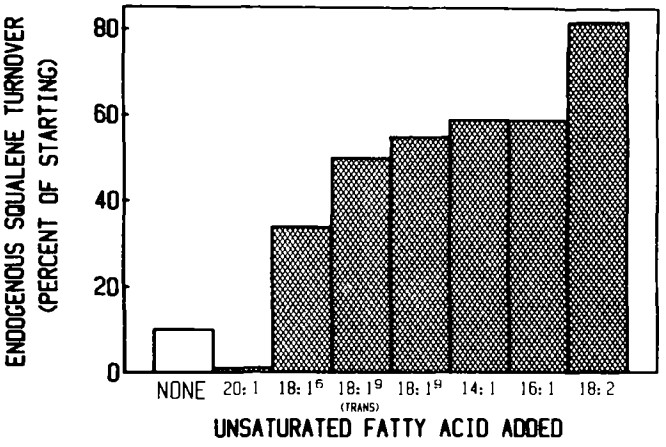

FIG. 1. Effect of unsaturated fatty acid supplements on squalene epoxidase activity. *S. cerevisae* strain GL7 was incubated for 14 hr in the absence of exogenous unsaturated fatty acids, with [1-^{14}C] acetate being added during the final two hr (pulse period) to label endogenous squalene. The cells subsequently were washed and incubated in the presence of one of the indicated unsaturated fatty acid supplements. After an additional six-hr incubation (chase period), cellular lipids were extracted and analyzed by TLC. The data are presented as the percent of endogenous ^{14}C-labeled squalene converted to squalene epoxide + squalene diepoxide.

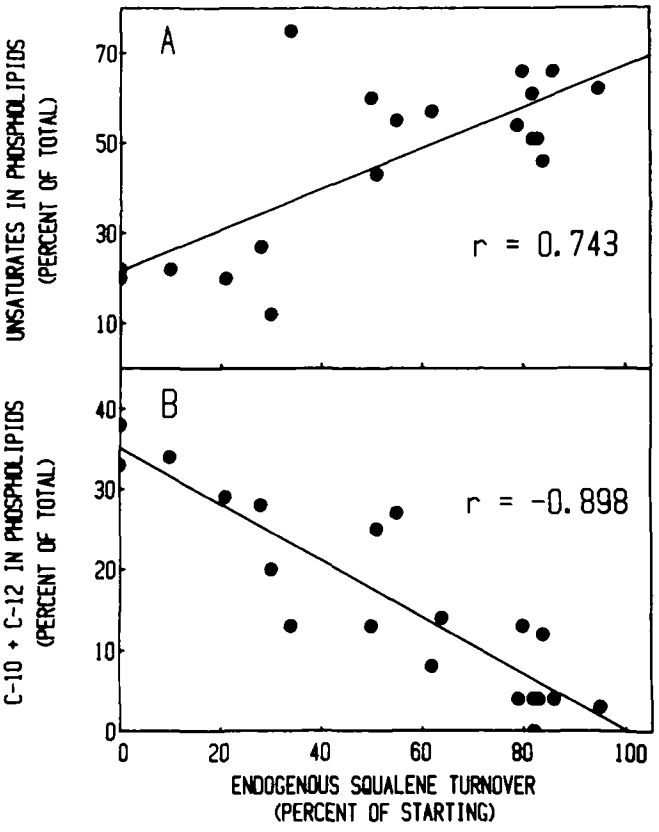

FIG. 2. Correlation between membrane fatty acid composition and squalene epoxidase activity. Phospholipid fatty acid compositions were determined for the cells analyzed in Figure 1, as well as for cells from three other identical experiments. The amount of endogenous ^{14}C-labeled squalene converted to squalene epoxide + squalene diepoxide during the six-hr chase period was plotted on the X-axis vs either the percent of unsaturated fatty acids (Panel A) or the percent of medium chain saturated fatty acids (C-10 + C-12) present in total cellular phospholipids on the Y-axis (Panel B). Linear regression analyses were performed to determine best-fit lines.

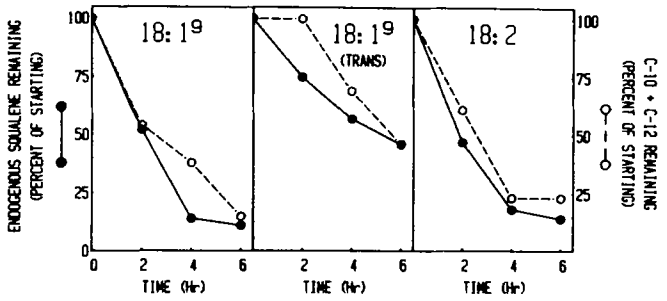

FIG. 3. Time-course of squalene and C-10 + C-12 fatty acid turnover in unsaturated fatty acid-supplemented cells. *S. cerevisiae* strain GL7 was subjected to the same pulse-chase protocol as described in the legend to Figure 1. During the chase period, cells were incubated in the presence of either oleic acid (18:1⁹), elaidic acid (*trans*-18:1⁹) or linoleic acid (18:2) and at two-hr intervals aliquots of the cultures were analyzed for turnover of both ^{14}C-labeled squalene and C-10 + C-12 fatty acids. The data are presented as the percent of either endogenous ^{14}C-labeled squalene or C-10 + C-12 fatty acids remaining at the indicated times.

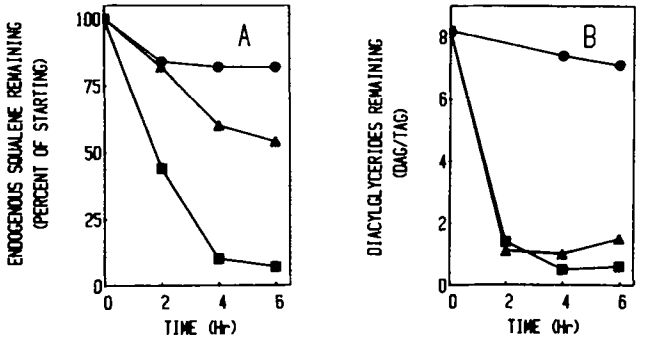

FIG. 4. Effect of cycloheximide on the turnover of squalene and diacylglycerides. *S. cerevisiae* strain GL7 was subjected to the same pulse-chase protocol as described in the legend to Figure 1. During the chase period, cells were incubated either in the absence (●) or presence (■) of oleic acid, or in the presence of oleic acid and cycloheximide (▲) and at 2-hr intervals aliquots of the cultures were analyzed for turnover of both ^{14}C-labeled squalene and ^{14}C-labeled diacylglycerides. The data are presented as either the percent of ^{14}C-labeled squalene remaining (left panel) or as the ratio of ^{14}C-labeled diacylglycerides to ^{14}C-labeled triacylglycerides (right panel) at the indicated times.

epoxidase activity (Fig. 2B), a negative correlation ($r = -0.898$) was obtained. The best-fit line shown in Figure 2B indicates that squalene epoxidase should be active maximally when C-10 + C-12 are absent from yeast membranes but it should be totally inactive when the amount of C-10 + C-12 fatty acids approaches 35% of total phospholipid fatty acids. Since unsaturated fatty acids and C-10 + C-12 fatty acids are incorporated primarily into the 2-position of cellular phospholipids (10; S.L. Brint and T.M. Buttke, unpublished data), it appears that squalene epoxidase activity totally is inhibited when the ratio of mixed-chain saturated phospholipids (i.e. those containing palmitic acid at the 1-position and a C-10 or C-12 fatty acid at the 2-position [11]) to phospholipids containing unsaturated fatty acids approaches 2:1.

To further correlate squalene epoxidase activity with the levels of C-10 + C-12 fatty acids in cellular phospholipids, strain GL7 was subjected to the same pulse-chase protocol described above, except that during the chase period aliquots were removed at two-hr intervals for subsequent lipid analyses. The data in Figure 3 show that in cells supplemented with 18:1Δ^9, *trans*-18:1Δ^9 or 18:2, squalene turnover parallels the disappearance of C-10 and C-12 fatty acids from membrane phospholipids, further demonstrating the relationship between membrane fatty acid composition and squalene epoxidase activity in yeast.

The restoration of squalene epoxidase activity that occurred following the readdition of olefinic supplements to unsaturated fatty acid-deprived cells could result from either the activation of pre-existing, but previously inactive squalene epoxidase enzyme, or from the de novo synthesis of new enzyme. In an attempt to distinguish between these two possibilities, strain GL7 was subjected to the usual pulse-chase protocol except that during the chase period cycloheximide was added to block de novo protein synthesis. At two hr intervals, aliquots were removed from the cultures, and the effects of the protein synthesis inhibitor on squalene turnover were determined. In the experiment shown in Figure 4A, the addition of cycloheximide (5 μg/ml) to 18:1Δ^9-supplemented cells inhibited the conversion of squalene to squalene epoxide and squalene diepoxide by 63% relative to control cells. This experiment was performed three times with cycloheximide inhibiting squalene epoxidase activity by an average of 71%. That cycloheximide was not merely blocking unsaturated fatty acid uptake or affecting cellular lipid metabolism in general was confirmed by assessing the effects of the drug on diacylglyceride turnover. As described previously (9), during unsaturated fatty acid deprivation, strain GL7 accumulated significant levels of diacylglycerides at the expense of triacylglycerides. Following the readdition of unsaturated fatty acid supplements, the accumulated diacylglycerides were rapidly turned over with the labeled diacylglycerides being chased primarily into triacylglycerides (9). As shown in Figure 4B, the addition of 5 μg/ml of cycloheximide had no effect on diacylglyceride turnover (for three different experiments the average inhibition was <5%), indicating that the drug did not inhibit lipid metabolism nonspecifically. These data suggest that at least a portion of the squalene epoxidase activity recovered following the addition of unsaturated fatty acids is derived from de novo protein synthesis.

In summary, the inhibition of squalene epoxidase activity that accompanies unsaturated fatty acid deprivation in *S. cerevisiae* strain GL7 seems to result from a replacement of olefinic residues at position 2 of membrane phospholipids with medium chain (C-10 + C-12) saturated fatty acids. The failure of the mixed-chain saturated phospholipids to support squalene epoxidase activity in yeast may stem from their tendency to adopt a unique bilayer structure (11).

Effects of Dietary Peanut Oil on Serum Lipoprotein Patterns of Rats

Josephine Miller* and **R.E. Worthington**
Department of Food Science, University of Georgia Agricultural Experiment Station, Experiment, GA 30212

Oils prepared from two varieties of peanuts and from a hybrid corn having linoleic acid concentrations substantially different from the respective commercial oils were compared with commercial oils for their effects on serum lipids of weanling female rats. In the first experiment, serum lipid patterns appeared to reflect linoleic acid content of the dietary oil. However, with a longer feeding period in the second experiment, serum lipid patterns were determined by the plant source of the dietary oil rather than its linoleic acid content; all peanut oils differed from both corn oils in their physiological effects. Diets containing triglyceride, hydrocarbon and sterol fractions obtained by liquid chromatography of peanut and corn oils were fed to female rats. The data provide no evidence that the hydrocarbon or sterol fractions of peanut oil are responsible for its unusual atherogenicity when fed as the sole fat source or that similar fractions from corn oil are protective against the effects of peanut oil.
Lipids 23, 72-75 (1988).

Atherogenicity of edible fats has been related to the degree of saturation of their component fatty acids (1); more unsaturated oils are reputed to be less cholesterolemic than those with fewer double bonds. However, peanut oil has been reported as unexpectedly atherogenic for rats, rhesus monkeys and rabbits (22), and its physiological effect is likened to that of a saturated fat. Corn oil was reported by Kritchevsky (3) to be the least atherogenic of several oils tested. In particular, peanut oil was more atherogenic than corn oil to rabbits (4) although both commercial oils contain about 80% unsaturated (oleic plus linoleic) fatty acids.

The hypocholesterolemic effects of unsaturated fats have been attributed to their content of polyunsaturated fatty acids (5). Linoleic acid is the major polyunsaturated fatty acid of corn and peanut oil, comprising about 60% of the totally fatty acids in commercial corn oil. Worthington and Hammons (6) reported values of 14 to 40% linoleic acid for oil derived from several peanut varieties.

Kritchevsky et al. (7) suggested that the triglyceride structure of peanut oil might be responsible for its physiological effects and presented preliminary evidence that randomized peanut oil was no more atherogenic than corn oil.

Although the acylglycerols of most seed oils make up at least 95% of the oils by weight, the remaining fraction consists of a mixture of classes of compounds including steroid and nonsteroid substances (8). The atherogenicity of peanut oil could be attributable to an alkali labile or soluble nonacylglycerol fraction that is lost during refining or randomization.

The major objective of these studies was to try to identify the component of peanut oil that is responsible for its atherogenicity. In the first two experiments, effects of concentration of dietary linoleic acid were evaluated by comparing oils from two genotypes of peanut in which the content of this polyunsaturated fatty acid was near the lower and upper limits reported for this species. Subsequent to the first experiment, grain from a hybrid corn with an unusually low linoleic acid concentration in its oil became available. Since the linoleic acid content of oil from the hybrid corn was about equal to that of oil from the high-linoleic acid peanut genotype, a comparison of their physiological effects seemed particularly appropriate.

Experiment 3 was designed to test nontriglyceride components of peanut oil for their effects on rat serum lipoprotein patterns.

A corollary to the hypothesis of an active atherogenic factor in peanut oil is the possibility that corn oil contains a factor that suppresses atherogenesis. Therefore, in the fourth study corn oil was fractionated to determine if some nontriglyceride part of this oil might modify the physiological response of the test animals to dietary peanut oil.

MATERIALS AND METHODS

Distribution of fatty acids in oils was determined by gas liquid chromatography following methylation in a mixture of methanol, benzene and sulfuric acid (9). Analyses were performed on a Microtek 220 chromatograph equipped with dual flame ionization detectors and a 180 × 0.4 cm glass column packed with 10% Silar 7CP on 80/100 Chromosorb W(AW)(DMCS) maintained at 210 C.

Native peanut and commercial corn oils containing about 32% and 59% linoleic acid, respectively, were fractionated using liquid chromatography on silica gel columns as described by Worthington and Hitchcock (8). The fraction, containing hydrocarbons and sterol esters (HC), was eluted with 2% ethyl acetate in hexane, the triacylglycerol (TG) fraction with 10% ethyl acetate in hexane, and the fraction containing free sterols (FS) with ethyl acetate. The percentages of these fractions in peanut and corn oils were HC, 0.5% and 0.8%; TG, 97.0% and 95.6%; and FS, 2.5% and 3.6%, respectively.

The experimental diets (Table 1) were adequate nutritionally for the rat and differed only in source of oil, which made up 20% of the weight of the diets. In experiments 1 and 2, the oil for each diet was derived solely from one of the selected peanut or corn sources. The components of the dietary oils for experiments 3 and 4 are set forth in Table 2 along with the designation for each diet that will be used henceforth. Whole oils and TG fractions were used as the sole source of lipid. HC and FS fractions were added in proportion to their content in the whole oil with the remainder of the dietary lipid provided by whole oil from the other oil seed (Table 2). During the feeding periods, an accurate measure of food intake by each rat was obtained.

Weanling female rats (Crl:CDR [SD]BR, Charles River Breeding Laboratories, Wilmington, MA) were housed

individually in stainless steel cages with wire mesh floors and provided with deionized water and diet ad libitum. The environment was maintained at 21 ± 1 C with 12-hr light-dark cycles. Following two days of acclimatization after being received in the laboratory, 10 rats were allotted on the basis of body weight to each dietary treatment group.

At the end of the test period, the rats were fasted overnight (15 to 18 hr) and 100–200 μl blood samples, obtained by amputating the tip of the tail, were collected in Microtainers (Becton-Dickerson, Rutherford, NJ) and centrifuged to separate serum for assessment of serum lipoprotein patterns. The rats again were fed for several days and then fasted overnight. With the animals under pentobarbital anesthesia, blood was obtained by a heart puncture in heparinized syringes for serum cholesterol determinations.

Lipoprotein patterns were evaluated by elecrophoresis on Aragose films (Agarose Universal Electrophoresis Film, Corning Medical, Medfield, MA). Two 1 μl aliquots of serum were added sequentially to sample wells, allowing sufficient time for diffusion of the first before addition of the second. Each sample was analyzed in triplicate

with each replication being applied to a different film. Electrophoretograms were developed and scanned as described previously (10). The low density lipoprotein (LDL) and high density lipoprotein (HDL) peak heights were measured in mm, and LDL/HDL ratios were calculated and averaged across replicates. Though the peak area may be a more accurate measure of the amount of a substance on a chromatogram than is peak height, the peaks measured were symmetrical, and their heights were considered adequately representative of lipoprotein quantity for the comparisons made in these studies.

Total cholesterol was determined in whole serum by a modification of the Abell-Kendall procedure (11). LDL were precipitated with heparin and manganese (12) and HDL cholesterol in the supernatant serum determined as described (11).

RESULTS AND DISCUSSION

The experimental diets promoted rapid growth of the young female rats throughout the test periods (Table 3).

[a]Ten rats per treatment. Values for each parameter within an experiment followed by no common letter are significantly different at $P \leq 0.05$.

[b]Linoleic acid content (% of total fatty acids) of oil in diet.

[c]Pooled standard error of dietary treatment means.

There were no statistically significant differences in weight gain due to dietary treatments in any of the experiments. Feed intake varied somewhat among the diet groups in experiment 3, resulting in a lower rate of conversion of feed to body mass by the group of rats fed peanut TG as a source of dietary fat.

The Jenkins jumbo peanut oil with 21% linoleic acid evoked significantly different serum lipoprotein and cholesterol responses in the female rats than did the commercial corn oil with 61% linoleic acid in experiment 1 (Table 4). The high LDL/HDL ratio and low ratio of HDL/total cholesterol in serum of rats fed this peanut oil are compatible with current theories of blood lipid composition that is conducive to atherogenesis. Serum lipid data for rats fed the White skin peanut oil in this experiment were intermediate between those for rats fed the other two oils. Since the linoleic acid content of the former oil also was intermediate between that of the latter two oils, these data could be interpreted to support the concept of an inverse relationship between polyunsaturated (linoleic) fatty acid content of an oil and its atherogenicity.

The feeding period was extended from 31 days in experiment 1 to 49 days in experiment 2. The higher values for LDL/HDL ratios found in the latter over those in the former reflect the longer exposure of the rats to the diets.

In experiment 2, the LDL/HDL ratio was higher for rats fed each of the diets containing peanut oil than for rats fed either of the diets containing corn oil. Despite the nearly identical linoleic acid content of the hybrid corn oil and the White skin peanut, rats fed diets containing the two oils exhibited distinctively different lipoprotein ratios and serum HDL cholesterol contents.

Although the commercial corn oil contained 59% linoleic acid and the hybrid corn oil 40%, both oils elicited

similar LDL/HDL ratios and serum cholesterol concentrations in the rats. In like manner, the three peanut oils with linoleic acid concentrations of 39%, 33% and 23% produced similar values for the serum lipid parameters among the groups of rats fed diets containing each of them.

The lack of significant difference in the first experiment between response of rats fed the White skin peanut oil with 39% linoleic acid and those fed corn oil could be attributable to the shorter time in which the rats were subjected to the dietary treatments. The serum lipid values characteristic of peanut oil may require more than 31 days for full development under conditions of these experiments. Also, the onset of differential response to type of dietary oil may occur several weeks after weaning in the rat.

In these studies, the physiological response to source of dietary oil appears to be characteristic of the species of plant from which the oil was derived rather than to the fatty acid composition of oil from individual genotypes.

The female rats in experiments 3 and 4 remained healthy and presented no overt evidence that the components of peanut and corn oil derived from the fractionation procedure were detrimental to growth performance of the animals. The LDL/HDL ratios were highest for the groups of rats fed whole peanut oil in both experiments (Table 4). Addition of the hydrocarbon fraction or FS fraction of peanut oil to diets containing whole corn oil resulted in lipoprotein patterns similar to those of rats fed only corn oil. Thus, the data from these studies provide no evidence that the hydrocarbon and FS fractions of peanut oil contain substances that can elevate the serum LDL/HDL ratio of rats.

In the last study, rats fed diets having the hydrocarbon fraction or the FS fraction of corn oil added to diets containing peanut oil had serum lipoprotein patterns similar to those of rats fed only peanut oil. These fractions of corn oil provided the rats with no protection against the physiological effects of peanut oil on their serum lipid profiles.

The effects of peanut TG fraction on the LDL/HDL ratio is ambiguous in these studies. The mean value for the ratio was between that for whole peanut and whole corn oil in both studies but was not discrete statistically from both of the oils in either. The results obtained could indicate partial loss of one agent or loss of one or more of multiple agents responsible for the metabolic effects of peanut oil during its fractionation by the described procedure. Further evidence relating to this hypothesis could be obtained in a future experiment in which the three components of fractionated peanut oil were recombined and effects on LDL/HDL ratio of the mixture compared with the original oil.

Total serum cholesterol values tended to be higher in rats fed diets containing 19-20% peanut oil or peanut TG than in those fed diets with most of the fat from corn, though those fed diets containing corn oil supplemented with peanut FS in experiment 3 and with peanut hydrocarbons in experiment 4 evidence somewhat higher sterol values than expected.

The data presented indicate that the physiological reponse of young female rats to dietary peanut oil is different from that to corn as a source of dietary lipids. The serum lipoprotein patterns and cholesterol levels elicited by peanut oil currently are believed to be conducive to atherogenesis and, thus, to be undesirable. The data do not substantiate the hypothesis that linoleic acid content of dietary fat is a decisive factor in determining its atherogenecity.

The fractionation scheme applied to the oils separated from the major TG component one portion of substances less polar than TG (e.g., HC) and another portion of components that would be slightly more polar than the TG such as FS. The data presented provide no evidence that either of these latter minor components of peanut oil are responsible for its atherogenecity or that either of the similar portions of corn oil counteract the physiological effects of peanut oil. The data do indicate that the elevation in serum LDL/HDL ratio might be somewhat less with the purified peanut TG fraction than with whole peanut oil. A different fractionation scheme might be found to reduce further the adverse effect of dietary peanut oil.

ERRATA

In the paper "Cytotoxic Activity of the Thioether Phospholipid Analogue BM 41.440 in Primary Human Tumor Cultures" by Dieter B.J. Herrmann and Herbert A. Neumann, *Lipids 22,* 955–957 (1987), the formula of BM 41.440 given in Scheme 1 on page 955 is incorrect. The correct formula is shown on page 952.

In the paper "Phase I Trial of the Thioether Phospholipid Analogue BM 41.440 in Cancer Patients" by Dieter B.J. Herrmann, Herbert A. Neumann, Wolfgang E. Berdel, Manfred E. Heim, Michael Fromm, Dietmar Boerner and Uwe Bicker, *Lipids 22,* 962–966 (1987), the chemical structure of BM 41.440 on page 962 is in error. The substituent in position-2 should be methoxymethyl. The correct structure is shown on page 952.

Effects of Cholesterol and 25-Hydroxycholesterol on Smooth Muscle Cell and Endothelial Cell Growth[1]

Donald C. Cox*, Karen Comai and Ann L. Goldstein
The Department of Pharmacology and Chemotherapy, Hoffmann-La Roche Inc., Nutley, NJ 07110

Auto-oxidation products of cholesterol may play a role in atherogenesis. In order to determine whether cholesterol or 25-hydroxycholesterol, a cholesterol auto-oxidation product, affected growth of vessel wall cells, sparse and confluent cultures of rabbit thoracic aorta smooth muscle cells and human umbilical vein endothelial cells were exposed to these compounds for 88 hr. The compounds were administered at 10^{-4}, 10^{-5}, 10^{-6} or 10^{-7} M in either ethanol or fetal bovine serum (FBS) vehicle. Cells were counted electronically, and the results were expressed as the percent growth in experimental vs control wells. Cholesterol did not inhibit cell growth under any experimental condition. 25-Hydroxycholesterol had the following effects: inhibited confluent smooth muscle cell growth at 10^{-4} M in ethanol vehicle only; inhibited sparse smooth muscle cell growth in a dose-related manner at 10^{-4}, 10^{-5} and 10^{-6} M in ethanol vehicle, but in FBS vehicle inhibited at only 10^{-4} and 10^{-5} M; inhibited confluent human umbilical vein endothelial cells at 10^{-4} M in ethanol vehicle only; and inhibited sparse human umbilical vein endothelial cell growth at 10^{-4} and 10^{-5} M in ethanol vehicle only. Thus, rabbit aortic smooth muscle cell growth was more sensitive to inhibition by 25-hydroxycholesterol than human umbilical vein endothelial cell growth was. ***Lipids 23,*** **85–88 (1988).**

Elevated levels of serum cholesterol have been associated with increased risk of developing atherosclerosis in man (1,2). Additionally, studies in rabbits have indicated that cholesterol and its oxygenated products enhance arterial lesion formation (3,4). Imai et al. (3) had demonstrated that USP-grade cholesterol contained contaminants that when concentrated and administered to rabbits by gavage, caused increased aortic smooth muscle cell death after 24 hr, compared with purified cholesterol. Further analysis showed that the principle active contaminants were 25-hydroxycholesterol and cholestane-3β,5α,6β-triol (4). These same compounds were reported to be cytotoxic to confluent cultured rabbit aortic smooth muscle cells at concentrations of 5×10^{-5} M to 1×10^{-4} M (5). Furthermore, scanning and transmission electron microscopic studies showed that when rabbits were given 25-hydroxycholesterol (2.5 mg/kg, intravenously) there were significantly more aortic lesions within 24 hr of injection in the 25-hydroxycholesterol groups than in the control group (6). Areas of endothelial cell damage and subendothelial edema were apparent (6). These studies have led to the suggestion that the oxidized derivatives of cholesterol, rather than cholesterol per se, are important in initiating atherosclerotic lesions (3–5,7).

While previous studies showed decreased cell growth in sparse cultures of L-cells (8), primary fetal liver cells and hepatoma cells (9) exposed to 25-hydroxycholesterol, these cell types are not involved in the atherosclerotic lesion. In the report concerning the effects of 25-hydroxycholesterol on cultured aortic smooth muscle cells by Peng et al. (5), only confluent cultures of smooth muscle cells were studied, and the cytotoxicity of 25-hydroxycholesterol was evaluated only by light microscopic estimation of the percentage of dead and dying cells.

The experiments reported here were initiated to determine in a quantitative fashion the effects of 25-hydroxycholesterol and cholesterol on in vitro growth of aortic smooth muscle cells (SMC) and endothelial cells (EC), two cell types that play major roles in the development of atherosclerotic lesions (10). To this end, both sparse (log phase) and confluent SMC and EC cultures were exposed to pure 25-hydroxycholesterol or recrystallized cholesterol. Sparse SMC cultures might approximate the conditions found as SMC begin to migrate from the media into the intima; confluent SMC cultures resemble the aortic media in that they are multilayered and relatively nonproliferative. Similarly, sparse EC cultures could be an approximate model for areas of intimal injury or denudation, while confluent EC cultures approximated the intact intima. EC derived from human thoracic aorta (HAEC) would have been ideal for these experiments; however, we have very limited access to normal adult human tissue. Therefore, we used EC derived from human umbilical vein (HUVEC). We occasionally have had access to HAEC for smaller experiments and have found similar patterns of response in the HAEC and HUVEC. The determination of cell numbers in control and treated cultures was the endpoint of these studies.

MATERIALS AND METHODS

Materials. All tissue culture materials, with the following exceptions, were purchased from Grand Island Biological Co. (Grand Island, NY): fetal bovine serum was obtained from Sterile Systems (Logan, UT), and human fibronectin and endothelial cell growth factor were from the laboratory of Robert Weinstein, Boston, MA. All culture vessels were from Falcon Plastics (Oxnard, CA). Factor VIII-related antigen was obtained from Atlantic Antibodies (Scarborough, ME). Heparin was from Sigma Chemical Co. (St. Louis, MO). Recrystallized cholesterol and pure 25-hydroxycholesterol were from the laboratory of John Partridge, Hoffmann-La Roche Inc. (Nutley, NJ).

Cells. Rabbit thoracic aorta SMC were obtained from a 15-week-old male New Zealand White rabbit by a modification of the explant technique of Tansik et al. (11). The thoracic aorta was removed under aseptic conditions and placed in ice-cold growth medium consisting of

[1]Part of this work was presented at the 10th Annual Hugh Lofland Conference on Arterial Wall Metabolism, Boston, MA, in 1985 and at the 70th Annual FASEB Meeting, St. Louis, MO, in 1986. It is published in abstract form (Fed. Proc. *45*;684, 1986).

Dulbecco's Modified Eagle's Medium supplemented with 100 U/ml penicillin, 100 μg/ml streptomycin, 2.5 μg/ml Fungizone and 10% fetal bovine serum. The vessel was passed over a dry glass rod to remove endothelial cells. The adventitia was removed with forceps under a dissecting microscope. Specimens of tissue were saved and examined histologically with hematoxylin and eosin stain to verify the absence of adventitia and endothelial cell layers. Pieces of tissue ca. 1 mm^3 were immobilized under glass cover slips in 60 mm-diameter culture dishes. When the cells in the dish virtually were confluent, the cells were harvested using a trypsin and ethylenediamine tetraacetic acid (EDTA) solution and plated into 75-cm^2 tissue culture flasks. Three serial passages at 20-min intervals were performed to minimize contaminating fibroblast cells. The cells were passaged twice before being frozen. Cultures utilized in the study were at no greater passage number than four.

HUVEC were obtained from the laboratory of Robert Weinstein, Boston, MA. They were found to be free of mycoplasma contamination (12) and exhibited a positive immunofluorescent response to antihuman factor VIII-related antigen (13). Stocks of these cells routinely were maintained in tissue culture vessels treated with human fibronectin applied at 5–10 $\mu g/cm^2$. HUVEC were grown in Medium 199 with Earle's salts supplemented with 100 U/ml penicillin, 100 μg/ml streptomycin, 2.5 μg/ml Fungizone, 90 μg/ml heparin (16.0 U.S.P. units/ml) and 100 μg/ml endothelial cell growth factor.

Cholesterol and 25-hydroxycholesterol were dissolved in 95% ethanol. When fetal bovine serum without ethanol was used as a vehicle, sonication in an L&R transistor/ultrasonic T-28 sonicator at maximum output was employed to reduce particle size and aid solubility. Care was taken so that the samples were not heated.

Experimental design. Sparse and confluent cultures were grown in 35 mm dishes. Sparse cultures were seeded at 1.4×10^4 cells per dish in 2 ml of the appropriate growth medium supplemented with 10% fetal bovine serum (FBS). After six hr, this medium was aspirated and replaced with the appropriate media supplemented with experimental sterol, vehicle and FBS concentration. Cultures exposed to sterols at 10^{-4} M, 10^{-5} M, 10^{-6} M and 10^{-7} M with ethanol as the vehicle had final ethanol concentrations of 1%, 0.1%, 0.01% and 0.001%, respectively. All dishes treated with sterols were compared with control dishes that had received equivalent amounts of vehicle. After 88 hr of treatment, the cells were trypsinized and counted electronically using a Coulter counter. Confluent cultures were treated identically to sparse cultures except that experimental treatment began one day after the cells reached confluence. After 88 hr of treatment, these cultures were trypsinized and counted. Duplicate or triplicate plates were counted for each experiment. Doses of 10^{-7} M in SMC and 10^{-6} M in HUVEC were tested only once. All other doses were repeated two to five times. Results are expressed as the percent growth in experimental dishes compared with appropriate control dishes.

Statistical analysis. A cell means model, an analysis of variance (ANOVA) varient (14), was employed to determine treatment significance. Results are reported as percent growth in experimental dishes vs control dishes ± standard error of the mean (SEM).

RESULTS

Fetal bovine serum concentration effects. FBS concentrations of 10%, 5%, 2.5%, or 1% were tested to try detecting any cytoprotective effect of FBS in cultures containing 25-hydroxycholesterol. There was no consistent influence of FBS on the effect of sterols on sparse or confluent SMC or HUVEC cultures. Therefore, for correct statistical analysis results have been pooled across serum concentrations.

Effects of ethanol on SMC and HUVEC growth. Ethanol at final concentrations of 1.0%, 0.1% and 0.01% had no effect on sparse or confluent SMC growth (Table 1). Similar results were obtained with sparse and confluent HUVEC cells (Table 1) except that sparse HUVEC growth was decreased significantly to 75% of control ($p \leq 0.001$) by 1.0% ethanol (Table 2).

Effects of cholesterol on SMC and HUVEC growth. Cholesterol in either FBS or ethanol vehicle did not affect significantly the growth of sparse or confluent SMC (Table 3). However, a trend to increased cell growth (119% of control) regardless of vehicle was observed with sparse SMC incubated with 10^{-4} M cholesterol (Table 3). Cholesterol also had no significant effect on HUVEC growth except in ethanol vehicle at 10^{-6} M, which stimulated proliferation (121% of control) in the sparse HUVEC cultures ($p \leq 0.0001$) (Table 4).

Effects of 25-hydroxycholesterol on SMC and HUVEC growth. Confluent SMC were unaffected by 25-hydroxycholesterol in FBS vehicle (Table 3). However, when ethanol was the vehicle, 25-hydroxycholesterol at 10^{-4} M decreased the number of confluent SMC to 50% of the control value ($p \leqslant 0.0001$). This decrease was caused by cell death because the final number of cells in the treated wells was lower than the number of cells in the confluent cultures at the initiation of treatment. Sparse SMC growth was inhibited by 25-hydroxycholesterol in FBS vehicle to 68% of control at 10^{-4} M ($p \leqslant 0.0001$) and to 52% of control at 10^{-5} M ($p \leqslant 0.001$). When ethanol was the vehicle, sparse SMC growth also was inhibited in a dose response fashion by concentrations of 25-hydroxycholesterol from 10^{-4} to 10^{-6} M ($p \leqslant 0.0001$) (Table 3). When FBS was the vehicle, 25-hydroxycholesterol did not affect growth in sparse or confluent HUVEC cultures (Table 4). With ethanol as the vehicle, confluent HUVEC growth was decreased to 50% of control by 10^{-4} M 25-hydroxycholesterol ($p \leqslant 0.0001$). As with the SMC, this decreased cell number was lower than the number of cells at initiation of treatment, reflecting cell death rather than inhibition of growth. Growth in sparse cultures was decreased 27% at both 10^{-4} M ($p \leqslant 0.001$) and 10^{-5} M ($p \leqslant 0.0001$) 25-hydroxycholesterol (Table 4). Growth was stimulated to 123% of control only in sparse HUVEC cultures by 10^{-6} M 25-hydroxycholesterol in ethanol vehicle ($p \leqslant 0.001$) (Table 4).

DISCUSSION

Several investigators (3–5,7,15) have proposed that auto-oxidation products of cholesterol rather than cholesterol itself are injurious to the arterial wall and consequently play a role in atherogenesis. This hypothesis largely is based on experiments that showed by morphological criteria that cholesterol auto-oxidation products, not purified cholesterol, were toxic to vascular smooth muscle cells in vitro (5) and to the endothelium in vivo (6). In the present study, the effects of recrystallized cholesterol and 25-hydroxycholesterol on the growth of sparse and confluent rabbit aortic SMC and HUVEC were measured after 88 hr of treatment. The results of these studies indicated that FBS concentration did not influence the effects of the sterols in either cell type. Ethanol, the vehicle most commonly used for in vitro studies of this type, also had no effect on cell growth except that 1.0% ethanol significantly did inhibit sparse HUVEC growth. Peng et al. (5) had reported that 0.8% ethanol caused no obvious morphological evidence of cytotoxicity in confluent SMC after 24 hr. Therefore, our results indicate that the growth assay may be a more sensitive measure of ethanol effects in sparse HUVEC cultures. Recrystallized cholesterol did not affect cell growth under any condition except at 10^{-6} M in ethanol vehicle, which stimulated sparse HUVEC growth.

As had been reported for other cell types (8,16), 25-hydroxycholesterol was more effective at inhibiting growth in sparse than in confluent SMC and HUVEC cultures. Presumably, sparse cultures with cells in the log phase of growth require more cholesterol for membrane formation than do confluent cultures (17). Since 25-hydroxycholesterol decreases HMG-CoA reductase activity by suppressing gene transcription (18) and by

increasing enzyme degradation by interacting with the membrane-embedded portion of the enzyme (19,20), sparse cultures are more affected than are confluent cultures.

HUVEC cultures were less sensitive to the growth inhibitory effects of 25-hydroxycholesterol than were SMC cultures. This effect may be due in part to the fact that the population doubling time is four-fold faster in SMC than in HUVEC cultures (data not shown). Only when the vehicle was ethanol did 10^{-4} M 25-hydroxycholesterol decrease the number of cells in confluent HUVEC cultures. Additionally, sparse HUVEC cultures were more resistant to 25-hydroxycholesterol than were sparse SMC cultures. In FBS vehicle, 25-hydroxycholesterol did not inhibit growth in sparse HUVEC cultures, whereas in ethanol vehicle there was growth inhibition at both 10^{-4} M and 10^{-5} M (Table 4).

In vivo experiments meant to demonstrate the effects of 25-hydroxycholesterol on arterial vessels either have yielded conflicting results or the results are interpreted very differently from investigator to investigator. One reason for this confusion is that a mixture of oxidized cholesterol contains numerous different compounds and varies tremendously in its composition, depending on the circumstances. Higley et al. (21) found that rabbits fed diets supplemented with either cholesterol or a mixture of oxidized cholesterol products showed greater lesion development in the cholesterol-supplemented diet than in the oxidized cholesterol-supplemented diet. Krut (22) reported that oxidized sterols enhanced the solubility of pure cholesterol implanted in rats and concluded that the presence of oxidized sterols enhanced the clearance of cholesterol and, therefore, decreased the risk of atherosclerosis. On the other hand, Peng et al. (6) and Taylor and Peng (7), using scanning and transmission electron microscopy, showed that damaged aortic endothelial cells could be detected within 24 hr in rabbits given concentrates of cholestrol oxidation products either intravenously or by gastric gavage. Confounding the problem in deciding the importance of oxidized sterols in atherogenesis is the lack of knowledge of the normal source of these compounds in vivo. Foods containing oxidized sterols and auto-oxidation products of serum cholesterol are potential sources of these compounds. However, it is difficult to measure accurately the levels of oxidized sterols in food and in serum (23). Additionally, 25-hydroxycholesterol was not detected using isotope dilution mass spectrometry in the serum of eight normal human volunteers in a report by Javitt et al. (24), although 26-hydroxycholesterol, an enzymic product of cholesterol metabolism, was detected. Thus, it remains a matter of speculation as to whether vessel wall exposure to low levels of oxidized sterols over the long time period required for atherogenesis represents a significant risk factor.

The in vitro results presented in this report indicate that relatively high concentrations of 25-hydroxycholesterol are required to inhibit the growth or cause the death of cultured aortic SMC and HUVEC, even when administered in ethanol vehicle that enhances the ability of these compounds to penetrate cell membranes (25). These in vitro data and the data of others (5,8,16,26) demonstrate that 25-hydroxycholesterol inhibits growth in many types of cultured cells. How these in vitro systems can be used to predict in vivo effects is unclear.

Rat Neutrophil Function, and Leukotriene Generation in Essential Fatty Acid Deficiency

Hans Gyllenhammar*[a], Jan Palmblad[a], Bo Ringertz[a], Ingiäld Hafström[a] and Pierre Borgeat[b]

Since the essential fatty acid linoleic acid is the precursor of arachidonic acid and thus of leukotriene B_4 (LTB_4), essential fatty acid deficiency (EFAD) may result in decreased synthesis of this stimulator of neutrophil granulocyte functions. Peritoneal and blood neutrophils from rats fed a diet with only 0.3% of energy requirements as linoleic acid and exhibiting biochemical evidence of EFAD showed substantial functional impairments compared to neutrophils from rats maintained on a diet with 3% of the energy requirement as linoleic acid. Oxidative burst activation (assessed by chemiluminescence), chemotaxis and aggregation were impaired upon stimulation with formylpeptides or the ionophore A23187. In contrast, these functions were intact on stimulation with exogenous LTB_4. Chemiluminescence was slightly but not significantly enhanced in EFAD rat neutrophils compared to controls when stimulated with phorbol myristate acetate (PMA). There were no differences between EFAD and control peritoneal neutrophils in the number of f-met-leu-phe (fMLP) receptors, or in their affinity for the ligand, assessed with fML(^{3}H)P. The fraction of responding cells also were similar, assessed with dichlorofluorescein diacetate fluorescence. Moreover, the endogenous LTB_4production in response to A23187 or fMLP was decreased by 57.7% and 63.5%, respectively, in EFAD peritoneal neutrophils. Thus, EFAD was associated with reductions of LTB_4 production and neutrophil responsiveness to A23187 and formylpeptides but not to LTB_4 or PMA, which supports the hypothesis that endogenous LTB_4 may contribute to the activation of neutrophil functions involved in inflammation and host defense.
***Lipids* 23, 89–95 (1988).**

Humans and many higher vertebrates are incapable of synthesizing linoleic acid (18:2n-6) (1) that consequently is an essential dietary requirement. Linoleic acid is metabolized by stepwise desaturation and elongation to arachidonic acid (AA, 20:4n-6), the obligate precursor to cyclooxygenase products, e.g. prostaglandins and thromboxanes of the 2-series and lipoxygenase products, e.g. the leukotrienes of the 4-series (2).

In neutrophils, the 5-lipoxygenase pathway predominates and one major product is 5(S),12(R)-dihydroxy-6,14-*cis*-8,10-*trans*-eicosatetraenoic acid, leukotriene B_4 (LTB_4), formed by a hydrolase from the unstable allylic epoxide intermediate, 5(S)-*trans*-5,6-oxido-7,9-*trans*-11,14-*cis*-eicosatetraenoic acid, leukotriene A_4 (LTA_4) (2). LTB_4 production substantially is increased in activated neutrophils, e.g. after in vitro stimulation with the ionophore A23187 (3,4), opsonized zymosan (5) or formyl peptides (2,6). Exogenous LTB_4 is a potent inducer of neutrophil adherence (7), chemotaxis (8) and aggregation (9). Neutrophil degranulation (9) and oxidative burst activity, assessed by chemiluminescence (CL) (10) or superoxide anion production (9,11), also are initiated by LTB_4. Based on these and other observations, LTB_4 has been proposed as a putative endogenous mediator of neutrophil function in inflammation and host defense (10).

Essential fatty acid deficiency (EFAD) has been associated with increased susceptibility to bacterial infections (12) and altered inflammatory responses (13,14). Such observations might be explained partly by impaired leukocyte function following diminished production of lipid mediators from arachidonic acid. EFAD is associated with a decrease in arachidonic acid content of neutrophils and reduced production of cyclooxygenase products, as reported previously by us (15) and others (16). Furthermore, it recently was reported that leukotriene production in rat neutrophils was depressed in EFAD (17).

Based on these considerations, the aim of this study was to assess whether neutrophil functions contributing to inflammatory response and host defense such as the oxidative burst activation, chemotaxis, aggregation and leukotriene generation were altered in rats with a dietarily induced EFAD. These studies could help to clarify the role of leukotrienes in the stimulation of neutrophil functions.

EXPERIMENTAL

Animals and diets. Two groups of male, adult Sprague-Dawley rats, maintained for several generations on diets differing in EFA content, were used for this study. Details of the animals, the diets, the EFAD state and nutritional status have been given previously (15,18).

Chemicals. Hanks' balanced salt solution (HBSS) was obtained from SBL (Stockholm, Sweden). Luminol (10), human serum albumin (HSA, essentially fatty acid free), phorbol myristate acetate (PMA) and sodium caseinate was obtained from Sigma Chemical Co. (St. Louis, MO). Dichlorofluorescein diacetate (DCHF-DA) was from Eastman-Kodak (Rochester, NY). Ficoll-Paque was obtained from Pharmacia Fine Chemicals (Uppsala, Sweden). Formyl-norleucyl-leucyl-phenylalanyl-norleucyl-tyrosyl-leucine (fNLPNTL), formyl-methionyl-leucyl-phenylalanine (fMLP) and formyl-methionyl-methionyl-methionyl-methionine (fMMMM) were from Peninsula Laboratory (San Carlos, CA). Synthetic leukotriene B_4 (LTB_4), dissolved in ethanol, was a gift from J. Pike (Upjohn Co., Kalamazoo, MI) and J. Rokach (Merck-Frosst, Dorval, Canada). The ionophore A23187 was from Calbiochem (LaJolla, CA). FML(3H)P (46.7 Ci/mmol) was from New England Nuclear (Boston, MA), Versilube F50

silicon fluid from General Electric Co. (Waterford, NY) and NCS tissue solubilizer from Amersham Corp. (Amersham, U.K.).

Preparation of neutrophils. Rats were anesthetized with ether by inhalation. Neutrophils were harvested from peritoneal cavities 22 hr after injection of sterile sodium caseinate (12 mg/ml) by peritoneal lavage with HBSS. The peritoneal exudates were purified further on Ficoll-Paque. Blood was obtained by decapitation of ether-anesthetized rats, and leukocytes were purified by a standard Ficoll-Paque technique (10). Peritoneal neutrophil preparations routinely were of 98% purity after purification and were suspended in HBSS with or without HSA, as indicated. Although the total yield of peritoneal cells was dependent on the amount of HBSS used in the lavage procedure, there were no consistent differences between the dietary groups. Typically, 80–100 $\times$ 10^6 neutrophils were obtained in technically successful lavages, the variation being from day to day rather than between dietary groups.

Due to paucity of animals and blood and the small amounts of neutrophils obtained from blood, peritoneal neutrophils were used in all assays except where specifically indicated.

Using the assays for functional responses described below, we assessed whether the peritoneal cell harvesting technique had activated the neutrophils. The spontaneous chemiluminescence was <5 mV, which is within the limits for unstimulated rat blood neutrophils. Although spontaneous aggregation was minimal for peritoneal cells, these migrated slightly farther than blood cells in absence of stimuli, thus activation of neutrophil functional responses could not be demonstrated consistently but cannot be excluded.

As reported, the peritoneal neutrophils from EFAD rats contained less linoleic acid and arachidonic acid than the control rats (15) and the relation of 20:3n-9/20:4n-6 was 0.42 (15), which demonstrates the EFAD state (19). In the control rat peritoneal neutrophils, 20:3n-9 was not measurable (15). The details of these analyses and of reduced generation of cyclooxygenase products in EFAD rat peritoneal neutrophils have been reported (15).

Eicosanoid analysis. Rat peritoneal neutrophils were preincubated five min at 37 C in HBSS (without HSA) at the concentration of 2 or 5 $\times$ 10^6/ml. The cells then were stimulated with 2 μM ionophore A23187, 1 μM FMLP or 10 μM PMA; after five min (A23187, PMA) or 30 min (fMLP (20), PMA) of incubation at 37 C, reactions were stopped by addition of an equal volume (1 ml) of methanol, and the samples were kept at -70 C.

Analysis of arachidonic acid metabolites was performed by reversed phase HPLC using a C_{18} Radial-Pak cartridge (100 $\times$ 8 mm ID, 10 μm particle size, Waters Associates, Milford, MA) protected by a C_{18} Guard Pak Cartridge (Waters Associates) as reported (21,22). The solvent system used has been described (22). PGB_3 (100 ng) was added to the methanol denatured samples as an internal standard, and these were centrifuged at 600 $\times$ g for 10 min. Supernatants were acidified and injected (injection volume, 1.8 ml) without further treatment (23).

Elution of the various compounds was monitored by UV photometry at 280 nm (LTs and PGB_2) and 229 nm (5-HETE). Reacylated 5-HETE was not quantitated. Identification of lipoxygenase products was assessed on the basis of their comigration with known standards and specificity of UV absorption at 280 or 229 nm. The quantification of LTs and 5-HETE was carried out by comparison of their peak areas with that of internal standard (PGB_2) and correction for differences in molar extinction coefficients and attenuation settings. The system used permits differentiation between 20-OH- and 20-COOH-LTB_4. Sensitivity of the system is 2–5 ng (21) for the different lipoxygenase products.

Functional studies. Chemiluminescence augmented by luminol was assessed with luminometers (1250 and 1251; LKB, Bromma, Sweden) essentially as detailed previously (10). Each 1 ml sample contained luminol (final concentration 0.17mM), 1.25 $\times$ 10^6 neutrophils and HBSS with 0.2% HSA. When A23187 was used as stimulus, HSA was omitted since albumin impaired its CL response. CL was read continuously for up to 15 min. Neutrophils were kept at 4 C and adjusted to 37 C prior to analysis. Stimuli used were fMMMM (1 μM), fNLPNTL (1 μM), A23187 (2 μM), PMA (10 μM) and LTB_4 (1 μM). Blood neutrophils were assessed in two experiments using fMMMM (1 μM), or PMA (10 μM). Due to the limited availability of blood neutrophils, these assessments were scaled down to 0.25 ml with preserved component ratios. In preliminary experiments, these concentrations of stimuli had been found optimal for assessment of chemiluminescence. fMLP was used in a prior study (15); however, the responses to fMMMM and fNLPNTL were found to be more consistent in the CL assay.

Neutrophil aggregation was assessed in a standard platelet aggregometer (model 300BD, Payton Assoc., Buffalo, NY) (23). An aliquot of 0.45 ml of the neutrophil suspension (10 $\times$ 10^6 neutrophil/ml) was added to a siliconized cuvette, containing a stir bar revolving at 900 rpm. After equilibration of the cells for two min, 50 μl of the stimulus (1–10 μM ionophore A23187 or 0.01–1 μM LTB_4) was added. The resulting change in light transmission was recorded as Δ T. Results for LTB_4 and fMLP are expressed as the maximal change in light transmission (peak response), time to peak and degree of desaggregation one min after peak, and for A23187 as Δ T three min after addition of stimulus because A23187 induced an irreversible aggregation response (24).

Chemotaxis. Spontaneous and stimulated migration was assessed with a modified Boyden chamber technique, using a 48 multiwell chamber (Neuroprobe Inc., Cabin John, MD). Cells, in HBSS supplemented with 0.4% HSA, were allowed to migrate into cellulose nitrate filters (Microfiltration Systems, Dublin, CA; 3 μm pore diameter) for 45 min at 37 C, 100% humidity and 5% CO_2. fMLP and LTB_4 were used as chemotactic factors and HBSS as control for spontaneous migration. Migration was assessed as the mean depth in micrometers of penetration into the filter of leading five cells in three microscopic fields in three replicate wells, and results are given as net migration (stimulated migration minus spontaneous migration, i.e. towards HBSS). Optimal migration for control peritoneal neutrophils occurred at 1–0.1 μM of fMLP and 0.1 μM LTB_4.

fML(^{3}H)P-binding was performed on ice as described (25). Briefly, fML(^{3}H)P only (total binding) or fML(^{3}H)P plus a 1,000-fold excess of nonradioactive fMLP (nonspecific binding) were added to suspensions of rat peritoneal neutrophils (5 $\times$ 10^6/ml in HBSS without

calcium and magnesium). In addition, at the end of the 30-min incubation an aliquot of cells from total binding tube was added to 1,000-fold excess nonradioactive fMLP to allow the surface-bound fML(^{3}H)P to be displaced off the cells (displaceable binding). The bound and free peptide were separated by centrifugation of cells through silicon oil. The difference between total and nonspecific binding of fML(^{3}H)P represented total specific binding of fML(^{3}H)P. By using the specific binding data at varying concentrations of fML(^{3}H)P, a Scatchard plot was performed (26).

Dichlorofluorescein fluorescence. Since neutrophil populations are inhomogenous in regard to the binding of fMLP (27), the fraction of responding cells (recruitment) was assessed. The H_2O_2 dependent DCHF-DA fluorescence (28) (not requiring phagocytosis) was assessed by fluorescence microscopy. Peritoneal neutrophils (1×10^6/ml) were incubated with DCHF-DA (10 μg/ml) for five min in HBSS without Ca^{2+} and Mg^{2+} (to minimize preactivation) at 37 C, pelleted at 200 × g and washed with HBSS. After resuspension in HBSS with Ca^{2+} and Mg^{2+}, neutrophils were stimulated with fMLP (0.1 or 1 μM), LTB_4 (0.1 μM) or A23187 (2 μM), concentrations previously found optimal, or HBSS (negative control) for five min (fMLP) or 20 min (A23187, PMA). The reaction was stopped on ice, and glutaraldehyde (2% v/v) was added. The cells were washed and resuspended in HBSS and studied under high power magnification in an Olympus fluorescence microscope with a reflected fluorescence light source. For each condition, 500 cells were counted in triplicate. The weak background fluorescence repeatedly was correlated with the unstimulated cells.

Statistical analysis was performed with Student's two-tailed t-test.

RESULTS

We studied the lipoxygenase product synthesis in neutrophils after stimulation with the ionophore A23187. Cells from normal rats released LTB_4, 20-COOH-LTB_4, 5-HETE as well as the products of nonenzymatic hydrolysis of LTA4, e.g., the 6-trans-12-epi-LTB_4, 6-trans-LTB_4 and the 5,6-DiHETEs. Neutrophils from EFAD rats produced the same metabolites but in significantly lower quantities. As shown in Figure 1, the levels of LTB_4, 20-COOH-LTB_4, 5-HETE and 6-trans-LTB_4 were decreased by 57.7 ± 1.2%, 39.6% ± 9.8%, 63.1 ± 9.6% and 26.4 ± 8.9%, respectively, compared to the control neutrophils (mean ± S.E.). LTB_4 production following fMLP stimulation was substantially lower than the A23187 induced formation being 2.7 ± 0.7 ng/10^6 neutrophils for the control animal cells. The EFAD neutrophils showed a decrease of LTB_4 production by 60.4 ± 6% (±SE, n = 3, $p < 0.01$). 20-COOH-LTB_4 was not detectable in EFAD or control neutrophils on fMLP stimulation. PMA stimulation did not induce any LTB_4 production. The peptidoleukotrienes LTB_4, D_4 and E_4, as well as 20-OH-LTB_4, were not detectable for any stimulus. Since both 20-OH- and 20-COOH-LTB_4 easily can be detected in the present HPLC system, a rapid turnover of 20-OH-LTB_4 to 20-COOH-LTB_4 is likely, preventing its accumulation and detection.

Given these data on endogenous LTB_4 production, we assessed neutrophil functional responses to see if there was a relation to endogenous LTB_4 production.

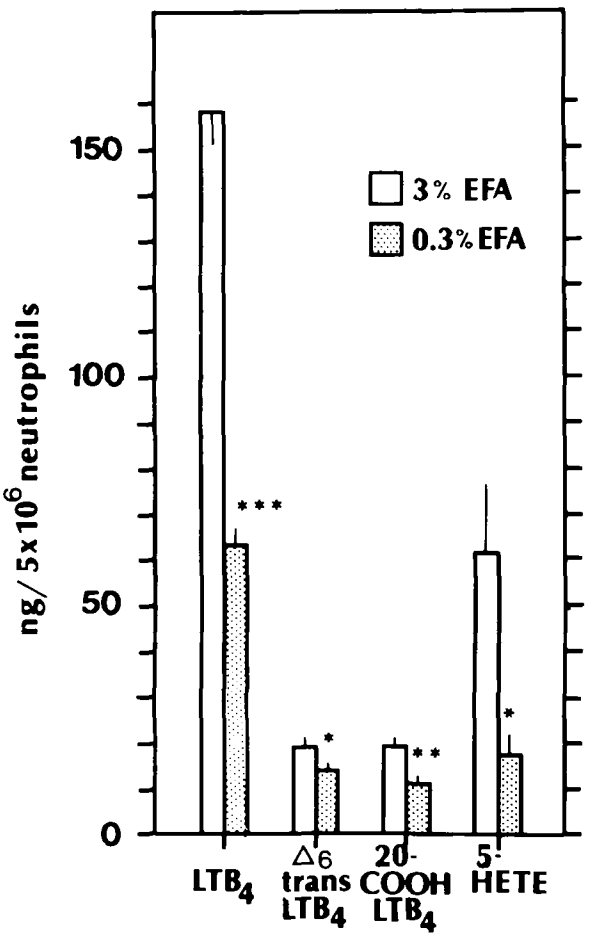

FIG. 1. Production of leukotrienes and 5-HETE in neutrophils from EFAD and control rats. Peritoneal neutrophils (5×10^6/ml) were stimulated with the ionophore A23187 (2 μM), analysis was performed by reversed phase HPLC as detailed in the Methods section. Results are given as ng/5×10^6 neutrophils (±SE, n = 4-5). *, $p < 0.05$; **, $p < 0.01$; ***, $p < 0.005$.

For assessment of oxidative burst activity, luminol augmented CL was applied. The CL responses from EFAD rats and controls were identical kinetically, and there was no difference in spontaneous CL. The response to formylpeptides showed a small initial peak with a duration of seconds, immediately continuing in a slightly more protracted major peak without returning to baseline values in between. All calculations were made from the second, major peak. The response to LTB_4 was of lesser magnitude than the response to formylpeptides and single-peaked, thus resembling the response from human blood neutrophils (10). A23187 and PMA-induced CL appeared considerably slower than for the other stimuli. This also is in accordance with findings for human neutrophils (10).

The responses to A23187 and the formylpeptides fMMMM and fNLPNTL significantly were diminished in the EFAD neutrophils compared with the controls (Fig. 2). In contrast, the CL response of EFAD cells to exogenous LTB_4 and PMA were slightly but not significantly increased as compared with the controls (Fig. 2). The CL generated by EFAD blood cells after stimulation with FMMMM was 4.6 ± 1.2 mV compared to 20.3 ±

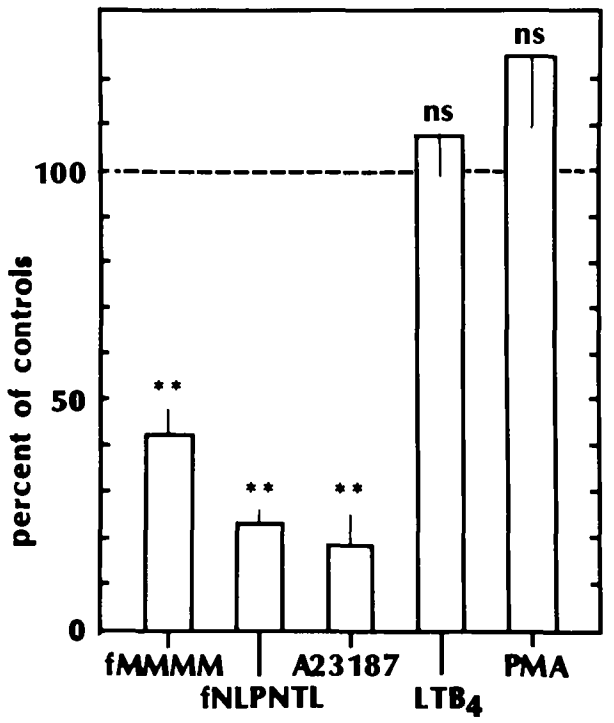

FIG. 2. Chemiluminescence (CL) augmented by luminol, produced by peritoneal neutrophils (1.25×10^6/ml) from EFAD rats expressed as percent of CL generated by neutrophils from control rats. CL was induced by the formylpeptides fMMMM and fNLPNTL (both 1 μM), A23187 (2 μM), leukotriene B4 (LTB_4, 1 μM) and phorbol myristate acetate (PMA, 10 μM). CL generated by control rat neutrophils stimulated by the different stimuli was fMMMM, 19.4 ± 1.1 mV; fNLPNTL, 12.9 ± 2 mV; A23187, 31.4 ± 4.2 mV; LTB_4, 2.5 ± 0.5 mV; PMA, 69.4 ± 3 mV (± S.E., n = 5-7). **, $p < 0.01$; ns, not statistically significant ($p > 0.05$).

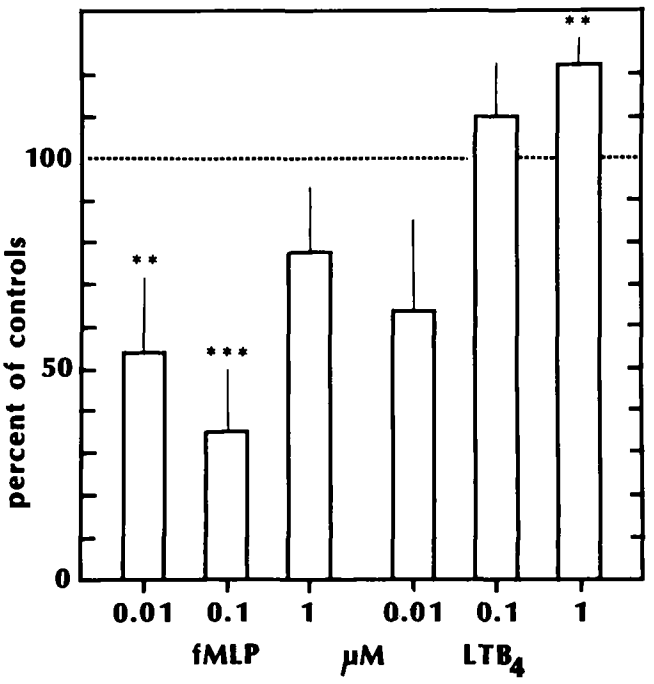

FIG. 3. Net migration (stimulated minus spontaneous migration) assessed as the leading front of neutrophils that were obtained from EFAD rats after stimulation with fMLP or LTB_4. Results are expressed as mean and S.E. values of simultaneously run controls (neutrophils from rats maintained on a diet with 3% linoleic acid). The distances migrated by control cells were for spontaneous migration 50+/−7 μm and for fMLP at 1 μM, 26+/−9, at 0.1 μM, 23+/−5, and at 0.01 μM 19+/− μM (net migration). The corresponding values for LTB_4 were 23+/−11, 38+/−6 and 26+/−6 μm. *, $p \oplus 0.05$; *, $p < 0.01$; ***, $p < 0.005$.

1.2 mV by the controls ($n = 2$, $p < 0.05$). When PMA (10 μM) was used as stimulus, EFAD blood cells responded with 26.1 ± 3.3 mV and controls with 29.3 ± 0.4 mV ($n = 2$, $p = 0.3$).

We next assessed neutrophil migration and aggregation. The spontaneous migratory capacity of peritoneal cells from EFAD rats was slightly but not significantly higher (118 ± 7%) compared to the controls ($p > 0.05$). Rat peritoneal neutrophils responded with a stimulated migration to both fMLP and, contrary to previous reports (24,29), LTB_4. When fMLP was used as chemoattractant, EFAD cells did not migrate as far as controls (Fig. 3). This difference was highly significant at fMLP concentrations of 0.1 μM ($p < 0.005$) and 0.01 μM ($p < 0.01$) but not significant at 1 μM. In contrast, no difference was observed when LTB_4 was used as chemoattractant, except at 1 μM where a small but significant ($p < 0.01$) enhancement was noted (Fig. 3). Chemotaxis of blood neutrophils also was assessed. Optimal migration was observed towards 0.1 μM fMLP. EFAD cells migrated only 46% of the distance of control rat cells (Table 1). When LTB_4 was used as stimulus, very small increments of migration was observed (in accordance with 24,29), being approximately 1/5-1/8 of what human neutrophils exhibit at optimal stimulus concentration (i.e. 10 nM). However, there was no difference between the dietary groups. Thus, the results from the experiments on blood neutrophils were similar to what was observed for peritoneal cells.

TABLE 1

Chemotaxis of Rat Blood Neutrophils

		fMLP, μM		LTB_4, μM	
		0.01	0.1	0.01	0.1
EFAD, μm	20 ± 7	21 ± 2	46 ± 13	12 ± 1	14 ± 1
Controls, μm	20 ± 4	47 ± 8	78 ± 4	12 ± 2	17 ± 3

Mean and SE for two separate experiments. In each experiment, triplicate analyses for each condition was performed. In addition to the stimulus concentrations given above, experiments were run with fMLP and LTB_4 at 1 nM and 1 μM; only small net increments of migration were observed in these experiments. Values given for fMLP and LTB_4 represent net migration.

The propensity to aggregate also was changed. Ionophore A23187 induced a continuous aggregation not followed by any desaggregation. The aggregation of EFAD peritoneal neutrophils was depressed at all tested A23187 concentrations and significantly at 1-10 μM ($p < 0.05$; Fig. 4). The kinetics of aggregation for control and EFAD cells were similar. Control neutrophils responded

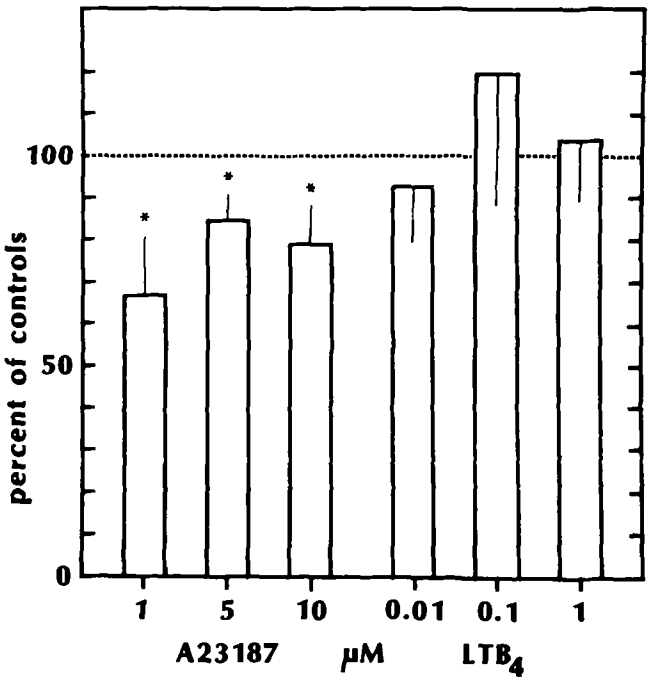

FIG. 4. Aggregation of EFAD neutrophils after stimulation with ionophore A23187 (1–10 μM; n = 5–9) and LTB_4 (0.1–10 μM; n = 5–9). The recorded change in light transmission (ΔT in mm) was measured three min after addition of A23187 and at peak for LTB_4. The results are expressed as mean and S.E. percent values of controls. *, $p < 0.05$.

to 1 μM LTB_4 stimulation with a peak after 40 sec and desaggregated with 35% of the peak value one min after the peak. The peak response to LTB_4 in EFAD rat neutrophils was of the same magnitude as to control cells, and desaggregation was not significantly different. However, the time to peak was delayed at all tested concentrations, and at 1 μM the peak was delayed by 16 sec ($p < 0.01$) (data not shown). As previously reported fMLP (0.1 μM) induced aggregation was depressed in EFAD compared to control animals (15).

It previously has been shown that chemoattractant receptor affinity is regulated by its lipid environment (30). As alteration of membrane lipid fluidity is conceivable in EFAD and thus may modulate receptor binding, we determined the fMLP (^{3}H)P binding to its receptors on peritoneal neutrophils from the differently fed rats.

In each of three experiments, there was no difference in total specific binding between the rats (Fig. 5) nor in displaceable or nondisplaceable binding.

Using Scatchard analysis, it was evident that the binding plots obtained were curvolinear for both dietary groups but also could fit two different linear functions calculated using linear regression analysis (plot A and plot B in Fig. 5), assuming a two-receptor model with different affinities. Figure 5 shows that the slope of plot A, a measure of binding affinity (slope = $-1/Kd = -Ka$) was similar for the EFAD and control rat cells (0.36 ± 0.16 vs 0.39 ± 0.10, respectively) and there was no difference between the slopes of data fitted by B-lines (−0.08 ± 0.02 vs −0.04 ± 0.1).

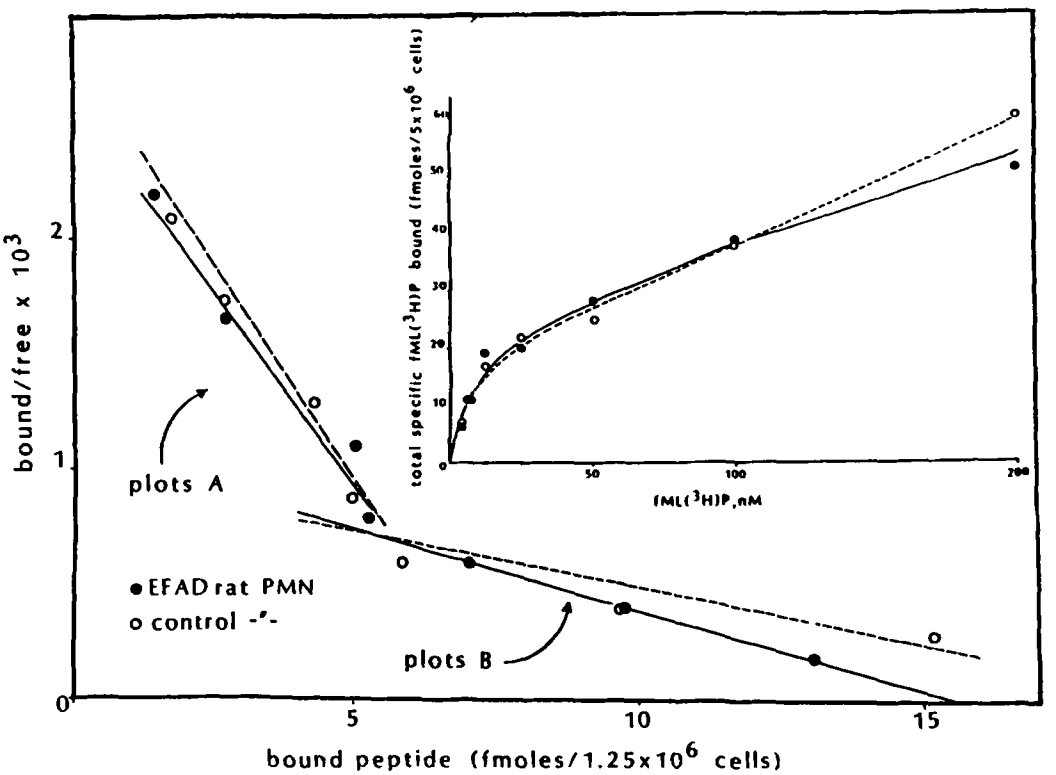

FIG. 5. Scatchard analysis of fML(^{3}H)P binding to peritoneal neutrophils from EFAD and control rats. The lines drawn are calculated using linear regression analysis. Points represent mean of three experiments. Insert, total specific fML(^{3}H)P binding to neutrophils from EFAD and control rats after 30 min incubation with increasing doses of fML(^{3}H)P at 4 C. Points represent mean of three experiments.

In these experiments, the number of binding sites per cell were 5725 ± 928 and 7000 ± 1427 (n = 3) for EFAD and control rat neutrophils, respectively. The small difference in receptor number was not statistically significant.

Finally, by studying the fraction of responding peritoneal neutrophils with DCHF-DA fluorescence, It was evident that the differences in CL between EFAD and control rat cells upon fMLP or A23187 stimulation were not due to a decreased fraction of responsive neutrophils (Table 2).

TABLE 2

Dichlorofluoresceindiacetat Fluorescence

Stimulus	Concentration μM	Percent responding cells	
		EFAD	Control
fMLP	0.1	76 ± 6.4	80 ± 3.3
fMLP	1.0	79.4 ± 2.2	81.7 ± 2.1
LTB_4	0.1	76.1 ± 1.5	79.2 ± 2.1
A23187	2.0	78.3 ± 1.8	80.3 ± 1.8
PMA	10.0	84.9 ± 5.8	84.8 ± 2.3

Performed as detailed in the Experimental section. Results are given as the fraction of responding (fluorescent) cells.
Mean ± SE, n = 3.

DISCUSSION

We previously have reported the fatty acid composition of these EFAD rat peritoneal nuetrophils (15). The decrease in cellular arachidonic acid content was 33%. However, in this study the production of some lipoxygenase metabolites were reduced by 60–70%, thus substantially lower than what would be expected from the arachidonic acid deficiency per se (Fig. 1) and in accordance with another report (17). The mechanism for this disproportionate 5-lipoxygenase product deficiency in EFAD neutrophils might be related to the presence in the test cells of the arachidonic acid analogue 20:3n-9 as suggested previously (17). This trienoic fatty acid, a derivative of oleic acid, is undetectable or present in only minor quantities in normal neutrophils but increased in EFAD (12,19) and significantly so in neutrophils from EFAD rats in this study (15). It is noteworthy that the irreversible inhibition of LTA_4 hydrolase by the 20:3n-9 metabolite, 5(6)-oxido-7,9,11-(E,E,Z)-eicosatrienoic acid (leukotriene A_3), reported recently (17), cannot account for the reduction of 5-lipoxygenase product synthesis reported herein since the formation of 5-HETE on A23187 stimulation, which occurs at a step above the LTA_4 hydrolase, also was inhibited. Clearly, further studies are required to clarify this issue.

LTB_4 has been postulated to be a mediator of neutrophil functions. The rapid generation of leukotrienes following stimulation with a variety of stimuli (2–6), the activation of neutrophil functional responses by LTB_4 (7–11) and to a lesser extent, the inhibiting effects of lipoxygenase inhibitors (4,11,31–33) constitute circumstantial evidence for a role of endogenous LTB_4. The EFAD neutrophil model offers an additional means to study the physiological significance of lipoxygenase products in neutrophil function.

In EFAD neutrophils, in which a defect of 5-lipoxygenase product synthesis has been shown, there also were functional impairments to stimuli that induce leukotriene synthesis, e.g. to A23187, which has potent and prompt leukotriene generation promoting ability (3,4). Responses to formylpeptides, which are weaker stimuli for leukotriene generation (2,6), also were affected. Thus, it is conceivable that full functional responsiveness may require unaltered leukotriene production. Finally, the noted impairments did not appear to be due to a general alteration of the EFAD neutrophil responsiveness since spontaneous migration and spontaneous CL both were intact in EFAD neutrophils. Furthermore, the response to exogenous LTB_4 (34) or PMA, which does not induce LTB_4 generation (35, and as shown here), was equal to controls, showing that the EFAD neutrophils retained full capacity to respond to stimulation.

The differences observed between EFAD and control neutrophils after stimulation with certain agents was similar in blood and peritoneal cells and indicated a discrete defect of the stimulus-response coupling. One explanation might be decreased membrane fluidity due to the altered fatty acid composition of membrane phospholipids, which can be of particular consequence for complex functions, e.g. chemotactic and aggregatory responsiveness. However, it previously has been shown that moderate EFAD in rats does not alter erythrocyte membrane fluidity to any appreciable degree (36). Also, a simple relation seems not to exist between cell membrane fluidity and EFA composition of the diet (37,38). Furthermore, responses to LTB_4 in this study showed that the chemotactic and aggregatory potential in response to a membrane receptor dependent stimulus, per se, was unaffected in EFAD peritoneal neutrophils.

Another explanation for the observed decrements of EFAD neutrophil responses could relate to previous observations that alterations of cell membrane fatty acid composition may be associated with altered surface receptor expression (16), e.g. due to receptor numbers and/or functional state. The normal responsiveness to exogenous LTB_4 argues against a general explanation based on reduced receptor numbers in the EFAD peritoneal neutrophils. However, the most pronounced reduction in activity of EFAD neutrophils was observed on stimulation with A23187, which does not depend on a receptor for activation.

The present data show that the fMLP-receptor on rat peritoneal neutrophils has high- and low-affinity states but that the receptor affinity and the receptor number were similar for EFAD and control rats. Thus, differences as to responses to fMLP between the groups were not due to receptor expression changes.

The data reported in this study support the concept that deficiency of endogenous LTB_4 may be related to the functional impairment in the EFAD neutrophils, a defect that can be overcome by addition of exogenous LTB_4. Given the reported biological activities of LTB_4, it is possible that the LTB_4 generated in the neutrophils upon stimulation, e.g. by fMLP, contributes to the effect of the given stimulus on the cells. It also is clear from previous studies that this LTB_4 cannot account for all of the neutrophil response; Sha'afi et al. have suggested that

fMLP can activate rat neutrophils through mechanisms independent of LTB_4 generation (39).

The results presented here show a striking similarity to what is to be reported from another study on the effects of EFAD on neutrophils, in which EFAD was induced by fat-free total parenteral nutrition (40). In that condition, EFAD develops rapidly, probably because a glucose-dependent hyperinsulinemia impedes mobilization of linoleic acid from adipose tissue. Regardless of the model of induction, it is apparent that several functional responses such as chemotaxis, aggregation, oxidative burst activation and degranulation (19,31) can be impaired. Such reductions may be significant when looking for explanations of EFAD-associated inflammatory dysfunctions and increased susceptibility to bacterial infections. EFAD finally may be clinically more important and prevalent than previously believed since it may occur as part of protein-energy undernutrition (41) because of deficiency of desaturating and elongating enzyme systems. Considering that LTB_4 is a potent activator of neutrophils, its reduced synthesis may cause impaired host defense in individuals with no overt, clinical signs of malnutrition.

ACKNOWLEDGMENTS

The skillful technical assistance of I. Friberg, A. Almquist, D. Onica, B. Cottell, G. Finnveden and S. Picard, and the skillful care of the animals by M. Frisk and E. Hjelm is gratefully acknowledged.

[Received March 13, 1987; Revision accepted September 10, 1987]

Synthesis of Platelet Activating Factor by Cholinephosphotransferase in Developing Fetal Rabbit Lung

Dennis R. Hoffman, Maureen K. Bateman and John M. Johnston*
Departments of Biochemistry and Obstetrics-Gynecology and The Cecil H. & Ida Green Center for Reproductive Biology Sciences, University of Texas Health Science Center at Dallas, 5323 Harry Hines Blvd., Dallas, TX 75235

Developing fetal lung is a possible source of the platelet activating factor (PAF, 1-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) present in amniotic fluid of women in labor. We have assayed the microsomal activities of a specific enzyme for the de novo synthesis of PAF in developing fetal and neonatal rabbit lung, 1-alkyl-2-acetyl-glycerol-dependent dithiothreitol-insensitive cholinephosphotransferase. The specific activity of this enzyme increased from 0.92 to 3.60 nmol × min^{-1} × mg^{-1} protein between day 21 and day 31 of gestation. In contrast, during this same period the activity of the PAF-biosynthetic cholinephosphotransferase in developing rabbit kidney did not change significantly. The specific activity of the diacylglycerol-dependent, dithiothreitol-sensitive cholinephosphotransferase that catalyzes the final step in phosphatidylcholine biosynthesis was not altered during late gestation in either fetal lung or kidney. Previously, increased amounts of pulmonary PAF had been found during the latter stages of gestation (Hoffman, Truong and Johnston (1986) *Biochim. Biophys. Acta 879,* 88–96) and may be attributed to increased activity of the PAF biosynthetic enzymes found in this investigation. This elevated level of PAF in fetal lung may serve to facilitate breakdown of glycogen that provides, in part, the carbon and energy source for surfactant biosynthesis. In addition, PAF may be secreted in association with surfactant into amniotic fluid in which it may interact with amnion tissue and subsequently participate in the events associated with the initiation of parturition.
***Lipids 23,* 96–100 (1988).**

The potent biologically active phospholipid, platelet activating factor (PAF, 1-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) first was identified with various pathological states such as inflammation, asthma and anaphylaxis (1,2). More recently, it is evident that PAF may have important normal cellular functions. We have proposed two potential physiological roles for PAF in reproductive biology: PAF may initiate glycogenolysis in fetal lung, the products of which provide energy and a carbon source for biosynthesis of the glycerophospholipids of surfactant (3–5), and PAF may be secreted from the fetal lung into amniotic fluid, in which it may interact with amnion to enhance the formation of prostaglandins by activation of the arachidonic acid cascade. Both prostanoids and PAF may facilitate the biochemical events of parturition (5,6).

PAF is only found in significant amounts in the amniotic fluid obtained from women in labor (7) and in part is associated with a lamellar body-enriched fraction containing surfactant. Since lamellar bodies are a primary secretory product of type II pneumonocytes of lung, we considered that fetal lung may be a potential source of the PAF present in amniotic fluid.

Abbreviations: CPTase, cholinephosphotransferase; DTT, dithiothreitol; PAF, platelet activating factor; PC, phosphatidylcholine.

In previous investigations, we have reported a three-fold increase in the concentration of PAF in vivo in developing fetal rabbit lung during the latter stages of gestation (4) and also in rapidly differentiating human fetal lung explants cultured for six days (3). In both of these model systems, a three-fold increase was found in the activity of 2-lysoPAF:acetyl CoA acetyltransferase (3,4), a major regulatory enzyme of the remodeling pathway of PAF biosynthesis (8).

PAF also can be synthesized by 1-alkyl-2-acetyl-*sn*-glycerol:CDP-choline cholinephosphotransferase (CPTase) (9,10). This enzyme catalyzes the last step in the de novo pathway for PAF biosynthesis (11). In this investigation, we have examined the specific activity of this enzyme in developing fetal and neonatal rabbit lung and kidney.

MATERIALS AND METHODS

Chemicals. Cytidine 5′-diphospho[methyl-^{14}C]choline (56 μCi/μmol) and [^{3}H]acetyl CoA (500 mCi/mmol) were purchased from Amersham Corporation (Arlington Heights, IL). Phospholipid standards were from Avanti Polar Lipids (Birmingham, AL). Fatty acid–free fraction V bovine serum albumin, 1-hexadecyl-*sn*-glycerol, 1,2-dioleoyl-*sn*-glycerol, and other general chemicals were obtained from Sigma Chemical Co. (St. Louis, MO). Unlabeled 2-lysoPAF was obtained from Calbiochem (La Jolla, CA).

Diradylglycerol preparation. 1-Alkyl-2-acetyl-*sn*-glycerol was synthesized as described by Woodard et al. (10). Briefly, 1-hexadecyl-*sn*-glycerol was chemically acetylated, the *sn*-3 acetate was cleaved by porcine pancreatic lipase treatment. The 1,2-isomer was separated from the 1,3-isomer on boric acid impregnated thin layer chromatography plates developed in chloroform:methanol (98:1.5, v/v). 1,2-Dioleoyl-*sn*-glycerol was purified chromatographically as above.

Tissue preparation. Timed pregnant New Zealand white rabbits (Hickory Hills, Flint, TX) were the source of fetal and adult tissues. Tissues were excised and rapidly homogenized (4 C) in 6:1 (vol/g tissue) with sucrose (0.25 M)/Tris-HCl (10 mM, pH 7.4)/EDTA (1 mM) using a Potter-Elvehjem vessel and a Teflon pestle. The suspension was centrifuged at 600 × g for 10 min to remove unbroken cells, cell debris and nuclei. The supernatant fraction was centrifuged at 18,000 × g for 15 min to obtain a pellet rich in mitochondria and lamellar bodies (12). The remaining supernatant fraction was centrifuged at 105,000 × g for 60 min to obtain the microsomal (pellet) and cytosolic fractions (supernatant). Protein concentrations were quantitated by the Bradford procedure (13).

Cholinephosphotransferase assay. The PAF biosynthetic activity of dithiothreitol (DTT)-insensitive CPTase (EC 2.7.8.16) was determined employing Tris-HCl (100 mM, pH 8.0 at 37 C), DTT (10 mM), EGTA (0.5 mM), 0.1% bovine serum albumin, $MgCl_2$ (10 mM), 1-hexadecyl-2-acetyl-*sn*-glycerol (0.2 mM in ethanol, final

ethanol concentration equals 2.5%), 25 μg microsomal protein and CDP-[methyl-^{14}C]choline (100 μM, 1 μCi/mmol) according to the procedure of Renooij and Snyder (9). Assay of phosphatidylcholine (PC) biosynthetic activity of CPTase (EC 2.7.8.2) was as above except the reaction was at pH 8.5, contained no DTT, and utilized 1,2-dioleoyl-*sn*-glycerol (0.2 mM) as substrate. The incubation was for 10 min at 37 C. PAF and PC were separated by thin layer chromatography on Kieselgel 60 plates (E. Merck, Darmstadt) developed in chloroform:methanol: concentrated ammonium hydroxide (60:35:8, v/v/v). Radioactivity comigrating with authentic PAF and PC added as carrier (20 μg each) was determined, and the values for both CPTase assays were corrected for the incorporation of [^{14}C]choline in the absence of diradylglycerol substrate. The assay was linear to 75 μg microsomal protein and for 20 min.

LysoPAF:acetyl-CoA acetyltransferase assay. The activity of this enzyme was determined using a modification of the procedure described by Wykle et al (8). Briefly, the reaction mixture includes Tris-HCl (30 mM, pH 7.4 at 37 C), DTT (1 mM), $CaCl_2$ (10 μM), 2-lysoPAF (40 μM), 0.025% bovine serum albumin, [^{3}H]acetyl CoA (250 μM, 6.4 μCi/μmol), 50 μg microsomal protein, and was incubated for 15 min at 37 C. PAF was separated and radioactivity determined as described. The assay was linear to 120 μg microsomal protein and for 20 min.

RESULTS

The PAF biosynthetic CPTase reaction is distinguished from the PC biosynthetic activity primarily by the inhibitory action of the sulfhydryl agent, dithiothreitol, on the latter activity (9). As illustrated in Table 1, when PAF biosynthesis was assayed utilizing 1-alkyl-2-acetyl-*sn*-glycerol as substrate the addition of DTT (10 mM) only slightly stimulated (19%) its biosynthesis. In contrast, PC biosynthesis with the same fetal rabbit lung microsomal preparation is inhibited by 95% in the presence of DTT. When alkyl-acetyl-glycerol was the substrate for the CPTase reaction, negligible amounts of [^{14}C]choline from CDP-[^{14}C]choline were incorporated into PC. Similarly, when dioleoyl-glycerol was utilized as substrate, [^{14}C] incorporation into PAF was less than 2% of that incorporated into PC.

The PAF- and PC-biosynthetic CPTase activities primarily were (66–68%) localized in the 105,000 × *g* (microsomal) pellet of adult rabbit lung (Table 2). This subcellular distribution of the DTT-insensitive CPTase is similar to that reported in rat liver and spleen (9). The distribution of CPTase activity nearly was identical to that of acetyltransferase in rabbit lung (Table 2).

Substrate specificity characteristics of the PAF and PC biosynthetic reactions were investigated in adult rabbit lung microsomal preparations. Reaction mixtures at pH 8.0 containing DTT favor PAF biosynthesis, however, inclusion of dioleoyl-glycerol at an equimolar concentration as the alkyl-acetyl-glycerol substrate (0.2 mM) causes a 36% decrease in PAF biosynthesis when compared to that

TABLE 1

Dithiothreitol Sensitivity of PAF and PC Biosynthetic Cholinephosphotransferases in Fetal Rabbit Lung Microsomes

Substrate	Specific activity (nmol × min^{-1} × mg^{-1} protein)	
	−DTT	+10 mM DTT
Alkyl-acetyl-glycerol	5.48 ± 1.08	6.54 ± 0.67
Dioleoyl-glycerol	1.49 ± 0.18	0.07 ± 0.04

Values (±S.E.M.) are from duplicate analysis in at least three separate samples.

TABLE 2

Subcellular Distribution of DTT-insensitive and DTT-sensitive Cholinephosphotransferases (CPTase) and LysoPAF:Acetyl-CoA Acetyltransferase Specific Activities in Adult Rabbit Lung

Enzyme	Subcellular fraction			
	Supernatant (600 × *g*)	Pellet (18,000 × *g*)	Pellet (105,000 × *g*)	Supernatant (105,000 × *g*)
	nmol × min^{-1} × mg^{-1} protein			
DTT-insensitive PAF-CPTase	1.06 ± 0.03	2.82 ± 0.07 (33)	5.83 ± 0.43 (67)	0
DTT-sensitive PC-CPTase	0.77 ± 0.13	1.07 ± 0.06 (34)	2.10 ± 0.07 (66)	0.01 ± 0
Acetyltransferase	0.54 ± 0.10	0.73 ± 0.11 (28)	1.78 ± 0.30 (69)	0.07 ± 0.01 (3)

Values are means (±S.E.M.) from four (CPTase) or three (acetyltransferase) separate experiments.

Values in parentheses are percent of total activity present in each subcellular fraction. Average recovery of the PAF-CPTase, PC-CPTase and acetyltransferase activities were 119, 63 and 98%, respectively.

containing only alkyl-acetyl-glycerol (i.e., 4.07 vs 6.33 nmol × min^{-1} × mg^{-1} protein, Table 3). Similarly, in a corresponding experiment alkyl-acetyl-glycerol inhibited PC biosynthesis by 36% (2.72 to 1.74 nmol × min^{-1} × mg^{-1} protein) in incubation mixtures at pH 8.5 and from which DTT was omitted. In the presence of equimolar concentrations of both substrates, total product formation, (2.13 nmol PAF formed × min^{-1} × mg^{-1} protein plus 1.74 nmol PC formed × min^{-1} × mg^{-1} protein) approaches a rate observed using only alkyl-acetyl-glycerol as substrate (i.e., 4.05 nmol PAF formed × min^{-1} × mg^{-1} protein). Although these results would be consistent with the view that both diradylglycerols are substrates for a single enzyme, the precise mechanism must await purification and characterization of the enzymes involved.

During late gestation in the rabbit (term = 31–32 days), only the activity of the PAF biosynthetic (DTT-insensitive) CPTase of fetal lung increased significantly (Figure 1). In contrast, this enzymatic activity was not altered significantly in fetal kidney. During neonatal development, the PAF biosynthetic activity increased in both lung and kidney to reach the adult level. The PC

Cholinephosphotransferase Diradylglycerol Substrate Specificity in Adult Rabbit Lung Microsomes

Substrate added (200 μM)		Alkyl-acetyl glycerol	Dioleoyl glycerol	Both
Reaction conditions	Product assayed	nmol × min^{-1} × mg^{-1} protein		
+DTT pH 8.0	PAF	6.33 ± 0.54	0.02 ± 0.01	4.07 ± 0.52
	PC	0.03 ± 0.03	0.02 ± 0.01	0
−DTT pH 8.5	PAF	4.05 ± 0.08	0.09 ± 0.04	2.13 ± 0.35
	PC	0	2.72 ± 0.93	1.74 ± 0.91

Values are the means (± SEM) of three separate experiments.

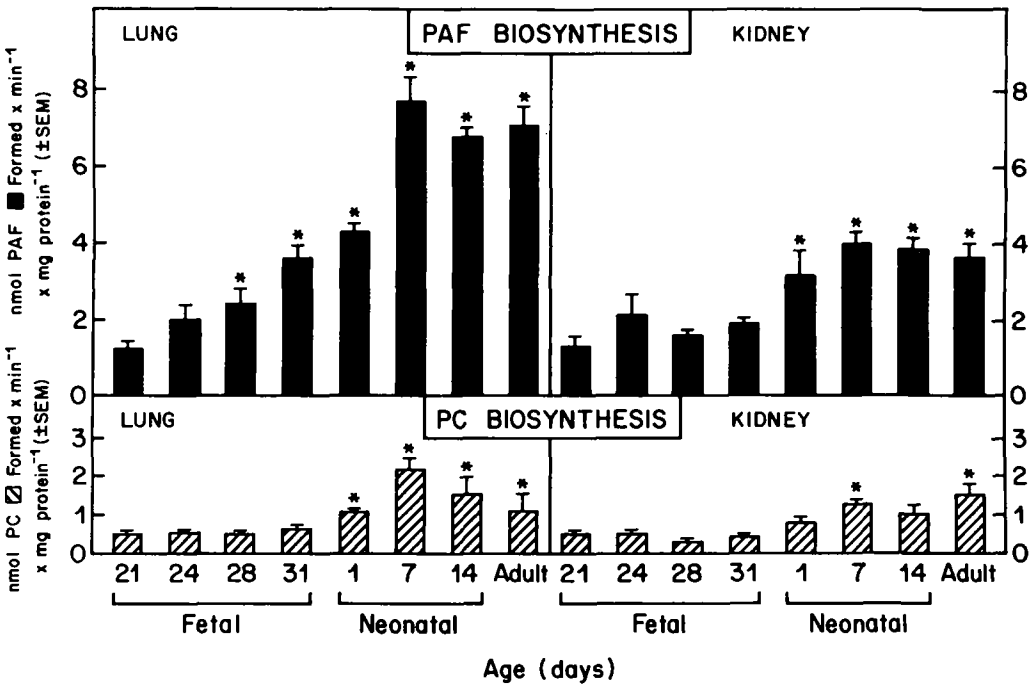

FIG. 1. Specific activity of the PAF (DTT-insensitive) and PC (DTT-sensitive) biosynthetic cholinephosphotransferases in microsomes of fetal, neonatal and adult rabbit lung and kidney. Biosynthetic activities were determined as described in Materials and Methods. Bars represent the mean ± SEM for a minimum of three separate experiments. * Indicates a significant difference ($p > 0.01$) from the day 21 value as determined by Student's t-test.

biosynthetic (DTT-sensitive) activity of CPTase was not altered during gestational development in the lung or kidney. In both neonatal lung and kidney, the PC-biosynthetic CPTase was elevated over the fetal level. In kidney, an adult level of enzymatic activity was reached and maintained; however, in neonatal lung, a peak of activity is reached at seven days followed by a return to an adult level comparable to that in the fetal lung.

We previously had found (4) that the microsomal 2-lysoPAF:acetyl CoA acetyltransferase specific activity in fetal rabbit lung microsomes increased significantly between days 21 and 24 of gestation (from 116 to 392 pmol PAF formed $\times$ min^{-1} $\times$ mg^{-1} protein) and remained elevated through day 31. The acetyltransferase activity in adult rabbit lung microsomes was further increased to 1780 $\pm$ 300 (S.E.M.) pmol $\times$ min^{-1} $\times$ mg^{-1} protein. In kidney (4), the enzyme activity also increased during the final 10 days of fetal development (from 68 to 187 pmol $\times$ min^{-1} $\times$ mg^{-1} protein). The adult rabbit kidney acetyltransferase (305 $\pm$ 50 [S.E.M.] pmol $\times$ min^{-1} $\times$ mg^{-1} protein) was elevated over fetal activities; however, neither the fetal nor adult rabbit kidney acetyltransferase activities reach the level of that in the lung at the corresponding age of development.

DISCUSSION

The insensitivity of the PAF biosynthetic activity of CPTase to DTT (Table 1) and localization in the 105,000 $\times$ *g* pellet (microsomal) fraction in rabbit lung (Table 2) are indicative of the presence of a similar enzymatic activity in this tissue to that described in adult rat kidney (9). The PC biosynthetic activity of CPTase in lung markedly was inhibited by DTT (Table 1) and each substrate, alkyl-acetyl-glycerol and diacyl-glycerol, influenced the ability of CPTase to utilize the other substrate (Table 3). The PAF and PC biosynthetic activities of cholinephosphotransferase(s) are thought to be two distinct enzymes (10). However, a distinction between the presence of one or two enzymes in lung tissue must await purification of the enzyme and further evaluation of the physical properties of the substrates utilized.

In this investigation, a stepwise increase in the activity of alkyl-acetyl-glycerol-dependent PAF-biosynthetic CPTase was found in fetal rabbit lung microsomes. This developmental pattern of the de novo PAF biosynthetic pathway is consistent with that found previously for a major regulatory enzyme of the remodeling pathway, lysoPAF:acetyl CoA acetyltransferase (4). However, the specific activity of the PAF biosynthetic CPTase (Figure 1) was found to be approximately 10-fold higher than the acetyltransferase activity in fetal lung and kidney and thus may contribute more significantly to the total pool of PAF in these tissues. A similar relationship between the activities of these two enzymes has been reported in adult rat kidney (10). Lipid substrate availability, however, may limit the in vivo activity of the PAF-biosynthetic CPTase as this substrate, alkyl-acetyl-glycerol, is derived from numerous enzymatic steps of the de novo ether lipid pathway. In contrast, we have quantitated the acetyltransferase substrate, lysoPAF, in the developing fetal lung and found it in great excess as compared with PAF concentrations (3,4).

The PC biosynthetic specific activity of CPTase did not change significantly between day 21 and day 31 in fetal rabbit lung (Figure 1) and confirms our earlier observations (14) of the ontogenic development of this enzymatic activity. Although it originally was suggested that CPTase was one of the primary enzymes involved in regulation of surfactant PC biosynthesis during fetal development (15,16), in rabbit it appears not to be the case (14,17–19). The PAF biosynthetic specific activity of CPTase was three- to six-fold higher than the PC biosynthetic activity throughout fetal lung maturation (Figure 1). This same relationship of enzymatic activity was observed in adult rat kidney (10) and may reflect a preferential synthesis of PAF under certain physiological circumstances. However, this paradox of higher PAF biosynthetic capacity compared to PC biosynthesis also may be attributable to the substrate availability in the developing fetal lung.

The activities of the PAF biosynthetic CPTase (Figure 1) and acetyltransferase (4) both increase at a time (starting at day 24 of gestation) when the epithelial lining of fetal rabbit lung rapidly is differentiating into type II pneumonocytes (20). It is well-established from both morphological and biochemical studies that during differentiation of type II pneumonocytes, the concentration of glycogen rapidly decreases (21–23) in association with increased synthesis of the glycerophospholipids unique to the surfactant fraction of these cells (23–26). We have demonstrated that increased concentrations of PAF also are found in fetal lung during this time period (3,4), possibly reflecting the increase in the activities of CPTase and acetyltransferase. We have proposed (3–5) and recently obtained experimental evidence (Hoffman and Johnston, unpublished data) that PAF may stimulate glycogenolysis in fetal lung in a manner similar to that originally reported by Shukla et al. (27) in isolated, perfused rat liver. Thus, PAF initiates or potentiates the breakdown of glycogen that may supply in part the energy and carbon moieties necessary for synthesis of surfactant glycerophospholipids. Other investigators have suggested that this is the case in fetal lung during the latter stages of gestation (24,25) because it receives only a small fraction of the cardiac output and primarily will utilize glycogen for surfactant biosynthesis rather than circulating blood glucose (25,28). The increased amounts of PAF in fetal lung also may become associated with surfactant and be secreted out into the amniotic fluid during late gestation just prior to parturition. This increased level of PAF in amniotic fluid is found in women at term and in labor (7). Thus, the presence of PAF in amniotic fluid only at the time of parturition is indicative of its role in the initiation of this process (6,29). The PAF that is present in amniotic fluid may interact with amnion tissue to stimulate prostaglandin synthesis (30), which in turn may participate in the events of parturition. PAF also directly can elicit the contraction of rat (31) and human (32) myometrium. Thus, it appears that the PAF synthesized in fetal lung, the last major fetal organ system to develop, also may be involved in the events of labor.

Uptake of Artificial Model Remnant Lipoprotein Emulsions by the Perfused Rat Liver[1]

Trevor G. Redgrave*[a], Raul C. Maranhao[a], Anna M. Tercyak[a], Elizabeth C. Lincoln and Henri Brunengraber[b]

[a]Biophysics Institute, Housman Medical Research Center, Boston University School of Medicine, 80 East Concord St., Boston, MA 02118, and [b]the Department of Nutrition, University of Montreal, Montreal, Quebec, H3C 3J7, Canada

In comparison with their precursor lipoproteins, the remnants of the triacylglycerol-rich lipoproteins are reduced in contents of triacylglycerols and apolipoproteins AI and AIV, whereas the contents of cholesterol (free and esterified) and apolipoprotein E are increased. In this study, lipid emulsion models of remnant lipoproteins were used to explore which of these factors are necessary for physiological rates of remnant uptake by the perfused rat liver. Uptake rates of lipid emulsion models of remnant lipoproteins in the presence of apolipoprotein E were similar to in vivo uptake rates.

Lipids 23, **101–105 (1988).**

After entering the bloodstream, the triacylglycerol-rich lipoproteins are hydrolyzed by lipoprotein lipase. The residual core remnant lipoprotein particles subsequently are taken up mostly by the liver (1,2).

The perfused rat liver was used to show that the uptake of remnants was more rapid than the uptake of the undegraded precursor triacylglycerol-rich lipoproteins (3–11). Uptake of remnants into hepatic parenchymal cells was by receptor-mediated endocytosis, with apolipoprotein E as the ligand (12,13), while the plasma C apolipoproteins were inhibitory. It was suggested that the different ratios of the E and C apolipoproteins between triacylglycerol-rich lipoproteins and remnants explained the differences in hepatic uptake (14–17). The uptake of nonremnant-like triacylglycerol emulsions by perfused livers was promoted by apolipoprotein E and impeded by the C apolipoproteins (18,19).

Recent studies in our laboratory showed that triacylglycerol-phospholipid emulsions containing small amounts of cholesterol were metabolized like natural chylomicrons (20). Increased amounts of cholesterol changed the metabolism of triacylglycerol-phospholipid emulsions so that they behaved like remnants with rapid uptake by the liver but without significant lipolysis (21). We found that this change in metabolism corresponded with changes in the amounts of apolipoproteins E and C that associated with the emulsions after incubation with whole plasma or with plasma subfractions.

We now report the uptake of the remnant-like emulsions by perfused rat livers. Our findings show that remnant-like emulsion models of lipoproteins are capable of imitating the metabolism of natural remnants only when sufficient apolipoprotein E is present.

METHODS

Materials. Male rats of the Holtzman strain were purchased from Charles River Breeding Laboratories (Wilmington, MA). Triolein, cholesteryl oleate and cholesterol were from Nu-Chek Prep (Elysian, MN), and egg lecithin was from Lipid Products (Surrey, UK). All had class purity >99% by thin layer chromatography. Bovine serum albumin (Fraction V, fatty acid poor, Miles Biochemicals, Kanakee, IL) before use was dialyzed for 48 hr as a 16% solution against six changes of Krebs-Ringer bicarbonate buffer in an artificial kidney dialysis machine. The dialyzed albumin solution then was stirred at 4 C for 16 hr with the emulsion particles from Intralipid (Cutter Laboratories, Berkeley, CA), previously separated from the excess phospholipid liposomes that are present in Intralipid by centrifugal flotation at 27,000 rpm for one hr at 4 C in the Beckman SW28 rotor. The ratio of Intralipid triacylglycerols to albumin solution was 25 g/l, and all treatments were under an atmosphere of 95% oxygen and 5% carbon dioxide to maintain physiological concentrations of calcium ion in the albumin-buffer solution. Finally, the emulsion particles were removed from the albumin solution by centrifugation under the same conditions. This treatment was required to purify the albumin of material that otherwise was inhibitory for physiological uptake by the perfused livers.

Preparation of emulsions. Emulsions of the required compositions were prepared by sonication and purified by ultracentrifugation as recently described (20,21). Mixtures of lipids in solvents were dispensed into vials, and tracer amounts of radioactive [^{3}H]cholesteryl oleyl ether (22) were added. Solvents were removed by evaporation under a stream of nitrogen followed by vacuum desiccation overnight. The mixtures (total mass 100 mg) were emulsified in 8 ml of 2.785 molal NaCl solution by sonication with a 1 cm probe in a Branson Cell Disruptor (Danbury, CT) at ~55 C. The mixture then was centrifuged using density gradients previously described (23) to obtain emulsion particles sized 50–100 nm in diameter. In brief, the crude sonicated emulsion was placed under gradients made from 1.065–1.006 g/ml density NaCl solutions, then larger emulsion particles were first removed by centrifugation in the Beckman SW41 rotor at 20 C for 22 min at 20,000 rpm. After removal of the large particles floating at the surface, the gradient was then recentrifuged at 20 C for 20 min at 40,000 rpm to float the desired particles to the top of the gradient. Smaller particles and liposome material remained in deeper regions of the gradient.

Preparation of chylomicron remnants. Mesenteric lymph was obtained by cannulation of the cisterna chyli of 250 g male rats. After surgery, the rats were placed in individual cages and fed regular rat chow. Tap water was available freely, and 0.15 M NaCl solution was delivered at 2.0 ml/hr through a gastric tube inserted at

the time of surgery. Lymph flow was 2.8 ± 0.81 ml/hr (mean±SD, n=16). To obtain radioactive chylomicrons on the second day after surgery, a meal with 75 μCi [1,2(n)-^{3}H]cholesterol (Amersham Corp., Arlington Heights, IL) dissolved in 0.5 ml of triolein was injected through the gastric tube.

The milky lymph was collected from one-half to six hr after the dose into vessels containing ethylenediamine tetraacetic acid (EDTA), gentamycin and reduced glutathione to final concentrations of 2.7 mM, 0.1 mg/ml and 1.6 mM, respectively. Collections were at room temperature (18-25 C), and the lymph was not cooled at any time. Cells were removed by centrifugation at 1,500 rpm for 15 min, then solid KBr 0.14 g/ml was added to bring the density to 1.10 g/ml. After degassing in vacuo, 14 ml of the lymph was placed under 24 ml continuous linear density gradients 1.006-1.10 g/ml for centrifugation in the Beckman SW28 rotor. Chylomicrons were obtained from the top 0.5 cm of the gradient after centrifugation at 20 C and 27,000 rpm for 4.0×10^{10} radian^2/sec, plus deceleration without braking. As previously described (16), the chylomicrons then were injected via the tail vein into 24 hr-fasted, functionally hepatectomized rats and allowed to circulate for 30 min before exsanguination by cardiac puncture. The remnants then were separated from the plasma by centrifugation at 39,000 rpm in the SW41 rotor at 20 C for 20 hr in the density gradient described above.

Apolipoproteins. Rat and human apolipoproteins were prepared from plasma very low-density lipoproteins and high-density lipoproteins by sequential centrifugations (24) in the Beckman 70Ti rotor. The lipoproteins were dialyzed against 0.01% EDTA, pH 8.0, lyophilized, then delipidated at 6 C with graded mixtures of ethanol/diethyl ether and finally washed with pure peroxide-free ether (25). The apolipoproteins were fractionated by gel chromatography on a 90 × 2.5 cm Sephacryl (Pharmacia, Piscataway, NJ) S-300 column equilibrated and eluted with 3 M guanidine HCl, 0.1 M Tris HCl (pH 8.0), 0.27 mM EDTA, 3.1 mM NaN_3 and 0.01 mM dithiothreitol (26). Human delipidated very low-density lipoproteins were taken up in buffer, centrifuged to sediment insoluble apolipoprotein B, then applied to the column to separate the E and C apolipoproteins.

To separate the apolipoproteins from human high-density lipoproteins, two columns were necessary, first with dithiothreitol omitted to obtain apolipoprotein AI and apolipoprotein AII (dimer) in one peak, then the C apolipoproteins as a group. After dialysis and lyophilization, the AI/AII mixture was chromatographed in the presence of dithiothreitol to separate AI and AII as the monomer.

The delipidated rat high-density lipoproteins were chromatographed as above to obtain the C apolipoproteins but apolipoproteins AIV, E and AI were distributed in an asymmetric peak that was divided into two pools containing either AIV and E, or E and AI. Each pool was then reapplied to a heparin-Sepharose affinity column (Pharmacia) as described by Shelburne and Quarfordt (27). Then, apolipoprotein AI or AIV were eluted with buffer containing 0.15 M NaCl before apolipoprotein E was eluted with buffer containing 2 M NaCl. Finally, all apolipoproteins were dialyzed against 0.01% EDTA pH 8.0 and lyophilized. Purity was monitored by polyacrylamide gel electrophoresis. Apolipoproteins were incubated with the emulsions in the proportions of 100 μg/mg lipid for two to three hr before adding to the perfusate.

Liver perfusions. Livers from overnight-fasted Holtzman rats weighing 244 ± 34 g were perfused in a recirculating system as described previously (28,29). Perfusate volume was ~150 ml of 4% albumin and 15 mM glucose in Krebs Ringer buffer, (pH 7.4) at 37 C. Bile was diverted by cannulation of the common bile duct. Sodium taurocholate continuously was infused into the system at 36 μmol/hr (30), and the pH was maintained with a pH-stat delivering 0.3 M NaOH.

The livers were equilibrated for 15 min in the system before a labeled emulsion or lipoprotein suspension was added to the perfusate reservoir, after removing the 8 μm Millipore filter that initially was present in the circuit. The perfusion rate was 59 ± 6.1 ml/min. Samples of 1.0 ml were taken at intervals of 4, 6, 8, 10, 12, 14, 17 and 20 min for measurement of residual radioactivity in the medium.

RESULTS

Prepared as described, the remnant-like emulsions had the composition triacylglycerols 73%, cholesteryl esters 5%, cholesterol 10% and phospholipids 12%. Figure 1

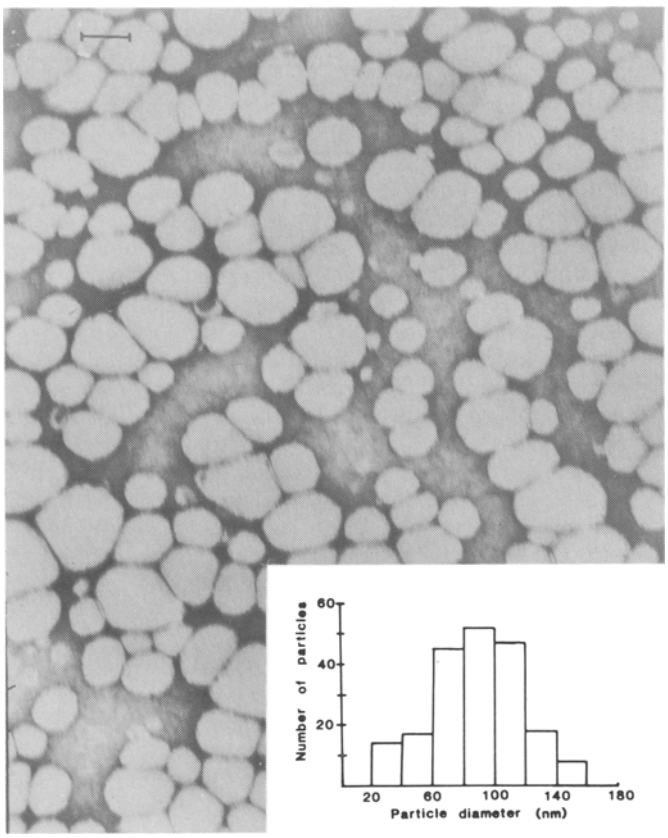

FIG. 1. Electron microscope appearance of the emulsions stained with 2% phosphotungstate. The bar indicates 100 nm. Some of the particles appear nonspherical, perhaps because of distortion from crowding on the grid. Particle diameters were measured as the means of two perpendicular measurements using a graticule, and the distribution shown is plotted as a histogram.

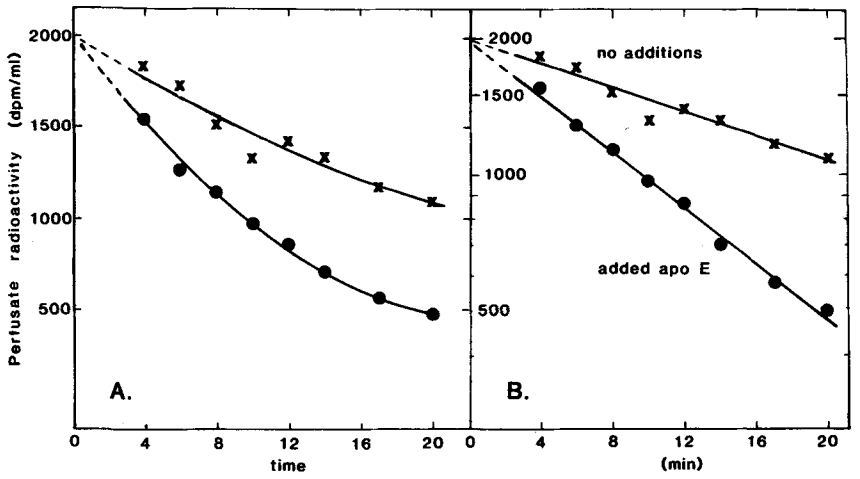

FIG. 2. The pattern of removal from the perfusate of the added emulsion radioactivity, plotted on linear and log-linear coordinates (A and B). Uptake was exponential. Added apolipoprotein E increased the rate of uptake. Uptake of natural remnants was almost identical with the emulsion in the presence of apolipoprotein E.

TABLE 1

Effect of Conditioning of the Perfusion Medium with Intralipid on the Removal of the Remnant-like Emulsion[a]

Perfusate	Rate of removal (%/min)
Unconditioned	0.1, 0.3
Conditioned	2.4 ± 0.5 (5)

[a]The removal rates were derived from the slopes of the exponential curves fitted to the data of radioactivity remaining in the perfusate collected during the first 20 min after adding the emulsions. Results are mean ± SD, (n)=number of experiments or each of duplicate experiments. The albumin used in the perfusion medium was treated as described in the Methods section. The mass of added emulsion was ≅2 mg total lipid.

TABLE 2

Effects of Apolipoproteins on Uptake of Remnant-like Emulsions[a]

Added apolipoprotein	Rate of removal (%/min)
None	2.4 ± 0.5 (5)
E (rat or human)	5.8 ± 1.7[b] (6)
C's (rat or human)	2.2 ± 1.1 (5)
AI (rat)	2.0 ± 0.5 (5)
AII (human)	1.1, 1.3
AIV (rat)	1.1

[a]Apolipoproteins were added to the emulsions in the proportion of 100 μg/mg lipid two to three hr before the liver perfusion. Where either rat or human apolipoproteins were used, uptake rates were similar with both. Other experimental details are as in Table 1.

[b]Significantly faster than with no addition, $p < 0.01$.

shows the electron microscope appearance of the emulsion after negative staining, and the histogram of particle sizes shows that most were between 60 and 120 nm in diameter. Although the emulsions were stable for at least one week, they always were used for perfusion studies within three days of preparation.

The livers continued to produce bile through the period of perfusion. Average bile flow was 0.265 ± 0.15 ml during the perfusion period (n=26). Not more than 0.1% of added emulsion or lipoprotein radioactivity was recovered in the bile. Figure 2 shows the pattern of removal of added radioactivity from the perfusate. Removal rates were exponential.

The requirement for preconditioning of the albumin used in the perfusion medium by treatment with Intralipid emulsion particles is shown by the data of Table 1. Without conditioning, the rate of removal of the added labeled emulsion from the perfusion system was very slow. Conditioning with Intralipid increased the rate by up to 20-fold and also increased the amount of radioactivity recovered in the liver (data not shown). Also effective in accelerating the rate of removal was triacylglycerol-rich emulsion added to the unconditioned medium during the perfusion with the radioactive test emulsion.

The effects of added apolipoproteins on uptake of the remnant-like emulsion are shown in Table 2. The extent of association of apolipoproteins with high-cholesterol emulsion was reported (21). Addition of apolipoprotein E accelerated the rate of removal, whereas apolipoproteins C or AI had little effect. Apolipoproteins AII and AIV appeared to be inhibitory for uptake but the numbers of experiments were insufficient for firm conclusions to be drawn.

Apolipoprotein E accelerated the rate of removal of chylomicrons from the perfusate as shown in Table 3 so that the removal was similar to that of natural remnants. Note that with added apolipoprotein E, the removal rate of the remnant-like emulsion (Table 2) also was similar to that of the natural remnants. With natural remnants, added apolipoproteins AI and AII appeared to slow the removal rate but again small numbers of observations prevent firm conclusions.

TABLE 3

Effects of Apolipoproteins on Uptake of Chylomicrons and Remnants[a]

Added apolipoprotein	Rate of removal (%/min)	
	Chylomicrons	Remnants
None	3.4	6.7 ± 2.3 (3)
E (rat)	6.5	
AI (rat)		4.3
AIV (rat)		4.4

[a]Additions of apolipoproteins and other experimental details as described in Tables 1 and 2.

DISCUSSION

The ligand for uptake of chylomicron remnants by the liver is apolipoprotein E (10), and hepatic receptors mediating remnant binding and uptake are designated B,E and E receptors (13,31). Because Watanabe heritable hyperlipemic rabbits that lack B,E receptors are able to metabolize chylomicron remnants efficiently (32), it must be concluded that the E receptors are implicated in remnant clearance. Similarly, chylomicrons appear to be metabolized normally in humans homozygous for defects in the B,E receptor.

We recently described the metabolism of emulsions prepared to model the in vivo metabolism of chylomicrons and remnants (20,21). Triacylglycerol-rich emulsions with low cholesterol content were metabolized like chylomicrons, whereas when the content of free cholesterol was high, the metabolism was like remnants. The emulsions modeling remnants were not hydrolyzed by lipoprotein lipase in peripheral vascular beds but were taken up by the liver without extensive depletion of triacylglycerols.

The differences in metabolism between emulsions with low or high cholesterol contents probably were explained by differences in affinity for the plasma apolipoproteins that associated with the emulsions after their intravenous injection. In vitro bindings of apolipoproteins AI and C were decreased by 35% and 26% for the emulsions with high cholesterol content, whereas the binding of apolipoprotein E was increased by 9% (21).

Compared with their precursor chylomicrons, remnants are high in their content of free cholesterol (1,16) so the same changes in lipoprotein affinities can be expected and have been observed (14,16). Thus, the increase in cholesterol content in remnants serves to facilitate the association with apolipoprotein E, which then mediates binding to the hepatic receptors.

In the present experiments with added apolipoprotein E, emulsions high in cholesterol were taken up by the liver similarly to natural chylomicron remnants, as shown by the data of Tables 2 and 3. Therefore, emulsions with high cholesterol content and with bound apolipoprotein E are adequate as models of chylomicron remnants, at least in terms of their uptake by the perfused liver.

In other studies of hepatic uptake of triacylglycerol-rich emulsions, the contents of cholesterol have been low, and therefore not a good model for remnants. Consistent with increased binding of the C apolipoproteins to emulsions low in cholesterol are the inhibitory effects on hepatic uptake produced by added C apolipoproteins. However, because emulsions high in cholesterol bind less of the C apolipoproteins inhibitory effects should be less. This expectation was supported by the data of Table 2.

Improvement of the rate of uptake by conditioning of the perfusion medium with Intralipid lipid particles probably also was explained by binding of apolipoproteins to the Intralipid emulsion. Commercial albumin was reported to contain contaminating apolipoprotein AI (33, 34). Our data provide preliminary evidence that apolipoproteins AII and AIV may be inhibitory for uptake, sufficient to justify further experiments specifically designed to test their possible role in remnant metabolism.

Recent in vivo data have shown clearance rates for chylomicron remnants and for emulsion models of remnants to be ≅10%/min for rats with a plasma volumes of ≅10 ml, and hepatic blood plasma flow of ≅6 ml/min. For a perfusate volume of ≅150 ml and a hepatic perfusion rate of ≅60 ml/min, as in our experiments, an uptake rate of ≅6.6%/min would be the expected physiological rate in the perfusion apparatus. Tables 2 and 3 show that for natural remnants and for emulsions in the presence of apolipoprotein E, the uptakes were 6.7 and 5.8%/min, respectively, close to the physiological rate.

When the perfusion medium contains erythrocytes, the mass of erythrocytes may exceed the liver mass (28,29), and cholesterol present in the erythrocyte membranes may transfer to added emulsions. In our studies, erythrocytes were absent to avoid this complication and, as shown previously, the liver viability was physiological (28–30).

Our findings provide further evidence that apolipoprotein B_{48} is not implicated in the uptake process of chylomicron remnants by the liver. Lipoproteins that contain apolipoprotein B_{48} but not E bind very poorly to receptors (35). Further, the metabolism of chylomicrons and remnants can be reproduced by emulsions entirely lacking in apolipoprotein B_{48} (20,21). Confirming results with very low-density lipoproteins (36), apolipoprotein B is neither necessary nor sufficient for receptor binding, whereas apolipoprotein E is essential. Similarly, the changes in lipid composition of remnants are a necessary but not a sufficient reason to account for remnant-like physiological behavior.

Effect of Essential Fatty Acid Deficiency on the Size and Distribution of Rat Plasma HDL[1]

K.E. Lowe[a], S. Pelkey[a], M.A. Williams[a,*] and A.V. Nichols[b]
[a]Department of Nutritional Sciences and [b]Department of Biophysics, University of California, Berkeley

Rat plasma high density lipoproteins (HDL) are comprised of two major particle size subpopulations, HDL_1 (255 Å–140 Å) and HDL_2 (140 Å–84 Å), in which the proportion of arachidonate in fatty acids of cholesteryl esters is greater than 50%. To determine whether decreased availability of arachidonate for cholesterol esterification would alter the distribution and/or amounts of the HDL subpopulations, we compared HDL subpopulations in EFA-deficient and control rats. To separate the effects of EFA deficiency and fat deficiency and to evaluate effects of different saturated fats, we used EFA-deficient diets that were fat-free or that contained 5% saturated fat. The control diets were the EFA-deficient diets plus 1% safflower oil. The saturated fats were hydrogenated coconut oil, hydrogenated cottonseed oil and saturated medium-chain triglycerides. All EFA-deficient diets decreased the proportion of the HDL_1 subpopulation and the peak diameter of the HDL_2 subpopulation. These changes appeared after quite brief EFA depletion in young rats and may be related to the increased liver cholesteryl ester concentrations typical of EFA-deficient rats.
Lipids 23, 106–114 (1988).

The major part of plasma cholesteryl esters (CE) in the rat are carried in high density lipoproteins (HDL), which consist of two major subpopulations, often termed HDL_1 and HDL_2 (1–4). Ultracentrifugal fractionation of the HDL has shown that the HDL_1 has both a lower density and larger particle size (255 Å–140 Å) than the HDL_2 subpopulation (140 Å–84 Å) (5–9). Both subpopulations contain apolipoprotein (apo) A-I, but only the HDL_1 contains apolipoprotein E (1–3,7–9).

In both subpopulations, the proportion of arachidonate in fatty acids of CE is greater than 50% (1), a fact that shows the importance of arachidonate in the transport of cholesterol and conversely the importance of cholesterol in the transport of arachidonate in the rat (10,11). Therefore, one might speculate that a change in the availability of arachidonate for cholesterol esterification would alter the distribution and/or amounts of the HDL subpopulations. Information on such changes is needed to understand the role of essential fatty acids (EFA) in plasma cholesterol metabolism.

Narayan and coworkers obtained evidence to support the idea that lack of EFA changes the distribution of HDL subpopulations. Narayan and McMullen (12) reported that EFA-deficient rats fed a fat-free diet had a lower concentration and proportion of plasma HDL in the fraction corresponding to the HDL_1 subpopulation than did rats fed a diet containing 4% corn oil. However, the level of dietary fat and the type of dietary fat affect the composition and distribution of HDL in rats fed diets adequate in EFA (13). Thus, the comparison of a fat-free diet with a 4% corn oil diet did not resolve whether lack of EFA or lack of fat caused the changes in HDL distribution observed by Narayan and McMullen. Earlier work (14,15) implied that the reduction in the HDL_1 subpopulation was an effect of EFA deficiency because this subpopulation was reduced in rats fed a 10% hydrogenated coconut oil diet (14) in comparison with rats fed a 10% corn oil diet in a previous experiment (15).

To distinguish more definitely the effects of EFA deficiency from those of fat deficiency and to evaluate how saturated fats of different fatty acid composition might influence HDL distribution in both EFA-deficient and control rats, we have investigated the distribution of HDL subpopulations in EFA-deficient rats fed diets that were fat-free or that contained 5% saturated fat, in comparison with rats fed these EFA-deficient diets supplemented with 1% safflower oil (SAFF). The saturated fats used were hydrogenated coconut oil (HCNO), hydrogenated cottonseed oil (HCSO) and saturated medium-chain triglycerides (MCT). Our results show that all of the EFA-deficient diets produced a large decrease in the proportion of the HDL_1 subpopulation.

MATERIALS AND METHODS

Animals and diets. Male weanling Sprague-Dawley rats (Bantin-Kingman, Fremont, CA) weighing 45–50 g at 21 days of age were assigned to diets so that the average initial body weights of each group were equal. Pairs of rats were housed in suspended, wire-bottom cages and given food and tap water ad libitum. The room was kept at 22 C with constant lighting (7 a.m. to 7 p.m.). Body weights and food intakes were recorded three times weekly to monitor growth. Table 1 shows the composition of the purified diets (16,17). EFA-deficient diet groups and respective controls were 0% fat, 1% safflower oil (SAFF); 5% hydrogenated coconut oil (HCNO), 5% HCNO + 1% SAFF; 5% hydrogenated cottonseed oil (HCSO), 5% HCSO + 1% SAFF; 5% medium-chain triglycerides (MCT), 5% MCT + 1% SAFF. A 5% corn oil (CORN) diet was fed to another EFA-adequate group. After 3, 4, 8, 12 or 13 weeks on the diet, rats were fasted for 16 hr (5 p.m.–9 a.m.) before receiving 50 mg sodium pentobarbital/kg body weight intraperitoneally (Nembutal, Abbott Laboratories, North Chicago, IL). Blood was collected by heart puncture.

Lipoprotein fractionation. Blood containing 1 mg Na_2EDTA/ml was spun at 2500 rpm (1223 × g) for 30 min at 4 C (IEC Centrifuge model PR-2, International Equipment Co., Boston, MA) to obtain plasma. For isolation of lipoproteins of d ⩽ 1.20 g/ml, 2 ml plasma were mixed with 4 ml salt solution (0.194 M NaCl, 4.506 M NaBr, d = 1.310 g/ml) to a final density of 1.217 g/ml. Samples were ultracentrifuged at 40,000 rpm (143,000 × g) for 24 hr at 15 C (Beckman 40.3 rotor, centrifuge model L2-65B, Beckman Instruments, Palo Alto, CA) (18). The top 1 ml fraction of each sample (d ⩽ 1.20 g/ml), which contained the total plasma lipoproteins, was stored at 4 C and electrophoresed within one wk. Fraction density was checked at 26 C with a Bausch and Lomb Abbe-3L Refractometer (Bausch and Lomb, Rochester, NY).

To isolate the HDL within the d 1.04–1.20 g/ml fraction, 4 ml rat plasma (from individual rats or equal volumes of plasma pooled from each of four rats) containing 10 mM phenylmethylsulfonyl fluoride were mixed with 2 ml salt solution (0.194 M NaCl, 0.479 M NaBr, d = 1.043 g/ml) and ultracentrifuged at 40,000 rpm (143,000 × g) for 24 hr at 15 C in a Beckman 40.3 rotor. The top 1 ml (d ⩽ 1.04 g/ml) was removed, and 1.230 g NaBr was added to the subnatant. The tubes were ultracentrifuged again at 40,000 rpm for 24 hr at 15 C. The top 1 ml fractions (d 1.04–1.20 g/ml) were stored at 4 C and electrophoresed within one wk.

Polyacrylamide gradient gel electrophoresis (PAGGE). Lipoproteins of the d ⩽ 1.20 g/ml top 1 ml fraction were electrophoresed through 4–30% or 2–16% polyacrylamide gradient slab gels (PAA 4/30, Pharmacia, Piscataway, NJ) at 125 V, constant voltage, at 10 C for 24 hr (Pharmacia Electrophoresis GE-2/4 Apparatus; LKB 2197 Power Supply, 2209 MultiTemp, LKB, Gaithersburg, MD) according to Nichols et al. (19) except that internal standard was omitted. Proteins were fixed in 10% sulfosalicylic acid for one hr and stained with 0.2% Coomassie blue R-250 in 50% methanol/10% acetic acid for 1.5 hr. Gels were destained in 7.5% acetic acid/5% methanol until background was completely clear.

Densitometry. An automated RFT densitometer (Transidyne General, Ann Arbor, MI) scanned the gels at 530 nm wavelength. A PDP8 computer (Digital Equipment Corp., Maynard, MA) calculated scan data, and a hard copier (Model 4631, Tektronix Inc., Beaverton, OR) recorded data displayed on a terminal (Model 4012, Tektronix). To calibrate particle size, the computer program generated a standard curve of peak R_f values vs logarithm of Stokes' radii of the reference proteins. R_f is the ratio of migration distances of a specific protein peak and of the peak of the furthest migrating standard protein in the same gel. Reference proteins (and radii in Å) were thyroglobulin (85.0), apoferritin (61.0), lactate dehydrogenase (40.8), and bovine serum albumin (35.5). Rat HDL peak R_f values were converted to particle diameters, and areas under the densitometric scans were integrated (19). The R_f ranges of the rat plasma HDL_1 subpopulation (0.16–0.40; corresponding to 255 Å–140 Å) and of the rat plasma HDL_2 (0.40–0.75; corresponding to 140 Å–84 Å) were assigned by inspection of the densitometric tracings.

SDS-PAGE of apolipoproteins. Plasma lipoproteins of the d ⩽ 1.20 g/ml top fraction were dialyzed 18 hr at 4 C against 0.05 M NaCl, 0.001 M Na_2EDTA, pH 6–8. Protein content was assayed by the method of Lowry et al. (20) using bovine serum albumin (Fraction V, Sigma) as standard. Samples of 20–30 μg protein were denatured by boiling for 15 min in 1% sodium dodecyl sulfate (SDS), with or without 5% 2-mercaptoethanol, and electrophoresed through 10% polyacrylamide tube gels (21) at constant current of 10 mA per tube for five hr at 16 C in the Weber and Osborn continuous buffer system (22). SDS-PAGE gels were processed as noted for polyacrylamide gradient gels and scanned densitometrically at 603 nm. The PDP8 computer generated a standard curve of peak R_f vs logarithm of molecular weight of the reference proteins. Standard proteins (MW in kilodaltons) were bovine serum albumin (67.0), human apoE (34.0), bovine apoA-I (28.0) and lysozyme (14.4).

Statistics. The average HDL_2 peak diameters of EFA-deficient rats were compared with those of corresponding control rats by Student's unpaired t-test (23).

RESULTS

Distribution of plasma lipoproteins (d ⩽ 1.20 g/ml) in 4–30% polyacrylamide gradient gels. Figures 1–4 show the PAGGE patterns, stained for protein, for individual

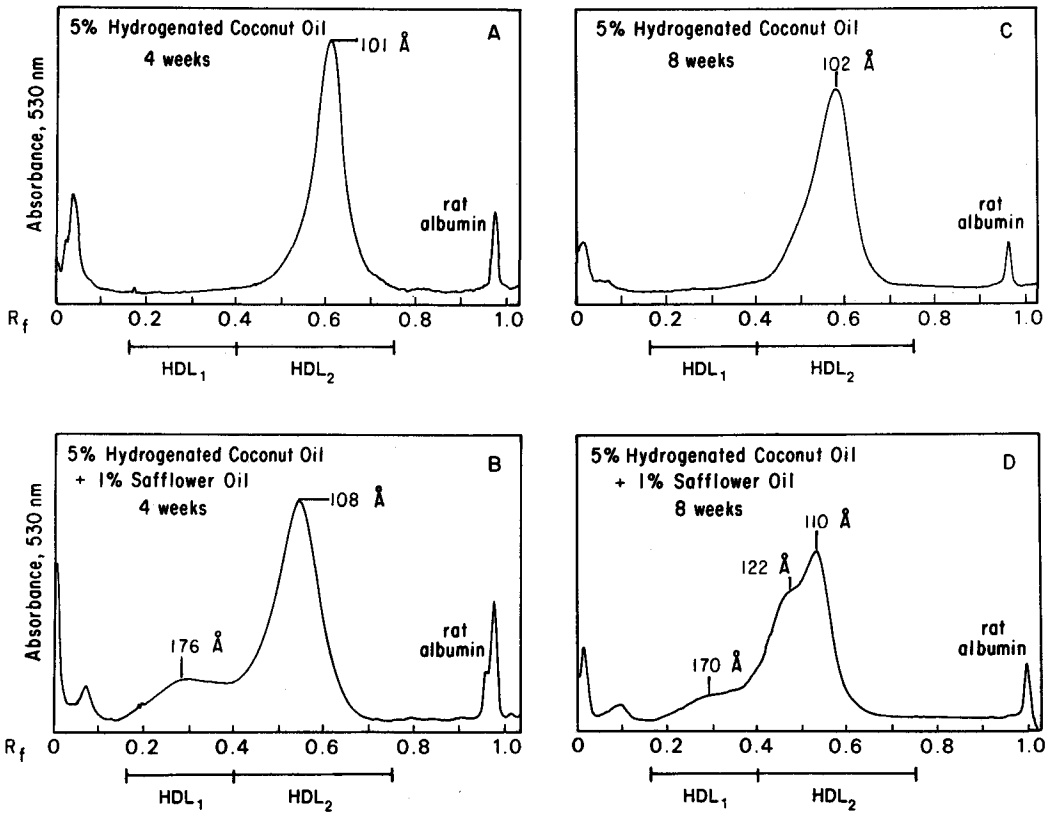

FIG. 1. Representative densitometric scans of 4–30% polyacrylamide gradient electrophoresis gels (PAGGE; Coomassie R-250 protein stain) of plasma HDL (d ≤ 1.20 g/ml fraction) from individual rats on an EFA-deficient 5% hydrogenated coconut oil (HCNO) diet for four or eight wk (A, C) compared with controls (B, D).

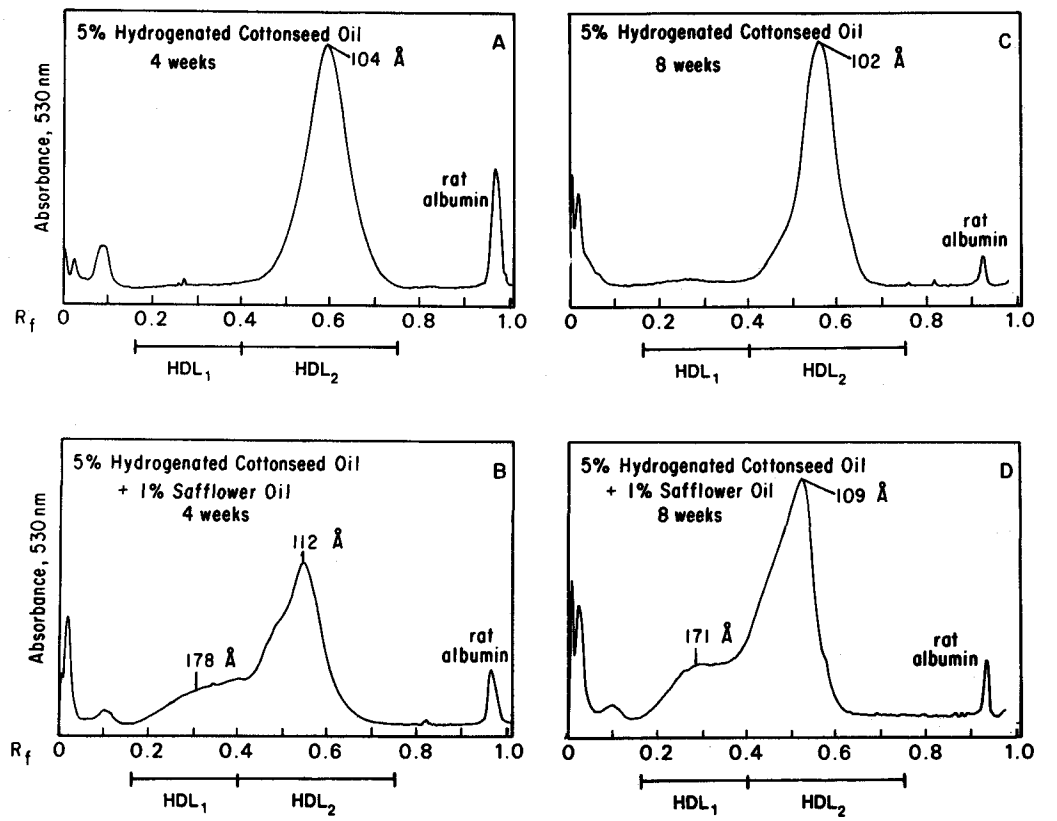

FIG. 2. Representative densitometric scans of 4–30% PAGGE of plasma HDL (d ≤ 1.20 g/ml fraction) from individual rats on an EFA-deficient 5% hydrogenated cottonseed oil (HCSO) diet for four or eight wk (A, C) compared with controls (B, D).

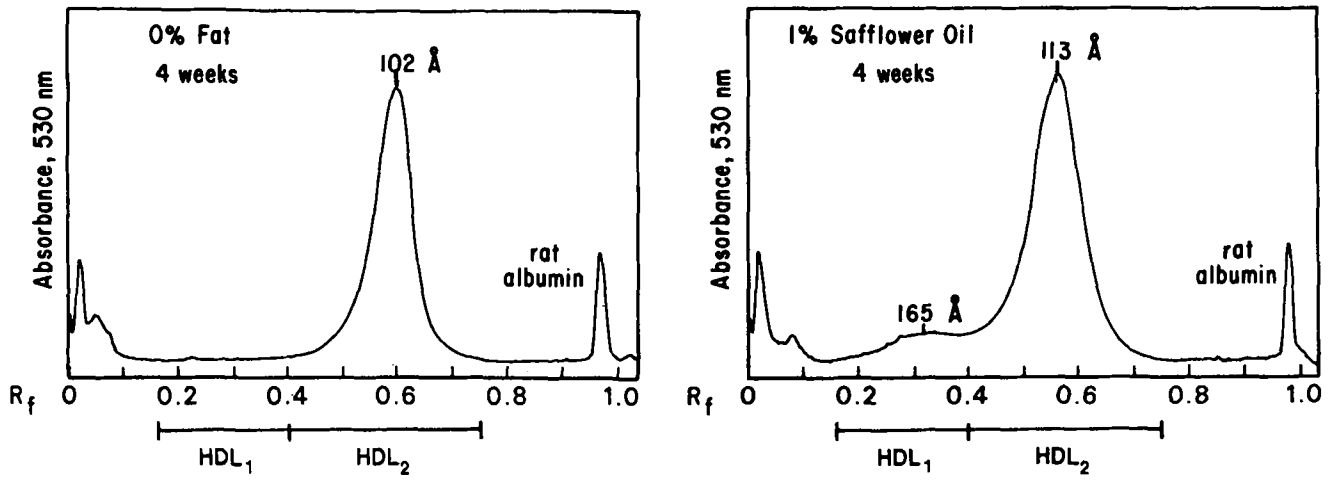

FIG. 3. Representative densitometric scans of 4-30% PAGGE of plasma HDL (d ≤ 1.20 g/ml fraction) from individual rats on an EFA-deficient 0% fat diet for four wk (left) compared with control (right).

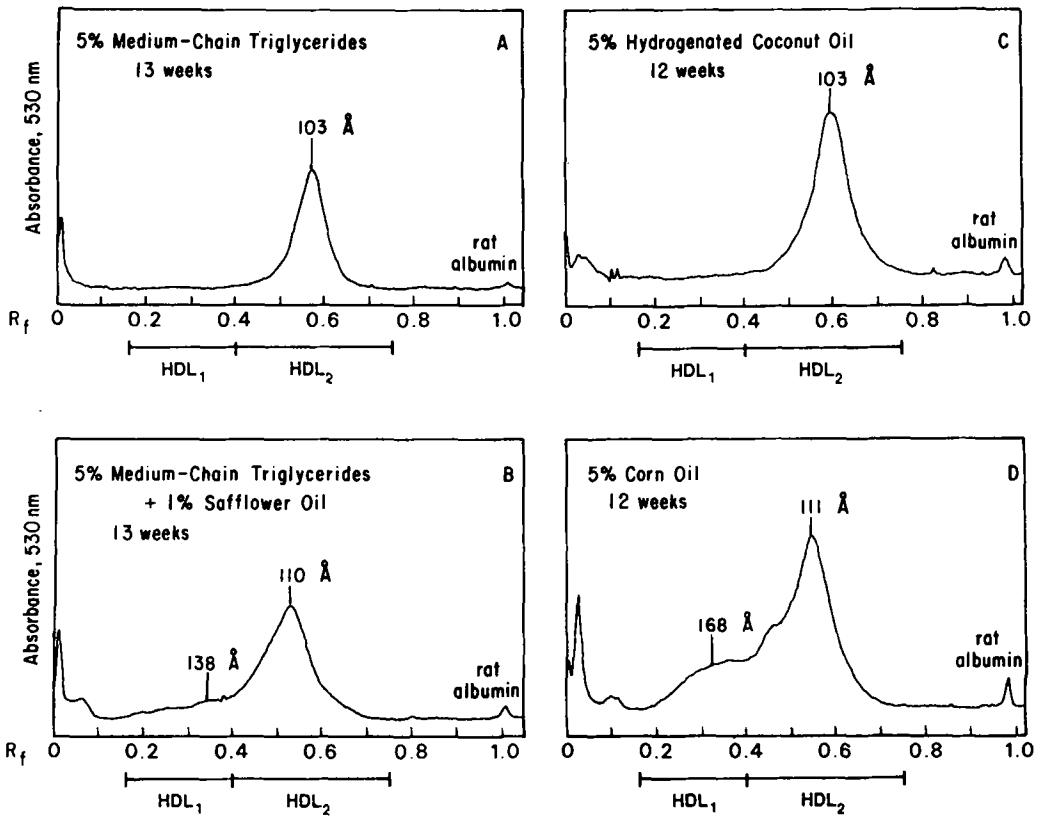

FIG. 4. Representative densitometric scans of 4-30% PAGGE of plasma HDL (d ≤ 1.20 g/ml fraction) from individual rats on a 5% medium-chain triglyceride oil (MCT) diet for 13 wk (A) or 5% HCNO for 12 wk (C) compared with EFA-adequate samples (B, D).

rats fed EFA-deficient and control diets for four wk or more. HDL patterns of rats fed control diets for four wk show significant amounts of material in the HDL_1 as well as in the HDL_2-size intervals. In contrast, the HDL patterns of EFA-deficient rats show a greater predominance of the HDL_2 species and very little material in the HDL_1 interval. The VLDL and LDL patterns of EFA-deficient rats, as evaluated by PAGGE on 2–16% gels (not shown), were very similar to those of EFA-supplemented rats.

A more quantitative evaluation of the 4–30% PAGGE tracings is given in Table 2, which shows the percent contribution of HDL_1 and HDL_2 to the total HDL pattern after three, four or eight weeks of feeding the test diets. In the EFA-deficient groups, the contribution of HDL_1

[d]Twelve wk on diet.

to the HDL pattern is only half (7–10%) that observed in the corresponding control groups (15–21%). These differences are statistically significant. The proportion of HDL_1 to total HDL in the fat-free diet group (7.0% of HDL pattern area) is similar to the HDL_1 proportions in the EFA-depleted 5% HCNO and 5% HCSO diet groups (6.9% and 7.4% of HDL pattern area, respectively). Thus, this change results from EFA deficiency, not from fat deficiency.

Table 3 shows the mean particle diameter determined by 4–30% PAGGE at peak maximum of the HDL_2 subpopulation from deficient and control rats. In all of the deficient groups, the mean HDL_2 diameter ranges from 100.0 to 102.9 Å. These values are significantly smaller (by 6–11 Å) than the mean diameters of the HDL_2 for the corresponding control groups.

In certain of the dietary studies, HDL were isolated in the density range of d 1.04–1.20 g/ml in order to reduce any contribution of LDL to the large particle end of the HDL pattern. Figure 5 shows the PAGGE distribution of the d 1.04–1.20 g/ml lipoproteins from rats fed the 5% HCNO diet and the 5% HCNO + 1% SAFF diet for three and four weeks. In comparison with controls fed the 5% HCNO + 1% SAFF diet, the changes in HDL subpopulation distribution and particle diameter in this density fraction from EFA-deficient rats are similar to the changes observed with the d ⩽ 1.20 g/ml lipoproteins (Tables 2 and 3). The changes in the d 1.04–1.20 g/ml fraction were evident in rats fed the 5% HCNO diet for only three wk (samples from individual rats) and were more pronounced after four wk (pooled plasma samples).

Plasma apolipoproteins separated by SDS-PAGE. Figures 6 and 7 show SDS-PAGE tube gels and densitometric tracings for the apoproteins of the total plasma

TABLE 4

Percentage of Contribution of Major Plasma Apolipoproteins to SDS-PAGE Profiles*

Diet (4 wk)	apoE	apoA-I	apoA-IV
	as % of scanning units (apoE + apoA-I + apoA-IV)		
1% SAFF	23.5	69.7	6.9
0% FAT	3.8	91.3	4.9
5% HCNO + 1% SAFF	17.2	75.0	7.8
5% HCNO	5.9	85.4	8.7

*Determined by analysis of 10% polyacrylamide-1% SDS tube gels (Fig. 6).

lipoprotein d ⩽ 1.20 g/ml fraction from individual rats fed the fat-free diet, the 1% SAFF diet, the 5% HCNO diet and the 5% HCNO + 1% SAFF diet. The proportion of apoE (expressed as % of the sum of the areas of the apoA-I, apoA-IV and apoE peaks) in the total lipoprotein fraction from EFA-deficient rats is only one-third to one-sixth that of the EFA-supplemented rats (Table 4). This decrease in apoE is consistent with the decreases in both the HDL_1 subpopulation, in which apoE is a major component (1, 7, 8), and the plasma triglyceride concentration in EFA-deficient rats (12,24). Correspondingly, the

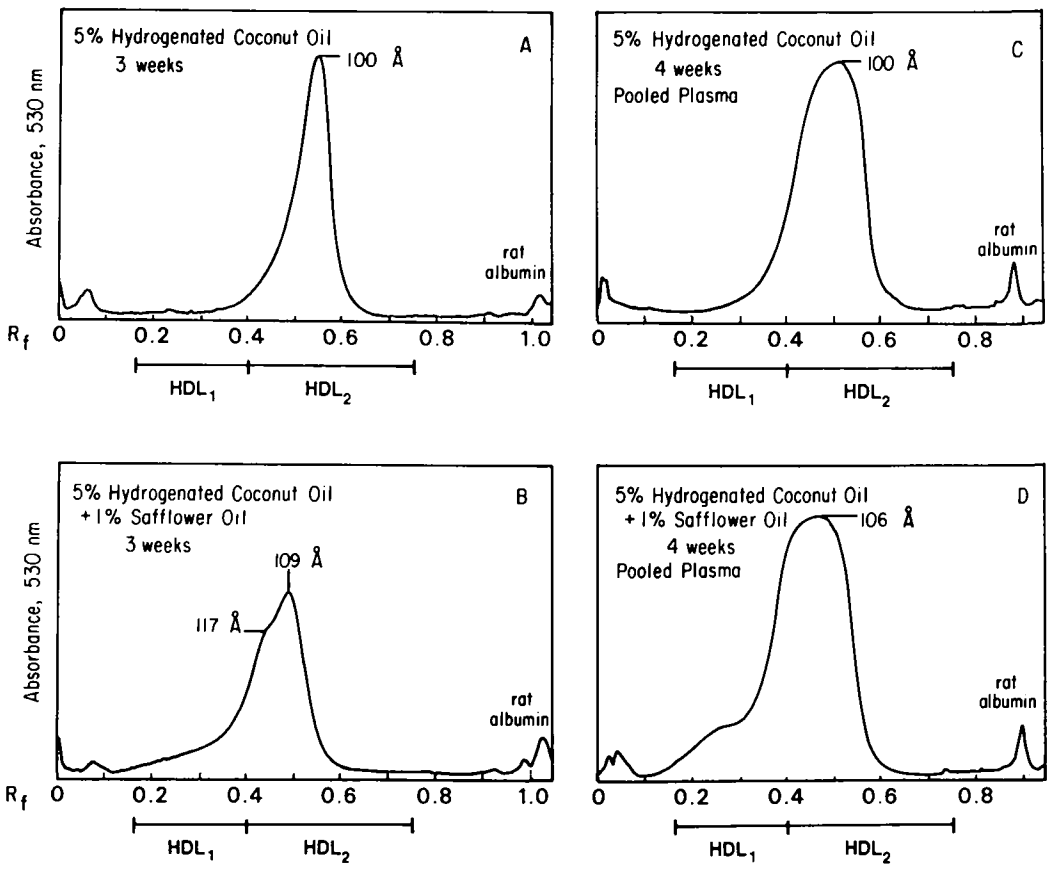

FIG. 5. Representative densitometric scans of 4–30% PAGGE of plasma HDL (d 1.04–1.20 g/ml fraction) from individual rats (A, B) on an EFA-deficient diet (5% HCNO) or control diet after three wk. Scans of HDL from plasma pooled equally from four rats of the same diet groups are shown in C and D.

proportion of the apoA-I peak is greater in samples from EFA-deficient rats than from their corresponding controls. Lastly, the proportion of the apoA-IV band is somewhat greater with the fat-containing diets than with the fat-free diet, an expected result if synthesis of apoA-IV is stimulated by fat feeding (25).

DISCUSSION

Changes in distribution and size of HDL subpopulations. We conclude that the changes in particle size distributions of HDL subpopulations in the EFA-deficient rats are due to a lack of EFA and not to a lack of dietary fat. The changes in particle size distribution also appear independent of the type of saturated fat in the diet, because the effects of EFA-deficiency were similar with diets supplying long chain saturated fatty acids (HCSO) or medium chain fatty acids (HCNO and MCT). All EFA-deficient groups showed a pronounced decrease in the proportion of the HDL_1 subpopulation and a decreased particle diameter of the main peak of the HDL_2 subpopulation in comparison with controls fed the same diet + 1% safflower oil. Furthermore, the distribution and size of the HDL subpopulations were similar in the EFA-deficient groups fed the fat-free diet and in those fed the diets containing 5% saturated fats.

Because the HDL subpopulation distribution and particle size were similar between the fat-free diet group and the groups fed the 5% saturated fat diets, we consider it unlikely that the difference between the control and EFA-deficient groups in HDL subpopulation distribution and particle size resulted from the slightly higher (1%) level of total fat in the control diets, rather than from the presence of EFA. In planning our experiments, we considered it more important to have the same amount of saturated fat in all the deficient and control diets because of evidence that saturated fat increases the need for EFA (26–28). Therefore, in preparing control diets we chose to add 1% safflower oil to the EFA-deficient diets containing 5% saturated fat rather than to maintain a constant total fat level by reducing saturated fat to 4%.

We extended the diet period from four wk to longer periods to test the effects of more pronounced EFA depletion and/or age. We found no additional decreases in the particle size of the HDL_2 subpopulation after eight wk depletion or more (12 and 13 wk, data not shown), despite the somewhat greater tissue EFA depletion (17). EFA depletion for eight wk or even longer generally is used in studies of EFA deficiency in rats to maximize tissue EFA depletion (12,29,30). However, even two weeks of EFA depletion will produce large changes in plasma and liver EFA in young rats (31–33). Thus, if distribution of HDL subpopulations depends on availability of EFA, then it is likely that changes in HDL subpopulation distribution should appear after EFA-depletion periods of two weeks or less. Evidence for such changes has recently been obtained (34).

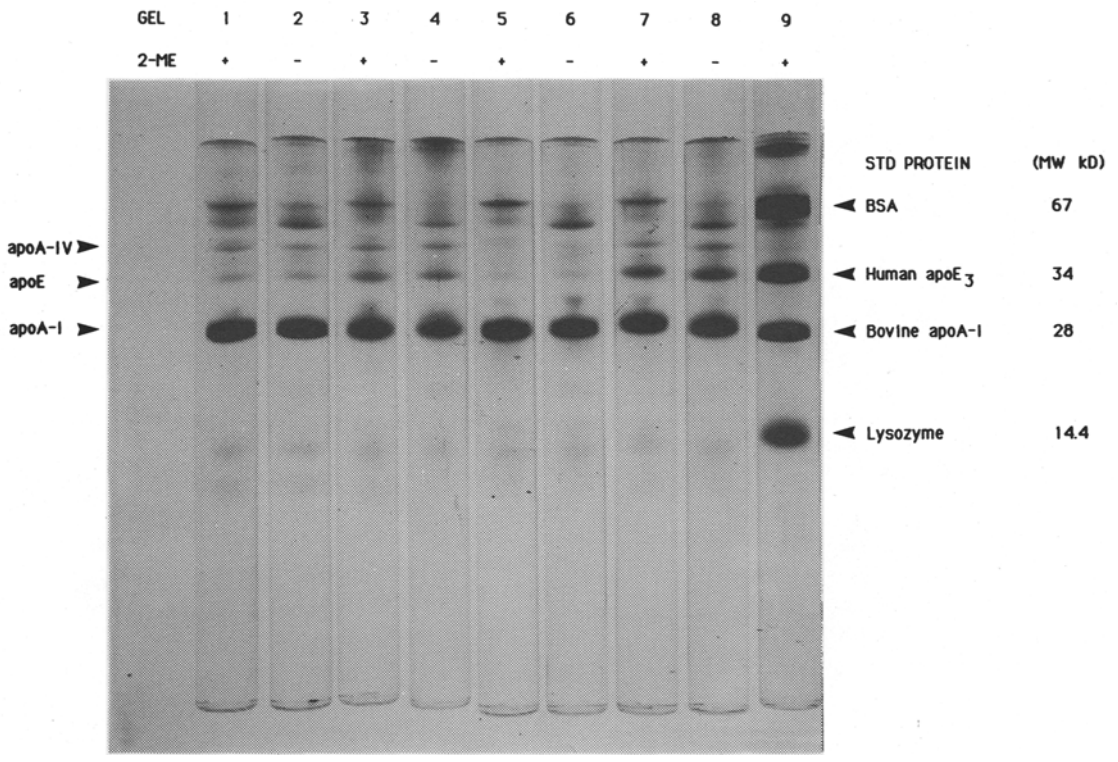

FIG. 6. 10% PAGE-1% SDS tube gels. Rat plasma lipoproteins (d ≤ 1.20 g/ml fraction) were denatured in the presence (+) or absence (−) of 2-mercaptoethanol. Gels 1–8 contain 30 μg protein. Gel 9 contains 55 μg standard protein mixture. 1,2: 5% HCNO diet, four wk. 3,4: (controls) 5% HCNO + 1% SAFF, four wk. 5,6: 0% FAT, four wk. 7,8: (controls) 1% SAFF, four wk.

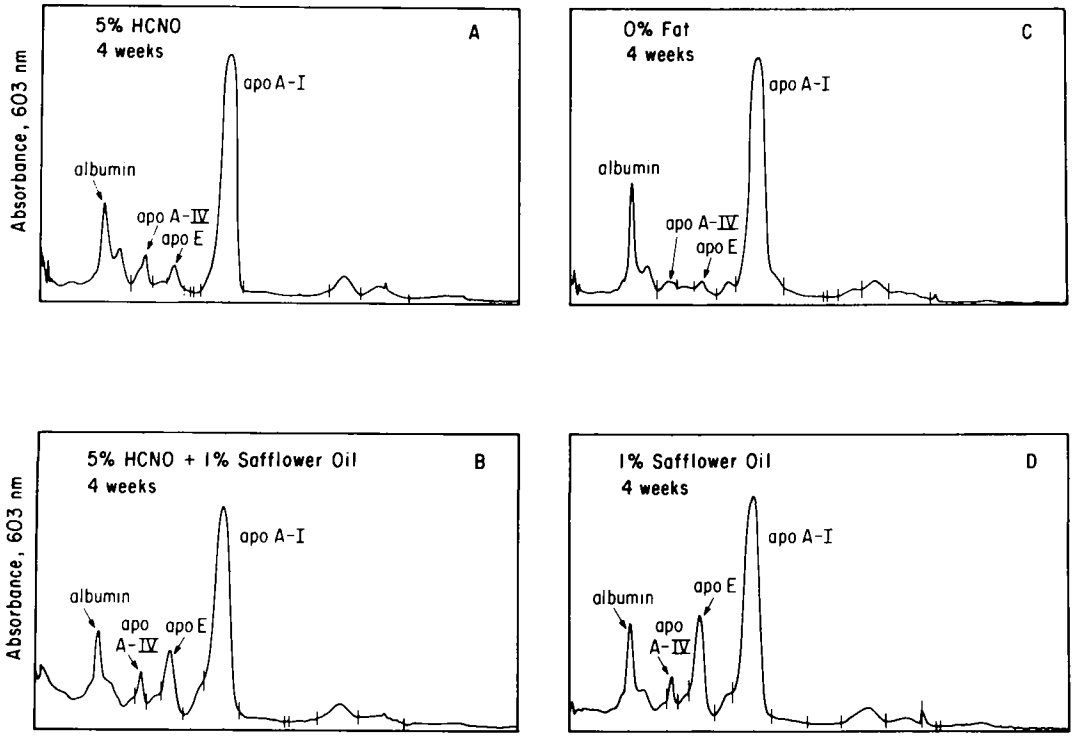

FIG. 7. Densitometric scans of rat plasma apolipoproteins (d ≤ 1.20 g/ml fraction) electrophoresed through 10% PAGE-1% SDS tube gels (see Fig. 6). A (gel 1): 5% HCNO four-week diet. B (gel 3): 5% HCNO + 1% SAFF four-wk control. C (gel 5): 0% FAT four-wk diet. D (gel 7): 1% SAFF four-wk control.

The mean diameter of particles in the HDL_2 subpopulation did not change between four and eight weeks in rats fed the control diets, except for the 5% HCSO + 1% SAFF group. However, with the latter group there was a considerable decrease between four and eight weeks in the mean HDL_2 diameter. This change cannot be attributed to lack of dietary EFA because a level of 1% safflower oil provides linoleate as ca. 1.5% of the food energy, a level that is 50% greater than the minimum EFA requirement. The adequacy of the linoleate intake of the 5% HCSO + 1% SAFF group also is supported by the fact that the levels of linoleate and arachidonate in liver phospholipids of this group are as high as in rats fed the 5% HCNO + 1% SAFF diet or the 5% corn oil diet (35). The size ranges of both the HDL_1 and the HDL_2 subpopulations in our control groups are very similar to values reported by Ha and coworkers, who used PAGGE to measure HDL particle size of rats fed a nonpurified diet (9).

Possible causes of the decrease in the HDL_1 subpopulation. The relative decrease in the HDL_1 subpopulation in the EFA-deficient groups could be caused by its reduced formation and/or increased removal. Reduced formation could occur because of decreased supply of potential precursor materials for HDL_1 production, e.g. VLDL surface components or the HDL_2 subpopulation (3). However, available evidence is not consistent with the possibility of reduced formation. In EFA-deficient rats, VLDL secretion and catabolism are increased, as indicated by increased plasma triglyceride secretion and catabolism (24), and plasma LCAT activity is also increased (29,36, 37). The amount of the HDL_2 subpopulation in deficient rats was similar to that in controls, as indicated by the PAGGE densitometric tracings of equivalent plasma volumes, although we have not made detailed analyses of the HDL subpopulations to determine the proportion and concentration of the lipid and protein components.

There is some evidence to support the possibility of more rapid removal of the HDL_1 subpopulation. This evidence includes increased hepatic uptake of radiolabeled plasma cholesterol (37) and increased concentrations of liver CE in EFA-deficient rats (24,35,38,39), despite decreased liver cholesterol synthesis in deficient rats (38,39). Increased liver CE, of course, could arise from other mechanisms, including increased hepatic ACAT activity (37), decreased biliary secretion of cholesterol and bile acids (40,41) or increased hepatic lipase activity (42,43). Hepatic ACAT activity is increased in EFA-deficient rats (37) but bile secretion and composition in EFA-deficient rats have not been tested critically (40). We have found no reports on hepatic triglyceride lipase activity in EFA-deficient rats. Yet, if hepatic lipase activity were increased in EFA deficiency, such an increase could result in greater transfer of cholesterol from HDL_1 to the liver, where HDL_1 cholesterol may be a preferred substrate for bile acid synthesis (44,45). The decreased hepatic cholesterol synthesis in EFA-deficient rats (38,39) also might lead to a compensatory increase in extrahepatic cholesterol synthesis (40) and reverse cholesterol transport (46). Future experiments should measure reverse cholesterol transport, hepatic triglyceride lipase activity, and biliary bile acid and cholesterol excretion as EFA deficiency develops. These measurements would show whether changes in these processes precede and lead to the increase in liver CE and the decrease in the HDL_1 subpopulation in EFA-deficient rats.

ACKNOWLEDGMENTS

We are indebted to J. Babiak, P. Blanche, R. Calendar, T. Forte, E. Gong, R. Nordhausen and J. Tinoco for their advice and assistance. B. Thomas and I. Hincenbergs provided superb animal care. Hydrogenated coconut oil was donated by California Fats and Oils (Richmond, CA); hydrogenated cottonseed oil by Wilsey Foods (San Francisco, CA); medium-chain triglycerides by Mead Johnson (Evansville, IN); and fat-free preparations of vitamins A, D and E by Sigma Chemical Co. (St. Louis, MO). This work was supported in part by grant NIH ROI AM12024 to M.A.W. and by NIH Program Project Grant HL 18574 from the National Heart, Lung, and Blood Institute of the National Institutes of Health to A.V.N. Support to K.E. Lowe was provided by NIH Training Grant GM07379-09.

[Received June 21, 1987; Revision accepted September 30, 1987]

Perfluoro-n-Decanoic Acid: Induction of Peroxisomal β-Oxidation by a Fatty Acid with Dioxin-like Toxicity

Earl H. Harrison*[a], J. Scott Lane[a], Scott Luking[a], Marc J. Van Rafelghem[b] and Melvin E. Andersen[b]
[a]Department of Biological Chemistry, Wright State University, School of Medicine, Dayton, OH, and [b]Toxic Hazards Division, Aerospace Medical Research Laboratory, Wright Patterson Air Force Base, OH

Perfluoro-n-decanoic acid (PFDA) produces toxic effects in rodents similar to those caused by 2,3,7,8-tetrachlorodibenzo-p-dioxin. A single, intraperitoneal dose (50 mg/kg) of PFDA to Sprague-Dawley rats caused disruption of the endoplasmic reticulum, mitochondrial swelling and increases in intracellular lipid droplets in hepatocytes similar to effects reported previously in dioxin toxicity. PFDA treatment led to large decreases in the activity of plasma membrane alkaline phosphodiesterase and mitochondrial cytochrome c oxidase without affecting lysosomal N-acetyl-β-glucoaminidase, endoplasmic reticulum NADPH-cytochrome c reductase or peroxisomal catalase activities. PFDA treatment led to moderate peroxisome proliferation and to very large (20–40-fold) increases in the activity of fatty acyl-CoA oxidase, the rate-limiting enzyme in the peroxisomal system of fatty acid β-oxidation.
Lipids 23, 115–119 (1988).

Perfluorocarboxylic acids and their derivatives are used commercially in applications that take advantage of their surfactant properties, chemical and thermal stabilities and antiwetting actions (1,2). In general, perfluorocarbons are considered to be metabolized very poorly and relatively nontoxic. Perfluoro-n-octanoic acid is moderately toxic with an oral LD50 in Sprague-Dawley rats of about 500 mg/kg (3). Perfluoro-n-decanoic acid (PFDA) is significantly more toxic than the octanoic derivative. The intraperitoneal LD50 in Fisher-344 rats for perfluoro-n-octanoic acid was 189 mg/kg, while that for PFDA was only 41 mg/kg (4,5). Rats dosed with perfluoro-n-octanoic acid died within five days. In contrast, PFDA produced toxic effects very similar to those caused by dioxin (2,3,7,8-tetrachlorodibenzo-p-dioxin). Similarities include delayed lethality, decreased food intake, thymic atrophy, bone marrow depression, hepatomegaly and disruption of hepatic architecture (4,5). PFDA differs from dioxin in that it causes severe testicular atrophy and necrosis, and it lacks the extreme species variability in toxic potency characteristic of dioxin. However, there are minor differences in PFDA toxicity between species and strains. For example, the intraperitoneal LD50 of PFDA in Fisher-344 rats is 41 mg/kg and in Sprague-Dawley rats is about 75 mg/kg.

Ultrastructural observations on liver of rats and mice treated with a single dose of PFDA near the LD50 demonstrated peroxisomal proliferation (7). Other agents that induce peroxisomes include the hypolipidemic drug clofibrate, its structural analogs, other hypolipidemic agents structurally unrelated to clofibrate, phthalate esters and acetylsalicylic acid (8). The effects of these compounds on peroxisome proliferation have been assessed by morphological analysis (increase in the number and volume of peroxisomes) or by biochemical analysis (increase in the activity of one or more peroxisomal enzymes). Quantitatively, the two measures of response are not well-correlated. Increases in catalase, the major peroxisomal enzyme, disproportionately may be smaller than the increase in peroxisomal volume. On the other hand, certain peroxisomal enzymes are induced to a much greater extent than catalase. The enzymes of the peroxisomal β-oxidation system are induced readily (8). For example, clofibrate treatment of female rats or bezafibrate treatment of male rats led to large elevations of the peroxisomal fatty acid oxidizing system with no increase in catalase activity and only a slight increase in peroxisomal volume (9).

To examine the hepatic responses to PFDA more completely, we have studied its effects on the activities of a number of liver enzymes and on ultrastructure in male Sprague-Dawley rats. We show here that a single dose of PFDA leads to moderate peroxisome proliferation and causes other morphological effects similar to some of those seen in dioxin toxicity. Biochemically, the most striking effect of PFDA was a very large (20- to 40-fold) increase in peroxisomal fatty acyl-CoA oxidase activity. Thus, perfluoro-n-decanoic acid appears to be the most potent inducer of peroxisomal β-oxidation yet described.

EXPERIMENTAL

Animals and materials. Male, weanling Sprague-Dawley rats were obtained from Harlan Industries (Indianapolis, IN). Rats were housed in individual plastic cages and had free access to water and a commercial, pelleted rat diet. PFDA (nonadecafluorodecanoic acid) was from Aldrich Chemical Co. (Milwaukee, WI). Fatty acyl-CoAs were obtained from P-L Biochemicals (Milwaukee, WI). Other enzyme substrates were from Sigma Chemical Co. (St. Louis, MO).

Biochemical methods. Peroxisomal fatty acyl-coenzyme A oxidase activity was assayed as described (10) using 35 μM palmitoyl-CoA as a substrate. The methods used in the assay of the other enzymes are given in previous publications (10,11). All enzyme assays were conducted on freshly prepared homogenates and were carried out under conditions such that product formation was proportional to the amount of enzyme-containing sample.

Protein was assayed by the method of Lowry et al. (12), and DNA was assayed by the fluorescent dye-binding method of LaBarca and Paigen (13).

Electron microscopy. Sections were dissected from the dorsal caudate lobe of the liver and immediately transferred into a petri dish containing 2.5% glutaraldehyde and 2% formaldehyde fixitive in 0.1 M cacodylate buffer (pH 7.4) in which they were sectioned into small blocks ca. 1 mm cubes. Approximately 20 blocks/animal were placed in small vials containing fixitive. After fixation, they were

Abbreviation: PFDA, perfluoro-n-decanoic.

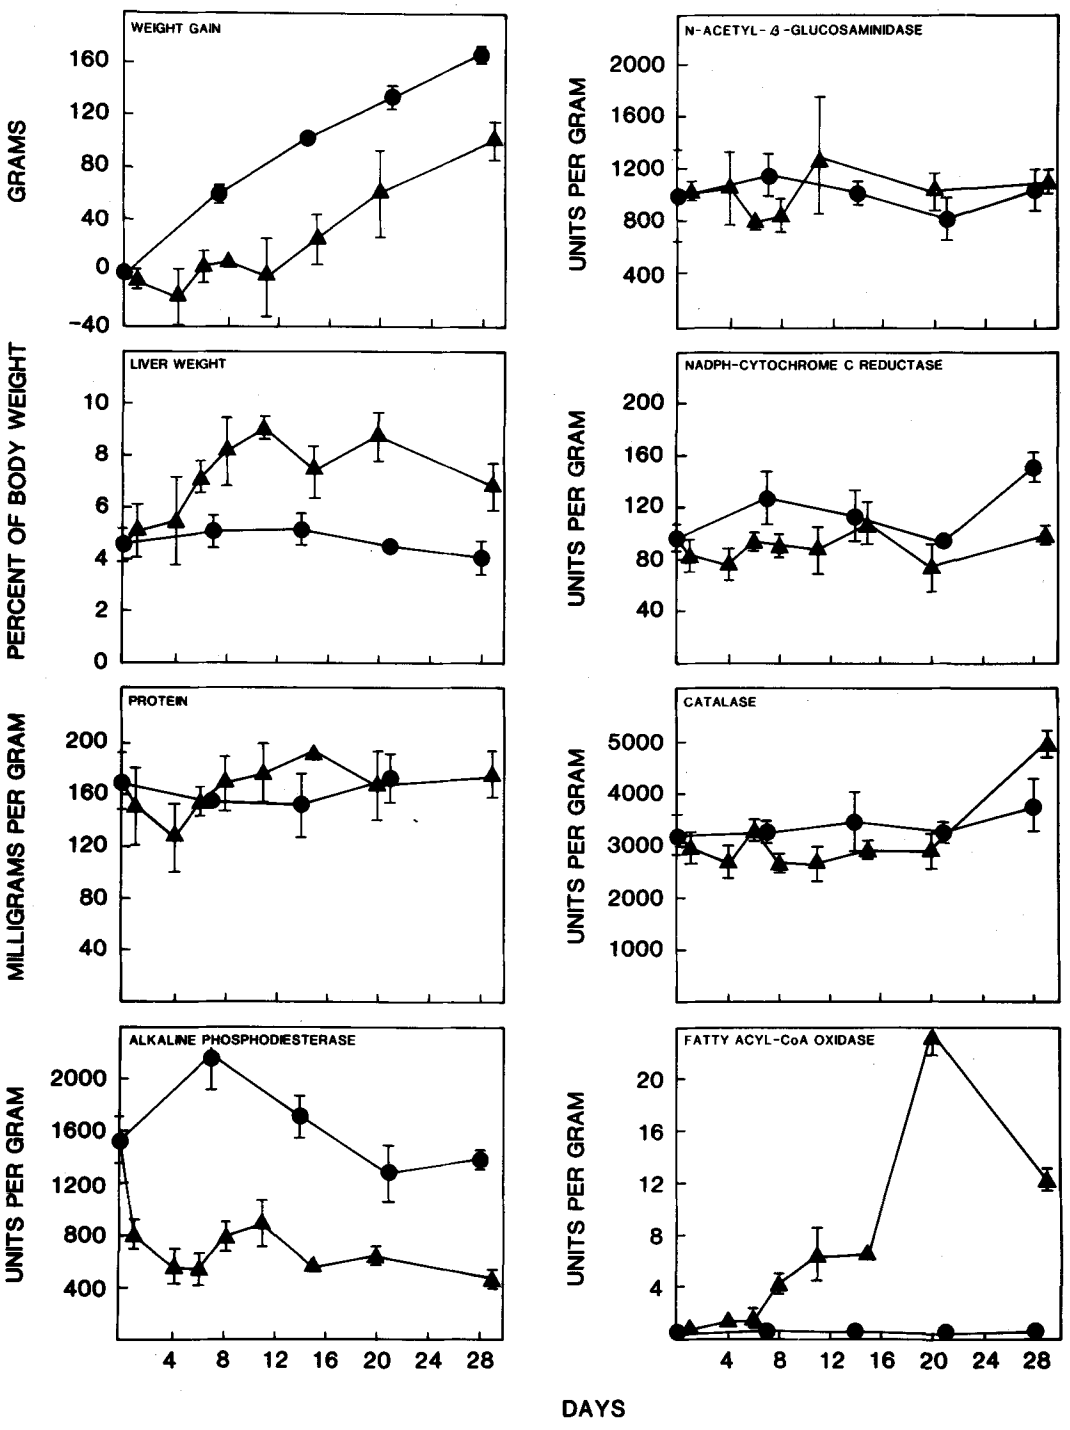

FIG. 1. Effects of a single dose of perfluoro-n-decanoic acid (PFDA) (50 mg/kg) on weight gain, liver weight, and hepatic protein and enzyme contents of male Sprague-Dawley rats. Rats were given a single intraperitoneal dose of PFDA dissolved in propylene glycol (triangles) or the vehicle alone (circles). At each indicated point, three animals were studied. Data are presented as means ± standard deviation for each parameter. Activity of fatty acyl-CoA oxidase is given in units of μmol/min and the activities of other enzymes in arbitrary units of absorbance or change in absorbance under the assay conditions employed.

post-fixed in 2% osmium tetroxide, dehydrated in graded alcohols and embedded in Epon 812. Representative thick sections (1 μm) from at least three tissue blocks per animal were mounted on glass slides, stained with toluidine blue and screened by light microscopy to determine areas for thin sectioning. Thin sections (80 nm) were prepared, stained with lead citrate and uranyl acetate, and photographed on a JEOL 100B electron microscope at three different magnifications.

Animal experiments. In experiment 1, rats weighing 150–200 g were given a single intraperitoneal injection of PFDA (50 mg/kg) dissolved in propylene glycol

(approx. 0.4 ml). Note that this dose of PFDA is approximately two-thirds of the LD50 for the Sprague-Dawley rat. Groups of three rats were killed by ether overdose on day 1, 4, 6, 8, 11, 15, 20 or 29. Control rats given the vehicle alone were killed in groups of three on day 0, 7, 12, 21 or 28. One of the 24 PFDA-treated rats died before the scheduled time of death. Livers were removed, weighed and homogenized in four volumes of 0.25 M sucrose containing 1 mM EDTA and 0.1% ethanol using a Polytron homogenizer. Homogenates then were assayed for total protein and for the following enzymes localized in the indicated subcellular organelles (14–16): catalase and fatty acyl-CoA oxidase (peroxisomes), alkaline phosphodiesterase (plasma membrane), NADPH-cytochrome c reductase (endoplasmic reticulum), and N-acetyl-β-glucosaminidase (lysosomes).

In experiment 2, 36 rats weighing 180–215 g were injected with PFDA as described above and studied on the days indicated in Figure 2. Nine control rats received the vehicle alone. No rats died before the scheduled time of death. At each time point, the rats were weighed, and their livers were removed and weighed. After dissection of small samples for morphological analysis, the remaining liver was homogenized as described above. The homogenates were then assayed for protein, DNA, cytochrome oxidase (mitochondria) and fatty acyl-CoA oxidase.

RESULTS AND DISCUSSION

In experiment 1 (Fig. 1), PFDA-treated rats showed an immediate cessation of growth persisting for about two weeks, after which body weight increased in parallel with the controls. Liver to body weight ratio of the treated rats increased to twice that of controls and remained elevated throughout the four-week experiment. Neither liver protein nor the activities of NADPH-cytochrome c reductase, catalase or N-acetyl-β-glucosaminidase were affected substantially by PFDA treatment. However, fatty acyl-CoA oxidase activity increased 20- to 40-fold over the controls and was maximal at three to four weeks after dosing. Alkaline phosphodiesterase activity rapidly fell to about 50% of control values and remained depressed thereafter. In experiment 2 (Fig. 2), PFDA treatment again caused cessation of growth and hepatomegaly. Concomitant with the increase in relative liver size was an increase in total hepatic DNA. Hypolipidemic agents (such as nafenopin, tibric acid, WY-14,643, and BR-931) cause an increase in total DNA as part of a primary mitogenic response that in part accounts for the liver growth (17–19). With PFDA, the etiology of the observed increase in DNA is unknown. PFDA treatment also markedly reduced mitochondrial cytochrome oxidase activity. However, as in experiment 1 the most dramatic effect of PFDA was a large increase in the activity of peroxisomal fatty acyl-CoA oxidase. The changes in hepatic enzymes caused by PFDA treatment persisted for as long as 50 days after a single dose (Fig. 2).

The morphological results obtained in experiment 2 are shown in Figs. 3–6. Hepatocytes of PFDA-treated rats at four days after dosing showed severe disruption of the endoplasmic reticulum and dilution of the cytoplasmic matrix (Fig. 4). Mitochondria were essentially normal at

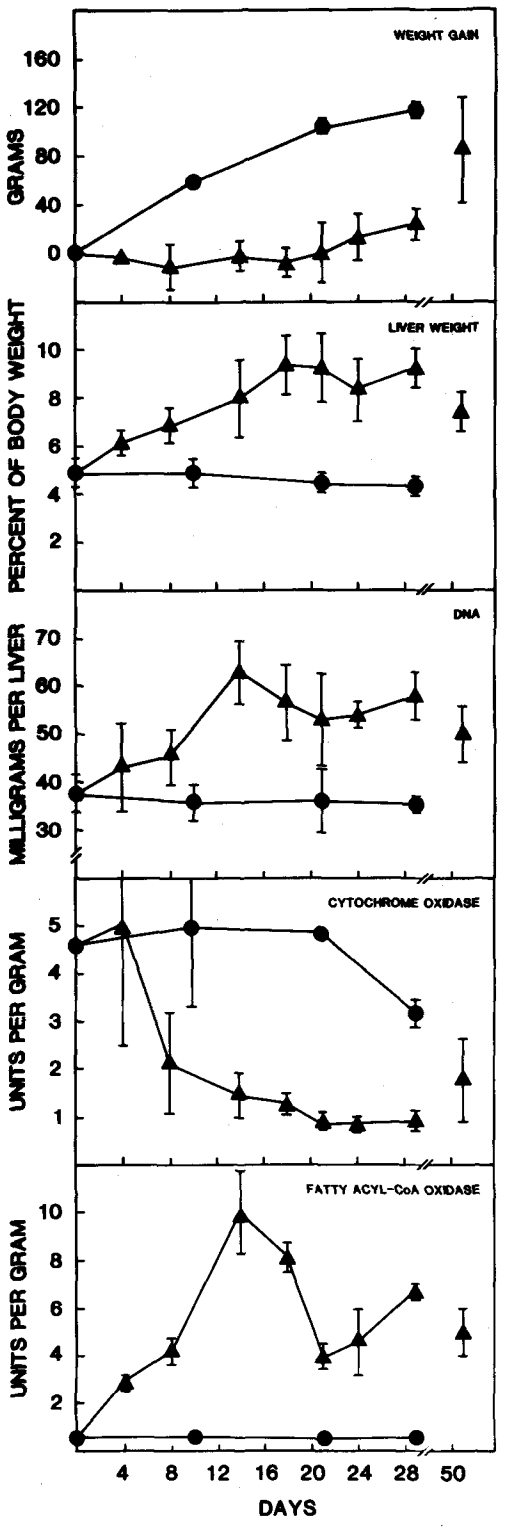

FIG. 2. Effects of a single dose of perfluoro-n-decanoic acid (PFDA) (50 mg/kg) on weight gain, liver weight, and hepatic content of DNA, fatty acyl-CoA oxidase and cytochrome oxidase in male Sprague-Dawley rats. Rats were given a single, intraperitoneal dose of PFDA dissolved in propylene glycol (triangles) or the vehicle alone (circles). At the days indicated, three (days 29 and 51) or five (days 4, 8, 14, 17, 21 and 24) dosed rats and two (days 10, 21 and 29) or three (day 0) control rats were studied. Data are presented as the mean ± standard deviation for each parameter. Activity of fatty acyl-CoA oxidase is given in units of μmol/min and that of cytochrome oxidase in the units previously described (10,11).

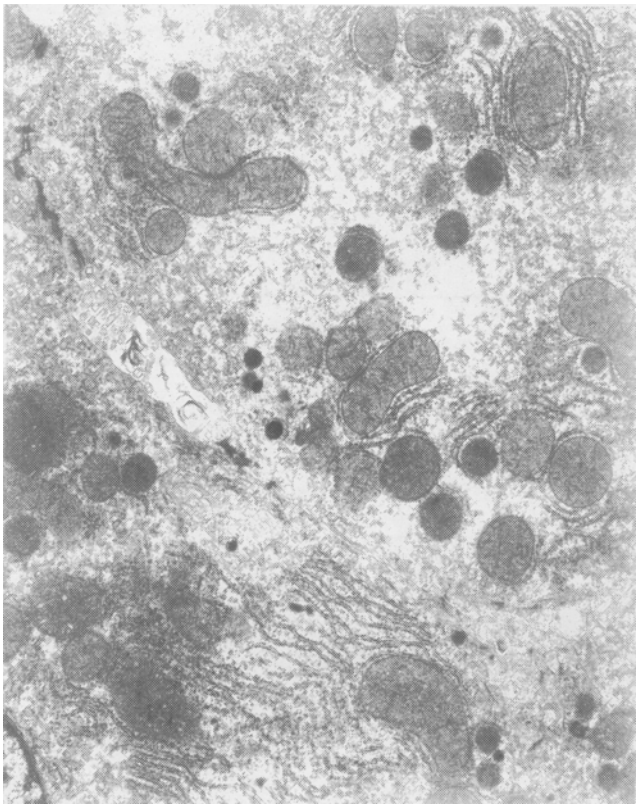

FIG. 3. Ultrastructure of the liver of a control rat (day 0). Note the organization of the cytoplasm and the normal appearance of the mitochondria. A well-developed endoplasmic reticulum particularly is evident at the bottom and upper-right of the field shown. More darkly staining peroxisomes with a dense core are also seen (as, for example, the four dark bodies in the upper-right of the field). Magnification is 8600×.

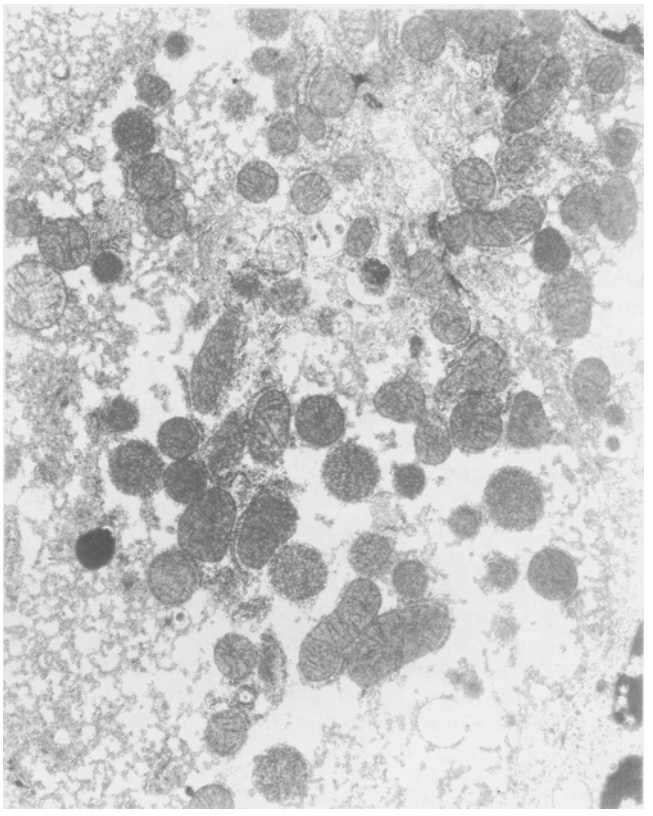

FIG. 4. Ultrastructure of the liver of a PFDA-treated rat (day 4). Note the dilution of the cytoplasmic matrix and the loss on a well-defined endoplasmic reticulum. Mitochondria appear normal. Magnification is 8600×.

this time. At days 14 (Fig. 5), 21 (Fig. 6) and 29 after dosing, the cytoplasmic alterations observed at day 4 remained unresolved. Mitochondria now were swollen, rounded and had lost their cristae. Marked accumulation of cytoplasmic lipid droplets also was observed. Peroxisome proliferation was moderate. In addition, larger, multiple nucleoli were observed in many of the hepatocyte nuclei of PFDA-treated rats. Although the hepatocytes of PFDA-treated rats at days 14 and 21 appear almost necrotic, these animals were not moribund, and most of the treated rats recovered from this dose of PFDA.

With clofibrate, doses from 200–500 mg/kg/day are administered daily for one to three weeks to achieve about a 10-fold induction of fatty acyl-CoA oxidase (8,9). Even for the more potent hypolipidemic drugs, such as bezafibrate, seven daily doses from 25 to 75 mg/kg led to only three- to four-fold increases in hepatic fatty acyl-CoA oxidase activity. With PFDA, a single dose of only 50 mg/kg leads to very large (20- to 40-fold) increases in activity that persist for as long as 50 days after dosing. To our knowledge, PFDA is the most potent inducer of peroxisomal β-oxidation yet described.

The mechanism of fatty acyl-CoA oxidase induction by PFDA is not known. We do know that the compound accumulates in liver (20) but a more complete description of its tissue distribution and pharmacokinetics awaits the completion of studies currently in progress. PFDA is metabolized to constituents more polar than the parent compound (20), and hence it may affect cellular membranes. We also have found that PFDA is an inhibitor of fatty acyl-CoA oxidase activity when added to the in vitro reaction mixture, and it is more potent in this regard than n-decanoic acid is.

While the toxic effects of PFDA resemble those of dioxin, to our knowledge dioxin does not cause peroxisome proliferation or induction of peroxisomal enzymes. However, dioxin does cause other profound changes in hepatic ultrastructure and liver enzymes when administered to rats and mice (21–23). Major ultrastructural changes include proliferation of the endoplasmic reticulum, swelling of mitochondria, increases in the number of autophagic vacuoles and lipid droplets, and loss of continuity of the plasma membrane. Biochemical correlates of these changes include induction of aryl hydrocarbon hydroxylase and a variety of cytochrome P-450 isozymes, increased microsomal lipid peroxidation and reduction in the activity of several plasma membrane enzymes. Thus, some of the effects of dioxin on the liver resemble those that we report here for PFDA, and others do not. Further comparative study of the effects of these two compounds at the cellular and biochemical level may shed light on their respective mechanisms of liver toxicity.

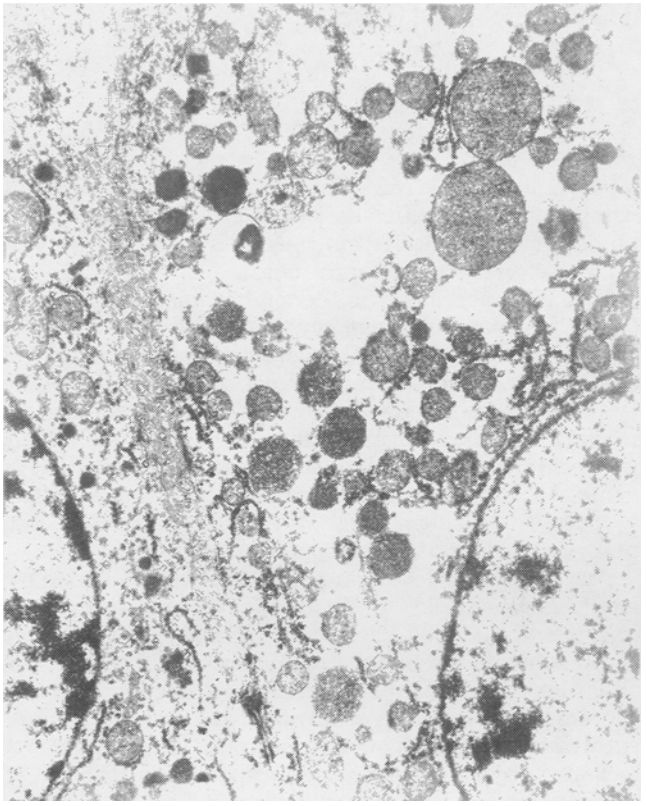

FIG. 5. Ultrastructure of the liver of a PFDA-treated rat (day 14). Cytoplasmic alterations seen on day 4 remained unchanged. In addition, the mitochondria now are swollen and rounded and have lost their cristae (see, for example, the two round, granular bodies in the upper right of the field). Smaller, more darkly staining peroxisomes also are observed. Note also parts of two clear areas in the extreme upper right that represent cytoplasmic lipid droplets. Magnification is 8600×.

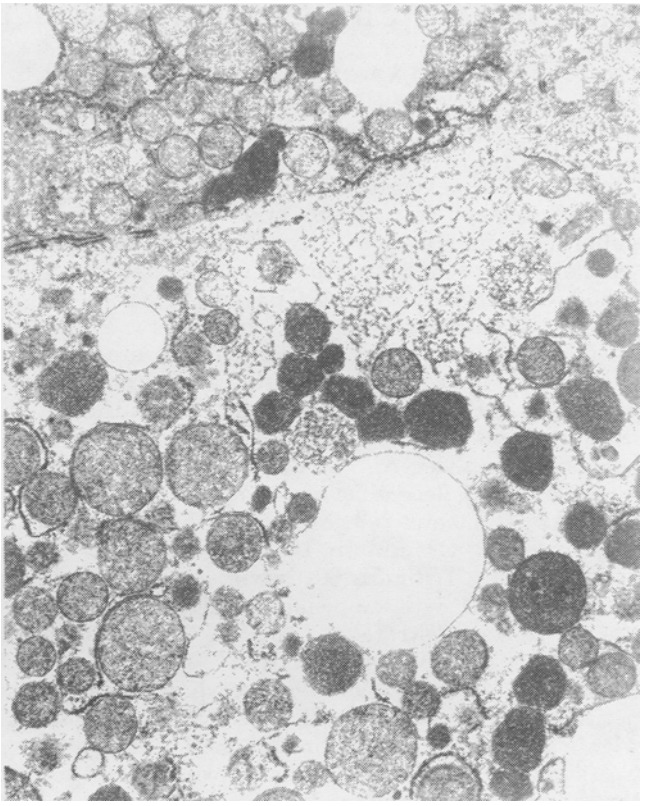

FIG. 6. Ultrastructure of the liver of a PFDA-treated rat (day 21). Mitochondrial and cytoplasmic alterations seen earlier remain unchanged. Note the presence of large lipid droplets (clear, round areas in cytoplasm) and numbers of darkly staining peroxisomes, some of which appear in clusters (center and lower right of the field). Magnification is 8600×.

Effects of Octylglucoside and Triton X-100 on the Kinetics and Specificity of Carnitine Palmitoyltransferase

Carol J. Fiol and **Loran L. Bieber***
Biochemistry Department, Michigan State University, East Lansing, MI 48824

The effects of octylglucoside on the substrate specificity, kinetics and aggregation state of purified carnitine palmitoyltransferase (CPT) from beef heart mitochondria were investigated and compared to the effects of Triton X-100. Conditions in which CPT can be assayed in the absence of micelles and albumin, thereby eliminating miceller effects on the kinetic parameters, are described. When octylglucoside is substituted for Triton X-100, the specificity of CPT in the forward direction shifts towards the long-chain acyl-CoAs, and large changes in the kinetic constants are observed. The $K_{0.5}$ for L-carnitine varied as much as 50-fold, depending on the acyl-CoA and detergent used. At pH 8.0 and 200 μM palmitoyl-CoA, the $K_{0.5}$ for L-carnitine is 4.9 mM in 12 mM octylglucoside and 0.2 mM in 0.1% Triton X-100. Octylglucoside enhances the activity of CPT with long-chain acyl-CoA and lowers the $K_{0.5}$ for these substrates. At pH 6.0, the $K_{0.5}$ for palmitoyl-CoA is 24.2 μM in 0.1% Triton X-100, in contrast to 3.1 μM in 12 mM octylglucoside. Octylglucoside is a competitive inhibitor of CPT with octanoyl-CoA as substrate with a K_i of 15 mM. Nonlinear kinetics for both acyl-CoAs and L-carnitine are observed when the concentration of octylglucoside is reduced to less than half of its critical micellar concentration (cmc). Gel filtration of CPT in octylglucoside below its cmc gives a single protein peak with a molecular mass of ca. 660,000 daltons. These data indicate that the catalytically active form of purified CPT is an aggregate that has quaternary structure and must have a very flexible catalytic site whose affinity for substrate and catalytic efficiency can be altered greatly by changes in environment and experimental conditions. *Lipids 23,* 120–125 (1988).

The acyl-CoA specificity of carnitine acyltransferases has been used to designate short- (acetyl), medium- (octanoyl) and long- (palmitoyl) chain acyltransferases (1,2). However, the substrate specificity profile of carnitine palmitoyltransferase (CPT) from beef heart mitochondria in the reverse direction (formation of acyl-CoA) is affected by micelles of either substrate or nonionic detergent (3). Therefore, the choice of experimental conditions for the determination of these profiles can greatly influence the results. Undoubtedly, this is a major factor in the large differences in the data from different laboratories reporting on the same enzyme (1). For example, Kopec and Fritz (4) reported relative rates of 2, 31 and 100% for octanoyl-, lauryl-, and palmitoylcarnitine esters using purified calf liver mitochondrial CPT, while West et al. (5) reported relative rates of 93, 152 and 100% for the same substrates using partially purified ox liver CPT. Clarke and Bieber (3) duplicated the different specificity profiles by varying the experimental conditions.

CPT from beef heart mitochondria has a high activity (V_{max}) for medium-chain acyl moieties in the forward direction but it shows a higher activity with long-chain acyl moieties in the reverse direction (6). Such specificity patterns have been attributed to increased substrate inhibition at the L-carnitine site, as the length of the acyl group increases (7,8). It has been proposed that detergents that activate the enzyme, such as Triton X-100 and (+)palmitoylcarnitine (9), prevent the acyl-CoA competitive binding at the L-carnitine site.

Previously, we determined the kinetics of purified beef heart mitochondrial CPT in micellar concentration (0.1%) of Triton X-100 (10). These data showed that the affinity of the enzyme for L-carnitine depends on the acyl-CoA chain length, namely a decrease in the chain-length of the acyl-CoA logarithmically increases the $K_{0.5}$ for L-carnitine. Thus, the concentration of L-carnitine can affect the "physiological substrate specificity" (11) of CPT and high activity with medium-chain acyl-CoA only occurs at high L-carnitine concentrations. The previous studies did not provide information about the effect of different environments, i.e. detergents, on the kinetic behavior of CPT. In these studies, the acyl-CoA specificity, substrate kinetics and aggregation state of CPT in the absence of detergent micelles in 12 mM octylglucoside have been determined.

EXPERIMENTAL PROCEDURES

Enzyme purification and detergent exchange. CPT was purified from beef heart mitochondria as described (10). Cibacron Blue Sepharose chromatography, the final step in the purification, also was used to exchange octylglucoside for Triton X-100 as follows. The concentration of Triton X-100 in the equilibrating buffer for the Cibacron Blue Sepharose column was reduced to 0.002%. After loading the partially purified enzyme, the column was washed with one bed volume of buffer in 0.002% Triton X-100 followed by three to five bed volumes of buffer in 25 mM octylglucoside. The enzyme was eluted by increasing the ionic strength of the buffer in 25 mM octylglucoside as described previously (10). The concentration of octylglucoside in the eluted enzyme was reduced to 12 mM by dialysis.

Determination of micelle formation. The formation of micelles was monitored by addition of either acyl-CoA or octylglucoside to a cuvette containing the assay media and 4 μM pinacyanol chloride. Formation of micelles is observed by a change in the extinction coefficient of the dye at 610 nm (12). This method was chosen over others because it gives the lowest estimates of critical micellar concentrations (cmc) for the acyl-CoAs.

Molecular weight determination. A 50 × 1.5 cm Fractogel TSK HW-55 column was equilibrated with buffer

Abbreviations: Bis Tris Propane, 1,3-bis[tris(hydroxymethyl)-methylamino]propane; cmc, critical micellar concentration; CPT, carnitine palmitoyltransferase; DTBP, 4, 4′-dithiobis-pyridine; DTNB, 5,5′-dithiobis-(2-nitrobenzoic acid); EDTA, ethylenediamine tetraacetic acid; Hepes, 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid.

containing 2.5 mM 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (Hepes), 0.25 mM ethylenediamine tetraacetic acid (EDTA), 300 MM KCl and 12 mM octylglucoside at pH 8.0. The column was calibrated using 10 mg/ml each of ovalbumin, BSA, aldolase, thyroglobulin and 1 mg/ml of ferritin. One unit of purified CPT was loaded, and 0.3 ml fractions were collected.

Assay methods. CPT activity was measured with the 5,5′-dithiobis-(2-nitrobenzoic acid) (DTNB) continuous rate assay as described (13). Kinetic measurements with purified CPT were made as described (10). The 2.0 ml reaction volume contained 50 mM 1,3-bis[tris(hydroxylmethyl)-methylamino]propane (Bis Tris Propane) buffer pH 6 or 8, 1.1 mM EDTA, 150 μM DTNB for pH 8 or 150 μM 4,4′-dithiobis-pyridine (DTBP) for pH less than 8 and concentrations of octylglucoside or 0.1% Triton X-100, L-carnitine and acyl-CoA as indicated in the figures and tables at 25 C, with (0.05–0.1) μg/ml of enzyme. Protein was determined by a fluorescamine method (14).

RESULTS

Effect of octylglucoside on CPT activity. Optimum CPT activity was obtained with 12 mM octylglucoside when palmitoyl-CoA was the substrate but the response with octanoyl-CoA was very different (Fig. 1). Increasing concentrations of octylglucoside above 12 mM had little effect on the activity of CPT with octanoyl-CoA but strong inhibition of activity occurred with palmitoyl-CoA as substrates.

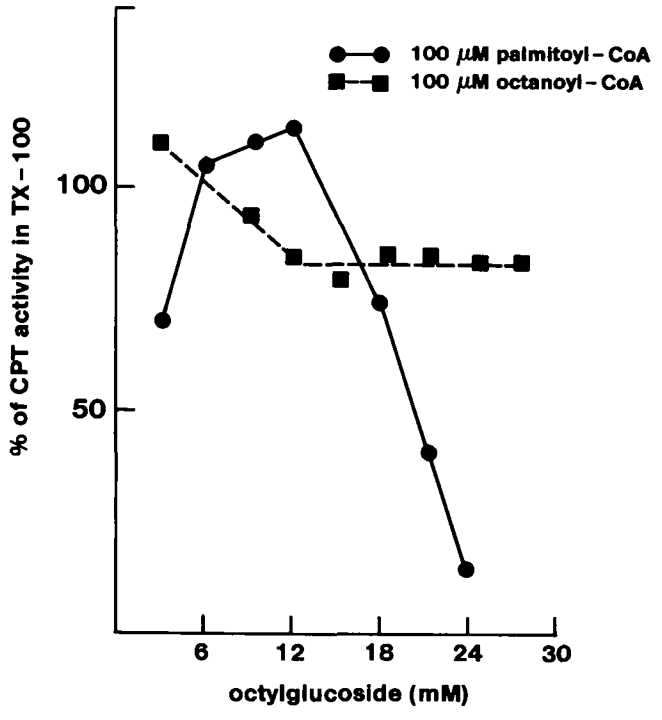

FIG. 1. Effect of octylglucoside on CPT activity. Activity was measured in the forward direction with the DTNB assay. L-carnitine was 1.1 mM and the acyl-CoA was 100 μM. Velocities are plotted relative to the V_{max} in 0.1% Triton X-100. The V_{max} in 0.1% Triton X-100 was 42 units/mg protein.

Substrate specificity profile of CPT in 12 mM octylglucoside and in Triton X-100. When octylglucoside is substituted for Triton X-100, changes in the acyl-CoA specificity pattern of CPT are apparent. For the shaded areas in Figure 2A and 2B, the patterns were determined with 1.1 mM L-carnitine and 200 μM acyl-CoAs. Although maximum activity with 1.1 mM carnitine was obtained with decanoyl-CoA in both detergents, the relative velocity with octanoyl-CoA was much less in octylglucoside. The acyl-CoA specificity with saturating levels of L-carnitine also is shown in Figure 2A and 2B (unshaded areas). In Triton X-100, the enzyme has the highest V_{max} with hexanoyl-CoA, and the V_{max} decreases as the acyl-CoA chain-length increases. In octylglucoside, the velocity is greatest with decanoyl-CoA.

Determination of nonmicellar assay conditions. To select suitable conditions in which to assay the enzyme in the absence of detergent micelles or mixed substrate/detergent micelles, the dye pinacyanol chloride was used to detect formation of micelles in the assay media. The cmc of octylglucoside in the assay media is greater than 30 mM, and in the absence of detergent palmitoyl-CoA forms micelles at 5.4 μM (data not shown). With 12 mM octylglucoside, no detergent micelles were detected but addition of palmitoyl-CoA to the assay media containing 12 mM octylglucoside reduced the cmc of palmitoyl-CoA to about 1 μM (Fig. 3). Octanoyl-CoA has a cmc greater than 200 μM in the assay media in the absence of detergent (data not shown). Addition of up to 150 μM octanoyl-CoA to the assay media containing 12 mM octylglucoside did not cause micelle formation (Fig. 3). Since octanoyl-CoA had a high V_{max} and did not form micelles with the assay conditions, it was used as the substrate for kinetic studies in a nonmicellar environment.

Determination of the molecular weight of CPT in the absence of detergent micelles. The molecular weight of purified CPT was determined in the presence of octylglucoside below its cmc by gel filtration. CPT activity and all detectable protein migrated as a single peak of constant specific activity with a molecular weight of 660,000 daltons (Fig. 4).

Effect of octylglucoside on the kinetics of CPT with L-carnitine. As shown in Table 1, at pH 8.0, the $K_{0.5}$ for L-carnitine is 4.9 mM in 12 mM octylglucoside with 200 μM palmitoyl-CoA. This is in contrast to assays in Triton X-100 in which the $K_{0.5}$ is much lower (0.2 mM). The $K_{0.5}$ for L-carnitine varies slightly with the concentration of the acyl-CoA used as cosubstrate (2.2 mM with 100 μM palmitoyl-CoA and 4.9 mM with 200 μM palmitoyl-CoA; compare values in Tables 1 and 2). Table 1 also shows that with octylglucoside the acyl-CoA chain length does not have the same effect on the $K_{0.5}$ for L-carnitine as in Triton X-100. The $K_{0.5}$ for L-carnitine increases with increasing concentrations of octylglucoside, reaching an apparent maximum of 8.5 mM with octanoyl-CoA and 4.4 mM with palmitoyl-CoA (see Table 2). Data from a typical experiment in nonmicellar assay conditions (12 mM octylglucoside and 100 μM octanoyl-CoA) in which L-carnitine is the varied substrate are shown in Figure 5. The Hill plot gave a n = 1.4. The $K_{0.5}$ for L-carnitine (palmitoyl-CoA as cosubstrate) increases as the pH decreases from 2.2 mM at pH 8.0 to 9.8 mM at pH 6.25 as shown in Table 3. This pH effect was the same as obtained in Triton X-100 (10). The highest V_{max} is at pH 7.0.

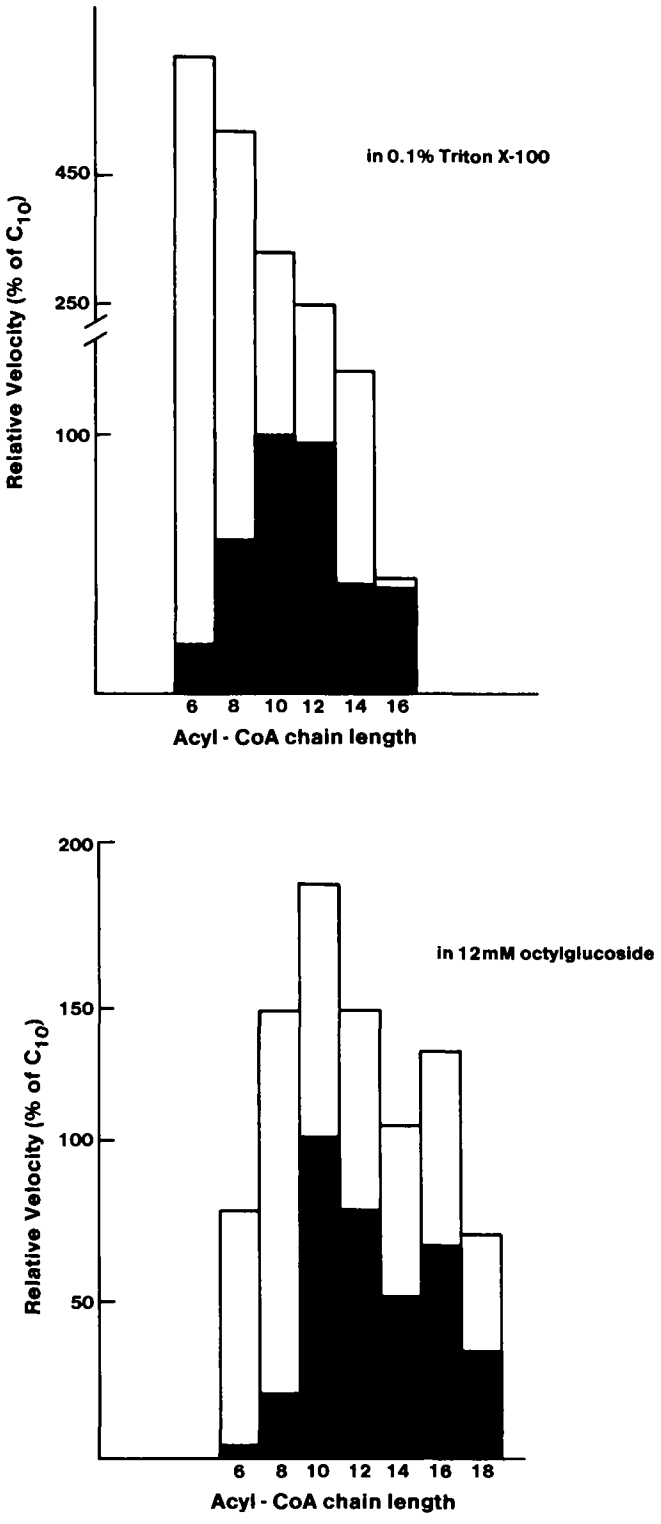

FIG. 2. Comparison of the substrate specificity profiles of CPT in 0.1% Triton X-100 and in 12 mM octylglucoside. For shaded areas, activity was measured with 1.1 mM L-carnitine and 200 μM acyl-CoA, with the kinetic analyzer as described (10). The specific activity of CPT with palmitoyl-CoA in 0.1% Triton X-100 and in 12 mM octylglucoside was 40 and 45, respectively, using saturating amounts of L-carnitine for each acyl-CoA substrate. Since the $K_{0.5}$ for carnitine depends on the acyl-chain length, the optimum L-carnitine level was determined for each. It varied between 6 and 30 mM, depending on the acyl-CoA used (unshaded area).

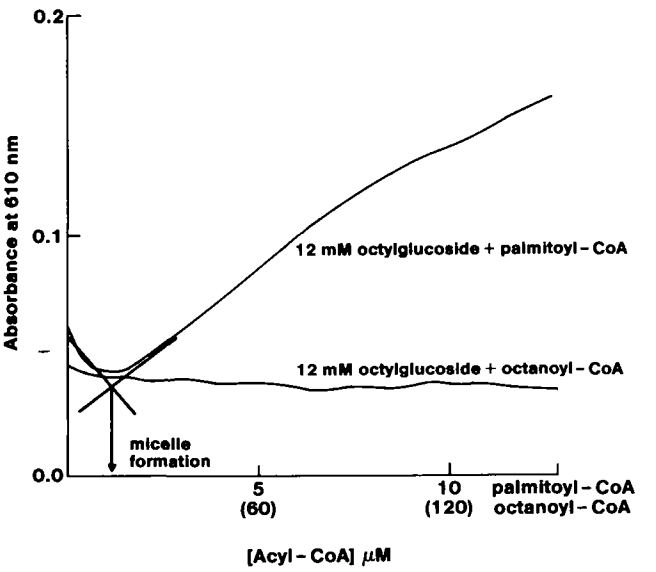

FIG. 3. Determination of the cmc of acyl-CoA in octylglucoside. Pinacyanol chloride (4 μM) was added to the DTNB assay media. The absorbance at 610 was recorded, while palmitoyl-CoA or octanoyl-CoA continuously was added from a pump driven syringe.

TABLE 1

Comparison of the $K_{0.5}$ for L-Carnitine in 12 mM Octylglucoside and 0.1% Triton X-100

Acyl-CoA chain length	Octylglucoside $K_{0.5}$ (mM)	Triton X-100* $K_{0.5}$ (mM)
6	11.1	2.9
8	10.2	1.5
10	11.1	0.64
12	4.2	0.53
14	4.9	0.35
16	4.9	0.2
18	3.8	

200 μM acyl-CoAs at pH 8.0 were used. The kinetic parameters were determined as described (10).

*Data taken from (11), Table 1.

Effect of octylglucoside on kinetic constants for acyl-CoA. Due to the high $K_{0.5}$ for L-carnitine in octylglucoside, its concentration was fixed at 40 mM to saturate the enzyme. As shown in Table 2, increasing concentrations of octylglucoside lowers the $K_{0.5}$ for palmitoyl-CoA. At pH 6.25, the $K_{0.5}$ for palmitoyl-CoA is 24.2 μM in 0.1% Triton X-100 (10) and 3.1 μM in 12 mM octylglucoside. Octylglucoside inhibits CPT activity with octanoyl-CoA and increases the $K_{0.5}$, apparently acting as a weak competitive inhibitor. The apparent K_i for octylglucoside is 15 mM (Fig. 6).

DISCUSSION

Small changes in detergent concentrations caused large changes in some of the kinetic parameters of CPT for medium-chain vs longer-chain acyl-CoAs. This is

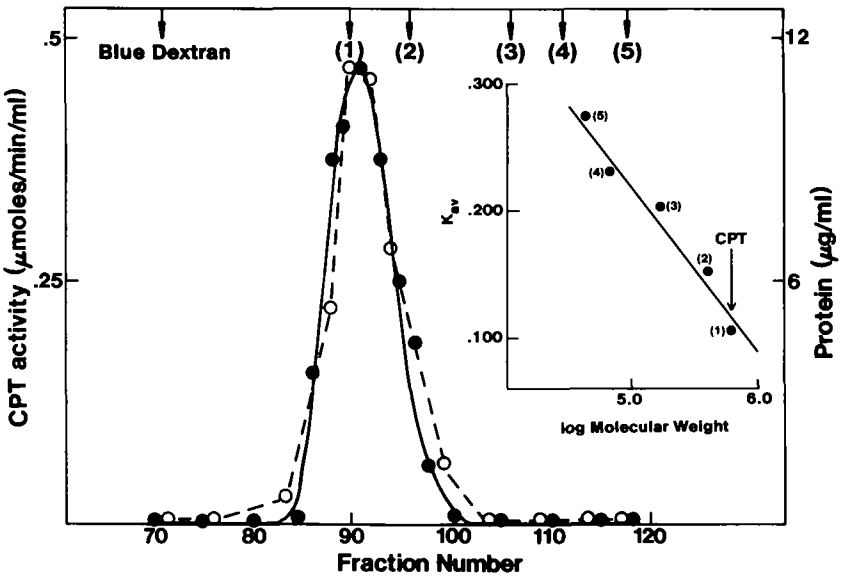

FIG. 4. Determination of the molecular weight of CPT in the absence of detergent micelles. Fractogel TSK HW-55 column was equilibrated with 12 mM octylglucoside as described in experimental procedures. Molecular weight standards were (1) thyroglobulin, (2) ferritin, (3) aldolase, (4) BSA and (5) ovalbumin. Open circles, protein and the closed circles, CPT activity.

**The pH was 6.25.

surprising and difficult to interpret. Both the concentration of detergent and the detergent composition affected the substrate specificity pattern of CPT. These data indicate that some of the differences observed in the specificity pattern of CPT for different CPT preparations and different assay conditions are due to the differences in detergent concentrations, cosubstrate concentrations and the type of detergent used. For example, with 12 mM octylglucoside the $K_{0.5}$ for L-carnitine with saturating amounts of medium-chain acyl-CoAs is about 11 mM. This large increase in the $K_{0.5}$ for L-carnitine produced low activities with medium-chain acyl-CoAs when the assay conditions of Figure 1 were used because L-carnitine was 1.1 mM. However, saturation with L-carnitine did not shift the V_{max} of the enzyme towards the 6- and 8-carbon chain acyl-CoA, as occurred in Triton X-100 (Fig. 2). The response of CPT to small changes in octylglucoside concentrations when octanoyl-CoA and palmitoyl-CoA are used as substrates must mean that the enzyme can respond to subtle changes in its environment. Increasing the concentration of octylglucoside from 12 to 24 mM had no effect on the rate with octanoyl-CoA but it inhibited the rate with palmitoyl-CoA ca. 80%. Such data suggest that perturbations of the active site may have more of an effect on catalysis when long-chain acyl-CoAs are the substrate or that some type of inhibitory palmitoyl-CoA/octylglucoside mixed micelle is formed whose concentration is dependent on the detergent concentration. Alternately, the effect of detergent on the velocity could be at the presumed alternate acyl-CoA

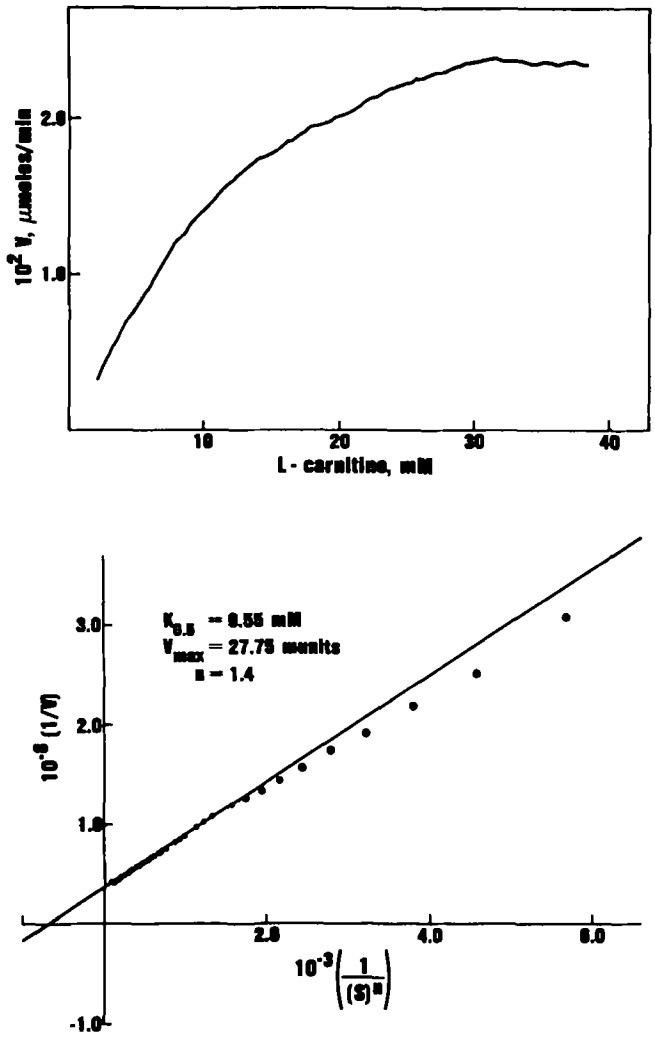

FIG. 5. Effect of L-carnitine concentration on CPT velocity. The concentration of octanoyl-CoA was 100 μM and L-carnitine was varied at pH 8.0. A double-reciprocal plot (1/v vs $1/s^n$) with a Hill n = 1.4 is shown in the bottom.

binding site that is involved in the acyl-CoA induced positive substrate cooperativity. The constancy of the Hill n seems to preclude the latter suggestion.

The changes in kinetic behavior of CPT caused by changes in experimental conditions are consistent with purified CPT being an oligomeric enzyme. The activities of such enzymes often are very responsive to small changes in their environment. The purified enzyme in octylglucoside is an oligomer. Although it has a monomeric molecular weight of 67,000 (3), its molecular weight in the absence of detergent micelles is about 660,000 (Fig. 4). Previously, we tentatively concluded CPT exists as an aggregate of about four to six monomers in 0.1% Triton X-100 (10). Our data now show that the aggregated molecular weight for the purified enzyme reported previously is not caused by several enzyme monomers binding to a detergent micelle. The slightly higher molecular weight estimate in 12 mM octylglucoside could indicate a higher aggregate, i.e. eight monomers, in the absence of detergent micelles or, alternatively, a greater amount of detergent bound to the enzyme. The amount of detergent bound to CPT is not known. The kinetics of the enzyme indicate that there is considerable interaction between the

TABLE 3

Effect of pH on the Kinetic Parameters of CPT for L-Carnitine in Octylglucoside

pH	$K_{0.5}$ mM	V_{max} milliunits	Hill n
6.25	9.8	14.8	1.5
6.5	7.4	14.7	1.5
6.75	5.0	13.3	1.6
7.0	4.6	17.8	1.5
7.25	3.9	12.5	1.5
7.5	3.0	12.0	1.5
8.0	2.2	10.1	1.5

Palmitoyl-CoA was 100 μM. Octylglucoside was 12 mM.
The kinetic parameters were determined as described (10) using the DTBP assay.

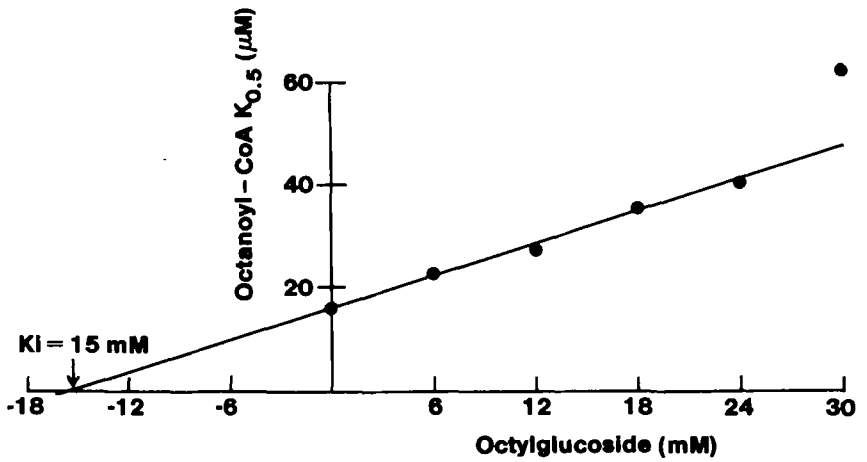

FIG. 6. Effect of octylglucoside on the $K_{0.5}$ for octanoyl-CoA. The $K_{0.5}$'s were determined as described (10) using the DTBP assay at pH 6.0. L-carnitine was 40 mM.

monomers, since the Hill coefficients for both substrates are greater than 1.0. The molecular weight of native CPT is unknown but the sigmoid kinetics for both cosubstrates with the membrane-bound enzyme (unpublished data) suggest interaction among subunits also occurs in the membrane-bound state. It has been shown that CPT of rat liver mitochondria also is an oligomer but its aggregated molecular weight is about half that reported herein for the enzyme from beef heart (16).

The data are similar to that observed in Triton X-100 in the following: the enzyme's kinetic parameters are strongly influenced by pH, the purified enzyme does not show inhibition by malonyl-CoA and it shows sigmoidal kinetics with both substrates even in the absence of detergent micelles. However, octylglucoside increases the $K_{0.5}$ for L-carnitine up to 25-fold compared with the $K_{0.5}$ in Triton X-100 and the relationship between the acyl-CoA chain length and the $K_{0.5}$ for L-carnitine is very different. With medium-chain acyl-CoA, the $K_{0.5}$ for L-carnitine is about twice the $K_{0.5}$ for L-carnitine with long-chain acyl-CoA (Table 2), and the large decrease in the $K_{0.5}$ for L-carnitine as the acyl chain lengthens is not observed (Table 1). The data do not differentiate between octylglucoside binding at an allosteric site and acting as a weak negative effector or its binding at the carnitine binding site, thereby having a direct effect on the $K_{0.5}$ for L-carnitine. The large increase in $K_{0.5}$ for L-carnitine in the presence of octylglucoside indicates a very flexible substrate binding site that responds to its environment.

[Received July 20, 1987; Revision accepted September 30, 1987]

Cupric Ion-dependent Inhibition of Lysosomal Acid Cholesteryl Ester Hydrolase in the Presence of Hydroxylamine

Mitsuo Tanaka*, Toshihiro Ito and Toshikazu Tabata
Showa College of Pharmaceutical Sciences, 1-8, Tsurumaki-5-Chome, Setagaya-Ku, Tokyo, Japan

In the presence of hydroxylamine or ascorbic acid, the inhibitory effects of Cu^{2+} on lysosomal acid cholesteryl ester hydrolase (acid CEH) partially purified from rat liver were studied.

Hydroxylamine stimulated the inhibition of acid CEH activity by Cu^{2+} but not that by Zn^{2+}, Fe^{2+}, Co^{2+}, Mn^{2+}, Ca^{2+}, Mg^{2+} and Hg^{2+}. This Cu^{2+}-dependent inhibition of acid cholesterol ester hydrolase (CEH) activity was completely prevented by ethylenediamine tetraacetic acid (EDTA), EGTA and o-phenanthroline, a chelator with a stability constant for Cu^{2+}, and also by sulfhydryl agents and cytoplasmic reducing agents such as cysteine, glutathione and mercaptoethanol. In addition, the stimulative effects of hydroxylamine on Cu^{2+}-dependent inhibition were maintained even after preincubation of Cu^{2+} with hydroxylamine.

On the other hand, ascorbic acid was found to replace the stimulation by hydroxylamine of the Cu^{2+}-dependent inhibition of acid CEH activity but the effects of ascorbic acid progressively became smaller with prolongation of the preincubation time. Moreover, addition of chemical radical scavengers to the reaction mixture did not prevent the Cu^{2+}-dependent inhibition of acid CEH activity in the presence of ascorbic acid. These results suggest that Cu^{2+} causes inhibition of lysosomal acid CEH activity through the formation of Cu^{1+} in a reductive medium. *Lipids 23,* **126–130 (1988).**

Acid cholesterol ester hydrolase (CEH), which is found in several tissues including those of the liver, spleen and aorta, is distributed broadly in all subcellular fractions although the major proportion of its activity appears to be localized in the lysosomal fraction (1–7). It has been suggested that acid CEH may play a role in the catabolism of cellular cholesteryl esters (8). We previously have reported that a cytosolic protein in rat liver inhibits acid CEH activity (7). However, the mechanism involved in the regulation of lysosomal acid CEH is not known.

On the other hand, hypercholesterolemia in cupric ion-deficient rats has been observed by many investigators (9–12), and we also have shown that the acid CEH activity in rats treated with cupric ion is decreased markedly in comparison with that in normal rats (13). However, the role of cupric ion in cholesterol metabolism still is unknown. In this study, on the basis of the above observations concerning the effect of cupric ion on serum and liver cholesterol metabolism, we tried to clarify the mechanism of Cu^{2+}-dependent inhibition of acid CEH activity in the presence of reducing agents such as ascorbic acid or hydroxylamine in vitro.

Abbreviations: CEH, cholesterol ester hydrolase; EDTA, ethylenediamine tetraacetic acid; EGTA, ethylene-bis-(oxyethylenenitrilo)-tetraacetic acid.

MATERIALS AND METHODS

Chemicals and radiochemicals. Cholesteryl [1-^{14}C] oleate (sp. act. 58.6 mCi/mmol) was purchased from New England Nuclear Corp. (Boston, MA). Phenolphthalein glucuronide, phenylphosphate, hemoglobin, cysteine, glutathione, sodium thiocyanate, mannitol, bilirubin, guanosine and catalase were purchased from Sigma Chemical Co. (St. Louis, MO). L-ascorbic acid, hydroxylamine and 2,2-biquinoline were purchased from Tokyo Kasei Chemical Co., Ltd. (Japan). Hydroxyapatite was purchased from Seikagaku Kogyo Co., Ltd. (Japan). Phenyl Sepharose CL-4B, Polybuffer Exchanger 94 and Polybuffer 74 were obtained from Pharmacia Fine Chemicals (Sweden).

Acid cholesteryl ester hydrolase assay. The activity of acid CEH was measured by the method of Brecher et al. (14). Preparation of the substrate was performed as described (7). This sensitive microassay was carried out in 0.1 M acetate buffer (pH 5.0) in a final assay volume of 0.3 ml. All assays were done using quantities of protein (usually less than 1 μg) and incubation times (30 min) that ensured nearly linear rates of substrate hydrolysis. All data points reported here represent the means of triplicate assays.

Assay of lysosomal marker enzymes. Cathepsin D was assayed by the method of Hirado et al. (15), and the amount of reaction products was assayed by the method of Lowry et al. (16). β-Glucuronidase was assayed using phenolphthalein glucuronide as the substrate. Phenolphthalein liberated from the substrate was measured by the method of Gianetto and De Duve (17). Acid phosphatase was measured using phenylphosphate as the substrate, essentially as described (18). Protein concentration was assayed by the method of Lowry et al. (16).

Determination of Cu^{1+} content. The determination of Cu^{1+} content in the reaction mixture was performed by the colorimetric procedure described by Sandell (19).

Purification of acid cholesteryl ester hydrolase. All preparation steps were carried out at 4 C. Acid CEH was isolated by a modification of the method of Klemets and Lundberg (20). Normal rat liver was homogenized in four volumes of ice-cold 0.25 M sucrose/1 mM ethylenediamine tetraacetic acid (EDTA)/0.01 M Tris-HCl buffer (pH 7.5). For the preparation of lysosomal fractions from liver, the method of Brecher et al. was followd (14). The precipitate (lysosome-rich fraction) was suspended in 0.2% Triton X-100/0.01 M sodium phosphate buffer (pH 7.0). The suspension was stirred at 4 C for 30 min and centrifuged at 50,000 × g for 30 min. The supernatant was applied to a hydroxyapatite column (5 × 10 cm) previously equilibrated with 0.01 M sodium phosphate buffer (pH 7.0) containing 5 mM mercaptoethanol. After washing the column with the same equilibration buffer, the enzyme was eluted with 0.05 M sodium phosphate buffer (pH 7.0). The enzyme fractions were pooled. The pooled fractions were applied to a column of Phenyl Sepharose CL-4B (2 × 10 cm) equilibrated with 0.01 M sodium phosphate

buffer (pH 7.0) containing 5 mM mercaptoethanol. After washing the column with the same equilibration buffer, elution was performed with a linear concentration gradient of 0 to 90% ethylene glycol in the same buffer. Fractions with enzyme activity were pooled and dialyzed against 5 l of 0.01 M sodium phosphate buffer (pH 7.0) containing 5 mM mercaptoethanol. The dialyzed fraction was applied to a column of Polybuffer Exchanger 94 (2 × 10 cm) equilibrated with 0.01 M sodium phosphate buffer (pH 7.0). The column was washed thoroughly with the same buffer, and then the enzyme was eluted with Polybuffer 74 at a pH gradient from 7.0 to 4.0. The fractions containing the highest enzyme activity were pooled, concentrated by membrane filtration and applied to a column of Sephadex G-75 to remove Polybuffer 74. The resulting partially purified protein preparation showed one major band and a few weak bands when examined by SDS-polyacrylamide gel electrophoresis according to Laemmli (21), the molecular weight of this major band was about 59,000 daltons (20). The pH optimum of the partially purified acid CEH was 5.0, and the enzyme had a specific activity of 30 μmol per min per mg protein. The preparation was stored at −30 C and used in all experiments.

RESULTS

Acid CEH partially purified from rat liver lysosomes was incubated with increasing concentrations of Cu^{2+} in the presence or absence of hydroxylamine. As shown in Figure 1, hydroxylamine markedly stimulated the inhibitory effect of Cu^{2+} on acid CEH activity, and the degree of the stimulatory effect was dependent upon the concentration of Cu^{2+}, the addition of about 8 μM Cu^{2+} causing approximately half-maximal inhibition of acid CEH activity. However, in the absence of hydroxylamine, Cu^{2+} showed an inhibitory effect only at high concentrations.

Figure 2 shows the effects of hydroxylamine or ascorbic acid concentration on the inhibition of acid CEH activity with or without Cu^{2+}. Acid CEH activity was inhibited significantly at a concentration of 50 μM of either hydroxylamine or ascorbic acid in the presence of Cu^{2+} (15 μM) but hydroxylamine and ascorbic acid did not by themselves inhibit acid CEH activity, even at higher concentrations. Therefore, we examined the effect of various radical scavengers on the Cu^{2+}-dependent inhibition of acid CEH activity in the presence of ascorbic acid. As shown in Table 1, these scavengers did not prevent the Cu^{2+}-dependent inhibition of acid CEH activity in the presence of ascorbic acid except for sodium thiocyanate.

It is well known that acid CEH is inhibited by certain divalent cations (4,7,22,23). Therefore, the stimulative effects of hydroxylamine on the inhibition of acid CEH activity by these divalent metal ions were compared (Table 2). Fe^{2+} (0.05 mM), Hg^{2+} (0.5 mM) and Zn^{2+} (1.0 mM) inhibited acid CEH activity up to about 62%, 49% and 60%, respectively, in the absence of hydroxylamine but

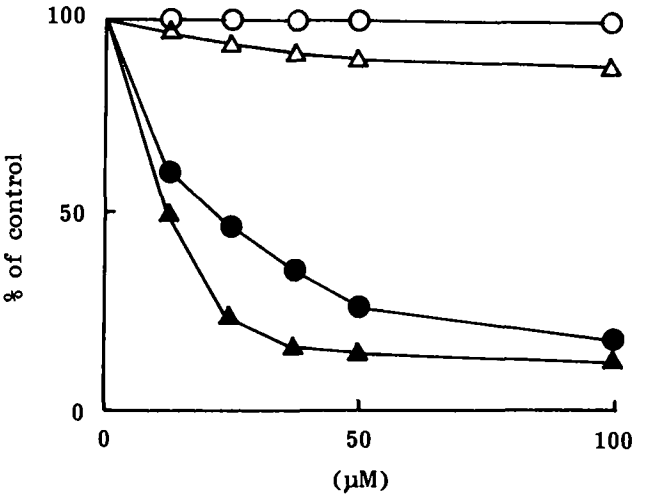

FIG. 2. Effect of hydroxylamine (●, ○) or ascorbic acid (▲, △) on acid CEH activity in the presence (closed symbols) and absence (open) of 15 μM Cu^{2+}. The 100% value is the activity under standard assay conditions.

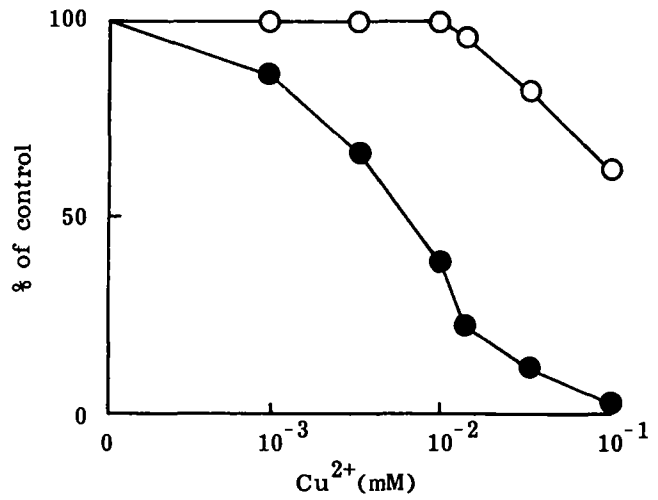

FIG. 1. Inhibition by Cu^{2+} of acid CEH activity in the presence (●) and absence (○) of 50 μM hydroxylamine. The 100% value is the activity under standard assay conditions.

TABLE 1

Effect of Radical Scavengers on Cu^{2+}-dependent Inhibition of Acid CEH Activity in the Presence of Ascorbic Acid

Scavenger	Final concn. (mM)	Activity (%)
None	—	18.7
Mannitol	1.0	16.8
Ethanol	1.0	18.9
Sodium benzoate	1.0	19.2
Potassium iodide	1.0	10.4
Guanosine	0.1	13.9
Bilirubin	0.5	10.7
Sodium thiocyanate	1.0	45.9
DMSO	1.0	19.4
Catalase	50 μg/ml	18.3

Reaction mixture contained ascorbic acid (50 μM), Cu^{2+} (20 μM) and the specified amounts of various scavengers in 0.1 M acetate buffer (pH 5.0). The 100% value was the activity under standard assay conditions. Activity was determined as described in the Materials and Methods section.

none of these divalent cations produced any increment in the inhibition of acid CEH activity like that observed when Cu^{2+} and hydroxylamine were coexistent.

Next, we tested the effects of chelators, sulfhydryl agents and reducing agents on the Cu^{2+}-dependent inhibition of acid CEH activity by hydroxylamine. As shown in Table 3, the Cu^{2+}-dependent inhibition of acid CEH activity in the presence of hydroxylamine was effectively prevented when 125 μM EDTA was present in the incubation medium. At the same concentrations, EGTA and o-phenanthroline also were able to replace EDTA and produce a preventive effect. Moreover, a similar effect was brought about by the sulfhydryl and reducing agents such as cysteine, glutathione and mercaptoethanol at the same concentrations (Table 3).

On the other hand, the inhibitory effect of Cu^{2+} was tested on the activity of other lysosomal enzymes, cathepsin D, acid phosphatase and β-glucuronidase in the presence or absence of hydroxylamine. The activities of these enzymes were not changed in the presence of Cu^{2+} and hydroxylamine (data not shown).

For further investigation of the enhancement by hydroxylamine of Cu^{2+}-dependent inhibitory action, the effects of preincubation of Cu^{2+} with hydroxylamine or ascorbic acid on acid CEH activity were studied (Fig. 3a, 3b). Even when Cu^{2+} was preincubated with hydroxylamine for 30 min, the level of Cu^{2+}-dependent inhibition of acid CEH activity did not change. However, in the case of ascorbic acid the Cu^{2+}-dependent inhibitory effects on acid CEH activity progressively became smaller with

TABLE 2

Effect of Divalent Metals on Acid CEH Activity in the Presence or Absence of Hydroxylamine

Divalent metal	Final concn. (mM)	Activity (%)	
		0 μM	50 μM
		Hydroxylamine	
None	—	100.0	100.0
Cu^{2+}	0.02	90.6	20.3
Fe^{2+}	0.05	61.5	49.5

Reaction mixture contained hydroxylamine (50 μM), Cu^{2+} (20 μM), and the specified amounts of various agents in 0.1 M acetate buffer (pH 5.0). The 100% value was the activity under standard assay conditions. Activity was determined as described in the Materials and Methods section.

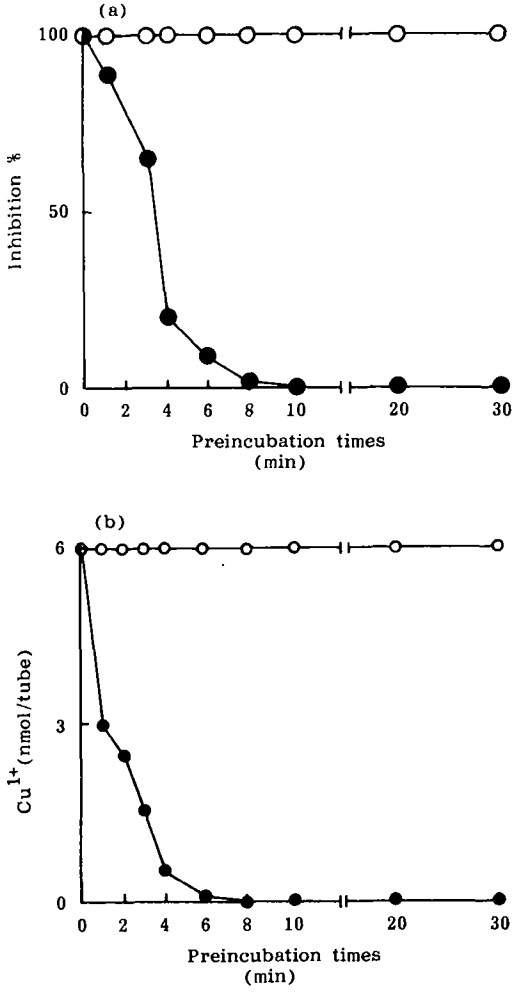

FIG. 3. Effect of the preincubation times on acid CEH activity (a) and Cu^{1+} contents (b) in the presence of Cu^{2+}-ascorbic acid (●) or Cu^{2+}-hydroxylamine (○). The preincubation medium contained 30 μM $^{2+}$ and 50 μM ascorbic acid or 50 μM hydroxylamine. After preincubation, (a) enzyme was incubated with the preincubation medium in 0.1 M acetate buffer (pH 5.0) in a final assay volume of 0.3 ml, (b) Cu^{1+} content was determined as described under Materials and Methods.

prolongation of the preincubation time, and the effects disappeared completely after preincubation for 8–10 min.

On the other hand, the amount of Cu^{1+} formed during preincubation with Cu^{2+} in the presence of hydroxylamine or ascorbic acid was measured by the Cu^{1+}-2,2-biquinoline complex method. As shown in Figure 3b, when Cu^{2+} was preincubated with hydroxylamine the amount of Cu^{1+} detected after a further 30-min period almost was identical to that measured after a two-min preincubation. In contrast, the amount of Cu^{1+} formed in the presence of ascorbic acid gradually decreased in parallel with the disappearance of Cu^{2+}-dependent inhibition.

Since Cu^{1+} is thought to be a powerful inhibitor of the acid CEH, we examined the direct effect of Cu^{1+} on acid CEH activity. Acid CEH was inhibited significantly by Cu^{1+}, the addition of about 10 μM Cu^{1+} causing approximately half-maximal inhibition of acid CEH activity (Fig. 4).

DISCUSSION

The results presented here show that hydroxylamine has a stimulative effect on Cu^{2+}-dependent inhibition of lysosomal acid CEH activity in rat liver. This inhibitory effect was shown to be dependent upon the Cu^{2+} concentration, and hydroxylamine did not inhibit the enzyme activity. Furthermore, this stimulative effect of hydroxylamine was decreased by the addition of chelating agents or sulfhydryl compounds. In addition, when Cu^{2+} was replaced by other divalent cations such as Fe^{2+}, Mn^{2+}, Co^{2+}, Zn^{2+}, Ca^{2+}, Mg^{2+} and Hg^{2+}, the stimulative effects of hydroxylamine were not observed. These results suggest that the stimulation by hydroxylamine of the Cu^{2+}-dependent inhibitory effect on acid CEH activity may be a specific characteristic of Cu^{2+}.

On the other hand, the sensitivity of ascorbic acid to the catalytic effects of minute traces of cupric ion is well known. In addition, transition metal ions such as Cu^{2+} and Fe^{2+} are known to exert a catalytic effect upon the oxidation of ascorbic acid. When hydroxylamine was replaced by ascorbic acid, the latter also revealed a similar inhibition of acid CEH activity in the presence of Cu^{2+}. However, as the preincubation time of Cu^{2+} with ascorbic acid was prolonged, Cu^{2+}-dependent inhibition resulted in a progressively smaller effect. These results suggested that an oxidized form of ascorbic acid was much less effective for inhibition of the enzyme. It is well known that activated oxygen species such as hydroxyl radicals and superoxide radicals are formed in the reaction of ascorbic acid and Cu^{2+} (24). Various radical scavengers, therefore, were added to the incubation medium containing acid CEH, and none of them prevented the Cu^{2+}-dependent inhibition in the presence of ascorbic acid with the exception of sodium thiocyanate. The slight recovery of Cu^{2+}-dependent inhibition in addition of sodium thiocyanate appears to be dependent upon the formation of insoluble cuprous thiocyanate. These results suggest that the inhibition of acid CEH activity by ascorbic acid and Cu^{2+} may not be due to activated oxygen species.

On the other hand, it also is known that Cu^{1+} is formed in the reaction of ascorbic acid or hydroxylamine with Cu^{2+} (19,25–27). When Cu^{2+} was preincubated with hydroxylamine, the degree of Cu^{2+}-dependent inhibition of acid CEH activity was maintained at the same level, and moreover, the amount of Cu^{1+} in the reaction mixture did not change at all during the preincubation period. However, in the combination of Cu^{2+} and ascorbic acid, neither Cu^{2+}-dependent inhibition nor Cu^{1+} in the reaction mixture could be detected for a few minutes. Moreover, the direct addition of Cu^{1+} to the incubation medium inhibited acid CEH activity at the similar levels to that obtained under coexistence with Cu^{2+} and ascorbic acid or hydroxylamine. These results indicated that Cu^{2+}-dependent inhibition of acid CEH activity in the presence of hydroxylamine or ascorbic acid was specifically caused by the Cu^{1+} formed in a reductive medium.

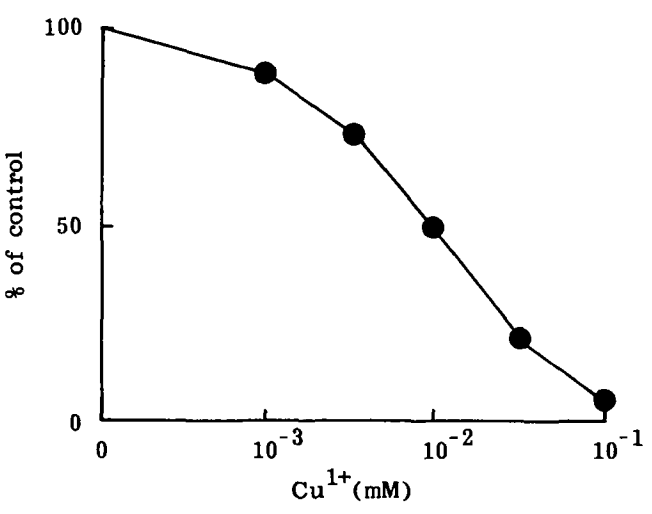

FIG. 4. Inhibition by Cu^{1+} of acid CEH activity. CuCl was solubilized in DMSO. The 100% value is the activity under standard assay conditions.

Cheek Cell Fatty Acids as Indicators of Dietary Lipids in Humans

Joseph Sampugna*[a], Luise Light[b], Mary G. Enig[a], D. Yvonne Jones[b], Joseph T. Judd[c] and Elaine Lanza[b]
[a]Department of Chemistry and Biochemistry, University of Maryland, College Park, MD 20742, [b]Cancer Prevention Studies Branch, Division of Cancer Prevention and Control, National Cancer Institute, NIH, DHHS, 9000 Rockville Pike, Bethesda, MD 20892, [c]Lipid Nutrition Laboratory, Beltsville Human Nutrition Research Center, ARS, USDA, Beltsville, MD 20705

Analysis of cheek cell lipids has been suggested as a noninvasive method for monitoring the fatty acid composition of diets in humans. In a pilot study conducted to determine the validity of the method, cheek cell samples were collected from subjects consuming a low fat (20% of calories) diet consisting of fatty acids with either a 1.0 or 0.3 P/S ratio. Neither total lipid nor polar lipid fatty acids in cheek cells consistently reflected the P/S ratio of the diets. However, there were trends, particularly in the nonpolar lipids, suggesting that cheek cell fatty acid ratios might be useful for monitoring the fatty acid composition of the diets. The diet with the higher P/S ratio (1.0 vs 0.3) consistently resulted in cheek cell lipids with lower ratios of 18:1/saturated fatty acids and greater 18:2/20:4, 18:2/18:1 and 18:2/18:0 fatty acid ratios. ***Lipids 23,*** **131–136 (1988).**

Risk for several chronic diseases, including coronary heart disease, atherosclerosis, and breast and colon cancers is thought to be associated with the amount and/or type of fat routinely consumed (1–4). However, objective validation of an association between dietary fat and these diseases has been difficult.

A major difficulty encountered in human studies has been the problem of reliably determining dietary lipid status. Most studies rely on current or retrospective reports of dietary intake. A more objective biochemical measure of fat intake would be useful for replacing or validating dietary reports in epidemiologic and intervention studies. Data presented in two recent studies suggest that cheek cells (buccal epithelial cells) might serve as a tissue lipid source that reflects dietary lipid status (5,6).

Although erythrocyte fatty acids (7,8), adipose tissue fatty acids (9–11) and serum lipids (9) have been suggested as indices of usual dietary lipid intake, there are problems with each of these. Serum cholesterol has been widely assumed to be a reflection of dietary fat intake but a direct relationship has yet to be proven (9). Serum cholesterol is influenced by changes in body weight, levels of total fat, saturated fat and, to a lesser degree, dietary cholesterol. Change in any or all of these components can be expected to affect serum cholesterol (9). What is more, there is a significant intra-individual variation in serum cholesterol levels over time (9). Adipose tissue generally is accepted as a measure of long-term fatty acid composition of diet and erythrocytes of medium- or shorter-term status. However, all require invasive techniques for sample collection and may be difficult to use in large field studies. Further, neither erythrocyte nor adipose tissue levels may be suitable for confirming reported short-term changes in lipid consumption such as might be desired in clinical trials or community intervention studies. A tissue with rapid turnover such as cheek cells was speculated to be more likely to reflect current diet than either erythrocyte or fat stores.

Compared with other biological measures of lipid intake, cheek cells offer several potential advantages. The method is relatively noninvasive, modest in cost and appears to be readily adaptable for use in large-scale field studies. In this paper, we report on the development, standardization and testing of methods used for the comparison of cheek cell lipids and dietary lipids.

METHODS

The study was performed as part of a larger project (12) conducted in collaboration with personnel from the National Cancer Institute and the Lipids Laboratory of the Human Nutrition Research Center of the U.S. Department of Agriculture, Beltsville, MD, and the Chemistry and Biochemistry Department of the University of Maryland, College Park, MD. The data presented herein represent 23 of the women in the original study (12) who agreed to provide cheek cell samples. Student's t-test was used for statistical comparison of cheek cell components. Complete details on the subjects who participated in the study are in the original paper (12).

During the study, subjects were permitted only foods prepared in the Human Nutrition Study Facility of the Beltsville Human Nutrition Research Center (BHNRC). On weekdays, the morning and evening meals were eaten in the BHNRC dining facility, and each subject was provided with an appropriate lunch. On weekends, subjects were given prepackaged meals prepared in the BHNRC facility.

All of the meals consisted of commonly available foods designed to yield a high (1.0) or low (0.3) polyunsaturated to saturated (P/S) dietary fatty acid ratio. All subjects were maintained on a high-fat diet (40% of calories) for four menstrual cycles and switched to a low-fat diet (20% of calories) for four additional menstrual cycles. Two cheek cell samples were collected from each subject, four days apart, during the mid-luteal phase of the last menstrual cycle of the low-fat dietary regimen.

Cheek cell samples were collected in the morning before eating. Subjects were asked not to brush their teeth, wear lipstick, gargle or use mouthwash prior to collection. Subjects rinsed their mouths three times with distilled water, swishing vigorously, and discarded the rinses. The study nurse then gently scraped the inside cheek just above the occlusal line three times on each side of the mouth using a plastic spoon. The cell residue on the spoon was washed off with distilled water into the collection cup. The subject rinsed a final time with distilled water and added this rinse into the collection cup. Gentamycin Sulfate (0.5 mg) was added to the sample, and it was kept on ice. Within two hr of collection, the suspensions were centrifuged at 12,000 × g × 30 min at 4 C. After discarding the supernatant, an estimate of the surface area of the pellet at

the bottom of the transparent tube was obtained, and the tube containing the pellet was capped and placed at −80 C overnight.

Homogenization and extraction. The frozen pellet was transferred with the aid of a spatula to a Potter-Elvejhem type tissue grinder, 1 ml of water was added, and the pellet was homogenized at 3,000 rpm with 10 passes of a motor-driven Teflon pestle. The homogenate was transferred to a volumetric flask using distilled water to rinse the homogenizer and to dilute the homogenate to 2 ml. After resuspending the contents, a 120 μl aliquot of the homogenate was stored at −20 C for protein and nucleic acid assays, and the remaining volume was noted and used to obtain a total lipid extract essentially as described by Folch et al. (13), except that butylated-hydroxytoluene (100 μg) was added to each sample, and the extract was filtered and concentrated without employing the traditional washing steps. All concentration steps were conducted with the exclusion of oxygen.

Two cheek cell pellets, isolated four days apart, were obtained from each subject. The lipid extract derived from the first set of pellets (Study I) was separated into polar and nonpolar lipid fractions, which were analyzed for fatty acid methyl esters (FAME) using an acidic catalyst. The total lipids derived from the second set of pellets (Study II) were analyzed for fatty acid composition after converting one portion of the lipid extract into FAME using an alkaline catalyst and converting the second portion of the lipid extract into FAME with an acidic catalyst.

Nonpolar and polar lipids. Silicic acid chromatography conducted essentially as described by Rouser et al. (14) was used to separate total lipids isolated in Study I into two fractions. The total lipid dissolved in a minimum volume of chloroform was applied to a column containing 3 g of Biosil A (Calbiochem, LaJolla, CA) and chloroform (30 ml) and methanol (30 ml) was used to elute the nonpolar and polar lipid fractions, respectively. After adding 10 μg of the internal standard (methyl heneicosanoate, 21:0), the fractions were concentrated under a stream of nitrogen and dissolved to a known volume with methylene chloride. Approximately 10% of each fraction was stored at −20 C for subsequent thin layer chromatography (TLC) studies, and the rest was converted to FAME, using an acidic catalyst, for analysis by glass capillary gas liquid chromatography (GCGLC), as described below.

Total lipids. Twenty μg of the internal standard (21:0) was added to the total lipid extract derived from the second set of cheek cell samples (Study II). After storing ca. 10% of the sample at −20 C for TLC studies, the remainder was divided into two portions. One portion was analyzed as FAME by GCGLC after transesterifying that portion with an alkaline catalyst; the second portion was analyzed after it was reacted with an acidic catalyst.

Preparation and purification of FAME. Lipids transesterified under acidic conditions were dissolved in 0.5 ml of methylene chloride and 2 ml of anhydrous methanolic HCl (1.5 N). After heating the samples for 24 hr at 80 C in tubes sealed with Teflon-lined caps, the FAME were extracted and purified as described previously (15), except that no attempt was made to separate FAME from dimethylacetals.

Lipids transesterified under alkaline conditions were dissolved in 1 ml of tetrahydrofuran and 2 ml of anhydrous methanol, containing 0.5 M $NaOCH_3$ and heated at 50 C for 10 min in tubes sealed with Teflon-lined caps. After adding 0.1 ml of glacial acetic acid, 5 ml of water and 5 ml of hexane, the FAME were extracted into the hexane layer and filtered through a small bed of anhydrous sodium sulfate containing 10% potassium bicarbonate, essentially as described by Christie (16). The filtered hexane extract was concentrated, and the crude FAME were purified by TLC as described (15).

Glass capillary gas liquid chromatography. Purified FAME were analyzed by GCGLC using three different columns installed in Hewlett-Packard (Avondale, PA) chromatographs equipped with flame ionization detectors. All samples were analyzed on a 25 m × 0.25 mm ID fused silica column that was coated with SP-2340 (Quadrex, New Haven, CT) and installed into a model 5880A GLC. The column temperature was maintained at 175 C for five min and then programmed at a rate of 0.75 C/min to a final temperature of 200 C, which was maintained for 10 min.

To facilitate the identification of FAME, all samples also were analyzed on a 12.5 m × 0.2 mm ID fused silica column, which was coated with a cross-linked dimethyl silicone (Hewlett-Packard, Avondale, PA) and installed into a model 5840 GLC. Several analyses at different constant temperatures and under temperature-programmed conditions were conducted for each sample. In addition, some samples were analyzed as previously described (15) on a 15 m × 0.25 mm ID glass capillary column coated with SP-2340. Other conditions pertinent to the operation of GCGLC column were similar to those described (15).

Identification of components was based on the retention times obtained for individual components compared to the retention times observed for available standards (NuChek, Elysian, MN; and Supelco, Bellefonte, PA). Quantitative data were derived with the aid of integrator-processors associated with the instruments, using standard mixtures of FAME to establish response factors for components of interest and using the internal standard to help convert the peak areas into μg of FAME.

Thin layer chromatography. Lipid classes were identified using TLC and densitometry. Premade Plates, containing a preabsorbent area and 10 channels (LK 5D, Linear K Silica Gel), purchased from Whatman, Inc. (Clifton, NJ) were developed in n-heptane/diethyl ether/formic acid (85:15:1, v/v/v) or in chloroform/ethanol/water/triethylamine (30:34:8:35, v/v/v/v) to resolve the nonpolar or polar lipids, respectively. Following development, components were visualized by charring essentially as described by Bitman et al. (17) and analyzed using a Kratos/Schoeffel Model SD-3000 spectrodensitometer (Westwood, NJ) equipped with a Hewlett-Packard 3390A Reporting Integrator (Avondale, PA).

Protein and nucleic acid determination. Protein was determined essentially as described by Hess and Lewin (18) using 200 μl aliquots of 50-fold dilutions of the original homogenates. The absorbance of duplicate samples was read at 750 nm in a Guilford Spectrophotometer (Oberlin, OH) and converted to protein concentration with the aid of a standard curve developed using bovine serum albumin, fraction V, purchased from Sigma Chemical Co. (St. Louis, MO).

To estimate the nucleic acid content in the cheek cell

homogenates, the absorbance of 1 ml aliquots of 50-fold dilutions of the original homogenates was measured at 260 nm and at 280 nm. An estimate of the nucleic acid content in the cuvette was obtained from the absorbance values and the following equation based on the extinction coefficients determined by Warburg and Christian (19):

$$\frac{A_{260} - [A_{280}\ (0.5728)]}{36.5942} = \text{mg nucleic acid/ml}$$

RESULTS

In preliminary experiments, we examined cheek cells pelleted at various g forces, including those recommended in the literature (5,6). Based on the yield of total FAME, as well as analysis of cheek cells by phase contrast microscopy, a considerable number of cells remained in the supernatant at forces less than 12,000 × g for 30 min. The cheek cell populations were heterogeneous, consisting of some single cells as well as several populations of contiguous cells. Based on dye exclusion tests using trypan blue (20), 10–30% of the pelleted cells did not take up the dye.

We also noted variable levels of contamination of cell pellets with microorganisms and food particles. The content and composition of FAME was affected dramatically when food particles were present but there was no obvious effect from contamination with microorganisms. In the main studies reported below, samples that obviously were contaminated with food particles, based on visual inspection, (Study I: 4 P/S 1.0 samples and 3 P/S 0.3 samples) or extremely high lipid content and unusual lipid profile (Study II: one P/S 1.0 sample), were excluded from the summary data presented.

Data for pellet size, protein content and μg of total FAME of cheek cell preparations examined in Study I and Study II are summarized in Table 1. As can be seen, there was considerable individual to individual variation and there were no statistically significant differences between diets for these parameters. The amount of cheek cells obtained using our methods was adequate for the routine analysis of nucleic acid content (data not shown) as well as protein and FAME. Based on the crude assay we used, nucleic acid was present in cheek cells at a level of about 25 μg/mg of protein.

Based on TLC, the cheek cell lipids contained relatively large amounts of triglycerides and unesterified fatty acids, variable amounts of cholesterol, relatively low levels of traditional phospholipids and a number of unidentified lipid classes. However, sample to sample variation was extremely high, suggesting that absolute levels of lipid classes were unrelated to protein level or pellet size. Nevertheless as total FAME, the nonpolar lipid fraction predominated for all samples examined and represented about 60% of the total lipid FAME.

In Study I, the cheek cell lipids were separated into nonpolar (NPL) and polar lipids (PL) before they were transesterified and analyzed by GCGLC. The major FAME in these samples, as weight percent of the total components that could be identified tentatively, are displayed in Table 2. In general, the FAME of the NPL and PL were similar but not identical. Compared to NPL, the PL contained higher percentages of 20:4 and 22:6 as well as saturated fatty acids with chain lengths greater than 18 carbon atoms. In contrast, the PL values for 14:0, 16:0 and 18:0 tended to be lower than those observed in the NPL fraction.

There was no statistically significant effect of dietary P/S ratio on the cheek cell FAME pattern. Nevertheless, there were trends toward a higher percentage of 18:2 and lower percentages of 18:1 and 20:4 in both the NPL and PL fraction derived from subjects who consumed the higher P/S diet. The extent to which factors other than sample variation may have obscured potentially significant differences was of concern. The presence of extremely long chain saturated fatty acids, particularly in the PL fraction, suggested that these samples contained amide-linked fatty acid lipid classes, which may have complicated the data by diluting out potentially significant effects of diet.

To distinguish between amide-linked and ester-linked fatty acids, in Study II the cheek cell lipids were converted to methyl esters in two ways. Aliquots were transesterified using an alkaline ($NaOCH_3$) catalyst and compared to those submitted to an acid catalyst (HCl-methanol). In addition, since our TLC studies revealed only low levels of typical phospholipids and as similar FAME patterns were observed for NPL and PL fractions, the total lipid was used as the source of FAME.

The data obtained for the major FAME in Study II are summarized in Table 3. As was expected, the percentages of long chain saturated fatty acids were considerably

[a]Values are averages and standard deviations for FAME as wt % of the total normalized FAME. N, number of individual cheek cell preparations examined.

[b]Other tentatively identified components, not included in the table were dimethylacetals, odd-chain and branched-chain fatty acids. In addition, there were some components for which a tentative identification could not be assigned.

lower in samples transesterified with $NaOCH_3$, compared to those submitted to the HCl-methanol method. In general, the two methods yielded the same percentages of mono- and polyunsaturated FAME, with the exception of the larger percentage of the component tentatively identified as *cis*-16:1 in the samples transesterified with $NaOCH_3$.

Although the results of Study II were encouraging, there were no statistically significant differences in the observed patterns that could be ascribed to differences

TABLE 4

Ratios of Selected FAME in Human Cheek Cell Lipids[a]

	Study I						Study II			
	Nonpolar lipid		Polar lipid		Total lipid		HCl-Methanol		$NaOCH_3$	
Diet P/S	1.0 (N = 7)	0.3 (N = 9)	1.0 (N = 7)	0.3 (N = 9)	1.0 (N = 7)	0.3 (N = 9)	1.0 (N = 10)	0.3 (N = 12)	1.0 (N = 10)	0.3 (N = 12)

[a]Values are averages of ratios in individual samples with the standard deviation shown in parentheses. Values for the total lipid were derived from summing the μg of FAME in nonpolar and polar lipids.

[b]Sat, sum of 14:0 + 16:0 + 18:0.

[c]PUFA, sum of n-3 and n-6 polyunsaturated fatty acids.

in dietary P/S ratio. The trends noted in Study I also were evident in Study II; that is, cheek cell lipids derived from subjects on the higher P/S diet contained slightly higher percentages of 18:2 and slightly lower percentages of 18:1 and 20:4.

To compare the data obtained in both studies, we calculated ratios for FAME. The values presented in Table 4 are for those ratios that consistently displayed a trend that appeared to be attributable to diet. Regardless of the method of analysis, the average values obtained for 18:2/20:4, 18:2/18:1 and 18:2/18:0 were always greater for cheek cell lipids derived from subjects consuming the higher P/S diet. There was also a trend for the polyunsaturated fatty acid/14:0 + 16:0 + 18:0 (Sat) to be higher in cheek cell lipids of subjects on the higher P/S diet. However, the 18:1/(Sat) tended to be lower in the women on the higher P/S diet.

DISCUSSION

Despite our efforts to standardize procedures for sampling cheek cells, there were large sample-to-sample variations in all parameters analyzed. Nevertheless, a number of trends were observed that suggest diet may influence observed FAME patterns in cheek cell lipids. Regardless of the procedures used to analyze the lipids, FAME of cheek cell preparations derived from subjects on the higher P/S diet displayed lower percentages of 18:1 and 20:4, a slightly higher percentage of 18:2, higher ratios for 18:2/20:4, 18:2/18:1 and 18:2/18:0 and a lower ratio for 18:1/(Sat).

The 18:2/18:1 values observed in cheek cell lipids (Table 4) were similar to the ratios calculated for the diets consumed by subjects in these studies (0.76 and 0.46 for the high and low P/S diets, respectively). These results suggest that some aspects of diet fatty acid composition may have a direct effect on cheek cell lipid composition. In contrast, the trends observed for 18:2/20:4 and 18:1/(Sat) in our studies are more difficult to interpret.

The ratio of 18:1/(Sat) was calculated to be 1.49 and 0.71 for the high and low P/S diets, respectively. Thus, the diet with the greater percentage of 18:2 and the greater ratio of 18:1/(Sat) apparently resulted in cheek cell lipids with lower values of 18:1 and 20:4, lower ratios of 18:1/(Sat) but higher ratios of 18:2/20:4.

The inverse relationship between the dietary percentage of 18:2 and the observed values for 18:1 and 20:4 in cheek cell lipids may be a reflection of the differential effect of the two diets on desaturase activities. A similar relationship between dietary 18:2 and 18:1 values in human adipose tissue triglycerides has been reported (10,21,22). While the difference in 20:4 in the cheek cells may reflect dietary levels, it is possible that these values also reflect an effect of the diet on desaturase activities. It is well known that the level and type of dietary fat may influence key enzymes involved in fatty acid biosynthesis and desaturation (23). For example, Herodek and Csakvary (24) have reported that saturated fatty acids increase desaturase activity in liver and adipose tissue of mice. In contrast, Jeffcoat and James (25) have shown that linoleic acid is a potent inhibitor of stearoyl-CoA desaturase activity in rat liver. In addition, Hagve and Christophersen (26) have reported higher Δ-6 desaturase activity in isolated liver cells derived from rats fed hydrogenated coconut oil compared with liver cells derived from rats fed soybean oil or standard rodent pellets. Moreover, polyunsaturated fatty acids have been shown to have a selective dampening effect on other lipogenic enzymes, including acetyl-CoA carboxylase (27). We believe that the data observed in our studies may be a reflection of similar controls on lipogenic enzymes in humans.

In contrast to the reports by McMurchie et al. (5,6), we found virtually identical P/S ratios in polar lipids of cheek cells. It is possible that differences in dietary P/S ratio during periods of low-fat intake (as was the case in our study) may have no visible effect on polar lipid FAME patterns. Moreover, since polar lipids are largely structural components, which also may participate in important cellular functions, it is likely that relatively rigorous metabolic controls act to minimize any drastic alteration in the composition of these constituents. In this regard, it should be noted that others have failed to observe differences in adipose tissue phospholipid P/S ratios of subjects on different P/S diets (10).

Whereas polar lipids are resistant to dietary manipulation, this is not the case for triglycerides. Alterations in tissue triglyceride fatty acid composition resulting from dietary lipid differences have been noted in several studies, including those in humans (10). In our studies,

it seems relevant that the greatest differences for P/S ratios in cheek cell lipids between the low and high P/S diets were observed for nonpolar lipids in Study I and for FAME resulting from $NaOCH_3$ transesterification in Study II (Table 4). In both cases, triglycerides would have contributed substantial proportions of fatty acids to the resulting FAME analyses. Future studies directed specifically at the fatty acyl composition of cheek cell triglycerides may shed light on this point.

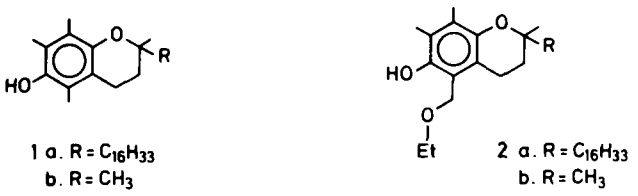
New Oxidation Products of α-Tocopherol

Cacang Suarna and **Peter T. Southwell-Keely***
School of Chemistry, University of New South Wales, P.O. Box 1, Kensington N.S.W., 2033 Australia

A major product of the reaction between α-tocopherol and *t*-butyl hydroperoxide in chloroform is 5-ethoxymethyl-7,8-dimethyl tocol, the source of the ethoxy group being the ethanol that is used to stabilize the chloroform. Two new products of this oxidation have now been identified as 2-(3′-hydroxy-3′,7′,11′,15′-tetramethylhexadecyl), 3-ethoxymethyl-5,6-dimethylbenzo-1,4-quinone and 5-ethoxycarbonyl-7,8-dimethyl tocol. These two compounds and another major product, 5-formyl-7,8-dimethyl tocol appear to be formed by further oxidation of 5-ethoxymethyl-7,8-dimethyl tocol.
Lipids 23, 137–139 (1988).

When α-tocopherol (**1a**) and its model compound, 2,2,5,7,8-pentamethyl-6-hydroxy chroman (**1b**) (Scheme 1), are oxidized by *t*-butyl hydroperoxide in purified chloroform to which ethanol has been added, 5-ethoxymethyl-7,8-dimethyl tocol (**2a**) and 5-ethoxymethyl-2,2,7,8-tetramethyl-6-hydroxy chroman (**2b**), respectively, are formed in amounts that vary with the concentration of ethanol (1). Oxidation does not occur in the absence of ethanol. If the reaction is performed in distilled, reagent-grade chloroform (containing 2% ethanol as stabilizer but with no additional ethanol), higher levels of **2a** and **2b** are produced together with a new dimeric quinone (Suarna, C., Craig, D.C., Cross, K.J., and Southwell-Keely, P.T., unpublished data) and other as yet uncharacterized compounds. The present work reports on the identification of several of these compounds.



SCHEME 1

MATERIALS AND METHODS

Infrared (IR) spectra were determined on a Perkin Elmer 580B spectrometer, ultraviolet (UV) spectra on a Perkin Elmer 124 double beam spectrophotometer and ^1H nuclear magnetic resonance (NMR) spectra on a Bruker CXP 300 spectrometer and a Bruker AM 500 spectrometer. NMR spectra were taken in $CDCl_3$ and are reported in parts per million downfield from tetramethylsilane as internal standard. Electron impact mass spectra were determined at 70 ev on an A.E.I. MS12 spectrometer and chemical ionization mass spectra on a Finnigan 3200 quadrupole spectrometer. High resolution molecular weights were determined on a Bruker Spectrospin Fourier Transform Ion Cyclotron Resonance spectrometer.

(±)-α-Tocopherol (**1a**, Roche Products, Sydney) was used without further treatment.

Distilled, reagent-grade chloroform (Ajax Chemicals, Sydney) was used as a solvent for the oxidation reactions.

Chloroform for thin layer chromatographic (TLC) plate elution was purified by washing with 18 M sulfuric acid and distilled water until the washings were neutral, drying (Na_2SO_4) and distilling immediately before use.

t-Butyl hydroperoxide (70%-EGA Chemie, Steinheim, FRG) was purified by the sodium salt method (2). Purity (iodometrically) was 95%.

The spiro dimer and spiro trimer of ***1a***, 5-formyl-7,8-dimethyl tocol (**7**); ***2a***, α-tocopheryl quinone; and 8a-ethoxy-α-tocopherone were prepared as reference compounds by known methods. (1,3–6).

*Oxidation of **1a** by t-butyl hydroperoxide.* A typical reaction was as follows: To **1a** (1011 mg, 2.25 mmol) in reagent grade chloroform (150 ml) was added *t*-butyl hydroperoxide (223 mg, 2.48 mmol) and the solution refluxed for 3 hr. The solution was then washed with 5% ferrous sulfate solution (6 × 30 ml) and distilled water (7 × 30 ml) and dried (Na_2SO_4), and the solvent was removed in vacuo. The residue was chromatographed on thin layers of Silica Gel GF_{254} (solvent: light petroleum (bp 60–80 C) ethyl acetate [9:1, v/v]), the products were located under UV light and eluted with purified chloroform and the solvent was removed under a stream of nitrogen and weighed. The following products were identified by comparison of their UV and ^1H NMR spectra with those of the prepared reference compounds; **7**, R_f 0.61; **2a**, R_f 0.53 (582 mg, 58%); **1a**, R_f 0.42. Products of unknown composition were isolated with R_f 0.87, 0.75, 0.69, 0.24, 0.17, 0.12 and 0.0.

The overlapping bands with R_f 0.12 (pink) and R_f 0.0 (yellow) were combined, rechromatographed on Silica Gel GF_{254} (solvent, light petroleum [bp 60–80 C] chloroform [2:8, v/v]) and resolved into three bands with R_f 0.21 (pale yellow, 11 mg, 1.1%), 0.34 (pink-orange, 24 mg, 2.4%) and 0.56. The compound with R_f 0.56 has been identified as a dimeric quinone (Suarna, C., Craig, D.C., Cross, K.J., and Southwell-Keely, P.T., unpublished data), while the compound with R_f 0.34 is under investigation.

2-(3′-Hydroxy-3′,7′,11′,15′-tetramethylhexadecyl)-3-ethoxymethyl-5,6-dimethyl-benzo-1,4-quinone (**4**) (R_f 0.21), a pale yellow oil, was identified by IR (KBr) 3450 (OH), 2930 (CH_3), 1650 (C=C–C=O), 1465, 1380,

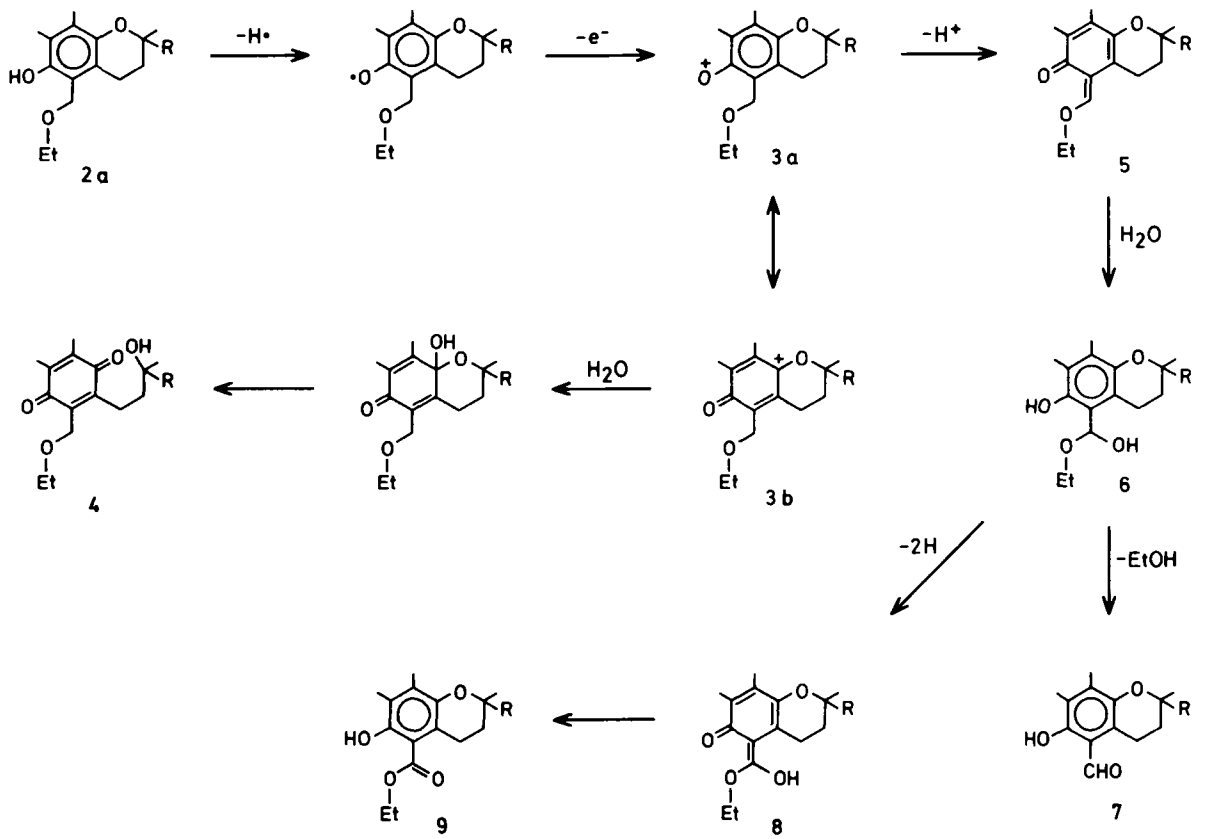
1305, 1100 (C-O-C) cm^{-1}; UV (hexane) λ_{max} 258, 267 (sh) nm; ^{1}H NMR ($CDCl_3$) δ 0.85 (m, 12H), 1.21 (t, 3H, J = 7.0 Hz, *CH_3*-CH_2-0-), 1.25 (broad m, 24H), 1.60 (m, 2H, =C-CH_2-*CH_2*-), 2.018 *(s, 3H,* =C-*CH_3*), *(s, 3H,* =C-*CH_3*), 2.65 (m, 2H, =C-*CH_2*-), 3.65 (q, 2H, J = 7.0 Hz, CH_3-*CH_2*-0-), 4.41 (s, 2H, =C-*CH_2*-0-) ppm. Irradiation of the singlet at 4.41 ppm led to an NOE on the multiplet at 2.65 ppm and on the quartet at 3.65 ppm, thus proving that the ethoxymethyl and methylene groups were attached to adjacent carbon atoms of the quinone ring. MS (ei) m/z (rel int) 490 (M^+, 0.5), 489 (0.5), 488 (1), 472 (0.5) (M^+-H_20), 444 (2) (M^+-C_2H_5OH), 442 (1), 431 (5), (M^+-C_2H_5-0-CH_2), 428 (3), 426 (1), 368 (3), 321 (50), 279 (52), 250 (13), 236 (21), 194 (100); MS (ci, methane) m/z (rel int) 491 (MH^+, 1), 490 (1), 489 (4), 473 (100) (MH^+-H_2O), 471 (14), 457 (4), 445 (10) (MH^+-C_2H_5OH), 427 (9) (MH^+-C_2H_5OH-H_2O). The normal methane adduct ions were noted at 519 $(M+29)^+$ and 531 $(M+41)^+$, confirming that the molecular weight was 490. Exact mass calculation for $C_{31}H_{54}O_4$ 490.4328; found, 490.4354.

*Isolation of 5-ethoxycarbonyl-7,8-dimethyl tocol (**9**).* Compound **2a** (300 mg), which had been kept in the refrigerator for two months, was rechromatographed on thin layers of Silica Gel GF_{254} [solvent, light petroleum (bp 60–80 C) ethyl acetate (9:1, v/v)]. Three bands were obtained with R_f 0.49 (**2a**), 0.60 (**7**) and 0.63.

Compound **9**. R_f 0.63, a bright yellow oil, was purified further by chromatography on Silica Gel GF_{254} [solvent, light petroleum bp 60–80 C/CCl_4 (16:9) ethyl acetate (99:1)] and was identified by IR (KBr) 3400 (weak H-bonded OH), 2930 (CH_3), 1656 (C=0), 1470, 1375, 1320, 1205, 1095 (C-O-C), 1030, 800 cm^{-1}; UVλ_{max} 260, 268, 350 nm; ^{1}H NMR ($CDCl_3$) δ 0.86 (m, 12H), 1.25 (broad m, 24H), 1.42 (t, 3H, J = 7.1 Hz; *CH_3*-CH_2-0), 1.72 (m, 2H, Ar-CH_2-*CH_2*-), 2.16 (s, 3H, Ar-*CH_3*), 2.18 (s, 3H, Ar-*CH_3*), 3.00 (t, 2H J = 6.9 Hz, Ar-*CH_2*-), 4.41 (q, 2H, J = 7.1 Hz, CH_3-*CH_2*-0-), 11.3 (s, 1H, OH); MS (ei) m/z (rel int) 488 (M^+, 100), 442 (47) (M^+-C_2H_5OH). Exact mass calculation for $C_{31}H_{52}O_4$ 488.4111; found, 488.4069.

*Oxidation of **2a** by t-butyl hydroperoxide.* To **2a** (36 mg) in reagent-grade chloroform (5 ml) was added *t*-butyl hydroperoxide (9 mg), and the solution was refluxed at 60 C for 3 hr. The solution was cooled, washed with 5% ferrous sulfate (2 × 10 ml), water (3 × 10 ml) and dried over anhydrous Na_2SO_4, and the solvent was removed in vacuo. The residue was chromatographed on thin layers of silica gel [solvent, light petroleum (bp 60–80 C)/ethyl acetate (9:1)], the products were located under UV light and eluted with chloroform, and the solvent was removed under a stream of nitrogen and weighed. The majority of products of this reaction have yet to be identified but their R_{fs} were as follows: R_f 0.65 unknown (0.6 mg; 2%); R_f 0.62 unknown (5 mg; 15%); R_f 0.61 unknown (2 mg; 5%); R_f 0.59, **7** (10 mg; 28.5%); R_f 0.54 **2a** (4 mg; 12%) R_f 0.51 unknown (6 mg; 16%); R_f 0.45 unknown (3 mg; 8.5%); R_f 0.15 unknown (4 mg; 12%).



SCHEME 2

Compound **7** was identified by UV λ_{max} 238 (ϵ 7012), 282 (ϵ 12053), 288 (ϵ 12196), 387 (ϵ 4022) nm; IR (KBr) 3400 (very weak H-bonded OH), 2920 (CH_3), 1635 (C=0), 1460, 1380, 1310, 1095 (C-O-C) cm^{-1}; ^{1}HNMR ($CDCl_3$) δ 0.85 (m, 12H), 1.05-1.65 (broad m, 24H), 1.82 (m, 2H, 3-CH_2), 2.15 (s, 3H, Ar-CH_3), 2.17 (s, 3H, Ar-CH_3), 3.03 (t, 2H, 4-CH_2, J = 6.6Hz), 10.2 (s, 1H, CHO), 12.1 (s, 1H, OH) ppm, Irradiation of the singlet at 10.2 ppm produced an NOE on the triplet at 3.03 ppm (4-CH_2), thus proving that the aldehyde group was on position 5 of the chroman; MS (ei) m/z (rel int) 444 (M^+ 85), 426, (21), 271 (6), 243 (12), 229 (12), 220 (47), 219 (24), 215 (18), 202 (44), 201 (100).

RESULTS AND DISCUSSION

Both compounds **4** and **9** appear to be formed by oxidation of **2a**. However, when **2a** is oxidized by *t*-butyl hydroperoxide in reagent-grade chloroform, the major product by far is **7**, so that the formation of **4** and **9** represents minor pathways.

The formation of these products may be explained by assuming that **2a** is oxidized in the same way as **1a**, through a tocopheroxyl radical (7,8) to a phenoxylium species (**3a,3b**) (9,10) and a quinone methide (**5**) (11,12) (Scheme 2). Water formed during the oxidation may add to the phenoxylium ion producing the benzoquinone (**4**) or it may add to the quinone methide producing a hemi-acetal (**6**). Compound **6** may lose ethanol to form the aldehyde (**7**) or it may be oxidized to a further quinone methide (**8**), which is the tautomer of the ester (**9**). Clearly, the conditions which favor the formation of **9** are very mild.

ACKNOWLEDGMENT

I. Gregor and M. Guilhaus are thanked for the FT-ICR high resolution molecular weight determinations of **4** and **9**.

Detection of *cis*-Vaccenic Acid in Palm Oil by ^{13}C NMR Spectroscopy

Soon Ng[*,a] and **Heng Fui Koh**[b]

[a]Department of Chemistry, University of Malaya, 59100 Kuala Lumpur, Malaysia, and [b]Guthrie Research Chemara, 70200 Seremban, Negeri Sembilan, Malaysia

The NMR signals of the carbonyl and olefinic carbons of the oils of some species of palm show some relatively weak peaks at characteristic positions that have not been identified previously. These peaks are most intense in the oil of the species *Elaeis oleifera*. On the basis of the chemical shift data of the carbonyl and olefinic carbons of several synthetic monoenic triacylglycerols and of the packed-column gas chromatogram of the methyl esters of the oil of *E. oleifera*, the peaks in question are assigned to *cis*-vaccenic acid (18:1,[*cis*]-11). ^{13}C NMR spectroscopy is an effective technique for the detection of *cis*-vaccenic acid and other monounsaturated fatty acids in vegetable oils or fats.

Lipids 23, 140-143 (1988).

Cis-vaccenic acid (*cis*-11-octadecenoic acid) (1) is well known to be a component fatty acid of microorganisms and animal tissues. Although it has been identified previously in plant sources (2), its presence in vegetable oils and plant lipids has not been well investigated, probably because of its low concentration and of some difficulties in conventional analytical procedures. Recent progress in capillary gas chromatography (GC) has made it possible to detect *cis*-vaccenic acid in the presence of other isomeric monoenoic acids in plant lipids (3). A new analytical procedure for determination of *cis*-vaccenic acid in plant lipids is by gas chromatography-mass spectrometry (GC-MS) through its pyrrolidine- and bis(methylthio)-derivatives (4). By the use of picolinyl ester derivatives, the GC-MS technique has been found to be advantageous in determining both the numbers and positions of the double bonds in fatty acids (5).

In this paper, we show that isomeric monoenoic acids in triacylglycerols can be differentiated easily in the ^{13}C NMR spectra of the carbonyl and olefinic carbons and, by this technique, *cis*-vaccenic acid in the oil of certain species of palm is detected.

MATERIALS AND METHODS

The samples of palm oil used in this study were obtained from the Guthrie Research Chemara (GRC) experimental station where various species of palm are grown and from local palm oil mills. The synthetic homogeneous triacylglycerols were obtained from Sigma Chemical Co. (St. Louis, MO).

For ^{13}C NMR analysis, the palm oil was dissolved in chloroform-*d* in the volume ratio 1:4 and then filtered. The synthetic triacylglycerols or mixtures of them also were dissolved in chloroform-*d* to form 2-3 mol % solutions. The ^{13}C NMR spectra were recorded on a JEOL FX100 high-resolution Fourier transform NMR spectrometer with the probe temperature at 28 C.

Packed-column gas chromatography (GC) was carried out with a Perkin Elmer model 8310 gas chromatograph equipped with a flame ionization detector (FID). Operating conditions were 2m × 3 mm i.d. glass column packed with 10% SP-2300 on 100-120 mesh Chromosorb W; column temperature, isothermal at 200 C. The fatty acid methyl esters (FAME) were prepared by normal procedures and then injected into the GC instrument, using the on-column injection technique via a glass liner.

RESULTS AND DISCUSSION

Recently, it has been shown that the carbonyl carbons of various fatty acids at the 1,3- and the 2-positions of the triacylglycerols of palm oil (or any vegetable oil or fat) have different chemical shifts and can be distinguished in the carbon-13 NMR spectrum (6). Similarly, the olefinic carbons of acyl groups in the two glycerol positions can be distinguished (7). The carbon-13 NMR spectra of the oil of several species of palm grown at the GRC experimental station have been examined. The spectra of the carbonyl and olefinic carbons of the oils of two species (*Elaeis oleifera* and a hybrid Dura (GRC code 395) show some relatively weak peaks at characteristic positions that previously have not been identified. These peaks are most intense in the case of the oil of *E. oleifera* and appear between those of the carbonyl carbons of the oleic and the saturated acyl groups and between the two groups of peaks for the olefinic carbons of the oleic acyl group, as shown in Figures 1 and 2. These spectra suggest the new peaks belong to a monoenic fatty acid. In the sample of oil of *E. oleifera* shown in Figure 1, it is present at about 5 mol % of the total fatty acid content by estimating from the intensities of the peaks (6). The existence of this fatty acid is also detectable (<1 mol %) by carbon-13 NMR in some palm oil samples obtained from palm oil mills, where the oil would be a mixture of oils from various plantation sources or palm species.

To identify the monoenic acyl group described above, the carbon NMR spectra of several synthetic homogeneous triacylglycerols in mixtures with triolein and/or tripalmitin were obtained. The chemical shift data for the carbonyl and olefinic carbons are shown in Tables 1 and 2. The spectra of the carbonyl and olefinic carbons of a mixture of tripalmitin, triolein and trieicosenoin are shown in Figure 3. Comparison of Figures 1 and 2 with Figure 3 immediately suggests that the new peaks detected in the former may be assigned to a *cis*-11-monoene.

The gas chromatogram (packed column) of the methyl esters of fatty acids in the oil of *E. oleifera* provides the following composition (in wt %): palmitic (16:0) 15.1, palmitoleic (16:1) 1.7, stearic (18:0) 0.9, oleic (18:1) 66.2, linoleic (18:2) 15.3, linolenic (18:3) 0.6, and arachidic (20:0) 0.1. No monoenoic fatty acid longer in chain than 18:1 is detected. The peak for methyl oleate is twice as broad

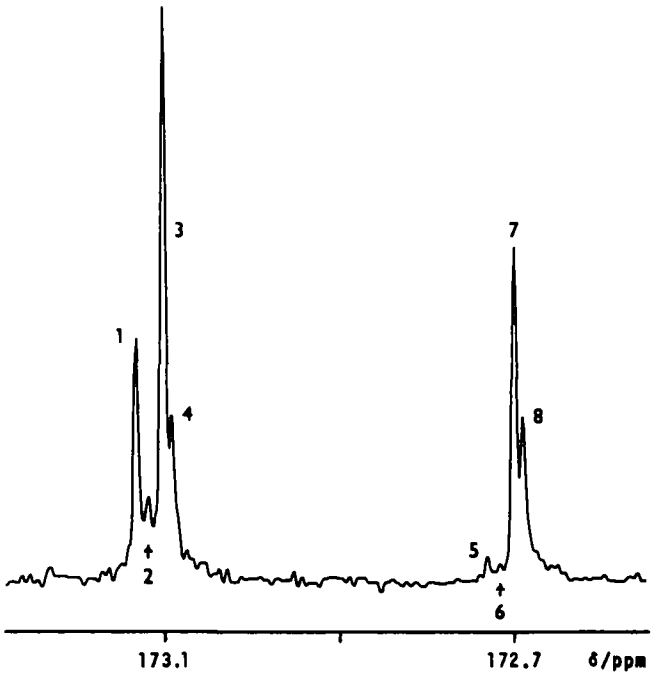

FIG. 1. 25.05 MHz ^{13}C NMR spectrum of the carbonyl carbons of the triacylglycerols in the oil of *E. oleifera* in chloroform-*d* solution, conc. 1:4 v/v, at 28 C. The group of peaks 1–4 pertains to acyl groups at the 1,3-positions, while the group of peaks 5–8 pertains to those at the 2-position. Peaks 1 and 5 belong to saturated acyl groups, peaks 3 and 7 belong to oleic (18:1,[*cis*]-9), and peaks 4 and 8 belong to linoleic (18:2,[*cis,cis*]-9-12) and linolenic (18:3,[*cis,cis,cis*]-9,12,15) acyl groups (6). Peaks 2 and 6 at δ 173.13 and 172.72 ppm, respectively, have not been identified previously.

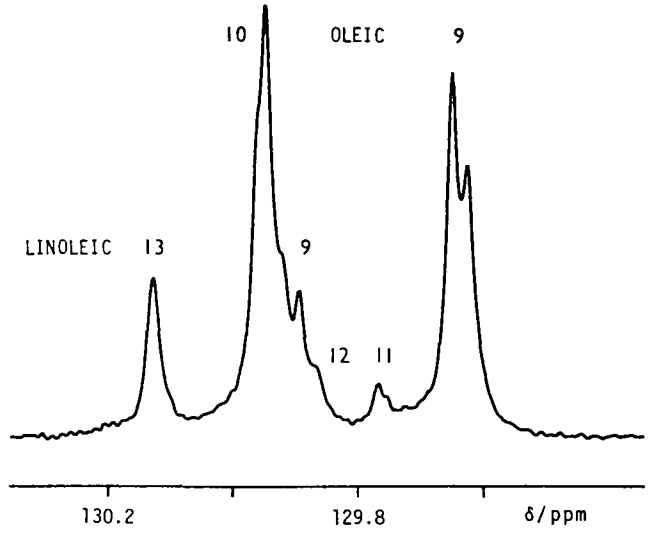

FIG. 2. 25.05 MHz ^{13}C NMR spectrum of the olefinic carbons of the triacylglycerols in the sample of the oil of *E. oleifera* described in Figure 1. Each olefinic carbon gives rise to two peaks, if resolved, because of the two glycerol positions (7). The labeling of the peaks corresponds to the positions of the olefinic carbons. The taller peak of C-9 of oleic pertains to the acyl groups at the 1,3-positions, while the lower peak pertains to that at the 2-position. The peaks of C-10 of oleic are not well-resolved; a shoulder appears on the high frequency side of the taller peak. Only the peaks of C-9 and C-13 of linoleic are shown; not shown are the peaks of C-10 and C-12 which are centered at δ 128.07 and 127.89 ppm, respectively. Peaks 11 and 12, at δ 129.89 and 129.79 ppm, respectively, have not been identified previously. Peak 11 has a shoulder on the low frequency side, as in the case of C-9 of oleic acid. The chemical shift between peak 12 and the main peak of 11 is 0.10 ppm.

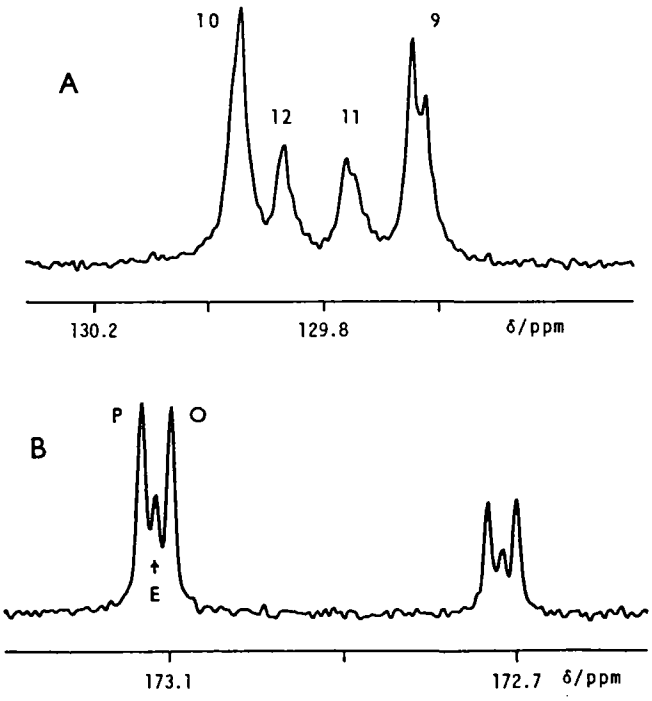

FIG. 3. 25.05 MHz ^{13}C NMR spectra of a mixture of synthetic tripalmitin, triolein and trieicosenoin in the mole ratio 2:2:1, respectively, in chloroform-*d* solution (total conc. 3.0 mol %) at 28 C. A, spectrum of the olefinic carbons. Peaks 9 and 10 belong to C-9 and C-10 of oleic (*cis*-9-monoene), while peaks 11 and 12 belong to C-11 and C-12 of eicosenoic (*cis*-11-monoene). The chemical shift between peak 12 and the main peak of 11 is 0.108 ppm. B, spectrum of the carbonyl carbons. The group of peaks at δ 173.1 ppm pertains to acyl groups at the 1,3-positions, while the group at δ 172.7 ppm pertains to those at the 2-position. Assignments are P, palmitic; O, oleic; E, eicosenoic; assignments are in the same order to the peaks for the 2-position.

TABLE 1

Chemical Shifts of Carbonyl Carbons in Triacylglycerols[a]

Triacylglycerol	δ(1,3)[b]	δ(2)[b]
Tripalmitin (16:0)	173.146	172.735
Tripalmitolein (16:1,[*cis*]-9)	173.114	172.703
Tripetroselinin (18:1,[*cis*]-6)	172.988	172.591
Triolein (18:1,[*cis*]-9)	173.113	172.702
Trielaidin (18:1,[*trans*]-9)	173.121	172.711
Trieicosenoin (20:1,[*cis*]-11)	173.130	172.719
Trierucin (22:1,[*cis*]-13)	173.137	172.726

[a]In chloroform-*d* solution at 28 C, conc. 2.0 mol %; spectrometer operating frequency 25.05 MHz. Chemical shift scale δ in ppm.
[b]δ(1,3) pertains to the acyl groups at the 1,3-positions and δ(2) to that at the 2-position.

as the other peaks and, as such, may be unresolved for a positional isomer, especially when it is of much lower abundance than the methyl oleate. Thus, the *cis*-11-monoene detected in Figures 1 and 2 tentatively is identified as *cis*-vaccenic acid (18:1,[*cis*]-11). This is to be confirmed by isolation of this fatty acid using high resolution capillary column GC. The presence of *cis*-vaccenic acid in palm oil has never been reported (8).

TABLE 2

Chemical Shift Data of the Olefinic Carbons of Monoenes in Triacylglycerols[a]

Triacylglycerol	Δ(1,3)[b]	Δ(2)[b]	δ_m(1,3)[c]
Tripetroselinin	1.613	1.638	127.719
Tripalmitolein	0.292	0.330	129.839
Triolein	0.292	0.330	129.839
Trielaidin	0.298	0.318	130.324
Trieicosenoin	0.108	0.124	129.852
Trierucin	0.038	0.048	129.861

[a]In chloroform-*d* solution at 28 C, conc. 2.0 mol %; spectrometer operating frequency 25.05 MHz. Chemical shift unit in ppm.

[b]Each olefinic carbon appears as two peaks, if resolved, because of the two glycerol positions (7). Δ(1,3) refers to the chemical shift difference in ppm of the two olefinic carbons of the acyl groups at the 1,3-positions, and Δ(2) to that at the 2-position.

[c]δ_m(1,3) refers to the mean of the chemical shifts in ppm of the two olefinic carbons of acyl groups at the 1,3-positions. The corresponding values for the acyl group at the 2-position, δ_m(2), is in every case less than δ_m(1,3) by 0.005 to 0.010 ppm.

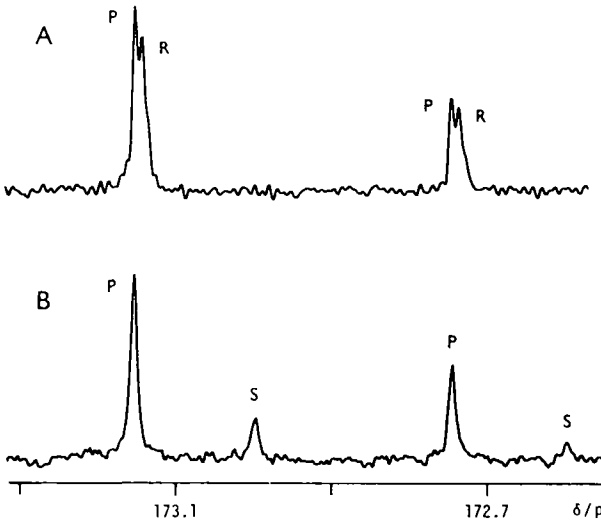

FIG. 4. 25.05 MHz ^{13}C NMR spectra of the carbonyl carbons of mixtures of synthetic triacylglycerols in chloroform-*d* solution (total conc. 2.0 mol %) at 28 C. See Figure 3 for assignment of resonance peaks to the glycerol positions. A, spectrum of the solution of tripalmitin (P) and trierucin (R), showing that the peaks for the carbonyl carbons of the *cis*-13-monoene all appear 0.009 ppm to low frequency of those of saturated tripalmitin. B, spectrum of the solution of tripalmitin (P) and tripetroselinin (S), showing that the peaks for the carbonyl carbons of *cis*-6-monoene appear to low frequency of those of saturated tripalmitin, 0.158 ppm in the case of the 1,3-positions and 0.144 ppm in the case of the 2-position.

The data in Table 1 show that the chemical shift of the carbonyl carbon of a *cis*-monoene in a triacylglycerol depends on the position of the double bond. This may be the result of steric interactions with the glycerol carbons and of the linear electric field effect of the double bond (9). The length of the free end of the acyl chain beyond the double bond does not appear to affect the chemical shift of the carbonyl carbon, as the data for tripalmitolein

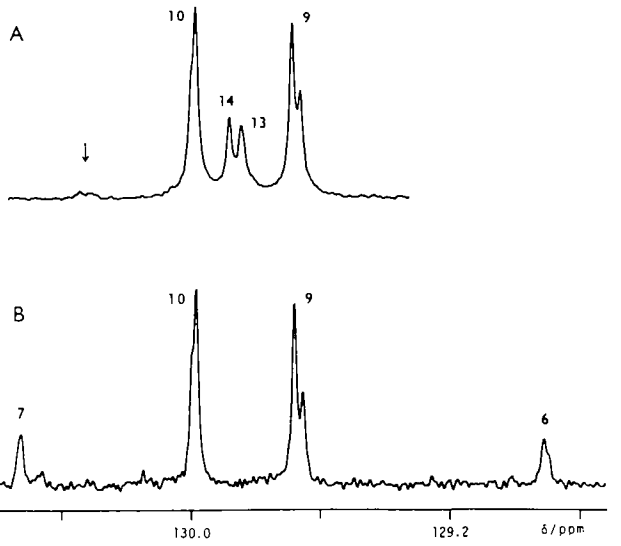

FIG. 5. 25.05 MHz ^{13}C NMR spectra of the olefinic carbons of mixtures of synthetic triacylglycerols in chloroform-*d* solution (total conc. 3.0 mol % in A and 2.0 mol % in B) at 28 C. See Figure 2 for assignment of the peaks to the glycerol positions. A, spectrum of the solution of triolein and trierucin, showing the relative positions of the resonance peaks of the olefinic carbons of *cis*-9- and *cis*-13-monoenes. Peaks 9 and 10 belong to C-9 and C-10 of triolein, while peaks 13 and 14 belong to C-13 and C-14 of trierucin (*cis*-form). The arrow indicates the corresponding peaks, centered at δ 130.34 ppm, of the *trans*-form of trierucin, which is present (ca. 10%) in the sample of trierucin. B, spectrum of the solution of triolein and tripetroselinin, showing the relative positions of the resonance peaks of the olefinic carbons of *cis*-9- and *cis*-6-monoenes. Peaks 9 and 10 pertain to triolein as described above, while peaks 6 and 7 belong to C-6 and C-7 of tripetroselinin.

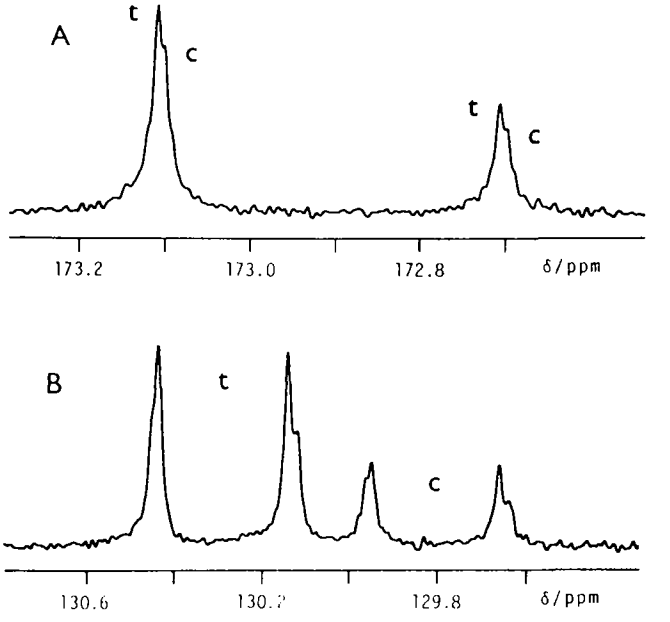

FIG. 6. 25.05 MHz ^{13}C NMR spectra of a mixture of triolein and trielaidin (*trans*-9-monoene), with the latter as the major component (total conc. 2.5 mol %) at 28 C. A, spectrum of the carbonyl carbons, showing that in the *trans*-form (t) each of the resonance peaks appears 0.008 ppm to high frequency of the corresponding peak in the *cis*-form (c). B, spectrum of the olefinic carbons, showing that the peaks for the *trans*-form (t) appear about 0.48 ppm to high frequency of the corresponding peaks in the *cis*-form (c).

(16:1,[*cis*]-9) and triolein (18:1,[*cis*]-9) indicate. When the double bond is nearer to the carbonyl, the resonance of the carbonyl is shifted farther to low frequency; relative to the saturated tripalmitin, the shift to low frequency in the dilute chloroform-*d* solution (ca. 2 mol %) is 0.158 and 0.144 ppm for the 1,3- and 2-glycerol positions, respectively, in the *cis*-6-monoene (tripetroselinin), whereas the shift is only 0.009 ppm for either of the glycerol positions in the *cis*-13-monoene (trierucin), as shown in Figure 4. By extrapolation of the data in Table 1, the shift in the carbonyl carbon resonance from that of the saturated palmitic acid is expected to be negligibly small at low magnetic field in the *cis*-15-monoene and to be undetectable even at high magnetic field in the *cis*-17-monoene.

Table 2 shows that the chemical shift between the two olefinic carbons of a monoene in a triacylglycerol depends on the position of the double bond, being larger when the double bond is nearer to the carbonyl. This may be mainly the result of the linear electric field effect of the head group dipole (9). In a mixture of monoenes, the spectrum of the olefinic carbons of a given monoene always appears inside that of the monoene whose double bond bears a smaller positional number, as shown in Figures 3 and 5. Earlier studies have reported similar chemical shift data for a large number of olefinic fatty acids and esters (10) and of unsaturated fatty acid methyl esters (11,12). Table 2 also shows the position midway between the resonances of the two olefinic carbons of a monoene. By extrapolation, the resonances of the two olefinic carbons are expected to converge at δ 129.87 ppm in the *cis*-17-monoene in dilute chloroform-*d* solution. The chemical shifts of the olefinic carbons of the *trans*-monoene occur at higher frequencies than the corresponding *cis*-monoene, as indicated for trielaidin and triolein in Table 2 and Figure 6, and for trierucin in Figure 5. The chemical shift between the olefinic carbons of a monoene appears to be the same in the *cis*- and the *trans*-isomers. Thus, by reference to or by interpolation of the data in Tables 1 and 2, any monoenoic fatty acid with olefinic positional number up to 15 can be identified by ^{13}C NMR spectroscopy.

This study shows that *cis*-vaccenic acid is present in detectable quantities in the oils of some species of palm, being most abundant in the oil of *E. oleifera*, and that ^{13}C NMR spectroscopy is an effective technique for its detection. Monounsaturated fatty acids and their positional isomers are distinguished easily in the ^{13}C NMR spectra of the carbonyl and the olefinic carbons. The disadvantage of this technique is its insensitivity to the length of the free end of the acyl chain beyond the double bond.

Recently the presence of *cis*-vaccenic acid in mango pulp lipids has been reported (4). It is noteworthy that an appreciable quantity of palmitoleic acid is present together with *cis*-vaccenic acid in the oil of *E. oleifera*, as the former acid is involved in the mechanism of formation of the latter (13). The synthesis of *cis*-vaccenic acid in the seeds of *Sinapis alba* through elongation of preformed palmitoleic acid has been observed recently (14).

Cellular Retinyl Esters and Retinol Among Parenchymal And Stellate Cells in Normal Rat Liver

M.R. Lakshman*[a], P.R. Sundaresan[b], Laura L. Chambers[a] and Pamela K. Shoff[c]

[a]Lipid Research Laboratory, V.A. Medical Center, Washington, DC, [b]Division of Nutrition, Center for Food Safety and Applied Nutrition, Food and Drug Administration, Washington, DC, and [c]Hemostasis Laboratory, V.A. Medical Center, Washington, DC

[11,12-^{3}H] Retinyl acetate (100 μg/20 μCi/rat) in corn oil was fed by stomach tube to normal male Wistar-Furth rats (~250 g body weight). After 15 days, the contents of retinyl esters and retinol (total retinol) and their ^{3}H-radioactivity were measured in the whole liver, crude parenchymal cells and the purified parenchymal cells, employing differential centrifugation, centrifugal elutriation and high performance liquid chromatography (HPLC) techniques. Of the total liver retinol (nmol/g liver), the crude parenchymal cells had nearly 90%, whereas the purified parenchymal cells had only 21% based on HPLC analysis. Furthermore, of the total liver retinol radioactivity (dpm/g liver) the crude parenchymal cell fraction had 85%, while the purified parenchymal cell fraction had only 16%. Based on the cell number, the crude parenchymal cell fraction was contaminated by retinoid-rich stellate cells to the extent of 4%. It, therefore, was concluded that the parenchymal cells accounted for 16-21%, whereas the stellate cells contributed 79-84% of total retinol stored in the liver under normal steady-state conditions. It also was calculated that on a per mg basis, stellate cells had 200 times more total retinol than parenchymal cells, whereas on a per cell basis each stellate cell had 74 times more total retinol than a parenchymal cell.

Lipids 23, 144-147 (1988).

Liver is the main storage site of retinyl esters and retinol in mammals (1,2). Under normal nutritional conditions, as much as 95% of total retinol of the body is stored in the liver, predominantly as retinyl palmitate in the rat (1,2). Liver accumulates dietary retinoids as retinyl esters from the circulating chylomicron remnants (3-6). Liver also plays a dynamic role in retinoid metabolism generating retinol from the stored retinyl palmitate (7-9) or resynthesizing the esters (2,3,10-12) as well as synthesizing the retinol binding protein, which is essential for the transport of retinol to extrahepatic tissues (13,14). Furthermore, liver has the necessary enzyme systems to oxidize retinol to retinal (15) and retinoic acid (16,17).

Liver is composed of two major classes of cells: the parenchymal cells (PC) and the nonparenchymal cells (NPC). The latter group includes the Kupffer, endothelial and stellate cells. Although it is well known that the liver cells play a major role in several aspects of retinoid metabolism, the distribution of retinoids in various types of liver cells is a subject of great interest and some controversy. Thus, depending on the study and the methodology employed, PC (18-20), Kupffer cells (21,22) or stellate cells (23-25) have been suggested as the major sites of vitamin A storage. Olson and Gunning (26) suggested that hepatic retinoids may be distributed equally between PC and stellate cells. These differences may be due to the lack of reproducible methodology for the isolation of these various cell types in pure form and to inconsistency in the vitamin A status of the animals used in these studies. However, a sophisticated methodology employing a centrifugal elutriation technique now has been developed for the isolation of various liver cells in pure form (24,27,28). Utilizing this technique, this study supports the previous observations and suggestions (29-31) that stellate cells are the major species of liver cells that store the vitamin. It will be demonstrated that liver PC account for only 21% of total retinol stored in the liver, whereas the stellate cells store the rest of the vitamin under normal steady-state conditions. This further is confirmed by the demonstration for the first time that based on the contents of labeled total retinol among these cells, parenchymal cells accounted for 16%, while the stellate cells stored 84% of the vitamin in a steady-state condition.

EXPERIMENTAL

[11,12-^{3}H] Retinyl acetate (specific activity 35 Ci/mmol) was a gift from Hoffmann-La Roche (Nutley, NJ). Betafluor and Hydrofluor scintillation fluids were from National Diagnostics (Somerville, NJ). Collagenase (CLS II) was from Worthington Biochemicals (Freehold, NJ). All other chemicals and reagents were of analytical grade.

Isolation and purification of parenchymal and stellate cell fractions from rats administered with [^{3}H] retinyl acetate. Male albino Wistar-Furth rats (Charles River Breeding Labs, Wilmington, MA) weighing 250 g were used throughout this study. The animals were maintained on normal rat chow (1 μg retinyl acetate per g diet) for at least two weeks before experimentation. Each rat was fed by stomach tube a single 100 μg dose of [11,12-^{3}H] Retinyl acetate (20 μCi) in 1 ml corn oil. The rats were fed ad *libitum* for a further period of 15 days to allow the administered tracer to be fully equilibrated with the endogenous pool and thus reach a steady-state (32). A small lobe of each liver was saved on the 15th day for the determination of total retinyl esters and retinol. The total liver cells were isolated from each rat by our published procedure (33), which was according to that of Krebs et al. (34).

Briefly, the liver was perfused at 37 C initially with Krebs-Henseleit bicarbonate buffer, pH 7.4, without $CaCl_2$ (KRB) at a flow rate of 1.5 ml/min/g for 10 min after which 30 mg Collagenase (CLS II) was added to

Abbreviations: CPC, crude parenchymal cells; HPLC, high performance liquid chromatography; KRB, Krebs-Henseleit bicarbonate; LDH, lactate dehydrogenase; NPC, nonparenchymal cells; PC, parenchymal cells; PPC, purified parenchymal cells.

100 ml of the KRB buffer, and the perfusion was continued for a further period of 20 min when the liver cells were ready to disperse easily. The whole liver was isolated, finely minced with scissors and suspended in Krebs-Henseleit bicarbonate buffer, pH 7.4, containing 1.5% bovine serum albumin, 20 mM dextrose and 2.5 mM $CaCl_2$ (KHB-BDC buffer). The cell suspension was filtered through a nylon filter (mesh size, 250 μm). The crude parenchymal cells (CPC) were sedimented from the total liver cell suspension by centrifugation at 50 $\times$ *g* for two min, leaving the crude NPC in the supernatant fraction. The CPC thoroughly were washed free of residual collagenase by resuspending in KHB-BDC buffer and resedimenting three times as before.

The final washed CPC (2×10^7 cells) were subjected to two successive centrifugal elutriations (27) in a Beckman J6 M centrifuge, using the standard Sanderson chamber in the JE-6 elutriation rotor revolving at 2500 rpm. The CPC were introduced into the chamber at a flow rate of 11 ml/min, which was increased stepwise with time to 13.5, 20, 23, 25, 38, and 53 ml/min. A volume of 100 ml of KHB-BDC buffer was washed through the cells in the chamber at each flow rate, and the effluent was collected. This elutriation procedure was repeated one more time, and the purified parenchymal cells (PPC) that sedimented in the chamber after the second elutriation step were collected. The liver lobe, CPC and PPC were extracted sequentially with 20 vol of methanol and 20 vol of hexane. All organic solvents contained 5 mg % (w/v) butylated hydroxytoluene. The combined lipid extracts were reduced in volume under a stream of nitrogen and analyzed for their retinyl ester and retinol contents by high performance liquid chromatography (HPLC) and for tritium radioactivity.

Characterization of the liver cells. Both PC and NPC were more than 90% viable as tested by trypan blue dye exclusion. PC satisfied all the criteria of intact, viable and metabolically active hepatocytes defined by Krebs et al. (34). Furthermore, the integrity of the plasma membrane of PC was tested by measuring the leakage of cellular lactate dehydrogenase (LDH) activity and of labeled total retinol into the medium when incubated in the KHB-BDC buffer. Only 5% of the total cellular LDH activity and 5-8% of cellular total retinol radioactivity were released into the medium even after three hr of incubation. The NPC fraction lost only 8% of its total retinol radioactivity under identical conditions. Thus, the various types of liver cells isolated in this study were characterized to be intact, viable and metabolically active. Fluorescent microscopy revealed that the CPC fraction was contaminated by stellate cells to the extent of 4% based on cell number. In contrast, the PPC fraction virtually was devoid of any contamination by stellate cells.

Determination of retinyl ester and retinol by HPLC. HPLC was run in a Beckman Model 346 system equipped with a Beckman Model 165 detector, auto sampler and model 450 data system. The sample was applied to a Zorbax TMS column (4.6 $\times$ 15 cm; E.I. Dupont de Nemours & Co., Wilmington, DE) using acetonitrile: water (85:15, v/v) with a flow rate of 1.2 ml/min. Authentic retinol, retinyl acetate and retinyl palmitate were eluted as sharp peaks at 2.2, 2.5 and 9.1 min, respectively. Recoveries of known quantities of all these retinoids, when added to the cell fractions before extraction, were more than 95% using this procedure. The detection limit of this method was 5-10 ng for each retinoid.

RESULTS AND DISCUSSION

Table 1 shows the relative levels of retinyl esters and retinol as well as the relative distribution of total retinol radioactivity in the whole liver, CPC, PPC and the stellate cells 15 days after oral administration of (11,12-^{3}H)retinyl acetate (100 μg/20 μCi/rat) to normal rats. Based on HPLC analysis, the normal rat liver had 679 nmol of total retinol per g wet wt under steady state conditions. Significantly, the CPC fraction had 611 nmol/g (data not shown), whereas the PPC fraction had 144 nmol/g (Table 1). Thus, the CPC had nearly 90%, while the PPC had only 21% of the liver total retinol. These data indicate that even though the crude parenchymal fraction contained most of the liver total retinol as observed by others (18,19) and in our preliminary report (20), purification by centrifugal elutriation led to the retention of only

TABLE 1

Relative Level of Total Retinol in Parenchymal and Stellate Cells

Cell type	Retinyl esters plus retinol[a] (nmol/g wet wt)	As % of total liver	Radioactivity[b] dpm $\times 10^{-5}$/g wet wt	As % of total liver
Total liver	679 ± 117	100	3.26 ± 0.37	100
Parenchymal	144 ± 29	21	0.53 ± 0.07	16
Stellate[c]	535 ± 91	79	2.73 ± 0.04	84

[a]Each value is the mean of six animals ± SE. 86.5% of the total amount was due to retinyl palmitate, 8.6% due to the sum of retinyl stearate and oleate and 4.9% due to retinol.
[b]Each value is the mean of four animals ± SE.
[c]These values were calculated by subtracting the values of parenchymal cells from the total liver values.

TABLE 2

Relative Concentration of Total Retinol in Parenchymal and Stellate Cells

	Parenchymal cells	Stellate cells	S/P cells
Total retinyl esters plus retinol[a] (nmol/g liver)	144	535	3.7
Mass of cell type (37) (mg/g liver)	810	15	0.02
No of cells $\times 10^{-6}$/g liver (38)	100	5	0.05
Retinyl esters plus retinol concentration			
nmoles/mg	0.18	35.67	200
nmoles/10^6 cells	1.44	107	74

[a]Values were taken from Table 1.

a small percentage of total retinol of the liver. This would mean that most of the vitamin recovered in the CPC fraction must have been due to the contaminating stellate cells. This is further confirmed by our finding of the relative distribution of total retinol radioactivity among various liver cells (Table 1). It was found that under identical conditions, the total retinol label in the whole liver was 3.26×10^5 dpm/g of which only 0.53×10^5 dpm/g were recovered in PPC. Thus, PPC accounted for only 16% while the other 84% of the liver total retinol label was due to the NPC. Of the NPC population, endothelial and Kupffer cells contain negligible amounts of the vitamin (30). Therefore, the only other NPC type that is the major storage site of liver vitamin A under steady-state conditions in normal rats is the stellate cell. It also is clear that PC contribute to the extent of 16-21% of the liver total retinol under identical conditions. This distribution pattern probably is most dependent upon the vitamin A status of the animals as well as their age. For example, PC seemed to play a major role in the uptake and storage in a vitamin A-deficient state (35,36) while stellate cells seemed to be the major storage site when the liver total retinol concentration was varied over a three-fold range from 140-390 μg/g (27). The relative roles of various liver cells in hypervitaminosis A remain to be explored.

As illustrated in Table 2, PC constitute 81%, whereas the stellate cells possibly account for only 1.5% of total liver mass (37). Therefore, one can calculate the concentration of total retinol on a wet weight basis of each cell type. Thus, the stellate cells contain 35.67 nmol/mg while the PC have 0.18 nmol/mg, a concentration difference of 200-fold. Each g wet weight of the liver contains 100×10^6 PC and 5×10^6 stellate cells (38). Thus, when the concentration of total retinol is calculated based on cell number, stellate cells contain 107 nmol/10^6, whereas PC have 1.44 nmol/10^6, which amounts to 74 times more total retinol per stellate cell than per PC.

[Received June 2, 1987; Revision accepted September 22, 1987]

A Highly Active Soluble Diacylglycerol Synthesizing System from Developing Rapeseed, *Brassica napus* L.

Denis J. Murphy
Department of Botany, University of Durham, Durham DH1 3LE, U.K.

The subcellular distribution of the enzymes of triacylglycerol biosynthesis has been studied in developing oilseed rape. All in vitro enzymatic activities from oleoyl-CoA to triacylglycerol were sufficient to account for the known rate of oleate deposition in triacylglycerol in vivo. The enzymatic activities from oleoyl-CoA to diacylglycerol preferentially were localized in a 150,000 g supernatant fraction, while the diacylglycerol acyl-transferase mostly was associated with the microsomal (20,000 g pellet and 150,000 g pellet) and oil-body fractions. The soluble (150,000 g supernatant) fraction rapidly incorporated oleate from [1-^{14}C]oleoyl-CoA into diacylglycerol with rates of 40 nm min^{-1} g^{-1} FW at 20 μM oleoyl-CoA. The pH optimum was 7.5–9.0, and normal saturation kinetics were seen with oleoyl-CoA; the $S_{0.5}$ was about 32 μM. Exogenous acyl acceptors, such as glycerol 3-phosphate, lysophosphatidic acid and lysophosphatidylcholine stimulated oleate incorporation into diacylglycerol. The detergents Triton X-100 and sodium cholate inhibited diacylglycerol formation at concentrations in the region of their critical micellar concentration, while n-octyl-β,D-glyco-pyranoside had no effect, even at high concentration. The significance of these findings for the mechanism of oil-body formation in developing oilseeds is discussed.
Lipids 23, 157–163 (1988).

Triacylglycerols are the major form in which lipid is stored in many plant tissues, especially the oilseeds. Despite the evident economic usefulness of oilseed triacylglycerols and the desirability of manipulating their acyl composition to produce improved crop varieties, many aspects of their deposition in developing seeds remain obscure. In particular, the subcellular localization of the enzymes involved in triacylglycerol biosynthesis and the mechanism of oil-body formation yet have to be resolved satisfactorily. Triacylglycerols are synthesized by the progressive acylation of glycerol 3-phosphate by three acyltransferases while the phosphate moiety is removed by a phosphatase. Together, these reactions constitute the Kennedy pathway (1) for triacylglycerol biosynthesis.

Heinz et al. have reported that pea and spinach leaves contain one soluble (chloroplast stroma) (2–4) and one membrane-bound (microsomal) (5) glycerol 3-phosphate acyltransferase (GP-AT) plus two membrane-bound (chloroplast envelope and microsomal) (6,7) lysophosphatidic acid acyltransferases (LPA-AT). It also has been reported that spinach leaves contain a membrane-bound (chloroplast envelope) diacylglycerol acyltransferase (DG-AT) (8,9). In the case of developing oilseeds, both a soluble (10) and a microsomal (11) GP-AT have been found, and there are several reports of microsomal DG-AT activity (12–14), one of which shows that the enzyme in maize and castor bean seeds derives from endoplasmic reticulum rather than plastid envelope membranes (14). Purified oil-body fractions from crambe (15) and rapeseed (16) have been shown to incorporate oleoyl-CoA into triacylglycerols and, therefore, must contain all of the above acyltransferases, i.e. GP-AT, LPA-AT and DG-AT. Similar activities also have been reported in soluble extracts of developing rapeseed (16) but the soluble and oil-body acyltransferases remain to be characterized.

The determination of the subcellular localization of the enzymes of triacylglycerol biosynthesis will be important in shedding light on the ontogeny of oil-bodies (spherosomes) in developing oilseeds. This currently is the subject of much controversy with some authors favoring the development of oil-bodies from endoplasmic reticulum (17–19), while others propose several alternative mechanisms (20–24). Quite apart from the possibility that oil-bodies may be formed from extra-plastid membrane systems such as endoplasmic reticulum it also is possible that they may be derived directly from plastid fatty acids in the following manner. Plastids are the major and possibly the unique site of acyl-CoA biosynthesis (25). Soluble cytoplasmic GP-AT, LPA-AT and phosphatidic acid (PA) phosphatase could interact with an oil-body DG-AT to synthesize triacylglycerols directly from plastidic oleoyl-CoA without recourse to endoplasmic reticulum enzymes. Such a hypothesis would be consistent with the cytoplasmic origin of oil-bodies as proposed by Bergfeld et al. (22).

In order to test the feasibility of this hypothesis, the soluble DG-synthesizing activities of developing rapeseed have been investigated and compared with those of oil-body and microsomal fractions. The data show that these soluble enzymes are capable of making a substantial contribution to total triacylglycerol biosynthesis in developing oilseeds.

MATERIALS AND METHODS

Materials. Rapeseed plants (*Brassica napus* L., var. Jet neuf) were grown in glasshouses at the Durham University Botanical Gardens. Developing seeds were harvested four to six weeks after flowering. This was the stage of maximum triacylglycerol deposition. These seeds contained virtually no erucic acid (<0.5% total fatty acid).

Radiochemicals were purchased from Amersham International (U.K.). Reagents and cofactors such as CoASH, oleoyl-CoA, reduced nicotinamide adenine dinucleotide (NADH), adenosine triphosphate (ATP) and lysophosphatidylcholines were obtained from Sigma (U.K.). Precoated TLC plates were from Anachem (U.K.). Analytical grade solvents were used throughout. Reference lipids used in chromatography were from Sigma.

Abbreviations: ATP, adenosine triphosphate; CMC, critical micellar concentration; DG, diacylglycerol; DG-AT, diacylglycerol acyltransferase; DTT, dithioltreitol; EDTA, ethylenediamine tetraacetic acid; FW, freshweight; G3P, glycerol 3-phosphate; GP-AT, glycerol 3-phosphate acyltransferase; LPA, lysophosphatidic acid; LPA-AT, lysophosphatidic acid acyltransferase; LPC, lysophosphatidylcholine; MG, monoacylglycerol; NADH, reduced nicotinamide adenine dinucleotide; PA, phosphatidic acid; PC, phosphatidylcholine.

Isolation of subcellular fractions. Intact embryos were dissected carefully out of the seeds and placed in a small volume of isolation buffer at 0 C. The isolation buffer consisted of 50 mM HEPES-KOH, pH 7.4, 1 mM ethylenediamine tetraacetic acid (EDTA), 1 mM dithioltreitol (DTT), and 0.5 M sucrose. The embryos gently were ground in a mortar and filtered through two layers of Miracloth, prewetted with isolation buffer. This crude homogenate was centrifuged at 12,000 g for 15 min to yield crude oil-body (O_1), pellet (P_1) and supernatant (S_1) fractions. The crude oil-body fraction was purified by further centrifugation as described by Cao et al. (14). The supernatant was made up to 50 mM $MgCl_2$ and centrifuged at 20,000 g for 20 min. The resulting pellet (P_2), which was light-green, was the crude microsomal fraction. The supernatant (S_2) from this step was centrifuged at 50,000 g for 30 min and finally at 150,000 g for 60 min. The final colorless pellet (P_4) was retained for assays, and the final clear supernatant (S_4) formed the soluble protein fraction.

Incubations. A rapid small-scale assay system was developed to deal with the large number of samples used in this study. Incubations normally were performed in duplicate except in which "internal duplicates" already were part of the protocol, e.g. a time course or a protein curve. The basic incubation medium consisted of 0.1 M potassium phosphate, pH 7.2, 10 mM $MgCl_2$, to which the appropriate protein fraction and 0.5 K Bq [1-^{14}C]-oleoyl-CoA was added at a final concentration of 20 μM unless otherwise stated, to give a total volume of 55 μl. Lipidic substrates (G3P, DG, MG, LPA, PA, LPC, PC) were added as sonicated dispersions as described elsewhere (26). Incubations were carried out either in open glass tubes or in 1.8 ml-capacity Eppendorf tubes. The latter had the advantage of allowing for the simultaneous processing of larger numbers of samples. The results of incubations and lipid extractions in glass tubes and Eppendorf tubes were identical.

Incubations were performed at 25 C in a shaking water bath. Reactions were terminated by the addition of 110 μl isopropanol, followed by heating at 80 C for five min. Either 1.1 ml chloroform/methanol (2:1, v/v) or dichloromethane/methanol (2:1, v/v) was added to each tube, which was vortexed before the addition of 220 μl of an aqueous solution of 0.1% acetic acid containing 0.7% NaCl. The tubes were vortexed thoroughly and centrifuged at 1,000 g to ensure adequate phase separation. All water-soluble constituents such as acyl-CoAs partioned into the upper, aqueous phase. The lower phase, containing the chloroform-soluble lipids, was recovered for analysis.

Analytical procedures. Total lipids were fractionated by chromatography on precoated 20 × 5 cm Silica Gel G plates. Neutral lipids were resolved in a hexane/diethylether/acetic acid (70:30:1, v/v/v) system following a preliminary double development with diethylether 3 cm above the origin in order to resolve monoacylglycerols from polar lipids. Plates were run with the authentic reference compounds, monoacylglycerol, diacylglycerol, unesterified fatty acid and triacylglycerol. Polar lipids were resolved in chloroform/methanol/water (65:25:4 or 65:35:5, v/v/v) or in chloroform/pyridine/formic acid (50:30:7, v/v/v) in the presence of authentic PC, LPC, PA and LPA. The latter system gave an excellent separation of PA without the streaking often observed in other systems (27) but did not resolve PC and LPC very well. Therefore, sometimes a double development was carried out with plates being run for 10 cm in the former systems, followed by a second running in the pyridine system. Normally, four lanes were run on each 20 × 5 cm thin layer plate. Radioactivity on thin layer plates was quantitatively detected using an Isomess RITA IM 3000 (Isotopen Messgeräte GmBH, Essen, West Germany) automatic plate scanner interfaced to an Apple IIe computer. The scanner was controlled, and data were evaluated using Nuclear Interface software routines (Nuclear Interface, Münster, West Germany). All data from the scanner were double checked by the scintillation counting of representative lipid bands from TLC plates and in this way, reliable quantitative values for radioactivity incorporation were obtained. Lipids were identified on the basis of cochromatography with reference compounds in at least two different TLC systems and also by the use of specific spray reagents. For routine localization of lipid bands, nonspecific staining with either iodine vapor or dichlorofluorescein (0.5% in methanol) was employed. Protein concentrations were assayed according to the method of Markwell et al. (28).

RESULTS AND DISCUSSION

The biosynthetic capacities of the three major subcellular fractions involved in acyl-CoA metabolism in developing rapeseed are compared in Table 1. The most striking difference between the subcellular fractions is the very low levels of phosphatidic acid (PA) and TG in the supernatant fraction as compared with the microsomal and oil-body fractions. The labeling pattern of the microsomal fraction was the same whether the 20,000 g pellet (P_2) or the 150,000 g pellet (P_4) was used for incubations. The oil-body and microsomal fractions utilized the exogenous acyl acceptors lysophosphatidic acid (LPA) and lysophosphatidylcholine (LPC) to form phosphatidic acid and phosphatidylcholine (PC), respectively, in the presence of [^{14}C]oleoyl-CoA. In contrast, the soluble fraction incorporated [^{14}C]oleoyl-CoA mostly into DG irrespective of the presence of lysophospholipid exogenous acyl acceptors (see also Fig. 4). These results are consistent with those of several recent reports on the biosynthetic capacities of subcellular fractions from developing mustard seed (29) and developing rapeseed (16).

The relative activities of the various subcellular fractions in the incorporation of oleoyl-CoA into total lipids show that the total microsomal fraction, which up to now has been regarded as the major source of TG-synthesizing activity in developing oilseeds in fact had the lowest biosynthetic activity (Table 1). The oil-body fraction was about 20% more active than the microsomal fraction but by far the most active subcellular fraction was 150,000 g supernatant (or soluble protein) fraction. The latter fraction showed two to three times more activity than either the microsomal or oil-body fractions. These differences were even more marked when oleoyl-CoA incorporation into DG was considered. The total microsomal and oil-body fractions showed approximately equal capacities for DG synthesis but the soluble fraction was capable of five- to seven-fold more DG synthesis than either of them. This high capacity of the soluble fraction for DG synthesis as

TABLE 1

The Incorporation of [1-^{14}C]oleoyl-CoA by Different Subcellular Fractions of Rapeseed

Subcellular fraction	Exogenous acylacceptor (20 μM)	Incorporation of oleate into acyl lipids (nmol min^{-1} g^{-1} FW)[a]

DG, diacylglycerol; LPA + LPC, lysophosphatidic acid + lysophosphatidylcholine; MG, monoacylglycerol; PA, phosphatidic acid; PC phosphatidylcholine; TG, triacylglycerol.

[a]Microsomes, oil-bodies and a soluble fraction from developing rapeseed were incubated for 2–10 min with 20 μM [1-^{14}C]oleoyl-CoA (0.05 μCi) in the presence of 20 μM of the three acylacceptors listed above as described in the Materials and Methods section. The figure for total oleate incorporation per subcellular fraction was calculated by the following equation:

$$\text{Total incorporation rate} = \text{incorporation rate per assay} \times \frac{\text{total protein volume per fraction}}{\text{protein volume per assay}}$$

[b]LPC, 1-palmitoyl lysophosphatidylcholine; LPA, 1-oleoyl lysophosphatidylcholine.

compared with the microcomal or oil-body fractions repeatedly was demonstrated using different seed batches and with a different variety of rapeseed (Mikado). On a protein basis, the DG-synthesizing capacities of the microsomal and soluble fractions were about equal but this cannot be a valid estimate of specific activity because, as shown by gel electrophoresis, the soluble fraction contained large amounts of the nonenzymatic seed storage proteins cruciferin and napin.

The maximal rate of oleate accumulation in developing rapeseed in vivo occurred between 28 and 35 days after flowering and was of the order of 2–3 mg oleate formed per day per gFW seed. The seeds used in this study were harvested at this developmental stage. The maximal rate of oleate incorporation into DG by the soluble protein fraction of such seeds at 20 μM oleoyl-CoA was 40 nmol min^{-1} g^{-1} FW, which corresponds to 0.7 mg oleate incorporated hr^{-1}, g^{-1} FW. Over a 12-hr day, this would give rise to an oleate incorporation rate in excess of 8 mg g^{-1} FW, which easily would account for the known rate of oleate accumulation in vivo. The much greater (four-fold) rate of oleate incorporation in vitro compared with the known rate of oleate deposition in vivo suggests that the enzymatic activities from oleoyl-CoA to DG are not rate limiting to TG synthesis.

The rate-limiting factor may be the final enzyme in the Kennedy pathway (1), i.e. the DG acyltransferase that converts DG into TG, although it has been suggested that in some developing oilseeds this enzyme too may have more than sufficient activity to account for the known rate of TG synthesis (14). In this study, the maximal rate of oleate incorporation into TG by microsomal and oil-body fractions of developing rapeseed (the soluble fraction had a much lower rate of oleate incorporation into TG) was about 30 nmol min^{-1} g^{-1} FW, albeit at high (120 μM) oleoyl CoA concentration. This translates to 0.5 mg oleate incorporated into TG hr^{-1} g^{-1} FW, which is far in excess of the known rate in vivo of 2–3 mg dy^{-1} g^{-1} FW. Even at much lower oleoyl-CoA concentrations (20 μM), the rate of oleate incorporation into TG was 0.11 mg hr^{-1} g^{-1} FW, which is of the same order as the in vivo rate. Therefore, it may be that rather than DG-AT activity it is the supply of oleoyl-CoA itself that is the ultimate rate-limiting factor in TG deposition in developing rapeseed.

Because the major lipid biosynthetic activity of the rapeseed soluble protein fraction was DG formation, it was decided to study this activity more closely. The formation of DG from [^{14}C]oleoyl-CoA by the soluble fraction was time-dependent and also was dependent on the amount of added protein, as shown in Figure 1A. At the lowest protein concentrations, the reaction was linear for up to 60 min but at higher protein concentrations the linear phase lasted only for about 10 min. There was no DG synthesis in the presence of boiled protein fractions. The major product of [^{14}C]oleoyl-CoA incubations with the soluble fraction was DG but with time there also was some accumulation of PC, LPA and MG. If [^{14}C]G3P were used as an acyl acceptor in the presence of unlabeled oleoyl-CoA, a slightly different labeling pattern was observed (Fig. 1B). DG still was the major product at the earlier incubation times but after one hr there was a steady increase in the formation of LPA and PC.

These results show that the soluble protein fraction of developing rapeseed contained very active G3P and LPA acyl transferases. Because DG was a major product and PA did not accumulate during incubations there also must be a soluble PA phosphatase in developing rapeseed. This enzyme up to now only has been detected as a membrane-bound activity associated with chloroplast

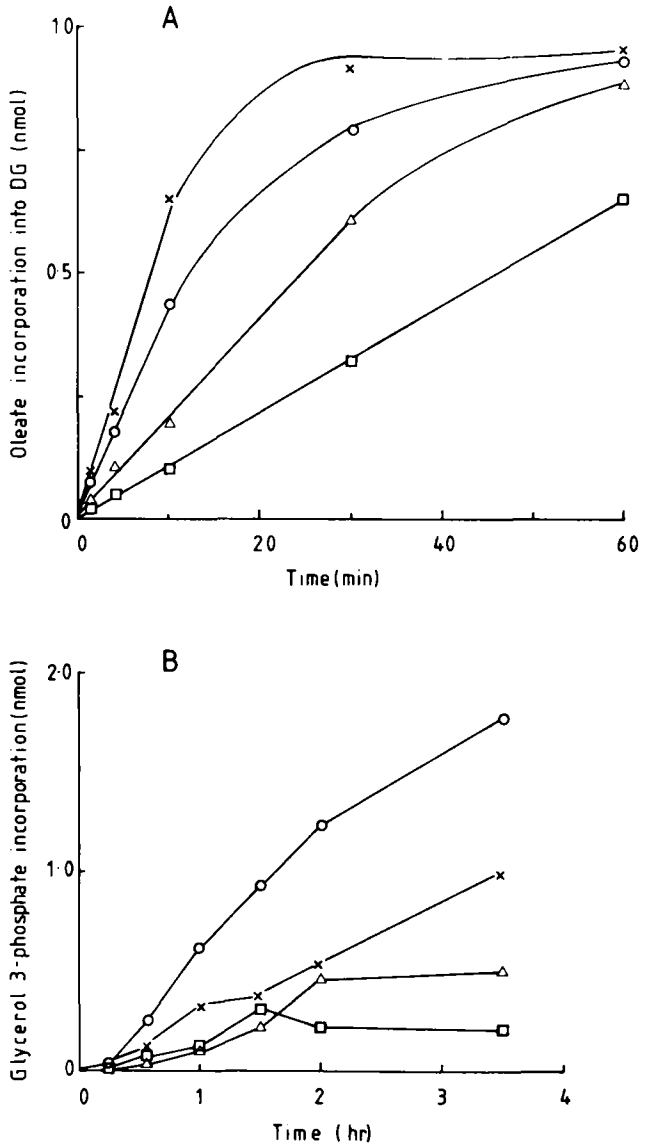

FIG. 1. Time course of the incorporation of oleate into diacylglycerol and other lipids following incubation of (A) various concentrations of a soluble protein fraction from developing rapeseed with [1-^{14}C]-oleoyl-CoA. Incubations contained 20 μM [1-^{14}C]oleoyl-CoA and 35 μM glycerol 3-phosphate in a total volume of 55 μl. Soluble fraction protein was added to each assay as follows: 20 μl, ×—×; 10 μl, ○—○; 5 μl, △—△; 2 μl, □—. Total volume of the soluble fraction was 4 ml from an original 500 mg FW peeled rapeseed. (B) The soluble protein fraction (10 μl) with [U-^{14}C]glycerol 3-phosphate. Incubations contained 100 μM oleoyl-CoA and 150 μM [U-^{14}C]glycerol 3-phosphate. Total lipid, ○—○; lysophosphatidic acid, ×—×; phosphatidylcholine, △—△; diacylglycerol, □—□.

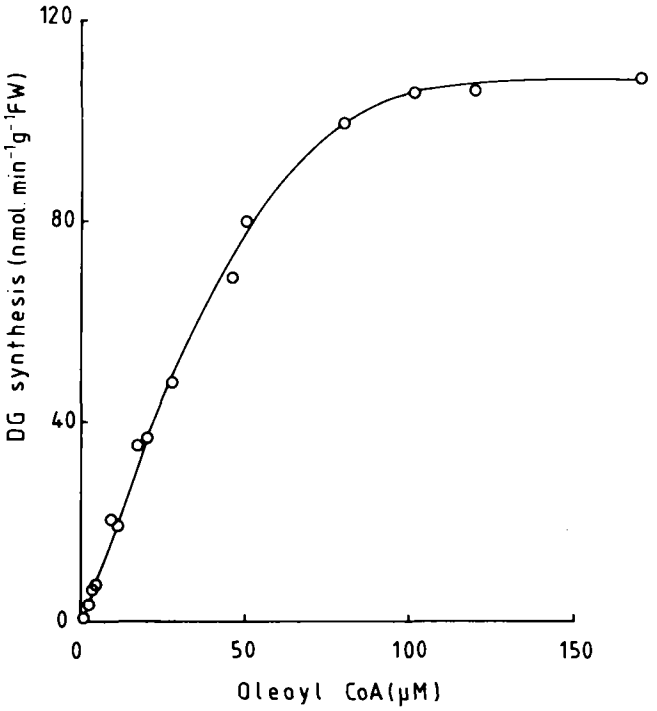

FIG. 2. Effect of oleoyl-CoA concentration on the incorporation of oleate from [1-^{14}C]oleoyl-CoA into diacylglycerol by a soluble fraction from developing rapeseed. Assays were for 20 min and contained 100 μM glycerol 3-phosphate, 20 μM [1-^{14}C]oleoyl-CoA, 10 μl soluble protein, 10 mM $MgCl_2$, 0.1 M potassium phosphate buffer, pH 7.2, in a total volume of 55 μl.

envelopes in leaf tissue (30). The accumulation of [^{14}C]PC following incubation with [^{14}C]G3P strongly suggests that there is a transfer of glycerol moieties between DG and PC. Because [^{14}C]PC also accumulated, albeit to a lesser extent, following incubation with [^{14}C]oleoyl-CoA it is possible that the entire DG molecule may be converted to PC by means of CDP-choline:1,2-DG cholinephosphotransferase, as suggested by Slack et al. (31,32).

DG formation from [^{14}C]oleoyl-CoA by the soluble protein fraction showed a relatively broad optimal pH range with maximum activity pH between 7.5–9.0. This pH optimum is slightly higher than most other TG-synthesizing enzymes studied to date, which typically show pH optima of 7–8 (3,11,12,14,33). DG formation exhibited normal saturation kinetics with respect to oleoyl-CoA with an $S_{0.5}$ of about 32 μM oleoyl-CoA (Fig. 2). Since at least three enzymatic activities were being measured here, it is not possible to derive further kinetic constants for any of the individual components. This must await the further purification of these enzymes, which now is underway in this laboratory.

The effect of various exogenous acyl acceptors on the incorporation of [^{14}C]oleoyl-CoA into DG is shown in Figure 3. DG formation was stimulated in the presence of 20 μM G3P and LPA. Since the oleoyl-CoA concentration in these incubations was 10 μM, it appears that oleoyl-CoA:acyl acceptor ratios in the region of 1:1 are optimal for DG formation, rather than their absolute concentrations over the range tested. At concentrations higher than 20 μM, G3P caused up to 50% inhibition compared to the maximal rate, while higher concentrations of LPA inhibited by as much as 80%. The strong inhibition of DG formation by high concentrations of LPA partially may result from a detergent effect. The addition of exogenous DG, MG and PA did not stimulate DG formation at any concentration but rather caused a 20–50% inhibition of the activity. In contrast to the other acyl acceptors, LPC additions resulted in 20% stimulation of DG formation even at LPC concentrations in excess of 200 μM. In all of the incubations shown in Figure 3, DG

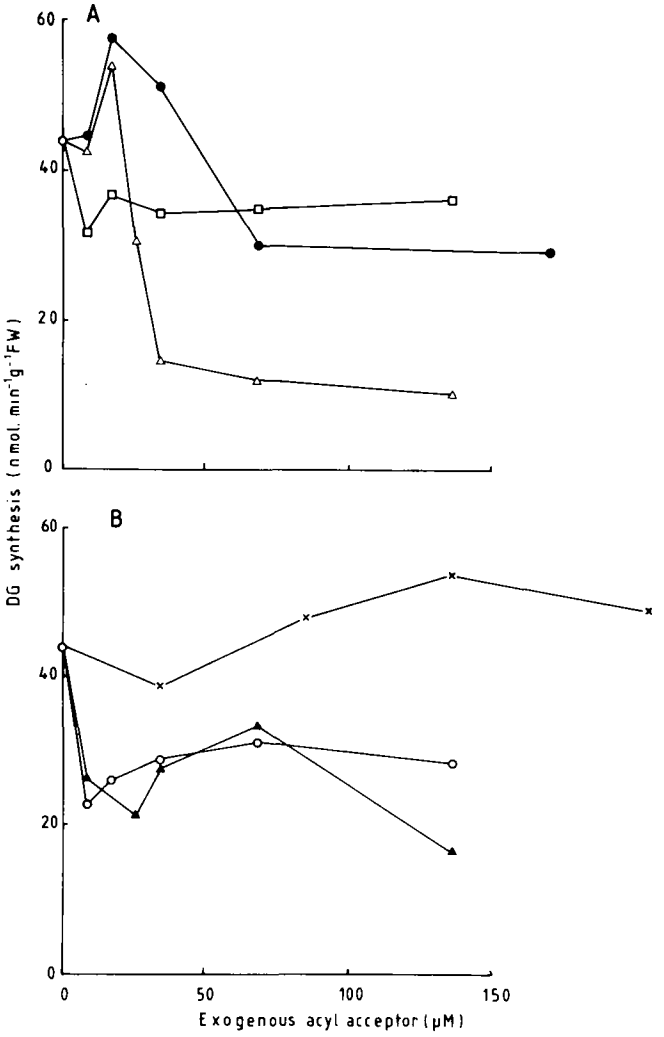

FIG. 3. Effect of different concentrations of various exogenous acyl acceptors on the incorporation of oleate from [1-^{14}C]oleoyl-CoA (10 μM) into diacylglycerol by a soluble fraction from developing rapeseed. Glycerol 3-phosphate, ●—●; lysophosphatidic acid (monooleoyl glycerol 3-phosphate), △—△; diacylglycerol (diolein), □—□; phosphatidic acid (dioleoylglycerol 3-phosphate), ▲—▲; monoacylglycerol (monoolein), ○—○; lysophosphatidic choline (monopalmitoyl glycerol 3-phosphocholine), ×—×. All incubations were for 20 min as described in Methods.

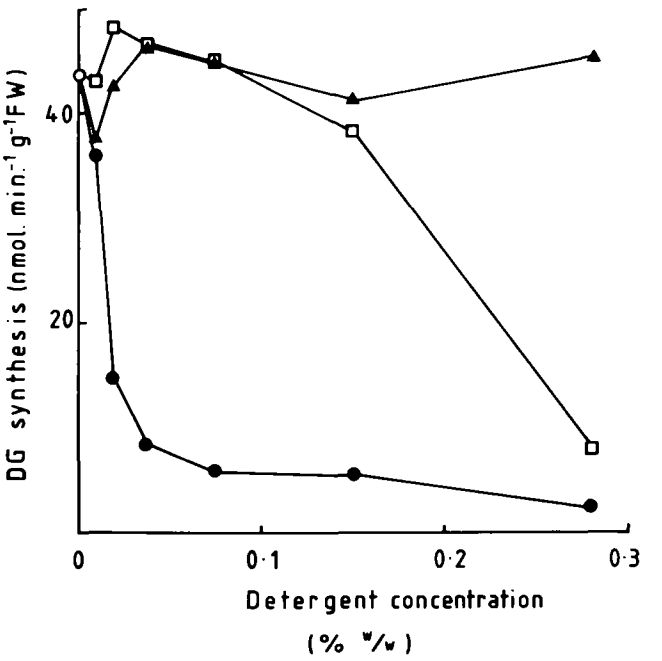

FIG. 4. Effect of different concentrations of various detergents on the incorporation of oleate from [1-^{14}C]oleoyl-CoA into diacylglycerol by a soluble fraction from developing rapeseed. *n*-Octyl β-D glycopyranoside, ▲—▲; Triton X-100, ○—○; sodium cholate, □—□. All incubations were for 20 min as described in Methods.

was overwhelmingly the major reaction product, constituting between 50–70% of total ^{14}C-labeled lipid. The proportion of ^{14}C-label in DG was slightly higher in the presence of G3P (60–70%) compared to the other acyl acceptors (50–60%).

The enzymes involved in DG formation by the 150,000 g supernatant from rapeseed were soluble but since their substrates and products are lipidic it was of interest to study the effect of detergents on the process. In Figure 4, the effect of various concentrations of three commonly used detergents, Triton X-100, sodium cholate and n-octyl β-D glucopyranoside, on DG formation from [^{14}C]oleoyl-CoA are shown. Triton X-100 inhibited DG synthesis by 90% even at relatively low concentrations while only inhibiting [^{14}C]oleoyl-CoA incorporation into total lipid by 50% with most of the balance of the [^{14}C] label accumulating in LPA. Therefore, Triton X-100 selectively inhibited DG formation while still allowing the synthesis of LPA to proceed. Although substantial inhibition of DG formation already was seen at Triton X-100 concentrations as low as 0.020%, it must be remembered that the CMC of this detergent is only 0.019%. Similar results were found with [^{14}C]G3P incorporation into DG in the presence of Triton X-100. Sodium cholate did not begin to inhibit DG formation until its concentration was almost 0.3% but since the CMC of cholate is very high (0.6%) in contrast to the other two detergents (34), this was not surprising. Unlike Triton X-100, sodium cholate did not cause any alteration in the labeling pattern of the lipid products of [^{14}C]oleoyl-CoA incubations, although the total incorporation of [^{14}C] label was reduced at higher detergent concentrations. In all of the cholate incubations, DG accounted for 70–80% of the total [^{14}C] label originally added as [^{14}C]oleoyl-CoA. Unlike the other two detergents, n-octyl β-D glucopyranoside did not inhibit either DG formation or total [^{14}C]oleoyl-CoA incorporation into lipid even at concentrations appreciably in excess of its CMC of 0.07% (24 mM). Interestingly, these results parallel the effects of sodium cholate and n-octyl β-D glucopyranoside on lysophospholipid acyltransferase activity in rapeseed microsomes (Murphy, D.J., unpublished data). The microsomal acyltransferases were relatively unaffected by n-octyl β-D glucopyranoside but substantially were inhibited by 100 μM sodium cholate.

These results show that developing embryos of rapeseed contain highly active enzymes capable of DG synthesis from oleoyl-CoA. The identity of the endogenous acyl acceptor is not yet clear since there was considerable DG synthesis from oleoyl-CoA even in the absence of exogenous acyl acceptors (Fig. 4). It is possible that a pool

of cytoplasmic G3P could be the endogenous acyl acceptor, in which case the lack of accumulation of LPA or PA intermediates would imply high levels of LPA-acyltransferase and PA phosphatase activities. The existence of soluble enzymes that utilize lipidic substrates is well-documented. For example, a soluble G3P acyltransferase recently has been purified from cocoa seeds (10), and soluble diacylglycerol kinases have been found in rat brain (35,36), bovine brain (37) and other tissues (38). In developing rapeseed, it was found that the oil-body, microsomal and soluble fractions each had sufficient diacylglycerol-forming activity to account for the rate in vivo. It is unwise to assign the subcellular localization of a metabolic pathway simply on the basis of in vitro assays of cell-free tissue fractions but the data presented here do raise the possibility that some reactions leading to TG synthesis may occur in the cytosol. The mechanism of oil-body formation still is controversial (17,23). It has been suggested that the endoplasmic reticulum is the site of TG synthesis (14,17-19). The deposition of TG in the lipid bilayer eventually will cause it to distend and bud off to form an oil-body surrounded by a proteinaceous monolayer of polar lipid (19,39,40). The results of this study are not entirely at variance with this mechanism since it is possible that the initial steps of TG synthesis could be catalyzed partly on soluble enzymes with only the final acylation of DG being confined exclusively to the endoplasmic reticulum.

Certain reservations about the above scheme, however, must be expressed. Oil bodies from a variety of seeds have a completely different polypeptide complement to that of the endoplasmic reticulum (Hills, M.J., and Murphy, D.J., personal communication, 22,41,42). Also, there is ultrastructural evidence for the initial deposition of oil in the ground cytoplasm of the cell near the surface of the plastids (22,43). At this stage, the oil droplets are not surrounded by a membrane, and they do not appear to be associated with the endoplasmic reticulum. Upon reaching a diameter of about 1 μm, the oil droplets become coated with a jacket of protein that apparently is derived from the endoplasmic reticulum. This protein jacket may or may not include a monolayer of polar lipid (22). Such a mechanism is consistent with the results of this present study. Oleate is produced in plastids and then is esterified to CoA to form oleoyl-CoA on the inner plastid envelope, resulting in the export of oleoyl-CoA into cytoplasm (44). Soluble acyltransferases in the cytoplasm will mediate the acylation of G3P to LPA and PA followed by phosphate removal by a soluble PA phosphatase to form DG. At this stage, the product will be a water-immiscible oil. The final acylation of DG to TG may be mediated by an enzyme made on the endoplasmic reticulum and transferred to the surface of the growing oil droplet.

It is possible that some triacylglycerol synthesis may occur on the endoplasmic reticulum. Indeed, it recently has been reported that a microsomal preparation from safflower seeds was able to form small, naked (without a protein coat) oil-bodies from acyl-CoA and G3P in vitro (45) although the subcellular origin of this membrane fraction was not studied. These investigations also have reported that microsomal fractions from developing rapesed were capable of TG formation at rates comparable with other oilseed species (Stymne, S. and Stobart, A.K., personal communication). In this study, it was found that oil-body, microsomal and soluble fractions of developing rapeseed embryos each had enough diacylglycerol-forming activity to account for the rate in vivo but that the soluble activity substantially was higher than that of the other two fractions. Although diacylglycerol synthesis is not confined to the soluble fraction, the possibility that some or even most of this synthesis occurs on soluble enzymes ought to be taken into account when consdering the mechanism of oil-body formation in oilseeds.

[Received January 21, 1987; Revision accepted September 11, 1987]

Effects of Dietary Fiber in Vervet Monkeys Fed "Western" Diets

David Kritchevsky*[a], Larry M. Davidson[a], Daniel A. Scott[a], J.J. Van der Watt[b] and Dennis Mendelsohn[c]
[a]The Wistar Institute, Philadelphia, PA 19104, [b]University of Pretoria, AEC Institute for Life Sciences, Pretoria, South Africa, and [c]Department of Chemical Pathology, University of Witwatersrand School of Medicine, Johannesburg, South Africa

Male Vervet monkeys (7/treatment) were fed a "Western" diet containing 46.2% calories as fat, 39.8% as carbohydrate and 14.0% as protein. The diet was augmented with 10% cellulose or 10% pectin. A third (control) group of seven monkeys was fed a commercial ration augmented with fruit and bread. After 34 weeks, serum cholesterol levels were elevated significantly in the two test groups compared with the controls but there was no difference between the two fiber-fed groups. Serum triglycerides were unaffected. Liver cholesterol levels were the same in all three groups but liver triglyceride levels were lower in the monkeys fed cellulose. Biliary lipids were similar in all three groups as were the calculated lithogenic indices. The average aortic sudanophilia (percent of total area) in the three groups was cellulose, 10.6 ± 2.5; pectin, 8.1 ± 2.5; and control, 1.1 ± 0.4. One animal in each of the groups fed "Western" diet exhibited an atherosclerotic plaque. The results indicate that there is no difference between pectin and cellulose with regard to their effects on either lipidemia or aortic sudanophilia in Vervet monkeys fed a Western-type diet.
***Lipids* 23, 164–168 (1988).**

A diet similar to that usually eaten in industrially developed countries (often called a Western diet) has been shown to lead to aortic sudanophilia and atherosclerosis when fed to Rhesus (1) or Vervet (2) monkeys. The "Western" diet usually is compared with a "prudent" diet, which is less sudanophilic. The effects of different dietary fibers on lipidemia and sudanophilia have been compared in monkeys fed semipurified diets (3–5) but not under conditions in which a diet of the type eaten in developed countries has been used. This communication describes a comparison of the effects of cellulose and pectin on lipidemia and aortic sudanophilia in Vervet monkeys fed a "Western" diet.

MATERIALS AND METHODS

Male Vervet monkeys *(Cercopithecus aethiops)* were used throughout. The monkeys (average starting weight 5.65 kg) were maintained in individual cages (one animal per cage) and daily were fed 150 gm of diet. They had ad libitum access to water. There were three dietary groups of seven monkeys each. The diet is described in Table 1. The diet provided 245 Kcal/100 gm; its caloric composition was 46.2% as fat, 39.8% as carbohydrate and 14.0% as protein. The diet was adjusted to provide 150 mg of cholesterol per 100 gm or 0.61 mg of cholesterol per Kcal. The ratios of animal to vegetable protein and fat were 6.39 and 5.31, respectively. The ratio of starch to sugar was 1.63. The fibers (cellulose or apple pectin) were added at a level of 10%. A third group was fed a commercial ration. The commercial diet was obtained from Epol (Pty) Ltd. (Johannesburg, South Africa) and contained 20% protein, 5% fat and about 65% carbohydrate. The cellulose and pectin used also were obtained from Epol (Pty) Ltd. The dietary composition was calculated from the tables of Paul and Southgate (6) and confirmed by analysis. The fatty acid composition of the two diets ("Western" and control) are presented in Table 2.

The monkeys were bled at the beginning of the study and then were bled at monthly intervals until the termination of the study 34 weeks later. Serum was analyzed for total cholesterol (7), triglycerides (8) and phospholipids (9). The high density lipoprotein (HDL) cholesterol was

TABLE 1

"Western" Diet*

Ingredient	Grams/100 gm
Ground beef	16.2
Eggs	8.1
Butter	3.3
Peanut oil	1.6
Potato	12.5
Carrot	12.5
Banana	6.3
Bread	8.0
Sugar	9.6
Skim milk powder	11.9
Fiber	10.0

*The ingredients were mixed thoroughly and baked at 160 C for two hr. Cholesterol (36 mg) was added per 100 g diet to provide 150 mg cholesterol/100 g. The diet provided 245 Kcal/100 g with 46.2% of calories as fat, 39.8% as carbohydrate and 14.0% as protein. Cholesterol content: 150 mg/100 g or 0.61 mg/Kcal cholesterol added to give a closer approximation to the cholesterol content of diets eaten by developed populations. The fiber was cellulose or apple pectin.

Abbreviations: HDL, high density lipoprotein; LDL, low density lipoprotein; VLDL, very low density lipoprotein.

analyzed after precipitation of very low density lipoprotein (VLDL) and low density lipoprotein (LDL) by sodium phosphotungstate (10). At the termination of the experiment, the monkeys were killed by exsanguination while under deep anesthesia. Livers were excised and weighed, and aliquots were extracted with chloroform/methanol 2:1 (11). The extracted lipids were separated by thin layer chromatography on silic acid. The various fractions were extracted from the silica gel (12) and analyzed colorimetrically. Biliary bile was aspirated and deproteinized with ethanol. The levels of cholesterol (13), phospholipid (9) and total bile acids (Sterognost 3αPHO enzyme kit) present in the bile were determined and the lithogenic index calculated (14). The aortas were fixed, stained with Sudan IV and the extent of lipid deposition assessed. The histological procedures have been described (4,15). Data were analyzed by Student's t-test (16).

RESULTS

The serum lipid levels averaged over the duration of the study are detailed in Table 3. We and others have reported on temporal variations in serum lipid levels in primates (17–20). Thus, we have opted to present the average levels over the course of the study and the levels determined at the end of the experiment (Table 4). Table 3 shows that total serum cholesterol levels in monkeys fed the Western diet were elevated significantly as compared with the starting or the final control values ($p < 0.001$). The LDL cholesterol levels also were elevated significantly (<0.001), and the LDL cholesterol levels in the monkeys fed pectin were significantly ($p < 0.05$) lower than in those fed cellulose. The HDL/LDL cholesterol ratio was reduced significantly in monkeys fed the Western diet. Triglyceride levels were unaffected by the dietary regimens.

The necropsy data are summarized in Table 4. Weight gains and liver weights were similar in all three groups. Serum cholesterol and phospholipid levels were elevated significantly in the two groups fed the Western diet. We did not assay LDL or HDL cholesterol levels in the sera obtained at autopsy but the HDL/LDL cholesterol ratios in sera obtained three weeks earlier were cellulose, 0.20 ± 0.05; pectin, 0.28 ± 0.03; and control, 0.52 ± 0.09. The ratio in the control group was significantly higher than

Lithogenic index	0.058 ± 0.008	0.049 ± 0.005	0.046 ± 0.004

Values in horizontal row bearing same letters are significantly ($p \leq 0.05$) different.

that in either of the other groups. Terminal triglyceride levels were unexplicably low in all three groups. Liver total cholesterol levels were similar in all three groups but levels of esterified cholesterol were elevated slightly in livers of the monkeys fed the pectin-containing diet. Liver triglyceride levels were 60% lower in the livers of the monkeys fed cellulose than in the other two groups but the differences were not significant. The lithogenic index, calculated from assayed levels of biliary cholesterol, phospholipid and total bile acid, was low in all three groups. Biliary cholesterol and phospholipids were similar in all three groups but the bile acid content of the cellulose-fed group was 23% lower than that in the pectin-fed group ($p < 0.01$) and 17% lower than that in the control group (not significant).

Fecal weight was monitored over the last six days of the study. Wet and dry weights of the feces were similar in all three groups ranging from 42–45 g/day and 7.5–8.5 g/day, respectively. Water content of the feces was 82.1 ± 0.43%.

The outlines of sudanophilic areas are shown in Figures 1–3. The area was determined independently by three investigators, and the average values for each aorta are given in Table 5. Average aortic sudanophilia in monkeys fed the Western diet plus cellulose was 31% (not significant) higher than in those fed pectin. Monkeys fed the control diet exhibited very little sudanophilia, 90 and 86% less than was seen in the cellulose or pectin groups, respectively. One animal in each of the groups fed Western diet exhibited an atherosclerotic plaque.

DISCUSSION

In general, pectin has been found to be hypocholesterolemic in rats (21–23), rabbits (24), chickens (25) and guinea pigs (21). It also is hypocholesterolemic in man (26,27). Cellulose, on the other hand, has no hypocholesterolemic effect and often is hypercholesterolemic in rats (28–30), rabbits (31), chickens (32) and guinea pigs (33).

*Average of evaluation by three independent investigators.
[a]Monkey bearing atherosclerotic plaque.

Cellulose has little influence on cholesterol levels in man (34). Compared to cellulose, pectin is antiatherogenic in chickens (35), and rabbits fed cellulose exhibit higher cholesterol levels and more severe atherosclerosis than those fed alfalfa (36). Pectin has been reported to raise cholesterol levels in pigs (37).

There are few reports of the effects of fiber on lipidemia or atherosclerosis in primates. We (20) found that baboons fed a semipurified diet in which the fiber was cellulose exhibited higher serum lipid levels and more severe aortic sudanophilia than those fed a diet consisting of commercial ration, bread and fruit. Vervet monkeys fed a semipurified diet containing no cholesterol exhibited higher serum levels than monkeys fed similar diets in which the fiber was alfalfa or wheat straw (4). Recently (5), we fed Vervet monkeys semipurified diets with or without 0.1% cholesterol and either cellulose or pectin, both fed as 15% of the diet. There were no significant differences in serum cholesterol levels or aortic sudanophilia, although that observed in the pectin-fed animals was higher. In this study we found that a Western diet is cholesterolemic and sudanophilic for Vervet monkeys. The type of fiber present in the diet (comparing only cellulose and pectin) does not affect weight gain. Comparison of the two fibers shows no effect on serum lipids or liver cholesterol but liver triglycerides are lower in monkeys fed cellulose. Severity of aortic sudanophilia was similar in the two fiber-fed groups, although the average was lower in aortas of monkeys fed pectin. One monkey in each group exhibited an atherosclerotic plaque. The results indicate that under the conditions of this experiment, cellulose and pectin have equivalent effects. Fiber-rich diets have been shown to enhance excretion of endogenously synthesized or dietary cholesterol in rabbits (38), and pectin has been shown to enhance bile acid excretion in rats (22) and man (26). This study is the second to show that dietary pectin does not influence lipidemia in Vervet monkeys. More work is needed to identify the mechanism(s) by which pectin fails to affect lipidemia in Vervet monkeys and to ascertain whether this lack of effect is restricted to the Vervet monkeys or is general for subhuman primates.

[Received June 22, 1987; Revision accepted September 22, 1987]

Effects of Cholesterol Feeding to Maternal Rats on Metabolism of Cholesterol and Bile Acids in the Dams and Their Offspring

Yoshikazu Ayaki*, Sachiko Endo[1], Yoshio Ogura and Michio Ogura
Department of Biochemistry, Tottori University School of Medicine, Yonago, Tottori 683, Japan

The influence of feeding cholesterol to rats during pregnancy and postpartum (from the 11th day of gestation to the third day after delivery) on the serum and hepatic cholesterol levels and on the bile acid composition in the pool and in the liver in relationship to the dams and their pups was examined. The hepatic content of cholesterol in both dam and offspring increased during cholesterol feeding without any changes in serum cholesterol level. In the dams, mainly the esterified cholesterol was increased; in the pups, mainly the free cholesterol was increased. Cholesterol feeding led to a pronounced increase in the pool of β-muricholic acid and a relative decrease in the lithocholic acid concentration in pregnant rats. In fetal rats, the chenodeoxycholic acid pool was increased by cholesterol intake. The lithocholic acid pool was larger in the postpartum rats fed cholesterol than in the controls, while the concentration of α- and β-muricholic acids was decreased. The neonates of cholesterol-fed dams had a larger pool of chenodeoxycholic acid but a smaller pool of β-muricholic acid. These results suggest that the metabolism of cholesterol and of bile acids in dams and their offspring respond differently to cholesterol intake. *Lipids 23,* 169–177 (1988).

In adult rats, cholesterol feeding caused a marked accumulation of cholesterol in liver and an increase in chenodeoxycholic, α-muricholic and β-muricholic acids in the bile acid pool with a relative decrease in cholic acid (1–3).

Such a metabolic alteration in the pregnant and the postpartum rats is likely to affect the metabolism of cholesterol and bile acids in the developing fetuses and in early neonatal life because cholesterol can pass through the placenta from the dam to the fetuses and also can be supplied to the neonates via milk through the mammary glands of the dam (4–7). In addition, a significant fraction of the bile acid pool in the fetuses might be derived from the dam (8,9).

We have carried out a series of experiments to study the effect of cholesterol feeding to the dam on the maternal metabolism of cholesterol and bile acids and to investigate whether these changes, if any, could affect the metabolism of cholesterol and bile acids in the fetal and the neonatal rats.

MATERIALS AND METHODS

Materials. β-Muricholic acid and ω-muricholic acid were synthesized according to the literature (10). Cholesterol (99.5% pure) was obtained from Wako Pure Chemical Industries (Osaka). Sodium tauro[24-^{14}C]cholate (44.5 mCi/mmol) was purchased from the New England Nuclear Corp. (Boston, MA). Reagents and organic solvents were of analytical grade, the latter being distilled once before use, if necessary.

Animals and diet. Female Wistar strain rats on the 11th day of gestation, each weighing 230–280 g, were obtained from the Shizuoka Agricultural Cooperative Association for Laboratory Animals (Shizuoka), and assigned to one of three groups. One group was fed a commercial rat diet (Clea CA-1, Nihon Clea Co., Tokyo); the second group was fed the same diet supplemented with 0.5% cholesterol; and the third group was fed a 2.5% cholesterol-supplemented diet. The diets contained 25.6% protein, 4.6% fat, 4.0% fiber and all vitamins at recommended levels. The cholesterol-supplemented diets also were prepared by the same manufacturer. The stock diet contained 1.36 ± 0.15 mg (mean ± SD, n = 4) of cholesterol and 137 ± 56 μg (mean ± SD, n = 4) of cholic acid/g, analyzed in our laboratory. The animals were maintained on the respective diets ad libitum during a period from the 11th day of pregnancy to the third postpartum day. They were housed in individual cages, and kept in an air-conditioned room (23 C) lighted from 6 a.m. to 6 p.m.

Twenty-day pregnant rats were killed under ethereal anesthesia, and 20-day prenatal rats were removed from the uterus. Three-day postpartum rats and three-day neonatal rats also were killed in the same way. Blood samples were obtained from maternal, fetal and neonatal rats by cardiac puncture, and the serum was separated from the blood. The liver and the intestine were excised separately and weighed. Samples from the fetal and the neonatal rats were pooled for analysis (three to five samples per pool). All operations for sampling were performed between 9 and 11 a.m., and all samples were stored at −20 C until analysis.

Analysis of cholesterol. Serum total and free cholesterol were determined enzymatically with Determiner TC'5' and FC (Kyowa Medex Co., Tokyo), respectively. A portion of the liver from maternal rats was extracted with chloroform/methanol (2:1, v/v) (11). The extracted lipids were chromatographed on silicic acid (AR, 100 mesh, Mallinckrodt Chemical Works, St. Louis, MO); the cholesterol fraction was eluted with hexane/chloroform (3:2, v/v). The cholesterol fraction was further separated into esterified and free cholesterol (12). Esterified cholesterol was saponified at 60 C for 30 min with 2 N KOH/propanol and extracted with hexane. Cholesterol was determined by gas chromatography as described below.

Fetal and neonatal liver were homogenized with ether/ethanol (1:1, v/v) and left to stand overnight. The tauro[24-^{14}C]cholate was added to some samples before homogenization as a recovery standard for bile acids. The crude lipid extract was partitioned between ether/heptane (1:1, v/v) and 50% aqueous ethanol (13). The ether/heptane extract was analyzed for esterified and free cholesterol as described above. The residual matter left after extraction with ether/ethanol and the aqueous ethanol extract

*To whom correspondence should be addressed.

[1]Present address: Department of Food and Nutrition, Faculty of Home Economics, Shimane Women's Junior College, Matsue, Shimane 690, Japan.

in the partitioning system were used for analysis of bile acids.

Analysis of bile acids. Another portion of the liver from the dams was homogenized in physiological saline and extracted by refluxing in 95% ethanol containing 0.5% ammonium hydroxide (14). The residue of fetal and neonatal liver remaining after the ether/ethanol extraction was extracted similarly, and the extract was combined with the residue of the aqueous ethanol layer in the partition system for the crude lipid extract from liver as mentioned above. The liver extract was dissolved in 0.1 N sodium hydroxide in physiological saline and chromatographed on Amberlite XAD-2 (15). Bile acids were eluted with 0.5% ammonium hydroxide in 95% ethanol, subjected to solvolysis in methanol/acetone (1:9, v/v) containing hydrochloric acid (16), and hydrolyzed in 2 N KOH solution at 130 C for three hr. Free bile acids were extracted with ether after acidification, methylated with diazomethane, and acetylated in acetic anhydride (17). In some samples of fetal and neonatal liver, the extraction efficiency of bile acids was checked by the recovery of [24-^{14}C]cholic acid added as its taurine-conjugate before extraction as mentioned above. Methyl ester acetates of bile acids were quantitated by gas chromatography. Intestinal tracts plus their contents were homogenized and refluxed in 20 volumes of 90% ethanol for two hr. Refluxing was repeated two times, and the pooled extract was analyzed as described above.

Gas chromatography. Samples dissolved in acetone were gas chromatographed in a Shimadzu Model GC-3BF unit with a coiled glass column (3 mm × 1.75 m) packed with 1.5% OV-1 on a Gas Chrom Q (100–120 mesh). Operating temperatures were injector, 255 C; column and detector, 230 C. Nitrogen was used as the carrier gas at a flow rate of 46.2 ml/min. Bile acids and free cholesterol were identified tentatively by comparing their retention times relative to deoxycholic acid (= 1.00) with those of the respective standards. Quantitative determination was made by comparing the peak area with those of a known amount of the corresponding standards using a Chromatopac C-R1A (Shimadzu Corp., Kyoto). Unidentified peaks suspected to be a bile acid were calculated as cholic acid.

Statistical method. Control and experimental values were compared using Student's t-test.

RESULTS

Metabolism of cholesterol and bile acids in the dam. Table 1 shows daily food intake, body weight, liver weight, and hepatic and serum levels of cholesterol for 20-day pregnant rats. The diet intake, body weight and liver weight in the cholesterol-fed groups did not differ from the corresponding value in the control group. There also were no significant differences in the level of any cholesterol fraction in serum between the control group and either cholesterol-fed group. The esterified cholesterol level in liver was higher in the cholesterol-fed groups than in the control group. In addition, the level of free cholesterol was also higher in the 2.5% cholesterol-fed group than in the control group.

Table 2 shows the composition of the bile acid pool (the sum of bile acids in the intestinal tract with its contents and those in the liver). The amount of chenodeoxycholic acid ($p < 0.10$), β-muricholic acid and others was greater in both cholesterol-fed groups than in the control group. Besides, in the 2.5% cholesterol-fed group, the amounts of lithocholic acid and hyodeoxycholic acid were less than those in the control group. In all groups, more than 95% of the total bile acid pool was distributed in the intestinal tract (data not shown).

Table 3 shows the hepatic content of bile acids. β-Muricholic acid and chenodeoxycholic acid ($p < 0.10$) were more abundant in the 2.5% cholesterol-fed group than in the control group. Also, in the 0.5% cholesterol-fed group, more β-muricholic acid ($p < 0.10$) was present as compared with the control.

Table 4 shows the daily food intake, body weight, liver weight and hepatic and serum levels of cholesterol in the three-day postpartum rats. Food intake, body weight and liver weight in either of the cholesterol-fed groups did not differ significantly from those in the control group. Cholesterol feeding caused no significant changes in the serum level of any cholesterol fraction. Esterified cholesterol was accumulated in the liver in both cholesterol-fed groups. In the 2.5% cholesterol-fed group, the free fraction also was accumulated. When the rats were fed the basal diet, the total cholesterol in the postpartum rats was lower than in the pregnant control rats owing to a decrease in the free cholesterol fraction (Tables 1 and 4).

Table 5 shows the composition of the bile acid pool in the postpartum rats. In the 2.5% cholesterol-fed group, the amount of lithocholic acid was greater but that of α-muricholic acid and β-muricholic acid was smaller than in the control group. The 0.5% cholesterol diet did not affect the bile acid composition significantly. In the control group, less lithocholic acid and more β-muricholic acid were found in the postpartum rats than in the pregnant rats (Tables 2 and 5).

The hepatic content of bile acids is shown in Table 6. The content of β-muricholic acid was higher in the 0.5% cholesterol-fed group than in the control group; 2.5% cholesterol feeding induced an accumulation of chenodeoxycholic acid and cholic acid ($p < 0.10$). Consequently, the total amount of bile acids was increased. Nevertheless, hepatic bile acids accounted for only 5% of the total pool in the body, as was the case for the control group (data not shown).

Metabolism of cholesterol and bile acids in fetal and neonatal rats. Table 7 shows body weight, liver weight, and cholesterol levels in liver and serum for 20-day fetal rats. Cholesterol feeding to the dam from the 11th to the 20th day of pregnancy did not affect the body weight or the liver weight in the 20-day fetal rats. Their serum cholesterol level also was unaffected by maternal cholesterol feeding. Hepatic total cholesterol level was, however, higher in both cholesterol-fed groups than in the control group owing to an increase in the free fraction.

Figure 1 shows typical gas chromatograms of methyl ester acetates of bile acids isolated from fetal pooled samples of the liver and of the gastrointestinal tract in the control group.

Table 8 shows the composition of the bile acid pool in the fetal rats. The content of chenodeoxycholic acid, α-muricholic acid ($p < 0.20$) and total bile acids was higher in the 0.5% cholesterol-fed group than in the control group. The content of chenodeoxycholic acid ($p < 0.10$) and total bile acids also was higher in the 2.5% cholesterol-fed group than in the control group.

The hepatic content of bile acids is shown in Table 9. Less cholic acid and β-muricholic acid ($p < 0.10$) were found in both cholesterol-fed groups than in the control group. There was a decrease in the hepatic content of total bile acids ($p < 0.20$) in the cholesterol-fed groups. In the control group, bile acids distributed in liver accounted for 37% of the total pool. The corresponding value for the 0.5% cholesterol-fed group was 22% and that for the 2.5% cholesterol-fed group 25% (data not shown).

Table 10 shows body weight, liver weight, and serum and liver cholesterol levels in the three-day neonatal rats. The body weight in both cholesterol-fed groups was

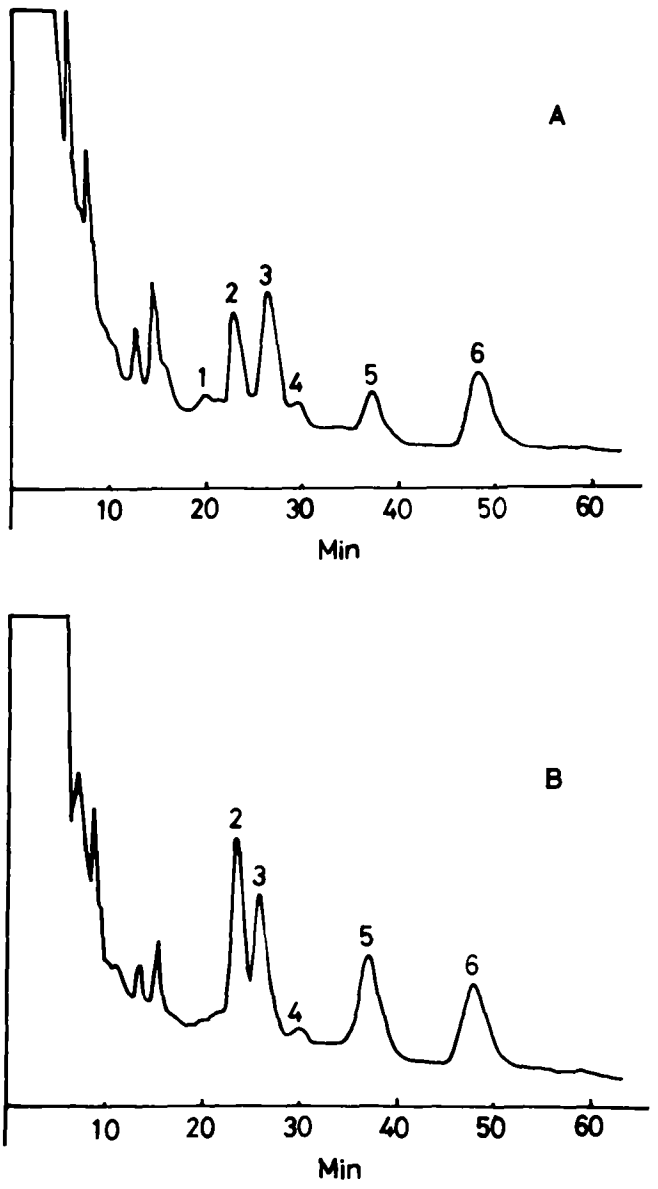

FIG. 1. Gas chromatograms of methyl ester acetates of bile acids isolated from the pooled samples of liver (A) and of gastrointestinal tract (B) in the control group of the 20-day fetal rats. The peaks identified were 1, deoxycholic acid; 2, chenodeoxycholic acid; 3, cholic acid; 4, hyodeoxycholic acid; 5, α-muricholic acid; 6, β-muricholic acid.

greater than that in the control group. There was no significant difference in liver weight between the control group and either cholesterol-fed group. The serum cholesterol level in the three-day neonatal rats was not affected by cholesterol feeding to the dam. The hepatic content of total cholesterol in both cholesterol-fed groups was higher than that in the control group. This was due to an increase in the free fraction in the 0.5% cholesterol-fed group and of the free and esterified cholesterol in the 2.5% cholesterol-fed group. The hepatic content of free and total cholesterol was higher in the neonatal control group than in the fetal control group (Tables 7 and 10).

Table 11 shows the composition of the bile acid pool. The chenodeoxycholic acid content was greater in the

2.5% cholesterol-fed group than in the control group, but the β-muricholic acid content was lower in the 2.5% cholesterol-fed group (0.5% cholesterol-fed group, $p < 0.10$) than in the control group. The bile acids in the neonatal rats were composed mainly of cholic acid, and the pool size of cholic acid was greatly expanded as compared with that in the 20-day fetal rats (Tables 8 and 11). These results were similar to those reported by Little et al. (9).

The hepatic content of bile acids is shown in Table 12. In the cholesterol-fed groups, there was a decrease in chenodeoxycholic acid but an increase in β-muricholic acid as compared with the control group. Only 2-3.5% of the bile acids in the total pool were found in the liver in all the groups of the neonatal rats (data not shown).

DISCUSSION

Cholesterol feeding induces accumulation of cholesterol in the liver without affecting the serum cholesterol level in the adult rats (18,19). The present results show that cholesterol feeding to the dams affects hepatic cholesterol metabolism not only in the dam but also in the pup. The level of free cholesterol in the rat liver remained within a relatively narrow range, whereas the amount of esterified cholesterol increased during cholesterol feeding. Hepatic esterified cholesterol is formed in situ by acyl-CoA:cholesterol acyltransferase (EC 2.3.1.26). Its activity can be altered by hepatic cholesterol content (20,21). Some reports have shown that by feeding pregnant rats a cholesterol-supplemented diet, cholesterol synthesis is reduced in the maternal liver but not in the fetal liver (7,22). In our experiments, the amount of cholesterol accumulated in liver may have been insufficient for inducing the activity of the cholesterol-esterifying enzyme in the fetus and the neonate. In the neonate of the 2.5% cholesterol-fed dam, however, the accumulated cholesterol in the liver might be sufficient for increasing the ability of esterification.

The resulting increase in hepatic cholesterol can affect bile acid metabolism. Wilson (23) demonstrated clearly that cholesterol feeding causes a great increase in excretion of bile acids in the adult rats. In addition, cholesterol feeding leads to the increase in chenodeoxycholic acid, α-muricholic acid, β-muricholic acid and hyodeoxycholic acid in the pool with a concomitant decrease of cholic acid (1-3). Such a shift in the bile acid spectrum in the cholesterol-fed rats indicates that the activity of cholesterol 7α-hydroxylase (EC 1.14.13.17) was accelerated, and 6β-hydroxylation of chenodeoxycholic acid and lithocholic acid was stimulated; however, 12α-hydroxylation leading to the formation of cholic acid was suppressed (3). Beher

et al. (1,2,24) have shown that the half-life of chenodeoxycholic acid is shorter than that of cholic acid in this species. Therefore, the increased synthesis of chenodeoxycholic acid is postulated to be a protective mechanism for excreting the excess of dietary cholesterol (1,2). The increase in β-muricholic acid synthesis also may be one of several protective mechanisms since this acid is nontoxic and ineffective in inhibiting bile acid synthesis (25,26). The change in the metabolism of bile acids except for hyodeoxycholic acid in the pregnant rats appears to be a response to a high level of dietary cholesterol occurring in the same way as the well-documented response of bile acid metabolism in adult rats to a high cholesterol diet. Hyodeoxycholic acid has been shown to be derived from the products of chenodeoxycholic acid, or β-muricholic acid and lithocholic acid (27,28). However, the increase of chenodeoxycholic acid pool size did not always elevate the concentration of hyodeoxycholic acid in the pool in spite of the increase in lithocholic acid or β-muricholic acid (29,30).

In the postpartum rats, bile acid synthesis seems to be inhibited by the increase in hepatic chenodeoxycholic acid and/or cholic acid, especially in the 2.5% cholesterol-fed group. The increase of chenodeoxycholic acid or cholic acid content in the adult rats can inhibit the bile acid synthesis (30-33). Besides, the resulting decrease of 6β-hydroxylation of chenodeoxycholic acid or lithocholic acid is assumed to increase the amount of lithocholic acid. The hormonal changes occurred after delivery alternatively may induce the changes in the response of bile acid metabolism to high dietary cholesterol not seen in the pregnant rats. In this connection, Subbiah and Buscaglia (34) found that the cholic acid/chenodeoxycholic acid ratio in the bile of pregnant rats was lower than in the bile of virgin female rats.

A part of the bile acids in fetal rats have been thought to originate from the maternal transfer across the placenta (9,35,36). However, Naseem et al. (37) have reported that the activity of cholesterol 7α-hydroxylase in the fetal rats was increased by cholesterol feeding during pregnancy. Therefore, an increase of some bile acids in the fetal rats by cholesterol intake may result from the stimulation of bile acid synthesis in them. Naseem et al. (37) also showed that bile acid synthesis in the neonatal rats is facilitated in the same way as the fetal rats by cholesterol feeding during pregnancy. In addition, Sprinkle et al. (38) has shown that in the neonatal rats born from dams fed a chenodeoxycholic acid-supplemented diet during gestation the activity of hepatic cholesterol 7α-hydroxylase was not inhibited in spite of a significant increase in the chenodeoxycholic acid content in the neonatal liver. In our experiments, the increase of chenodeoxycholic acid in the neonatal rats was induced by cholesterol intake but β-muricholic acid synthesis was relatively suppressed; consequently, the total amount of bile acids was not significantly changed.

Although the effect of high cholesterol intake of the dams on bile acid metabolism in the fetal and the neonatal rats has not been identified clearly, the response of bile acid metabolism in the fetal and the neonatal rats to high cholesterol intake of the maternal rats may be independent of that in the dams. In contrast to rats, neonatal bile acid synthesis in guinea pigs is reduced by feeding cholesterol or chenodeoxycholic acid to the dam (39,40). It is not known if the difference between the rat and the guinea pig neonates is species-related, but it is known that guinea pigs do not respond well to dietary cholesterol (41).

Linoleic Acid Requirement of Rats Fed *trans* Fatty Acids

J.L. Zevenbergen*, U.M.T. Houtsmuller and J.J. Gottenbos
Unilever Research Laboratorium Vlaardingen, Olivier van Noortlaan 120, 3133 AT Vlaardingen, The Netherlands

The amount of linoleic acid required to prevent undesirable effects of C18 *trans* fatty acids was investigated. In a first experiment, six groups of rats were fed diets with a high content of *trans* fatty acids (20% of energy [en%]), and increasing amounts of linoleic acid (0.4 to 7.1 en%). In a second experiment, four groups of rats were fed diets designed to compare *trans* fatty acids with saturated and *cis*-monounsaturated fatty acids of the same chain length at the 2 en% linoleic acid level. After 9-14 weeks, the oxygen uptake, lipid composition and ATP synthesis of heart and liver mitochondria were determined.

The phospholipid composition of the mitochondria did not change, but the fatty acid compositions of the two main mitochondrial phospholipids were influenced by the dietary fats. *Trans* fatty acids were incorporated in all phospholipids investigated. The linoleic acid level in the phospholipids, irrespective of the dietary content of linoleic acid, increased on incorporation of *trans* fatty acids. The arachidonic acid level had decreased in most phospholipids in animals fed diets containing 2 en% linoleic acid. At higher linoleic acid intakes, the effect of *trans* fatty acids on the phospholipid arachidonic acid level diminished. However, in heart mitochondrial phosphatidylethanolamine, *trans* fatty acids significantly increased the arachidonic acid level. Despite these changes in composition, neither the amount of dietary linoleic acid nor the addition of *trans* fatty acids influenced the mitochondrial function. For rats, a level of 2 en% of linoleic acid is sufficient to prevent undesirable effects of high amounts of dietary C18 *trans* fatty acids on the mitochondrial function.
***Lipids* 23, 178-186 (1988).**

Trans fatty acids from partially hydrogenated oils and from ruminant fats form part of the human diet. Throughout the years, there has been a marked interest in the biological effects of *trans* fatty acids. It now is recognized that they are well-absorbed by both man and experimental animals, and that they are found in most tissues (1-5). *Trans* fatty acids are incorporated into triacylglycerol and phospholipids of biological membranes (1,2,6). The effect of the incorporation of *trans* fatty acids on the biological function of membranes is an unanswered question.

Many investigators have used mitochondria to investigate the effects of dietary fatty acids on biological membranes (7-14). Mitochondrial oxygen uptake and ATP synthesis are regarded as sensitive markers for the functionality of the mitochondria. Changes in the fatty acid composition of mitochondria were shown to cause diminished mitochondrial function in rats fed diets containing erucic acid (9,15,16). The amount of essential fatty acids in the diet also affected the mitochondrial composition and/or function (7,11,12). The amount of *trans* fatty acids incorporated into mitochondrial membranes may be as high as 17% of the total fatty acid content (17).

Trans fatty acids formed during the partial hydrogenation of vegetable oils appear not to have undesirable effects when compared with saturated or *cis*-monounsaturated fatty acids, provided sufficient linoleic acid is present in the diet (1-3,6,18). It was our aim to quantify the amount of linoleic acid necessary.

In a first experiment, we investigated the effects of diets having a constant amount of C18 *trans* fatty acids and an increasing amount of linoleic acid on the mitochondrial composition and function. In the second, we compared the effects of *trans* fatty acids with those of long chain (C16,C18) saturated and *cis*-monounsaturated fatty acids at a linoleic acid level of 2 en%.

EXPERIMENTAL

Materials. Partially hydrogenated soybean oil (PHSO) was specially prepared by Van den Bergh and Jurgens (Rotterdam, The Netherlands); hydrogenated coconut oil (HCNO) from Chempry BV (Raamsdonkveer, The Netherlands), sunflower seed oil (SSO) from Union (Antwerpen, Belgium) and cocoa butter (CB) from J. Schoenmaker BV (Zaandam, The Netherlands). Olive oil (OV) was purchased from Fol Jr & Co. (Krimpen aan de IJssel, The Netherlands) and the low-linoleic acid olive oil (OV-LL) was a gift from Elais (Greece). Bovine serum albumin (fraction V, essentially free from fatty acid), L-glutamate, and DL-malate were from Sigma Chemical Co. (St. Louis, MO); ADP and ATP were from Boehringer (Mannheim, FRG), Nagarose from *Bacillus amyloboliquefaciens* was from Serva (Heidelberg, FRG), ethylenediamine tetraaceticacid (EDTA) (p.a.), diethyl ether and hexane were from Baker Chemicals (Deventer, The Netherlands), sucrose was from BDH Chemicals Ltd. (Poole, England), 2,6-di-*tert*-butyl-*p*-cresol (BHT) was from Fluka AG (Buchs, Switzerland). The HPTLC plates (Silica gel F254), and all other reagents were from Merck (Darmstadt, FRG).

Animals and diets. Weanling male SPF-Wistar rats (CPB=WU, Central Breeding Station TNO Zeist, The Netherlands) were used in both experiments. The animals were housed individually in a climatized room. The mean temperature was 23 C, the relative humidity was 45-70%, and there was a day/night cycle of 12/12 hr. The animals had free access to water and food. This food, a semisynthetic diet with 40 en% fat, was composed of (in $g.MJ^{-1}$) casein, 14.8; vitamin mixture, 0.2; salt mixture, 1.3; cellulose, 3.8; maize starch, 25.2; experimental fat, 10.3 (for composition of vitamin and salt mixture see ref. 19). The animals were weighed and examined weekly.

For the first experiment, PHSO, HCNO, OV and SSO were mixed to yield six diets having a graduated linoleic acid content (0.4-7.1 en%) but a constant *trans* fatty acids

level of 20 en% (Table 1). Two fats served as references, one consisting of HCNO and OV (2 en% linoleic acid), another consisting mainly of OV (5 en% linoleic acid). Table 2 shows the calculated fatty acid compositions of the experimental fats. Seven groups consisted of 12 animals each and one of 24 animals: group 3. The rats were fed the experimental diets for 13–14 wk.

In the second experiment, four groups of 24 rats each (randomly selected from 24 litters of four rats) were fed diets containing either 20 en% *trans* fatty acid, PHSO,

or mainly saturated fatty acids, CB, or *cis*-monounsaturated fatty acids, OV-LL, or a mixture of PHSO, CB and OV (PHSO mix, 10 en% *trans* fatty acids, see Table 3). All diets contained 2 en% linoleic acid and were fed for 9–11 weeks. The *(trans)* fatty acid compositions are given in Table 4.

Analytical: fatty acid composition of dietary fats. The composition of PHSO was determined by a combination of $AgNO_3$-thin layer chromatography (TLC) separation and capillary gas chromatography (GC). Fatty acid methyl esters were prepared by methylation of fatty acids with BF_3 and subsequent separation on precoated thin-layer SiO_2-plates (impregnated with $AgNO_3$) by elution with toluene. The fatty acid methyl ester fractions were analyzed according to Scholfield (20). The compositions of the other fats and oils were determined by GLC (5% DEGS packed column) after *trans*-methylation with methanolic HCl.

Mitochondrial oxygen uptake and ATP synthesis. At the end of the feeding period, the animals were fasted overnight, weighed and killed by aorta cannulation under ether anesthesia. Heart and liver were removed immediately and washed in an ice-cold buffer. The liver mitochondria were prepared essentially as described by Clouet and Bezard (21). The heart mitochondria were prepared according to Hülsmann (22). The mitochondrial respiration was measured according to Swarttouw (23) using a Clark oxygen electrode (Gilson Oxygraph, Gilson Electronics, Middleton, WI). Glutamate and malate were used as substrate. The reaction was started by adding ADP. The state-3 respiratory rate in the presence of ADP, the state-4 respiration after exhaustion of ADP, the respiratory control ratio, the ADP/O ratio, and the ATP synthesis rate were calculated as described by Estabrook (24).

Lipid composition of mitochondrial membranes. Immediately after isolation and addition of BHT, part of the mitochondria were frozen and stored at −25 C. Before analysis, six samples within each group were pooled. Lipid was extracted according to Bligh and Dyer (25). The phospholipid fraction of the liver mitochondria (first experiment) was isolated on a silica gel column; the phospholipid classes were separated by HPLC according to Patton et al. (26). The phospholipid fraction of the heart mitochondria (both experiments) was isolated on TLC. Phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS), phosphatidylinositol (PI), cardiolipin (CL) and sphingomyelin (S) were isolated by TLC according to Christie (27). The phospholipids were quantitated as described by Bartlett (28). The fatty acids of PC and PE were *trans*-methylated with methanolic HCl and analyzed by GLC using a packed (5% DEGS) column or a glass capillary column (Silar 88). The fatty acid distribution was expressed as area percentage. Because the fatty acid analyses were performed on two or four pooled samples of six animals each, only the means and no standard errors of the means are given.

Statistical. The mitochondrial respiration data were subjected to an analysis of variance according to the randomized complete blocks design. Days of killing served as blocks in the first experiment, litters in the second. In the first experiment, Dunnett's procedure was applied to find which groups differed systematically from the standard group (group 3, 20 en% *trans* fatty acids and 2 en% linoleic acid). In the second experiment, the Student-Newman-Keuls multiple-range test was applied to locate possible systematic differences between the dietary treatments.

RESULTS

General condition of the animals. All animals were in good health in both experiments, showing no overt signs of EFA deficiency. Macroscopic examination of the animals did not reveal treatment-related differences. Systematic differences in food consumption or body weight related to dietary treatment did not occur in either experiment. At the time of killing, the weight of the animals ranged

from 370–400 g in the first experiment and from 350–400 g in the second.

Oxygen uptake and ATP-synthesis in mitochondria. The data on the heart mitochondria, i.e. oxygen consumption (QO_2), number of ADP mol converted into ATP per mol O (ADP/O), rate of ATP-synthesis (*r*ATP) and respiratory control ratio (RCR), have been depicted in Table 5 (first experiment). No significant differences, induced by the dietary treatments, could be detected. Even at a very low linoleic acid intake (0.4 en%), the functionality of the mitochondria was not impaired. The respiratory capacity of the liver mitochondria was also analyzed (Table 5). In the liver mitochondria of group 2 (0.8 en% linoleic acid), the QO_2, *r*ATP, ADP/O and RCR decreased significantly compared to group 3 (2.0 en% linoleic acid). There were no significant differences between group 3 (20 en% *trans* fatty acids and 2 en% linoleic acid) and the reference groups 7 and 8. Data on the respiratory capacity of the heart mitochondria (second experiment) are given in Table 6. No significant differences were detected between any of the groups.

Phospholipid composition of mitochondria: heart. There was some variation between the groups in the phospholipid composition of the heart mitochondria of the first experiment (Table 7), although no trends in phospholipid levels induced by the dietary linoleic acid could be detected. No effect of *trans* fatty acids on phospholipid distribution was observed. In the second experiment, a similar distribution of phospholipids in the mitochondria was found (Table 8). The differences in the phospholipid composition (mainly that of the minor phospholipids) in both experiments probably were caused by slight differences in the preparation procedure of the mitochondria and by differences in the phospholipid analysis. Since reliable values for phospholipids other than PC cannot be given, the phospholipid composition of the CB group is incomplete. Only minor differences between the groups can be detected. The differences between the groups fed diets containing *trans* fatty acids (PHSO and PHSOMix) were in the same order of magnitude or even greater than those between groups fed *trans* fatty acids and those fed other diets, indicating that no changes related to *trans* fatty acid were induced.

[a]Each value represents the mean value ± s.e.m. of 24 animals.
[b]QO_2, oxygen consumption (nmol.min^{-1}.mg^{-1} protein).
[c]*r*ATP, rate of ATP-synthesis.
[d]ADP/O, mol ADP converted into ATP per mol O.
[e]RCR, respiratory control ratio.

Liver. The phospholipid composition of the liver mitochondria was somewhat different from that of the heart mitochondria (Table 7): their PC level was higher, whereas their cardiolipin level was lower. Increasing linoleic acid intake increased the fraction of PC of the phospholipids at the expense of PE. No effects of *trans* fatty acids were observed.

Fatty acid composition of phosphatidylcholine: heart. Saturated and monounsaturated fatty acids hardly were influenced by the amount of linoleic acid in the diet except for a slight decrease in the 18:1 level with increased

—, Not determined.

linoleic acid intake (first experiment; Table 9). Surprisingly, the 18:2 level (mainly linoleic acid) remained rather constant despite its wide range of dietary levels (0.4–7.1 en%). With an increasing linoleic acid intake, the level of arachidonic acid increased to about 34%, then it remained constant; this level was reached with 2–3 en% linoleic acid. The 22:5n-6 level doubled as the linoleic acid intake rose from 0.4 to 7.1 en%. With 22:6n-3, the reverse was observed. A significant incorporation of 20:3n-9, an indicator of essential fatty acid deficiency, could not be detected, not even at the lowest intake of linoleic acid (0.4 en%).

The effects of dietary *trans* fatty acids on the fatty acid composition of PC were more pronounced than those of linoleic acid in the range 0.4–7.1 en%. Compared to the two reference diets (groups 7 and 8), the diets containing *trans* fatty acids decreased the amount of saturated fatty acids (mainly 18:0) irrespective of the linoleic acid level. The 18:1 levels were doubled, probably because of the incorporation of *trans*-18:1 (in this experiment, no differentiation was made between *cis* and *trans* fatty acids). The 18:2 level had increased significantly, which can be explained only partially by the incorporation of the *trans* isomers of linoleic acid. See below.

The arachidonic acid level of PC in the reference groups is only slightly higher than that in the corresponding *trans* fatty acid groups. The fatty acids, 22:5n-6 and 22:6n-3, however, were more affected by the change in dietary fatty acids. The amount of total n-6 fatty acids in the groups containing *trans* fatty acid is similar to that of the corresponding reference group, despite all changes in the levels of n-6 fatty acids (including 18:2).

In the second experiment, heart mitochondrial PC contained 6.0% *trans* 18:1 in the group fed PHSO (about 40% dietary monoenoic *trans* fatty acids) (Table 10). A decrease of 50% in dietary *trans* fatty acids (PHSOMix) more than halved the *trans* 18:1 content. The incorporation of *trans* isomers of linoleic acid was low: maximally 0.5% of *trans,trans*-isomers and 0.6% *trans,cis* or *cis,trans* isomers in PC.

[a]Each value represents the mean of two pools of six animals.

[b]The notation indicates chain length and number of double bonds.

[c]Mean of four pools of six animals.

[d]References.

[e]Both *cis* and *trans*-isomers.

[f]Total n-6 and total sat = the sum of the relative amounts of n-6 polyunsaturated fatty acids and 18:2, and saturated fatty acids, respectively.

The diets containing *trans* fatty acids (PHSO and PHSOMix) increased the 18:1-level and decreased the 18:0 level in PC compared to the other diets. The amount of total saturated fatty acids and *trans*-18:1 together is fairly constant over all groups, except for the CB group, in which this sum is considerably higher. The 18:2 level in the groups fed *trans* fatty acids was significantly higher than that in the other two groups (18:2 levels in the pooled samples ranged from 7.5–8.0 in the PHSO group, and from 3.0–3.6 in the OV group), despite the same content of linoleic acid in the diets. The level of 9-*cis*,12-*cis*-18:2 (linoleic acid) as found by capillary GLC clearly was lower than that found in the fatty acid analyses by packed-column GLC. This difference could not be ascribed to *trans* isomers of linoleic acid because of the low level of these components in the phospholipids investigated. *Cis,cis* isomers of linoleic acid were only present in trace amounts. So, since both capillary GLC and packed-column GLC indicated the difference in the linoleic acid level of PC in the PHSO and PHSOMix groups (20 and 10 en% *trans* fatty acids, respectively), it must be concluded that *trans* fatty acids increased the level of linoleic acid in this phospholipid. The arachidonic acid level in the two groups fed *trans* fatty acids diminished compared to that of the other two groups (levels in the PHSO group ranging from 22.2–26.2, in the OV group from 27.2–29.1). However, there is no apparent relation with the amount of dietary *trans* fatty acids.

Liver. Liver mitochondrial PC (Table 9) has a fatty acid pattern similar to that of heart mitochondrial PC. Mitochondrial PC from the liver was more susceptible to changes in linoleic acid intake than that from the heart. In PC, 20:3n-9 was present at low levels of linoleic acid but not at higher levels.

Trans fatty acids decreased the arachidonic acid level in liver mitochondrial PC only at the linoleic acid levels of 2 en%; at the 5 en% level, this effect had disappeared. The 18:2 level increased, irrespective of its dietary level. *Trans* fatty acids had no effect on the level of 20:3n-9.

Fatty acid composition of phosphatidylethanolamine: heart. The effects of increasing amounts of dietary linoleic acid (first experiment) on both saturated and monounsaturated fatty acids, and 18:2 content of heart mitochondrial PE were similar to those in heart mitochondiral PC

	total sat[f]	26.9	26.3	25.0	25.4	22.8	23.3	37.7	33.8

[a]Each value represents the mean of two pools of six animals.
[b]The notation indicates chain length and number of double bonds.
[c]Mean of four pools of six animals.
[d]References.
[e]Both *cis* and *trans*-isomers.
[f]Total n-6 and total sat = the sum of the relative amounts of n-6 polyunsaturated fatty acids and 18:2, and saturated fatty acids, respectively.

(Table 11). However, in this phospholipid the arachidonic acid level was much less affected by an increasing linoleic acid intake than it was in PC; it even tended to decrease slightly as the dietary level of its precursor increased. The effects of dietary *trans* fatty acids on the fatty acid composition of PE and PC did not differ very much either except for a striking increase in arachidonic acid levels in PE caused by *trans* fatty acids. This increase was compensated for by a reduction in 22:5n-6 and 22:6n-3 fatty acids.

In the second experiment (Table 12), similar changes occurred. *Trans* fatty acids caused a significant increase in the sum of the n-6 polyunsaturated fatty acids; these fatty acids were incorporated partially at the expense of 22:6n-3. Unfortunately, determination of the fatty acid composition of PE of the CB group was impossible. In PE, *trans* monoenoic and dienoic acids were incorporated to an extent similar to that in PC (*trans*-18:1 max. 7.1%; *trans*-18:2 isomers max. 0.9%). The sum of all saturated fatty acids and *trans* 18:1 in the PHSO group was slightly lower than that in the other two groups.

Liver. The influence of dietary linoleic acid on the fatty acid composition of PE in the liver mitochondria (Table 11) was similar to that of PC (Table 9) with respect to the levels of arachidonic acid, 22:5n-6 and 22:6n-3. There was far less similarity in this respect between PE from liver on the one hand and heart on the other. Compared to the reference groups, the 22:6n-3 level was significantly lower in the *trans* fatty acid groups. Moreover, it decreased with an increasing level of linoleic acid. Arachidonic acid was not influenced by *trans* fatty acids.

DISCUSSION

We observed that *trans* fatty acids could significantly alter the fatty acid composition of mitochondrial membranes, irrespective of the linoleic acid level. However, with 2 and 5 en% linoleic acid in the diet, no influence of *trans* fatty acids on the function of the mitochondria was found. Also, in the second experiment no differences in mitochondrial function were detected between the two groups that were fed *trans* fatty acids and the two reference groups.

	18:2 total		4.5	3.7

[a]Each value represents the mean value of four pools of six animals.
[b]The notation used for the fatty acids indicates chain length and number of double bonds, *c* = *cis*-isomer, *t* = *trans*-isomer.
[c]Total n-6 and total sat = the sum of the relative amounts of n-6 fatty acids and 18:2 and saturated fatty acids, respectively.

The effect of *trans* fatty acids on the mitochondrial respiration has been the subject of many publications (29–34). It generally is agreed that specific effects of *trans* fatty acids on the mitochondrial respiration cannot be detected, provided an adequate level of linoleic acid is present in the diet (31,32,34). We have demonstrated that 2 en% linoleic acid is enough to prevent effects of *trans* fatty acids on the mitochondrial respiration.

The high RCR and ADP/O-values in the first experiment show that the mitochondria were coupled tightly. The QO_2 and ATP-values also were high compared with the results of other investigators (30,31,34). In the second experiment, the values for QO_2 (and consequently the ATP synthesis) were much lower than those in the first experiment and even lower than those found by other investigators (30,31,34). However, the RCR and ADP/O values demonstrate the good quality of these mitochondria. This low QO_2 value probably can be ascribed to the use of a different batch of nagarose in the second experiment, which may have resulted in a mitochondrial fraction contaminated with another protein-rich fraction.

Many adverse effects have been attributed to linolelaidic acid (9-*trans*,12-*trans*-18:2) on the basis of both in vitro experiments and feeding studies (36–39). However, as has been pointed out in some reviews the amount of this fatty acid in commercial partially hydrogenated oils is very low (1–3,35). As a consequence, the total dietary intake of 9-*trans*,12-*trans*-18:2 by humans can be neglected.

Monoenoic *trans* fatty acids in partially hydrogenated oils and ruminant fats form a heterogenous group of positional isomers (4,40). The metabolism of the isomers may differ significantly (3); the biological effects of the isomers therefore could vary accordingly. In most experiments dealing with *trans* fatty acids, use is made of PHSO; the advantage is that both monoenoic and polyenoic *trans* fatty acids are found in the experimental diet. Moreover, in PHSO the distribution of these fatty acid isomers matches that of the human diet. The conclusion drawn with regard to the nutritive value of food products containing *trans* fatty acids therefore is more realistic.

As can be concluded from the capillary GC analysis of the fatty acid composition (second experiment), the incorporation of *trans* isomers of linoleic acid is low in heart mitochondrial phospholipids. *Trans* monoenoic fatty acids are incorporated readily in these phospholipids, their level depending on the diet. The changes in the fatty acid composition of the heart mitochondrial phospholipids in both experiments corresponded well except for a slight difference in the relative levels of the main fatty acids probably caused by contamination of the mitochondrial fraction in the isolation of the mitochondria in the second experiment.

The fatty acid composition of heart mitochondrial PC in the HCNO/OV-group (group 7) of the first experiment corresponds well with that of the CB group of the second experiment. The influence of the medium chain saturated fatty acids, as present in the HCNO/OV-diet, seemed to be similar to that of long chain saturated fatty acids. Although the polyunsaturated fatty acid compositions of heart mitochondrial phospholipids were affected considerably by a decrease of the linoleic acid intake, even at very low linoleic acid levels (0.4 en%) no 20:3n-9 appeared. This is in contrast to the liver phospholipids and may indicate a highly specific uptake or incorporation of polyunsaturated fatty acids by the heart.

Trans fatty acids (both 10 and 20 en%) when compared with saturated fatty acids and *cis*-monounsaturated fatty acids, decreased the arachidonic acid level in heart mitochondrial PC. However, in PE the arachidonic acid level increased and partially was compensated for by a decrease in 22:6n-3. These may be effects of dietary *trans* fatty acids on PE in heart tissue (30,31,41). The regulation of polyunsaturated fatty acids of heart mitochondrial PC probably is different from that of PE (31).

In liver mitochondrial PC, the *trans* fatty acids decreased the arachidonic acid level only at a linoleic acid level of 2 en% or lower. The arachidonic acid content of PE in liver mitochondria did not change upon the incorporation of *trans* fatty acids in the diet. The linoleic acid level, however, had increased upon incorporation of *trans* fatty acids in both PE and PC.

The effect of the *trans* fatty acids in PHSO on the fatty acid composition of PC is different from that on PE. The mechanism responsible for the effects is not clear yet. However, *trans* fatty acids change the fatty acid composition in both phospholipids, compared to saturated or

cis-monounsaturated fatty acids. Despite these changes, the C18 *trans* fatty acids do not influence the mitochondrial function in the presence of 2 en% or more linoleic acid. This supports the view of Royce and Holmes (34) that, in non-EFA-deficient animals, the mitochondrial membranes adapt to a changing fatty acid composition in a way that leaves their functional properties unaffected.

ACKNOWLEDGMENTS

The authors wish to thank C. Ter Horst and A. vd. Beek for the respiration measurements, H. J. van Oosten for the fatty acid analysis in the partially hydrogenated soybean oil, G. H. Jouvenaz and H. G. Scholten for the lipid analyses and R. N. Lussenburg for the statistical analyses. Animal care was supervised by J.S.W. Kleinekoort.

Hypocholesterolemic Action of Chitosans with Different Viscosity in Rats

Michihiro Sugano[a,*], Shuji Watanabe[a], Akihiro Kishi[a], Masato Izume[b] and Akira Ohtakara[c]

[a]Laboratory of Nutrition Chemistry, Kyushu University School of Agriculture 46-09, Fukuoka 812, [b]Tsukuba Research Institute, Katakura Chikkarin Co., Tsuchiura 300, and [c]Department of Agricultural Chemistry, Saga University, Saga 840, Japan

The relationship between hypocholesterolemic efficacy and average molecular weight of chitosan was studied in rats fed a cholesterol-enriched (0.5%) diet. Several chitosan preparations with a comparable degree of deacetylation but differing widely in average molecular weight, as demonstrated by viscosity, almost completely prevented the rise of serum cholesterol at the 5% dietary level. At the 2% level, chitosans with viscosities at both extremes exerted a comparable cholesterol-lowering action. The glucosamine oligomer composed mainly of three to five aminosugar residues was not effective. The results indicate that the hypocholesterolemic action of chitosans is independent of their molecular weight within the tested viscosity range.

Lipids 23, 187–191 (1988).

Chitosan, a polymer of glucosamine, has been shown to have a potent hypocholesterolemic effect in rats (1–6). Although the mechanism of the cholesterol-lowering action of chitosan is not well understood, the aminosugar polymer appears to interact with bile acid and/or cholesterol in the intestinal lumen and to stimulate fecal excretion of neutral steroids (1,3) by interfering with the absorption process (7,8). Since the viscosity could be responsible for the effective hypocholesterolemic potential of dietary fiber and since the intra-luminal behavior may differ with respect to the viscosity (9,10), it seems worthwhile to know the relationship between the viscosity (hence, the molecular weight) and the cholesterol-lowering effect of chitosan. Although the viscosity of chitosan preparations commercially available differs widely (10), previous studies (1–5) have not examined the influence of the viscosity, except for one preliminary study (6).

In view of these considerations, the effect of the difference in the viscosity of chitosan on the serum cholesterol level of rats was investigated. The efficacy of the oligomer of glucosamine with water-like viscosity also was tested.

MATERIALS AND METHODS

Animals and diets. Male Sprague-Dawley rats purchased from Seiwa Experimental Animals (Fukuoka, Japan) were housed individually in an air-conditioned room (20–23 C, lights on 0800–2000 hr) and acclimated for three to four days before starting the experiments. Three sets of experiments were performed. In experiment I with five-wk old rats, five groups with eight animals in each group were fed experimental diets ad libitum for 21 days to examine the effect of the difference in the viscosity of chitosan on the serum cholesterol level. In experiment II with four-wk old rats, six groups with six to seven animals in each group were fed for 22 days to examine the effect of the oligomer of glucosamine as well as chitosans with different viscosities on the plasma cholesterol levels. In experiment III with four-wk old rats, five groups with six animals in each group were fed for 28 days to determine the effect of the glucosamine oligomer. We previously have shown that these age differences of animals at the start of experiments and lengths of feeding did not alter the observed effects on serum cholesterol (1,4). The composition of the diet was, in weight percent: casein, 20; lard, 10; vitamin mixture, 1; mineral mixture, 4; choline bitartrate, 0.2; cholesterol, 0.5; Na-cholate, 0.125; test materials, 5 (Exp. I), 4 (Exp. III, one group of rats received a mixture of 2%-oligomer and 2% pectin), or 2 (Exp. II); and sucrose, to 100. Vitamin and mineral mixtures according to Harper (11) were purchased from Oriental Yeast Co. (Tokyo). In all experiments, after depriving the rats of diets for five hr (0830–1330 hr), blood was withdrawn weekly from the tail vein for enzymatic measurement of serum cholesterol (Cholesterol C-Test, Wako Pure Chemicals, Osaka). Finally, animals were killed by decapitation after overnight fasting (1800–0900 hr), blood was collected, and the liver and cecum were excised.

Materials. Samples of chitosan, prepared from crab shell chitin by alkali fusion, were provided by Katakura Chikkarin, Co. (Tokyo), and their properties are listed in Table 1. The glucosamine oligomer, prepared by hydrolyzing chitosan with microbial chitosanase (12), was used as a lactate salt. The preparation was composed of di- to heptamers with tri- to pentamers as major constituents. Two kinds of lignins, containing sodium lignosulfonate as a major component (60%, SAN X-P252, Lignin A) or purified and partially desulfonated sodium ligninosulfonate (97%, Vanillex Rn, Lignin B), were a gift from the Sanyo-Kokusaku Pulp Co. (Tokyo). Pectin (citrus) was purchased from Nakarai Chemicals (Kyoto).

Lipid analyses. Serum and liver cholesterol (13), triglyceride (14) and phospholipid (15) were measured as reported.

Statistical analysis. The results were analyzed by a one-way analysis of variance followed by the inspection of all differences between pairs of means by Student's t-test at $p < 0.05$ (16).

RESULTS

Food intake, growth and liver weight. The results of food intake, growth and liver weight are summarized in Table 2. In rats fed diets containing chitosan at the 5% level (Exp. I), weight gain was significantly lower than that in rats fed cellulose, except for group two, although food intake was similar. However, at the dietary level of 2% or 4%, chitosan reduced neither body weight gain nor food intake (Exps. II and III). The glucosamine oligomer at the 4% but not at the 2% level caused a significant reduction of food intake and, hence, weight gain (Exp. III). However, when the oligomer was fed at the 2% level in combination with the same amount of pectin, it did not

Weight gain for 21, 22 and 28 days in Experiments I, II and III, respectively. Average initial body weight was 134, 100 and 100 g, and supplementary levels of test materials were 5, 2 and 4% in Experiments I, II and III, respectively.

[a,b,c]Values are expressed as mean ± SE of eight, six to seven and five rats for Experiments I, II and III, respectively, and in each experiment those in the same column not sharing a common superscript are significantly different at $p < 0.05$.

cause a reduction in weight gain. The relative liver weight was significantly lower in all chitosan groups than in corresponding cellulose groups, while oligomer and pectin were without effect. The weight of the cecum tended to be heavier in rats fed low viscosity chitosans. However, the weight of the cecal content was comparable among the different groups (mean values, 1.02–1.18 g).

Time course of serum cholesterol levels. Figure 1 shows that chitosan at the 5% level was extremely effective in preventing the rise of serum cholesterol due to feeding cholesterol (Exp. 1). The levels attained were almost similar to those of rats given a cholesterol-free diet (the starting level), and no difference could be seen in the hypocholesterolemic effect among chitosan preparations with various viscosities.

As Figure 2 shows, the hypocholesterolemic effect of chitosan still was marked even at the 2% dietary level as compared to that of cellulose (Exp. II). Although the cholesterol-lowering activity appeared to be somewhat greater in chitosan with a high viscosity, the difference was not significant statistically. Also, the glucosamine oligomer was not effective in lowering serum cholesterol, and the levels apparently were similar to those observed in the cellulose group. Two lignin preparations induced

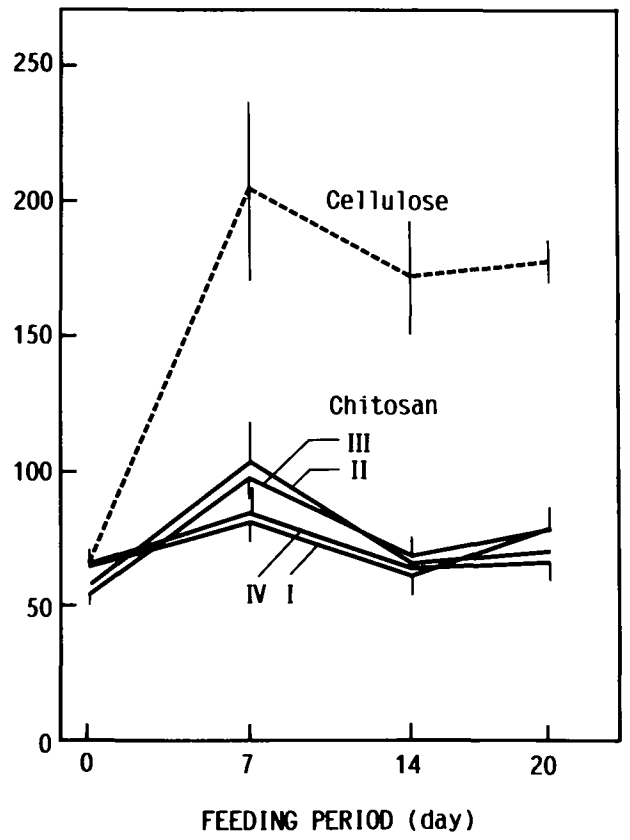

FIG. 1. Time course of the effects of chitosan with various viscosities on serum cholesterol levels (Experiment I). Each point represents mean and SE of eight rats. Cholesterol levels in rats fed chitosan are all significantly different ($p < 0.05$) from the corresponding values for rats fed cellulose.

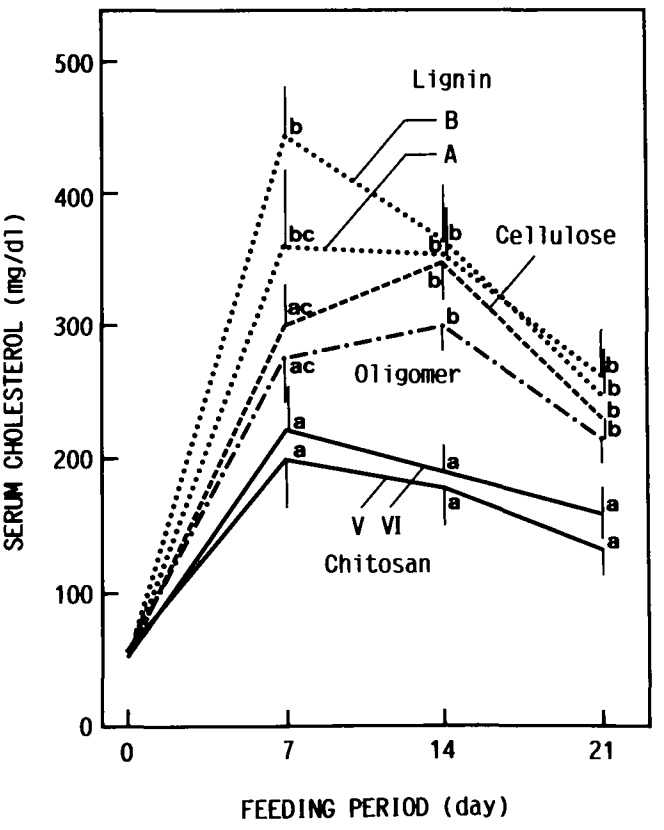

FIG. 2. Time course of the effects of chitosan and glucosamine oligomer on serum cholesterol levels (Experiment II). Each point represents mean and SE of six to seven rats. Values in the same time point not sharing a common letter are significantly different at $p < 0.05$.

a sharp rise of serum cholesterol above that observed with cellulose in the first week and the levels remained high thereafter.

As shown in Figure 3, chitosan showed a marked hypocholesterolemic effect at the 4% level (Exp. III). The glucosamine oligomer was again not effective in lowering serum cholesterol even when the dietary level was increased to 4% and, in addition, did not strengthen the hypocholesterolemic effect of pectin.

Serum and liver lipid concentrations. In three sets of experiments, there were significant reductions of serum cholesterol after overnight fasting as compared with the levels of the weekly blood samples obtained with five-hr fasting (in 25–45% of the weekly samples). The extent of this reduction was greater in the groups with higher cholesterol levels and, consequently, the variation in cholesterol levels decreased. Thus, the fluctuations seen in Figures 1 to 3 may be due, in part, to the blood sampling five hr after food deprivation. However, the diet-dependent difference still remained in the samples from overnight-fasted rats and the fasting serum cholesterol levels of the chitosan groups were as low as those observed in rats not fed dietary cholesterol (the starting level) in all experiments. The serum triglyceride levels were variable, and no significant differences among the various groups were ever observed in this study. Serum phospholipid concentrations were comparable in all different groups throughout this study.

The results of liver lipid analyses are summarized in Table 3. Liver cholesterol concentrations were decreased markedly in all chitosan groups. Pectin moderately lowered liver cholesterol while the glucosamine oligomer was ineffective. No significant differences were found in concentrations of liver triglyceride among various groups. Liver phospholipid was elevated in five of the seven chitosan groups.

DISCUSSION

This study examined the effect of differences in the viscosity of chitosan preparations on the serum cholesterol levels of rats fed a cholesterol-enriched diet. Since the degree of polymerization of the glucosamine unit is the major determinant of viscosity when the extent of deacetylation is comparable (10), the results can be attributed to the differences in chitosan molecular weight. In Experiment I (Table 1), in which chitosans with various viscosities were added to the diet at the 5% level, the hypocholesterolemic effect relative to cellulose was too marked to differentiate their relative potencies. The marked reductions of liver cholesterol in these rats (Table 3) indicate that chitosan effectively interferes with cholesterol absorption. These observations agreed with those reported previously for specific chitosan preparations (1–5).

When chitosans with viscosity of both extremes were added at the 2% level (experiment II, Table 1), we again

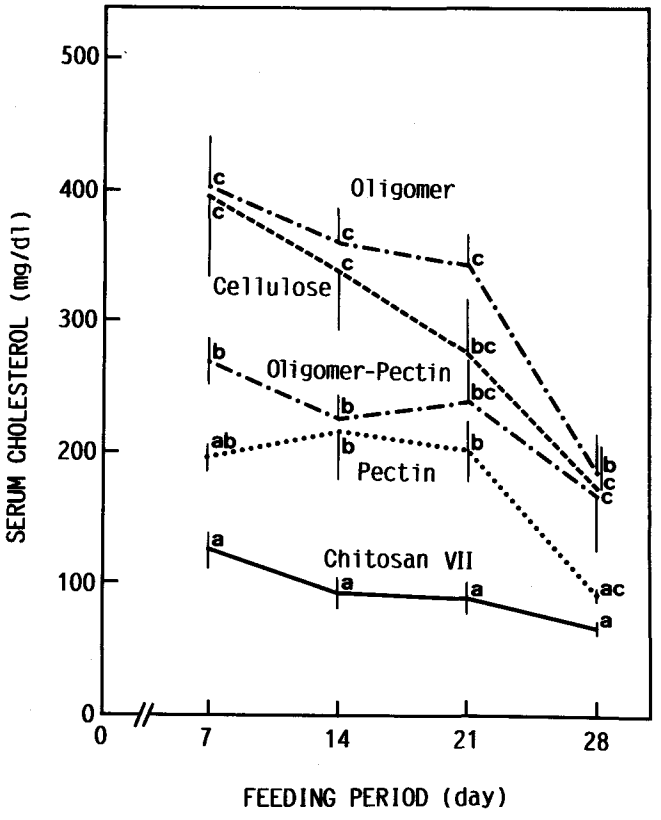

FIG. 3. Time course of the effects of chitosan, glucosamine oligomer and pectin on serum cholesterol levels (Experiment III). Each point represents mean and SE of six rats. Values in the same time point not sharing a common letter are significantly different at $p < 0.05$.

TABLE 3

Liver Lipid Levels (Experiments I to III)

Experiments and groups	Liver lipids (mg/g)		
	Cholesterol	Triglyceride	Phospholipid
Experiment I			
Cellulose	68.9 ± 3.5^a	41.0 ± 4.0	32.9 ± 1.4^a
Chitosan 1	15.8 ± 4.3^b	63.7 ± 17.3	37.6 ± 2.1^b
Chitosan 2	18.3 ± 5.4^b	59.0 ± 12.4	37.1 ± 1.4^{a,b}
Chitosan 3	11.6 ± 3.4^b	34.0 ± 10.7	42.2 ± 1.0^c

Glucosamine oligomer 2 + pectin (1:1)	36.8 ± 3.0^{b,d}	40.8 ± 6.3	36.1 ± 1.2^a
Pectin	31.7 ± 2.1^d	32.0 ± 8.0	36.5 ± 0.7^a

^{a,b,c}Values are mean ± SE of eight, six to seven and six rats per group in Experiments I, II and III, respectively. In each experiment, values in the same column not sharing a common superscript are significantly different at $p < 0.05$.

confirmed a hypocholesterolemic activity of these two preparations. Although highly viscous chitosan in relation to the chitosan of low viscosity showed a somewhat greater efficacy, the difference was not significant. Ishii et al. (6) reported that the serum cholesterol-lowering action of chitosan was greater in highly deacetylated than in moderately deacetylated preparations when the viscosity was comparable. Judging from the ineffectiveness of the glucosamine oligomer with water-like viscosity, it is suggested that some degree of polymerization is required to provoke a cholesterol-lowering activity.

These observations are favorable for the application of chitosan as a hypocholesterolemic agent because the extent of polymerization of the glucosamine residue may differ greatly depending on both the source of chitin and the extent of alkaline treatment (10). Thus, it is evident that various commercially available chitosan preparations generally are applicable for this purpose.

The nondigestibility in the upper gastrointestinal tract, high viscosity, polymeric nature and high water-binding properties, together with low water binding in the lower gastrointestinal tract, are all responsible for the effective hypocholesterolemic potential of dietary fiber (9). Chitosan meets most of these criteria, and it seems reasonable that the preparation with an appropriate viscosity together with the high degree of deacetylation is preferable for this purpose. In addition, chitosan has a highly characteristic property in relation to other dietary plant fibers; it can bind in vitro a variety of anions such as bile acids or free fatty acids at low pH by ionic bonds resulting from its amino group (10). However, it is not clear whether chitosan could interact with bile acids in the intestinal lumen since it increases the excretion of neutral sterols but not acidic steroids (1,3). Thus, this glucosamine polymer may not be hazardous to the morphology and, hence, the functioning of the intestine, as compared to a bile acid sequester resin, cholestyramine (7,17), or to the viscous fiber, pectin (18), although its hypocholesterolemic activity is comparable to that of cholestyramine (1).

Because of these considerations together with its low toxicity (5,19), chitosan seems to be a realistic hypocholesterolemic agent, although its effect on lipase as observed with a related aminosugar compound, neomycin (20), remains unclear. In addition, chitosan may interfere with the absorption of glycerides by the intestine (7) and thereby may exert a hypoglyceridemic effect under certain nutritional conditions.

ACKNOWLEDGMENT

The authors thank J. A. Ontko, Oklahoma Medical Research Foundation, OK, for his valuable suggestions in the preparation of this manuscript.

Human Placenta Gangliosides

Takao Taki*[a], Ken-ichi Matsuo[a], Kaname Yamamoto[a], Toshiko Matsubara[b], Akira Hayashi[b], Tadayuki Abe[c] and Makoto Matsumoto[a]

[a]Department of Biochemistry, Shizuoka College of Pharmacy, 2-2-1 Oshika, Shizuoka 422, Japan, [b]Department of Chemistry, Faculty of Science and Technology, Kinki University, 3-4-1 Kowakae, Higashiosaka 577, Japan, and [c]Department of Obstetrics and Gynecology, Kosei Hospital, Kitabancho, Shizuoka 420, Japan

Gangliosides extracted from human placenta were composed of four major components (G1–G4), which were purified by silica beads column chromatography. The structures of these gangliosides were analyzed by exoglycosidase treatments, 400 MHz proton magnetic resonance spectroscopy and gas chromatography-mass spectrometry and were concluded to be as follows:

G-1, NeuAcα2-3Galβ1-4Glcβ1-1ceramide;

G-2, NeuAcα2-3Galβ1-4GlcNAcβ1-3Galβ1-4Glcβ1-1ceramide;

G-3, NeuAcα2-3Galβ1-4GlcNAcβ1-3Galβ1-4GlcNAcβ1-3Galβ1-4Glcβ1-1ceramide;

G-4, NeuAcα2-3Galβ1-4GlcNAcβ1 (6) (3) Galβ1-4GlcNAcβ1-3Galβ1-4Glcβ1-1ceramide.
NeuAcα2-3Galβ1-4GlcNAcβ1

Gangliosides containing more than 10 sugar residues were observed in addition to the above four major components. But ganglio-series gangliosides were undetectable in the placenta.

Lipids 23, 192–198 (1988).

Gangliosides are characteristic components of plasma membranes. They exist in the outer leaflet of the phospholipid bilayer of plasma membrane, and are involved in the recognition of biological signals from outside the cells. The complexity of ganglioside molecules, the organ specificity of their composition and some biological functions have been reported (1–3). The composition of gangliosides alters in association with differentiation of cells, development of animals and also oncogenic transformation (4–6). The placenta is an unique organ from the viewpoints of cell differentiation, the special relationship between mother and embryo, very rapid proliferation of cells, and selective transport of nutrients and proteins. However, the ganglioside composition of this organ has not been reported yet. In this paper, we describe the ganglioside composition of human placenta and the determination of the structures of four major gangliosides. This organ was characterized by the presence of ganglioside species containing lactosamine or lactosamine-repeating structure as the backbone core.

MATERIALS AND METHODS

Human placenta. The isolated human placentas were washed with water to remove red blood cells completely. Mean wet weight of the organ was 342 g.

Extraction and separation of gangliosides. Placentas were homogenized in 1.5 vol of a mixture of chloroform/methanol (2:1, v/v) with a Waring blender for five min, then suspended in 7 vol of the same solvent mixture. After filtration, the residues were suspended in 4 vol of a mixture of isopropanol/hexane/water (55:25:20, v/v/v) to complete the extraction of higher gangliosides.

Each extract was concentrated under reduced pressure in a rotary evaporator, dialyzed against distilled water and then lyophilized. Total lipids were dissolved in a mixture of chloroform/methanol/water (30:60:8, v/v/v) and applied to a DEAE Sephadex A-25 column according to the method of Ledeen et al. (7). Neutral lipid, phospholipid and neutral glycolipids were eluted with the solvent mixture, and total gangliosides were eluted with a mixture of chloroform/methanol/0.8 M NaOAc (30:60:8, v/v/v). Gangliosides eluted from the column were concentrated under reduced pressure in a rotary evaporator, dialyzed against distilled water and lyophilized.

Purification of gangliosides. Ganglioside fraction was dissolved in 10 ml of a solvent mixture of chloroform/methanol/water (83:16:0.5, v/v/v) and applied to an Iatrobeads column (2.0 × 120 cm) equilibrated with the same solvent mixture. Gangliosides were eluted with a linear gradient formed from 400 ml of chloroform/methanol/water (83:16:0.5, v/v/v) in the mixing chamber and 480 ml of chloroform/methanol/water (20:80:5, v/v/v) in the reservoir. Then gangliosides left in the column were eluted with 400 ml of the second solvent mixture. Fractions of 6 ml were collected. An aliquot was taken from each fraction and checked by thin layer chromatography.

Thin layer chromatography. The purity of each ganglioside was determined by high performance thin layer chromatography (HPTLC) with various solvent systems: A, chloroform/methanol/0.2% $CaCl_2$ (60:35:8, v/v/v); B, chloroform/methanol/0.2% $CaCl_2$ (60:40:9, v/v/v); C, chloroform/methanol/0.2% $CaCl_2$ (60:30:6, v/v/v); D, n-propanol/ammonium hydroxide/water (6:1:3, v/v/v). Gangliosides were visualized by spraying the plate with resorcinol/HCl reagent. Gangliosides were determined by densitometric analysis using GM3 as the standard.

Enzymatic degradation of glycolipids. The carbohydrate sequence and anomeric configuration of gangliosides were determined by sequential application of various exoglycosidases. Hydrolysis using β-galactosidase and β-hexosaminidase (purchased from Sigma Chemical Co., St. Louis, MO) from jack bean was performed as described by Li and coworkers (8,9). Hydrolysis of ganglioside with *Clostridium perfringens* neuraminidase was performed as described by Barton et al. (10).

Nuclear magnetic resonance (NMR) spectroscopy. The 400 MHz spectra of intact gangliosides (4–5 mg) were obtained on a JEOL FX-400 spectrometer in the Fourier transform mode. The operation was performed at 90 C, in dimethyl-d-sulfoxide (Me_2SO-d_6) solution and then in a Me_2SO-d_6 solution containing D_2O at the same temperature. Chemical shifts are given as σ(ppm) from the peak of the internal standard, tetramethylsilane.

Methylation analysis. The linkages between different sugar units were determined by permethylation analysis. The purified gangliosides were permethylated according to the method of Hakomori (11).

The partially methylated alditol acetates were analyzed by gas chromatography-electron impact-mass spectrometry

*To whom all correspondence should be addressed.

Abbreviation: HPTLC, high performance thin layer chromatography.

using a JEOL JMS-HX 100 mass spectrometer. Neutral sugar derivatives of partially methylated alditol acetates were separated on a glass column (2 mm × 200 cm) packed with 3% OV-225 coated on Gaschrom Q at 160–230 C, programmed at 4 C/min, and aminosugar derivatives were separated on a glass column (2 mm × 100 cm) packed with 3% ECNSS-M coated on Chromosorb W (80–100 mesh) at 160–200 C, programmed at 4 C/min.

Analysis of long-chain bases. The long-chain bases were determined by gas liquid chromatography according to the method of Gaver and Sweeley (12) and also by thin layer chromatography. About 100 μg of ganglioside was hydrolyzed in 2.0 N HCl/MeOH at 80 C for three hr. The hydrolysate was mixed with hexane to remove fatty acid methyl esters, and pH was adjusted to 10.0 by the addition of 1.0 N NaOH. The long-chain bases were extracted with hexane. The extract was applied to gas chromatography and also to thin layer chromatography. Dihydrosphingosine, sphingosine and phytosphingosine were used as standards. The detailed analytical conditions of gas chromatography have been described previously (13).

Solvent system for analysis of the long-chain bases by thin layer chromatography was chloroform/methanol/water (60:35:8, v/v/v). The long-chain bases were visualized by spraying the plate (HPTLC plate) with ninhydrine reagent and determined by densitometric analysis.

RESULTS

Isolation of four major gangliosides. Four major resorcinol-positive bands were recognized in HPTLC of the total ganglioside fraction derived from human placenta in solvent system B, as shown in Figure 1. The elution profile of placenta gangliosides from Iatrobeads column chromatography is shown in Figure 2. The four major gangliosides were clearly separated by gradient elution (Fig. 2A). They are designated as G-1 to G-4 from the fastest migrating resorcinol-positive band to the slowest one.

After elution of G-4 ganglioside from the Iatrobeads column, very slowly migrating gangliosides were eluted with the solvent mixture of chloroform/methanol/water (20:80:5, v/v/v). Seven to eight resorcinol-positive spots, including G-4 ganglioside, were separated on HPTLC with solvent system C (Fig. 2B). These gangliosides were rather minor components and were not subjected to structure analysis in the present study.

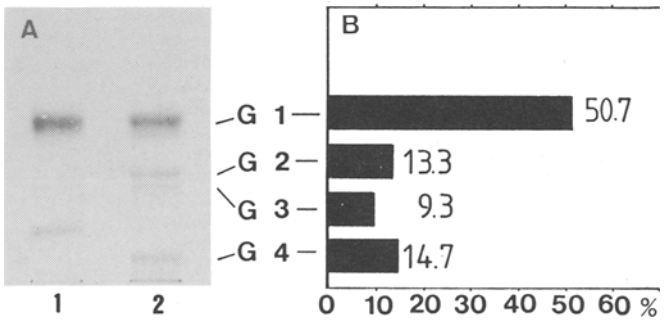

FIG. 1. HPTLC profile (A) and composition (B) of human placenta gangliosides. A, lane 1, GM3; lane 2, gangliosides of human placenta. Solvent B was used for developing. Gangliosides were visualized by spraying with resorcinol reagent.

Each of the four major ganglioside fractions obtained above (Fig. 2A) was compared with standard gangliosides, as shown in Figure 3. G-1 migrated as fast as GM3 obtained from human liver (11) and G-2 showed similar mobility to sialosyllactoneotetraosylceramide obtained from bovine erythrocytes on HPTLC. The G-3 fraction contained small amounts of G-2 and G-4 gangliosides. This component migrated on HPTLC a little more rapidly than i-type ganglioside (IV^{3}NeuGc-lactoneohexaosylceramide) isolated from bovine erythrocytes (14). G-4 ganglioside migrated a little more slowly than I-type ganglioside isolated from bovine erythrocytes (15).

Since fractions G-3 and G-4 were contaminated with other gangliosides, these components were further purified by rechromatography on the Iatrobeads column for structure analysis.

Stepwise degradation of gangliosides by exoglycosidases. Sequential arrangements of sugar in gangliosides were determined by hydrolysis with exoglycosidases followed by identification of the product on HPTLC (Fig. 4, A–D). All gangliosides readily could be hydrolyzed

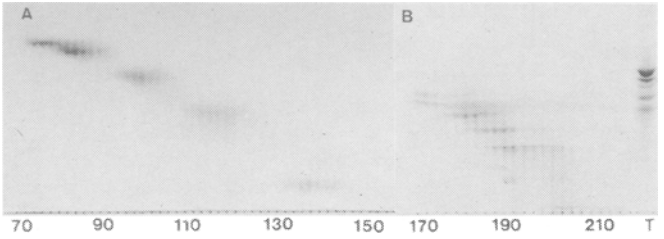

FIG. 2. Elution profile of placenta gangliosides from an Iatrobeads column. A, gangliosides were separated by gradient elution with a solvent mixture of chloroform/methanol/water (83:16:0.5–20:80:5, v/v/v). An aliquot from each fraction was checked by HPTLC with solvent system B. B, higher gangliosides eluted with a mixture of chloroform/methanol/water (20:80:5, v/v/v) after the gradient elution. Gangliosides were developed to the middle of the plate with solvent system C then developed to the top with solvent system A after drying. T, total ganglioside.

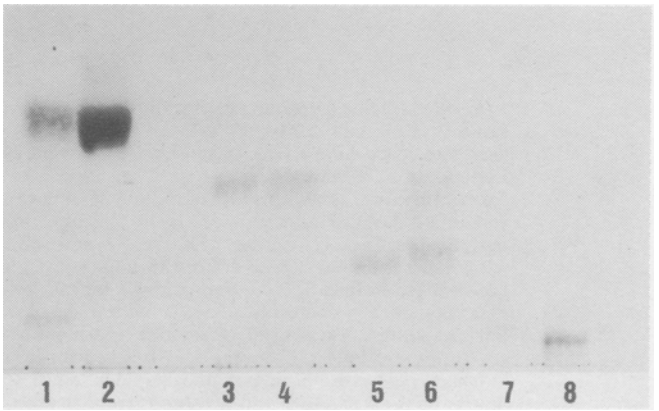

FIG. 3. HPTLC profile of ganglioside fractions separated with Iatrobeads column chromatography. Lanes 1, 3, 5 and 7 are standard gangliosides. Lane 1, GM3; lane 2, G-1; lane 3, sialosylparagloboside (IV^{3}NeuAc-nLc$_4$Cer); lane 4, G-2; lane 5, i-ganglioside (VI^{3}NeuGc-nLc$_6$Cer); lane 6, G-3; lane 7, I-ganglioside (VI^{3}NeuGc-IV^6(II^{3}Gal-nLcNAc)-nLc$_6$Cer); lane 8, G-4. Solvent B was used for developing. Gangliosides were visualized with resorcinol reagent.

to the asialogangliosides by *Cl. perfringens* neuraminidase without addition of detergent. Thus, neuraminic acid seemed to be attached to the terminal sugar component of the gangliosides.

G-1 was converted to a glycolipid with mobility similar to that of lactosylceramide by neuraminidase treatment, and the product was further hydrolyzed to a glycolipid having the same mobility as glucosylceramide by jack bean β-galactosidase treatment. These results indicate that G-1 has the same sugar sequence as GM3 ganglioside (Fig. 4A).

G-2 was hydrolyzed to a glycolipid having the same mobility as lactoneotetraosylceramide on HPTLC by neuraminidase treatment. The product was converted to a glycolipid with the same mobility as lactoneotriaosylceramide by β-galactosidase treatment. Then the product was further converted to lactosylceramide and glucosylceramide by treatment with β-hexosaminidase followed by the β-galactosidase, as shown in Figure 4B. From these observations, G-2 was concluded to have the following anomeric configurations and sugar sequence: sialic acid-βGal-βGlcNAc-βGal-βGlc-ceramide.

G-3 and G-4 were hydrolyzed to lactosylceramide by exoglycosidase treatments in the following order: neuraminidase, β-galactosidase, β-hexosaminidase, β-galactosidase and β-hexosaminidase (Fig. 4C and D). These experimental results indicate that both G-3 and G-4 have a repeating lactosamine unit as their backbone structure. For both G-3 and G-4, the first hydrolysis with β-hexosaminidase after neuramidase and β-galactosidase treatments gave glycolipids having the same mobility as lactoneotetraosyl-ceramide on HPTLC. However, the first neuraminidase treatment and following β-galactosidase treatment of G-3 and G-4 gave glycolipids with different mobilities on HPTLC. Products derived from G-4 migrated much more slowly than those derived from G-3, as shown in Figure 4C and D. These data suggested that G-3 has the following lactosamine repeating unit

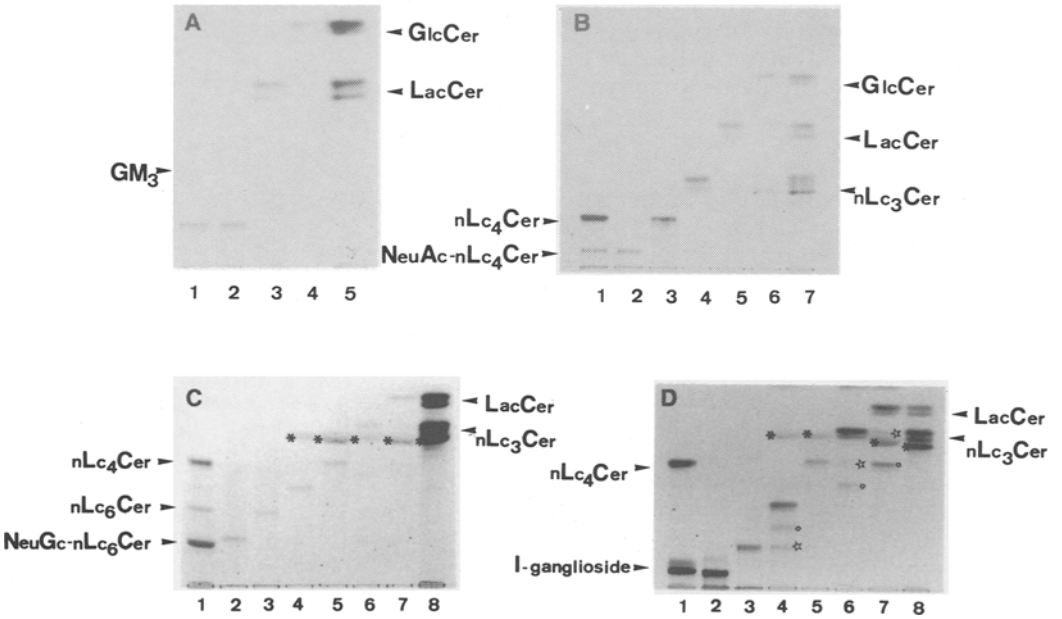

FIG. 4. Stepwise degradation of gangliosides by exoglycosidases. A, enzyme treatment of G-1 ganglioside. Lane 1, GM3; lane 2, G-1; lane 3, G-1 treated with *Cl. perfringens* neuraminidase; lane 4, lipid in lane 3 + β-galactosidase; lane 5, GlcCer and LacCer. Solvent system C was used. B, enzyme treatment of G-2 ganglioside. Lane 1, nLc$_4$Cer and IV^{3}NeuAc-nLc$_4$Cer; lane 2, G-2; lane 3, G-2 + neuraminidase; lane 4, lipid in lane 3 + β-galactosidase; lane 5, lipid in lane 4 + β-hexosaminidase; lane 6, lipid in lane 5 + β- galactosidase; lane 7, GlcCer, LacCer and nLc$_3$Cer from the top. Solvent system C was used. C, enzyme treatment of G-3 ganglioside. Lane 1, nLc$_4$Cer, nLc$_6$Cer, i-ganglioside from bovine erythrocytes; lane 2, G-3; lane 3, G-3 treated with neutraminidase; lane 4, lipid in lane 3 + β-galactosidase; lane 5, lipid in lane 4 + β-hexosaminidase; lane 6, lipid in lane 5 + β-galactosidase; lane 7, lipid in lane 6 + β-hexosaminidase; lane 8, LacCer, nLc$_3$Cer and detergent (sodium taurodeoxycholate). Band of sodium taurodeoxycholate is marked with an asterisk. Solvent system A was used. D, enzyme treatment of G-4 ganglioside. Lane 1, nLc$_4$Cer and I-ganglioside (bovine erythrocytes); lane 2, G-4; lane 3, G-4 + neuraminidase; lane 4, lipid in lane 3 + β-galactosidase; lane 5, lipid in lane 4 + β-hexosaminidase; lane 6, lipid in lane 5 + β-galactosidase; lane 7, lipid in lane 6 + β-hexosaminidase; lane 8, LacCer, nLc$_3$Cer and detergent from the top. Solvent system A was used. Glycolipids were visualized by spraying with orcinol reagent. Maltibands are seen in lane 4, 6 and 7. Bands marked with a circle in lane 4 seemed to be a glycolipid having a following structure: Gal-GlcNAc-Gal-GlcNAc-Gal-Glc-Cer, which was

GlcNAc

a product obtained by the release of one galactose moiety from asialo-G-4 (lipid in lane 3). The lipid marked with a circle in lane 6 should be agalacto-derivative of the lipid marked with a circle in lane 4. A band marked with a circle in lane 7 is the hydrolysis product (nLc$_4$Cer) derived from circle-marked band in lane 6. Bands marked with a star show the rest of the substrate of glycosidase used in each lane.

structure: sialic acid-βGal-βGlcNAc-βGal-βGlcNAc-βGal-βGlc-ceramide. Further, G-4 has the following lactosamine repeating unit structure with branched chain:

sialic acid-βGal-βGlcNAc
\
βGal-βGlcNAc-βGal-βGlc-ceramide.
/
sialic acid-βGal-βGlcNAc

It is quite interesting that no ganglio-series ganglioside could be detected in human placenta.

Proton magnetic resonance (proton NMR) spectra of gangliosides. Proton NMR spectra of the isolated gangliosides taken in Me_2SO-d_6 containing D_2O are shown in Figure 5. Most of the signals were assigned according to the data reported by Koerner et al. (16) and ourselves (17,18). Figure 5A shows that G-1 contained N-acetylneuraminic acid (NeuAc), β-galactose (βGal) and β-glucose (βGlc) in a molar ratio of 1:1:1. G-2 ganglioside was found to contain NeuAc, βGal, βGlcNAc and βGlc in a molar ratio of 1:2:1:1 from the spectrum in Figure 5B.

G-3 ganglioside contained NeuAc, βGal, βGlcNAc and βGlc in a molar ratio of 1:3:2:1 (Fig. 5C).

A characteristic peak at 4.410 ppm appeared in the NMR spectra of G-4 ganglioside (Fig. 5D). It was assigned to the β-anomer proton of N-acetylglucosamine linked to the C-6 position of hexose according to the data reported by Vliegenthart et al. (19) and Dabrowski et al. (20). Other anomeric proton peaks at 4.615, 4.284 ppm and 4.196 ppm were assigned to βGlcNAc, βGal and βGlc, respectively. From the peak areas of the anomeric protons, the molar ratio of sugar components of G-4 was determined to be NeuAc:βGal:βGal(branched position):βGlcNAc:βGlcNAc(1-6R linkage):βGlc=2:3:1:2:1:1.

The peaks appeared between 5.6 and 5.7 in each NMR spectrum were assigned to the protons of double bond of long-chain base. The long-chain bases of these four gangliosides were determined by gas chromatography and also by thin layer chromatography. $C_{18:0}$ Sphingosine base was predominant, and no other sphingosine species was detectable in the four gangliosides.

Methylation analysis. The four separated gangliosides were permethylated and derivatized to partially methylated alditol acetates to analyze the linkage arrangement between sugars. These data are summarized in Table 1. The analytical data indicate that G-1 ganglioside has the same linkage between sugars as GM3 ganglioside. From the methylation analysis together with the enzymatic degradation data and NMR spectra, G-1 ganglioside was determined to be NeuAcα2-3Galβ1-4Glcβ1-1ceramide.

Components of partially methylated alditol acetates derived from G-2 indicated that G-2 had the same sugar linkage as lactoneotetraosylceramide. This result was consistent with the enzymatic degradation data and NMR spectra. Based on these results, G-2 was determined to be NeuAcα2-3Galβ1-4GlcNAcβ1-3Galβ1-4Glcβ1-1ceramide.

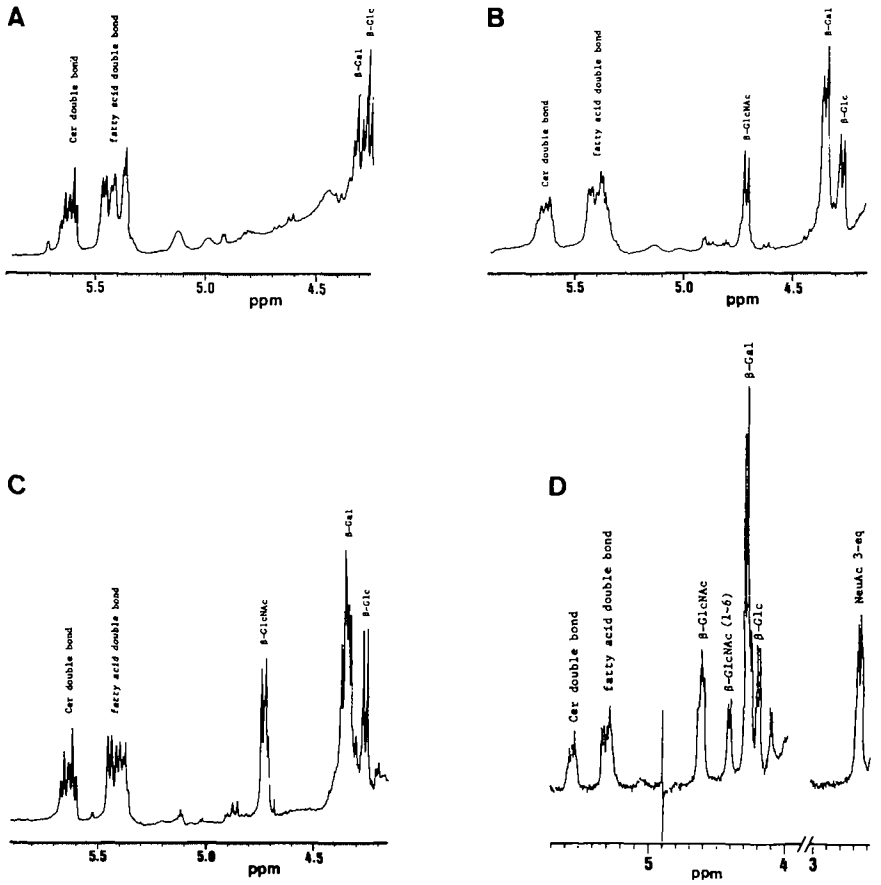

FIG. 5. The 400 MHz proton NMR spectra of placenta gangliosides measured at 90 C in Me_2SO-d_6 containing D_2O solvent. A, G-1 ganglioside; B, G-2 ganglioside; C, G-3 ganglioside; D, G-4 ganglioside.

	NeuAcα2-3Galβ1——— 4GlcNAcβ1							
H-1		4.287	4.410	4.615	4.284	4.615	4.249	4.196
H-3eq	2.740							

In the case of G-3, the partially methylated alditol acetates were the same as those of G-2. As mentioned in connection with the enzymatic degradation study, the presence of a lactosamine repeating unit structure was suggested. From these results and based on the NMR spectra, G-3 was determined to be NeuAcα2-3Galβ1-4GlcNAcβ1-3Galβ1-4GlcNAcβ1-3Galβ1-4Glcβ1-1ceramide.

As compared with the other three gangliosides, G-4 gave a unique derivative of methylated alditol acetate, 2,4-di-0-methyl-1,3,5,6-tetra-0-acetylgalactitol, indicating that this ganglioside has a branching structure at a galactose moiety. This result was consistent with the NMR data. Based on the methylation analysis together with NMR spectra and enzymatic degradation studies, the structure of G-4 was determined to be

NeuAcα2-3Galβ1-4GlcNAcβ1
$\backslash$
$^{6}_{3}$Galβ1-4GlcNAcβ1-3Galβ1-4Glcβ1-1ceramide.
/
NeuAcα2-3Galβ1-4GlcNAcβ1

The NMR peak assignments, listed in Table 2, were consistent with the above structures.

DISCUSSION

Major gangliosides of human placenta were separated and purified, and their structures were determined to be GM3, IV^{3}NeuAc-nLc$_4$Cer, VI^{3}NeuAc-nLc$_6$Cer and VI^{3}NeuAc,IV^6-[II^{3}NeuAc-LcNAc]-nLc$_6$Cer. These gangliosides were characterized as glycolipids containing a lactoneotetraosyl core as the backbone structure, but not a gangliotetraosyl core. Sialosyllactoneohexaosylceramide (i-type ganglioside) and I-type disialoganglioside (VI^{3}NeuAc,IV^6[II^3-NeuAc-LcNAc]-nLc$_6$Cer) were isolated from human erythrocytes (21), and sialosyllactoneohexaosylceramide was separated from chronic myelogenous leukemia cells (22). However, the contents of these components in human erythrocytes are quite low (I-type ganglioside was reported to be 1.8% of total ganglioside of human erythrocytes), and it was very difficult to isolate the pure forms (21). Placenta tissue can be recommended as an excellent source of these lactoneo-series gangliosides.

"Ii" antigens have been characterized as human alloantigens (23–25). I-type ganglioside was detected in adult-type erythrocytes and i-type alloantigen was detected in embryonic erythrocytes (26). I-type ganglioside has been identified as differentiation antigen of human erythrocytes (15,27). In erythrocytes from an embryo and a

newborn baby, i-type erythrocytes are predominant but within a year-and-a-half after birth the erythrocytes have been reported to change from i-type to I-type (26). Further, in an experimental system of human leukemia cell line K-562 (28), expression of i-type changed to I-type accompanying the differentiation of the leukemia cells into erythrocyte-type cells. Similar changes of expression of i and I antigens during differentiation have been demonstrated in mouse myeloid leukemia cells (M1) by Kannagi et al. (29). In the present study, we detected both i- and I-type gangliosides in human placenta, and they are major components in the tissue. "Ii" antigens have been proposed to be precursor substances for ABO-type alloantigens in erythrocytes (15). In the case of erythrocytes, before the transfer of N-acetylneuraminic acid to the terminal galactose of i or I antigen, fucose can be attached to the galactose, and then further addition of α-galactose or α-N-acetylgalactosamine can occur during the development of erythrocytes. However, in the case of placenta before the transfer of fucose to the terminal galactose of i or I antigen, N-acetylneuraminic acid would be transferred to the galactose. This sialylation seems to represent a kind of termination of further glycosylation. This termination signal by transfer of N-acetylneuraminic acid might indicate the termination of gestation (Fig. 6).

Quite recently, we have examined the effect of this I-type ganglioside on the cell growth in a chemically defined medium. Upon addition of the ganglioside, morphological differentiation as well as inhibition of cell growth was observed.

Besides these four major gangliosides, we detected at least five higher gangliosides containing more than 10 sugar residues. Recently, we have separated some of these higher gangliosides by high performance liquid chromatography. This work and the results of a structure study will be reported elsewhere.

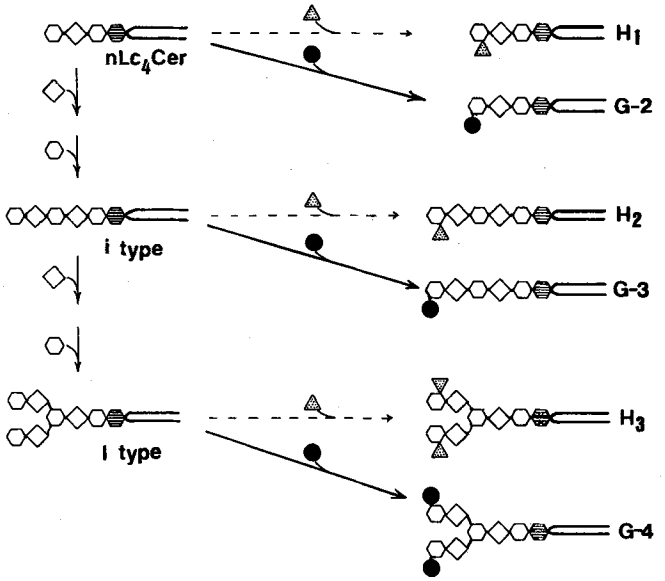

FIG. 6. Proposed metabolic relationship among blood group "Ii," ABO(H)-type and gangliosides in human placenta. In human placenta, G-2, G-3, and G-4 gangliosides were found as characteristic components. Lactoneotetraosylceramide seems to be a precursor ganglioside of these gangliosides. Lactoneotetraosylceramide is converted to i-type glycolipid by the transfer of N-acetylglucosamine (diamond) followed by the transfer of galactose (open hexagon). The i-type glycolipid is converted to I-type lipid by the transfer of N-acetylglucosamine at the C-6 position of the second galactose of i-type lipid, followed by the transfer of galactose. Watanabe et al. (15) proposed that these three glycolipids were converted to blood group AB type lipids through H_1, H_2 and H_3 type lipids by the transfer of fucose to each glycolipid in erythrocytes (indicated by dotted lines). However, in human placenta most of these asialo-type precursor lipids seem to be converted to the respective gangliosides by the transfer of N-acetylneuraminic acid to the terminal galactose. Because fucosylated i- or I-type glycolipids were not detectable in the placenta (data not shown). Since I-type glycolipid has been reported to increase in association with differentiation and development, the appearance of I-type ganglioside in the placenta may correspond to the termination of gestation period. Horizontal fork, ceramide; shaded hexagon, glucose; open hexagon, galactose; diamond, N-acetylglucosamine; shaded circle, n-acetylneuraminic acid; dotted triangle, fucose.

Male, female and castrated rats, three wk of age, were fed a low-fat diet for 14 wk followed by high-fat diets (20% by weight) for one wk containing graded levels of erucic acid from 1 to 50%, to evaluate the effect of short-term feeding and interaction of male sex hormones on formation of heart lesions. Some rats within each group were returned to the low-fat diet for one wk after the test period. For comparison, one group of three-wk-old male rats was fed the high fat 50% erucic acid diet for 15 wk. Erucic acid depressed growth rate and food consumption and increased cardiac lipidosis and triglycerides proportional to the erucic acid content of the diet. There were no sex differences, and the effects disappeared once rats were returned to the low-fat diet for one week. There was a significance ($P < 0.05$) in the incidence of myocardial necrosis among male rats fed increased levels of erucic acid for one week, but the response was not linear to the increase in dietary erucic acid. Furthermore, the response was much less than in males fed the 50% erucic acid diet continually for 15 weeks. These results suggest that the short-term model is not a suitable substitute for the long-term feeding trial to test the cardiopathogenicity of a vegetable oil. The significantly lower incidence in myocardial lesions in female and castrated male rats compared with male rats suggests involvement of sex hormones. However, the process appears to be long term, since changes in cardiac lipids and their fatty acid pattern between sexes became evident after one wk on diet but was significant only after long-term feeding.
Lipids 23, 199–206 (1988).

Male Sprague-Dawley rats were shown to be very sensitive to the development of myocardial necrosis; the incidence increased significantly with the amount of fat and erucic acid (22:1n-9) in the diet (1). Previous studies showed that it was necessary to feed weanling rats for at least 16 wk to produce these heart lesions (1–3). Svaar (4) claimed recently that it was not necessary to feed rats for that period of time since the irreversible heart lesions could be produced by feeding adult male rats test diets for only a few days (short-term model). Svaar suggested that myocardial necrosis was due to an interaction of specific fatty acids such as 22:1n-9 with male sex hormones, and he cited the reduction in lesion incidence in castrated male rats but not female rats as evidence in support of his argument.

To test this short-term model, male, female and castrated male rats were fed high-fat test diets for one wk, after 14 wk on a low-fat control diet. The test fat contained graded levels of 22:1n-9 from 1–50%. Some rats were killed after the one-wk feeding period, and the remainder were killed a week later after being placed back on the low-fat control diet. This was done to reduce the myocardial lipidosis known to be associated with the consumption of docosenoic acids (2).

MATERIALS AND METHODS

Diets. The diets were formulated as described (5). The high-fat diet contained 20% by weight rapeseed/canola oil mixtures and a casein/DL-methionine mixture (97/1). The low fat diet contained 5% by weight corn oil and 45% instead of 30% starch. Six dietary oils were used: canola oil (0.7% 22:1n-9), high erucic acid rapeseed (HEAR) oil (49.0% 22:1n-9), and four mixtures of the two rapeseed oils to give a concentration of about 10, 20, 30 and 40% 22:1n-9. Both canola and HEAR oil were obtained from J. D. Jones, Food Research Centre, Agriculture Canada, Ottawa, Ontario, and were of the variety Tower and R-500, respectively. The fatty acid composition of the oils and oil mixtures are shown in Table 1. Two rapeseed oils were mixed to assure that the remaining fatty acids in the oil mixture were similar in composition, i.e. low in saturates, high in 18:3, and intermediate in 18:2.

Animals. A total of 305 male and 40 female weanling Sprague-Dawley rats weighing between 50 and 60 g were purchased from Charles River Canada Inc. (St. Constant,

Abbreviations: C, cholesterol; CE, cholesterol esters; DPG, diphosphatidylglycerol; HEAR, high erucic acid rapeseed; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; SP, sphingomyelin; TG, triglycerides; TLC, thin layer chromatography.

Quebec). The animals were weighed, ear-notched for identification, and the males allocated randomly to seven groups of 40 and one group of 25; females were in a separate group. All animals were housed individually. The housing and feeding conditions were described (5). One group of 40 male rats was castrated surgically after four wk on the diet (male c group). Individual body weights were measured every two wk, and every week during diet changes. Data on feed consumption was obtained from groups of five rats per diet by a feed weighback at the end of the 14th, 15th and 16th wk.

Procedures. At the end of the 15th week, 25 rats from each diet were killed by exsanguination while under CO_2 anesthesia. The hearts were removed immediately. Twenty hearts from each diet were fixed in 10% neutral buffered formalin, and the remaining five hearts were extracted immediately for total lipids as described (6). At the end of the 16th week, the remaining 15 rats per diet (except male rats fed HEAR oil continuously) were killed; 10 hearts were used for pathological evaluation, and five were used for lipid analyses.

Three sections from each heart were stained with hematoxylin and eosin, and one section was stained with oil red 0. For details regarding histological procedures, see Charlton et al. (7).

The cardiac lipids were quantitated using the Iatroscan method as described (8). The cardiac lipid classes were separated by three directional TLC (9), removed from the TLC plates, and the lipids were transesterified with anhydrous HCl/CH_3OH (5% w/w). The fatty acid methyl esters were purified by TLC using the developing solvent hexane/diethyl ether (90:10, v/v) before GLC analysis on fused silica capillary columns (10).

Analyses of variance were applied to all measurements, except myocardial necrosis data, for which the log-linear model approach, described by Fienberg (11), was used. Significance of heart lesion data and heart lipid classes was determined at $P < 0.05$ and $P < 0.01$, while the remaining data were assessed at $P < 0.01$ and $P < 0.001$.

RESULTS AND DISCUSSION

Growth. The results in Table 2 confirm the growth depression and reduced feed intake in rats fed diets rich in 22:1n-9 (1,2,12). However, the results were confounded by an increase in body weight as a result of switching from a diet containing 5% fat to one containing 20% fat. As a result, dietary groups with low levels of 22:1n-9 experienced a greater gain in body weight per wk for wk 14 to 15 than for wk 12 to 14, while dietary groups with high levels of 22:1n-9 had similar or decreased body weight gains per week. The growth depressing effect of 22:1n-9 was removed on return to the non-22:1n-9 diet. The weight gain per week of the remaining rats in each

[f]Comparison of male, castrated male and female rats fed 50% 22:1n-9 for one wk.

group was similar to that prior to the one-wk test period. Female and castrated male rats grew and ate significantly less than entire males irrespective of the diet, which is consistent with previous observations (13).

Myocardial lipidosis. Within one wk of feeding HEAR oil diets, significant myocardial lipidosis was induced in adult rats (Fig. 1). The response was directly related to the dietary level of 22:1n-9. Of the diet sums of squares (162.3), almost all (156.4) were accounted for by the linear trend in 22:1n-9. These results are in agreement with those previously reported (2,4). There was no significant difference ($P > 0.05$) in severity between adult male, female and castrated male rats fed the same diet similar to that observed in young rats (14–16). Continuous feeding of the same HEAR oil diet reduced the severity of myocardial lipidosis significantly ($P < 0.01$) compared with rats fed the diet for only one wk (Fig. 1), which is consistent with the finding that maximum myocardial lipidosis occurs after one wk (2). The relatively high residual lipidosis in males fed HEAR oil for 15 wk may be due to the high dietary concentration of 22:1n-9.

Substitution of the diets containing 22:1n-9 with corn oil for one wk reduced myocardial lipidosis dramatically, as shown (2). No significant differences in lipidosis were observed between adult male, female and castrated male rats, although females had a slightly lower incidence, similar to that observed in young rats (16). The switch also involved a reduction in the level of fat in the diet from 20% to 5% by weight, which might have expedited the regression of myodardial fat infiltration.

Myocardial necrosis. The incidence and severity of myocardial necrosis was not significantly different in rats examined after the 15th and 16th wk, and for this reason the results were combined in Table 3.

Among males fed increasing levels of 22:1n-9 for one wk, there was a significant difference in incidence ($P < 0.05$) but not severity of myocardial necrosis. The response to dietary 22:1n-9, however, was not linear. These results are not consistent with those reported by Svaar (4), who observed a good correlation between the dietary concentration of 22:1n-9 and the severity of heart lesions in male rats after one wk. In fact, it was for this reason that Svaar (4) suggested that a one-wk feeding to adult male rats (short-term model) could be used to test the cardiopathogenicity of a dietary oil, instead of the usual 16-wk feeding period. It appears highly unlikely that the difference in strains of rats used (Wistar [4] vs Sprague-Dawley) would account for the discrepancy, since the Sprague-Dawley male rat used in this study is known to be more sensitive to the development of myocardial necrosis than the Wistar male rat (1,17). Our results therefore would suggest that a one-wk feeding period to adult male rats would not lead to a conclusive evaluation of the cardiopathogenicity of a vegetable oil.

Long-term feeding of the same diet (50% 22:1n-9) resulted in a much higher incidence and severity of

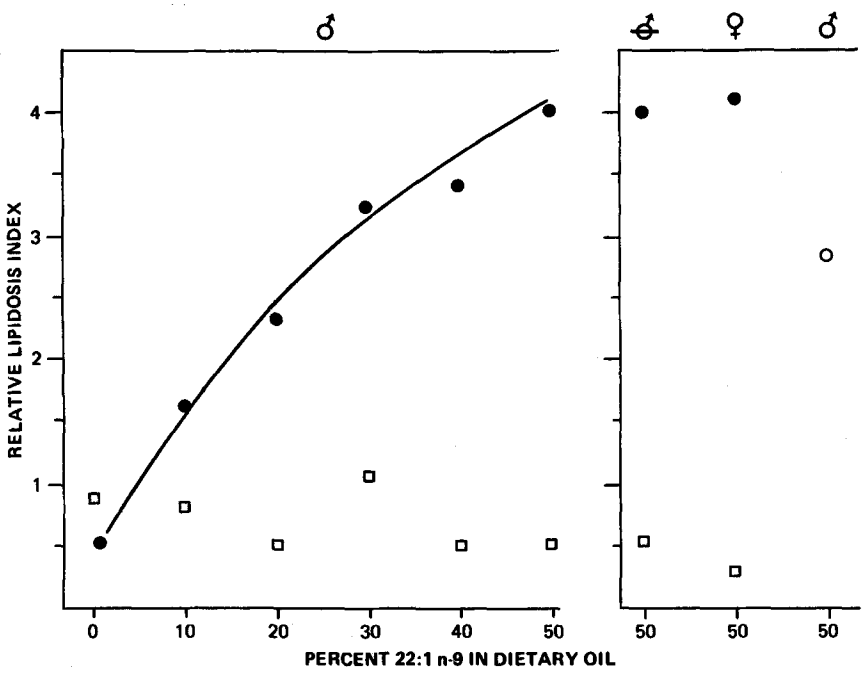

FIG. 1. Mean myocardial lipidosis scores of male rats (n = 20) fed the experimental diets containing graded levels of erucic acid (22:1n-9) from 1 to 50% for one wk (●). An additional 10 rats in each group were examined a week later after having been returned to the 5% corn oil diet (□). Castrated male (♂-) and female rats (n = 20) also were fed an experimental diet containing 50% 22:1n-9 for one wk (●), and an additional 10 rats in each group were fed a 5% corn oil diet for another week (□). One group of male rats (n = 20) were fed a rapeseed oil containing 50% 22:1n-9 for 15 wk (○). Lipidosis scores as determined by oil red 0: 0, no fat stain; 1, very slight; 2, slight; 3, moderate; 4, marked; 5, severe.

TABLE 3

Myocardial Necrosis in Sprague-Dawley Rats Fed the Experimental Diets for 15 and 16 Weeks[a]

Diet group	Incidence	Severity index[b]

Male—15 wk, 50%	20/20	0	0	2	18
χ^2 Analysis[c]					
Comparisons (d.f.)	Incidence	Severity[d]			
All 1-wk diets (7)	22.37**	2.71			
Diet[e] (5)	13.07*	2.43			
Sex[f] (2)	10.51**	0.96			

[a]Twenty rats of each group were examined histologically for H&E staining after 15 wk; an additional 10 rats were examined from all diets at 16 wk. The results of both time periods were combined because these were not significantly different.

[b]Severity of myocardial necrosis represents the number of rats with one, two, three to six, and > six lesions per heart (3 sections/heart were examined).

[c]The χ^2 analysis was according to a method described by Fienberg (11); d.f., degrees of freedom; and significance levels at $P < 0.05$ (*) and $P < 0.01$ (**).

[d]For statistical analysis of severity two groups were compared, rats with one lesion vs rats with more than one lesion.

[e]Comparison of male rats fed for one wk diets containing 1 to 50% 22:1n-9.

[f]Comparison of male, castrated male and female rats fed for one wk the diet containing 50% 22:1n-9.

myocardial necrosis than the one-wk trial (Table 3). These results suggest that long-term feeding will be necessary in any case to differentiate fats and oils of similar cardiopathogenic response.

The suggestion has been made that the cardiac injury might be due to an interaction of male sex hormones with specific dietary fat components, such as 22:1n-9 (4,13). The lower incidence of myocardial necrosis in female (15,18,19) and castrated male rats (13), compared with males (Table 3), would support this view. However, even though all three groups ate the same diet, their growth rate and feed consumption were markedly different (males > castrated males > females), see Table 2. The effect of differences in growth and feed consumption cannot be ignored in view of the following evidence. First, for a particular diet light male rats showed significantly ($P < 0.01$) less myocardial necrosis than heavier rats (20). Second, male rats that ate similar diets but weighed less after the same feeding period, had a lower incidence of heart lesions (21). Third, in one study castrating Sprague-Dawley male rats had no effect on growth, and the incidence of myocardial necrosis was similar (22). It is this evidence that suggests that both sex hormones and growth rate are involved in the etiology of myocardial necrosis in rats. The relative contribution of these two factors, however, is impossible to separate at this time.

Cardiac lipid classes. Only the data from selected diets were analyzed to determine if diet or sex resulted in cardiac lipid changes that might reflect the observed cardiopathological responses.

There were only a few sex differences in cardiac lipids after feeding the HEAR oil diet for one week (Table 4). However, a common trend was observed. Male rats had a higher concentration of cardiac phospholipids (DPG, PE, PC, and SP) than either females or castrated males; the latter two groups were similar. Prolonged feeding (15 wk) of the same HEAR oil diet resulted in a further increase of these cardiac phospholipids. On the other hand, male rats fed the diet low in 22:1n-9 had a phospholipid composition more like that of female and castrated male rats. These results suggest that an increase in all cardiac phospholipids could be related to an increase in the incidence and severity of myocardial necrosis. The cardiac lipid changes already were evident after one wk but were more pronounced on long-term feeding. Some of the published reports showed an increase in either PC (23), DPG (24) or SP (25) when male rats were fed diets rich in 22:1n-9, but the results had not been consistent nor shown for all cardiac phospholipids (26).

There was no difference between sexes in the amount of cardiac TG accumulated within one wk in adult Sprague-Dawley rats (Table 4). Female hearts contained slightly lower levels of cardiac TG than males or castrated males, but this was not statistically significant. These results are in marked contrast with the only other study in which sex differences were investigated and young Wistar males were shown to have a 3.5 times higher cardiac TG level than females fed for three days a partially hydrogenated fish oil containing 14.5% 22:1 isomers (27). It does not appear that differences in age and strain of rat, diet (type of 22:1 isomer), or length of feeding could explain these large differences. Furthermore, the unusually low values of cardiac TG in their results (8.3 to 47.5 nmol/g of heart) (27) are about 1/100th of those reported by others (6,28).

Triglycerides. The fatty acid composition of cardiac TG (Table 5) was not significantly different among the three sex groups (males, castrated males and females) fed the same HEAR oil (50% 22:1 n-9) diet for one wk. Thomassen et al. (27) also reported no sex difference in the fatty acid composition of the accumulated TG, despite a 3.5-fold higher level of cardiac TG in male compared with female weanling Wistar rats fed fish oil high in 22:1n-11.

Continued feeding of a diet rich in 22:1n-9 may have increased the rat's capacity to metabolize 22:1n-9 as evidenced by a lower level of 22:1n-9 and higher levels of 20:1n-9 and 18:1n-9 compared with male rats fed the same diet for only one wk (Table 5). These products were shown to be formed by peroxisomal β-oxidation of 22:1n-9 in rat heart (29,30) and liver (31). The results from this study suggest that the metabolism of the long chain monounsaturated fatty acids, even in adult rats, is slow and very similar between sexes.

Phospholipids. It is not the intent in this study to discuss the characteristic differences between cardiac phospholipids, but simply to identify differences that could be related to differences in cardiopathogenic response. Many of the differences between the Canola and

HEAR oil group were related to dietary monounsaturated fatty acids (18:1, 20:1 and 22:1), and thus provide no critical evaluation (Table 6). On the other hand, male, female and castrated male rats, fed the same diet for one wk, might yield compositional differences that could be related to known sex differences in cardiopathogenic response.

In general, there were few sex differences, and these were found mainly in the composition of PI and DPG (Table 6). Castrated males differed in their cardiac fatty

Abbreviations: C, castrated; LSD, least significant differences ($P < 0.01$); Canola, canola oil; HEAR, high erucic acid rapeseed; PUFA, polyunsaturated fatty acids; NS, not significant at $P > 0.01$; significant at $P < 0.01$ (*) and $P < 0.001$ (**).

[a]Statistics were based on analysis of variance of pooled data. Sex comparison was among the three groups of rats (males, castrated males and females) fed the HEAR oil diet (50% 22:1n-9) for one wk. The Canola oil comparisons were between males fed the canola oil (1% 22:1n-9) for one wk and the HEAR oil (50% 22:1n-9) for 15 wk; the HEAR oil comparison was between the three groups of rats (male, castrated males and females) fed the HEAR oil diet for one wk.

[b]DMA, dimethylacetals.

acid composition of PI and DPG from both males and females, while the latter two groups were similar in composition. This was unexpected, since the cardiopathogenic response showed a similarity between castrated males and females, and both were significantly different from males (Table 3). Likewise, the incorporation of 22:1n-9 into cardiac phospholipids showed little evidence of being related to the incidence of myocardial necrosis. Although there were no significant sex differences in 22:1n-9 accumulation in cardiac phospholipids (except DPG), the trend was always the same, females < males < castrated males. This suggests that 22:1n-9 was not solely responsible for the development of myocardial necrosis, as concluded (32).

Previous studies showed that the incidence of myocardial necrosis in male rats was inversely related to the concentration of dietary saturates and directly related to the concentration of dietary 18:3n-3 (5,33,34). The heart lipids had increased levels of saturates and a high level of C22n-3 PUFA in all cardiac phospholipids (except DPG), which correlated well with the incidence of heart lesions in male rats (35). In this study, the differences in content of saturates and C22n-3 PUFAs in cardiac lipids between sexes was occasionally significant (Table 6), but did not parallel the observed incidence of myocardial necrosis (Table 3). Castrated rats generally were different from male and female rats. It should be noted, however, that male rats fed the 50% 22:1n-9 diet for 15 weeks had significantly higher levels of C22n-3 PUFA in all cardiac phospholipids and generally lower levels of saturates. These results indicate that the fatty acid composition was slower to change in adult rats (this study) than in weanling rats (35) fed similar diets for one wk. This in turn might explain the relatively low severity of myocardial necrosis observed in adult rats fed the HEAR oil diets for one wk compared with feeding the diet for 15 wk.

Sphingomyelin. Male rats fed the 50% 22:1n-9 diet for one wk had a reduced level of saturated fatty acids in cardiac SP, and this reduction was significant on continuous feeding (15 wk) of the HEAR oil diet (Table 7). Saturated fatty acids containing 20 or more carbon atoms decreased while long-chain monounsaturates (18:1n-9, 22:1n-9 and 24:1n-9) increased in male rats fed HEAR oil for one week, and even more so when the male rats were fed for 15 wk. The results were consistent (females < castrated males < males—1 wk < males—15 wk), and the trend paralleled the observed incidence of myocardial necrosis. Even though SP is not a major component of cardiac phospholipids, its influence might be significant, since it is present in selected membranes such as the outer membrane of mitochondria (36) and it has the highest net incorporation of 22:1n-9 among cardiac phospholipids. The net incorporation includes 22:1n-9 itself (~7%), plus the increase in 24:1n-9 (~12%) above levels that occur in rats fed diets such as corn or soybean oils (37), since 24:1n-9 is the product of chain elongation of 22:1n-9 (38–40).

The results of this study indicate that the well-known, high incidence of myocardial necrosis in male rats fed HEAR oil diets (41) could not be duplicated by a one-wk feeding, even when the animals were fed during the age of sexual maturation (presumed sensitive period). Based on this study, a much larger number of rats and a high level of test oil in the diet will be required to obtain a more conclusive answer regarding the cardiopathogenicity of an oil, if the one-wk feeding period proposed by Svaar (4), was implemented. Furthermore, such a short-term feeding study might not provide information as to the cause and development of myocardial necrosis from non-brassica vegetable oils.

Our results suggest that we might not be dealing with an acute cardiopathogenic agent(s) in vegetable oils, but rather with a nutritional problem in the rat, specifically

TABLE 7

in fast-growing albino male rats (20). The development of myocardial necrosis, although not totally understood, appears to be caused by a combination of factors such as an alteration of cardiac phospholipids and/or their fatty acid composition (saturates, C22n-3 PUFAs, and long-chain monoenes of 20:1, 22:1 and 24:1). The compositional changes were evident after one wk on these experimental diets but much more so after continued feeding.

([3]H)Forskolin- and ([3]H)Dihydroalprenolol-binding Sites and Adenylate Cyclase Activity in Heart of Rats Fed Diets Containing Different Oils

Syed Q. Alam*, Yun-Fang Ren and **Bassima S. Alam**
Department of Biochemistry and Molecular Biology, Louisiana State University Medical Center, 1100 Florida Ave., New Orleans, LA 70119

The characteristics of the cardiac adenylate cyclase system were studied in rats fed diets containing fish oil (menhaden oil) and other oils. Adenylate cyclase activity generally was higher in cardiac homogenates and membranes of rats fed diet containing 10% menhaden oil than in the other oils. The increase in enzyme activity, especially in forskolin-stimulated activity, was associated with an increase in the concentration of the [3H]forskolin-binding sites in cardiac membranes of rats fed menhaden oil. The β-adrenergic receptor concentration was not significantly altered although the affinity for [3H]dihydroalprenolol-binding was lower in membranes of rats fed menhaden oil than those fed the other oils. ω-3 fatty acids from menhaden oil were incorporated into the cardiac membrane phospholipids. The results suggest that the observed increase in myocardial adenylate cyclase activity of rats fed menhaden oil may be due to an increase in the number of the catalytic subunits of the enzyme or due to a greater availability of the forskolin-binding sites. ***Lipids 23,*** **207–213 (1988).**

The lipid dependence of adenylate cyclase has been shown by a number of studies (1–4). Because the composition of cell membrane lipids can be altered by dietary modifications, it is reasonable to expect concomitant changes in adenylate cyclase activity. Indeed, in several tissues changes in basal and hormone-stimulated adenylate cyclase activity have been observed after feeding diets containing different lipids (5–7). The changes in enzyme activity generally were associated with structural changes in membrane fatty acyl group composition. There is substantial evidence that the feeding of diets with different lipids results in modifying the fatty acid composition of cardiac phospholipids (8–10). There have been a number of studies to determine if the diet-induced changes in cardiac membranes also result in functional changes. Awad and Chattopadhyay (11) reported that feeding rats coconut oil-rich diet for four wk resulted in a significant decrease in 5′-nucleotidase, phosphodiesterase I and p-nitrophenylphosphatase activity of cardiac sarcolemma as compared with feeding rats safflower oil. In another study (12), the feeding of diets high in oleic, linoleic, linolenic and erucic acids to rats altered the fatty acid composition of mitochondrial phospholipids in rat heart, but did not affect the mitochondrial β-oxidation. In a previous study, we have shown that essential fatty acid (EFA) deficiency (13) resulted in a decrease in adenylate cyclase activity and β-adrenergic receptor content in rat heart. The changes in enzyme activity and in β-adrenergic receptor content were associated with modification in acyl group composition of cardiac membrane phospholipids. Because the fatty acid composition of cardiac membrane phospholipids can be altered by means other than an EFA deficiency such as by feeding oils of different fatty acid composition; this study was undertaken. Corn oil (relatively rich in ω-6 fatty acids), menhaden oil (relatively rich source of ω-3 fatty acids) and a mixture of 8% coconut oil + 2% corn oil (relatively rich in saturated fatty acids and sufficient in EFA) were used for the purpose of inducing structural changes in fatty acid composition of cardiac membrane phospholipids and to study their effects on adenylate cyclase system.

Abbreviations: DHA, dihydroalprenolol; EFA, essential fatty acid.

MATERIALS AND METHODS

All the biochemical reagents were obtained from Sigma Chemical Co. (St. Louis, MO). Dietary ingredients were purchased from Teklad (Madison, WI) except menhaden oil was a product of ICN Nutritional Biochemicals (Cleveland, OH). Radioisotopes: α-[32P]ATP (specific activity 619 Ci/mmol) was purchased from ICN (Cleveland, OH), [3H]cyclic AMP (specific activity 55 Ci/mmol), [3H]dihydroalprenolol (specific activity 38 Ci/mmol) were purchased from Amersham (Arlington Heights, IL) and [3H]forskolin (specific activity 40 Ci/mmol) was purchased from Dupont, NEN (Boston, MA).

Male weanling Sprague-Dawley rats (Holtzman Co., Madison, WI) were fed Purina Rat chow for seven days in order to get them acclimatized to the laboratory conditions. Rats were weighed and randomly divided into three groups of 27 rats each so that the average weight per group was the same. They were fed semipurified diets containing 10% corn oil (group 1), 8% coconut oil + 2% corn oil (group 2), or 10% menhaden oil (group 3). The diets contained (%): casein, 20.0; DL-methionine, 0.3; sucrose, 45.0; starch, 15.0; cellulose, 5.0; oil, 10.0; vitamin mixture (AIN-76A), 1.0; salt mixture (AIN-76A), 3.5; choline, 0.2; and BHT, 0.002. The diets were analyzed for their fatty acid composition after extracting 1 g aliquots of the freshly prepared diets with chloroform/methanol (2:1), esterifying aliquots of the lipid extracts with boron trifluoride methanol and subsequent gas chromatography on a Silar-10 C column as described (14).

The fatty acid composition of the three diets is shown in Table 1. The diet containing 10% corn oil had high levels of ω-6 fatty acids (58% of 18:2ω-6) and almost negligible amounts of ω-3 fatty acids. On the other hand, the diet containing menhaden oil had relatively high levels of ω-3 fatty acids (20:5, 22:5 and 22:6) and very low levels of ω-6 fatty acids. The diet supplemented with 8% coconut + 2% corn oil had high levels of medium chain saturated fatty acids, no ω-3 fatty acids and had some ω-6 fatty acids.

Rats were housed individually in suspended stainless steel cages in a temperature- and light-controlled room (22–23 C, 12 hr light-dark cycle) and were fed diets and tap water ad libitum for six wk. Although we did not measure the peroxide values of the diets, to minimize rancidity, the diets were stored at 4 C, and the diets left over in the food cups were discarded and replaced with the fresh diets daily. Rats were weighed at weekly intervals.

TABLE 1

Fatty Acid Composition of the Diets

At the termination of the experiment, rats were killed over a period of three days (between 8–10 a.m.). Hearts were removed, rinsed several times with cold physiological saline, chopped into small pieces with scissors and homogenized in a Potter-Elvejhem homogenizer with 9–10 volumes of a medium containing 0.32 M sucrose, 0.05 M Tris buffer (pH 7.4) and 1 mM $MgCl_2$. The homogenates were filtered through four layers of cheesecloth, and crude plasma membranes were prepared by differential centrifugation as described (13). Membranes and homogenates were aliquoted in small vials and stored in liquid nitrogen until assayed. No changes in adenylate cyclase activity or receptor binding were observed in samples stored in liquid nitrogen up to four wk. Aliquots of the homogenates and membranes were used for adenylate cyclase assays. The binding assays using [^{3}H]forskolin and [^{3}H]dihydroalprenolol (DHA) were carried out with the membranes.

β-receptor binding assays using [^{3}H]DHA as a radioligand were performed as described (13). Briefly, aliquots of cardiac membranes (150–350 μg protein) were incubated for 15 min with 0 to 29 nM [^{3}H]DHA in a final volume of 500 μl of a buffer (50 mM Tris-HCl, 10 mM $MgCl_2$, pH 7.4 at 37 C). The bound radioligand was separated by vacuum filtration on Whatman GF/A glass fiber filter, and the radioactivity was determined by liquid scintillation. The specific binding of [^{3}H]DHA is defined as the difference between the total binding and the binding in the presence of 1 mM alprenolol. All assays were done in duplicates. The dissociation constant (K_d) and the concentration of the binding sites (B_{max}) were determined by Scatchard analysis using a computer.

Adenylate cyclase activity was measured in triplicate samples in homogenates and membranes by determining the conversion of [α-^{32}P]ATP to cyclic [^{32}P]AMP and isolating the product by sequential column chromatography (15). Details of the adenylate cyclase assay have been provided (14). The basal activity was measured without the addition of any stimulating agent in the incubation medium. The stimulated activity was measured in the presence of sodium fluoride (15 mM), isoproterenol (20 μM) or forskolin (0.1 M). In terms of the well-established three component adenylate cyclase system, isopreterenol activates the enzyme by stimulating the β-adrenergic receptor, fluoride by activating the guanine-binding regulatory proteins, and forskolin activates it by binding to the catalytic unit of the enzyme.

For [^{3}H]forskolin binding studies, cardiac membranes (25 μg protein) were incubated at 37 C for 30 min with 12.5 to 210 nM [^{3}H]forskolin in a final volume of 200 μl of buffer (50 mM Tris-HCl, 10 mM $MgCl_2$, pH 7.4). Preliminary studies had shown that maximum binding of [^{3}H]forskolin was obtained under these conditions after 20 min of incubation and that there was no change in binding for up to 90 min. The specific binding was defined as the difference between the total binding and binding in the presence of 50 μM unlabeled forskolin. The unlabeled forskolin was dissolved in a mixture of ethanol/dimethyl sulfoxide (29:18%) in the above buffer as described by Ho and Shi (16). The final solvent concentrations for ethanol and dimethyl sulfoxide were 2.9 and 1.8%, respectively. At these concentrations, the solvents had little effect on radioligand binding or adenylate cyclase activity. At the end of the incubation period, all the tubes were placed in an ice-cold water bath followed by rapid filtration under vacuum through Whatman GF/A glass fiber filters. Filters were rapidly washed three times with 4 ml of the ice-cold incubation buffer to separate the bound and free radioligand. After drying, the bound radioactivity remaining on the filters was counted using a liquid scintillation spectrometer (Beckman LS6800). All binding assays were done in duplicate. The data for the saturation curves were analyzed by a computer to estimate the equilibrium dissociation constants (K_D) and the maximum number of the binding sites (B_{max}) using Scatchard analysis (17).

Fluorescence polarization was measured according to the procedures of Shinitzky and Inbar (18) and Shinitzky and Barenholz (19) as described (20). In brief, cardiac membranes were incubated with diphenyl hexatriene (DPH) in phosphate-buffered saline, and fluorescence polarization was measured using an SLM 4800 fluorescence polarization spectrophotometer (SLM Instruments, Inc., Urbana, IL) with two cross-polarized channels. The excitation was 366 nm. Scattering of the emitted light was reduced by using a 389 nm cut-off filter.

Total lipids were extracted from the cardiac homogenates and membranes using Bligh and Dyer's method (21). Phospholipids were separated by column chromatography (22). Methyl esters were prepared from aliquots of total lipids and phospholipids using boron trifluoride-methanol (23), and the fatty acid composition was determined by gas chromatography as described (14).

The data pertaining to the three dietary groups were treated statistically using analysis of variance and the significance of the differences among the groups was calculated using Newman-Keul's test (24).

RESULTS

There was no significant difference in the body weight gains of rats fed the various diets.

5′-Nucleotidase generally is used as a marker enzyme for plasma membranes. The crude membrane preparations that we used had 10–13-fold enrichment in 5′-nucleotidase activity over that of the homogenates. There was no significant difference in the relative purity of the membranes among the three dietary groups as evaluated by the activity of succinic dehydrogenase for mitochondria and glucose-6-phosphatase for microsomal contamination. Also, there was no difference in the yield of membranes among the three dietary groups.

Adenylate cyclase activity in heart homogenates (Table 2) was higher in rats fed menhaden oil than in the other two groups. The basal activity was 40–50% higher, and the stimulated activity (fluoride, isoproterenol or forskolin) was two- to three-fold higher in cardiac homogenates of rats fed diet containing menhaden oil than in that of the other two groups. There was essentially no difference in adenylate cyclase activity between the groups fed 10% corn oil or 8% coconut oil + 2% corn oil.

Adenylate cyclase activity in cardiac membranes of rats fed the three diets is shown in Table 3. As in the homogenates, basal and forskolin-stimulated activity was the highest of the three groups in membranes of rats fed diet containing menhaden oil. However, such differences were not observed in fluoride- or isoproterenol-stimulated activity. Although these activities still were higher in membranes of rats fed menhaden oil than those fed 8% coconut oil + 2% corn oil, there was no difference between the groups fed menhaden oil vs corn oil.

The saturation curves for the specific [^{3}H]DHA-binding to the cardiac membranes of rats fed diets containing different oils are shown in Figure 1A. The Scatchard plots (Fig. 1B) and the data in Table 4 show a lower affinity (higher K_D values) in membranes of rats fed menhaden oil than in the other two oils. There was a slight but nonsignificant ($P > 0.05$) increase in the number of binding sites in cardiac membranes of rats fed diet containing menhaden oil than the other two oils.

To determine the characteristics of [^{3}H]forskolin-binding to rat myocardial membranes, we conducted a preliminary study. Membranes were prepared from heart of adult male Sprague-Dawley rats by the differential centrifugation method similar to the one described above for isolating the cardiac membranes from rats fed the three diets.

The total, specific and nonspecific [^{3}H]forskolin binding as a function of the incubation time is shown in Figure 2. The binding was very rapid during-the first one to two min and reached a plateau at about 20 min of incubation. Therefore, in subsequent experiments a 30-min incubation time at 37 C was used routinely. The specific binding was linear over a range of 12.5 to at least 50 μg protein. Therefore, in subsequent experiments 50 μg or lower amount of membrane protein was used for [^{3}H]forskolin-binding studies.

The specific binding of [^{3}H]forskolin to the cardiac membranes of rats fed menhaden oil was higher than in those fed the other two oils. The values shown in Table 5,

TABLE 2

Adenylate Cyclase Activity in Heart Homogenates of Rats Fed Diets Containing Different Oils

Diet fed	Basal	+ Fluoride	+ Isoproterenol	+ Forskolin
10% Corn oil	13.7 ± 0.3^a	51.0 ± 10.3^a	31.0 ± 6.2^a	138.5 ± 18.5^a
8% Coconut oil + 2% corn oil	13.0 ± 0^a	52.8 ± 5.2^a	25.3 ± 4.3^a	137.8 ± 19.7^a
10% Menhaden oil	19.0 ± 0^b	110.5 ± 10.9^b	75.3 ± 11.8^b	291.5 ± 36.2^b

Values are mean ± SE of four assays/group; each assay was done in triplicate. Values with different superscripts in the same column are significantly different ($P < 0.01$) from each other using analysis of variance, Newman-Keul's test. Enzyme activity is shown in pmol/mg protein/min. The final concentrations of the activators in the incubation mixture were fluoride, 15 mM; isoproterenol, 20 μM; and forskolin, 0.1 mM.

TABLE 3

Adenylate Cyclase Activity in Heart Membranes of Rats Fed Diets Containing Different Oils

Diet fed	Basal	+ Fluoride	+ Isoproterenol	+ Forskolin
10% Corn oil	24.1 ± 1.1^a	163.2 ± 8.0^a	39.2 ± 2.4^a	328.7 ± 12.0^a
8% Coconut oil + 2% corn oil	21.0 ± 1.0^b	119.5 ± 4.2^b	28.3 ± 1.2^b	244.8 ± 20.4^b
10% Menhaden oil	27.9 ± 1.1^c	167.0 ± 6.6^a	43.0 ± 1.8^a	394.7 ± 13.5^c

Values are mean ± SE of three assays/group; each assay was done in triplicate. Values with different superscripts in the same column are significantly different ($P < 0.05$) from each other using analysis of variance, Newman-Keul's test. Enzyme activity is shown in pmol cAMP/mg protein/min. The final concentrations of the activators were fluoride = 15 mM, isoproterenol = 20 μM, and forskolin = 0.1 mM.

(A) Saturation curves for the specific binding of [^{3}H]DHA to cardiac membranes of rats fed diets containing different oils. 10% corn oil, ●—●; 8% coconut oil + 2% corn oil, ○—○; 10% menhaden oil, ▲—▲. Each point represents a mean ± SE of four experiments, each done in duplicate. (B) Scatchard plot.

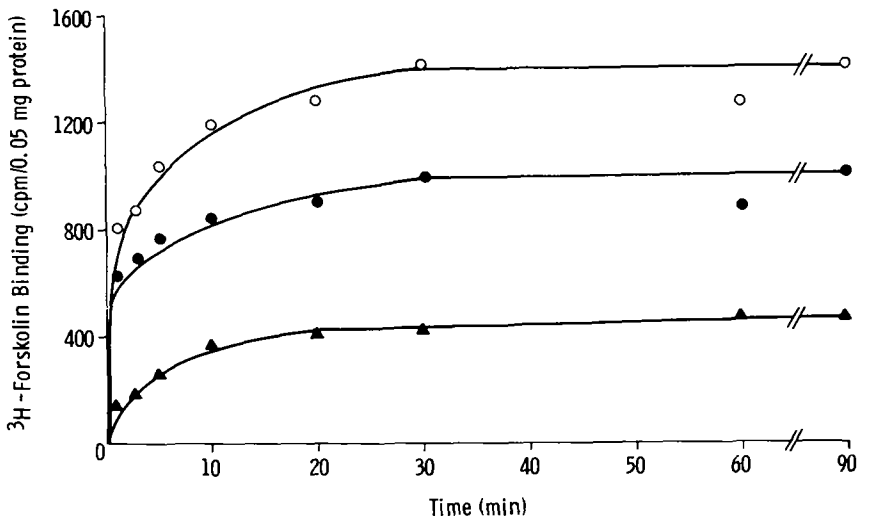

FIG. 2. Time course of [^{3}H]forskolin binding to cardiac membranes of rats. Membranes (50 μg protein) were incubated in 10 mM $MgCl_2$, 50 mM Tris-HCl buffer (pH 7.4) and 50 nM [^{3}H]forskolin (final concentration) at 37 C for the specific time periods. Bound radioactivity was separated from the free radioactivity by rapid filteration assay as described in Methods. Each data point represents a mean of duplicate assays. Total binding, ○—○; nonspecific binding (in the presence of 50 μM forskolin), ▲—▲; specific binding, which represents the difference between the total binding and the nonspecific binding, ●—●.

TABLE 4

[^{3}H]DHA-Binding to Cardiac Membranes of Rats Fed Diets Containing Different Oils

Diet fed	K_D	B_{max}
	nM	pmol/mg protein
10% Corn oil	2.44 ± 0.41[a]	0.223 ± 0.041[a]
8% Coconut oil + 2% corn oil	3.50 ± 0.48[a]	0.234 ± 0.047[a]
10% Menhaden oil	6.54 ± 1.16[b]	0.357 ± 0.076[a]

Values are mean ± SE of four assays/group; each was done in duplicate. Values with different superscripts in the same column are significantly different P(<0.05) from each other using analysis of variance, Newman-Keul's test.

TABLE 5

[^{3}H]Forskolin-Binding to Rat Heart Membranes

Diet fed	K_D	B_{max}
	μM	pmol/mg protein
10% Corn oil	0.24 ± 0.03[a]	4.75 ± 0.16[a]
8% Coconut oil + 2% corn oil	0.22 ± 0.04[a]	4.49 ± 0.67[a]
10% Menhaden oil	0.27 ± 0.04[a]	8.42 ± 0.52[b]

Values are mean ± SE of three assays/group; each was done in duplicate. Values with different superscripts in the same column are significantly different P(<0.01) from each other using analysis of variance, Newman-Keul's test.

which were calculated from the Scatchard plots, show a higher concentration of the binding sites in membranes of rats fed menhaden oil than in the other two groups. There was, however, no difference in the affinity of the binding sites among the three groups.

The stimulation in adenylate cyclase activity with different concentrations of forskolin (Fig. 3) also showed a significant increase in the enzyme activity in cardiac membranes of rats fed diets containing menhaden oil. This was the case at each concentration of forskolin.

The fatty acid composition of total phospholipids of cardiac homogenates and membranes (Table 6) showed relatively higher proportions of 22:6 ω-3 (17–18% of the total fatty acids) and 20:5 ω-3 (4–5% of the total fatty acids) in rats fed menhaden oil than the other two oils. The levels of ω-6 fatty acids (18:2, 20:4 and 22:4) were lower in rats fed diet containing menhaden oil than those in the other two dietary groups. The double bond index, a measure of the degree of unsaturation, was higher in membrane phospholipids of rats fed diet containing menhaden oil than in the other two oils (173 in 10% corn oil, 171 in 8% coconut oil + 2% corn oil, and 213 in the group fed 10% menhaden oil).

The fluorescence polarization of DPH measured at different temperatures in cardiac membranes was essentially the same among the three dietary groups (Fig. 4).

DISCUSSION

We have reported (13) that EFA deficiency resulted in a decrease in adenylate cyclase activity and in the concentration of β-adrenergic receptor in rat heart. Since the levels of linoleic acid in menhaden oil are quite low, this raises the possibility of an EFA deficiency by feeding of a diet containing 10% menhaden oil. However, there was no evidence of an EFA deficiency as shown by the fatty acid composition of total lipids of plasma (data not shown). Although the 20:4ω-6 levels were lower in rats fed 10% menhaden oil (10% vs 32–33% in the other two dietary groups), there was no accumulation of 20:3ω-9. It constituted less than 0.5% of the total fatty acids in plasma of rats fed 10% menhaden oil.

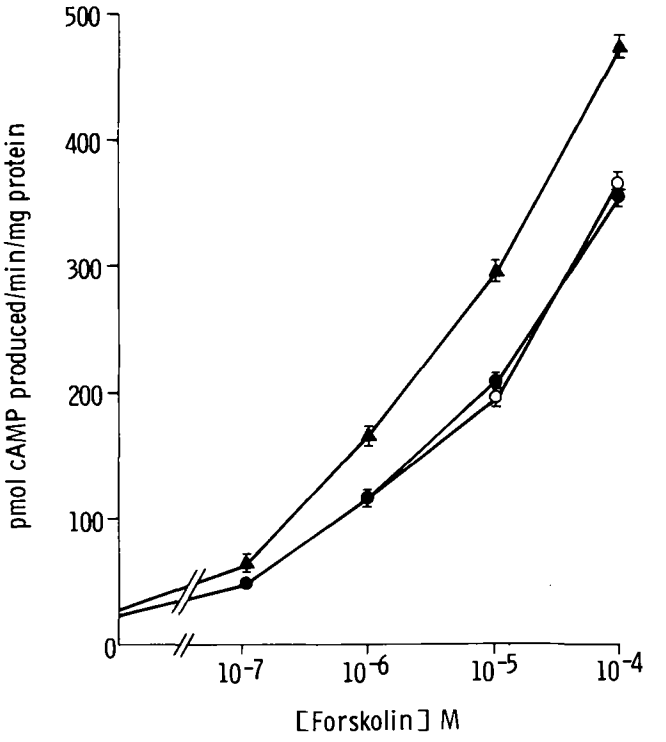

FIG. 3. Forskolin-stimulated adenylate cyclase activity in cardiac membranes of rats fed diets containing different oils. 10% corn oil, ●—●; 8% coconut oil + 2% corn oil, ○—○; 10% menhaden oil, ▲—▲. Each point represents a mean of four experiments, each done in triplicate. The bars represent SE.

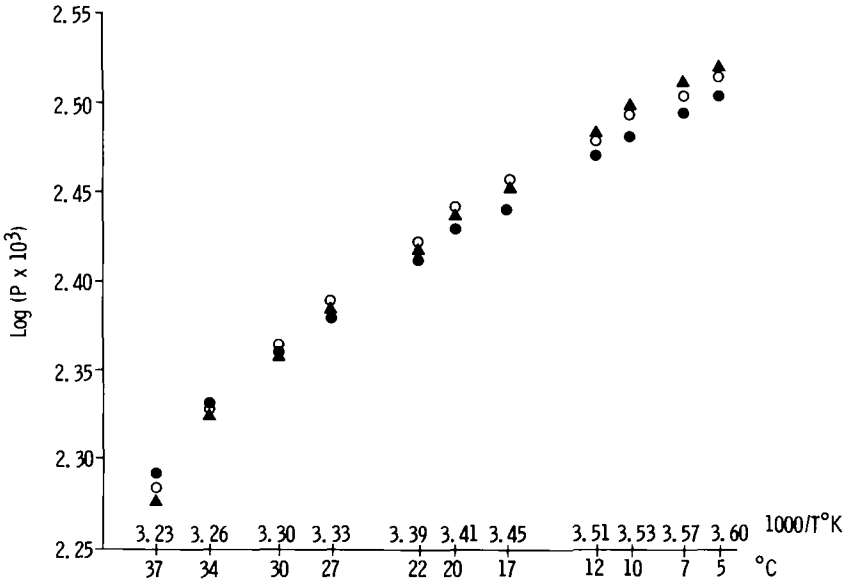

FIG. 4. Fluorescence polarization of DPH in cardiac membranes of rats fed diets containing 10% corn oil, ●; 8% coconut oil + 2% corn oil, ○; or 10% menhaden oil, ▲. Fluorescence polarization was measured at different temperatures (5–37 C).

Adenylate cyclase system consists of a hormone-sensitive receptor (R), guanine-nucleotide binding regulatory proteins (G_s and G_i) and the catalytic subunit (C). Changes in any of these components theoretically may explain the increase that we observed in the stimulated adenylate cyclase activity in heart of rats fed menhaden oil. Since the B_{max} of [^{3}H]forskolin binding was almost doubled in cardiac membranes of rats fed diet containing menhaden oil, it appears that the main reason for an increase in adenylate cyclase activity in this group is an increase in the number of the catalytic subunits of adenylate cyclase or a greater availability of the [^{3}H]-forskolin-binding sites. The catalytic subunit being the last step in the adenylate cyclase activation very well could become the rate-limiting step. Therefore, any increase in the concentration of this catalytic subunit by feeding menhaden oil also would result in a higher adenylate cyclase activity, even if the β-adrenergic receptor concentration and that of the G proteins remains the same.

Cardiac membrane phospholipids showed a preponderance of 20:5, 22:5 and 22:6 in rats fed menhaden oil; the level of 22:6 were especially high (17% of total). This was at the expense of ω-6 fatty acids such as 18:2, 20:4 and 22:4, which were reduced. Since the highly unsaturated fatty acids such as 20:5, 22:5 and 22:6 would constitute a more fluid domain around the catalytic subunit, it is tempting to speculate that a greater number of the binding sites would be available for [^{3}H]forskolin as was observed in membranes of this group.

In addition to the fatty acid composition of the membrane phospholipids, other variables such as cholesterol to phospholipid ratio and the proportion of various phospholipids also could influence membrane fluidity. Although we did not measure these parameters, the fluidity of the membranes among the three dietary groups was essentially the same as measured by fluorescence polarization of DPH. Since fluorescence polarization measures the "average" fluidity of the membrane, this observation does not exclude changes in the enzyme microenvironment.

[^{3}H]forskolin binding sites characteristics have been examined in heart of rats fed a standard diet (25). Our data on B_{max} and K_D for forskolin binding are consistent with this finding. In another study (26), the effect of feeding coconut oil (rich in saturated fatty acids) and sunflower oil (rich in polyunsaturated fatty acids) on rat heart adenylate cyclase and β-adrenergic receptor was examined. A decrease in adenylate cyclase activity (basal, norepinephrine- and fluoride-stimulated) was reported in atrial homogenates of rats fed sunflower oil relative to the coconut oil. The K_D and B_{max} of [^{3}H]DHA-binding also were decreased in atrial homogenates from rats fed sunflower oil. The values for the affinity and the concentration of [^{3}H]DHA-binding sites in our study essentially are similar to those obtained by Wince and Rutledge (26). Although the incorporation of fish oil fatty acids into cardiac (27) and other tissues (28) has been reported, to our knowledge, there are no previous studies on the effects of fish oils on cardiac adenylate cyclase system or on [^{3}H]forskolin-binding sites in heart as affected by dietary lipids.

Structural Modifications of Rat Serum High Density Lipoprotein by Pancreatic Phospholipase A_2

John B. Swaney* and **Margaret W. Orishimo**
Department of Biological Chemistry, Hahnemann University, Broad and Vine, Philadelphia, PA 19102

An important and unusual aspect of the high density lipoprotein (HDL) in the rat is its tendency to undergo marked alterations in structure in response to physiological perturbations. In this study, the role of the surface lipids for maintenance of HDL integrity were investigated. Hydrolysis by pancreatic phospholipase A_2 of the phospholipids of rat HDL in the presence of the d > 1.21 g/ml fraction of rat serum results in an increase in the particle diameter and an uptake of apo-E and apo A-IV from the lipoprotein-free fraction; augmentation of the albumin concentration in the incubation mixture intensified the observed changes, probably due to enhancement of the compositional changes brought about by phospholipase treatment. Phospholipase A_2 treatment of the d < 1.21 g/ml fraction of rat serum produces only minor changes in the properties of the isolated HDL. These data suggest that changes in apoprotein content reflect an uptake of A-IV and E by the rat HDL, rather than a net loss of apo A-I. Likewise, titration of the action of pancreatic phospholipase A_2 on HDL apoprotein composition showed that initially a modest increase in apo A-IV content occurred, but with more extensive phospholipolysis there was a considerably greater increase in the apo-E content of the particle. The data suggest that hydrolysis of phospholipids such as occurs physiologically through the action of lecithin:cholesterol acyl transferase and hepatic lipase may alter the HDL structure independently from changes effected in the neutral lipid core.
Lipids 23, 214–219 (1988).

An important feature of the plasma lipoproteins is that these complex protein-lipid assemblies undergo continuous remodeling in the circulation due to the action of enzymes involved in lipid metabolism, such as lecithin:cholesterol acyl transferase (LCAT) and hepatic lipase. Proteins responsible for the transfer of both neutral and polar lipid components among the lipoprotein classes appear to influence HDL structure as well (1). An important consequence of the structural rearrangements effected by these agents is the observed heterogeneity within lipoprotein classes.

An intriguing feature of lipid metabolism in the rat is the tendency for rat HDL to show marked changes in apoprotein distribution in response to various metabolic stimuli. For example, feeding a diet high in cholesterol causes rat HDL to become depleted in apo-E (2,3), while induction of diabetes causes a loss of both apo-E and apo A-IV (2,4). By contrast, the apoprotein content of human HDL has been found to be fairly constant.

Abbreviations: BSA, bovine serum albumin; CE, cholesterol ester; CHOL, cholesterol; DTNB, 5,5′-dithiobis(2-nitrobenzoate); FFA, free fatty acid; HDL, high density lipoprotein; LCAT, lecithin:cholesterol acyl transferase; LDL, low density lipoprotein; LYSO, lysophosphatidylcholine; PL, phospholipid; PLASE, phosphalipase A_2; SDS, sodium dodecyl sulfate; SDS-PAGE, polyacrylamide gel electrophoresis in the presence of sodium dodecylsulfate; TG, triglyceride; VLDL, very low density lipoprotein.

Recent investigations have documented that the LCAT enzyme causes major modifications of the HDL molecule, which are reflected in altered chemical composition and increased size (5–7). In the rat, there has been considerable evidence that there also are major redistributions of apoproteins resulting from LCAT action, with increased amounts of apo A-IV and apo-E becoming associated with the particle (7,8). Since the first step in the LCAT-mediated reaction is a phospholipase A_2-like reaction, we initiated studies to evaluate whether phospholipase A_2 alone would cause the changes in HDL properties associated with LCAT, apart from the cholesteryl ester formation catalyzed by LCAT.

Earlier studies on the treatment of isolated human HDL by snake venom phospholipases showed that despite extensive hydrolysis of fatty acids from phosphatidylcholine and phosphatidylethanolamine, the HDL remained intact and retained its physical properties (9,10). Preliminary studies in our laboratories showed that phospholipase treatment of rat serum followed by isolation of the HDL fraction resulted in considerable change to both the chemical and physical properties of the HDL. The present studies were undertaken to compare the action of phospholipase on HDL in the presence or absence of serum components and to provide more complete chemical characterization of these products than has been available previously.

MATERIALS AND METHODS

Serum treatment and HDL isolation. Serum was obtained from male Sprague-Dawley rats (270–350 g) by exsanguination from the abdominal aorta. In all cases, 5-5′-dithiobis(2-nitrobenzoate) (DTNB) in 0.075 M sodium phosphate buffer, pH 7.4, was added immediately upon collection (final concentration, 1.5 mM) to inhibit LCAT activity. All blood samples were allowed to clot on ice for three hr, and the serum was recovered by centrifugation. For some studies, various fractions, including the d > 1.21, the d < 1.21, and the d 1.063–1.21 g/ml fraction, were isolated by ultra-centrifugation (11). After dialysis against 0.15 M NaCl containing 0.01% EDTA pH 7.4, the various fractions or whole serum were incubated with porcine pancreatic phospholipase A_2 (Sigma Chemical Co., St. Louis, MO) for 18 hr at 37 C. In most studies, the amount of phospholipase used was 15 units/ml; calcium chloride was added to the incubations at final concentrations of either 3 mM or 21 mM. Incubations of HDL or the d < 1.21 fraction were buffered with 0.2 M Tris-HCl, pH 7.5, to prevent precipitation due to changes in pH during lipolysis.

In some cases, albumin was added incrementally to the mixture; this was added either before the incubation or afterward, followed by a 6–18 hr equilibration at 4 C to allow binding of the lipolytic products.

The HDL fraction was isolated in the d 1.063–1.21 density interval by the addition of KBr to the incubation mixture and ultracentrifugation. This material was

deliberately not "washed" at d 1.21 g/ml in order to minimize losses that are known to result from ultracentrifugation. The d < 1.063 material was dialyzed against 0.15 m NaCl, 0.27 mM EDTA, pH 7.5, and centrifuged for 20 hr to obtain the VLDL. All fractions were dialyzed against 0.15 M NaCl, 0.27 mM EDTA, pH 7.6, before analysis.

Titration of phospholipase action on apoprotein distribution. To evaluate the effects of phospholipase at various concentrations, rat serum was incubated at 37 C for 18 hr with various concentrations of phospholipase A_2 ranging from .005–15 units/ml. After incubation, the HDL was isolated by ultracentrifugation and analyzed by SDS gel electrophoresis; relative apoprotein quantitation was achieved by scanning densitometry of the stained gels.

Pore limit electrophoresis. The size of HDL particles was determined using a 4–30% acrylamide gradient gel essentially as described by Anderson et al. (12) using a voltage of 150 V for 44 hr applied to Pharmacia PAA 4/30 gels (Piscataway, NJ) or, alternatively, gradient slab gels were prepared and run in a homemade apparatus. The sample volume was adjusted in each case so that 10 μg of protein were applied in each slot; following electrophoresis, the gel was stained with Coomassie Brilliant Blue G-250. Protein standards for estimating molecular dimensions were purchased from Pharmacia, and the following values for Stokes' diameter were used: thyroglobulin, 17.0 nm; apoferritin, 12.2 nm; catalase, 10.2 nm; lactate dehydrogenase, 8.1 nm; and serum albumin, 7.1 nm (13). The relationship between molecular size and electrophoretic mobility in these gels originally was described by Felgenhauer (14).

SDS gel electrophoresis and chemical cross-linking. SDS slab gel electrophoresis was performed using 3–27% acrylamide gels as described (15). Sample volumes were adjusted so that 25 μg of protein was loaded in each lane of the gel. Gels were stained with Coomassie Brilliant Blue G-250 and destained in 7% acetic acid, 5% methanol. In some cases, HDL samples were cross-linked using dimethylsuberimidate (Pierce Chemical Co., Rockford, IL) (16) and were electrophoresed on SDS gels along with cross-linked apo A-I and hemocyanin (Sigma Chemical Co.) and cross-linked bovine serum albumin as molecular weight standards.

Chemical analyses. Protein content was determined by the method of Lowry et al. (17) as modified by Markwell et al. (18). Total and free cholesterol were measured enzymatically, using a reagent kit prepared by Fermco (Elk Grove Village, IL); a sample of control human serum (Control H, Sigma Chemical Co.) was analyzed on each occasion to verify the reproducibility of results from day-to-day. The mass of cholesteryl ester was computed from the difference between total and free cholesterol by utilizing a factor of 1.7. Triglyceride was determined enzymatically using a kit prepared by Sigma Chemical Co. Free fatty acids were analyzed enzymatically using reagents (NEFA kit) prepared by Wako Chemical Company (Dallas, TX). Phospholipid phosphorus was quantitated by the method of Marinetti et al. (19). Phosphorus was corrected to mass of phospholipid by using a factor of 25 for intact phospholipid and 17 for lysophosphatidylcholine.

Phospholipid species were determined by analysis of the phosphorus in lipid spots separated by thin layer chromatography. Folch extracts were spotted on Silica Gel 60 plates (E. Merck, Darmstadt) and chromatographed using chloroform/methanol/acetic acid/water 25:14:4:2, v/v/v/v).

Statistical analysis. Data were analyzed for statistical significance using the Students' t-test.

RESULTS

Effect of phospholipolysis upon HDL composition. A summary of the effects of phospholipolysis on the chemical composition of isolated HDL are presented in Tables 1 and 2; data on the incubation of pancreatic phospholipase A_2 with whole serum or with the HDL fraction (d1.063–1.21 g/ml) plus the d > 1.21 g/ml fraction are given in Table 1, while data for incubation of phospholipase with the d < 1.21 g/ml fraction or with HDL is shown in Table 2.

The action of phospholipase on HDL in the presence of the d > 1.21 fraction (either as d > 1.21 or in whole serum) (Table 1) led to increases in protein content simultaneous with loss of intact phospholipid and accumulation of lysolecithin and free fatty acid. Specifically, the protein in HDL of whole serum increased from 40.7% to 48.8% ($p < .005$), and for HDL + d > 1.21 g/ml the protein content increased from 36% to 45% ($p < .005$). The addition of bovine serum albumin (BSA) either during the incubation or following the incubation led to a major reduction in lysolecithin and free fatty acid.

On the other hand, phospholipolysis of either HDL or the d < 1.21 g/ml fraction (Table 2) did not lead to significant increases in the protein content despite extensive hydrolysis of phospholipid (i.e., HDL protein content changed from 33.0% to 33.5% when HDL alone was treated with phospholipase, while this value changed from 37.4% to 40.7% for the d < 1.21 g/ml fraction). However, there was much greater accumulation of FFA and lysolecithin in the absence of the d > 1.21 components as compared with Table 1. The addition of albumin reduced the FFA and lysolecithin contents and increased the percentage of other lipoprotein constituents.

Effect of phospholipolysis on HDL particle size. The Stokes' diameter of the HDL particle following phospholipolysis under the conditions described for Tables 1 and 2 was determined by pore limit electrophoresis, and results are summarized in Table 3. Phospholipase A_2 treatment of whole serum or HDL plus the d > 1.21 fraction led to about a 1 nm increase in HDL diameter, while the presence of albumin yielded an increment of about 2 nm. On the other hand, phospholipolysis of HDL alone or of the d < 1.21 g/ml fraction led to a decrease of 0.4 nm; inclusion of albumin prevented this decrease in size but did not produce a significant increase in diameter.

Effect of phospholipolysis upon HDL protein content per particle. The utility of chemical cross-linking for establishing the relative amounts of protein on human HDL_2 and HDL_3 has been demonstrated previously (20). The total mass of protein located on the rat HDL particle isolated after the phospholipolysis treatments described above was estimated by cross-linking the particle with dimethylsuberimidate, followed by SDS gel electrophoresis to determine mass relative to cross-linked standards. One such experiment is shown in Figure 1; molecular weights were determined relative to cross-linked apo A-I, cross-linked bovine serum albumin, and

[a]Protein mass in kilodaltons as determined by SDS gel electrophoresis of cross-linked HDL reisolated from incubation mixtures of the indicated serum fractions treated at 37 C for 18 hr with or without pancreatic phospholipase A_2, and with or without BSA added to increase the albumin concentration by 50 mg/ml.

[b]Protein mass ± standard deviation. The number in parentheses indicates the number of separate determinations.

[c]The probabilities that the population means are the same for the following pairs of observations: [A] − [B], $p < .001$; [B] − [C], $P < .03$; [D] − [E], not significant; [E] − [F], not significant.

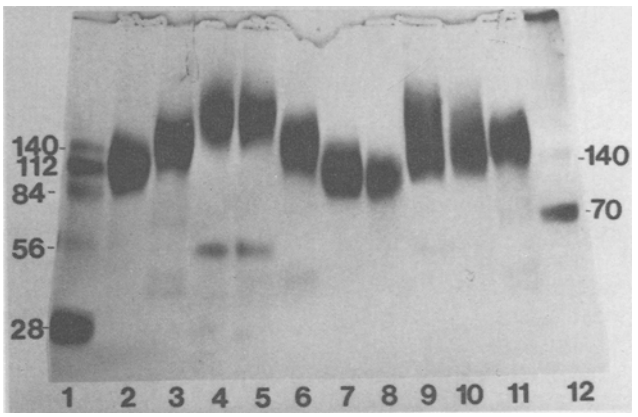

FIG. 1. Cross-linking of HDL isolated from incubation mixtures of isolated HDL with other serum fractions, in the presence or absence of phospholipase. Cross-linked apo A-I oligomers (Lane 1) and cross-linked hemocyanin oligomers (Lane 12) are run as markers for protein mass; molecular weights for these oligomers (in kilodaltons) are indicated on the sides of the figure. The incubations used for preparing the HDL run in lanes 2–11 all contained HDL (d 1.063–1.21 g/ml) and the following additions: Lane 2, d > 1.21; Lane 3, d > 1.21 and PLASE; Lane 4, d > 1.21, BSA, and PLASE; Lane 5, d > 1.21 and PLASE, with addition of BSA after incubation; Lane 6, d < 1.006 g/ml and PLASE; Lane 7, no additions; Lane 8, PLASE; Lane 9, BSA and PLASE; Lane 10, PLASE, with addition of BSA after incubation; Lane 11, d > 1.21 and PLASE (3 mM Ca^{++}).

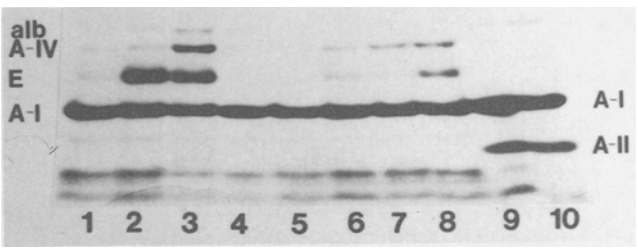

FIG. 2. SDS-PAGE of HDL isolated from incubation mixtures containing the following compositions: Lane 1, rat serum; Lane 2, rat serum plus PLASE; Lane 3, rat serum plus BSA plus PLASE; Lane 4, rat serum; Lane 5, rat HDL; Lane 6, rat HDL plus PLASE; Lane 7, rat d < 1.21 g/ml; Lane 8, rat d < 1.21 g/ml plus PLASE; Lane 9, human serum; Lane 10, human serum plus PLASE. All incubations contained 1.4 mM DTNB and 3 mM Ca^{++}.

cross-linked hemocyanin. Average values from several experiments are presented in Table 4. When whole serum or HDL plus the d > 1.21 g/ml fraction were treated with phospholipase, the HDL protein mass increased by about 30,000 and by almost 100,000 when albumin was included in the incubation or added afterward. On the other hand, phospholipolysis of isolated HDL or of the d < 1.21 g/ml fraction yielded no increase in protein mass unless albumin was present, and then only an increase of 25,000 was observed.

It should be noted that in cross-linked samples from incubations with added BSA, a band is observed at a molecular weight corresponding to the albumin monomer (Fig. 1, lanes 4 and 5). This reflects the fact that some albumin contamination of the isolated HDL occurs because of its high concentration but that most or all of it does not reside on the HDL particle itself.

Effect of phospholipolysis upon apoprotein distribution. The relative content of the HDL apoproteins was determined by SDS gel electrophoresis of the various HDL species studied. Figure 2 shows some typical results with HDL isolated from phospholipase-treated serum or HDL isolated from a d < 1.21 g/ml fraction treated with phospholipase. Although there was some between-sample variation, in general there was always a major increase in the proportions of apo E and apo A-IV, in serum or HDL + d > 1.21 samples following phospholipolysis either in the presence or absence of albumin. On the other hand, treatment of HDL by phospholipase in the presence or absence of albumin produced no change in the E/A-I or A-IV/A-I ratios. Phospholipolysis of the d < 1.21 fraction resulted in a partial increment in the E/A-I ratio as compared with that observed with serum but no significant change in the A-IV/A-I ratio. Interestingly, identical treatment of human serum by pancreatic phospholipase did not result in any changes in the apoprotein distribution (Fig. 2, lanes 9 and 10).

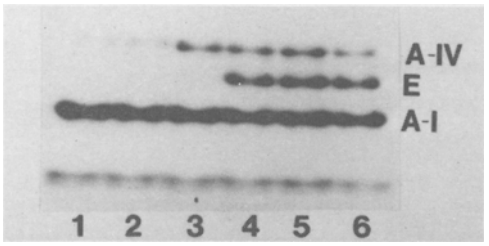

FIG. 3. SDS-PAGE of HDL isolated from rat serum treated with various concentrations of pancreatic phospholipase A_2 for 18 hr at 37 C. Final concentrations of PLASE used were: Lane 1, 0 units/ml; Lane 2, 0.005 units/ml; Lane 3, 0.05 units/ml; Lane 4, 0.5 units/ml; Lane 5, 3.0 units/ml; Lane 6, 15 units/ml.

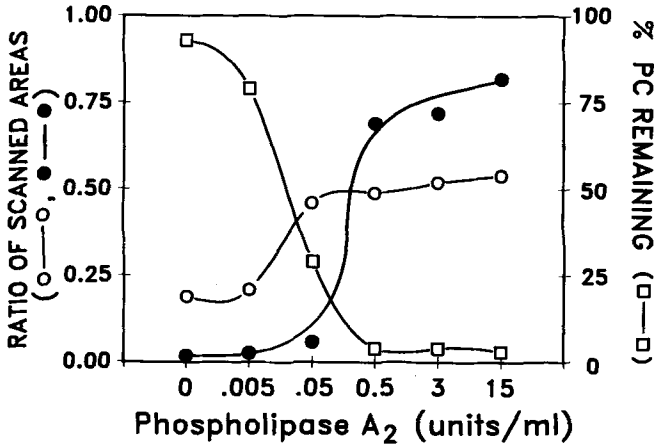

FIG. 4. Changes in apoprotein content of HDL following PLASE treatment of rat serum at various levels of enzyme activity. The SDS-PAGE gel from Figure 3 was scanned densitometrically to quantitate the changes in relative apoprotein content in these HDL. The ratio of area for the apo A-IV band to apo A-I is represented by the open circles, and the ratio for apo-E to apo A-I by the closed circles. The amount of intact phosphatidylcholine as a percentage of the sum of PC and lysoPC is represented by the open squares.

Titration of phospholipase action on apoprotein distribution. Since the standard conditions that we employed resulted in near total hydrolysis of phosphatidylcholine and phosphatidylethanolamine on the HDL, experiments were performed using a range of phospholipase activities in order to titrate the effects of phospholipase A_2 upon the HDL (Fig. 3). A quantitative treatment of these data is given in Figure 4, in which whole serum was incubated overnight with various amounts of phospholipase A_2 ranging from 0 to 15 units/ml, and the apoprotein ratios were quantitated; the extent of phospholipolysis is presented as the amount of phosphatidylcholine remaining.

DISCUSSION

Studies have shown that the HDL subpopulations are acted upon by numerous agents responsible for changes in their physicochemical properties; such agents include the LCAT enzyme, hepatic triglyceride lipase, the cholesteryl ester exchange protein and a putative "conversion factor" (1,21,22). Incubation of rat serum when LCAT is active leads to increased size of the particle (7), a shift of apolipoprotein A-IV from the lipoprotein-free portion of plasma into the HDL (8) and an increase in apo-E in the HDL fraction (7). Although the details of how these changes occur in the HDL fraction remain obscure, it appears that changes in the balance of surface and core lipid components may occur during normal metabolism of HDL in the circulation.

In these studies, pancreatic phospholipase A_2 was used as a tool to alter the surface lipids of the HDL without altering the core lipids. In executing these studies, LCAT was inhibited to prevent the formation of cholesteryl ester. Rat serum, which is devoid of the cholesteryl ester exchange protein (23), was used to avoid transfers of core lipid components during incubations and ensure that only changes in the surface lipids were being studied.

Our data demonstrate that when whole serum or a reconstituted $d > 1.063$ g/ml fraction (HDL + $d > 1.21$) is treated with phospholipase, the changes seen are similar to those observed with LCAT treatment of rat serum (7). Specifically, there is an increase in the Stokes' diameter of the particle by about 1 nm, the protein content increases as shown by chemical cross-linking and the proportions of apo-E and apo A-IV on the particle increase. These changes appear to be related to the loss of lipolysis products through binding to albumin (24), since the further addition of albumin exacerbates the observed changes and since phospholipolysis of isolated HDL or the $d < 1.21$ g/ml fraction fails to produce these changes. In fact, phospholipolysis of isolated HDL appears to cause a small decrease in Stokes' diameter, as judged by pore limit electrophoresis. Similarly, it has been reported that phospholipolysis of human HDL fractions causes negligible effects on the physicochemical properties of human HDL (9,10,25).

It appears that phospholipolysis of HDL alone causes a small loss of phospholipid components, since not all of the lysolecithin and free fatty acids produced remain on the particle (Table 2). When albumin is present, either added exogenously (Table 2) or as a serum component (Table 1), there is extensive removal of lysolecithin and free fatty acids. Treatment of HDL or $d < 1.21$ g/ml with phospholipase A_2 fails to show extensive changes in apoprotein distribution (Fig. 2), implying that this treatment causes protein uptake from the $d < 1.21$ fraction rather than a phospholipase-induced loss of apo A-I from the HDL.

It is of interest that phospholipase treatment of human serum produces no apparent changes in the apoprotein content of the human HDL as contrasted with equivalent treatment of rat serum, which results in substantial changes in the protein content of the rat HDL (Fig. 2). This appears consistent with the observation that while rat HDL undergoes marked changes in the content of apo-E and apo A-IV in response to physiological perturbations, human HDL shows a remarkably constant apoprotein composition. This suggests that the surface of human HDL differs for unknown reasons from that of rat HDL in being unsuitable for the acquisition of the A-IV or E proteins. Weinberg and Spector, for example, have shown that human apo A-IV has only a slight affinity for human HDL_3 and is displaced readily during prolonged incubations such as we have studied here (26).

Although the scanning densitometry data alone cannot distinguish increases in apo-E and apo A-IV on the

particle from loss of apo A-I, titration experiments of phospholipase action help to resolve the uncertainty (Fig. 4). If the change in apoprotein distribution was attributable to a loss of apo A-I accompanying the hydrolysis of phospholipid, we would observe a simultaneous increase in the E/A-I and the A-IV/A-I ratios. Since greater phospholipolysis is needed to alter the E/A-I ratio than to alter the A-IV/A-I ratio, we believe that this shows that E and A-IV are added separately to the particle, although some loss or redistribution of A-I also may take place.

In comparing the apoprotein distributions for HDL treated with phospholipase (Fig. 2, lanes 6 vs 5) with the $d < 1.21$ g/ml fraction similarly treated (lane 8 vs 7), it was apparent that during incubation neither apo A-IV nor apo-E were transferred to the HDL from the VLDL or LDL in any significant proportion when compared with the transfer that occurs with whole serum (lanes 2 and 3 vs 1). However, there did occur some transfer of apo-E from the $d < 1.063$ g/ml fraction, although the increment in E content of the HDL was much less than observed during phospholipolysis of whole serum (data not shown).

In summary, phospholipid treatment of whole serum and various fractions containing the HDL have demonstrated that physicochemical changes in the HDL result largely from an imbalance in the ratio of polar surface lipids and the neutral core lipids. When albumin and a source of lipid-poor apoproteins are present, there occurs a net uptake of protein and possibly some lipid to cause formation of a somewhat larger particle with a markedly different apoprotein content. Since both the LCAT and hepatic triglyceride lipase enzymes possess phospholipase activities (27,28), the changes in HDL associated with production of lysolecithin or free fatty acids and with their removal by albumin are likely to occur in vivo.

[Received June 3, 1987; Revision accepted November 2, 1987]

Dissolution of Cholesterol Gallstones by Bile Acids in the Prairie Dog

Bertram I. Cohen*, Erwin H. Mosbach, Syoji Kuroki and Charles K. McSherry
Departments of Surgery, Beth Israel Medical Center and The Mount Sinai School of Medicine of The City University of New York, NY.

The effect of chenodeoxycholic acid, ursodeoxycholic acid and hyodeoxycholic acid on gallstone dissolution was studied in the prairie dog. Cholesterol gallstones were found in all animals after feeding a semipurified diet plus 1.2% cholesterol for six wk. Gallstone regression was examined by feeding a chow diet containing the bile acids (chenodeoxycholic acid, ursodeoxycholic acid or hyodeoxycholic acid) alone (30 mg/kg/day) or in combination (chenodeoxycholic acid plus ursodeoxycholic acid) for an additional six wk. Chenodeoxycholic acid was effective in dissolving established cholesterol gallstones (two out of 16 animals still had stones) and cholesterol crystals (six out of 16 animals had crystals); the hydrophilic bile acids, ursodeoxycholic acid and hyodeoxycholic acid, were ineffective in the six-wk regression study. The lithogenic indices averaged 1.09 at the end of the induction period; all biles became unsaturated with respect to cholesterol after the six-wk regression period (group 1, 0.82; group 2, 0.66; group 3, 0.81; group 4, 0.84; group 5, 0.66). Cholesterol levels in liver, plasma and bile were elevated after the six-wk induction phase (4.59 mg/g, 610 mg/dl and 0.36 mg/ml, respectively) but returned to near normal levels after the six-wk regression period. Biliary bile acids contained increased levels of the dietary bile acid administered to each group. This experiment shows that relatively hydrophobic bile acids may be more effective than hydrophilic bile acids for gallstone dissolution during the period studied.

Lipids 23, 220-224 (1988).

The etiology, dissolution and prevention of cholesterol gallstones are topics of intense interest to clinicians. New methodologies (1) and new drugs (2,3) are under active investigation. Large scale human trials with cholelitholytic bile acids are fraught with difficulties (dose, patient population) such as those encountered in the National Cooperative Gallstone Study (4). Consequently, the use of an effective animal model to test the efficacy of new drugs before human trials remains an important area for research.

Our laboratory has used the prairie dog as an animal model to study the prevention of cholesterol gallstones (5-7). In this rodent, hydrophilic bile acids clearly were superior to hydrophobic bile acids for gallstone prevention. The hydrophilic bile acid, hyodeoxycholic acid (HDCA), inhibited gallstone formation in the presence of supersaturated bile via a phase transition mechanism (cholesterol monohydrate → liquid crystals) (6). The hydrophobic bile acid, chenodeoxycholic acid (CDCA), and the more hydrophilic acid, ursodeoxycholic acid (UDCA), caused a significant reduction in the incidence of cholesterol gallstones; a high dose of CDCA (30 mg/kg/day) and a low dose of UDCA (15 mg/kg/day) were most effective in preventing gallstones (5). The efficacy of HDCA was tested further in the prairie dog to determine whether it functioned as an effective agent for gallstone dissolution (8). In that study, using a semipurified diet only partial dissolution of cholesterol gallstones was achieved; it was hypothesized that longer time periods and perhaps larger doses of HDCA would be required for complete dissolution.

To determine whether the prairie dog could function as an effective animal model for gallstone dissolution, we tested two bile acids currently administered to man, CDCA and UDCA. These bile acids were fed in a chow diet during a six-wk regression period. In addition, we also investigated the possibility that HDCA fed in chow would be more effective as a cholelitholytic agent than in an earlier study (8) when it was fed in a semipurified diet.

MATERIALS AND METHODS

Male prairie dogs (*Cynomys ludovicianus*), bred in captivity, were purchased from R-Zoo (Neshkoro, WI). After weaning, the animals were maintained on a diet of alfalfa-corn in order to produce maximal positive response to the lithogenic diet (9). Upon arrival at our animal facility, the prairie dogs were quarantined for two wk in individual rabbit cages during which time they were fed alfalfa-corn and water ad libitum. The 59 animals then were weighed, and the diet was changed to a semipurified diet (SSD) plus 1.2% cholesterol (Teklad, Madison, WI). This diet consisted of sucrose, 56.5%; cornstarch, 13.9%; soy protein, 20.2%; corn oil, 1.2%; cellulose, 2.6%; mineral mix (Teklad 170820) and vitamin mix (Teklad 40060). Cholesterol (1.2%) was incorporated into the diet as egg yolk (0.6%) and crystalline cholesterol (0.6%). The diet was fed to all 59 animals for six wk (period 1). At wk 6, five animals (group 0) were killed to determine the incidence of cholesterol crystals and cholesterol gallstones. All five animals had biliary cholesterol crystals and gallstones (see Table 1). The remaining 54 animals were divided into five groups of similar average weights for gallstone regression, as follows: group 1, chow; group 2, chow + CDCA (30 mg/kg/day); group 3, chow + UDCA (30 mg/kg/day); group 4, chow + HDCA (30 mg/kg/day); and group 5, chow + CDCA (15 mg/kg/day) + UDCA (15 mg/kg/day). These diets were administered for six wk (period 2). The total feeding period was 12 wk. The average initial weights (wk 6) (range 833-933) and final weights (wk 12) (range 1024-1199) for the animals in groups 1-5 were not different statistically. During the 24 hr period before killing (at wk 6 or wk 12), the animals were starved to assure adequate quantities of gallbladder bile for biliary lipid analyses. All animals were anesthetized with 100 mg of ketamine hydrochloride and 20 mg of xylazine (Haver-Lockhart, Shaw-

[e]Differs significantly from group 1, $p < 0.02$.

nee, KS), killed by exsanguination, and blood was collected for determination of serum cholesterol. The gallbladder of each animal was removed intact and inspected visually for cholesterol gallstones. Bile was aspirated with a 500 μl Hamilton syringe, and a drop was examined immediately by polarized light microscopy (Olympus MCHAP microscope equipped with camera, Olympus Corp., Lake Success, NY) to determine the presence of liquid crystals and/or cholesterol crystals. The liver was removed and weighed, aliquots were obtained for determination of liver cholesterol and preparation of microsomes (5).

Gas-liquid chromatography and gas-liquid chromatography-mass spectrometry. Gas-liquid chromatography of cholesterol in liver, plasma and bile was carried out as described (5–7). Biliary bile acids were analyzed as their methyl ester acetate derivatives using capillary gas chromatography (SPB-5 column, 15 meters, 0.25 mm ID; temperature program: 200 C - 10 min, rate of temperature increase 10 C/min to 270 C; 270 C for 20 min). Positive identification of the individual bile acids was made using a Hewlett-Packard 5992B mass-spectrometer as follows: four–ft glass column, 2 mm ID, 4 mm OD, packed with 3% SP 2250 on 100/120 mesh Supelcoport; column temperature 260 C; injector temperature 265 C; source pressure 2×10^{-6} torr; source temperature 140 C.

Reference compounds. Chenodeoxycholic acid (Canada Packers, Inc., Ontario, Canada) and ursodeoxycholic acid (Tokyo Tanabe Co., Tokyo, Japan) were analyzed as their methyl ester trimethylsilylether derivatives by gas-liquid chromatography and found to be greater than 99.5% pure. Hyodeoxycholic acid (Sigma Chemical Co., St. Louis, MO) was analyzed by the same derivatization and found to be greater than 97% pure. 3α,7α-Dihydroxy-12-keto-5β-cholanoic acid (Steroloids Inc., Wilton, NH) was used as a recovery standard for determination of biliary bile acids.

Biliary lipid composition. Gallbladder bile obtained at death immediately was centrifuged in a Beckman microfuge at 2000 X g for 10 min to remove cholesterol crystals. Aliquots of bile were used for determination of the three biliary lipids (5–7). The lithogenic indices were calculated by a computer program (10,11).

Enzyme assay. Liver microsomes were prepared, and HMG-CoA reductase activity was determined as described (5–7).

Statistical calculations. The data are reported as the average ± SEM. Analysis of variance was used on the values where the F statistic was significant, followed by Student's t-test to determine significance (12–14). Differences in incidence of gallstones and cholesterol crystals were analyzed by 2 x 2 chi-square.

RESULTS

The study reports the effects of gallstone induction with a semisynthetic lithogenic diet for six wk and gallstone regression using various bile acids fed in a chow diet for six additional wk. All five animals killed at wk six had both gallstones and crystals (Table 1); on the basis of these results and previous experiments (8), it was assumed that all of the remaining 54 animals also had stones. The lithogenic diets then were discontinued, and the remaining animals (54) were fed the regression diets (groups 2–5).

After feeding the regression diets for six wk, all animals were killed (wk 12) to determine the presence or absence of gallstones (Table 1). Animals fed chow alone showed a slow spontaneous dissolution of gallstones; 73% of these animals had stones and 80% had cholesterol crystals. Significant acceleration of stone dissolution was observed with CDCA (only 12.5% of the animals had stones and 37.5% had cholesterol crystals). The two hydrophilic bile acids tested (UDCA and HDCA) failed to produce a significant litholytic

effect (UDCA, stones 89%, crystals 78%; HDCA, stones 78%, crystals 67%). Surprisingly, when a combination of CDCA and UDCA was fed, no gallstone dissolution occurred (group 5) as had been observed with CDCA alone.

The rate–limiting enzyme of hepatic cholesterol synthesis, HMG-CoA reductase, was examined after completion of the regression period (Table 1). For animals given chow plus CDCA (group 2), the HMG-CoA reductase activity was lower by 38 units but this was not significant statistically because of the large intra-group variation. Animals fed chow plus HDCA had an enzyme activity nearly double that of the other group (196.8) (Table 1), and this activity was significantly different from those fed only chow (group 1) ($p < 0.02$).

Biliary lipid composition for the various groups is summarized in Table 2. The biles obtained from the five animals after the induction period (group 0) were supersaturated with cholesterol (L.I., 1.09). At the end of the regression period, all the biles became unsaturated with respect to cholesterol (L.I. <1.0). As expected, the mol % cholesterol was highest in group 0 (5.2 mol %). This value decreased significantly in all groups after the regression period and ranged from 2.7 to 3.2 mol %. The mol % of phospholipids and biliary bile acids in the various groups did not differ significantly ranging from 9.1 to 14.6 mol % and 80.2 to 88.2 mol %, respectively. The total lipid concentration was similar in all groups.

Cholesterol concentrations in liver, plasma and bile were determined at wk 6 and 12 (Table 3). Animals fed the gallstone induction diet had elevated cholesterol levels (wk 6) in liver, plasma and bile, averaging 4.59 mg/g, 610 mg/dl and 0.36 mg/ml, respectively. At wk 12, plasma, liver and bile cholesterol levels returned to normal and ranged from 174 to 226 mg/dl, 2.79 to 3.60 mg/g and 0.20 to 0.24 mg/ml (groups 1–5), respectively.

Biliary bile acid compositions are summarized in Table 4. The major biliary bile acids for animals fed SSD plus 1.2% cholesterol are cholic acid (CA) and CDCA. At the end of the regression period (wk 12), animals fed the chow diet alone tended to show a slight decrease in the amount of CDCA (18.3%) and a slight increase in the amount of CA (80.2%). The group of prairie dogs fed chow plus CDCA had the largest amount of CDCA in the bile (83.2%). Animals fed UDCA or HDCA showed increased concentrations of the administered bile acid (22.5% and 26.3%, respectively) but these enrichment levels were well below that for the CDCA-fed group.

DISCUSSION

The hydrophobic bile acid, chenodeoxycholic acid, fed in a chow diet was the most effective cholelitholytic agent in this study. All animals were fed a semipurified diet plus 1.2% cholesterol for six wk to induce a 100% incidence of cholesterol gallstones. This diet is known to induce gallstones in the prairie dog (15,16). The advantage of a semipurified diet is that the amount of each ingredient is known and the composition can be duplicated from batch to batch. However, we recently noted that the semipurified diet with 0.4% cholesterol produced some hepatotoxicity when fed for a period of only eight wk (moderate bile duct proliferation, portal fibrosis and inflammatory infiltration) (8). The semipurified diet plus cholesterol was more effective in producing gallstones when compared to a chow diet plus cholesterol (7). A 100% incidence of gallstones is essential for this study because the number of animals per group is relatively small. All animals are fed alfalfa-corn before the induction period to increase their susceptibility to the cholelithogenic effect of the diet. It was found that alfalfa-corn increases the activity of HMG-CoA reductase as compared to chow and increases stone incidence on lithogenic diet (9). Consequently, all animals were maintained on the alfalfa-corn diet before starting the lithogenic diet. We employed a semipurified diet for the induction period (up to wk 6) and a chow diet for the regression period (up to wk 12) to minimize liver hepatotoxicity.

[c]Hyodeoxycholic acid.

In accord with previous observations in our laboratory, the activity of hepatic microsomal HMG-CoA reductase was greater in animals fed laboratory chow than those fed a (cholesterol-free) semipurified diet (7). The addition of CDCA to the chow regression diet produced a 35% decrease in enzyme activity (this trend was not statistically significant), while UDCA produced a negligible change (Table 1). The failure to show a significant lowering of HMG-CoA reductase levels after CDCA administration probably is ascribable to large intra-group variations that also have been observed by others (17). Because the prairie dogs currently in use are either trapped in the wild or are the direct offspring of such animals, they are likely to be quite heterogeneous, genetically and metabolically. The very hydrophilic HDCA stimulated the activity of the rate-limiting enzyme almost two-fold, presumably because this bile acid interferes with the intestinal absorption of cholesterol (7). However, in these experiments with animals maintained on low-cholesterol chow the reduced absorption of cholesterol was not reflected in a lowering of serum or liver cholesterol levels. This is in contrast with the striking reduction in tissue cholesterol levels produced by HDCA in previous experiments with cholesterol-fed animals (6).

Tissue cholesterol levels analyzed at wk 6 showed a significant response to the increased dietary cholesterol. Liver, plasma and bile cholesterol concentrations were elevated in all animals. These levels returned to near normal values in all groups after the six-wk regression period. Thus, the administration of the chow diet (with and without bile acids) reverses the elevations in cholesterol in the tissues studied.

The biles of all animals in groups 1–5 had become unsaturated with respect to cholesterol (L.I. <1.0) (wk 12) but only CDCA was able to dissolve the cholesterol gallstones. The relative ineffectiveness of the hydrophilic bile acids UDCA and HDCA fed either alone or in combination (CDCA plus UDCA) may be ascribed to a number of factors. First, a relatively short regression period of six wk was chosen, which may have been inadequate to demonstrate appreciable dissolution. Second, although all biles were unsaturated at the end of 12 wk it is conceivable that the rates of desaturation were not identical and were slower for the more hydrophilic bile acids. Third, we

were unable to demonstrate the formation of liquid crystalline phases in the biles of the prairie dogs treated with UDCA or HDCA, suggesting that the phase transition from crystalline cholesterol monohydrate to cholesterol/phospholipid mesophase was inoperative or at least nonobservable under the conditions employed. Fourth, after the administration of UDCA this bile acid accounted for only 23% of total biliary bile acids. The failure of administered UDCA to accumulate in the gallbladder bile of prairie dogs had been observed in gallstone prevention experiments (5) and was attributed to the partial conversion of UDCA to CDCA. In addition, HDCA, which was not transformed into CDCA, accounted for only about 26% of total biliary bile acids; epimerization of HDCA to the hydrophilic 3α,6β-dihydroxy-5β-cholanoic acid also was very small (5%) as compared to previous studies (20-30% [6]). Therefore, it seems possible that with the chow diet used for the regression studies, hydrophilic bile acids may not be absorbed as efficiently as they were when given in cholesterol-containing semipurified diets.

Our studies suggest some important differences that should be considered when examining bile acids for gallstone prevention vs gallstone dissolution. First, in prevention studies the bile acid is administered simultaneously with the start of the lithogenic diet. Since no gallstones are present at time 0, the drug can either prevent bile saturation (L.I. <1.0) or solubilize large amounts of cholesterol in supersaturated bile (in vesicles, L.I. >1.0). Chenodeoxycholic acid and hyodeoxycholic acid operate via these respective mechanisms. For gallstone dissolution, other factors may be operative. These include the number and size of the gallstones present at the start of the regression period. Thus, bile acids that can desaturate bile most rapidly, such as hydrophobic compounds, should be most effective in the short term. In the present study, only CDCA dissolved gallstones in six wk even though the biles of all groups had become unsaturated with respect to cholesterol (L.I. <1.0). Igimi and Carey reported from their in vitro studies that chenodeoxycholic acid should dissolve gallstones faster than ursodeoxycholic acid (18). We now know that factors other than micelle formation play a role in gallstone dissolution (18). Thus, it is well known that in man UDCA and UDCA/CDCA combination dissolve stones at least as rapidly as CDCA. These drugs presumably all act by lowering the cholesterol saturation of bile (19,20). Desaturation of bile no doubt favors stone dissolution but no longer can be considered the sole, necessary condition for achieving dissolution. The formation of liquid crystalline phases of high cholesterol content characteristic of hydrophilic bile acids is a second mechanism potentially favoring cholelitholysis. A multiplicity of factors, in addition to type and dosage of bile acid, and duration of treatment may play a role in gallstone dissolution in the prairie dog model. Not only bile composition but also structure and surface characteristics of the stones remain important considerations in development of a satisfactory prairie dog model for gallstone dissolution.

Normalization of High Density Lipoprotein in Fish Eye Disease Plasma by Purified Normal Human Lecithin: Cholesterol Acyltransferase

Leif Holmquist* and **Lars A. Carlson**
King Gustaf V Research Institute and Department of Internal Medicine, Karolinska Institute and Karolinska Hospital, Stockholm, Sweden

Plasma from a patient with fish eye disease has been enriched with autologous high density lipoproteins (HDL) and supplemented with highly purified normal human plasma lecithin:cholesterol acyltransferase (LCAT). Incubation of such plasma at 37 C in vitro resulted in normalization of its low HDL cholesteryl ester percentage, from 23% to 79%, associated with a two-fold increase in both the cholesteryl ester and triglyceride contents of the HDL fraction, as compared to incubation experiments with absent or heat-inactivated purified normal LCAT.

The normalization of the HDL cholesteryl ester percentage induced by incubation with purified normal LCAT also was accompanied by an increase in the size of the original fish eye disease HDL particles, which had a mean mass of 115 kd, to HDL particle populations with mean particle masses ranging from 130-220 kd, depending on the concentration of purified LCAT in the incubate. Both HDL cholesterol esterification and particle enlargement were abolished completely by the LCAT inhibitor DTNB and by heat inactivation of the purified normal LCAT. The results give further evidence that fish eye disease is an α-LCAT deficiency.
Lipids 23, 225–229 (1988).

Fish eye disease is a rare hereditary hypoalphalipoproteinemia showing plasma high density lipoprosein (HDL) cholesterol and apolipoprotein A-I concentrations that both are reduced by about 90% as compared to what is normal (1,2). Only about 20% of the total cholesterol of the HDL particles is esterified in this disease (3). By contrast, normal HDL contain about 80% of its total cholesterol in the esterified form. A further abnormality of the fish eye disease HDL relates to its apparent mean particle size or mass, which is 115 kilodalton (kd) as compared to mass values ranging from 130 to 350 kd for normal HDL particles (2). Recently, we demonstrated that fish eye disease plasma has a specific lack of lecithin:cholesterol acyltransferase (LCAT) activity that is present in normal plasma and specifically seems to catalyze the esterification of the free cholesterol of HDL (4). Although cholesterol of HDL in fish eye disease plasma is not esterified by autologous LCAT, the free cholesterol of the combined plasma very low density (VLDL) and low density lipoproteins (LDL) is esterified at an apparently normal rate in this disease as revealed by both esterification rate experiments and compositional analyses of VLDL and LDL cholesteryl ester percentages and fatty acids (4).

To explain the unique plasma cholesterol esterification situation in fish eye disease, we introduced the hypothesis that there exist two LCAT activities of different substrate specificities in normal plasma (4,5). The enzyme activities specific for the free cholesterol of HDL or that of combined VLDL and LDL were denoted α- and β-LCAT, respectively. Thus, fish eye disease was classified as an α-LCAT deficiency syndrome. In a series of papers, we showed that neither impaired or deficient plasma lipid transfer proteins (6–8) nor qualitatively defective apolipoproteins (9) seem likely causes of the apparent specific lack of HDL cholesterol esterification in fish eye disease plasma.

In this study, we have supplemented fish eye disease plasma with normal human LCAT purified more than 20,000–fold over its occurrence in normal plasma and with retained α- and β-LCAT activities (10). The effect of this enzyme on the particle size and relative cholesteryl ester content of the fish eye disease HDL is reported herein.

EXPERIMENTAL PROCEDURES

General methods. The only living Swedish fish eye disease patient No. 1, now 73 years old, has been characterized in detail (2). Venous blood was taken from the patient in the mornings after an overnight fast into vacutainer plastic tubes containing disodium ethylenediamine tetraacetate (EDTA). The tubes immediately were placed into crushed ice. Plasma was recovered within 30 min by low speed centrifugation at 2 C and stored in crushed ice. Merthiolate®, normally added to plasmas at our work with lipoproteins, was omitted. Free cholesterol and cholesteryl esters were quantified enzymatically in duplicate directly on aliquots of plasma or on the isolated lipoprotein fractions obtained after ultracentrifugation using the kits 14106, 14107 and 14108 (E. Merck, Darmstadt, FRG). Triglyceride concentrations were estimated in duplicate on aliquots of isolated lipoproteins as previously described (2). The coefficients of variation (number of estimates in parentheses) were 3.5% (57), 3.1% (57) and 2.7% (75) for between-run reproducibility of determinations of free cholesterol, esterified cholesterol and triglycerides, respectively. Polyacrylamide gradient gel electrophoresis was performed as reported (2). Ultracentrifugations were carried out in a Beckman Model L5-55 ultracentrifuge (Beckman Instruments Inc., Palo Alto, CA) using a 50.3 Ti rotor and 6 ml Bell-Top and 2 ml open Ultra-Clear® tubes at 1 C. After completed ultracentrifugation, tube fractions were collected by the tube-slicing technique, using a

Abbreviations: DTNB, disodium 5,5-dithiobis-(2-nitrobenzoate); EDTA, ethylenediamine tetraacetic acid; HDL, high density lipoproteins; LCAT, lecithin:cholesterol acyltransferase; LDL, low density lipoprotein(s); VLDL, very low density lipoprotein(s).

Beckman Tube-Slicer in combination with a special template to yield fractions of desired volumes. Concentrated fish eye disease HDL were prepared as described and dialyzed at 5 C against 0.15 mol/l sodium chloride solution (8). Briefly, the density of fish eye disease plasma was raised to 1.063 kg/l by the addition of solid sodium bromide. After centrifugation, each tube (6 ml) was sliced to give a bottom fraction of 3.37 ml. The density of this fraction was raised to 1.21 kg/l. New centrifuge tubes (6 ml) were filled with this solution and run for 67 hr at 50,000 rpm (7.2×10^8 g x min). Concentrated HDL was obtained from the 1 ml top of the tube (supernatant d=1.21 kg/l). For analysis of the lipid composition of the HDL fraction of native fish eye disease plasma, these lipoproteins were isolated as a 1.063–1.21 kg/l density fraction by means of sequential ultracentrifugations as reported earlier (12). Double immunodiffusion against anti-human apolipoprotein D, which we obtained as a gift from P. Alaupovic, Oklahoma City, was performed in Ouchterlony 1% agarose gel plates.

Purified normal human LCAT was obtained by covalent chromatography as described in detail (10). The enzyme accepted the free cholesterol of both heat-inactivated HDL-deficient or combined VLDL- and LDL-deficient plasmas as substrate when a modified Glomset and Wright method (4,5) was used for enzyme activity tests. The highly purified enzyme was electrophoretically and immunologically free of apolipoproteins A-I, A-II, C and E, and the enzyme did not show zones that could be assigned to known lipid transfer proteins (11) on SDS-gelelectrophoresis. Supplementation with apolipoprotein A-I was necessary to transform lecithin:cholesterol liposomes into substrates for the purified LCAT. The final enzyme purification on hydroxyapatite (10) was performed batch-wise just before the intended use of the enzyme that had a specific activity of more than 43,000 units/mg corresponding to a purification degree of more than 20,000 over its occurrence in plasma (10).

Incubation experiments. Native fish eye disease plasma (1 ml) was mixed with concentrated autologous fish eye disease HDL (1 ml) and either purified LCAT in 1 mmol/l phosphate buffer, pH 6.8, containing 4 mmol/l 2-mercaptoethanol but with no other stabilizer (0.2 ml) or with the same amount of a solution of this enzyme after 60 min heat inactivation at 56 C or with 0.15 mol/l sodium chloride (0.2) ml containing 4 mmol/l 2-mercaptoethanol as control. Incubations performed in the presence of DTNB (disodium 5,5-dithiobis-2(-nitrobenzoate)) as LCAT inhibitor were made by addition of phosphate buffered 100 mmol/l DTNB, pH 7.4 to the relevant incubation mixture to give a 2 mmol/l final concentration. The final volumes (2.24 ml) of all incubation mixtures were equalized by addition of 0.15 mol/l sodium chloride. Incubations were performed at 0 and 37 C in the dark under nitrogen atmosphere for 24 hr.

The concentrations of free cholesterol and cholesteryl esters of native fish eye disease plasma, of the fish eye disease plasma HDL fraction and of the concentrated fish eye disease HDL (see general methods) used in the incubation experiments with purified normal LCAT are compiled in Table 1.

TABLE 1

Concentrations of Free, Esterified and Total Cholesterol (mmol/l of Incubation Mixture) and Cholesteryl Ester Percentage of Native Fish Eye Disease Plasma, its HDL Fraction and of Isolated Concentrated Fish Eye Disease HDL, Prepared for Incubation Experiments

	FC	CE	TC	CE
Specimen from fish eye disease		(mmol/l)		(%)
Concentrated HDL	0.33	0.10	0.43	23
Native plasma	2.76	3.73	6.49	57
HDL in native plasma	0.10	0.03	0.13	23

FC, free cholesterol; CE, cholesteryl esters; TC, total cholesterol as sum of free and esterified cholesterol.

After completed incubation, each incubation mixture was parted into two equal volumes. From one of the volumes, the total lipoproteins were isolated by ultracentrifugation at density 1.21 kg/l, obtained by addition of sodium bromide solution of d=1.46 kg/l, for 65 hr and 145,000 x g. The other volume was utilized for isolation of the HDL fraction (d=1.063-1.21 kg/l) of the incubation mixture by means of sequential density ultracentrifugation as reported earlier (12).

Isolated lipoprotein fractions were submitted to polyacrylamide gradient gel electrophoresis and cholesterol analyses as described above.

RESULTS

The concentration of free, esterified and total cholesterol and the cholesteryl ester percentage of the isolated total plasma lipoproteins ($d < 1.21$ kg/l) obtained after 24 hr of incubation at 37 C of fish eye disease plasma or such plasma mixed with purified normal LCAT are compiled in Table 2. This table also shows corresponding concentration values obtained at total LCAT inhibition by DTNB and at experiments with added heat-inactivated purified enzyme.

When fish eye disease plasma was incubated without addition of normal LCAT, the free cholesterol content of the total plasma lipoproteins decreased by 0.27 mmol per l of incubation mixture as compared to the same incubation mixture stored at 0 C. Concomitantly, the cholesteryl ester content of the total lipoproteins in relation to total cholesterol increased from 57% to 65% in incubations with active autologous β-LCAT esterifying the free cholesterol of combined VLDL and LDL in the mixture.

Incubation of fish eye disease plasma with purified normal LCAT at a subnormal amount of 0.8 mg per l (normal plasma concentration is 4-8 mg/l) of incubation mixture or with twice this amount of enzyme resulted in increases in the cholesteryl ester percentages of the total plasma lipoproteins to 70 and 73%, respectively. This latter increase was reflected by a decrease of the free cholesterol of about 0.4 mmol per l of incubation mixture. When the LCAT inhibitor DTNB was included in the incubation mixture of fish

eye disease plasma and purified LCAT, the values for the contents of free cholesterol and cholesteryl esters and for the cholesteryl ester percentage were close to corresponding values obtained for fish eye disease plasma stored at 0 C (Table 2).

Addition of heat-inactivated purified normal LCAT to fish eye disease plasma, followed by incubation at 37 C yielded essentially the same values for free cholesterol concentration and cholesteryl ester percentage as were obtained for fish eye disease plasma without addition of purified normal enzyme.

After incubation of the different mixtures, their HDL fractions were also isolated and analyzed for free, esterified and total cholesterol and triglycerides. These results are presented in Table 3. Compared to fish eye disease plasma stored at 0 C for 24 hr, the free and total cholesterol contents of HDL from all mixtures incubated at 37 C were reduced. The reduction of total cholesterol of HDL was 64% (from 0.22 to 0.08 mmol/l) in incubation experiments with both fish eye disease plasma alone and with such plasma mixed with purified normal LCAT and incubated in the presence of 2 mmol/l DTNB for total LCAT inhibition. The corresponding reduction of total HDL cholesterol in incubation experiments with fish eye disease plasma mixed with heat-inactivated purified normal LCAT was 72% (from 0.22 to 0.06 mmol/l). In all these latter three experiments, the cholesteryl ester percentage of the isolated HDL was 50% after completed incubation, as calculated from total cholesterol contents that were of the same order of magnitude in all these three incubation experiments.

When purified normal LCAT was added to fish eye disease plasma, the HDL cholesteryl ester percentage increased to 64 and 79% on incubation when 0.8 and 1.6 mg of enzyme per l of incubation mixture, respectively, was used. The reduction of total cholesterol of HDL was 36% (from 0.22 to 0.14 mmol/l) in these experiments, as calculated from the total HDL cholesterol content obtained at incubation at 0 C. In addition, there was a net increase in cholesteryl ester content of the isolated HDL after incubation, from about 0.05 to 0.10 mmol/l when added purified normal LCAT was active (Table 3).

Incubation experiments with fish eye disease plasma with and without LCAT inhibitor or with such plasma that had been mixed with heat-inactivated purified normal LCAT demonstrated HDL particles of molecular masses around 115 kd (Fig. 1). When fish eye disease plasma was incubated with purified normal LCAT at a subnormal concentration of 0.8 mg per l of incubate, HDL particles of apparent masses around 130 kd were produced, and all particles of apparent masses of 115 kd disappeared (Fig. 1). At an enzyme concentration of 1.6 mg per l of incubation mixture, still larger HDL particles, around 200 kd appeared.

DISCUSSION

Fish eye disease plasma lacks the property to esterify the free cholesterol of HDL (4). It recently was demonstrated that when such native plasma was incubated at 37 C, both free cholesterol and phospholipids disappeared from its HDL as a manifestation of the lack of esterification of the cholesterol of this lipoprotein (7). No increase in HDL cholesteryl ester content occurred in these experiments with native fish eye disease plasma (7). As the originally present cholesteryl ester content remained unchanged in the HDL fraction after incubation, its percentage of esterified cholesterol increased from 20% to 50%. However, this increase was not accompanied by an increase in the apparent mean particle size of HDL (7) in contrast to what is observed when there is a net increase in the cholesteryl ester content and percentage of both normal and fish eye disease HDL induced by incubation with α-LCAT present in normal, lipoprotein depleted plasma (4,13,14). Instead, it could be demonstrated by

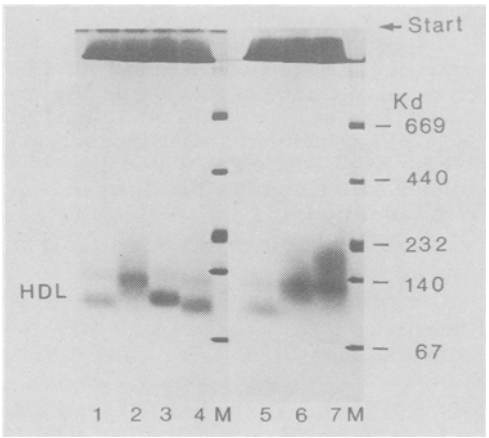

FIG. 1. Electrophoretogram of polyacrylamide gradient gel electrophoresis of total lipoproteins (d < 1.21 kg/l) isolated from different mixtures containing native fish eye disease plasma enriched with autologous HDL and incubated for 24 hr at 37 C with the following additives per l of incubation mixture (same incubation mixtures as described in Tables 2 and 3).
1 and 5, 0.15 mol/l sodium chloride; 2 and 6, 0.8 mg of purified normal LCAT; 3, 0.8 mg of purified normal LCAT and 2 mmol of DTNB; 4, 0.8 mg heat-inactivated purified normal LCAT; 7, 1.6 mg of purified normal LCAT; M, Molecular mass markers (Pharmacia Biotechnology International); Kd, Kilodalton.

polyacrylamide gradient gel electrophoresis that the HDL of native fish eye disease plasma gradually disappeared after prolonged incubation at 37 C, probably as a result of reduction of particle size as discussed in detail earlier (7). It seems reasonable to conclude that on incubation the free cholesterol and phospholipids of fish eye disease HDL diffuse to the plasma VLDL and LDL and are utilized at these lipoproteins as substrates for an active β-LCAT.

In this study, in agreement with previous observations (7) incubation at 37 C for 24 hr resulted in a disappearance of the free cholesterol of the HDL fraction of fish eye disease plasma enriched with autologous HDL. Supplementation with HDL was made to get enough material for all different analyses. Consonant with previous observations (7) the disappearance of free cholesterol from HDL also occurred in incubation experiments with LCAT inhibitor (Table 3).

In incubation experiments with fish eye disease plasma without LCAT inhibitor, there was a net increase in cholesteryl ester content of the total lipoproteins (d<1.21 kg/l), as compared to the LCAT inhibited situation, due to esterification of the free cholesterol of combined VLDL and LDL, demonstrating a functioning β-LCAT activity in accordance with previous findings (4,5). The decrease in free cholesterol of the fish eye disease HDL particles resulted in an increase in the cholesteryl ester percentage from 23% to 50% but did not increase the apparent HDL particle size or mass.

We recently developed a new procedure for the purification of normal human LCAT (10) with retained α- and β-LCAT activities as previously defined (4,5). This enzyme, which was purified more than 20,000-fold over its occurence in plasma by covalent chromatography on Thiopropyl-Sepharose accepted artificial lecithin-cholesterol (molar ratio 4:1) liposomes as substrates only after supplementation with purified apolipoprotein A-I.

Incubation of this highly purified enzyme with fish eye disease plasma at 37 C for 24 hr resulted in an increase in the cholesteryl ester percentage of the total lipoproteins from 65% to more than 70%. This net increase in cholesteryl esters of the total lipoproteins was reflected by a net increase in esterified cholesterol in HDL isolated after incubation. The cholesteryl ester content increased two-fold as compared with that of fish eye disease HDL from plasma not supplemented with normal purified LCAT. The induced esterification of the free cholesterol of the fish eye disease HDL also strongly counterbalanced the HDL particle degradation process with disappearance of more than 60% of its total cholesterol content. Furthermore, a net increase in the triglyceride content of HDL isolated after incubation at 37 C compared with what was found at incubation at 0 C also could be demonstrated. This increase in HDL triglyceride content is expected to occur due to a functioning bidirectional cholesteryl ester-triglyceride transfer between HDL and lipoproteins of lower densities and induced by the increase in the cholesteryl ester content of the HDL on incubation with normal purified LCAT with α-LCAT activity. All the incubation-induced effects of purified normal LCAT on fish eye disease HDL and total lipoprotein cholesterol were abolished completely by heat inactivation of the purified LCAT before it was added to the incubation mixtures (Tables 2 and 3).

In addition to apolipoprotein A-I, apolipoprotein D, which also resides in normal HDL, has been reported to be involved as a cofactor in the LCAT-mediated esterification process of the free cholesterol of plasma (15). This apolipoprotein, whose role in the esterification process is disputed (16), also seems to be the most persistently remaining impurity in even the highest purified LCAT preparations (17).

In fish eye disease plasma, both apolipoprotein A-I, which is normal qualitatively (9), and apolipoprotein D are present, although in strongly reduced amounts (2). As demonstrated in Figure 2, fish eye disease HDL produced a precipitation arc on double immunodiffusion against anti-apolipoprotein D. The presence of apolipoprotein D in fish eye disease HDL, combined with the observed inability of heat-inactivated purified normal LCAT to effect HDL cholesterol esterification make it reasonable to conclude that the demonstrated incubation-induced normalization of the fish eye disease HDL cholesteryl ester content is caused by an α-LCAT activity characteristic of the normal purified LCAT used in this study and not by traces of apolipoprotein D, which is temperature resistant, in the purified LCAT preparation.

The normalization of the cholesteryl ester content of isolated total lipoproteins and HDL, observed after incubation of fish eye disease plasma supplemented with purified normal LCAT, was found to be accompa-

nied by a normalization of the apparent mean particle size or mass of these HDL. Incubations with the subnormal LCAT concentration yielded a rather homogeneous population of particles that were larger than those of native fish eye disease HDL (Fig. 1). Mean particle masses of the HDL increased as a function of increasing purified LCAT concentration in the incubation mixture. The particle enlargement induced by the action of normal purified LCAT, resulted in HDL particles of the same size or mass as found for small HDL_3 particles in normal plasma (Fig. 1). It seems that when the cholesteryl ester percentage of HDL reaches a value of about 60%, accompanied by a decrease in free cholesterol content of the HDL particle surface, whose decrease might render the particle less rigid (18), an HDL particle fusion process may start (8). A fusion process in transformation of small model discoidal lipoprotein complexes to HDL_3-like species previously has been demonstrated by Nichols et al. (19). The effect of the purified normal LCAT on fish eye disease HDL was abolished completely by the LCAT inhibitor DTNB or by heat inactivation of the purified normal enzyme.

These findings demonstrate that α-LCAT activity of normal purified LCAT is necessary and sufficient for the initiation of this HDL particle enlargement in fish eye disease plasma, although additional factors affecting HDL particle size might be involved at later steps of the process in this as well as in normal plasma (14,20).

The results of this study clearly show that fish eye disease plasma, consistent with earlier findings in experiments with lipoprotein-depleted plasma fractions (4,5), lacks an enzyme activity (α-LCAT) that is present in normal highly purified LCAT, although the free cholesterol of the combined VLDL and LDL is esterified at an apparently normal rate in this condition. Supplementation of fish eye disease plasma in vitro with purified normal LCAT followed by incubation at 37 C for 24 hr resulted in normalization of both the cholesteryl ester content and the apparent mean particle size or mass of the fish eye disease HDL.

Lithocholic acid (LCA)-induced intrahepatic cholestasis is associated with increased de novo synthesis of hepatic cholesterol and augmented cholesterol content of the liver cell plasma membrane fraction enriched in bile canalicular complexes (BCM). To determine whether inhibition of cholesterol synthesis could prevent LCA-induced cholestasis, adult male Wistar rats were treated daily with the hypocholesterolemic agents, clofibrate (250 mg/kg) or mevinolin (25 mg/kg), for one, two or four days. After bile duct cannulation and bile collection for one hr, the animals were injected intravenously with 120 μmoles/kg of LCA or its carrier (albumin). Cholesterol synthesis was measured in liver homogenates, and its contribution to the BCM was estimated. LCA reduced bile flow by 51%, 35% and 25% after clofibrate pretreatment for one, two and four days, respectively, and by 51%, 30% and 42% in mevinolin-pretreated animals after one, two and four days. In control animals, cholesterol synthesis and the contribution of newly synthesized cholesterol in the BCM were increased after LCA injection. However, despite that cholesterol synthesis and the contribution of newly synthesized cholesterol in the BCM were reduced in drug-pretreated rats, LCA injection caused a relative increase in these parameters of a magnitude similar to that observed in controls. Thus, the ability of LCA injection to augment de novo cholesterol synthesis and its transport to the BCM may be an important pathogenetic step in the development of cholestasis.
Lipids 23, 230-233 (1988).

Cholestasis generally may be defined as a primary disturbance in bile formation. While current understanding of the pathogenesis of intrahepatic cholestasis remains fairly rudimentary, considerable attention has been focused on monohydroxy bile acid-induced cholestasis (1-4). Monohydroxy bile acids have been identified in the meconium and urine of newborns (5-8), and de novo synthesis of these bile acids in fetus and newborn infant has been suggested (9-10). More recently, the concentration of lithocholic acid (LCA), a monohydroxy bile acid, was found to be increased in the bile of adult patients treated with chenodeoxycholic acid for gallstones (11-13), and there have been reports of elevated biliary LCA levels in subjects receiving total parenteral nutrition (14-15). It is of interest that the hepatic structural alterations noted in some of these patients are somewhat similar to those produced in animals by LCA (13). Therefore, elucidation of the pathogenesis of LCA-induced cholestasis could prove useful in the management of prevention of cholestasis in these high-risk patients.

Existing evidence indicates that LCA enhances de novo cholesterol synthesis in microsomes as well as cholesterol transport from the microsomes to the bile canalicular membrane (BCM) into which it becomes incorporated (16). Cholesterol accumulation in the BCM then could increase the membrane's viscosity and thereby decrease its permeability to water, resulting in cholestasis (16-20). Therefore, it has been suggested that LCA-induced cholestasis could be prevented by agents that interfere with hepatic cholesterol synthesis and consequently reduce cholesterol content of the BCM. This hypothesis was tested with clofibrate (ethyl-p-chlorphenoxy isobutyrate), a hypolipidemic drug that suppresses the conversion of acetate into cholesterol in liver homogenates (21), and mevinolin (1,2,6,7,8 α - hexahydro-β,δ-dihydroxy-2,6-dimethyl-8-(2-methyl-1-oxobutoxy-1-naphtalene hepatonic acid δ-lactone, MK-803), a highly potent specific competitive inhibitor of 3-hydroxy-3-methyl glutaryl coenzyme A reductase (HMG-CoA), the rate-limiting enzyme in cholesterol biosynthesis (22).

MATERIALS AND METHODS

Effect of clofibrate and mevinolin on lithocholate-induced cholestasis. Male Wistar rats (High Oak Ranch, Montreal, Québec) with an average body weight of 200 g were kept under controlled conditions of humidity and lighting with free access to water and Purina lab chow. They were divided into three groups. The two treatment groups were given per os for one, two or four days either clofibrate (gift from Ayerst Laboratories, Montreal, Canada) at a daily dose of 250 mg/kg body weight or mevinolin (gift from Merck Sharp & Dohme, Montreal, Canada) at a daily dose of 25 mg/kg body weight. The third group served as untreated controls. Within one hr after the last oral dose of clofibrate or mevinolin, a biliary fistula was created under nembutal anesthesia, and bile was collected for one hr (0-60 min collection). Half of the animals of each of the three groups were injected intravenously with either 120 μmol LCA-Na/kg body weight (Calbiochem-Boehring Corp., La Jolla, CA); purity 90% as checked by thin layer chromatography (TLC) and gas liquid chromatography (GLC) or with the LCA carrier, 7.5% albumin in saline. The LCA injected was labeled with ^{14}C-LCA (Amersham, Oakville, Ontario); specific activity 55 μCi/mmole, 98% of the ^{14}C radioactivity was recovered with LCA when analyzed with thin layer chromatography (TLC) using a solvent system made up of iso-octane/ethyl-acetate/acetic acid/N-butanol (10:5:1.5:1.5). Bile was col-

lected for one hr (60–120 min collection) following the injection of LCA or albumin solution, and its volume was measured gravimetrically. The rats remained under anesthesia during bile collections (120 min), and body temperature was maintained at 36.5 C with a heat lamp thermostatically controlled. At the end of the experiment, the livers were homogenized in bicarbonate buffer, and specimens were solubilized in tissue solubilizer and counted for radioactivity. Blood samples were taken from rats injected with ^{14}C-LCA, and their radioactivity was determined. The methodology for the radioactivity measurements in liver tissues and blood has been reported earlier by this laboratory (16). Experimental and control animals were studied simultaneously to exclude diurnal variation in bile acid and cholesterol metabolism.

Effect of clofibrate and mevinolin on cholesterol synthesis and liver cell plasma membrane composition. These experiments were designed to determine the effects of the hypocholesterolemic drugs on hepatic cholesterol synthesis and on cholesterol content of liver cell plasma membrane fractions, utilizing the recently described ^{14}C/^{3}H ratio technique (16,20). Because results from the first phase of the study showed that maximum protection against LCA-induced cholestasis was obtained after four days of clofibrate and two days of mevinolin treatment, two groups of rats received these agents for such periods of time before half of them were injected with 120 μmol LCA/kg body weight or its carrier (albumin 7.5% in saline). A third group of rats untreated with hypocholesterolemic drugs served as controls, half the animals were injected with LCA and the other half with the LCA carrier as previously described. Sixteen hours before the LCA or albumin injection, all the animals were injected intraperitoneally with 25 μCi of ^{3}H cholesterol/100 g body weight (1,2-^{3}H cholesterol, New England Nuclear, Montreal; specific activity 50 mCi/mmol) to label the hepatic cholesterol pool. The rats were later injected IV with 10 μCi of ^{14}C mevalonic acid/100 g body weight (New England Nuclear, Montreal; specific activity 49 mCi/mmol) at the same time of the injection of LCA or its carrier to label the newly synthesized cholesterol. An hour later, the animals were killed. Their livers were washed with an infusion of 20 ml of 0.1 mM $NaHCO_3$ and 0.05 mM $CaCl_2$ buffer and were homogenized in the same buffer (1:2, W/V). A pellet of sodium hydroxide was added to each ml of homogenate, and the mixture was hydrolyzed for one hr at 70 C. Neutral lipids then were extracted with petroleum ether and the extracts dried under nitrogen at 60 C. The lipids were solubilized with 1 ml of methanol, and total cholesterol was measured by GLC (23), after which 1 ml of 5% digitonin (Fisher Scientific Co., Fairlawn, NJ) was added to precipitate the cholesterol. The mixture then was centrifuged at 3000 g at 4 C; the pellet was dissolved in 2 ml of hot methanol; and 0.5 ml was taken for the measurement of radioactivity, using a Beckman liquid scintillation system (Model L5 700) equipped with an external standard. The specific activities of cholesterol were determined, and the ^{14}C/^{3}H ratio was calculated. This ratio represents the relative contribution of newly synthesized cholesterol to the total cholesterol pool from the time of injection of LCA or its carrier up to the end of the experiment (one hr), because ^{3}H specific activity of hepatic cholesterol was in a steady state between 12–24 hr after ^{3}H cholesterol injection.

The rest of the liver homogenate was used for the processing of liver cell plasma membrane fractions, as described (2,16). Two fractions were obtained, one enriched in bile canalicular structures, the other mainly containing sheets and vesicles derived from the sinusoidal surface of the cell. Lipids were extracted with chloroform/methanol (2:1), total cholesterol was determined by gas liquid chromatography (GLC), and the ^{14}C and ^{3}H radioactivities were estimated as described for liver homogenate extract. The ^{14}C/^{3}H ratios of the specific activity of cholesterol in the membrane fractions then were calculated. The data were evaluated statistically by Student's t-test and a P-value of <0.05 was considered statistically significant.

RESULTS

Body and liver weight. The percentage of liver to body weight ratio was increased significantly ($p < 0.05$) after two and four days of clofibrate treatment (% liver to body weight ratios were 4.29 ± 0.28, 4.70 ± 0.18 and 4.88 ± 0.45 for one, two and four days of treatment, respectively). Mevinolin administration had no such effect.

Bile flow. In clofibrate-treated rats, basal bile flow (0–60 min collection period) decreased after one and two days of treatment as compared with controls but this trend disappeared after four days (Table 1). A similar response pattern was observed following treatment with mevinolin.

LCA in control animals that had not been treated with clofibrate or mevinolin decreased bile flow by 58% within one hr following its injection (Table 2). Similarly, in clofibrate-treated rats for one, two and

TABLE 2

Percentage of Distribution of LCA Radioactivity in Various Tissues

Treatment	Serum	Liver	Bile
Control + LCA	8.5 ± 4.9	48.5 ± 3.5	43.0 ± 8.5
Clofibrate 1 day + LCA	2.5 ± 1.9[a]	44.5 ± 13.5	53.0 ± 14.4
Clofibrate 2 days + LCA	2.9 ± 1.9[a]	31.1 ± 8.4[a]	67.0 ± 10.0[a]
Clofibrate 4 days + LCA	2.8 ± 1.9[a]	26.3 ± 14.3[a]	70.9 ± 11.2[a]
Mevinolin 1 day + LCA	5.0 ± 1.0	44.0 ± 6.9	51.0 ± 7.3
Mevinolin 2 days + LCA	3.5 ± 2.6	29.6 ± 13.6[a]	66.9 ± 17.8[a]
Mevinolin 4 days + LCA	2.3 ± 1.1[a]	29.4 ± 10.3	68.3 ± 11.7[a]

Values are the means ± SD of eight animals except for control + LCA, the number of animals was four.
[a]Significantly different ($p < 0.05$) from the control group.

four days, bile flow was reduced by 51, 35 and 25%, respectively. At four days, bile flow was significantly greater ($p < 0.05$) than in controls injected with LCA.

In rats given mevinolin, LCA reduced bile flow by 51, 30 and 43% after one, two and four days of treatment, respectively. Although bile flow after two days of mevinolin administration was significantly higher ($p < 0.05$) than in control animals receiving LCA, this difference was not seen after four days of treatment (Table 1.)

Distribution of LCA in liver, serum and bile. Table 2 shows the percentage distribution of radioactive LCA in liver, serum and bile. In control animals, LCA was distributed equally in liver and bile (48 and 43%, respectively), whereas the serum contained only 8% of the dose injected. Both clofibrate and mevinolin increased the recovery of LCA in bile, and this was accompanied by proportionate reductions in liver and serum.

Cholesterol content and relative cholesterol synthesis. As seen in Table 3, none of the treatments significantly influenced the total cholesterol content of liver homogenates or the $^{14}C/^{3}H$ ratio.

Cholesterol content in the BCM was increased by 30% after LCA injection in control animals (no drug pretreatment). Clofibrate or mevinolin treatments for four or two days, respectively, reduced cholesterol content in the BCM by 30% (compared to control animals not treated with LCA). Injection of LCA in the drug-pretreated animals did not result in an increase in the membrane cholesterol (compared to control animals injected with LCA). The cholesterol content of the PM fraction after LCA injection was not affected in control animals (not treated with drugs); cholesterol was reduced, however, by 30–50% in drug treated animals irrespective of LCA or albumin injection.

The $^{14}C/^{3}H$ ratio, which indicates the relative contribution of the newly synthesized cholesterol in the total cholesterol content of the membrane, was increased in the BCM by 30% after the injection of LCA in controls (not treated with drugs). This ratio was reduced by a similar percentage in clofibrate and mevinolin treated rats. Injection of LCA in the later groups increased the $^{14}C/^{3}H$ ratio to the level seen in control animals (not injected with LCA).

In the PM fraction, the $^{14}C/^{3}H$ ratio was increased after LCA injection in control animals. This ratio was reduced in the drug treated groups whether injected with LCA or albumin. The difference in the $^{14}C/^{3}H$ ratios between BCM and PM may indicate a different rate of contribution of newly synthesized cholesterol to cholesterol content in these two membrane fractions.

DISCUSSION

The purpose of these studies was to test the hypothesis that the increased de novo synthesis of cholesterol after LCA treatment and its accumulation in the canalicular membrane are important pathogenetic steps in the development of LCA-induced cholestasis.

It was assumed that inhibition of cholesterol synthesis by the hypocholesterolemic drugs, clofibrate and mevinolin, may prevent cholesterol accumulation in the canalicular membrane and the cholestatic response to LCA. The data obtained in these studies do not support this hypothesis; despite the fact that clofibrate and mevinolin both reduced the relative cholesterol synthesis and cholesterol content in the BCM (Table 3), bile flow was not improved significantly after LCA injection (Table 1) (with the exception of clofibrate treatment for four days in which bile flow was reduced by 25% vs 58% in control. But, clofibrate effect was not time- or dose-dependent (unpublished data). However, in clofibrate and mevinolin-treated rats, LCA caused an increase in the relative contribution of de novo cholesterol synthesis in the BCM (C^{14}/H^{3} 0.08 in clofibrate vs 0.11 in clofibrate + LCA injection and 0.08 in mevinolin vs 0.10 in mevinolin + LCA injection). This increase was similar to that obtained in control rats (C^{14}/H^{3} 0.12 in controls vs 0.15 in LCA injection). These data suggest that the ability of LCA injection to increase de novo synthesis of cholesterol and its transport to the BCM may be an important step in the pathogenesis of LCA-induced cholestasis.

Recently, it was shown in vitro that cholestatic bile acids such as LCA and its sulfate and glucuronide derivatives possess higher calcium-binding properties than noncholestatic bile acids (24,25). This finding raised the possibility that a disturbance of cellu-

Values are the means ± SD of four samples per group.
BCM refers to membrane fractions enriched in bile canalicular complexes (bile canaliculi and lateral membranes).
PM refers to membrane fractions containing vesicles derived mainly from sinusoidal and lateral membranes of hepatocytes.
The $^{14}C/^{3}H$ ratio is used as a measure of the newly synthetized cholesterol (ref. 16).
[a]Significantly different ($p < 0.05$) from control injected with albumin.
[b]Significantly different ($p < 0.05$) from control injected with LCA.

lar calcium homeostasis could occur after exposure to LCA with pathologic consequences. If this is proven in vivo, it remains to be determined to what extent changes in cellular calcium could modulate the mobilization of cholesterol from microsomes to canalicular membranes that occurs after LCA injection.

The increased biliary secretion of ^{14}C-LCA in drug-pretreated rats could be due to increased metabolites of LCA. Preliminary experiments show that 92% of ^{14}C LCA was secreted unchanged in controls, while only 50% was secreted in clofibrate-treated rats. However, if this was the case it does not seem that the increased secretion of LCA (or its metabolites) was significant enough to prevent its cholestatic effect.

In summary, this and other studies (2,16,20) from our laboratory confirm the association between the cholesterol synthesis and the cholestatic effect of LCA. Furthermore, it shows that under the present experimental conditions hypolipidemic drugs do not prove useful in prevention of LCA-induced cholestasis.

ACKNOWLEDGEMENTS

Rats were fed diets containing 10%, 30% or 50% energy as fat derived predominantly from butter or lard. The protein content of the diets was maintained at 20%. After three weeks on the diets, the rats were killed and the following parameters measured: prostacyclin production in vitro from abdominal aorta and mesenteric artery; platelet aggregation to ADP and thrombin; fatty acid composition of the phospholipids in plasma, thoracic aorta and liver; smooth muscle reactivity and release of endothelial derived relaxing factor (EDRF) from aortic endothelium stimulated by acetylcholine. There was no significant effect of increasing fat content of the diets (neither lard nor butter) on platelet aggregation. In contrast, prostacyclin production in both the mesenteric artery and the abdominal aorta fell in a concentration-dependent manner in the butter-supplemented rats. However, no effect on prostacyclin production was detected in arteries from the lard-supplemented animals. The effects of the diets on prostacyclin (PGI_2) production correlated very well with the changes in plasma, aortic and liver phospholipid arachidonic acid (AA) and eicosapentaenoic acid (EPA) contents. AA decreased in a concentration-dependent manner in the rats fed the butter-enriched diets but did not change in those fed the lard-enriched diets, whereas EPA rose in a concentration-dependent manner in the butter-fed rats and was unchanged in the lard-fed animals. The clear-cut effects of the butter-enriched diets on aortic phospholipid fatty acid composition and aortic PGI_2 production were accompanied by a significant reduction in smooth muscle relaxation to EDRF. These results indicate that in the rat, enrichment of the diet with butter can reduce the concentration of AA and increase that of EPA in plasma and tissue phospholipids with a parallel reduction in arterial PGI_2 production and EDRF.

Lipids 23, 234-241 (1988).

It now is accepted widely that high levels of saturated fat in the diet increase the risk of coronary heart disease (1,2). The effects of dietary saturated fat appear to be mediated through two major pathways: elevated plasma cholesterol levels, resulting in increased risk of atherosclerosis (1), and increased thrombosis tendency (3). The mechanism by which thrombosis tendency is increased is not well understood. Renaud and coworkers have reported that dietary saturated fat is associated with an increase in the concentration of the fatty acid 20:3n-9 in plasma and platelet lipids in rats and humans (4,5), a phenomenon that usually occurs only in essential fatty acid deficiency (6). They attributed the increased thrombin-induced platelet aggregation associated with dietary saturated fat to the presence of this fatty acid (5). However, it also is possible that the increased levels of 20:3n-9 are a marker of other changes in plasma and tissue fatty acid composition that may affect directly the production of the arachidonic acid (AA)-derived prostanoids (prostacyclin [PGI_2] and thromboxane A_2) and thereby modulate thrombosis tendency. To examine this possibility, the aim of this study was to determine the effects of increasing the proportion of two different dietary fats (butter and lard) on vascular PGI_2 production and platelet aggregation, and plasma, aortic and liver phospholipid fatty acid composition in the rat. In addition, the effects of increased dietary fat (butter) on aortic smooth muscle reactivity and the release of endothelial derived relaxing factor (EDRF) were assessed.

METHODS

Animals. Male Sprague-Dawley rats weighing 120–170 g were used in all studies. They were housed in a temperature-controlled room with a 12-hr light-dark cycle. Food and water were provided ad libitum and food consumption and body weights recorded three times each week.

Diets. The nutrient composition of the experimental diets is shown in Table 1 and their fatty acid composition is given in Table 2. The diets were prepared from whole meal flour and skim milk powder (providing all the carbohydrate and protein) and lard or butter (providing most of the fat). The proportion of energy derived from protein was constant in all diets, while the proportions of fat and carbohydrate varied inversely. The P/S ratio fell as the proportion of fat rose on both the lard and butter diets, however the fall was more pronounced on the butter diet as the P/S ratio of butter is much lower than that of lard. Vitamins and minerals were added to reach the levels recommended by the American Institute of Nutrition (7).

Platelet aggregation. After three weeks on the diet, the rats were anesthetized with sodium pentobarbitone (50 mg/kg intraperitoneally), and blood was taken by cardiac puncture into 3.8% sodium citrate (9 vol blood: 1 vol citrate). The citrated blood was centrifuged

at 150 × g for 10 min at room temperature to prepare platelet-rich plasma (PRP). After removal of the PRP, the remaining blood was centrifuged for 15 min at 3000 × g at room temperature to obtain platelet-poor plasma (PPP). The platelet count of the PRP was determined using a Coulter Counter (Model SII) and adjusted with PPP to give a count of 300,000 platelets/μl. Platelet aggregation measurements were performed with a Payton dual-channel aggregometer: 450 μl PRP was stirred at 1000 rpm at 37 C and 50 μl of the appropriate aggregating agent added: ADP (2 and 5 μM), thrombin (1 and 2 U/ml) or AA (6.4 mM). Platelet aggregation was monitored continuously for four min. To quantitate platelet aggregation, the maximum change in light transmittance through PRP was expressed as a percentage of the light transmittance through PPP. Five min after the addition of the aggregating agent, a 200 μl aliquot was mixed with 200 μl of ethanol, centrifuged and the supernatant stored at -20 C for subsequent radioimmunoassay of thromboxane B_2 (TXB_2), the stable metabolite of thromboxane A_2 (TXA_2) (8).

Vascular PGI_2 production. Immediately after blood collection, the rat was perfused with Krebs Ringer Bicarbonate buffer (KRB), pH 7.4, containing 5.5 mM glucose, to flush out the remaining blood, leaving the artery preparations free of adhering blood clots. The mesenteric artery and abdominal aorta were removed carefully, cleared of connective tissue and cut into rings. These rings were incubated in 4 ml of KRB containing 5.5 mM glucose at 37 C for three hr in a shaking water bath and 100 μl aliquots taken at zero time and 15, 30, 60, 120 and 180 min later. These samples were stored at -20 C and the time course of PGI_2 production determined subsequently by radioimmunoassay of its stable metabolite, 6-keto $PGF_{1\alpha}$ (9). At the end of the incubation, the rings were removed, blotted on filter paper and weighed to obtain the "wet weight." In order to control for the presence of any cross-reacting material interfering with the RIA of 6-keto-$PGF_{1\alpha}$ produced during the incubation of arteries, we incubated aortic rings from butter-fed rats (10% and 50%) in the presence and absence of indomethacin (10 μg/ml). Indomethacin completely prevented the production of any immuno-reactive material from these aortea, confirming the specificity of the assay for 6-keto-$PGF_{1\alpha}$.

Aortic smooth muscle reactivity and the release of EDRF. Rats were stunned and the thoracic aorta carefully dissected free of surrounding tissue. The aorta was pinned down at either end on a silastic rubber-coated dish filled with cold, oxygenated Krebs' solution composition (in mM) Na^+ 144, K^+ 5.9, Ca^{++} 2.5, Mg^{++} 1.2, Cl^- 128.7, HCO_3^- 25, SO_4^{2-} 1.2, glucose 11, EDTA 0.27 aerated with a gas mixture of 95% O_2 and 5% CO_2. Two three-ring segments each 3 mm long were cut transversally from the aorta. Each ring was suspended on two surgical stainless steel Z-shaped support wires 500 μm diameter in a heated organ bath. One wire was attached to an isometric force transducer (Grass FTO3C), the second wire to an acrylic leg mounted on a micrometer screw gauge. After 30 min

equilibration, the micrometer was advanced to stretch the artery in steps every minute. The passive force-diameter relationship was determined from the measurements as described (10). The internal diameter (D) and circumference (L) of the vessel was calculated for an equivalent transmural pressure of 100 mm Hg. The artery was released slightly to a circumference of 0.9 L and left at this passive stretch for the remainder of the experiment. These initial steps were taken to ensure that each artery segment was under similar resting passive tone before drug addition. From each rat, one ring was contracted to a steady level of active force by phenylephrine hydrochloride 1 μM, then relaxed by the cumulative addition of acetylcholine bromide at 0.5 log unit increments (from 10–1000 nM) to test the EDRF activity. Relaxation responses were averaged at fixed concentrations of each.

Fatty acid composition of plasma aortic, and liver phospholipids. Lipid extracts were prepared from plasma, thoracic aorta and liver by chloroform/methanol extraction (11). Phospholipids were separated by thin layer chromatography and the concentration of the component fatty acids determined by capillary gas liquid chromatography using heptadecanoic acid as an internal standard as described (12). The identification of 20:3n-9 was based on identical retention times with 20:3n-9 isolated from essential fatty acid deficient rat liver when separated on a 50 m x 0.32 mm bonded phase capillary column coated with CP Sil 88. On this column, 20:3n-9 was separated clearly from 20:2n-6, 20:3n-6 and 22:0.

Statistical analyses. Differences between groups were established using analysis of covariance or Student's unpaired t-test. Results are expressed as mean ± SEM.

MATERIALS

Pentobarbitone sodium was purchased from Civa Chemicals (Hornsby, N.S.W., Australia), ADP, TXB_2 standard, 6-keto $PGF_{1\alpha}$ standard, acetylcholine bromide and indomethacin were from Sigma Chemical Co. (St. Louis, MO); thrombin (Fibrindex, human) from Orthodiagnostic Systems Inc. (Raritan, NJ); arachidonic acid and heptadecanoic acid were from NuChek Prep (Elysian, MN), TXB_2 antibody was a gift from Laurence Levine, Brandeis University (Waltham, MA); 6-keto-$PGF_{1\alpha}$ antibody was a gift from L.C. Best, University of Sheffield (Sheffield, U.K.); tritiated 6-keto-$PGF_{1\alpha}$ and TXB_2 were from Amersham International (Amersham, U.K.); bonded phase capillary column from Chrompak (Middelburg, The Netherlands); and phenylephrine hydrochloride from Stirling Pharmaceuticals (Sydney, Australia).

RESULTS

Whether the rats were fed butter or lard diets did not affect their weight gain. At 10%, 30% and 50% butter diets, the rats gained 7.3 ± 0.1, 7.0 ± 0.3 and 6.3 ± 0.3 g/day, while with the 10%, 30% and 50% lard diets they gained 7.5 ± 0.1, 7.1 ± 0.2 and 6.1 ± 0.3 g/rat/day. However, in both dietary studies (butter and lard), there was a reduction in weight gain as the fat content of the diet increased. This probably was due in large part to the major changes in salt and water balance that occur on low carbohydrate diets (13,14).

There was no effect of either type of dietary fat on ADP-induced platelet aggregation (Table 3). Although there was a trend towards increased platelet aggregation in response to the higher concentration of thombin (2 U/ml) with increasing fat intake (both lard and butter), it was not statistically significant. Thromboxane production by platelets in vitro was not influenced by either type of dietary fat (Table 3).

The effect of increasing the level of butter in the diet on the time-course of PGI_2 production by the abdominal aorta is shown in Figure 1. PGI_2 production over the three hr was reduced consistently as the proportion of dietary fat rose from 10% to 50% of energy (analysis of covariance, $p < 0.001$). Subsequent results are presented as the PGI_2 production in the first hour

Mean ± SEM.

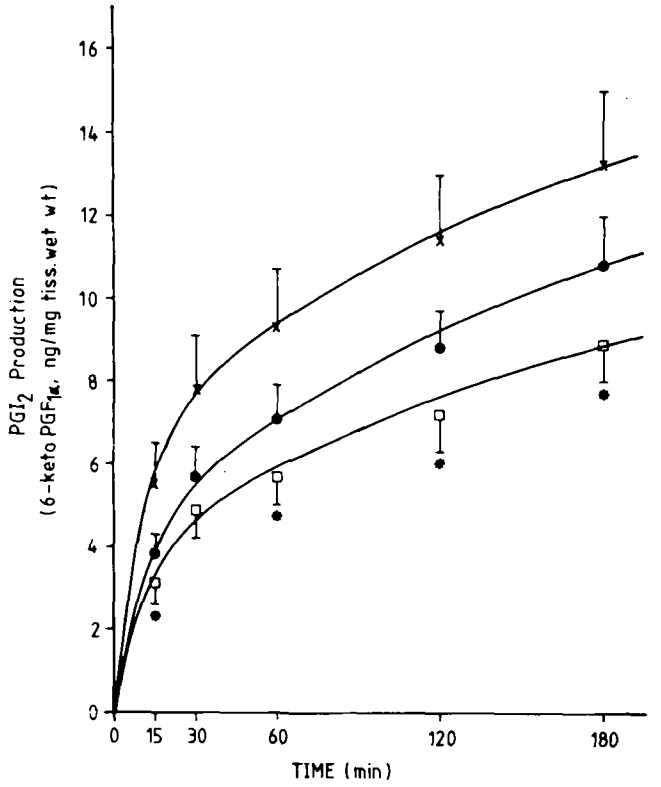

FIG. 1. Time course of prostacyclin production by rings of abdominal aorta from rats fed diets containing 10% (x), 30% (•) or 50% (□) energy from butter (ng 6-keto $PGF_{1\alpha}$/mg tissue wet weight, mean ± SEM).

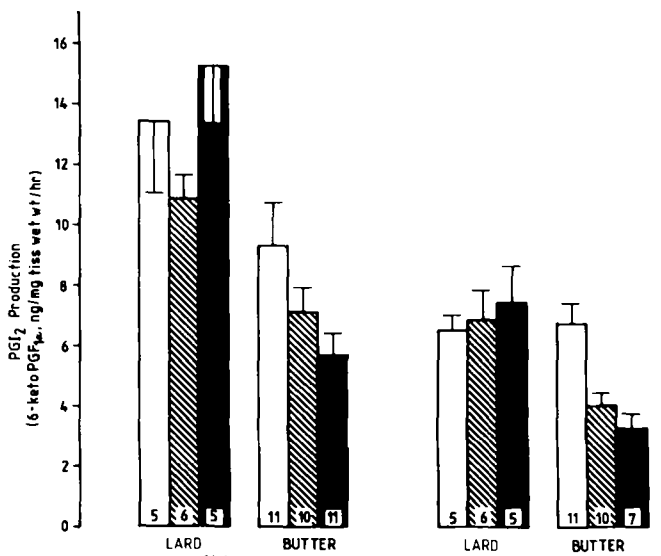

FIG. 2. Prostacyclin production by rings of abdominal aorta and mesenteric artery from rats fed diets containing 10% (open bars), 30% (hatched bars) or 50% (black bars) energy from butter or lard.

Statistics:	Abdominal aorta	Mesenteric artery
10% vs 30%	butter n.s., lard n.s.	butter $p < 0.005$, lard n.s.
10% vs 50%	butter $p < 0.05$, lard n.s.	butter $p < 0.001$, lard n.s.
30% vs 50%	butter n.s., lard n.s.	butter n.s., lard n.s.

of incubation in order to summarize the data in a single figure (Fig. 2). In both the mesenteric artery and the abdominal aorta, the PGI_2 production decreased in a dose-dependent manner as the proportion of butter in the diet rose from 10% to 50% energy. In contrast, lard supplementation had no detectable effect on PGI_2 production in either artery.

The effects of butter-enrichment on the fatty acid composition of plasma phospholipids are shown in Table 4. Increasing the butter content of the diet was associated with striking concentration-dependent changes in the proportions of the eicosanoid fatty acids: AA fell ($p < 0.001$), EPA rose ($p < 0.001$) and eicosatrienoic acid (20:3 n-9) rose ($p < 0.001$). In contrast, lard-enrichment had no effect on the plasma phospholipid fatty acid composition. None of the lard diets differed from the 10% butter diet or from each other (Table 5).

The effect of increasing the butter content of the diet on the fatty acid composition of aortic phospholipids is presented in Table 6. The major changes were in the proportions of the eicosanoid fatty acids that were similar but less pronounced than those in the plasma phospholipids. The proportion of AA fell but that of EPA and 20:3 n-9 rose as the butter content of the diet increased. Enrichment of the diet with lard had no effect on the fatty acid composition of aortic phospholipids.

The concentration of phospholipid in plasma fell dose-dependently on the butter-enriched diets: 10% = 54.8 ± 3.0, 20% = 50.0 ± 2.1, 50% = 41.6 ± 2.6 mg phospholipid fatty acid / 100 ml plasma (50% < 10%, $p<0.01$; 50% < 30%, $p<0.05$). The concentration of phospholipids in aorta and liver was not affected by increasing the butter content of the diet. Increasing the proportion of dietary fat as lard did not affect the phospholipid concentration in plasma, aorta or liver. The data are not shown but in all three lard-enriched diets, it was essentially the same as that in the 10% butter diet.

In view of the changes in aortic lipid composition and the marked reduction in aortic prostacyclin production on the butter-enriched diets, we considered the possibility that the synthesis and/or release of EDRF from the endothelium also could have been influenced. To test for this possibility, aortic smooth muscle reactivity and the release of EDRF were determined. There was a small but significant difference in the contraction response to submaximal concentrations of phenylephrine (1 μM) between the 10% butter diet (2.73 ± 0.08 g, n=6) and the 50% butter diet (3.09 ± 0.07 g, n=6, $p<0.02$) (Fig. 3). In the 50% butter diet, the maximum relaxation to acetylcholine was significantly less (1.08 g) than that on the 10% butter diet (1.62 g). In percentage terms, these relaxations were 34.9% and 59.3%, respectively. The sensitivity EC_{50} of the two diet groups to acetylcholine was similar (EC_{50}: 10% butter diet = 0.21 μM, 50% butter diet = 0.33 μM).

DISCUSSION

The major finding in this study was that increasing the level of butter in the diet resulted in a progressive reduction in PGI_2 production in aorta and mesenteric

artery in vitro. This effect on arterial PGI_2 production was accompanied by profound changes in the fatty acid composition of plasma phospholipids which were also evident but less marked in aortic phospholipids. The proportion of AA fell markedly as the level of butter in the diet increased, whereas the proportion of EPA and eicosatrienoic acid (20:3n-9) rose. The reductions in arterial PGI_2 production can be explained in terms of these fatty acid changes: the fall in the concentration of its precursor (AA) in arterial wall phospholipids, the rise in the concentration of EPA (an inhibitor of cyclooxygenase [15]), or a combination of both.

Substitution of lard for butter as the major source of fat in the diet did not result in any changes in fatty acid composition of plasma, aortic or liver phospholipids, nor was it associated with any reduction in arterial PGI_2 production. This latter result provides good evidence that the progressive reduction in arterial PGI_2 production in the butter–fed rats was not due to the increasing proportion of dietary fat per se. It also raises a number of questions.

Were the different responses to enrichment of the diet with butter or lard due to the different P/S ratios of the diets? The P/S ratios of the 10% fat diets were quite similar regardless of whether lard or butter were used (0.54 and 0.56, respectively). However, as the fat content of the diet was increased to 30% and 50% the P/S ratio fell much more with butter (0.10 and 0.05) than it did with lard (0.24 and 0.19). It is possible that both the concentrations and the relative proportions of particular polyunsaturated fatty acids (PUFA) are critical factors in determining the changes in phospholipid fatty acid composition and the consequent physiological responses.

What was the source of the increased concentration of EPA in plasma and tissue phospholipids of the butter–fed rats? It is unlikely to have come from the butter itself because the only PUFA we could detect in butter were linoleic and linolenic acids. A more likely explanation could be that the ratio of linoleic acid/linolenic acids was much lower in the butter than the lard diets. In the 50% fat diets, this ratio was 9:1 with lard and only 2:1 with butter. Since linolenic acid is a more effective competitor for the desaturase enzymes than linoleic acid in the rat (16), the lower linoleate/linolenate ratio in the butter diets may have facilitated the synthesis of EPA at the expense of AA.

Studies on the effects of different types of dietary fat on arterial PGI_2 production in the rat and rabbit have yielded conflicting results (17–20). Not unexpectedly, essential fatty acid deficiency reduced aortic PGI_2 production (17). Diets enriched with linoleic acid (the precursor of AA) have not been associated with enhanced PGI_2 production but rather a reduction (18,19). Lard supplementation has been reported not to change (20) or to increase (19) basal aortic prostacy-

clin production and to stimulate PGI_2 synthesis from exogenous AA (20). In contrast to the results of the present study, Galli and coworkers reported increased aortic PGI_2 production in rabbits red diets containing 25% energy as butter (19). It is possible that the variable effects of dietary saturated fat on aortic prostacyclin production in the rat that have been reported in the literature (18–21) also may be due to variations in the fatty acid composition of the rat chows used for the control diets. We have observed wide variations in plasma phospholipid fatty acid composition between rats fed different batches of chow (purchased from the same supplier), which is the reason we now prepare all diets in the laboratory. In the few instances in which effects of the diets on the fatty acid composition of aortic phospholipids have been measured, any changes in PGI_2 production have been mirrored by changes in aortic phospholipid AA content. When AA content increased (19,20) so did PGI_2 production and vice versa (17,22). This highlights the importance of measuring effects of diets on phospholipid fatty acid composition. In this study, changes in plasma phospholipid fatty acid composition were similar but more pronounced than those in the aorta.

Sinzinger and coworkers have suggested that the relative resistance of rats to the dietary induction of atherosclerosis may be related, at least in part, to their particularly high capacity for arterial PGI_2 synthesis relative to man, rabbit and a series of other animals that were tested (23). This characteristic, in turn, may be related to the high levels of AA in rat arterial phospholipids (20). It also is possible that the negligible thromboxane production by platelets after stimulation with ADP and thrombin also could contribute to this resistance to vascular disease.

Although the butter-enriched diets had clear-cut effects on the fatty acid composition of plasma and tissue phospholipids that correlated well with reductions in arterial PGI_2 production in vitro, there were no significant effects on ADP or thrombin-induced platelet aggregation. It is possible that the diet period (three weeks) was not sufficiently long for any such effects to be evident (24). Longer feeding periods

should clarify this question. Similarly, TXA_2 production by platelets in vitro was not affected by increasing levels of either type of fat in the diet. Indeed, TXA_2 production by platelets after stimulation with ADP and thrombin generally was insignificant, i.e. not significantly greater than that generated by the PPP "blank."

These results also may shed light on the observation of Morita and coworkers that dietary supplementation with EPA inhibited platelet aggregation in rats only when the background diet had been enriched with butter (25). The mechanism by which butter–enrichment unmasked this effect of EPA may be related to effects on the fatty acid composition of platelets. Presumably, the butter, being particularly low in PUFA and with an unusually low linoleate/linolenate ratio. would have been associated with reduced AA synthesis and thereby have facilitated the incorporation of the EPA dietary supplement into platelet phospholipids, resulting in reduced platelet aggregation. The data from the present study suggest that there is enrichment of tissue phospholipids with EPA even in the absence of supplementation.

In view of the changes in aortic phospholipid fatty acid composition on the butter–enriched diet, the possibility that alterations in membrane lipids could affect the synthesis and/or the release of EDRF from the endothelial cell or even the membrane receptor for the EDRF releasing agonist such as acetylcholine was considered. A very recent paper (26) has identified EDRF as nitric oxide (NO), at least in bovine endothelial cells stimulated by bradykinin. EDRF is a highly labile (27) nonprostanoid factor released from endothelial cells that has a powerful vasodilatory action on the underlying smooth muscle in response to some vasoactive substances such as acetylcholine, substance P, bradykinin and ATP (28). Because in the rat aorta (as in other species) the relaxation response to acetylcholine completely is endothelium-dependent (29), the reactivity to acetylcholine can be used to assess the entire process from EDRF release to smooth muscle relaxation. The 50% butter diet attenuated the magnitude of the EDRF-mediated response range suggesting either a reduction in the EDRF synthesis or release, or in smooth muscle responsiveness. Our experiments cannot distinguish between these possibilities. The sensitivity (ED50) was altered little, suggesting that the acetylcholine receptor coupling probably was unaffected by the dietary change. These changes to the EDRF activity may have been related to the marked changes in the PUFA composition of aortic phospholipids. However, the marked reduction in prostacyclin release measured in the separate series of experiments could not have been responsible for these changes in EDRF response since indomethacin was present throughout these latter experiments.

In conclusion, these results provide strong evidence that in the rat (i) dietary saturated fat in the form of butter can reduce the concentration of AA in plasma and tissue phospholipids, (ii) vascular PGI_2 production appears to be modulated directly by the level of AA in arterial wall phospholipids and/or inversely by the level of EPA, (iii) changes in plasma phospholipid fatty acid composition appear to be an accurate reflection of changes in arterial wall phospholipid fatty acid composition, (iv) these changes in aortic phospholipid fatty acid composition and PGI_2 production were accompanied by a reduction in smooth muscle relaxation to EDRF. Finally, butter-supplementation may provide an ideal model in which to examine the effects of particular PUFA supplements on vascular PGI_2 production in the rat.

Lipogenic Enzyme Activities in Primary Cultures of Adult Mouse Hepatocytes

Lewis A. Hillyard, C.Y. Lin and S. Abraham*
Children's Hospital-Oakland Research Institute, 747 Fifty-Second St., Oakland, CA 94609

The effects of various unsaturated fatty acids such as oleic (18:1n-9), linoleic (18:2n-6) and arachidonic (20:4n-6) on the activities of fatty acid synthetase (FAS), malic enzyme (ME), glucose-6-phosphate dehydrogenase (G6PDH) and 6-phosphogluconate dehydrogenase (6PGDH) all were determined in primary cultures of mouse hepatocytes. Activities of FAS and ME were found to decrease with time in culture regardless of whether hepatocyte donors were fed diets containing polyunsaturated fatty acid-free hydrogenated cottonseed oil (HCTO) or corn oil (CO). On the other hand, while G6PDH activity also declined in cultured hepatocytes obtained from HCTO-fed mice, the activity of this enzyme increased in cells cultured from CO-fed mice. 6PGDH activity was found to increase in hepatocytes obtained from both diet groups. Neither 18:2 nor 20:4 when added to media could alter FAS or ME activities compared with those observed with either 18:1-containing or fatty acid-free media. Since lactic dehydrogenase activity and the rate of incorporation of [^{3}H] leucine into FAS protein were unaltered with time in hepatocyte cultures, the decreased activities of FAS and ME cannot be attributed to a loss in cell viability during culture but rather appear to be specific for those enzymes which respond to diet hormones in vivo. Examination of the fatty acid contents of the cells after the culture period showed that the values for the ratios of 16:0/16:1 and of 18:0/18:1 were elevated when either 18:2 or 20:4 was added to the medium even though there was no evidence for elongation of the added 18:2 or for 20:4 being converted to 22:4. This result suggest that Δ9-desaturase activity was inhibited by these polyunsaturated fatty acids and that conversion of 18:2 to 20:4 was not required for such action.

The rate of synthesis determined by the relative rate of incorporation of [^{3}H]leucine into FAS was two to five times higher in hepatocytes prepared from mice fed the HCTO diet than in hepatocytes from mice fed the CO diet. We have concluded that the mechanisms for long-term regulation may not be contained entirely within the liver.

Lipids 23, 242–247 (1988).

Previously, we examined the influence of 18- and 20-carbon-chain-length fatty acids on the mechanisms involved with lipogenesis in mouse liver (1,2) as part of our continuing investigation of the long-term control of this process. Such control is accomplished through the regulation of the cellular contents of specific enzymes (3–5) rather than through allosteric mechanisms. In those studies, we showed that linoleic acid (18:2n-6), α-linolenic acid (18:3n-3), columbinic acid (5-*trans*,9-*cis*,12-*cis*-18:3n-6) and arachidonic acid (20:4n-6), either in the diet or administered by injection, reduced the levels of fatty acid synthetase (FAS), malic enzyme (ME) and ATP-citrate lyase in the liver when compared with saturated or monounsaturated fatty acids, neither of which had any effect. If the mechanisms involved in the polyunsaturated fat inhibition of lipogenesis are contained entirely within the liver, experiments with isolated cells might reveal these mechanisms. Hence, in this study we employed primary hepatocyte cultures since these cells maintain for several days many of the morphological and biochemical characteristics observed in situ (6–12). We examined in the hepatocyte cultures the influence of the nature of the dietary fat fed to donor mice on cellular fatty acid composition, on FAS, ME, glucose-6-phosphate dehydrogenase (G6PDH), 6-phosphogluconate dehydrogenase (6PGDH) and lactic dehydrogenase (LDH) activities, and on the relative rate of synthesis of the enzyme FAS. We also examined the effect of pure fatty acids (18:1n-9, 18:2n-6 and 20:4n-6) when added to the media during culture on the levels of FAS and ME.

MATERIALS AND METHODS

Animals and diets. BALB/c mice were used throughout. They originally were obtained from Simonsen Labs (Gilroy, CA) and currently are bred and maintained in our vivarium. The mice were housed on pine shavings in plastic cages and were kept in a temperature-controlled room (22–23 C) on a 12-hr light, 12-hr dark cycle. Purina mouse chow #5015 and tap water were available ad libitum before use. The chow diet contained 11% fat, of which 44% of the constituent fatty acids was linoleate. Mice employed as liver donors were allowed to eat the semipurified diets ad libitum for one week. These isocaloric diets were prepared in our laboratory and contained either 10% hydrogenated cottonseed oil (HCTO) or 10% corn oil (CO). The composition of the semipurified diets (13) and the fatty acid composition of the two fats (14) have been reported. Corn oil contains about 60% of its constituent fatty acids as linoleic acid, whereas HCTO has less than 0.5%.

Isolation of hepatocytes and culture conditions. Hepatocytes were isolated from adult BALB/c mice following perfusion of the liver in situ according to the procedure described by Dougherty et al. (15). The portal vein was cannulated and sterile Hank's Balanced Salt Solution (HBSS) containing 0.19 mg/ml EGTA at 37 C was pumped through the liver for seven min at a rate of 7.2 ml/min. This was followed by perfusion with HBSS containing 0.5 mg/ml collagenase (Sigma Type IV) for an additional 24 min at the same

*To whom correspondence should be addressed.

Abbreviations: CO, cottonseed oil; FAS, fatty acid synthetase; G6PDH, glucose-6-phosphate dehydrogenase; HBSS, Hank's balanced salt solution; HCTO, hydrogenated cottonseed oil; ME, malic enzyme; 6PGDH, 6-phosphogluconate dehydrogenase.

rate. The liver was removed, minced and filtered through 64 μM mesh nylon bolting cloth. The cells obtained were washed three times with perfusion buffer without enzyme, and their viability determined by trypan blue exclusion. Only preparations judged to have a viability of 95% or greater were used. The hepatocytes then were suspended in culture medium at a concentration of 0.9×10^6 cells per ml and aliquots (3 ml) added to each 60 mm Primaria tissue culture dish (Falcon). The cells were incubated at 37 C in an atmosphere of air/CO_2 (95%:5%).

The basic culture medium was Waymouth's medium (MB 752/1) supplemented, per liter, with 11.2 mg L-alanine, 24 mg L-asparagine, 12.8 mg L-serine, 2.24 g $NaHCO_3$, 100 mg streptomycin sulfate, 84 mg gentamicin sulfate, 61 mg (100,000 units) penicillin, 1 mg insulin and 550 mg sodium pyruvate. The plating medium contained the basic culture medium to which 10% fetal bovine serum was added. After allowing the cells to attach to the plates for four hr, the plating medium was replaced with basic culture medium containing 1×10^{-6} M triiodothyronine, 1×10^{-6} M hydrocortisone, 1×10^{-7} M insulin and 0.5% BSA either fatty acid–free or with 0.34 mM of either oleate, linoleate or arachidonate. The medium was replaced every 24 hr thereafter with fresh basic medium containing the appropriate additions.

Enzyme protein synthesis. The synthesis of fatty acid synthetase was determined directly by measuring the rate of incorporation of L-[4,5,^{3}H]leucine into fatty acid synthetase relative to the rate of incorporation into the total soluble protein of the cytosol (1,16). For this purpose, hepatocyte cultures were incubated with basic medium containing 10 μc L-[4,5^{3}H]leucine per ml for two hr at 37 C. The hepatocytes were washed four times with cold 0.25 M sucrose, homogenized at 0–4 C in a Potter-Elvehjem tissue grinder with 0.7 ml 0.25 M sucrose, centrifuged for one hr at 100,000 × g, and the clear supernatent (cytosol) removed. Methods for the isolation of total soluble protein, the immunoprecipitation of fatty acid synthetase and the assay of radioactivity have been described (1).

Analytical procedures. Procedures for the saponification of lipids, the extraction of fatty acids, preparation of methyl esters and the determination of fatty acid composition by gas liquid chromatography were described previously (17). The fatty acid methyl esters were identified by comparison of retention times

TABLE 1

Effect of Dietary Fat Fed to Hepatocyte Donors and Time in Culture, on Specific Enzyme Activities[a]

Expt. series	Dietary fat (10%)	Enzyme	Added fatty acid	Time in culture (hr) 4	22	70

[a]Results are presented as mean ± S.D. of enzyme specific activity (nmol substrate converted to product/min per mg cytosol protein). Figures in parentheses are the number of experiments with different hepatocyte preparations; four cultures were analyzed per time period in each experiment. The concentration of 18:1, 18:2 and 20:4 added to the medium after the four-hr plating period was 0.34 mM.
[b]Significantly different from corresponding CO values at $p < 0.05$.
[c]Significantly greater than corresponding values for 4- or 22-hr culture at $p < 0.05$.

with those of authentic standards obtained from NuCheck-Prep, Inc. (Elysian, MN).

The assay procedures for fatty acid synthetase (18), malic enzyme (E.C. 1.1.1.40) (19), glucose-6-phosphate dehydrogenase (E.C. 1.1.1.49) (20), 6-phosphogluconate dehydrogenase (E.C. 1.1.1.44) (21) and lactic dehydrogenase (E.C. 1.1.1.27) with lactate as substrate (22) have been reported. Units of enzyme activity are given as nmol pyridine nucleotide oxidized or reduced per minute at 30 C under the conditions of the specific assay. Protein was determined by the method of Lowry et al. (23).

RESULTS

We as well as others (6,10–12) have found that during culture, the activities of several hepatic lipogenic enzymes decrease with time (Table 1). Various culture modifications were made in attempts to maintain the activities of the lipogenic enzymes at the levels observed in freshly isolated hepatocytes. Although insulin (10^{-7} M) and pryruvate (5 mM) slowed the decline in the activities of fatty acid synthetase and malic enzyme, the loss of enzyme activity could not be prevented completely. The compounds studied included hydrocortisone or dexamethasone, thyroxine, triiodothyronine, glucagon, α-tocopherol, testosterone, 17-β-estradiol and L-ascorbic acid. Even under the best conditions used, from 60–80% of the enzyme activity observed for FAS and ME in the freshly isolated hepatocytes was lost during the subsequent 70–hr incubation period (Table 1).

This rate of decline in FAS and ME activities observed during culture was similar for hepatocytes isolated from livers of mice fed either the HCTO or the CO diet (Table 1). The alterations in G6PDH and 6PGDH activities differed from those observed with FAS and ME. The activity of G6PDH declined in hepatocytes prepared from HCTO–fed mice and increased significantly in those from CO–fed mice. The activity of 6PGDH consistently increased after the first 22 hr of culture in hepatocytes from both HCTO–fed and CO–fed mice. However, the differences in activities observed for all four enzymes in freshly isolated hepatocytes between HCTO– and CO–fed hosts were maintained in culture and were significant at all three time periods examined. The magnitude of the difference in activities, as well as in the rates of decline in activity for both FAS and ME, were similar even if hepatocyte donors were fasted overnight before cell isolation (data not shown). On the other hand, neither the activity of a nonadaptive enzyme, lactic dehydrogenase (Table 1, Expt. Series 3), nor the rate of incorporation of [^{3}H]leucine into FAS protein (Table 2) declined during the culture period. Hence, the decrease in the activities of FAS and ME observed could not be attributed to a loss in hepatocyte viability during the culture period but rather appears to be specific for only certain adaptive enzymes.

No significant difference could be found in the FAS and ME activities between cultures without added fatty acids or those with either oleate, linoleate or arachidonate (Table 1). To determine whether the fatty acids added to the medium were taken up and metabolized by the cells, the fatty acid composition of hepatocyte lipids also was measured. When either oleate, linoleate or arachidonate was added to the medium as the sole fatty acid, each readily was taken up by the hepatocytes (Table 3). Freshly isolated hepatocytes from HCTO–fed mice contained 3.5% of the n-9 fatty acid 20:3, a product of 18:1 metabolism, but after 70 hrs of culture these cells contained only 0.6% (Table 3). Surprisingly, the proportion of 20:4 in the cells did not increase when 18:2 was added to the medium, although 22:4 levels were increased when

TABLE 2

Incorporation of [^{3}H]Leucine into Fatty Acid Synthetase (FAS) and Total Soluble Protein (TSP) of Cultured Hepatocytes Isolated From Either HCTO-fed or CO-Fed Mice[a]

Diet fed hepatocyte donor	Hr in culture	Added fatty acid	[^{3}H]Leucine incorporation into TSP (cpm/0.1 ml cytosol)	[^{3}H]Leucine incorporation into FAS (cpm/0.1 ml cytosol)	FAS/TSP ($\times 10^2$)

18:0/18:1	0.15 ± 0	0.12 ± 0.01	0.34 ± 0.02	0.37 ± 0.04

[a]Results are presented as the mean percentage of total fatty acids ± SD for two experiments. Two cultures were analyzed for each condition in each experiment.

20:4 was the fatty acid added. The values for the ratios of 16:0/16:1 and of 18:0/18:1 were increased by the presence of either 18:2 or 20:4. Such findings suggest that desaturase activity was inhibited under these conditions, although elongation of 20:4 to 22:4 was not influenced.

The fatty acid composition of hepatocytes isolated from the livers of mice fed either the HCTO or the CO diet and cultured in fatty acid–free medium also was determined (data not shown). Under these conditions, a reduction in the percentage of polyunsaturated fatty acids and an increase in the proportion of oleate were observed. Based on experience with intact animals, this is exactly what one would expect to occur in the absence of exogenous PUFA.

The activities of lipogenic enzymes in cultures of hepatocytes from mice fed either the HCTO or the CO diet declined at the same rate. Since the time-course of change in enzyme activity is a function of the rate of degradation (24,25), the rate of degradation of FAS and ME appears to be unaffected by the previous nutritional state.

However, the data from the direct [^{3}H]leucine incorporation method (Table 2) show that the rate of synthesis of new FAS in hepatocytes is determined by the type of diet fed to the donor mice.

The relative rates of FAS synthesis were from two to five times higher for hepatocytes isolated from HCTO–fed mice than for those from CO–fed mice (Table 2, Expt. 2). The synthesis of FAS was maintained at a relatively constant rate during the 46–hr culture period in hepatocytes prepared from HCTO–fed mice. However, the relative rate of synthesis appeared to decline between 22 and 46 hr of culture in hepatocytes prepared from CO–fed mice. When either 18:1 or 20:4 was the sole fatty acid added to cultures of hepatocytes isolated from HCTO–fed mice, the values for the rates of incorporation of [^{3}H]leucine into FAS were the same (Table 2, Expt. 1). Indeed, the relative rates of synthesis of FAS in hepatocyte cultures in the presence of these fatty acids were comparable to those observed in the four hr cultures before adding the fatty acid–containing media. Thus, under these conditions, 20:4 did not depress the synthesis of FAS.

DISCUSSION

Studies with mice show that fats containing linoleate or other polyunsaturated fatty acids bring about a severe reduction in hepatic fatty acid synthesis (26) and depress the lipogenic response to refeeding (27). Allman and Gibson (26) and Muto and Gibson (28) suggested that polyunsaturated fatty acids are most effective in regulating hepatic lipogenesis in rats and mice. We found that a diet containing 15% safflower oil (linoleate content of more than 70%) reduced hepatic lipogenesis in both rats and mice (27). Musch et al. (29) have demonstrated that α-linolenate also decreased hepatic lipogenesis. Subsequently, we could show that dietary linoleate, α-linolenate, arachidonate and columbinate depressed hepatic lipogenesis and reduced the liver's content of key lipogenic enzymes (1,2). Hence, although it is well-established that di-and polyunsaturated fatty acids of both the n6 and n3 series depress hepatic lipogenesis, little is known about the mechanism and almost nothing is

known about the compound(s) that trigger the mechanism.

This study shows that FAS can be synthesized when the hepatocytes are cultured but the rates of synthesis always are higher when hepatocytes come from HCTO–fed than from CO–fed mice. In addition, the rates of decline in FAS and ME activities with time observed in these experiments with cultured hepatocytes suggest that the rate of enzyme degradation may not be affected by the previous nutritional state, since the time course of change in enzyme activity is a function of the rate of degradation (25,30) and not of synthesis. Hence, it would appear that the rates of synthesis in culture are not sufficient to maintain the enzyme content of these cells at a high level.

Since long-term regulation is accomplished through alterations in the rate of synthesis of key lipogenic enzymes, the decline in lipogenic enzymes in hepatocyte cultures indicates that important elements of the mechanism for long-term regulation either are missing or are not functional in such cultures. This would explain our finding that neither 18:2 nor 20:4 inhibit lipogenesis even though they readily are taken up and metabolized by the cells in these cultures.

Based on the values for the 16:0/16:1 and the 18:0/18:1 ratios of the total fatty acids from hepatocyte cultures, desaturase activity is inhibited by either 18:2 or 20:4. These results support the view that these polyunsaturated fatty acids enter the hepatocytes in sufficient quantities to affect some aspects of lipid metabolism and that regulation of the desaturase activity and the synthesis of lipogenic enzymes such as FAS and ME is accomplished through different mechanisms. Thus, it would appear that under certain conditions desaturase and fatty acid synthetase activities do not necessarily act in parallel as has been proposed by Jeffcoat and James (31).

Kelley et al. (12) reported that the prior dietary status of rats influences the activities of lipogenic enzymes in subsequent primary hepatocyte cultures. Hepatocytes obtained from rats fasted 24 hr and subsequently fed a high-carbohydrate diet for 48 hr yielded high values for liver FAS activity, which declined rapidly after the hepatocytes were cultured (12). Such results are consistent with our experience with mouse hepatocytes. However, these workers showed that when rats were fed a chow diet that contains a high PUFA content and thus similar to our corn oil-containing diet, FAS activity in such hepatocytes increased over two-fold during the culture period. We did not observe an increase in FAS activity in our primary mouse hepatocyte cultures.

Boogaerts et al. (32) have shown that hepatocytes in primary culture retain adaptive changes in lipogenesis and lipoprotein secretion induced in vivo by feeding rats a sucrose-enriched diet. The results of their study suggest that the increase in synthesis and secretion of triglyceride induced by media glucose is due to an increase in substrate availability rather than to long-term regulation that involves an increase in protein synthesis. Indeed, from this study with rats, Boogaerts et al. (32) suggested that the in vivo induction by dietary carbohydrate requires factors not contained within the isolated hepatocyte system. From the results presented here, we also have concluded that the long-term control of fatty acid synthesis exercised by certain dietary polyunsaturated fatty acids also does not occur entirely within the hepatocytes of the mouse.

Recently, Salati and Clarke (33) reported that saturated and polyunsaturated fatty acids equally suppress the hormonal induction of acetyl-CoA carboxylase in primary cultures of rat hepatocytes. Hence, the effect was nonspecific and therefore unrelated to the influence of dietary polyunsaturated fat on lipogenesis. These authors (33) suggested that an inhibitory factor derived from dietary polyunsaturated fatty acids might be produced in extrahepatic tissues and transported via the blood to the liver. Normal liver functions are known to be strongly influenced by the portal circulation (32,33–36), and thus the involvement of extrahepatic sites in hepatic adaptive processes appears feasible. Indeed, the liver appears to be the only tissue that responds to dietary polyunsaturated fat with a decrease in lipogenic capacity (17). Such additional evidence supports the hypothesis that substances in the portal circulation may play a role in long-term regulation of lipogenesis.

In conclusion, from the results presented here and by others (6–12,24,32,33,37), it would appear that certain adaptive changes caused by both carbohydrate and fat function only in intact animals and not in cultured hepatocytes. Therefore, it is possible that dietary constituents (i.e. carbohydrates and polyunsaturated fatty acids) induce in extrahepatic sites such as the gastrointestinal tract the production of regulatory compounds, which are transported via the portal vein to the liver where they may act on the hepatocyte apparatus responsible for the synthesis of the adaptive lipogenic enzymes. Thus, the polyunsaturated fatty acid-activated mechanisms for long-term regulation of fatty acid synthesis may not be contained entirely within the mouse hepatocyte. However, from the results obtained here it appears only those mechanisms that cause a suppression of desaturase activity by polyunsaturated fatty acids are still operational within the hepatocyte when cultured.

Effects of Cyclopropenoid Fatty Acids on Fungal Growth and Lipid Composition

Katherine M. Schmid[1] and **Glenn W. Patterson***
Department of Botany, University of Maryland, College Park, MD 20742

Cyclopropenoid fatty acids (CPE) isolated from *Sterculia foetida* oil by urea clathration and reverse phase high performance liquid chromatography (HPLC) were introduced into fungal cultures. Stearate levels in phospholipids and triacylglycerols from *Ustilago maydis* sporidia rose considerably in response to 30 μM CPE. In addition, CPE themselves were incorporated into glycerolipid fractions. Sterol composition was unaffected. Changes in lipid composition were accompanied by inhibition of dry weight accumulation and sporidial number. Treated sporidia showed irregular wall deposition and a branched morphology. Oleate alleviated CPE effects on growth and morphology. Hyphal extension by *Rhizoctonia solani* was inhibited somewhat by 30 μM sterculate, while *Fusarium oxysporum* showed no appreciable response. Although CPE appeared to inhibit fatty acid desaturation by *F. oxysporum*, gross increases in the proportion of stearate were limited to the triacylglycerol fraction during 30 μM treatments. The possibility that the CPE synthesized by plants serve as antifungal agents is discussed.

Lipids 23, 248-252 (1988).

Cyclopropenoid fatty acids (CPE), compounds synthesized both by plants allied with order Malvales and by certain gymnosperms (1–6), are well-known inhibitors of fatty acid desaturation in higher animals (6–8). Evidence that CPE also affect insect stearoyl-CoA desaturase (9,10) and interfere with the maturation and reproduction of some insect species (9–12) prompted suggestions that in addition to their traditional role as storage lipids, CPE also serve as protective agents (9,10).

Similarities between animal and fungal Δ^9 desaturase systems (13) led us to hypothesize that CPE also play an antifungal role in plants. Early work by Reiser et al. (14) indicated that *Saccharomyces cerevisiae* accumulates palmitate (16:0) at the expense of palmitoleate (16:1) when treated with CPE-containing *Sterculia foetida* oil. Recently, Moreton (15) reported that although tested *S. cerevisiae* strains did not respond to CPE these compounds increased the proportion of saturated fatty acids in several other yeasts. Here, we present evidence that CPE inhibit fatty acid desaturation in two fungi of interest to plant pathologists. We also report that low levels of CPE interfere with cytokinesis by sporidia of *Ustilago maydis*.

Abbreviations: CPE, cyclopropenoid fatty acids; HPLC, high performance liquid chromatography; TLC, thin layer chromatography.

MATERIALS AND METHODS

Isolation of CPE methyl esters. Two CPE, sterculate (1-cyclopropene-1-octanoic acid, 2-octyl) and malvalate (1-cyclopropene-1-heptanoic acid, 2-octyl), were isolated from *Sterculia foetida* oil. The oil was transesterified with sodium methoxide, and the methyl esters sere subjected to urea clathration (16,17). Clathration mixtures containing 15 g urea, 4 ml methanol and 40 ml petroleum ether/g of methyl ester generated filtrates containing primarily sterculate, malvalate and linoleate (18:2). Individual CPE then were isolated by reverse phase high performance liquid chromatography (HPLC) on a Varian Model 5000 liquid chromatograph equipped with an 8 mm X 30 cm Varian MicroPak MCH-10 semipreparative column. Peaks were eluted with acetonitrile/water (82:18, v/v) at 6 ml/min and detected at 200 nm. Samples up to 15 μl gave separations similar to those obtained by Loveland et al. (18) using an analytical protocol. Although 16:0 and 18:1 overlap the sterculate peak under these conditions, removal of the bulk of these compounds by clathration and collection of the peak after the leading edge had reached half-height permitted sterculate preparations exceeding 97% purity by gas chromatography. Due to the relative stability of CPE methyl esters compared to free CPE, the purified methyl esters were used directly in fungal treatments. For the purposes of this study, it was hypothesized that metabolism of these methyl esters by fungi is analogous to metabolism of the natural glycerol esters.

Culture methods. Ustilago maydis (DC) Cda., ATCC 14826 sporidia were grown on a 200 rpm rotary shaker for periods up to 64 hr. Temperatures ranged from 26–30 C. The culture medium of Coursen and Sisler (19) was supplemented with 2.0 g KH_2PO_4 and 1.5 g K_2HPO_4 per liter (medium 72). Fatty acid methyl esters were added in 4 or 5 ml methanol per l; control flasks contained the corresponding amount of pure methanol.

Fusarium oxysporum Schlecht isolated by Kaufman and Blake (20) was maintained on potato dextrose agar. The liquid medium used for fatty acid analysis work contained 0.6 g KH_2PO_4, 0.2 g K_2HPO_4, 0.2 g NH_4NO_3, 0.2 g $MgSO_4 \cdot 7H_2O$, 1 mg $FeSO_4 \cdot 7H_2O$, 2.0 g sucrose and 1.0 g yeast extract per liter with an initial pH of 6.3 (21). Mycelium was transferred from a plate to liquid culture three days before an experiment and to fresh medium twice before inoculation of the test cultures. Methyl esters were added to the latter as above, and cultures were grown for 16 hr at 30 C on a 200 rpm rotary shaker. *Rhizoctonia solani* Kuhn AG 4, isolate SN-1 of A. Ogoshi, was grown on potato dextrose agar.

Morphological studies. Fluorescence microscopy was performed on a Leitz SM-LUX microscope with Epi-Fluorescence and a 100 W ultra-high pressure mercury lamp. Cell wall material was stained with 0.2% Calcofluor White (22) and observed using a UG-1

excitation filter, a TK400/K430 suppression filter and a K430/K460 barrier filter. Nuclei stained with mithramycin (23) were observed using a KP500 excitation filter, a TK510/K515 suppression filter and a K510/530 barrier filter.

Growth measurements. For dry weight measurements, 40–ml aliquots of liquid cultures were pelleted. Fungal material was washed twice with distilled water, transferred to tared pans, and dried at 80 C for 24 hr. For cell counts and viability studies, sporidia were diluted appropriately and vortexed briefly to minimize clumping. Any remaining clumps observed in the hemocytometer were registered as single branched cells. Viability tests were performed on medium 72 plates containing 20 g agar per liter. Colonies were counted after two to three days. Hyphal extension rates were determined on plates containing potato dextrose agar supplemented with either 30 μM methyl sterculate in methanol (4 ml/l medium) or methanol alone.

Lipid analysis. Ustilago maydis and *Fusarium oxysporum* harvested by centrifugation were washed twice with distilled water, flash frozen and lyophilized. Dry material was homogenized and extracted with chloroform/methanol (2:1, v/v) at room temperature for one hr with agitation. Extraction mixtures were supplemented with an internal standard containing tripentadecanoin, diheptadecanoyl phosphatidylcholine and methyl nonadecanoate.

Filtered extracts were separated into two fractions on BioSil A (BioRad, Richmond, CA) columns (24). Neutral lipids were eluted with chloroform followed by acetone. Phospholipids were flushed from the BioSil with methanol. Neutral lipids were further fractionated by thin layer chromatography (TLC) on aluminum–backed plates coated with 0.2 mm Silica Gel 60F-254 (EM Science, Cherry Hill, NJ) and developed with petroleum ether/diethyl ether (85:15) (25). Bands were visualized with Rhodamine 6G. For gas chromatography, glycerolipid fractions were transesterified with room temperature sodium methoxide (16). Free fatty acid fractions were methylated with boron trichloride/methanol (10% w/v) (Applied Science Lab, Deerfield, IL) at 60 C (26). Fatty acid methyl ester fractions from derivatization mixtures or from TLC plates were transferred to hexane, washed with water and dried over anhydrous sodium sulfate before gas chromatography.

Analyses were performed on a Varian 3700 Gas Chromatograph coupled with a Varian Vista 401 Chromatography Data System. Detection was carried out at 240 C by an Aerograph Flame Ionization Detector given 30 ml/min hydrogen and 300 ml/min air. With the exceptions of methyl oleate (18:1), methyl linoleate (18:2) and methyl linolenate (18:3), all methyl esters present in significant quantities could be separated on a 6 ft X 1/16 in ID glass column packed with 3% SP-2100 on 80/100 Supelcoport (Supelco Inc., Bellefonte, PA) (27). The injection temperature was 220 C, the column temperature 180 C and the helium flow 29 ml/min. The 18:1/18:2/18:3 ratio was determined at 210 C on a 60 m X 0.25 mm inside diameter fused silica capillary with a 1 micron film of SPB-1 (Supelco). The injection temperature was 220 C, the helium carrier flow 0.63 ml/min, and the split ratio 40/1. Helium make-up gas was supplied at 30 ml/min.

For sterol analysis, crude extracts were saponified under nitrogen and fractionated by alumina column chromatography (28). Sterols were quantitated by gas chromatography at 240 C on a 6 ft $\times$ 1/16 in glass column packed with 3% SE-30 on 100/120 Gas-Chrom Q (Applied Science). The injector temperature was 290 C, the detector temperature 300 C, and the helium flow 11 ml/min.

RESULTS

Lipid composition. CPE had two major effects on lipid compositions of *Ustilago maydis* and *Fusarium oxysporum*. First, the two fungi were able to incorporate CPE into both phospholipids (Table 1) and triacylglycerols (Table 2). CPE incorporation by *U. maydis* was more pronounced than incorporation by *F. oxysporum*. Traces of sterculate were detected in *U. maydis*

TABLE 1

Fatty Acid Composition of Phospholipids from *Ustilago maydis* and *Fusarium oxysporum*

sporidia grown in 1 μM sterculate. After 30 μM treatments, CPE comprised more than 20% of glycerolipid fatty acids in this organism. Phospholipids and triacylglycerols from *F. oxysporum* given 30 μM sterculate contained less than 2% CPE. In all, roughly 10% of the CPE added to *F. oxysporum* cultures during 30 μM treatments was recovered from the fungal tissue. Per gram of lyophilized material, 0.2 mg sterculate was recovered in the original methyl ester form, another 0.2 mg from the triacylglycerols and 0.5 mg from the phospholipid fraction. *U. maydis*, on the other hand, accumulated 50% of the material added: 0.2 mg/g dry weight as methyl esters, 5.4 mg in the phospholipids and 5.1 mg in the triacylglycerols. No CPE were recovered in free fatty acids from either species, although the relative instability of free CPE (29–30) should be kept in mind. Malvalate accumulation by *U. maydis* was comparable to sterculate accumulation.

Acyl lipids from CPE-treated fungi also were more saturated than control lipids. *U. maydis* sporidia showed a clear increase in triacylglycerol 18:0 following 1 μM sterculate treatments, although phospholipid fatty acids were relatively unaffected. When cultures were supplemented with 30 μM sterculate, the proportion of 18:0 in triacylglycerols rose from 9 to 44% in *U. maydis* and from 7 to 32% in *F. oxysporum* (Table 2). The proportion and quantity of 18:0 in *U. maydis* phospholipids also increased substantially under these conditions, whereas *F. oxysporum* phospholipids were relatively unaffected by 30 μM sterculate (Table 1).

Despite the large shifts in *U. maydis* fatty acid composition induced by 30 μM sterculate or malvalate, sterol profiles of treated sporidia were indistinguishable from those of controls. Ergosterol, the primary sterol in all samples examined, remained at levels around 2.4 mg per gram dry wt.

Growth and morphology. On plates containing 30 μM sterculate, *Rhizoctonia solani* AG4 hyphae grew at about three-fourths of their rate on control plates. Hyphal extension by *F. oxysporum* was unaffected under the same conditions. Dry wt of *F. oxysporum* in liquid cultures also showed no consistent inhibition by 30 μM sterculate. Reduced dry weight accumulation by *U. maydis* cultures was evident at CPE concentrations as low as 10 μM and approached a maximum inhibition at concentrations greater than 30 μM (Fig. 1). There was no indication that *U. maydis* sporidia differed in their response to sterculate and malvalate.

Progress in dry weight accumulation and sporidial number during batch culture of *U. maydis* is illustrated in Figure 2. Whereas dry weights in cultures treated with 30 μM sterculate diverged from those in control cultures only after the latter had reached the late log phase, the number of sporidia in treated cultures was severely depressed within 12 hr and remained virtually unchanged while control cultures passed through log phase and into stationary phase. That cultures eventually recovered from the treatment is evident by either measurement and probably reflects depletion of CPE from the medium.

Morphologically, almost all control sporidia were cigar-shaped and divided longitudinally (Fig. 3A); they retained these characteristics in the presence of

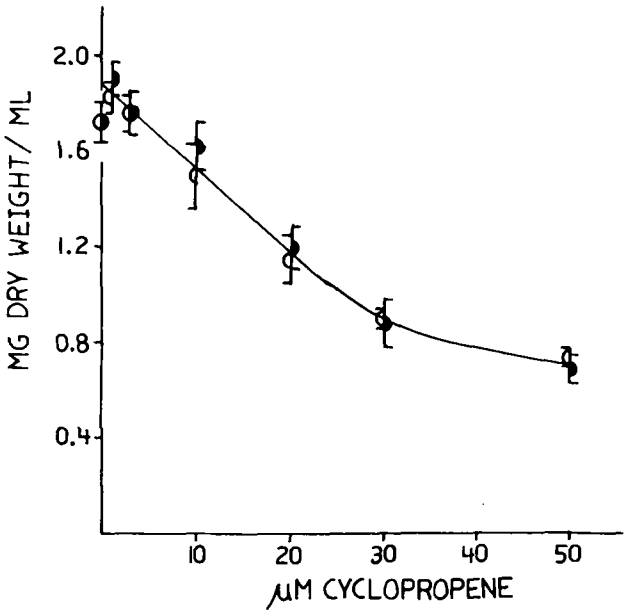

FIG. 1. Effects of CPE methyl ester concentration on growth of *Ustilago maydis* sporidia (mg dry wt/ml culture medium). Cells were harvested after 20 hr growth, washed twice with distilled water and dried at 80 C. ∮ = sterculate; ∮ = malvalate. Bars represent standard errors of six flasks.

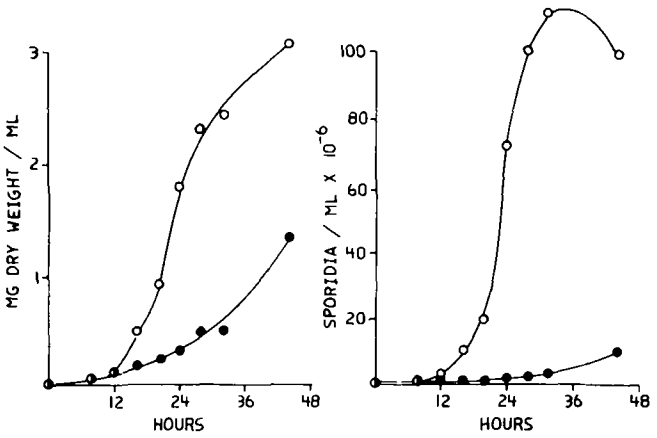

FIG. 2. Growth of *U. maydis* sporidia in the presence of 30 μM methyl sterculate. A, Dry wt accumulation over time (mg/ml). B, Changes in number of sporidia over time (sporidia/ml). Sporidia were grown on a 200 rpm rotary shaker at 30 C. Points represent average values for four flasks from two experiments. ○, control; ●, 30 μM sterculate treatment.

methyl 16:0, methyl 18:1 or methyl 18:2. In contrast, populations treated with methyl CPE were heterogeneous. Some cells were indistinguishable from control cells. Other sporidia became excessively elongate, while many became branched and tended to clump. Among branched sporidia, simple Y-shapes predominated at earlier times. Increasingly, bizarre forms and clumping became common as the treatment progressed. Figures 3B-D illustrate sporidia showing swollen areas and varying degrees of branching.

The morphological symptoms discussed appear linked to a failure in cytokinesis. Mithramycin staining revealed multiple nuclei in both branched and ab-

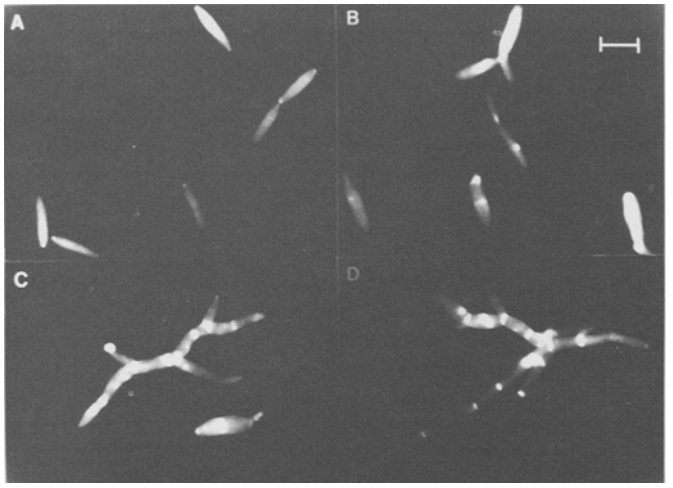

FIG. 3. Calcofluor staining of *U. maydis* sporidia. A, control sporidia; B-D, treated sporidia; bar, 10 μm.

normally long sporidia. Ordinary cigar-shaped cells had one or in cells approaching division two nuclei. Calcofluor staining of cell walls showed that the CPE-affected cells were multicellular (Figs. 3B-D). Septum formation did occur but the daughter cells failed to pinch off. Irregular patches of staining along the walls of treated cells may indicate abnormalities in the deposition of wall material.

The maximum number of *U. maydis* colony forming units in the presence of CPE would be limited both by the reduced number of sporidia available and by their viability. Approximately 30% of sporidia in cultures in which 22% of individuals were branched failed to produce colonies.

Relief of CPE effects by oleate. The effects of sterculate on sporidia could be mitigated by 18:1 (Table 3). Under conditions in which 30 μM sterculate reduced dry weight production to 47% of the control level, cultures given 30 μM sterculate plus 30 μM 18:1 showed normal dry wt accumulation. The number of sporidia and the proportion of branched sporidia in cultures treated with the fatty acid mixture were intermediate between values for controls and for cultures given only sterculate.

DISCUSSION

As discussed earlier, CPE inhibit Δ^9 fatty acyl desaturase in a number of organisms and might be expected by analogy to affect desaturation in fungi. In vertebrate and insect systems, various secondary disorders also are associated with CPE ingestion (6,9–12). This research was undertaken to determine whether CPE shift fatty acid profiles in fungi and, if so, whether they are detrimental to the organisms. It was hypothesized that CPE play a role as protective agents in plants.

The elevated 18:0 levels expected if CPE inhibit stearoyl-CoA desaturase were observed both in *Ustilago maydis*, the basidiomycete responsible for corn smut, and in *Fusarium oxysporum*, a filamentous imperfect fungus. In both organisms, triacylglycerol fatty acid composition responded to CPE more readily than did phospholipid composition, although both fractions showed a sizable response when *U. maydis* sporidia were treated with 30 μM CPE. Increased saturation of bulk lipid also has been reported to follow CPE treatment of some basidiomycetous and ascomycetous yeasts (14,15). A second effect of CPE on lipid composition, incorporation of the compounds into triacylglycerols and phospholipids, has not been reported previously for fungal systems (14,15). CPE are found in acyl lipids from treated vertebrates (31,32) and cultured hepatoma cells (33) but accumulate preferentially in the triacylglycerol fraction (32,33).

Dry weight accumulation by *U. maydis* cultures was inhibited by CPE levels as low as 10 μM. In animal systems, both desaturation in vitro and secondary effects in vivo are less responsive to malvalate than to sterculate (7,31). However, in this study there was no indication that *U. maydis* differentiated between the two. Plots of dry weight accumulation vs methyl sterculate and methyl malvalate concentrations (Fig. 1) were indistinguishable at a 5% confidence level. Increases in 18:0 and CPE incorporation also were similar for the two compounds.

The morphological responses of *U. maydis* sporidia to CPE were very similar to those reported for sporidia deficient in ergosterol. Sporidial branching is characteristic both of cultures exposed to fungicides inhibiting ergosterol biosynthesis (34) and of a mutant blocked at the C-14 demethylation step (35). In the same vein, Calcofluor staining and electron microscopy reveal irregular wall deposition in fungicide-treated *Ustilago* (36,37) and other fungi (38–40). Inhibition of ergosterol synthesis by CPE, therefore, might have been expected, particularly given the decreased levels of cytochrome P450 in trout fed the compounds (41). Nevertheless, sterol profiles of sporidia treated with 30 μM CPE mirrored those of control cells.

At the same time, it seems unlikely that these paral-

TABLE 3

Effects of Oleate on CPE-Induced Symptoms in *U. maydis* Sporidia

Treatment	Dry weight (mg/ml)	Sporidia/ml	% Branched sporidia
Control	0.32 ± 0.09	$(11.9 \pm 3.2) \times 10^6$	3.4 ± 1.4
30 μM Sterculate	0.15 ± 0.02	$(1.8 \pm 0.8) \times 10^6$	17.9 ± 3.0
30 μM 18:1	0.34 ± 0.08	$(13.3 \pm 3.9) \times 10^6$	4.2 ± 0.5
30 μM Sterculate + 30 μM 18:1	0.31 ± 0.03	$(9.0 \pm 2.0) \times 10^6$	7.6 ± 1.1

lels are coincidental. Discussions of ergosterol deficiency symptoms often note that wall deposition requires membrane-bound enzymes and suggest a link between altered membrane composition and changes in fungal morphology (34,37,40,42). A similar argument would hold for CPE-treated *U. maydis*, in which comparable irregularities are accompanied by severely altered phospholipid fatty acids. The contention that changes in fatty acid composition ultimately are responsible for CPE-induced changes in morphology is supported by the observation that 18:1, the product of the desaturation reaction blocked by CPE, suppresses development of the symptoms.

Whatever the specific mechanisms by which CPE affect *U. maydis* growth and morphology, the observation that they do so is consistent with the hypothesis that CPE serve as antifungal agents. Not all fungi are equally sensitive: when *Rhizoctonia solani* and *Fusarium oxysporum* were grown under identical conditions, hyphal extension by *R. solani* was somewhat inhibited by 30 μM CPE, while *F. oxysporum* appeared to grow normally. The resistance of *F. oxysporum* may be linked to an ability to degrade or exclude the compounds, since only about 10% of the CPE added to liquid cultures of the fungus was recovered. Also of interest is the finding that in contrast to the situation in the sensitive *U. maydis*, *F. oxysporum* phospholipids were relatively stable in the presence of 30 μM CPE. Variations in fungal susceptibility to CPE also have been noted by Moreton (15), who found that while most yeasts tested grew normally except at very high CPE concentrations some strains of *Lipomyces* were unable to grow in their presence.

Further work is needed to determine the range of fungi reacting to CPE and the levels of these compounds available to the organisms in vivo. We find that CPE levels in roots of several Malvaceous species exceed those used in this study (43). The observation that 18:1 will alleviate symptoms induced in *U. maydis* by CPE suggests that the fatty acid background in which CPE occur also will be significant. The response of fungi to natural CPE-containing mixtures is likewise of interest given that at least some CPE-producing plants also synthesize low levels of epoxy fatty acids (3), compounds that are fungistatic against *Pyricularia oryzae* (44).

ACKNOWLEDGMENTS

This paper is Scientific Article No. A-4593, Contribution No. 7689 of the Maryland Agricultural Experiment Station. We thank N.E. Pawlowski for the *Sterculia foetida* oil, R.H. Leiner for the *Rhizoctonia solani* culture, J.J. Motta for use of the fluorescence microscope and H.D. Sisler for his advice and encouragement.

METHODS

Quantitation of 1,2-Diacylglycerol in Rat Heart by Iatroscan TLC/FID

Kenji Okumura*, Hidekazu Hashimoto, Takayuki Ito, Kouichi Ogawa and Tatsuo Satake

The Second Department of Internal Medicine, Nagoya University School of Medicine, Nagoya 466, Japan

1,2-Diacylglycerol, which has been recognized as one of the intracellular second messengers, was measured quantitatively in the lipid extract from rat hearts using the thin layer chromatography and flame ionization detection (TLC/FID) method. Cholesterol acetate was added to the tissue as an internal standard, and the crude lipids from the tissue were purified with silicic acid column to eliminate phospholipids. Development of Chromarods was carried out using two solvent systems and a three-step development technique. The relationship of the peak area ratio detected by flame ionization detector to weight ratio was linear compared with cholesteryl acetate. The 1,2-diacylglycerol content in the rat heart in the unstimulated condition was 72.5 ± 15.3 ng/mg wet wt (mean ± SD).

Lipids 23, 253–255 (1988).

It is accepted widely that hormones and neurotransmitters that elicit intracellular mobilization of Ca^{++} cause phosphoinositide hydrolysis by phospholipase C. The products of this reaction, inositol triphosphate and 1,2-diacylglycerol (DG), both play an important role in the signal transduction process (1,2). An increase in 1,2-DG content in the tissue is thought to have multiple metabolic roles. 1,2-DG produces the activation of protein kinase C and releases fatty acids including arachidonate. Accordingly, 1,2-DG has been recognized as one of the second messengers in the transmembranous cellular signal transduction process. Despite recent interest in the role of 1,2-DG, very few direct measurements have been made on the extent and duration of the 1,2-DG accumulation in response to hormones because of the small amount in the tissue. Therefore, it is difficult to estimate the exact amount of 1,2-DG. In particular, the function and role of 1,2-DG accumulation in the myocardium is unknown. Although lipids labeled with radioactive fatty acids, followed by separation of 1,2-DG by thin layer chromatography (TLC), have been used often (3), this method does not provide a quantitative estimate of 1,2-DG content. For quantitative measurement for tissue 1,2-DG, TLC (4), gas liquid chromatography mass spectrometry (5), and high performance liquid chromatography (HPLC) have been used (6). We have employed a modification of the TLC/FID (flame ionization detection) method for a reliable quantitative estimate of tissue 1,2-DG.

MATERIALS AND METHODS

Materials. 1,2,3-Tri-*cis*-9′-octadecenoyl-*rac*-glycerol (triolein), *cis*-9′-octadecenoic acid (oleic acid), cholesterol, 1,3-di-*cis*-9′-octadecenoyl-*rac*-glycerol (1,3-diolein), 1,2-di-*cis*-9′-octadecenoyl-*rac*-glycerol (1,2-diolein) and 1-*cis*-9′-octadecenoyl-*rac*-glycerol (monoolein) were purchased from the Sigma Chemical Co. (St. Louis, MO). Cholesteryl acetate and butylated hydroxytoluene were obtained from the Wako Chemical Co. (Osaka, Japan). All other chemicals were of analytical reagent grade. Adult male Wistar rats weighing 200–300 g were deprived of food for 12 hr overnight but allowed free access to water. Following decapitation, the heart rapidly was excised and washed with normal saline. A 60–80 mg tissue sample from the left ventricle near the apex was removed and frozen rapidly in liquid N_2.

Instrumentation. Sample analyses were carried out with the Iatroscan TH-10 TLC/FID analyzer (Iatron Inc., Tokyo, Japan) under the following conditions: flow-rate of hydrogen, 160 ml/min; flow-rate of air, 2000 ml/min; and a scan speed, 2.39 sec/cm. Silicagel, 75-μm precoated thin-layer rods (Chromarods-SII, Iatron Inc., Tokyo, Japan) were in sets of 10. Peak areas were calculated using a potentiometric recorder (Chromatocorder 11, System Instrument, Tokyo, Japan) connected to the analog output of the Iatroscan TH-10.

Neutral lipid extraction. Lipids were extracted by the method of Folch et al. (7) with some modification. The sample was placed in 5.5 ml ice-cold chloroform/methanol mixture (2:1, v/v) containing 0.01% butylated hydroxytoluene as an antioxidant and cholesteryl acetate (0.1 mg per tube) as an internal standard, and homogenized in a motor-driven Potter-Elvehjem homogenizer kept in ice for 20 sec as soon as the tissue began to soften. The homogenate was chilled on ice for 30 min and filtered through Toyo filter paper. The filtrate was evaporated to dryness under a stream of N_2 at 30 C. Dried lipids were resuspended in 500 μl of chloroform and applied to 0.5-ml silicic acid (minus 325 mesh from Bio-Rad, Richmond, CA) column (20 mm x 5.5 mm), equilibrated with chloroform. Neutral lipids and free fatty acids were eluted thoroughly with 6 ml chloroform, concentrated under a stream of N_2 at 30 C, and dissolved in 20 μl chloroform.

Chromarod development and scanning. The Chromarods were activated by passing through the Iatroscan TH-10 analyzer before use. Two μl of the lipid extracts was applied carefully to the rods with a 10 μl Hamilton syringe. The set of rods was equilibrated before each development for five min over the developing solvent. The first development was carried out in a solvent system of 1,2-dichloroethane/chloroform/acetic acid (46:8:0.05, v/v/v) until the solvent front had migrated ca. 9 cm. The rods were air-dried at room temperature for 15 min, then were subjected to the second development in the same way as the first one. After the rods were dried as above for 15 min, the last development was carried out in a solvent system of *n*-hexane/diethyl ether/acetic acid (98:2:1, v/v/v) in the same direction until the solvent front had mi-

grated ca. 11 cm. Chromarods then were dried at 50 C and scanned in the Iatroscan TH-10. Each sample was analyzed with four Chromarods, and the results were averaged.

RESULTS AND DISCUSSION

The separation pattern of the standard mixture under the above mentioned condition is shown in Figure 1. The relative mobilities (R_f values) of butylated hydroxytoluene, cholesteryl acetate, triolein, oleic acid, cholesterol, 1,3-diolein and 1,2-diolein (ca. 0.4:2:1:1:1:1:1; by weight) were 0.90, 0.75, 0.63, 0.50, 0.35, 0.24, and 0.16, respectively. However, the R_f value of each authentic lipid upon separate developing was a little different from that in the standard mixture solution. Monoolein migrated a little (R_f=0.03, data not shown). These standard mixtures gave a very good separation of neural lipids. Figure 2A shows the peaks of 1,2-diolein and cholesteryl acetate (1:15, w/w) standard mixture solution. After the entire extraction procedure utilized here for rat hearts, the ratio of 1,2-diolein/cholesteryl acetate was not changed compared with that before the extraction as shown in Figure 2B. The recovery of 1,2-diolein by the extraction involving the silicic acid column procedure compared with cholesteryl acetate (i.e. the change in the ratio of the two) was 99.5±9.4% (SD, n=4), indicating that the intraassay coefficient of variation was 9.5% in the extraction and assay according to this method. The cholesteryl acetate and 1,2-DG peaks also were separated well in the extract from rat hearts containing cholesteryl acetate as an internal standard although triglycerides and free fatty acids were not clearly separated (Fig. 3A), and 1,2-diolein (1/15 of cholesteryl acetate, w/w) added to the tissue before the extraction migrated on the same peak of 1,2-DG in the myocardium, confirming that peak b in Figure 3A corresponds to the 1,2-DG peak (Fig. 3B). The standard curve for weight ratio and peak area ratio of 1,2-diolein to cholesteryl acetate is illustrated in Figure 4 and conform to the linearity throughout the ratio range tested. On the basis of the improved TLC/FID method, 1,2-DG content in rat hearts was 72.5±15.3 ng/mg wet wt (mean ± SD, n=8), whereas cholesterol content was 1.77±0.17 μg/mg wet wt (n=8).

Recently, it has been suggested that 1,2-DG is formed from phosphatidylcholine by agonists that stimulate protein kinase C as well as from phospho-

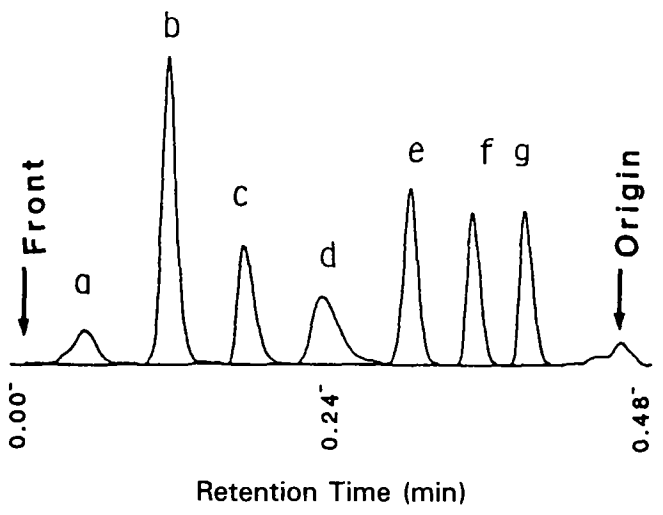

FIG. 1. TLC/FID analysis of the standard lipids. The peaks are as follows: a, butylated hydroxytoluene; b, cholesteryl acetate; c, triolein; d, oleic acid; e, cholesterol; f, 1,3-diolein; g, 1,2-diolein. First and second developments in 1,2-dichloroethane/chloroform/acetic acid (46:8:0.05, v/v/v) to 9 cm; third development in *n*-hexane/diethyl ether/acetic acid (98:2:1, v/v/v) to 11 cm.

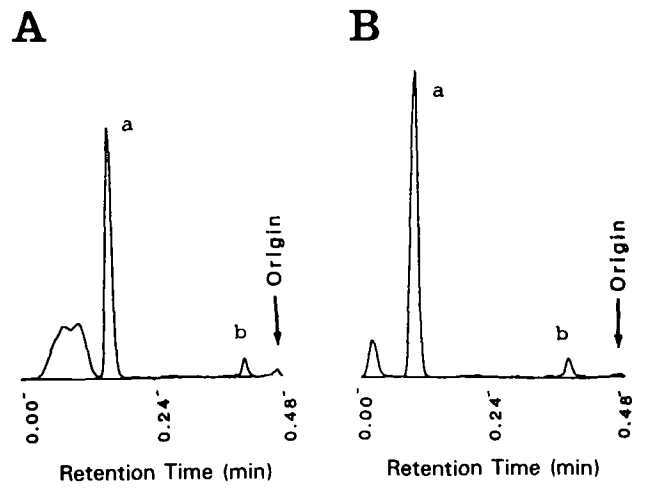

FIG. 2. TLC/FID analysis of 1,2-diolein (b) and cholesteryl acetate (a) standard mixture (1:15, w/w) with (B) and without (A) silicic acid column procedure, indicating that silicic acid column chromatography will not affect adversely the quantitative recovery of these compounds.

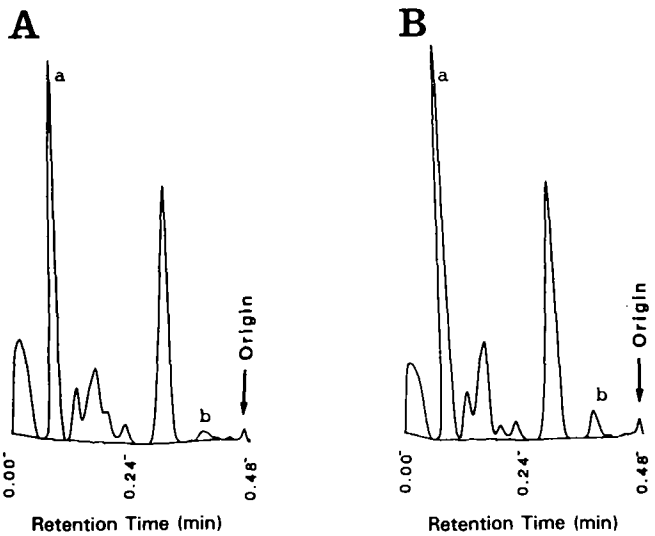

FIG. 3. TLC/FID separation of the tissue sample from rat heart (A) and the 1,2-diolein added tissue sample (B) (1:15 ratio of the added 1,2-diolein amount *[b]* to cholesteryl acetate as an internal standard *[a]*).

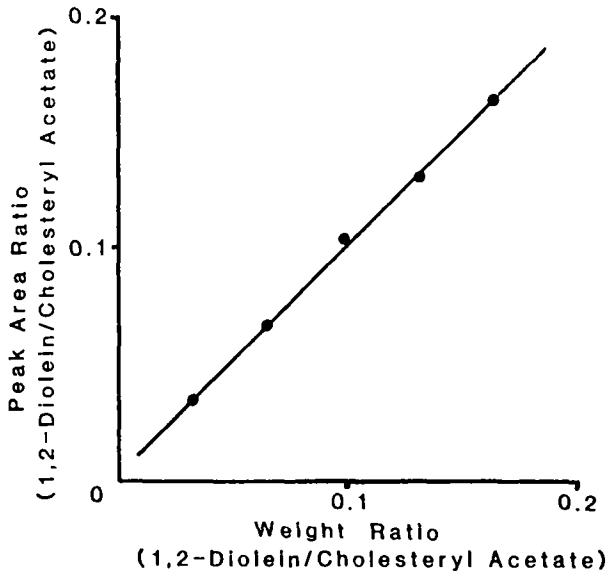

FIG. 4. The relationship between weight ratio and peak area ratio of 1,2-diolein to cholesteryl acetate by the FID response.

inositide hydrolysis (8). 1,2-DG is also a central intermediary metabolite in phospholipid and triglyceride synthesis. Despite recent interest in the role of phosphoinositide hydrolysis and 1,2-DG accumulation, few direct measurements of 1,2-DG have been made in tissue. Labeling of lipids with radioactive fatty acids may lead to mistaken conclusions about changes in 1,2-DG content when specific activity of the precursors and the fatty acid composition of 1,2-DG are unknown. The HPLC method for the estimation of 1,2-DG content has been developed recently (6,9), but TLC methods that have been used widely for lipid separation reveal a 1,2-DG spot isolated from other lipids, and they are very simple and fast. The difficulty in using the TLC method is quantitative estimation of 1,2-DG, because of the need for scraping plates and then re-extracting lipids. Therefore, accurate evaluation of 1,2-DG content is likely to be compromised.

This study established the method using TLC/FID to evaluate the amount of 1,2-DG. The phospholipid composition has been examined in the myocardium using TLC/FID (10,11). Christie and Hunter (12) have shown a separation of neutral lipids by means of the Iatroscan TH-10 analyzer. We chose cholesteryl acetate as an internal standard to enable quantitative estimation of 1,2-DG and cholesterol content. A three-step development of the neutral lipids on Chromarods in the same direction gave a good separation. The neutral lipids were separated by a silicic acid column because, in the presence of phospholipids, the resolution of 1,2-DG is not clear. Based on the analysis of the improved TLC/FID methods presented here, the 1,2-DG content in the myocardium is one-third and one-half of those previously reported for gerbil brain with TLC (13) and for isolated hepatocytes with HPLC (9), respectively. However, it almost is compatible with those from gerbil brain using HPLC (6) and from rat hearts using TLC (14). Both studies utilized a quick freezing and careful extraction method. This discrepancy of the control value of 1,2-DG content in tissues not only is due to differences among species and organs but may be due to the technique used to extract 1,2-DG.

In summary, we demonstrated a method for determining 1,2-DG content in myocardial lipids using a TLC/FID technique.

Long-chain Alkanediols: Biological Markers for Cyanobacterial Contributions to Sediments

R.J. Morris[*,a] and **S.C. Brassell**[b]

[a]Institute of Oceanographic Sciences, Brook Road, Wormley, Godalming, Surrey GU8 5UB, U.K., [b]Organic Geochemistry Unit, School of Chemistry, University of Bristol, Bristol, Avon BS8 1TS, U.K.

One significant family of sedimentary lipids of widespread occurrence are series of C_{28}-C_{32} alkanediols and hydroxyketones. The recognition of the same series of alkanediols as major lipid components of a field population of the cyanobacterium *Aphanizomenon flos-aquae* leads us to propose that these lipids are markers for cyanobacterial inputs to sediments. The frequency of occurrence of the alkanediols in sedimentary environments supports the recent finding that cyanobacteria are major contributors to the aquatic biomass.

Lipids 23, 256-258 (1988).

An increasing number of the lipid components recognized in sediments have become established markers of contributions from specific organisms (1,2). For example, sedimentary 4-methylsterols (3–5) and 4-methylsterones (5) are derived from dinoflagellates, various acyclic isoprenoids are indicators of methanogenic (6) or other archaebacteria (7), long-chain alkenones originate from prymnesiophyte algae (8,9) and *n*-alkane distributions with an odd/even predominance in the C_{27}–C_{33} range denote contributions from higher plants (10).

Long-chain C_{28}-C_{32} alkane-1,15-diols together with a series of related 15-oxyalkan-1-ols first were recognized in Unit 1 sapropellic sediments from the Black Sea (11). Their structures were deduced from the mass spectral characteristics of their trimethylsilyl derivatives by analogy with synthetic, shorter chain standards (i.e. octadecane-1,12-diol and 12-oxyoctadecan-1-ol) (11). Similar series of alkanediols now have been found, often as major components, in a wide range of marine sediments (Table 1) and also have been observed in both recent (17,18, N. Robinson, G. Eglinton and P.A. Cranwell, unpublished data) and ancient (17) lacustrine sediments. Typically, they range from C_{28} to C_{32} with the mid-chain hydroxyl group in a number of positions (12) but dominantly at C-13 and C-15 for the C_{28} and C_{29}, and C_{30}-C_{32} components, respectively. The biological origins of these significant compounds and their related oxyalkanols have been the subject of much speculation and interest (11–13,19,20), which is resolved by this report of their discovery in a field population of the cyanobacterium *Aphanizomenon flos-aquae*.

EXPERIMENTAL

Samples were collected during a research cruise of RV Aranda in the Baltic Sea (59°50.99'N, 24°49.88'E) on July 25, 1984, while a virtually unispecies bloom of *Aphanizomenon flos-aquae* (M. Huttunen, personal communication) was in progress. Water was pumped from 3 m depth and passed through a continuous-flow spinning cup centrifuge (21,22) at a flow rate of 5 liters/hr^{-1}. Under these conditions, the effluent contains no particles > 1 μm (22). The wet cells were removed from the cup, an aliquot was taken for phytoplankton counting and identification and the remainder was placed directly in $CHCl_3$/MeOH (2:1, v/v) at - 30 C under N_2. Lipids were extracted (23), saponified and separated into acidic and neutral lipid fractions (24). Both fractions were analyzed by gas chromatography (GC), after methylation (BF_3/MeOH) and silylation (BSTFA), respectively, using a Carlo Erba 4160 instrument equipped with an on-column injector and fitted with a SE-30 flexible silica capillary column (25 m × 0.3 mm id), temperature programmed from 40–100 C at 8 C min^{-1} and then 100–280 C at 4 C min^{-1}. The detector was held at 300 C and the injector at 40 C. Lipid identification was made by gas chromatography-mass spectrometry (GC-MS), employing a Carlo-Erba Mega chromatograph equipped with an on-column injector and fitted with an OV-1 flexible silica column (22 m), temperature programmed from 50–140 at 6 C min^{-1}, then 140–300 at 4 C min^{-1}, and interfaced directly to a Finnigan 4000 quadrupole mass spectrometer scanned from m/z 50-600 at one sec intervals. Data acquisition and processing utilized an INCOS 2300 data system.

RESULTS AND DISCUSSION

Examination of the extractable lipids revealed an assemblage typical of phytoplankton. The principal constituents were phytol, carboxylic acids, sterols, alkanols and hydrocarbons (Table 2) together with a significant proportion of C_{28}-C_{32} alkanediols. The alkanediols were characterized from the mass spectra of their tetramethysilane (TMS) ethers that permitted elucidation of the position of the mid-chain hydroxyl group and the presence of double bonds from the m/z values of key fragment ions (11,12). Such mass spectral features enabled the recognition of the various isomers present (e.g. 1,13-,1,14- and 1,15-triacontanediols), despite their GC coelution. The range of alkanediols in the cyanobacterium population (Fig. 1) was similar to that observed previously in sediments from the Mediterranean (12) and elsewhere (Table 1); the dominant C_{28} and C_{29} components were 1,13-diols, whereas the C_{30}-C_{32} components were principally 1,15-diols. Minor amounts of 30:1 and 32:1 1,15-alkanediols also were present. This distribution of alkanediols is closely similar to those in surficial sediments from the same region of the Baltic Sea (Morris, unpublished data) and in an S_1 sapropel from the Eastern Mediterranean (1,2).

Such comparability suggests a direct link between their occurrence in cyanobacterial blooms and in bottom sediments. Hence, the presence of alkanediols in sediments may be taken as an indication of lipid contributions from planktonic cyanobacteria. In addition, the abundance of these alkanediols in sediments illustrates the importance of such organisms in many marine environments. Significantly, the alkanediols only were present, if at all, at comparatively low levels of abundance in contemporary sediments from the Peru upwelling region and from Walvis Bay (Morris, unpublished data), and in Pleistocene sediments from Walvis Ridge (Brassell, unpublished data) (Table 1). These data suggest that the cyanobacteria that biosynthesize the alkanediols cannot compete and coexist with diatoms in such productive waters.

The recognition of a biological source for the alkanediols prompts consideration of the origin of the structurally similar hydroxyketones (11–13). It is plausible that the latter are oxidation products of the former, given the parallels (11,12) in their carbon number distributions. Alternatively, the hydroxyketones may be biosynthetic products generated by the cyanobacteria at other growth stages. In any event, the clear structural relationship between the alkanediols and the hydroxyketones (11) demonstrates that they are produced by a common biosynthetic pathway. Hence, the hydroxyketones also may be regarded as markers for cyanobacterial contributions to sediments.

The precise role of the alkanediols in cyanobacterial biochemistry or physiology is unclear. Their occurrence in *A. flos-aquae* in concentrations equivalent to those of sterols (Fig. 1) suggests that they may have a function in some aspect of metabolism or membrane structure. The specificity of the positions of their hydroxylation (*viz.* 1,13- and 1,15) may provide a clue to the pathways responsible for the biosynthesis of these unusual lipid components. Evidence for their biological importance comes from the frequency of their occurrence (Table 1) and their abundance in both marine (11,12) and lacustrine (17) sediments, which in turn supports the recent finding that cyanobacteria are major contributors to the aquatic biomass (14). In addition, the geological record of these compounds, as indicated by their presence in Eocene sediments (17), demonstrates that they have been biosynthesized actively for the greater part of the Tertiary (i.e. the last 50 Ma).

TABLE 2

Relative Abundance of Major Lipid Classes in Field Population of *A. flos-aquae*

Lipid class	%	Major compound
Carboxylic acids	40.5	Hexadecanoic acid
Alkanols	16.7	Docosanol
Sterols	15.1	Cholest-5-en-3β-ol
Alkanediols	13.0	Dotriaconta-1,15-diol
Phytol	10.0	Phytol
Hydrocarbons	2.0	Diploptene
Others	2.7	

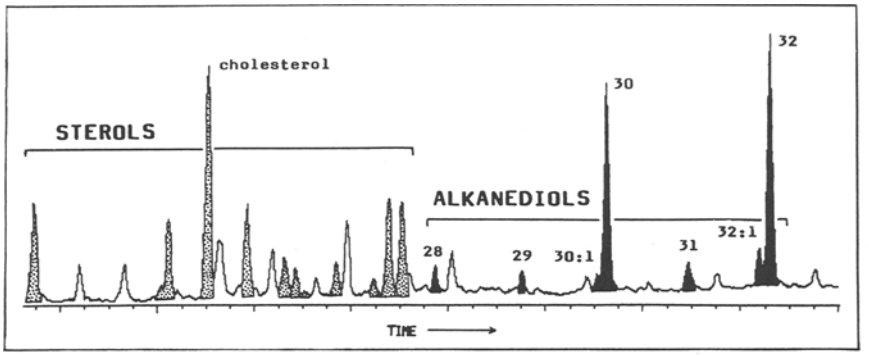

FIG. 1. Partial reconstituted ion chromatogram from GC-MS analysis of the neutral fraction (after trimethylsilylation) of *A. flos-aquae*. The region containing sterols and alkanediols is illustrated, and the carbon number of the latter compounds is shown. The sterols are C_{26}-C_{29} components with Δ^5, $\Delta^{5,22}$, $\Delta^{5,7,22}$ or $\Delta^{5,24(28)}$ unsaturation. No 5α(H)-stanols or 4-methylsterols were present. Hence, the recognition of such sterols in all the sediments containing alkanediols (11,12,15,16) is consistent with their presumed origin from dinoflagellates (3–5) and demonstrates that cyanobacteria are not the sole phytoplankton contributing sterols to the sediments.

ACKNOWLEDGMENTS

We thank Arno Viopio, director of the Institute of Marine Research, Helsinki, Finland, for making possible the visit of R.J. Morris to Finland. The assistance and hospitality of colleagues at the institute and that of the officers and crew of RV Aranda is gratefully acknowledged. We also thank Ake Niemi (University of Helsinki), Jan de Leeuw (Delft University of Technology) and colleagues at Bristol for helpful discussions and the NERC for their support of the GC-MS facility at Bristol University (GR3/2951 and GR3/3758 to G. Eglinton).

[Received July 17, 1987; Revision accepted September 24, 1987]

High Density Lipoproteins from Bovine Plasma and Follicular Fluid Do Not Possess a High Affinity for Glycosaminoglycans

S.A. Brantmeier, R.R. Grummer* and R.L. Ax
Department of Dairy Science, University of Wisconsin-Madison, Madison, WI

Possible interactions between glycosaminoglycans and high density lipoproteins (HDL) in plasma and follicular fluid were examined. Total lipoproteins (d < 1.21 g/ml) were obtained from plasma of five Holstein cows by ultracentrifugation and fractionated by gel filtration. Every other fraction from the HDL peak or fractions corresponding to the base and ascending portion of the HDL peak were composited and applied to a heparin-Sepharose affinity chromatography column. Elution profiles from both composites showed a peak that did not bind to the column that contained HDL devoid of apolipoprotein-E as determined by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and silver staining and immunoblot analysis. Elution of lipoproteins from the ascending portion of the HDL peak resulted in a second minor peak eluting at 0.35 M NaCl, which was low density lipoprotein (LDL) contamination. Lipoproteins (d < 1.21 g/ml) isolated from follicular fluid obtained from small, medium or large follicles also were subjected to heparin-Sepharose affinity chromatography. Two peaks were observed, one corresponding to the lipoprotein that did not bind to the column, the other eluted at 0.5 M NaCl and accounted for less than 2% of the protein applied. The second peak did not contain apolipoprotein-E or LDL. Bovine follicular fluid glycosaminoglycans (GAG) were isolated and subjected to HDL-Sepharose affinity chromatography. Less than 2% of the total GAG bound to the HDL column. Therefore, HDL in bovine specimens did not interact appreciably with heparin or GAG isolated from follicular fluid.
Lipids 23, 269-274 (1988).

Lipoproteins are a source of cholesterol for ovarian tissue. In bovine luteal and granulosa cell cultures, high density lipoproteins (HDL) and low density lipoproteins (LDL) can maintain progesterone production in serum-free media (1,2). In porcine, humans and rats, the preferential source for steroidogenesis by ovarian tissue is the same lipoprotein fraction that accounts for the highest proportion of cholesterol in plasma. It may be expected that bovine ovarian tissue utilizes HDL sterol because its total concentration of plasma cholesterol is 15 times greater than LDL. HDL also is the predominant lipoprotein in bovine, porcine and human follicular fluid (1,3,4). HDL can be accumulated into steroidogenic tissue by several pathways. One pathway, via the B, E receptor originally described by Goldstein et al. (5), is specific for HDL-bearing apolipoprotein-E, an arginine-rich glycoprotein. A second pathway also is receptor-dependent and specific for HDL devoid of apolipoprotein-E (6). Recently, Nestler et al. (7) demonstrated HDL binding that did not require a high-affinity binding site.

Glycosaminoglycans (GAG) also are constituents of bovine follicular fluid (8). They are polysaccharides composed of repeating disaccharide units and usually are attached to a protein core. In bovine follicular fluid, their concentrations decrease with increasing follicular size (9) and are negatively correlated with estradiol 17-β concentrations (10). GAG can bind apolipoprotein-B and E in nonruminants (11). Apolipoprotein-B and E are rich in basic amino acids that bind to negatively charged sulfate groups in GAG. Sulfation of GAG seems crucial for interaction because desulfated GAG do not interact with lipoproteins (12).

Contradictory reports can be found in the literature regarding the presence of apolipoprotein-E in bovine plasma. Forte et al. (13) demonstrated the presence of an apolipoprotein at the same molecular weight as nonruminant apolipoprotein-E (35,000 daltons), while other researchers (14,15) did not find any apolipoproteins in that molecular weight range. Rat granulosa cells in vitro produce apolipoprotein-E (16). Both cyclic adenosine monophosphate (cAMP) and follicle-stimulating hormone (FSH) stimulate apolipoprotein production. Thus, the rat granulosa cells might be modifying follicular fluid lipoproteins. If apolipoprotein-E is needed for cholesterol binding to rat granulosa cells, the cells could be generating a receptor ligand to increase cellular cholesterol uptake.

This study was designed to determine if bovine plasma or follicular fluid contained apolipoprotein-E and if there was an interaction between GAG and HDL from blood or follicular fluid. If HDL cholesterol is an important precursor for steroidogensis, GAG-HDL interactions may influence ovarian function.

MATERIALS AND METHODS

Plasma lipoprotein isolation. Two hundred fifty ml of blood were obtained from the jugular veins of five Holstein cows at various stages of lactation. The blood was collected in a flask containing disodium ethylene diaminetetraacetate (Na_2EDTA), sodium azide (NaN_3), gentamycin sulfate, ε-amino caproic acid and phenylmethylsulfonyl fluoride to provide final concentrations in blood of 0.1, 0.05, 0.005, 0.13 and 0.26%, respectively. Plasma was obtained by low-speed centrifugation and was adjusted to a density of 1.21 gm/ml with solid potassium bromide and centrifuged at 35,000 rpm (Beckman 50.2 Ti rotor) at 20 C for 18 hr.

Total lipoproteins were collected by aspiration and concentrated to a volume of 10 ml by ultrafiltration (50 ml Amicon stirred cell, Model 8050, Diaflow Membrane: YM10). The lipoprotein sample then was subjected to gel filtration chromatography. Bio-Gel A5-M, 200-400 mesh (Bio-Rad Laboratories, Richmond, CA) was packed to a bed height of 92 cm in a K 26/100 column (Pharmacia, Uppsala, Sweden). Samples were applied to the column

*To whom correspondence should be addressed at the Department of Dairy Science, University of Wisconsin-Madison, 1675 Observatory Drive, Madison, WI 53706.

Abbreviations: cAMP, cyclic adenosine monophosphate; FSH, follicle-stimulating hormone; GAG, glycosaminoglycans; HDL, high density lipoproteins; LDL, low density lipoproteins; Na_2EDTA, disodium ethylenediaminetetraacetate; NaN_3, sodium azide; SDS-PAGE, sodium dodecylsulfate polyacrylamide gel electrophoresis; VLDL, very low density lipoprotein.

and eluted at 20 C with 0.15 *M* sodium chloride (NaCl) containing Na_2EDTA, NaN_3, gentamycin sulfate, ε-amino caproic acid and phenylmethylsulfonyl fluoride at final concentrations of 0.01, 0.2, 0.02, 0.13 and 0.26%, respectively (pH 8.0).

Ninety 5-ml fractions were collected at an elution rate of 17 ml/hr. Protein was monitored at 280 nm. Cholesterol (Sigma Cholesterol 20, St. Louis, MO) and protein (Pierce BCA Lowry Protein Assay, Rockford, IL) concentrations were measured on the fractions in the HDL peak. Fractions of interest were composited and concentrated by ultrafiltration (10 ml Amicon stirred cell Model 12, Diaflo Membrane YM10, Danvers, MA) and protein measured according to Bradford (17) before affinity chromatography.

Follicular fluid lipoprotein isolation. Follicular fluid was aspirated from small (<6 mm), medium (6–10 mm) or large (11–20 mm) follicles within 30 min of slaughter (Packerland Packing, Green Bay, WI). Granulosa cells were removed by centrifugation (2,575 × g). Protease inhibitors were added at concentrations of 0.2% NaN_3, 0.02% gentamycin sulfate, 0.13% ε-amino caproic acid, and 0.26% phenylmethylsulfonyl fluoride. Fluid was frozen and stored at −20 C. Fluid was thawed, adjusted to a density of 1.21 g/ml with solid potassium bromide and centrifuged at 35,000 rpm (Beckman 50.2 Ti rotor) for 18 hr at 20 C. Total lipoproteins were aspirated, concentrated by ultrafiltration and resuspended in affinity column starting buffer (2 mM phosphate buffer, 50 mM NaCl, 0.02% NaN_3, pH 7.4).

Affinity chromatography. Affinity chromatography was performed as described (18). Briefly, 10 mg of lipoprotein were applied to the heparin-Sepharose affinity column (1.5 × 9 cm, heparin Sepharose CL-6B, Pharmacia, Uppsala, Sweden) after equilibration with starting buffer. The column was washed with 40 ml starting buffer to elute unbound proteins. A 120 ml, 0.05 to 1.5 M NaCl linear gradient was used to elute bound proteins (0.3 ml/min). Three ml fractions were collected, and the absorbance of light at 280 nm and conductivity of each fraction were monitored. SDS-PAGE followed by silver staining (19) was performed to determine the apolipoprotein profile of lipoproteins contained within each peak.

HDL-Sepharose chromatography. Columns were prepared by linking 80 mg of HDL to Sepharose (1.5 × 4.5 cm, CnBr activated 4B, Pharmacia, Uppsala, Sweden) by the procedure of Hay and Getz (20). Follicular fluid GAG were obtained as described (21) from small (<6 mm) or large (11–20 mm) follicles. Follicular fluid GAG concentrations were calculated with reference to a standard curve of commercially available heparin (Calbiochem, La Jolla, CA). Three mg of GAG isolated from fluid of small or large follicles were applied to the HDL-Sepharose affinity column. Twenty-five ml of starting buffer (10 mM Tris, 10 mM $CaCl_2$, 0.02% NaN_3, pH 8.0) was used to elute unbound GAG. A 40 ml, 0 to 2 M linear gradient was used to elute bound proteins (flow rate = 0.2 ml/min). One ml fractions were collected, and GAG were quantitated by gel filtration high performance liquid chromatography (HPLC; I-125 column, Waters Associates, Framingham, MA [22]). Conductivity of each fraction was measured to determine the molarity at which GAG eluted.

Immunoblot analysis. Immunoblot analysis was performed according to (23) using antihorseradish peroxidase as the second antibody. Antisera to human and porcine apolipoprotein-E were donated by Walter McConathy, Oklahoma Medical Research Foundation and Alan D. Attie, Department of Biochemistry, University of Wisconsin, respectively. Antiserum to porcine apolipoprotein-E was developed in chickens and antiserum to human apolipoprotein-E was developed in rabbits. Human VLDL was a gift from Attie.

RESULTS

A representative elution profile obtained when fractionating total lipoproteins by gel filtration is shown in Figure 1. The three peaks corresponded to very low density lipoproteins (VLDL), LDL, and HDL; HDL and LDL could not be separated completely. Cholesterol and protein were measured on the fractions containing HDL; there was a positive relation between lipoprotein particle size and cholesterol to protein ratio (Fig. 1). Fractions containing the largest HDL particles had minor LDL contamination that probably accounted for a small proportion of the increase in cholesterol to protein ratio. However, it was reported that the least dense HDL particles have a higher cholesterol content (24,25).

To avoid LDL contamination, lipoprotein fractions 58 to 70 from the HDL peak represented by the solid line in Figure 1 were composited and applied to the heparin-Sepharose column. Two peaks eluted, one corresponding to lipoprotein that did not bind to the column, the other eluting at 0.3 M NaCl. SDS-PAGE revealed that lipoproteins that did not bind to the column contained predominantly a 28,000 dalton protein (data not shown). Insufficient protein was present in the second peak to be analyzed by SDS-PAGE and silver staining of proteins.

Cholesterol-rich lipoproteins from fractions 53 to 58 represented by the dotted line (Fig. 1) also were applied to the heparin-Sepharose column. The chromatogram is shown in Figure 2. Peak A represents lipoproteins that did not bind to the column and lipoproteins in peak B eluted at 0.3 M NaCl. As noted with the low cholesterol HDL fraction, proteins in peak A contained substantial apolipoprotein A-I (28,000 daltons), which is indicative of HDL (Fig. 3). In addition, a 12,000 dalton protein of unknown identity was enriched in the cholesterol-rich HDL fraction. Whether this is a native protein or protein fragment is not known. Peak B obtained after affinity chromatography of cholesterol-rich lipoproteins contained small amounts of A-I. Bovine LDL isolated by gel filtration previously has been shown to contain apolipoprotein A-I (Grummer et al., unpublished data). Also observed were large molecular weight proteins that are probably B apolipoproteins. Bovine LDL isolated by gel filtration show multiple high molecular weight proteins when silver stain (but not coomassie blue stain) is used with SDS-PAGE, and these proteins do not appear to be due to proteolytic cleavage of protein after sampling blood (Grummer et al., unpublished data). Thus, peak B was considered to be LDL contamination of cholesterol-rich HDL. As recently reported (26), heparin-Sepharose affinity chromatography separates bovine HDL from LDL. Apolipoprotein-E has been reported to have a molecular weight of 35,000 daltons in nonruminants (27). From our data, bovine HDL appears to lack a protein of similar size.

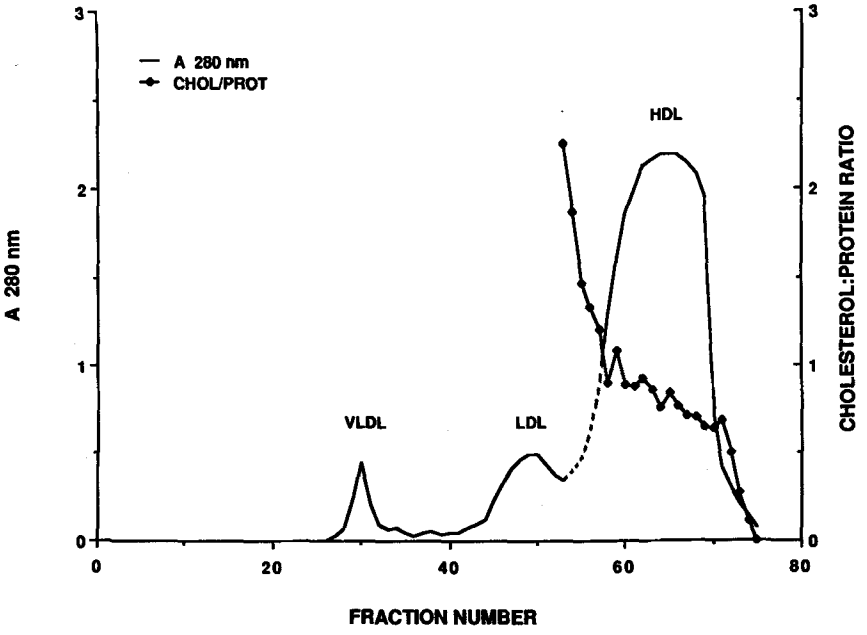

FIG. 1. Elution profile obtained by subjecting total plasma lipoproteins to gel filtration chromatography. Protein in each fraction was monitored at 280 nm (—— or – – – –). Fractions represented by (– – – –) are defined as containing cholesterol-rich HDL. Cholesterol and protein were assayed in each HDL fraction to determine cholesterol to protein ratios (——◆——).

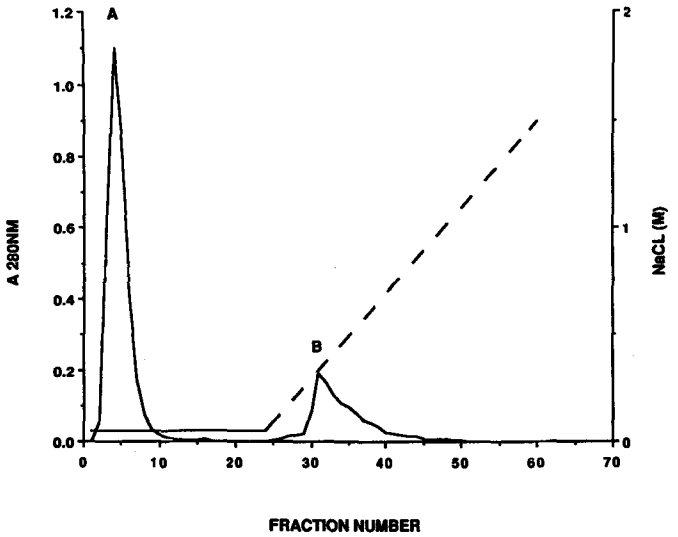

FIG. 2. Elution profile obtained by heparin-Sepharose affinity chromatography of cholesterol-rich fractions that are represented by the dotted line (– – – –) in Figure 1. Forty ml of equilibrating buffer was applied followed by 120 ml linear gradient from 50 mM to 1.5 *M* NaCl. Protein (A 280 nm, ——) and conductivity (– – – –) of each fraction was monitored. Peak A represents unbound lipoprotein while protein in peak B eluted at 0.3 *M* NaCl.

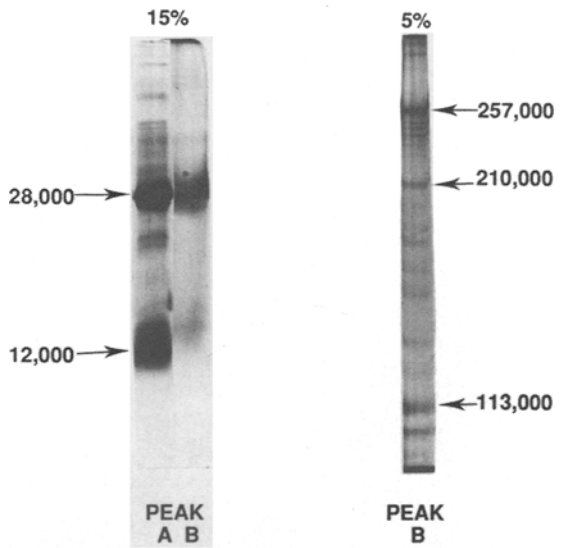

FIG. 3. SDS-PAGE gels (5 and 15% acrylamide) of proteins eluting in peak A or B (Fig. 2) during heparin-Sepharose chromatography of cholesterol-rich HDL.

Lipoproteins (d < 1.21 g/ml) isolated from follicular fluid of small, medium or large follicles also were analyzed by heparin chromatography to determine if follicular and plasma lipoproteins exhibited chemical differences. Lipoproteins isolated from the fluid of small follicles were applied and eluted from the heparin-Sepharose column; two peaks resulted (Fig. 4). Peak A represents lipoproteins that did not bind to the column, while lipoproteins within peak B eluted at 0.5 M NaCl. Heparin-Sepharose affinity chromatography of lipoproteins from medium and large follicles resulted in similar elution profiles. SDS-PAGE followed by silver staining of apolipoproteins in

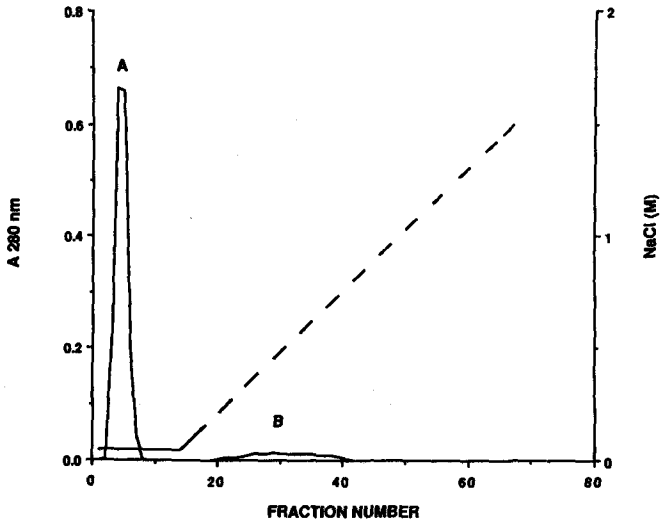

FIG. 4. Elution profile obtained when subjecting lipoproteins isolated from fluid of small follicles (<6 mm) to heparin-Sepharose affinity chromatography. Forty ml of equilibrating buffer was applied followed by a 120 ml linear gradient from 50 mM to 1.5 *M* NaCl. Protein (A 280, ——) and conductivity (– – – –) of each fraction was monitored. Protein in peak A did not bind to the column, while protein in peak B eluted at 0.5 *M* NaCl.

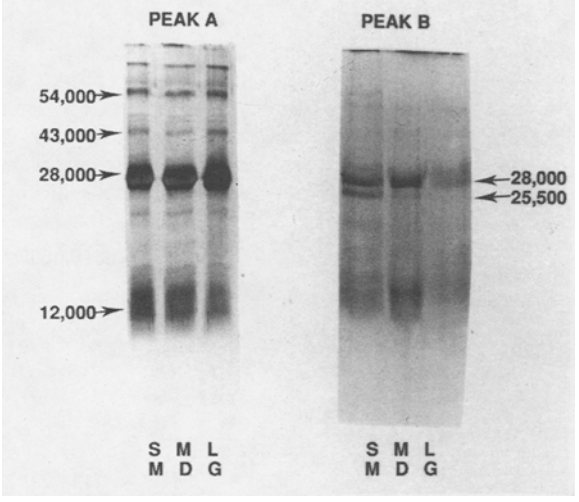

FIG. 5. SDS-PAGE (15% acrylamide) of proteins eluting in peak A or B (Fig. 4) during heparin-Sepharose chromatography of lipoproteins isolated from the fluid of small follicles.

the unbound fraction showed they contained an apolipoprotein profile similar to plasma HDL. The lipoproteins that eluted at 0.5 M NaCl contained an additional protein of unknown identity at 25,500 daltons, which decreased in intensity with increasing follicle size (Fig. 5). Large molecular weight B apolipoproteins were not observed (5% acrylamide, gels not shown) in the d < 1.21 g/ml fraction, therefore, HDL appears to be the only lipoprotein in follicular fluid. Furthermore, the lipid and protein composition of the d < 1.21 g/ml fraction averaged 28.3% phospholipid, 29.8% cholesterol (total), nondetectable triglyceride and 41.9% protein, which is

TABLE 1

similar to bovine plasma HDL composition (28), particularly smaller, more dense HDL that are more likely to penetrate the blood-follicular fluid barrier. Less than 2% of total protein applied to heparin columns bound (Table 1), indicating little interaction between follicular fluid lipoproteins and commercially available heparin linked to Sepharose.

Heparan sulfate and chondroitin sulfate are the two predominant GAG in follicular fluid (29), not the heparin that is linked commercially to Sepharose. Thus, the extent to which naturally occurring GAG isolated from bovine follicular fluid bind to a HDL-Sepharose affinity column was examined. A representative elution profile obtained when GAG isolated from follicular fluid was applied to the HDL-Sepharose affinity column is shown in Figure 6. In Table 2, the percentage of total GAG that bound to HDL-Sepharose and eluted from 0 to 1 M NaCl and 1 to 2 M NaCl are shown. Greater than 95% of the GAG did not bind to the column. Therefore, using homologous preparations, very little interaction between bovine follicular fluid GAG and HDL occurred. Purified dermatan sulfate (a subclass of chondroitin sulfate and most abundant follicular fluid GAG) from large follicles or commercial heparin was applied to a LDL-Sepharose column that was prepared in the same manner as the HDL-Sepharose column. Sixteen percent of the dermatan sulfate from large follicles and 67% of the heparin bound to the column and was eluted with 2 M NaCl. GAG bind to LDL via apolipoprotein-B (11), therefore, the methodology we employed should have been valid for demonstrating apolipoprotein-(E)-GAG interaction.

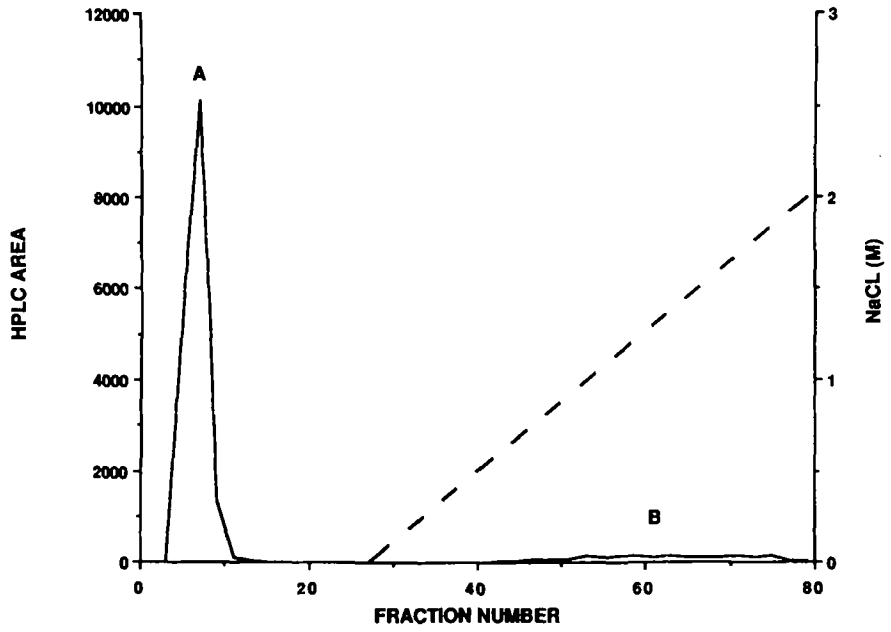

FIG. 6. Elution profile obtained when subjecting GAG isolated from fluid of small follicles to HDL-Sepharose affinity chromatography. Twenty-five ml of equilibrating buffer was applied followed by a 40 ml linear gradient from 0 to 2 *M* NaCl. GAG content (HPLC Area, Waters I-125, ——) and conductivity (– – – –) of each fraction was monitored. GAG in peak A did not bind to the column while GAG in peak B bound from 0.5 to 2 *M* NaCl.

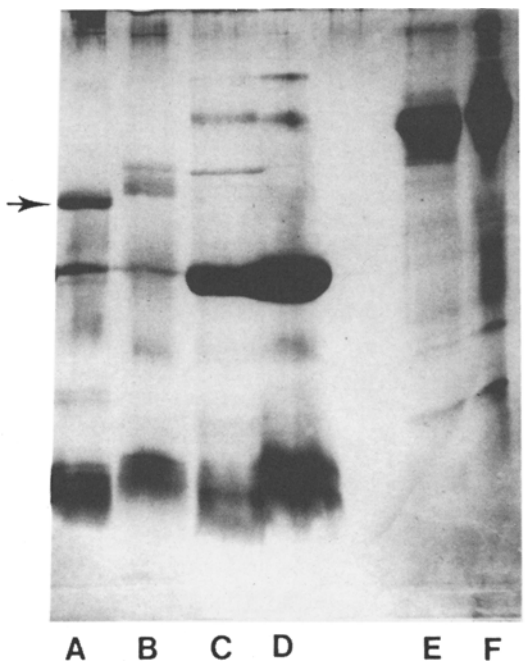

FIG. 7. SDS-PAGE gel (15% acrylamide) of: A-porcine plasma VLDL, B-bovine plasma VLDL, C-bovine follicular fluid HDL, D-bovine plasma HDL, E-follicular fluid subnatant from total lipoprotein spin (density > 1.21 g/ml), F-plasma subnatant from total lipoprotein spin (density > 1.21 g/ml). Arrow indicates porcine VLDL protein immunoreactive with anti-apolipoprotein-E sera.

Although steps were taken to minimize loss of apolipoprotein-E. (single slow-speed ultracentrifugation and gel filtration), some may have occurred during isolation. Therefore, the subnatant obtained after isolation of total lipoproteins from plasma and follicular fluid was subjected to SDS-PAGE. Those fractions as well as plasma and follicular fluid HDL generated from the same samples all appeared void of apolipoprotein-E (Fig. 7). Immunoblot analysis using antisera specific for either porcine or human apolipoprotein-E (generated in chickens and rabbits, respectively) demonstrated that those fractions as well as bovine VLDL were deficient in apolipoprotein-E or that the antibody did not cross react with bovine apolipoprotein-E. However, both porcine and human VLDL apolipoprotein-E were precipitated with either antiserum.

DISCUSSION

Results from this study confirm other reports that HDL devoid of apolipoprotein-E does not interact with commercially available GAG (30,31). Results from studies examining if bovine plasma contains apolipoprotein-E are contradictory (13,14). Other species such as the rat have cholesterol-rich particles (HDL_c) below a density of 1.063 g/ml that contain apolipoprotein-E (32). It was hypothesized that bovine HDL would contain apolipoprotein-E since bovine plasma contains cholesterol-rich, α-migrating lipoproteins having a density less than 1.063 g/ml (25,28,33).

Cordle et al. (26) applied a combined bovine LDL-HDL fraction to a heparin-Sepharose column and did not observe apolipoprotein-E in the bound lipoprotein fraction eluting from the column. Since a combined LDL-HDL fraction was used, insufficient apolipoprotein-E-rich HDL may have been applied to the column. Additionally, a relatively insensitive stain, Coomassie blue, was used for detecting proteins after SDS-PAGE of eluted lipoproteins from the heparin-Sepharose affinity column. However,

in agreement with Cordle et al. (26), our results from heparin-Sepharose affinity chromatography of cholesterol-rich plasma HDL, coupled with use of silver stain for protein detection and immunoblot analysis following SDS-PAGE of lipoprotein fractions, indicated the absence of apolipoprotein-E in bovine plasma HDL. HDL obtained from bovine follicular fluid also showed limited interaction with heparin-Sepharose. Thus, bovine plasma and follicular fluid HDL do not appear to contain a lipid or apolipoprotein moiety that binds to heparin.

Since GAG are a very heterogeneous class of compounds (34), an additional experiment was performed to determine if naturally occurring GAG isolated from follicular fluid (chondroitin sulfate and heparan sulfate; 29) possessed an affinity for HDL, permitting a homologous comparison that might reflect physiological interactions. This is the first study, to our knowledge, to examine if GAG found in follicular fluid interact with HDL. However, little interaction was seen between these GAG and HDL-Sepharose (Table 2). Therefore, if GAG are affecting steroidogenesis, it is not likely due to them binding HDL and preventing delivery of cholesterol to granulosa cells. The possibility remains that GAG affect lipoprotein metabolism at the cellular level since LDL degradation is inhibited in a dose-dependent manner by increased concentrations of GAG in porcine granulosa cell cultures (35).

Indirect evidence from this study indicates that the bovine granulosa cell probably is not producing appreciable quantities of apolipoprotein-E and sequestering it into the follicular fluid HDL. The apolipoprotein-E that was produced in rat granulosa cell cultures was found at a density less than 1.21 g/ml (16). The researchers hypothesized it was attached to a lipoprotein but did not provide any evidence to confirm this. HDL appears to be the only class of lipoproteins found in bovine follicular fluid ([1] Fig. 5) and would be the only exogenous source of cholesterol for progesterone production by granulosa cells. Bovine granulosa cells produce copious quantities of progesterone prior to ovulation (36). Thus, before vascularization of the granulosa cell layer, tremendous amounts of substrates are necessary for progesterone production. HDL cholesterol found in follicular fluid is a logical substrate. Without apolipoprotein-E on the HDL molecule, bovine granulosa cell receptors must recognize a different HDL constituent. The characteristics of those receptors and the possibility that GAG affect their function need to be determined.

ACKNOWLEDGMENTS

We would like to thank Dave Miller, Sarah Bushmeyer and Tom Coyle for help in the collection of the follicular fluid, and Dale Ripley for the isolation of GAG. We also would like to thank Mary Bellin for purifying follicular fluid GAG, Diane Carroll and Debbie Schneider for performing the LDL-Sepharose chomatography, and Sandra Bertics for conducting immunoblot analysis. We also express appreciation to Packerland Packing (Green Bay, WI) for allowing us to collect the fluid. This project was supported by the University of Wisconsin College of Agricultural and Life Sciences, Hatch Grant 2778, and a Biomedical Research Support Grant (Project #161412) from the University of Wisconsin Graduate School.

[Received August 17, 1987; Revision accepted November 3, 1987]

Effects of Relative Humidity on Lipid Autoxidation in a Model System

J.L. Kahl[a], W.E. Artz[b] and E.G. Schanus[a,*]

[a]Department of Food Science and Human Nutrition, Washington State University, Pullman, WA 99164-6330, and [b]Department of Food Science, University of Illinois, Urbana, IL 61801

A new model system was developed for the study of autoxidation of thin films of neat lipid and the effect of relative humidity on the oxidation reaction. In the model system, the surface-to-volume ratio of lipid was large and measureable, and the relative humidity (RH) and oxygen partial pressure were controlled. Methyl linoleate, oxidized at six different RH as a thin film in an atmosphere of pure oxygen, exhibited a maximum rate of oxidation at 32% RH and minimum rates at 0% and 100% RH. The rates of oxygen uptake, determined manometrically, were linear and reproducible at all six RH. The maximum rate at 32% RH was attributed to solvation and stabilization of the propagation transition state by water. Increasing the RH beyond 32% resulted in solvation of the peroxy radical, sterically hindering the radical from entering the propagation transition state.

Lipids 23, 275-279 (1988).

Free radical-mediated lipid autoxidation is the major cause of quality deterioration (rancidity) and decreased nutritional quality and safety in lipid-containing foods (1,2). The importance of lipid oxidation extends beyond the economic considerations associated with food. The biological problems associated with lipid peroxidation include damage to membranes, enzymes, vitamins and cell metabolism (3,4). Lipid autoxidation has been implicated in some species in several normal and abnormal processes including aging, cancer, hemolytic anemia, reproductive dysfunction and lung damage, among many others (5,6).

The complex and varying make-up of biological material causes difficulty in pinpointing any single element, compound or condition as the sole cause of a given effect. It is essential to have a model system that can be used to study the interaction of lipids with water, proteins, carbohydrates, and other biological molecules and the affect of these components on the rate and mechanism of lipid autoxidation. For this reason, a model system that can be used to evaluate these interactions was developed.

The primary goal of this study is to investigate and better understand the effect of water on the rate of lipid autoxidation. A unique relationship exists between the moisture content of biological material such as food and the rate of lipid autoxidation. Water exhibits both a pro- and antioxidant effect on lipid oxidation in these systems (1). To gain a better understanding of the relationship between moisture content and lipid autoxidation, the effect of relative humidity on the oxidation of a thin film of methyl linoleate is investigated.

EXPERIMENTAL PROCEDURES

The model consists of a thin film of lipid on a chemically modified glass support. Silica gel has been used in many studies as a support for lipid films (7-10), but the surface area of the irregularly shaped silica gel is difficult to determine. A 22 mm diameter circular glass coverslip was used as the support. The thickness of the lipid film can be varied to simulate the physical conditions of many different biological materials. For example, a thick film can be used to simulate the surface of bulk fats, a thin film can be used to simulate fat as it occurs in some foods, and a monolayer can be used to simulate membranes.

Acid treatment of glass coverslips. The glass coverslips were treated with hydrofluoric acid to form a thin layer of silica gel on the surface. The disks were treated by submerging them in concentrated hydrofluoric acid for four to five sec, rinsing with distilled water, neutralizing in 30% sodium hydroxide and rinsing thoroughly with distilled water. Care should be taken not to allow skin contact with concentrated hydrofluoric acid, and it should be stored in plastic containers. The treated disks were dried in a desiccator containing phosphorous pentoxide under nitrogen for a minimum of 48 hr and were stored in the desiccator until used. Later, it was discovered that a more consistent lipid film would form on the disks if the treated glass disks were baked in a 140 C oven overnight and used directly from the oven after a few minutes of cooling. Methyl linoleate formed an even layer without beading on the treated glass disks.

Reaction vessel. A modified Warburg Respirometer was used to monitor oxygen consumption during the reaction. The reaction vessel (Fig. 1) and manometer were modified by adding a 29/32 standard taper glass joint (Schott Glass KPV 29) to accept the 22 mm glass disk. The main chamber contained a glass pedestal to suspend the disk over a reservoir (2 ml) of water, desiccant or salt slurry for relative humidity (RH) control. A sidearm port with detachable septum was included to aid in purging the system with oxygen. The assembled reaction flask was

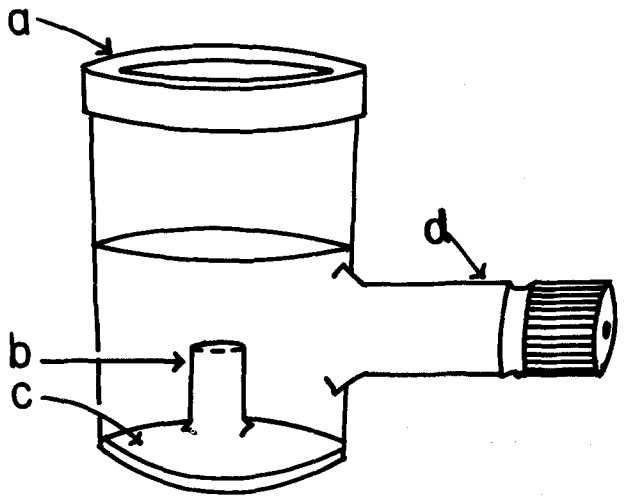

FIG. 1. Modified Warburg reaction flask: a) wide mouth to accept 22 mm disk; b) pedestal to support disk above reservoir; c) reservoir for saturated salt slurry, water or desiccant; and d) sidearm port for flushing system with oxygen.

*To whom correspondence should be addressed.

Abbreviation: RH, relative humidity.

immersed in a constant temperature water bath (37 C ± 0.5 C). The modified flask was calibrated according to standard Warburg procedures (11).

Humidity control and thin film preparation. The effect of relative humidity on autoxidation of a thin film of methyl linoleate was used to evaluate the reproducibility of the thin film model and the effect of water on lipid autoxidation. Methyl linoleate (Sigma Chemical Co., St. Louis, MO) was purified by the method of Privett and Blank (12) and stored under nitrogen at −20 C. The lipid was diluted with benzene to ca. 10 mM, and the equivalent of 2.7 mg of lipid was spread on an acid-treated glass disk and the benzene evaporated. The lipid on the disk was equilibrated to the desired relative humidity by placing it in a desiccator with the appropriate saturated salt slurry (13) or desiccant under nitrogen in the dark. If the disk was to be dried to 0% RH, it was left in the phosphorus pentoxide desiccator for a minimum of 48 hr. After equilibration, the disk was placed in the modified Warburg reaction flask on the pedestal above a 2 ml reservoir of the same saturated slurry, water or desiccant ($CaSO_4$) as needed to maintain the desired RH. The system was flushed with oxygen that had been adjusted to the desired RH by bubbling the oxygen through the appropriate salt slurry or desiccant. The rate of oxygen uptake was monitored manometrically at two- to four-hr intervals.

Reproducibility. The reproducibility of the new model system was verified statistically. Six independent runs at 72% relative humidity and five independent runs at 100% RH were measured, and an analysis of variance of beta regression coefficient (slope) was performed on each treatment. Within each treatment, the six (or five) runs were placed randomly in two groups and the F test used with the null hypothesis showed that there was no difference.

Tritiated water studies. The amount of water bound to a thin film of lipid was estimated by incubation with tritiated water. Tritiated water (1 mCi/ml, New England Nuclear, Boston, MA) was diluted with double glass-distilled water to a specific activity of 0.5 mCi/ml and placed in a ground glass weighing dish. Acid-washed glass wool under a perforated teflon disk supported the glass disks above the water. The perforation allowed for free circulation of vapor throughout the system. The previously dried disks were placed on the teflon support in an atmosphere of nitrogen or air, and the lid was sealed with high-vacuum grease. A styrofoam cooler insulated the weighing dish against sudden temperature changes and drafts, which tended to cause condensation of water on the disks. The disks were dried a minimum of 48 hr in the P_2O_5 desiccator before applying the lipid film and again were dried for 48 hr. After exposure to tritiated water for a minimum of 25 hr, the disks were broken and placed in scintillation vials for counting. Counting was performed in a Packard Tri-Carb 460C scintillation counter.

RESULTS AND DISCUSSION

The model system. The main goal in developing the new model system was to eliminate oxygen diffusion through the lipid as a variable (14), which would result in the system reaching equilibrium rapidly. Eliminating the dependence of the rate on oxygen diffusion required forming a thin film of lipid, 4–30 μm thick (15), to allow oxygen diffusion to occur rapidly. Other considerations were to maintain a constant oxygen partial pressure and control the RH of the system. Controlling all these factors allowed the study of the effect of individual variables of the lipid autoxidation rate.

Three μl (2.7 mg) of methyl linoleate were used to form the thin film. On the 22 mm glass disk, 2.7 mg of lipid formed a film that was ca. 7.9 μm thick or a vertical layer of at least 10,000 molecules of methyl linoleate. Thus, the lipid was not in a monolayer. The lipid molecules at the silica gel-lipid interface of the disk are oriented largely with the polar heads closely associated with the polar groups of the silica gel, and the hydrophobic tails extending into the bulk lipid of the film (7,8,10). The intermediate bulk lipid, separating the silica gel-lipid and lipid-air interfaces, was free to orient in its lowest free energy form. At the lipid-air interface, the hydrophobic tails of the lipid molecules would orient to the media of the lowest dielectric constant. As the relative humidity was increased in the system, the dielectric constant of the air increased, and the lipid molecules at the air interface probably would orient with the polar heads exposed to the air, where they would bind with water. The amount of water bound to the lipid would increase correspondingly, contributing to the overall effect that humidity has on the rate of oxidation, possibly by binding preferentially to the most polar parts of the lipid molecules and solvating or sterically hindering reaction intermediates.

The thin film had a large surface-to-volume ratio, eliminating the role of oxygen diffusion into the lipid (8), and the small sample size decreased the amount of time needed to reach equilibrium conditions. To assure that oxygen did not become limiting in the reaction system, pure oxygen was used. It has been argued that the use of pure oxygen may affect which termination reaction predominates; however, as long as $pO_2 > 100$ mm Hg, the predominant termination reaction is the homolytic addition of two peroxy radicals (16). Therefore, the system with pure oxygen will have the same oxidation mechanism as a system in which air is used as the source of oxygen and is replaced at regular intervals.

Relative humidity. The necessity of a reservoir of humidity-controlled solution in the model system was clearly demonstrated by the observed increased water-binding during oxidation (Fig. 2). Water bound to the lipid in both air and nitrogen atmospheres, but the oxidizing lipid bound more water than the lipid under nitrogen. Water-hydrogen bonded to the polar oxidation products as they formed. Without the presence of an infinite reservoir of water in the model system, the relative humidity of the system would decrease continually during oxidation of the lipid. The reservoir of saturated solution or water in the reaction vessel replaced the water removed from the atmosphere, preventing any change of RH in the system.

Preliminary studies suggest that the water-binding was primarily at the lipid-air interface because the water/lipid ratio was dependent on lipid layer thickness. This surface phenomenon can be explained by considering the orientation of the hydroperoxides and resulting oxidation products at the lipid-air interface. Water will hydrogen-bond to the polar groups on the oxidation products at the

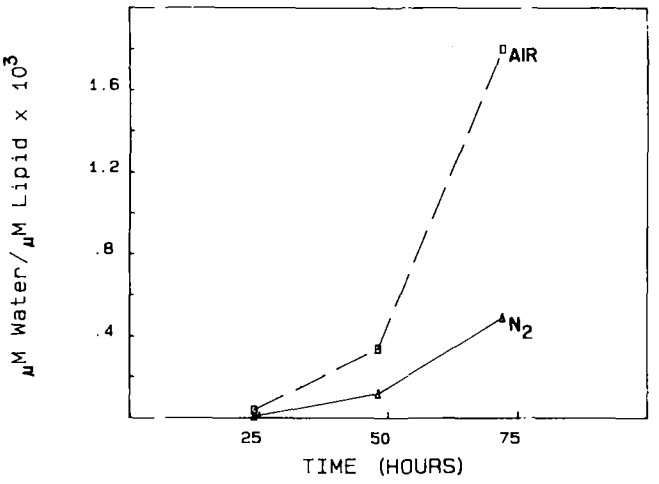

FIG. 2. Micromoles of water bound per μmol methyl linoleate under air and under nitrogen vs time, as determined with tritiated water.

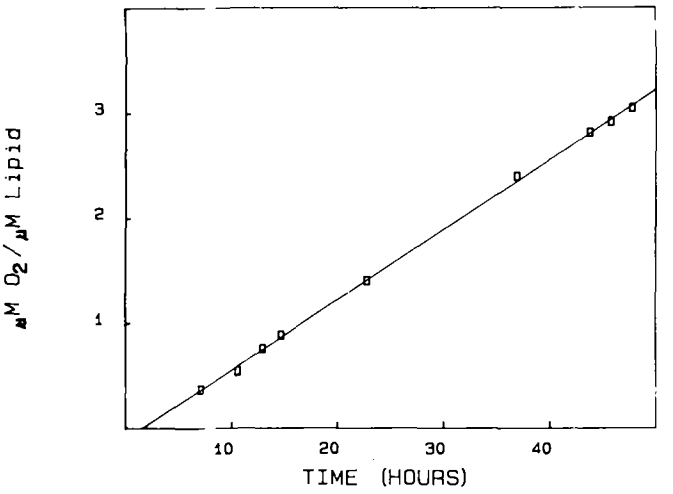

FIG. 3. Typical oxygen uptake for 2.7 mg lipid in a thin film. Oxygen uptake per μmol methyl linoleate vs time, lipid surface-to-volume ratio = 1.27 cm²/μl.

interface, inhibiting them from changing orientation. Thus, most of the lipid-water interactions are expected to occur at the lipid-air interface.

Surface-to-volume ratio, rates and reproducibility. The substrate concentration, oxygen partial pressure and relative humidity of the system were controlled in the model system, and linear uptake of oxygen was observed. The effect of the surface-to-volume ratio of lipid on the rate also was evaluated in the model system. All of the oxygen uptake measurements used to determine the rates reported were performed in the system with a surface-to-volume ratio of 1.27 cm²/μl. Figure 3 shows a typical oxygen uptake vs time plot for a 1.27 cm²/μl thin film. To investigate the effect of the surface-to-volume ratio on the rate of oxidation, a thick film of methyl linoleate with a surface-to-volume ratio of 0.0125 cm²/μl (100-fold smaller than Fig. 3) was placed in the reaction vessel under pure oxygen at 37 C. The nonlinearity of the results shown in Figure 4 demonstrates that the small surface-to-volume ratio sample had not reached steady state at 15 hr, while the large surface-to-volume ratio samples (Fig. 3) took under one hr to reach steady-state.

An analysis of variance was performed at 72% and 100% RH at 37 C by randomly placing the five or six individual slopes in two groups. The beta coefficient (slope) showed no significant difference within runs at the 95% level (Table 1). The alpha regression coefficient (intercept) was not reproducible. However, the degree of oxidation will affect the intercept and result in increasingly greater intercepts as the lipid oxidizes. The intercept would be important if the initiation reactions or the induction period were being studied. Also, the intercept would affect measurement of the induction period. However, neither the initiation reactions nor the induction period were the focus of this study. Once autoxidation is at steady-state, the oxygen uptake rate is independent of the initial condition of the lipid and will remain at steady-state as long as neither oxygen nor substrate become limiting.

The linear rates at all six RH indicate that the reaction was at steady-state; the pseudo-zero order rate generally

is expected when substrate is not limiting (17-20). Although the sample size was small, gas chromatographic analyses of the oxidized lipid after oxygen uptake measurement consistently showed that the samples were at least 60% unreacted methyl linoleate.

To demonstrate the linearity of the rates, the averages of the correlation coefficients for the linear regressions at six different RH are included in Table 2 with the average rates of oxidation.

Depending on the amount present, water can have a prooxidative or antioxidative effect as demonstrated by the maximum rate at ca. 32% RH and minimum rates at 0% and 100% RH in Figure 5. At 32% RH, the rate reached a maximum, and from 32% to 100% RH the rate decreased with increasing RH. A linear rate of oxidation was observed at all six relative humidities, with no change in the order of the reaction rate with increasing RH and with no change in rate with extent of reaction. The only change in rate of reaction occurred after 60 hr, when substrate became limiting; at that point, the rate of oxygen uptake decreased.

There was no significant induction period, as is common for oxidations of lipid monolayers (10). However, the lipid was not in a monolayer. This would indicate that although the lipid was not in a monolayer, the thin layer of lipid was exposed to an effectively unlimited amount of oxygen, as are monolayers.

To explain the response of the oxidation rate to different RH as observed in the present model system, we propose that the initial addition of water to the oxidizing lipid system increased the rate of oxidation through solvation and stabilization of the propagation transition state, as documented by Lloyd (21). At some relative humidity between 11% and 32%, a maximum stabilization was achieved, resulting in a maximum rate of oxidation. The addition of more water solvated the peroxy radical, decreasing its reactivity through steric hindrance and slowing the overall rate of oxidation.

It is possible that the inhibitory effect on the propagation rate, observed at a solvent polarity beyond the maximum polarity for stabilization, was caused by a decreasing concentration of "reactive" or nonsolvated peroxy radicals. The total concentration of peroxy radicals would not change, but extensive hydrogen-bonding at the higher relative humidities could render some of the radicals nonreactive. Termination possibly may be affected in the same way.

The extent of oxidation measured in the model system was greater than expected and in most cases exceeded one mole of oxygen per mole of lipid. The large amount of oxygen taken up cannot be explained at this time, but we have hypothesized that reactive hydroxyl radicals from hydroperoxide decomposition may abstract hydrogens from already oxidized products, resulting in highly oxidized compounds. In spite of this, it is to be expected that in general the free radical chain reaction will be affected by relative humidity in the same way. Studies are underway to characterize the oxidation products.

[Received June 8, 1987; Revision accepted November 3, 1987]

Preparation of Methyl *cis*-9,*cis*-12,*cis*-15-Octadecatrienoate-15,16-d_2 and Methyl *cis*-9,*cis*-12,*cis*-15-Octadecatrienoate-6,6,7,7-d_4

Henry Rakoff
Northern Regional Research Center, ARS/USDA, 1815 N. University St., Peoria, IL 61604

Methyl *cis*-9,*cis*-12,*cis*-15-octadecatrienoate-15,16-d_2 was obtained from Wittig coupling of methyl 12-oxo-*cis*-9-dodecenoate, *18*, and 3,4-dideutero-*cis*-3-hexenyltriphenylphosphonium bromide, *16*. Compound *18* was obtained by periodic acid oxidation of methyl 12,13-dihydroxy-*cis*-9-octadecenoate, *17*, obtained from *Vernonia* oil. Compound *18* also was synthesized from methyl oleate as the starting material. The deuterated fragment, *16*, was prepared from 3-hexynol and using Lindlar's catalyst and deuterium gas to introduce the deuterium atoms.

Methyl *cis*-9,*cis*-12,*cis*-15-octadecatrienoate-6,6,7,7-d_4 was prepared by Wittig coupling of 3,6-nonadienyltriphenylphosphonium iodide, *5*, with methyl 9-oxononanoate-6,6,7,7-d_4, *11*. Deuterium atoms were introduced during the synthesis of *11* from 3-butynol and 5-bromopentanoic acid with deuterium gas in the presence of $[Ph_3P]_3$-RhCl. For the preparation of *5*, the 3,6-nonadiynol intermediate was reduced to 3,6-nonadienol with P-2 Nickel and hydrogen.

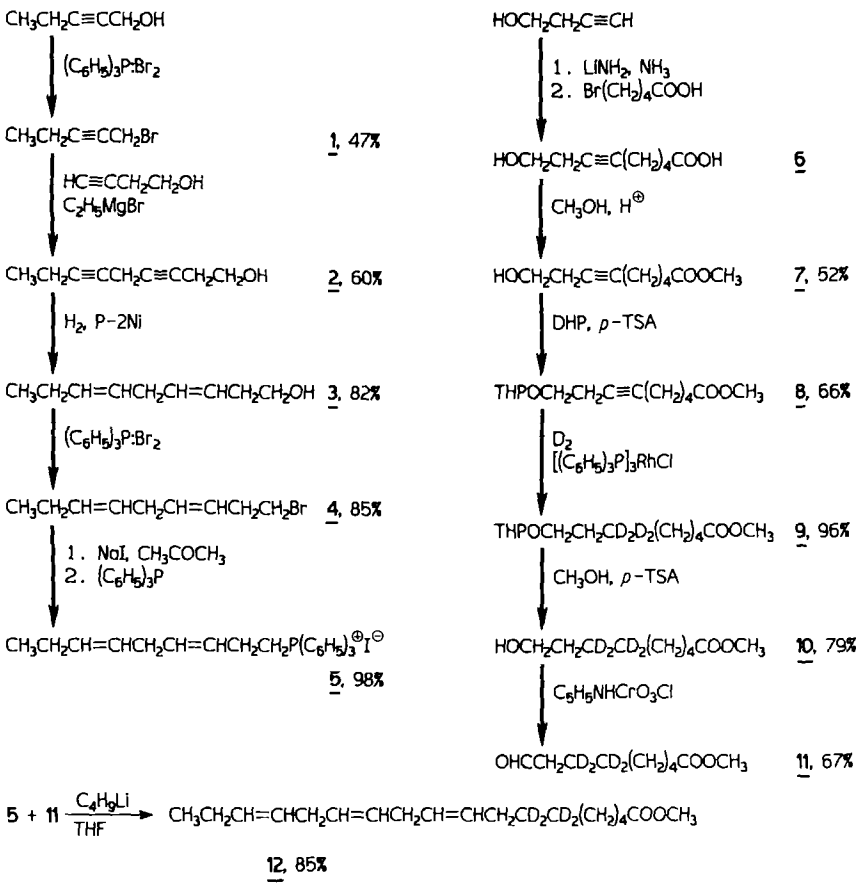
The final products were separated from isomers formed during the synthetic sequences by silver resin chromatography.

Lipids 23, 280–285 (1988).

For our study of the metabolism in humans of fatty acids formed during the hydrogenation of soybean oil (1,2), we have synthesized various deuterated monoenoic (3), dienoic (4) and trienoic acids (5). In all cases, we have been able to avoid putting the deuterium atoms on the double-bonded carbon atoms or on the carbon atoms immediately adjacent to them. As the number of double bonds in the molecule is increased, it becomes more and more difficult to locate the deuterium atoms on carbons that are not joined by a double bond or are immediately adjacent to them. We now have synthesized methyl linolenate containing four deuterium atoms in the 6,6,7,7 positions and methyl linolenate containing two deuterium atoms on the #15 and #16 double-bonded carbon atoms for use in a study to ascertain if there is a "deuterium isotope effect" in the metabolic processes of humans.

DISCUSSION

Methyl linolenate-6,6,7,7-d_4, 12, was obtained by a Wittig coupling of two fragments that were prepared by acetylenic coupling (Scheme 1). For the preparation of 3,6-nonadienyltriphenylphosphonium iodide, 5, 2-pentynol was converted to 1-bromo-2-pentyne, 1, with triphenyl-



SCHEME 1. DHP, Dihydropyran; THP, tetrahydropyranyl; *p*-TSA, *p*-toluene-sulfonic acid; THF, tetrahydrofuran.

phosphine dibromide. Compound 1 then was coupled in a Grignard reaction with 3-butynol to give 3,6-nonadiynol, 2, which was reduced with P-2 Nickel (6) and hydrogen to 3,6-nonadienol, 3. (Lindlar's catalyst is reported [7] to give a mixture of isomeric products with diynes. By contrast, P-2 Nickel reduction goes rapidly to the diene stage in good yield.) Reaction of 3 with triphenylphosphine dibromide gave 1-bromo-3,6-nonadiene, 4, which was converted to the iodide with sodium iodide and to the phosphonium salt, 5, by reaction with triphenylphosphine in acetonitrile.

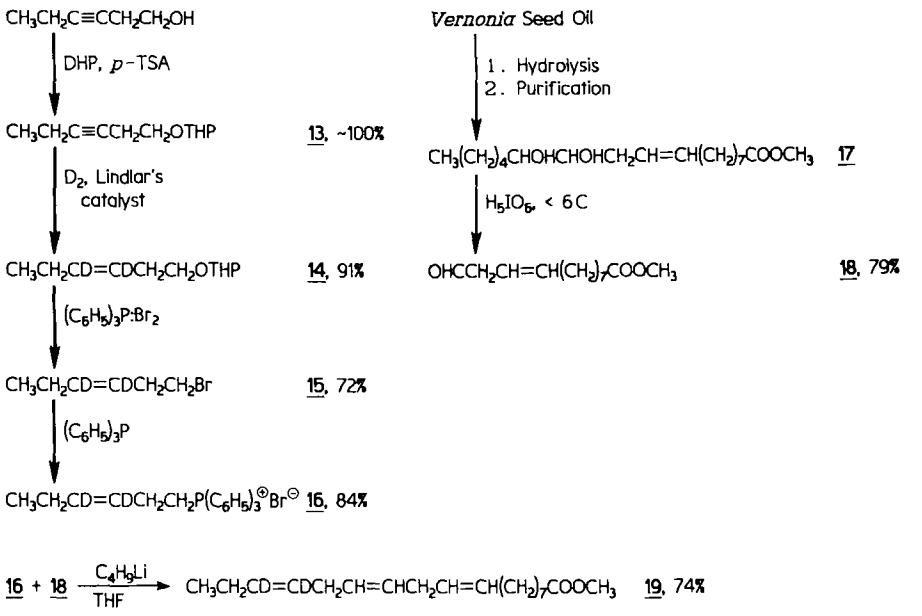
For the aldehyde ester required, methyl 9-oxononanoate-6,6,7,7-d_4, 11, 3-butynol and 5-bromopentanoic acid were coupled by lithium amide in liquid ammonia to give 6, 9-hydroxy-6-nonynoic acid. (The same reaction with methyl 5-bromopentanoate gives a complex mixture of products.) To prevent deuterium-hydrogen exchange during the catalytic deuteration, 6 was esterified to 7 and the hydroxy group was protected as the tetrahydropyranyl ether, 8. Deuteration of 8 with deuterium gas in the presence of *tris*(triphenylphosphine)chlororhodium gave methyl 9-(2-tetrahydropyranyloxy)nonanoate-6,6,7,7-d_4, 9. The tetrahydropyranyl group was removed with methanol and *p*-toluenesulfonic acid to give 10, which was oxidized to 11 with pyridinium chlorochromate (8).

Wittig reaction between 5 and 11 with butyl lithium in tetrahydrofuran gave 12. The all-*cis* isomer was separated from the small amounts of the other isomers generated during the reaction sequence by silver resin chromatography (9).

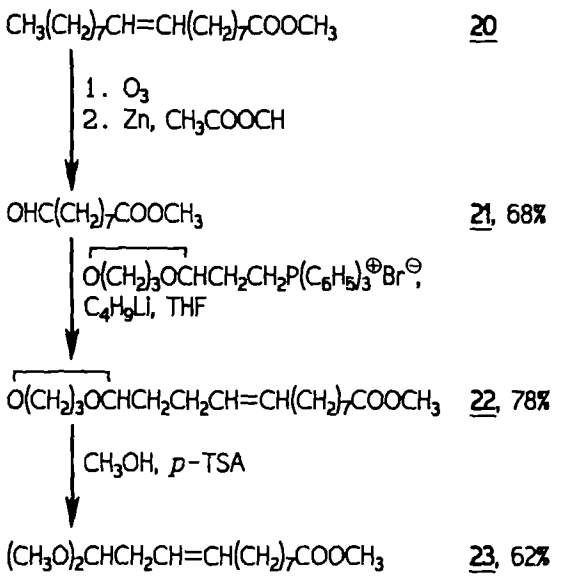
Methyl linolenate-15,16-d_2, 19, was obtained by Wittig coupling (Scheme 2) of 3,4-dideutero-3-hexenyltriphenylphosphonium bromide, 16, and methyl 12-oxo-*cis*-9-dodecenoate, 18, with butyl lithium in tetrahydrofuran. The all-*cis* isomer was separated from the other isomers formed by silver resin chromatography (9). The synthesis of the phosphonium salt started with 3-hexynol, which was converted to the tetrahydropyranyl ether, 13, to prevent hydrogen-deuterium exchange in the subsequent deuteration reaction with deuterium gas and Lindlar's catalyst. The dideuterated tetrahydropyranyl ether, 14, was converted to the bromide, 15, with triphenylphosphine dibromide and to the phosphonium salt, 16, with triphenylphosphine in acetonitrile.

The unsaturated aldehyde ester, 18, was obtained by periodic acid oxidation, below 6 C (10), of methyl *threo*-12,13-dihydroxy-*cis*-9-octadecenoate, 17. This dihydroxy ester was obtained from *Vernonia* oil. The mixture of acids obtained from acetolysis and saponification of *Vernonia* oil contained about 67% dihydroxyoleic acid. This was increased to 84% by distribution between aqueous acetonitrile and petroleum ether and to 96.6% by recrystallization from ethyl ether-petroleum ether.

Compound 18 is a very useful intermediate and was used in our synthesis of mono-, di- and trienoic fatty esters containing a 12,13 double bond (11). Since *Vernonia* oil is not commercially available and was available to us only in limited amounts, we devised a synthesis (Scheme 3) of this material from methyl oleate, which is readily available from the esterification of Palmolyn 100, a commercial source of oleic acid. Palmolyn 100 methyl esters (about 94% methyl oleate), 20, was ozonized, and the ozonide was reduced with zinc and acetic acid to yield 21, methyl 9-oxononanoate (methyl azelaaldehydate). This compound was coupled (12) in a Wittig reaction with [2-(1,3-dioxan-2-yl)ethyl]triphenylphosphonium bromide and butyl lithium in tetrahydrofuran to give the *cis* (75%) and *trans* (25%) isomers of methyl 11-dioxanyl-9-undecenoate, 22. The geometric isomers were separated on a 100% Ag/Na (9) column, and the *cis* isomer was transacetalized with methanol and *p*-toluenesulfonic acid (5) to methyl 12,12-dimethoxy-*cis*-9-dodecenoate, 23. This compound gave the same ^{13}C NMR spectrum as the methyl 12,12-dimethoxy-*cis*-9-dodecenoate obtained by the periodic acid oxidation in methanol of methyl *threo*-12,13-dihydroxy-*cis*-9-octadecenoate obtained from



SCHEME 2. DHP, Dihydropyran; THP, tetrahydropyranyl, *p*-TSA, *p*-toluene-sulfonic acid; THF, tetrahydrofuran.



SCHEME 3. *p*-TSA, *p*-toluenesulfonic acid; THF, tetrahydrofuran.

Vernonia oil (10). Hydrolysis of the acetal ester yields the β, γ-unsaturated aldehyde ester contaminated with small amounts of the α, β-isomer, the quantity of which depends on the reagents and conditions used for the hydrolysis.

If the Wittig reaction between 21 and the dioxanylethylphosphonium salt is carried out under thermodynamic control (4), the reaction mixture will contain a larger percentage of the *trans* isomer of 22. This can be separated and transacetalized to methyl 12,12-dimethoxy-*trans*-9-dodecenoate, which can be used to make other isomers.

EXPERIMENTAL

Reagents. [2-(1,3-Dioxan-2-yl)ethyl]triphenylphosphonium bromide, butyl lithium, triphenylphosphine, dihydropyran, pyridinium chlorochromate, ethyl magnesium bromide, sodium borohydride, 5-bromopentanoic acid, 3-butynol, Molecular Sieve 4A and Lindlar's catalyst (5% Pd on calcium carbonate poisoned with lead) were obtained from Aldrich Chemical Co. (Milwaukee, WI). 2-Pentynol, 3-hexynol and 3-butynol were purchased from Farchan Laboratories (Gainesville, FL). *Tris*(Triphenylphosphine)chlororhodium was obtained from Strem Chemicals (Newburyport, MA) and Palmolyn 100 from Hercules, Inc. (Wilmington, DE).

Procedures. A 50 m × 0.25 mm CPS-2 capillary column (Quadrex Corp., New Haven, CT) was used for analyzing binary mixtures of geometric isomers. For other analyses, a 6 ft × 4 mm column packed with 3% EGSSX on 100/120 GasChrom Q or a 6 ft × 4 mm column packed with 3% OV101 on 80/100 Supelcoport was employed.

^{13}C-NMR. ^{13}C-NMR spectra were recorded with a Bruker WM 300 WB pulsed Fourier transform spectrometer operating at 75.5 MHz. Typically, 2500 transients were collected from solutions in $CDCl_3$, which served as both the internal lock and secondary reference, using 5 mm tubes. Sweep widths of 200 ppm and 8 K real data points limited acquisition time to 0.54 sec and were used to obtain chemical shift values within ±1.85 Hz, i.e. ±0.05 ppm. A pulse width of 3 us (40°) was employed with no delay between pulses. Decoupling power was held to ca. 1 W to provide adequate broadband decoupling power while minimizing sample heating.

Mass spectroscopy. Mass spectra were determined on a Finnigan 4500 mass spectrometer using isobutane chemical ionization with data processing of the isotope distribution against standards (13).

Preparation: 1-bromo-2-pentyne, 1. Triphenylphosphine (164 g, 626 mmol) was dissolved in CH_2Cl_2 (400 ml) in a one-l, three-necked flask equipped with a mechanical stirrer, a low-temperature thermometer, a burette or dropping funnel and a $CaCl_2$ drying tube. While a slow stream of N_2 was passed through the apparatus immersed in an ice bath, bromine (31.8 ml, 99.2 g, 620 mmol) was added dropwise over one hr while the temperature varied between 0 and 6 C. 2-Pentynol (50.27 g, 598 mmol) dissolved in CH_2Cl_2 (50 ml) was added to the slurry over 0.5 hr while the temperature was maintained below 8 C. The ice bath was removed, and about two hr later the reaction mixture was diluted with hexane (400 ml) to precipitate triphenylphosphine oxide. The filtrate and the washings of this precipitate were passed through a column (3 × 50 cm) of silica gel (100 g). Because the bromopentyne codistills with the solvents, the mixture was distilled through a column packed with glass helices (15 mm × 21 cm) to remove the solvent (some bromopentyne still distilled). 1-Bromo-2-pentyne (41.62 g, 47.3% yield) was obtained, bp 130–140 C at atmospheric pressure. ^{13}C NMR in $CDCl_3$ (C#, ppm): 1, 12.6; 2, 74.6; 3, 89.4; 4, 13.5; 5, 15.6.

Preparation: 3,6-nonadiynol, 2. 3-Butynol (21.7 g, 310 mmol) was dissolved in tetrahydrofuran (400 ml) in a one-l, three-necked flask equipped with a mechanical stirrer, a low-temperature thermometer, a septum inlet and a condenser and cooled in an ice bath. Ethyl magnesium bromide in tetrahydrofuran (2.04 M, 310 ml, 630 mmol) was added dropwise from a syringe through the septum inlet over one hr while the temperature was maintained between 7 and 14 C. Thirty min later, the ice bath was removed, and one hr after that CuCl (0.5 g) was added. Thirty min later, 1-bromo-2-pentyne (41.17 g, 280 mmol) in tetrahydrofuran (20 ml) was added over 20 min with the temperature maintained at 24–31 C by intermittent use of an ice bath. One hr later, the reaction mixture was heated to the reflux temperature and maintained there for 19 hr. The pale-green opalescent liquid was cooled in an ice bath and acidified with 5 N H_2SO_4 (ca. 110 ml). Water (250 ml) was added, and the mixture was extracted with ethyl ether (1 × 250 ml, 2 × 100 ml). The combined ether layers were washed with saturated NH_4Cl (200 ml) and saturated NaCl (100 ml) solutions and dried over Na_2SO_4. After filtration, the solvent was removed on a rotary evaporator and compound 2 was obtained by distillation, bp 90–97 C @ 1.2 torr (22.64 g, 59.5% yield). ^{13}C NMR in $CDCl_3$ (C#, ppm): 1, 60.95; 2, 22.99; 5, 9.60; 7, 81.95; 8, 12.24; 9, 13.74; Unassigned, 76.82, 73.38, 73.05.

Preparation: 3,6-nonadienol, 3. Sodium borohydride (1 g) was dissolved in 95% ethanol (25 ml) and 10% NaOH (1 ml), and the solution was filtered. In a 500 ml round-bottom flask equipped with a magnetic stirrer and connected to an apparatus for maintaining one atmosphere pressure was placed $Ni(C_2H_3O_2)_2.4H_2O$ (4.15 g, 16.6 mmol)

in 95% ethanol (150 ml). The borohydride solution (19 ml, 20 mmol) was added via syringe. There was a rapid evolution of gas, and the mixture turned black. Ethylenediamine (2 ml) was added, and the system was evacuated and flushed several times with H_2. Then, 3,6-nonadiynol (22.64 g, 166 mmol) in 95% ethanol (25 ml) was added, and stirring was started. When absorption of H_2 had almost ceased, the reaction mixture was filtered through a pad of Celite and Darco 6-60 in a Buchner funnel. The pad then was washed with 95% ethanol (2 × 50 ml). The combined ethanol extracts, which had a permanganate color, were concentrated on the rotary evaporator to 65 ml. Water (100 ml) was added, and the mixture was extracted with ethyl ether (3 × 40 ml). The combined ether extracts were washed with saturated NaCl solution (2 × 40 ml) and dried over Na_2SO_4. Distillation gave compound 3 (19.08 g, 81.9% yield), bp 92–98 C @ 4.5 torr. ^{13}C NMR in $CDCl_3$ (C#, ppm): 1, 61.95; 2, 30.67; 3, 131.94; 4, 126.77; 5, 25.51; 6, 125.32; 7, 130.93; 8, 20.42; 9, 14.06.

Preparation: 1-bromo-3,6-nonadiene, 4. In a manner similar to the conversion of 2-pentynol to 1-bromo-2-pentyne, 1, 3,6-nonadienol, 3, (19 g, 136 mmol) was treated with triphenylphosphine dibromide to give compound 4 (23.4 g, 85% yield), bp 82–89 C @ 3.75 torr. ^{13}C NMR in $CDCl_3$ (C#, ppm): 1, 32.36: 2, 30.83: 3, 131.22; 4, 126.51; 5, 25.69; 6, 126.06; 7, 132.27; 8, 20.57; 9, 14.19.

Preparation: 3,6-nonadienyltriphenylphosphonium iodide, 5. A solution of 4 (23.4 g, 115 mmol) in acetone (50 ml) was added to a solution of NaI (21.6 g, 144 mmol) in acetone (100 ml). The mixture was heated at the reflux temperature for 1.5 hr; the white solid was removed by filtration; and the filtrate was concentrated on the rotary evaporator to an orange liquid and yellow solid (total weight 33.07 g). The liquid was decanted into a 500 ml round bottom flask, and the yellow solid was washed with acetonitrile, which was added to the flask. Triphenylphosphine (35 g, 134 mmol) was added together with the remainder of 200 ml of acetonitrile. Xylene (1 ml) was added as an internal standard, and the reaction mixture was heated at the reflux temperature by means of an oil bath. Samples were analyzed on a 3% OV101 column. After three hr, only 16.6% of the iodo compound remained; after 19 hr, only 1.5% remained. Solvent was removed on the rotary evaporator, the thick liquid was transferred to a beaker and triturated several times with portions of ethyl ether until it deposited crystals. These were washed with ether, pulverized on a clay plate and dried in a vacuum desiccator to give compound 5 (57.8 g, 98% yield). ^{13}C NMR in $CDCl_3$ (C#, ppm): 1, 23.22; 2, 20.25; 5, 25.31; 8, 20.14; 9, 13.95; Unassigned: 132.19; 130.68; 125.97; 125.82; 125.77.

Preparation: methyl 9-hydroxy-6-nonynoate, 6 and 7. Liquid ammonia (ca. 800 ml) was charged to a two-l, three-necked flask equipped with a mechanical stirrer and a dry ice-cooled condenser and immersed in a box of Vermiculite insulating material. As catalyst for the formation of lithium amide, $Fe(NO_3)_3.9H_2O$ (0.5 g) was added. Then, lithium metal (9.67 g, 1380 mmol) was added in small pieces over one hr. The reaction mixture became blue-black at first but then changed to a grey slurry. To this was added a solution of 3-butynol (48.3 g, 690 mmol) in tetrahydrofuran (125 ml) over a period of one hr. Two hr later, a solution of 5-bromopentanoic acid (26.4 g, 146 mmol) in tetrahydrofuran (100 ml) was added over 45 min. Stirring was continued for about 1.5 hr. The stirrer was stopped, the Vermiculite was removed, and the ammonia was permitted to evaporate overnight. Ammonia remaining was flushed out with a stream of argon while the reaction vessel was immersed in a warm water bath. Water (60 ml) was added slowly followed by 5 N H_2SO_4 (350 ml) until acidic, and the temperature was maintained at 20 C with an ice bath. The product mixture was extracted into ethyl ether (1 × 250 ml and 2 × 100 ml), and the combined ether extracts were washed with saturated NH_4Cl solution (100 ml) and saturated NaCl solution (100 ml). After drying over Na_2SO_4, the ether was removed on the rotary evaporator to give a reaction mixture (74.66 g). Excess 3-butynol present in this mixture was removed by distillation under reduced pressure, and the material remaining was treated with methanol and H_2SO_4 at the reflux temperature. This reaction mixture was neutralized with solid $NaHCO_3$, concentrated on the rotary evaporator and extracted into ether. Compound 7 (13.75 g, 52% yield) was obtained by distillation, bp 98–115 C @ 0.2 torr. ^{13}C NMR in C_6D_6 (C#, ppm): 1, 173.6; 2, 33.6; 3, 23.5; 4, 28.6; 5, 18.7; 6, 81.4; 7, 77.8; 8, 24.3; 9, 61.7; OCH_3, 51.1.

Preparation: methyl 9-(2-tetrahydropyranyloxy)-6-nonynoate, 8. Methyl 9-hydroxy-6-nonynoate (7 g, 38 mmol) and *p*-toluenesulfonic acid (0.5 g) were dissolved in ethyl ether (10 ml) in a 100 ml round bottom flask equipped with a magnetic stirring bar and a reflux condenser. Dihydropyran (4 g, 48 mmol) in ether (10 ml) was added dropwise. Heat was evolved, and the reaction mixture darkened. After three hr, the reaction mixture was washed with saturated Na_2CO_3 solution (10 ml), dried and distilled under reduced pressure in the presence of a pellet of KOH to give compound 8 (6.74 g, 66% yield) bp 140–147 C @ 0.2 torr. ^{13}C NMR in $CDCl_3$ (C#, ppm): 1, 173.5; 2, 33.4; 3, 23.9; 4, 28.2; 5, 18.3; 6, 80.3; 7, 77.2; 8, 20.1; 9, 66.0; OCH_3, 51.2. THP group: 2, 98.5; 3, 30.5; 4, 19.3; 5, 25.4; 6, 61.9.

Preparation: methyl 9-(2-tetrahydropyranyloxy)-nonanoate-6,6,7,7-d_4, 9. Compound 8 (6.7 g, 25 mmol) in benzene (200 ml) was treated with deuterium gas at atmospheric pressure in the presence of *tris*(triphenylphosphine)chlororhodium (1 g) in the manner described previously (3). The benzene was removed on the rotary evaporator, and the residue was passed through a column (1.5 × 25 cm) of silica gel (15 g) with hexane to remove the catalyst. Removal of the solvent gave compound 9 (6.63 g, 96% yield). ^{13}C NMR in $CDCl_3$ (C#, ppm): 1, 174.2; 2, 34.1; 3, 24.9; 4–5, 28.9–29.0; 8, 29.4; 9, 67.6; OCH_3, 51.3: THP group: 2, 98.8; 3, 30.8; 4, 19.7; 5, 25.4; 6, 62.3.

Preparation: methyl 9-hydroxynonanoate-6,6,7,7-d_4, 10. Compound 9 (6.63 g, 24 mmol) was stirred in methanol (150 ml) with *p*-toluenesulfonic acid (0.35 g) in a nitrogen atmosphere. Two hr later, solid Na_2CO_3 was added, and the mixture was concentrated to a thick liquid on the rotary evaporator. Saturated Na_2CO_3 solution (40 ml) was added, and the mixture was extracted into ethyl ether (2 × 25 ml) and dried over Na_2SO_4. The drying agent and solvent were removed and compound 10 (3.62 g, 78.7% yield) was obtained by distillation, bp 113–120 C @ 0.35 torr. ^{13}C NMR in $CDCl_3$ (C#, ppm): 1, 174.2; 2, 34.0; 3, 24.8; 4–5, 28.8–28.9; 8, 32.4; 9, 62.7; OCH_3, 51.3.

Preparation: methyl 9-oxononanoate-6,6,7,7-d_4, 11. Pyridinium chlorochromate (11.54 g, 53 mmol) was slurried

in CH_2Cl_2 (100 ml, dried over Molecular Sieve 4A) in a 250 ml three-necked flask equipped with a mechanical stirrer, a thermometer and a $CaCl_2$ drying tube. Compound **10** (6.8 g, 35.4 mmol) dissolved in CH_2Cl_2 (20 ml) was added to the orange slurry, which darkened rapidly and deposited a tarry material on the walls of the flask. The temperature was maintained at 20 ± 2 C by intermittent use of an ice bath. Two hr later, ethyl ether (100 ml) was stirred into the mixture and then decanted. This was repeated three times with 25 ml portions of ether. The combined decantates were passed through Florisil (20 g) in a column (1.5 × 25 cm), and the column was flushed with ether (50 ml). The solvents were removed on a rotary evaporator to give a green liquid (6.67 g), that was distilled to give compound **11** (4.47 g, 66.7% yield), bp 96–102 C @ 0.35 torr. ^{13}C NMR in $CDCl_3$ (C#, ppm): 1, 174.0; 2, 33.9; 3, 24.8; 4–5, 28.6–28.8; 8, 43.5; 9, 202.6; OCH_3, 51.3.

Preparation: methyl cis-*9*,cis-*12*,cis-*15-octadecatrienoate-6,6,7,7-*d_4, ***12.*** A slurry of **5** (13.5 g, 26.4 mmol) in tetrahydrofuran (100 ml) was prepared in a 250 ml three-necked flask equipped with a mechanical stirrer, a low temperature thermometer, a dropping funnel and a $CaCl_2$ drying tube. A stream of N_2 was passed through the flask and it was cooled in an ice-salt bath to about 1 C. Butyl lithium in hexane (2.42 M, 15 ml, 36 mmol) was added. The temperature rose to about 14 C, and the yellow slurry changed to a deep orange-red color. Compound **11** (4.4 g, 23 mmol) in tetrahydrofuran (12 ml) was added over six min at a temperature of 1–6 C. There was no noticeable color change. The ice bath was removed, and 30 min later the reaction mixture was transferred to a separatory funnel and washed with saturated NaCl solution (100 ml). The organic layer was dried over anhydrous Na_2SO_4. The thick oil (17.33 g) remaining after removal of the solvent was passed through a column (2.2 × 35 cm) of silica gel (40 g) in hexane to give a mixture of isomers (5.87 g, 85% yield). Mass analysis: 0.24% d_2, 0.46% d_3, 98.91% d_4, 0.32% d_5.

To isolate the all *cis* isomer, the reaction mixture (19.03 g) was separated on a silver resin column (9), 5 × 82 cm, Amberlyst XN1010 (40/80 mesh), 100% Ag/H, using as eluant a solution of acetonitrile (300 ml) in methanol (3.7 l). There was obtained 8.6 g (35% overall yield based on the aldehyde ester used) of the all *cis* isomer, better than 98% pure by gas-liquid chromatography on the CPS-2 capillary column. ^{13}C NMR in $CDCl_3$ (C#, ppm): 1, 174.2; 2, 34.1; 3, 25.0; 4–5, 28.9–29.1; 8, 27.0; 9, 130.2; 10, 127.7; 11, 25.6; 12, 128.3; 13, 128.3; 14, 25.5; 15, 127.1; 16, 131.9; 17, 20.6; 18, 14.3; OCH_3, 51.4.

Preparation: 2-(3'-hexynyloxy)tetrahydropyran, ***13.*** 3-Hexynol (49 g, 500 mmol) and *p*-toluenesulfonic acid (1.9 g, 10 mmol) were mixed in a 500 ml three-necked flask equipped with a mechanical stirrer, a thermometer and a dropping funnel. While a stream of N_2 was passed through the apparatus, dihydropyran (50.4 g, 600 mmol) was added dropwise over 15 min with the temperature maintained at 23–27 C by intermittent use of an ice bath. The reaction mixture developed a pale pink-amber color. It was passed through a column (3 × 50 cm) of silica gel (100 g) in petroleum ether. Yield of compound **13** was almost 100%.

Preparation: 2-(3'-4'-dideutero-3'hexenyloxy)tetrahydropyran, ***14.*** Compound **13** (45 g, 247 mmol) and ethyl acetate (100 ml) were placed in a 250 ml round bottom flask equipped with a magnetic stirring bar and connected to an apparatus for maintaining one atmosphere pressure. The apparatus was evacuated and flushed three times with D_2. Then, Lindlar's catalyst (1 g) and quinoline (0.8 ml) were added, and a pressure of one atmosphere of D_2 was maintained as the reaction mixture was stirred rapidly. After absorption of D_2 had ceased, the reaction mixture was filtered through a pad of Celite to remove the catalyst. Ethyl acetate was removed by distillation at atmospheric pressure and compound **14** (41.91 g, 91% yield) was obtained by distillation, bp 63–68 C @ 0.4 torr. Mass spectral analysis indicated better than 99% d_2.

Preparation: 1-bromo-3-hexene-3,4-d_2, ***15.*** In a manner similar to the conversion of 2-pentynol to 1-bromo-2-pentyne, **1**, compound **14** was converted to compound **15** in 72% yield, bp 120–140 C. Compound **15** tends to codistill with the solvents employed.

*Preparation: 3,4-dideutero-*cis*-3-hexenyltriphenylphosphonium bromide,* ***16.*** Triphenylphosphine (28.8 g, 110 mmol), compound **15** (17.8 g, 108 mmol) and toluene (1 ml) were mixed in acetonitrile (100 ml) in a 250 ml round bottom flask equipped with a magnetic stirring bar and a reflux condenser. The mixture was heated with stirring at the reflux temperature, and the ratio of bromohexene to toluene was followed by GLC on an OV101 column. After 30 hr, only about 9% of bromohexene remained. Acetonitrile (45 ml) was removed on the rotary evaporator, and the residue was triturated several times with fresh portions of ethyl ether. The white solid that formed was dried in a vacuum desiccator to give compound **16** (39.8 g, 86.4% yield), mp 164–167. ^{13}C NMR in $CDCl_3$ (C#, ppm): 1, 23.07; 2, 20.15; 5, 20.03; 6, 13.7; aromatic ring: 1, 118.03; 2, 133.50; 3, 130.37; 4, 134.95.

*Preparation: methyl 12-oxo-*cis*-9-dodecenoate,* ***18.*** Methyl 12,13-dihydroxy-*cis*-9-octadecenoate (50 g, 152 mmol) was dissolved in tetrahydrofuran (150 ml) in a 500 ml Erlenmeyer flask equipped with a magnetic stirring bar and a low-temperature thermometer and immersed in an ice-salt bath. Paraperiodic acid, H_5IO_6 (43.5 g, 190 mmol) was dissolved in H_2O (87 ml) and cooled in an ice bath. The periodic acid solution was added in portions over 40 min so that the temperature did not rise above 4 C. The reaction mixture was diluted with H_2O (150 ml), the organic layer was separated, and the aqueous layer was extracted with hexane (2 × 50 ml). The combined organic layers were washed with H_2O (1 × 25 ml) and dried over Na_2SO_4 and Drierite. After removal of the drying agents and solvent, the residue was freed of any other volatiles (especially hexanal) by use of a vacuum pump at room temperature. The residue was then distilled through a falling film molecular still (0.05 torr, refluxing xylene) to give compound **18** (27.36 g, 79% yield).

Preparation: methyl cis-*9*,cis-*12*,cis-*15-octadecatrienoate-15,16-*d_2, ***19.*** Compound **16** (39.03 g, 91.4 mmol) was slurried in tetrahydrofuran (200 ml) in a 500 ml three-necked flask equipped with a mechanical stirrer, a low-temperature thermometer, a dropping funnel and a $CaCl_2$ drying tube. A stream of N_2 was maintained through the apparatus as it was cooled in an ice-salt bath. Butyl lithium in hexane (2.5 M, 40 ml, 100 mmol) was added in portions with the temperature varying between 0 and 18 C. Then compound **18** (27.25 g, 120 mmol) in tetrahydrofuran (10 ml) was added over 12 min to the blood

red reaction mixture. The maximum temperature was 7 C, and the reaction mixture formed a pale-tan slurry. The ice bath was removed, and about one hr later the reaction mixture was shaken with saturated NaCl solution (100 ml). The organic layer was dried over Na_2SO_4 and Drierite. After filtration, the solvent was removed on the rotary evaporator, and the residue (71.71 g) was placed on a column (3 × 50 cm) containing silica gel (100 g) in hexane. Elution with hexane yielded a mixture of isomers (19.81 g, 73.7% yield). This mixture was separated on a 5 × 82 cm column packed with Amberlyst XN1010 (40/80 mesh) 100% Ag/H resin (9) with the eluant being acetonitrile (300 ml) in methanol (3.7 l), to give the all-*cis* isomer (7.69 g, 28.4% yield based on the phosphonium salt used). Mass spectral analysis: 0.41% d_0, 0.29% d_1, 99.26% d_2. ^{13}C NMR in $CDCl_3$ (C#, ppm): 1, 174.1; 2, 34.0; 3, 24.8; 4-7, 29.0-29.4; 8, 27.1; 9, 130.1; 10, 127.6; 11, 25.3-25.5; 12, 128.1; 13, 128.1; 14, 25.3-25.5; 17, 20.3; 18, 14.1.

Preparation: methyl 9-oxononanoate, 21. Compound 21 was prepared in 64% yield essentially as previously described (14) but with the use of Sudan Red (0.01 g in 10 g of cyclohexane) as an indicator of the completion of the ozonolysis and Palmolyn 100 methyl esters as the source of methyl oleate.

Preparation: methyl 11-dioxanyl-9-undecenoates, 22. Compound 22, bp 140-152 C @ 0.2 torr, was obtained in 78% yield by the method previously described (5,12) for the synthesis of another dioxanyl ester. Mass spectroscopy showed a parent peak at 284 m/z and a large peak at 87 m/z corresponding to the dioxanyl group. ^{13}C NMR chemical shifts were consistent with the structure assigned. The *cis* and *trans* isomers of 22 (73.4% *cis*) were separated on a 3.5 × 30 cm column of 100% Ag/Na (9) Amberlyst XN1010 ion exchange resin (200-270 mesh). From a sample of 1.84 g, there was obtained 1.19 g (88% of theory) of the *cis* isomer.

Preparation: methyl 12,12-dimethoxy-cis-9-dodecenoate, 23. Compound 23, bp 132-140 C @ 0.25 torr, was obtained in 62% yield from 22 by a method described (5,12). The ^{13}C NMR spectrum is identical to that of the dimethylacetal ester prepared by periodic acid oxidation in methanol (10) of methyl 12,13-dihydroxy-*cis*-9-octadecenoate. During GC/MS analysis, the dimethyl acetal apparently loses CH_3OH to give methyl 12-methoxy-9,11-dodecadienoate, which gives a parent peak at 240 m/z and an M-31 peak at 209 m/z. The base peak is at 97 m/z corresponding to $CH_3\overset{\oplus}{O}=CH_2\text{-}(CH=CH)_2$.

Purification of 12,13-dihydroxy-cis-9-octadecenoic acid. (1) By distribution between aqueous acetonitrile and petroleum ether. The mixture of acids obtained from the acetolysis and saponification of *Vernonia anthelmintica* seed oil (15) was analyzed by GLC on 3% EGSSX after the acid group had been converted to the methyl ester and the hydroxy groups had been converted to a dioxolane with acetone and $BF_3.CH_3OH$. This acid mixture (301 g) showed 67% dihydroxyoleic acid. It was suspended in a mixture of acetonitrile (700 ml) and H_2O (70 ml) and extracted with petroleum ether (3 × 250 ml). Removal of the CH_3CN-H_2O gave a product (204.3 g) that analysis showed to contain 84% dihydroxyoleic acid. (2) By crystallization from ethyl ether-petroleum ether. A sample (230 g) of *Vernonia* acids containing 84% dihydroxyoleic acid was dissolved with stirring in ethyl ether (400 ml). Addition of petroleum ether (500 ml) caused a haziness that was cleared up by addition of ethyl ether (20 ml). The mixture was cooled in an ice bath for several hours with stirring, and the precipitate that formed was filtered with suction and washed with petroleum ether to remove a small amount of contaminating dark oil. The solid was pulverized and air-dried to give a product (61.26 g) analysis of which showed 96.6% dihydroxyoleic acid, 1.57% linoleic acid, 0.38% oleic acid, 0.36% palmitic acid and 1.04% of a material eluting after dihydroxyoleic acid. Mp 49-50 C.

[Received June 24, 1987; Revision accepted November 10, 1987]

Uptake of Fatty Acids by the Developing Rat Brain

Gregory J. Anderson and **William E. Connor***
Department of Medicine, Division of Endocrinology/Metabolism and Clinical Nutrition, The Oregon Health Sciences University, Portland, OR 97201

Polyunsaturated fatty acids are avidly taken up by the developing rat brain. To explore the specificity of this process, [1-^{14}C]labeled 16:0, 18:2n-6, 18:3n-3, and 22:6n-3 each were co-injected with [^{3}H]18:1n-9 into the jugular vein of two-wk-old functionally hepatectomized and sham-operated control rats. The radioactivities present in the brain, liver and serum were assessed 30 min after injection. Uptake of labeled fatty acids into brain lipids steadily increased with increasing degree of unsaturation, with more than twice as much uptake of 22:6n-3 compared to 16:0. Phosphatidylcholine was the principal radioactive species in the brain except for animals injected with [1-^{14}C]22:6n-3, in which more of the label was incorporated into phosphatidylethanolamine. Determination of water-soluble oxidation products in the brain and serum revealed that the greater uptake of the more unsatrated fatty acids did not result from differences in rates of degradation.
Lipids 23, 286–290 (1988).

The n-3 fatty acids are highly enriched in nervous tissue and are assumed to have important functions. Nutritional studies have suggested that these species are essential in the diet and that the symptoms produced by n-3 fatty acid deficiency are distinct from those produced by n-6 fatty acid deficiency (1–4). While the pathway leading to the synthesis of docosahexaenoic acid (22:6n-3), the principal n-3 fatty acid in the brain, is well-understood (5), the process by which this fatty acid actually reaches the brain is less clear. It is known that in rats, most of the adult complement of brain 22:6n-3 is laid down after birth during the period of brain development preceding myelination (6,7). However, it is not known to what extent the brain synthesizes 22:6n-3 from precursor molecules such as 18:3n-3, or how specifically or in what quantity the brain takes up 22:6n-3 and other fatty acids from the circulation. A number of studies have examined the question of uptake of unsaturated fatty acids by the developing brain (8–13), with delivery of the isotope either orally or by intraperitoneal injection. We decided to compare brain uptake of 22:6n-3, 18:3n-3 and other fatty acids more directly by injecting the labeled fatty acids intravenously and by removing the liver from the circulation to reduce secondary metabolism of the label.

MATERIALS AND METHODS

All isotopes were purchased from NEN Research Products (Boston, MA) and [9,10-^{3}H]18:1 n-9 was purified by silica gel thin layer chromatography (TLC) before use. In each experiment, ca. 5 μCi of ^{14}C fatty acid was used together with 5 μCi of [^{3}H]18:1 to provide an internal reference. To prepare samples for injection, labeled fatty acids (in ethanol solution) were dried under nitrogen, redissolved in 0.6 ml 20% rat serum in normal saline (14), and stirred magnetically for 15 min. Before injection, an aliquot was removed for determination of radioactivity.

The animals used were unfasted two-wk-old male Sprague-Dawley rat pups (median age 15 days, range 13–16 days) weighing 37.2 ± 3.6 g. At this age, the uptake of polyunsaturated fatty acids by the brain is maximal (6,7). Dams were fed standard laboratory chow ad libitum. The rat pups were anesthetized with 0.03 ml i.p. of a ketamine cocktail (100 mg/ml ketamine, 20 mg/ml xylazine, and 10 mg/ml acepromazine) and were functionally hepatectomized by placing a Biemer clip (Aesculap Instruments Corp., Burlingame, CA) on the porta hepatis to interrupt circulation to the liver. The livers of these animals immediately turned pale and remained so except for occasional periods when they again became pink during "deep breaths." This probably explains the presence of radioactivity in these livers (Table 1). Sham-operated controls were treated in an identical manner except that the liver was not compromised.

Fatty acids were injected into the jugular vein by means of an indwelling catheter consisting of a snapped-off 23-gauge needle connected to a three-way stopcock by PE-50 tubing. Patency was verified by drawing back a small amount of blood before injection. Approximately 0.55 ml of the fatty acid solution was slowly introduced and was followed by a wash of 0.2 ml 20% rat serum in normal saline.

After 30 min, a small amount of blood was drawn from the vena cava and the animal decapitated. The brain and liver (weighing ca. 1 g each) then were quickly removed, rinsed in saline, blotted and frozen. These tissues were extracted according to Folch et al. (15) and an aliquot from both the aqueous and organic phases counted in Beckman HP-b cocktail on a Beckman LS-9000 scintillation counter capable of simulaneously determining ^{3}H and ^{14}C. The ^{3}H in the aqueous phase was not quantitated, since labeled oxidation products arising from [9,10-^{3}H]18:1 cannot be compared with those arising from [1-^{14}C] labeled fatty acids.

The ^{14}C and ^{3}H DPM in the organic phase, expressed per gram wet weight tissue, were dose-corrected to 5 μCi. These individual values then were normalized to compare uptake of the various [^{14}C] labeled fatty acids relative to the internal standard, [^{3}H]18:1. The normalization was carried out by multiplying each individual [^{14}C] uptake by the ratio (mean uptake of [^{3}H]18:1 from all experiments):(respective individual uptake of [^{3}H]18:1). The means of the normalized uptakes of the various ^{14}C labeled fatty acids were then compared by multiple t-tests, using the BonFerroni inequality (16) to control the overall α-level. No attempt was made to quantify the radioactivity remaining in the carcass or exhaled as CO_2.

To examine the distribution of label within the tissues, the total lipids of brain, liver and serum were fractionated by silica gel TLC with hexane/chloroform/ethyl ether/acetic acid (80:10:10:1.5). Brain lipids also were

chromatographed on silica gel 60 plates with methyl acetate/propanol/chloroform/methanol/0.25% KCl (25:25:25:10:9, v/v/v/v/v) (17) to separate phospholipid classes. Scintillation cocktail was sprayed onto the plates to visualize the bands, which then were scraped directly into counting vials. Because free fatty acid was the major component of the serum lipids but only a minor component of the brain lipids of hepatectomized animals and because of the seven-fold higher ^{3}H:^{14}C ratio in the free fatty acid fractions of the serum lipids vs brain lipids (data not shown), it was possible to determine by successive approximations that the amount of ^{14}C in the brain lipids that actually was due to contaminating serum was very low, on the order of 1-2%.

The fatty acid composition of the brain, liver and serum of two-wk old rat pups was determined by capillary gas chromatography as described (1).

RESULTS

The IV injection of radiolabeled fatty acids into two-wk-old rat pups resulted in a measurable accumulation of radioactivity in the developing brain of these animals 30 min after their injection (Table 1). Substantially more radioactivity reached the brain of the functionally hepatectomized pups. There was a steady and significant increase in uptake of [1-^{14}C] fatty acid as the degree of unsaturation increased; 22:6n-3 showed more than twice as much uptake as 16:0 and considerably more than 18:2n-6.

Most of the label in the brain was present as phospholipid, with small amounts of labeled cholesterol, fatty acid and triglyceride (Table 2). For 16:0, 18:1, 18:2n-6 and 18:3n-3, the bulk of the phospholipid radioactivity was found in the phosphatidylcholine fraction. In contrast, 22:6n-3 was incorporated principally into phosphatidylethanolamine. Interestingly, there was roughly twice as much label in the brain phosphatidylinositol fraction of the animals injected with 18:3n-3 than in the phosphatidylinositol of the animals injected with the other fatty acids. There was little change in the distribution of radioactivity in the brains of sham-operated controls except that slightly less material was present in phospholipid, with a corresponding increase in the amount of cholesterol and triglyceride (data not shown).

The presence of a portion of the label from each experiment in the cholesterol fraction of the brain lipids indicates that some fatty acid must have been oxidized to acetate with subsequent synthesis of cholesterol. This reuse of breakdown products by the developing rat brain has been noted before (11,12,21,29,30). About twice as much cholesterol was formed from 18:3n-3 than from the other ^{14}C-labeled fatty acids, suggesting that more of this fatty acid was oxidized in the brain. This observation is supported by the data in Table 3, in which water-soluble ^{14}C was measured in the brain, liver and serum of both the hepatectomized and control pups. Twice as much degradation product(s) was present in the brains of animals injected with 18:3n-3 than in animals injected with the other fatty acids. The special susceptibility of 18:3n-3 to oxidation has been noted (12,13,18).

It also can be seen in Table 3 that there was no decrease in oxidation products with increasing degree of unsaturation of the injected fatty acid. In fact, the opposite was true, i.e. there was somewhat more oxidation of those fatty acids that accumulated to a greater extent in the brain. This also was the case in serum. In general, there was about a three-fold increase in the amount of oxidation product measured in the brains of sham-operated controls than in hepatectomized animals.

The distribution of serum lipids was also investigated by TLC (Table 4). When the liver was removed from the circulation, the bulk of the serum lipid radioactivity (representing about 1% of the injected dose) still was present as fatty acid 30 min after injection, although significant quantities of 18:3n-3 and 22:6n-3 were found as phospholipid. However, in sham-operated controls roughly 3% of the injected dose was found in serum lipids, and most of this was present as triglyceride. This probably represents very low density lipoprotein (VLDL) secreted by the liver. The anomalously high proportion of ^{3}H label found in the fatty acid fraction of serum lipids

from both the hepatectomized and control rats is an artifact due to degradation products which co-migrate with fatty acid, since this anomaly was not seen when [1-^{14}C]18:1n-9 was injected (data not shown).

Despite interruption of the normal blood supply to the liver in the functionally hepatectomized animals, some radioactivity was found in these livers (Table 1). However, there was no differential metabolism of the various fatty acids. On the other hand, sham-operated controls showed considerable uptake of fatty acid by the liver, roughly 30–40 times that of the brain on a per gram basis.

The liver showed an even stronger preference for 22:6n-3 than the brain, with the liver accumulating four times more radioactivity from this fatty acid than from the other fatty acids, which were not significantly different in their uptakes. This selectivity by the liver for 22:6n-3 has been noted (10). The distribution of label in liver lipids was quite different from brain. For 18:2n-6, the label was found about equally in phospholipid and triglyceride. Two-thirds of the label from 18:3n-3 was present in triglyceride and about one-third in phospholipid, while the reverse was true for 22:6n-3 (data not shown). Very little of the radioactivity was present in cholesterol or cholesteryl ester.

To compare the tissue uptake of the injected fatty acids with the relative amounts of these fatty acids present in the tissues, the fatty acid composition of brain, liver and serum from two-wk-old rat pups was determined (Table 5). The relative uptake of [1-^{14}C] labeled 16:0, 18:2n-6, 18:3n-3 and 22:6n-3 by the brain and liver bore no relationship to the relative concentration of each species in the total fatty acids of these tissues. With regard to the high uptake of 22:6n-3 by the two-wk-old liver, the concentration of 22:6n-3 in liver total fatty acids was twice as high as in normal adult rat liver (19).

DISCUSSION

During the suckling period, the developing rat brain accumulates most of its eventual adult complement of polyunsaturated fatty acids, including 22:6n-3. This process occurs at a linear and maximal rate 10–16 days after birth (6,7). For this reason, we chose 15-day-old suckling rats for our study. We compared the brain uptake of IV-injected, ^{14}C labeled 16:0, 18:2n-6, 18:3n-3 and 22:6n-3 by relating each of these to the uptake of a co-injected reference fatty acid, [^{3}H]18:1n-9. Brain uptake in the functionally hepatectomized animals increased steadily with increasing degree of unsaturation, suggesting that the brain is not neutral in its selection of fatty acids from the circulation. Functional hepatectomy improved the uptake of fatty acid into the developing brain to a lesser extent than it did in adult rats injected with 16:0 or 18:2n-6 (23,26).

The difference in uptake between 18:3n-3 and 22:6n-3 was unexpectedly small. For example, Sinclair (11) found that oral feeding of 18:3n-3 and 22:6n-3 to two-wk-old rats led to the accumulation in the brain of 10 times more label from 22:6n-3 than from 18:3n-3. A similar disparity was noted by Hassam and Crawford (9) for orally fed 18:2n-6 vs 20:4n-6. Apparently, when the potential for metabolism and/or oxidation of the delivered fatty acid is reduced by bypassing the intestines and removing the liver from the circulation, a more moderate selectivity by the brain for the more unsaturated fatty acids is revealed. One might argue that the relative accumulation of label seen in Table 1 is the result of less degradation of the more unsaturated fatty acids, either before they entered the brain, or after. This is not consistent with the data in Table 3, however, where it is seen that more not fewer oxidation products of 18:3n-3 and 22:6n-3 were detected in the brain and serum of functionally hepatectomized rats.

Phosphatidylcholine was the most highly labeled brain lipid after IV injection of radioactive 16:0, 18:1n-9, 18:2n-6 and 18:3n-3, a result consistent with previous experiments on adult and suckling rats (12,13,20–23). However, the presence in phosphatidylethanolamine of the major portion of the label from IV-injected [1-^{14}C]22:6n-3 was not expected based on the results from intracranial injection (24). Fifteen min after direct injection of 22:6n-3 into the brain of 18-day-old rats, roughly 50% of the label was in phosphatidylcholine and about 40% in phosphatidylethanolamine. The distribution was approximately unchanged after 60 min. This contrasts with only 26% of the label in phosphatidylcholine and 42% in phosphatidylethanolamine after 30 min in our experiments. Thus, it is possible that 22:6n-3 passing to the brain through the capillary endothelium enters a different compartment than 22:6n-3 injected directly into the brain.

A question not addressed by our study was the degree to which the injected fatty acids were desaturated and chain-elongated. One possible explanation for the relatively high uptake of label from [1-^{14}C]18:3n-3 would entail the metabolism of this compound to 22:6n-3 followed by enhanced uptake by the brain relative to 18:3n-3 proper. However, the striking difference in the fate of the

label from [1-^{14}C]18:3n-3 and [1-^{14}C]22:6n-3 suggests that 18:3n-3 did not enter the brain as "22:6n-3." With the present data, we cannot make any statement about the extent to which each fatty acid was further elaborated after reaching the brain.

There is controversy over the chemical form of the essential fatty acids taken up by the brain. That is, it is not clear whether free fatty acid (bound to albumin or perhaps α-fetoprotein in the case of 22:6n-3 [25]) is the preferred form of lipid taken up by the brain, as has been proposed (26). For example, most of the 22:6n-3 in the serum of two-wk-old suckling rats actually is present in phosphatidylcholine, and most of the 18:3n-3 is present as triacylglycerol (23). It also is not clear to what extent the liver is involved. The presence of significant quantities of 22:6n-3 in the serum lipoproteins of rat pups suckling mothers fed diets high in 18:3n-3 has been interpreted as implying a role for the liver in the desaturation/elongation of essential fatty acids, and their repackaging for export to the developing brain (27). On the other hand, Cook (28) found the developing brain itself to have a high capacity for desaturation of essential fatty acids. By studying the kinetics of lipid uptake after IV injection of 18:3n-3, 22:6n-3 and other fatty acids in a variety of chemical forms and vehicles, we should be able to better characterize the uptake process and the role of the liver.

[Received August 17, 1987; Revision accepted November 10, 1987]

Mevalonate 5-Pyrophosphate Decarboxylase in Isolated Villus and Crypt Cells of Chick Intestine

J. Iglesias, D. Gonzalez-Pacanowska, G. Caamaño and E. Garcia-Peregrin*
Department of Biochemistry and Molecular Biology, University of Granada, 18071-Granada, Spain

Mevalonate 5-pyrophosphate decarboxylase was studied in isolated enterocytes obtained from duodenal, jejunal and ileal villi and crypts. In our assay conditions, decarboxylase activity was linear for 60 min and up to 0.3 mg of protein. The subcellular location of decarboxylase in chick enterocytes was investigated. About 94% of the total activity was recovered in the cytosol. The distribution of enzyme activity in epithelial cells also was studied. Maximal specific activity was found in cell fractions from jejunum followed by ileum and duodenum. About 80% of total activity was recovered in the villus cells, indicating an active role of these cells in cholesterogenesis. Ileal cells showed the highest cholesterol content. In all the intestinal epithelial cells assayed, free cholesterol represented about 95% of the total cholesterol.
Lipids 23, 291-294 (1988).

The small intestine plays a key role in cholesterol metabolism both because it is the site for absorption of dietary sterol and because it is one of the major sites for de novo cholesterogenesis (1). However, current understanding of the regulation of cholesterol metabolism in the small intestine is incomplete. From the early work of Dietschy and Siperstein (2), it was postulated that cholesterol synthesis in the intestine, unlike the liver, was not inhibited by dietary cholesterol. Likewise, Shefer et al. (3) observed no differences in intestinal 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase activity in rats fed 2% cholesterol when compared with that of rats fed normal chow, while cholesterol feeding resulted in the inhibition of intestinal reductase in hamsters (4) and guinea pigs (5,6). Recently, we have reported the inhibitory effect of cholesterol feeding on chick intestine HMG-CoA reductase (7).

Although HMG-CoA reductase is considered to be the rate-limiting enzyme for cholesterogenesis in liver and other tissues (8,9), the existence of secondary sites of regulation beyond mevalonic acid (MVA) formation has been suggested (10,11). In this sense, we have shown that feeding a 2% cholesterol diet from hatching resulted in a significant inhibition of mevalonate 5-pyrophosphate (MVAPP) decarboxylase from chick intestine, while mevalonate kinase and mevalonate 5-phosphate (MVAP) kinase remained unaltered (12). These results, together with the developmental pattern shown by MVAPP decarboxylase during embryonic (13) and postnatal (14) periods as well as its changes in response to different nutritional conditions (12,15-17), demonstrate the important role of this enzyme in the regulation of cholesterol biosynthesis.

Until now, the enzymes responsible for the intestinal transformation of mevalonate to isopentenyl pyrophosphate have not been characterized. The purpose of this study was to investigate the distribution of MVAPP decarboxylase in the epithelial cells isolated from chick duodenum, jejunum and ileum in a villus-to-crypt gradient to compare with that of HMG-CoA reductase and to resolve the controversy over which intestinal cell type (villus or crypt) is responsible for cholesterol synthesis.

MATERIALS AND METHODS

White Leghorn male chicks *(Gallus domesticus)* 30-35 days old were used. Newborn animals were obtained from a commercial hatchery and maintained fed ad libitum on a commercial diet (Sanders A-00) in a chamber with a light cycle from 09.00 to 21.00 hr and controlled temperature. D-[2-^{14}C]Mevalonate 5-pyrophosphate (ammonium salt) and [6-^{3}H]thymidine were supplied by Amersham International (Amersham, U.K.). All other reagents used were analytical grade.

Chicks were killed by decapitation at the same hour every day (2 p.m.). Intestines were removed, chilled and then divided into three segments designated duodenum (between gizzard and biliar conduct junction), jejunum (a 12-cm region from 15 cm after biliar conduct junction) and ileum (a 12-cm region proximal to the ileo-cecal junction). Enriched isolated epithelial cell fractions from different locations along the villus-crypt axis were prepared according to Weiser (18) with the modification suggested by Raul et al. (19), consisting in the eversion of the intestine fragment prior to incubation in the chelation buffers. To define the enterocyte fraction isolated after various time intervals, alkaline phosphatase was determined as marker enzyme for differentiated villus cells (18), while thymidine kinase, determined according to Klemperer and Haynes (20) and Breitman (21) was regarded as an indicator for crypt cells. Acid phosphatase, measured by the method of Bingham and Zittle (22), was characteristic for both cell types (23).

Incubations carried out according to Weiser (18) for 20-min intervals up to a total of 160 min yielded succesive cell fractions with varying activities of the marker enzymes. Thus, the specific activity of alkaline phosphatase decreased gradually in cells progressively harvested, while the specific activity of thymidine kinase increased in the final cell fraction relative to the initial fraction. Acid phosphatase showed a practically similar specific activity in all fractions recovered, so that the observed differences in alkaline phosphatase and thymidine kinase were not due to differences in cell stability.

According to these results, the various cell fractions were combined in four separate pools designated as upper (0-40 min), mid (40-80 min) and lower (80-120 min) villus cells and as crypt cells (120-160 min) from duodenum and jejunum. In ileum, similar pools were considered according to the following intervals of time: 0-30 min, 30-60 min, 60-90 min and 90-120 min, respectively. These terms represented only a functional classification based upon the enzyme content of these groups of enterocytes and probably should not be taken as a literal indication of the anatomic sources for the various cells

(24). Protein contents were determined by the method of Lowry et al. (25) using bovine albumin as standard.

Subcellular fractionation was carried out by centrifugation of homogenates obtained by sonication of cell suspensions. The homogenates were centrifuged at 500 × g for 15 min to collect the nuclear fraction. The supernatant fraction was centrifuged at 15,000 × g for 15 min to yield mitochondria. Microsomal and cytosolic fractions were isolated from the postmitochondrial supernatant by centrifugation at 105,000 × g for 60 min. The entire fractionation was carried out at 0–4 C.

MVAPP decarboxylase activity was assayed using [2-^{14}C]MVAPP as substrate of the reaction as previously described (14). Enzyme activity was expressed as nmol of alcohols liberated/min/mg protein.

Lipids were extracted with chloroform/methanol (2:1, v/v) according to Folch et al. (26). Total and free cholesterol contents were determined by enzymatic colorimetric methods using "Test-Combination Cholesterol" or "Test-Combination Free Cholesterol," respectively, from Boehringer Mannheim GmbH (Germany).

RESULTS

The first group of experiments was undertaken to define the optimal conditions for measuring MVAPP decarboxylase activity in a large pool of isolated enterocytes obtained from both duodenal, jejunal and ileal villi and cripts. As shown in Figure 1, decarboxylase activity was linear with respect to the amount of cell protein in the incubation vial up to 0.3 mg. Likewise, enzyme activity was studied as a function of incubation time. As can be seen in Figure 2, the specific activity was linear up to 60 min of incubation.

The subcellular localization of MVAPP decarboxylase in chick villus and crypt cells is reported in Table 1. Maximal specific activity was found in the cytosolic fraction, with a recovery of about 94% of total activity.

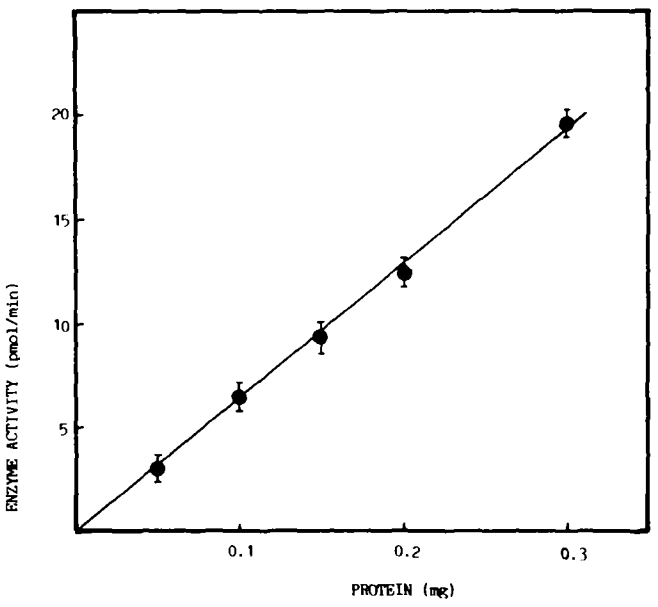

FIG. 1. Effect of protein content of a large pool of enterocytes isolated from duodenal, jejunal and ileal villi and crypts on MVAPP decarboxylase activity. Results are expressed as means ± SEM of three determinations.

The distribution of MVAPP decarboxylase activity in epithelial cells isolated from duodenum, jejunum and ileum, as described in Materials and Methods, is shown in Table 2. Maximal specific activity was found in all fractions from jejunum, although differences with duodenum and ileum were small. The crypt and lower villus cells showed the highest specific activities in each intestinal fragment. When multiplied by the mass of protein recovered in each of these fractions, more than 80% of total decarboxylase activity was found in villus cells. Duodenum showed the highest total activity of the three fragments assayed.

The total cholesterol content was determined in chick villus and crypt cells. As can be seen in Table 3, ileum showed the highest cholesterol content, followed by duodenum and jejunum. In all the intestinal epithelial cells assayed, free cholesterol represented about 95% of total cholesterol.

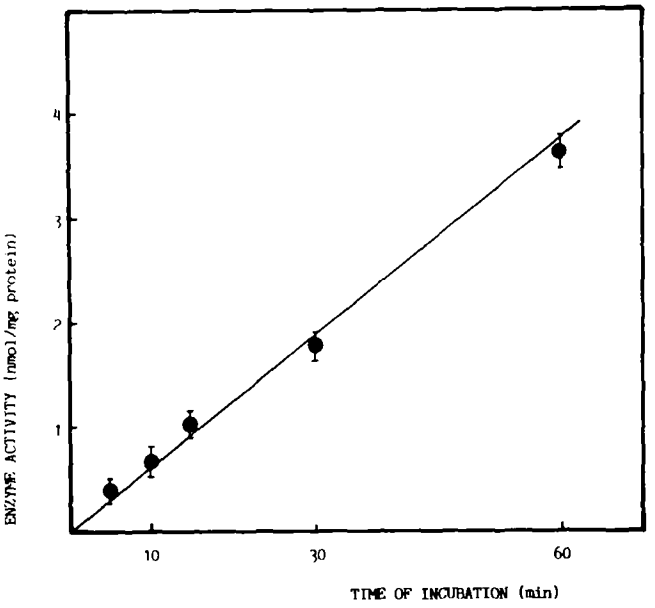

FIG. 2. Effect of incubation time on MVAPP decarboxylase activity from chick enterocytes. Results are expressed as means ± SEM of three determinations with a large pool of enterocytes isolated from duodenal, jejunal and ileal villi and crypts.

DISCUSSION

In this work, we have studied for the first time the distribution of MVAPP decarboxylase in isolated villus and crypt cells. The subcellular fraction with the highest specific activity was the cytosol, in agreement with previous results obtained on this (12) and other chick mevalonate-activating enzymes (28). However, it is important to remark that HMG-CoA reductase activity isolated from epithelial cells from chick intestine was found in the microsomal and mitochondrial fractions (unpublished results), thus demonstrating the existence of a gross contamination of the different organelle fractions similar to that reported in rat intestine (29,30). Because of this, we have used in this work the whole homogenate for comparative studies with reductase.

The distribution of MVAPP decarboxylase in the different intestinal segments was practically similar to that found for HMG-CoA reductase; jejunal cells showed the maximal specific activities of both enzymes. About 80% of total decarboxylase activity was recovered in the villus cells, thus indicating an active role of these cells in cholesterol synthesis. Similar results previously were obtained on the distribution of HMG-CoA reductase: about 70% of its total activity was found in the upper and the mid-villus fraction (unpublished results).

Concerning the cholesterol content of intestinal epithelial cells, the fact that absorption of luminal sterols in the chick occurs mainly in the proximal portion (31) led us to postulate that a large part of the cholesterol content of the ileum may be synthesized in situ. This intestinal segment was the richest in total cholesterol, sterol that accumulated almost exclusively in the free form. High free cholesterol levels would be in good agreement with the low acyl-CoA:cholesterol acyltransferase specific activity previously reported for this region (32). Likewise, the accumulation of free cholesterol did not determine an inhibition of cholesterogenic enzyme activities HMG-CoA reductase and MVAPP decarboxylase, as has been reported in other physiological conditions in which the variations observed in free cholesterol were parallel to those found in both enzyme activities (13,32).

ACKNOWLEDGMENTS

This work was supported in part by a grant from "Comisión Asesora de Investigación Científica y Técnica" (1219-84). We thank "Granja Los Arcángeles" from Alcalá de Henares (Madrid) for the generous supply of newborn male chicks.

Analysis of Autoxidized Fats by Gas Chromatography-Mass Spectrometry: X. Volatile Thermal Decomposition Products of Methyl Linolenate Dimers

E.N. Frankel*, W.E. Neff, E. Selke and D.D. Brooks
Northern Regional Research Center, ARS/USDA, Peoria, IL 61604

High-molecular weight compounds previously were found to be important secondary products from autoxidation of polyunsaturated fatty esters. The contribution of dimers to oxidative deterioration was investigated by analyzing their volatile thermal decomposition products by capillary gas chromatography-mass spectrometry. Dimers were isolated by gel permeation chromatography from autoxidized linolenate and from the corresponding monohydroperoxides, cyclic peroxides and dihydroperoxides. Major volatile decomposition products identified from these oxidative dimers were similar to those formed from the corresponding monomeric hydroperoxides. However, dimers from linolenate hydroperoxides produced more propanal and methyl 9-oxononanoate than the corresponding monomers but less methyl octanoate and much less or no 2,4-heptadienal and 2,4,7-decatrienal. Significant differences in minor volatile products also were observed between dimeric and monomeric products of methyl linolenate oxidation compounds. Mechanisms are suggested for the formation of volatile decomposition products from different dimeric structures. These dimers are believed to be important sources of volatile compounds contributing to flavor and oxidative deterioration of fats.
Lipids 23, 295–298 (1988).

Much work has been reported on the monomeric and volatile oxidation products of fats, but relatively little information is available on the nature of the high-molecular weight products, especially those from linolenate. Early reports indicated that high-molecular weight compounds from linoleate and linolenate may be important sources of flavor compounds in vegetable oils (1–6). The thermal polymerization of oxidized methyl linolenate in the absence of air generated a complex mixture of oxygen-containing compounds that included 70% dimers (4).

Dimer structures with conjugated diene systems were reported from linoleate hydroperoxide oxidized at 38 C in the presence of a free radical initiator and absence of oxygen (7). More recently, peroxidic dimers that contained either allylic hydroperoxide or hydroxy substituents were identified in linoleate autoxidized at 30 C (8–11). Small amounts of ether-linked dimers also were identified from decomposed linoleate hydroperoxides (11). In the decomposition of linoleate dimers at 30 C, a mixture of hydroxy aldehydes, hydroxy esters and hydroxy aldehyde esters were identified (12).

We recently identified the dimers formed either directly during the autoxidation of methyl linolenate or by decomposing linolenate hydroperoxides, hydroperoxy epidioxides and dihydroperoxides at 40 C. The linolenate dimers carbon linkages (13). Different volatile decomposition products were identified from methyl linolenate hydroperoxides when decomposed either thermally at 150 C or catalytically with ferric chloride and ascorbic acid at room temperature (14). This paper extends these studies to clarify the decomposition pathways of dimeric products isolated from oxidized linolenate, its hydroperoxides and corresponding secondary oxidation products.

EXPERIMENTAL

Procedures for the preparation of oxidation products from methyl linolenate were as described (15). Autoxidized methyl linolenate, pure linolenate mono- and di-hydroperoxides, and hydroperoxy epidioxides were decomposed with air at 40 C. The decomposition mixtures were dissolved in methylene chloride and separated by gel permeation chromatography into oligomeric, monomeric and low-molecular weight fractions (13,14). The oligomeric fractions consisted mainly of dimeric components with molecular weights varying from 625–930 (13).

Volatile thermal decomposition products of monomeric and dimeric fractions formed after injection at 200 C in a gas chromatograph (GC) (Perkin-Elmer, model Sigma 300, Norwalk, CT), were analyzed with a capillary column (DB 1701, J & W Scientific Co., Rancho Cordova, CA) cooled to −20 C with liquid nitrogen. Column temperature was programmed to 260 at 5 C per min with a final hold of 10 min. Integrated relative peak areas obtained with flame ionization detection were calculated as weight percentage of methyl hexanoate used as internal standard (14). Volatile decomposition products separated and characterized by capillary gas chromatography-mass spectrometry (GC-MS), were identified by matching their mass spectra and by comparing their GC retention data to those of known reference compounds (16,17).

RESULTS

Dimeric fractions isolated by gel permeation chromatography from methyl linolenate autoxidized at 40 C varied from 0.1 to 10.1% by weight in direct proportion to the peroxide values (13). Dimers were isolated by gel permeation chromatography in 60–90% yields from pure monohydroperoxides, 65% from hydroperoxy epidioxides, and 55% from dihydroperoxides of methyl linolenate decomposed at 40 C. GC profiles obtained with oxidative dimers of methyl linolenate were complex and included about 20 components. Major volatile components are compared in Table 1.

Dimers from autoxidized methyl linolenate and linolenate hydroperoxides showed similar volatile decomposition product profiles with more 2,4-heptadienal and 2,4,7-decatrienal from the autoxidized linolenate dimer. Methyl 9-oxononanoate, the major decomposition product, was 63–72% from hydroperoxide dimers and 47%

from dimers of autoxidized methyl linolenate. 2-Pentenal, 2,4-heptadienal and 2,4,7-decatrienal were found in much higher amounts from monomeric hydroperoxides than from the corresponding dimers obtained at 40 C. Methyl 9-oxononanoate, on the other hand, was found in much higher levels from dimers than the corresponding monomers.

When the volatiles from monomeric hydroperoxy epidioxides were compared with the volatiles from the corresponding dimers, significant differences were found in major components. More 2,4-heptadienal was found in the monomers than the dimers. The monomers produced 2% 2,4,7-decatrienal, but the dimers did not produce this aldehyde. More methyl 9-oxononanoate was formed from the dimers than the monomers. The major volatiles from linolenate dihydroperoxides, including propanal, methyl octanoate and 9-oxononanoate, were similar in the monomers and dimers. As with the monohydroperoxides, more 2,4-heptadienal was formed from the dihydroperoxide monomers than the corresponding dimers (Table 1). Minor volatile thermal decomposition products included 1-penten-3-ol from linolenate monohydroperoxide dimers; 2/3-hexenal, epoxy heptenal, methyl 8-oxo-octanoate, furan octanoate, 10-oxo-8-decenoate and 11-oxo-9-undecenoate from the other oxidative dimers (Table 1).

All volatiles listed in Table 1, except ethyl furanone, previously were found among thermal decomposition products from monohydroperoxides (15), hydroperoxy epidioxides and dihydroperoxides of methyl linoleate and linolenate (18,19). Ethyl furanone is a unique volatile compound detected among the decomposition products of autoxidized methyl linolenate, and the oxidative dimers of linolenate mono- and dihydroperoxides. This compound, referred to in the literature as the lactone of 4-hydroxy-2-hexenoic acid, previously was identified in thermally oxidized trilinolein (20,21), and had the same mass spectral peaks as those reported by Tressl et al. (22). In another study, monomeric 9,16-dihydroperoxide of methyl linolenate was decomposed at 160 C and only methyl octanoate and methyl 9-oxononanoate were observed by GC with a packed Carbowax column (23).

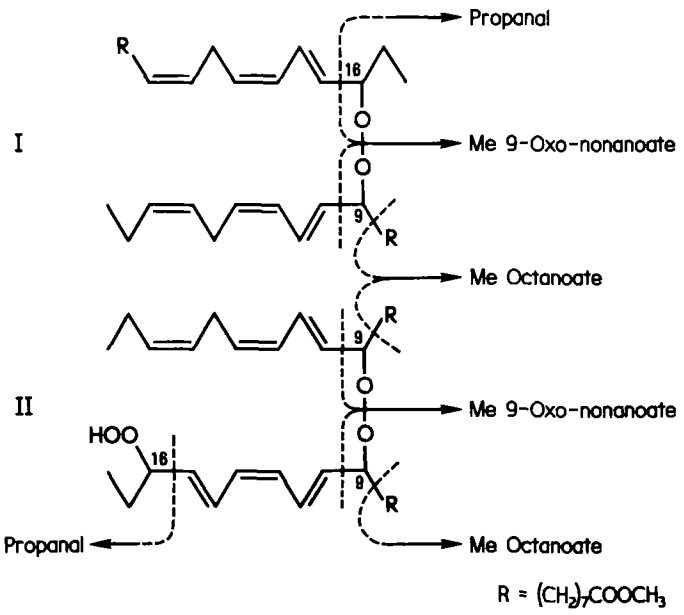
DISCUSSION

In this study, we found significant differences in volatile products generated from monomers and dimers derived from the decomposition of autoxidized methyl linolenate, its monohydroperoxides and other secondary oxidation products. The origin of volatile cleavage products observed in this work can be explained by considering mechanisms for the thermal decomposition of methyl linolenate hydroperoxides and secondary oxidation products (16,18,19) in terms of the dimeric structures established for the oxidation products of methyl linolenate (13).

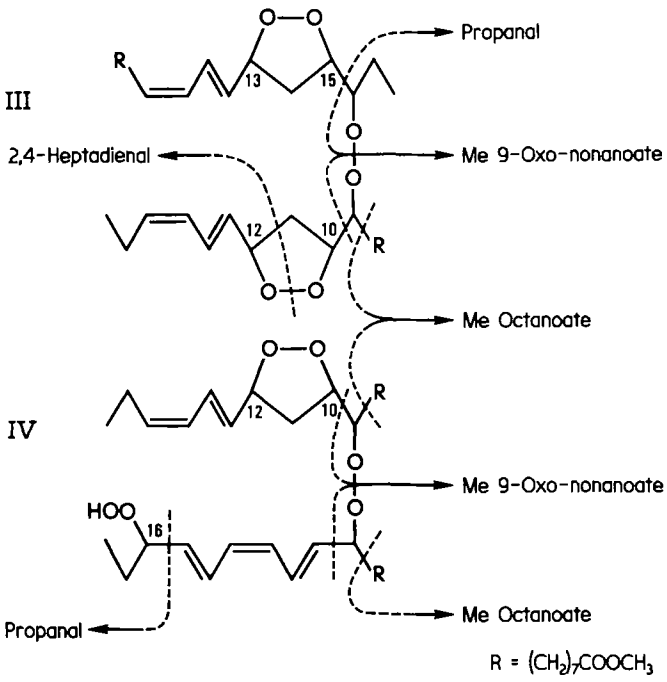
The principal cleavage mechanisms recognized for methyl linolenate hydroperoxides involve homolytic scission on each side of the hydroperoxide group (16,24,25). With the 9-hydroperoxide isomer (ranging from 30–35%), cleavage on each side of the 9-OOH group produces methyl 9-oxononanoate and decatrienal plus methyl octanoate as main decomposition products. With the 12-hydroperoxide isomer (ranging from 10–13%), cleavage on one side of the hydroperoxide forms 2,4-heptadienal. With the 13-hydroperoxide isomer (ranging from 11–13%), the same cleavage produces 3-hexenal, which readily isomerizes into a mixture of 2- and 3-isomers. With the 16-hydroperoxide isomer (ranging from 41–52%), this cleavage forms propanal as an important volatile product (16). The hydroperoxy epidioxides of methyl linolenate cleave like the monohydroperoxides and form similar products, which include methyl 9-oxononanoate, methyl octanoate and 2,4-heptadienal from the 9-hydroperoxy

epidioxide, and propanal from the 16-hydroperoxy epidioxide (18). In addition to these volatile products, 2,3-pentanedione, which is reported to have a strong butter-like smell, also has been observed among the decomposition products of the 16-hydroperoxy epidioxide of methyl linolenate (23). From our studies of volatile decomposition products, we concluded that the cyclic peroxides and other secondary products of methyl linolenate are important precursors of volatile compounds that can contribute to the flavor and oxidative deterioration of edible fats (18).

The predominant dimeric structures previously identified from methyl linolenate autoxidized at 40 C possessed structural features of the monomeric components, including monohydroperoxide, hydroperoxy epidioxide and dihydroperoxide (13). This study showed that the dimers were mixtures involving monohydroperoxides, dihydroperoxides and hydroperoxy epidioxides condensed mainly through peroxide (88%) and through ether and/or carbon linkages (12%). The major volatile decomposition products expected from different peroxide-linked dimer structures (I-IV) are summarized in Schemes 1 and 2. Cleavage between the peroxide link and the olefinic side of the 9- and 16-hydroperoxide groups would produce methyl 9-oxononanoate from dimers I and II (Scheme 1). This type of cleavage apparently is most favored because methyl 9-oxononanoate is the most important thermal volatile decomposition product observed in this study. Cleavage on the opposite side of the peroxide links accounts for the formation of methyl octanoate on one side and propanal on the other side of the first monomer unit of dimer structure I. Dimer structure II would undergo cleavage on the right to produce methyl 9-oxonoanoate and methyl octanoate, and cleavage on the left to produce propanal (Scheme 1). With both structures I and II, cleavage does not appear to take place to form 2,4,7-decatrienal from the 9-hydroperoxide isomer as it does



SCHEME 1



SCHEME 2

in the monohydroperoxide (16). Alternatively, this polyunsaturated aldehyde may be polymerized under our conditions of decomposition.

Scheme 2 shows cleavages expected from the two dimers III and IV containing hydroperoxy epidioxides, and dihydroperoxide components, cross-linked through either 9- or 16-hydroperoxide groups. Methyl 9-oxononanoate is formed by cleavage between peroxide linkages and propanal by cleavage on the 16-peroxide linkage in dimer III and the 16-hydroperoxide group in dimer IV. Methyl octanoate would be formed by cleavage of the alkyl substituents on the opposite side of the peroxide linkage on carbon-9 of these dimer structures. Cleavage across the epidioxide rings of the cyclic peroxide components in dimers III and IV would account for the formation of 2,4-heptadienal. The relatively small amounts of this compound observed (Table 1) suggest, however, that either this cleavage is minor or that this polyunsaturated aldehyde is decomposed under our conditions. 2,4-Heptadienal was also a minor product of the dimers of hydroperoxy epidioxides and dihydroperoxides. The origin of minor volatile decomposition products may be explained by the same mechanism discussed in the literature for autoxidized methyl linolenate and the monohydroperoxides and corresponding secondary oxidation products (16,24-26). Ethyl furanone may be derived from dimers containing hydroperoxide or peroxide linkage on carbon 13, by hydrogen abstraction followed by reaction with oxygen and cyclization.

This work showed that oxidative dimers of methyl linolenate and its oxidation products form volatile decomposition products related to the monomeric hydroperoxide precursors. Therefore, we believe that dimers like the monomer precursors may be important sources of volatile compounds contributing to flavor and oxidative deterioration of fats.

Fluorescent Substances Derived from the Reaction of 13-Monohydroperoxylinoleic Acid and Methylamine

Kiyomi Kikugawa[a,*] and **Shigenobu Watanabe**[b]

[a]Tokyo College of Pharmacy, 1432-1 Horinouchi, Hachioji, Tokyo 192-03, Japan, and [b]Kanagawa Prefectural Public Health Laboratories, 52-1 Nakao-cho, Asahi-ku, Yokohama 241, Japan

Reaction of 13-monohydroperoxylinoleic acid and methylamine in the presence of ferric ions produced at least four fluorescent substances. They were separated by high performance liquid chromatography with a reverse phase column, and major fluorescent substances 1 and 3 were isolated. Fluorescent substances 1 and 3 showed the same fluorescence spectra with excitation maxima at 360 nm and emission maxima at 430 nm, and the same ultraviolet spectra with absorption maxima at 275 and 360 nm. Fluorescence of 1 and 3 was lost in alkaline media owing to the instability of the fluorophores. The fluorophores of 1 and 3 were destroyed on treatment with borohydride. The fluorescence characteristics of 1 and 3 were similar to those of the age-related fluorescent substances produced in tissues. They were different from those of the fluorescent substances derived from malonaldehyde and resembled those of the fluorescent substances derived from monofunctional aldehydes.
Lipids 23, 299–303 (1988).

Fluorescent lipofuscin granules develop in aging cells or tissues (1,2). Several researchers have isolated and analyzed fluorescent lipofuscin pigments in various tissues (3–7). The isolated lipofuscin pigments showed fluorescence with excitation maxima at 345–395 nm and emission maxima at 420–490 nm (3–7), and the fluorescence was quenched in alkaline media (5,7). Accumulation of the fluorescent lipofuscin pigments has been assumed to be due to lipid oxidation in cells or subcellular organisms (8,9). Although it has been shown that oxidized lipids or fatty acids give rise to fluorescence by interaction with primary amines or proteins (10–20), the structures and the properties of the fluorophores produced in these reactions are not known. Only a few preliminary studies showing the formation of multiple fluorescent substances in the reaction of mixed fatty acid hydroperoxides have appeared (14,17,18).

In this study, we investigated the formation of fluorescent substances in the reaction of 13-monohydroperoxylinoleic acid (13-LOOH) and methylamine as a model for fluorescent lipofuscin pigment formation in tissues. The fluorescent products were purified, and their fluorescence characteristics were elucidated. The fluorescence characteristics of the products were compared with those of the fluorescent lipofuscin pigments and the fluorescent substances derived from malonaldehyde or monofunctional aldehydes.

MATERIALS AND METHODS

Materials. 13-Monohydroperoxylinoleic acid (13-LOOH) was prepared according to the method of Gardner (21) by use of linoleic acid (grade III, Sigma Chemical Co., St. Louis, MO) and lipoxydase (type 1: 130,000 units/mg, Sigma Chemical Co.). Purity of the hydroperoxide estimated on the basis of ultraviolet absorption coefficient at 234 nm: 24,500 (22) was 95.1%. High performance liquid chromatography (HPLC) with a straight phase column of the sample after methylation with diazomethane revealed that it was consisted of *trans,trans* and *cis,trans* isomers (23).

Analysis. Ultraviolet absorption spectra were measured with a Hitachi 323 recording spectrophotometer. Fluorescence spectra were measured with a Hitachi 204 fluorescence spectrophotometer. Relative fluorescence intensity was expressed as the percentages of the intensity of 0.1 μM quinine sulfate in 0.1 N sulfuric acid (excitation at 353 nm and emission at 445 nm). Silicic acid (Mallinkcrodt, St. Louis, MO) column chromatography was performed with the solvent system chloroform/methanol (3:1). A Sephadex LH-20 column was used for the removal of salts with 0.017% acetic acid/methanol/acetonitrile (3:1:1) as solvent.

HPLC was performed on a Shimadzu liquid chromatograph fitted with a stainless steel column packed with Unisil QC-18 5 μm (16.7 × 300 mm) or LiChrosorb RP-18 5 μm (4.6 × 25 mm). The columns were eluted with a mobile phase composed of 8.3 mM $(NH_4)_2HPO_4$ (pH 3.5)/methanol/acetonitrile (3:1:1, v/v/v) at a flow rate of 3.5 or 0.8 ml/min, respectively. Fluorescent peaks were detected by use of a Hitachi fluorescence monitor with excitation at 360 nm and emission at 440 nm. Ultraviolet absorbing peaks were detected by use of a Hitachi wavelength turnable effluent monitor.

Mass spectra were taken with a JEOL JMS DX300 instrument equipped with a fast atom bombardment (FAB) ion source and a DA5000 data system. The sample was dissolved in methanol and placed on a stainless steel probe target with glycerol matrix. FAB/MS was operated with xenon gas at an emission current of 20 mA and an accelerating voltage of 6 KV in the positive mode.

RESULTS

A solution containing 2 mM 13-LOOH and 200 mM methylamine in methanol/water was incubated at 37 C in the absence and presence of ferric ions. Time course studies of the fluorescence intensities of the reaction mixtures (Fig. 1) showed that the formation of fluorescence was gradual in the absence of ferric ions, and was accelerated in the presence of ferric ions. Degradation of 13-LOOH by ferric ions promoted fluorescence formation. The reaction mixtures exhibited fluorescence with an excitation maximum at 363 nm and an emission maximum at 428 nm in methanol. The reaction mixtures of 13-LOOH alone did not produce any significant fluorescence irregardless of whether ferric ions were present.

Isolation of the fluorescent substances was attempted. A mixture containing 20 mM 13-LOOH, 2 M methylamine and 0.1 mM ferric ions was incubated at 37 C for

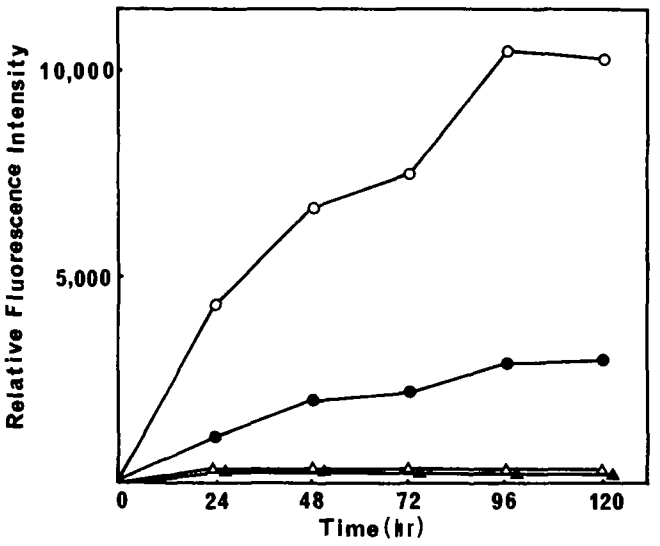

FIG. 1. Time course of the formation of fluorescence in the reaction of 13-LOOH and methylamine. A mixture of 2 mM 13-LOOH, 200 mM methylamine hydrochloride and 0.1 mM ferric chloride (○), 2 mM 13-LOOH and 200 mM methylamine hydrochloride (●), 2 mM 13-LOOH and 0.1 mM ferric chloride (△) or 2 mM 13-LOOH alone (▲) in methanol/water (1:1) adjusted at pH 5.5 by addition of 1 N NaOH was incubated at 37 C. Fluorescence spectra of the mixtures were taken after 100-fold dilution in methanol. Relative fluorescence intensities measured at the excitation (363 nm) and emission (428 nm) maxima were expressed as the percentages of the intensity of 0.1 μM quinine sulfate in 0.1 N sulfuric acid.

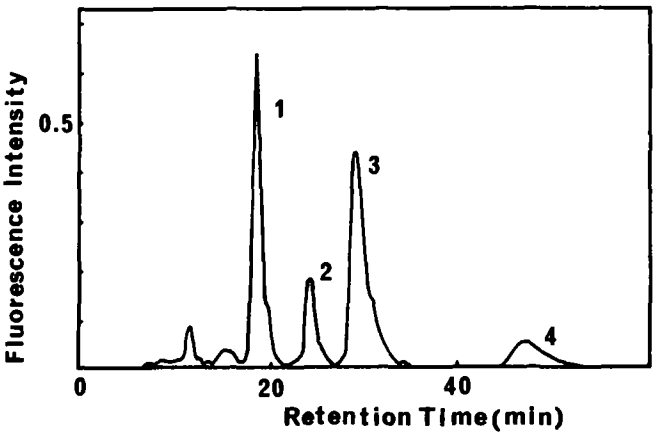

FIG. 2. HPLC of the fluorescent substances derived from the reaction of 13-LOOH and methylamine. A 10 ml mixture of 20 mM 13-LOOH, 2 M methylamine hydrochloride and 0.1 mM ferric chloride in methanol/water (1:1) adjusted at pH 5.5 was shaken at 37 C for 120 hr. The mixture was evaporated to dryness, and the residue was applied to a silicic acid (25 g) column. The fluorescent eluate was collected and evaporated to dryness. The residue was subjected to HPLC using a Unisil QC-18 5 μm column at a flow rate of 3.5 ml/min. The peaks were detected with excitation at 360 nm and emission at 440 nm.

120 hr. The reaction mixture was passed through a column of silicic acid to remove most of the salts. The fluorescence spectrum of the eluate was unchanged during column chromatography, and 80% of the fluorescence was recovered (Table 1). The fluorescent substances were then separated by HPLC using a preparative reverse phase column (Fig. 2). Four fluorescent peaks were detected, and each fraction was collected. The fluorescence spectra of the fractions were the same as the spectrum of the reaction mixture, indicating that the fluorescent substances were unchanged by HPLC (Table 1). Forty-three percent of fluorescence of the reaction mixture was recovered in the four peaks.

The fluorescent eluate from the silicic acid column was dissolved in methanol, ethanol, 2-propanol or chloroform and kept at room temperature for up to 20 hr. HPLC of the solutions revealed that none of the fluorescent substances was degraded in the solvents. The fluorescent eluate was dissolved in the buffered solutions of various pH values and kept for up to 20 hr. HPLC of the solutions revealed that the fluorescent substances 1, 2 and 3 were unchanged in the solutions at pH 4.9 and 7.0, but they were degraded in the solutions at pH 10.0 and 11.5 (Fig. 3). The intensities of the peaks diminished to less than 20% after 20 hr at pH 10.0 and after five hr at pH

TABLE 1

Fluorescence Spectra and Recovery of the Fluorescent Substances Derived from the Reaction of 13-LOOH and Methylamine

Samples	Fluorescence[a]			
	Excitation maximum (nm)	Emission maximum (nm)	Relative fluorescence intensity[b]	Recovery (%)
Reaction mixture[c]	363	428	198,000	100
Silicic acid column chromatography[c]	360	425	158,000	80
HPLC[c]				
1	363	425	27,000	14
2	364	425	12,000	6
3	363	425	31,000	16
4	370	423	13,000	7

[a]Spectra were measured in methanol.

[b]Relative fluorescence intensity was based on 10 ml of the solution and expressed as percentages of the intensity of 0.1 μM quinine sulfate.

[c]The same as described in the legend to Figure 2.

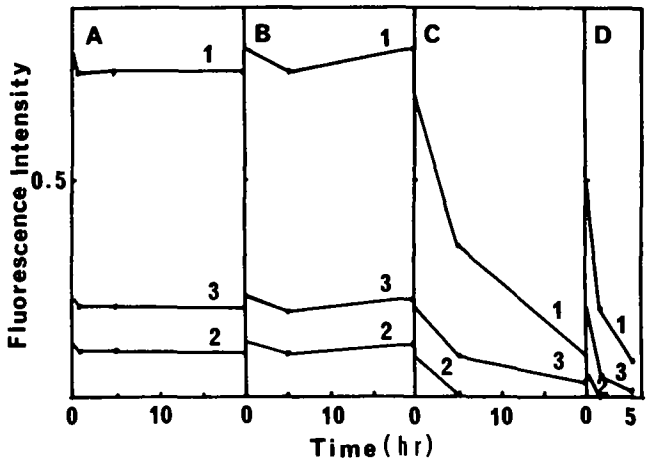

FIG. 3. Stability of fluorescent substances 1, 2, and 3 at various pH values. The fluorescent eluate of the silicic acid column was evaporated to dryness and dissolved in the buffer. The solutions were kept at room temperature for up to 20 hr and analyzed by HPLC with a LiChrosorb RP-18 5 μm column at a flow rate of 0.8 ml/min. 0.05 M citrate buffer, pH 4.9 (A); 0.07 M phosphate buffer, pH 7.0 (B); 0.05 M borate buffer, pH 10.0 (C); and 0.025 M borate buffer, pH 11.5 (D).

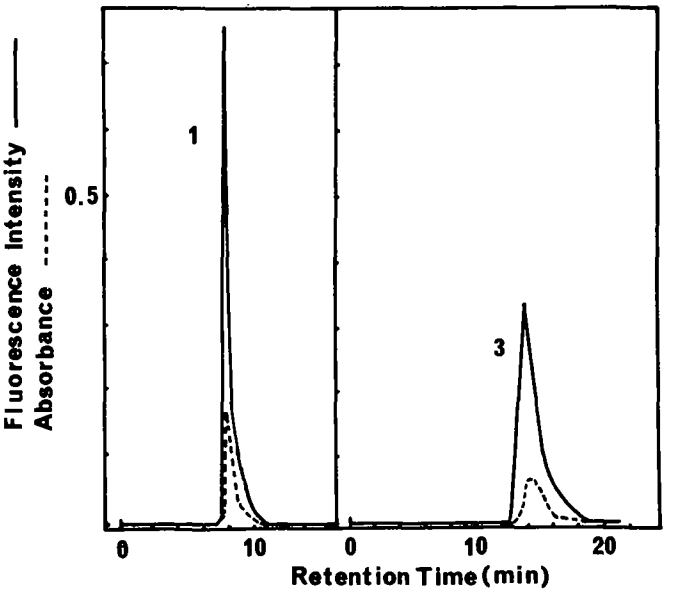

FIG. 4. HPLC of the purified samples of 1 and 3. Fluorescent substances 1 and 3 obtained in Figure 2 were rechromatographed, and the fluorescent fractions were desalted through a Sephadex LH-20 column. The fractions of 1 and 3 were analyzed with a LiChrosorb RP-18 5 μm column at a flow rate of 0.8 ml/min. The peaks were detected by fluorescence with excitation at 360 nm and emission at 440 nm, and by ultraviolet absorption at 360 nm.

11.5. The initial fluorescence intensities of the eluate could not be recovered when the eluate was kept at pH 11.5 for five hr and subsequently adjusted to pH 4.9.

Two major fluorescent substances, 1 and 3, were rechromatographed by HPLC with the same preparative column, and the salts in the eluates were removed by passing through a Sephadex LH-20 column. Fluorescent substances 1 and 3 thus purified showed single fluorescent and ultraviolet absorbing peaks at retention times of 8.0 min and 14.5 min, respectively, when analyzed by HPLC with an analytical reverse phase column (Fig. 4).

Purified samples of 1 and 3 in methanol showed similar fluorescence spectra with an excitation maximum at 360 nm and an emission maximum at 430 nm, and similar ultraviolet absorption spectra with absorption maxima at 275 and 360 nm (Fig. 5). Fluorescence intensities of the purified samples of 1 and 3 in methanol (adsorbance at 360 nm: 1.0) relative to 0.1 μM quinine sulfate were 48,000% and 47,000%, respectively. In order to elucidate the structures of the compounds, mass spectra were measured by using a fast atom bombardment ion source. However, no reproducible mass fragmentation patterns were obtained because of the presence of impurities without fluorescence or ultraviolet absorption. The structures of the compounds could not be elucidated.

Fluorescence spectra of the purified samples of 1 and 3 showed little change in methanol, ethanol, 2-propanol, chloroform and water, but the fluorescence intensities were different (Table 2). While 1 and 3 exhibited intensities in ethanol, 2-propanol and water comparable to those in methanol, much lower intensities were observed in chloroform.

Fluorescence intensities of 1 and 3 were little influence in methanol/1 N HCl, but they were greatly lowered in methanol/1 N NaOH (Table 2). This loss in fluorescence is due to the instability of 1 and 3 in alkaline media. The fluorescence intensities of 1 and 3 in methanol/10 mM borohydride (pH 9.2) also were lowered. This decrease

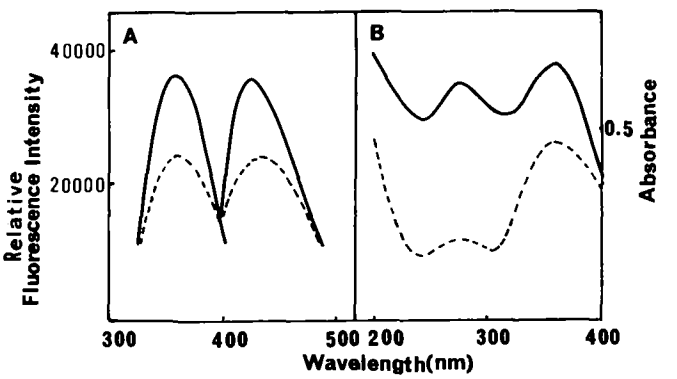

FIG. 5. Fluorescence (A) and ultraviolet absorption (B) spectra of the purified samples of 1 (——) and 3 (– – –) in methanol. Relative fluorescence intensities of the solutions assessed for ultraviolet absorption spectra were expressed as the percentages of the intensity of 0.1 μM quinine sulfate.

could not be accounted for by the high pH values because the intensities in methanol/10 mM NaOH (pH 9.4) retained about half of the intensities observed at neutral pH. The fluorophores of 1 and 3 were destroyed on treatment with borohydride.

DISCUSSION

Previously, we have shown that linoleic, linolenic and arachidonic acids produced fluorescent substances with excitation maxima at 355–370 nm and emission maxima at 420–440 nm by reaction with methylamine under aerobic conditions (18). The fluorescence was influenced

TABLE 2

Fluorescence Spectra and Intensities of the Purified Samples of 1 and 3 under Various Conditions

[c]pH 9.2.

little in acidic media but was affected differently in alkaline media with the fatty acids. The characteristics of the fluorescent substances indicate that they differ in structure depending on fatty acids from which they are derived.

In this investigation, the fluorescent substances in the reaction of 13-LOOH with methylamine were isolated, and their fluorescence characteristics were clarified. The fluorescent substances were produced during degradation of the hydroperoxide, and at least four components were produced. Fluorescence spectra of the products were similar and had excitation maxima at 360 nm and emission maxima at 430 nm. The products were degraded in alkaline solutions, and thus the fluorescence intensities were diminished greatly. This is in good agreement with the observations that the fluorescence of the isolated lipfuscin of human and rat testes was quenched in alkaline media (5,7). The fluorophores in these products were destroyed upon treatment with borohydride.

Malonaldehyde, one of the degradation products of the hydroperoxide, is a possible candidate for the production of the fluorophores. It reacts with methylamine, primary amines or proteins to produce fluorescence due to 1,4-dihydropyridine-3,5-dicarbaldehyde moieties under close to physiological conditions (24-28). These fluorophores revealed the longer wavelengths in fluorescence excitation (385-405 nm) and emission (440-470 nm) and the higher fluorescence intensities. Fluorescence intensities of these compounds in methanol (absorbance 1.0) relative to 0.1 μM quinine sulfate was 50,000-150,000% (27,28). The fluorescence of the compounds was quenched in acidic media but not in alkaline media, and the fluorophores were destroyed upon treatment with borohydride (27,28). The fluorescence characteristics of 1 and 3 were different from those of the fluorophores derived from malonaldehyde.

Monofunctional aliphatic aldehydes that also are produced during the degradation of the hydroperoxide can form fluorescent substances by reaction with primary amines (29,30) or proteins (13,19,20,31), which exhibited excitation maxima at 340-370 nm and emission maxima at 400-440 nm. Fluorescence spectra of 1 and 3 are similar to those of these fluorescent substances. Fluorescence intensities of 1 and 3 are close to those of these compounds: 300-30,000% (30). However, these compounds resisted borohydride reduction, and the fluorescence intensities were quenched in the aqueous solutions through a wide pH range (30). While the fluorescence spectra of 1 and 3 were similar to those of the fluorophores produced from the monofunctional aliphatic aldehydes, their fluorescence characteristics were not identical in every respect.

13-LOOH produced several fluorescent substances by reaction with methylamine. The fluorescence characteristics of the substances were similar to those of the fluorescent lipofuscin pigments with respect to maximum wavelengths and loss of fluorescence in alkaline media. These substances were distinguishable from the fluorescent products derived from malonaldehyde and resembled those derived from monofunctional aldehydes.

Adenylate Cyclase and β-Receptors in Salivary Glands of Rats Fed Diets Containing *Trans* Fatty Acids

Y-F. Ren[a], S.Q. Alam[a,*] B.S. Alam[a] and L.M. Keefer[b]

[a]Department of Biochemistry and Molecular Biology, and [b]Department of Physiology, Louisiana State University Medical Center, 1100 Florida Ave., New Orleans, LA 70119

The effects of *trans* fatty acids on adenylate cyclase were determined in the submandibular salivary glands (SMSG) of rats fed diets containing 20% corn oil, 20% partially hydrogenated soybean oil (PHSBO) or 18% PHSBO + 2% corn oil. The fluoride- and isoproterenol-stimulated adenylate cyclase activities were higher in the SMSG from rats fed 20% PHSBO than in the control group fed 20% corn oil. The feeding of 2% corn oil with the diet containing 18% PHSBO resulted in a complete restoration of isoproterenol-stimulated and a partial restoration of fluoride-stimulated adenylate cyclase activity. There was no significant difference in the concentration of the β-adrenergic receptor or in the receptor-binding affinity constants among the three dietary groups as measured by [^{3}H]dihydroalprenolol (DHA)-binding. Higher fluorescence polarization of diphenyl hexatriene (DPH) was observed in SMSG membranes of rats fed diet containing 20% PHSBO than in the other two oils, suggesting that membrane fluidity may play a role in adenylate cyclase activity.

Lipids 23, 304-308 (1988).

Partially hydrogenated vegetable oils contain a number of positional and geometric isomers of unsaturated fatty acids. Like the naturally occurring *cis*-isomers, the *trans* fatty acids also can be incorporated into various tissues of animals (1) and man (2). Studies from our laboratory have shown that dietary *trans* fatty acids can be incorporated into various lipids of the submandibular salivary glands (SMSG) (3) and in the lacrimal glands (4). The fluorescence polarization of diphenylhexatriene (DPH) was higher in plasma membranes of the exocrine glands of rats fed diets containing partially hydrogenated soybean oil (PHSBO) than corn oil, suggesting a lower membrane fluidity in the former group. Since membrane fluidity is considered to be important in controlling a number of physiological phenomena, including the activities of some membrane-associated enzymes (5,6), we have been investigating the effects of feeding diets containing *trans* fatty acids on the activity of adenylate cyclase (ATP pyrophosphate lyase [cyclizing], EC 4.6.1.1) in different tissues. An increase in fluoride-stimulated adenylate cyclase activity was observed in membranes of the lacrimal glands from rats fed 20% PHSBO (4). Because of the physiological importance of adenylate cyclase in the secretory mechanisms of the salivary glands, we have studied the effects of feeding diets containing *trans* fatty acids on adenylate cyclase in the SMSG. By using [^{3}H]dihydroalprenolol-binding analysis, the characteristics of β-adrenergic receptors as affected by feeding diets containing *trans* fatty acids also were studied.

MATERIALS AND METHODS

All the biochemical reagents were purchased from Sigma Chemical Co. (St. Louis, MO). Cyclic [^{3}H]AMP (41 Ci/mmol), α-[^{32}P]ATP (410 Ci/mmol) and [^{3}H]dihydroalprenolol (55 Ci/mmol) were obtained from Amersham (Arlington Heights, IL). All the dietary ingredients were purchased from TEKLAD (Madison, WI). PHSBO was supplied by Kraft Inc. (Glenview, IL).

Feeding study. Three groups of male weanling Sprague-Dawley rats (Holtzman Co., Madison, WI), 16-20/group, were fed ad libitum semipurified diets containing 20% corn oil (CO) (group 1), 20% PHSBO (group 2) or 18% PHSBO + 2% CO (group 3). The composition of the basal diet was similar to that of AIN-76A (7,8). It contained (in %) casein (vitamin-free), 20.0; DL-methionine, 0.3; sucrose, 50.0; oil (corn oil, PHSBO or 18% PHSBO + 2% CO), 20.0; cellulose, 5.0; mineral mixture (AIN-76A), 3.5; vitamin mixture (AIN-76A), 1.0; choline bitartrate, 0.2 and butylated hydroxytoluene, 0.002. The fatty acid composition of the oils was determined by gas chromatography and is shown in Table 1. PHSBO contained about 48% of the total fatty acids as *trans* octadecenoic acid (t-18:1). Rats were housed individually in suspended stainless steel cages in a temperature- and light-controlled room (22-23 C, 12-hr light-dark cycle). Rats had free access to water and feed and were weighed at least once a week. Diets were prepared fresh every two to three weeks and were stored at 4 C.

Membrane preparation. Rats were killed by decapitation after 16 or 18 wk of feeding the diets. The SMSG

TABLE 1

Fatty Acid Composition of the Oils

Fatty acid	Corn oil	PHSBO	18% PHSBO + 2% corn oil
14:0	—	0.2	0.2
16:0	11.0 ± 0.2^{a,b}	10.5 ± 0.1^{a}	11.2 ± 0.1^{b}
16:1	0.3	0.2	0.2
18:0	2.1 ± 0.1^{a}	13.1 ± 1.5^{b}	14.6 ± 0.1^{b}

Abbreviations: DHA, dihydroalprenolol; DPH, diphenyl hexatriene; EFA, essential fatty acids; PHSBO, partially hydrogenated soybean oil; SMSG, submandibular salivary glands; TLC, thin layer chromatography.

were dissected out, separated from the sublingual glands, rinsed with physiological saline and weighed. To obtain sufficient samples for analyses, at each time point (16 and 18 wk) the SMSG were pooled from four to five rats within each dietary group for the preparation of plasma membranes for adenylate cyclase activity determinations and for lipid analyses. A similar number of rats was used for the preparation of plasma membranes for studies on the binding of [^{3}H]dihydroalprenolol and for fluorescence polarization studies. Plasma membranes were prepared by the differential centrifugation method of Durham et al. (9) as described (10). Membranes were stored under liquid nitrogen until assayed.

Plasma membranes and homogenates of SMSG were assayed for 5′-nucleotidase (11) and Mg^{2+}-ATPase (12), marker enzymes for plasma membranes. Mitochondrial and microsomal contamination of the membranes was assessed by measuring succinic dehydrogenase (13) and glucose-6-phosphatase (14) activities, respectively. Protein content was measured by the method of Lowry et al. (15) using bovine serum albumin as standard.

[^{3}H]Dihydroalprenolol (DHA) binding. [^{3}H]DHA-binding was measured by incubating 0–29 nM [^{3}H]DHA with 250 μg of the membrane protein for 15 min at 37 C in the presence of 50 mM Tris buffer, pH 7.4, and 10 mM $MgCl_2$ in a final volume of 0.5 ml. The reaction was terminated by immersing in ice the tubes containing the reaction mixture. This was followed by rapid filtration on GF/A glass fiber filters (Whatman Lab Sales, Inc., Hillsboro, OR). The residue was washed with 3 × 4 ml of the ice-cold incubation buffer. The filters were transferred to scintillation vials, dried at room temperature, 10 ml of liquid scintillation fluid (Ready-Solv, EP, Beckman) was added, and the radioactivity was counted using a Liquid Scintillation Spectrometer (Beckman LS 6800, Fullerton, CA).

[^{3}H]DHA-binding to membranes from each dietary group was measured in duplicate in three independent experiments per group. For each concentration of labeled DHA, a companion "nonspecific" incubation in the presence of 1 mM unlabeled DHA was conducted. All binding data then were analyzed using the LIGAND-PC programs (1986, version 2.3.10) (16) on a Zenith 171 personal computer. Data files for each experiment were prepared using SCAHOT, and the three data files per group were analyzed simultaneously using SCAFIT. SCAFIT uses weighted nonlinear least-squares curve-fitting to estimate binding parameters (affinity constant, dissociation constant, receptor capacity and nonspecific binding estimate). Each group of data was subjected to both one-site and two-site model analysis, using the automatic initial parameter estimates provided by SCAFIT.

Adenylate cyclase activity. Adenylate cyclase activity was determined in triplicate samples of the membranes (50 μg protein) by monitoring the conversion of α-[^{32}P]ATP to cyclic [^{32}P]AMP using the procedure of Sinensky et al. (17). The product, cyclic [^{32}P]AMP, was separated from the unreacted substrate by sequential column chromatography using Dowex and alumina columns according to the method of Salomon et al. (18). To monitor the recovery of cyclic [^{32}P]AMP, cyclic [^{3}H]AMP was added to the samples after incubation and before column chromatography. The details of the procedure have been described (10). Stimulated enzyme activity was measured in the presence of 15 mM sodium fluoride or 20 μM isoproterenol. The basal activity was measured in the absence of fluoride or isoproterenol.

Fluorescence Polarization Studies. Membranes were labeled by incubating them at 37 C for one hr with a solution of DPH in phosphate-buffered saline as described (3), and fluorescence polarization was measured in a SLM fluorescence polarization spectrophotometer (SLM 4800) according to the procedure of Shinitzky and Inbar (19) and Shinitzky and Barenholz (20).

Fatty acid composition. Total lipids were extracted from aliquots of the SMSG membranes using Bligh and Dyer's method (21). Phospholipids were separated by column chromatography (22). Methyl esters were prepared from the dietary lipids and the SMSG membrane phospholipids using borontrifluoride-methanol (23). Fatty acid methyl esters were analyzed by argentation thin layer chromatography (TLC) and gas chromatography as described (3). The fatty acid composition of the dietary oils also was determined by using a similar method as described (3).

Statistical analyses. There was no significant difference in adenylate cyclase activity or [^{3}H]DHA-binding in the membranes prepared after 16 or 18 wk of feeding. Therefore, the data from 16 and 18 wk were combined and are presented as mean ± SE. The differences in means among the three dietary groups were analyzed using analysis of variance, Newman-Keul's test (24).

RESULTS

Rats fed 20% PHSBO had a lower growth rate than that of the control group fed 20% CO (Table 2). The incorporation of 2% CO in the PHSBO diet resulted in a partial restoration of the rate of growth. The weights of the SMSG followed a pattern similar to that of the body weights among the three dietary groups. When expressed on the basis of 100 g of body weights, however, the gland weights essentially were the same in the three groups. These values were (mg SMSG/100 g body wt, mean ± SE): 64.5 ± 2.2 in 20% CO group, 65.2 ± 0.6 in 20% PHSBO group and 60.8 ± 2.5 in 18% PHSBO + 2% CO group.

TABLE 2

Body Weight Gains of Rats Fed Diets Containing PHSBO

	Weeks on diets			
Diet	4	8	12	16
20% CO	202.2^a ±3.4	380.4^a ±9.2	473.3^a ±13.6	539.3^a ±26.6
20% PHSBO	176.5^b ±3.1	302.6^b ±5.8	366.9^b ±6.6	398.3^b ±9.6
18% PHSBO + 2% CO	188.2^b ±4.5	343.6^c ±9.5	437.8^a ±7.6	492.9^a ±13.7

Values are in g, mean ± SEM of 16–20 rats in each group. Values with different superscripts in the same column are significantly different from each other ($P < 0.01$) using analysis of variance, Newman-Keul's test. The initial body weight was 77.7 ± 1.6 g.

CO, corn oil; PHSBO, partially hydrogenated soybean oil.

There was no significant difference in the purity of the plasma membranes among the three dietary groups as evaluated by marker enzymes (5'-nucleotidase and Mg^{2+}-ATPase for plasma membranes, succinic dehydrogenase for mitochondria and glucose-6-phosphatase for microsomes). The specific activity of 5'-nucleotidase was the same in the three dietary groups (20% corn oil, group 1, 20.4 ± 2.4; 20% PHSBO, group 2, 19.6 ± 2.9; 18% PHSBO + 2% corn oil, group 3, 20.5 ± 1.9). Similarly, Mg^{2+}-ATPase activity was also the same (94.9 ± 2.3 in group 1, 98.6 ± 5.9 in group 2 and 98.2 ± 5.4 in group 3). The values are mean ± SEM, μmol Pi per mg protein/hr. Mitochondrial contamination was about 3% as measured by succinic dehyrogenase activity. There was some glucose-6-phosphatase activity in the membranes, indicating a cosedimentation of microsomes with the plasma membranes fraction. However, there was no difference in glucose-6-phosphatase activity among the three dietary groups.

Adenylate cyclase activity in plasma membranes of rats fed the various diets is shown in Table 3. There was no difference in the basal activity. However, fluoride-, and isoproterenol-stimulated adenylate cyclase activity and fold stimulation was the highest in membranes of the SMSG of rats fed 20% PHSBO. When 2% PHSBO was replaced by an equivalent amount of CO, the adenylate cyclase activity in the SMSG membranes was similar to that of the control group fed 20% CO. However, the fold-stimulation of adenylate cyclase by fluoride only partially was restored to that of the control levels.

The mean specific binding of [^{3}H]DHA to the SMSG plasma membranes of rats from the three dietary groups is shown in Figure 1. Specific binding for each determination was calculated (total − nonspecific = specific) using the nonspecific binding value estimated in LIGAND, which ranged from 13.8 to 17.8% of total bound counts and averaged 15.9% ± 0.42 (SEM). There was no apparent difference in the saturation curves for the three groups. The binding parameters obtained from LIGAND analysis of the data are shown in Table 4. No significant difference in either adrenergic receptor capacity or binding affinity was caused by the dietary treatments.

Trans 18:1, the main component constituting about 48% of the total fatty acids in PHSBO, was incorporated into the membrane phospholipids (Table 5). The levels of c,c-18:2 and 20:4 were lower in the SMSG membrane phospholipids of rats fed 20% PHSBO than in those fed 20% corn oil. Also, 20:3 ω-9 constituted about 4–5% of the total fatty acids in the phospholipids of membranes of rats fed 20% PHSBO. Only trace amounts of this fatty acid were present in the other two groups. The ratio of 20:3 ω-9/20:4, an established index of essential fatty acids (EFA) deficiency (25), was >0.4 in the SMSG membrane phospholipids of rats fed 20% PHSBO. This ratio and the

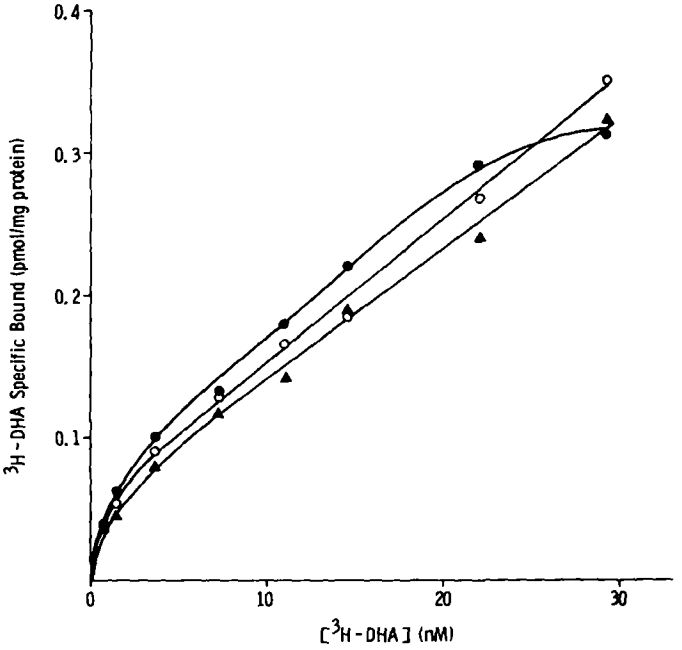

FIG. 1. Specific [^{3}H]DHA-binding to the SMSG membranes of rats fed different diets: 20% CO ●—●, 20% PHSBO ○—○, 18% PHSBO + 2% CO ▲—▲. Nonspecific binding, as estimated by LIGAND (16) analysis, was subtracted from total binding data. Each data point is the average of three assays, each done in duplicate, and the abscissa values are the total [^{3}H]DHA concentrations. Nonspecific binding was 15.9% ± 0.42 of total bound (mean ± SEM).

TABLE 3

Basal, Fluoride- and Isoproterenol-activated Adenylate Cyclase Activity in SMSG Plasma Membranes of Rats Fed PHSBO

Diet	Basal	+Fluoride	+Isoproterenol
20% CO	6.7 ± 0.8^a (1.00)	23.0 ± 1.8^a (3.43)	13.3 ± 1.2^a (1.99)
20% PHSBO	6.5 ± 1.0^a (1.00)	33.4 ± 2.6^b (5.14)	19.1 ± 1.9^b (2.94)
18% PHSBO + 2% CO	6.0 ± 0.7^a (1.00)	26.9 ± 2.5^{a,b} (4.48)	12.7 ± 1.4^a (2.12)

Enzyme activities are expressed as pmol cAMP formed/mg protein/min. Values are mean ± SEM of eight to nine assays per group; each assay was done in triplicate.

Values with different superscripts in the same column are significantly different from each other ($P < 0.05$) using analysis of variance, Newman-Keul's test. Fold-stimulation is shown in parentheses.

Fluoride, 15 mM; isoproterenol, 20 μM; CO, corn oil; PHSBO, partially hydrogenated soybean oil.

TABLE 4

Binding Parameters for [^{3}H]DHA-binding to SMSG Membranes From Rats Fed PHSBO

Diet	K_A ($M^{-1} \times 10^{-8}$)	[Ro] (pmol/mg protein)	K_D (nM)
20% Corn oil	2.01 ± 0.27	0.282 ± 0.023	4.97 ± 0.66
20% PHSBO	2.02 ± 0.25	0.263 ± 0.020	4.95 ± 0.60
18% PHSBO + 2% CO	1.97 ± 0.26	0.232 ± 0.020	5.07 ± 0.67

Values (mean ± SEM) were determined using LIGAND, simultaneously analyzing the data from three separate experiments for each individual group. The one receptor-site model thereby was determined the most appropriate for the data. None of the differences among groups is significant by either one-way analysis of variance or Student-Newman-Keul's test.

fatty acid patterns were restored to the control values (20% corn oil group) when 2% corn oil was fed with 18% PHSBO.

The fluorescence polarization of DPH is shown in Figure 2. Higher P-values were observed in membranes of rats fed 20% PHSBO compared with the other two groups. Fluorescence polarization was higher, especially at temperature above 20 C, in membranes of rats fed 18% PHSBO + 2% corn oil than in membranes of rats fed 20% corn oil.

DISCUSSION

The lipid dependence of adenylate cyclase has been reported in a number of studies (26-28). There are very few studies, however, on the effects of *trans* fatty acids upon the activities of adenylate cyclase. In one published report, an increase in adenylate cyclase activity (basal, fluoride-, and PGE_1-stimulated) was reported in membranes from mouse LM cells grown in a medium supplemented with *trans* octadecenoate (29). This observation is consistent with our present findings of an increase in fluoride-, and isoproterenol-stimulated adenylate cyclase activity in the SMSG and similar findings in the lacrimal glands (4) of rats fed 20% PHSBO.

The adenylate cyclase system consists of three essential components: membrane receptor, guanine-binding regulatory proteins (G_s and G_i) and the catalytic unit of adenylate cyclase. Theoretically, any of these components may be altered by nutritional modifications. Because neither the concentration of β-adrenergic receptor nor its [^{3}H]DHA-binding were significantly affected by feeding 20% PHSBO, it appears that the observed increase in isoproterenol-stimulated adenylate cyclase activity in plasma membranes of SMSG of rats fed 20% PHSBO was not due to any modifications in β-adrenergic receptor. An increase in fluoride- and isoproterenol-stimulated activity, therefore, may be due to the possible changes in the levels of guanine nucleotide binding regulatory proteins, an increase in the stimulatory proteins (G_s) or a decrease in the inhibitory proteins (G_i). Fluoride is known to activate adenylate cyclase by direct interaction with the G proteins (30-32). It also is possible, however, that the characteristics (K_m or V_{max}) of the catalytic subunit of adenylate cyclase may be altered as a result of feeding diets containing 20% PHSBO.

Our results on [^{3}H]DHA-binding to the rat SMSG membranes showed a single binding site, an observation that is consistent with our previous findings (33) and with those of Bylund et al. (34) and Cutler et al. (35). Also, the affinity of the binding sites and their density was similar to that previously reported by us (33) and by these investigators (34,35). However, there was no significant effect of *trans* fatty acids on the characteristics of radioligand binding. We have found that the feeding of diets supplemented with 1-2% cholesterol resulted in an increase in the affinity of the [^{3}H]DHA-binding sites and a decrease in β-adrenergic receptor content in the rat SMSG (33).

TABLE 5

Fatty Acid Composition of Total Phospholipids of SMSG Membranes of Rats Fed Diets Containing PHSBO

Fatty acid	Diet fed		
	20% CO	20% PHSBO	18% PHSBO + 2% CO
14:0	2.0 ± 0.1[a]	3.6 ± 0.3[b]	2.3 ± 0.3[a]
16:0	21.3 ± 0.7[a]	18.0 ± 0.7[b]	18.2 ± 0.6[b]
16:1	—	5.4	4.5

22:6	1.9 ± 0.1[a]	3.2 ± 0.3[b]	2.1 ± 0.3[a]

Values are area percentage, average of triplicate analyses within each group (mean ± SEM).

Values with different superscript letters (a, b and c) in the same row are significantly different ($P < 0.05$) using analysis of variance, Newman-Keul's test.

c, fatty acids containing *cis* double bonds; t, fatty acids containing a *trans* double bond; —, not detectable.

*c,t or t,t.

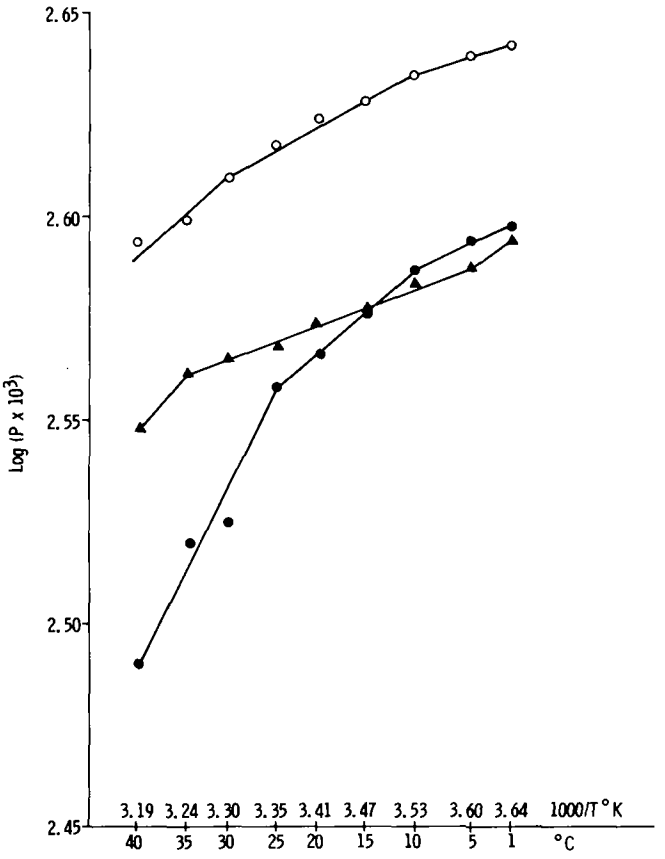

FIG. 2. Fluorescence polarization of DPH in plasma membranes from SMSG of rats fed different diets: 20% CO ●—●, 20% PHSBO O—O, 18% PHSBO + 2% CO ▲—▲.

The rats fed 20% PHSBO were deficient in EFA as indicated by reduced body weight gains, an increase in the levels of 20:3 ω-9 fatty acid in plasma and SMSG and a ratio of 20:3 ω-9/20:4, which was >0.4 in the SMSG membrane phospholipids and in plasma. A 20:3 ω-9 to 20:4 ratio greater than 0.4 in tissues and plasma is considered an established index of EFA deficiency (25). With the replacement of 2% of the PHSBO with corn oil, there was no biochemical evidence of EFA deficiency as evaluated by the above criteria. In a previous study (10), we also have observed an increase in fluoride-stimulated adenylate cyclase activity in SMSG membranes of rats fed an EFA-deficient or a marginally EFA-deficient diet. An increase in adenylate cyclase activity in our previous study (10) was associated with a decrease in membrane fluidity as shown by higher fluorescence polarization of DPH. Since our present results and previous findings (3) show that the feeding of *trans* fatty acid-containing diet such as 20% PHSBO to rats resulted in their incorporation into the SMSG lipids and in a decrease of membrane fluidity, it appears reasonable to conclude that the observed increase in adenylate cyclase activity may be associated with an EFA deficiency induced by feeding a diet containing high levels of *trans* fatty acids and deficient in EFA. Only 2.0% of the total fatty acids were contributed by linoleic acid (18:2) in the 20% PHSBO diet. On caloric basis, 0.8% of the total calories were derived from 18:2, which makes it somewhat deficient in EFA because the minimum requirements of EFA for growing rats are 1-2% of the total calories (25). Dietary *trans* fatty acids have been shown to intensify EFA deficiency (36-38). In the 18% PHSBO + 2% CO diet, 3% of the total calories were derived from 18:2, thus making it adequate with respect to the EFA requirements. The 20% corn oil diet contained about 23% of the total calories as 18:2.

In another recent study (33), we have observed that adenylate cyclase activity, the concentration of β-adrenergic receptor and membrane fluidity as measured by the fluorescence polarization of DPH were decreased in membranes prepared from rats fed cholesterol-supplemented diets. Since the membrane fluidity was affected in the same direction, i.e. decreased in the two nutritional models, whereas adenylate cyclase activity was altered in an opposite direction (increased by feeding *trans* fatty acids and decreased by feeding cholesterol), it appears that in addition to the membrane fluidity, other more specific factors also may be important in regulating the enzyme activity. For adenylate cyclase, this may include changes in the receptor content or its affinity, a modification of the levels of the guanine nucleotide-binding regulatory proteins (G_s and G_i) and in the characteristics of the catalytic unit of adenylate cyclase. Studies along these lines are underway in our laboratory to get a better understanding of the mechanism(s) of the diet-induced changes in adenylate cyclase activity.

ACKNOWLEDGMENTS

This study was supported by National Institute of Health Grant #DE 05978. We thank Kathleen Frick for providing technical assistance, Linda Armstrong for manuscript preparation, and R. G. Krishnamurthy of Kraft Inc. for providing the partially hydrogenated soybean oil.

[Received May 4, 1987; Revision accepted November 18, 1987]

The Influence of n-6 and n-3 Fatty Acids on Kidney Phospholipid Composition and on Eicosanoid Production in Aging Rats

Uno O. Barcelli*, Dorothy C. Beach and Victor E. Pollak
Division of Nephrology, Department of Internal Medicine, University of Cincinnati Medical Center, Cincinnati, OH

Changes in eicosanoid production may contribute to some of the complications of the aging process such as atherosclerosis and glomerular sclerosis. Polyunsaturated fatty acids of the n-6 and n-3 series are precursors of eicosanoids. We fed diets containing safflower oil as a source of n-6 fatty acids, fish oil as a source of n-3 fatty acids or beef tallow as a source of saturated fats to three groups of normal rats from 2–18 months of age. We demonstrated incorporation of the n-3 fatty acids, 20:5n-3 and 22:6n-3 into kidney phospholipids. Feeding of the diet containing n-3 fatty acids was associated with a markedly decreased glomerular production of PGE, 6-keto-$PGF_{1\alpha}$ and TXB_2. It also decreased the aortic production of 6-keto-$PGF_{1\alpha}$ and platelet production of TXB_2. No significant effect of n-6 fatty acids on dienoic eicosanoid production was observed. There were no adverse effects on kidney function as measured by urinary protein excretion and serum creatinine levels or on renal morphology by any diet. A diet enriched in n-3 fatty acids for 18 months remains effective in decreasing dienoic eicosanoids in the aging rat.
Lipids 23, 309–312 (1988).

The spontaneous occurrence of glomerular sclerosis in aging rats (1) and humans (2,3) is well documented. Senescent glomerular sclerosis correlates with extra and intrarenal vascular changes (4–6) or may result from the same pathogenetic factors that determine the development of atherosclerosis such as changes in plasma lipids (7), platelet function (8) or hemodynamic factors. Altered eicosanoid production may have a pathogenetic role in both atherosclerosis and glomerular sclerosis.

Dietary polyunsaturated fatty acids (PUFA) are incorporated into tissue phospholipids and are precursors of eicosanoids. This experiment was conducted to study the influence of substituting n-6 or n-3 PUFA for saturated fats in the diet of normal rats for a prolonged period. We determined the fatty acid composition of kidney phospholipids and dienoic eicosanoid production by kidney glomeruli, platelets and aorta.

METHODS

Animals and diets. Two-month-old female Wistar rats (Harlan Labs, Indianapolis, IN) were divided into three groups and fed three different diets from 2–18 months of age. These diets (TEKLAD, Madison, WI) differed only in their fat composition; they contained 200 g/kg of protein as vitamin-free casein and were in compliance with current nutritional recommendations (9). The saturated fatty acid (SFA) diet provided 190 g/kg of beef tallow and 10 g/kg of soybean oil. The n-6 PUFA diet contained 200 g/kg safflower oil (TEKLAD), and the n-3 PUFA diet contained 200 g/kg of MaxEPA (registered trademark of Seven Seas Health Care, Ltd., Hull, England); MaxEPA is a concentrated blend of fish oils from which vitamin A and D have been removed and to which vitamin E (0.5 mg/g) has been added. An antioxidant (BHA 26 mg/kg) was added to all diets. The vitamin mix used was Teklad #40060, providing 0.24 g/kg diet of dry vitamin E acetate. The n-3 PUFA diet therefore contained 0.1 g/kg more vitamin E than the other two diets. The mineral mix used was AIN-76, the composition of which has been reported (9). The major fatty acids of the dietary fats analyzed by gas chromatography are shown in Table 1. Rats were fed a measured amount of the SFA diet (approximately 20 g) every day. Rats in the other two groups received the same volume of food, but due to the higher weight per volume of the n-6 and n-3 PUFA compared to the SFA diets, rats fed these diets had approximately 12% more food available. At 16 months of age, blood pressure was measured by the tail cuff method in unanesthetized animals in restraining cages; urine was collected by placing rats in metabolic cages for 16 hr without food but with water freely available. At 18 months of age, rats were killed under ketamine-xylazine anesthesia. Blood was withdrawn by cardiac puncture. Kidneys were perfused in vivo with Hank's balanced salt solution (HBSS, Gibco, Grand Island, NY), removed and decorticated. Kidney samples were stored at −20 C for phospholipid fatty acid determinations. Other tissue samples were fixed in Mossman's formalin fixative for light microscopy. Renal glomeruli were isolated, and a segment of the thoracic aorta was excised to measure prostaglandin production.

Kidney phospholipid fatty acid composition. For this analysis, samples of tissue were selected randomly from each dietary group. Kidney tissue was homogenized in

Abbreviations: ANOVA, analysis of variance; GC, gas chromatograph; HBSS, Hank's balanced salt solution; PAS, periodic acid Schiff; PG, prostaglandin; PUFA, polyunsaturated fatty acid; RIA, radioimmunoassay; SFA, saturated fatty acid.

saline and extracted with chloroform/methanol (10). Total lipids were separated using a silica SEP PAK cartridge (Waters, Milford, MA) with the phospholipid fraction eluting with methanol (11). Phospholipids were methylated in boron trichloride in methanol at 90 C for one hr under nitrogen. Methyl esters of fatty acids were separated on a Supelcowax 10 wide-bore capillary column, using polyethylene glycol as a stationary phase (Supelco, Bellefonte, PA). Prepurified helium, at 12 ml/min was used as the carrier gas. A 5790A Hewlett Packard gas chromatograph (GC) was used with an injector temperature of 210 C. The GC was interfaced with a 3390A Hewlett Packard integrator. Fatty acids were identified with a combination of PUFA 1 and PUFA 2 standards (Supelco, Bellefonte, PA) and 18:3, 24:0 and 24:1 (NuChek Prep., Elysian, MN). All reagents were HPLC-grade (Fisher, Cincinnati, OH).

Glomerular eicosanoids. Kidneys were perfused in vivo with HBSS and heparin (2 U/ml). Glomeruli were isolated and pooled from kidneys of two rats using a previously reported sieving technique (12) and were determined microscopically to be about 80% pure and about 95% decapsulated. Glomeruli were incubated in a total volume of 0.5 ml in HBSS, containing 0.1% BSA (Fraction V, Sigma Chemical Co., St. Louis, MO) pH 7.4, at 37 C for one hr. Samples then were centrifuged immediately and supernatants saved for prostaglandin (PG) radioimmunoassay (RIA). Glomerular pellets were saved for protein determination by the Lowry method. For RIA, tritiated prostaglandins and scintillation cocktail were purchased from New England Nuclear (Boston, MA), and standards and antibodies were obtained from Seragen, Inc. (Boston, MA). The smallest detectable doses of PG standard on the linear portion of the standard curves were 4.7 pg for PGE, 12.0 pg for 6-keto-$PGF_{1\alpha}$ and 5.2 pg for TXB_2. Nonspecific binding was always less than 3.0%. Intra- and interassay coefficients of variation were 2.7% and 5.5%, respectively, for all assays.

Aortic 6-Keto-$PGF_{1\alpha}$ production. This was measured in the incubation media by RIA after segments of aorta were incubated in HBSS and 0.1% BSA (pH 7.4) at 37 C for one hr in a total volume of 1.0 ml. Tissue was air-dried and weighed and the results expressed as ng/mg tissue.

Platelet TXA_2 production. This was measured after clotting whole blood at 37 C for 30 min with subsequent centrifugation. TXB_2, the stable metabolite of TXA_2 was measured in serum by RIA.

Urinary protein. This was measured using the Bradford reagent (Bio Rad, Rockville Ct., NY), and plasma creatinine was determined colorimetrically using the Jaffe reaction. For light microscopy, kidney tissue was stained with periodic acid Schiff (PAS) and examined blind-coded for the presence of glomerular sclerosis or hypercellularity and tubular changes.

Statistics. Comparisons between groups were tested by one-way analysis of variance (ANOVA). Differences between individual groups were established by the Duncan's test.

RESULTS

The fatty acid composition of the kidney phospholipids for each dietary group is shown in Table 2. Rats fed n-6 PUFA had a significantly higher proportion of 18:2n-6 than rats fed SFA and reduced monounsaturated fatty acids 16:1 and 18:1. Rats fed n-3 PUFA had significantly higher proportions of 20:5n-3 and 22:6n-3 and lesser amounts of 18:2n-6 and 20:4n-6 than animals fed the SFA and n-6 PUFA diets. The levels of 18:1 were lower in the n-3 PUFA group in comparison to the SFA group but higher than those in the n-6 PUFA group.

TABLE 2

Fatty Acid Composition of Kidney Phospholipids

Fatty acid	SFA (n = 6)	n-6 PUFA (n = 5)	n-3 PUFA (n = 4)
16:0	20.6 ± 1.5	21.5 ± 5.0	23.7 ± 2.7
16:1	1.3 ± 0.4	0.2 ± 0.4**	1.7 ± 0.3
18:0	20.6 ± 2.1	23.4 ± 1.2	23.9 ± 0.6

24:1	1.1 ± 0.9	0.7 ± 0.7	2.0 ± 2.3

*$p < 0.01$ vs SFA and n-6 PUFA groups.
**$p < 0.01$ vs SFA and n-3 PUFA groups.
Values are percentage of total area ± SD.

The results of eicosanoid determinations are shown in Table 3. Compared with the rats fed SFA, rats fed n-3 PUFA had a markedly diminished gomerular production of all eicosanoids measured. The levels of aortic 6-keto-$PGF_{1\alpha}$ and platelet TXB_2 observed in the n-3 PUFA fed rats were 50% of those values found in the SFA-fed groups. The effects of n-6 PUFA diet on dienoic eicosanoid production were not statistically significant from the SFA-fed group.

Body weight, blood pressure, serum creatinine and urinary protein excretion are shown in Table 4. Rats fed n-6 and n-3 PUFA diets gained more weight than those fed the SFA diet. No significant differences between groups were observed for blood pressure, serum creatinine and urinary protein excretion. Light microscopic examination of kidney samples did not show any significant degree of glomerular sclerosis or tubular abnormalities in any of the rats.

DISCUSSION

We have demonstrated significant incorporation of n-6 and n-3 dietary PUFA into kidney phospholipids at the end of a 16-month feeding period in aging rats. These findings extend shorter-term observations by other workers (13).

We also observed a significant reduction in tissue production of dienoic eicosanoids, which are derived from linoleic acid. This inhibition was much more pronounced on the kidney glomeruli than on aorta or platelets; the suppressing effect of eicosapentaenoic acid on dienoic eicosanoids has been shown (14). Eicosapentaenoic acid competes with arachidonic acid as a substrate at the enzymatic level. Previous reports have demonstrated suppression of urinary PGE and 6-keto-$PGF_{1\alpha}$, decreased

TABLE 3

Effects of n-6 and n-3 PUFA on Eicosanoid Production by Isolated Glomeruli, Aorta and Platelets

	SFA	n-6 PUFA	n-3 PUFA	Number of observations
		Isolated glomeruli		
PGE (pg/mg prot)	1590 (770, 3280)	603 (226, 1600)	21* (11, 40)	7,7,6
6-keto-$PGF_{1\alpha}$ (pg/mg prot)	230 (91, 630)	108 (40, 287)	<20* (ND)	8,7,5
TXB_2 (pg/mg prot)	721 (323, 1580)	960 (440, 2120)	17* (10, 28)	7,7,5

[b]Values are geometric means (−SD, +SD).

6-keto-$PGF_{1\alpha}$ by kidney and decreased serum TXB_2 in rats after four wk of being fed a diet in which 40% of the daily energy intake was provided by cod-liver oil, while safflower oil had an increasing effect on serum TXB_2 only (15). MaxEPA oil at 20% energy in the diet of normal rats for six wk suppressed serum TXB_2, urinary 6-keto-$PGF_{1\alpha}$ and PGE_2, and aortic production of 6-keto-$PGF_{1\alpha}$ (16). Other reports have shown similar results feeding cod-liver oil for five wk in the dexamethasone-treated hypertensive rat (17) and the one kidney-one clip hypertensive rat (18). The present experiment has the importance of extending these observations for 16 months, demonstrating preservation of the dienoic eicosanoid suppressor effect of the fish oil-supplemented diet. We did not observe a significant effect of n-6 PUFA diet on dienoic eicosanoid production. These effects were not associated with any evidence of significant renal pathology, as evidenced by normal levels of serum creatinine and urinary protein excretion and by the absence of significant renal abnormalities by light microscopy. The levels of 18:2n-6 and 20:4n-6 were similar in tissues from the SFA and n-6 PUFA groups despite the significantly lower body weights in the SFA-fed group. These weight differences may have been due to higher food intake by rats in the n-6 and n-3 PUFA groups. It is unlikely that the weight differences had a major influence on the dienoic eicosanoid suppression found in the n-3 PUFA-fed rats.

The role of dietary factors, specifically of polyunsaturated fats in development of glomerular sclerosis and progressive renal disease, has been discussed (19,20). Several reports have shown beneficial effects of PUFA-enriched diets on the progression of immunologic (21–23) and nonimmunologic (24–28) models of renal disease in which the hallmark of progression is the development of glomerular sclerosis. It is attractive to propose that

PUFA might be a useful part of a dietary strategy to prevent glomerular sclerosis of aging. Long-chain n-3 PUFA derived from fish oil have other well-known biologic effects that may have potential benefit on development of atherosclerosis (29,30) and possibly of glomerular sclerosis.

The role of eicosanoids during the aging process is not clear. In the aorta of aging rats, investigators report decreased PGI_2 production by smooth muscle cells (31), increased PGI_2 production by aortic strips (32), decreased PGI_2 by endothelial cells in male rats, yet increased PGI_2 in smooth muscle homogenates by both male and female rats (33). In the kidney, PGI_2 formation from arachidonic acid decreases with age (34), while the ratio of urinary TXA_2 to creatinine increases with age in normal humans (35). Since PGI_2 is a vasodilator and TXA_2 a vasoconstrictor, these changes may have a pathophysiologic role in the reduction of renal function with age. We have shown that dienoic eicosanoid production can be altered by using n-3 PUFA for long periods in the diet of normal aging rats without deleterious effects on renal function or morphology.

ACKNOWLEDGMENTS

This work was supported by a New Investigator Grant AM 34489 from NIH, and a grant from Dialysis Clinic, Inc. Research and Educational Fund. The authors thank Mark Weiss for light microscopy of kidney, and Remmy Yunker and Brian Thompson for GC analysis of phospholipids. We acknowledge D. Davis of Scherer Corp., Troy, MI, for the gift of MaxEPA.

[Received July 23, 1987; Revision accepted November 20, 1987]

Triacylglycerol Structure of Plant and Fungal Oils Containing γ-Linolenic Acid

Larry D. Lawson* and **Bronwyn G. Hughes**
Department of Research and Development, Murdock International, 10 Mountain Springs Parkway, Springville, UT 84663

The triacylglycerol stereospecific structure was determined for the major plant oils containing γ-linolenic acid (GLA): evening primrose oil (EPO), black currant oil (BCO), borage oil (BO), and *Mucor javanicus* fungal oil (MJO). It was found that GLA, although not α-linolenic acid, resisted pancreatic lipase hydrolysis. Therefore, the 2-position analysis was determined using phospholipase C-generated 1,2-diacylglycerol and phospholipase A_2-generated lysophosphatidylcholine. GLA was found to be concentrated in the 3-position of EPO and BCO, the 2-position of BO, and the 2- and 3-positions of MJO. In BCO, octadecatetraenoic acid (n-3), also a Δ-6 fatty acid, was distributed similarly to GLA, but α-linolenic acid was found predominantly in the 1-position. Linoleic acid was nearly evenly distributed in all positions of EPO and BCO but was concentrated in the 1-position of BO and the 2-position of MJO. Both palmitic and stearic acids were found predominantly in the 1-position of all of the oils. The results demonstrate similarities and differences in the positional distribution of fatty acids in GLA-containing oils.
Lipids 23, 313-317 (1988).

γ-Linolenic acid (GLA) (6,9,12-18:3), the Δ6-desaturase metabolite of linoleic acid (LA), is considered the agent responsible for the apparent effectiveness of evening primrose seed oil (EPO) *(Oenothera biennis)* in the treatment of a variety of diseases (1-3), including premenstrual syndrome and atopic eczema, which may be caused by low or impaired Δ6-desaturase activity (4,5). The occurrence of significant levels of GLA in plant sources is rare and first was reported in 1949 for EPO, which contains 8-10% by weight of GLA (6). More recently, higher levels of GLA have been found in borage seed oil (BO) *(Borago officinalis)* (7), with 24-25% GLA, black currant seed oil (BCO) *(Ribes nigrum)* (8), which is 16-17% GLA, and fungal oils, such as *Mucor javanicus* (MJO) with 16-19% GLA.

Unknown among the GLA-containing oils is the distribution of the GLA and other fatty acids in the triacylglycerol structure. The triacylglycerol structure can influence the metabolism of an oil. It has been shown for peanut oil (9,10) and for synthetic oleoylstearoyltriacylglycerols (11) that the triacylglycerol structure can significantly affect fatty acid absorption, particularly when an unusual fatty acid is present. Hence, we chose to determine and compare the stereospecific structure of the major GLA-containing oils.

MATERIALS AND METHODS

Oils. Evening primrose oil and borage oil were obtained from the Efamol Research Institute (Kentville, Nova Scotia). Glanolin brand (American Health, Orangeburg, NY) black currant oil was purchased at a local store. *Mucor javanicus* fungal oil was obtained from Alcolac, Inc. (Baltimore, MD). No oil contained more than 1% 1,2;2,3-diacylglycerol or more than 1.5% 1,3-diacylglycerol.

Pancreatic lipase hydrolysis. Hydrolysis of the oils by porcine pancreatic lipase (Type II, Sigma Chemical Co., St. Louis, MO) was performed essentially according to the method of Luddy et al. (12). To 4 mg oil, 1.1 ml of buffer containing 1 M tris (hydroxymethyl)-amino methane, pH 8.0, 0.15 M $CaCl_2$ and 0.01% bile salts were added. After addition of 4 mg (64 units) of ether-extracted lipase, the mixture was rapidly stirred in a heating block at 37 C for four min. The reaction products were extracted three times with 3 ml ether, concentrated with a nitrogen stream and separated by thin layer chromatography on unmodified Whatman silica gel K6 plates developed in chloroform/acetone/acetic acid (96:4:0.4, v/v/v). Only trace amounts of acyl migration to 1,3-diacylglycerols could be found on the plates.

Synthesis of phosphatidylcholines. Random diacylglycerols (7-9 mg) were produced by the action of the Grignard reagent, ethyl magnesium bromide (Aldrich Chemical Co., Milwaukee, WI), on 60 mg of triacylglycerol according to the method of Myher and Kuksis (13). After separation of the 1,3- and 1,2;2,3-diacylglycerols by thin layer chromatography on unmodified K6 plates, the 1,2;2,3-diacylglycerols were extracted from the silica gel two times with 6 ml chloroform/methanol (2:1, v/v) and evaporated to dryness. Quantitation of the 1,2;2,3- and 1,3-diacylglycerols by gas chromatography of the methyl esters revealed a nearly theoretical ratio of 2.04:1 (SEM = 0.09, n = 15), respectively, indicating that no significant degree of acyl migration had occurred.

Phosphatidylcholines were prepared by phosphorylation of the 1,2;2,3-diacylglycerols with phosphorus oxychloride (Aldrich Chemical Co.) followed by reaction with choline chloride (13). It was critical that the highly hygroscopic choline chloride crystals were washed thoroughly with acetone or pyridine and the adhering solvent removed by evaporation in a gentle nitrogen stream immediately before use. The 1,2;2,3-phosphatidylcholines were purified by thin layer chromatography on K6 plates developed in chloroform/methanol/water (65:35:4, v/v/v) followed by extraction three times with 5 ml of chloroform/methanol (1:1, v/v). Yields were typically 1-2 mg (20-40%).

Phospholipase A_2 hydrolysis. Nearly complete hydrolysis of the 2-position of 1,2-phosphatidylcholine and no hydrolysis of 2,3-phosphatidylcholine was achieved by incubation of half of the 1,2;2,3-phosphatidylcholines, dissolved in 3 ml ether, with one unit of phospholipase A_2 from bee venom (Sigma Chemical Co.) dissolved in 0.6 ml buffer (0.5 M tris (hydroxymethyl)-amino methane and 2 mM $CaCl_2$, pH 7.5). After rapid shaking at 37 C for 45 min, 0.2 ml of 1 N HCl was added and the reaction products extracted with 6 ml chloroform/methanol (2:1, v/v).

Abbreviations: BCO, black currant oil; EPO, evening primrose oil; GLA, γ-linolenic acid; LA, linoleic acid; LPC, 1-lysophosphatidylcholine; MJO, *Mucor javanicus* fungal oil.

The 1-lysophosphatidylcholine, free fatty acid, and unreacted 2,3-phosphatidylcholine were separated by thin layer chromatography using chloroform/methanol/water (65:25:4, v/v/v). Lack of hydrolysis of the 2,3-phosphatidylcholine was verified using 2,3-dipalmitoylphosphatidylcholine (Sigma Chemical Co.). The nonspecificity of bee venom phospholipase A_2 for different fatty acids was demonstrated by hydrolysis of the phosphatidylcholines prepared from a mixture of triolein, trilinolein, trigamma-linolenin, and trialpha-linolenin (Nu Chek Prep, Elysian, MN).

Phospholipase C hydrolysis. Hydrolysis of 1,2-phosphatidylcholine to 1,2-diacylglycerol with no hydrolysis of 2,3-phosphatidylcholine was accomplished by incubation of the 1,2;2,3-phosphatidylcholines, dissolved in 3 ml ether, with three units of phospholipase C from *Clostridium welchii* (Type XIV, Sigma Chemical Co.) dissolved in 1 ml buffer (1 M tris (hydroxymethyl)-amino methane and 1 mM $CaCl_2$, pH 7.3). After rapidly shaking for 60 min at 37 C and extraction with 6 ml of chloroform/methanol (2:1, v/v), the 1,2-diacylglycerol was isolated by thin-layer chromatography in hexane/ether/acetic acid (50:50:1, v/v/v). No hydrolysis of 2,3-dipalmitoylphosphatidylcholine could be detected, even after six hr of incubation. The phospholipase C was nonspecific toward the phosphatidylcholines prepared from a mixture of triolein, trilinolein, trigamma-linolenin and trialpha-linolenin.

Fatty acid analysis. Fatty acid methyl esters of all final reaction products and small portions of the intermediate products were prepared by addition of 2–3 ml of benzene/14% BF_3 in methanol (1:1, v/v) to the silica gel scrappings or the evaporates in teflon-lined, screw-cap test tubes followed by heating at 90 C for 30 min or incubating at room temperature overnight. After cooling and addition of water, the methyl esters were extracted with 5 ml of hexane, evaporated to dryness with a nitrogen stream, redissolved in 0.35 ml of octane and analyzed by gas chromatography. The addition of benzene to the silica gel scrappings was essential for quantitative esterification for both phospholipids and glycerolipids.

Fatty acid analyses were performed on a Hewlett-Packard 5880A gas chromatograph equipped with a flame ionization detector. Components were separated on a 30 m × 0.32 mm Supelcowax 10 bonded phase carbowax capillary column (Supelco, Bellefonte, PA) at a split ratio of 30 and a column flow rate of 2.4 ml helium/min. The oven was operated isothermally at 200 C or programmed from 180 C to 230 C, depending on the analysis.

RESULTS

Comparison of methods for determining triacylglycerol structure. A comparison of several methods of determining the stereospecific composition of the triacylglycerols

[a]Values are means ± standard deviations for four to six experiments.

in evening primrose oil is shown in Table 1. Pancreatic lipase initially was employed to generate 2-monoacylglycerols, 1,2;2,3-diacylglycerols, and free fatty acids released from the 1- and 3-positions of the oils. The accuracy of the composition of free fatty acids released from the 1- and 3-positions can be checked in two ways, namely by subtracting the 2-monoacylglycerol composition from the triacylglycerol composition and by the composition of the 1,3-diacylglycerol produced by the Grignard reaction. A comparison of these three methods (items 2–4 of Table 1) reveals good agreement for all fatty acids except for GLA, which is present at only about half the concentration in the lipase-released free fatty acids as in the Grignard-generated 1,3-diacylglycerol or in the calculated 1,3-composition, indicating that GLA resists lipase hydrolysis. Further evidence that GLA resists lipase action is apparent from the 45% higher concentration of GLA in the lipase-released 1,2;2,3-diacylglycerol than in the Grignard-generated 1,2;2,3-diacylglycerol (items 5 and 6 of Table 1). The lipase-released 2-monoacylglycerol appears to be less of a concern because its GLA content was only 10% higher ($P < 0.01$) than that of two other methods used for determining the 2-position composition (items 10–12 of Table 1). Similar levels of discrimination against hydrolysis of GLA-containing triacylglycerols by pancreatic lipase also were observed with BO, BCO and MJO (data not shown).

Interestingly, pancreatic lipase hydrolysis of BCO showed a similar discrimination against octadecatetraenoic acid (6,9,12,15-18:4) but not against α-linolenic acid (9,12,15-18:3). Similar discrimination also was found for tripetroselinin (tri-6-18:1) (data not shown). Apparently, triacylglycerols with a fatty acid containing a double bond in the 6-position are poor substrates for pancreatic lipase. Heimermann et al. (14) have reported that triacylglycerols containing octadecenoic acids of varying double-bond position were poor substrates for pancreatic lipase when the double bond was within seven from the carboxyl-end. Furthermore, marine oil docosahexaenoic acid (4,7,10, 13,16,19-22:6) and especially eicosapentaenoic acid (5,8, 11,14,17-20:5) have been shown to resist pancreatic lipase hydrolysis due to the close proximity of their double bonds to the carboxyl-end and perhaps to steric hindrance (15). GLA also has its double bonds situated unusually close to the carboxyl-end and likewise may be expected to resist pancreatic lipase hydrolysis, as was found. Therefore, free fatty acids and 1,2;2,3-diacylglycerols released by pancreatic lipase cannot be used to determine the stereospecific structure of oils containing GLA and lipase-generated 2-monoacylglycerols should only be used as an approximate check of other methods.

The 1-lysophosphatidylcholine (LPC) released from phosphatidylcholine is considered a reliable representation of the 1-position composition. As a check on the LPC composition, a representative 2-position composition was subtracted from the composition of the 1,2-diacylglycerol released by phospholipase C (items 8 and 9 of Table 1), which closely verified the 1-position analysis.

In addition to the pancreatic lipase-released 2-monoacylglycerol, three other methods were used to determine the composition of the 2-position. These methods were free fatty acid released from the 1,2-phosphatidylcholine by phospholipase A_2, subtracting the triacylglycerol composition from the 1,2;2,3-diacylglycerol composition, and subtracting the LPC composition from the composition of the phospholipase C-released 1,2-diacylglycerol. Items 11–13 of Table 1 indicate close agreement between these methods, especially for the unsaturated fatty acids. The GLA content of the free fatty acids was slightly, but significantly, higher than the GLA content determined by the other two methods. The free fatty acid composition generally is considered inferior to other methods due to acyl migration during the phospholipase A_2 reaction and because of the ease of contamination of the free fatty acid fraction (16). Use of the 1,2;2,3-diacylglycerol composition for determining the 2-position composition is an important verification for oils containing easily oxidized fatty acids such as GLA because it is produced in a single two-min reaction; whereas, the free fatty acids and 1,2-diacylglycerols also require a 16-hr phosphatidylcholine synthesis and a one-hr phospholipase incubation, including three thin layer chromatography separations. However, because any error in the 1,2;2,3-diacylglycerol composition is multiplied by four in the calculation, greater variation usually is found than when using the 1,2-diacylglycerol composition, which is multiplied only by two. Therefore, subtracting the LPC composition from the 1,2-diacylglycerol composition is probably the best way to determine the 2-position composition for oils that resist pancreatic lipase hydrolysis and was the method used in this paper.

The composition of the 3-position was determined either by subtracting the phospholipase C-released 1,2-diacylglycerol from the triacylglycerol composition or by subtracting the LPC composition from the Grignard-generated 1,3-diacylglycerol. Even though 1,3-diacylglycerols generally are considered inferior products for triacylglycerol structure determination, due to acyl migration of the 1,2;2,3-diacylglycerols during the Grignard reaction and subsequent separation, the two methods showed excellent agreement (items 14 and 15 of Table 1).

Comparison of the triacylglycerol structure of GLA-containing oils. Using a single method for determining the composition of each acyl position, the structure of the four GLA-containing oils are compared in Table 2. Several differences and similarities between the oils were found. Very little GLA was found in the 1-position of any of the oils except for MJO. The highest levels of GLA were found in the 3-position of EPO and BCO, the 2-position of BO and the 2- and 3-positions of MJO. In BCO, octadecatetraenoic acid (18:4n-3), like GLA, has its first double bond in the 6-position and has a similar distribution to GLA. However, α-linolenic acid, an isomer of GLA with its first double bond in the 9-position, preferentially is acylated in the 1-position of BCO rather than the 3-position as for GLA. Linoleic acid showed a small preference for the 2-position of EPO and BCO, a larger preference for the 2-position of MJO, a preference for the 1-position of BO and an avoidance of the 3-position of BO and MJO. Oleic acid was distributed evenly among all positions for EPO but accumulated in the 3-position of BO and 2-position of MJO. Stearic acid was excluded from the 3-position of EPO and BCO but was concentrated in the 1-position of all of the oils. Palmitic acid was nearly excluded from the 2-position and most concentrated in the 1-position of all the oils. The long-chain monounsaturates (20:1n-9 and 22:1n-9) of BO and the 24:0 of MJO were concentrated in the 3-position.

DISCUSSION

The common fatty acids of most plant oils are symmetrically distributed between the 1- and 3-positions with a preferred distribution of saturated fatty acids in the 1- and 3-positions and of linoleic acid in the 2-position (17). Oils containing ≥C20 fatty acids usually show a preferred distribution of these fatty acids in the 3-position. The GLA-containing oils, however, showed considerable deviation from the norm for the common fatty acids due in part to the asymmetric distribution of GLA. In EPO and BCO where GLA was concentrated in the 3-position, stearic acid was excluded from the 3-position and both stearic and palmitic acids were preferentially located in the 1-position. In BO and MJO, linoleic acid was excluded from the 3-position. Interestingly, the linolenic acid (α plus γ) of human plasma triglycerides is also preferentially esterified in the 3-position while palmitic and stearic acids also are located preferentially in the 1-position (18).

Very little is known about the role of triacylglycerol structure in the metabolic fate of fatty acids. An exception is the atherogenic effect of peanut oils, which contain a high amount of very long chain (C20-24) saturated fatty acids, located exclusively in the 3-position. Randomization of peanut oil distributes all the fatty acids equally and greatly reduces its atherogenic potential (10). Several peanut oils containing the same amounts of the very long chain saturated fatty acids were shown to have significantly different atherogenic potential (9). The main difference between peanut oils of high and low atherogenicity was a high level of linoleic acid and a high ratio of linoleic to oleic acid in the 2-position of the highly atherogenic peanut oil. It is thought that the high level of linoleic acid in the 2-position may allow a higher degree of hydrolysis of peanut oil with a consequent greater absorption of the very long chain saturated fatty acids as 3-monoacylglycerols.

Since GLA may be absorbed poorly due to its resistance to pancreatic lipase, it also may be true with GLA-containing oils as with peanut oils that a high linoleic acid or high linoleic acid to oleic acid ratio in the 2-position may facilitate GLA absorption. Of the GLA-containing oils, evening primrose oil has both the highest linoleic acid and linoleic acid to oleic acid ratio in the 2-position. Therefore, if GLA is poorly absorbed in man it is possible that the GLA in EPO may be more efficiently absorbed than from other known GLA-containing oils.

Finally, as in the case of peanut oils and atherogenesis, it is possible that the variations in triacylglycerol composition that we have observed will lead to differences in biological activities between the various GLA-containing oils.

Dietary Fiber Supplements: Effects on Serum and Liver Lipids and on Liver Phospholipid Composition in Rats

David Kritchevsky[a,*], Shirley A. Tepper[a], Subramanian Satchithanandam[b], Marie M. Cassidy[c] and George V. Vahouny[b,]**

[a]The Wistar Institute of Anatomy and Biology, Philadelphia, PA, [b]Department of Biochemistry, George Washington University Medical Center, Washington, D.C., and [c]Department of Physiology, George Washington University Medical Center, Washington, D.C.

Rats (6 per group) were fed semipurified diets containing either particulate fibers (alfalfa, 10%; cellulose, 10%; bran, 10%), a soluble ionic fiber (pectin 5%), soluble, nonionic fibers (guar gum, 5%; Metamucil, 10%), a mixed fiber preparation (Fibyrax, 10%, or an insoluble, ionic bile acid-binding resin (cholestyramine, 2%). The control group was fed the unsupplemented diet. The feeding period, during which diet and water were provided ad libitum, was 28 days.

Compared with the control group, serum total cholesterol levels were increased by more than 10% in rats fed alfalfa and decreased by more than 10% in rats fed cellulose, guar gum, Fibyrax and cholestyramine. There were no significant differences in percentage of plasma HDL cholesterol. Serum triglycerides were elevated in the groups fed alfalfa, pectin, guar gum or Fibyrax and reduced in the group fed Metamucil. Plasma phospholipids were elevated in rats fed alfalfa or bran, unaffected in rats fed pectin or Metamucil and reduced in the other groups. Liver total cholesterol was elevated in all groups but those fed wheat bran and cholestyramine. The percentage of liver cholesterol present as ester was elevated in every group except that fed cholestyramine. Liver triglycerides were reduced in rats fed guar gum or Metamucil and elevated in those fed alfalfa. Liver phospholipids were lowered in the group fed cellulose.

Liver phospholipids were fractionated by thin layer chromatography to give phosphatidylcholine (PC), phosphatidylethanolamine (PE), sphingomyelin (Sph), lysophosphatidylcholine (LPC) and phosphatidylinositol plus phosphatidylserine (PI + PS). PC was elevated in all test groups (7–25%); PE levels ranged from 14% below to 0.3% above controls; Sph levels were sharply lower (20–53%) in all groups. LPC and PI + PS levels were close to the control value in all test groups.

The results demonstrate that different dietary fibers can affect liver phospholipid composition. In view of the critical roles of phospholipids in many biological reactions, it will be interesting to survey the influence of dietary fiber on phospholipid spectra of other tissues.
Lipids 23, **318–321 (1988).**

There have been numerous reports on the effects of various dietary fibers on serum and liver lipids of man and other animal species. Many of the data appear in a recent book (1). The lipids analyzed primarily have been free and esterified cholesterol and triglycerides. On occasion, plasma or liver phospholipids also are assayed. There have been no reports of the effects of dietary fiber on the levels of individual phospholipids. In view of our finding that fibers could bind phospholipids in vitro (2), we thought it would be of interest to determine if dietary fibers could influence the phospholipid spectrum of the liver in vivo. Our findings are the basis of this report.

MATERIALS AND METHODS

Male Wistar rats weighing about 200 g were used in this study. They were randomized into groups of equal average weight (6 rats/group) and maintained at 23 C on a 12-hr light-dark cycle. The rats were fed a basal diet containing (g/100 g): dextrose, 55; casein, 25; corn oil, 14; salt mix, 5; and vitamin mix, 1. Additions of fibers to the diet were made at the expense of the dextrose. The additions were alfalfa (10%) (North Hampton County Farm Bureau, Nazareth, PA); cellulose (10%) (Archer Daniels Midland, Decatur, IL); Fibyrax (10%), a mixed fiber preparation obtained from Farma Foods, Inc., McLean, VA; guar gum (5%) (Freeman Industries, Tuckahoe, NY); 7% methoxylated citrus pectin (5%) (Freeman Industries, Tuckahoe, NY); Metamucil (10%) (G.D. Searle and Co., Skokie, IL) this product contained 50% sugar; and cholestyramine (2%) (Mead-Johnson Co., Evansville, IN). The diets were mixed to our specifications and pelleted by Bio-Serv, Frenchtown, NJ.

The rats were provided their respective diets and water ad libitum for 28 days. Before the end of the study, feces were collected for analysis of fecal steroids and divalent cations. The results of the fecal analyses are reported elsewhere (3). The rats were killed by barbiturate injection and sera and livers taken for further analysis.

Sera were analyzed for total (4) and high density lipoprotein (HDL) cholesterol (5), triglycerides (6) and phospholipids (7). Livers were homogenized in chloroform/methanol (2:1, v/v), the lipid extract was dried over anhydrous Na_2SO_4, and aliquots of the dried extract were used for analysis of free and total cholesterol (8), triglycerides (6) and total phospholipid (7). Individual phospholipids were separated by the thin layer method of Skipski et al. (9) using a solvent mixture consisting of chloroform/methanol/acetic acid/water (25:15:4:2, v/v/v/v). Phospholipids were visualized using iodine vapor (10) and, after the areas on the plate corresponding to individual compounds had been outlined, the iodine was permitted to sublime from the plate, the silicic acid areas scraped off the plate and the phospholipids eluted and analyzed (7). Data were analyzed by analysis of variance (11).

RESULTS

The data on weight gain are presented elsewhere (3). The control rats gained 121 ± 12 g during the four-wk feeding

**Deceased.

Abbreviations: LPC, lysophosphatidylcholine; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PI + PS, phosphatidylinositol plus phosphatidylserine; PS, phosphatidylserine; Sph, sphingomyelin.

period. Rats fed cellulose, wheat bran, Fibyrax or cholestyramine showed similar weight gains, namely, 129 ± 6; 127 ± 5; 123 ± 5; and 134 ± 11 g, respectively. Rats fed the other fibers showed a lesser weight gain (76 ± 0.8 g), which was 41% below the average weight (128 ± 2 g) of the other four groups. Actual weight gains (g ± SEM) were alfalfa, 76 ± 9; pectin, 75 ± 14; guar gum, 74 ± 17; and metamucil, 78 ± 16. Differences in weight gain statistically were significant. The feed efficiency ratios ([weight gain/total food intake] × 100) was highest in rats fed the control or cholestyramine-containing diets (23.7 ± 2.4 and 26.0 ± 2.1, respectively), lowest in those fed Metamucil (12.8 ± 2.6), guar gum (12.9 ± 3.0), and alfalfa (14.0 ± 1.7), and intermediate in those fed pectin (15.9 ± 3.0), wheat bran (18.7 ± 0.7), Fibyrax (19.6 ± 0.8), and cellulose (19.8 ± 0.9).

Table 1 is a summary of the serum lipid data. Serum total cholesterol levels for the entire experiment were significantly different. Compared with the fiber free diet, highest cholesterol levels were observed in rats fed alfalfa, wheat bran or pectin and lowest levels in those fed guar gum or Fibyrax. HDL cholesterol levels (as percentage of total cholesterol) among groups were not significantly different and ranged from 62–82%. Serum triglyceride levels were elevated (compared to control) in rats fed alfalfa, pectin, guar gum or Fibyrax (elevation greater

*PC, phosphatidylcholine; PE, phosphatidylethanolamine; Sph, sphinogmyelin; LPC, lysophosphatidylcholine; PI, phosphatidylinositol; PS, phosphatidylserine.

than 30%). Triglyceride levels in the other groups were within the normal range. Serum phospholipids were highest in the rats fed alfalfa or wheat bran and lowest in those fed Fibyrax or cholestyramine. Rats fed alfalfa or wheat bran appeared to have the highest levels of total serum lipids.

Liver lipids (Table 2) were significantly different among groups. Total liver cholesterol was highest in rats fed Fibyrax or Metamucil. The percentage of cholesterol present as ester was within the normal range only in the rats fed cholestyramine or Metamucil (normal being defined here as control value ± 15%). Liver cholesterol levels were lowest in the groups fed the soluble, nonionic fibers and highest in the group fed Fibyrax. Liver phospholipid levels were considerably below normal levels only in rats fed cellulose.

The distribution of individual liver phospholipids is summarized in Table 3. Differences among groups are statistically significant for each phospholipid. Levels of PC were elevated in all test groups with the differences ranging from 7 to 25%. PE levels were equal to or slightly lower than the control value in all test groups. (Control, 33.9 ± 0.4%; average for all test groups, 31.4 ± 0.6%.) Sph content was reduced considerably in all the test groups with reductions ranging from 20 to 53%. Levels of LPC and of PI + PS generally were close to control levels in all groups. The range of difference of LPC was from −15% (pectin) to +25% (Fibyrax); the range for PI + PS was from −5% (alfalfa) to +20% (Fibyrax) but with control levels of LPC and PI + PS being 6.0 ± 0.4 and 7.6 ± 0.3%, the averages of the test groups were 6.3 ± 0.3 for LPS and 8.0 ± 0.2 for PI ± PS.

DISCUSSION

In this study, we compared simultaneously the effects of many types of dietary fiber: particulate, soluble ionic and nonionic, and mixed. No distinct or consistent patterns of effects on serum or liver lipids emerge. Generally, rats fed alfalfa exhibited the highest overall levels of serum lipids. If we arbitrarily assume that levels of lipids 15% higher or lower than those seen in the control group are indicative of an effect, we find lowering of serum cholesterol by guar gum and Fibyrax; elevation of serum triglycerides in rats fed alfalfa, pectin, guar gum or Fibyrax; and elevation of serum phospholipids in rats fed alfalfa or wheat bran and reduction in those fed guar gum. Liver total cholesterol levels were elevated in rats fed every fiber, but wheat bran, guar gum and cholestyramine and esterified cholesterol was elevated in every group except that fed cholestyramine. Triglycerides were elevated in rats fed alfalfa or Fibyrax and reduced in those fed guar gum or Metamucil. Liver phospholipid levels were reduced only in rats fed cellulose.

Although the values for total cholesterol are different, direct comparison showed no significant differences (by Student's t-test) between any of the test groups and the control. However, rats fed cellulose, Metamucil, Fibyrax or cholestyramine all excreted twice as much total bile acid (8.8 ± 0.19 mg/day) as did the control group (4.4 ± 0.7 mg/day) (3). Compared directly with the control group, only rats fed alfalfa or pectin exhibited significantly elevated triglyceride levels. These differences cannot be explained on the basis of weight gain or feed efficiency.

Total liver cholesterol levels cannot be correlated with either fecal bile acid or neutral steroid excretion. The level of hepatic cholesteryl ester content is an indication of cholesterol deposition. The finding that hepatic cholesteryl ester levels were 18–113% higher than control in every group except that fed cholestyramine was surprising and suggests an effect on endogenous cholesterol metabolism that merits further study.

In examining the distribution of liver phospholipids, two consistent effects were observed. Liver PC was higher

than the control level in all fiber-fed groups, and liver Sph consistently was lower in all test groups. The average percentages of PC and Sph in livers of control rats were 42.8 ± 1.6 and 9.3 ± 1.3%, respectively. Average PC and Sph for the eight test groups were 48.7 ± 1.1 and 6.2 ± 0.4. The ranges of PE, LPC and PI + PS content were small and within a few percentages of the control values.

To our knowledge, this is the first study of the effects of dietary fiber on liver phospholipid spectrum. The observed differences suggest that dietary fibers may play a hitherto unsuspected role in membrane structure and in lipid metabolism in general. It would be of future interest to determine if fiber affected the phospholipid composition of specific lipoprotein molecules.

The influence of dietary fibers on phospholipid metabolism also may be of interest with regard to tumor growth. There are differences between membrane phospholipids of rat or mouse liver and rat or mouse hepatomas (12,13). Comparison of phospholipid of normal and transformed human diploid cells showed two significant differences; PS levels were lower in the transformed cells and Sph levels were higher. Levels of all other phospholipids were unchanged in the transformed cells (14).

Relative Inhibitory Potencies of Flavonoids on 12-Lipoxygenase of Fish Gill

R.J. Hsieh, J.B. German and J.E. Kinsella*
Lipid Research Laboratory, Institute of Food Science, Cornell University, Ithaca, NY 14853

The relative efficacy of 10 flavonoid compounds and some common antioxidants in inhibiting 12-lipoxygenase of fish gill was determined. Lipoxygenase activity was measured by oxygen consumption with polarography and formation of hydroxy fatty acid using thin layer chromatography with autoradiography. Generally, the inhibition of 12-lipoxygenase by flavonoids was noncompetitive. The lipoxygenase product pattern did not change in the presence of flavonoids. Fisetin (3,3′,4′,7-tetrahydroxyflavone) and quercetin (3,3′,4′,5,7-pentahydroxyflavone) were the most potent inhibitors of 12-lipoxygenase, with IC_{50}'s of 0.25 and 0.4 μM respectively. These were compared with IC_{50}'s values of 5, 1000 μM for BHA (t-butylhydroxyanisole) and BHT (t-butylhydroxytoluene) respectively. Possible inhibitory mechanisms and relationships between flavonoid structure and inhibitory potencies are discussed.
Lipids 23, 322–326 (1988).

The high degree of unsaturation of the component polyunsaturated fatty acids renders fish lipids very susceptible to oxidation. Though lipid oxidation is thermodynamically favored, direct reaction between unsaturated fatty acids and oxygen is spin-forbidden (1). This kinetic spin restriction can be overcome by free radical reactions, but these require an activation mechanism to facilitate the initiation reaction to produce catalytic free radicals (1). Several enzymatic and nonenzymatic processes such as autoxidation photosensitized oxidation, lipoxygenase, peroxidase and microsomal enzymes have been suggested to generate reactive oxygen species that can function as initiators of lipid oxidation in muscle tissues (1–4). Because all of these intiation mechanisms may occur, their relative importance and individual contribution to the overall processes needs to be understood. The ability of lipoxygenase to produce fatty acid hydroperoxides and its widespread occurrence in animal tissues suggest that it may be important in initiation of lipid oxidation (2,5,6).

Peroxy-enzyme radical complexes exist during the catalytic cycle of lipoxygenase (7,8). These release hydroperoxides that serve as sources of free radicals. Currently, it is not clear if lipoxygenase functions similarly to free radicals as an initiator of lipid oxidation. In this regard, specific inhibitory compounds could be useful in differentiating between lipoxygenase reactions and other free radical reactions. Compounds with free radical quenching ability should inhibit free radical oxidation but may not be lipoxygenase inhibitors. Flavonoids, with their free radical quenching and metal chelating abilities, are potential inhibitors of lipid oxidation (9–11). The available evidence indicates that some flavonoids may specifically interfere with the lipoxygenase reactions and their inhibitory potencies may be related to their structures rather than their free radical quenching abilities (12–17). Thus, it is possible that two positional isomers of hydroxyl groups of flavonoids may have similar free radical quenching abilities but differ in their capacity to inhibit lipoxygenase. This suggests that structurally different flavonoids may be used as specific inhibitors of lipoxygenase; thereby helping to distinguish lipoxygenase from other free radical reactions.

In this report, the highly active 12-lipoxygenase of gill tissue (2,5) was used in a model system to study the inhibition of lipid oxidation by various hydroxy isomers of flavonoids and some common antioxidants such as nordihydroguaiaretic acid (NDGA), propyl gallate (PG), t-butylhydroxyanisole (BHA) and t-butylhydroxytolune (BHT). The differing inhibitory effects of these compounds on lipoxygenase are demonstrated and discussed.

MATERIALS AND METHODS

Materials. Arachidonic acid (20:4,n-6) was obtained from NuChek Prep (Elysian, MN). [1-^{14}C]arachidonic acid was bought from New England Nuclear (Boston, MA). Caffeic acid, esculetin, glutathione (GSH), BHA, BHT, PG, NDGA and indomethacin were purchased from Sigma Chemical Co. (St. Louis, MO). Eicosatetraynoic acid (ETYA) was a gift from W. Scott (Hoffman LaRoche, Nutley, NJ). Flavonoids such as fisetin, apigenin, naringenin, catechin, 3-epicatechin, chrysin, myricetin, quercetin, rutin and esculin were obtained from G. Hrazdina (Institute of Food Science, Cornell University). Ethyl acetate was obtained from Fisher Scientific Co. (Rochester, NY). Methanol was purchased from J. T. Baker Chemical Co. (Phillipsburg, NJ). Chloroform and glacial acetic acid were from Mallinckrodt Inc. (St. Louis, MO).

Lipoxygenase preparation. Samples of gill tissue (1 g) carefully were excised from young, freshly killed rainbow trout (15 g) (Tunison Fish Laboratory, Cortland, NY) and homogenized in 40 ml 0.05 M (pH 7.4) phosphate buffer with 1 mM glutathione using a Polytron homogenizer. The homogenate was centrifuged for 15 min. at 15,000 × g at 4 C. The resultant supernatant fraction was used as the crude enzyme source without further purification (2,5,6). The enzyme preparation either was used immediately or stored at −70 C as beads of droplets instantaneously frozen in liquid nitrogen. Protein concentration was estimated by phenol reagents with bovine serum albumin as standard (18).

Lipoxygenase assay. To verify the activity and specificity of the lipoxygenase reactions and to determine inhibitory effects of flavonoids, the enzyme preparation (1 mg protein/ml) was incubated at 25 C with arachidonic acid (50 μM) using labeled [1-^{14}C]arachidonic acid as tracer. The extent of enzymatic reaction was calculated from the conversion of radioactive substrate fatty acid into its hydroxy analog following 10 min incubation. The reaction was quenched by acidification with formic acid

to pH 3.0 and the products were extracted twice with 1 ml ethyl acetate as described (2). Extracted lipids were separated by thin layer chromatography (TLC) using a solvent system consisting of chloroform/methanol/acetic acid/water (90:8:1:0.8, v/v/v/v) (19). The radiolabeled product, 12-hydroxy-5,8,10,14-eicosatetraenoic acid, from labeled arachidonic acid, was generated due to the activity of gill lipoxygenase and was detected qualitatively by autoradiography as reported (20). The extent of product formation during the reaction period was quantified by locating, and scraping the corresponding bands and measuring by liquid scintillation counting the radioactivity in each band (5,6).

Calculations of enzyme velocity. The rate of lipoxygenase-catalyzed reaction was determined by oxygen consumption using a polarographic cell (Hansatech oxygen electrode, Hansatech Ltd., Norwich, England). For enzyme assays, the lipoxygenase preparation (1 mg protein/ml) was equilibrated in phosphate buffer (0.05 M, pH 7.4) in a water-jacketed oxygen electrode chamber at 25 C for one min. Then the flavonoid or specific inhibitor in ethanol (1 μl) was introduced into the enzyme assay mixture and incubated for 10 min. The enzyme activity then was initiated by the addition of arachidonic acid (25 nmol) in ethanol (1 μl), and the oxygen concentration was monitored by the electrode and recorded continuously using a microcomputer (Fig. 1a). The experimental data were smoothed to eliminate random electronic noise (21). The first differential of the oxygen concentration vs time data (dO_2/dt) was calculated (Fig. 1b). The maximal rate and lag time required to reach this rate were obtained from these first differential plots. The appropriate programs for performing these analyses were written in Forth for the Apple IIe.

Relative inhibitory efficacy of flavonoids and antioxidants on gill lipoxygenase. Various antioxidants, and flavonoids were tested to compare their inhibitory effects on gill lipoxygenase. The gill lipoxygenase was prepared as described above. The enzyme was preincubated with an inhibitor at 25 C for 10 min. The radiolabeled substrate, arachidonic acid, then was added to initiate enzyme reaction. The reaction was stopped after an additional 10 min. incubation; the products were separated by thin layer chromatography and detected by autoradiography as mentioned above. The inhibitory effect of each inhibitor was estimated by measuring the radioactivity in the product by liquid scintillation counting as stated above. At least five concentrations of each inhibitor were employed to determine its inhibitory potency. The IC_{50} value, the concentration of inhibitor causing 50% reduction of enzyme activity, was calculated by linear regression analysis (22).

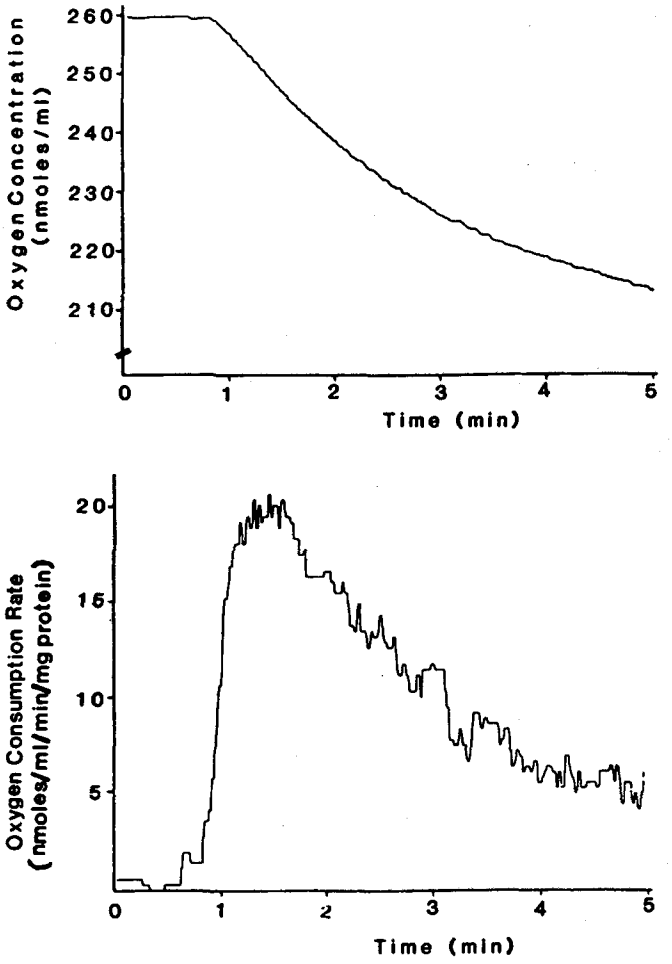

FIG. 1. The progress curve (1a) and the first differential (1b) of oxygen consumption by 12-lipoxygenase-catalyzed oxidation of arachidonic acid. Gill 12-lipoxygenase (0.5 mg protein) in 0.5 ml phosphate buffer was incubated at 25 C for one min. Oxygen consumption following the addition of fatty acid was measured by polarography. Reaction details as described in Materials and Methods.

RESULTS

A significant and practical advantage of using trout gill lipoxygenase is its freedom from other oxygen-consuming reactions (20). The rate of lipoxygenase-catalyzed reaction was determined from oxygen consumption. The addition of arachidonic acid to the gill enzyme system resulted in rapid oxygen consumption after a brief lag phase (Fig. 1a and 1b). The formation of product was accompanied by the consumption of oxygen as shown on Fig. 1a. The apparent Km-value of gill 12-lipoxygenase for arachidonic acid as determined by polarography was 20 μM (Fig. 2).

The specificity of lipoxygenase reaction was verified by TLC analysis of the products formed following incubation with radiolabeled arachidonic acid (peak I) (Fig. 3), which showed that the main reaction product (peak II) was 12-hydroxy-5,8,10,14-eicosatetraenoic acid (2,5). The addition of inhibitors reduced product formation but did not change the nature of the product.

Effect of enzyme inhibitors. The effects of various inhibitors on product formation were determined using thin layer autoradiography and liquid scintillation counting of TLC products bands. Indomethacin (1–100 μM), a known cyclooxygenase inhibitor, exerted no inhibitory effect on the gill lipoxygenase, indicating the absence of cyclooxygenase in the gill preparation. The nonspecific lipoxygenase competitive inhibitor, ETYA, inhibited gill enzyme activities (IC_{50} = 50 μM) (Table 1). Esculetin caused a dose-dependent inhibition on gill lipoxygenase system with an IC_{50} of 0.02 μM (Table 1).

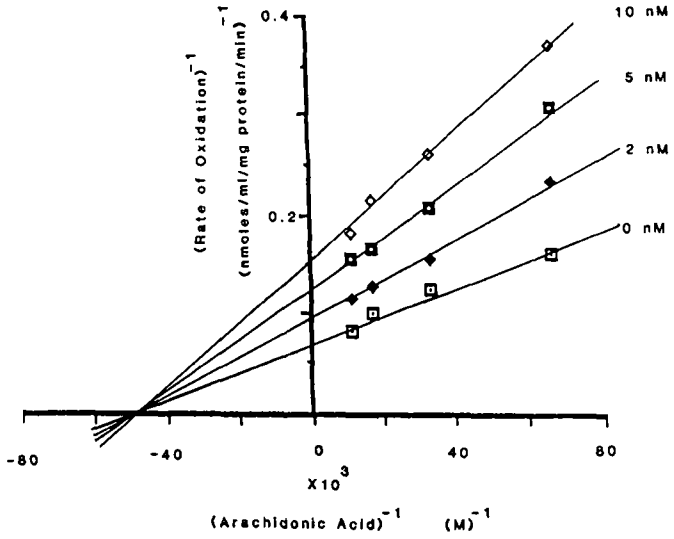

FIG. 2. Lineweaver-Burk plot showing the inhibition of trout gill 12-lipoxygenase by fisetin. Gill 12-lipoxygenase (0.5 mg protein) in 0.5 ml phosphate buffer was incubated at 25 C for one min. Various concentrations of fisetin were added to the enzyme assay system and incubated for an additional 10 min. Oxygen consumption, following the addition of arachidonic acid, was measured by polarography. Reaction details as described in Materials and Methods.

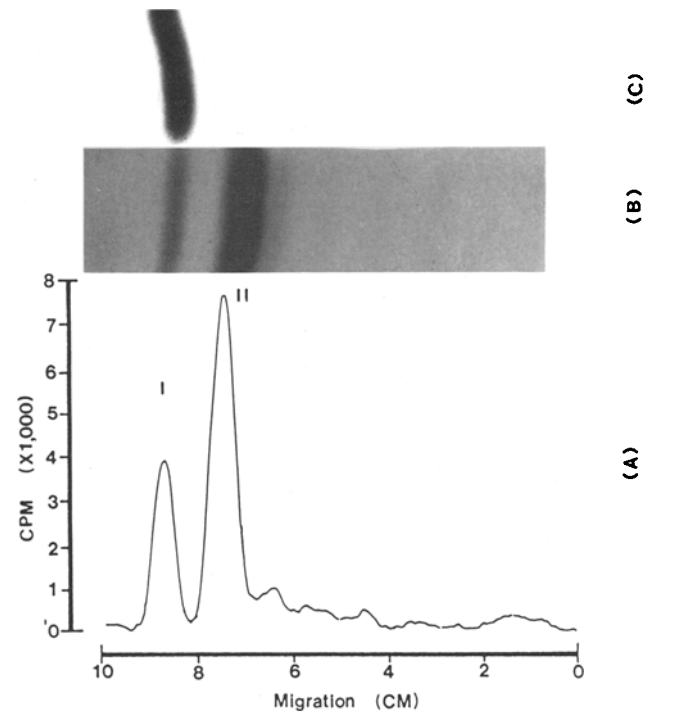

FIG. 3. Autoradiogram and its scan (a) of products generated during 10 min incubation of arachidonic acid (50 μM) with the 12-lipoxygenase from trout gill in the absence (b) and presence (c) of 10 μM fisetin. Extraction, TLC and detection of labeled metabolites were performed as described in Materials and Methods. Peak I is arachidonic acid, 30% of the total area; whereas, peak II is its 12-hydroxy fatty acid, 70% of the total area.

Various antioxidants and free radical quenchers were tested to compare their inhibitory effects. Propyl gallate was a potent inhibitor of gill lipoxygenase (IC_{50} = 0.02 μM) while NDGA was less effective (IC_{50} = 2.5 μM). The widely used phenolic antioxidant BHA also inhibited gill 12-lipoxygenase moderately (IC_{50} = 5 μM), whereas BHT, a similar type of antioxidant, had negligible inhibitory effects (IC_{50} > mM). Comparable disparities among BHA, BHT, PG and NDGA in inhibitory potencies previously were observed for lipoxygenase of mice epidermis (23) and reticulocytes (7).

The inhibitory effects of specific hydroxy isomers of flavonoids on lipoxygenase revealed that fisetin and quercetin were the most potent of all the flavonoids tested with IC_{50}'s of 0.25 and 0.4 μM, respectively (Table 1). These compounds possess a catechol (1,2-benzenediol) structure in the B ring (3′ = hydroxyl, 4′ = hydroxyl). Whereas chrysin (3′ = hydrogen, 4′ = hydrogen) (IC_{50} = 30 μM), naringenin (3′ = hydrogen, 4′ = hydroxyl) (IC_{50} = 40 μM), and apigenin (3′ = hydrogen, 4′ = hydroxyl) (IC_{50} = 5 μM) were 100, 100 and 10 times less inhibitory, respectively. Hydroxylation at the 5′-carbon of quercetin decreased the inhibitory effect as exemplified by myricetin (IC_{50} = 2 μM). Hydrogenation of the double bond at the 2-carbon position and absence of the carbonyl function at the 4-carbon position reduced the inhibitory efficiency as exemplified by catechin (IC_{50} = 3 μM). 3-epicatechin (IC_{50} = 1 μM) was almost as active as catechin as an inhibitor of gill lipoxygenase (Table 1). Glycosidation at 3-hydroxyl group, such as the addition of rutinose (6-o-a-L-rhamnosyl-D-glucose) to quercetin to yield rutin (IC_{50} = 7 μM) or the addition of glucose (6-glucoside) to esculetin (IC_{50} = 0.02 μM) to give esculin (IC_{50} = 500 μM) resulted in loss of the inhibitory potency of these compounds (Table 1).

A dihydroxyl group on flavonoids was required for inhibition of rat 5-lipoxygenase (16) and 15-lipoxygenase (13,16). The position and number of hydroxyl groups in the coumarin skeleton are important for the inhibition of platelet 12-lipoxygenase (15) and the 5-lipoxygenase in polymorphonuclear leukocytes (24).

The mechanism of the inhibitory effects of flavonoids on 12-lipoxygenase activity was assayed by polarography at various concentrations of arachidonic acid in the presence of increasing concentrations of inhibitors. The data for fisetin showed a concentration-dependent inhibition of lipoxygenase in the nanomolar range, and the inhibition was consistant with noncompetitive mechanism. The IC_{50} value of fisetin on lipoxygenase obtained by polarography was consistent with that determined by TLC-radioactivity counting. The product specificity was not altered in the presence of inhibitors.

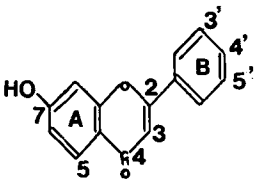
Similar noncompetitive inhibition of 12-lipoxygenase of rat platelet; 5-lipoxygenase of mast tumor cells; and 5-, and 12-lipoxygenase of rat basophilic leukemia cells have been reported for esculetin (15), caffeic acid (25), and cirsiliol(3′,4′,5′-trihydroxy-6,7-dimethoxyflavon) (26), respectively.

DISCUSSION

Phenolics, catechols and pyrogallols, with oxidation potential 0.92, 0.74 and 0.61 volts, respectively, traditionally are considered as antioxidants that scavenge

TABLE 1

The Relative Inhibitory Effects of Various Phenols, Flavonoids, and Antioxidants on Fish Gill 12-Lipoxygenase



Test compounds	Substituents					IC_{50} (μM)[a]	Radical quenching[b]	Oxidation potential[c] (volts)
	3-C	5-C	3'-C	4'-C	5'-C

scavenge alkoxy and alkperoxy radicals (27,28). The effects of BHA, BHT (phenolics), caffeic acid, NDGA (catechols), and PG (pyrogallol) indicated that the inhibition of gill lipoxygenase by these antioxidants was not related to their oxidation potentials. BHA and BHT have similar oxidation potentials (0.65 and 0.68 volts respectively), but BHA was a much stronger lipoxygenase inhibitor than BHT. NDGA, with a catechol structure, has a lower oxidation potential than BHA (27). Nonetheless, NDGA showed the same inhibition potency as BHA. Caffeic acid with a catechol structure was a weaker lipoxygenase inhibitor than NDGA. PG (with a pyrogallol structure) had a lower oxidation potential than esculetin (with a catechol structure) (27), but they showed similar inhibition potencies toward lipoxygenase. These findings suggest that the oxidation potential of an antioxidant is not related to its inhibitory potency on lipoxygenase. Comparable disparities in inhibitory potencies among BHA, BHT and NDGA were reported in reticulocyte and mice skin lipoxygenases (7,23). Schewe et al. attributed the difference in inhibition to the structure and accessibility of antioxidants toward the catalytic site in the lipoxygenase in which an enzyme radical complex is formed (7).

Flavonoids by virtue of their free radical quenching, electron transport and metal chelating abilities are potential inhibitors of lipid oxidation (9–11). Specific requirements for the number and position of hydroxy groups, as exemplified by catechol (1,2-benzenediol) structure in the B rings of quercetin and fisetin, for the inhibition of lipoxygenase-initiated lipid oxidation were indicated from the data. Catechol, with an oxidation potential of 0.74 volts, is easily oxidized and capable of scavenging superoxide and hydroxy radicals and inhibiting lipid oxidation (29,30). Replacement of the hydroxy group in the catechol structure (B ring) with hydrogen (e.g. apigenin, with a phenol structure, and chrysin, with a benzene structure) resulted in higher oxidation potential, higher radical quenching ability (27) but lower inhibitory potencies on lipoxygenase. Myricetin, with a pyrogallol structure, has a lower free radical quenching ability and was a less potent lipoxygenase inhibitor than quercetin.

Esculetin, with a catechol structure and oxidation potential 0.76 volts (31), is a potent inhibitor of fish lipoxygenase. Glycosidation at one of the hydroxy groups of catechol structure converts esculetin to esculin that is a less potent lipoxygenase inhibitor than esculetin.

However, the presence of catechol structure is not sufficient for flavonoids to be lipoxygenase inhibitors. Glycosidation of a hydroxy group such as the 6-glycosidation of quercetin to rutin, change neither the catechol structure nor the free radical quenching ability (14). But rutin is 20 times less potent than quercetin as a lipoxygenase inhibitor. Alternation of the flavonoid structure from a flavone (such as quercetin) to a flavan (such as catechin and epicatechin), or from a flavone (such as apigenin) to a flavanone (such as naringenin) retains the catechol structure in the B ring and has similar free radical quenching abilities (14). Nonetheless, catechin and epicatechin are less potent than quercetin as 12-lipoxygenase inhibitors. Naringenin is not as potent as apigenin in inhibiting lipoxygenase activity. These findings indicate that small alternations in the flavonoid structure that did not influence oxidation potential or free radical quenching ability, markedly changed the inhibition potency of 12-lipoxygenase.

Molecules with a catechol structure can form complexes with the active ferric form of soybean and reticulocyte lipoxygenases and thereby cause inhibition (7,32). This implies that the small structural change such as glycosidation may influence the conformation of flavonoid and hinder its accessibility to the active site of lipoxygenase and lower its inhibitory potency.

Our observations suggest that both oxidation potential and specific structure should be considered in choosing flavonoids as selective lipoxygenase inhibitors. Particular pairs of flavonoids with minor differences in their structures and similar free radical quenching ability, e.g. esculetin and esculin or quercetin and rutin, may be used as selective lipoxygenase inhibitors to distinguish lipoxygenase reactions from other free radical involved reactions. The fish gill lipoxygenase system, because of its high lipoxygenase and absence of cyclooxygenase activities, may be useful for studying the metabolism of lipoxygenase pathways.

[Received December 29, 1986; Revision accepted December 3, 1987]

Changes in Plasma Lipids, Lipoproteins, Triglyceride Secretion and Removal in Chicks with Estrogen Implants

Jeong R. Park and **B.H. Simon Cho***
Department of Food Science and Division of Nutritional Sciences, University of Illinois, Urbana, IL, and Harlan E. Moore Heart Research Foundation, Champaign, IL

Estradiol implants in chicks resulted in marked elevation of all major plasma lipids with greatest increase in triglyceride (TG) followed by phospholipid (PL) and cholesterol (C). During the two-wk period, plasma TG level in estrogen (E)-treated chicks increased to about 45 times that of controls (139.6 vs 6,368.3 mg/dl). The level of cholesterol also increased steadily during the same period, attaining nearly a six-fold increase in comparison with the control (150.7 vs 871.8 mg/dl), and the level of PL was markedly elevated from 209 to 2,861 mg/dl. Besides the induction of hyperlipidemia, E treatment also resulted in a notable alteration in the fatty acid composition of plasma lipids; there was an increase in oleic acid concomitant with a decrease in polyunsaturated fatty acids, particularly, linoleic acid. One day after implantation, the percentage of oleic acid in TG fraction increased from 39.2 to 43.7%, reaching 55.4% of the total fatty acids at day 14. In contrast, the levels of linoleic and arachidonic acid decreased significantly from 16.1 to 8.3% and 4.3 to 0.6%, respectively, during the same period. In cholesteryl ester (CE) and PL, the oleic acid level also increased from 25.2 to 47.3% in the former and from 11.9 to 29.6% in the latter, reflecting enhanced hepatic lipogenesis. Analysis of plasma lipoproteins in E-treated chicks revealed dramatic alterations in the concentrations of lipids and protein in individual lipoprotein fractions, especially very low density lipoprotein (VLDL) fraction. The respective levels of TG, C and PL in the VLDL fractions were 10.0, 0.6 and 1.0 mg/dl in the control, and 3,904.4, 530.3 and 1,365.2 mg/dl in chicks implanted with estrogen for seven days. The concentrations of TG, C and PL also were markedly increased in the low density lipoprotein (LDL) fraction in these birds. However, the cholesterol content of the high density lipoprotein (HDL) fraction was decreased dramatically in E-treated chicks (47.1) relative to the control (121.5 mg/dl). The protein level in the VLDL fraction from E-treated chicks was profoundly elevated to a level 300-fold greater than controls. TG secretion rates were measured in vivo following the administration of Triton WR-1339. In control chicks, plasma TG secretion rate was 2.29 mg/min; whereas, chicks treated with E for one and three days showed significantly higher TG secretion rates of 3.18 and 5.27 mg/min, respectively. TG removal rates were measured in vivo after administration of a 10% fat emulsion. Although plasma TG concentrations were different between control and E-treated birds, no significant differences were found in TG removal rates in those birds, indicating no impairment of TG clearance in E-treated chicks.
Lipids 23, 327–333 (1988).

Abbreviations: C, cholesterol; CE, cholesterol ester; CHD, coronary heart disease; E, estrogen; EDTA, ethylenediamine tetraacetic acid; HDL, high density lipoprotein; IDL, intermediate density lipoprotein; LDL, low density lipoprotein; PL, phospholipid; TG, triglyceride; VLDL, very low density lipoprotein.

Epidemiological evidence that women have a lower incidence of coronary heart disease (CHD) than age-matched men has led to the popular theory that endogenous estrogenic hormones in some way protect women against atherosclerosis (1). This suspected protective effect coupled with reports of reduced coronary atherosclerosis with exogenous estrogen treatment in some experimental animals (2,3) stimulated the testing of estrogens for the prevention of CHD in man. However, human trials in subjects with prior myocardial infarction resulted in an increased rather than decreased risk of thromboembolism (4). Similarly, the use of exogeneous estrogen in the treatment of advanced prostatic cancer resulted in increased arterial and venous thromboembolism and mortality (5). In addition, an elevation of the concentration of plasma TG was a frequent metabolic side-effect induced by the estrogenic component of oral contraceptives (6,7). The widespread use of such preparations, and the well-established association between hyperlipidemia and CHD has generated some interest in the mechanism underlying estrogen-induced hyperlipidemia (8,9). However, studies of human endogenous hypertriglyceridemia have provided conflicting accounts; the results of some kinetic studies indicate increased production (9–11), while others indicate diminished disposal of TG (12,13).

In birds, estrogen administration causes hyperlipidemia (14), a phenomenon that is spontaneously developed in hens upon sexual maturity for the egg laying. Estrogen-induced hyperlipidemia is characterized by the marked elevation in the levels of VLDL and, to the less extent, LDL, but a concomitant decrease in HDL (15). The HDL-lowering effect of estrogen in birds appears to be opposite from that of humans in whom HDL generally increases (16). However, the development of hyperlipidemia in both humans and avian species as a consequence of estrogen treatment establishes the chick as a suitable animal model to study TG metabolism.

The present study, therefore, was undertaken to examine changes in the levels of plasma lipids (triglyceride [TG], cholesterol [C] and phospholipid [PL]) and the composition of lipoproteins (very low density lipoprotein [VLDL], low density lipoprotein [LDL] and high density lipoprotein [HDL]) in chicks following estrogen implants. Since estrogen-induced hyperlipidemia could be due to overproduction or underdisposal, the TG secretion and its removal rates were investigated in vivo using Triton WR-1339 and Intralipid, respectively. Because of possible changes in the fatty acid profiles under estrogenic influence, the fatty acid composition of plasma lipids in these chicks also was determined.

MATERIALS AND METHODS

Animals. Male crossbred 10–13-wk-old chicks (New Hampshire male × Colombian female) were used in these experiments. These birds had wing veins large enough to

facilitate blood withdrawal. The birds were housed individually in wire cages under a consistent lighting program (09:00-21:00 hr). Chicks were fed ad libitum a regular grain diet (University of Illinois pretest chick diet No. 4) composed of 23% crude protein, 3% fat, 5% crude fiber, over 60% carbohydrate and a mineral and vitamin premix. The fatty acid composition of the grain diet was as follows (%): myristic—0.8; palmitic—15.9; palmitoleic—0.8; stearic—3.0; oleic—30.6; linoleic—47.6 and linolenic—1.3.

Estrogen implants. For the study of time-course changes in individual plasma lipids under estrogenic influence, 10 birds were randomly selected and implanted with estrogen-filled tubes. Estrogen tubes were prepared by the method of Smith et al. (17). Briefly, polymethylsiloxane tubing (Silastic, Dow Corning Corp., Midland, MI; 1.5 mm i.d. × 3.13 mm o.d.) was cut into 6-cm length, filled with ca. 50 mg of β-estradiol dipropionate powder (Sigma Chemical Co., St. Louis, MO), and both ends of tubes were sealed with Medical Adhesive Silicon Type A. Before implantation, the tubes were incubated in 0.01 M phosphate-buffered saline solution (pH 7.4) for 48 hr at 37 C. Under light ether anesthesia, the neck skin of chicks was incised (0.5-1.0 cm) with a surgical knife, and tubes were inserted through the incisions. Incisions were closed with an Auto Suture skin stapler. Empty tubes constructed in the same way were implanted into control chicks.

Triglyceride secretion. The in vivo secretion of TG in chicks was determined following Triton WR-1339 (p-isooctyl polyoxyethylene phenol polymer) injection (18). In preliminary experiments, series of Triton concentration were administered into estrogen-treated hyperlipidemic chicks (10-wk-old) to determine the dosage of Triton, which adequately will block the TG removal. Chicks with plasma TG values ranged from 1,527 to 2,925 mg/dl were administered 200, 400, 500, 600, 700 and 800 mg Triton/kg body weight via wing vein. Blood samples were taken at 60 min after the Triton injection and plasma TG contents were determined. The doses of 600 mg or above of Triton resulted in maximum accumulation of TG (Fig. 1), indicating an adequate inhibition of TG removal at these Triton concentrations. In the main experiments, 12 male chicks (10-wk-old) fed the basal grain diet were selected randomly. Eight chicks were implanted with estrogen-filled tubes, and the rest were used as sham-operated controls. In the estrogen group, the TG secretion study was carried out one and three days after implantation and in the control group, two days after sham operation. The chicks were fasted overnight (14 hr), and Triton WR-1339 was injected intravenously into the right wing vein at the level of 600 mg/kg body weight. Blood samples were taken from the left wing vein at 0, 30 and 60 min after the Triton injection. The TG secretion rate was calculated by multiplying the slope of the least-squares regression of plasma TG concentration over time with the plasma volume. The plasma volume was estimated by the total blood volume based on body weight and hematocrit measurement (19).

Triglyceride removal. The in vivo TG removal rate was determined following the IV injection of a 10% fat emulsion (Intralipid, Cutter Laboratories, Inc., Berkeley, CA) as described by Carlson and Rossner (20). Twelve male chicks (13-wk-old) maintained on a grain diet were selected randomly. Eight chicks were implanted with estrogen-filled tubes, and the rest were used as sham-operated controls. TG removal rate was measured one and three days after the implantation in the estrogen group and two days after the sham operation in the control group, respectively. The chicks were fasted overnight (14 hr), and Intralipid (10% emulsified lipid solution) was injected intravenously into the right wing vein at the level of 500 mg/kg body weight. Blood samples were collected from the left wing vein at 0, 10, 20 and 30 min after the Intralipid injection. The TG removal rates were calculated by multiplying the slope of the least-squares regression of plasma TG concentration over time, with the plasma volume estimated by the total blood volume based on body weight and hematocrit measurement (19).

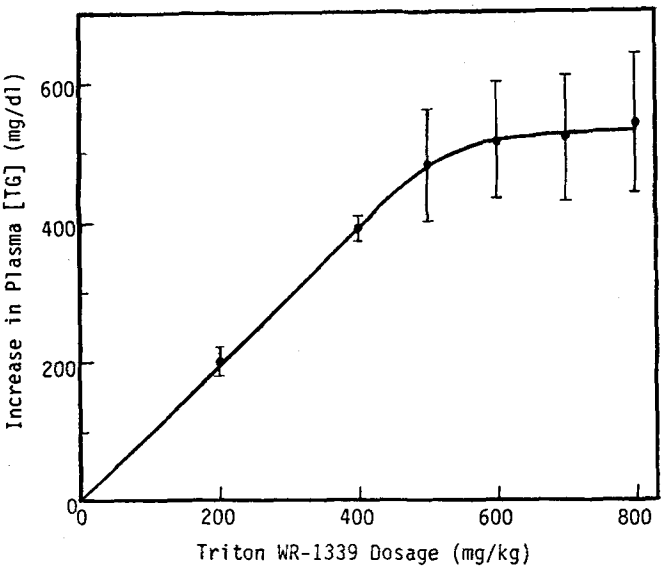

FIG. 1. Effects of various Triton WR-1339 concentrations on the plasma triglyceride accumulation in estrogen-treated chicks. Each point of the curve represents the mean ±SD values of three animals.

Lipoprotein analysis. Chicks implanted with estrogen for seven days and control chicks that were fasted overnight had blood samples drawn from the wing vein into tubes containing ethylenediamine tetraacetic acid (EDTA) (1.0 mg/ml blood). The separation of plasma lipoproteins was carried out by sequential preperative ultracentrifugation with Ti 60 rotor at 12 C in a Beckman Model L5-50 ultracentrifuge as described by Havel et al. (21). Three lipoprotein fractions were isolated: VLDL ($\varrho <$ 1.006 g/ml), LDL (1.006 $< \varrho <$ 1.063 g/ml) and HDL (1.063 $< \varrho <$ 1.21 g/ml). Within each lipoprotein fraction, the total C, TG and PL contents were analyzed using the methods described for plasma lipids below. The protein content within each lipoprotein fractions was determined by the method of Lowry et al. (22).

Agarose gel electrophoresis. The whole plasma and isolated lipoproteins from the control and E-treated chicks were electrophoresed in 0.6% agarose gels with 0.5% BSA in 0.05 M barbital buffer at pH 8.6 as described by Noble (23). Gels were stained for lipid with Sudan Black B.

Analysis of blood lipids and fatty acid composition. After an overnight fast, blood samples were drawn from the wing vein of the control and E-implanted chicks into

tubes containing EDTA (1 mg/ml of blood) by means of butterfly needles (Abbott Hospital, Inc., Chicago, IL). The plasma was separated by centrifugation at 1,500 × g for 20 min at 4 C. The level of plasma total cholesterol was determined enzymatically (24) by using A-Gent cholesterol reagent (Abbott Laboratories, Inc., Chicago, IL). The value of plasma TG was measured by the method of Foster and Dunn (25). For the determination of plasma PL content, total lipid material was extracted from an aliquot of plasma according to the method of Folch et al. (26), and then the total PL value was determined from aliquots of lipid extracts after perchloric acid digestion (27). Aliquots of lipid extracts from blood plasma also were applied to silica gel thin layer plates, and neutral lipids were separated by petroleum ether/diethyl ether/acetic acid (85:15:1, v/v/v). Lipid spots were detected by spraying rhodamine 6G (0.025% in 95% ethanol) and viewing under ultraviolet light. For the analysis of fatty acid composition, the areas on thin layer plates corresponding to CE, TG and PL were scraped into glass ampules, and fatty acid methyl esters were prepared in the presence of silica gel with 4% (v/v) sulfuric acid in absolute methanol at 90 C for two hr. The analyses of fatty acid methyl esters were carried out with a Hewlett-Packard 5710A gas chromatograph as described (28).

Data were analyzed by the difference between means, and statistical significance was based on Student's t-test or Fisher's Least Significant Difference multiple comparison test (29).

RESULTS

Time-course changes in plasma TG, C and PL levels in chicks following estrogen treatment are shown in Table 1. The implantation of estradiol resulted in marked elevation of all major plasma lipids, with the greatest increase in TG followed by PL and C. One day after implantation, the TG level increased almost three-fold, and this pattern of increase progressed almost linearly until day 14. During the two-wk period, plasma TG levels in estrogenized birds increased to about 45 times that of the controls (139.6 vs 6,368.3 mg/dl). Although the elevation of C was not as dramatic as that of TG, the level of C increased steadily during the same period, attaining nearly a six-fold increase in comparison with the controls (150.7 vs 871.8 mg/dl). As the level of plasma total C increased, the percentage of free C rose from 37.9% to 57.1%. During the two-wk treatment, the level of plasma PL also increased significantly from 209.0 to 2,861.4 mg/dl. During the 14-day period, in untreated birds no changes in those plasma lipid levels were observed.

Changes in the fatty acid composition of plasma TG during estrogen treatment are shown in Table 2. In control chicks, oleic acid was the major fatty acid (39.2%) of plasma TG followed by palmitic (25.5%), linoleic (16.1%) and stearic (10.7%) acid; a low level of arachidonic acid also was present (4.3%). Estrogen treatment resulted in substantial alteration of the fatty acid composition with a marked increase in a monoenoic fatty acid and concomitant decreases in polyunsaturated fatty acids. One day after implantation, the percentage of oleic acid increased from 39.2% to 43.7%; this increase progressed steadily with time, reaching about 55% of the total fatty acids by day 14. In contrast, the level of linoleic acid decreased significantly from 16.1% to 8.3%, and the arachidonic acid level also decreased from 4.3% to 0.6% during the same period. Changes in the saturated fatty acids were less obvious, and both palmitic and stearic acids decreased only slightly by day 14.

TABLE 1

Time-course Changes of Plasma Lipids in Chicks Implanted with Estrogen[a]

Day	Triglyceride	Cholesterol	Phospholipid
		Control

In normal chicks, plasma CE contained a very high level of unsaturated fatty acids, which composed nearly 80% of the total fatty acids (Table 2). Among fatty acids esterified to C, linoleic acid was predominant (45.4%), followed by oleic (25.2%) and palmitic acid (17.6%). As was the case in TG, the estrogen treatment resulted in a significant increase in oleic acid from 25.2% to 47.3%, whereas linoleic acid decreased from 45.4% to 21.5% during the 14-day period. The arachidonic acid level decreased slightly, but the levels of saturated fatty acids were relatively unchanged. The fatty acid composition of plasma PL differed from that of other plasma lipid classes because of its high level of arachidonic acid, which composed about 19% of the total fatty acids (Table 2). The level of saturated fatty acid also was very high, with palmitic and stearic acids composing 53% of the total fatty acids. As in the cases of plasma TG and CE, estrogen treatment also resulted in notable changes in the fatty acid composition of phospholipid, especially with regard to oleic acid. During the 14-day period, the level of oleic acid increased from 11.9% to 29.6%. During the same period, the level of stearic, linoleic and arachidonic acid decreased from 26.0% to 18.2%, 14.7% to 9.9%, and 18.9% to 10.2%, respectively.

The whole plasma and isolated lipoproteins were electrophoresed on the agarose gel (Fig. 2). In control chicks, the VLDL, LDL and HDL had three distinct electrophoretic mobilities (pre-β, β, α), whereas the lipoprotein of pre β-mobility was absent in E-treated chicks. In contrast with the control VLDL, the VLDL from E-treated chicks exhibited β-mobility similar to LDL, which may indicate that VLDL and LDL from E-treated chicks are indistinguishable. In fact, the presence of a continuum of particles in the VLDL-intermediate density lipoprotein (IDL)-LDL range; the similarity in the apoprotein composition of VLDL and LDL from E-treated chicks (15) supports this possibility.

Table 3 shows the distribution of TG, C, PL and protein in the VLDL, LDL and HDL fractions of the control and chicks implanted with estrogen for seven days. From the total lipid values shown, the control chicks were normolipidemic, while E-treated chicks were grossly hyperlipidemic, and the hyperlipidemia was reflected primarily in the VLDL-TG. Compared with the control, VLDL-TG increased 386-fold in E-treated chicks (10.1 vs 3,904.4 mg/dl). For LDL-TG, the increase was about eight-fold, but HDL-TG concentration remained the same as that of the control. Concerning the distribution of C, the VLDL-C showed an 829-fold increase in E-treated chicks, relative to the value in the control. For LDL-C, there was a 1.4-fold increase, but HDL-C showed a 2.6-fold decrease in the E-treated chicks, relative to the control values. For phospholipid, there was an overwhelming 1,379-fold increase in the VLDL of E-treated chicks compared with the control values. The LDL-PL in the E-treated chicks was 3.4-fold that in the control. However, compared with the value in the control, HDL-PL showed a 1.7-fold decrease in E-treated chicks. The protein concentration in the VLDL fraction of E-treated chicks was elevated profoundly. Relative to control values, the increase was about 300-fold. LDL-protein was increased about three-fold, but HDL-protein showed a 2.7-fold decrease in E-treated chicks relative to the values in the controls.

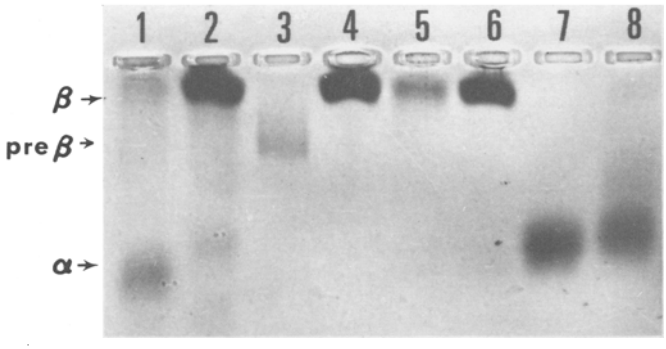

FIG. 2. Agarose gel electrophoresis of whole plasma and isolated lipoproteins from control (C) and estrogen-treated (E) chicks: (1) C-plasma, (2) E-plasma, (3) C-VLDL, (4) E-VLDL, (5) C-LDL, (6) E-LDL, (7) C-HDL, (8) E-HDL.

TG secretion rates in control and esterogen-treated chicks was monitored in vivo following the administration of Triton WR-1339 as shown in Table 4. The action of Triton upon TG metabolism is thought to be mediated by its detergent properties that bind TG, thereby inhibiting lipoprotein lipase activity (18). The linear increases in plasma TG concentrations were obtained in both control and estrogen-implanted chicks during the 60-min post-Triton period. In the control chicks, the level of plasma TG increased from the initial level of 140.6 to 257.0 mg/dl, resulting in a net TG secretion rate of 2.29 mg/min. Chicks implanted with estrogen for one day had an initial TG level of 388.7 mg/dl, which increased to 547.4 mg/dl at 60 min after Triton WR-1339 treatment. The average TG secretion rate in those birds was 3.18 mg/min, and was significantly higher than that of control chicks. Chicks implanted with estrogen for three days had a plasma TG level of 1,048.6 mg/dl that rose to 1,305.9 mg/dl at 60 min after Triton treatment, resulting in the TG secretion rate of 5.27 mg/min. The measurement of TG secretion rate in chicks with estrogen implant for more than five days was not possible due to the development of extreme hypertriglyceridemia in those birds.

TG removal was measured in control and estrogen treated chicks following Intralipid (10% fat emulsion) administration as shown in Table 5. The concentrations of plasma TG decreased linearly in both control and estrogen-treated chicks during the 30 min post-Intralipid period. In control chicks, the plasma TG level at 10 min after the Intralipid injection was 697.6 mg/dl, which decreased to 409.9 mg/dl at 30 min, resulting in a TG removal rate of 15.34 mg/min. In chicks with estrogen implants for one and three days, their plasma TG levels reached 827.5 and 1,195.2 mg/dl at 10 min and decreased to 574.5 and 941.9 mg/dl at 30 min after Intralipid injection, resulting in TG removal rates of 13.81 and 13.58 mg/min, respectively. In spite of marked differences in plasma TG levels in those birds, no significant differences were found in TG removal rates between control and estrogen-treated chicks.

DISCUSSION

Hypertriglyceridemia associated with estrogen administration has been reported in humans (6–9) and animals (14,30). In rats, estrogen treatment produces a biphasic effect; high doses decrease plasma cholesterol, and lower

TABLE 3

Composition of Plasma Lipoproteins in Chicks with Estrogen Implants[a]

	Triglyceride	Cholesterol	Phospholipid	Protein
Control				
Plasma	114.41 ± 11.29	159.55 ± 18.23	216.32 ± 19.73	449.73 ± 54.43

doses elevate it (30). In this study, the implantation of β-estradiol dipropionate into chicks resulted in a marked elevation of plasma lipids, and particularly TG, in which a three-fold increase was noted within 24 hr. Elevation of the plasma TG level progressed almost linearly during the 14 days of treatment. Besides hypertriglyceridemia, estrogen treatment in chicks also induced hypercholesterolemia and hyperphospholipidemia. The degree of increases in cholesterol and phospholipid was much less than that in triglyceride, but the time-course changes of these lipids exhibited a similar pattern of elevation during the 14-day period. Since the chicks were fed a low-fat, cholesterol-free grain diet, it is very clear that these plasma lipids were from endogenous synthesis.

In addition to elevating plasma lipids, estrogen treatment altered the fatty acid composition of TG, CE and

PL. Estrogen implantation induced a significant modification of fatty acid composition in triglyceride as well as phospholipid and cholesteryl ester. Among the fatty acids, the level of oleic acid was most affected. The increase in the level of oleic acid was accompanied by a decrease in the level of polyunsaturated fatty acids such as linoleic and arachidonic acids. This finding is similar to that observed in hens with increased lipogenesis at the onset of sexual maturity (31). The selective increase in the level of oleic acid indicates that both de novo fatty acid synthesis and fatty acid desaturation are stimulated greatly under estrogenic influence. Several studies have shown a strong correlation between increased hepatic lipogenesis in animals treated with estrogen and hyperlipidemia (14,32). The activities of the hepatic lipogenic enzymes, fatty acid synthetase and acetyl-CoA carboxylase were reported to be increased in chicks (33) and rats (34) following estrogen treatment. Estrogen also has been shown to affect gene transcription, resulting in an increased hepatic production of mRNA for apo VLDL-II, an apoprotein of VLDL (35). Therefore, estrogen seems to have the concerted effect of increased hepatic lipogenesis and secretion of triglyceride-rich VLDL.

Present data on the lipoprotein composition revealed remarkable increases in the concentrations of TG, C, PL and protein in VLDL and, to lesser extent, in LDL fractions, but these lipoprotein components were found to be decreased significantly in the HDL fraction with E treatment. These findings are consistent with those reported by Kudzma et al. (15). The factor underlying the decrease in HDL production is not clear. However, recent findings in estrogenized chicks and turkeys (15,36) suggest estrogen may cause an adverse effect on the production of apoprotein A-1, a major lipoprotein of HDL. Since the synthesis of vitellogenin and VLDL are stimulated markedly under estrogenic influence, reduced synthesis of other plasma proteins such as apoprotein A-1 may be the result of competition at the level of mRNA translation on the endoplasmic reticulum (36). There appears to be an opposite effect of estrogen on HDL between mammals and avian species. Although estrogen treatment in birds lowers the level of HDL in plasma (15), there are reports that in humans (16) and rats (37) treated with estrogen the level of HDL is increased. However, in light of the inverse relationship between HDL concentration and the incidence of coronary heart disease (38) this influence of estrogen on the modulation of HDL production needs to be elucidated.

Beside compositional changes in lipoproteins, the distribution of lipoprotein particles also appears to be modified in estrogen-induced hyperlipidemia. Kudzma et al. reported the presence of a continuum of particles of the VLDL-IDL-LDL range in E-treated chicks, whereas lipoproteins of density less than 1.06 g/ml were clearly separated into discrete VLDL and LDL fractions in untreated birds (15). This observation seems to indicate that conventional density intervals applied for the isolation of plasma lipoproteins may not reveal sufficient details about discrete lipoprotein subspecies in E-treated hyperlipidemic chicks; the use of continuous density gradient ultracentrifugation can provide more information regarding the multiple subspecies.

In this study, the hepatic TG secretion rate observed in vivo following the administration of Triton WR-1339 strongly indicates that an accelerated secretion of hepatic triglyceride into the circulation plays an important role in the endogeneous hypertriglyceridemia of estrogenized chicks. Compared with the control, the treatment with estrogen resulted in a significantly higher rate of triglyceride secretion, which was much greater after three days than after one day. Similar findings have been reported in rats in which hepatic triglyceride secretion increased following the injection of estradiol benzoate for 21 days (39).

In addition to the augmented hepatic synthesis and secretion of triglyceride, the removal of triglyceride from the plasma also has been suggested as a possible mechanism responsible for the hyperlipidemia associated with estrogen (12,13). A decrease in lipoprotein lipase activity and an enhanced adrenalin-induced lipolysis in the adipose tissue were reported in rats treated with estrogen (39,40). In humans, the activity of the hepatic triglyceride lipase in post-heparin plasma also has been shown to decrease following estrogen administration (41). However, decreases in those lipase activities do not seem to correlate well with triglyceride clearance from the plasma. In this study, although plasma triglyceride levels were markedly different between the control and E-treated chicks, no significant differences in triglyceride removal rates were observed. Similar findings have been reported in humans in which the clearance of exogeneously administered fat was unchanged following E treatment; when a combination of estrogen and progesterone was given, the clearance actually increased (9,10).

Now, the relationship between estrogen and coronary heart disease is highly controversial (42). However, since hyperlipidemia is a risk factor for coronary heart disease, the effect of estrogen-induced hyperlipidemia on the development of atherosclerosis deserves further attention.

[Received April 22, 1987; Revision accepted December 11, 1987]

Phospholipid Profile and Production of Prostanoids by Murine Colonic Epithelium: Effect of Dietary Fat[1]

N.M. Robblee[a], E.R. Farnworth[b] and R.P. Bird[a,*]

[a]Ludwig Institute for Cancer Research, Toronto Branch, 9 Earl St., Toronto, Ontario M4Y 1M4, and Department of Nutritional Sciences, Faculty of Medicine, University of Toronto, Toronto, Ontario, and [b]Animal Research Centre, Research Branch, Agriculture Canada, Ottawa, Ontario K1A OC6

Dietary fat and abnormal production of various prostanoids have been linked to various disease states of the large bowel, including cancer of the colon. Studies were conducted to determine the effect of dietary fat (beef tallow or corn oil) on the lipid composition and prostanoid production of the murine colon.

Female C57BL/6J mice were fed high-fat (HF) diets (47% of calories as fat) or low-fat (LF) diets (10% of calories as fat). After four wk of dietary treatment, the mucosa was scraped, and lipids were extracted from the mucosal and muscle layers. The fat content of the diets did not significantly alter the amount of phospholipid (PL) or neutral lipid in the colonic tissue. However, the HF affected the PL profile of the colonic mucosa. For example, the ratio of phosphatidylcholine (PC) to phosphatidylethanolamine (PE) was significantly higher for both the HF groups compared with that of the two LF groups (0.76 ± 0.15 and 0.80 ± 0.13 vs 0.31 ± 0.20 and 0.34 ± 0.18). Production of 13,14-dihydro-15-keto-PGE_2 (measured as bicyclic PGE_2) and TXB_2 (a stable metabolite of TXA_2) and $PGF_{1\alpha}$ (a stable metabolite of PGI_2) was unaffected by the dietary treatments. The muscle had a different PL profile (PC:PE is 2.6 ± 0.1) than the mucosa and contributed a larger proportion of the prostanoids formed. This study demonstrates that the phospholipid polar head group composition of normal colonic mucosa is altered by dietary fat, but the ability of the mucosa to synthesize metabolites of PGE_2, TXA_2 and PGI_2 is not affected.

Lipids 23, 334-339 (1988).

Epidemiological studies have suggested that there is a positive association between the consumption of dietary fat and mortality from colon cancer (1,2). The possible role of dietary fat in colon carcinogenesis also has received support from studies in animal models (3,4). However, not all dietary fats enhance colon tumorigenesis. High-fat diets containing coconut oil, olive oil or fish oil have no enhancing effect on colon tumor promotion (5,6). The varied effect of different types of fat on colon carcinogenesis suggests that the fatty acid composition of the diet may be an important factor in colon tumorigenesis.

The mechanism by which high-fat diets exert their effect on the colon is not understood. Many studies suggest that the effect of dietary fat on colon carcinogenesis is mediated through an increase in the concentration of fecal secondary bile acids (7,8). However, several investigators have failed to find such an association (9,10). It also has been hypothesized that high-fat diets may exert their effect by altering the membrane structure and function (11,12). Because fish oils inhibit colon tumorigenesis, prostanoids may be involved in mediating the fat effect (6,13). Various lines of evidence suggest that prostanoids may be implicated in tumor development (14-17). In spite of an association made between dietary fat, prostanoids and tumorigenesis in the colon, very little information is available regarding the influence of dietary fat on metabolism in the large bowel or in primary colonic tumors. Therefore, this study was designed to examine the effect of the type and level of dietary fat on lipid composition and prostanoid synthesis by the colon.

MATERIALS AND METHODS

Animals and diets. Female C57BL/6J mice (Jackson Laboratory, Bar Harbor, ME) weighing 10-15 g were fed high-fat (HF) semipurified diets containing 47% of calories as fat or low-fat (LF) semipurified diets containing 10% of calories as fat. The fats used in this study were corn oil (CO) and beef tallow (BT). Sucrose was adjusted to equalize the caloric content of the diets. The fatty acid composition of the diets is shown in Table 1. The beef tallow was mixed with a small percentage of corn oil in order to meet the essential fatty acid needs of the animals. The mice were maintained in a temperature-controlled room (21 ± 1 C) with a 12 hr light-dark cycle. The mice were housed in plastic cages (5 mice per cage) with wire tops and sawdust bedding. Water and experimental diets were provided ad libitum. The diets were fed for four wk. After four wk of dietary treatment, the animals weighed 17.7 ± 0.4 g and 18.4 ± 0.6 g for low fat and high fat respectively.

Analysis of colonic lipids. The mice were killed by cervical dislocation, and 4 cm of colon from two mice were

TABLE 1

Fatty Acid Composition of the Diets

Major fatty acids % w/w	Percentage of total fatty acids			
	HFCO	HFBT	LFCO	LFBT
16:0	6.26	16.73	8.23	16.81
18:0	1.90	34.02	1.65	24.56
18:1	27.32	42.63	26.52	34.77
18:2	63.04	6.63	63.60	22.43

The high-fat diets contained 23.5% fat (w/w), and the low-fat diets contained 5% fat. Sufficient corn oil was added to the beef tallow diets to meet the essential fatty acid requirements of the animals. In the low-fat diets, sucrose was substituted for fat so that the caloric density of the essential nutrients remained the same.

*To whom all correspondence should be addressed.

Abbreviations: HF, high fat; HFBT, high-fat beef tallow; HFCO, high-fat corn oil; LF, low fat; LFBT, low-fat beef tallow; LTCO, low-fat corn oil; PC, phosphotidyl choline; PE, phosphotidyl ethanolamine; PGE_2, prostaglandine E_2; $PGF_{1\alpha}$, 6-keto-prostaglandin $F_{1\alpha}$; PGI_2, protacyclin; PL, phospholipid; TXA_2, thromboxane A_2; TXB_2, thromboxane B_2

pooled for each sample prepared. The colons were removed and washed several times in Krebs Ringer to remove fecal material. The mucosa was scraped, and lipids were extracted from the mucosal and muscle layer by the method of Folch et al. (18).

The neutral lipids and the phospholipid classes were quantified by using thin layer chromatography performed on thin silica-coated quartz rods (Chromarod S., Technical Marketing Associates, Mississauga, Ontario, Canada) followed by flame ionization detection on an Iatroscan. The rods were saturated with copper sulphate (19).

For fatty acid analysis, phospholipids and triglycerides were separated by thin layer chromatography and fatty acid methyl esters were prepared with boron trifluoride methanol reagent (20). Fatty acid methyl esters were analyzed in a gas chromatograph (Hewlett Packard 5890A) on a fused silica capillary column, 30 m × 0.25 m). The gas chromatograph was equipped with a flame ionization detector and was programmed from 190–220 C at 10 C/min with a helium carrier gas flow rate of 45 cm/sec.

Measurement of prostanoids. After four wk of dietary treatment, the colon was removed, and the mucosal and muscle layers were incubated in a Krebs-Ringer solution for 30 min. The reaction was stopped with the addition of indomethacin (10 μg/ml). Stable metabolites of three prostanoids, prostaglandin E_2 (PGE_2), thromboxane A_2 (TXA_2) and prostacyclin (PGI_2) were measured by radioimmunoassay using kits available commercially from Amersham (Amersham Corporation, Arlington Heights, IL). The assay systems combine the use of tritiated stable derivatives of prostanoids and antiserum specific for them. In the case of PGE_2, the assay system is based on the conversion of the major PGE_2 metabolite 13,14-dihydro-15-keto-prostaglandin E_2 to the stable, bicyclic compound 11-deoxy-13-14-dihydro-15-keto-11β, 16ξ-cyclo prostaglandin E_2. The cross reactivity of this radioimmunoassay with TXB_2 or PGF_1 is less than 0.0001%. TXA_2 and PGI_2 both are very unstable compounds and undergo spontaneous hydrolysis and form stable inactive metabolites thromboxane B_2 (TXB_2) and 6-keto-prostaglandin $F_{1\alpha}$ ($PGF_{1\alpha}$).

Statistical evaluation. The significance of dietary effects on the data was determined using Student's t-test.

RESULTS

Effect of diet treatment on colonic cell neutral lipid and phospholipid content. The dietary treatments did not result in a significant difference in the percentage of neutral lipid or in the percentage of cholesterol or cholesterol ester in the mucosa or muscle layers. The effect of dietary fat on the phospholipid content of the colonic mucosa and muscle is shown in Table 2. The level of fat in the diet had a significant effect on the relative amounts of phosphatidylcholine (PC) and phosphatidylethanolamine (PE) in the colonic mucosa. When high-fat diets were fed, the ratio of PC:PE was 0.76 ± 0.15 and 0.80 ± 0.13 for the corn oil and beef tallow diets, respectively. Low-fat feeding resulted in a significantly lower PC:PE ratio for the LFCO and LFBT diets of 0.31 ± 0.20 and 0.34 ± 0.18, respectively.

The ratio of PC:PE was significantly higher in the muscle than in the mucosa, but there was no effect of the dietary treatments on the PC:PE ratio in the muscle (Table 3).

Effect of diet on phospholipid fatty acid composition of colonic mucosa and muscle. The fatty acid composition of the colonic mucosa phospholipids in the mice fed the different diets is shown in Table 4.

In the case of mucosal lipids, the type and level of dietary fat influenced the percent composition of only certain fatty acids. For example, the mucosal phospholipids of the beef tallow-fed animals (LFBT and HFBT) contained higher ($p \leq 0.05$) levels of oleic acid but not 18:0. In comparison, although the level of 18:2 was significantly higher in the HFCO group, generally the percent composition of 18:2 in mucosal phospholipids was less influenced by the level in the diet. Similarly, the level of 20:4 was unaffected by the dietary treatments (Table 4).

The colonic muscle phospholipids exhibited a slightly different pattern of fatty acid composition (Table 5). The level of 18:1 was higher in the beef tallow groups than in the high-fat corn oil group and was significantly lower than the level present in the mucosal phospholipids. Also, the levels of 18:2 and 20:4 were not related to the dietary treatments. Muscle phospholipids also contained substantially higher levels of 22:4 and 22:5 than those recorded for the mucosal fraction.

TABLE 2

Effect of Dietary Fat on the Phospholipid Content of the Colonic Mucosa

	% of total phospholipids			
	HFCO	HFBT	LFCO	HFBT
PC	35.3 ± 6.9	39.2 ± 9.9	20.2 ± 10.8	19.3 ± 6.7
PE	49.5 ± 12.3	50.2 ± 5.5	66.5 ± 10.0	64.6 ± 14.4
PC:PE	0.76 ± 0.15[b]	0.80 ± 0.13[b]	0.31 ± 0.20[a]	0.34 ± 0.18[a]
SM	5.3 ± 3.7	5.9 ± 6.5	3.3 ± 4.5	3.4 ± 5.9
Others	10.0 ± 5.2	4.6 ± 5.6	10.7 ± 3.2	12.6 ± 4.6

Values are means ± SEM; n = 5 for each group, and each n represents a pool of two mouse mucosas. Differences in horizontal means without a common superscript are statistically significant ($p \leq 0.05$). Rows without any superscripts contain values that are not significantly different.

PC, phosphatidylcholine; PE, phosphatidylethanolamine; SM, sphingomyelin.

Effect of diet on triglyceride fatty acid content of colonic mucosa and muscle. The fatty acid composition of the colonic mucosa and muscle triglycerides is shown in Tables 6 and 7. The fatty acid profile was similar in the muscle and mucosal triglycerides. In both, the percentage of composition of triglyceride fatty acids only partially reflected the fat composition of the diets. For example, the beef tallow diets resulted in high levels of 18:1 but

TABLE 3

Effect of Dietary Fat on the Phospholipid Content of the Colonic Muscle

Values given are means ± SEM; n = 5 for each group and each n represents either one mucosa or one muscle. Values expressed as ng × 10^3/g/30 min. Symbols of significance are the same as in Table 4.

PGE_2, prostaglandin E_2; TXB_2, thromboxane B_2; $PGF_{1\alpha}$, prostaglandin $F_{1\alpha}$; HFCO, high-fat corn oil; HFBT, high-fat beef tallow; LFCO, low-fat corn oil; LFBT, low-fat beef tallow.

only small increases in 18:0 in the triglycerides. Corn oil feeding resulted in higher levels of 18:2 in colonic triglyceride.

Effect of dietary fat on prostanoid production by murine colon. The effect of dietary fat on the production of TXB_2, $PGF_{1\alpha}$ and bicyclic PGE_2 is shown in Table 8. The dietary treatments did not result in a significant difference in the production of TXB_2, $PGF_{1\alpha}$ or PGE_2 by either the mucosa or the muscle. However, in each case the muscle layer contributed a larger percentage of the total prostanoids formed.

DISCUSSION

In this study, we examined the effect of two different types of fat (corn oil and beef tallow) that vary widely in their fatty acid composition.

Beef tallow is high in saturated fatty acids (16:0, 18:0), while corn oil is high in the polyunsaturated fatty acid 18:2. However, both types of fat promote colon tumorigenesis when they are included in the diet at high levels (5). In view of the similar effects of these fats on colon carcinogenesis, we wanted to determine whether high-fat feeding of these two fats would result in common compositional and biochemical alterations. The results of this study indicate that the type of fat fed does not affect the phospholipid content of the colonic mucosa or muscle. However, the quantity of fat in the diet appears to be a significant determinant of the phospholipid profile of the colonic musosa. Mice fed the high-fat diets had significantly higher ratios of mucosal PC:PE. It is possible that a change in the polar head group composition may result in a change in the function of the membrane in vivo (21). The small polar head group of phosphatidylethanolamine allows very close packing and reduces the permeability and fluidity of the membrane (22). Any changes in the fluidity of the membrane caused by increased PC could to some extent depend on the fatty acid composition of the newly synthesized PC. However, it is not possible to conclude from this study if the plasma membrane composition of mucosal cells was altered or if the phospholipid changes reflect differences in the amount of certain organelles in the colonocytes. Another limitation of this study is that although the fecal material was removed and the colons were rinsed very thoroughly, it still is possible that bacteria may remain adhered to the mucosa, thus contaminating the lipid sample.

In mammals, changes in membrane lipid composition have been achieved by feeding different dietary fats (23,24). The activity of lipid-dependent enzymes may be dependent on the polar head group composition of membranes (25) or on the fatty acid composition of the membrane (26). Changes in membrane fluidity have been shown to influence the conformation of the active site of some membrane-associated enzymes (27).

The fluidity and permeability of biological membranes also is determined by the fatty acid composition of phospholipids of cell membranes (28). The phospholipid fatty acid composition reflected only partially the composition of dietary fat. Overall, the levels of 18:0 and 20:4 were unaffected by dietary treatments. This suggests and supports the findings of others that a homeostatic mechanism is operative in biological membranes with respect to fatty acid composition (29). This mechanism may be effective in maintaining a certain level of unsaturation in the membrane lipids. It previously has been observed in platelets and other tissues that an increase of 18:2 over a threshold level may not lead to a further increase in membrane arachidonic acid (30).

Dietary fat did not change the level of the prostanoids that were measured in this study. Bicyclic PGE_2, TXB_2 and $PGF_{1\alpha}$ were measured because colonic carcinomas have been found to synthesize increased levels of PGE_2 (15). In addition, TXA_2 or its active metabolite stimulate tumor cell replication, whereas prostacyclin or its active metabolite inhibits tumor cell growth (17). We hypothesized that a high-fat diet would alter the synthesis of these prostanoids in the colonic tissue. However, dietary fat irrespective of the type and level did not influence synthesis of any of these compounds by the colonic mucosa or the muscle layer. This is interesting in view of a high-fat diet increasing the relative proportion of PC in the mucosal cells but unable to change the level of arachidonic acid in the membrane lipids of colonic mucosa and muscle layers. Because the level of arachidonic acid in the membrane was not different between the diets, it might be expected that no difference would occur in the production of prostanoid metabolites at this site. Another noteworthy finding is that in comparison to the mucosa, the muscle layer did contain higher levels of arachidonic acid in the phospholipids. Furthermore, muscle synthesized significantly higher levels of prostanoids studied, especially TXB_2 and $PGF_{1\alpha}$. This observation corroborates the findings that colonic muscle synthesizes significantly more prostanoids than the mucosal layer (31). These observations suggest that prostanoid synthesis is dependent on the local requirement of the organ. These observations are made on total colonic mucosa or muscle, and no distinction was made between the cell types. It may be of interest in future studies to compare the proliferative compartment with the nonproliferative compartment.

The mechanism by which prostanoid production is regulated in normal or pathological situations in the colon is not known. However, it is apparent that many disease states including cancer, do lead to altered production of certain prostanoids in the gastrointestinal tract (32). Whether the level and type of fat will affect prostanoid production in the neoplastic colon and whether certain prostanoids are causally related to cancer remains to be investigated. Further studies are in progress to investigate the effect of dietary fats on the normal and neoplastic colons.

Characterization of HETEs and Related Conjugated Dienes by UV Spectroscopy

Christiana D. Ingram and **Alan R. Brash***
Division of Clinical Pharmacology, Department of Pharmacology, Vanderbilt University School of Medicine, Nashville, TN 37232

Three distinct pairs of HETEs can be distinguished on the basis of their UV spectra. We used hydroxy-linoleates (hydroxy-octadeca-*cis-trans*-dienoates) as a base for comparisons; both the 9- and 13-hydroxy isomers have identical chromophores with λ_{max} near 234 nm. The presence of a double bond three carbons removed from the conjugated diene (the chromophore of 9- and 11-HETE) causes a shift in the observed λ_{max} to near 235 nm. A double bond β to the chromophore (5- and 15-HETE) gives a further shift of 1.5 nm, giving a λ_{max} between 236–236.5 nm. With double bonds in both these positions (8- and 12-HETE), the λ_{max} is observed near 237 nm. It is apparent that the exact λ_{max} of the *cis-trans* diene chromophore is influenced in a consistent way by the adjacent methylene interrupted *cis* double bonds.
***Lipids* 23, 340–344 (1988).**

The λ_{max} of the UV chromophores in HETEs and related hydroxy dienes usually is quoted in the range of 234–237 nm. It is well recognized that these *cis-trans* conjugated hydroxy dienes can be distinguished from the *trans-trans* analogues (λ_{max} 230–232 nm).

We noticed that there are more subtle but reproducible differences in the chromophore of the individual HETEs. Here we report that the precise λ_{max} and shape of the HETE chromophore depends on the arrangement of the adjacent *cis* double bonds and that three pairs of HETEs can be distinguished by their UV spectra.

METHODS

Preparation and purification of HETEs. HETEs were prepared by autoxidation of 100 mg quantities of arachidonic acid with α-tocopherol (1). Briefly, the arachidonic acid was mixed with 10% w/w α-tocopherol (Sigma Chemical Co., St. Louis, MO) and left under an oxygen atmosphere for three days at 37 C. After three days, the autoxidation mixture contained 15–20% hydroperoxides. Before HPLC purification, the hydroperoxides were reduced with a molar excess of triphenylphosphine in methanol. The HETEs then were separated on an Alltech Semi-Prep silica column (250 × 10 mm) and further purified on an Alltech Analytical silica column (250 × 4.6 mm) using a solvent of hexane/isopropanol/glacial acetic acid (100/1.6/0.1, v/v/v). Additional RP-HPLC separation and purification of the 12- and 15-HETEs was performed on an Alltech Semi-Prep C-18 column. Concentrated solutions of pure HETEs (0.2–5 mg/ml) were stored in methanol or ethanol under argon at −70 C.

The 9-hydroxy and 13-hydroxy-octadecadienoates were prepared by the same method. The pair with the *cis-trans* conjugated diene was obtained by autoxidation of the methyl ester of linoleic acid, and the *trans-trans* pair from methyl linoelaidate (9*trans*,12*trans*-18:2).

HHT was recovered from an incubation of arachidonic acid with human platelets and was purified by RP- and SP-HPLC. All the standards were identified by gas chromatography-mass spectrometry (2,3).

Recording of UV spectra. A Beckman DU-7 scanning spectrophotometer was used with the standard slit. The resolution is quoted by the manufacturers as 2 nm, and can be judged from the appearance of the two small UV peaks in the Holmium oxide filter, Figure 1.

Concentrated solutions of pure conjugated dienes (0.2–5 mg/ml) were diluted in ethanol, and the concentration was carefully adjusted to give an absorbance of exactly 0.90 AU (ca. 12 μg/ml, assuming ε = 23,000 [4]). The solutions were scanned from 300–200 nm at 300 nm/min with ethanol as background. The spectra were stored in memory and plotted together as shown in the figures. The calculation of the first derivative of absorbance included a smoothing factor (delta λ); this was set at 0.8 nm, the lowest possible value compatible with the scanning speed. "Delta λ" is the range of wavelength used in the point by point measurement of slope for calculation of $dA/d\lambda$.

RESULTS AND DISCUSSION

UV spectra of hydroxy-18:2. The 9- and 13-hydroxy derivatives of linoleic acid represent the basic *cis-trans* conjugated diene (with no adjacent nonconjugated double

Abbreviations: HETE, hydroxyeicosatetraenoic acid; HHT, 12-hydroxy-heptadeca-5,8,10-(*cis,trans,trans*)-trienoic acid; hydroxy-linoleate, describes the two primary products of linoleate oxygenation, more properly named 9-hydroxy-octadeca-10*trans*,12*cis*-dienoate and 13-hydroxy-octadeca-9*cis*,11*trans*-dienoate. Hydroxy-linoelaidate refers to the corresponding *all-trans* dienes. RP-HPLC, reversed-phase high pressure liquid chromatography; SP-HPLC, straight-phase high pressure liquid chromatography.

bonds). They have identical UV spectra with λ_{max} near 234 nm. The corresponding *trans-trans* analogues are another identical pair with a λ_{max} 3 nm lower, near 231 nm. Figure 2 depicts the four spectra over a 50 nm range (215–265 nm).

The exact λ_{max} can be determined by inspection of the first derivative of the chromophore. The point at which the first derivative crosses zero corresponds to $dA/d\lambda = 0$, and consequently equals the λ_{max}. Figure 3a shows the first derivative of the entire chromophore of the four hydroxy-octadecadienoates (215–265 nm). Figure 3b focuses on the range 230–240 nm, allowing the precise λ_{max} to be measured.

UV spectra of HETEs. An overlay of the spectra of six HETEs (5-, 8-, 9-, 11-, 12-, and 15-HETE) is shown in Figure 4. It is apparent that there are only three different chromophores. Each represents a pair of HETEs: 9- and 11-HETE have the lowest λ_{max} (near 235 nm), the middle pair is 5- and 15-HETE (λ_{max} 1.5 nm higher), and 8- and 12-HETE have the highest λ_{max}, near 237 nm. Again, the exact λ_{max} can be determined by looking at the first derivative of the chromophore (Fig. 4b). This also emphasizes the three distinct pairs of HETEs.

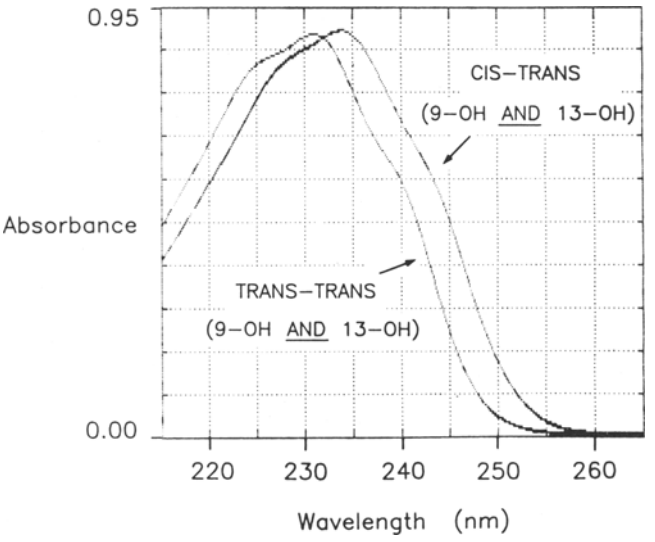

FIG. 2. UV spectra of four conjugated dienes: 9- and 13-hydroxy linoelaidates *(trans-trans)* and 9- and 13-hydroxy linoleates *(cis-trans).*

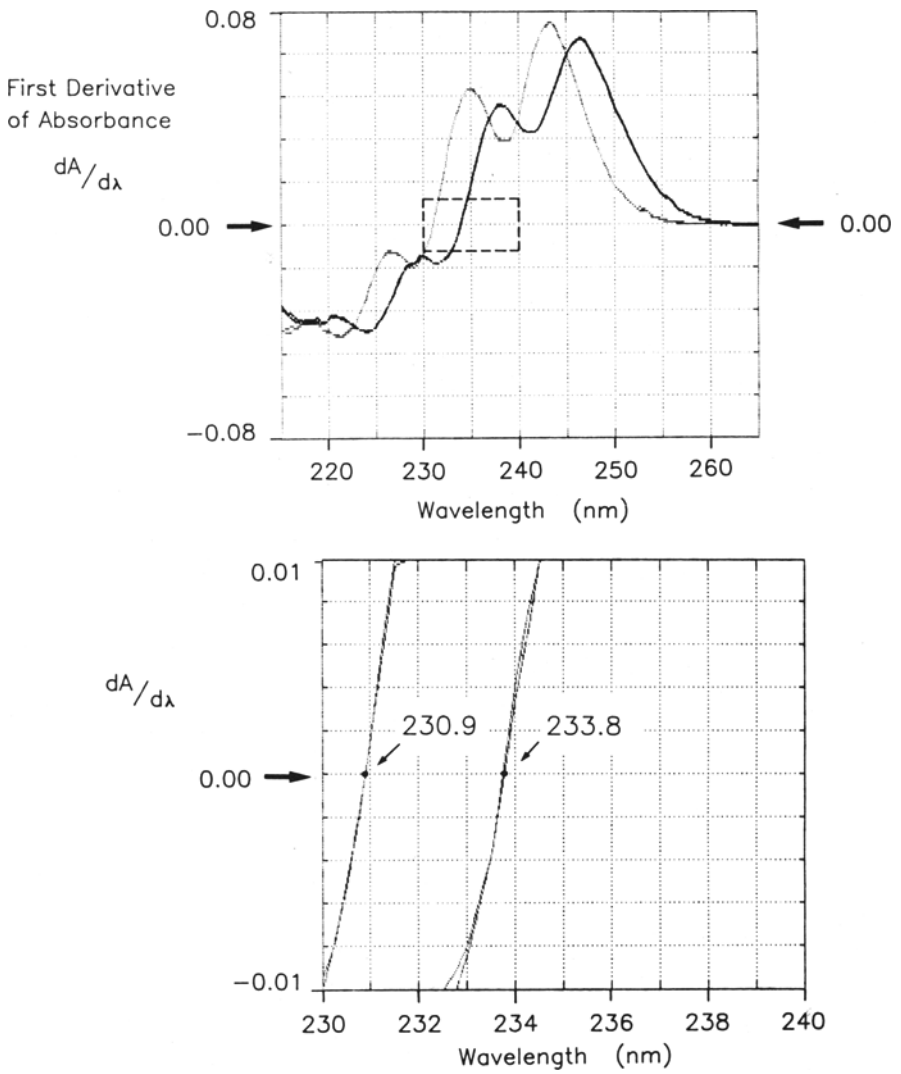

FIG. 3. First derivative of absorbance of compounds shown in Figure 2. Top, 215–265 nm; below, expansion of the boxed area, 230–240 nm.

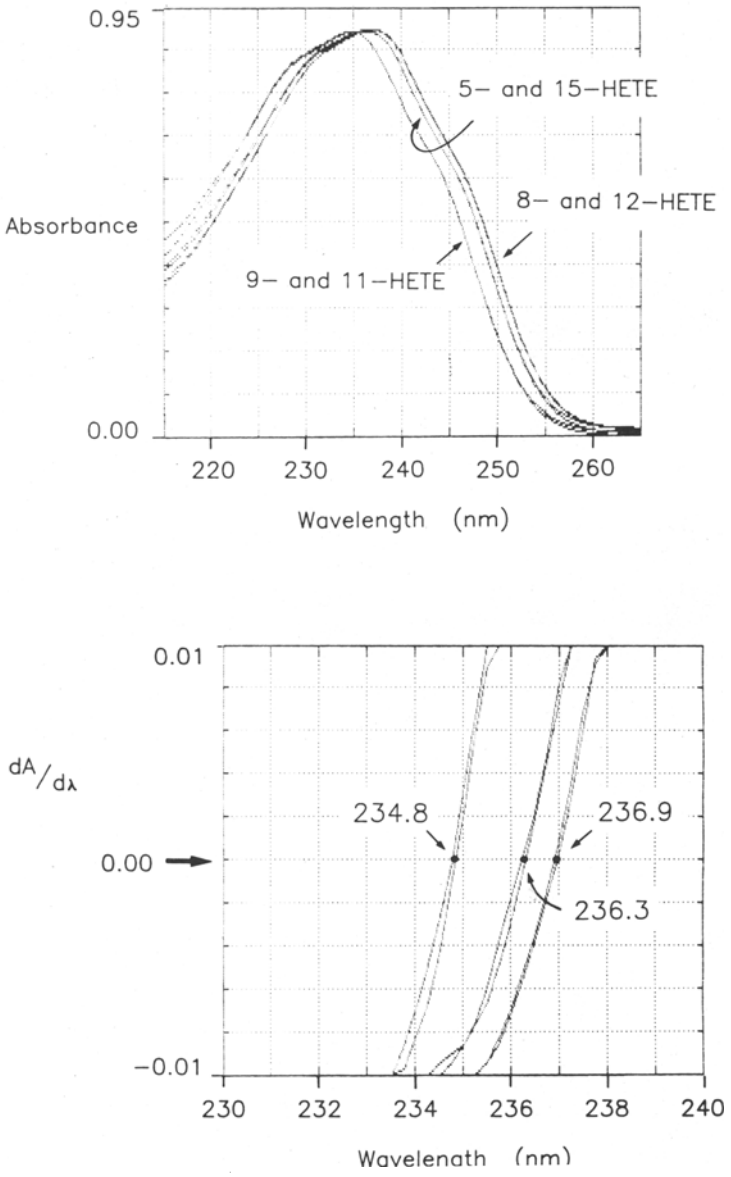

FIG. 4. Overlay of UV spectra of six HETEs. Top, absorbance spectra; below, expanded view of first derivative.

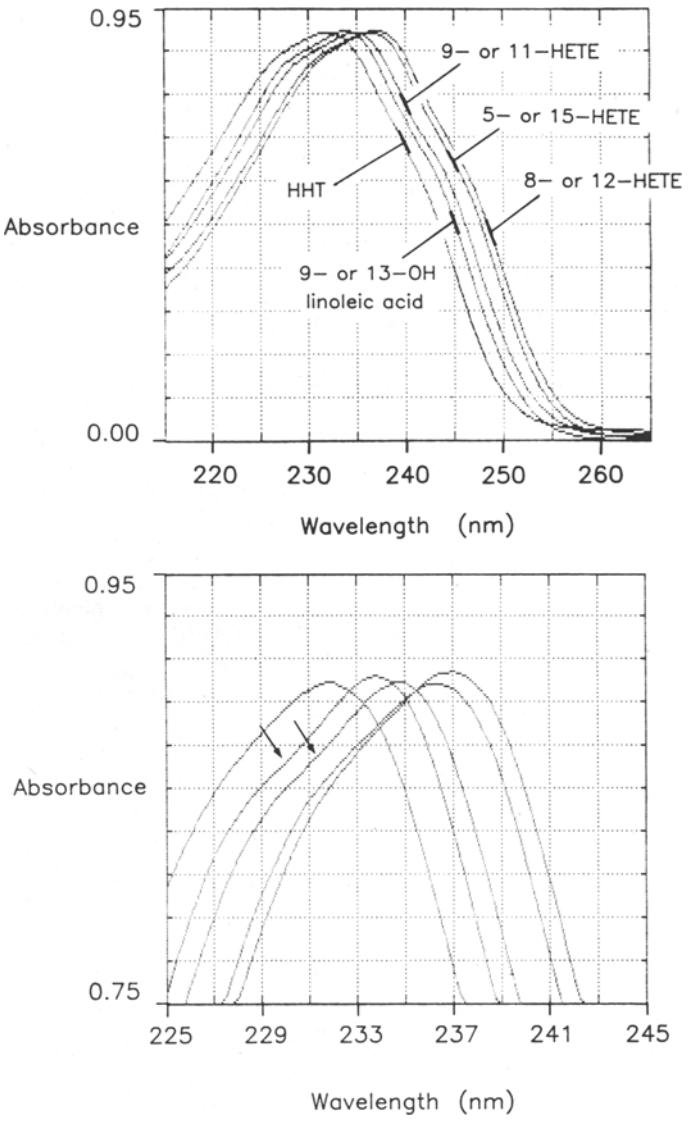

FIG. 5. Comparative shapes of UV spectra of conjugated dienes. Top, absorbance spectra 215–265 nm; below, expansion near the λ_{max}; arrows highlight the more distinct shoulder in the hydroxy-octadecadienoates and in 9- or 11-HETE. The *trans-trans* hydroxy-octadecadienoates (not shown in this figure) also have a distinct hypsochromic shoulder.

Shape of chromophore. At wavelengths above the λ_{max}, the conjugated diene chromophores are identical in shape. This is evident as the "parallel" nature of the chromophores in Figure 5. There are subtle differences in the shoulder just below the λ_{max}; there is a more distinct "notch" in the spectra of the hydroxy-octadecadienoates and in 9- and 11-HETEs (arrows in Fig. 5b). This figure also emphasizes the assymetrical character of the top of the conjugated diene chromophore.

"Rules" of diene absorbance. The structures of several conjugated dienes and their λ_{max} are listed in Table 1. The adjacent "non-conjugated" double bonds in the chromophore shift the λ_{max} from the base value of hydroxy-linoleate (233.8 nm): a double bond three carbons from the conjugated diene gives an increase of 1.0 nm (9- and 11-HETE); a double bond two carbons removed from the diene increases the base value 2.5 nm (5- and 15-HETE); a diene with double bonds on both sides of the conjugated diene increases the base value 3.1 nm (8- or 12-HETE).

Lack of additive effects. If the effects of double bonds on both sides of the chromophore were additive, the predicted value for 8- and 12-HETEs would be 3.5 nm above base (1 + 2.5 nm). The observed increase (3.1 nm) falls slightly short of this value.

Differences for cis-trans *and* trans-trans *systems.* The difference in the λ_{max} of the *cis-trans* and *trans-trans* hydroxy-octadecadienoates is 3 nm. The only other *trans-trans* conjugated diene we compared was HHT. Based on the observed λ_{max} of HHT, it would appear that the "rules" that govern the position of λ_{max} are different for *trans-trans* and *cis-trans* conjugated dienes. HHT has a

TABLE 1

Influence of "Nonconjugated" Double Bonds on the Diene Chromophore

Chromophore	Compound	λ_{max}	λ_{max} Relative to base value
	9- or 13-hydroxy linoleate	233.8	± 0 = base
	9- or 11-HETE	234.8	+ 1.0
	5- or 15-HETE	236.3	+ 2.5
	8- or 12-HETE	236.9	+ 3.1
	9- or 13-hydroxy-linoelaidate	230.9	± 0 = base *(trans/trans)*
	HHT	231.8	+ 0.9 nm *(trans/trans)*

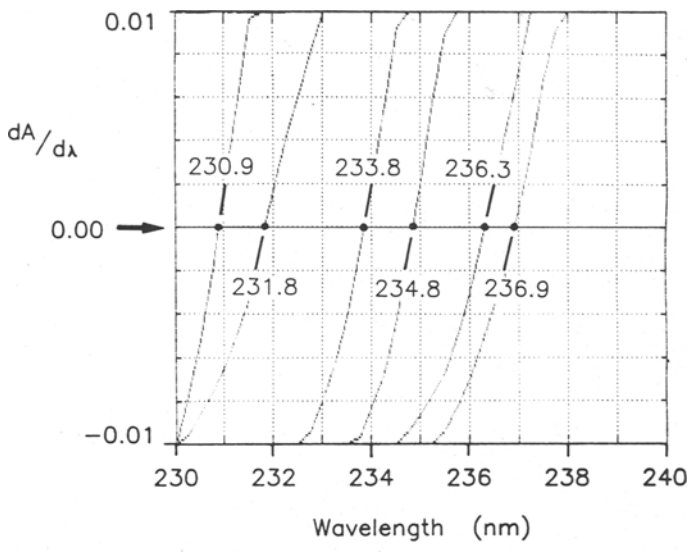

FIG. 6. Comparison of the λ_{max} of different conjugated dienes. In order of increasing λ_{max}, the compounds are hydroxy-linoelaidate (230.9 nm), HHT (231.8 nm), hydroxy-linoleate (233.8 nm), 9- or 11-HETE (234.8 nm), 5- or 15-HETE (236.3 nm), and 8- or 12-HETE (236.9 nm).

double bond two carbons from the conjugated *trans-trans* diene. Using the observations on the *cis-trans* dienes, the expected increase above base value due to the double bond is 2.5 nm (c.f. 5- and 15-HETE). The base value of a *trans-trans* conjugated diene is 230.9 nm, giving a predicted λ_{max} of HHT of 233.4 nm (230.9 + 2.5 nm). This is considerably different from the observed value for HHT (231.8 nm). The relative separations are summarized in Figure 6.

Application to other polyunsaturated fatty acids. We have not completely characterized the UV spectra of related hydroxy dienes, but we have seen evidence that the general trends in these rules do apply to other compounds. For example, in the series of hydroxy-eicosapentaenoic acid derivatives, the 9- and 14-hydroxy-eicosapentaenoates have the same arrangement of the double bonds around the diene as do 9- and 11-HETEs. These two EPA derivatives have a λ_{max} near 235 nm. In terms of the UV chromophore, the 11-hydroxy-eicosapentaenoate is an analog of 8- or 12-HETE, and its λ_{max} is near 237 nm (5). These observations fit with the "rules" in Table 1.

Caveats in identification of HETEs: instrument calibration and precision. The precise value of λ_{max} varies with calibration of the spectrophotometer, and a set of appropriate HETE standards are needed for direct comparisons. We want to emphasize that the precise values we quote here may vary from values obtained on another instrument. We used the phrase "near 235 nm" to allow for this. Over the course of months, the values found on our own instrument may vary by 0.5 nm, although the differences between individual spectra remain unchanged. Changes in resolution (slit width) of the spectrophotometer also can cause very slight changes in the observed λ_{max}. This relates to the assymetric character of the HETE chromophore (Fig. 5b): as the slit is widened, the higher absorbance on the hypsochromic side results in a bias which shifts the observed λ_{max} to lower wavelength. In the Beckman DU-7 spectrophotometer, there is a closely related artifact in the calculation of the first derivative of absorbance. The software uses a smoothing factor called "delta λ" that averages the calculation of dA/dλ over a chosen range of wavelength (0.2–16 nm). The use of even relatively low values of "delta λ" (0.8–2 nm) smooths the curve but also causes

a slight shift of the apparent λ_{max} ($dA/d\lambda = 0$) to lower wavelength.

Caveats in identification of HETEs: requirement for pure compounds. Because the diene chromophore is near the lower end of the UV, slight differences in end absorption can change the apparent λ_{max}. High end absorption will shift the apparent λ_{max} to lower wavelength, while oversubtraction of background can have the opposite effect. It is difficult to obtain a quality spectrum on less than 5–10 μg of pure compound. With smaller amounts of material, the most reliable spectra can be obtained with an on-line detector on HPLC.

Inhibition of Cytochrome c Oxidase and Hemolysis Caused by Lysosphingolipids

Hideki Igisu[a,*], Naotaka Hamasaki[b], Akio Ito[c] and Weija Ou[c]

[a]Department of Environmental Toxicology, University of Occupational and Environmental Health, Kitakyushu 807, Japan, [b]Department of Biochemistry, Faculty of Medicine, Fukuoka University, Fukuoka 814-01, Japan, and [c]Department of Biology, Faculty of Science, Kyushu University, Fukuoka 812, Japan

Galactosylsphingosine, glucosylsphingosine and sphingosine all inhibited cytochrome c oxidase activity in mitochondria from rat liver; more than 50% inhibition was caused by 5 μM lipid (0.1 μmol/mg mitochondrial protein). However, these lysosphingolipids did not suppress the activity of purified cytochrome c oxidase. When the enzyme was "reconstituted" with phosphatidylcholine, the lysosphingolipids clearly inhibited the activity. On the other hand, galactosylsphingosine, glucosylsphingosine and sphingosine all hemolyzed erythrocytes, indicating that lysosphingolipids can disrupt the membrane. Thus, it appears that the inhibition of cytochrome c oxidase, a membrane-bound enzyme in mitochondria, is due to perturbation of the environment of the enzyme and that the primary attacking site of the lysosphingolipids is the membrane. Because the potency to inhibit cytochrome c oxidase and to hemolyze erythrocytes did not differ among these lysosphingolipids and because galactosylceramide caused neither inhibition of cytochrome c oxidase nor hemolysis, the free amino group in the lysosphingolipids seems to be essential to give the effects. In addition, both inhibition of cytochrome c oxidase and hemolysis caused by lysosphingolipids were completely abolished by albumin, suggesting that toxic effects of lysosphingolipids may not be apparent in blood.
Lipids 23, 345-348 (1988).

Although enzymatic defects have been well-established in most sphingolipidoses, including Krabbe and Gaucher disease (1,2), it has not been defined how the defect of an enzyme causes the pathology. In Krabbe disease (globoid cell leukodystrophy), a striking accumulation of galactosylsphingosine (psychosine), which is a natural substrate of the missing enzyme (3,4), has been demonstrated (5,6). Since galactosylsphingosine is cytotoxic, the devastating pathology in Krabbe disease may be explained by the toxic effects of the accumulated lipid (6). In Gaucher disease, accumulation of another lysosphingolipid (glucosylsphingosine) has been shown (7) and a similar pathophysiology as in Krabbe disease has been suspected. However, the mechanism of cytotoxicity of these lysosphingolipids is not known.

We previously have noted that galactosylsphingosine is a powerful inhibitor of cytochrome c oxidase in mitochondria (8). In this study, we have examined whether glucosylsphingosine and sphingosine have similar effects of galactosylsphingosine. Furthermore, we studied the effects of these lysosphingolipids on cytochrome c oxidase, either in purified or in "reconstituted" form and their effects on erythrocytes compared with those of galactosylceramide.

Abbreviation: HPTLC, high performance thin layer chromatograph.

MATERIALS AND METHODS

Materials. Galactosylsphingosine, glucosylsphingosine, sphingosine, galactosylceramide (cerebroside from bovine brain, "lower spot") and γ-globulin (from human serum) were purchased from Sigma Chemical Co. (St. Louis, MO), crystalline human serum albumin from Chemical Dynamics Corporation (South Plainfield, NJ), phosphatidylcholine (from egg) from Koch-Light (Cohnbrook Berks, England) and cytochrome c from Boehringer-Mannheim-Yamanouchi (Tokyo, Japan). Ion exchange cellulose (DE-52) was from Whatman KK (Tokyo, Japan) and Sephacryl S-300 gel from Pharmacia KK (Tokyo, Japan). All other chemicals were reagent grade. The reduced form of cytochrome c was prepared as described (8).

Centrifree (centrifuging ultrafiltration apparatus) was purchased from Amicon (Danvers, MA), Sep-Pak cartridge from Waters (Milford, MA), and HPTLC (high performance thin layer chromatograph) plate (silica gel 60) from E. Merck (Darmstadt, West Germany). Borate impregnation of the HPTLC plate was done as described (9).

Preparation of samples. Mitochondria from the liver of rats (Wistar, male) were prepared by a slightly modified method (8) of Borgese and Meldolesi (10). The mitochondria were kept on ice (for cytochrome c oxidase measurement) or at −80 C (for cytochrome c oxidase purification).

Purification of cytochrome c oxidase was done following the method of Merle and Kadenbach (11). After final purification by gel filtration, the peak fraction was collected and frozen in liquid nitrogen without further concentration of the enzyme. The enzyme was kept at −80 C until use.

The purified enzyme was activated by phosphatidylcholine as follows. Phosphatidylcholine (0.1 mg) in chloroform/methanol (2:1, v/v) was dried as a thin film under a stream of nitrogen. After 1 ml of the buffer (50 mM glycylglycine buffer [pH 7.4] containing 3.1 mM Tris-HCl [pH 7.4] and 2 mM EDTA-2K) was added and vortexed vigorously for 30 seconds, the solution was sonicated in a water-bath type sonicator for two min. The solution (0.0426 ml) was cooled in ice, and 0.025 ml (6.75 μg protein) of the purified enzyme was added and vortexed for 30 seconds. The mixture was left on ice for one hr and diluted with 0.1825 ml of the buffer.

Human blood was obtained from a healthy male and heparinized. Erythrocytes were washed and suspended as described (12) and the hematocrit was adjusted to 4.5%.

Determination of cytochrome c oxidase. The enzyme activity was measured spectrophotometrically (13). When the activity in mitochondria was determined, the changes of the absorbance of 550-540 nm was measured in a Hitachi 557 spectrophotometer (dual-wave length mode).

The activity of the purified and "reconstituted" enzyme was measured at 550 nm in a Beckman DU-7HS spectrophotometer. When necessary, the "log rate" of the reaction velocity was calculated with the built-in computer. The temperature of the cuvette holder was kept at 25 C with a circulating water bath (Lauda RM3 or RM6).

The reaction mixture (0.8 ml) contained 50 mM glycylglycine buffer (pH 7.4), 3.1 mM Tris-HCl (pH 7.4), 2 mM EDTA-2K, and 0.08% cytochrome c (reduced form). Lysophingolipid and galactosylceramide were dissolved first in ethanol and dimethyl sulfoxide, respectively, and added to the reaction mixture. The maximum concentration of ethanol and dimethyl sulfoxide in the reaction mixture was 2.5%, and any effects of the solvent were corrected (subtracted).

The protein concentration of the enzyme source (0.02 ml) was 1 or 2 mg/ml (mitochondrial suspension in 0.25 M sucrose with 5 mM Tris-HCl [pH 7.4]), and 0.27 mg/ml (purified cytochrome c oxidase) or 0.027 mg/ml ("reconstituted" cytochrome c oxidase). The protein was measured by the method of Lowry et al. (14).

The effects of albumin and γ-globulin on cytochrome c oxidase activity were examined by adding 0.08 ml of the 10% protein solution to the reaction mixture.

Hemolysis of erythrocytes. The isotonic buffer (30 mM Tris-HCl [pH 7.4] with 120 mM NaCl, 5 mM KCl and 2 mM $MgCl_2$) (0.675 ml) and 0.025 ml of ethanol (with or without lysosphingolipid) or dimethyl sulfoxide (with or without galactosylceramide) were mixed. After the erythrocyte suspension (0.3 ml) in the isotonic buffer was added and incubated at 37 C for one hr with gentle shaking, 1.5 ml of the isotonic buffer was added and vortexed. After centrifugation at 1,000 × g for 15 min, the absorbance of the supernatant at 540 nm was measured. The percentage of hemolysis was calculated, taking the absorbance of the supernatant without lipid as 0% hemolysis and that of the supernatant obtained after incubation with water as 100% hemolysis.

The effects of albumin or γ-globulin on lysosphingolipid-induced hemolysis were examined by mixing 0.675 ml of the buffer (with or without protein), 0.3 ml of erythrocyte suspension and 0.025 ml of ethanol containing lysosphingolipid.

Binding of lysosphingolipids to proteins. Ethanol (0.025 ml) containing 6 mM lysosphingolipid and 0.695 ml of the buffer (30 mM Tris-HCl [pH 7.4] with 120 mM NaCl, 5 mM KCl and 2 mM $MgCl_2$) were mixed, then 0.08 ml of the buffer without protein, or the buffer containing either 10% albumin or γ-globulin was added. An aliquot (0.7 ml) was placed in the Centrifree and centrifuged at 1,500 × g for 25 min at 25 C. Methanol (1.8 ml) and water (2.7 ml) were added to 0.6 ml of the filtrate. This mixture was applied twice to Sep-Pak C18 cartridge. After the cartridge was washed with 70 ml of water, the lipid was eluted with 5 ml of methanol and 10 ml of chloroform/methanol (2:1, v/v) and dried under a stream of nitrogen. The physical set-up and washing of the cartridge were done as described (15). The lipid was dissolved in 0.075 ml of chloroform/methanol (2:1, v/v) and 0.02 ml was applied to borate-impregnated HPTLC plate. After developed in chloroform/methanol/ammonia water (75:25:5, v/v/v) without paper-lining, the lipids were visualized by spraying with cupric acetate and heating (150 C) (16). The plate was scanned with a Shimadzu CS-930 TLC scanner at 370 nm.

RESULTS

Effects on cytochrome c oxidase. Galactosylsphingosine, glucosylsphingosine and sphingosine all inhibited cytochrome c oxidase in mitochondria (used within 6 hr after preparation). The potency to inhibit cytochrome c oxidase did not differ among the lysosphingolipids and 5 μM (0.1 μmol/mg mitochondrial protein) caused more than 50% inhibition. In contrast, galactosylceramide did not inhibit the enzyme, but it activated cytochrome c oxidase mildly at 25 μM or higher (Fig. 1).

The purified cytochrome c oxidase was not inhibited but activated by lysosphingolipids of 40 μM or less. The activation by sphingosine was less pronounced than that by galactosylsphingosine or glucosylsphingosine. In addition, at 75 μM or higher, sphingosine inhibited the activity, but galactosylsphingosine and glucosylsphingosine still activated the enzyme to some extent (Fig. 2A). Galactosylsphingosine activated the enzyme even at 200 μM.

Addition of sonicated phosphatidylcholine activated the purified cytochrome c oxidase more than 40-fold. Galactosylsphingosine, glucosylsphingosine and sphingosine showed a clear inhibitory effect on this activated enzyme preparation. The potency to inhibit the enzyme did not differ among the lysosphingolipids (Fig. 2B).

Hemolysis. Galactosylsphingosine, glucosylsphingosine and sphingosine all hemolyzed washed human erythrocytes, but galactosylceramide did not. The potency to hemolyze erythrocytes did not differ among the lysosphingolipids, and 50% hemolysis was caused by approximately 50 μM of the lysosphingolipids (Fig. 3).

Suppression of lysosphingolipid effects by albumin. The complete inhibition of cytochrome c oxidase (in mitochondria) either caused by galactosylsphingosine, glucosylsphingosine or sphingosine was completely and immediately abolished upon addition of 1% albumin but not by 1% γ-glubulin (Fig. 4).

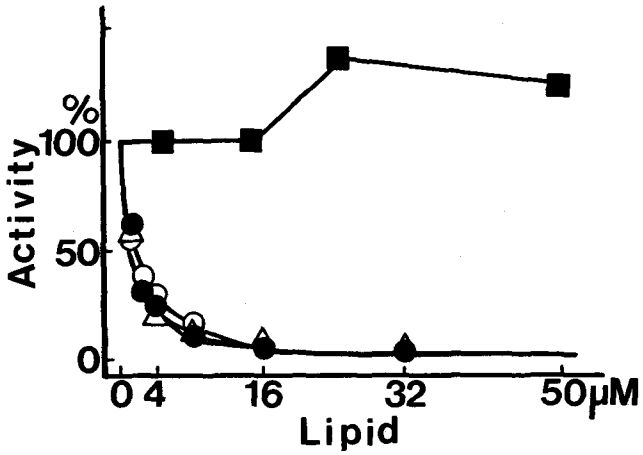

FIG. 1. The effects of galactosylsphingosine (●), glucosylsphingosine (○), sphingosine (△) and galactosylceramide (■) on cytochrome c oxidase activity in mitochondria. The reaction mixture (0.8 ml) contained 20 μg of mitochondrial protein.

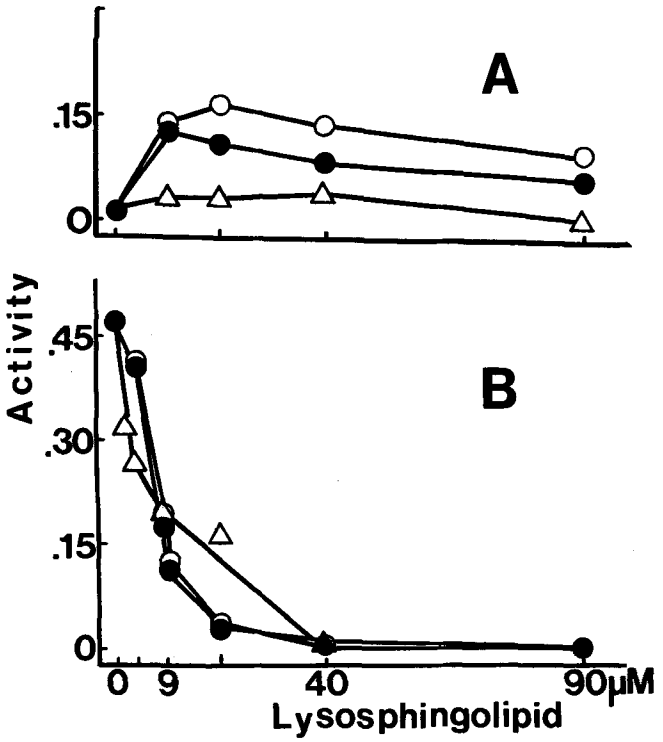

FIG. 2. The effects of galactosylsphingosine (●), glucosylsphingosine (○) and sphingosine (△) on the purified cytochrome c oxidase (A) and on the cytochrome c oxidase "reconstituted" with phosphatidylcholine (B). The reaction mixture (0.8 ml) contained 5.4 μg protein of cytochrome c oxidase in A and 0.54 μg protein in B. The activity (ordinate) is expressed in terms of arbitrary units ("log rate"/sec/mg protein).

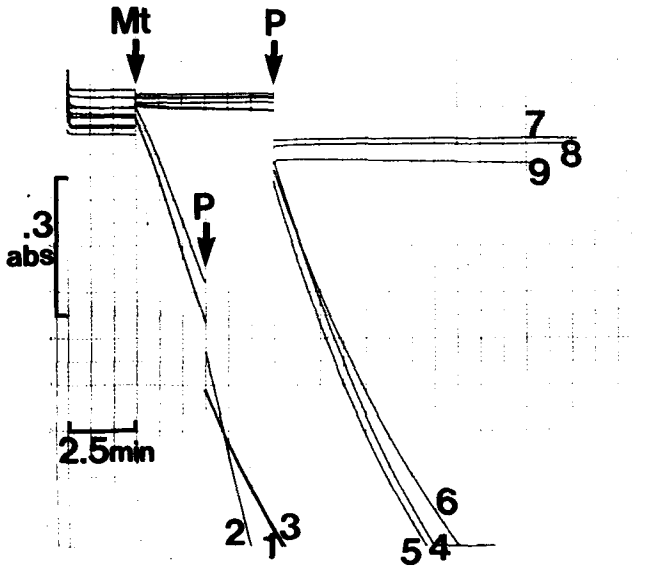

FIG. 4. The effects of albumin and γ-globulin on lysosphingolipid-induced inhibition of cytochrome c oxidase in mitochondria. The reaction was started by adding 0.02 ml of mitochondrial suspension (40 μg of protein) at Mt to the reaction mixture (0.78 ml). The speed of the decrease of the absorbance (550–540 nm) indicates the enzyme activity. No lysosphingolipid was present in 1, 2 and 3. At P, 0.08 ml of water was added to 1, 0.08 ml of 10% albumin (dissolved in water) to 2, and 0.08 ml of 10% γ-globulin (dissolved in water) to 3. One hundred μM galactoslysphingosine was present in 4 and 7, 100 μM glucosylsphingosine in 5 and 8, and 100 μM sphingosine in 6 and 9. After the cytochrome c oxidase activity was completely inhibited for five min, 0.08 ml of 10% albumin was added to 4, 5 and 6 at P, and 0.08 ml of 10% γ-globulin to 7, 8 and 9. The inhibition of the enzyme activity caused by lysosphingolipids was immediately abolished upon addition of albumin but not by γ-globulin.

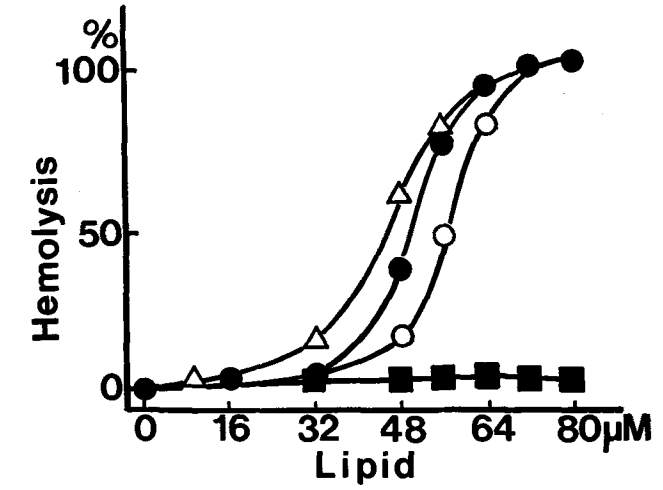

FIG. 3. Hemolysis caused by galactosylsphingosine (●), glucosylsphingosine (○), sphingosine (△) and galactosylceramide (■).

The 100% hemolysis, which occurred in the presence of 100 μM lysosphingolipids, also was completely prevented by 1–2% albumin but not by 1–4% γ-globulin (data not shown).

After mixing with γ-globulin and ultrafiltration, more than 50% of the galactosylsphingosine or glucosylsphingosine was recovered in the filtrate, but less than 3% of the lysosphingolipid was found in the filtrate when mixed with albumin (Fig. 5). Since solutions containing sphingosine did not filtrate well, binding of sphingosine to albumin could not be established by the present method.

DISCUSSION

Galactosylsphingosine, glucosylsphingosine and sphingosine all inhibited cytochrome c oxidase in mitochondria. When the enzyme was purified, however, these lysosphingolipids did not inhibit but did activate the enzyme to some extent. Cytochrome c oxidase is one of the typical membrane-bound enzymes (17), and its activity is very low in purified form. Hence, lipids, especially phospholipid(s), or a detergent is necessary to activate the purified enzyme (18). The present results show that even lysosphingolipids, which do not appear to be normal constituents of the mitochondrial membrane (19), can activate the enzyme to a limited extent. Phosphatidylcholine is one of the major lipids of mitochondria (19) and addition of sonicated phosphatidylcholine markedly activated the purified cytochrome c oxidase. The lysosphingolipids showed a clear inhibitory effect on this enzyme preparation, which suggests that the physiological lipid environment of the enzyme is necessary for lysosphingolipids to inhibit cytochrome c oxidase.

On the other hand, galactosylsphingosine and glucosylsphingosine caused hemolysis as reported by Taketomi and Nishimura (20) and by Taketomi and Yamakawa (21),

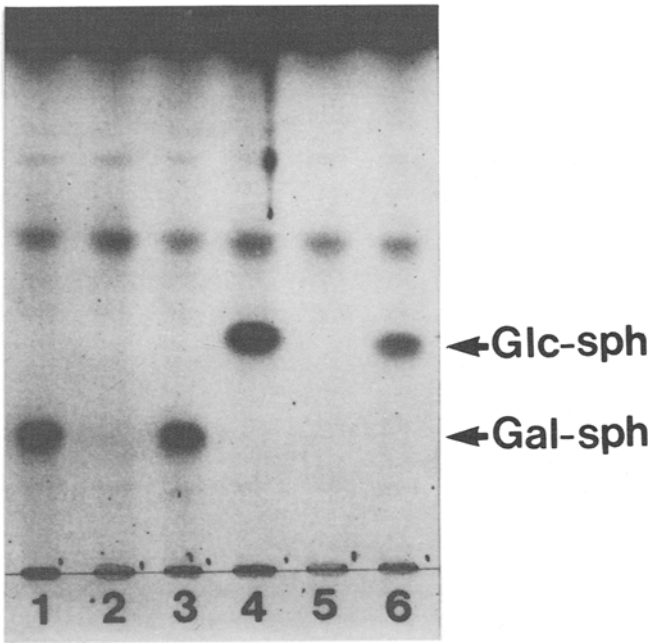

FIG. 5. Thin layer chromatogram of lipids recovered in the ultrafiltrate after mixing with no proteins (lanes 1 and 4), with albumin (lanes 2 and 5) and with γ-globulin (lanes 3 and 6). More than 50% of the control (lanes 1 and 4) of galactosylsphingosine (Gal-sph) or glucosylsphingosine (Glc-sph) are found in lanes 3 and 6 but less than 3% of the control in lanes 2 and 5.

respectively. In addition, we found that sphingosine also causes hemolysis. The mechanism of hemolysis is unclear, but obviously these lysosphingolipids can disrupt the erythrocyte membrane.

Taking these findings together, it seems possible that lysosphingolipids inhibit cytochrome c oxidase by perturbing its environment in mitochondrial membrane. The primary attacking site of lysosphingolipids may be the membrane structure of the cell, including mitochondria. However, it appears that not all membrane-bound enzymes are equally affected by lysosphingolipids. For instance, inhibition of NADH-cytochrome c reductase by galactosylsphingosine was much less than that of cytochrome c oxidase (8), and galactosylsphingosine showed no consistent effect on Na,K-ATPase of the erythrocyte membrane (Igisu et al., unpublished data). Thus, cytochrome c oxidase in mitochondria appears especially vulnerable to alteration of the membrane caused by lysosphingolipids.

The potency to hemolyze or to inhibit cytochrome c oxidase did not differ among galactosylsphingosine, glucosylsphingosine and sphingosine. This indicates that the sphingosine moiety plays an important role in the above effects. Moreover, since galactosylceramide showed neither effect, the free amino group in the sphingosine moiety appears responsible for either the inhibition of cytochrome c oxidase in mitochondria or the hemolysis.

The finding that albumin could counteract the effects of the lysosphingolipids may be of clinical relevance. Albumin is synthesized only in liver, and after being secreted it circulates in the bloodstream, but does not enter cell (22,23). Therefore, albumin cannot suppress the effects of lysosphingolipids within the cell, but the toxic effects of these lipids may not become apparent in blood because of the presence of serum albumin (>3 g/dl) (24).

Triterpene Alcohols, 4-Methylsterols and 4-Desmethylsterols of Eggplant Seed Oil: a New Phytosterol

Marie Farines, Serge Cocallemen and **Jacques Soulier***
Laboratoire de Chimie Organique des Substances Naturelles, Universite, Avenue de Villeneuve, F66025 Perpignan, France

4-Desmethylsterols, 4-methylsterols and triterpene alcohols of eggplant seed oil were isolated and characterized by ^1H nuclear magnetic resonance (NMR) and mass spectrometry. In addition to several compounds that have been shown to be present in eggplant seed oil, one triterpene alcohol and three sterols are described for the first time. One of these sterols, 14α-methyl-5α-cholest-9(11)-en-3β-ol, never before had been observed in plant lipids.
Lipids 23, 349–354 (1988).

This paper reports the study of the composition of 4-desmethylsterols, 4-methylsterols and triterpene alcohols of eggplant seeds (*Solanum melongena* L., Solanaceae). This plant is not used as a fat supply, and very few studies have been carried out on the sterolic and triterpenic composition of the lipid fractions of its seeds (1–5). Previous studies report only frequently found components, and our aim was to confirm prior investigations and to identify minor compounds. Since gas liquid chromatography (GLC) determination of relative retention time (RRT) of compounds is not sufficient proof of structure, a nonambiguous identification was performed by mass spectrometry (MS) and proton nuclear magnetic resonance (NMR); the latter technique required separation of pure components.

MATERIALS AND METHODS

Eggplant seeds were separated from the pulp of mature fruit by flotation in water and dried in an oven. They then were finely ground and Soxhlet extracted for 24 hr by hexane, producing a dark oil containing 1.8% of unsaponifiables after saponification with a 1 M solution of alcoholic potash. Thirty g of neutral alumina (E. Merck, Darmstadt, FRG) hydrated at 5% were used to chromatograph 1 g of the unsaponifiable fraction. The elution was carried out sequentially, first by pure hexane and then by hexane/diethyl ether mixtures of increasing polarity. The triterpene alcohols, eluted by a 80:20 mixture (v/v), represent 12% of the unsaponifiable lipids; the 4-methyl-sterols (22%) were eluted by a 70:30 mixture, and finally a 60:40 mixture separated the 4-desmethylsterols (30%). A GLC chromatogram of each fraction was taken (Delsi chromatograph equipped with a OV1701 capillary column [25 m long and 0.32 mm i.d.]; vector gas was helium [1 bar pressure], oven temperature was 270 C; oven temperature of injector and detector was 350 C). The RRT are expressed relative to cholesterol.

The triterpene alcohols (TA) were fractionated first by thin layer chromatography (TLC) on 0.2 mm-thick silica gel plates impregnated with silver nitrate (6,7). The elution was performed by four successive developments in CCl_4/CH_2Cl_2 (5:1, v/v). It must be pointed out that unlike the 4-desmethylsterols, acetylation is not necessary for good separation. The bands were visualized under UV light at 360 nm after spraying the plate with a 0.05% alcoholic solution of 2′,7′-dichlorofluorescein. The main bands were scraped off and extracted three times with hot chloroform. The resultant solution was filtered, evaporated, and the purity of the three fractions thus obtained was checked by GLC. The second and third fractions corresponded to pure compounds (**5h** and **5c**). The first fraction, which yielded two other pure components **4a** and **5a**, was analyzed by high performance liquid chromatography (HPLC) (Waters chromatograph equipped with a Merck Lichrosorb RP18 t μ column, 25 cm long and 4 mm i.d.; detection by refraction index (RI) variation; the mobile phase was anhydrous methanol at a flowrate of 0.8 ml/mn). The TA occurring in proportions less than 1.5% were not isolated. The four TA were studied by proton NMR and as tetramethylsilane (TMS) derivatives by mass spectrometry. The mass spectrometer was a Ribermag instrument (electron impact, 70 eV); the NMR instrument was a Bruker AC 360; spectra were taken in $CDCl_3$ solution with TMS as internal standard.

The 4-methylsterols (MS) were separated by semipreparative HPLC (Merck Lichrosorb RP18 7 μ column, 25 cm long and 10 mm i.d.; the mobile phase was anhydrous methanol with a flow rate of 4 ml/mn). Each fraction was purified by analytical HPLC; four major MS **3a, 3c, 3e** and **3f** were obtained pure. MS present in concentrations less than 2% were not isolated.

The 4-desmethylsterols (DS) first were separated by semipreparative HPLC; the five fractions thus obtained were analyzed by GLC and compared with the chromatogram of the whole DS fraction. The last two fractions were purified by analytical HPLC; the first three, which are mixtures, were acetylated overnight by acetic anhydride/pyridine at room temperature (6) and subjected to argentation TLC; elution was performed by six consecutive developments in CCl_4/CH_2Cl_2 (5:1, v/v). The major bands were scraped and then extracted by chloroform. The resultant solutions were filtered, evaporated, and the sterol acetates saponified. Purity was checked by GLC. All these procedures led to eight different sterols: **1a, 1b, 1c, 1d, 1e, 1f, 1g** and **2a**, which were studied by mass spectrometry and proton NMR. All DS representing more than 1% of the total sterolic fraction were isolated.

RESULTS

The isolated compounds were identified by analysis of the mass and proton NMR spectra, and by comparing the measured RRT with those reported in the literature (8,9).

The systematic study of the NMR spectra showed that seven of the eight isolated DS (**1a** to **1g**) possessed an intracyclic double bond in 5 (Scheme 1), according to the typical chemical shifts of H_6 and of the methyl groups

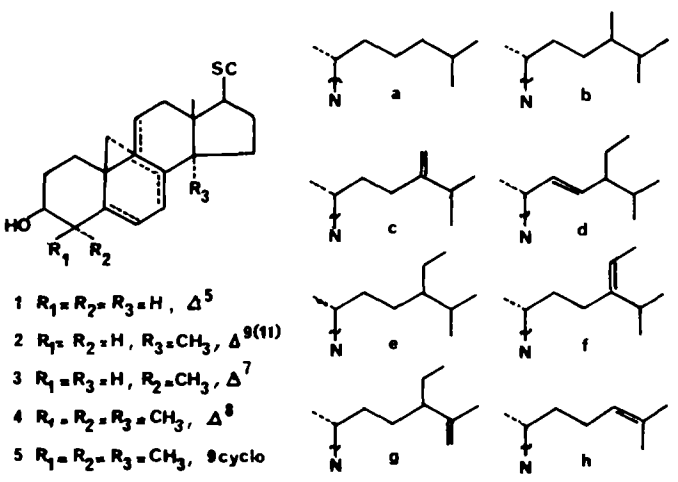

SCHEME 1

18 and 19 as shown in Table 1. This was confirmed by the mass spectra of the TMS derivatives of these DS (Table 2) leading, among others, to the ions of mass M-129 and 129 (10). The side chain of each of these seven DS was cleaved in mass spectrometry, with peak 255 (M^+-SC-TMSOH) always being observed; its formula was easily deduced from M^+-255+90. The location of the possible double bond was indicated in NMR by the chemical shifts and the signal multiplicity of the ethylenic protons. The configuration of C-24 was established, if necessary, according to the chemical shifts of methyl groups 21, 26, 27 and 28 (or 29) and compared with literature data (11-14): the methyl or ethyl substituent was α in every case (24*R* for **1b**, **1e** and 24*S* for **1d**), except for **1g** where it was β (24*S*); it corresponded to the biosynthesis of these structures as reported by Benveniste (28).

Sterol **2a** had a molecular mass of 472 (TMS derivative), which corresponded to a compound having 28 carbon atoms and a single double bond. The chemical shift of the intracyclic double bond ethylenic proton was 5.288, which did not correspond to a double bond in 5 (H-6: δ = 5.34 to 5.39) (15-16) or in 7 (H-7: δ = 5.14 to 5.16) (17,18). This led us to consider a double bond in 9 (11), rarely encountered in sterols but recently reported by Akihisa et al. (19), who observed a chemical shift of 5.29 for the H-11 proton of **2d**. Benveniste and Rahier (personal communication) found a chemical shift of 5.289 for the H-11 proton of synthetic 4α,14α-dimethyl-5α-ergost-9(11)-en-3β-ol acetate, while Gupta and Gupta (20) observed the corresponding signal at 5.35 in 5α-stigmasta-9(11),22-dien-3β-ol acetate. The cleavage of the side chain in mass spectroscopy (peaks 359 and 269) indicates a saturated side chain containing only eight carbon atoms, implying a 20-carbon atom nucleus. The NMR spectrum showed three singlets corresponding to nuclear methyl groups (δ = 0.661, 0.965, 0.750); the H_a-3 signal actually was a triplet of triplets, which excluded the structure of a 4-methylsterol, so the third methyl group must be in 14. It is pointed out that in mass spectrometry the M-Me peak is 100, which is characteristic of 14α-methylsterols (21). We thus suggest the 14α-methyl-5α-cholest-9(11)-en-3β-ol structure to take into account these observations. To our knowledge, this sterol has not yet been described

in a plant but has recently been reported by Goad et al. (22,23) in a sea animal (sea cucumber, *Psolus fabricii*). Our mass spectrometry (TMS derivative) and NMR (free DS) data are in good agreement with those reported by these authors, who studied acetates or free sterols. (The various spectral and chromatographic data are reported in Tables 1 and 2.)

On comparing our results with those in the literature (1,2) for eggplant seed 4-desmethylsterols, we confirm the presence of cholesterol **1a**, campesterol **1b**, stigmasterol **1d**, sitosterol **1e**, isofucosterol **1f**. The (24*S*) stigmasta-5,25-dien-3β-ol **1g**, and the 24-methylenecholesterol **1c** had not been reported previously in eggplant seed oil. The 14α-methylcholest-9(11)-en-3β-ol **2a** probably was confused with brassicasterol (1).

The four isolated 4-methylsterols have the nucleus of 4α-methyl-5α-cholest-7-en-3β-ol or lophenol according to the chemical shift values of methyl groups in 18 and 19, as well as that of H-7. The structure of the side chain was deduced from the mass spectra and from the NMR study of the ethylenic region (Tables 3 and 4). This was confirmed in mass spectrometry by intense fragments characteristic of Δ^7 sterols. In each case, we observed the typical peaks (24,25) $M^+ - SC$, $M^+ - SC - ROH$, $M^+ - SC - 2H - ROH$. The isolated compounds were 4α-methyl-5α-cholest-7-en-3β-ol (or lophenol, **3a**), 4α-methyl-5α-ergosta-7,24(28)-dien-3β-ol (or 24-methylenelophenol, **3c**), (24*R*) 4α-methyl-5α-stigmast-7-en-3β-ol (or 24*R*-ethyllophenol, **3e**) and (24*Z*) 4α-methyl-5α-stigmasta-7,24(28)-dien-3β-ol (or citrostadienol, **3f**). We could not isolate some minor MS as reported by Itoh et al. (3), among which was 4α,14α-dime-thylcholest-9(11)-en-3β-ol recorded at a trace level.

The four TA have a side chain of eight or nine carbon atoms according to their mass spectra (Table 5); three of them, **5a**, **5c** and **5h**, belong to the cycloartane series because of their specific cleavages in mass spectrometry ($M^+ - C_9H_{14} - TMSOH$) and of the characteristic signals of cyclopropanic protons in NMR (Table 6). These data and eventually the ethylenic proton patterns allowed an easy identification of cycloartanol (**5a**), cycloartenol (**5h**) and 24-methylenecycloartanol (**5c**). The authors who have studied NMR spectra of cycloartanol and its derivatives (e.g. 4,36–42) reported the same set of values for the chemical shifts of methyl groups 18, 30, 31, 32, but the correlations differ. The values we propose are based on the work by Iida and Kikuchi (43), who studied NMR spectra of **5a**, **5h** and **5c** in solutions containing increasing amounts of tri-(dipivalomethanato)europium, which allowed a nonambiguous proposition for methyl groups chemical shifts. These findings are confirmed by NMR data (19,44) relative to derivatives of pollinasterol (14α-methyl-9(19)cyclocholestan-3β-ol), which lacks 30 and 31 methyl groups. The fourth TA, **4a**, even though being

Unknown	0.1				

chemical shift values of the methyl groups 18, 19 and 32 are in agreement with a Δ^8 lanostane nucleus structure (35); **4a** is therefore the 24,25-dihydrolanosterol.

This study completes our knowledge of eggplant seed oil sterolic compounds, and Table 7 summarizes the qualitative and quantitative composition of this fraction. Components **2a**, **1c**, **1g** and **5c** never have been reported in that oil, and 14α-methyl-5α-cholest-9(11)-en-3β-ol **2a** been described among plant sterols; it belongs to 14α-methyl-$\Delta^{9(11)}$-sterol series, a member of which (**2e**) recently has been described by Akihisa et al. (19) in *Cucumis sativus* aerial parts.

The biosynthetic pathway seems to be usual (26–28) for the most abundant sterols. Note the presence of **4a**, a lanostane series compound. This type of skeleton frequently is found in botanical families such as Solanaceae (29); the origin of lanostane-type compounds is always a matter of controversy (30). The Δ^8 unsaturation can be produced either by a direct cyclization of squalene epoxyde, as it is the rule in nonphotosynthetic organisms, or by opening of the cyclopropane ring of cycloartenol **5h** or its derivatives; that pathway could be demonstrated in vivo (31) and even in vitro on Euphorbiaceae latex (32,33). Similar problems arise for the $\Delta^{9(11)}$ sterol **2a**, related to the triterpene parkeol (5α-lanosta-9(11),24-dien-3β-ol). If evolution of the side chain and the loss of methyl groups in 4 presumably are performed in the usual way, the $\Delta^{9(11)}$ double bond could have several origins. The first eventuality implies a migration of lanosterol (or a Δ^8 sterol) double bond towards the $\Delta^{9(11)}$ position; this is in contradiction with a very recent work by Akhila et al. (45), who studied the biosynthesis of 5α-stigmast-9(11)-en-3β-ol in *Costus speciosus* fed with labeled mevalonate. These authors observed that a tritium atom, coming from the carbon atom in 9, was found in the 8-position after the rearrangement, which excludes a Δ^8 intermediate. A second eventuality corresponds to a direct formation of parkeol from squalene epoxyde, the final rearrangement involving one more bond than in lanosterol biosynthesis in nonphotosynthetic species, but we could not find

parkeol in TA fraction of eggplant seed oil. A third eventuality is the opening of a 9,19 cyclopropane ring to give a $\Delta^{9(11)}$ sterol. Such a possibility has been shown to occur in vitro by action of a strong acid (34). A similar transformation could affect cycloartenol or its metabolites in the Solanaceae family (29).

ACKNOWLEDGMENTS

We are indebted to P. Benveniste and to A. Rahier who examined the manuscript; we thank Odile Morin from Iterg, Pessac (France), for performing the mass spectrometry, and Aubert, from Inra, Montfavet (France), for donating the eggplant seed.

[Received August 4, 1987; Revision accepted December 21, 1987]

METHODS

A New Quantitative Method for the Analysis of Monoacylglycerol Isomers Using ^{13}C Nuclear Magnetic Resonance Spectroscopy[1]

R.D. Dawe and **J.L.C. Wright***
National Research Council of Canada, Atlantic Research Laboratory, 1411 Oxford St., Halifax, Nova Scotia, Canada, B3H 3Z1

Current methods for determining the regiochemistry of monoacylglycerols are lengthy, tedious and aggravated by the ready isomerization of 2-acyl-*sn*-glycerols. A new method employs a very rapid adsorption chromatography step in which isomerization is kept to a minimum, followed by formation of the isopropylidene derivatives using mild procedures. These cyclic derivatives of 1- and 3-acyl-*sn*-glycerols and 2-acyl-*sn*-glycerols are stable thermally and display certain characteristic ^{13}C NMR resonances. Integration of these resonances yields directly the proportion of monoacylglycerol isomers in the mixture. The method was applied to the analysis of monoacylglycerols produced by enzymatic hydrolysis of synthetic and naturally occurring triacylglycerols.
Lipids 23, 355–358 (1988).

Fatty acid monoesters of glycerol can differ in the location of the fatty acid residue (1- or 3-acyl-*sn*-glycerols or 2-acyl-*sn*-glycerol) and in the chain length and degree of unsaturation of the fatty acid residues. For the purpose of the following discussion, the two regiochemically distinct species will be referred to as 1- and 2-monoacylglycerols, respectively. Such compounds, together with diacylglycerols, find wide use in the food industry to facilitate more homogeneous and more easily processed foods. In biology, monoacylglycerols are important intermediates and products of many lipid reactions. Characterization of monoacylglycerols, therefore, is important for process control in industry and in defining their role and distribution in the cell.

A number of methods have been developed to determine the proportions of 1- and 2-monoacylglycerols in a mixture including periodate oxidation (1), thin layer chromatography (TLC) on boric acid-impregnated silica gel (2,3), gas liquid partition chromatography (GLC) of tetramethylsilyl derivatives (3–5) and high pressure liquid chromatography (HPLC) (6–8), which has not yet fulfilled its obvious potential. However, the periodate method is tedious and prone to errors due to isomerization through intramolecular acyl migration (9), quantitation by TLC has been questioned (6), and the GLC method proved more sensitive to the chain length of the acyl chain than its position on glycerol (4). Conversion of monoacylglycerols to allyl esters, before and after periodate oxidation, apparently provided quantitative information not only on monoacylglycerol composition but also the fatty acid distribution in each type of monoacylglycerol (10).

[1]NRCC No. 28475.

Abbreviations: AT, acquisition time; DMP, 2,2-dimethoxypropane; FA, flip angle; GLC, gas liquid chromatography; HPLC, high performance liquid chromatography; PPTA, pyradinium *p*-toluenesulfonate; RT, repetition time; SW, sweep width; TLC, thin layer chromatography.

The purpose of this communication is to report an alternative quantitative method of determining the proportions of 1- and 2-monoacylglycerols by converting them to five- and six-membered cyclic isopropylidene derivatives, respectively, and subsequently identifying and estimating their proportions through integration of the characteristic quaternary acetal carbon resonances in the ^{13}C NMR spectrum. This nondestructive method has additional advantages that accrue from a mild derivatization procedure that precludes intramolecular acyl migration in the monoacylglycerols, and the insensitivity of the quaternary acetal carbon resonances to the nature of the acyl residues in the derivatives.

MATERIALS AND METHODS

Materials. Pancreatin (Grade II, porcine pancreas), monopalmitoylglycerol, trilinolenoylglycerol and tricaproylglycerol were obtained from Sigma Chemical Co. (St. Louis, MO). Peanut oil was purchased from BDH Chemicals (Toronto, Ont.), and olive oil and coconut oil were obtained as commercial food-grade oils.

Instrumentation. GLC analyses were performed using a Varian 3400 operating in the FID mode and equipped with a fused silica capillary column (30 m × 0.25 mm) liquid phase DB-5, carrier gas He, flow rate 3 ml/min, injection port 310 C, detector 310 C, operation was programmed from 150–270 C at 5 C/min. All samples for NMR analyses were dissolved in $CDCL_3$ using TMS as internal standard. Pulse Fourier Transform ^1H NMR spectra were recorded at 300 MHz at ambient temperature using a Bruker model MSL 300 spectrometer, sweep width (SW) 4504 Hz, data size 16384 Hz, acquisition time (AT) 1.82 s flip angle (FA) 90°, repetition time (RT) 6.8 sec. ^{13}C NMR spectra were recorded either at 20 MHz at ambient temperature using a Varian FT 80A spectrometer, SW 4132 Hz, AT 0.99 s, FA 40°, pulse delay (PD)0 s, ^1H broadband decoupling, or at 75.4 MHz using a Bruker model MSL 300; spectral width 16.7 KHz, data size 16 K zero-filled to 32 K [1.00 Hz/pt.], 30° pulse, (RT) 1 s, ^1H broadband decoupling, 5 mm tubes. Some spectra also were recorded with samples containing chromium (III) acetylacetonate (5 mg/ml), PD 2 s, and suppression of Nuclear Overhauser Enhancement (NOE) for comparison of ^{13}C intensities.

Mass spectra were obtained with a DuPont model 21-110B double-focusing spectrometer used in the electrical detection mode, 8 kV accelerating voltage, 70 eV ionizing energy. Accurate mass measurements were made by peak matching against a perfluorokerosene reference.

Enzymatic hydrolysis. Triacylglycerol (0.5 g) was suspended in a mixture of tris (hydroxymethyl) methylamine buffer (6 ml, 0.5 M, pH 7.5), aqueous $CaCl_2$ (0.5 ml, 45% w/v) and aqueous sodium deoxycholate (2 ml, 1% w/v). Pancreatin (0.5 g) was suspended in tris

(hydroxymethyl) methylamine buffer (3 ml, 0.5 M, pH 8.0). The suspensions were warmed to 40 C, combined, and agitated for 10 min. The aqueous suspension was extracted with dichloromethane (2 × 25 ml), washed with distilled water, dried (anhydrous Na_2SO_4) and evaporated to dryness. The residue was dissolved in diethyl ether/hexane (10:90, v/v), applied to a short silica gel (Mallinckrodt silicAR CC-7, 200–325 mesh) column (3 cm × 4.5 cm), and eluted under vacuum with portions (100 ml) of (a) diethyl ether/hexane (20:80, v/v), (b) diethyl ether/hexane (50:50, v/v) and (c) diethyl ether. Fractions eluted with solvents (a), (b) and (c) contained fatty acids and triacylglycerols, diacylglycerols and monoacylglycerols, respectively. Fractions were monitored by TLC (Merck pre-coated sheets, silica gel 60F-254: eluant ethyl acetate/hexane [50:50, v/v]). Evaporation of the diethyl ether fraction gave pure monoacylglycerol.

Isopropylidene formation. The monoacylglycerol (0.13 g) was dissolved in a mixture of dichloromethane (2 ml) and 2,2-dimethoxypropane (2 ml) containing pyridinium *p*-toluenesulfonate (0.01 g). The reaction mixture was maintained at ca. 35 C for two hr and then worked up by either method A or B. Method A: the reaction mixture was diluted with dichloromethane (30 ml), washed with aqueous $NaHCO_3$ (15 ml, 5%), dried (anhydrous Na_2SO_4) and evaporated to yield the monoacylglycerol isopropylidene derivative (yield 95%). Method B: solid $NaHCO_3$ (ca. 0.5 g) was added to the reaction mixture, which was stirred (10 min) and then evaporated to dryness. The residue was extracted with hexane (30 ml), filtered and evaporated to yield the monoacylglycerol isopropylidene derivative (yield 95%).

2,2-dimethyl-1,3-dioxan-5-yl hexanoate. Tricaproylglycerol (0.3 g) obtained from Sigma Chemical Co. was hydrolyzed using porcine pancreatin, and the monoacylglycerol product (0.094 g) was treated with DMP and traces of PPTS as described above to yield the dioxane (0.108 g, 95%); υ_{max}(neat) 1735, 1375, 1172, 830 cm^{-1}; ^1H NMR ($CDCl_3$). Δ_H 0.90 (3H, t, J = 6.6 Hz), 1.32 (6H, m), 1.44 (6H, s), 1.65 (2H, m), 2.38 (2H, t, J = 7.5 Hz), 3.81 (2H, dd, J = 3.3 and 12.8 Hz) 4.09 (2H, dd, J = 3.3 and 12.8 Hz), 4.70 (1H, t, J = 3.3 Hz); ^{13}C NMR ($CDCl_3$)δ_cc 13.88(q, C-6′), 22.34(t, C-5′), 24.67(t, C-4′), 25.77(q, acetal Me), 31.34(t, C-3′), 34.29(t, C-2′), 62.04(t, glycerol CH_2), 66.07(d, glycerol CH), 98.45 (s, acetal C), 173.40 (s, carbonyl); MS, M/Z 230 (M+, not observed), 215, 173, 99.

RESULTS AND DISCUSSION

1-Monopalmitoylglycerol was obtained commercially, and 2-monoacylglycerols were obtained by hydrolysis of natural or synthetic triacylglycerols with porcine pancreatin (11,12). Monoacylglycerols were isolated from the hydrolysis mixture in 10 min or less following rapid chromatography on a short dry-packed pad of silica gel. Thus, exposure of the labile 2-monoacylglycerols to silica gel was kept to a minimum.

2,2-Dimethoxypropane (DMP) has been used to make isopropylidene derivatives of 1,2- and 1,3-diols under very mild conditions and in high yields (13). This reagent readily derivatizes 2-monoacylglycerols, in contrast to acid/acetone, which promotes acyl migration rather than formation of the isopropylidene derivative (10,14). In this approach, DMP in the presence of a catalytic amount of pyridinium *p*-toluenesulfonate (PPTS) (15,16) or *p*-toluenesulfonic acid, rapidly (ca. two hr) and cleanly converts 1-monoacylglycerols 1 and 2-monoacylglycerols 2 to the respective isopropylidene derivatives 3 and 4 (Fig. 1). These conditions do not promote isomerization, even after prolonged reaction times (e.g. eight hr). To our knowledge, 2,2-dimethyl-1,3-dioxanes 4 have not been reported previously, and representative physical data are reported in Materials and Methods.

During the course of the reaction, intermediates were observed by TLC, especially when a 2-monoacylglycerol was the substrate. ^{13}C and ^1H NMR showed these intermediates to be the expected acyclic intermediates 5 and 6 in this stepwise acetal-exchange reaction: the resonances δ_c 48.46 and δ_H 4.20 ppm were characteristic of a methoxyl group and the resonance at δ_c 100.36 ppm was assigned to the quaternary carbon of an acyclic acetal. These intermediates were converted to the cyclic dioxolane or dioxane products under the reaction conditions. The addition of a small amount of *p*-toluenesulfonic acid increased the rate of this conversion without affecting the nature of the products.

Once formed, the isopropylidene derivatives 3 and 4 freeze the distribution of monoacylglycerol isomers in the mixture. These derivatives also are quite stable at room temperature and can be readily analyzed by ^{13}C NMR spectroscopy (Fig. 2). The quaternary dioxolane or dioxane carbons resonate at very different frequencies in an area of the spectrum that is virtually unique to this type of carbon, i.e. 95–115 ppm. The resonance frequency of the quaternary carbon of the dioxolane 3 (δ_c 109 ppm) and of the dioxane 4 (δ_c 98 ppm) are more than 10 ppm apart (17,18), and their chemical shift is independent of fatty acid chain length. Thus, the ratio of 3 to 4 can be determined directly by integration of these two signals. It also is worth pointing out that in these derivatives the glycerol carbons of 3 (δ_c 64.59, 66.56 and 73.84 ppm) and 4 (δ_c 62.04 and 66.07 ppm) are sufficiently distinct to be useful as an additional check on the quantitative results. For example, analysis of monolinolenoylglycerol, produced by enzymatic hydrolysis of trilinolenoylglycerol, gave the following results (% of 2-monoacylglycerol): 78% (acetal carbon), 76% (C-1 and C-3), 76% (C-2), average 76%. This compares with a value of 75% determined by GC analysis. The results of enzymatic hydrolysis of other triacylglycerols are shown in Table 1.

Under the GLC conditions described here, the derivatized monoacylglycerols appeared as a pair of peaks in

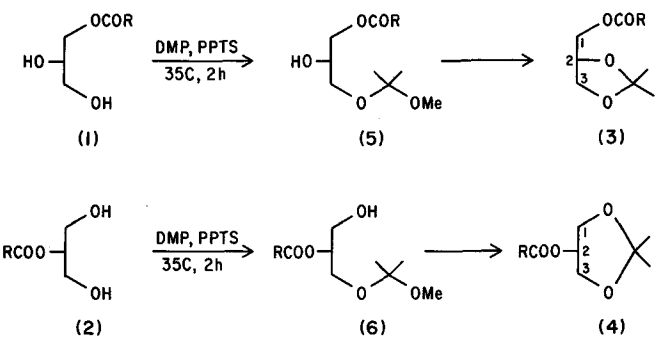

FIG. 1.

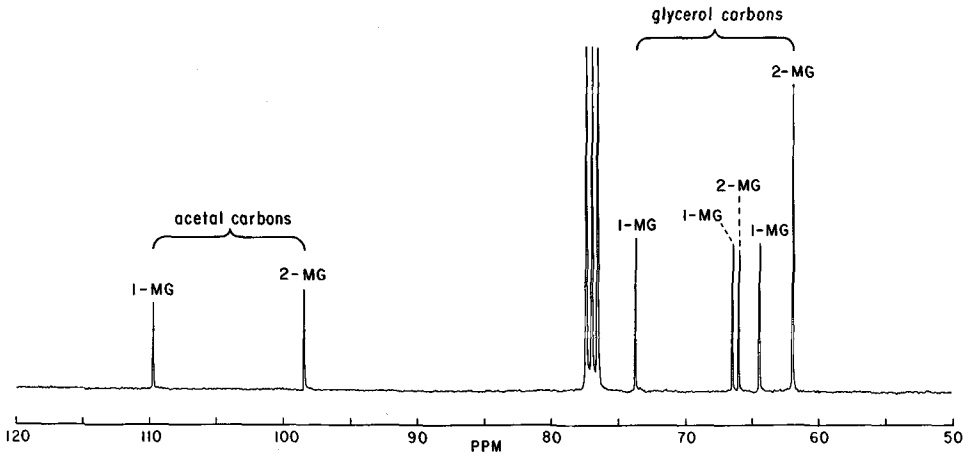

FIG. 2.

TABLE 1

Percentage of 2-acyl-*sn*-glycerol Produced by Deacylation of Synthetic and Natural Triglycerides with Porcine Pancreatin[a]

Triacylglycerol	Monoacylglycerol	% 2-acyl-*sn*-glycerol[c]	Reported[b]
	1(3)-monopalmitin (Sigma)	0[d]	
Olive oil	by enzymatic hydrolysis	≤97[d] (94)	84
Coconut oil	by enzymatic hydrolysis	88 (90)	88
Peanut oil	by enzymatic hydrolysis	86	—
Tricaproylglycerol	by enzymatic hydrolysis	92 (91)	63
	by enzymatic hydrolysis (30 min)	88 (82)	—
	by enzymatic hydrolysis and adsorption on silica (60 min)	74 (77)	—
Trilinolenoylglycerol	by enzymatic hydrolysis	75	59

[a]Each hydrolysis was performed as described in Materials and Methods. Data are the result of at least two separate experiments.

[b]Proportion of monoacylglycerol isomers determined by the periodate method (11,12).

[c]Ratios calculated from spectra recorded using standard conditions for proton noise decoupled (PND) spectra. The use of relaxation reagents [Cr(acac)$_4$] and prolonged delay times, yielding normalized spectra gave the same values. The values in parentheses correspond to the ratios determined by GLC analysis. The ratio of 1-acyl-*rac*-glycerol to 2-acyl-*sn*-glycerol isopropylidene derivatives in the oils was calculated by comparing the total integrated area of peaks corresponding to each isomer.

[d]Other isomer below detection limits.

which the 1-monoacylglycerol derivative is eluted before the 2-monoacylglycerol derivative. In a (complex) mixture like coconut oil or olive oil, these isopropylidene derivatives were eluted as a series of pairs of peaks, each pair corresponding to the nature and chain length of the attached fatty acid. The proportion of 1- and 2-monoacylglycerol derivatives in the mixture was calculated by comparing the total integrated area of peaks corresponding to each isomer. It is interesting to note that within error, the ratio of peaks for each pair in the mixture appears to be the same.

In all cases, the relative amounts of 2-monoacylglycerol determined by the ^{13}C method were equal to or greater than those determined by the periodate method (11,12) (see Table 1). It generally is assumed that most 1-monoacylglycerol arises from isomerization of 2-monoacylglycerol during the enzymatic hydrolysis or subsequent work-up (19). Since the hydrolysis used here was performed essentially as described, it appears that this method permits less isomerization during work-up and provides a more accurate representation of the ratio of 2- to 1-monoacylglycerols produced by enzymatic hydrolysis. For example, the improved yields of 2-monolinolenoylglycerol and 2-monocaproylglycerol are particularly noteworthy, as previous results were interpreted to mean that these compounds are particularly susceptable to isomerisation (19). In fact, in this NMR method, there is almost no isomerization of the 2-monoacylglycerol

following hydrolysis of tricaproylglycerol (Table 1). The lack of isomerization most likely is due to the rapid chromatography step and the mild conversion to the isopropylidene derivative, which is completely resistant to isomerization even at room temperature.

A higher proportion of 1-monoacylglycerol also was formed after hydrolysis of coconut and peanut oil. This was not due to the presence of 1-monoacylglycerol in the original mixture since treatment of the natural oil with DMP/PPTS yielded a product displaying none of the characteristic NMR signals associated with the isopropylidene derivatives. In the case of tricaproylglycerol, increasing enzyme reaction time to 30 min or prolonged treatment with DMP/PPTS had little effect on the monoacylglycerol ratio. It is more likely that isomerization occurs during the chromatography step and prolonged exposure (one hr) of underivatized 2-monocaproylglycerol to silica gel did increase the amount of 1-monoacylglycerol. However, if necessary the chromatography step can be eliminated, the hydrolysis products derivatized directly, and the mixture analyzed in the usual manner.

This nondestructive ^{13}C NMR method utilizing the stable isopropylidene derivatives is a useful and convenient tool for analysis of monoacylglycerol mixtures. The simplicity of the sample handling combined with the reliability of the results make it an attractive alternative to current methods of analysis. The further utility of these isopropylidene derivatives in GLC and GLC/MS analysis is also under investigation and shows some promise since the 1- and 2-monoacylglycerol derivatives display different mass spectral fragmentation pathways.

[Received March 6, 1987; Revision accepted October 21, 1987]

Separation of α-Tocopherol and Its Oxidation Products by High Performance Liquid Chromatography

Yeong L. Ha[1] and **A. Saari Csallany***
Department of Food Science and Nutrition, University of Minnesota, St. Paul, MN 55108

A very sensitive high performance liquid chromatographic (HPLC) method was developed for the separation of α-tocopherol (α-T) and its five oxidation products: α-tocopheryl quinone (TQ), dimer (D), dihydroxy dimer (DHD), trimer (T) and 9-methoxy-α-tocopherone commonly called α-tocopheroxide (TO). The separation was achieved on a normal-phase silica-based column (Ultrasphere-Si), using a mobile phase of hexane/chloroform/isopropanol (95:4.5:0.5, v/v/v) at a flow rate of 0.4 ml/min, and the eluants were monitored simultaneously at their maximum absorptions using a variable-wavelength UV detector. The minimum detection limit is 0.01 μg for α-T, TQ and TO, 0.05 μg for DHD and D, and 0.1 μg for T/injection. This normal-phase method has the combined advantages of being very sensitive, fast and capable of separating all six compounds at the same time.
Lipids 23, 359-361 (1988).

α-Tocopherol (α-T), a naturally occurring antioxidant, reacts with free radicals or oxidizing agents to form several oxidation products. Some of these oxidation products include α-tocopheryl quinone (TQ), and dihydroxy dimer (DHD), dimer (D) and trimer (T) of α-tocopherol and 9-methoxy-α-tocopherone commonly called α-tocopheroxide (TO) (1-6). The first four of these oxidation products have been isolated as metabolites, and TQ was found to be the major metabolite (1,3,7).

Quantitative determination of α-T and its oxidation products (TOP) can be used to measure the degree of cell membrane peroxidation and the metabolic pathways of α-T, and useful in the prediction of the stability of oils (7,8). Gas chromatography, column chromatography and thin layer chromatography were methods used commonly for the separation of α-T and TOP (9-12). These methods have serious limitations because of their comparatively low sensitivity, long analysis time and possibility of increased oxidation. Lately, various high performance liquid chromatographic (HPLC) methods have been applied successfully to determine α-T in foods and feeds (13,14), and in tissues (15,16). HPLC methods also were reported for the simultaneous separation of α-T, TQ or TO (17-21) and for the separation of dimers of α-T (22).

Currently, a HPLC method is not available in the literature for the simultaneous separation of α-T and its five oxidation products (TQ, DHD, D, T and TO) with a very high sensitivity.

The present method is not only capable of simultaneously separating α-T and its most important five oxidation products in a single injection, but it has higher sensitivity than the previously published methods.

[1]Present address: Food Research Institute, Department of Food Microbiology and Toxicology, University of Wisconsin, Madison, WI 53706.

*To whom correspondence should be addressed.

Abbreviations: α-T, α-tocopherol; AUFS, absorption unit full scale; D, dimer; DHD, dihydroxy dimer; HPLC, high performance liquid chromatography; T, trimer; TO, α-tocopheroxide; TOP, α-T oxidation products; TQ, α-tocopheryl quinone.

MATERIALS AND METHODS

Reagents. α-T was purchased from Eastman-Kodak Company (Rochester, NY). Hexane (HPLC grade), methylene chloride (HPLC grade), methanol (ACS grade), ethanol (ACS grade) and diethyl ether (ACS grade) were purchased from Fisher Scientific Co. (Itasca, IL). Aluminum oxide was purchased from Bio-Rad Laboratory (Richmond, CA). All other chemicals used were reagent grade.

Synthesis and purification of standard TOP. The TQ was synthesized by the method of Eggitt and Norris (23), DHD, D and T according to Csallany et al. (3) and TO by the modified method of Boyer (24). Modification consisted of a change from ethanol to methanol in the synthesis of the compound. The TQ, DHD, D and T were purified by column chromatography on aluminum oxide, deactivated with 6% water, followed by HPLC on a 250 mm × 10 mm (i.d.) C_{18} reversed-phase semipreparatory column packed with Ultrasil-ODS (10 μm) (Beckman Instruments, Inc., Berkeley, CA). Purification of TO was carried out only on the above-mentioned reversed-phase C_{18} column. Standard stock solutions were made weight by volume. The HPLC was performed with a mobile phase of methanol/hexane/methylene chloride (95:4:1, v/v/v) at a flow rate of 0.4 ml/min for the purification of TQ and TO, and a mobile phase of methanol /hexane/methylene chloride (30:21:1, v/v/v) at a flow rate of 1.5 ml/min for the purification of D, DHD and T. The absorption spectrum of each purified compound was monitored by a DU-8 Spectrophotometer (Beckman Instruments, Inc.), using a quartz cuvette (1 × 1 cm).

HPLC equipment and conditions. The HPLC equipment for the separation of α-T and TOP consisted of a model 110A solvent metering pump (Beckman Instruments, Inc.) and an Altex Model 210 solvent injector equipped with a 100-μl loop (Beckman Instruments, Inc.). A normal-phase HPLC chromatography was performed on a 6-μm Ultrasphere-Si, 250 mm × 4.6 mm (i.d.) column, using a mobile phase of hexane/chloroform/isopropanol (95:4.5:0.5, v/v/v), at a flow rate of 0.4 ml/min to separate α-T, TQ, DHD, D, T and TO. The UV absorptions were monitored at 292, 268, 292, 294, 298 and 240 nm for α-T, TQ, DHD, T, D and TO, respectively, using a Beckman model 165 variable-wavelength detector (with two channels) equipped with a 20-μl quartz flow cell (Beckman Instruments, Inc.). The wavelength was changed from 295 nm to 292 nm in the first channel after eluting T, D and DHD in order to monitor α-T at their maximum absorptions. Similar changes were made in the second channel which monitored TO at 240 nm, and ollowed by TQ at 268 nm. The detector was operated at a sensitivity of 0.05 absorption unit full scale (AUFS).

For preparation of the mobile phase, methanol was glass distilled, filtered through a 0.45-μm α-metricel filter (Gelman Sciences, Ann Arbor, MI), and degassed under vacuum. Hexane and methylene chloride also were degassed under vacuum.

TABLE 1

Preparation of Stock Solutions and Working Solutions of α-T and TOP

Compounds	Dilutants	Stock solutions (μg/ml)	Working solutions (μg/ml)
α-Tocopherol	a	310	30.8 – 6.2
α-Tocopheryl quinone	a	450	45.0 – 0.9
Dihydroxy dimer	a	370	37.4 – 0.6
Dimer	a	580	58.0 – 2.4
Trimer	a	460	230.0 – 8.7
9-Methoxy-α-tocopherone	a	230	22.7 – 3.8

[a]Hexane/chloroform/isopropanol (95:4.5:0.5, v/v/v).

Preparation of calibration curves of α-T and TOP. The stock solutions containing 310 μg α-T, 450 μg TQ, 370 μg DHD, 590 μg T and 230 μg TO/ml were diluted with the mobile phase to the desired concentrations for the preparation of standard curves (Table 1). A 60-μl of diluted standard solution was injected with a 100-μl blunt-needle Hamilton syringe (Rainin Instrument Co., Inc., Woburn, MA) onto the column. Peak heights and areas were recorded by a Spectra Physics 4270 computing integrator (Arlington, IL).

RESULTS AND DISCUSSION

Purification of TOP. Five TOP (TQ, D, DHD, T and TO) were synthesized and purified. After purification, each peak of the TOP was collected from a separate chromatographic run of a given sample on a reversed-phase C_{18} semipreparatory column and scanned from 400 nm to 200 nm. The absorbance maxima were found to be for α-T, TQ, DHD, D, T and TO at 292, 268, 292, 298, 294 and 240 nm, respectively, in the appropriate mobile phase. No changes were observed in absorbance maxima of α-T and the five TOP, when solvents were changed from the mobile phase of the C_{18} column to hexane/chloroform/isopropanol (95:4.5:0.5, v/v/v), which is used for the normal-phase HPLC. The absorbance maxima were slightly different in the mobile phase for α-T and TOP when compared to the published data (5,24) because absorbances of α-T, DHD, D and T were measured in isooctane, and TO was measured in ethanol.

Separation of α-T and TOP by HPLC. A typical separation of α-T and the five TOP on a normal-phase column, using a mobile phase of hexane/chloroform/isopropanol (95:4.5:0.5, v/v/v) at a flow rate of 0.4 ml/min is demonstrated in Figure 1. Elution times for T, D, DHD and α-T recorded by the first channel were 5.3, 6.9, 7.5 and 14.0 min, respectively. Elution times for TO and TQ recorded by the second channel were eluted at 10.5 and 52.0 min, respectively. Widicus and Kirk (20) have reported the separation of TO and TQ by normal-phase HPLC, however, these compounds were closely eluted. The rest of the TOP, therefore, do not separate well in this system. In the present method, the elution time is about 40 min between TO and TQ, thus the TOP can separate very well.

Calibration curves. Calibration curves, prepared by injection of 50 μl working solutions, were obtained by measuring the peak height response (Figs. 2 and 3). The relationships of peak heights to the amounts injected under these conditions were linear in the tested range. The following linear regression equations were obtained: Y = 4438X + 125, α-T; Y = 8831X + 105, TO; Y = 33878X + 0.99, TQ; Y = 6312X − 251, DHD; Y = 4768X + 570, D; and Y = 500X + 20, T. Correlation coefficients were found to be greater than 0.999 for each compound. Correlations of peak areas to the amounts injected also were calculated but no differences were found in comparison

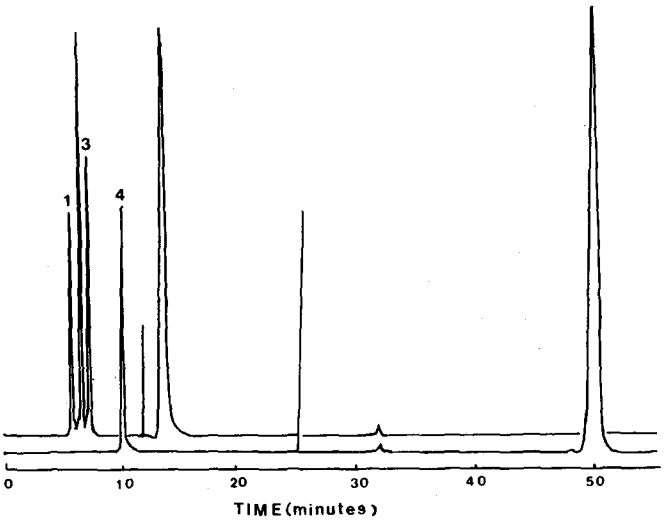

FIG. 1. Elution profile of α-tocopherol and its oxidation products on a 5-μm Ultrasphere-Si, 250 mm × 4.6 mm (i.d.). Peaks identification: trimer (1); dimer (2), dihydroxy dimer (3); 9-methoxy-α-tocopherone (4); α-tocopherol (5); α-tocopheryl quinone (6). Conditions: mobile phase, hexane/chloroform/isopropanol (95:4.5:0.5, v/v/v); flow rate, 0.4 ml/min; detector with 295 nm for trimer, dimer and dihydroxy dimer, 292 nm for α-tocopherol, 240 nm for tocopherone and 268 nm for α-tocopheryl quinone; and attenuation at 0.05 AUFS.

FIG. 2. Calibration curves for high performance liquid chromatography of α-tocopherol (■—■), α-tocopheryl quinone (●—●) and 9-methoxy-α-tocopherone (O—O) on a 5-μm Ultrasphere-Si, 250 × 4.6 mm (i.d.). Data points represent the means of triplicate sample measurements; SEM was less than data point.

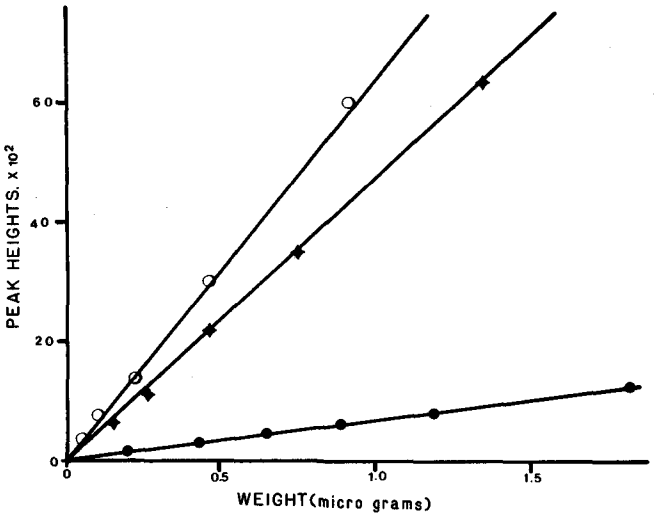

FIG. 3. Calibration curves for high-performance liquid chromatography of dihydroxy dimer (■—■), dimer (●—●), and trimer (○—○) on a 5-μm Ultrasphere-Si, 250 × 4.6 mm (i.d.). Data points represent the means of triplicate sample measurements; SEM was less than data point.

to peak heights. The lowest amounts detected by these newly developed normal-phase HPLC method were 0.01 μg for α-T, TQ and TO; 0.05 μg for DHD and D; and 0.1 μg for T/injection.

In summary, α-T, TQ, DHD, D, T and TO simultaneously were separated on a Ultrasphere-Si column using a mobile phase of hexane/chloroform/isopropanol (95:4.5:0.5, v/v/v). This new normal-phase HPLC method has the following advantages compared to the previously published methods: the simultaneous separation of α-T and five TOP by a single chromatographic run, much higher sensitivity, and relatively longer retention time between TO and TQ ensuring good separation of TOP.

Microcomputer-based System for Data Acquisition and Analysis of Oxygen Uptake Studies

E.G. Schanus*, G.O. Caviness, J.L. Kahl and I.W. Herrick
Department of Food Science and Human Nutrition, Washington State University, Pullman, Washington 99164-6330

The use of a Warburg Respirometer to study oxidation reactions is tedious and time-consuming. A microcomputer-based oxygen uptake device that is more sensitive than a Warburg Respirometer is described. The device consists of stainless steel or Teflon reaction vessels coupled to ultrasensitive pressure transducers. A high speed analog to digital convertor is used to poll the transducers. The direct memory access (DMA) controller of an IBM XT is used to poll the convertor and store the data in memory. Software used to program the DMA controller and IBM XT is described. The reproducibility and utility of the device is demonstrated with a brief study of lipid oxidation.
Lipids 23, 362-366 (1988).

The majority of the studies of oxidation of lipids in food and other biological systems entail monitoring the concentration of byproducts of the oxidation reaction. Compounds such as thiobarbituric reacting substances, conjugated dienes and volatiles classically are determined and correlated to the degree of oxidation (1). A more direct approach to evaluating the degree of oxidation in a food system is continuous determination of the rate of oxygen uptake. Assessment of oxygen uptake is faster and results in an accurate evaluation of oxidation in food systems. The Warburg Respirometer has been used in many classical studies of lipid oxidation in model food systems to monitor oxygen uptake during oxidation reactions (2–5) and is sensitive and accurately reflects the degree of oxidation in food systems. However, the major disadvantage of the Warburg Respirometer is that the change in pressure must be determined manually at appropriate intervals. This is tedious, time-consuming and results in collections of few data points over a long period of time. The purpose of this research was to develop, assemble and program a microcomputer–based device modeled after a Warburg Respirometer. The advantages of this device would be increased sensitivity, accuracy and resolution and be less labor-intensive.

MATERIALS AND METHODS

Reaction vessel. The reaction vessel in which the oxidation reactions take place was fabricated from 303 stainless steel. Figure 1 shows the basic design of the vessel. The volumes of the vessels were determined using standard Warburg Respirometer methods (6).

Pressure transducers. Low range pressure transducers (Setra Systems, Acton, MA, Model 239, ± 1 PSID) were fitted to the vessel to monitor pressure changes during oxidation.

Analog to digital convertor. An IBM XT compatible single board analog and digital input/output system (Data Translations, Marlboro, MA, Model DT2801/5714) was used to poll and convert the analog output from the transducers to a digital signal. A screw terminal and signal conditioning panel (Data Translations, Model DT707) was used to connect the transducers to the analog board. No signal conditioning is required with this A/D configuration.

Computer. An IBM XT, (IBM Inc., Boca Raton, FL, 10 Megabyte hard disk, 8087 math coprocessor, and color graphics adapter) and SixPacPlus (AST Research, Inc., Irvine, CA, 384K random access memory [RAM]) were used to acquire and process the data. An assembler (Microsoft, Corp., Redmond, WA, Macroassembler Version 4.0) and IBM Pascal compiler (IBM Inc., version 2.0) were used to compile the software.

Miscellaneous electronic components. A 60 Hz power line-driven clock was assembled to drive the A/D

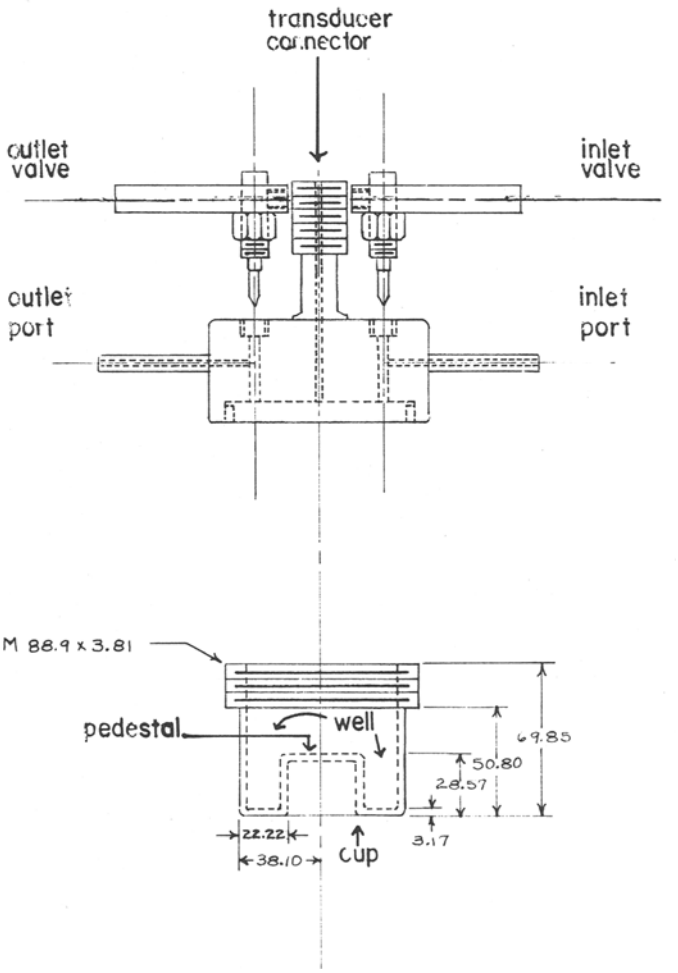

FIG. 1. Engineering details of reaction vessels.

Abbreviations: CPU, central processing unit; DMA, direct memory access; RH, relative humidities.

convertor. A conventional regulated 24 volt DC power supply was used to drive the transducers. A standard pi filter was used to filter the input AC voltage for the clock, power supply and IBM XT.

Oxygen uptake experiment. The reproducibility of the device was evaluated by measuring the rate of oxygen uptake of a thin film of methyl linoleate equilibrated at two different relative humidities (RH). Three mg of methyl linoleate were spread on a 22 mm glass coverslip, placed in the reaction vessel and the vessel flushed with humidified oxygen. The inlet and outlet ports of the vessel were sealed, and oxygen consumption was monitored at 37 C for 48 hr. The data acquisition rate was set at one min.

RESULTS AND DISCUSSION

Reaction vessel. The reaction vessel used in this system was modeled after a glass Warburg flask. The stainless steel cylindrical vessel had a slightly larger volume than a Warburg Flask; however, the volume was kept as small as possible to increase the sensitivity of the apparatus (Fig. 1). The vessel contained a pedestal in the center of the cup to support a 22 mm cover slip above a reservoir that could be used to contain saturated salt solutions to control the relative humidity in the vessel. The sample was placed on a 22 mm circular glass cover slip and placed on the pedestal. The cover of the vessel has two Teflon-seated needle valves to facilitate flushing the system with air or other gases.

Glass vessels eliminate the possibility of corrosion by the salt solutions; however, the connection of metal transducers to glass vessels was not possible. Teflon reaction vessels also eliminate the possibility of corrosion and increase the utility of the system. A Teflon vessel without a pedestal would allow for magnetic stirring, and the system could be used for aqueous biological experiments. However, to assure there would be no change in volume with a change in pressure, the walls of a Teflon cup would have to be thick, and the poor heat transfer in Teflon results in a longer thermal equilibration time.

Pressure transducers. Of the transducers evaluated, only one met all of criteria set for the device. The Setra System Model 239 accurately senses a change in pressure as small as 1/100,000 of an atmosphere, 10 times more sensitive than the Warburg Respirometer (7). The transducer connects directly to the reaction vessels, increasing mobility, eliminating dead volume and the possibility of leaks at couplings and joints. Each transducer weighs eight oz and was supplied with an eight-foot cable, which gives greater mobility. The transducer is resistant to oxygen and other corrosive gases used in experiments, has an internal volume of 0.03 c in, has voltage regulation and thermal compensation circuitry allowing for operation at different temperatures.

The only disadvantage is that this transducer is a differential pressure sensor that necessitates the use of a thermobarometer. An absolute pressure sensor would be preferable and eliminate the need for a thermobarometer. An absolute pressure transducer that met the sensitivity requirements was not available, and therefore the differential transducer was selected.

Analog to digital convertor. The primary concern in selecting an analog to digital (A/D) convertor was matching the sensitivity of the convertor to the transducer. A 14-bit convertor discriminates one part in 120,000 of an atmosphere with this device. Other considerations were minimum eight channel differential inputs, complete software programmability, Direct Memory Access (DMA) data transfer capability, and programmable gain compatible with the pressure transducers.

A single board IBM XT compatible A/D convertor was chosen over a free–standing data logger because a single board unit was more cost effective. The IBM personal computer with a memory expansion unit has more than adequate memory to store the data. If the convertor has DMA capabilities, the microcomputer can be used to perform other tasks simultaneously with data acquisition and for considerably less cost than most data loggers.

Miscellaneous electronic components. The DT2801/5714 convertor has an internal programmable clock for periods of 5 μsec to 0.1638 sec. To allow for slower data acquisition, an external clock was assembled and used in place of the on-board clock. The period of external clock ranged from 0.2 to 6553 sec.

Figure 2 shows a schematic diagram of the complete oxygen uptake device. Up to eight transducers can be connected and monitored with the A/D convertor. The clock triggers the convertor to poll each transducer sequentially. The converted digital number is then output to a register and read by the microcomputer.

Software. The software necessary for data acquisition with a microcomputer is available widely in

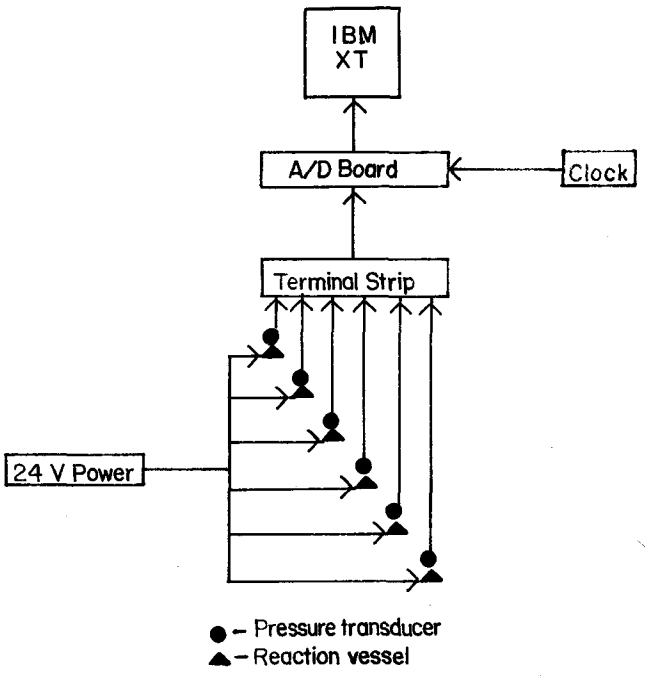

FIG. 2. Schematic drawing of complete oxygen uptake device.

varied price ranges. Because of the special capabilities on this system, special software was written. Several important factors were considered in writing the software for the device. The main goal in writing the software was not to dedicate the microcomputer solely to data acquisition. The microcomputer had to be multipurpose, available to perform other tasks such as data analysis simultaneous with data acquisition. The IBM PC and XT are capable of operation in the foreground/background mode.

The basic principle in running a microcomputer in the foreground/background mode is to use the 8237A-5 DMA controller in the IBM microcomputer for high-speed data transfers between the convertor and memory without processor intervention. Because the central processing unit (CPU) of the computer is not used during these operations, other processing can occur simultaneously. The DMA controller of the IBM microcomputers is user-accessible and can be programmed to acquire data from the convertor and transfer it to random access memory (RAM).

Programming the A/D convertor is done by sending commands to the appropriate register of the convertor. The registers and commands are specific for each convertor and generally explained in the documentation for specific convertors. Once the convertor is programmed and ready for the data acquisition, the DMA controller must be programmed and started before the convertor is started. Programming the DMA controller is similar to programming the convertor.

The DMA controller has four channels. One channel refreshes memory every 840 ns. Another channel is used to transfer data between memory and floppy disk drives, and if the microcomputer has a hard disk drive a third channel is used to transfer data from memory to hard disk. Therefore, an IBM PC has DMA channels 1 and 3 available for data acquisition while an XT only has channel 1 available. IBM (8) has a description of the 8237A-5 DMA controller.

The programming of the DMA controller was done with a Pascal procedure. First, channel 1 is initialized to read data from a peripheral device and write to memory in the autoinitialize mode. The autoinitialize mode is a continuous read from a device with no set number of bytes to be read. Next, the absolute address of data storage is sent to the controller. Several excellent books (9,10) or other computer texts give a detailed explanation of the segment and offset address system used by the IBM microcomputers. The data will be placed in memory starting at base address 0.

The controller is programmed to run in the autoinitialize mode. The controller will read continuously and write the data starting at base address 0, and automatically increment the base address for each byte read. The highest base address is 65535 or FFFFh, the maximum number of bytes the DMA controller can place in memory. After reading FFFFh bytes, the controller reinitializes and places data at memory base address 0. The result is that the controller will write over the existing data starting at address 0. This is a limitation of the computer and cannot be changed.

The remainder of the absolute memory address, segment or page is sent to the controller. The IBM PC/XT has 16 pages of 65536 bytes or 1,048,576 bytes of addressable memory. Some of these pages are reserved for special functions, such as video buffers and read only memory. Ten pages or ca. 640,000 bytes are available for storing data. Because the software must allow for the simultaneous data acquisition and use of the CPU for running other programs, memory must be reserved for both functions. Greater than 95% of computer software evaluated including the data analysis program used by this device used a maximum of four pages of memory. Four pages of memory were reserved for these programs, and six pages or approximately 400,000 bytes were reserved for data acquisition. The absolute requirement for memory during data acquisition is 64K bytes. The additional memory is used as storage of raw data prior to processing. There is more than adequate unused memory available under most conditions in a microcomputer, making a data logger unnecessary for data acquisition. Furthermore, the RAM of IBM microcomputers can be expanded to more than 8 mill. bytes by the addition of one or more Enhanced Expanded Memory System boards. Pages 4 through 9 were used for data acquisition. Before specifying the page address, the memory usage of commonly used programs should be evaluated. There are many programs available to evaluate memory usage. The authors can supply a program that performs this task.

The programmed DMA controller is started by sending the enable command. The final step is to start the programmed A/D convertor. The convertor is enabled to read continuously using the DMA controller and the external clock.

After starting both the convertor and controller, data acquisition is independent of the CPU, and the computer program used to program the controller and convertor can be terminated without affecting data acquisition. Other programs such as word processors, spreadsheets and data bases, if they do not use the memory locations specified for data acquisition, can be started and used simultaneously with data acquisition. The major disadvantage of running in the foreground/background mode is that data acquisition is free running and is not under the control of the CPU. It is not possible to modify the programming of either the controller or convertor without stopping all data acquisition.

It would be convenient to be able to add another channel for data acquisition without stopping all of the channels. This is not possible in the foreground/background mode. This problem was overcome by running all channels, whether a specific channel was being used to run an experiment or not. A new channel, one that currently is running but collecting useless data, is added by loading the reaction vessel of the channel and injecting a positive voltage spike from a 1.5 V battery to signify the start of the experiment or a negative spike to signify the end of the experiment. When the data is analyzed, data before a positive spike and after a negative spike is discarded and only experimental data is saved.

A Pascal program was used to retrieve and analyze data. The flowchart of the program is shown in Fig-

ure 3. The first part of the program polls the DMA controller to determine the number of bytes read. Second, the data is retrieved from RAM. The page number is entered by the user with the keyboard. The base address is always 0. Because the data is stored sequentially in RAM by the DMA controller, only the starting address is required and the base address is incremented by one after reading a byte. A data point consists of two bytes representing a 14-bit number. The data point is converted to a word, then integer, then real4 and finally converted to a voltage, pressure or concentration.

The data point is stored in the long heap using pointers. The data cannot be stored in variable arrays because the data segment of most interpreters and compilers is limited to 65536 bytes, which usually is exceeded in an experimental run. Therefore, the long heap was used temporarily to store the data until output to a disk. It is beyond the scope of this article to discuss the use of the long heap and pointers. There are several excellent books on the Pascal language (10,11). General data maintenance such as discarding nonsense bytes before or after a start/stop voltage spike are performed. The data can be analyzed further by linear or curvilinear least squares or other functions or stored on a disk in a format compatible with commonly used spread sheet or graphic programs. All functions can be performed simultaneously with data acquisition.

Although these programs are specific for the Data Translations A/D convertor and IBM XT, they can be modified to be used with other hardware. However, after modification they must be compiled with a IBM/Microsoft Pascal or other compatible compiler.[1]

Oxygen uptake experiment. To demonstrate the reproducibility of the device, the oxidation rates of thin films of methyl linoleate were determined. Figure 4 shows the change in oxygen pressure versus time for a typical uptake experiment. The initial nonlinearity in the uptake rate is due to thermal equilibration and is dependent on technique. Keeping the vessel at the

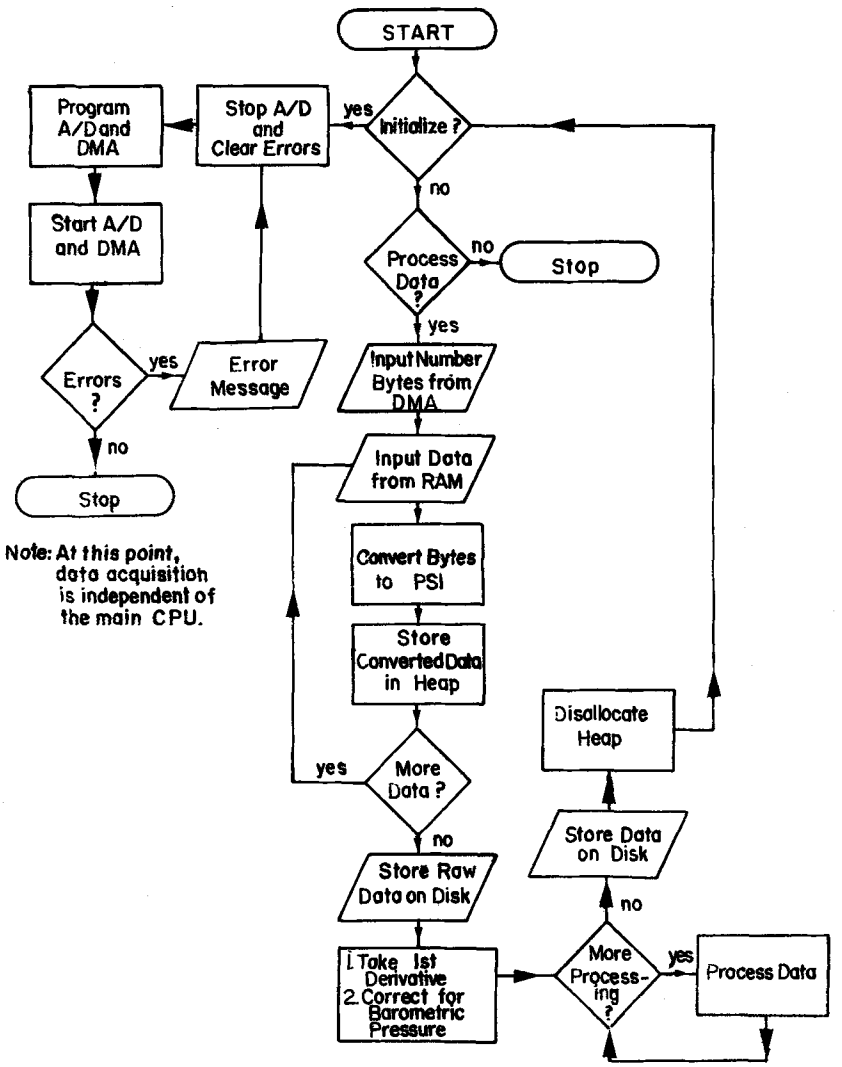

FIG. 3. Flow chart of data acquisition and analysis software.

[1]Copies of the data acquisition software and other utility programs can be obtained from the Department of Food Science and Human Nutrition, Washington State University, Pullman, WA 99164-6330, by submitting $5 to cover shipping and handling costs.

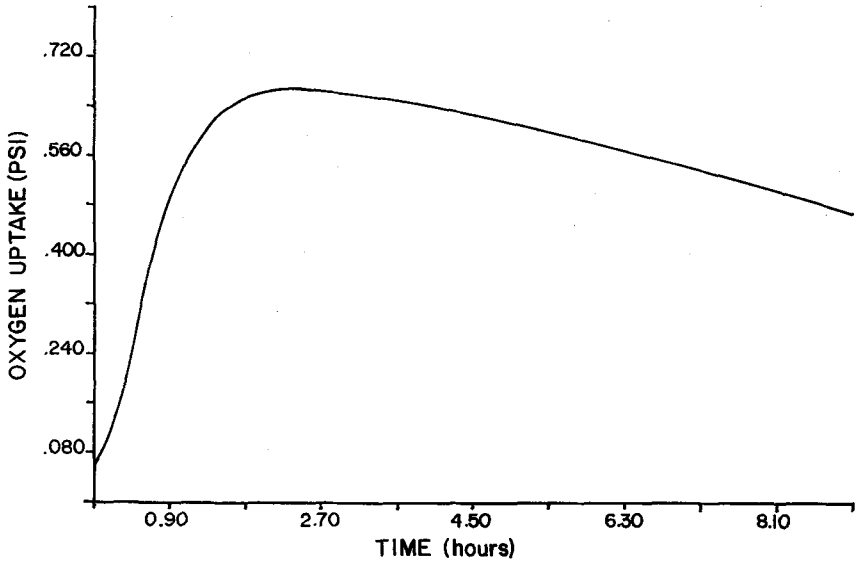

FIG. 4. Graph of change in oxygen pressure vs time of an oxidizing thin film of methyl linoleate.

experimental temperature during loading appreciably shortens the thermal equilibrium time. Thermal equilibrium and linearity in uptake rate usually is obtained within two hr. The use of differential pressure transducers necessitates the use of a thermobarometer. The transducers sense changes in barometric pressure, and the raw data must be corrected for these changes. A sealed empty vessel is used to obtain barometric pressure changes, which are subtracted from the raw data by the computer program used to retrieve data from memory.

The oxygen uptake rate was determined by linear least squares analysis of the linear portion of the curve. The oxygen uptake rates for thin films of methyl linoleate at two different relative humidities is shown in Table 1. The reproducibility of the runs is ca. 2–3%.

TABLE 1

Oxygen Uptake Rates by Thin Films of Methyl Linoleate at Different Relative Humidities

Relative humidity (%)	N	Oxygen uptake rate[a] (μmoles O_2/1 hr/mg Lipid)
0.0	4	.1041 ± 0.0032
50	11	.1727 ± 0.0030

[a]Plus or minus standard error of the mean.

In conclusion, the microcomputer-based oxygen uptake device has marked advantages over a Warburg Respirometer. The device is 10 times more sensitive and is more reproducible than the Warburg. The use of a microcomputer obviates the need for manual reading of the manometer and data entry into a computer. The computer is not dedicated to data acquisition because the computer is operated in the foreground/background mode. The result is that the computer can be used for data analysis, word processing or most other software simultaneous with data acquisition.

The Use of a Microwave Oven in the Chemical Transformation of Long Chain Fatty Acid Esters

Marcel S.F. Lie Ken Jie* and **Cheung Yan-Kit**
Department of Chemistry, University of Hong Kong, Pokfulam Road, Hong Kong

The use of a microwave oven as an energy source allowed transformation of fatty acid derivatives to be complete in a few minutes. Hydrolysis of triglycerides, esterification of free fatty acids, epoxidation of unsaturated fatty acid esters, cyclization of dioxostearates and oxounsaturated fatty acid esters into furanoid derivatives, conversion of epoxystearate to oxostearate derivatives, and substitution of a tosyl group by an azide all took about five min to complete and were in very high yields. The most sluggish reaction encountered was the acid catalyzed hydrolysis (ring opening) reaction of a furanoid ester to the corresponding 1,4-dioxo derivative, which required three 10-min periods of heating. The use of microwaves not only decreased the reaction time considerably but also allowed smaller volumes of solvent and lower quantities of reagents to be used as compared with the conventional methodologies reported.
Lipids 23, 367-369 (1988).

Microwaves are used extensively for telecommunication, industrial processes and biomedical applications (1,2). In research laboratories, microwave spectroscopy forms a powerful analytical technique for the determination of dipole moments in molecules and also in the study of internuclear distances and bond angles in certain molecules, in which changes in structural features hardly are observable by other methods (3). More recently, the use of microwave ovens in organic synthesis has been reported to reduce considerably the reaction time of an array of classical organic reactions (4,5). Here, we present results of a study of thermal reactions involving long chain fatty acid esters that normally would require many hours of heating or stirring at room temperature.

METHODS

A Sharp microwave oven, model R7370, 650 W, microwave frequency 2450 MHz, was used with a low setting. Reagents, substrates and solvents were placed in an autoclavable thick-walled, screw-capped pyrex test tube (20 ml). The charged test tube was embedded in vermiculite (a porous absorbant used as packing material for shipment of liquid chemicals) contained in a rectangular box (8 × 8 × 18 cm) designed with a beveled sliding lid and made of high-heat resistant Corian polymer (0.6 cm thickness, Dupont Inc., Wilmington, DE) provided by the Noland Co. The box was obtained through R. J. Giguere of the Department of Chemistry, Mercer University, Macon, GA. The box containing the reaction vessel was placed on the revolving dish of the microwave oven and irradiated for 1-10 min. After irradiation, the system was allowed to cool for five min inside the oven with the door opened. The plastic box then was removed to a fume hood, and the lid opened to allow further cooling for another five min. The product subsequently was isolated, purified and identified by methods described in the references in Table 1.

RESULTS AND DISCUSSION

Epoxidation of unsaturated fatty acid esters. When samples of methyl oleate were heated with *meta*-chloroperbenzoic acid in dichloromethane in a microwave oven for three and five min, respectively, gas liquid chromatography (GLC) analysis of the reaction products showed 93.6 and 98.8% conversion of the unsaturated substrate into the corresponding epoxy derivate. Thin layer chromatography (TLC) analysis of the reaaction product obtained from treatment of methyl linoleate for five min under similar conditions indicated a 100% conversion into the diepoxy derivative (methyl 9,10;12,13-diepoxystearate decomposed on GLC analysis). Methyl ricinoleate readily was converted in five min to methyl 12-hydroxy-*cis*-9,10-epoxystearate as shown by TLC analysis. The latter reaction furnished 82.5% of the product upon isolation.

Formation of C18 furanoid esters. When a mixture of methyl 12-oxo-*cis*-9-octadecenoate (obtained by oxidation of methyl ricinoleate) was heated for five min with mercuric acetate in acetic acid, 81.5% of the furanoid ester (methyl 9,12-epoxy-9,11-octadecadienoate) was obtained. A repeat reaction showed that a 97.3% conversion was attained after seven min of microwave heating. Two positional C18 furanoid fatty acid derivatives were obtained when methyl 9,10;12,13-diepoxystearate that was dissolved in a mixture of propyl iodide, sodium iodide and dimethylsulfoxide was subjected to microwave heating for five min. TLC analysis of the product showed complete transformation of the diepoxy substrate to the furanoid derivatives. Isolation of the product allowed 87.9% of the furanoid esters to be recovered. It appeared that not only did microwave treatment provide the thermal energy for the reaction, but since the reactions were carried out in sealed test tubes the pressure generated by the evaporating solvent also increased the reaction rates of these reactions.

Hydrolysis of triglycerides and esterification of free fatty acids. Hydrolysis of castor oil in the presence of KOH in ethanol and esterification of a sample of free fatty acid with 2% sulfuric acid in absolute methanol required only five min to complete. In both reactions, no double bond migration was observed, and no other by-products were produced.

Miscellaneous reactions involving fatty acid ester derivatives. The reaction of methyl *cis*-9,10-epoxystearate with a mixture of propyl iodide, sodium iodide and dimethylsulfoxide gave a mixture of methyl 9- and 10-

oxostearates (72.4%) in five min. In a bimolecular nucleophilic substitution reaction of a tosyl group by azide, methyl 12-azido-*cis*-9-octadecenoate was obtained in 85.7% yield after five min from microwave treatment of methyl 12-tosyl-*cis*-9-octadecenoate with sodium azide in dimethylacetamide. The most sluggish reaction involving long chain fatty acid esters was found in the ring opening (acid-catalyzed hydrolysis) of a C18 furanoid fatty acid derivative with aqueous sulfuric acid in methanol. When the reaction mixture was heated in the microwave oven for 10 min, only 57% of methyl 9,12-dioxostearate was obtained. Upon reheating the cooled reaction mixture for another 10 min, the yield increased to 86%. Only when the reaction mixture was heated for another 10-min period was the conversion of the furanoid ester to the dioxo derivative complete. It was found necessary to heat the sealed test tube for periods not exceeding 10 min to prevent the reaction vessel from exploding, hence, the need to cool and reheat the reaction mixture after each 10-min microwave treatment.

The use of the microwave oven as a source of energy demonstrates the large savings in reaction time to the researcher. Beside obtaining high yields for these reactions, further savings were made by the use of much smaller volumes of solvents and lesser amounts of reagents per equivalent of substrate. While it appeared that most reactions seemed to benefit from this technique, we were unable to control the tosylation reaction of methyl ricinoleate with tosyl chloride. On heating of a mixture of tosyl chloride, methyl ricinoleate and dichloromethane, the analysis of the reaction product revealed an array of polar and nonpolar material. This reaction currently is being investigated further to identify the various products formed because tosylation of methyl ricinoleate was achieved readily without any heating when left at room temperature overnight.

Malondialdehyde Excretion by Subjects Consuming Cod Liver Oil vs a Concentrate of n-3 Fatty Acids

L.A. Piché, H.H. Draper* and P.D. Cole
Department of Nutritional Sciences, University of Guelph, Guelph, Ontario, Canada N1G 2W1

Urinary malondialdehyde (MDA), an indicator of lipid peroxidation in the diet and in the tissues, was determined in human adults consuming a supplement of n-3 fatty acids derived from a pharmaceutical grade of cod liver oil (CLO) without added antioxidants vs a concentrate of n-3 acids containing dodecyl gallate and vitamin E. MDA excretion increased immediately in the subjects consuming CLO but remained unchanged in those ingesting the concentrate for 50 days. The increase in the subjects taking CLO was attributable to MDA in the oil. The results indicate that consuming unstabilized fish oils as a source of n-3 fatty acids may entail exposure to potentially toxic products of lipid peroxidation.
Lipids 23, 370–371 (1988).

Fish oils and concentrates of n-3 fatty acids from fish oils have been widely promoted for the prevention of heart attacks. In as much as feeding fish oils is a classical method of inducing vitamin E deficiency in experimental animals, the question arises whether long-term ingestion of such oils may jeopardize the vitamin E status of humans. Long-term feeding of cod liver oil (CLO) to rats results in a significantly greater excretion of malondialdehyde (MDA) in the urine after a subsequent fast than is seen in rats fed corn oil, indicating an increase in peroxidation of fatty acids in vivo (1). This increase is inhibited partially but not entirely by feeding a high level of dietary antioxidants.

The possible presence in fish oils of peroxides and their degradation products including malondialdehyde, a mutagen (2) and reported carcinogen (3), is a further consideration in their long-term ingestion. Feeding a diet containing CLO to rats results in an immediate, marked increase in urinary MDA, reflecting a high level of this compound in the diet (4). MDA excretion in humans has been reported to increase following a meal of rancid foods (5).

In this study, the effect on MDA excretion by human adults of ingesting a commercial CLO product without added antioxidants vs a commercial fish oil concentrate containing a mixture of antioxidants was investigated.

METHODS

Experiment 1. Six adults consumed 30 ml of CLO (10 ml with each meal) for 14 days in conjunction with a free choice diet. The oil was a pharmaceutical product (Life Brand, Shoppers Drug Mart, Toronto, Ontario), labeled as a "natural source" containing no preservatives. On the basis of its reported content of eicosapentaenoic and docosahexaenoic acids (6% each) (6), this product provided about 1.5 g of each acid per day. After being opened, the bottles were kept at 4 C. Morning urine samples, one collected on the day before CLO ingestion began and the other on the last day of ingestion, were analyzed for MDA by the high performance liquid chromatography (HPLC) method of Draper et al. (1).

Experiment 2. Seven adults consumed a low-MDA diet (i.e. one devoid of meats and high-fat foods) and abstained from alcoholic beverages for three days, during which time consecutive morning urine samples were collected. For a further three days they consumed 30 ml of CLO, as in Experiment 1, in conjunction with a low-MDA diet, and three additional morning urine samples were collected for MDA analysis.

Experiment 3. Seven adults consumed 10 capsules per day of a concentrate of n-3 acids from fish oil (MaxEPA, Seven Seas Health Care Ltd., Kingston-upon-Hull, U.K.) for 50 days. The gelatin-coated capsules contained 100 ppm dodecyl gallate and provided 1.9 g eicosapentaenoic acid, 1.2 g docosahexaenoic acid and 10 IU of dl-α-tocopheryl acetate per day. Two consecutive 24-hr urine samples were obtained for MDA analysis immediately before supplementation began and on days 49 and 50. One day before and during each urine collection period, the subjects consumed a low-MDA diet.

RESULTS AND DISCUSSION

In Experiment 1, ingestion of CLO was associated with an increase in MDA excretion in all six subjects (Table 1). The mean increase of 37.5%, from 24.5 ± 3.5 μg to 34.7 ± 2.5 μg MDA (mean ± SEM), was significant ($P < 0.01$) using a two-tailed paired t-test.

In Experiment 2, CLO ingestion again was associated with an increase in MDA excretion in all subjects (Table 2). The mean increase of 54.3%, from 31.7 μg to 49.1 μg MDA/sample was highly significant ($P < 0.001$).

MDA excretion was unaffected by MaxEPA ingestion. Urinary MDA was 148 ± 15 μg/24 hr before

MaxEPA consumption and 139 ± 15 μg/24 hr after its consumption for 49–50 days (Table 3). This finding indicates that the fish oil concentrate was not a significant source of MDA in the diet or of MDA generated as a result of enrichment of the tissues with fatty acids of the n-3 series. It further indicates that the increase in MDA excretion seen during consumption of CLO was due to MDA present in the oil. Repeated extraction of a solution of CLO in hexane with 10% $NaHCO_3$ solution yielded sustained amounts of MDA, showing that the oil was undergoing continuous oxidative decomposition and further indicating that it was the source of the increase in MDA in the urine of the subjects consuming this product.

The proportion of ingested MDA excreted in the urine by humans is unknown but, judging from the results of studies on animals, it probably is small. Following stomach intubation with ^{14}C-MDA, rats excreted about 10% more ^{14}C in the urine than after intubation with ^{14}C-acetate (7). Sixty to 70% of the radioactivity was recovered in expired $^{14}CO_2$ within 12 hr.

Protracted consumption of n-3 fatty acids must be presumed to increase the vitamin E requirement. There is a need not only for an antioxidant capable of stabilizing these acids during storage but for a biologically active antioxidant capable of preventing their oxidation in vivo. Whether the normal diet provides enough vitamin E to meet the additional need for a biologically active antioxidant arising from consumption of n-3 fatty acids in unsupplemented fish oils is problematical. The results of this study indicate that the amounts of antioxidants present in MaxEPA are sufficient to suppress the oxidation of n-3 fatty acids in this product both in the capsules and in the tissues. They further indicate that ingestion of unstabilized fish oils entails a risk of exposure to potentially toxic products of n-3 fatty acid peroxidation. This is a particular consideration in jurisdictions, such as Canada, where the use of concentrates of n-3 fatty acids currently is prohibited.

Differential Utilization of Long Chain Fatty Acids During Triacylglycerol Depletion. II. Rat Liver After Starvation

S.C. Cunnane*
Efamol Research Institute, Kentville, Nova Scotia, Canada B4N 4H8

Rats starved for 96 hr were shown to have a 94% reduction in liver triacylglycerol. Among the long chain fatty acids in liver triacylglycerol, only stearic acid and arachidonic acid were proportionally increased (2.5 and 6 times, respectively); palmitic and linoleic acids were unchanged, and palmitoleic and oleic acids were proportionally decreased. Stearic and arachidonic acids (mg%) were correlated positively within the triacylglycerol fraction, and both fatty acids varied inversely with total triacylglycerol (mg/g) in fed and starved rats. The utilization of long chain fatty acids from liver triacylglycerol during starvation resulted in selective retention of arachidonic acid and stearic acid and suggests that differential hydrolysis of liver triacylglycerol by hepatic lipase may occur or selective reacylation of these specific fatty acids may occur during starvation.
Lipids 23, 372–374 (1988).

The composition of arachidonic acid (20:4n-6, mg%) in rat liver triacylglycerol (TG) varies widely depending on the nutritional state of the animal (1). In liver and plasma, this variability has recently been shown to be a function of the total TG in liver or plasma (2,3); in starvation, low liver TG is associated with a higher proportion of 20:4n-6 in TG (4) and, in fatty liver syndromes, the reverse is seen (1,2). Although the proportional composition of 20:4n-6 in TG shows a significant inverse correlation with the total TG in individual animals within a species, the absolute composition of 20:4n-6 (μg/g tissue, μg/ml plasma) derived from TG is similar between individual animals. Hence, there is stability in the quantitative pool of 20:4n-6 in liver and plasma TG (2). With the exception of stearic acid (18:0), the apparent stability of the 20:4n-6 pool in TG is unique in comparison with 16- and 18-carbon fatty acids including linoleic acid (18:2n-6), which show no significant relation (positive or negative) with total TG or phospholipid in liver or plasma (2). This study has sought to determine whether, during starvation-induced depletion of liver TG, certain long chain fatty acids are utilized selectively while others, e.g. 20:4n-6, may be retained selectively in the TG.

EXPERIMENTAL

Twenty-four male Sprague-Dawley rats (200–250 g) were housed individually in polypropylene cages (Nalgene). They were fed a semi-synthetic diet of the recommended nutrient content: 20% casein, 50.5% sucrose, 15% cellulose, 10% corn oil (54% linoleic acid), 3.5% AIN-76 mineral mix and 1% AIN-76A vitamin mix (5). This diet was available for four wk along with distilled water given ad libitum. Food intake was determined once a week during this period (mean ± SD, 3.2 ± 0.7 g/100 g/day). Sixteen rats then were starved for 96 hr; eight rats continued to receive food ad libitum. The rats then were anesthetized with ether and the livers excised, blotted, weighed and frozen for lipid analysis.

The livers were homogenized in chloroform/methanol (2:1, v/v) containing 0.02% butylated hydroxytoluene as antioxidant. The TG component of the total lipid extract was separated by thin layer chromatography and transmethylated with boron trifluoride-methanol. The composition of the fatty acid methyl esters was determined by gas liquid chromatography (GLC) under the conditions specified (2). The quantitative content of TG in the liver was determined by GLC using triheptadecanoin as an internal standard that was added to the liver extract during homogenization.

Student's t-test was used for statistical evaluation of differences between groups.

RESULTS

The proportional composition of the major long chain fatty acids in the liver TG of fed and starved rats is shown in Figure 1. In comparison with fed rats, starved rats had a similar content (mg%) of palmitic acid (16:0) and

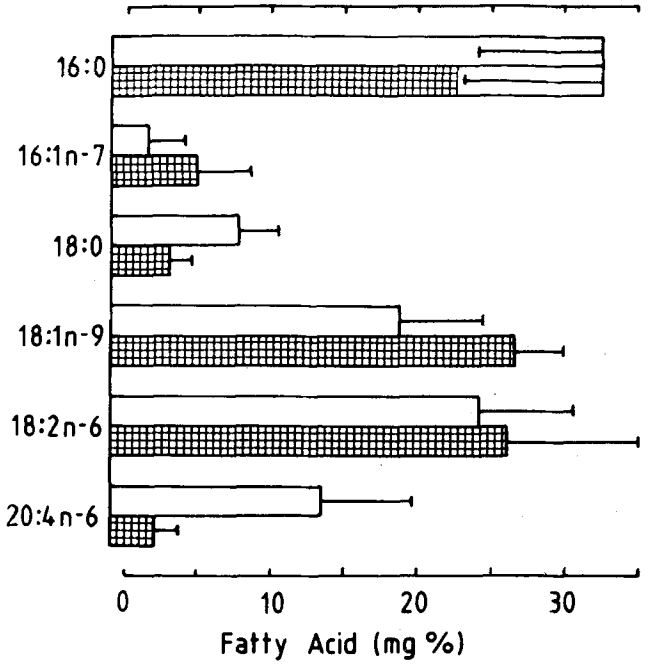

FIG. 1. Fatty acid composition (mean ± SD, mg%) of liver TG from 96-hr starved (open bar) or ad lib-fed (hatched bar) rats. In starved rats, palmitic acid (16:0) and linoleic acid (18:2n-6) were unchanged, palmitoleic acid (16:1n-7) and oleic acid (18:1n-9) were decreased ($p < 0.01$) and stearic acid (18:0) and arachidonic acid (20:4n-6) were increased ($p < 0.01$).

*To whom correspondence should be addressed at the Department of Nutritional Sciences, Faculty of Medicine, University of Toronto, Toronto, Canada M5S 1A8.

Abbreviations: GLC, gas liquid chromatography; TG, triacylglycerol; 16:0, palmitic acid; 16:1n-7, palmitoleic acid; 18:0, stearic acid; 18:1n-9, oleic acid; 18:2n-6, linoleic acid; 20:4n-6, arachidonic acid; 22:5n-3, docosapentaenoic acid; 22:6n-3, docosahexaenoic acid.

18:2n-6, a 29% reduction in oleic acid (18:1n-9, $p < 0.01$), a 67% reduction in palmitoleic acid (16:1n-7, $p < 0.01$), an increase in 18:0 of 157% ($p < 0.01$) and an increase in 20:4n-6 of 533% ($p < 0.01$). The total essential fatty acid content (18:2n-6 and 20:4n-6) of the liver TG was 25 mg% in the fed rats but was ca. 38 mg% in the starved rats (Fig. 1). Quantitation of the fatty acid data on a per g tissue basis (wet weight) showed that all the long chain fatty acids (16+ carbons) were decreased significantly in the liver TG of the starved compared with fed rats (Table 1). 16:0, 16:1n-7, 18:1n-9 and 18:2n-6 were present in the liver TG of the starved rats at <7% of their values in the fed rats, whereas 18:0 was present at 19% ($p < 0.01$) and 20:4n-6 at 34% ($p < 0.01$) of their respective values in the fed rats. The greatest difference between the starved and fed rats in the fatty acid composition (μg/g wet weight) of liver TG was in 16:1n-7 (−98%) and the smallest difference was in 20:4n-6 (−66%).

Only 20:4n-6 and 18:0 were proportionally higher in the liver TG of the starved compared with fed rats. To assess whether the relative retention of 20:4n-6 in the liver TG of the starved rats may have been related to that of 18:0, correlations were determined between these two fatty acids and total liver TG. Figure 2 shows that there was a significant inverse correlation between the total TG in liver and its content (mg%) of 18:0 and 20:4n-6. Hence, in fed rats (high liver TG) 20:4n-6 and 18:0 were both proportionally lower than in the starved rats (low liver TG). No other 16- or 18-carbon fatty acids were correlated significantly (positively or negatively) to the TG content of the livers of the starved or fed rats. In addition to being inversely correlated with total TG content, the proportional composition of 20:4n-6 and 18:0 was correlated positively (Fig. 3); in livers in which 20:4n-6 was low, 18:0 was also low and vice-versa. Interestingly, however, 20:4n-6 and 18:0 were not correlated in fed rats (high liver TG); they were only significantly correlated ($r = +0.70$, $p < 0.01$) in starved rats (low liver TG, Fig. 3).

TABLE 1

Absolute Composition of Long Chain Fatty Acids in Liver Triacylglycerol (TG) and Total TG of Fed or Starved Rats

Fatty acids	Ad lib fed[a]	96-Hr starved[b]	% Hydrolyzed
16:0	2000 ± 1607[c,d]	106 ± 70**	95

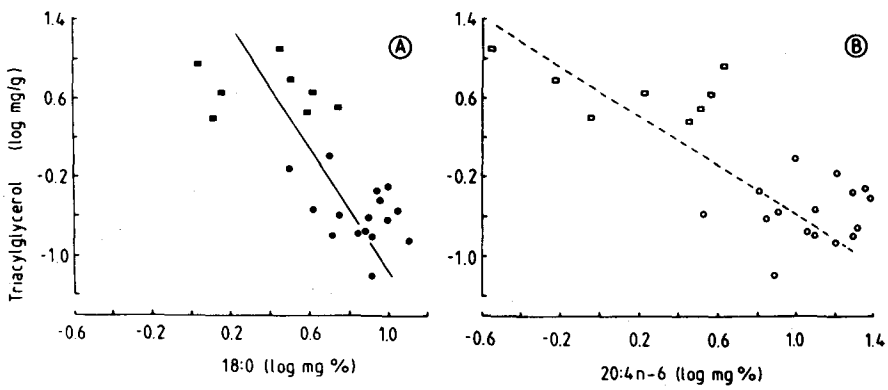

FIG. 2. Correlation regression analysis of the relation between liver TG (log mg/g) and its content of stearic acid (18:0, A; log mg%) and arachidonic acid (20:4n:6, B; log mg%) in ad lib-fed and 96-hr-starved rats. ■, stearic acid/fed; ●, stearic acid/starved; □, arachidonic acid/fed; ○, arachidonic acid/starved. Stearic acid − $r = -0.76$, $y = -0.34x + 0.66$, $p < 0.001$; Arachidonic acid − $r = -0.75$, $y = 0.96x + 0.58$, $p < 0.001$.

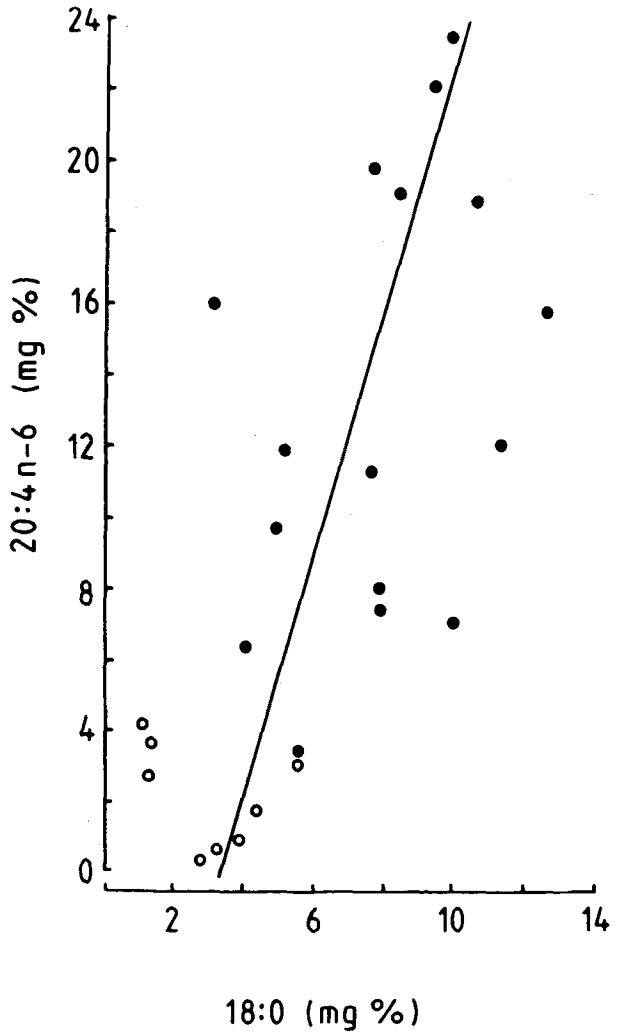

FIG. 3. Correlation regression analysis of the relation between the composition (mg%) of stearic acid and arachidonic acid in rat liver TG of 96-hr starved (●) and ad lib fed (○) rats: r = +0.65, y = 0.29x + 3.39, p < 0.001.

DISCUSSION

This study sought to establish whether the composition of long chain fatty acids in the total TG of the liver was altered differentially during starvation. The present data indicate that this is the case, particularly for 20:4n-6 and to a lesser extent for 18:0. As demonstrated (1-3), 20:4n-6 (mg%) also was found to be inversely correlated with total liver TG. Although the proportion of 20:4n-6 (mg%) was six times higher in starved vs fed rats, its absolute content was 66% less. 20:4n-6 is normally one of the smallest component fatty acids in liver TG of fed rats (1-2 mg%), but in the starved rats 20:4n-6 values of 20 mg% were not uncommon; 30 mg% have been observed previously (unpublished data). Hence, there was selective retention (on a proportional basis) of 20:4n-6 by rat liver TG during starvation.

These observations point to a marked differentiation between the proportional and absolute composition of 20:4n-6 in TG. It also is evident that long chain fatty acids are differentially hydrolyzed from liver TG or hydrolyzed and selectively reacylated during starvation with the following preference for hydrolysis: 16:1n-7 > 16:0 = 18:1n-9 = 18:2n-6 > 18:0 > 20:4n-6 (Table 1). The fact that net hydrolysis of 20:4n-6 was the least among these fatty acids would be expected in view of its unsaturation and chain length. The retention of 18:0 in the liver TG during starvation in amounts relatively greater than 18:1n-9 or 18:2n-6 was not expected. In view of the significant positive correlation between 20:4n-6 and 18:0 in the liver TG of the starved rats (Fig. 3), the proportional retention of 20:4n-6 and 18:0 may have been due to low specificity of the hepatic TG lipase for TG species containing 20:4n-6 and 18:0 or may have been due to net reacylation of these two fatty acids. These results are supported by a previous report showing that perfusion of intermediate density lipoproteins through the rat heart in vitro reduces their TG content by 60% (6). After perfusion, the percent composition of docosapentaenoic acid (22:5n-3) and docosahexaenoic acid (22:6n-3) in the TG of the lipoproteins was 2.2 times higher than before perfusion. It was concluded that differential hydrolysis of long chain fatty acids from lipoproteins by lipoprotein lipase occurs in the heart (6). These observations are analogous to the present TG data obtained from rat liver after starvation and suggest that TG depletion under various circumstances, e.g. from lipoproteins after perfusion through the heart (6), from endogenous stores in the perfused rat heart (7) or from rat liver during starvation (present data), results in selective retention not only of 20:4n-6 and possibly 22-carbon fatty acids but also of 18:0. The possibility that a significant proportion of 18:0 and 20:4n-6 are present in the same TG species in rat liver is currently being investigated.

Metabolism of 2(*RS*),3-Epiminosqualene to 24(*RS*),25-Epiminolanosterol by *Gibberella fujikuroi*

W. David Nes* and **Edward J. Parish**[1]
Plant and Fungal Lipid Group, Plant Physiology Research Unit, Richard Russell Research Center, USDA, Athens, GA 30613

The metabolic fate of 2*(RS)*,3-epiminosqualene (Isq.), a demonstrable inhibitor of the 2,3-oxidosqualene-lanosterol cyclase, has been studied in *Gibberella fujikuroi*. The fungus transforms Isq. to a tetracyclic product for which the 24*(RS)*,25-epiminolanosterol (EL) formulation was indicated by chromatographic and spectral data. The results are consistent with the pathway: Isq. → 2,3-imino-22, 23-oxidosqualene → EL.
Lipids 23, 375–376 (1988).

2,3-Epiminosqualene (Isq.) is a potent inhibitor of the enzymic cyclization of 2,3-oxidosqualene to sterols (1,2). This biochemical attribute has led to studies in which Isq. has been used to inhibit sterol biosynthesis in situ, thereby inhibiting fungal growth (3,4) and cell proliferation of cultured mammalian cells (5). Isq. also has been added to microsome preparations together with squalene analogues to assess the specificity of the enzymatically catalyzed epoxidation (6). The results described here show for the first time that Isq. is not a metabolically inert compound but may enter into the sterol pathway and undergo structural modifications analogous to squalene, viz. epoxidation and cyclization.

MATERIALS AND METHODS

Gibberella fujikuroi was incubated with 10 μg/ml Isq. for eight days as described (3). Authentic standards of Isq. and EL were prepared by the addition of iodine azide to the corresponding olefin (7). Mycelia undergoing growth adaptation were ground with sea sand and extracted overnight in a Soxhlet apparatus with refluxing acetone. The medium was extracted overnight with chloroform using a liquid-liquid apparatus. The mycelia and media extracts were monitored by thin layer chromatography (TLC) with the plates developed in solvent system I, benzene/ether, (9:1, v/v), and solvent system II, ethyl acetate/triethylamine, (99:1, v/v). The plates were sprayed with a 50% aq. H_2SO_4 solution and heated. R_f values for Isq. and EL in S.S.I and S.S.II were origin/origin and 0.42/0.25. Gas liquid chromatography (GLC) was performed with 3% SE-30 and 3% OV-17 packed columns operated isothermally at 245 C. Retention times were relative to cholesterol: RRT_c for Isq. and EL on the two columns was 0.80/0.70 and 2.63/3.21, respectively. Gas chromatography-mass spectrometry was performed using a 30 M DB-5 capillary column with the ion-source temperature for EI-MS maintained at 150 C. ^{1}HNMR was performed at 200 MHz as described (8). We noted that the authentic synthetically prepared iminoisopentenoids (7) produced a late shoulder on the parent GLC peak with varying intensity (from 0–40% of the parent peak). The formation of the shoulder is dependent on the hydroscopic state of the sample and has been observed also when

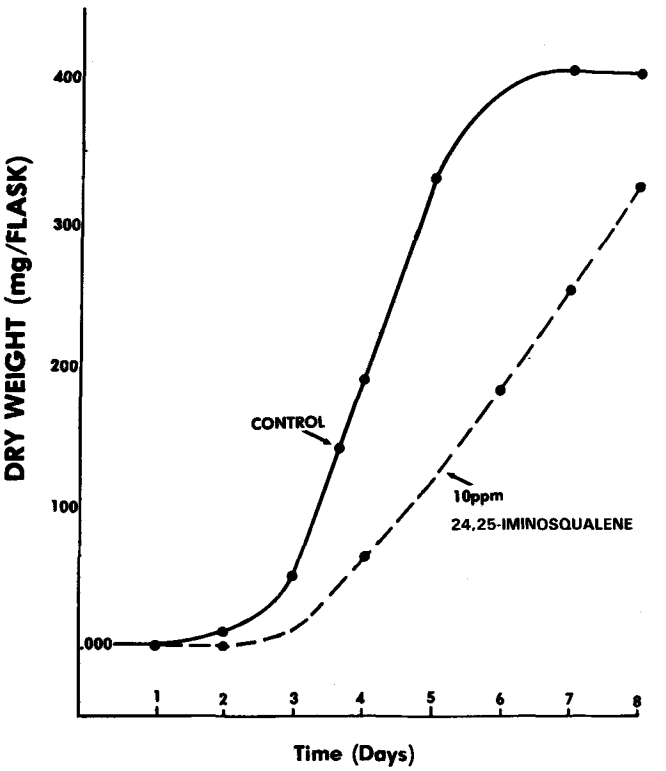

FIG. 1. Growth response of *Gibberella fujikuroi* with and without 10 μg/ml Isq. supplementation.

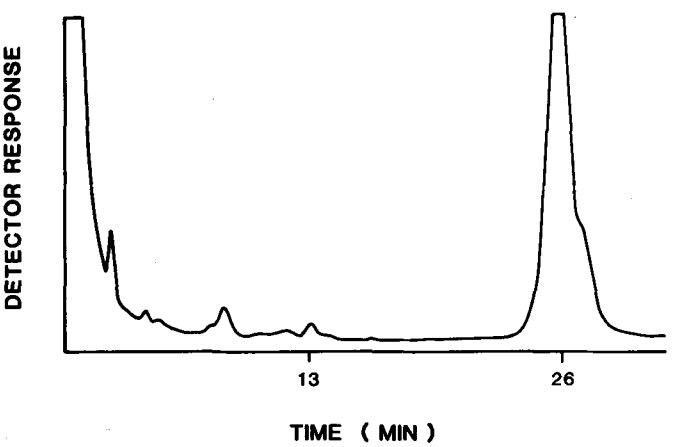

FIG. 2. GLC profile (3% SE-30 column operated at 245C) of the TLC band having R_f 0.25 in solvent system 2. Note the shoulder on peak at RRT_c-2.63 is a breakdown product. See text for details.

the injector port accumulates bound water and needs to be cleaned.

RESULTS AND DISCUSSION

In recent studies using *G. fujikuroi*, we demonstrated that the fungus produced ergosterol and other 24β-methylsterol end products (3,8). Isq. added to the cultures at 1 μg/ml inhibited growth somewhat and induced the fungal accumulation of squaleneoxide and the depression of [2-^{14}C]acetate incorporation into sterol end products (3). When the level of Isq. was increased to 10 μg/ml, mycelial growth ceased. However, after a few days of chronic treatment with Isq. the mycelia recovered and grew in a manner analogous to control cultures. We now have repeated the study to determine whether a developmentally delayed biochemical detoxifying mechanism operates to modify Isq. to form a noninhibitory end product.

Isq. was incubated at 10 μg/ml for eight days with *G. fujikuroi* as shown in Figure 1. The mycelia initially were inhibited, then growth resumed. The cultures at harvest apparently had recovered to the inhibitor at an earlier time than we had shown in a previous study (3). Media extracts that were monitored for Isq. at harvest failed to possess significant levels of the dietary Isq. However, mycelial extracts contained in addition to Isq. a major unidentified compound that was visible in the second TLC system and that was sensitive to the separation of N-isopentenoids i.e., at R_f 0.25. This material eluted in GLC with authentic EL (Fig. 2) and exhibited a characteristic fragmentation pattern for an aziridine steroid: M^+, 441(62%), 426(100%), 409(6%), 400(9%), 166(27%), 99(62%), 98(57%), 84(78%), 70(45%), 58(28%); ^{1}HNMR δ C-18(0.69s), C-19(1.00s), C-21(0.91d), C-26(1.25s), C-27(1.16s), C-30(0.98s), C-31(0.81s), C-32(0.88s) ppm. The amount of EL per culture flask was quantified at 10 μg/80 mg dry wt mycelium. At physiological pH, the protonated aziridine is a reactive species capable of undergoing a ring-opening reaction with a nucleophile. Through a biomimetic approach, we have shown that 24,25-epiminolanosterol is converted to 25-aminolanosterol using hydrogen and Raney nickle (9). Thus, the continued transformation of the aziridinium salt to 25-aminolanosterol (AL) is possible; preliminary evidence in fact has been presented for the EL to AL conversion by *G. fujikuroi* (10). Studies in progress should resolve whether deamination of the 25-amino grouping occurs; this would effectively produce a nontoxic metabolite, viz. a Δ^{24}-steroid, which then could reenter into the sterol C-24 alkylation pathway.

The biosynthetic scheme presented in Figure 3 for the metabolic conversion of Isq. to EL is consistent with the mechanistic considerations implicit in the studies cited (6,11-13).

ACKNOWLEDGMENT

We thank Patrick Hanners for his skilled assistance in this study.

Fatty Acids of the Milk and Food of the Platypus (*Ornithorhynchus anatinus*)

Robert A. Gibson[a,*], **Mark Neumann**[a], **T.R. Grant**[b] and **Mervyn Griffiths**[c]

[a]Department of Paediatrics Flinders Medical Centre, Bedford Park (Adelaide), S.A. 5042, Australia, [b]School of Zoology, University of New South Wales, Kensington, N.S.W. 2033, Australia, and [c]Protein Chemistry Group, Australian National University, Canberra, ACT 2601, Australia

Platypus milk fat contains 98.5% triglyceride. Polyunsaturates (C18:2–C22:5) account for 29% of the triglyceride fatty acids in the milk fat and 32% of the total fatty acids in the lipid of the food of the platypus. Linoleate and arachidonate are the major ω6 polyunsaturates of both food and milk lipids. However, while the ω3 polyunsaturates linolenate and eicosapentaenoate are present in both food and milk, docosapentaenoate is present in meaningful amounts in milk only. It is suggested that with the exception of 22:5ω3, the polyunsaturates in platypus milk originate in the diet.

Lipids 23, 377–379 (1988).

Platypuses *(Ornithorhynchus anatinus)* living in the waters of South Eastern Australia breed in spring and lay their eggs early in September. This takes place in a burrow in which the progeny live solely on milk for at least 3.5 months until they emerge in late January or in February. The milk triglyceride contains relatively large amounts of long-chain polyunsaturates (1–4). In contrast to this, the milk triglyceride of the echidna, an egg-laying mammal related to the platypus, living on its natural diet of ants and termites contains linoleic and linolenic but, apart from a trace of arachidonic acid, no long-chain polyunsaturates of 20 or 22 carbons (1,4). Total fatty acids of the lipids of a species of ant and of a termite eaten by echidnas have been determined, and the C20–C22 long-chain polyunsaturates are absent (4). Since the fatty acid composition of echidna milk fat can be changed by altering the composition of the fatty acid intake (1,2,4), it is possible that platypus milk fat differs from that of echidnas due to a difference in fatty acid intake. To test this notion, the fatty acid composition of the lipid in the food of the platypus was determined. Since the classes of lipid in platypus milk, other than triglyceride measured by yield from Florisil columns, have never been defined, these also were determined.

MATERIALS AND METHODS

Eleven lactating platypuses were captured in the Shoalhaven River N.S.W. by the method of Grant and Carrick (5) during a three-day period in mid-December 1984 and injected intramuscularly with 0.2 ml (2 I.U.) of oxytocin (Sandoz). Milk then was squeezed out of the mammary glands and taken up in Pasteur pipettes. The cream was separated from each sample by centrifugation at 1,000 × g for 20 min at 2–4 C. It then was removed and stored under nitrogen at −20 C.

The diet of the platypus in the Shoalhaven consists mainly of aquatic insect larvae (Trichoptera, Diptera, Coleoptera, Ephemeroptera, Odonata) shrimps and bivalve molluscs (6). Samples of available items were taken in the winter (3/7/84), summer (8/12/85) and autumn (15/3/86) by means of a Surber Sampler and a plankton net in the riffle areas and pools in which the lactating platypuses were trapped. Upon removal from the nets, the pooled samples of organisms were frozen and stored at −10 C.

The milk fat was extracted by the method of Gibson and Kneebone (7) and the classes of lipid isolated by thin layer chromatography. The fatty acids of the lipids were transesterified in 1% H_2SO_4 in methanol (v/v) by heating to 70 C for three hr (8); the resultant methyl esters were analyzed by gas chromatography (7).

The lipid of the pooled samples of food items was extracted by the method of Bligh and Dyer (9).

RESULTS AND DISCUSSION

Thin layer chromatography showed that 98.5% of the milk lipid was in the form of triglyceride; the remainder was made up of phospholipid (1%) and free fatty acids. Very small amounts of cholesteryl esters were detectable in five of the samples only. Data in Table 1 show that unsaturates predominate in all four classes of lipid, accounting for over two-thirds of the fatty acids present in the milk fat. Of these 29% of the total present in the triglyceride are polyunsaturates (C18:2–C22:5), in agreement with the data of Griffiths et al. (1) and Grant et al. (3), which give 27% and 32%, respectively. From Table 1, it also can be seen that the concentration of arachidonic acid (20:4ω6) in the phospholipid is higher than that in the triglyceride; however, 98% of the total arachidonic acid is in the latter fraction. The greater part of the arachidonic acid present in human milk fat is also present in the triglyceride (10,11).

The fatty acid composition of the lipid in the pooled samples of platypus food is shown in Table 2. From this, it is clear that about 60% of the fatty acids are unsaturates; polyunsaturates account for about 32% of the total fatty acids. Because it is known that dietary intake of polyunsaturates by lactating women leads to the appearance of those acids in their milk (8,12–14), it would be fair to conclude that the presence of polyunsaturates in platypus milk is due to ingestion of those acids present in their food. Likewise, it affords an explanation of the absence of long-chain polyunsaturates from the milks of echidnas because their food lipid apparently lacks C20-C22 polyunsaturates (4). However, while 18:2ω6, 20:4ω6, 18:3ω3 and 20:5ω3 were present in high amounts in both food and milk lipids, 22:5ω3 was present in large amounts in milk only. Because 22:5ω3 can be converted readily from 20:5ω3, it is likely that some chain lengthening of fatty acids has occurred, most likely in the liver.

Small amounts of 22:6ω3 were found in platypus food lipids and in their milk lipid. However, Griffiths et al. (1) reported the presence of 0.6–1.1% of 22:6ω3 in milk triglyceride of platypuses living in habitats different from

the Shoalhaven River. The discrepancy may be due to differences in the levels of 22:6ω3 in the food items selected by the animals. In addition, we report here less 12:0 and 14:0 in the triglyceride fraction than reported in an earlier study (15). While this may be due to seasonal or biological differences, we are satisfied that the methylation procedure used in this study does not cause selective losses of C12 and C14 fatty acids.

The origin of the polyunsaturates in the food of the platypus is unknown but the ultimate foodstuffs of aquatic molluscs and insect larvae are detritus and algae (16). It is known that benthic marine algae contain long-chain polyunsaturated fatty acids (17), so it is not unlikely that fresh water algae will prove to be the primary source of C20-C22 polyunsaturates in platypus milk.

[Received July 20, 1987; Revision accepted October 21, 1987]

Fatty Acid Composition of Macrophage Phospholipids in Mice Fed Fish or Borage Oil

Robert S. Chapkin*, Scott D. Somers, Leslie Schumacher and Kent L. Erickson
Department of Human Anatomy, School of Medicine, University of California, Davis, CA 95616

The polyunsaturated fatty acid (PUFA) composition of murine peritoneal macrophage phospholipids was dramatically altered in vivo following the four-wk feeding of specific dietary oils. Fish oil (containing 20:5n-3 and 22:6n-3) feeding significantly increased macrophage 20:5n-3, 22:5n-3, and 22:6n-3 ($P < 0.05$), while borage oil (containing 18:2n-6 and 18:3n-6) increased ($P < 0.05$) the macrophage 20:3n-6/20:4n-6 ratio, relative to safflower oil (containing 18:2n-6) and hydrogenated coconut oil (containing 12:0)-fed animals. The macrophage phospholipid PUFA profiles were compared with those of the liver, lung and spleen. The significance of the PUFA alterations is discussed.
Lipids 23, 380–383 (1988).

Depending upon the availability of membrane-bound fatty acids, determined largely by dietary constituents, cellular eicosanoid biosynthesis may be redirected in favor of a particular autacoid (1). For instance, it has been demonstrated that the oral administration of primrose oil, containing 9% γ-linolenic acid (18:3n-6), has the potential for increasing tissue biosynthesis of 1-series prostaglandins (PG_1) (2,3). This observation is of particular interest in view of the antiphlogistic properties of PG_1 (4,5). In addition, there are an impressive number of reports suggesting that dietary supplementation with fish oil, containing eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3), may attenuate the phlogistic response (6,7). The efficacy of fish oil as a modulator of the immune system has been attributed to its content of n-3 fatty acids, which serve as precursors of cyclooxygenase and lipoxygenase metabolites (6,7).

Macrophages play a pivotal role in the amplification and suppression of inflammation and immune responses (8). These cells secrete prodigious quantities of arachidonic acid (20:4n-6)-derived eicosanoids (8). To further investigate the role of dietary manipulation involving 18:3n-6 and 20:5n-3 on macrophage phospholipids, mice were administered diets mixed with borage oil (BOR) containing 18:2n-6 and 18:3n-6, menhaden fish oil (MFO) containing 20:5n-3 and 22:6n-3, safflower oil (SAF) containing 18:2n-6, and hydrogenated coconut oil (HCO) containing 12:0. The polyunsaturated fatty acid (PUFA) profiles of macrophage total phospholipids were compared to those of the liver, lung and spleen.

MATERIALS AND METHODS

Pathogen-free female C57BL/6NCR mice (Charles River, Wilmington, MA), weighing 15–20 g were used. All mice had been fed a commercial pelleted mouse diet (Ralston-Purina, St. Louis, MO) and were housed (6–8 animals per cage) in autoclaved cages with laminar flow hoods in order to minimize spontaneous macrophage activation (9). On day zero of the experiment, the mice randomly were assigned to one of four purified diets for four wk, each adequate in all nutrients except 18:2n-6 (10). The diet varied only in the type of oil fed, i.e. either safflower, borage, fish or hydrogenated coconut oil made up 10% of the diet by weight. All dietary components were purchased from ICN Nutritional Biochemicals (Cleveland, OH), except where noted. The basic composition of the purified diet was casein, 20%; DL-methionine, 0.3%; corn starch, 15%; sucrose, 44%; cellulose, 5%; mineral mix, 3.5% (11); vitamin mix, 2% (11); choline chloride, 0.2%; and either SAF, 10% (California Oils, Richmond, CA); BOR, 10% (Traco Labs, Champaign, IL); MFO, 10% (Zapata-Haynie, Reedville, VA); or HCO, 10% (Capital City Products, Columbus, OH). The major fatty acids of the HCO diet were (in wt %) 8:0, 7.9%; 10:0, 6.9%; 12:0, 50.9%; 14:0, 18.2%; 16:0, 7.8%; 18:0, 7.1%; 18:1n-9, 1.0%; SAF diet, 16:0, 7.0%; 18:0, 2.5%; 18:1n-9, 10.7%; 18:2n-6, 78.2%: BOR diet, 16:0, 12.4%; 18:0, 4.4%; 18:1n-9, 19.6%; 18:2n-6, 36.6%; 18:3n-6, 25.2%; and MFO diet, 14:0, 7.6%; 16:0, 16.0%; 18:0, 2.8%; 18:1n-9, 10.5%; 18:2n-6, 1.2%; 18:3n-6, 0.6%; 20:4n-6, 0.6%; 20:5n-3, 16.9%; 22:5n-3, 2.5%; 22:6n-3, 12.0%. The diets were adequate in all nutrients, except HCO and MFO, which were deficient in 18:2n-6 (10). A diurnal light cycle of 12 hr was maintained, and food and autoclaved water were available ad libitum. The powdered diets were mixed and stored under N_2 at −20 C. Fresh diet was provided daily to each group to minimize auto-oxidation. Diets were checked periodicaliy by determination of the fatty acid composition. The profiles did not vary significantly in the diets over the four-wk feeding period. Body weights were recorded weekly, and the food intake of the SAF, BOR, MFO and HCO animals were diurnally monitored and not found to be significantly ($P > 0.05$) different (data not shown).

Macrophage cultures. Mice were injected intraperitoneally with 2 ml of 1.5% sterile sodium caseinate three days before being killed. Primary cultures of peritoneal macrophages were established from responsive cells as described previously (12).

Lipid analysis. Livers, spleens and lungs were excised, rinsed in ice-cold saline, flash frozen in liquid N_2 and held at −70 C for lipid extraction. Same-day macrophage cultures and frozen tissues were extracted (13), and the total phospholipids isolated by thin layer chromatography (14). Fatty acids were quantitated by gas chromatography (15). All data were subjected to one-way analysis of variance using multiple comparisons, with the upper level of significance chosen at $P < 0.05$.

RESULTS AND DISCUSSION

No differences between the diets were noted with respect to numbers or relative proportions of resultant peritoneal inflammatory exudate populations after sodium caseinate injection (data not shown). The data in Table 1 show that

the n-3 fatty acids, 20:5n-3 and 22:6n-3, were readily incorporated into macrophage phospholipids in MFO-fed animals. Interestingly, 18:3n-6 was not detected in BOR macrophages, which contrasted with liver (Table 2), spleen (Table 3) and lung (Table 4) phospholipids, in which 18:3n-6 levels were significantly elevated ($P < 0.05$) relative to HCO-, SAF- and MFO-fed mice. In addition, the macrophage 20:3n-6/20:4n-6 ratio was elevated significantly ($P < 0.05$) in BOR animals. This ratio was highest in the macrophage (0.28 ± 0.02) relative to the liver (0.11 ± 0.01), spleen (0.18 ± 0.01) and lung (0.18 ± 0.02). These results suggest that the macrophage is capable of elongating 18:3n-6 into 20:3n-6 and that the Δ5 desaturase, the enzyme that catalyzes the transformation of 20:3n-6 into 20:4n-6, is rate-limiting. This scenerio is consistent with our earlier findings (16), in which the presence of a PUFA chain elongase in mouse peritoneal macrophages in vitro was noted. The striking elevation of BOR 20:3n-6/20:4n-6 is of particular interest because 20:3n-6 can serve as a precursor for the biosynthesis and increase of 1-series prostaglandins. These monoenoic eicosanoids possess anti-inflammatory properties (4,5).

The accumulation of 20:3n-9 and the depression of 18:2n-6 in HCO tissues is indicative of essential fatty acid deficiency (EFAD) (17). Of the cells or organs examined, the 20:3n-9/20:4n-6 ratio was greatest in the liver. The significant depression ($P < 0.05$) of macrophage 18:2n-6 and 20:4n-6 in MFO-fed mice as shown in Table 1 is also indicative of EFAD. This finding is in accord with the results of Lokesh et al. (18).

Only mice receiving MFO had significant levels of docosapentaenoic acid (22:5n-3) in the phospholipid pool. Since only small quantities of 22:5n-3 are found in the MFO diet, it is likely that this n-3 fatty acid was derived via chain elongation of 20:5n-3. Interestingly, in MFO-fed mice, the 20:5n-3/22:5n-3 ratio was lowest in the macrophage (0.54 ± 0.05) relative to liver (4.52 ± 0.53), spleen (1.35 ± 0.07) and lung (2.12 ± 1.42). These data do not provide definitive proof but suggest, as mentioned above, that macrophages possess an active long chain PUFA chain elongase. Consistent with these observations are the results of Magrum and Johnston (19), who similarly reported an increase in rat peritoneal macrophage phospholipid 22:5n-3 levels after feeding an n-3 fatty acid rich diet. Although it has been demonstrated that dietary MFO is capable of inhibiting the conversion of 20:4n-6 into pro-inflammatory eicosanoids in the macrophage (18,20), further work is needed to determine whether n-3 fatty acid incorporation alters macrophage functional properties, i.e. cytolytic capacity.

In conclusion, the PUFA composition of macrophage phospholipids can be manipulated in vivo by administering specific dietary oils. Because the macrophage plays a central role in the immune system, further work is needed to fully evaluate the effects of borage and fish oil feeding on the mechanisms of signal transduction and production of regulatory factors by this complex cell type.

ACKNOWLEDGMENTS

We thank Panda Chen and Kevin Kisich for their expert technical assistance. This work was supported by grants from the American Cancer Society IM-452, and the Gustavus and Louise Pfeiffer Research Foundation. We also thank Steven Lanning of Capital City Products, A. P. Bimbo of Zapata-Haynie Corporation, and Sid Tracy of Traco Labs for providing the hydrogenated coconut, menhaden and borage oils.

Membrane Lipid Alteration: Effect on Cellular Uptake of Mitoxantrone

C. Patrick Burns*, Bradley N. Haugstad, Craig J. Mossman, James A. North and **Leah M. Ingraham**
Department of Medicine, University of Iowa College of Medicine, Iowa City, IA 52242

We have studied the effect of membrane structural alteration on the cellular association of the anticancer drug mitoxantrone whose uptake is not carrier-mediated. Membrane fatty acids of L1210 cells were modified by incubating the cells with the highly unsaturated docosahexaenoic acid (22:6), which results in isolated plasma membranes with 37% of the fatty acids as 22:6, or with the monounsaturated oleic acid (18:1), which results in 58% of the fatty acids as 18:1. The rate of uptake by 22:6-enriched cells during the first min was 62% greater than by those enriched with 18:1. The higher rate was recorded at 0.5–16 μM, pH 6.6–7.6 and temperatures 10–40 C. The difference in cell-associated drug apparently was not due simply to a change in mitoxantrone solubility as measured by partitioning of the drug in lipophilic-hydrophilic systems containing lipids from the fatty-acid altered cells. We conclude that the type of fatty acids contained in L1210 cell membranes can affect the cell association of mitoxantrone. This effect could be on transmembrane flux or be due to differences in binding of the drug to intracellular structures.
Lipids 23, **393–397 (1988).**

It has been shown that alteration of fatty acids affects permeation in artificial membrane systems (1). It also has been demonstrated in biological systems that alteration in fatty acids influences carrier-mediated transport (2). However, it is unclear whether lipid alteration can affect simple diffusion through cellular membranes. We recently have reported that the unidirectional influx and efflux of mitoxantrone or 1,4-dihydroxyl-5,8-bis[[2-[(2-hydroxyethyl) amino]ethyl]amino]-9,10-anthracenedione dihydrochloride in murine leukemia cells occur by passive diffusion (3). Mitoxantrone is an investigational antitumor drug with reported activity in advanced breast cancer, lymphomas and acute leukemias. There is considerable information on its chemistry (4,5), mechanism of action (6–8) and pharmacokinetics (9). Attempting to understand better the role of membrane lipids in diffusion, we studied mitoxantrone uptake by L1210 cells whose membrane lipids had been altered experimentally. For these studies, we utilized a method previously reported by us for altering the types of lipids in the membranes of L1210 leukemia cells (10). This type of alteration results in a change in membrane molecular order as measured by electron spin resonance (11) and in transport of compounds whose transmembrane movement is governed by a carrier-mediated process (12–15). We report here that fatty acid alteration influences the cell association of a molecule that requires neither a carrier nor expenditure of energy.

MATERIALS AND METHODS

L1210 murine leukemia cells were grown and maintained in suspension culture at 37 C in medium consisting of RPMI 1640 (Grand Island Biological Co., Grand Island, NY), 5% fetal bovine serum (Hazleton Research Products, Denver, PA) and gentamicin sulfate (50 μg/ml) in a humid atmosphere of 5% CO_2/95% air. These cells originally were obtained from David Vistica of the National Institutes of Health. Cells were harvested during exponential growth phase and resuspended in balanced salt solution (BSS: 132 mM NaCl, 16 mM Na_2PO_4, 5 mM KCl, 1 mM $MgSO_4$, 5.6 mM glucose, pH 7.4) for transport studies.

[^{14}C]mitoxantrone, labeled in the carbon atoms α to the arylamine groups, was supplied by B. M. Silber, American Cyanamid Company (Pearle River, NY). It was received as a powder (40 Ci/mol), was constituted with distilled water and then frozen at −70 C in aliquots until use. Purity after thawing and just before use was 99% as determined in our laboratory using high performance liquid chromatography (16).

Permeability studies were performed by modification of previously described techniques from our laboratory (3,13,17,18). Studies were carried out in small vessels containing 1×10^6 cells in 0.5 ml BSS. After temperature equilibration, [^{14}C]mitoxantrone was added. At the termination of incubation, the cell suspension was transferred to 1.5 ml tapered Eppendorf microcentrifuge tubes at 0 C containing 0.25 ml n-butyl phthalate/corn oil (2.75:1, v/v) layered beneath 0.3 ml BSS. Rapid separation of the cells from incubation medium was accomplished by immediate centrifugation at 15600 × g for 30 sec in an Eppendorf 5412 centrifuge. The supernatant then was aspirated, and the tip of the tapered tube containing the cell pellet was severed and placed in a scintillation vial containing 0.5 ml NCS tissue solubilizer (Amersham, Arlington Heights, IL). After 60 min, Neutralizer scintillation mixture (Research Products International, Elk Grove Village, IL) was added and radioactivity determined using a Beckman LS3133T scintillation spectrometer. Drug uptake at each concentration was corrected for rapid association with the plasma membrane except where indicated in the time course studies. It was estimated by measuring cell association of [^{14}C]mitoxantrone at 0 C in a time interval of less than three sec. Temperature dependence of transport was determined at 2 C intervals from 10 C to 40 C. Incubations were for 45 sec in the presence of 8 μM mitoxantrone following a five-min equilibrium period for the cells and medium at the respective temperature. Efflux studies were performed using L1210 cells pre-loaded with [^{14}C]mitoxantrone (4 μM, 30 min, 37 C), which then were rapidly chilled and washed at 0 C. Cells were resuspended in balanced salt solution at 37 C to initiate efflux.

To modify the cellular and membrane fatty acid composition, cells were grown for two days under identical conditions in medium further supplemented with either oleic acid (18:1) or docosahexaenoic acid (22:6) (NuChek Prep, Inc., Elysian, MN) (fatty acids are abbreviated as number of carbon atoms:number of double bonds). Specific quantities of sodium salts of each fatty acid were added dropwise to the fetal bovine serum used to prepare the growth medium so that their concentration in the final growth medium was 32 μM. Cellular protein was determined (19). Those cells modified with 22:6 contained

*To whom correspondence should be addressed.

138.39 ± 13.29 μg protein per 10^6 cells (n = 9), and this was not significantly different from the 18:1 modified cells that contained 151.79 ± 18.75 μg.

Octanol partitioning of the drug was measured by dissolving 2.5 μg (4.25 × 10^5 dpm) of [^{14}C]mitoxantrone in 500 μl of phosphate-buffered saline (NaCl 136.8 mM, Na_2HPO_4 8.06 mM, KCL 2.68 mM, KH_2PO_4 1.47 mM, $CaCl_2$ 0.9 mM, $MgCl_2$ 0.6 mM) at pH 7.2 previously saturated with octanol. An equal volume of octanol previously saturated with phosphate-buffered saline was added. After mixing, the phases were separated by centrifugation at 300 × g and the radioactivity in each phase determined (20). The study was repeated in the presence of lipid extracts from 18:1- and 22:6-enriched cells using 1.5 × 10^7 cells.

Partitioning of the radiolabeled drug into lipid-containing compartments to measure interaction of drug with lipids was assayed by a modified Folch-type extraction (21). L1210 cells (1 × 10^7) enriched in 22:6 or 18:1 were extracted with $CHCl_3/CH_3OH$ (2:1) and 2.5 μg [^{14}C]mitoxantrone (4.2 × 10^5 dpm) was added. The mixture was shaken, and 5 ml of 0.04 N KCl were added, mixed and the phases allowed to separate overnight. The separate phases were collected, dried under N_2, solubilized with NCS tissue solubilizer, and the radioactivity determined.

To prepare purified plasma membranes, L1210 cells grown in medium supplemented with either 22:6 or 18:1 were washed and disrupted as described (13). Subcellular fractions were separated using two discontinuous sucrose gradients (22,23). 5′-Nucleotidase (E.C. 3.1.3.5) activity as a plasma membrane marker, was determined on each fraction in each experiment (24), and the plasma membrane fraction collected at the 10%–30% interface was enriched an average of 12-fold as compared with the homogenate.

The plasma membrane fractions from the discontinuous gradients for 18:1- and 22:6-modified cells were extracted using $CHCl_3/CH_3OH$ (2:1, v/v) (25). The lipids then were saponified for 60 min at 56 C in 1.2 N KOH and 80% ethanol (26). Fatty acids in the saponifiable fraction were methylated for 10 min at 95% with 14% BF_3/CH_3OH (27), and the methyl esters were separated by gas chromatography using a 1.8 m column packed with 10% SP2340 on 100/120 mesh Chromosorb (Supelco, Inc., Bellefonte, PA). Peak areas were quantitated and identified by comparison of retention times to those of standards obtained from Supelco.

RESULTS

Lipid analysis. To ascertain the extent of fatty acid modification that occurred in the plasma membranes of the cells grown in lipid-supplemented media, the fatty acid composition of the purified membrane fractions was determined. There was considerable enrichment of the membranes with the fatty acid supplemented in the medium (Table 1). The membranes from the 18:1-enriched cells contained 61% monoenic fatty acids, the majority (59%) being 18:1. The membranes from the 22:6-enriched cells contained 44% polyenoic fatty acids; 37% of the fatty acids were 22:6. The 22:6 membranes contained more than two-fold greater proportion of double bonds.

Time course of mitoxantrone uptake. The uptake of mitoxantrone by both 18:1-modified and 22:6-modified L1210 cells was studied at nine time points between 15 sec and 30 min (Fig. 1). Initial uptake was linear for 60 sec and then gradually slowed to reach a plateau by about 20 min. The rate of cell association during the initial 60 sec was greater by the 22:6-enriched cells (slope = 91.7 ± 8.6) than by the 18:1-enriched cells (slope = 56.5 ± 11.3) ($p = 0.03$, n = 5). The rapid association of drug with the plasma membrane measured experimentally at 0 C was not significantly different between the two modified cell types. The differences in the accumulation of drug disappeared at later time points (Fig. 1, insert).

Concentration dependence of mitoxantrone uptake. The concentration dependence of drug uptake for both types of enriched cells was linear for a drug concentration range 0.5–16 μM. The amount of drug taken up was higher by the 22:6-enriched cells at all seven concentrations, and this difference was statistically significant at all but the

TABLE 1

Fatty Acid Composition of L1210 Plasma Membranes[a]

Fatty acid	Fatty acid composition (%)	
	22:6-Supplemented	18:1-Supplemented
Individual acids		
16:0[b]	14.4 ± 2.0[c]	11.7 ± 1.7
16:1	ND[d]	2.0 ± 0.6
18:0	18.7 ± 0.8	13.0 ± 1.2
18:1	21.8 ± 0.8	58.8 ± 1.5
18:2	0.2 ± 0.1	0.5 ± 0.3
18:3	0.3 ± 0.3	3.9 ± 0.3
20:4	3.7 ± 0.3	5.2 ± 0.5
20:5	1.3 ± 0.1	0.4 ± 0.2
22:5	1.4 ± 0.5	2.4 ± 0.4
22:6	37.4 ± 3.6	1.5 ± 0.2
Other[e]	0.8	0.6
Classes		
Saturates	33.6 ± 2.6[f]	25.0 ± 2.1

Mean chain length	19.3 ± 0.2	18.0 ± <0.1

[a]L1210 cells were grown for 48 hr in RPMI 1640 supplemented with either 22:6 or 18:1 at a concentration of 32 μM. Cells were washed three times, mechanically disrupted and subcellular fractions prepared by gradient centrifugation. Lipids extracted from the membranes were subjected to alkaline hydrolysis. Fatty acids contained in the saponifiable fraction were methylated and the methyl esters separated by gas liquid chromatography.

[b]The fatty acids are signified as number of carbon atoms: number of double bonds.

[c]Mean ± S.E. of determinations made on individual membrane samples shown are from three to four separate experiments. Among the individual acids, the amounts of 18:1, 18:3, and 22:6 ($p < 0.001$), 18:0, 20:5 and 20:4 ($p < 0.05$) are significantly different between the supplemented cell membranes.

[d]ND, not detected.

[e] Includes small amounts of 14:0, 20:1, 20:3, 22:1, 22:4 and unidentified fatty acids.

[f]Among the classes of fatty acids, the amounts of polyenoics, monoenoics, average number of double bonds ($p < 0.001$), average chain length and saturates ($p < 0.05$) are significantly different between the supplemented cell membranes.

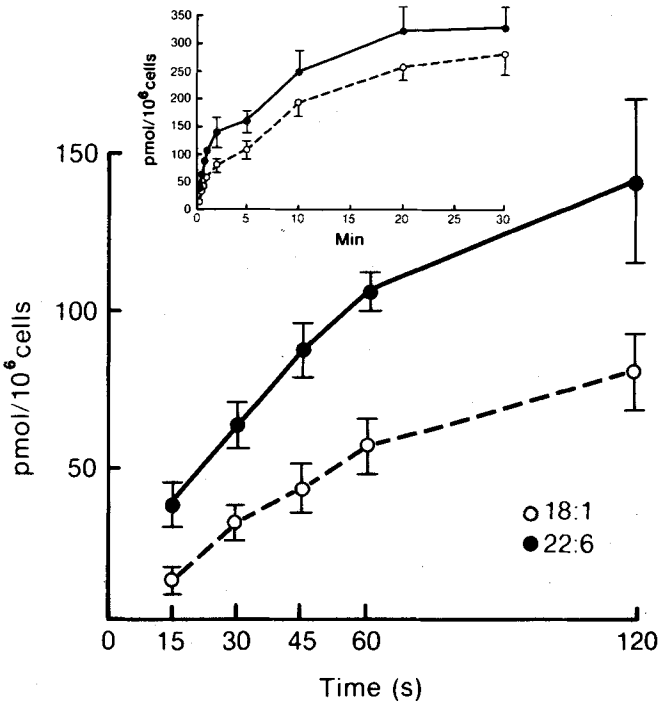

FIG. 1. Time course of mitoxantrone uptake by fatty acid-modified L1210 cells. L1210 cells enriched with 22:6 or 18:1 were incubated at 37 C with 4 μM [^{14}C]mitoxantrone in balanced salt solution. At the termination of the incubation, the cells were rapidly centrifuged through an oil layer, and the radioactivity of the cell pellet was determined. Each point represents the mean ± S.E. of at least four determinations. Insert shows uptake at later time points.

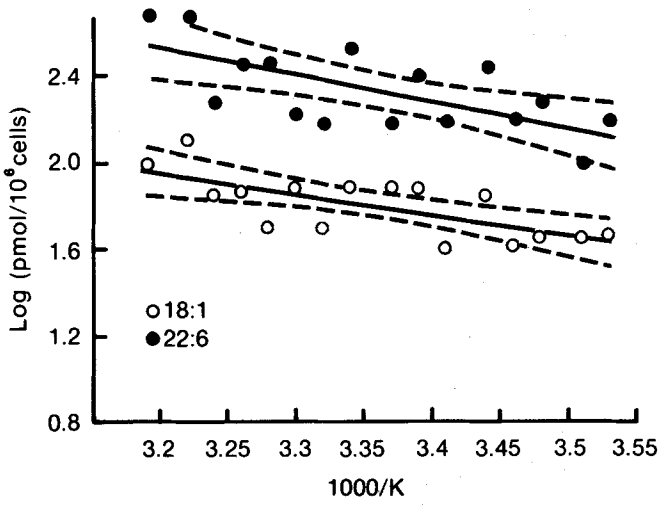

FIG. 2. Arrhenius plot of temperature dependence of mitoxantrone transport. Fatty acid modified L1210 cells were incubated with 8 μM [^{14}C]mitoxantrone for 45 sec at 2 C intervals from 10–40 C. Cells were rapidly centrifuged through an oil layer, and radioactivity in the pellet was determined. Shown are the mean of three experiments and the 95% confidence limits.

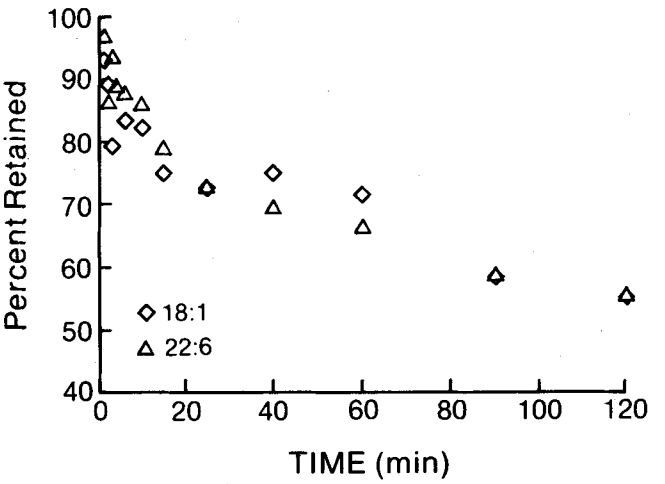

FIG. 3. Efflux of mitoxantrone by fatty acid modified cells. L1210 cells were incubated with 4 μM [^{14}C]mitoxantrone for 30 min at 37 C. Cells were chilled, washed at 0 C and efflux measured by determining intracellular radioactivity at specified times.

lower concentrations. When the slopes of the linear regression lines (for 18:1, $y = 24.53x - 0.18$, $r = 0.99$; for 22:6, $y = 36.74x - 7.39$, $r = 0.99$) were compared, that of the 22:6-enriched cells was greater than the 18:1-enriched cells ($p = 0.008$).

Effect of temperature and pH. Both 18:1- and 22:6-enriched L1210 cells demonstrated limited temperature dependence for initial mitoxantrone cell association. Three separate experiments were performed, during which the initial uptake during 45 sec of 8 μM drug was studied at 2 C-intervals from 10–40 C. All studies demonstrated an increased uptake with increasing temperature (Fig. 2). Although the relationship appeared to be roughly linear ($r = 0.712$ for 18:1, $p = 0.002$ and $r = 0.657$ for 22:6, $p = 0.006$), the noise in the data precludes identification of break points. If linearity is assumed, the slope for the 18:1-enriched cells (−0.012 ± <0.001) was not different from the slope for the 22:6-enriched cells (−0.012 ± 0.003). However, the uptake of drug by the 22:6-enriched cells was higher at all temperatures. At each of the four pH values tested between 6.6 and 7.7, the 22:6-enriched cells had a higher rate of influx than the 18:1-enriched cells.

Efflux. We next examined the rate of efflux of mitoxantrone from 18:1- and 22:6-enriched cells that were preloaded with drug. Initial efflux was rapid and linear for both cell types during the first 15 min with a subsequent decrease during the next 105 min (Fig. 3). Both reached a plateau of about 55% retention at 120 min. Neither the rate of efflux nor the plateau level were different for the cell lines. The values could represent the kinetics of efflux through the membrane or dissociation of drug from a binding site. The decline of cell associated drug to only 50% of the amount when loaded suggests there is a major binding component in either case.

Drug partitioning experiments. The octanol:water partition results demonstrated that mitoxantrone is a fairly lipophilic drug. A majority of the drug partitioned in the octanol (85% ± 1, n = 4) and the partition ratio (ratio of drug in octanol to that in aqueous phase) was 6.1 ± 0.7. The presence of lipids extracted from 22:6- or 18:1-enriched cells resulted in a decrease in partition ratio (18:1, 2.99 ± 0.18 vs 22:6, 2.88 ± 0.41), and in percentage of drug partitioning into octanol (18:1, 75.30% ± 1.55

TABLE 2

Effect of L1210 Lipids Extracted from 22:6- and 18:1-Enriched Cells on Partitioning Between Lipophilic and Hydrophilic Phases in a Folch Biphasic System

	Percentage of [^{14}C]mitoxantrone		
	Lipophilic	Hydrophilic	Interface
22:6	85.4 ± 3.3	9.6 ± 3.7	5.0 ± 1.8
18:1	81.8 ± 0.6	13.3 ± 2.2	5.1 ± 1.7
No cells	4.2 ± 0.4	95.8 ± 0.5	—

L1210 cells enriched with 22:6 or 18:1 were extracted with chloroform/methanol (2:1, v/v) and [^{14}C]mitoxantrone added. To separate the layers, 0.04 N KCl was added, mixed, and the phases allowed to separate. The separate phases were then collected, dried under N_2, solubilized, and the radioactivity determined. Values are the mean and S.E. of four replicates.

vs 22:6, 73.40% ± 2.66) but were not different between lipids from the two types of modified cells.

We also compared the physical association of mitoxantrone with the lipids extracted from modified cells using a Folch extraction. L1210 cells enriched with either 22:6 or 18:1 were lipid extracted using chloroform/methanol (2:1, v/v). We have shown that there was no difference in total acylglycerols, phospholipids or cholesterol between L1210 cells enriched with 22:6 or 18:1 (2,11). [^{14}C]Mitoxantrone was added, and the phases separated by the addition of 0.04 N KCl. The lower lipophilic phase, the upper hydrophilic phase and the protein-rich precipitate at the interface were separated and the radioactivity in each determined. Table 2 shows the proportion of drug partitioning into each phase. The majority of the drug partitioned into the lipophilic phase. Most importantly, there was no difference in the proportion of drug in the lipophilic layer extracted from 22:6 vs 18:1 cells. This shows that there is no differential complexing of mitoxantrone with lipids in vitro. This is consistent with relative octanol partitioning, which likewise showed no difference. It is interesting that the majority of the drug partitioned into the hydrophilic phase when no cell extract was present; however, the presence of lipids resulted in the partitioning of drug into the lipophilic phase.

DISCUSSION

These results indicate that L1210 cells that have enrichment of their membrane phospholipids with polyunsaturated fatty acids have a more rapid rate of cell-association of the anticancer drug mitoxantrone as compared with L1210 cells enriched with monoenoic fatty acids. The higher rate of association is time and drug concentration dependent. The difference was apparent at all temperatures and all medium pH-values studied. The observations of the present study are important because mitoxantrone uptake is not mediated by a membrane carrier nor does its influx require energy expenditure. Data from our laboratory and others have indicated that a number of transport systems of murine and human tumor cells are affected by the types of fatty acid modification that can be produced. For example, the apparent Km for high-affinity transport of the anticancer drug methotrexate (13), α-aminoisobutyrate (12), choline (14) and taurine (15) is lowered when the cells are enriched with polyunsaturated fatty acids. In each of those cases, the transport process is carrier-mediated, and the effect probably results from changes in binding of the substrate to the carrier due to a lipid-mediated change in conformation of the membrane carrier molecule. We have reported that fatty acid alteration affects the accumulation of Adriamycin by L1210 cells (18), a drug whose permeation mechanism has not been definitely characterized yet (18,28–30). However, we have reported that mitoxantrone enters cells by passive diffusion (3). Therefore, the observation that a lipid structural change influences its cell-association indicates that the effect is a result of changes in the lipids themselves and the interaction of the anticancer drug with the membrane lipids. The uniqueness of the study is the observation that the lipids may affect permeation directly rather than through an interaction with a membrane-based carrier molecule or by an effect on an energy requiring or potential-driven reaction.

The efflux studies indicate that there is a considerable amount of binding of drug to intracellular structures. It is possible that the rates of uptake measured in our kinetic studies are rates of binding to intracellular components rather than unidirectional influx. The apparently concentrative accumulation of drug even at early time points raises the possibility that the rates being measured are those of binding. In this regard, it has been reported that aminoanthraquinones bind to two distinct low molecular weight intracellular macromolecular lipids in L1210 cells (31). However, the fact that the process is nonsaturable up to 1 mM at both 0 and 37 C and that there is an almost two-fold difference in cell-association between 37 C and 0 C would be more compatible with unidirectional influx (3). We cannot distinguish with assurity whether the lipid alteration is influencing nonmediated permeation or intracellular binding.

No studies of the parent unmodified L1210 cell line were performed since we feel that such data could be misleading if compared with modified cells. Any differences or similarities found in a comparison of unmodified and lipid-modified cells could be ascribed to exposure of cells to fatty acids in the media per se rather than fatty acid modification. It was our intention to compare the effect of alteration of membrane fatty acids of diverse chemical and physical properties. The 18:1-modified cells in this sense act as a control to study the effect of enrichment with polyunsaturated fatty acids. Furthermore, the fatty acid composition of 18:1-enriched cells is similar to that of unmodified cells (11). We reported the mitoxantrone uptake characteristics of the parent line (3).

The mechanism by which fatty acid modification alters the uptake of mitoxantrone is unclear. The dissimilar uptake by the lipid modified cells could be related to a difference in membrane order. Current concepts of the mechanisms of diffusional permeation of substances across the membranes of isolated cells have been reviewed recently (32). We reported that in vitro modification of L1210 leukemia membrane lipids with 22:6 results in a highly significant decrease in the order parameter of an electron spin resonance probe (11). The molecular basis of diffusion and the relationship of membrane order and permeability is complex (32,33), but it is likely that the

permeation of mitoxantrone proceeds more rapidly through 22:6-enriched membranes as a result of a change in physicochemical properties. The octanol partitioning experiments demonstrated no difference in drug solubility in membranes enriched in the fatty acids. However, the partitioning across a single homogeneous phase boundary as measured is likely to be a poor model for membranes in an aqueous environment. We cannot rule out the possibility of differences in the unstirred layer or in thickness of the plasma membrane induced by fatty acid modification. However, these possibilities seem considerably less likely to explain mitoxantrone flux differences as compared with the change in membrane order. If a component of measured uptake represents binding, a possibility discussed above, then the altered lipids represent a plausible site for such binding. Experimental modification of a binding site with resulting change in binding affinity would provide a possible explanation for differences in cell-association.

Molecular Species of Glycerolipids of Ehrlich Ascites Cells and of Their Fat Granules

J.J. Myher, A. Kuksis*, S. Pind and E.R.M. Kay
Banting and Best Department of Medical Research and Department of Biochemistry, University of Toronto, Toronto, Ontario, Canada M5G 1L6

Ehrlich ascites cells were grown in mice and were isolated by centrifugation of the ascites fluid. The cells were lysed with distilled water, and the floating fat particles were collected by centrifugation. The particles contained about 90% neutral and 10% polar lipid. The neutral lipid was made up of about 50% triacylglycerol, 30% alkyldiacylglycerol, 3% cholesteryl esters, 3% free cholesterol and 4% free diacylglycerols. The phospholipid fraction was comprised of about 50% phosphatidylcholine, 35% phosphatidylethanolamine, 10% sphingomyelin and small amounts (less than 5% total) of serine and/or inositol phosphatides. The triacylglycerol and alkyldiacylglycerol fractions possessed total carbon number and fatty acid compositions closely similar to those reported in the literature for whole ascites cells and for a cell membrane preparation. Likewise, the fatty acid composition of phospholipids from the granules in general was similar to that reported for Ehrlich ascites cells. On the basis of the polar and neutral lipid ratio, the lipid granules of the ascites cells were calculated to possess lipid core diameters of 30–50 nm, which were 40–70 times smaller than those (up to 2μ) measured for the lipid granules of the intact cells by electron microscopy. The characterization of the lipid composition of the Ehrlich ascites lipid granules was completed by determining the molecular species composition of the diacyl, alkylacyl and alkenylacyl phosphatidylethanolamines and of the diacyl and alkylacyl phosphatidylcholines of the ascites cells. It is concluded that the alkyldiacylglycerols of the Ehrlich ascites cells occur largely in the cytoplasmic lipid granules, which appear to consist of many particles of the size and structure of very low density lipoproteins enclosed in membranous sacs.
Lipids 23, 398–404 (1988).

The composition of fatty chains of neutral lipids and phospholipids of whole Ehrlich ascites cells and of a membrane fraction has been described in great detail by Wood (1). More recent studies have confirmed and extended these findings (2–5), and the characteristic presence of excessive amounts of ether-linked phospholipids and neutral lipids in tumor tissues and neoplastic cells now is generally recognized (6,7).

Early work by DiPaolo et al. (8) had identified a lipoid granule fraction in Ehrlich ascites cells, which later workers had not bothered to isolate and examine separately. This particle had been observed to contain a high proportion of an unidentified neutral lipid, which was recovered along with the steryl esters from a silicic acid column. We recently have reisolated the granule fraction from Ehrlich ascites cells and have shown that the unknown ester is an alkyldiacylglycerol similar to that previously characterized by Wood and Snyder (9) from whole cell extracts. In the course of this study, we also have determined the molecular association of the fatty chains in the diacyl, alkylacyl and alkenylacylglycerol moieties of the glycerophospholipids of whole Ehrlich ascites cells, which had not been reported previously.

MATERIALS AND METHODS

Cells. The cells used in this study were a hyperdiploid strain of the Ehrlich-Lettre ascites carcinoma. It was obtained originally from the tissue bank of the Roswell Park Memorial Cancer Institute, Buffalo, NY. The tumor was maintained by making serial transplants of 0.2 ml ascites fluid containing cells intraperitoneally into female mice of the CFW strain, or of the Connaught strain, as obtained in this university. The procedure for maintaining the tumor was essentially as described (10). After 10 days of tumor development, the mice were killed by anesthesia using diethyl ether, and the skin of the enlarged abdomen was punctured by scissors, after swabbing the area with 70% ethanol. The fluid was quickly drained into a collecting vessel. The fluid generally was the color of serum and contained mainly suspended ascites cells. Very few erythrocytes were detected by microscopic examination. The fluid was used for further transplants as described or for the preparation of the lipid granules enclosed in these cells.

Lipid granules. For the preparation of the intracellular particles, the ascites fluid was centrifuged for 10 min at 200 × g at 4 C. The supernatant fluid was discarded, and the cells were washed at least two times with 0.9% NaCl; the centrifugation was repeated. Packed cell pellets obtained from at least 10 mice were pooled and suspended in cold distilled water in a ratio of 1:10 and the lipid particles collected essentially as described by DiPaolo et al. (8). The suspension was stirred in the cold or was gently homogenized to facilitate cell rupture. This was carried out with a motor-driven homogenizer using a Teflon and glass mortar and pestle. The stages in cell rupture and release of the particles were monitored by phase contrast microscopy. The particles and lipid-containing components of the cell could be obtained by flotation, if allowed to stand. It proved to be more convenient to adjust the suspending medium to a concentration of 0.25 M sucrose and to centrifuge for approximately 30 min at 9,000 × g. The supernatant then was free of mitochondria and cell debris, and the lipid particles in it could be collected by centrifugation at 145,000 × g for two hr using a Spinco L-65 centrifuge. The floating white band at the top of the centrifuge tube was recovered using a Pasteur pipet.

Lipid analyses. The lipids of the cells and the lipid granules were extracted with chloroform/methanol (2:1, v/v) (11) and the solvents evaporated under nitrogen. The

Abbreviations: TMS, trimethylsilyl; VLDL, very low density lipoproteins; GLC, gas liquid chromatography; TLC, thin layer chromatography.

total lipid extracts were resolved by preparative thin layer chromatography (TLC) and the individual neutral and phospholipid classes recovered as described (12). An aliquot of the total lipid extract was applied to a 20 × 20 cm Silica Gel H plate (250 μm thick layer) about 2.5 cm from the bottom edge, and the plate was developed with a polar solvent system made up of chloroform/methanol/4 N ammonia (65:25:4, v/v/v), which resolved phosphatidylcholine and phosphatidylethanolamine from the sphingomyelin and phosphatidylserine and phosphatidylinositol, which overlapped. The total neutral lipid fraction was carried to the solvent front. The lipid bands were located by dichlorofluorescein and the gel scrapings were eluted with chloroform/methanol/acetic acid/water (50:39:1:10, v/v/v/v) (13). The recovered neutral lipids were resolved into free sterols, free fatty acids, triacylglycerols, alkyldiacylglycerols and cholesteryl esters using petroleum ether (bp 30–60 C)/diethyl ether (60:10, v/v) as the developing solvent (14). The bands were located with fluorescein and were extracted with chloroform/methanol (2:1, v/v). The individual phospholipid classes were digested with phospholipase C from *Bacillus cereus* as described (15) and the diradyl moieties recovered by extraction with diethyl ether. An aliquot of the diradylglycerol fraction was converted into the trimethylsilyl (TMS) ethers for direct gas liquid chromatographic (GLC) examination (15). The remaining diradylglycerols were converted into the t-butyldimethylsilyl (t-BDMS) ethers and resolved by TLC into the diacyl, alkylacyl and alkenylacyl subclasses using benzene as the developing solvent as described (16).

GLC of the TMS and t-BDMS ethers of the diradylglycerols was performed (15,16) on a Hewlett-Packard model 5880 automatic gas chromatograph with a level IV terminal and 10 m open tubular glass column (0.25 mm i.d.) with its wall coated with SP-2330 liquid phase (68% cyanopropyl and 32% phenylsiloxane) supplied by Supelco (Bellefonte, PA). The temperatures of the injector and detector were both maintained at 270 C. Separations of diradylglycerol derivatives were made isothermally at 250 C using a split injection (split ratio 7:1) and hydrogen as a carrier gas. Separations of fatty acid methyl esters and dimethylacetals were made by temperature programming the column from 100 to 160 C at 20 C/min and then at 2 C/min or alternatively from 100 to 180 C at 20 C/min and then at 2 C/min, using hydrogen as carrier gas. The peaks were identified by reference to previous work with well-characterized $AgNO_3$-TLC fractions of the t-BDMS ethers derived from rat heart phosphatidylethanolamines (16). Carbon number profiles of the intact cholesteryl esters, triacylglycerols and alkyldiacylglycerols isolated by TLC, and the lipid profiles of the total lipid extracts of the ascites cells and of the lipid granules were determined by GLC on 50 cm × 0.2 cm i.d. stainless-steel columns packed with 3% OV-1 (a methylsilicone polymer) on 100–120 mesh Gas-Chrom (Applied Science Laboratories, State College, PA) using nitrogen as the carrier gas in the temperature range 175–355 C, as described (17). The peak identification and composition of samples were calculated in relation to tridecanoylglycerol internal standard. Fatty acid methyl esters and dimethyl acetals were prepared from the neutral and phospholipids by methylation with 6% H_2SO_4 in methanol, while methyl esters were prepared by methylation with sodium methoxide. The alkylglycerol moieties of the glycerolipids were determined by GLC on the short nonpolar columns (17) following saponification and trimethylsilylation.

Microscopy and histochemistry. The Ehrlich-Lettre ascites carcinoma cells and isolated lipid granules (Morrish, R. B., and Kay, E.R.M., unpublished observations) were examined by phase contrast microscopy. Oil red 0 was used as stain, if required. In some cases, the cells and isolated lipid granules were examined by electron microscopy. For this purpose, the cells and the granules were fixed in phosphate buffered (pH 7.4) 5% glutaraldehyde, followed by post-fixation in 2% osmium tetroxide (pH 7.4).

RESULTS

Physical properties of cells and granules. Figure 1 shows a preparation of ascites cells fixed and stained with glutaraldehyde and osmic acid. The cells are roughly spherical in shape, with numerous microvilli on the surface. The cytoplasm contains several osmic acid dense structures, corresponding in size (less than 2μ), number and distribution, with the refractile bodies seen in the phase contrast microscope. The particles seen within the cells by electron microscopy are generally of fairly uniform size. When the flotation and washing procedures are carried out with care, the isolated lipid particles appear clean and similar in size to those seen intracellularly and only occasionally contaminated with ribosomal elements. Likewise, phase contrast microscopy and the

application of oil red 0 staining revealed uniform particles free of extreneous material.

Chemical composition of lipid granules. Table 1 gives the lipid class composition of the lipid granules obtained in the present work and by DiPaolo et al. (8) along with the values for whole ascites cells tabulated by Wood (1). About 50% of the lipid in the granules is triacylglycerol, and about 30% is alkyldiacylglycerol. Cholesteryl esters and free cholesterol each make up about 3% of the total, while phospholipids account for about 10% of the particle lipid. These values are close to those reported by DiPaolo et al. (8) and differ significantly from those reported for whole ascites cells (9) and a cell membrane fraction (1,18), which contain much smaller proportions of triacylglycerols and especially alkyldiacylglycerols. The isolated particles gave neutral/polar lipid ratios corresponding to calculated (19) lipid core average diameters of 30–50 nm.

Table 2 compares the carbon number distribution of the cholesteryl ester, alkyldiacylglycerol and triacylglycerol fractions of the lipid granules as determined in the present work along with the corresponding values from whole ascites cells and the membrane fraction analyzed previously (1,18). The overall range and proportion of the carbon numbers of the triacylglycerols and alkyldiacylglycerols are similar to those of the corresponding neutral lipids of whole Ehrlich ascites cells. There is a much higher proportion of the longer chain length components in the cholesteryl esters of the lipid granules than in the membranes or in whole cells analyzed previously (1,18). Cholesterol was the only sterol present. The results obtained by analysis of intact lipid molecules are supported by analysis of the component glyceryl ethers and fatty acids.

Table 3 compares the alkylglycerol composition of the alkyldiacylglycerol fraction of the lipoid granules determined in this study and those recovered from the alkyldiacylglycerol fraction of whole Ehrlich ascites cells (1). There are significant differences in the actual fatty chain composition, but the carbon number proportions do not differ too much, thus accounting for the similarity in the overall carbon number distribution of the alkyldiacylglycerols from the two sources.

Table 4 compares the fatty acid composition of the triacylglycerol and alkyldiacylglycerol fractions isolated from the fat granules by us and by DiPaolo et al. (8) and of the choline and ethanolmine phosphatides isolated from the fat granules and the whole cells in our laboratory. While the fatty acids of the triacylglycerol fractions from both isolations possess closely similar compositions, the alkyldiacylglycerol fraction isolated by DiPaolo et al. (8) contains much more oleic and less docosahexaenoic acid

*The choline phosphatides of whole cells also contained 0.9% 16:0 and 0.4% 18:0 alkenyl, and a total of 16.5% alkyl chains, while the ethanolamine phosphatides also contained 7.1% 16:0, 2.8% 18:0 and 1.7% 18:1 alkenyl as well as a total of 6.5% alkyl chains.

Fatty acids are identified by their carbon number:double bond number. The ω-values indicate the location of the last double bond by the number of carbons from the methyl terminal.

than that obtained in this study. Although the longer chain acids could have been incompletely recovered in the earlier work, there is no obvious explanation for the high proportion of oleic relative to linoleic acid in this fraction. The fatty acid composition of the choline and ethanolamine phosphatides of the lipid granules is closely similar to that of the corresponding lipid classes from whole cells, and not unlike that described by Wood et al. (18) for the ascites cell membranes. However, the choline phosphatides of whole cells contained about 15% alkyl chains and the ethanolamine phosphatides 6% alkyl and 13% alkenyl chains, which were not determined in the phosphatide fractions of the lipid granules.

Molecular species of glycerolipids in intact cells. Figure 2 gives the polar capillary GLC profiles of the total, diacyl, alkenylacyl and alkylacylglycerol subclasses of the ethanolamine phosphatides of whole tumor cells. The preliminary separation of the various subclasses of phosphatides has permitted effective resolution of the individual molecular species, which overlap extensively in the chromatogram recorded for the mixed ethanolamine phosphatides. In this instance, the alkenylacyl and alkylacylglycerol species possessed by far the largest proportion of the longer polyunsaturated chain lengths, reflecting mainly the presence of a high proportion of docosahexaenoic acid. A similar observation has been made by Nakagawa and Waku (20).

Figure 3 shows the polar capillary GLC profiles of the diacyl and alkylacyl subclasses of the phosphatidylcholines of Ehrlich ascites tumor cells. There is an essentially complete resolution of all molecular species, although some minor ones do not project very clearly above the baseline. The combinations of the major chain lengths are markedly different in the two types of the phosphatidylcholines, with the alkylacyl species containing a significantly higher proportion of the longer polyunsaturated chain lengths.

Table 5 lists the various molecular species identified by polar capillary GLC along with the quantitative estimates for each subclass of the two phosphatides in whole Ehrlich ascites cells. The diacyl and the alkylacylglycerol subclasses of the choline phosphatides made up, respectively, 70% and 26% of the total. The remaining 4% was contributed by alkenylacyl species, which were not analyzed in detail for this phospholipid class. Wood and Snyder (9) reported 64% and 36%, respectively, for the diacyl and alkylacylglycerol subclasses of phosphatidylcholine from whole ascites cells. The diacyl, alkylacyl and alkenylacylglycerol subclasses of the ethanolamine phosphatide made up, respectively, 61%, 13% and 26% of total. Wood and Snyder (9) reported 56%, 29% and 15% of the total in the corresponding subclasses of the ethanolamine phosphatide of whole ascites cells, which, however, is the reverse of our values for the alkylacyl and alkenylacyl species. Summation of the major molecular species by carbon number gave molecular weight distributions for the diacyl, alkylacyl and alkenylacylglycerols of these phosphatides, which were rather similar to those obtained by Wood and Snyder (9) by GLC on nonpolar columns. Direct analyses of the fatty chain pairing in individual molecular species of the glycerophospholipids of Ehrlich ascites cells had not been reported.

DISCUSSION

The present study confirms the earlier reported (8) presence of lipid granules in Ehrlich ascites tumor cells. Isolation and chemical analysis of the particles gave calculated lipid core diameters, which were 40 to 70 times smaller than the diameters of the lipid granules seen in the intact Ehrlich ascites cells. Because the calculation (19) represents a valid method of estimating the particle size of lipoproteins, it is suggested that each granule in the cell is a membranous bag filled with lipid particles of a size and structure comparable to very low density lipoproteins (VLDL). It was not determined if there are any apolipoproteins associated with the fat granules of the Ehrlich ascites cells.

The previously unidentified fatty ester, which on silicic acid columns had migrated with the cholesteryl esters, was identified as a mixture of alkyldiacylglycerols, which Wood and Snyder (9) had characterized from whole Ehrlich ascites cells. However, the relative proportion of alkyldiacylglycerols in the fat granules was many times higher than that in the whole cells and approached the quantitates estimated for the Liebermann-Burchard negative material isolated along with the cholesteryl ester fraction by DiPaolo et al. (8). We could not confirm the high proportion of oleic acid reported for the alkyldiacylglycerol fraction of the fat granules by DiPaolo et al. (8). The small cholesteryl ester fraction of the lipid granules was found to possess an unusually high proportion of the longer chain length polyunsaturated fatty acids (C_{20} and

Fatty chain identification by number of carbons:number of double bonds. The fatty acids on the left side of the molecular species pair is to be read as either acyl, alkyl or alkenyl chain depending on the phosphatide subclass.

C_{22}), when compared with the cholesteryl esters of the total Ehrlich ascites cell.

An examination of the phospholipid composition of the lipid particles was limited to a determination of the fatty acids, which was rather similar to that found for the corresponding phospholipid classes of the ascites cell. However, the phosphatides isolated from whole cells also contained alkyl and alkenyl fatty chains, which would not have been detected in the glycerophosphatides isolated from the fat granules, because the sodium methoxide used for transmethylation would not break the ether linkages. Although Wood et al. (1,18) have claimed an essential absence of both alkyl and alkenylacylglycerol subclasses from the choline and ethanolamine phosphatides of a membranous material isolated from Ehrlich ascites cells, it is unlikely that the alkyl and alkenyl ether phosphatides would be absent from the fat granules, which presumably depend upon microsomal lipid synthesis (4,21). Furthermore, Friedberg and Halpert (3) have reported that the amounts of *O*-alkyl lipids in the surface membranes of Ehrlich ascites cells are the same or greater than the amounts of *O*-alkyl lipid found in the microsomes, mitochondria and whole cell homogenates. These workers could not account for the findings of Wood et al. (18). In view of these considerations, it is likely that the molecular species composition of the choline and ethanolamine phosphatides of the whole cells also represents that of the fat granules. However, a possible preferential concentration of the alkyl and alkenyl species of the phosphatides in the granules could not be ruled out in view of the marked enrichment in the alkyldiacylglycerols there. An extensive equilibration of cholesteryl esters and the alkyldiacyl and triacylglycerols between their sites of synthesis in the cell and the lipid granules also would be unlikely in view of the marked differences in the qualitative and quantitative composition of the molecular species.

There has been little speculation about the origin and the metabolic role of the fat granules in the Ehrlich ascites tumor cells. A slow staining of these granules with Janus Green B and their location in opposition to mitochondria have led MacKenzie et al. (21) to suggest that they may possess enzymes and furnish substrate for mitochondria. Because no specific enzymic activities were demonstrated, it is possible that the staining was due to an association of apoproteins with these particles, which would be anticipated in view of the hepatic origin of the ascites cells and of their general similarity to VLDL. Alkyldiacylglycerols have been observed to accumulate also in other cancer cells (6), in Ehrlich ascites cells (22) and in normal cells in culture (23). This has been attributed to an enhanced rate of glucose utilization via the dihydroxyacetone pathway (6) combined with a decreased activity of the alkyl ether cleavage enzyme (24). It also has been suggested (1) that the ascites cells may have reverted to a more primitive stage of lipid metabolism characterized by the ability of direct utilization of products of lipase activity. The presence of specialized lipid granules containing the alkyldiacylglycerols, however, has not been demonstrated in tumor cells other than Ehrlich ascites cells. Neither have attempts been made to isolate them from any other cell types.

This study provides the first quantitative analysis of the specific molecular association of the fatty chains in the choline and ethanolamine phosphatides of the Ehrlich ascites tumor cells, although extensive investigations have been reported of the carbon number distribution (1) and of fatty acid composition of the subfractions of the diacyl, alkylacyl and alkenylacylglycerol moieties of these phospholipids following $AgNO_3$-TLC (4,5). The complete resolution of the molecular species of the diradylglycerols obtained on the polar capillary columns confirms the preferential association of the long chain polyunsaturated fatty acids with the alkyl and alkenyl chains in the ethanolamine phosphatides. Likewise, there is a good agreement between the present direct and previous indirect analyses of the other major molecular species of diacyl and alkylacyl subclasses of the choline and ethanolamine phosphatides. A further rationalization of the composition of the molecular species of the neutral and polar glycerolipids of the Ehrlich ascites tumor cells and of the lipid granules isolated from them requires a better understanding of glycerolipid metabolism in general.

[Received October 20, 1987; Revision accepted December 29, 1987]

Effect of Dietary Vitamin E and Selenium on Susceptibility of Brain Regions to Lipid Peroxidation

Mohsen Meydani*, John B. Macauley and **Jeffrey B. Blumberg**
USDA Human Nutrition Research Center on Aging at Tufts University, 711 Washington St., Boston, MA 02111

The effect of dietary vitamin E and/or selenium (Se) supplementation (200 IU and/or 0.2 ppm, respectively) or deficiency for two months on lipid peroxidation in cerebrum, cerebellum, mid-brain, and brain stem of one-month-old male F344 rats was investigated. Dietary treatment had a minimal effect on weight gain of rats for the period tested. Plasma α-tocopherol (α-T) concentration and glutathione peroxidase (GSH-Px) activity were reflective of dietary treatments. Supplementation of diets with vitamin E and/or Se increased plasma α-T and/or GSH-Px activity, while diets devoid of these nutrients reduced them significantly. Increased GSH-Px activity in Se-supplemented rats was further enhanced by vitamin E supplementation. Differential concentrations of α-T among brain regions were affected by dietary vitamin E but not by Se. In vitro lipid peroxidation of brain homogenates was inhibited by dietary vitamin E supplementation and increased by deficiency. Addition of 0.25 mM ascorbic acid or 0.1 mM of Fe^{2+} to brain homogenates markedly increased in vitro lipid peroxidation. Ascorbic acid-induced lipid peroxidation was inversely correlated with dietary vitamin E and Se in cerebrum. In vitro Fe^{2+}-addition induced the greatest stimulation of lipid peroxidation, with cerebellum and brain stem of vitamin E-deficient rats showing the highest response to Fe^{2+} challenge. These findings indicate that concentrations of α-T among the brain regions are different and can be altered by dietary vitamin E treatments, cerebellum and brain stem are more susceptible to in vitro challenge by peroxidative agents than other regions, and the degree of lipid peroxidation of brain regions is partially affected by dietary vitamin E but not by Se in the levels tested. *Lipids 23,* **405–409 (1988).**

Vitamin E deficiency in experimental animals induces pathological changes in the reproductive, cardiovascular and nervous systems, and in other tissues (1–4). Neurological signs of chronic vitamin E deficiency include axonal swelling and dystrophy, demyelination, increased oxidative enzyme activity and neuronal pigment accumulation (1,4–8). Neuropathological observations linking vitamin E deficiency to neurological disorders in humans indicate the importance of dietary vitamin E in central nervous system function (9–11). The interaction between dietary vitamin E and selenium (Se) incorporated into glutathione peroxidase (GSH-Px) has been well-documented (12,13). The concentration and uptake of vitamin E and the activity of Se-dependent GSH-Px vary among the brain regions (14–17). The antioxidative functions of vitamin E and Se suggest that changes in the concentration of these nutrients in particular brain regions may influence regional susceptibility to lipid peroxidation. Most information on the influence of antioxidants on brain lipid peroxidation has emerged from use of either whole brain or cerebrum tissue (18–21). In a previous study, we reported that lipid peroxidation of cerebrum is affected by dietary vitamin E and Se (22). Different brain regions in rats are well-defined and composed of a variety of neuronal processes with specific biochemical and neurological functions. Therefore, this study was undertaken to extend our previous work to examine the influence of feeding vitamin E- and Se-deficient and/or supplemented diets on the lipid peroxidative capacity of different brain regions of rat: cerebrum, cerebellum, mid-brain and brain stem. Our findings are consistent with the concept that vitamin E protects lipid components of neuronal tissue from free radical reactions and peroxidation.

MATERIALS AND METHODS

Forty-eight, one-month-old male Fischer 344 rats (Charles River Breeding Lab., Inc., Wilmington, MA) were randomly assigned to six dietary treatment groups. Group A (control) received the basal diet (containing no vitamin E and Se, Table 1) supplemented with 30 IU α-tocopheryl acetate/Kg diet and 0.1 ppm Se as sodium selenite as recommended by National Research Council and National Academy of Science for normal growth and reproduction (23). Group B (+E+Se) received the basal diet supplemented with 200 IU α-tocopheryl acetate and 0.2 ppm Se. Group C (−E+Se) received the basal diet supplemented with 0.2 ppm Se. Group D (+E−Se) received the basal diet supplemented with 200 IU α-tocopheryl

TABLE 1

Composition of Basal Diet

Ingredient	Percent
Torula yeast[a]	30.0
Sucrose[a]	56.7
α-Tocopherol stripped lard[a]	5.0
α-Tocopherol stripped corn oil[a]	2.0
DL-Methionine[a]	0.3
Mineral mix (selenium free)[a,b]	5.0
Vitamin mix (vitamin E free)[c]	1.0
Total	100.0

[a]Teklad, Madison, WI.

[b]Hubbell-Mendel-Wakeman (3.08 g of $MnSO_4.H_2O$ per kg of mineral mix was added). Mineral contribution from torula yeast gave final percentage concentration in diet as follows: Ca, 1.16; P, 0.77; K, 1.2: Na, 0.16; Mg, 0.10; Fe, 0.017; Cu, 0.0023; Mn, 0.0055; Zn, 0.0037.

[c]Vitamin content in 1 kg of diet: thiamine HCl, 4.0 mg; riboflavin, 4.8 mg; pyridoxine HCL, 2.0 mg; calcium pantothenate, 20.0 mg; niacin, 100.0 mg; menadione, 1.0 mg; folic acid, 2.0 mg; biotin, 1.0 mg; vitamin B_{12} (0.1% trituration), 10.0 mg; retintyl palmitate, 100 mg; cholecalciferol, 4 mg; sucrose was added to make total vitamin mix 10 g.

acetate/Kg diet. Group E (−E−Se) received only the basal diet. Group F was pair fed to the double-deficient group E with the group A diet.

Rats were individually housed in stainless steel wire mesh cages and maintained at 22 C with 12 hr light-dark cycles. All the animals were fed ad libitum except the pair-fed rats (group F). After eight wk of dietary treatment, animals were fasted overnight then killed by decapitation. Blood was collected in heparinized tubes and plasma separated and stored at −70 C. Brain was removed from the skull, placed on an ice-cold platform, and immersed with ice-cold buffer. The cerebrum, cerebellum, mid-brain (including hypothalamus, striatum, and hippocampus) and brain stem (including medulla oblongata and pons) were dissected with precooled dissecting tools within one to two min of decapitation. Ten percent homogenates of the brain regions were prepared using ice-cold 1.15% KCl. Following addition of α-tocopheryl acetate containing 0.1% butylated hydroxytoulene in ethanol to the homogenate or plasma, α-tocopherol (α-T) was extracted with hexane, dried under a stream of nitrogen and reconstituted in ethanol. α-T was measured by the modified high performance liquid chromatography method described by Bieri et al. (24) using 100% methanol as the mobile phase and fluorometric detection (Exc:292, Emm:340 nm) for enhanced sensitivity. Detection limits for α-T in plasma and brain samples were 0.2 μg/ml and 10 μg/mg, respectively. Glutathione peroxidase (GSH-Px) activity in plasma was measured by the method of Paglia and Valentine (25). Thiobarbituric acid reactive substances (TBARS) were measured (26) as an index of lipid peroxidation in brain homogenates with and without incubation at 37 C for two hr, and in the presence and absence of 0.25 mM L-ascorbic acid or 0.1 mM Fe^{2+} as ferrous sulfate. Malonaldehyde bisdimethylacetal was used as a standard to calculate the molar equivilance of malonaldehyde (MDA) for TBARS assessment (27). Total protein in brain homogenates was measured by the Lowry method (28). Factorial analysis of variance and Duncan multiple means range test at 5% probability were employed for statistical analysis of the data.

RESULTS

Overall weight gain of animals among the groups was not significantly affected by dietary treatments for the period tested. The highest gains were observed in rats fed the vitamin E-supplemented diets (431% for group B and 451% for group D), while the lowest weight gains were noted in rats fed double-deficient diet (group E) and the matched pair-fed control (group F) (345% and 337%, respectively).

Plasma GSH-Px activity and α-T concentration in plasma and brain regions are shown in Table 2. GSH-Px activity and α-T concentration of plasma reflected dietary treatments. Rats fed diets supplemented with either vitamin E or Se showed increased plasma α-T or GSH-Px activity, while those fed diets devoid of these nutrients had lower plasma α-T or GSH-Px activity, respectively. Presence of vitamin E in Se-supplemented diets appeared to enhance the increment of plasma GSH-Px activity (group B vs group C). The decrease of plasma GSH-Px in the rats fed Se-deficient diets (group D vs group E) was not alleviated by vitamin E supplementation. Se deficiency or supplementation had no effect on plasma α-T concentrations from rats fed vitamin E supplemented or deficient diets (group D vs group B and group E vs group C). Plasma α-T and GSH-Px activity of pair-fed rats did not differ from those fed control diet ad libitum (group A). Concentration of α-T in brain regions varied within and between the dietary groups. The most significant increases of α-T were found in the brain regions of rats fed either +E+Se or +E−Se diets. Among the brain regions in rats fed these diets, cerebrum and mid-brain had higher α-T concentrations than cerebellum and brain stem. Conversely, feeding vitamin E-deficient diets (−E−Se and −E+Se) significantly reduced α-T in all four brain regions. Among the brain regions of rats fed these deficient diets, cerebellum and brain stem had lower α-T concentrations than cerebrum and mid-brain. The concentration of α-T in all brain regions of group F (pair-fed to group E with the control diet) was significantly higher than those of group E (−E−Se). However, cerebrum and brain stem of rats from group F had significantly lower α-T concentrations than those from group A (fed control diet ad libitum).

The influence of dietary treatment on lipid peroxidation in brain was not evident from TBARS measurements in homogenates without incubation. Endogenous TBARS levels from the brain regions of rats did not vary significantly among different dietary treatment groups (Table 3). The overall rank order of endogenous TBARS

among the brain regions of rats from different dietary treatments was brain stem > cerebellum > mid-brain = cerebrum.

Incubation of brain homogenates under air for two hr showed dietary effects as manifested by differential susceptibilities of brain regions to lipid peroxidation (Table 4). Cerebrum and mid-brain from rats fed either of the vitamin E-supplemented diets (+E+Se or +E−Se) had significantly lower capacities to produce TBARS than cerebrum and mid-brain from rats fed either of the vitamin E-deficient diets (−E+Se or −E−Se). The effect of doubly supplemented or deficient diets on TBARS relative to control diet was significant only in cerebrum. Dietary vitamin E supplementation had an inhibitory effect on in vitro lipid peroxidation in cerebellum (group D vs groups C and E). Incubation of homogenates showed brain stem of rats treated with any of the diets (except group C) to produce a higher TBARS level than other regions. Brain stem from double-deficient rats showed the highest in vitro TBARS level compared with other dietary treatments. Se-supplemented or deficient diets had no effect on TBARS production under this in vitro condition.

In vitro addition of 0.25 mM ascorbic acid or 0.1 mM Fe^{2+} to the homogenates increased TBARS production several-fold (Tables 5 and 6). Ascorbic acid-induced lipid peroxidation in cerebellum was higher than in other brain regions; brain stem lipid peroxidation was higher than cerebrum and mid-brain in all dietary groups. An effect of dietary treatment on the potential for lipid peroxidation was manifested in cerebrum in response to ascorbic acid challenge. Ascorbic acid-induced lipid peroxidation in cerebrum of rats fed vitamin E-deficient diets (−E+Se and −E−Se) showed significantly higher TBARS than those fed the other diets. A similar trend was observed in mid-brain and cerebellum of −E+Se and −E−Se fed rats and brain stem of −E−Se fed rats but did not reach statistical significance.

In vitro addition of 0.1 mM Fe^{2+} also induced TBARS production in the brain homogenates. However, Fe^{+2} stimulation was greater than ascorbic acid challenge in cerebrum and mid-brain of all dietary groups and as well as in the cerebellum of group A and brain stem of groups B, D, E and F. Vitamin E-deficient rats, particularly those fed −E−Se diet showed the highest in vitro lipid peroxidation in all four brain regions in response to Fe^{2+} challenge. Among the brain regions, cerebellum and brain stem showed the highest responses.

DISCUSSION

Relative to the other tissues, brain contains a low level of vitamin E- and Se-dependent GSH-Px activity (18,29). Furthermore, brain regions vary in their α-T concentration (14–16) and, as shown here, are affected differentially by dietary vitamin E and Se. These components also have been shown to be altered by other physiological and

pathological factors (30,31). The level of α-T in brain regions appears principally affected by dietary vitamin E, an important lipid-soluble antioxidant that influences tissue susceptibility to in vitro and, presumably, in vivo lipid peroxidation.

The changes in α-T concentration induced by dietary treatment vary among the brain regions. For example, in this study, feeding rats with 200 IU of vitamin E for two months increased α-T concentration in cerebellum by 77% (relative to control-fed rats) but only by 36% in cerebrum. Brain tissue has been reported to exhibit a low level of Se-dependent GSH-Px activity relative to other organs (29), and its activity varies among brain regions (17). The biochemical interrelationship between vitamin E and Se is known (32), and their effect on the metabolism of each other and lipid peroxidation has been demonstrated in several tissues (33). However, in this study, supplementation or deficiency of Se did not have any significant effect on α-T level or lipid peroxidation of brain regions during the test period.

It has been reported that susceptibility to lipid peroxidation is markedly influenced by dietary vitamin E and tissue α-T levels (20,32). Brain tissue, due to its high rate of oxygen consumption and high phospholipid content with polyunsaturated fatty acids, is particularly susceptible to peroxidative agents, free radical generating compounds, and lipid peroxidation. However, vitamin E, vitamin C, GSH-Px, superoxide dismutase and other antioxidant defense mechanisms are present in different brain regions with varieties of concentrations and activities (14–17,35–37), working against lipid peroxidation in different brain regions. These cooperative antioxidant defense mechanisms minimize oxidative damage, quench free radical propagation and limit lipofuscin accumulation (6). Although significant differences in α-T concentration were found in the brain regions examined, endogenous levels of lipid peroxidation products, measured as TBARS, did not reflect dietary treatment. Therefore, without in vivo stimulation of lipid peroxidation, measurements of endogenous TBARS of brain regions did not reveal differential effects of dietary vitamin E and Se supplementation or deficiency. However, the presence of relatively low levels of α-T and the detection of relatively higher levels of TBARS in cerebellum and brain stem (Table 2) indicate that these brain regions might be more prone to lipid peroxidation following an in vivo oxidative insult.

Incubation of brain homogenates at 37 C for two hr revealed the influence of dietary treatments on susceptibility to lipid peroxidation. The magnitude of lipid peroxidation was inversely correlated with α-T content. Among the brain regions, brain stem had the highest

capacity for in vitro lipid peroxidation under atmospheric oxygen pressure. Cerebrum and mid-brain regions were least susceptible to lipid peroxidation and possessed the highest concentration of vitamin E.

Addition of ascorbic acid or Fe^{2+} resulted in a several-fold increase of TBARS as reported (38–40). The addition of a low concentration of ascorbic acid reduces oxidized iron and increases lipid peroxidation via initiation of a Fenton-type reaction (41). Differences in the concentration of endogenous iron in brain regions have been partially implicated in the differential susceptibility of brain areas to lipid peroxidation (38). Addition of ascorbic acid to the tissue homogenate upsets the balance between ferric and ferrous iron leading to lipid peroxidation. Our data (Table 5) shows that the cerebellum, relative to other brain regions, had a higher response to the in vitro ascorbic acid challenge, suggesting lipid peroxidation in cerebellum may be related to the high iron content of this brain region. Our data also indicate the cerebellum is more susceptible to ascorbic acid-induced lipid peroxidation, relative to cerebrum and mid-brain even in a state of vitamin E and Se sufficiency. This is in contrast to Noda et al. (39), who found the greatest increase of lipid peroxidation in cerebral cortex, corpus callosum and hippocampus in response to hyperbaric oxygen. They postulated that iron-rich areas in brain generally are vulnerable to iron-catalyzed free radical reactions under hyperbaric oxygen. However, their findings do not closely parallel local brain iron concentrations. The difference between our findings and those of Noda et al. probably is related to the in vivo TBARS metabolism in brain areas after hyperbaric oxygen administration, vs the in vitro ascorbic acid challenge in this study. Thus, the varying iron content of brain tissues may correlate with lipid peroxidation, while the nature of the proxidant challenge may influence the quantitative outcome. It should be noted that ascorbic acid-induced lipid peroxidation still was significantly influenced by dietary intervention in cerebrum and mid-brain where levels of endogenous iron are known to be lower than in cerebellum.

Exogenously added Fe^{2+} further augmented in vitro lipid peroxidation. The addition of Fe^{2+} had a greater stimulatory effect on lipid peroxidation in brain regions with relatively low α-T content and in those regions known to have low dopamine activity. Dopamine has been shown to be effective in ligation of in vitro Fe^{2+} (38). In vitamin E-deficient rats, cerebellum and brain stem, areas with relatively low dopamine activity, showed a slightly higher degree of lipid peroxidation after Fe^{2+} challenge than cerebrum and midbrain.

In this in vitro system, our findings suggest there is a differential susceptibility between brain regions to lipid peroxidation that varies with the peroxidative agent used. In F344 rats, cerebellum and brain stem are more susceptible to lipid peroxidation than other brain regions. This susceptibility is partially affected by the α-T content of these regions, which can be manipulated by dietary vitamin E, but not Se, intervention. Several other endogenous factors, and relative regional distribution of compounds known to be involved in lipid peroxidation processes including total iron, ascorbate, catalase and superoxide dismutase, as well as the composition of fatty acids, phospholipids and neurotransmitters, may contribute to the susceptability of brain regions to lipid peroxidation and the efficacy of dietary vitamin E and Se intervention.

[Received March 2, 1987; Revision accepted January 8, 1988]

Isolation and Characterization of Proteolipids from Rat Liver (LSP) and Kidney (KSP)

Dieter Jüngst*, Johann Blumenstingl and Wolfgang H. Caselmann
Department of Medicine II, Klinikum Grosshadern, University of Munich, Federal Republic of Germany

In this study, the biochemical characteristics of proteolipids of rat liver and kidney homogenates were compared. In all preparations, the proteo-lipids were eluted at the void volume of the Biogel A-15 m column after gel chromatography, and a molecular weight over 15×10^6 was estimated. Electron microscopy of the concentrated void volume fractions showed globular particles with diameters of 30–100 nm for liver (LSP) and 30–60 nm for kidney (KSP) preparations that might be formed from plasma membrane fragments. After ultracentrifugation in a CsCl gradient, rat LSP and KSP floated in a small density range from 1.16–1.17 g/ml. There was no significant difference between the relative percentages of phospholipids, triglycerides and cholesterol of both proteo-lipids. However, the relative mean amount of total protein in rat KSP (60.4% vs 50.4%) was significantly higher and the content of free fatty acids (4.3% vs 12.6%) significantly lower compared to rat LSP. SDS-PAGE revealed at least 12 protein subunits ranging from 15,000–130,000 in both preparations, but one protein of about M_r 49,000 might represent a liver specific component. The isolated proteo-lipids from rat liver and kidney homogenates showed similar biochemical characteristics as those from human sources, which could explain the known cross-reactivity of antibodies against these preparations.

The putative function of these proteo-lipids is not known, although there is some evidence from human studies that they carry receptor proteins.
Lipids 23, 410–414 (1988).

Cellular and humoral immune reactions against the liver-specific membrane lipoprotein complex (LSP) have been widely reported in patients with liver disease (1,2). LSP is a large, lipid-associated complex containing several antigens, including species-specific and species cross-reactive determinants, of which at least two seem to be liver specific, but their precise identity has not been established (3–5). Immunochemical and electron microscopical evidence suggests that LSP is derived from the liver cell plasma membrane (6–8). An important role of the plasma membrane is to transmit biochemical signals generated by ligand-receptor interaction at the cell surface across the lipid bilayer and into the cell (9). Recently, the hepatic asialo-glycoprotein receptor (hepatic lectin) has been detected as a minor component of liver-specific membrane lipoprotein (10). To our knowledge, this has been the first time that any component of LSP has been positively identified.

Further studies have shown that LSP is a far more complex particle than was first recognized. It has an apparent molecular weight (by gel filtration) of more than 20×10^6, contains phospholipids and triglycerides, and shows multiple protein subunits on SDS-polyacrylamide gel electrophoresis (4). Behrens and Paronetto (11) have demonstrated that kidney extract (KSP) handled in the same manner as liver extract has many similarities to LSP and that antibodies against LSP and KSP give the same immunofluorescence pattern in sections of liver, kidney and stomach. Furthermore, LSP and KSP cross-react in double gel diffusion.

These findings point against a complete organ specificity of LSP in humans in accordance with later studies by Riisom and Diederichsen (12). Hopf et al. tested LSP from different species and showed that rat LSP cross-reacted weakly with human LSP (6). However, Kakumu et al. demonstrated that antiserum to rat LSP, absorbed with normal human plasma, gave a single line on immunodiffusion against purified LSP from rat and human livers. Furthermore, antisera to rat and human LSP reacted almost equally with both rat and human hepatocytes, respectively (1). Whereas biochemical investigations have concentrated on human LSP and more recently KSP, there were to our knowledge no data on the biochemical characterization of these proteo-lipids in rat liver and kidney.

In view of the demonstrated shared antigenic properties, we performed an extensive characterization of these proteo-lipids in rats, which permits a comparative evaluation with the results of the previous studies in humans.

MATERIALS AND METHODS

Preparation of rat liver and kidney membrane lipoproteins. Rat livers and kidneys were obtained from male Sprague-Dawley rats weighing ca. 150 g. The preparation of the membrane lipoproteins was performed at +4 C according to Behrens and Paronetto (11) and McFarlane et al. (4). The liver and kidney tissue was cut into small pieces and washed for five hr in 0.25 M sucrose solution adjusted to pH 8.0 with 0.1 M NaOH, changing the solution every 20 min. For each of the 10 different preparations, 10 rat livers and 20 kidneys were pooled. After crushing the tissue pieces in 0.25 M sucrose solution (wt/vol, 1:1) with an Ultra-Turrax blender, homogenization in a potter homogenizer was performed. The homogenate was ultracentrifugated at 100,000 *g* for one hr using a Beckman 60 Ti-rotor. Two hundred IU/ml penicillin and 10 μg/ml gentamicin were added to the supernatant, and 4 ml were incubated at 20 C with 1.0 μCi of ethanolic [1,2-^{3}H]cholesterol (New England Nuclear, Boston, MA), which is incorporated in the protein lipid complexes and serves as an easily detectable, highly sensitive but not quantitative marker of the lipid moiety. Afterwards, gel chromatography was performed on a 95.0×3.0 cm Biogel A-15 m column with 0.1 M Tris HCl, pH 8.0, containing 0.2 M NaCl and 1 mM Na_2 EDTA as elution buffer.

Abbreviations: KSP, kidney specific preparations; LSP, liver-specific preparations; PAG, polyacrimide gel; SDS-PAGE, sodium dodecyl sulfate polyacrimide gel electrophoresis.

Usually, 80 to 90 8.4 ml fractions were collected. The absorbance at 280 nm was recorded with a Beckman spectrophotometer. After addition of 5.0 ml Bray-scintillation solution to 0.1 ml aliquots of the fractions, the β-radiation emitted by [1,2-^{3}H]cholesterol was measured in a Betaszint BF 5000 counter. All fractions containing [1,2-^{3}H]cholesterol were pooled and concentrated to about 10% of the original volume using PM 10 membranes (Amicon, Witten, FRG). Further characterization was done by chemical assay, electron microscopy, density gradient ultracentrifugation and SDS-polyacrylamide gel electrophoresis.

Biochemical assays. Protein was measured by the method of Lowry after precipitation of the proteins with trichloracetic acid (13). Total cholesterol and triglyceride determinations were performed enzymatically with commercial test kits (Boehringer Mannheim, FRG) (14,15). The colorimetric NEFA C-test (Wako Chemicals, Osaka, Japan) was used for the quantification of unesterified fatty acids (16). The total phospholipids were determined in chloroform/methanol extracts (3:1, v/v) according to Fiske and Subbarow (17). Further fractionation of the phospholipids was achieved by thin layer chromatography on 20 × 20 cm glass plates coated with silica gel (Merck, Darmstadt, FRG).

Chloroform/methanol/water (65:35:8, v/v/v) was used as solvent system. The separated phospholipids were made visible with iodine vapor and stained individually. Cardiolipin, phosphatidylcholine, sphingomyelin, phosphatidylinositol and ethanolamine glycerophospholipids served as reference substances. Afterwards, a colorimetric phospholipid determination was performed. The accuracy was tested by Precilip E.L. standard sera (Boehringer, Mannheim, FRG).

Density gradient ultracentrifugation. One ml of the sample was added to 3.4 ml of CsCl-solution (density 1.25 g/ml). During 72 hr of ultracentrifugation at 4 C and 50,000 rpm in a Beckman SW-60 rotor, a concave gradient from 1.06 to 1.43 g/ml was established (18). Eleven 0.4 ml fractions were obtained by pipetting from the top. The densities were calculated by weighing 0.2 ml portions. The absorbance at 280 nm and the counts per min were

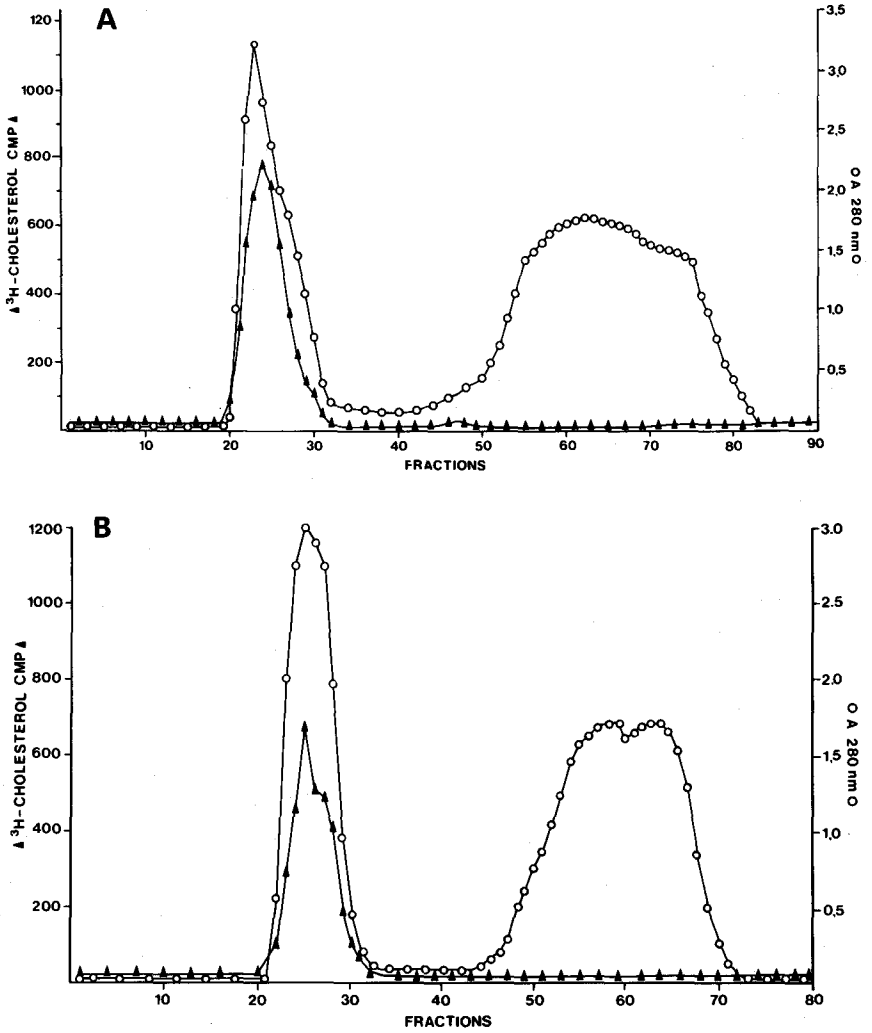

FIG. 1. Typical gel chromatographic elution profile of the concentrated 100,000 g supernatant of liver (A) and kidney homogenates (B) on Biogel A-15 m. Column size 95 × 3.0 cm. Points represent cpm emitted by [1,2-^{2}H]cholesterol (▲) and the absorbance at 280 nm (O) in each collected fraction. V_o, void volume.

measured in each fraction and compared with the position of the macroscopically visible turbid disk of ca. 1-mm height.

Electron microscopy. Electron micrographs were taken with a Siemens 101 electron microscope at 80 kV. The membrane lipoprotein preparations were negatively stained with 2% potassium phosphotungstate, pH 7.0 (19). A small drop of the suspension was placed on a 200 or 300 Formavar carbon-coated grid and examined after drying at room temperature.

SDS-Polyacrylamide gel electrophoresis. For SDS-PAGE, aliquots of the samples were diluted (1:4, v/v) with 37.5 mM Tris HCl buffer (pH 8.8) containing 1 g/dl SDS and 4% 2-mercaptoethanol. After incubation for three min at 95 C, the electrophoretic protein separation was performed in ultrathin (0.36 mm) SDS-polyacrylamide pore gradient gels (T = 4.0–22.5%) on PAG films. The protein subunits were stained with silver nitrate (20). The molecular weights were estimated by comparison with calibration standards (Pharmacia, Freiburg, FRG) according to the method of Weber and Osborne (21).

Statistical analysis. Using mean and standard deviation of the mean for further statistical analysis of our data, Student's t-test was applied.

RESULTS

The elution profile of the 100,000 g liver and kidney supernatants on a Biogel A-15 m column showed rising absorbance at 280 nm, coinciding with elevated counts/min in the first peak as well as high protein absorbance without evidence of radioactivity in the second peak (Fig. 1).

Liver (Fig. 1A, first peak) and kidney (Fig. 1B, first peak) proteo-lipids showed similar elution patterns. Both were eluted in the void volume of the Biogel A-15 m column, indicating a molecular weight of more than 15×10^6.

The determination of the void volume (v_0) had been performed with 10% Dextran 5000 (Serva, Heidelberg, FRG) composing macromolecules of up to 40×10^6.

The chemical analysis of the pooled and concentrated fractions revealed 50.4% protein, 23.2% phospholipids, 12.6% free fatty acids, 11.2% triglycerides and 5.6% total cholesterol (mean values) for liver and 60.4% protein, 20.5% phospholipids, 11.1% triglycerides, 4.7% total cholesterol and 4.3% free fatty acids (mean values) for kidney lipoproteins (Table 1).

The percentage of total protein in rat KSP was significantly ($p < 0.02$) higher and the percentage of free fatty acids significantly ($p < 0.001$) lower compared with the relative amounts in rat LSP. The composition of the phospholipid moiety fractionated by thin layer chromatography is illustrated in Table 2. There were no significant differences for cardiolipin, ethanolamine glycerophospolipids, phosphatidylcholine, phosphatidylinositol and sphingomyelin in both preparations.

An average density of 1.16 g/ml was measured for rat LSP and of 1.17 g/ml for rat KSP by CsCl-gradient ultracentrifugation (Fig. 2A and B). After negative staining, electron microscopy showed globular macromolecules with diameters of 30–100 nm for liver and of 30–60 nm for kidney preparations (Fig. 3A and B). Assuming that one spheric particle on the photograph corresponded to a single molecule, an average molecular weight of 100×10^6 and 50×10^6 was calculated for liver and kidney proteo-lipid complexes, respectively. The particles consisted of at least 12 protein subunits with a molecular weight ranging from 15,000 to 130,000, separated by SDS-PAGE (Fig. 4A and B).

The protein profiles on the gels following SDS-PAGE of rat LSP and rat KSP were similar but show one interesting difference. The protein at about M_r 49,000 appears to be more heavily stained on the liver sample compared with the kidney sample and also may be slightly smaller. The other differences in the electrophoretic profiles of both samples seemed to be caused by varying concentrations of corresponding subunits macroscopically visible by the slightly different intensity of the silver nitrate staining. These visual impressions have been confirmed by a quantitative densitometric scan of these gels.

DISCUSSION

The findings reported here indicate that LSP and KSP could be prepared by standard methods from rat liver and kidney. There were some variations in terms of lipid/protein ratio and the relative amount of the major lipids (phospholipids, free fatty acids, triglycerides, cholesterol) between the 10 different preparations of LSP and KSP. This might be caused by the isolation procedure that composed multiple steps as crushing of the tissue, homogenization, ultracentrifugation, gel chromatography, ultrafiltration and thin layer chromatography. In all preparations, rat LSP and rat KSP were eluted in a single peak at the void volume of the column after gel chromatography. From these results, a molecular weight of rat LSP and rat KSP over 15×10^6 is estimated. However, because of the hydrophobic nature, proteo-lipids may behave atypical on gel filtration, and aggregation of

TABLE 1

Relative Composition of Lipids and Protein in the Rat Liver and Kidney Membrane Lipoproteins of 10 Preparations (Mean ± SEM)

	Liver (%)	Kidney (%)	p-Value
Protein	50.4 ± 2.2	60.4 ± 3.2	<0.02
Phospholipids	23.2 ± 3.9	20.5 ± 2.6	n.s.
Free fatty acids	12.6 ± 1.1	4.3 ± 0.5	<0.001
Triglycerides	11.2 ± 1.8	11.1 ± 2.4	n.s.
Cholesterol	5.6 ± 0.5	4.7 ± 0.7	n.s.

TABLE 2

Relative Composition of Phospholipids in the Rat Liver and Kidney Membrane Lipoproteins of 10 Preparations (Mean ± SEM)

	Liver (%)	Kidney (%)	
Cardiolipin	5.4 ± 1.7	9.3 ± 3.0	n.s.

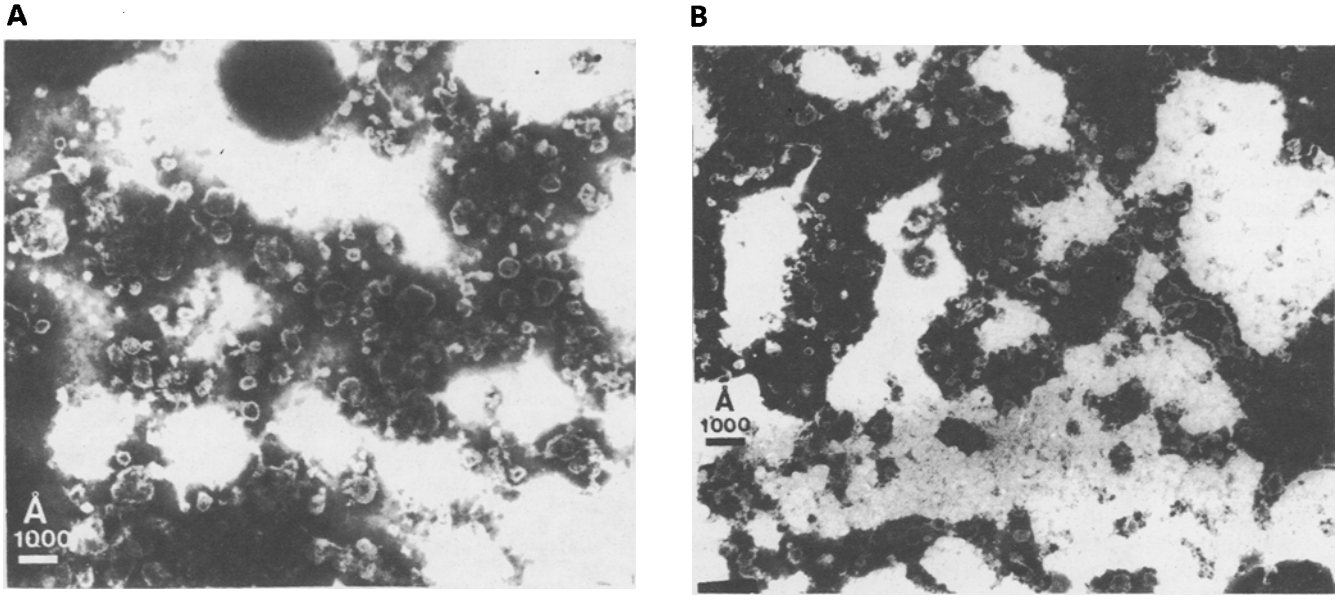

FIG. 3. Electron microscopy of the liver (A) and kidney (B) membrane lipoprotein preparation using a Siemens 101 electron microscope and a negative staining technique with 2% potassium phosphotungstate, pH 7.0 (×60,000).

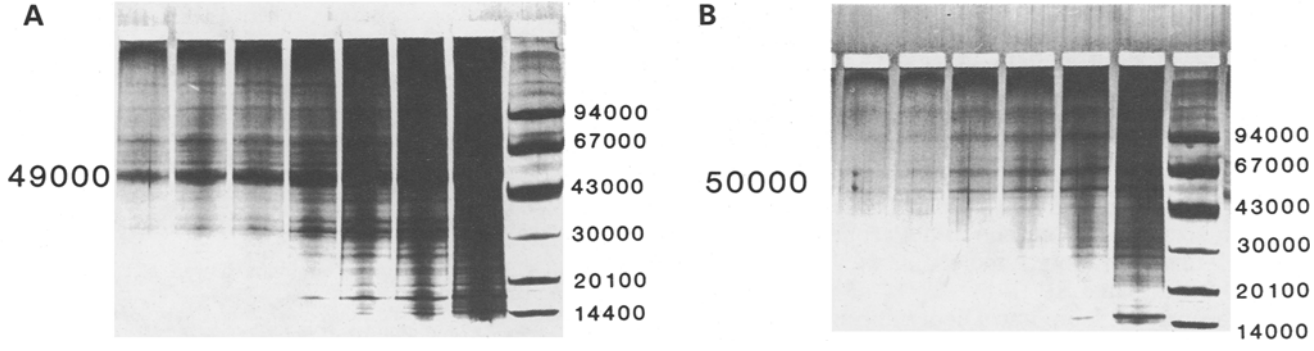

FIG. 4. SDS-PAGE of the liver (A) and kidney (B) membrane lipoprotein preparation on ultrathin (0.36 mm) pore gradient gels (T, 4.0–22.5%) in increasing concentrations. The standard calibration kit is shown in the right lane.

molecules to higher molecular weight complexes is likely. The electron microscopy of the concentrated void volume fractions showed globular particles with diameters of 30–100 nm for liver and 30–60 nm for kidney preparations. These particles could represent vesicles that might have been formed spontaneously from isolated plasma membrane fragments as has been suggested by others from electron microscopical studies on human LSP and KSP (22).

The density gradient ultracentrifugation revealed in all preparations a highly reproducible macroscopically visible turbid disk of ca. 1 mm height with a density between 1.16 g/ml and 1.17 g/ml. This reflects the rather constant protein/lipid ratio of all preparations.

The results of gel chromatography, electron microscopy and density gradient ultracentrifugation showed similar properties of rat LSP and rat KSP. However, further biochemical investigation demonstrated some significant differences between both preparations. The relative mean percentage of total protein in rat KSP (60.4 vs 50.4) was significantly higher and the percentage of free fatty acids (4.3 vs 12.6) significantly lower compared with the relative amounts in rat LSP. However, the free fatty acids might be formed as an artifact during the isolation procedure, and the difference between liver and kidney preparations could be due to different lipolytic activity in these samples. The SDS-PAGE revealed at least 12 protein subunits ranging from 15,000–130,000 in both preparations. One protein at about M_r 49,000 appeared to be more heavily stained on the liver sample compared with the kidney sample and also might be slightly smaller (49,000 vs 50,000). This protein could represent an organ-specific component.

Our results of the quantitative protein-lipid determination in rats were in accordance to the data in humans published by other authors. The average lipid protein ratio of 0.98 in the liver preparations fits in the range of 0.24–1.09 described by Lebwohl and Gerber (8). The mean protein content of 50.4% and the phospholipid moiety of 23.2% showed a similar ratio as reported by McFarlane et al. (4). The phospholipid distribution pattern on cardiolipin, ethanolamine glycerophospholipids, phosphatidylcholine, phosphatidylinositol, sphingomyelin as well as the mean relative amount of triglycerides (11.2%) corresponded to the results of human LSP preparations by Hütteroth and Meyer zum Büschenfelde (5).

Human KSP preparations showed similar gel chromatographic elution patterns and comparable densities compared with our data obtained in rat KSP (11). Furthermore, the lipid protein ratio and the lipid composition resembled those of membrane lipoproteins isolated from human urinary fluid (23). In view of the known cross-reactivity of anti-sera against human LSP and rat LSP, a comparison of the protein profiles of these preparations was of special interest. Studies from McFarlane et al. and Lebwohl and Gerber have indicated that human LSP may be comprised of up to 13 protein subunits of different molecular sizes (4,8). Behrens and Paronetto observed eight protein subunits with molecular weights of 40,000 to 96,000 in human LSP (11).

More recently, Riisom and Diederichsen separated in human LSP and KSP samples four major bands corresponding to molecular weights of 66,000, 60,000, 55,000 and 50,000, and a number of minor protein subunits with molecular weights between 350,000 and 29,000 (12). Our electrophoretic profiles of rat LSP and KSP resembled those of Riisom and Diederichsen very closely, and there was no evidence for a species-specific subunit. These strong similarities could explain the shared antigenic properties of human and rat LSP.

We conclude from our data that large molecular proteo-lipids can be highly reproducibly isolated from rat liver and rat kidney homogenates using standard procedures. Obviously, these proteo-lipids are easily soluble in the cytosol, but immunochemical and electromicroscopical studies of these proteo-lipids from other sources suggest that they constitute fragments of the plasma membrane. There were some differences between rat liver and rat kidney preparations in regard to the relative amounts of protein, free fatty acids and the electrophoretic profile. A 49,000 protein subunit in rat LSP might represent an organ-specific antigen. According to the similar biochemical properties, a close relationship between rat and human LSP and KSP must be assumed. The putative function of these proteo-lipids is not known, although there is some evidence from human studies that they carry receptor proteins for asialo-glycoproteins.

Hydroxyacid Derivatives in Human Epidermis

Philip W. Wertz* and **Donald T. Downing**
Marshall Dermatology Research Laboratories, 270 Medical Laboratories, Department of Dermatology, University of Iowa College of Medicine, Iowa City, IA 52242

The principal objective of this investigation was to examine the ω-hydroxyacid derivatives in the cornified layer of human skin. Toward this end, sunburn peelings were collected, and the lipids were extracted with chloroform/methanol. Comparison with authentic standards by thin layer chromatography (TLC) indicated the presence of both N-(ω-acyloxy)acylsphingosine (acylceramide) and ω-acyloxy fatty acid (acyl acid), which accounted for 1.7% and 2.0% of the total lipid, respectively, as estimated by photodensitometry of the charred chromatograms. Each of these lipids was isolated by preparative TLC, hydrolyzed, and the resulting fragments were further analyzed by TLC and by gas liquid chromatography (GLC) of appropriate derivatives. In both of these lipids, the predominant ω-hydroxyacid proved to be the 30-carbon saturated species (56–59% of the total), while linoleate was the major ester-linked fatty acid. Linoleate was more abundant in the acyl acid (38.0%) than in acylceramide (21.4%). These findings represent the first demonstration of acyl acid in human skin and support the proposition that acyl acid, like the other linoleate-rich ω-hydroxyacid derivatives, functions as a molecular rivet in maintaining epidermal structure and function.
Lipids 23, 415–418 (1988).

It has long been recognized that proper differentiation and function of the epidermis is dependent upon an adequate supply of linoleic acid in the diet (1). In the absence of this essential fatty acid, the skin becomes scaly and much more permeable to water. The skin scaliness associated with this dietary deficiency appears to be the result of reduced production of prostaglandins (2); however, the barrier function depends more directly on the availability of linoleate or linoleate-containing molecules in the epidermis (2–4). Several linoleate-containing molecules have been identified recently, and these now are thought to underlie epidermal barrier function (4–9).

In 1978, Gray et al. discovered in pig and human epidermis an unusual glucosylceramide that contains ester-linked linoleic acid (5). Subsequently, our laboratory has shown that this lipid contains very long ω-hydroxyacids amide-linked to sphingosine (6), and the ester-linked linoleate was shown to be attached to the ω-hydroxyl group (7). A structurally related linoleate-rich acylceramide also has been identified in pig and human epidermis (8,10,11). Recently, an analog called acyl acid, in which the sphingosine moiety has been removed, was reported to occur in pig and rat epidermis (9,12). In each of these linoleate-rich epidermal lipids, linoleate is ester-linked to the ω-hydroxyl group of 30- and 32-carbon ω-hydroxyacids.

In this study, we have examined human sunburn peelings, which consist mainly of stratum corneum, to determine whether acyl acid also is present in human skin. Our results demonstrate that acyl acid represents 2.0% of the total lipid extracted from this source. Linoleate composes 38% of the ester-linked fatty acids in this lipid fraction, and the predominant ω-hydroxyacid is the 30-carbon saturated species. The acylceramide isolated from the same material contained a lower proportion of linoleate (21.4%) but had a nearly identical ω-hydroxyacid composition.

Abbreviations: GLC, gas liquid chromatography; TLC, thin layer chromatography.

MATERIALS AND METHODS

Reference materials. Acylceramide was prepared from pig epidermis as described (8). Pig epidermal acylceramides (8) and giant-ring lactones from donkey sebum (13) served as sources of standard ω-hydroxyacids.

Acyl acid was synthesized by treating 5 mg ω-hydroxyacids prepared from donkey sebum with a 10% molar excess of linoleoyl chloride in 0.25 ml pyridine. After two hr at room temperature, the reaction mixture was chilled in a beaker of crushed ice, and 3 ml chloroform was added. The chloroform solution then was washed three times with 3 ml portions of cold 0.2 N aqueous HCl. The separated chloroform solution was taken to dryness, and acyl acid (1 mg recovered) was purified by preparative thin layer chromatography (TLC) on Silica Gel H using a mobile phase of chloroform/methanol/acetic acid (190:9:1, v/v/v).

Lipid extraction. Four samples of sunburn peelings were dried en vacuo, weighed and extracted for two hr at room temperature in each of three chloroform/methanol mixtures (2:1, 1:1 and 1:2, v/v, v/v and v/v). The combined extracts from each sample were dried under nitrogen and redissolved in a small volume of chloroform/methanol (2:1, v/v). These solutions were filtered through organic-solvent-resistant millipore filters to remove fine particulate material. The solutions then were taken to dryness in tared tubes, and lipid weights were determined. After examination by analytical TLC, the lipid extracts were pooled.

Chemical procedures. Isolated acyl acid and acylceramide were saponified by a slight modification of the procedure described by Gray et al. (5). Basically, the lipid was treated for one hr at 50 C with methanol/chloroform/10 M aqueous NaOH (7:2:1, v/v/v). The reaction mixture was cooled, the pH was adjusted to ca. 4 by addition of aqueous 2 N HCl, and the products were extracted into chloroform.

Amide linkages were hydrolyzed by treatment with 1 M HCl in methanol containing 20 M water at 70 C for 18 hr (14). One volume of water and two volumes of chloroform then were added to the reaction mixture, and after shaking, the chloroform phase was separated. The water/methanol layer then was made alkaline and reextracted with chloroform. The combined chloroform extracts were taken to dryness under a gentle stream of nitrogen.

Isolated long-chain bases were identified as sphingosines by comparison on TLC with an authentic standard (Sigma Chemical Co., St. Louis, MO). This identification was confirmed by gas liquid chromatography (GLC) of

the aldehydes produced by oxidation with sodium periodate as described by Sweeley and Moscatelli (15).

Fatty acids were converted to methyl esters by treatment with 10% BCl_3 in methanol. The methyl esters were extracted into hexane and taken to dryness by evaporation under nitrogen. Acetylation of ω-hydroxy fatty acid methyl esters was achieved by treatment with acetic anhydride/pyridine (1:1, v/v) at room temperature for two hr. Excess reagents were removed by evaporation under nitrogen.

Thin layer chromatography. All analytical TLC employed 0.25 mm-thick layers of Silica Gel G (E.M. Reagents, Darmstadt, West Germany) scribed into 6-mm-wide lanes. Samples were spotted 2 cm from the bottom of the plate. Development with chloroform/methanol/acetic acid (190:9:1, v/v/v) separated the acylceramide and acyl acid from other components. After development, chromatograms were air-dried, sprayed with 50% sulfuric acid and charred at 220 C (16). The charred chromatograms were quantitated by photodensitometry using a Shimadzu model CS-930 photodensitometer.

For preparative TLC, 0.5 mm-thick Silica Gel H (E.M. Reagents, Darmstadt, West Germany) was used. The sample of sunburn lipid was applied as a thin streak 2 cm from the bottom of the plate, which then was developed with chloroform/methanol/acetic acid (190:9:1, v/v/v). After development, plates were sprayed with an ethanolic solution of 2′,7′-dichlorofluorescein. The regions of silica containing the lipids of interest were located under ultraviolet light, scraped from the plate and placed in short, cotton-plugged glass columns. The lipids were then eluted with chloroform/methanol/water (50:50:1, v/v/v).

The products released by saponification of acyl acid and acylceramide were separated by preparative TLC using the same methods described above.

Before analysis by GLC, fatty acid methyl esters were purified by preparative TLC with toluene as the mobile phase. ω-*O*-Acetyl fatty acid methyl esters were purified using a solvent system consisting of hexane/ethyl ether/acetic acid (70:30:1, v/v/v). They then were fractionated according to degree of unsaturation using this same mobile phase and plates containing Silica Gel H impregnated with 10% $AgNO_3$.

Gas liquid chromatography. Fatty acid methyl esters were analyzed using a Varian 3740 gas chromatograph equipped with a 50-meter CP SIL 88 quartz capillary column (Chrompak, Inc., Bridgewater, NJ) and an electronic integrator. The initial column temperature of 160 C was maintained for five min, after which the oven temperature was increased at a rate of 5 C/min until 220 C was reached. Standards included methyl esters of saturated fatty acids ranging from 14 through 24 carbons (kit KF, Applied Science, State College, PA) and a mixture including methyl palmitoleate, methyl oleate and methyl linoleate (kit CE1-62, NuChek-Prep, Elysian, MN).

A 25-meter BP1 quartz capillary column (Scientific Glass Engineering, Inc., Austin, TX) was used at 300 C for analysis of ω-*O*-acetyl fatty acid methyl esters. Previously characterized ω-*O*-acetyl fatty acids prepared (6,8) from pig epidermal lipids and from donkey giant-ring lactones (13) were used as reference materials in these analyses.

RESULTS

Figure 1 shows the separation of acylceramide and acyl acid from other epidermal lipids. Densitometry of similar

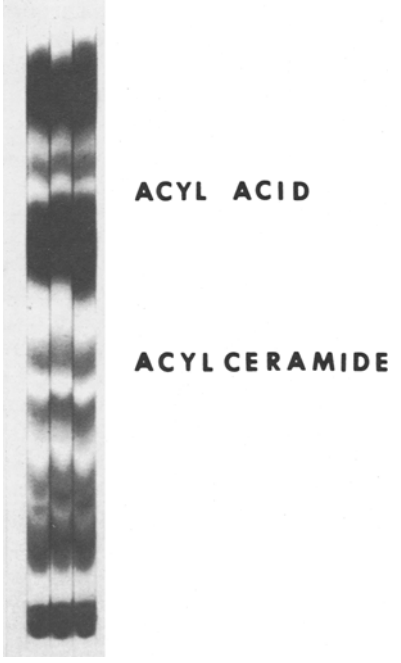

FIG. 1. TLC of the lipids from human sunburn peeling. The spots corresponding to acyl acid and acylceramide are indicated.

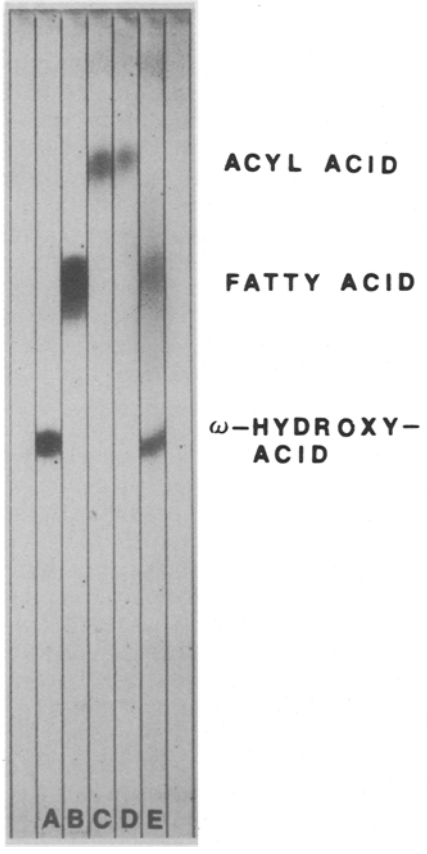

FIG. 2. Characterization of isolated acyl acid. (A) ω-Hydroxyacid prepared from the giant-ring lactones of donkey skin (13). (B) Palmitic acid. (C) Synthetic acyl acid. (D) Acyl acid isolated from sunburn peelings. (E) Products obtained by saponification of human acyl acid.

chromatograms indicated that the acylceramide and acyl acid represent 1.7% and 2.0% of the total lipid, respectively. These values are similar to estimates of acyl acid (9) and acylceramide (8,9) reported for pig stratum corneum.

In Figure 2, acyl acid isolated from the sunburn lipid is compared with synthetic acyl acid and other standards. Also shown, in lane E, are the free fatty acid and ω-hydroxyacid products obtained by saponification of the sunburn acyl acid. The ratio of ω-hydroxyacid to fatty acid in the saponification mixture was estimated by photodensitometry to be 1.6. This observation is in accord with the proposed structure because a charrable carbon ratio of 1.7 would be predicted for an acyl acid in which linoleate is esterified to a 30-carbon ω-hydroxyacid.

The compositions of the fatty acids and ω-hydroxyacids from acylceramide and acyl acid are given in Tables 1 and 2. The major ester-linked fatty acid in each of these lipids was linoleic acid, as shown in Table 1. The predominant ω-hydroxyacid in each lipid is the 30-carbon saturated species. These observations are in good agreement with published findings concerning human acylceramide (10,11). Acyl acid has not been reported to occur in human epidermis.

TABLE 1

Composition of Ester-linked Fatty Acids from Human Acyl Acid and Acylceramide

Fatty acid	Acyl acid (wt %)	Acylceramide (wt %)
14:0	3.8	5.0
14:1	2.3	3.3

34:1	4.1	2.8

DISCUSSION

The demonstration that acyl acid is present in human sunburn peelings, although not surprising, is significant in that this is the first report of this unusual lipid in human tissue. Furthermore, in the earlier identification of acyl acid from pig epidermis (9), the ω-hydroxyacid components were examined by TLC only. Indirect evidence was presented indicating that the ω-hydroxyacids in acyl acid are mainly monounsaturated (9). In this work, the ω-hydroxyacids derived from human acyl acid have been examined by TLC on silicic acid, by argentation TLC and by GLC. The predominant ω-hydroxyacid so identified is the 30-carbon saturated species that accounts for 58.9% of the total.

Related to the acyl acid and the acylceramide is a structurally analogous acylglucosylceramide (4–7,9,12), which is present only in the living portion of the epidermis, where it is associated with the epidermal lamellar granules (17). In the later stages of epidermal differentiation, the lamellar granule contents are extruded into the extracellular space, where they fuse in an edge-to-edge manner to produce the multilamellar lipid sheets that fill the intercellular spaces of the keratinized portion of the epidermis (18,19). These extracellular lipid sheets represent the barrier to water loss through the skin (20).

It has been suggested that the acylglucosylceramide and acylceramide act as molecular rivets to hold lipid lamellae in close apposition within the lamellar granules and in the intercellular spaces of the stratum corneum, respectively (4,8). Within this context, it is thought that the ω-hydroxyacyl chain in either of these sphingolipids could span one lipid bilayer, while the ester-linked fatty acid is inserted into an adjacent bilayer, thus riveting the two together. This sort of interaction could promote the flattening and stacking of lipid vesicles to produce the lamellae observed in lamellar granules, and could stabilize the intercellular lamellae within the stratum corneum. Acyl acid also would appear to be geometrically suitable to serve as a molecular rivet in the stratum corneum.

Recently, an alternative hypothesis has appeared in which it is proposed that the linoleate chains of acylceramide and acyl acid are acted on by a lipoxygenase to produce oxy or polyoxy derivatives that modulate epidermal differentiation (12). In this regard, the difference in linoleate content between acylceramide and acyl acid found in this work may reflect differential utilization of these two substrates by this lipoxygenase. Additional work is necessary to determine the relative merits of these two hypotheses and to further document the metabolism of the acylsphingolipids and acyl acid. It should be noted that these two hypotheses are not mutually exclusive. It is possible that acylglucosylceramide, acylceramide and acyl acid serve as molecular rivets, determine physical properties of the epidermal membranes of which they are significant constituents, and are partially converted via lipoxygenase action into regulators of the keratinization process.

[Received November 20, 1987; Revision accepted January 12, 1988]

Trifluoperazine Increases Fatty Acid Turnover in Phospholipids in Cultured Human Fibroblasts

Cecile Mazière*, Jean-Claude Mazière, Liliana Mora, Martine Auclair and Jacques Polonovski
Laboratoire de Chimie Biologique and U.A. 524, Faculté de Medecine Saint Antoine, 27 rue Chaligny, 75012 Paris, France

A 24-hr pretreatment of cultured human fibroblasts with trifluoperazine induced a marked increase in incorporation of saturated (stearic, palmitic) and unsaturated (oleic, arachidonic) fatty acids into phospholipids (1.5- to 2-fold for 5.10^{-5} M trifluoperazine). Concomitantly, incorporation into cholesteryl esters was strongly inhibited (20% of control for 5.10^{-5} M trifluoperazine). The drug did not change the phospholipid composition of treated cells. The effect of trifluoperazine on oleic acid incorporation into phospholipids was time-dependent and reached a maximum after a six-hr preincubation with the drug. Trifluoperazine also induced an increase in the rate of chase of oleic acid from the different phospholipid classes. In vitro preincubation of cell-free extracts with trifluoperazine resulted in activation of phospholipid acyltransferases, whereas cholesterol acyltransferase activity was decreased. The rapid effect of trifluoperazine together with its effect on a cell-free system suggests a direct action of this amphiphilic drug on the acyltransferase activities, probably by modification of the structural organization of cellular membranes.
Lipids 23, 419-423 (1988).

Trifluoperazine is an amphiphilic cationic drug of the series of the antipsychotic agents phenothiazines. Levin and Weiss (1,2) first demonstrated that in the presence of calcium, trifluoperazine binds to calmodulin and inhibits its effects. However, it appears that trifluoperazine might exert its action independently of calmodulin. The amphiphilic property of the drug could explain the fact that it partitions readily into cellular membranes (3), thus affecting the activity of membrane-bound enzymes such as calmodulin-independent ATPases (4) or calcium pumps (5).

Phospholipids are important components of cellular membranes, and the composition and turnover of these compounds might be implicated in the regulation of membrane-bound enzymes. It has been shown that trifluoperazine and chlorpromazine inhibit phosphatidylcholine synthesis by incorporation of radioactive choline (6) in HeLa cells. Furthermore, some enzymes of phospholipid metabolism have been shown to be modulated by chlorpromazine, another amphiphilic drug of the phenothiazine series. This drug can activate phosphatidate cytidyltransferase (7) and CDP diacylglycerol inositol phosphatidyltransferase (8), whereas the enzyme phosphatidate phosphohydrolase is inhibited (9,10).

In this work, it is demonstrated that trifluoperazine induced an increase in saturated and unsaturated fatty acids into phospholipids. Concomitantly, incorporation of these fatty acids into cholesteryl esters, taken as internal standard, appeared to be inhibited. In vitro measurement of the acyltransferase activities demonstrated that the drug has a direct effect on the enzyme activities.

MATERIALS AND METHODS

Materials. Trifluoperazine was from Sigma Chemical Co. (St. Louis, MO); [1-^{14}C]stearic acid (51 mCi/mmol), [1-^{14}C]-palmitic acid (53 mCi/mmol), [1-^{14}C]oleic acid (53 mCi/mmol) and [^{32}P]sodium orthophosphate (20 mCi/mg) were from CEA (Saclay, France); [1-^{14}C]arachidonic acid (58 mCi/mmol), [1-^{14}C]oleoyl-coenzyme A (50 mCi/mmol) and [1-^{14}C]palmitoyl-coenzyme A (58 mCi/mmol) were from Amersham (Buckinghamshire, U.K.); Dulbecco's modified medium with Earle's salts and fetal calf serum were from Gibco (Grand Island, NY). MRC5 human fetal lung fibroblasts were purchased from BioMérieux, Paris (France). Silica Gel F 1500 plates were from Schleicher and Schuell (Dassel, West Germany).

Cell culture. MRC5 fibroblasts were cultured in 60 mm Nunc Petri dishes containing 2 ml Dulbecco MEM medium supplemented with 20 mM Hepes buffer (pH 7.4), 100 units/ml penicillin, 100 μg/ml streptomycin and 10% (v/v) fetal calf serum at 37 C in a humidified atmosphere of 5% CO_2. Experiments were performed on confluent cells seven days after seeding.

Incorporation of fatty acids into phospholipids and cholesteryl esters. After evaporation to dryness under nitrogen, fatty acids were resuspended in a fatty acid-free human serum albumin solution (0.2 g/l). Cells were incubated for one hr (pulse) in culture medium containing radiolabeled fatty acids: stearic acid 39 μM (2 μCi/ml), palmitic acid 38 μM (2 μCi/ml), oleic acid 19 μM (1 μCi/ml) and arachidonic acid 3.4 μM (0.2 μCi/ml). After incorporation, cells were washed four times with a phosphate-buffered solution, pH 7.4, harvested with a rubber policeman and centrifuged. The pellet was resuspended in 9 g/l NaCl. Protein determination was performed on aliquots of the cell suspension by the method of Lowry et al. (11). Phospholipid and neutral lipid separations were performed by thin layer chromatography on silica gel plates in chloroform/methanol/acetic acid/water (50:30:8:4, v/v/v/v) for phospholipids and hexane/diethyl ether/acetic acid (70:30:2, v/v/v) for neutral lipids. The main radiolabeled phospholipids were phosphatidylcholine, phosphatidylethanolamine and phosphatidylinositol. Aliquots of the cell suspension were applied directly to the plates before chromatography as described (12). After autoradiography, phospholipid and cholesteryl ester spots were cut out and counted by liquid scintillation with an Intertechnique instrument. Results are expressed in pmol of precursor incorporated/mg protein and calculated as percentages of control.

Phospholipid composition. Cells were grown during 48 hr in the presence of 50 μCi/ml [^{32}P]sodium orthophosphate in the presence or absence of the drug. After harvesting, an aliquot of the cell suspension was applied on a silica gel plate and analyzed by bidimensional chromatography: first migration, chloroform/methanol/H_2O (65:25:4, v/v/v); second migration, tetrahydrofuran/methanol/methylal/NH_4OH 2 N (40:20:20:4, v/v/v/v). After autoradiography, the phospholipid spots were cut out and counted in an Intertechnique instrument.

Acyltransferases assay. Acyltransferase activities were measured on sonicated homogenates with a method previously described (13). Each assay, containing 150 μg of protein, phosphate buffer 10^{-1} M (pH 7.4), $MgCl_2$ (5×10^{-3} M), bovine serum-albumin (0.2 mg/ml), was preincubated 15 min at 37 C under gentle shaking in the presence or in the absence of the drug. Final concentrations of trifluoperazine was 10^{-5} to 10^{-3} M, to achieve the same ratio of the absolute number of drug molecules/cell proteins, which was used for in situ experiments (e.g. for in situ incorporation of ^{14}C-oleic acid, 10^{-4} M in 1 ml of medium = 10^{-7} mol of drug/150 μg of cell protein; for in vitro ACAT measurement, 10^{-3} M in 100 μl incubation mixture = 10^{-7} mol of drug/150 μg of cell proteins). After preincubation with the drug, the reaction was initiated by addition of [1-^{14}C]oleoyl coenzyme A or [1-^{14}C]palmitoyl coenzyme A (0.1 μCi) diluted with nonlabeled substrate (final concentration 10^{-5} M). The final incubation volume was 100 μl. The reaction was carried out for five min at 37 C. An aliquot of the incubation mixture then was applied to a silica gel plate, and separation of phospholipids and neutral lipids was achieved by thin layer chromatography. Results are expressed in pmol oleic acid incorporated/five min/mg protein.

RESULTS

The effect of trifluoperazine on saturated and unsaturated fatty acid incorporation into phospholipids and cholesteryl esters is presented in Figure 1. It can be observed that the drug enhanced saturated and unsaturated fatty acid incorporation into phospholipids, whereas the incorporation into cholesteryl esters is inhibited. Furthermore, the two phenomena appeared dose-dependent. After treatment with 5.10^{-5} M of the drug, incorporation into phospholipids reached 150%–220% of control, depending on the fatty acid, and incorporation into cholesteryl esters decreased to about 20% of control. It is of note that the distribution of radioactivity among the different labeled phospholipid classes (phosphatidylcholine, phosphatidylethanolamine and phosphatidylinositol) is not affected by the presence of trifluoperazine (Table 1). Thus, it might be concluded that the drug equally stimulated fatty acid incorporation into the different phospholipid classes, independently of the polar head group moiety. It must be noted that one-hr incorporation represented a pulse period for fibroblasts taken in the described conditions. The consumption of the radiolabeled fatty acids during this period accounted for approximately 1% of total for stearic and palmitic acids, 2% for oleic acid and 9% for arachidonic acid.

One of the questions raised is whether the composition of phospholipids is modified in treated cells. By isotopic equilibrium technique utilizing [^{32}P]orthophosphate incorporation into the polar head groups of phospholipids, it was found that the composition in percentages of phospholipids is not affected (Table 2), nor is the phospholipid/protein ratio (results not shown). So, if the phospholipid composition is unchanged and if incorporation of fatty acids is stimulated, then it means that the turnover of fatty acids is accelerated in phospholipids. Pulse-chase experiments then were performed, and it was found that in our system trifluoperazine increases the rate of chase of oleic acid from labeled phosphatidylcholine, phosphatidylethanolamine and phosphatidylinositol (Table 3).

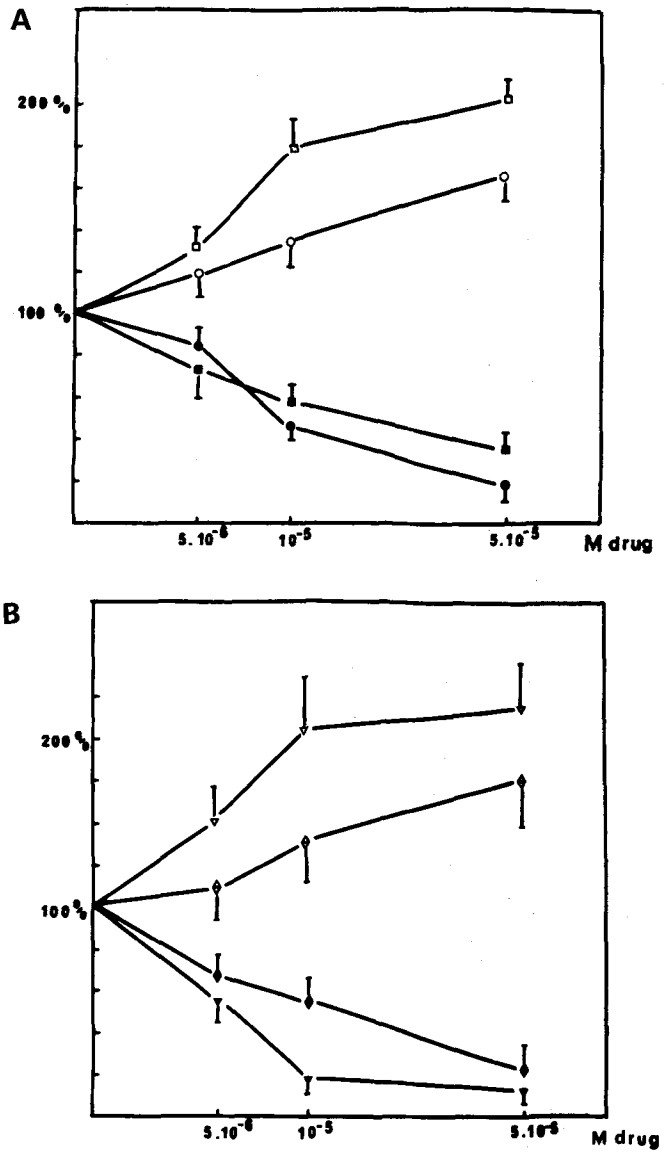

FIG. 1. Effect of trifluoperazine on incorporation of saturated (A) and unsaturated (B) fatty acids into phospholipids and cholesteryl esters. Incorporation was performed during one hr after a 24-hr pretreatment with the drug. Results are expressed as percentages of control (means of 3 experiments ± SD). The absolute values are in pmol of the fatty acid incorporated/mg proteins, stearic acid: (■), cholesteryl esters 110, (□), phospholipids 3857; palmitic acid: (●), cholesteryl esters 48, (○), phospholipids 2718; oleic acid: (▼), cholesteryl esters 143, (▽), phospholipids 4623; arachidonic acid: (◆), cholesteryl esters 46, (◇), phospholipids 2854.

We further investigated the time-dependency of oleic acid incorporation after pretreatment with trifluoperazine, and the results are presented in Table 4. It appeared that the effect of the drug on oleic acid incorporation into phospholipids and cholesteryl esters is rapid and can be observed as soon as two hr after incubation with the drug. The effect increased with preincubation time up to six hr incubation, when incorporation into phospholipids reached 190% of the control value.

TABLE 1

Effects of Trifluoperazine (TFP) on Incorporation of Fatty Acids into Different Lipid Classes

Precursor	Addition	Cholesteryl esters	Triacyl-glycerols	Phosphatidyl-choline	Phosphatidyl-ethanolamine	Phosphatidyl-inositol
Stearic acid	None	110 ± 6	903 ± 110	2198 ± 181	926 ± 72	733 ± 79
	TFP 10^{-5} M	63 ± 7	560 ± 52	4286 ± 318	1713 ± 154	1393 ± 126
Palmitic acid	None	48 ± 3	737 ± 67	2310 ± 183	163 ± 9	272 ± 26
	TFP 10^{-5} M	22 ± 2	594 ± 48	3150 ± 293	217 ± 15	384 ± 39
Oleic acid	None	143 ± 12	931 ± 82	3144 ± 296	647 ± 58	832 ± 76
	TFP 10^{-5} M	29 ± 3	830 ± 57	6298 ± 520	1242 ± 97	1647 ± 124
Arachidonic acid	None	46 ± 4	58 ± 5	1341 ± 111	913 ± 72	600 ± 46
	TFP 10^{-5} M	25 ± 2	42 ± 3	1609 ± 134	1141 ± 92	752 ± 53

Incorporation was performed one hr after 24-hr pretreatment with trifluoperazine 10^{-5} M. Results are expressed in pmol fatty acid incorporated/mg proteins. Means of three experiments ± SD.

TABLE 2

Phospholipid Composition of Human Cultured Fibroblasts in the Presence or Absence of Trifluoperazine

Addition	Sphingomyelin	Phosphatidylcholine	Phosphatidylethanolamine	Phosphatidylinositol
None	13.6 ± 1.5	61.1 ± 2.3	17.6 ± 1.9	7.7 ± 0.9
TFP 10^{-5} M	13.2 ± 0.9	59.8 ± 3.5	18.2 ± 1.2	8.8 ± 1.0

Cells were incubated 48 hr with ^{32}P sodium orthophosphate 50 μCi/ml, and phospholipids were analyzed by bi-dimensional chromatography. Results are expressed in percentages of total radioactivity.

TABLE 3

Effect of Trifluoperazine on Pulse Chase Experiments with Oleic Acid

Addition	Phosphatidylcholine	Phosphatidylethanolamine	Phosphatidylinositol
None	89% (±7%)	87% (±6%)	76% (±7%)
TFP 10^{-5} M	62% (±5%)	65% (±6%)	57% (±5%)

Cells were pretreated 24 hr with the drug before radiolabeled oleic acid addition during one hr (pulse). After washing, cells were further incubated in nonlabeled medium in the presence or absence of the drug for six hr (chase). The values obtained after the pulse period are taken as 100% for each phospholipid. Results are expressed in percentages of radioactivity found after the chase period for each phospholipid. Means of three experiments ± SD.

TABLE 4

Kinetics of the Effect of Trifluoperazine on Oleic Acid Incorporation into Phospholipids and Cholesteryl Esters

Addition	Preincubation time	Oleic acid incorporated into (percentages of control)	
		Cholesteryl esters	Phospholipids
		100%	100%
Trifluoperazine 10^{-5} M	2 hr	68 ± 5	133 ± 9
	4 hr	37 ± 4	171 ± 11
	6 hr	27 ± 3	192 ± 11
	17 hr	24 ± 3	215 ± 18
	24 hr	22 ± 2	220 ± 19

Cells were preincubated for the indicated time with trifluoperazine 10^{-5} M. [1-^{14}C]Oleic acid, 1 μCi/ml, was then added and incroporaton followed during one hr. Results are expressed in percentages of control. Means of three experiments ± SD.

TABLE 5

Effect of Trifluoperazine Preincubation with Cell-free Extracts on Palmitic Acid and Oleic Acid Transfer to Different Lipid Classes

Substrate	Addition	Cholesteryl esters	Phospholipids			
			Phosphatidyl-choline	Phosphatidyl-ethanolamine	Phosphatidyl-inositol	Total
Palmitoyl-coenzyme A	None	48 ± 4	897 ± 72	238 ± 14	332 ± 24	1467 (100%)
	TFP 10^{-5} M	37 ± 3	912 ± 81	252 ± 18	376 ± 27	1540 (105%

	TFP 10^{-3} M	6 ± 2	1300 ± 112	326 ± 25	560 ± 49	2186 (149%)
Oleoyl-coenzyme A	None	58 ± 5	978 ± 115	172 ± 21	374 ± 42	1524 (100%)
	TFP 10^{-5} M	49 ± 5	1056 ± 95	189 ± 19	408 ± 36	1653 (108%)
	TFP 10^{-4} M	31 ± 4	1223 ± 114	203 ± 23	430 ± 49	1856 (122%)
	TFP 10^{-3} M	9 ± 2	1492 ± 163	272 ± 32	598 ± 54	2362 (155%)

Cell extracts were preincubated 15 min with trifluoperazine at the indicated concentration before measurement of acyltransferase activities with [1-^{14}C]oleoyl-coenzyme A or [1-^{14}C]palmitoyl-coenzyme A as described in the text. Results are expressed in pmol incorporated/five min/mg protein. Means of three experiments ± SD.

The short-term effect of trifluoperazine on oleic acid incorporation into phospholipids suggests a direct effect of the drug on enzyme activity. On the other hand, as it is well-known that phospholipid acyltransferases are specific for saturated and unsaturated fatty acids, the activity of acyltransferases were measured on cell-free extracts after in vitro preincubation with the drug with two different substrates: palmitoyl-coenzyme A and oleoyl-coenzyme A. Results from Table 5 clearly indicate that a 15-min preincubation of cell extract with the drug is sufficient to induce an increase in phospholipid acyltransferase activities and a decrease in cholesterol acyltransferase activity. Again, it can be noted that incorporation into the different phospholipid classes is equally stimulated. Preincubation with 10^{-3} M trifluoperazine resulted in about 1.5-fold increase of phospholipid acyltransferase activities, whereas cholesterol acyltransferase decreased to 15% of control.

DISCUSSION

A 24-hr pretreatment of cultured fibroblasts results in stimulation of fatty acid incorporation into phospholipids, namely phosphatidylcholine, phosphatidylethanolamine and phosphatidylinositol. It is of note that while the acidic phospholipid phosphatidylinositol derives from cytidine-diphosphodiacylglycerol, the two other phospholipids, phosphatidylcholine and phosphatidylethanolamine, have a common precursor, diacylglycerol. Trifluoperazine stimulating fatty acid incorporation into the three phospholipids suggests that the drug exerts its action through the acyltransferase activity itself rather than through the availability of phospholipid precursors. Another line of evidence arises from the fact that incorporation of fatty acids into triacylglycerols, another neutral lipid derived from diacylglycerol, is either poorly affected or decreased by the drug under the same conditions (Table 1). The described effects of trifluoperazine also are observed in our system with another amphiphilic cationic drug, chlorpromazine (results not shown). Martin et al. (14) recently reported that chlorpromazine inhibited the synthesis of phosphatidylcholine and triacylglycerols in isolated rat hepatocytes by using radiolabeled oleate and glycerol. These authors concluded that chlorpromazine partially acts through the rate of conversion of phosphatidate to the common precursor, diacylglycerol. In our system, however, incorporation of oleate into phospholipids is enhanced by trifluoperazine and chlorpromazine. One reason that might explain the discrepancy of the results is the difference in the cell types utilized by these authors and by ourselves. This hypothesis is further supported by the fact that phosphatidylcholine synthesis from choline is sensitive to phenothiazines in HeLa cells (15) and not in rat hepatocytes (16).

The isotopic equilibrium method demonstrated that the phospholipid composition itself is unchanged in trifluoperazine-treated cells. As within the cells, phospholipids undergo a cycle of deacylation-reacylation reactions, it thus appears that trifluoperazine accelerates the rate of turnover of saturated and unsaturated fatty acids in the phospholipid molecules. This is confirmed by pulse-chase experiments performed with oleic acid (Table 3). In this regard, the question of an eventual modification of the fatty acid composition of the different phospholipid classes in trifluoperazine-treated cells might be raised.

The rapid effect of trifluoperazine suggests a direct activation of the phospholipid acyltransferase enzyme. This is confirmed by in vitro measurement of the acyltransferase activities in cell-free extracts after preincubation with the drug. It was demonstrated that the enzyme acyl coenzyme A:cholesterol-acyltransferase is inhibited, while the phospholipid acyltransferases measured either with oleoyl-coenzyme A or with palmitoyl-coenzyme A are stimulated. The mechanism whereby phenothiazines modulate these enzyme activities has to be elucidated. It is well-known that phenothiazines bind to the hydrophobic domain of calmodulin (17,18) and thus block the action of Ca^{2+}-calmodulin. Thus, the hypothesis of a regulation by Ca^{2+}-calmodulin of the acyltransferase activities must be considered. However, besides this effect on calmodulin, phenothiazines might independently act on cell metabolism, especially by means of membrane-bound enzymes, by modifying the physico-chemical characteristics of membranes such as membrane potential (19)

or by modulating the conformation of membrane structure (20). Another explanation might be that trifluoperazine can regulate the subcellular partition of membrane-bound enzymes. Such a regulation mechanism has been reported for some enzymes of phospholipid synthesis such as CTP:phosphocholine-cytidylyltransferase (21) and phosphatidate phosphohydrolase (22).

[Received February 24, 1987; Revision accepted January 8, 1988]

Disposition and Metabolism of Pristane in Rat

A.M. Le Bon*, J.P. Cravedi and **J.E. Tulliez**
I.N.R.A., Laboratoire des Xénobiotiques, B.P. 3, 31931 Toulouse Cedex, France

The fate of pristane (2,6,10,14-tetramethylpentadecane), a widespread isoprenoid hydrocarbon, has been studied in rats after a single per os administration of ^{3}H-labeled pristane. The balance study showed an extensive fecal excretion (66%) mainly as unchanged hydrocarbon, whereas about 14% of ingested pristane was excreted in urine as pristane metabolites and tritiated water. After one wk, 8.3% of the ingested ^{3}H still was stored in the carcass, and radioactive distribution in tissues and organs showed a preferential incorporation into adipose tissue and liver. Over 75% of the radioactivity stored in the carcass was associated with pristane metabolites and tritiated water. Tissue metabolites were characterized by thin layer chromatography, gas chromatography and mass spectrometric analyses. Four metabolites were identified: pristan-1-ol, pristane-2-ol, pristanic acid and 4,8,12-trimethyltridecanoic acid. These demonstrate that this isoprenoid hydrocarbon undergoes subterminal hydroxylation or terminal oxidation followed by the classical β-oxidation process. Incorporation of metabolites in phospholipids and more particularly in the phosphatidylserine fraction has been observed and is discussed.
***Lipids 23,* 424-429 (1988).**

Much of the information on the fate of saturated hydrocarbons in vertebrates deal with the metabolism and disposition of n-alkanes; less has been reported for branched-alkanes. Among the latter, pristane (2,6,10,14-tetramethylpentadecane) and phytane, both of which may be of either biogenic or petrogenic origin, usually are abundant in living matter. Pristane was found at concentrations of 80-1070 ppm in fish oil (1) and 2-52 ppm in human and mammal tissues (2).

As early as 1967, these residues were considered as resulting from the difference between the rates of input and removal, thus it was suggested that branched-chain hydrocarbons are not inert in the animal tissues but are metabolized rapidly (2). It was reported several years later that rats are able to oxidize phytane to alcohols and acids (3); nevertheless, no information was available regarding biotransformation of pristane in higher animals.

The purpose of this study was to establish the metabolic balance of pristane in rats and to characterize pristane metabolites isolated from the whole body and the liver. Furthermore, because unusual long chain alcohol or branched-chain fatty acids may result from the ω-oxidation of pristane, as described for microorganisms (4,5), incorporation of metabolites into lipid compartments was investigated.

MATERIALS AND METHODS

Chemicals. Pristane was purchased from Aldrich-Chimie (Strasbourg, France). [^{3}H]Pristane (142 MBq/μmol) was prepared by direct contact of pristane with tritium gas (Wilzbach method) at the C.E.A. (Saclay, France), then purified by chromatography on a silica gel column (Kieselgel 60, Merck), using hexane as solvent. The purity, as evaluated by gas chromatography (GC) and reverse phase high pressure liquid chromatography (HPLC), was higher than 96%.

Tetramethylpendadecanoic acid was the gift of J. Flanzy (INRA, CNRZ, Jouy en Josas, France).

Animal experiments. Wistar male rats weighing about 200 g were accustomed for one wk before studies to a semisynthetic diet (casein 18%, wheat starch 39%, sucrose 24%, peanut oil 8%, cellulose 3%, minerals and vitamins 8%). The night before the experimental diet was given, the animals were fed moderately.

(a) Experiment 1: metabolic balance. Three animals were held in individual metabolism cages. At the beginning of the experiment, each animal received a 59.2 MBq [^{3}H]pristane dose previously incorporated in the peanut oil of the diet. After complete consumption of the impregnated feed, free access to the untreated semisynthetic diet again was given to the animals.

Urine and feces were collected separately and daily for seven consecutive days. A few drops of HCl (1 N) were added to urine for storage. Animals were killed on the seventh day after dosing, and various tissues and organs were sampled.

After careful removal of the gastrointestinal tract contents, the remainder of the carcasses were minced using a domestic machine. Feces and aliquots of homogenized carcass were saponified with ethanolic KOH, then the unsaponifiable fraction was extracted with hexane. Hydrocarbons were isolated by column chromatography on activated silica by hexane elution.

Urine analysis was performed by successive extractions with hexane and ethyl acetate.

(b) Experiment 2: metabolites identification and incorporation of ^{3}H into lipids. Administration of labeled pristane (20 MBq) occurred as described in experiment 1, except that before the incorporation of the hydrocarbon in the peanut oil, the specific radioactivity of [^{3}H]pristane was adjusted to 278 KBq/μmol with unlabeled pristane (Aldrich-chimie).

Lipid and metabolite analyses were performed as described in the following paragraphs.

Hepatic lipid analysis. The distribution of radioactivity in hepatic tissues was studied after lipid extraction according to the procedure of Folch (6). Total lipids were separated into particular classes on silica cartridges (Sep-Pak, Waters, Milford, MA) by successive hexane, chloroform and methanol elutions, yielding hydrocarbon, neutral lipid and phospholipid fractions, respectively (7). Phospholipids then were separated into different components by HPLC (8). Purity of fractions was tested by thin layer chromatography (TLC) on Silica Gel G using chloroform/methanol/acetic acid/water (100:55:16:4, v/v/v/v) as solvent system.

Metabolites analysis. (a) Isolation procedures. Livers were homogenized in 10 ml of water with a Polytron homogenizer at room temperature. The same procedure

*To whom correspondence should be addressed.

Abbreviations: TMS, trimethylsilyl; GC, gas chromatography; GC-MS, gas chromatography-mass spectrometry; HPLC, high pressure liquid chromatography; TLC, thin layer chromatography.

was used for carcasses, after careful removal of the gastrointestinal contents. Homogenates were saponified with ethanolic KOH; then the unsaponifiable fraction was extracted with hexane. Hydrocarbons and unsaponifiable metabolites were isolated from this fraction by chromatography on a silica gel column (Kieselgel 60, Merck, Darmstad, FRG) by successive hexane and chloroform/methanol (2:1, v/v) elutions. After acidification by HCl, fatty acids were extracted with hexane from the aqueous phase. A flow chart of the different steps is summarized in Figure 1.

(b) Analytical procedures. (1) TLC: Kieselgel 60, 250 μ chromatographic plates (Merck, Darmstadt, Germany) were used with hexane/ethyl ether/acetic acid (80:20:1, v/v/v) as the solvent system. Radioactive areas were located with a radiochromatogram scanner LB2832, Berthold (Wildbad, FRG). (2) GC: A Hewlett Packard 5710A gas chromatograph equipped with a 2m × 1/8" stainless steel column packed with 3% Dexsil 300 on 100/120 Supelcoport (Supelco Inc., Bellefonte, PA) was used, programmed from 120 C to 340 C at 10 C/min. For methyl ester analyses by radio-GC, the gas chromatograph was connected to a reactor (RGC 170 Bodenseewerk Perkin-Elmer Co. Ueberlingen, Germany), in which tritium gas was measured with a proportional counting tube after hydrogenative cracking of the ^{3}H-labeled compounds. (3) GC/MS: A Hewlett Packard model 5992 B gas chromatograph/mass spectrometer equipped with a 15 m × 0.2 mm flexible fused silica column with OV1 coating (Hewlett-Packard) was used, programmed from 150 C to 250 C at 10 C/min and with a He (carrier gas) flow rate of 1 ml/min.

Derivatization. Fatty acid methyl esters were obtained from acids by esterification with methanol/benzene/sulfuric acid (17:2:1, v/v/v) for three hr at 96 C.

Fatty alcohols, having been extracted (fraction II) and purified by TLC, were acetylated with acetic anhydride/pyridine (4:1, v/v) at ambient temperature during three hr.

Trimethylsilyl (TMS) derivatives were prepared by treating the various compounds with BSTFA + 1% TMCS or with BSTFA/TSIM/TMCS (100:50:1, v/v/v) mixtures (Pierce Chemical Co., Rockford, IL) in anhydrous acetonitrile for four hr at 70 C.

Radioactivity measurements. Aliquots of urine samples were counted directly by liquid scintillation counting (Packard Minaxi 4000 apparatus). The total radioactivity of tissues, organs and carcasses was measured after combustion of aliquots (200–500 mg) in an oxidizer (Oxymat, Intertechnique, Kontron, Trappes, France) that ensures trapping of ^3H_2O in a scintillation mixture (Triox, Kontron).

Estimation of tritiated water was obtained by comparing the radioactivity in fresh and lyophilized samples after it has been established that no loss of unchanged hydrocarbon or metabolites occurred during the freeze-drying process.

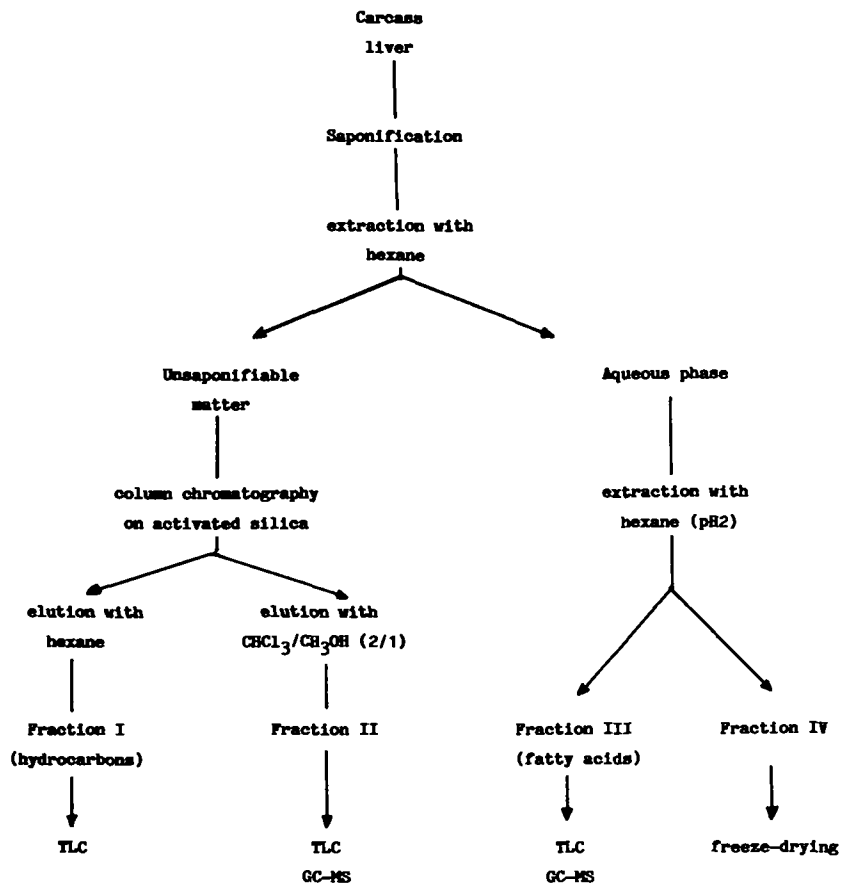

FIG. 1. Schematic diagram for the analysis of tissues from rats dietary exposed to [^{3}H]pristane.

RESULTS

The specific activity of ^{3}H-pristane measured before administration and after the residual hydrocarbon has been isolated from tissues indicates that hydrogen exchange did not occur to any significant extent (Fig. 2).

Balance study. The distribution of ^{3}H in excreta and whole carcass of rat following a single dose of [^{3}H]pristane is reported in Table 1. This table shows that radioactivity was excreted mainly in feces, whereas 8.26% of the ingested ^{3}H was still stored in the carcass after one wk. Only 23.5% of the radioactivity present in the carcass was due to pristane. The occurrence of metabolites (20.5%) and tritiated water (56%) underline the intensity of metabolic transformations of pristane in rat.

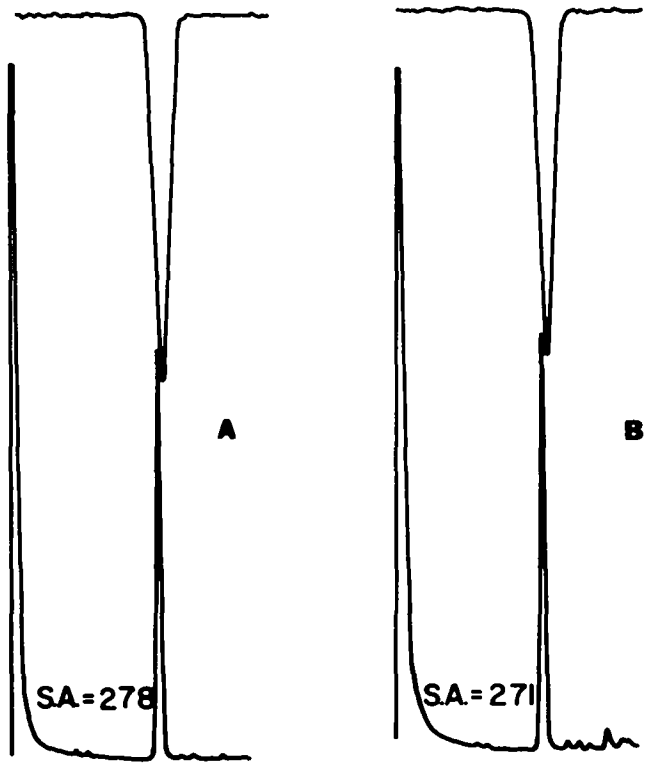

FIG. 2. Radio gas chromatography of hydrocarbon fed (A) and of hydrocarbon in carcass (B): upper trace, radioactivity; lower trace, mass; S.A., specific activity (KBq/μmol).

TABLE 1

Distribution of ^{3}H in Carcass and Excreta Seven Days after Oral Ingestion of [^{3}H]pristane (Expressed as % of Administered Dose)[a]

	Tritiated water	Metabolites	Hydrocarbon	Total radioactivity
Carcass	4.65	1.70	1.91	8.26 ± 0.81
Feces	1.50	10.78	53.94	66.22 ± 1.64
Urine	3.88	10.98	n.d.[b]	14.86 ± 1.25
Total recovery				89.34 ± 2.02

[a][^{3}H]pristane dose was 59.2 MBq. Values are means ± SD from three animals.

[b]n.d., Not detected.

The kinetics of the distribution of the radioactivity in feces indicates that by this route, excretion reached its maximum level between 24 hr and 48 hr (Fig. 3). A more detailed analysis of the kinetics of depletion of fecal radioactivity over the seven-day period shows a rapid elimination of pristane, whereas metabolite excretion occurs more slowly than with hydrocarbons.

The excretion of radioactivity was much lower in urine than in feces (Table 1). The data presented in Figure 4 show a rapid urinary elimination; more than 65% of urinary ^{3}H was excreted during the first 48 hr. During the first few days, radioactivity excretion occurred mainly as pristane metabolites; then, ^{3}H was equally distributed between metabolites and tritiated water. No trace of hydrocarbon was detected in urine.

The disposition of ^{3}H among body tissues and organs, as measured one wk after oral administration of [^{3}H]-pristane, is shown in Table 2: specific activities levels in perigastric adipose tissue and in liver were higher than those in kidney, lung, spleen and heart.

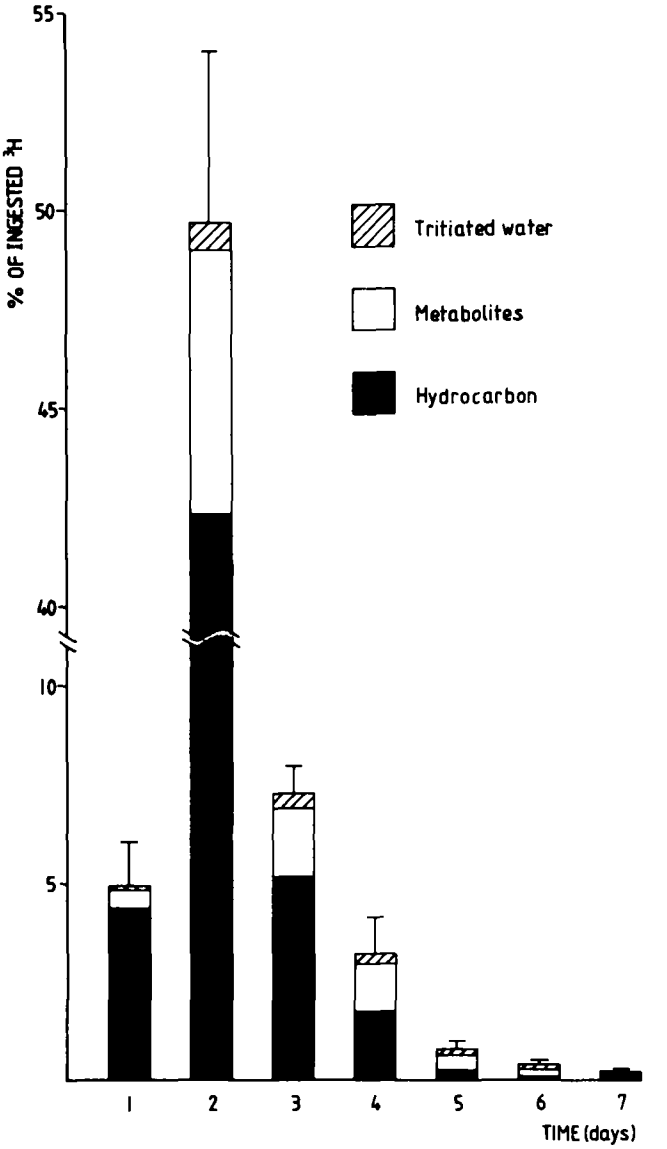

FIG. 3. Evolution and distribution of ^{3}H in feces of rats fed [^{3}H]pristane.

Distribution of ^3H in hepatic lipids. The incorporation of tritium into hepatic lipids was studied six hr, 24 hr and one wk after ingestion of [^{3}H]pristane (Table 3). The radioactivity was associated mainly with the hydrocarbon fraction throughout the experiment. However, labeling of neutral lipids and phospholipids fraction already was significant at six hr; at this time, specific activity of neutral lipids was higher than that of phospholipids.

However, after one wk labeling of neutral lipids and phospholipids was 900 and 1010 Bq/g respectively. The separation of the different classes of phospholipids (Table 4) revealed that most of the radioactivity was bound to phosphatidylcholine. However, when expressed as Bq/g the major incorporation of ^{3}H was detected in phosphatidylserine.

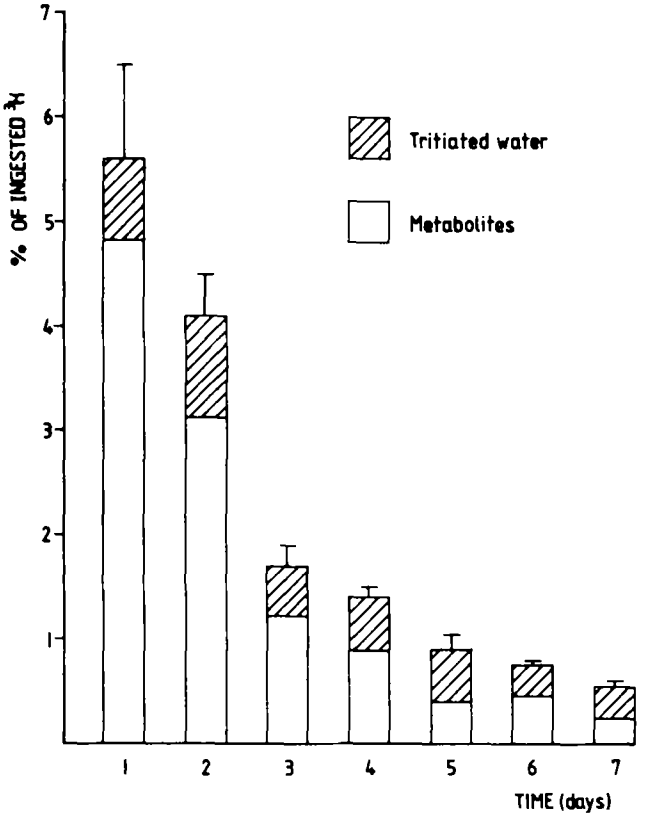

FIG. 4. Evolution and distribution of ^{3}H in urine of rats fed [^{3}H]pristane.

Identification of metabolites. Liver and carcass metabolites were analyzed after saponification. The different fractions (see Fig. 1) were analyzed by TLC followed by radiochromatogram scanning. Confirmation of the identity of metabolites was obtained through GC/MS analysis.

(a) Fraction I. The labeled compound detected in this fraction possessed TLC and GC properties identical with those of pristane. This fraction represented the major part of liver radioactivity eight hr after [^{3}H]pristane administration (Table 5). It accounted for 23.6% of carcass radioactivity after seven days.

(b) Fraction II. ^{3}H detected in this fraction accounted for 10.9% and 13.7% of carcass and liver radioactivity, respectively. TLC analysis of this fraction revealed a radioactive zone at R_f 0.25. This R_f-value was similar to that of a long-chain alcohol. Acetylation of this fraction, in addition to unchanged material, resulted in a less polar product with chromatographic mobility similar to that of a long-chain alcohol acetate. GC analysis of fraction II confirmed it to be a mixture of two metabolites with retention times of 10.23 (A) and 11.61 min (B).

TABLE 2

Distribution of ^{3}H in Tissues Seven Days after Oral Administration of [^{3}H]pristane[a]

	(% of ingested ^{3}H) × 10^3	Kbq/g
Liver	508 ± 57	31.0 ± 5.5
Adipose tissue	—[b]	38.7 ± 9.4
Kidney	56 ± 8	16.9 ± 3.0
Spleen	27 ± 3	21.6 ± 3.6
Lung	53 ± 15	16.2 ± 4.5

Sph	4.3	58,580	2.3	22,630	7.1	3,650

[a]Values are from pooled samples from two animals.
PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; PC, phosphatidylcholine; Sph, sphingomyelin.

When analyzed by GC-MS, the mass spectra from (A) and (B) showed significant ions at m/e (266(M-18) and 59(C_3H_7O), indicating that these metabolites are both hydroxylated derivatives of pristane.

The TMS derivative of (A) exhibited characteristic fragment ions at m/e 341 (M-15) and 131 ($(CH_3)_2$-CO-TMS), which are characteristic of the TMS ether of a tertiary alcohol. The TMS derivative of (B) presented the same significant ion at m/e 341 but also a characteristic signal at m/e 103, indicating a primary alcohol function. These mass spectral results suggest that metabolite (A) was pristan-2-ol and metabolite (B) pristan-1-ol (Fig. 5). Quantitative analysis by TLC and GC revealed that pristan-2-ol accounted for 88% of the mixture of the two pristanols in carcass.

(c) Fraction III. Radioactivity detected in this fraction was slightly lower than in Fraction II (Table 5). The TLC behavior of both underivatized (R_f 0.4) and methylated (R_f 0.8) Fraction III material suggested the presence of fatty acids.

After successive elimination of unsaturated and linear fatty acids (9), radio-GC analysis of the liver fatty acid methyl esters showed that the radioactivity was bound to an unusual fatty acid (metabolite C). Radio-GC of carcass fatty acid methyl esters resulted in two labeled peaks. The major one exhibited the same retention time as metabolite C (10.49 min). The retention time of the second product (metabolite D) was 8.35 min.

Study of the methyl ester of metabolite (C) by GC-MS exhibited an apparent M^+ at m/e 312 and significant fragments at m/e 88 (rearrangement ion: -$CH(CH_3)$-CO-O-CH_3) and 101 (CH_2-$CH(CH_3)$-CO-O-CH_3). The comparison between this mass spectrum and the fragmentation of 2,6,10,14-tetramethylpentadecanoic acid methyl ester indicated that metabolite C was pristanic acid (Fig. 5). The mass spectrum of the methyl ester of metabolite D showed a molecular ion at m/e 270 and characteristic peaks at 87 (CH_2-CH_2-CO-O-CH_3) and 74 (CH_2-CO-O-CH_3), indicating that (D) corresponded to 4,8,12-trimethyltridecanoic acid (Fig. 5).

(d) Fraction IV. In liver and carcass, it has been shown after lyophilization that ^3H detected in this fraction was associated with tritiated water. This was the principal labeled compound detected in carcass (Table 5).

TABLE 5

Distribution of Radioactivity in the Different Analytical Fractions from Carcass and Liver[a]

Fractions	Carcass[b]	Liver[c]
I (Hydrocarbons)	23.6	62.3
II (Fatty alcohols)	10.9	13.7
III (Fatty acids)	8.5	11.1
IV (Tritiated water)	57.0	12.9

Reported values are expressed as percentage of total radioactivity and are from three pooled samples.

[a]For detail, see Figure 1.

[b]Seven days after [^3H]pristane administration.

[c]Eight hr after [^3H]pristane administration.

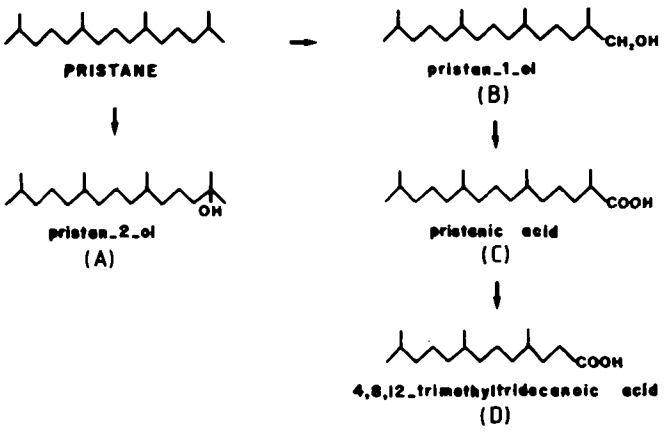

FIG. 5. Proposed metabolic pathways of pristane in the rat.

DISCUSSION

This study was initiated to obtain more detailed knowledge of the fate of alkanes in mammals. Previous studies on alkane metabolism have been conducted using n-heptadecane and dodecylcyclohexane as models of normal and monocyclic alkanes, respectively (10,11). Our results clearly show that absorption, storage and oxidation of pristane occur in the same way as for these two alkanes.

In feces, more than 80% of the radioactivity was attributable to pristane. Several authors have shown that no hydrocarbon oxidation by the microbial flora occurs in rat gut (3,12). Moreover, in a study concerning the biliary excretion of hydrocarbons in rat, we have observed that no elimination of unchanged hydrocarbon occurred via this route (Tulliez and Le Bon, unpublished results). Therefore, we could estimate the digestive absorption of pristane as the dose ingested minus the amount of pristane in feces, i.e. in this study a digestibility level of 46%.

This value is lower than those observed for other alkanes such as n-heptadecane (10) and dodecylcyclohexane (11), but is close to the results previously reported for a 15-mg dose of pristane (13).

An appreciable amount of radioactivity remained in the carcass beyond seven days. As expected, considering the lipophilic nature of hydrocarbons, the highest levels of labeling were found in adipose tissue and liver.

The fact that after one wk, more than 75% of the radioactivity stored in the carcass was associated with pristane metabolites and tritiated water demonstrates that pristane is thoroughly metabolized in rat. Fatty alcohols are the first step of this biotransformation, as confirmed by the studies of PerduDurand and Tulliez (unpublished results) who studied in vitro oxidation of pristane. Detection of two isomers of pristanol shows that pristane hydroxylation may occur in ω or ω-1 position of the alkyl chain. The subterminal hydroxylation (ω-1) leads to pristan-2-ol that could be a metabolic dead end; hydroxylation on a tertiary carbon would prevent any further oxidative step and may explain the substantial amounts of this metabolite in tissues of rat. This must be related to the findings of Albro and Thomas (3) who observed, in studying the metabolism of phytane in rat, the presence of phytan-2-ol in rat liver.

The subsequent oxidation of pristan-1-ol to pristanic acid may explain the low amount of primary pristanol detected in carcass and liver. Pristanic acid undergoes the classical fatty acid β-oxidation pathway, as shown by the presence of 4,8,12-trimethyltridecanoic acid and tritiated water in tissues.

The isolated metabolites demonstrate that methyl substituents in position 2,6,10,14 do not prevent the classical mechanisms of terminal and β-oxidation mentioned by several authors for n-alkanes (10,14). However, it must be noted that the metabolic pathways of pristane in rat are limited in comparison with microorganisms in which oxidation at both ends (15,16) or attack on carbon 3 (17) may occur in addition to the terminal oxidation.

Liver lipid analysis demonstrates the occurrence of pristane metabolites in neutral lipids and phospholipids. As reported in labeled heptadecane and dodecylcyclohexane studies (10,11), the greater deposition of radioactivity in phospholipids occurred in the phosphatidylcholine fraction. However, measurements of specific activities show a preferential incorporation of pristane metabolites in phosphatidylserine. Specific role of this phospholipid in some membrane enzymatic processes has been demonstrated (18). Thus, it will be of interest to investigate the possible interactions of branched-chain fatty acids with the biochemical mechanisms in which the structural lipids are involved. The assessment of toxicological significance of these uncommon fatty acids must be questioned because it has been shown that high levels (>5%) of a branched-chain fatty acids mixture in rat diet resulted in growth inhibition and accumulation of these fatty acids in tissue lipids (19).

Nevertheless, the present work demonstrates that, at low levels in the diet, pristane is rapidly metabolized by terminal oxidation and then, as for dietary fatty acids, by successive β-oxidation reactions. These results complete previous data on alkane metabolism and give a better understanding of their metabolic utilization by mammals.

Oxidation of 1-*O*-(Alk-1-enyl)-2,3-Di-*O*-Acylglycerols: Models for Plasmalogen Oxidation[1]

Thomas A. Foglia*, Edwin Nungesser and **William N. Marmer**
ARS/USDA, Eastern Regional Research Center, 600 E. Mermaid Lane, Philadelphia, PA 19118

Alk-1-enyl diacyl glycerides, model compounds for plasmalogen lipids, were synthesized for use as substrates in oxidation studies. The neutral plasmalogen glycerides prepared included 1-*O*-(hexadec-1-enyl)-2,3-di-*O*-stearoylglycerol (*4a*) and 1-*O*-(hexadec-1-enyl)-2-*O*-linoleoyl-3-*O*-stearoylglycerol (*4b*). Oxidative disappearance of these glycerides was followed directly by high performance liquid chromatography (HPLC). The extent of oxidation of the side chains of these glycerides, i.e. the alkenyl ether and fatty acyl functions, was monitored by conversion of the side chains to dimethylacetal and methyl ester by methanolysis, followed by subsequent gas chromatography (GC) of the methanolysis products. Both analytical approaches show that the alkenyl ether function of neat *4a* oxidizes more slowly than neat ethyl linoleate. However, the rate of alkenyl ether loss from *4a* is accelerated in the presence of added ethyl linoleate. Moreover, when the linoleoyl group is incorporated into the 2-position of the alkenyl glyceride, as in *4b*, the rate of loss of the alkenyl group was shown to be similar to the rate of loss of the linoleoyl group. These results suggest that oxidation of plasmalogen glycerides should not be ignored as a factor that contributes to the oxidative instability of animal tissue.
***Lipids 23,* 430–434 (1988).**

In muscle and other animal tissue, phosphatides are not confined just to the diacyl variety. Substantial amounts of the long-chain groups at the glycerol *sn*-1-position are in the form of alkyl ethers, and as much as a third of the choline glycerophosphatides and two-thirds of the ethanolamine phosphatides are plasmalogens, i.e. *sn*-1-(alk-1-enyl) ethers (1). Studies of lipid oxidation in foods typically are focused on the role of autoxidation of polyunsaturated acyl groups in phosphatides (generally at the *sn*-2 position), especially with regard to the course of such oxidation in the development of rancidity in meat (2–5). On the other hand, only very recently has attention been focused on the autoxidation of the double bond in plasmalogens as a potential contributor to such rancidity (6). In the latter report, it was shown that a model enol ether, ethyl hexadec-1-enyl ether, was prone to in vitro autoxidation, especially in the presence of polyunsaturated esters. Other studies have shown that natural plasmalogens are subject to in vivo peroxidation by enzymatic systems (7–9) and that alk-1-enyl ethers are subject to attack by singlet oxygen (10,11). This study was undertaken to investigate whether the alk-1-enyl functionality of neutral plasmalogen glycerides undergoes autoxidation as do simple vinyl ethers and to assess the effect of polyunsaturated acyl functionality, both inter- and intramolecular, on the course of such autoxidation.

MATERIALS AND METHODS

Hexadecanal was prepared from hexadecanol (Aldrich Chemical Co., Milwaukee, WI) by oxidation using dimethylsulfoxide (DMSO) and dicyclohexylcarbodiimide (Sigma Chemical Co., St. Louis, MO) according to the method of Fenselau and Moffatt (12). Glycerol-1,2-carbonate was prepared by the ester interchange of D,L-1-*O*-benzylglycerol (Sigma Chemical Co.) and diethyl carbonate (Aldrich Chemical Co.), followed by removal of the benzyl group by hydrogenolysis with palladium on charcoal following the method of Cunningham and Gigg (13). Stearoyl and linoleoyl chloride were obtained from their corresponding acids by reaction with oxaloyl chloride (Aldrich Chemical Co.) by the method of Bosshard et al. (14).

Thin layer chromatography. TLC was carried out on plates of Silica Gel G (250μ) obtained from Analtech (Newark, DE). Visualization of acetal and alk-1-enyl ether products was accomplished by fuchsin-bisulfite spray after exposure of the plates to concentrated hydrochloric acid vapors for one min; aldehydes so liberated were detected as purple to red spots. All products were visualized by spraying the plates with 6% copper sulfate in 50% phosphoric acid, followed by charring.

Gas chromatography. GC was conducted on a Sigma-3 gas chromatograph (Perkin-Elmer, Norwalk, CT) equipped with a capillary injector and flame ionization detector (FID). Separations were obtained using a fused silica wall-coated open tubular column 1.2 m × 0.2 mm i.d. (Hewlett-Packard, Avondale, PA) coated with 0.33μ thick, cross-linked methyl silicone. Determinations were made using helium as a carrier gas (1 ml/min) with a split ratio of 80:1 and the following oven program: seven min at 155 C, then 5 C/min to 200 C. Ethyl heneicosanoate (21:0) served as internal standard because it did not undergo oxidation under the experimental conditions. Signal analysis was accomplished by routing the detector output to the integrating terminal of a Hewlett-Packard 5880A gas chromatograph. A GC trace that shows the separation of the components of interest is shown in Figure 1.

High performance liquid chromatography. HPLC was carried out with a system consisting of a Beckman (Fullerton, CA) Model 110 A solvent delivery module equipped with a Tracor (Austin, TX) Model 945 (FID, an Altex Model 210 loop injector and a 20 μl loop. The HPLC column used was an Altex Ultrasphere-ODS, 5μ particle size, stainless steel column, 4.6 mm i.d. × 25 cm. The FID output was routed to a Hewlett-Packard Model 3390 integrator to determine retention times and peak areas. Triheptadecanoin (NuChek Prep, Elysian, MN) served as internal standard for the HPLC separations shown in Figure 2. Samples were eluted with methylene chloride/

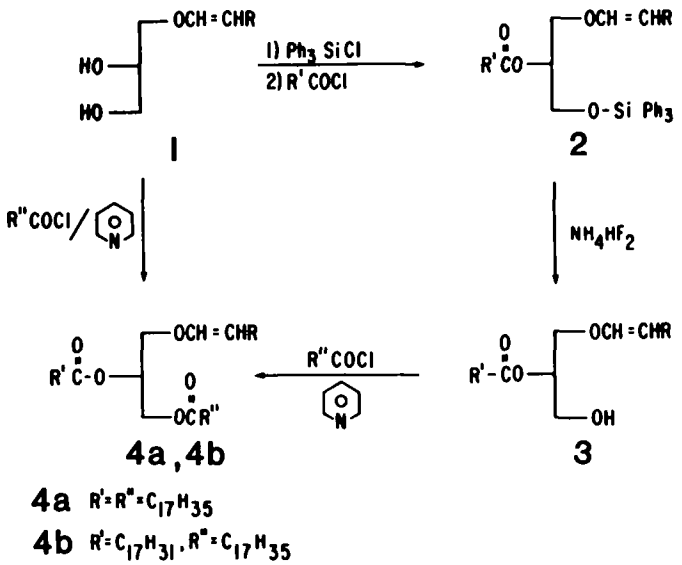
acetonitrile (55:45, v/v) at a flow rate of 1 ml/min. Samples were dissolved in the eluent and 20 μl injected.

Synthesis of cis/trans-*1-O-(hexadec-1-enyl)glycerol.* Hexadecanal (20 mmol) was converted to its bis-(2,3-carbonylglycerol) acetal by reaction with glycerol-1,2-carbonate (50 mmol) in the presence of methanesulfonic acid (1 mmol) in 30 ml of benzene/N,N-dimethylformamide (99:1) heated at reflux using a modification of the procedure of Chebyshev et al. (15). The acetal was purified by recrystallization from ether, yield 30%, m.p. 75–79 C. TLC of this product, R_f 0.21, CH_2Cl_2 solvent, showed only one component. Reaction of the acetal with phosphorus pentachloride according to the method of Chebyshev et al. (16) and then elimination of hydrogen chloride with triethylamine, according to the method of Gigg and Gigg (17), gave 1-*O*-(hexadec-1-enyl)glycerol-2,3-carbonate. The latter compound was purified by flash chromatography on silica gel (grade 60, 230–400 mesh, Aldrich Chemical Co.) using ether as eluent, TLC R_f 0.76, ether as eluent. Saponification of 1-*O*-(hexadec-1-enyl)glycerol-2,3-carbonate with methanolic potassium hydroxide (17) gave 1-*O*-(hexadec-1-enyl)glycerol (**1**, Scheme 1) in 68% yield, m.p. 43–44 C recrystallized from isooctane, TLC R_f 0.64 for *trans* isomer, 0.79 for *cis* isomer, eluent ether.

Synthesis of cis/trans-*1-O-(hexadec-1-enyl)-2,3-di-O-stearoylglycerol (4a).* To a solution of 1-*O*-(hexadec-1-enyl)-glycerol 1 (2 mmol) in carbon tetrachloride (10 ml) was added pyridine (10 ml) and stearoyl chloride (4.4 mmol). The reaction mixture was heated at 40 C for one hr under nitrogen, cooled to ambient temperature and filtered through neutral alumina (20 g, 80–200 mesh, Fisher Scientific Co., Fairlawn, NJ) to remove the precipitated pyridinium hydrochloride. The column was washed with an additional 40 ml of carbon tetrachloride, and the eluates were combined. The solvents were removed in vacuo and the residue chromatographed on silica gel (10 g). Elution with methylene chloride/hexane (3:1) gave compound **4a** in 55% yield, R_f 0.90 using methylene chloride/hexane (3:1), m.p. 51–52 C after recrystallization from hexane.



SCHEME 1

Synthesis of cis/trans-*1-O-(hexadec-1-enyl)-2-O-linoleoyl-3-O-stearoylglycerol (4b).* To a solution of 1-(*O*-hexadec-1-enyl)glycerol 1 (2 mmol) in carbon tetrachloride/pyridine (20 ml, 1:1) was added chlorotriphenylsilane (Aldrich Chemical Co.) (2 mmol in 5 ml of carbon tetrachloride). The resulting mixture was stirred at ambient temperature for one hr. TLC of the reaction mixture showed completeness of reaction. Linoleoyl chloride (2 mmol) was added to this solution, and the reaction mixture was heated to 40 C for one hr. The mixture was filtered through a column of neutral alumina (5 g), and the column was washed with chloroform (40 ml). The column eluates were combined, the solvents removed in vacuo, and the residue was chromatographed on silica (20 g) using methylene chloride/hexane (3:1) as eluent. TLC of fractions showed product 2 (Scheme 1) as a mixture of *cis* (R_f 0.62) and *trans* (R_f 0.54) isomers, solvent hexane/ether (4:1), yield 60%. A solution of 2 (1 mmol) in acetone (6 ml) and pyridine (0.2 ml) was heated at reflux for one hr in the presence of ammonium hydrogen fluoride following the procedure of Chebyshev et al. (18). Chromatography on silica gel and elution with methylene chloride/hexane (3:1) gave pure **3**, Scheme 1 as a viscous oil, R_f 0.24, hexane/ether (3:1) in 42% yield. Reaction of **3** (1 mmol) with stearoyl chloride (1.1 mol) in carbon tetrachloride/pyridine (1:1) as described above gave compound **4b**, Scheme 1, in 72% yield after chromatography on silica gel using methylene chloride/hexane (3:1) as eluent. Purified **4b** had an R_f of 0.77, hexane/ethyl acetate (3:1).

Oxidation procedure. Carefully weighed mixtures of either alk-1-enyl ether **4a** or **4b**, the appropriate internal standard and ethyl linoleate in the amounts listed in Table 1 were prepared in 500 μl of pentane. Aliquots of 50 μl then were transferred to each of nine serum vials (120 ml capacity; nominally 100 ml), the pentane removed in vacuo, the vacuum broken with air and the vials sealed with aluminum caps fitted with PTFE-lined butyl rubber septa (Perkin-Elmer). The sealed vials were immersed in a constant temperature water bath at 86 C. Vials were withdrawn at half-hour intervals and allowed to cool to room temperature. Reaction mixtures then were analyzed by either of the following procedures. HPLC analysis: the inside wall of the cooled vial was washed down with 600 μl

TABLE 1

of methylene chloride and 400 μl of acetonitrile, the resulting solution was transferred by means of a Pasteur pipette to a 1-ml serum vial, and 20 μl was injected onto the HPLC column. GC analysis: to each cooled vial 2 ml of 1% H_2SO_4 in methanol was added. The vial was heated on a steam bath for 15 min with occasional shaking and then cooled to room temperature. Saturated aqueous ammonium acetate (4 ml) added, and the resulting mixture was extracted with hexane (2 ml × 2). The combined extracts were dried over anhydrous Na_2SO_4, and 3 μl of the dried extract were injected onto the GC column for analysis.

RESULTS AND DISCUSSION

Synthesis of model neutral plasmalogens. The structures for the model 1-*O*-(alk-1-enyl) glycerides (neutral plasmalogens) synthesized for this study are shown in Scheme 1. Compound **4a**, 1-*O*-(hexadec-1-enyl)-2,3-di-*O*-stearoylglycerol, was prepared directly from 1-*O*-(hexadec-1-enyl)glycerol (**1**) by reaction with two equivalents of stearoyl chloride. Compound **4a** served as a model for studying the 1-*O*-(alk-1-enyl) functionality, found in plasmalogens, for its susceptibility to oxidation. The stearoyl residues of **4a** were not anticipated to be prone to oxidation because we had previously shown that saturated fatty esters, in particular ethyl stearate, are stable under the experimental conditions used in this study (6).

1-*O*-(Hexadec-1-enyl)-2-*O*-linoleoyl-3-*O*-stearoylglycerol, **4b** (Scheme 1), was prepared as a model neutral plasmalogen having internal polyunsaturation. Compound **4b** was obtained from compound **1** by protection of the 3-*O*-position of glycerol with chlorotriphenylsilane to yield compound **2** (Scheme 1). The latter compound, after acylation with linoleoyl chloride and subsequent removal of the silyl protective group, yielded compound **3** (Scheme 1). Reaction of **3** with stearoyl chloride gave the desired compound **4b**. Placement of the linoleoyl residue at the 2-*O*-position of the glycerol backbone of **4b** was opted because this is the position in which unsaturated acyl residues typically are located in naturally occurring neutral and polar plasmalogens (19).

Monitoring techniques for following autoxidation. Table 1 lists the amounts of each substrate used in the oxidation experiments described herein. Two complementary analytical procedures, HPLC and GC, were used in monitoring the oxidative disappearance of the neutral plasmalogens **4a** and **4b**. For Runs 1, 2 and 6, Table 1, substrate depletion was followed by GC using methyl heneicosanoate as an internal standard. In this procedure, the plasmalogens were converted to dimethyacetals and methyl esters with methanol containing 1% sulfuric acid and brief heating at 100 C (Fig. 1). With this procedure, we were able to follow not only the loss of 1-*O*-(hexadec-1-enyl) functionality but also the loss of linoleoyl functionality in **4b**, the latter of which is subject to oxidation under the experimental conditions. Runs 3, 4 and 5, Table 1, were monitored by following the direct disappearance of plasmalogens **4a** and **4b** by HPLC coupled with a FID. Triheptadecanoin was used as internal standard in these experiments. Though loss of linoleoyl functionality in **4b** could not be followed, the loss of added ethyl linoleate to **4a** could be monitored (Fig. 2).

Autoxidation results. The results of the oxidative disappearance of **4a** and **4b** are presented graphically (Figs. 3–6) for a series of experiments carried out at 86 C, a temperature that allowed for a measurable rate of substrate disappearance over a five-hr reaction period. The data are graphed in normalized fashion to show the percentage of remaining components at specified reaction times. All experiments in Table 1 were carried out in sealed vials of sufficient volume (120 ml) to ensure an excess of oxygen (1100 μmol) to eliminate oxygen content as a reaction variable. For oxidation of **4a**, the combined results obtained from Runs 1 and 2 are shown graphically in Figure 3 and combined results from Runs 3 and 4 in Figure 4. For oxidation of **4b**, results from Run 5 are shown in Figure 5 and Run 6 in Figure 6.

Oxidation of 4a. Run 1 (Fig. 3) shows the GC results obtained when compound **4a** (Scheme 1, devoid of polyunsaturation) was subjected to the oxidation conditions employed in these studies. Over the 4.5-hr reaction time of this experiment, a slow but measurable disappearance

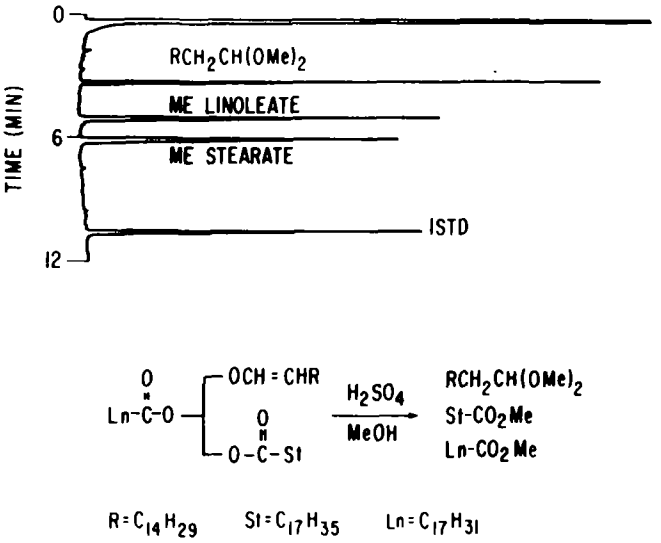

FIG. 1. GC separation of the ethanolysis products of plasmalogen glyceride *4b*; internal standard (ISTD) = methyl heneicosanoate. Conditions as in Materials and Methods.

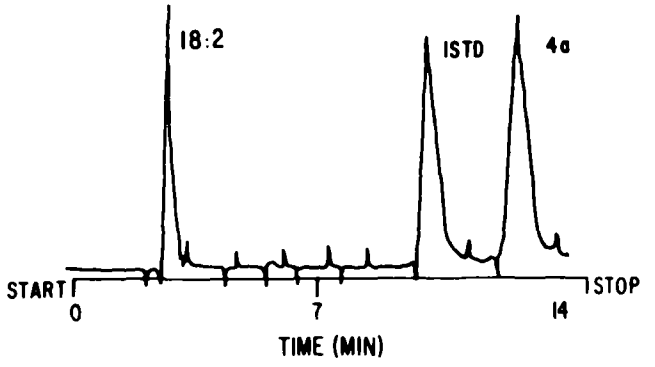

FIG. 2. HPLC of plasmalogen glyceride *4a*, ethyl linoleate (18:2) and triheptadecanoin (internal standard, ISTD). Conditions as in Materials and Methods.

of the 1-*O*-(alk-1-enyl) functionality of 4a was observed; by the end of the reaction period ca. 15% of the original amount of 4a had reacted. This run, which used ethyl heneicosanoate as internal standard, also showed that the stearoyl residues of 4a were unreactive under the conditions employed, a result in agreement with our previous work (6) with ethyl stearate.

The oxidative nature of the disappearance of 4a was established by repeating Run 1 with 0.1% antioxidant, w/w (Tenox 5; Kodak, Rochester, NY). The presence of antioxidant led to complete inhibition of decomposition of 4a over the five-hr reaction time. In addition, reactions failed to proceed when nitrogen was substituted for air in the vial headspace. Thus, loss of alk-1-enyl functionality in 4a cannot be attributed to hydrolysis by trace amounts of acid or water.

Also shown in Figure 3 are the results of Run 2, the oxidation of 4a in the presence of added ethyl linoleate. It is seen that linoleate oxidizes at a much faster rate than does 4a; however, the disappearance of 4a is accelerated in the presence of ethyl linoleate in that by the end of Run 2 almost twice the amount of 4a had reacted compared with Run 1. This result implied that there is accelerated oxidation of the 1-*O*-(alk-1-enyl) functionality of 4a by the oxidation products of linoleate.

In Run 3, Figure 4, the course of the reaction was followed by HPLC, which allowed for the direct measurement of disappearance of 4a, rather than its methanolysis

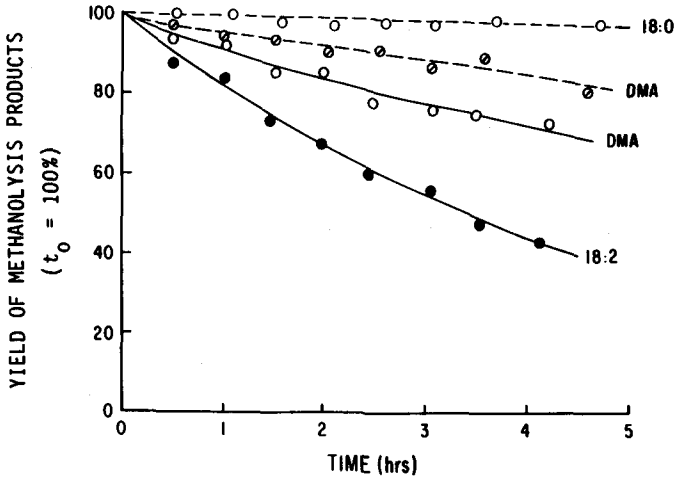

FIG. 3. Course of reaction at 86 C of *4a* as followed by GC of methanolysis products after treatment of oxidized 4a with H_2SO_4/methanol. – – – –, Run 1 (oxidation of *4a* in absence of ethyl linoleate); ——, Run 2 (oxidation of *4a* in presence of ethyl linoleate). 18:0, methyl stearate; DMA, dimethyl acetal of hexadecanal; 18:2, methyl linoleate; internal standard, methyl heneicosanoate; t_o denotes starting time of oxidation reaction.

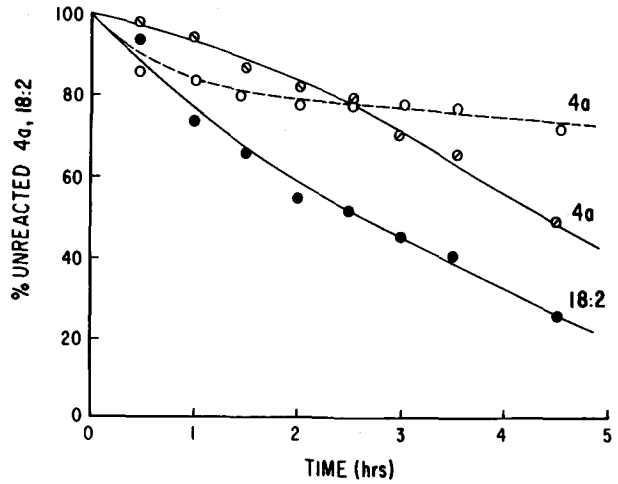

FIG. 4. Course of reaction at 86 C of *4a* as followed by HPLC. – – – –, Run 3 (oxidation of *4a* in absence of ethyl linoleate); ——, Run 4 (oxidation of *4a* in presence of ethyl linoleate). 18:2, ethyl linoleate; internal standard, triheptadecanoin.

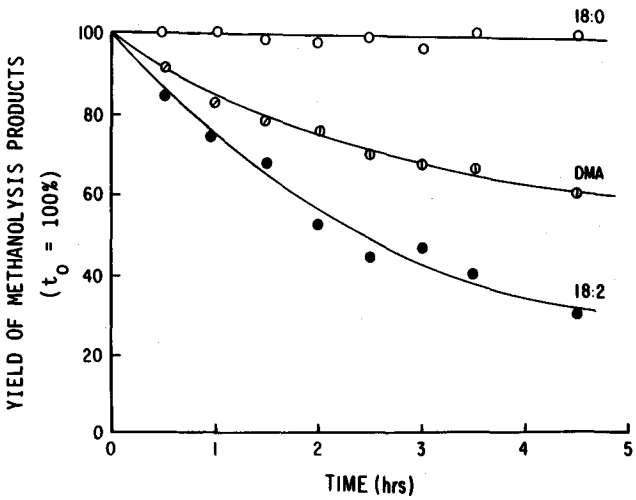

FIG. 6. Course of reaction at 86 C of *4b* (Run 6) as followed by GC of methanolysis products. 18:0, methyl stearate; 18:2, methyl linoleate; DMA, dimethyl acetal of hexadecanal; internal standard, methyl heneicosanoate; t_o denotes starting time of oxidation reaction.

products as in Run 1. In this manner, it was possible to compare the extent of oxidation on each side on the ether structure, that which occurred on the unsaturated (alk-1-enyl) side of the ether vs the saturated (CH_2 of glycerol backbone) side. A comparison of these two runs (1 and 3) shows a 20% disappearance of **4a** in Run 3 vs a 15% loss in Run 1. Accordingly, it is estimated that ca. 75% of the oxidation of **4a** occurs on the unsaturated side of the molecule, and 25% occurs on the saturated side. This result was in agreement with our earlier findings on the oxidation of the simple enol ether model, ethyl hexadec-1-enyl ether.

Run 4, Figure 4, is a repeat of Run 2, oxidation of **4a** in the presence of ethyl linoleate. Run 4 was followed by HPLC instead of by GC. As noted in Run 2, there was an accelerated depletion of **4a** in the presence of added ethyl linoleate; a 35% loss of **4a** was observed in Run 4. The initial rate of loss of **4a** was diminished in the presence of added linoleate, but as linoleate oxidation proceeded the rate of loss of **4a** increased even beyond that of Run 2 (Fig. 3). This result implied that the initial oxidation of linoleate retarded the loss of **4a**; however, as linoleate oxidation proceeded, the accumulation of its oxidation products accelerated the loss of **4a**. This indicated an interaction of linoleate oxidation products, presumably hydroperoxides (20), with the 1-*O*-(alk-1-enyl) function of **4a**. To test this hypothesis, we subjected ethyl linoleate alone to the oxidation conditions and obtained a depletion curve similar to that shown in Figure 4. HPLC of the resulting reaction mixtures showed, in addition to residual ethyl linoleate, a peak eluting earlier in the chromatogram, which could be ascribed to linoleate hydroperoxides (20). Unreacted **4a** in a nitrogen atmosphere then was added to this oxidation mixture, and this mixture was heated at 86 C for one hr. HPLC analysis of the latter mixture showed a loss of ca. 7% of **4a**, indicating a small but significant interaction of the alk-1-enyl function of **4a** with preformed linoleate oxidation products. Presumably, the greater loss of **4a** in the presence of oxidizing linoleate arises from a stronger intermolecular interaction of **4a** with linoleate oxidation intermediates, hydroperoxy radicals, than with linoleate oxidation products, hydroperoxides.

Oxidation of 4b. To assess the effect of intramolecular interaction of linoleate oxidation products with the alk-1-enyl ether functionality of plasmalogens, experiments were carried out using the internally polyunsaturated compound **4b**, Scheme 1, as substrate. Run 5, Figure 5, shows the results obtained when the oxidation of **4b** was followed by HPLC. From this run, it is seen that there is a rapid oxidation of substrate **4b** to the extent that the depletion curve resembles that of linoleate itself. This result was not totally unexpected because compound **4b** contained both of the oxidizable functional groups within its structure. A better picture of the course of oxidation of **4b** was obtained when the reaction was followed by GC, since with this technique it was possible to monitor the loss of alk-1-enyl and linoleoyl functionalities of **4b** separately. As the data show (Run 6, Fig. 6), loss of linoleoyl group amounted to ca. 60%. This confirmed the faster oxidation of linoleoyl residue over the alk-1-enyl functionality. Nevertheless, loss of alk-1-enyl group of **4b** was comparable to or exceeded that observed when **4a** was oxidized in presence of added ethyl linoleate, thus confirming a strong intramolecular interaction between the two oxidizing species. Finally, a comparison of the total oxidation loss of the two functional groups of **4b**, Figure 6, with oxidation loss of intact **4b**, Figure 5, indicated that both functional groups within **4b** are oxidized simultaneously.

From the above series of experiments, it has been demonstrated that the alk-1-enyl functionality of plasmalogens is subject to oxidation under relatively mild oxidizing conditions. More importantly, the data suggest that more easily oxidized polyunsaturated esters accelerate autoxidation of the alk-1-enyl ether functionality of plasmalogens. This acceleration of oxidation by polyunsaturated acyl residues has been shown to occur by either an inter- or intramolecular process. This is highly significant because natural plasmalogens typically also are highly polyunsaturated. Accordingly, the results suggest that oxidation of the alk-1-enyl ether functionality of plasmalogens should not be ignored as a factor that contributes to the oxidative instability of animal tissue or the development of rancidity in meat products.

Lipids of Dermatophytes. III. Sterol-induced Changes in the Lipid Composition and Functional Properties of *Epidermophyton floccosum*

S. Sanadi, R. Pandey and **G.K. Khuller***
Department of Biochemistry, Postgraduate Institute of Medical Education and Research, Chandigarh-160012, India

Sterol supplementation, alone or in the presence of cerulenin, resulted in an increase in the total sterol content of *Epidermophyton floccosum*. While the total phospholipid levels of *E. floccosum* exhibited only marginal changes with sterol supplementation, the fatty acid profiles of these phospholipids were highly varied. In the presence or absence of cerulenin, the oleic acid content of phospholipids were increased significantly by cholesterol supplementation, whereas linoleic acid levels were enhanced by ergosterol supplementation. These variations resulted in higher unsaturated/saturated phospholipid fatty acid ratios in sterol-supplemented cells. The uptake of labeled amino acids (aspartic acid, lysine, glycine) was influenced by sterol supplementation. Alterations in the number of binding sites for the membrane probe, 1-anilino-naphthalene-8-sulfonate (ANS), were seen based on Scatchard plot calculations. The results indicate a correlation between sterol-induced changes in membrane lipid composition and function.
Lipids 23, 435–438 (1988).

Sterols, the important components of some prokaryotes and eukaryotes, function as major determinants of fluidity, integrity and membrane structure (1,2). Yeast cells are known to exhibit altered sterol contents when grown in media supplemented with ascorbic acid, hydroquinone, methylene blue or potassium persulfate, resulting in altered amino acid uptake (3,4). In dermatophytes, little is known about the dependency of cellular functions on sterol composition. To explore these aspects in human pathogenic fungi, *Epidermophyton floccosum* cultures were grown in media supplemented with cholesterol or ergosterol in presence/absence of cerulenin, a known inhibitor of fatty acid and sterol synthesis. Further, attempts have been made to correlate sterol-induced alterations in the lipid composition with the structural and functional changes in the membranes of *E. floccosum*.

MATERIALS AND METHODS

Materials. Cholesterol, ergosterol, glycine, aspartic acid and lysine were procured from Sigma Chemical Co. (St. Louis, MO). Cerulenin was obtained from Makor Chemicals (Jerusalem, Israel). Labeled amino acids [U-^{14}C]lysine (sp. act. 288 mCi/mmol); [2-^{14}C]glycine (sp. act. 11.2 mCi/mmol), [U-^{14}C]aspartic acid (sp. act. 152 mCi/mmol) were obtained from BARC, Bombay. Novozyme '234' was purchased from M/S Novo Industries (Bagsvaerd, Denmark), and Cellulase CP was procured from Sturge Biochemicals (Selby, U.K.). Ficoll-paque was procured from Pharmacia Fine Chemicals Co. (Uppsala, Sweden). 1-Anilinonaphthalene-8-sulfonate (Mg salt) was obtained from Fluka (Buchs, Switzerland). Membrane filters (0.45 μM) and a 12-place sampling manifold, used for the amino acid uptake experiments, were obtained from Whatman Inc., London, and Millipore Inc. (Bedford, MA), respectively. All other chemicals used were of the highest quality available.

Growth of culture. Source and maintenance of *E. floccosum* have been described (5). *E. floccosum* was grown in Sabouraud's broth as shaking cultures. Minimum inhibitory concentration of cerulenin and the optimum concentrations of sterols (dissolved in minimum amounts of ethanol) were added directly to the sterile medium before inoculation. Sterol-grown cells, in the presence/absence of cerulenin, were harvested in mid-log phase (5 days) and then processed for sterols, DNA, lipid extraction and membrane studies.

Quantitation of phospholipids. The lipids were extracted from the cells by Folch's extraction procedure (6). Total phospholipids were estimated by the method of Bartlett as modified by Marinetti (7). Single-dimensional thin layer chromatography was carried out to resolve individual phospholipids, using the solvent system chloroform/methanol/7 N ammonia (65:25:4, v/v). Total phospholipids were separated from neutral lipids by acetone precipitation and were used for fatty acid analysis. The fatty acids were converted into their methyl esters by transesterification with methanol in the presence of thionyl chloride, as described (5). The methyl esters were analyzed on a M/S Nucon Engineers, AIMIL Gas Chromatograph, fitted with a flame ionization detector, on columns containing 20% diethylene glycol succinate (DEGS) on 60–80 mesh chromosorb-W. Nitrogen, at a flow rate of 40 ml/min, was used as the carrier gas. The fatty acids were quantitated by triangulation.

Quantitation of sterols. Sterols were extracted by boiling the cells in 10% alcoholic KOH for one hr. The hydrolysates were cooled and extracted three times with petroleum ether. Sterols were estimated by the method of Zlatkis et al. (8).

Quantitation of DNA. DNA extraction was achieved by homogenizing the cells in 10% cold trichloroacetic acid. The pellet obtained after centrifugation at 2,000 × g was dissolved in a known volume of 0.5 M perchloric acid and digested at 80 C in water bath for 15 min. The samples again were centrifuged, and supernatant was taken for DNA estimation by the method of Burton (9).

Preparation of spheroplasts. Spheroplasts were prepared by the procedure of Larroya et al. (10). Log-phase cells (1 g) were incubated under sterile conditions with 30 mg each of two commercial cell-wall degrading enzymes, novozyme '234' and cellulase CP, in a conical flask in citrate phosphate buffer (pH 6.5), containing 0.7 M NaCl, for 10 hr in a shaker at 27 C. Formation of spheroplasts was monitored microscopically. At the end of incubation, the reaction mixture was removed by centrifugation at 1,000 × g for 10 min. The pellet was washed twice with citrate phosphate buffer and lightly homogenized. Spheroplast preparation then was purified by centrifugation at 400 × g for 15 min on a ficoll-paque density gradient. The purified spheroplast preparation was used

for structural studies with the fluorescent probe 1-anilinonaphthalene-8-sulfonate (ANS).

Amino acid uptake studies. Amino acid uptake in whole cells was determined by incubating 1 ml of cell suspension (40–50 mg fresh wt. of cells in 1 ml of citrate phosphate buffer, pH 6.5) at 27 C for seven min, which was within the linear range of uptake. The reaction was initiated with the addition of amino acid (final concentration was 4 mM), and it was terminated by adding chilled buffer and filtered rapidly through 0.45 μM membrane filters. The cells on the filter paper were washed twice, dried and weighed. Radioactivity on the filters was counted in a toluene-based scintillation fluid in a Packard Tricarb Liquid Scintillation Counter.

Structural studies with ANS. 1-Anilinonaphthalene 8-sulfonate (ANS) was used to study the structural changes in the membranes of spheroplasts prepared from variously grown *E. floccosum* cells. The basic assay mixture consisted of a total volume of 2 ml in 10 mM citrate phosphate buffer, pH 6.5, containing 0.7 M NaCl, ANS conc. 10–100 μM and spheroplast protein ranging from 20 to 200 μg. The fluorescence emission was recorded in a Kontron SFM-25 Spectrofluorimeter. The number of binding sites were calculated from the Scatchard plot (11). Protein was estimated by Lowry's method (12).

RESULTS AND DISCUSSION

Manipulation of membrane lipid composition by supplementing various additives to the growth medium is a valuable tool for studying the role of various lipid components in microorganisms. To examine the role of sterols, *E. floccosum* was grown in the presence of optimum concentration of ergosterol (natural sterol) or cholesterol (a sterol foreign to the fungus), alone or in combination with the minimum inhibitory concentration (MIC) of cerulenin (0.5 μg/ml). Cerulenin inhibits more than 90% of growth and endogenous fatty acid synthesis, and partially blocks (60%) phospholipid and sterol synthesis at the MIC (13). Different concentrations of cholesterol and ergosterol ranging from 0 to 30 μg/ml were supplemented in the medium, and no inhibition in the growth as compared to control was observed up to 10 μg/ml. This concentration of sterol(s) was used throughout this study.

Ergosterol supplementation, with or without cerulenin, did not alter the total phospholipid (TPL) levels as compared with the control. However, the total phospholipid levels were significantly decreased in cells supplemented with cholesterol alone or along with cerulenin (Table 1). Individual phospholipid composition also was examined. Phosphatidylserine (PS) and phosphatidylinositol (PI) were pooled together, the latter being the minor component with a mobility close to PS. Minor changes were observed in all the phospholipid components, with a significant decrease in PS + PI and phosphatidylcholine (PC) levels in cholesterol-supplemented cells. Ergosterol supplementation in the presence or absence of cerulenin resulted in a significant increase in choline-containing lipids, which probably is due to enhanced methylation of phosphatidylethanolamine (PE) to PC. In yeast mutant

Concentrations used: cholesterol, 10 μg/ml; ergosterol, 10 μg/ml; cerulenin, 0.5 μg/ml.

GL7, ergosterol also has been shown to stimulate the methlation of PE to PC (14). The increased levels of lipophosphatidylcholine (LPC) in cells supplemented with ergosterol (both in presence and absence of cerulenin) might be due to the conversion of PC to LPC because dermatophytes possess an active phospholipase A (15). Alterations in the individual phospholipid composition resulted in changes in the ratio of zwitterionic to anionic phospholipids and the ratio of choline-containing phospholipids to PE in the variously grown cells (Table 1). The levels of total sterols (mainly free sterols because esterified sterols represent less than 5% of the total sterols) were increased on supplementation of cholesterol and ergosterol, alone or in the presence of cerulenin. These results indirectly indicate the capacity of the cells to take up exogenous sterols. Sterol to phospholipid ratio increased in all the supplementations as compared with control, in the order, ergosterol (1.1-fold) < cerulenin plus ergosterol (1.4-fold) < cholesterol (1.8-fold) < cerulenin + cholesterol (2.2-fold) (Table 1).

Sterol supplementation in the presence or absence of cerulenin not only affected the phospholipid and sterol composition but also the acyl groups of phospholipids. A significant decrease in the levels of palmitic acid were observed in all the types of cells as compared with control (Table 2). Cholesterol supplementation in the presence and absence of cerulenin resulted in a significant increase in oleic acid levels, whereas linoleic acid levels increased significantly on supplementation of ergosterol with/without cerulenin. The observed increase in oleic acid content of cholesterol-grown *E. floccosum* cells is similar to that observed in yeast sterol auxotroph (RD5-R) (16). Supplementation of ergosterol, cerulenin plus ergosterol/cholesterol resulted in a significant increase in U/S ratio, whereas supplementation of cholesterol alone did not alter the U/S ratio significantly. In yeast, increased percentages of saturated fatty acids were observed on supplementation of the growth medium with sterols (17). It has been further suggested that sterol replacement regulates the fatty acid composition to a considerable degree.

The lipid composition of the cell membrane plays an important role in regulating the functions of the cells. Therefore, the functional properties of membranes in response to changes in lipid composition, as a result of sterol supplementation, were studied by measuring the steady-state accumulation of amino acids (one each of basic, neutral and acidic amino acids). It is evident from Table 3 that amino acid uptake was altered in the variously grown cells. The changes may be attributed to alterations observed in phospholipid composition including those in the ratio of zwitterionic and anionic lipid species as well as degree of unsaturation of acyl groups of phospholipids, as has been demonstrated earlier in dermatophytes (18,19), bacteria (20) and yeast (21). These changes also could be due to a change in the affinity of the carriers of these amino acids. Singh et al. (22) have

demonstrated alterations in the uptake of various amino acids due to changes in the ergosterol levels in *C. albicans*, similar to our observations with *E. floccosum*.

Structural alterations due to changes in the membrane surface charge density, in the spheroplast membrane prepared from *E. floccosum* cultures grown in sterol-supplemented media, were monitored using an ANS membrane probe. ANS fluorescence provides information about membrane surface charge and membrane potential (23, 24). The Scatchard plot analysis showed decreased binding sites in spheroplasts prepared from cholesterol-supplemented cells, whereas no alteration was observed in ergosterol-supplemented cells (Fig. 1). The number of binding sites were found to increase in spheroplasts prepared from cells grown in the presence of cerulenin and cholesterol/ergosterol, as compared with the control cells. Increased/decreased binding sites might be due to changes in the membrane surface charge resulting from changed ratio of zwitterionic to anionic phospholipids as well as altered ratio of unsaturated to saturated fatty acids, as seen from Tables 1 and 2. In addition, PC also is known to regulate the charge of the membranes (25), and a significant decrease in PC content was seen in cholesterol-supplemented cells, which possibly explains the decreased binding sites in spheroplasts prepared from these cells. The changes observed in ANS binding also may be due to changed hydrophobic environment around the dye due to integral membrane proteins (25). The dye mainly binds to the membrane surface, hence changes observed demonstrate a role of membrane phospholipids, sterols and proteins, because these are the only components of the cell that come in contact with ANS.

We have shown that supplementation of sterols, alone or in the presence of cerulenin, induces changes in the lipid composition of *E. floccosum*, which in turn affects its structural and functional properties.

Occurrence of Cholesterol as a Major Sterol Component in Leaf Surface Lipids

Manjiro Noda*, Mitsunobu Tanaka, Yukari Seto, Takaaki Aiba and Chiyo Oku
Department of Agricultural Chemistry, Kinki University, Kowakae, Higashiosaka 577, Japan

Cholesterol has been detected as one of the major sterols in the surface lipids of higher plant leaves. It was widely distributed among the plant leaves of various species as a common main sterol component with a few exceptions. The content of cholesterol amounted to 71.5% of the total sterols in the surface lipids of rape leaves. However, the proportion of cholesterol in the intracellular lipids of rape leaves was lower than that in the surface lipids, and the seed lipids contained only a trace amount of cholesterol, as reported in the literature. In the leaf surface lipids examined, a minor amount of cholestanol associated with cholesterol often was detected by capillary gas chromatography and gas chromatography-mass spectrometry. The related analysis for the surface lipids of fruits showed that cholesterol was one of the major component sterols also in those lipids of several species.
Lipids 23, 439-444 (1988).

Cholesterol up to now has been believed to be a minor component sterol, 4-desmethylsterol, in higher plants. It was detected in vegetable oils by gas chromatography and existed in a small proportion up to 5% of the total sterols or mostly in only trace amounts (1-3). Previous workers have reported that, in general, a slight amount of cholesterol or no cholesterol was found in the plant seed lipids of various species (4-7,11,14,15). The component sterol data for roots (6,8), leaves (7-13), pericarps (8,12) and seedlings (6,8,11) also showed that cholesterol was a minor component sterol in their sterol fractions. However, several studies have revealed the existence of cholesterol as a major component sterol in chloroplasts and other subcellular organelles of leaves (16,17) and shoots (18), poinsettia plant (19), pollens (20) and *Sorghum bicolor* grains in their early developing stage (14).

In analyzing the leaf and silique waxes of rape, we have found that they contained an unusually large proportion of cholesterol in their sterol fractions. Our further experiments for the detection of cholesterol also have showed that cholesterol was present as one of the usual major component sterols in the leaf surface lipids of various plant species, though several species had cholesterol as the minor component sterol. Moreover, a substantial proportion of cholesterol has been observed in the component sterols of several fruit surface lipids. This paper describes the detection and determination of cholesterol in plant lipids by capillary gas chromatography and its identification by gas chromatography-mass spectrometry (GC-MS).

MATERIALS AND METHODS

Plant materials. Fully matured seeds and leaves of rape *(Brassica napus)* and the immature siliques of rape harvested at 30 days after flowering were used for these experiments. The full-grown leaves of the cultivated *Viburnum awabuki* tree were collected in the summertime. Fresh leaves of spinach *(Spinacia oleracea),* cabbage *(Brassica oleracea),* radish *(Raphanus sativus),* crown daisy *(Chrysanthemum coronarium)* and leek *(Allium tuberosum),* all sold commercially as food, were used.

Immature green fruits, such as the legumes of broad bean *(Vicia faba),* the capsules of okra *(Abelmoschus esculentus)* and the fruits of green pepper *(Capsicum annuum)* were obtained from vegetable markets.

Reference sterols and solvents. Cholesterol, campesterol, stigmasterol and sitosterol were obtained from Sigma Chemical Co. (St. Louis, MO). Cholestanol was purchased from the Nakarai Chemical Co. (Kyoto, Japan). Brassicasterol was prepared from rapeseeds. All solvents used for extraction were purified by distillation before use.

Isolation of sterols. Leaves and fruits (100-1000 g) without cutting were immersed in hexane (1-3 l) and allowed to stand for two days at room temperature with occasional shaking. The hexane extract was separated by filtration, and the residual plant bodies were then reextracted twice by gentle refluxing with fresh hexane for each one hr. All hexane extracts were combined, and the separated water layer was removed. After drying over anhydrous sodium sulfate, the hexane layer was evaporated to dryness under reduced pressure. The extracted lipids contained mainly the plant surface lipids. In the case of rape leaves, a portion of the extracted lipids was divided for the separation of the steryl lipid classes.

The lipids were hydrolyzed with a solution of potassium hydroxide (1 g) in aqueous ethanol (5 ml) by refluxing for two hr. The hydrolysates were extracted with diethyl ether, and the ether extract was washed with water and dried with anhydrous sodium sulfate. Evaporation of ether from the extract gave unsaponifiable matter.

The component lipid classes in the unsaponifiable matter were separated on Silica Gel G plates, with hexane/diethyl ether/acetic acid (70:30:1, v/v/v) used as the developing solvent. The band corresponding to that of free sterol was detected by Rhodamine 6G spraying, scraped and then extracted with ether and hexane. The extracted lipid fraction was comprised of a mixture of the sterols originated mainly from free sterols and steryl esters in the surface lipids.

Intracellular lipids were extracted by homogenization with chloroform/methanol (1:1, v/v) from the plant residue after the hexane extraction described above. The extracted rape leaf lipids were separated into four lipid classes containing sterols. Thin layer chromatography (TLC) was applied on Silica Gel G plates for the separation of free sterols from steryl esters with the solvent system, hexane/diethyl ether/acetic acid (70:30:1, v/v/v), and of sterylglycosides from acylsterylglycosides with chloroform/methanol/acetone (80:16:4, v/v/v). The component sterols were recovered separately from sterylglycosides and acylsterylglycosides by the acid hydrolysis

with 0.5 N HCl in methanol for two hr, followed by the alkali hydrolysis described above in the case of acylsterylglycosides.

Reversed-phase TLC using Kieselguhr G plates impregnated with kerosene was employed for purification of cholesterol with the developing solvent of acetic acid/acetonitrile (1:2, v/v).

Gas chromatography (GC). Sterols were analyzed by packed-column and capillary GC as free sterols or trimethylsilyl ethers of sterols (TMS sterols). TMS sterols were prepared by the reaction of sterols with N,O-bis-(trimethylsilyl)acetamide (BSA)/pyridine (1:3, v/v) at 80 C for 10 min.

The free sterols and their TMS derivatives were separated and identified on a glass column (3 mm × 2 m) packed with 3% SE-30 on Chromosorb W at 260 C.

Capillary GC was carried out for precise analysis of sterol with a Shimadzu GC-8A gas chromatograph equipped with a flame-ionization detector. A fused silica capillary column (chemically bonded type, 0.24 mm i.d. × 50 m), ULBON HR-52, which corresponded to SE-52 (Shinwakako Co., Kyoto, Japan), was used. The column temperature was 280 C, and the carrier gas was nitrogen at a flow rate of 0.7 ml/min and split ratio 1/136. Relative retention time (RRT) to TMS cholesterol (retention time, 11.5–12 min) was employed for characterization of the TMS sterols.

Gas chromatography-mass spectrometry. Electron impact GC-MS data were obtained by using a model JEOL JMS-HX 100 system fitted with a glass column (2 mm × 1 m) packed with 1% OV-1 on Chromosorb W, with a column temperature of 245 C; ion source temperature was 200 C, accelerating voltage 5.0 kV, and ionizing voltage 70 eV.

Another model Hitachi M-80A system for GC-MS also was employed. In this system, the GC separation was carried out at 260 C on a column (3 mm × 1 m) packed with 2% OV-101 on Chromosorb WHP. The ionizing voltage was 20 eV, and the ion source temperature was 180 C.

Other analytical methods. ^{1}H NMR spectroscopy was performed at 60 MHz on a Hitachi instrument, model R-600, in $CDCl_3$ with tetramethylsilane as internal standard. Addition of increasing amounts of the shift reagent, $Eu(fod)_3$, made it possible to assign some of the proton signals on the NMR spectra of sterols (21). The infrared (IR) spectrum of sterol was obtained with a KBr disk.

Sterols were estimated by the color reaction with acetic anhydride/concentrated sulfuric acid (19:1, v/v). Intensities of the developed color were measured at 620 nm after 30 min.

RESULTS

Separation of rape sterols by capillary GC. A mixture of sterols was recovered from leaves, seeds or fruits by hexane extraction, saponification and subsequent TLC separation. The sterol content of surface lipids ranged from 3 to 50 mg per 100 g of the individual fresh plant matter examined.

Capillary GC showed good separations for TMS derivatives of sterols on a fused silica capillary column, ULBON HR-52 (Fig. 1). Separation and identification were possible for cholesterol and cholestanol in their mixtures that were inseparable on SE-30, OV-1 and OV-101 packed

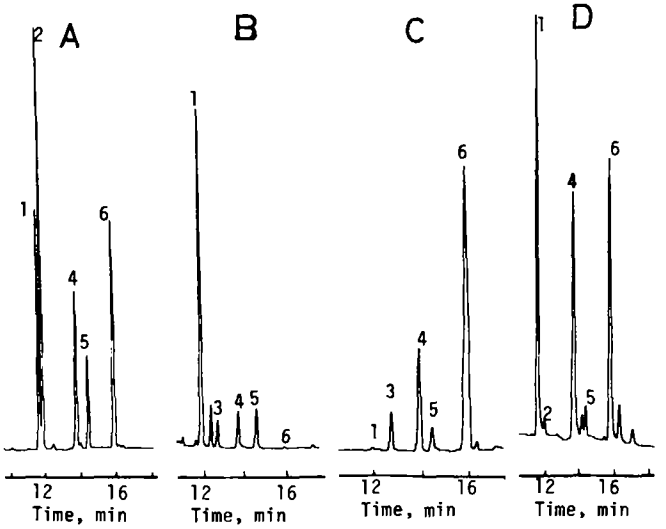

FIG. 1. Capillary gas chromatograms of TMS sterols from plant lipids. A, standard sterols; B, sterols from surface lipids of rape leaves; C, sterols from intracellular lipids of rape seeds; D, sterols from surface lipids of broad bean *(Vicia faba)* fruits. Peaks of TMS sterols: 1, cholesterol; 2, cholestanol; 3, brassicasterol; 4, campesterol; 5, stigmasterol; 6, sitosterol; other peaks were not identified. Column, ULBON HR-52 (0.24 mm i.d. × 50 m); temperature, 280 C.

columns. A marked difference in sterol composition was observed between rape leaf and seed lipids. The main sterol component of rape leaf surface lipids was cholesterol (71.5%), and a minor sterol was sitosterol (0.6%), whereas the seed intracellular lipids contained sitosterol as a dominant sterol (67.3%) and a trace amount of cholesterol (0.7%) as shown in Figure 1 and Table 1 (1–3). Cholesterol was a member of the major component sterols also in the leaf intracellular lipids, although sitosterol was predominant in these lipids. The surface lipids of immature rape green siliques contained a large proportion of cholesterol.

The sterol compositions of sterol ester, free sterol, acylsterylglycoside and sterylglycoside in hexane extracts of rape leaves are given in Table 2. No marked difference in their sterol compositions was observed among these lipid classes, in which cholesterol was the principal sterol. The hexane extracts of rape leaves consisted mainly of the wax components such as hydrocarbons, wax esters including sterol esters, triacylglycerols, free fatty acids, free aliphatic alcohols and free sterols; their detailed compositions will be reported elsewhere. It is unclear whether sterylglycoside and acylsterylglycoside existed as the wax components or as the contaminants by partial extraction of the intracellular lipids.

Identification of cholesterol and cholestanol by GC-MS and other methods. The peak agreeing with that of authentic cholesterol on gas chromatogram was further characterized by GC-MS. Figure 2 shows a mass spectrum of the peak identified on a gas chromatogram as TMS cholesterol from rape leaf lipids. Characteristic fragment ions of TMS cholesterol appeared on this spectrum, which agreed with that reported in the literature (22). GC-MS data of rape and other plant leaf sterols as free sterols also showed that one of the detected major sterols was cholesterol which gave the typical ions at m/z 386 (M^+),

TABLE 2

Sterol Composition of Rape Leaf Lipid Classes Containing Sterols (%)

Major sterol	RRT[a]	Sterol ester	Free sterol	Acylsteryl-glycoside	Steryl-glycoside
Cholesterol	1.00	77.1	61.6	66.6	62.0
Unknown 1	1.05	0.4	5.3	5.7	7.4
Brassicasterol	1.07	2.1	3.0	5.6	7.1
Campesterol	1.18	6.4	10.7	8.9	8.3
Stigmasterol	1.24	13.3	9.9	12.4	13.7
Sitosterol	1.36	0.7	9.5	0.8	1.5

[a]Relative retention time (RRT) is the same as that in Table 1.

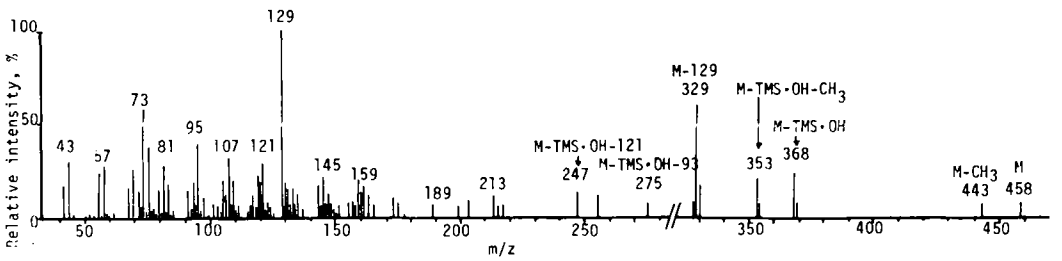

FIG. 2. Mass spectrum of the TMS sterol detected and identified as TMS cholesterol on gas chromatogram of rape leaf surface sterols as their TMS derivatives. A glass column (2 mm × 1 m) packed with 1% OV-1 on Chromosorb W was used at 245 C for GC separation and ionizing voltage was 70 eV.

371 ($M^+ - CH_3$), 368 ($M^+ - H_2O$), 301 ($M^+ - 85$), 275 ($M^+ - 111$), 273 (M^+ − side chain), 213 ($M^+ - 173$), etc., agreeing with those of authentic cholesterol (Fig. 3) (11).

GC-MS analysis of the plant surface sterols further proved that these plant sterol fractions often contained cholestanol as a minor component sterol that was inseparable from cholesterol on a GC-packed column. For example, a GC-MS spectrum of the peak of cholesterol in spinach leaf sterols is shown in Figure 3A. It was found that the cholesterol was contaminated with a minor amount of cholestanol, giving the characteristic ions at m/z 388 (M^+), 373 ($M^+ - CH_3$), 275 (M^+ − side chain), 233 (M^+ − side chain − C_3H_6), 215 ($M^+ - 173$), etc. These findings coincided with those in capillary GC by which cholesterol and cholestanol were separated from each other and differentiated (Figs. 1A and 1D).

A fraction corresponding to cholesterol was separated on reversed-phase TLC from the sterol mixture of rape

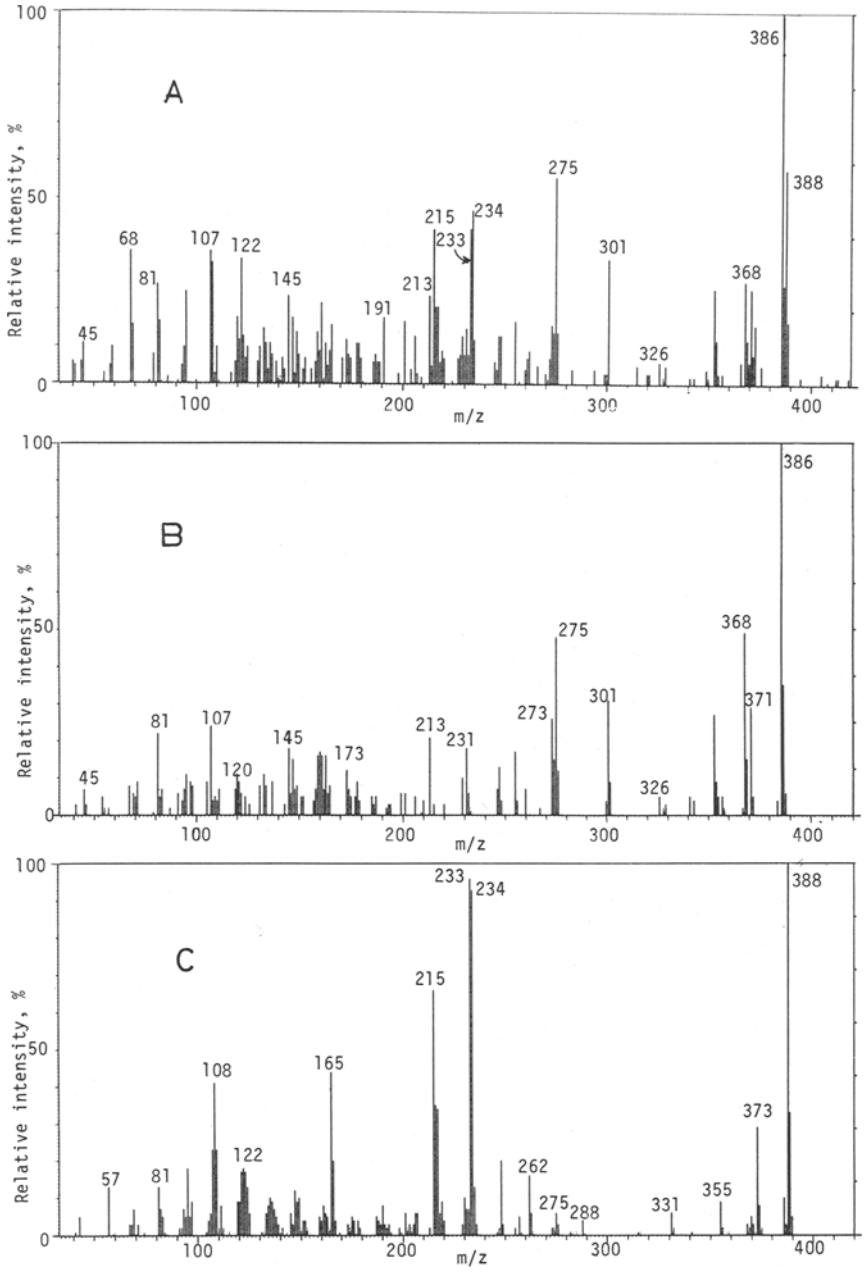

FIG. 3. Mass spectra of free sterols. The spectra were taken at the peak corresponding to that of cholesterol on a GC column (3 mm × 1 m) packed with 2% OV-101 on Chromosorb WHP at 260 C. Ionizing voltage was 20 eV. A, a cholesterol fraction from surface lipids of spinach leaves; B, standard cholesterol; C, standard cholestanol.

leaf surface lipids. The main component of this fraction was characterized as cholesterol by capillary GC, and the ^{1}H NMR spectra showed the presence of Δ^5 double bond (δ 5.34 ppm, br. *s*, 1H, =C<u>H</u>- at C-6) and absence of both Δ^7 and Δ^{22} double bonds, because the olefin protons at C-22 and 23 (δ 5.09, *m*, 2H) and at C-7 (δ 5.15, br. *s*, 1H) (11) were not detectable. In addition, the presence of the C-7 methylene protons could be confirmed by use of downfield shift plots of the proton signals by incremental addition of Eu(fod)$_3$ to the sample. An IR spectrum of the fraction showed the absorptions (KBr disk) at 3400, 2940, 2860, 1660, 1460, 1380 and 1060 cm^{-1}, which were characteristic of sterol.

From these analytical data, the sterol agreeing with authentic cholesterol in its GC retention time was identified as cholesterol.

Distribution of cholesterol in plant species. The sterol compositions of leaf surface lipids in various plant species other than rape are listed in Table 3, in which the sterol compositions of some green immature fruits also are given in comparison with those of green leaves. Cholesterol was found to be one of the major component sterols of leaf surface lipids in the different plant species examined and its proportion reached over 10% in most cases with few exceptions. Even in spinach and chrysanthemum leaves, cholesterol remained as a major sterol, although

TABLE 3

Sterol Composition of Plant Surface Lipids[a] (%)

[a]The composition of sterols represents that of the recovered sterols from the unsaponifiable matter after alkali hydrolysis.
[b]Unidentified sterols of Δ^5- and Δ^7-series.
[c]Contains spinasterol and other Δ^7-sterols.

these species were expected to contain considerable amounts of Δ^7-sterols. Similarly, many of the fruit surface lipids seem to contain cholesterol as a common sterol component. However, the cholesterol contents were exceptionally small in cabbage leaves and green pepper fruits. Cholestanol also was detected as a minor component of leaf and fruit surface sterols in many plant species.

DISCUSSION

The present results demonstrate that the majority of the plant species examined contain a considerable proportion of cholesterol in the component sterols of leaf and fruit surface lipids. Therefore, cholesterol seems to be a common and important component sterol also in plants. These facts up to now have been overlooked, presumably because plant sterol compositions have been estimated generally with seed lipids that contain cholesterol as a minor component sterol.

It is probable that cholesterol may be present as a common major sterol also in the fruit surface lipids of various plant species with few exceptions. The detailed data on the sterol compositions of fruit surface lipids will be reported in the near future. A remarkable difference in the cholesterol content was observed even in the same plant genus, as shown between rape and cabbage (Tables 1 and 3).

In Table 1, the proportion of cholesterol was lower in the leaf intracellular lipids than in the surface lipids, in spite of a high proportion of cholesterol in chloroplast sterols as reported by Knights (16). This may suggest the specific localization of cholesterol among cell organelles. It is not known if the chlorophyll content of leaves is responsible for the cholesterol content. Further experiments may be necessary on the changes in cholesterol content in the leaf surface lipids during development of leaves, and also on the mechanism of the localization of cholesterol on the leaf surface.

The biosynthesis of ecdysteroids by insects has been discussed generally on the assumption that cholesterol as the precursor of ecdysone may be metabolized mainly from 24-alkylsterols such as sitosterol, stigmasterol, campesterol, etc., because cholesterol was regarded as the minor component sterol in plant leaves (23). However, the direct synthetic route from cholesterol in leaf lipids may not be negligible in consideration of the presence of a significant amount of cholesterol in leaf sterols as reported here.

Analytical data on the sterol compositions of vegetable foods should be reexamined from the viewpoint of the distribution and localizatoin of cholesterol as a major sterol component in vegetables.

ACKNOWLEDGMENTS

We wish to thank M. Morita (Kinki University) and A. Shibahara (Kobe-Gakuin University) for performing the GC-MS.

Premalignant Alterations in the Glycosphingolipids of Small Intestinal Mucosa of Rats Treated with 1,2-Dimethylhydrazine

R. Dahiya, P.K. Dudeja and **T.A. Brasitus***
Departments of Medicine, University of Chicago Hospitals and Clinics and Michael Reese Hospital, Pritzker School of Medicine of the University of Chicago

1,2-Dimethylhydrazine is a procarcinogen with selectivity for the colon and proximal small intestine. In weekly subcutaneous (s.c.) doses of 20 mg/kg body weight, this agent produces colonic and proximal small intestinal tumors in a high percentage of rodents with a latency period of approximately six months. To determine whether alterations in the glycosphingolipid content of rat proximal and/or distal small intestinal mucosa existed before the development of dimethylhydrazine-induced cancer, rat were given s.c. injections of this agent (20 mg/kg body weight per wk) or diluent for five wk. Animals were killed at this time, and mucosa was isolated from each small intestinal segment of both groups. Glycosphingolipids then were extracted from these tissues and analyzed by high performance thin layer chromatography and gas liquid chromatography.

The results of these studies demonstrated that (1) the content of neutral and acidic glycosphingolipids was significantly decreased (approximately 20%) in the proximal small intestine of treated rats compared with their control counterparts; (2) no significant difference in the glycosphingolipid content was seen, however, in the distal small intestinal mucosa of control and treated rats; and (3) while significant differences were noted in the majority of fatty acids of G_{M3}, glucosyl- and globotriaosylceramide in the proximal small intestine of control and treated animals, differences in the fatty acids of these glycosphingolipids in the distal segment of these groups were confined to stearic (18:0) acid and/or arachidic (20:0) acid.

***Lipids 23,* 445–451 (1988).**

During the past several years, the relationship between glycosphingolipids and the malignant transformation process has received considerable attention (1–3). Recently, utilizing the 1,2-dimethylhydrazine model of colonic adenocarcinoma (4,5) our laboratory has demonstrated alterations in the glycosphingolipid composition and content of colonic epithelial cells of rats administered dimethylhydrazine (20 mg/kg body weight/wk) s.c. for five wk (6). Because this treatment regimen produces colonic tumors in virtually 100% of rodents with a latency period of about six months (4,5), these glycosphingolipid changes induced by this procarcinogen were noted before the development of histologically detectable tumors and, therefore, were termed "premalignant." Their exact relationship to the malignant transformation process, however, remained unclear.

In this regard, the dimethylhydrazine model used in our earlier experiments has been studied extensively (4,5). One aspect of this model that generally has not been appreciated, however, is the predilection for this procarcinogen to produce tumors in the proximal small intestine as well as in the colon (4). At a dosage of 20 mg/kg body weight/wk s.c. for 20–24 wk, a significant percentage of rats develop adenocarcinomas of the duodenum and proximal jejunum but not of the ileum (4). Therefore, the present studies were undertaken to examine and compare the glycosphingolipid content and composition of proximal and distal small intestinal mucosa of rats administered diluent or dimethylhydrazine for five wk. The results obtained from these experiments adds support to our earlier contention that alterations in glycosphingolipids may be an early event in the intestinal malignant transformation process induced by 1,2-dimethylhydrazine (6) and serves as the basis for the present report.

MATERIALS AND METHODS

Materials. Sphingosine standards and 3% OV-1 on Anakron ABS were purchased from Analabs (North Haven, CT). Phytosphingosine was obtained from Calbiochem (La Jolla, CA). Florisil (60–100 mesh) and fluorescamine (Fluram-Roche) were obtained from Fisher Scientific (Fairlawn, NJ). Mixtures of nonhydroxy and hydroxy fatty acid standards and EGSS-X 10% on Gas Chrom P and Power-Sil-Prep were obtained from Alltech/Applied Science Lab. Inc. (State College, PA). The ganglioside standards G_{M1}, G_{D1a}, G_{T1a} and G_{T1b} were purchased from Supelco (Belleforte, PA). G_{M2} isolated from Tay-Sachs brain was a gift from G. Dawson. G_{M3} was isolated and purified by the method of Glickman and Bouhours (7) from rat small intestine. Ceramide was purchased from Analabs. Glucosyl-, lactosyl-, globotriaosyl- and globotetraosylceramide were gifts from S. K. Kundu and were purified from human erythrocytes (8). All other chemicals were purchased from Fisher Chemical Co. (St. Louis, MO) or Sigma Chemical Co. (St. Louis, MO), unless otherwise indicated.

Lipid extraction. Male albino Sherman rats weighing 75 to 100 g were given s.c. injections of diluent (24 rats) or 1,2-dimethylhydrazine (Sigma Chemical Co.) (24 rats) at a dose of 20 mg/kg body weight per week for five wk as described (6). After five wk, control (3 groups of 8 rats) and dimethylhydrazine-treated animals (3 groups of 8 rats) were fasted for 18 hr with water ad libitum before being killed. Weight gain was comparable in all groups at this time. The animals were killed by cervical dislocation, and the proximal one-third and distal one-third of the small intestines of each group of animals were excised. The mucosa of each segment was scraped off with a glass slide and pooled with members of its respective group. Each of the samples then was homogenized in a waring blendor in methanol and extracted with 20 volumes of chloroform/methanol (2:1, v/v), overnight (9). The protein residue was collected by filtration and re-extracted with chloroform/methanol (1:2, v/v). The filtrates were

Abbreviations: GLC, gas liquid chromatography; HPTLC, high performance thin layer chromatography.

combined, dried in a rotary evaporator and redissolved in chloroform/methanol (2:1, v/v) for further analysis (see below).

Glycosphingolipid and ceramide purification and identification by high performance thin layer chromatography (HPTLC). Total lipid extracts were partitioned with water and the lower phase washed five times with Folch upper phase (chloroform/methanol/water; 3:48:47, v/v/v) to insure complete extraction of gangliosides into the upper phase (9). The upper phase gangliosides then were purified by C18 reverse-phase chromatography (Sep-pak cartridges) as described (10).

The neutral glycolipids and ceramide were purified by chromatography of the acetylated neutral lipids on a Florisil column (11). The gangliosides, ceramide and the deacetylated neutral lipids were analyzed by HPTLC on Silica-gel 60 precoated plates (E. Merck, Darmstadt, West Germany) in the solvent system chloroform/methanol/water/2% $CaCl_2$ (60:35:7:1, v/v/v/v) (12). Glycolipids were visualized by α-naphthol-sulfuric acid spray, while gangliosides were visualized by resorcinol spray (13).

Individual neutral glycolipids and ceramide also were identified by brief exposure to iodine vapor and then quantified after scraping the silica gel area corresponding to their position following migration. The amount of sphingoid bases liberated by methanolysis was determined by fluorimetry following reaction of the free bases with fluorescamine (11). Quantification of the various gangliosides was performed using a Beckman densitometer as described by Mullin et al. (12). All of the bands from each ganglioside species were analyzed in the present experiments. Recoveries were determined using radiolabeled glycosphingolipids as described by Suzuki et al. (14). Recoveries for G_{M3}, ceramide, glucosyl-, lactosyl- globotriaosyl- and globotetraosylceramide were 77 ± 6, 82 ± 7, 81 ± 6, 78 ± 4, 85 ± 6 and 79 ± 5%, respectively (N = 3). The variations in recoveries of these various lipids were not found to be significantly different.

Desialylation of G_{M3}. Desialylation of purified G_{M3} was performed by acid hydrolysis using 0.1M H_2SO_4 at 80 C for 1.5 hr as described (15). N-glycolyl and N-acetylneuraminic acids were separated on HPTLC plates using a solvent system of n-propyl-alcohol/water/ammonium hydroxide (60:28:1.5, v/v/v) (16) and visualized with resorcinol.

Analysis of carbohydrate moieties of G_{M3} and neutral glycolipids. Carbohydrate moieties were identified by gas liquid chromatographic (GLC) analysis of their trimethylsilyl derivatives as described (7,17).

Analysis of fatty acids and long-chain bases of glycosphingolipids and ceramide. Individual glycosphingolipids and ceramide were separated and identified by HPTLC (see above) and after scraping the silica gel area corresponding to their position were hydrolized in 1 ml of dry methanolic HCl (0.75 N) at 80 C for 16 hr, followed by extraction of fatty acid methyl esters by hexane (18). The methanolic phase then was alkalinized with aqueous NaOH and the long chain bases extracted by diethyl ether (19).

Nonhydroxy and hydroxy fatty acids were separated by chromatography on a Florisil column as described (20). In certain experiments, a known amount of C_{21} fatty acid methyl ester was added as an internal standard to quantitate the nonhydroxy and hydroxy fatty acids in the samples (21). Nonhydroxy fatty acid methyl esters were dissolved in a small volume of hexane while hydroxy fatty acid methyl esters were silylated before chromatography (21). Analyses of both nonhydroxy and hydroxy fatty acids were performed on a Hewlett-Packard 5790A gas liquid chromatograph equipped with a flame ionization detector and interfaced with a Hewlett-Packard 3390A integrator as described (21). Peak identification was based on identical retention times with known standards run under the same conditions (21).

Long-chain bases, free from fatty acids, were dissolved in chloroform, washed with 0.1 M NaOH and then repeatedly washed with water. The chloroform phase was dried under N_2 and the residue silylated as described (22). The long-chain bases then were analyzed by GLC on an OV-1 column operated with temperature programming from 245 to 305 C at 3 C per min (21). Identification was based on identical retention times with known standards run under the same conditions (21).

Histological studies. At five wk, 1-cm proximal and distal segments from each control and dimethylhydrazine-treated animal immediately were fixed in 4% paraformaldehyde. Fixed specimens then were embedded in paraffin for light microscopic examination and stained with hematoxylin and eosin as described (23).

Statistical methods. Unless otherwise indicated, all results are expressed as mean values ± S.E. Paired or unpaired Student's t-tests were used for all statistical analysis. $P < 0.05$ was considered significant.

RESULTS

Light microscopic studies. In the present studies, despite extensive sampling of both control and treated small intestinal mucosa, no evidence of severe atypia, carcinoma in situ or microscopic adenocarcinoma was seen in either the proximal or distal-thirds of the small intestine after five wk of administration of diluent or dimethylhydrazine (not shown).

Analysis of glycosphingolipids and ceramide in control and dimethylhydrazine-treated small intestinal mucosa. In agreement with earlier studies by our laboratory (24) and others (7,21,25), as assessed by HPTLC the major neutral glycosphingolipids of the control proximal and distal-thirds of the small intestinal mucosa were glucosylceramide and globotriaosylceramide (Table 1), and the major ganglioside was G_{M3} (Table 2). Smaller amounts of lactosyl- and globotetraosylceramide as well as ceramide, a non-sugar-containing compound, also were present in both of these control segments (Table 1). In the dimethylhydrazine-treated segments, these same neutral and acidic glycosphingolipids predominated, and their relative percentages were similar to their control counterparts.

As shown in Tables 1 and 2, however, the overall content of the neutral glycosphingolipids and gangliosides of the proximal segment of dimethylhydrazine-treated rats, as assessed by HPTLC, each were decreased significantly (approximately 20%) compared with the content of these glycosphingolipids in the proximal segment of control rats. In contrast, the content of these lipids in the distal segment was similar in control and treated animals (Tables 1 and 2).

Analysis of the sugar moieties of these glycosphingolipids by GLC further established their identities and

showed similar molar ratios of these moieties for each of the glycosphingolipids of control and dimethylhydrazine-treated samples of proximal and distal small intestinal mucosa (not shown).

After acid hydrolysis, the sialic acid moieties of G_{M3} of control and dimethylhydrazine-treated proximal and distal segments were found to contain both N-acetyl and N-glycolylneuraminic acid. The latter form, however, predominated in both segments and was approximately equal in control and treated samples (Table 3).

To detect any other possible differences between the glycosphingolipids of control and treated-intestinal mucosa, the long-chain bases and fatty acids of neutral and acidic glycolipids of both segments were examined and compared. Earlier studies by our laboratory (24) and others (21) have shown that the long-chain base of the various glycolipids was predominantly phytosphingosine (4D-hydrosphinganine) in control rat small intestinal mucosa. As shown in Table 4, the principal base of each neutral glycosphingolipid as well as G_{M3} in control and dimethylhydrazine-treated proximal and distal segments also was found to be phytosphingosine, although lesser quantities of sphingosine also were present in each of these glycosphingolipids. No significant differences, however, were noted in the relative percentages of these bases in the various glycosphingolipids of control and treated intestinal mucosal segments examined (Table 4).

In agreement with earlier studies performed in rat small intestinal mucosa (21), G_{M3}, glucosyl- and globotriaosylceramide in both intestinal segments of control animals contained hydroxy and nonhydroxy fatty acids (Tables 5-7). The fatty acids of G_{M3} and glucosylceramide in these tissues were predominantly hydroxylated (Tables 5 and 6), whereas the fatty acids of globotriaosylceramide predominantly were found to be nonhydroxylated (Table 7) (21). In the present studies, the relative percentages of hydroxy and nonhydroxy fatty acids in these three glycosphingolipids were similar in dimethylhydrazine-treated and control preparations (Tables 5-7).

In contrast to these findings, however, analysis of the individual fatty acids of treated and control G_{M3} revealed significant differences, particularly in the proximal intestinal segments (Table 5). As can be seen in this table, the hydroxy and nonhydroxy levels of palmitic (16:0), stearic (18:0), oleic (18:1), arachidic (20:0) and behenic (22:0) acids of G_{M3} in the treated proximal segment differed significantly from their control counterparts.

*$P < 0.05$ or less compared with control values of that segment.

Moreover, marked increases were noted in the levels of nonhydroxy-lignocenic acid (24:0) and hydroxy-cerotic acid (26:0) of G_{M3} in the treated proximal segment (Table 5). In the distal segment, differences in the hydroxy and nonhydroxy levels of the fatty acids of G_{M3} only were seen with respect to stearic acid (Table 5).

Similarly, as shown in Tables 6 and 7 small but significant differences were noted in many of the hydroxy and nonhydroxy fatty acids of glucosyl- and globotriaosylceramide present in proximal treated and control preparations, whereas in the distal segments only the levels of hydroxy and nonhydroxy stearic and arachidic acids were found to differ in these neutral glycosphingolipids of control and treated animals.

DISCUSSION

In an earlier publication (6), our laboratory demonstrated that a number of alterations could be detected in colonic

epithelial cells of rats administered dimethylhydrazine s.c. (20 mg/kg body weight/wk) for five wk. While changes in the acidic and neutral glycosphingolipids of small intestinal mucosa also were noted in the present experiments using this same treatment regimen, it is of interest to compare and contrast the results obtained in these two studies.

In this regard, dimethylhydrazine treatment significantly reduced the total content of glycosphingolipids in the rat colon and proximal small intestine by approximately 11% and 20%, respectively, whereas it did not affect the glycolipid content of the rat distal small intestine. Furthermore, this agent increased the content and relative percentage of colonic globotriaosylceramide and decreased the content and relative percentage of colonic G_{M3} and globotetraosylceramide, while not significantly affecting these glycosphingolipids in either segment of rat small intestine. In both small and large intestines, dimethylhydrazine did not appear to influence the relative percentages of the long-chain bases of the major glycosphingolipids of these organs or the relative percentage of the sialic acid moieties of G_{M3}. However, dimethylhydrazine did appear to influence the individual hydroxy and nonhydroxy fatty acids of the principal glycosphingolipids of rat colon and small intestine. It should be noted that the changes induced by this agent involved a number of different fatty acids in the glycosphingolipids of rat colon and proximal small intestine, while in the distal small intestine the changes were confined to stearic and/or arachidic acids. These results deserve further comment.

First, it is important to note that in the present studies the dimethylhydrazine-induced decrease in glycosphingolipid content was confined to the proximal small intestine. Furthermore, while alterations in the individual fatty acids of the major ganglioside, G_{M3}, and the major neutral glycolipids, glucosoyl- and globotriaosylceramide, were detected in both small intestinal segments, the compositional changes clearly were more generalized and impressive in the treated proximal segment. These findings are particularly interesting in view of the predilection for the development of tumors in the proximal small intestine of animals treated with this procarcinogen (4). The specific reason(s) that underlie this increased propensity to develop proximal intestinal neoplasia in this cancer model remain unclear (4), although earlier investigations (4) have suggested that this phenomenon may be related to biliary contents, particularly bile salts, acting as promoters of carcinogenesis at this intestinal site. These results, taken together with our earlier findings, which demonstrated that dimethylhydrazine treatment also produced changes in the composition of glycosphingolipids in the rat colon, strongly suggest that these changes may be involved in the malignant transformation process induced by this agent. Despite extensive sampling, no evidence of severe atypia, carcinoma in situ or microscopic adenocarcinomas was seen in treated or control small or large intestinal (6) tissues in these studies; these data would suggest that these glycolipid alterations may represent "premalignant" alterations.

Second, as summarized by Hakomori (1,3) glycolipid changes associated with oncogenic transformation appear to involve three categories: incomplete synthesis, neosynthesis and organizational rearrangement of membrane glycolipods. In our earlier studies in dimethylhydrazine-treated rat colon (6), the decreases in G_{M3} and globotetraosylceramide appeared to be due, at least in part, to decreases in the activities of the enzymes responsible for their biosynthesis. In the present studies, while the mechanism(s) responsible for the 20% decrease in glycosphingolipids in treated proximal small intestine are unclear, given the colonic data described above, it would seem reasonable to suggest that these changes may involve a decrease in biosynthesis as well. Clearly, these findings also could be secondary to an increase in degradation. Further studies will be necessary to clarify this issue.

Finally, it should be noted that if one examines the "premalignant" changes in glycospingolipids induced by five wk of administration of dimethylhydrazine in the rat colon and proximal small intestine, no particular pattern of change is seen in both treated tissues. This would suggest that these changes may be organ-specific. However, it will be of interest to determine in future experiments whether longer periods of administration of dimethylhydrazine (10–15 wk) at times before the development of tumors (24–26 wk) produce additional changes in the glycosphingolipids in these organs. If a consistent pattern of "premalignant" changes can be detected in both tissues at these later time points, such changes may provide additional and potentially important information on the mechanism(s) involved in the malignant transformation process induced by dimethylhydrazine.

ACKNOWLEDGMENTS

The authors thank Evelyn Thornton for her secretarial support and L. Chowdhury for his assistance in the histological examinations performed in this study. This investigation was supported by grant CA 36745 awarded by the National Cancer Institute. T. A. Brasitus is the recipient of a Merit Award from the N.C.I./N.I.H.

[Received August 5, 1987; Revision accepted December 14, 1987]

Analysis of Cardiac Membrane Phospholipid Peroxidation Kinetics as Malondialdehyde: Nonspecificity of Thiobarbituric Acid-reactivity[1]

David R. Janero* and **Barbara Burghardt**
Department of Pharmacology and Chemotherapy, Hoffmann-La Roche Inc., Roche Research Center, Nutley, NJ 07110

When exposed to xanthine oxidase (superoxide)-dependent, iron-promoted Fenton chemistry, purified cardiac membranes evidenced, by the thiobarbituric acid (TBA) test, a virtually instantaneous peroxidative response with a maximal linear rate of 5.8 nmol malondialdehyde (MDA)-equivalents/mEquivalents lipid ester reacted/min. Yet when the lipids purified from these same membranes and reconstituted into liposomes were peroxidized under identical reaction conditions, the TBA test indicated that a pronounced (~20-min) lag period preceded a maximal peroxidation rate of only 2.1 nmol MDA-equivalents/mEquivalents lipid ester reacted/min. After 120 min of peroxidation, the cardiac membranes yielded some 300 nmol TBA-reactive MDA-equivalents/mEquivalent ester, whereas the isolated membrane lipids evidenced ~40% less TBA-reactivity. To verify that these quantitative and kinetic differences in membrane (phospho)-lipid peroxidation occurred with removal of the lipids from their membrane milieu, the MDA produced during both cardiac membrane peroxidation and the peroxidation of the lipids derived therefrom was isolated as its free anion by ion-pair high-pressure liquid chromatography. As quantified spectrophotometrically, true MDA production during myocardial membrane peroxidation was identical in kinetics and in amount to the production of TBA-reactive substance from the peroxidized isolated membrane lipids. These results demonstrate that significant non-MDA, TBA-reactive species are generated during the peroxidation of cardiac membranes, especially before the maximal rates of bona fide MDA production. As a direct consequence, artifactual levels and kinetics of membrane lipid peroxidation do result.
Lipids 23, 452–458 (1988).

Free radical-mediated membrane lipid peroxidation through Fenton-type, metal-promoted oxygen chemistry is increasingly being appreciated as a causative pathogenic factor, especially in myocardial injury (2). Consequently, importance rests with the reliable detection and quantitative assessment of the extent and dynamics of membrane lipid peroxidation. The most extensively employed method for the detection and analysis of peroxidation is the thiobarbituric acid (TBA) test, predicated upon the reactivity of a colorless aldehyde end-product of lipid peroxidation, malondialdehyde (MDA), with TBA to produce a red adduct (3). The convenience, ease and and rapidity of the TBA test have tended, in practice, to mitigate against such considerations as the nonspecificity of TBAs chemical reactivity (4), the low efficiency of fatty-acid hydroperoxide breakdown to MDA (5), and the effects that procedural modifications have upon color development (6). The TBA test has been employed repeatedly in a variety of cardiac oxidative injury models to measure myocardial membrane lipid peroxidation (e.g., 7,8).

This report details quantitative and kinetic investigations of the relationship between TBA-reactivity and bona fide MDA production during the peroxidation of cardiac membranes and their lipids. A defined, physiologically relevant oxidative injury system based upon xanthine oxidase (XOD)-mediated, superoxide ($O_2^{\cdot-}$)-dependent, iron-promoted Fenton chemistry (2) is employed. The results demonstrate that only when isolated cardiac membrane lipids are peroxidized does TBA-reactivity reflect MDA production and, hence, lipid peroxidation. The fact that no qualitative or quantitative reliability could be demonstrated to support the use of the TBA test as an analytical tool with which to monitor the peroxidation of the cardiac membranes themselves would urge that caution be exercised when applying the TBA test to membrane/membraneous organelle systems.

EXPERIMENTAL PROCEDURES

Materials. Allopurinol, N-2-hydroxyethylpiperazine-N′-2-ethanesulfonic acid (HEPES), dithiothreitol, tris(hydroxymethyl)aminomethane (Tris), hydroxylamine hydrochloride, ADP, TBA, and tetramethoxypropane were from Sigma Chemical Co. (St. Louis, MO). XOD (analytical preparation from bovine milk; 1.0 unit/mg) and superoxide dismutase (SOD; analytical preparation from bovine erythrocytes; 5000 units/mg) were purchased from Boehringer-Mannheim (Indianapolis, IN). Desferrioxamine B (Desferal) was a gift from Ciba A.G. (Basle, Switzerland). α-Tocopherol was synthesized by Hoffmann-La Roche. All solvents were of analytical grade (Burdick and Jackson, Muskegon, MI).

Isolation of rat myocardial membranes. The procedure was carried out in a dehumidified cold-room (3 C). Conscious male Sprague-Dawley rats (~275 g; Charles River, Boston, MA) maintained on a normal rodent diet were decapitated. Each heart was rapidly excised and perfused via the aorta with 20.0 ml ice-cold 10 mM HEPES buffer, pH 7.4. The trimmed ventricular muscle masses were pooled, minced, and homogenized (100 mg tissue/ml ice-cold HEPES) for 3 × 5 sec with a Tissumizer (Tekmar, Cincinnati, OH) at maximal setting. The homogenate was filtered through four-ply cheesecloth, and the myocardial membranes were isolated from the filtrate by utilizing KCl extraction to remove contractile protein and differential centrifugation in 10.0 mM Tris-HCl, pH 7.4, containing 2.0 mM dithiothreitol (9). The membranes were used immediately after having been washed twice with 25.0 ml 10 mM HEPES-0.145 M KCl, pH 7.4.

Abbreviations: HEPES, N-2-hydroxyethylpiperazine-N′-2-ethanesulfonic acid; MDA, malondialdehyde; $O_2^{\cdot-}$, superoxide anion radical; SOD, superoxide dismutase (superoxide:superoxide oxidoreductase, EC 1.15.1.1); TBA, thiobarbituric acid; Tris, tris(hydroxymethyl)-aminomethane; XOD, xanthine oxidase (xanthine:oxygen oxidoreductase, EC 1.2.3.2); HPLC, high pressure liquid chromatography.

Lipid extraction and quantification. Lipids were extracted and purified from the myocardial membranes by a modified Bligh-Dyer (10) procedure (11). The final chloroform phase containing the purified lipid represented quantitative recovery of myocardial membrane lipid: >98% of the radioactivity associated with the organic fraction obtained by direct saponification (12) of membrane metabolically labeled in vivo from [^{14}C]acetate, sodium salt, (54.0 mCi/mmol, sp. act. [New England Nuclear, Boston, MA]) was recovered in the saponified fraction from the lipid extracted out of an identical amount of membrane. The myocardial membrane total lipid extract was resolved into its constituent phospholipid and neutral lipid fractions by Sep-Pak silica column chromatography (Waters, Milford, MA) (13). All lipids were stored in chloroform under argon at −20 C (14).

Lipid phosphate was determined microchemically on perchloric acid digests (15). The hydroxamate reaction was used to measure lipid ester (16); L-α-phosphatidylcholine dipalmitate (Avanti Polar Lipids, Birmingham, AL) was used as standard.

Preparation of cardiac liposomes. A known amount of myocardial membrane lipid in chloroform was placed into a rotating glass flask and taken to dryness under nitrogen at room temperature. The lipid was taken up in 10 mM HEPES-0.145 M KCl, pH 7.4, and was resuspended by indirect anaerobic sonication for 15 min at room temperature. The liposomes were used immediately.

Peroxidation reaction system. Cardiac liposomes or membranes (at equal lipid concentrations) were subjected to $O_2^{\cdot-}$-dependent, iron-promoted peroxidation in glass tubes. Ninety minutes before the start of the reaction, a chelate was formed in 10.0 mM HEPES-0.145 M KCl buffer, pH 7.4, between Fe^{3+} (1.0 mM $FeCl_3$, final conc.) and ADP (10.0 mM, final conc.) with continuous stirring at room temperature. The peroxidation reaction, in a final volume of 1.0 ml, contained the following components at their specified final concentrations: 10 mM HEPES-0.145 M KCl, pH 7.4; 1.0 mM hypoxanthine; 0.1 mM Fe^{3+}-1.0 mM ADP chelate; 125 μg lipid (as membrane or liposomal suspension); and 10 mUnits XOD. The reaction was started by adding the XOD, mixing, and incubating at 37 C in a shaking water bath. Membrane/liposome samples also were incubated in parallel to the same final lipid concentration but without free radical generator (i.e., without hypoxanthine, Fe-ADP, and XOD). The peroxidation incubation was ended on ice by lipid extraction, acidification, or SOD addition, depending upon the subsequent analysis (below). Solutions of α-tocopherol were prepared under yellow lighting in ethanol such that the final solvent concentration in the peroxidation reaction was 1,000-fold below that which affected peroxidation. Desferrioxamine and allopurinol were solubilized in 10 mM HEPES-0.145 M KCl, pH 7.4. Dose-response curves to define, quantitatively, the effects of these agents were generated with the programming assistance of RS/1 software (BBN Corp., Cambridge, MA) on an IBM PC-AT (IBM, Boca Raton, FL).

Determination of the production of conjugated dienes and TBA-reactive substance during peroxidation. For conjugated diene analysis, lipids were extracted (11) out of 2.0 ml of peroxidation reaction mixture and the parallel, nonperoxidized membrane or lipid samples. The purified lipids were dissolved in 1.0 ml spectro-grade cyclohexane. Spectra of the lipids were taken against cyclohexane from 190 nm–400 nm in a DU-7 kinetic spectrophotometer (Beckman, Palo Alto, CA). Spectra of the lipids of nonperoxidized liposomes and membranes and of the peroxidation reaction mixture itself were the blank spectra. Raw spectra were corrected for Rayleigh scattering (17), and the nonperoxidized lipid and reagent blank spectra were subtracted from the appropriate experimental, peroxidized lipid spectra to obtain difference spectra. Calculation of net conjugated diene formation was made from the difference spectra using the molar absorptivities given (18).

The TBA test was conducted by the following modification of published methods (5,6,19). The peroxidation incubation was terminated on ice by acidification with 0.15 ml ice-cold 76% TCA-2.3 N HCl per 1.0 ml sample (pH = 2.2), and 0.35 ml of a freshly-prepared mixture of H_2O/7.14 M butylated hydroxytoluene in ethanol/1.51% TBA in 0.2 M Tris, pH 7.0, (1:1:5, v/v/v) was added. After thorough mixing, the samples (final pH = 2.4) were incubated in an 80 C shaking water bath for 30 min. After this time, the tubes were plunged into an ice-water bath, and the TBA test was immediately stopped with 0.5 ml ice-cold 91% TCA followed by 2.0 ml $CHCl_3$. After centrifugation for 30 min at 2000 × g, 4 C, the absorbance of the upper phase at 532 nm was read. Various amounts (9.8–40.0 nmol) of MDA standard, freshly prepared by acidification of 1,1,3,3-tetramethoxypropane with 76% TCA-2.3 N HCl (0.15 ml acid mixture with 1.0 ml suitably diluted tetramethoxypropane), were subjected to the identical TBA test procedure as the basis for constructing a standard curve of TBA-reactivity as MDA-equivalents. Computer-assisted regression analysis of the standard curve was used to quantify the molar amounts of MDA-equivalents in the experimental samples. Net peroxidative production of MDA-equivalents was taken as the difference in TBA-reactivity between peroxidized samples that had been incubated in the complete peroxidation reaction system and non-peroxidized samples that had been incubated in parallel without free radical generator. The TBA reaction per se was not affected by the components of the radical generator, α-tocopherol, desferrioxamine, allopurinol or SOD.

Chromatographic MDA isolation and quantification. When the peroxidation reaction was to be analyzed by high pressure liquid chromatography (HPLC) for MDA content, the peroxidation incubation was stopped by adding SOD to a final concentration of 10^{-7} M and freezing the mixture in dry ice-acetone. MDA was then isolated from the sample by an ion-pair HPLC technique (20) based on the work of Bull and Marnett (21). The HPLC system (Beckman Instruments) was equipped with a μBondapak C_{18} stainless-steel 3.9 mm × 30 cm analytical column preceded by a radially packed C_{18} guard column (Millipore/Waters, Milford, MA). MDA, as the enolate anion, was resolved out of the peroxidation reaction by isocratic elution at 3.0 ml/min with a mobile phase of acetonitrile/50.0 mM myristyltrimethylammonium bromide in 0.9 mM sodium phosphate, pH 6.7 (15:85, v/v). Detection was based on UV absorbance at 267 nm, and quantitation was computerized by peak integration with reference to MDA standard. Net peroxidative production of MDA was taken as the difference in MDA content between peroxidized samples that had been incubated in

the complete peroxidation reaction system and parallel, nonperoxidized samples that had been incubated without free radical generator. MDA for the calibration chromatograms was prepared by hydrolysis of malonaldehyde-bis-diethylacetal (Merck, Darmstadt, Germany) with H_2SO_4, as described (22). Absolute MDA concentration in the solution was checked by UV spectrophotometry at 267 nm with the extinction coefficient of 34,000 M^{-1} cm^{-1} (22).

Assessment of "bound" MDA. To liberate any bound MDA before HPLC analysis, membranes/liposomes were hydrolyzed in base (NaOH) at pH 12.0, 60 C, for 30 min (23). The hydrolysis reaction mixtures then were subjected to rapid ultrafiltration through a YM2 membrane (Amicon, Danvers, MA) to exclude high-molecular-weight (>1000) molecules and the cardiac membranes or liposomes themselves. The clarified filtrates were then neutralized (pH ~7.4) with HCl before HPLC analysis for MDA. Bound MDA was considered the difference in MDA content between parallel samples that had or had not been hydrolyzed. Recovery of standard MDA in this procedure was >96%.

Protein determination. Protein was quantified with a dye-binding microassay (24).

RESULTS

Properties of the isolated myocardial membranes. The biochemical characteristics of the isolated rat-heart membranes are summarized in Table 1. The efficiency of myocardial contractile protein extraction by salt was readily apparent from the dramatically lower protein content of the membranes with respect to starting homogenate. In contrast, the membranes represented over 70% of the heart-muscle homogenate lipid. The high recovery of cardiac phospholipid, localized virtually exclusively in membrane (25), and the three-fold increase in lipid:protein ratio of the membranes over homogenate indicate that the isolated membranes were representative of the myocardial membranes in situ. Additional support for this conclusion rests with the finding that, upon sucrose density-gradient subfractionation of the myocardial membranes (26), ~90% of the total membrane phospholipid was found associated with mitochondria, ~7% with sarcoplasmic reticulum and ~3% with sarcolemma; this distribution is reminiscent of the relative membrane areas of the three organelles in the intact heart muscle cell (27).

Conjugated diene production and TBA-reactivity during myocardial membrane and membrane lipid peroxidation. With exposure of isolated cardiac membranes and the total membrane lipid or phospholipid but not neutral lipid to $O_2^{\cdot-}$-dependent, iron-promoted oxy-radical chemistry, net formation of lipid conjugated dienes was observed (Fig. 1). Because in all cases diene formation was normalized to the actual amount of lipid reacted, the parallelisms in both the pattern and level of lipid conjugated diene production from the intact cardiac membranes and from the purified membrane total lipid and phospholipid would indicate that the phospholipid was the membrane target for oxidative damage. By 120 min of reaction, the levels of diene intermediates decreased when, presumably, the propagation phase of peroxidation ended as conjugated

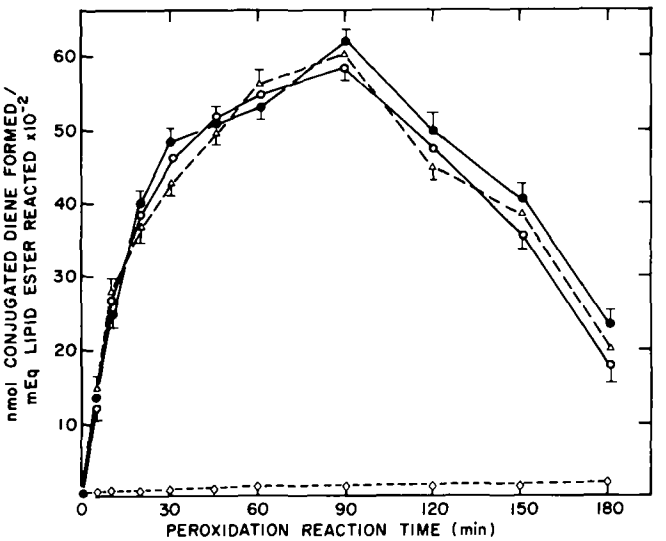

FIG. 1. Conjugated diene production during myocardial membrane and membrane lipid peroxidation. Isolated myocardial membrane (●—●) and the membrane total lipid (○—○), phospholipid (△—△) and neutral lipid (◇—◇) purified therefrom were subjected to peroxidative injury by exposure to XOD ($O_2^{\cdot-}$)-dependent, iron-promoted Fenton chemistry. Samples were taken over 180 min of reaction, and the lipids were extracted and analyzed spectrophotometrically for conjugated diene content. The mean difference in conjugated diene content between the peroxidized samples and non-peroxidized membrane/lipid controls was calculated as the conjugated diene formed during peroxidation. These values, normalized to the amount of lipid reacted, are graphed ± S.D. (n ≥ 6).

TABLE 1

Biochemical Properties of Rat Myocardial Membranes[a]

	Protein		Lipid				
			Ester		Phosphate		
Fraction	(%)	(mg/heart)	(%)	(mEquivalents/heart)	(%)	(μg/heart)	Lipid:Protein
Heart muscle homogenate	100	49.8 ± 2.9	100	6.9 ± 0.3	100	312.0 ± 18.5	0.15 ± 0.01
Myocardial membranes	24.1 ± 0.5	12.0 ± 1.0	72.5 ± 2.6	5.0 ± 0.3[b]	73.2 ± 1.9	228.5 ± 18.4	0.45 ± 0.02

[a]Myocardial membranes were isolated from rat-heart ventricular muscle essentially as described (9). Results are means ± S.D. (n = 6).
[b]90.5 ± 2.6% of the lipid ester is found in membrane phospholipid; the remainder is associated with neutral lipid.

intermediates increasingly converted to products such as lipid peroxides and MDA (5,6).

Exposure of myocardial membranes or liposomes comprised of either the total membrane lipid or the membrane phospholipid to free radical generator resulted in the production of TBA-reactive substance (Fig. 2). As was the case with conjugated diene production (Fig. 1), myocardial membrane neutral lipids evidenced a negligible peroxidative response. However, each of the other myocardial substrates for oxy-radical attack, in contrast to their similar patterns of diene production, showed markedly distinctive kinetics of TBA-reactivity. The intact myocardial membranes evidenced a linear propagation phase through the first 30 min of reaction with an apparent maximal peroxidation rate of 5.8 ± 0.3 nmol MDA-equivalents produced/mEquivalents lipid ester reacted/min (mean ± S.D.; n = 6) and an accumulation of some 300 nmol MDA-equivalents by 180 min. The total myocardial membrane lipid complement, however, displayed a conspicuous lag-period of about 20 min, whereupon an apparent maximal peroxidation rate of 2.1 ± 0.1 nmol MDA-equivalents produced/mEquivalents lipid ester reacted/min led to a net accumulation of about 150 nmol MDA-equivalents by 180 min. Production of TBA-reactive substance from the isolated myocardial membrane phospholipid began virtually instantaneously upon exposure to oxy-radicals, with a linear propagation rate and a net accumulation of TBA-reactive substance that approximated those of the total myocardial membrane lipid.

The lag-period in the production of TBA-reactivity from myocardial membrane total lipid is an effect of the high

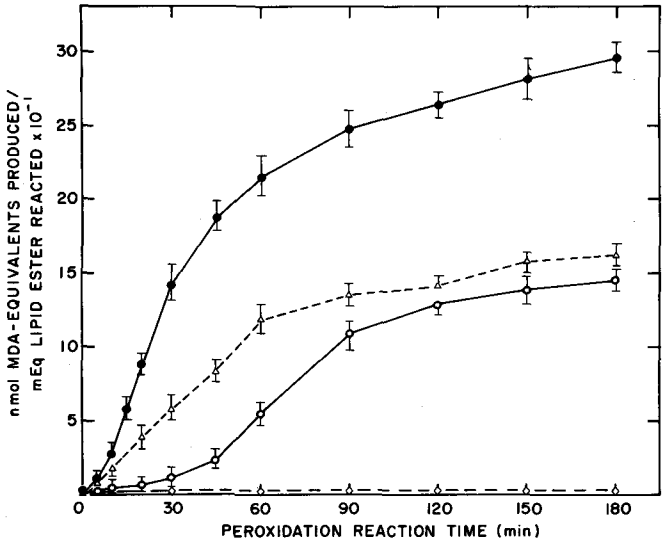

FIG. 2. Generation of TBA-reactive substance during myocardial membrane and membrane lipid peroxidation. Isolated myocardial membranes (●—●) and the membrane total lipid (○—○), phospholipid (△--△) and neutral lipid (◇--◇) purified therefrom were peroxidized by incubation with XOD + hypoxanthine + iron. Membranes/lipids also were incubated in parallel without free radical generator. Samples taken over 180 min of peroxidation reaction were subjected to the TBA test, and the content of TBA-reactive substance in each sample was expressed as MDA-equivalents and normalized to the amount of lipid reacted. The mean difference in MDA-equivalents between peroxidized and non-peroxidized samples was calculated as the MDA-equivalents produced during peroxidation and graphed ± S.D. (n ≥ 6).

myocardial membrane α-tocopherol content (28); the peroxidized isolated membrane phospholipids demonstrated an instantaneous TBA response (Fig. 2). Nonetheless, upon exposure to oxy-radical generator, the membranes, containing both the phospholipids and the α-tocopherol, always generated TBA-reactive substance more rapidly and to a greater extent than did the membrane phospholipids.

HPLC analysis of myocardial membrane peroxidation as MDA. The comparative TBA-reactivity data (Fig. 2) appeared to indicate that profound quantitative and kinetic changes in myocardial membrane phospholipid peroxidation resulted from removal of the lipid out of its membrane milieu. To attempt to verify this conclusion, TBA-reactivity was obviated by isolating MDA throughout the course of myocardial membrane and membrane lipid peroxidation. To avoid the conditions (acid, heat) of the TBA reaction and to ensure complete independence from TBA-reactivity, isolation of, for example, a TBA-MDA adduct was not carried out.

We first defined an effective means of stopping the peroxidation reaction other than by the acidification protocol required for the TBA test, so that precise end-points could be established without jeopardizing subsequent analyses. As shown in Table 2, the XOD ($O_2^{\cdot-}$)-dependent, iron-promoted Fenton chemistry supporting oxidative injury in this system could be blocked at several critical points. Inhibiting XOD with a substrate analog (allopurinol [29]), chelating the iron in the system with desferrioxamine (30), intercepting lipid radicals that would otherwise propagate peroxidation with α-tocopherol (31), and dismutating $O_2^{\cdot-}$ with SOD (32) all were effective means of blocking the generation of TBA-reactive substance from isolated cardiac membrane lipids exposed to XOD + hypoxanthine + iron. The system was most sensitive to SOD: 10.0 nM SOD completely inhibited the generation of TBA-reactive material (as well as the formation of conjugated dienes) from cardiac lipids. Consequently, SOD was added to a final concentration of 100.0 nM to the peroxidation reaction system to dismutate the $O_2^{\cdot-}$ therein and thereby halt the progression of oxidative damage before HPLC analysis for MDA.

To isolate the MDA anion directly out of the peroxidation reaction system without preparatory sample manipulation or clean-up, a variety of amino-phase (33), reverse-phase (34), size-exclusion (35) and ion-pairing (21) HPLC techniques were tested. Ion-pairing chromatography appeared to have the most potential, but the exact conditions of Bull and Marnett (21) offered incomplete resolution of MDA standard from the reactants in the Fenton peroxidation system. With modification of the chromatographic conditions as detailed under Experimental Procedures, MDA could be separated rapidly from the constitutents of the Fenton reaction (Fig. 3) and eluted as a well-resolved peak, 7.0 pmol being the lower-limit of MDA quantitation. Only the material eluting from the column at ~4.9 min evidence TBA-reactivity, had the UV spectrum characteristic of MDA (Fig. 3, inset), and co-eluted with standard MDA. Recovery of known amounts of MDA standard subjected to HPLC isolation was >98%.

With these data, the HPLC technique was adopted to determine directly the MDA produced during oxidative injury to myocardial membranes and their purified lipids

TABLE 2

Inhibition of the Generation of TBA-reactive Substance from Myocardial Membrane Lipid[a]

Agent	Action	Concentration of agent that inhibits TBA-reactivity by: 50%	100%
Allopurinol	XOD inhibition	5.0×10^{-4} M	5.0×10^{-2} M
Desferrioxamine	Iron chelation	—[b]	1.0×10^{-4} M
α-Tocopherol	Chain-breaking antioxidant	8.5×10^{-7} M	1.0×10^{-5} M
SOD	$O_2^{\cdot-}$ dismutation	5.0×10^{-9} M	1.0×10^{-8} M

[a]Liposomes comprised of total myocardial membrane lipid were exposed to XOD + hypoxanthine + iron as radical generator for 60 min either in the absence (control) or presence of varying concentrations of each listed agent. After one hr, the samples were run in the TBA test, and the level of TBA-reactive substance in each was expressed relative to the control samples as inhibition of TBA-reactivity.

[b]Because of the stoichiometric nature of iron chelation by desferrioxamine (30), only complete inhibition was noted at a desferrioxamine concentration equal to the iron concentration in the system.

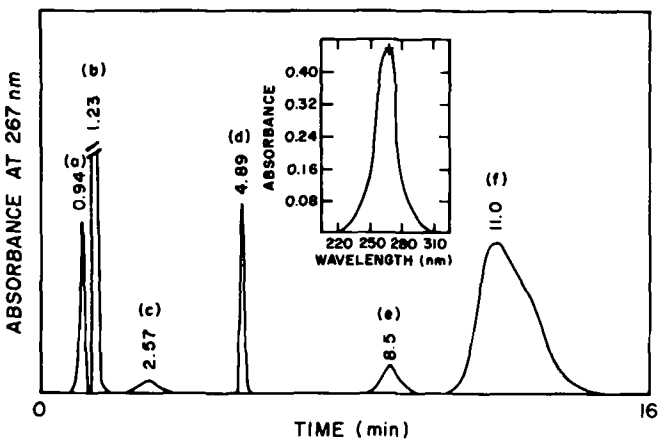

FIG. 3. HPLC isolation of MDA produced during myocardial membrane lipid peroxidation. Myocardial membrane total lipid (125 μg lipid) was reacted with XOD + hypoxanthine + iron in the Fenton peroxidation system described (Experimental Procedures). At one hr of reaction, SOD was added (100 nM, final concentration), and 250 μl of the 1.0 ml sample was subjected to ion-pair chromatography with spectrophotometric detection at 267 nm. Retention times are given above each peak in minutes. The identities of the peaks are (a) hypoxanthine, (b) xanthine, (c) uric acid, (d) MDA, (e) Fe-ADP, (f) ADP. Inset shows the on-line spectrum of the MDA in peak (d) as taken during its elution from the HPLC column; the absorption maximum is indicated by the cross at 267 nm.

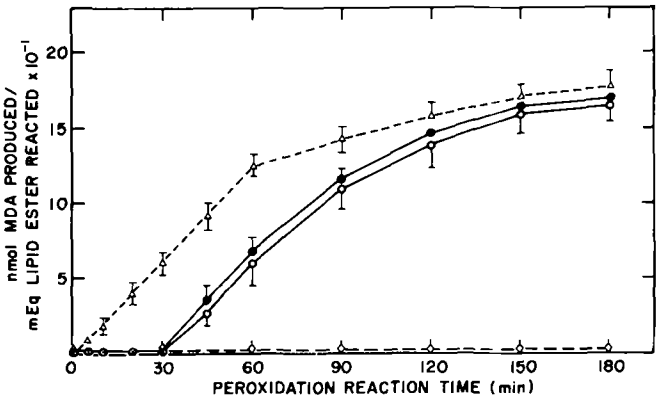

FIG. 4. Production of MDA during myocardial membrane and membrane lipid peroxidation. Isolated myocardial membranes (●—●) and the membrane total lipid (○—○), phospholipid (△—△) and neutral lipid (◇—◇) purified therefrom were peroxidized by exposure to XOD ($O_2^{\cdot-}$)-dependent, iron-promoted Fenton chemistry with XOD + hypoxanthine + iron as oxy-radical generator. Membranes/lipids also were incubated in parallel without free radical generator. Samples were taken over 180 min of peroxidation and were analyzed for their content of MDA (as its enolate anion) by ion-pairing HPLC (Fig. 3). The mean difference in MDA content between peroxidized and non-peroxidized samples was calculated as the MDA produced during peroxidation. MDA production was normalized to the amount of lipid reacted and graphed ± S.D. ($n \geq 6$).

(Fig. 4). Production of MDA during the peroxidation of purified myocardial membrane total lipid, phospholipid or neutral lipid was equivalent in kinetics and magnitude to the accumulation of TBA-reactive substance (expressed as MDA-equivalents; Fig. 2). However, MDA production during peroxidation of isolated myocardial membranes paralleled the MDA production from the purified cardiac membrane lipids (Fig. 4) and did not resemble the levels or pattern of membrane TBA-reactivity (Fig. 2). Because both the TBA-reactivity and MDA production were normalized to the amount of lipid reacted, these results would indicate that non-lipid related TBA-reactive substance generated during myocardial membrane peroxidation was responsible for the apparent attenuation in cardiac membrane lipid peroxidation when the lipids were extracted out of the membranes.

The non-lipid related TBA-reactivity was generated with its own kinetics, as could be demonstrated from the difference curve between TBA-reactivity (as MDA-equivalents) and MDA production upon exposure of myocardial membranes to oxy-radical generator (Fig. 5). It is evident that non-lipid related TBA-reactive substance was generated most rapidly early in the exposure of membranes to the radicals (before ~20 min of reaction) and

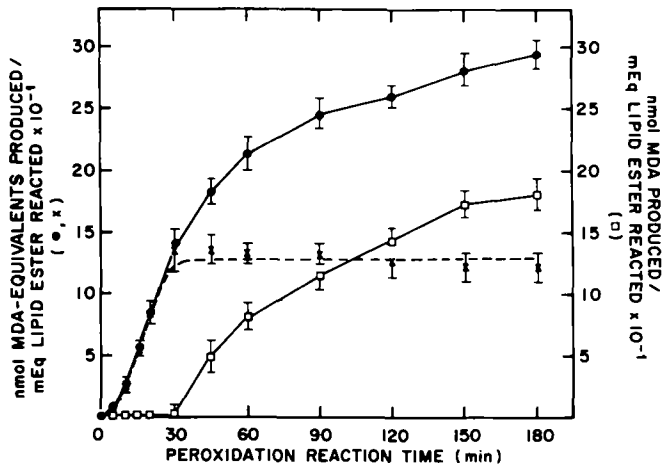

FIG. 5. Production of non-lipid associated TBA-reactive substance during myocardial membrane peroxidation. The generation of TBA-reactive substance (● — ●) and the production of MDA (□—□) during myocardial membrane peroxidation by Fenton-type oxy-radical chemistry are re-plotted from Figs. 2 and 4, respectively. The mean difference (± range) between the amount of TBA-reactive substance and the actual amount of MDA at each sampled time during the 180 min of reaction was calculated and plotted (×——×) as non-lipid related TBA-reactive substance.

ultimately accounted for some 40% of the total TBA-reactivity of the system.

Membrane source of non-lipid related TBA-reactive substance. Several attempts were made to define chemically the source of non-lipid associated TBA-reactivity when myocardial membranes are peroxidized. The acidic conditions and heat of the TBA test will liberate MDA bound to membrane constituents (especially peptide lysine residues) by hydrolyzing Schiff-base linkages (36), whereas the linkages are stable under the mild conditions (no heat) of both the peroxidation reaction (pH = 7.4) and the HPLC run (pH = 6.8). Consequently, additional studies were undertaken in which samples of peroxidized and non-peroxidized membranes were hydrolyzed in base (pH = 12.0) with heating before HPLC isolation of MDA from the filtered, neutralized hydrolysates. This procedure would convert any bound MDA to free MDA that then could be detected as HPLC analyte (23). From comparisons between hydrolyzed membrane samples and non-hydrolyzed samples run in parallel in the peroxidation reaction, some 7% (i.e., 12.2 ± 0.6 nmol MDA/mEq lipid ester reacted; mean ± S.D., n = 6) of the total MDA produced during cardiac membrane peroxidation was in the bound form. This level of bound MDA was too low to account for the 40% difference between membrane TBA-reactivity (as MDA-equivalents) and bona fide MDA generated during membrane peroxidative injury. The bound MDA level remained at ~12 nmol/mEq lipid ester during the course of the peroxidation reaction, indicating that the capacity of the isolated membranes to take up free MDA is limited relative to the MDA yields from peroxidation. This conclusion is substantiated by the finding that cardiac membranes (or their isolated lipids) incubated at 37 C with known amounts of free MDA standard in HEPES-KCl buffer, pH 7.4, yield levels of MDA-equivalents (by the TBA test) or free MDA (by HPLC) that were always >90% of those expected from the standard (data not shown).

Because free acylneuraminic acids are known to react with TBA (37) and cardiac membranes contain acylneuraminic acids (38), it was investigated whether membrane acylneuraminic acids could have contributed to the observed TBA-reactivity of peroxidized rat heart-muscle membranes. To this intent, membranes that had been treated with neuraminidase (acylneuraminyl hydrolase from *Clostridium*; EC 3.2.1.18) (39) or that had undergone controlled acid hydrolysis (40), conditions known to liberate sialic acid from membrane glycoconjugates (41), were peroxidized. The treated cardiac membranes evidenced no statistically significant decrease in the levels and rates of TBA-reactivity development with respect to non-treated membranes (data not shown). Peroxidation of the myocardial membrane protein recovered during the extraction of the membrane lipid did not yield appreciable TBA-reactive substance (data not shown).

DISCUSSION

Growing realization that oxidative damage to membrane lipids is critical in the pathogenesis of a variety of diseases (5,7,8) has placed increased importance upon the application and evaluation of methodology with which membrane lipid peroxidation dynamics are assessed. This study explored in quantitative and kinetic terms the relationships between TBA-reactivity and MDA production during myocardial membrane peroxidation through $O_2^{\cdot-}$ (XOD)-dependent, iron-promoted oxy-radical chemistry of the type believed to occur in myocardial ischemia (2). The data demonstrate that while there is a direct and quantitative relationship between the production of TBA-reactive substance and the generation of free MDA during peroxidation of isolated cardiac membrane (phospho)lipids, no such relationship exists when the myocardial membranes are peroxidized. Generation of non-lipid related, non-MDA TBA-reactive substance with its own kinetics during cardiac membrane peroxidation, if unrecognized, would have led to overestimations of the development and extent of lipid peroxidation and an erroneous peroxidative kinetic profile.

Gutteridge (42) has concluded that the close agreement between the production of TBA-reactive substance and the generation of fluorescent MDA-phospholipid complexes during the peroxidation of isolated ox-brain phospholipid validates the TBA test as an indicator of lipid peroxidation. Although brain membranes were not peroxidized by Gutteridge, and MDA was not isolated, his conclusion is supported by the present data on the reliability of the TBA test in assessing the peroxidation of purified myocardial membrane phospholipids.

Warso and Lands (5,43) have documented extensively that human plasma TBA-reactivity bears no relationship to plasma hydroperoxide level. Specifically, 80% of the TBA-positive material in human plasma was found not to have originated from lipid hydroperoxide conversion to MDA. Quantitatively, these high plasma levels of non-lipid related TBA-reactivity are reminiscent of our finding that ~40% of the TBA-reactive substance produced during the peroxidation of myocardial membrane is not bona fide MDA and does not arise directly from membrane phospholipid peroxidation.

The chemistry and precise source(s) of the non-lipid related TBA-reactive substance generated during cardiac

membrane peroxidation remain to be defined. It is possible that molecular interactions/conformational changes at the membrane level induced during free-radical attack are required to incite formation of TBA-reactive substance beyond that which would be formed from the MDA product of membrane lipid peroxidation (44). Such reasoning has been invoked (45) to explain why the conversion of hydroxyl groups to aldehydes at the termini of cell-surface carbohydrate chains enhances the peroxidation of erythrocyte ghosts by periodate.

The direct quantitative comparison between the production of TBA-reactive substance and the generation of MDA during cardiac membrane and membrane phospholipid peroxidation made herein, along with the work of others in nonmembrane systems (5,42,43), would argue that the TBA test lacks the requisite chemical specificity to be used as a reliable measure, or even as an indicator, of lipid peroxidation, unless purified lipid is the sole oxidative substrate in the system. Independent verification of even the qualitative, comparative significance of a positive TBA test would appear to be necessary to use the TBA reaction as anything other than an empirical indicator of the occurrence of (per)oxidation in biological membrane samples.

ACKNOWLEDGMENTS

[Received November 9, 1987; Revision accepted February 1, 1988]

Lack of Protein-mediated α-Tocopherol Transfer between Membranes in the Cytoplasm of Acites Hepatomas

Hiro-omi Mowri[1], Shoshichi Nojima[1] and Keizo Inoue*
Department of Health Chemistry, Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113, Japan

Transfer-stimulating activity for α-tocopherol and the concentration of α-tocopherol and peroxidized lipids in rat ascites hepatoma cells were compared with those from normal and regenerating liver.

The ability of supernatants from ascites hepatomas (AH-13, AH-60C, AH-109A) to enhance the transfer of α-tocopherol was much lower than that from normal livers. The α-tocopherol per mg protein of supernatant from ascites hepatomas was lower than that from normal liver. Regenerating liver showed almost the same values as normal liver in activity to stimulate the transfer of α-tocopherol and α-tocopherol content of the supernatant. By gel filtration, about 60% of α-tocopherol in the supernatant of normal liver was detected in the fractions containing the 30 K protein, which stimulates transfer of α-tocopherol between membranes, whereas no significant amount of α-tocopherol was detected in 30 K protein fractions of AH-60C supernatant. Little stimulating activity for α-tocopherol transfer was detected in AH-60C, AH-109A and AH-13.

All ascites hepatomas tested contained less arachidonic acid and docosahexaenoic acid than normal and regenerating liver. An absorption peak with maximum intensity at 233 nm, which is due to conjugated dienes, was observed in UV-absorption spectra of ascites hepatoma total lipids, indicating that peroxidized lipids accumulate in these cells. With normal and regenerating liver, no significant peak due to conjugated dienes was detected.
Lipids 23, 459-464 (1988).

α-Tocopherol is widely distributed in animal tissues and may function as a lipid antioxidant (1,2). α-Tocopherol, which is orally administered, is absorbed in the intestinal mucosa and then is transported in various lipoprotein fractions in plasma (3-6). The mechanism of intracellular transport of α-tocopherol taken up by cells, however, has not been clarified. We (7) and Murphy and Mavis (8) have demonstrated that rat liver cytoplasm contains a protein that stimulates the transfer of α-tocopherol between membranes. The molecular weight of this protein was estimated to be about 30,000. Behrens and Madere (9) showed that α-tocopherol might be partly bound to a protein with a molecular weight of 32,000 in rat liver cytoplasm in vivo. There may be a pool of α-tocopherol that binds to the transfer protein in the cytoplasm.

Lipid peroxidation in tissues is prevented by biological antioxidants such as α-tocopherol (10-12) and enzymes such as superoxide dismutase (13) and glutathione peroxidase (14-16). There are reports (17-20) showing that activity of these peroxidation-protective enzymes in tumor cells is lower than that in normal tissues. The role of α-tocopherol in protection against peroxidation in these cells cannot be evaluated now because intracellular transport and distribution of α-tocopherol in hepatoma cells have not been elucidated, although some reports (19,21, 22) have compared α-tocopherol content in microsomes of hepatomas with that of rat liver.

Polyunsaturated fatty acids, which are substrates for lipid peroxidation, are lower than those in normal liver in tumor cells such as ascites hepatomas (23), Novikoff hepatomas (21) and Morris hepatomas (21,22).

In this paper, cytosolic activity to enhance the transfer of α-tocopherol between membranes and the cytoplasmic α-tocopherol concentration, as well as the fatty acid composition of total lipids and the amount of peroxidized lipids were examined with rat ascites hepatomas, normal and regenerating liver.

MATERIALS AND METHODS

Materials. Ascites hepatoma cells (AH-13, free cells; AH-60C, island-forming cells; AH-109A, mixture of island and free cells) were donated by H. Sato of the Sasaki Institute (Tokyo, Japan). D-α-[5-Methyl-^{14}C]tocopherol (9.2 Ci/mol), α-tocopherol and tocopherol derivatives were provided by Eisai Co. (Tokyo, Japan). Stock solution of tocopherols was stored in toluene/ethanol (9:1, v/v) at −20 C, and their purity was checked periodically by Silica Gel G thin layer chromatography. Glycerol-tri[9,10(n)-^{3}H]oleate (500 Ci/mol) and glycerol-tri[^{14}C]oleate (52 Ci/mol) were purchased from the Radiochemical Center (Amersham, England). Egg yolk phosphatidylcholine was prepared by chromatography on aluminum oxide and Unisil (Clarkson Chemical Co., Williamsport, PA). Egg yolk [N-methyl-^{3}H]phosphatidylcholine was synthesized by the method of Stoffel et al. (24). Bovine serum albumin (Fraction V) (Sigma Chemical Company, St. Louis, MO) and Sephadex G-100 (Pharmacia Fine Chemicals, Uppsala, Sweden) also were used.

Preparation of homogenate, supernatant and membrane fractions from rat liver and ascites hepatomas. Donryu female rats (100-200 g) were killed by decapitation, and their livers were perfused with cold phosphate-buffered saline (pH 7.5) and then rapidly excised. The liver was minced with scissors, and an homogenate containing 20% (w/v) liver tissue in cold buffer A (0.25 M sucrose, 1 mM EDTA, and 50 mM Tris-HCl, pH 7.4) was prepared with three passes of a Teflon-glass homogenizer.

Ascites hepatoma cells (AH-13, AH-60C, AH-109A) were injected intraperitoneally into Donryu female rats weighing approximately 100 g ($1-2 \times 10^6$ cells per rat). Cells were harvested from the ascites between five and eight days following injection (AH-13, 5-6 days; AH-60C and AH-109A, 7-8 days). All subsequent operations were performed at 4 C. The ascites containing hepatoma cells were centrifuged at 120 × g for five min, and the supernatant was removed; $2-5 \times 10^8$ cells were obtained from the ascites of each rat. Cells were washed in ice-cold phosphate-buffered saline (pH 7.4) several times. The

[1]Present address: Faculty of Pharmaceutical Sciences, Teikyo University, Sagamiko, Kanagawa 199-01, Japan.

Abbreviation: Buffer A, buffer containing 0.25 M sucrose, 1 mM EDTA and 50 mM Tris-HCl (pH 7.4).

homogenate containing 20% (w/v) hepatoma cells in buffer A was prepared with a Teflon-glass homogenizer. The homogenates were centrifuged at 600 × g for 15 min to precipitate nuclei and cell debris. The supernatants were centrifuged at 105,000 × g for 60 min to obtain supernatant and membrane fractions.

Determination of the transfer of α-tocopherol and phosphatidylcholine from liposomes to mitochondria. The procedure was based on the experiment of Bloj and Zilversmit (25). For study of α-tocopherol transfer from liposomes to mitochondria, liposomes composed of 10 μmol egg yolk phosphatidylcholine, 1.0 μmol dicetylphosphate with a trace of α-[^{14}C]tocopherol (0.1 μCi) and [^{3}H]glyceroltrioleate (1.5 μCi) as a "non-exchangeable" marker were prepared as described (7). Lipids were dispersed in 1.0 ml of buffer A with a vortex mixer. The final concentration of liposomes was 10 μmol phospholipid/ml. The lipid suspension was sonicated for 10 min with a microprobe in a Branson Sonifier (model W 185) at 0 C under a stream of nitrogen. The preparation was centrifuged at 15,000 × g for 15 min, and the supernatant was used. Liposomes (0.2 μmol phospholipid) were incubated with mitochondria (0.5 mg protein) in the presence or absence of the supernatants in 2.0 ml of buffer A. Then the mitochondria were precipitated by centrifugation at 15,000 × g for 15 min, and the sample of supernatants (1.0 ml) was counted in a Packard liquid scintillation counter (model 3255). By this procedure, about 90% of the liposomes were recovered in the supernatant. The percentage transfer of α-[^{14}C]tocopherol from liposomes to mitochondria was calculated from the formula:

$$\left(1 - \frac{^{14}\text{C}/^{3}\text{H of liposomes after incubation}}{^{14}\text{C}/^{3}\text{H of liposomes before incubation}}\right) \times 100\%.$$

The ability of the supernatant to stimulate transfer of egg yolk phosphatidylcholine from liposomes to mitochondria was assayed as follows: liposomes composed of 10 μmol egg yolk phosphatidylcholine and 1.0 μmol dicetylphosphate with trace amounts of 0.2 μCi [^{14}C]glyceroltrioleate and 5.0 μCi [^{3}H]egg yolk phosphatidylcholine were incubated with mitochondria (1.5 mg protein) in the presence or absence of the supernatant. After incubation at 37 C for 30 min, the radioactivity recovered in the liposomes was determined. The percentage transfer of [^{3}H]-egg yolk phosphatidylcholine from liposomes to mitochondria was calculated in a similar way to the transfer of α-tocopherol.

Measurement of α-tocopherol content. α-Tocopherol contents of homogenate, supernatant and membrane fractions were estimated by the method of Thompson and Hatina (26). Tocopherol was extracted with hexane/ethanol (5:1, v/v), injected into the column (Zorbax Sil) and eluted with hexane/dioxane/ethanol (97.6:2:0.4, v/v/v). The flow rate was 1.5 ml/min, and the fluorescence in the eluate was measured at excitation 289 nm and emission 325 nm in Shimazu Fluorescence Spectromonitor (RF-530).

Fractionation of 105,000 × g supernatant by Sephadex G-100 column chromatography. A sample of 105,000 × g supernatant was applied to a column containing Sephadex G-100 equilibrated with 100 mM KCl, 50 mM Tris-HCl buffer (pH 7.5), and the fractions were collected. The intensity of the absorption at 280 nm of the fraction was measured in a Hitachi spectrophotometer (model 200-10) in a cell of 1 cm light path. The stimulating activity of α-tocopherol transfer and α-tocopherol content in the fraction also were measured.

Lipid analysis. Total lipids were prepared from homogenates by the method of Bligh and Dyer (27). Phosphatidylcholine and phosphatidylethanolamine were prepared from the total lipids by chromatography on aluminum oxide and Unisil. The fatty acid composition of total lipids, phosphatidylcholine and phosphatidylethanolamine was determined by gas liquid chromatography (Shimadzu Seisaku-sho, GC-OAP). Lipids were dissolved in 2 ml of methanol in water (1:1, v/v) and hydrolyzed by incubation with 0.27 ml of 85% KOH at 80 C for 60 min. Then, the mixture was cooled, acidified with 6 N HCl and extracted three times with diethyl ether. The extracts were combined, washed three times with 2% KCl and evaporated. The residue was methylated with CH_2N_2, and methyl esters were analyzed by gas chromatography on a column (3 mm × 3 m) of 20% EGSS-X on Chromosorb WAW (Gasukuro Kogyo Co.) at 215 C.

Preparation of regenerating liver. Partial hepatectomy was performed according to the method of Higgins and Anderson (28). Donryu female rats (150 g) were anesthetized with diethyl ether, and the abdomen was opened. The median and laberal lobes of the liver were removed. Rats were killed on the fifth day after partial hepatectomy.

Other analytical methods. Phospholipid phosphorus was determined by the method of Gerlach and Deuticke (29). Protein was determined according to the method of Lowry et al. (30).

RESULTS AND DISCUSSION

The transfer of α-tocopherol from liposomes to mitochondria was determined in the presence of the supernatant from normal liver, regenerating liver and ascites hepatomas (Fig. 1A). Transfer-stimulating activity of the supernatant of regenerating liver was almost the same as that of normal liver. The specific activity of AH-13 supernatant (210 pmol/hr/mg protein) was about one-fourth of that of normal liver (900 pmol/hr/mg protein). The supernatant of either AH-60C or AH-109A showed no appreciable transfer-stimulating activity. Low activity in the supernatant of ascites hepatoma cells was not due to the presence of an inhibitor because the activity of normal liver supernatant was not affected by supplement of supernatant from hepatoma cells (data not shown).

As shown in Figure 1B, the supernatant of normal liver also contained phosphatidylcholine-transfer activity as found by Bloj and Zilversmit (25) and Poorthuis et al. (31). The activity could be detected in supernatants of all hepatoma cells tested. It is noteworthy that the transfer-stimulating activity for phosphatidylcholine in the supernatant of AH-60C and AH-109A, which showed no appreciable transfer activity for α-tocopherol, was 60–70% of that of normal rat liver. The activity in the supernatant of AH-13 was a little higher than that of rat liver.

As shown in Table 1, the α-tocopherol content of ascites hepatoma homogenates was the same as homogenates

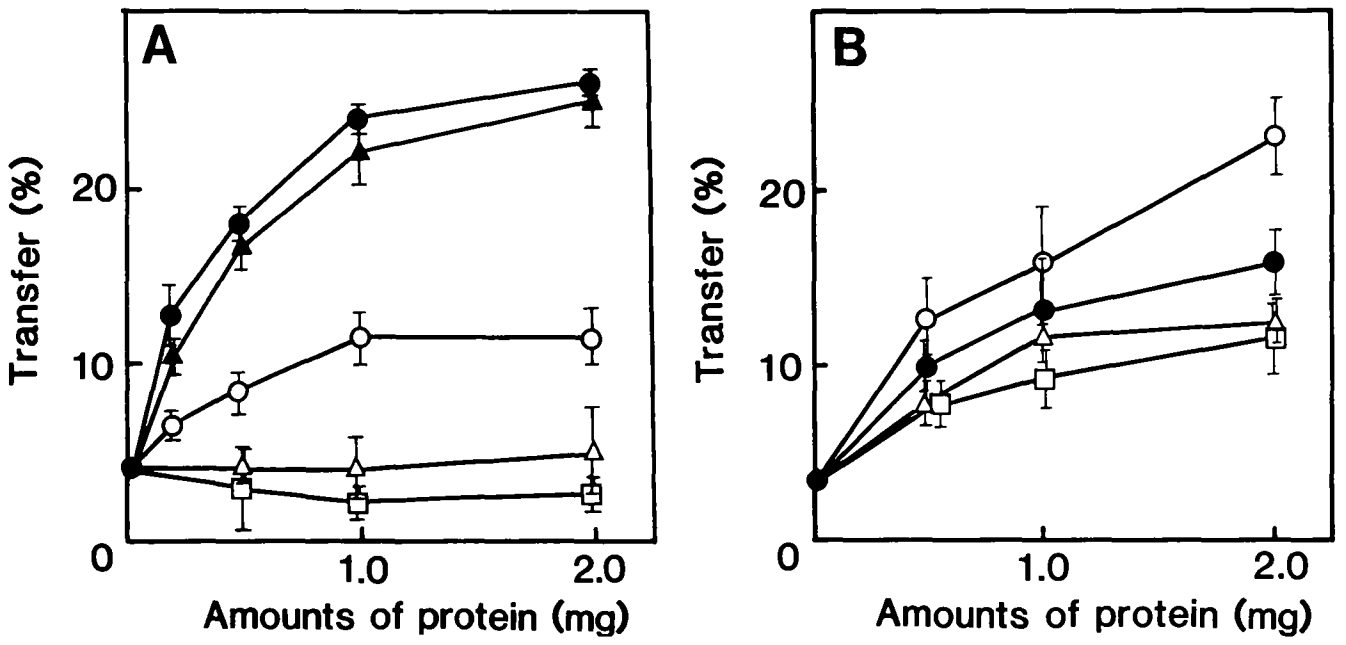

FIG. 1. Transfer-stimulating activity of the supernatant prepared from normal rat liver, regenerating liver or ascites hepatoma cells. (A) Liposomes (0.2 μmol phospholipid) composed of egg yolk phosphatidylcholine, dicetylphosphate (molar ratio, 10:1), a trace of α-[^{14}C]tocopherol and [^{3}H]glyceroltrioleate were incubated with rat liver mitochondria (0.5 mg protein) at 37 C for 15 min in the presence of various amounts of supernatant prepared from normal rat liver (●), regenerating liver (▲) or ascites hepatoma cells (○, AH-13; △, AH-60C; □, AH-109A). The mitochondria were precipitated by centrifugation, and radioactivity of samples of supernatants was measured. Values are expressed as means ± SD of three separate preparations. (B) Liposomes (0.2 μmol phospholipid) comprised of [^{3}H]egg yolk phosphatidylcholine, dicetylphosphate (molar ratio, 10:1) and a trace of [^{14}C]glyceroltrioleate were incubated with rat liver mitochondria (1.5 mg protein) at 37 C for 30 min with the supernatants.

TABLE 1

α-Tocopherol Contents of Homogenate, Supernatant and Membrane Fractions Prepared from Normal Rat Liver, Regenerating Liver or Ascites Hepatoma Cells

	Rat liver		Ascites hepatoma	
Fraction	Normal (nmol/mg protein)	Regenerating (nmol/mg protein)	AH-13 (nmol/mg protein)	AH-60C (nmol/mg protein)
Homogenate	0.20 ± 0.04	0.20 ± 0.06	0.23 ± 0.01	0.19 ± 0.06
Supernatant	0.08 ± 0.01	0.08 ± 0.02	0.02 ± 0.02	0.01 ± 0.01
Membrane	0.40 ± 0.13	0.46 ± 0.07	0.93 ± 0.05	0.45 ± 0.15

To a sample (1 ml) of homogenate, supernatant or membrane fraction prepared from rat liver and ascites hepatomas, 1 ml of ethanol containing 1 nmol tocol (an internal standard) was added. After further addition of 5 ml of hexane, the mixture was mixed vigorously, then centrifuged at 1,800 × g for 10 min. A sample of hexane layer (4 ml) was dried under a stream of nitrogen and dissolved in 50 μl of hexane. The results are means ± SD of the tocopherol content from three separate preparations (one or two rats per preparation).

from normal rat liver (0.2 nmol/mg protein). The α-tocopherol contents in the supernatants of AH-13 or AH-60C were, however, much lower than that of normal liver. The content in the membrane fraction of AH-13 was two times higher than that of normal liver. The value in AH-60C membrane fraction was almost the same as that of normal liver. In regenerating liver, the values in homogenate, supernatant and membrane fractions were almost the same as those of normal liver, respectively.

The supernatants of normal liver and AH-60C also were fractionated by gel filtration. α-Tocopherol transfer activity and α-tocopherol content in each fraction were determined. As shown in Figure 2A, the transfer-stimulating activity in rat liver cytosol appeared in fractions 70–85, whose molecular weight was estimated to be about 30,000, as described (7). About 60% of α-tocopherol in the supernatant also was detected in these fractions. These results are in good agreement with those of Behrens and Madere (9) and suggest that a portion of the cytosolic α-tocopherol exists in the form of a complex with a carrier protein (30 K transfer-stimulating protein). α-Tocopherol also was detected in the fractions just after the void volume. These fractions showed no appreciable activity to stimulate the transfer of α-tocopherol. The amount of

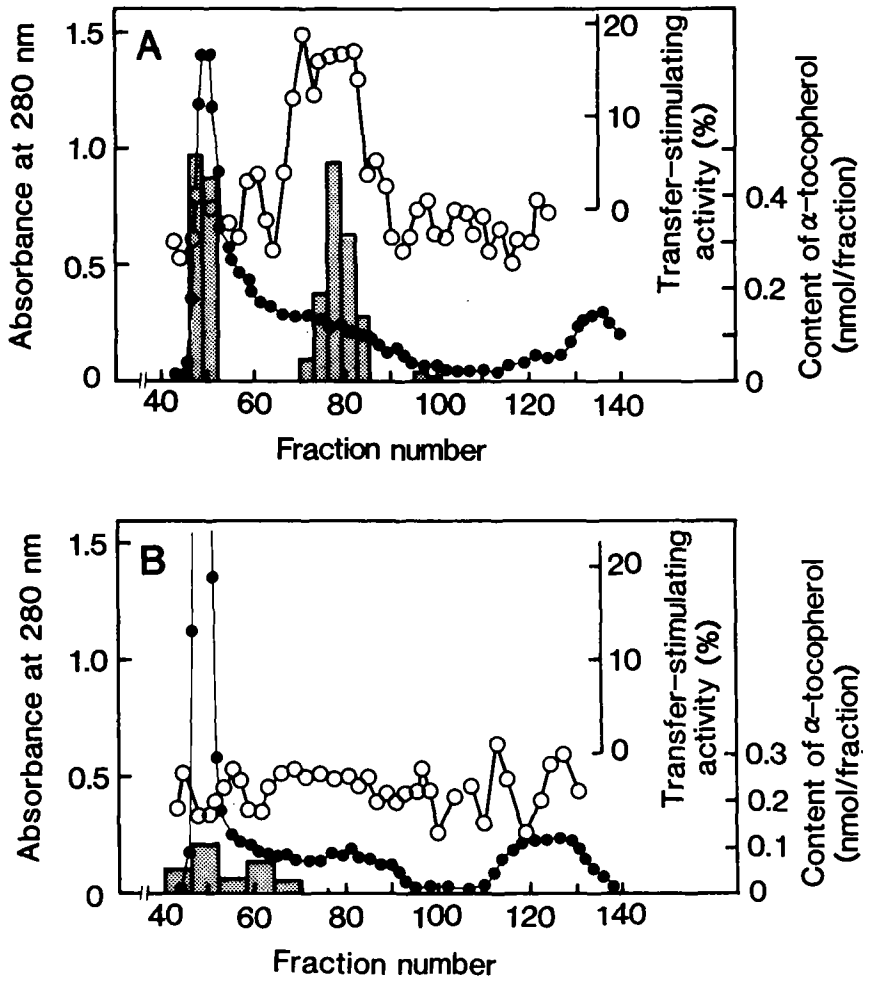

FIG. 2. Distribution of α-tocopherol in the 105,000 × g supernatant. Rat liver cytosol (A) (40 mg protein in 4 ml buffer A) or AH-60C cytosol (B) (20 mg protein in 4 ml buffer A) was applied to a column of Sephadex G-100 (2.6 × 70 cm) equilibrated with 100 mM KCl, 50 mM Tris/HCl buffer (pH 7.5) and eluted with the same buffer at 4 C. The flow rate was about 30 ml/hr, and 4 ml fractions were collected. Elution of protein was determined by measuring the absorbance at 280 nm (●). The transfer-stimulating activity of each fraction (○) was determined as described in Materials and Methods. Transfer-stimulating activity is expressed as the percentage transfer in the presence of each fraction (1 ml) minus the percentage of spontaneous transfer. The α-tocopherol content of each fraction of the supernatant was measured as follows: fractions were combined (12 ml), and 12 ml of ethanol containing tocol (1 nmol) was added. Then, 60 ml of hexane was added and was mixed vigorously. The mixture was allowed to stand at room temperature for five min. A sample of hexane layer (50 ml) was dried with a rotary evaporator, and the residue was dissolved in 50 μl of hexane. A sample of hexane solution (10 μl) was injected into the column. Values are expressed as dotted bars.

labeled α-tocopherol recovered from these fractions was not decreased in the presence of large amount of unlabeled α-tocopherol (7). Behrens and Madere (9) also reported that gel filtration of the rat liver cytosol revealed the presence of a protein with a molecular weight of more than 1,500,000, which binds α-tocopherol with less affinity and specificity. Sklan and Halevy (32) showed that tocopherol was associated with a lipid-protein aggregate with a molecular weight of about 2×10^6 in chick liver cytosol.

With AH-60C supernatant, the amount of α-tocopherol recovered from the 30 K protein fraction by gel filtraton was much smaller than that recovered with rat liver supernatant (Fig. 2B). A significant amount of α-tocopherol was recovered from the fractions whose molecular weight was more than 30,000. None of the fractions, however, showed transfer-stimulating activity. It was concluded that there was no appreciable pool of α-tocopherol bound to the transfer-stimulating protein (30 K protein) in the supernatant of AH-60C.

Decreases in both transfer-stimulating activity and the amount of cytosolic α-tocopherol may not be characteristic of dividing cells because regenerating liver cytosol showed virtually the same transfer-stimulating activity and α-tocopherol content as observed in normal liver cytosol.

Assuming that the 30 K protein plays an important role in distributing α-tocopherol to proper intracellular sites, this suggests that the α-tocopherol apparently associated

TABLE 2

Fatty Acid Composition of Total Lipids of Normal Rat Liver, Regenerating Liver and Ascites Hepatoma Cells

Fatty acid	Normal (wt%)	Regenerating (wt%)	AH-13 (wt%)	AH-60C (wt%)	AH-109A (wt%)
16:0	17.2 ± 1.7	16.8 ± 0.7	18.8 ± 2.1	18.7 ± 2.0	18.1 ± 0.8
18:0	22.1 ± 1.8	25.0 ± 2.5	19.0 ± 2.0	16.9 ± 2.0	19.6 ± 2.0
18:1	12.1 ± 2.9	9.3 ± 0.7	25.6 ± 2.3	31.6 ± 1.1	19.3 ± 2.3
18:2	15.2 ± 0.9	14.6 ± 1.4	24.2 ± 1.2	17.2 ± 0.5	22.2 ± 1.1
20:4	17.7 ± 4.0	16.8 ± 1.2	5.0 ± 1.9	7.0 ± 1.8	8.7 ± 1.6
22:6	7.9 ± 0.5	9.7 ± 1.5	N.D.	2.3 ± 1.3	3.2 ± 0.4
Double-bond index[a]	161	164	94	108	118

[a]The double-bond index was calculated from the sum of the values obtained when the percentage of the unsaturated fatty acid was multiplied by the number of double bonds in the fatty acid (41).

Total lipids (0.2 μmol phospholipid) were hydrolyzed and esterified as described in Materials and Methods. The results are means ± SD of percentage of each fatty acid derived from three separate preparations (one or two rats per preparation).

N.D., not detected.

with membrane fractions of hepatoma cells may not be located on organellar membranes but remain on the plasma membranes or lysosomal membranes. The exact localization of α-tocopherol in tumor cells, therefore, should be examined, although the fractionation of hepatomas as described by various investigators (33–39) is rather difficult now.

The fatty acid composition of total lipids from ascites hepatomas (AH-13, AH-60C, AH-109A) was quite different from that of normal rat liver (Table 2). In ascites hepatomas, the relative amount of polyunsaturated fatty acids, such as arachidonic acid and docosahexaenoic acid, was much smaller than that of normal rat liver. On the other hand, the relative amount of oleic acid in ascites hepatomas was larger than that of normal liver. The lower degree of unsaturation of fatty acids in ascites hepatoma total lipids was indicated clearly by the marked change in the double-bond index. These results are in good agreement with those of Utsumi et al. (23). The composition of regenerating rat liver was almost the same as that of normal rat liver.

Table 3 shows fatty acid composition of phosphatidylcholine and phosphatidylethanolamine prepared from normal rat liver or AH-60C. The fatty acid composition of phosphatidylcholine from AH-60C was quite different from that of rat liver. The arachidonic acid and docosahexaenoic acid content in AH-60C was much lower than that of normal liver. In contrast, the oleic acid content in AH-60C phosphatidylcholine was higher than that of normal liver. AH-60C phosphatidylcholine showed a lower double-bond index as compared with normal liver phosphatidylcholine. However, phosphatidylethanolamine of AH-60C contained almost the same amount of arachidonic acid as that of normal rat liver. The decrease of polyunsaturated fatty acids also was observed in phosphatidylcholine of Morris hepatoma 5123c (40) and with phosphatidylcholine, phosphatidylethanolamine and phosphatidylinositol of Yoshida hepatoma AH130 (41). The distribution profile of these polyunsaturated fatty acids in phospholipids may be different among hepatomas.

TABLE 3

Fatty Acid Composition of Phosphatidylcholine and Phosphatidylethanolamine of Rat Liver or AH-60C

	Rat liver		AH-60C	
Fatty acid	PC (wt%)	PE (wt%)	PC (wt%)	PE (wt%)
14:0	4.1	3.1	4.5	3.4
16:0	14.9	18.0	24.3	6.8
18:0	28.7	23.1	13.5	18.1
18:1	6.1	5.4	27.4	19.2
18:2	11.5	9.5	14.9	7.2
20:4	24.5	21.8	9.2	20.3
22:6	7.7	12.4	N.D.	4.6
Double-bond index	173	186	94	142

PC, phosphatidylcholine; PE, phosphatidylethanolamine; N.D., not detected.

Phosphatidylcholine or phosphatidylethanolamine (0.2 μmol phospholipid) prepared by chromatography on aluminum oxide and Unisil was hydrolyzed and esterified as described in Materials and Methods. Values are expressed as percentage of each fatty acid.

Conjugated dienes could be detected in total lipids by measuring the ultraviolet absorption spectrum of the total lipids fraction (Fig. 3). An absorption peak with maximum intensity at 233 nm, which is due to conjugated dienes (42), was observed with total lipids of ascites hepatomas (AH-13, AH-60C, AH-109A). No appreciable peak due to conjugated dienes was detected with total lipids of either normal or regenerating liver of rats. Thus, ascites hepatoma cells appear to contain a larger amount of conjugated diene-containing peroxidized lipids than either normal or regenerating liver.

These results raise the possibility that polyunsaturated fatty acid residues in ascites hepatomas may be more susceptible to peroxidation in vivo than those from normal rat liver. The decrease in the polyunsaturated fatty

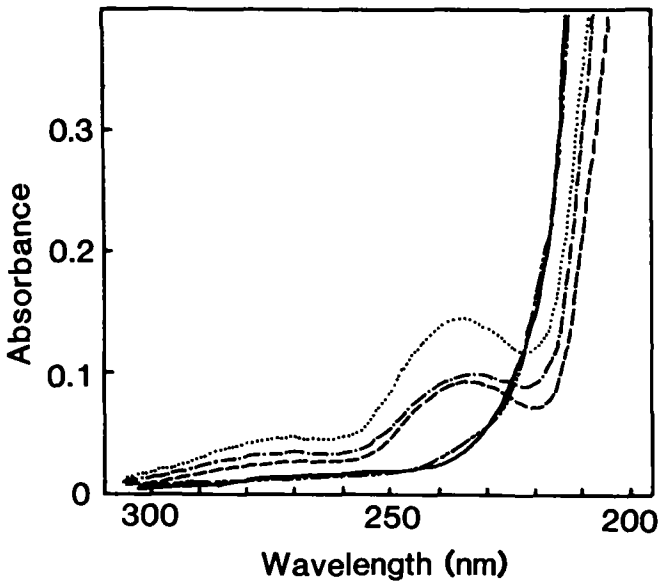

FIG. 3. Ultraviolet absorption spectra of total lipids of rat liver and ascites hepatomas. Total lipids, which were prepared as described in Materials and Methods, were dissolved in ethanol (50 μM phospholipid), and then the spectrum was recorded. ——, Normal rat liver; —··—, regenerating liver; — — —, AH-13; ····, AH-60C; —·—·—, AH-109A.

acid content of hepatoma cells may be due partially to their higher susceptibility to peroxidation of lipids in the cells. The decreases in the transfer-stimulating activity and in the level of α-tocopherol in ascites hepatoma cytosol may be involved in increase of lipid peroxidation in these cells.

ACKNOWLEDGMENTS

We thank H. Sato of the Sasaki Institute (Tokyo, Japan) for providing ascites hepatomas cells and suggestions for their maintenance; we also thank the Eisai Company (Tokyo, Japan) for providing tocopherols and their derivatives.

[Received November 30, 1987; Revision accepted February 9, 1988]

Effect of 7-Methylated Bile Acids and Bile Alcohols on Cholesterol Metabolism in Hamsters

Naoyuki Matoba, Syoji Kuroki, Bertram I. Cohen, Erwin H. Mosbach* and Charles K. McSherry
Departments of Surgery, Beth Israel Medical Center and the Mount Sinai School of Medicine of the City University of New York, New York, NY

The effect of 7-methyl substituted bile acid and bile alcohol analogues on cholesterol metabolism was studied in the hamster. Animals were fed chow plus 0.1% cholesterol supplemented with 0.1% of one of the following steroids: chenodeoxycholic acid, 7-methyl-chenodeoxycholic acid, 7β-methyl-24-nor-5β-cholestane-3α,7α,25-triol, cholic acid, 7-methyl-cholic acid, or 7β-methyl-24-nor-5β-cholestane-3α,7α,12α,25-tetrol. Cholesterol absorption was determined from fecal analysis after feeding of radiolabeled cholesterol and β-sitosterol.

Of the six compounds studied, chenodeoxycholic acid and 7-methyl-chenodeoxycholic acid decreased intestinal cholesterol absorption (17% and 31% decrease, respectively). Only 7-methyl-chenodeoxycholic acid decreased serum cholesterol concentration (29% decrease), but there were no analogous changes of liver and biliary cholesterol concentration and cholesterol saturation of bile. Total fecal neutral sterol excretion was increased in the groups fed chenodeoxycholic acid and 7-methyl-chenodeoxycholic acid. In addition, the production of coprostanol was increased in both groups. These data suggest that 7-methyl-chenodeoxycholic acid resembles chenodeoxycholic acid in its effect on cholesterol metabolism and may be a potential candidate for further studies of its gallstone-dissolving properties.
***Lipids 23,* 465–468 (1988).**

Chenodeoxycholic acid (CDCA) and ursodeoxycholic acid (UDCA) are known to be effective agents for the medical dissolution of gallstones in a selected group of patients (1,2) and in some experimental animals (3). We postulated that introduction of a methyl group at the 7-position of naturally occurring dihydroxy bile acids prevents intestinal bacterial 7-dehydroxylation and, therefore, the production of the potentially hepatotoxic metabolite, lithocholic acid (LCA). Therefore, we synthesized 7-methyl substituted bile acid analogues (4,5) and studied their metabolism in experimental animals (6–9). These studies revealed that 7-methylated bile acids were absorbed and participated efficiently in the enterohepatic circulation of bile acids; they appeared to be resistant to bacterial 7-dehydroxylation.

Recently, Une et al. developed a simple method for the synthesis of 7-methyl bile acids as well as certain C_{26} bile alcohol analogues (Une, M., Yamanaga, K., Mosbach, E.H., Kuroki, S., and Hoshita, T., unpublished data). With this improved technique, it was possible to obtain sufficient quantities of these 7-methyl bile acids and bile alcohols to investigate their chemical and metabolic properties. This study describes the effect of 7-methylated bile acids and bile alcohols on cholesterol metabolism, and particularly on cholesterol absorption, in the hamster.

Abbreviations: CDCA, chenodeoxycholic acid; LCA, lithocholic acid; UDCA, ursodeoxycholic acid; GLC, gas liquid chromatography.

MATERIALS AND METHODS

Unlabeled compounds. Cholesterol was obtained from Sigma Chemical Co. (St. Louis, MO). β-Sitosterol (94% pure) was provided by Eli Lilly and Co. (Indianapolis, IN). Cholic acid (CA) (Inolex, Park Forest South, IL) and chenodeoxycholic acid (CDCA) (Weddel Pharmaceuticals, London, U.K.) were greater than 99% pure as determined by gas liquid chromatography (GLC) of the methyl ester-trimethylsilyl ether derivatives. 7-Methyl bile acid and bile alcohol analogues, namely 3α,7α-dihydroxy-7β-methyl-5β-cholanoic acid (7-Me-CDCA), 3α,7α,12α-trihydroxy-7β-methyl-5β-cholanoic acid (7-Me-CA), 7β-methyl-24-nor-5β-cholestane-3α,7α,25-triol (7-Me-NCT), and 7β-methyl-24-nor-5β-cholestane-3α,7α,12α,25-tetrol (7-Me-NCTe), were synthesized as described (4,5, Une, M., Yamanaga, K., Mosbach, E.H., Kuroki, S., and Hoshita, T., unpublished data).

Labeled compounds. [1α,2α(n)-^{3}H]Cholesterol (sp. act. 84.6 mCi/mg) and [4-^{14}C]β-sitosterol (sp. act. 135 μCi/mg) were purchased from NEN Research Products (Boston, MA). The radioactive purity of each compound was better than 97% and 98%, respectively, as determined by radio thin layer chromatography.

Animals and diets. Male golden Syrian hamsters (40 animals) weighing an average of 94 g were purchased from Charles River Breeding Laboratories (Wilmington, MA). All the animals were weighed and placed into individual cages. They all were quarantined for 10 days and fed Purina rodent chow ad libitum. They were then fed a diet of Purina rodent chow (Teklad) containing 0.03% cholesterol and supplemented with 0.1% crystalline cholesterol (group 1). This diet was further supplemented with 0.1% of one of the following (groups 2–7): (2) CDCA; (3) 7-Me-CDCA; (4) 7-Me-NCT; (5) CA; (6) 7-Me-CA; (7) 7-Me-NCTe. The animals were maintained on the different diets and water ad libitum for 12 days. There was no significant weight change in the animals during the experiment. The average food intake of the animals was 7.7 g/day, and there were no significant differences among the seven groups.

The labeled sterols (^{3}H-cholesterol and ^{14}C-β-sitosterol) were diluted with unlabeled carriers to obtain specific activities of 1.1×10^7 cpm/mg and 2.5×10^6 cpm/mg, respectively. The mixture of radioactive sterols was dissolved in 6 ml of acetone and added with stirring to a 30 g portion of each powdered diet (groups 1–7, 5 g/animal). After complete removal of acetone by evaporation, this radiolabeled diet was fed to each animal on day 13 of the experiment. Feces were collected quantitatively on days 14, 15 and 16. The animals then were fed the experimental, steroid-containing diets for an additional eight days after isotopic labeling (days 14–21). At the end of the experiment (day 21), the animals were killed under anesthesia (ketamine hydrochloride and ether). Samples of blood and liver were obtained for the determination of cholesterol concentrations; gall bladder bile was used for the determination of biliary lipids.

Analytical procedures. Determination of cholesterol content of serum, liver and bile was carried out as described (10). Biliary bile acids were quantitated by GLC (8). Bile phospholipids were determined colorimetrically by a procedure described elsewhere (11). Cholesterol saturation of bile was calculated using a computer program (12) based on the tables of Carey (13). The method used for the extraction of the fecal neutral steroids was principally that of Miettinen et al. (14), as modified by Cohen et al. (15). Three-day fecal samples for each animal were pooled. The neutral sterols were extracted with hexane after alkaline hydrolysis, and an aliquot was used for radioisotope measurements. ^{3}H and ^{14}C were determined by liquid scintillation counting (Beckman LS-8000 liquid scintillation system, Beckman Instruments, Fullerton, CA) with the use of external standardization for quench correction. Cholesterol absorption was calculated according to method IV of Quintao et al. (16).

Quantitation of neutral steroids in feces was carried out by GLC of the trimethylsilyl ether derivatives. 5α-Cholestane was added to each sample as an internal standard. The methods and conditions of the GLC analyses were those described (15). All analyses were carried out with a Hewlett-Packard 5830A gas chromatograph.

The results in the tables are expressed as mean ± SE. The significance of differences among various groups studied was calculated by Student's t-test (17).

RESULTS

These studies were carried out to examine the effect of 7-methyl bile acid and bile alcohol analogues on the intestinal absorption of cholesterol and on the activity of those intestinal bacteria responsible for the hydrogenation of cholesterol to coprostanol.

Total recoveries of ^{14}C-β-sitosterol in feces during the three-day collection period are shown in Table 1. The excretion of β-sitosterol was similar in all groups (84.7–88.3%). Calculation of cholesterol absorption was made by method IV of Quintao et al. (16). The results are shown in Table 1. In groups 2 and 3, fed CDCA and 7-Me-CDCA, respectively, cholesterol absorption was reduced in comparison with the control group (group 1, [17% and 31% decrease, respectively]).

Table 2 shows the concentration of serum, liver and biliary cholesterol. The administration of 7-Me-CDCA caused a significant decrease (29%) in serum cholesterol concentration, while 7-Me-CA produced a significant increase (31%), in comparison with the controls. In the groups fed CA or 7-Me-CA, liver cholesterol was increased about two-fold. In contrast, biliary cholesterol levels were similar in all groups.

Cholesterol saturation indices (CSI) of each group are listed in Table 3. Only CA changed the CSI compared with that of control group 1; the decrease produced by

[c]Five animals.

7-Me-CDCA was not significant. The other compounds had no significant effect on the CSI.

Biliary bile acid composition was determined at sacrifice. In the groups fed CDCA (group 2) and CA (group 5), these bile acids were major components of the bile, 54.6% and 40.9%, respectively. The 7-methylated bile acid analogues, 7-Me-CDCA and 7-Me-CA, composed 19.3% and 13.6%, respectively. The administered bile alcohols, 7-Me-NCT (group 4) and 7-Me-NCTe (group 7), were detected as minor components in bile and comprised 2.2% and 7.8%, respectively.

Daily sterol outputs in feces are shown in Table 4. These measurements were obtained from GLC analyses of the neutral sterol fraction of the feces. CDCA and 7-Me-CDCA increased daily total neutral sterol output, while compounds with the cholic acid-type nucleus (trihydroxy substituents) showed no effect. There were no significant changes in cholesterol output. However, the amount of coprostanol was 1.6- and 2.1-fold higher in the hamsters fed CDCA or 7-Me-CDCA (groups 2 and 3) than in the controls (group 1). We compared the coprostanol/cholesterol ratios to obtain information about the effect of the added steroids (groups 2–7) on intestinal bacterial function. Of the compounds studied, CDCA and its analogues (7-Me-CDCA and 7-Me-NCT), seemed to enhance the formation of coprostanol. The other compounds had no effect.

DISCUSSION

This study deals with the effect of naturally occurring bile acids, 7-methyl bile acids and C_{26} 7-methyl bile alcohol analogues on cholesterol absorption and other aspects of cholesterol metabolism in hamsters. Several methods for measuring intestinal cholesterol absorption are known (16,18). In this study, we adopted method IV of Quintao et al. (16). Although longer fecal-collection periods are required in the case of human subjects, a three-day fecal collection was considered adequate to measure cholesterol absorption in the hamsters. About 85% of the administered labeled β-sitosterol was recovered during this three-day period (Table 1), probably because of the short intestinal transit time of the hamster. Earlier studies had demonstrated that a 12-day adjustment period was adequate to obtain a steady-state in hamsters (24). Thus, this procedure allows us to obtain a measurement of cholesterol absorption.

Cholesterol absorption studies during bile acid administration revealed that in the rat only cholic acid and its conjugates produced significant increases in cholesterol absorption (19), while monohydroxy or dihydroxy bile acids had no effect (20,21). In this study, administration of CA did not enhance the absorption of cholesterol. It is not clear whether this result is due to the relatively low concentration of dietary cholesterol employed or whether it is characteristic of the hamster model. However, there is controversy whether CDCA alters cholesterol absorption (22). Several studies showed that CDCA had no effect on cholesterol absorption in rat and man (20,23), while other studies suggested an inhibitory effect in man (22). In this report, CDCA and 7-Me-CDCA inhibited the absorption of cholesterol to a significant level in comparison with the controls. Thus, at least in the hamster, dihydroxy bile acids seem to inhibit the intestinal absorption of cholesterol compared with the trihydroxy analogues.

7-Me-CDCA was the only compound in this study that decreased serum cholesterol to a significant extent; this compound did not alter liver and biliary cholesterol compared with controls (Table 2). Moreover, the cholesterol

TABLE 4

Effect of Bile Acid and Bile Alcohols on Fecal Sterol Output

saturation index of bile in this group (group 3) was not affected (Table 3). Similar results were reported earlier in hamsters fed diets containing cholesterol plus UDCA (24). Because 7-Me-CDCA is substituted both in the 7α- and 7β-position, it is possible that it may share certain characteristics of both CDCA and UDCA. It is known, however, that CDCA and 7-Me-CDCA are considerably more hydrophobic than UDCA (4).

Kuroki et al. reported that 7-Me-CA increased serum and liver cholesterol and inhibited HMG-CoA reductase activity in the hamster (25). Although we confirmed that the concentrations of serum and liver cholesterol were increased by the administration of 7-Me-CA, there seemed to be no change in intestinal cholesterol absorption. Thus, it was not possible to demonstrate directly that the inhibition of HMG-CoA reductase by 7-Me-CA was related to the increased hepatic cholesterol concentration caused by increased cholesterol absorption.

Bile alcohol analogues with a methyl group at the 7-position had little effect on cholesterol absorption. We have not examined the metabolism of these compounds in detail, and therefore it is unclear whether these compounds are efficiently absorbed from the intestine, extracted by the liver and excreted into the bile. Kibe et al. reported that in the rat following the intra-abdominal injection of 24-nor-5β-cholestane-3α,7α,12α,25-tetrol, the compound was excreted into the bile as a glucuronide (26). According to Hoshita et al., the intestinal absorption of bile alcohols is not as efficient as that of the bile acids (27). The absorption of the free bile alcohol and bile alcohol 3-glucuronide were 60% and 30%, respectively, during a 24-hr period (27). Therefore, it seems likely that the bile alcohol analogues examined in this study exerted little effect on cholesterol metabolism because they did not participate effectively in the enterohepatic circulation.

It is well-known that bile acid feeding affects intestinal bacterial function (28). In this respect, we showed that 7-Me bile acid analogues diminished the bacterial 7-dehydroxylation of naturally occurring bile acids (25,29). In this present study, we examined the effect of 7-Me compounds on the conversion of cholesterol to coprostanol. Earlier studies had shown that the formation of coprostanol from cholesterol is affected by a number of dietary factors, such as protein, cerebroside, fiber and bile acids (30–33). In this study, 7-Me-CDCA as well as CDCA increased total neutral sterol and coprostanol output; as a result, there was an increase of the coprostanol/cholesterol ratio (Table 4). However, under the conditions employed, it was not possible to state whether these bile acids have a direct effect on the bacterial enzyme(s) involved. Because cholesterol absorption was decreased in these groups (groups 2 and 3), and presumably there was an increased intestinal sterol concentration, it might have been expected that the coprostanol/cholesterol ratio should have decreased (34).

In summary, in this study the most significant effects of the 7-Me-bile acid analogues were observed with 7-Me-CDCA. Administration of the latter produced a decrease in intestinal cholesterol absorption and serum cholesterol concentration and did not affect the biliary cholesterol saturation. In addition, this analogue of CDCA increased fecal neutral sterol output and the coprostanol/cholesterol ratio. Because 7-Me-CDCA prevents the formation of cholesterol gallstones and accelerates their dissolution in the prairie dog model, further studies with this compound seem indicated.

Fatty Acid Allene Oxides. III. Albumin-induced Cyclization of 12,13(*S*)-Epoxy-9(*Z*),11-octadecadienoic Acid[1]

Mats Hamberg* and **Molly A. Hughes**
Department of Physiological Chemistry, Karolinska Institutet, Box 60400, S-104 01 Stockholm, Sweden

Recently, corn *(Zea mays L.)* hydroperoxide dehydrase was found to catalyze the conversion of 13*(S)*-hydroperoxy-9*(Z)*,11*(E)*-octadecadienoic acid into an unstable fatty acid allene oxide, 12,13*(S)*-epoxy-9*(Z)*,11-octadecadienoic acid. This study is concerned with the chemistry of 12,13*(S)*-epoxy-9*(Z)*,11-octadecadienoic acid in the presence of vertebrate serum albumins.

Albumins were found to greatly enhance the aqueous half-life of the allene oxide, i.e. 14.1 ± 1.8 min, 11.6 ± 1.2 min and 4.8 ± 0.5 min at 0 C in the presence of 15 mg/ml of bovine, human and equine serum albumins, respectively, as compared with ca. 33 sec in the absence of albumin. Degradation of allene oxide in the presence of bovine serum albumin led to the formation of a novel cyclization product, i.e. 3-oxo-2-pentyl-cyclopent-4-en-1-octanoic acid (12-oxo-10-phytoenoic acid, in which the relative configuration of the side chains attached to the five-membered ring is *trans*). Steric analysis of the cyclic derivative showed that the compound was largely racemic (ratio between enantiomers, 58:42).

12-Oxo-10,15*(Z)*-phytodienoic acid, needed for reference purposes, was prepared by incubation of 13*(S)*-hydroperoxy-9*(Z)*,11*(E)*,15*(Z)*-octadecatrienoic acid with corn hydroperoxide dehydrase. Steric analysis showed that the 12-oxo-10,15*(Z)*-phytodienoic acid thus obtained was not optically pure but a mixture of enantiomers in a ratio of 82:18.

***Lipids* 23, 469–475 (1988).**

In recent work, a fatty acid allene oxide, 12,13*(S)*-epoxy-9*(Z)*,11-octadecadienoic acid, was identified as the product formed from 13*(S)*-hydroperoxy-9*(Z)*,11*(E)*-octadecadienoic acid in the presence of corn hydroperoxide dehydrase (previously referred to as corn hydroperoxide isomerase) (1). The allene oxide was rapidly hydrolyzed ($t_{1/2}$ about 30 sec at 0 C) in aqueous medium into the previously recognized stable α-ketol, 12-oxo-13-hydroxy-9*(Z)*-octadecenoic acid. Treatment of allene oxide with an excess of methanol led to the formation of a trapping product, 12-oxo-13-methoxy-9*(Z)*-octadecenoic acid. Instability of the allene oxide was not confined to hydroxylic solvents. Thus, in acetonitrile solution the allene oxide structure was subject to intramolecular attack by the carboxyl group to yield two isomeric macrolactones, 12-oxo-9*(Z)*-octadecen-11-olide and 12-oxo-9*(Z)*-octadecen-13-olide (2).

Unstable eicosanoids like thromboxane A_2, prostaglandin I_2 and leukotriene A_4 are stabilized in the presence of vertebrate serum albumins (3–5). The aim of this work was to examine whether 12,13*(S)*-epoxy-9*(Z)*,11-octadecadienoic acid was stabilized in the same way. In the course of the investigation, a novel cyclization product formed from 12,13*(S)*-epoxy-9*(Z)*,11-octadecadienoic acid in the presence of bovine serum albumin was isolated and characterized.

EXPERIMENTAL PROCEDURES

Materials. 13*(S)*-hydroperoxy-9*(Z)*,11*(E)*-octadecadienoic acid (13*(S)*-[1-^{14}C]HPOD) (specific radioactivity, 37 and 1.4 kBq/μmol) and 13*(S)*-hydroperoxy-9*(Z)*,11*(E)*,15*(Z)*-octadecatrienoic acid (13*(S)*-[1-^{14}C]HPOT) (specific radioactivity, 1.5 kBq/μmol) were prepared by incubation of [1-^{14}C]-linoleic and [1-^{14}C]α-linolenic acids, respectively, with soybean lipoxygenase as previously described (6). 13*(S)*-[9,10,12,13-$^2H_4$]-HPOD was prepared from [9,10,12,13-$^2H_4$]linoleic acid as described (1). Crystalline, fatty acid-free (less than 0.005%) serum albumins were purchased from Sigma Chemical Co. (St. Louis, MO).

Enzyme preparation. A preparation containing corn hydroperoxide dehydrase was obtained by extraction of defatted corn germ with potassium phosphate buffer followed by ammonium sulfate precipitation (0–45% saturation) as described (1). Precipitate dissolved in ice-cold 0.1 M potassium phosphate buffer, pH 7.4 (1.6 mg of protein per ml buffer) was used for the incubations.

Methyl 12-oxo-10,15(Z)*-phytodienoate* (1). 13*(S)*-[1-^{14}C]-HPOT (8.4 mg) was dissolved in 0.5 ml of acetonitrile and shaken with 45 ml of enzyme preparation (72 mg of protein) at 0 C for 15 min. Methanol (3 vol.) was added, and the mixture was carefully acidified to pH 3 and extracted with two portions of diethyl ether. The product (recovery of radioactivity, 93%) was treated with diazomethane and subjected to thin layer chromatography (TLC) (solvent system, ethyl acetate/hexane [15:85, v/v]). A broad peak of radioactivity appeared (about 80% of the radioactivity applied, R_f = 0.26–0.36). This material was subjected to reversed-phase high performance liquid chromatography (HPLC). Three peaks of radioactivity appeared, i.e. methyl 12-oxo-13-hydroxy-9*(Z)*,15*(Z)*-octadecadienoate (67%; 18.6–20.2 ml effluent), methyl 13*(S)*-hydroxy-9*(Z)*,11*(E)*,15*(Z)*-octadecatrienoate (3%; 22.2–23.0 ml of effluent), and methyl 12-oxo-10,15*(Z)*-phytodienoate (30%; 23.0–24.6 ml of effluent). The last mentioned material was collected (yield, 1.3 mg). Its identity as methyl 12-oxo-10,15*(Z)*-phytodienoate (*1*, Fig. 1; see ref. 7 for original isolation and characterization of this compound) was based on 1) its UV spectrum, which showed λ_{max} at 221 nm (ε about 12,000), 2) its mass spectrum, which showed prominent ions at m/e 306 (M, 36%), 275 (M-31, 27), 238 (M-68 [β-cleavage with loss of C_5H_8], 47), 206 (238-32, 18), 177 (M-129 [loss of $\cdot(CH_2)_5$-$COOCH_3$], 41), 163 (M-143 [loss of $\cdot(CH_2)_6$-$COOCH_3$], 53), 149 (M-157 [loss of $\cdot(CH_2)_7$-$COOCH_3$], 49), 109 (65), 107 (42), 96 (100) and
