(+ 131% in cholesterol and −77% in triglycerides). No further increase in plasma cholesterol occurred when the cystine diet was given for a longer time. (At 20 weeks, plasma cholesterol was equal to 1.32 ± 0.20 mg/ml.) Cessation of the cystine diet did not induce a quick return to a normal plasma-cholesterol level. Hypercholesterolemia persisted for eight weeks after replacement of the cystine diet (given previously for four weeks) with the standard diet (Fig. 2). It persisted for 28 weeks after replacing the cystine diet given for 20 weeks with the standard diet (1.40 ± 0.20 mg/ml). It is interesting that, in Wistar rats fed the semipurified diet (sucrose-rich and containing lard) ad libitum, the plasma-triglyceride level is very high when animals are not fasted before blood sampling.

In contrast to human plasma cholesterol that is carried mainly by LDL ($1.019 < d < 1.063$) and contains only apoB, the rat plasma cholesterol is carried essentially by HDL ($1.063 < d < 1.21$). The rat lipoproteins of density range 1.019–1.063 are constituted by two fractions as shown by ultracentrifugation in a zonal system or on an isopycnic gradient—the lightest is apoB-rich (LDL) and the heaviest (HDL_1) is apoE-rich (27). In the present study, LDL of density range 1.006–1.063 have been separated into 2 fractions—LDL_1 ($1.006 < d < 1.040$) and LDL_2 ($1.040 < d < 1.063$), according to Fidge and Poulis (28). LDL_1 contain mainly apoB (over 70% of total proteins, results not shown), whereas LDL_2 contain apoE, $apoA_I$ and apoC as major apolipoproteins and a minor amount of apoB. In this study, although HDL_1 (or apoE-rich HDL) had not been isolated by affinity chromatography (29) or electrophoresis (30), the low apoB and high apoE contents of LDL_2 suggest that this lipoprotein fraction is largely constituted of HDL_1. The low apoE and high $apoA_I$ contents in HDL ($1.063 < d < 1.21$) reflect that these HDL are mainly $apoA_I$-rich HDL, or HDL_2. Nevertheless, taking into account the absolute amounts of proteins in lipoproteins and the relative proportions of the different apolipoproteins, it can be estimated that the absolute amount of apoE in LDL_2 is similar to that in HDL (about 50 μg/ml plasma), but the amount of $apoA_I$ is about 20 times greater in HDL (about 800 μg/ml plasma), than in LDL_2 (about 40 μg/ml). Therefore, assuming that the apoE content could reflect the presence of HDL_1, similar amounts of HDL_1 seemed to be present in the 2 fractions, LDL_2 and HDL. Therefore, HDL_1 would be the major lipoprotein contained in LDL_2, but only a minor one in HDL.

The characteristics of hypercholesterolemia from endogenous origin, obtained in rats fed a cystine-enriched diet, are opposite to those of hypercholesterolemia from exogenous origin, obtained in rats fed a cholesterol-enriched diet. As compared with normal rats, in rats fed the cystine-enriched diet for eight weeks, cholesterol distribution in lipoproteins is characterized by a decrease in chylomicrons + VLDL (fractions 1 + 2 in the density gradient), an increase in LDL_2 (fractions 7–11), that particularly affects fraction 10 (+395%), and an increase in HDL (fractions 12–18). In cholesterol-fed rats, high chylomicrons + VLDL levels and low LDL_2 and HDL levels were reported (9). Whereas, in control rats with cholesterol essentially being carried by HDL (63%) and LDL_2 (20%), eight weeks of cystine feeding enhances the participation of LDL_2 in the cholesterol transport (41%). The hypercholesterolemia with the relatively high LDL_2- and HDL-cholesterol content of the cystine diet, which was given for 4 or 8 weeks, persisted for eight more weeks after replacement with the normal diet. Cessation of the cystine diet did not induce a quick return to a normal situation, because 40% of the plasma cholesterol is still transported by LDL_2 (C8S8).

Some changes in the chemical composition of lipoproteins were observed from the fourth week of cystine feeding (Table 3). The relative proportions of cholesterol in chylomicrons + VLDL, LDL_1 and LDL_2 were increased, and those of triglycerides in LDL_1 and LDL_2 (C4) in chylomicrons + VLDL, LDL_1 and LDL_2 (C8) were decreased. Replacement of the cystine diet with the standard diet was not sufficient to recover a normal chemical composition of these lipoproteins, which remained cholesterol-enriched and triglyceride-poor. Both the low triglyceride proportion and the low triglyceride levels in the lighest lipoproteins certainly resulted from a very active lipolysis.

The plasma apoE content in LDL_2 and in HDL was similarly increased (fivefold) in cystine-fed rats, resulting again in identical apoE amounts in these two lipoprotein fractions. The $apoA_I$ content was multipled by three in LDL_2 and by 1.5 in HDL, and the apoB content in LDL_2 was 10-fold that of control rats. The increase in apoE-rich lipoproteins could result from an increased apoE production. The increase in apoB-rich LDL could be explained by either an increased production or a delayed catabolism, because apoE and apoB compete for binding to the apoB,E receptor (31). After eight weeks of cystine feeding, cessation of the cystine diet for eight more weeks decreased the absolute amount of apoE in HDL, which returned to control values, but that of LDL_2 remained high.

In the rat, the plasma HDL_1 level depends on the nutritional or experimental conditions. It is increased by diets enriched with cholesterol and propylthiouracil (PTU), which is an antithyroid drug (2,5), PTU alone (32), cystine excess (9), and by copper-deficient diet (33). The plasma HDL_1 level decreases with a cholesterol-enriched diet, without addition of PTU (5,9), and with essential fatty acid deficiency (34). It can be noted that apoE-rich HDL, normally not present in human plasma, have been observed in some pathological disorders as primary biliary cirrhosis (35), familial lecithin:cholesterol acyl transferase (LCAT) deficiency (36) and alcoholic hepatitis (37).

The origin of HDL_1 is now largely documented, although all the mechanisms involved in production of this lipoprotein are not fully understood. First, it was suggested that HDL_1 could originate as a product of the catabolism of chylomicrons (27). Now it is well known that lipolysis of the triglyceride-rich lipoproteins provides surface constituents (free cholesterol, phospholipids and apolipoproteins) in the HDL density range (HDL_3 and very high density lipoproteins or VHDL) (38,39). It also was demonstrated that the conversion of HDL_3 to HDL_2, and then to HDL_1, occurs with free cholesterol- and apoE-enrichment and esterification of free cholesterol by LCAT (30,31,40). In species devoid of cholesteryl ester transfer protein (CETP), such as the rat (15), the conversion is complete. In the presence of CETP, the conversion is stopped at HDL_2, because esterified cholesterol

can be transported from HDL_2 to VLDL, with the remaining lipoprotein returning to the HDL_3 density range (40). This explains why, under normal conditions, rat plasma, in contrast to human plasma, contains HDL_1. Our own results with control, cholesterol-fed and cystine-fed rats (26) show a strong correlation between liver-cholesterol synthesis and the plasma LDL_2 (rich in HDL_1) level, and suggest that cholesterol necessary for the formation of HDL_1 can be provided by the liver, perhaps in synergy with apoE production. Other recent experiments, not yet published, suggest that the hepatic lipase, which is involved in the lipolysis of triglyceride-rich lipoproteins, play an important role in the appearance of apoE-rich HDL_1.

Because rats fed a cystine-enriched diet developed a relatively long-lasting hypercholesterolemia, the effects of two drugs known to be hypocholesterolemic were investigated. Results showed that both drugs were effective in this model of hypercholesterolemia. HDL-cholesterol levels returned to normal values, but LDL_2-cholesterol levels were not fully normalized by the drugs at the dosage used.

In conclusion, rats fed a cystine-enriched diet constitute, even after cessation of this particular diet, a new tool for investigating the mechanisms that increase plasma-cholesterol and, in particular, apoE-rich-HDL_1 levels.

Hydrolysis of a Fluorescent Substance Formed From an Oxidized Phospholipid and an Amino Compound by Phospholipase A_2

Toshihiro Ito and **Kazuaki Yoden***
Showa College of Pharmaceutical Sciences 1-8, Tsurumaki 5-chome, Setagaya-ku, Tokyo, Japan, 154

Phosphatidylcholine hydroperoxide produced a fluorescent substance (FS-III) through reaction with 1-aminopentane after preincubation with heme methyl ester as a model system. The FS-III was retained at the 2-position of the glycerol backbone of phosphatidylcholine without breakdown into low molecular weight compounds. Phosphatidylcholine oxidized by catalysis with ferrous ion and ascorbic acid also produced the same fluorescent substance (FS-III). Phospholipase A_2 specifically hydrolyzed the FS-III attached to the phospholipid, making it possible to elute the same fluorescent substance (FS-II) as that obtained from oxidized methyl linoleate. The release of FS-II by hydrolysis of FS-III attached to phospholipid increased with greater phospholipase A_2 activity. It is suggested that, with aging, the accumulation of fluorescent lipofuscin pigments in biomembranes may be related to changes in the peroxidized phospholipid content and that phospholipase A_2 may play a role in decreasing the formation and accumulation of fluorescent phospholipids in biomembranes.
Lipids 23, 937-941 (1988).

The degradative compounds derived from hydroperoxides (HPO) of polyunsaturated fatty acids (PUFA) in the presence of metals, ascorbic acid or heme methyl ester (heme) compounds are involved in fluorescence formation through reaction with amino compounds in vitro (1,2). These fluorescent substances exhibit fluorescence spectra with excitation and emission maxima at 320-350 nm and 410-430 nm, respectively. These are very similar to the fluorescence spectra of fluorescent lipofuscin pigments, associated with aging, in animal tissues (3-5).

We recently have reported that both the 9- and the 13-HPO of methyl linoleate (ML) produced fluorescent substances exhibiting the same fluorescence spectra through reaction with 1-aminopentane (1-AP) as a model amino compound after preincubation with heme (6). PUFA are acylated mainly at the 2-glycerol position of phospholipid and are converted to HPO without release from phospholipid at the early stage of lipid peroxidation (7,8). For example, linoleic acid attached to phospholipid produces 9- and 13-HPO derivatives without fatty acid release (8). HPO of 1-palmitoyl-2-linoleoyl-phosphatidylcholine (PLPC) also showed similar fluorescence characteristics through reaction with 1-AP in the presence of heme (9). Moreover, the fluorescent substance was attached to PLPC and was released from the glycerol backbone after transmethylation. These results suggest that acylated fatty acid peroxides in phospholipids may play an important role in the formation of fluorescent substances with various amino compounds in biomembranes.

Abbreviations: 1-AP, 1-aminopentane; heme, heme methyl ester(s); HPO, hydroperoxide(s); ML, methyl linoleate; PLPC, 1-palmitoyl-2-linoleoyl-phosphatidylcholine; PUFA, polyunsaturated fatty acid(s); HPLC, high performance liquid chromatography; TLC, thin layer chromatography.

PUFA moieties attached to the 2-glycerol position of phospholipids generally can be hydrolyzed with phospholipase A_2. It recently was reported that phospholipase A_2 also preferentially hydrolyzes peroxidized fatty acid esters in phospholipids (10-12). In the present study, therefore, we investigated the phospholipase A_2-dependent hydrolysis of the fluorescent substances attached to the 2-position of the glycerol backbone of phosphatidylcholine. The role of phospholipase A_2 in the accumulation of fluorescent lipofuscin pigments in biomembranes is discussed.

MATERIALS AND METHODS

Materials. Linoleic acid, ML, PLPC, hemin (type I), soybean lipoxygenase (Type I) and phospholipase A_2 (from porcine pancreas, 650 units/mg protein) were purchased from Sigma Chemical Co. (St. Louis, MO). 1-AP and 5% methanolic *m*-trifluoromethylphenyltrimethyl ammonium hydroxide were purchased from Tokyo Kasei Kogyo Co., Ltd. (Tokyo, Japan). Heme was prepared according to the method of Ortiz de Montellano et al. (13).

Preparation of ML-HPO, PLPC-HPO and oxidized ML or PLPC. ML-HPO and PLPC-HPO were prepared using lipoxygenase, according to the methods previously reported (9). Direct oxidation of ML and PLPC by iron and ascorbate was carried out by the following procedure. To ML or PLPC (1 μmol each) dispersed with 0.2 ml of 0.1% Tween 80 solution by vortexing, 1.4 ml of 0.1 M Tris buffer (pH 7.4), 0.2 ml of 0.1 mM $FeSO_4$ and 0.2 ml of 1 mM ascorbic acid were added, and this mixture was incubated at 37°C for 3 hr. Oxidized ML or PLPC was extracted with 5 ml of a chloroform/methanol (2:1) mixture and the chloroform layer was evaporated under an N_2 stream.

Formation of fluorescent substances. Fluorescence formation through reaction of ML-HPO or PLPC-HPO (100 nmol) with 1-AP (1 μmol) in the presence of heme (1 nmol) was carried out, according to the method previously reported (6,9). Oxidized ML or PLPC was dissolved in 0.2 ml of chloroform, and 1.8 ml of methanol was added. This solution was preincubated with or without heme (1 nmol) at 37°C for 30 min. One ml of 1-AP (1 μmol) in methanol was added to each respective preincubation mixture and the mixture was further incubated, at 37°C for 20 hr, for fluorescence formation. Fluorscence spectra were measured with a Hitachi MPF-3 fluorescence spectrophotometer (Hitachi Ltd., Tokyo, Japan) and fluorescence intensity was expressed as a percentage of that intensity of a quinine sulfate standard (0.1 μg/ml in 0.1 N H_2SO_4). The total fluorescence intensity of each sample was adjusted to the same fluorescence strength (700%) by concentration under an N_2 stream, and an aliquot of each was subjected to high performance liquid chromatography (HPLC). HPLC was performed on a μ-Bondapak FAA column (3.9 × 300 mm, Waters Associates, Milford, MA), using methanol/water (8:2) for the first 10 min, followed by methanol/water (9:1) as the mobile phases at a flow rate of 1.0 ml/min. A packed guard column (4 ×

50 mm, Unisil C_{18}, 10 μm, Gasukuro Kogyo Inc., Tokyo, Japan) was used. Fluorescence peaks were monitored at excitation and emission maxima, 350 nm and 420 nm, with a Hitachi 650-10LC fluorescence spectrophotometer (Hitachi Ltd., Tokyo, Japan). The fluorescent substances were then subjected to thin layer chromatography (TLC) (Kieselgel 60, Merck, Darmstadt, FRG) and developed with chloroform/methanol (9:1).

Hydrolysis of fluorescent substances with phospholipase A_2. Fifty μl of each fluorescent sample were evaporated under an N_2 stream and were dispersed in 0.2 ml of 10 mM sodium deoxycholate by vortexing. The reaction was carried out at 37°C for 30 min in 2 ml of 0.1 M Tris buffer (pH 8.4), containing 5 mM $CaCl_2$ and 13 units of phospholipase A_2. Reaction products were extracted with 5 ml of chloroform/methanol (2:1) and methylated with diazomethane in ethyl ether at 25°C for 15 min.

RESULTS

Purified ML-HPO or PLPC-HPO and oxidized ML or PLPC were separately incubated with 1-AP in methanol solution at 37°C for 20 hr after preincubation with or without heme. Both ML-HPO and PLPC-HPO produced fluorescent substances exhibiting the same fluorescence spectra with excitation and emission maxima at 340–350 nm and 410–425 nm, respectively, while those HPO incubated without heme produced only a small number of fluorescent substances (Table 1). On the other hand, both oxidized ML and PLPC directly produced fluorescent substances having the same fluorescence spectra, through reaction with 1-AP in the absence of heme. Moreover, these fluorescence intensities showed a twofold increase, after preincubation with heme, accompanied by degradation of their HPO.

We previously reported that fluorescent substances formed from secondary oxidation products of ML with 1-AP in methanol solution revealed two fluorescence peaks (FS-I and FS-II) upon reverse-phase HPLC (14). Similarly, oxidized ML also produced two fluorescent substances, FS-I and FS-II, by reaction with 1-AP, as shown in Figure 1 B, and ML-HPO revealed one major fluorescence peak (FS-II) and one small peak (FS-I). On the other hand, when fluorescent substances formed from PLPC-HPO with 1-AP after decomposition by heme were subjected to reverse-phase HPLC, a new major fluorescence peak (FS-III) was eluted at a retention time of 18.5 min, but only small peaks of FS-I and FS-II were detected (Fig. 1A). However, oxidized PLPC produced the new fluorescence peak (FS-III) and the FS-I peak, but not FS-II. It could be inferred from these results that FS-I was formed from both oxidized ML and PLPC, but not from the degraded compounds produced from ML-HPO and PLPC-HPO by heme.

The fluorescent substances formed from both PLPC-HPO and oxidized PLPC were transmethylated with *m*-trifluoromethylphenyltrimethyl ammonium hydroxide in methanol solution according to the method previously described (9). After transmethylation, the FS-II peak appeared at a retention time of 8.5 min, but the FS-III peak disappeared (Fig. 2A). The appearance of the FS-II peak after transmethylation supports the possibility that the new major fluorescent substance (FS-III) is retained at the 2-position of glycerol backbone in PLPC.

Phospholipase A_2 preferentially hydrolyzes PUFA esters at the 2-position of phospholipids. Therefore, the possible role of phospholipase A_2 in the release of fluorescent substances formed from oxidized phospholipids also was examined in this study. When the fluorescent substances formed from PLPC-HPO were incubated with

TABLE 1

Fluorescence Formation from Oxidized PLPC or ML and their HPO with 1-AP

	heme	Excitation maximum (nm)	Emission maximum (nm)	Fluorescence intensity (%)
PLPC-HPO	−	348	418	21.6
	+	348	420	114.2
ML-HPO	−	348	418	28.0
	+	350	418	140.0
Oxidized PLPC	−	350	418	125.8
	+	350	420	226.0
Oxidized ML	−	348	418	147.3
	+	350	420	276.7

Both PLPC- and ML-HPO (100 nmol) were separately preincubated with or without heme (1 nmol) in 2 ml of methanol at 37°C for 30 min. One μmol of PLPC or ML oxidized with Fe^{++} and ascorbate also was preincubated with or without heme (1 nmol) under the same conditions. One ml of 1-AP (1 μmol) in methanol was added to the each preincubation mixture and then incubated at 37°C for 20 hr for fluorescence formation.

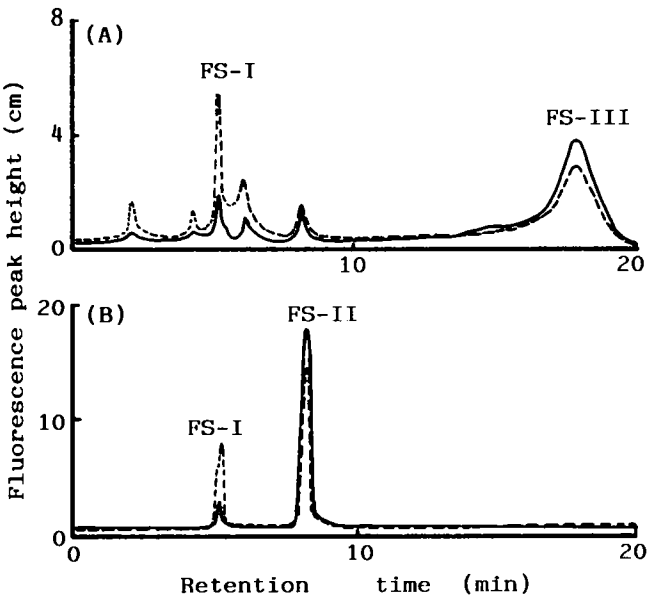

FIG. 1. HPLC of fluorescent substances formed from oxidized PLPC or ML and their HPO with 1-AP. Reverse-phase HPLC was performed on a μ-Bondapak FAA and elution was carried out with methanol/water (80:20 and 90:10) mixtures at a flow rate of 1 ml/min Aliquots of fluorescent solution formed from PLPC-HPO (A, ——), oxidized-PLPC (A, – – –), ML-HPO (B, ——) or oxidized-ML (B, – – –) with 1-AP in the presence of heme were subjected to HPLC using the methods described in Materials and Methods.

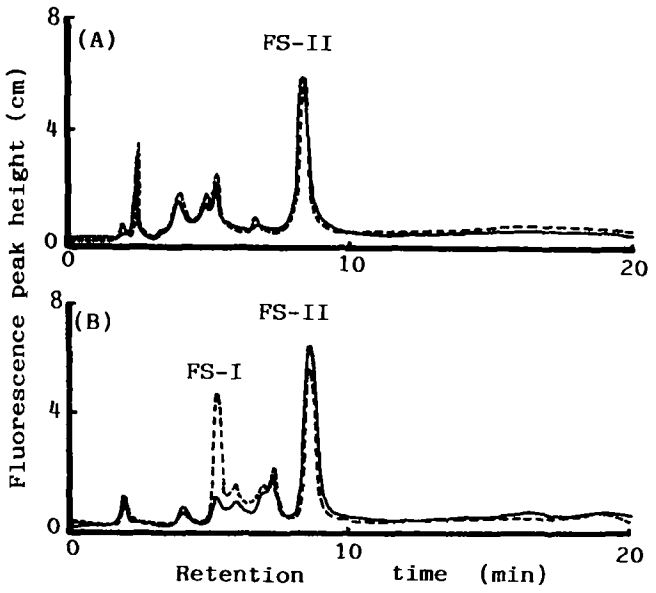

FIG. 2. HPLC of fluorescent substances formed from PLPC-HPO or oxidized PLPC with 1-AP after transmethylation and phospholipase A_2 hydrolysis. HPLC was performed as described in Fig. 1. Fluorescent substances formed from both PLPC-HPO (—) and oxidized PLPC (– – –) were transmethylated (A) or hydrolyzed with phospholipase A_2 (B) as described in Materials and Methods.

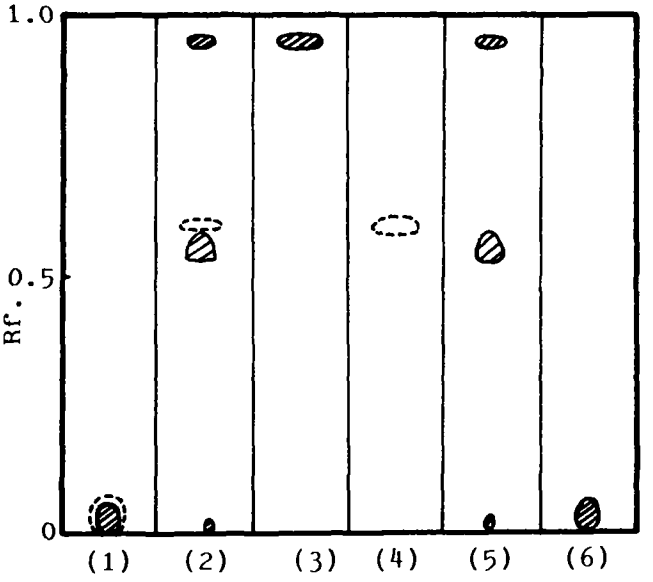

FIG. 3. TLC of fluorescent substances formed from ML-HPO or PLPC-HPO with 1-AP. Aliquots of fluorescent solution formed from PLPC-HPO were subjected to TLC before (1) and after (2) phospholipase A_2 hydrolysis. ML (3), fluorescent substances (4) formed from ML-HPO and PLPC incubated with (5) and without (6) phospholipase A_2 were also subjected to TLC. Fluorescent spots (broken oval) were detected by excitation at around 360 nm, while other spots (crosshatched oval) were detected under iodine vapor.

phospholipase A_2 and methylated with diazomethane, the FS-III peak disappeared completely and the FS-II peak appeared at a retention time of 8.5 min in HPLC (Fig. 2B). Similarly, the FS-III formed from oxidized PLPC also changed to the FS-II, following the same treatment as described above, but the FS-I peak was not influenced by hydrolysis with phospholipase A_2 and eluted at the same retention time.

A diagram of the TLC plates is shown in Figure 3. The fluorescent substance (FS-II) formed from ML-HPO showed an R_f of 0.60, and the FS-III spot formed from PLPC-HPO was detected at the origin. After treatment of FS-III with phospholipase A_2, the fluorescent substance was detected at the same R_f value (0.60) as that of FS-II.

When FS-I and FS-III formed from oxidized PLPC were collected by HPLC and separately incubated with phospholipase A_2, FS-III specifically produced FS-II and the level of FS-II released from hydrolysis of FS-III increased with greater phospholipase A_2 activity (Fig. 4), but FS-I did not appear to be influenced by phospholipase A_2.

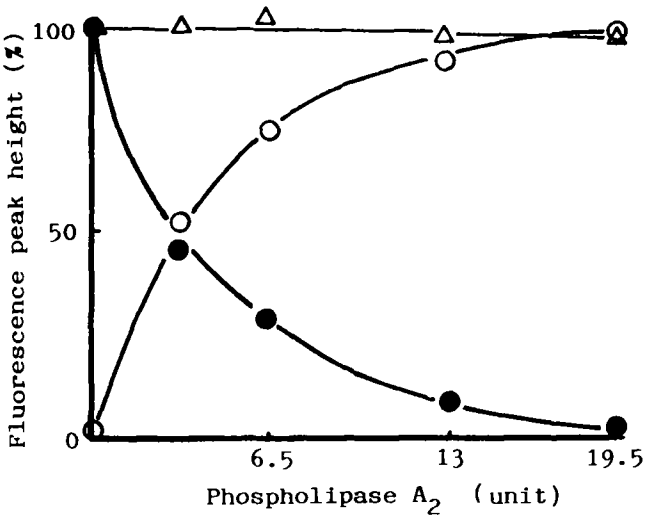

FIG. 4. Hydrolysis of FS-III with phospholipase A_2 and appearance of FS-II. FS-I and FS-III formed from oxidized PLPC with 1-AP were purified by HPLC. An aliquot of each fluorescent substance was hydrolyzed with phospholipase A_2 and methylated with diazomethane. After that, each fluorescence peak height of FS-I (△), FS-II (○) and FS-III (●) was measured on HPLC using the method as described in Materials and Methods. Fluorescence intensities were expressed as the percentage of a nontreated sample.

DISCUSSION

Fluorescent lipofuscin pigments associated with aging are believed to be formed from lipid peroxides with amino compounds in animal tissues (4,5). Although malondialdehyde reacts with amino compounds to form fluorescent substances in vitro (15,16), malondialdehyde has not yet been conclusively identified in biological tissues. Therefore, the role of malondialdehyde in the in vivo formation of lipofuscin pigments seems to have been exaggerated (4).

On the other hand, there are numerous reports that HPO are easily degraded by many types of catalysts such as metals, ascorbic acid or heme compounds (17–19), and that the degradative compounds produced are involved in the formation of fluorescent substances through reaction with amino compounds (1,2,20). For example,

through autoxidation, ML produces 9- and 13-positional monohydroperoxide isomers having the *cis-trans* and *trans-trans* configurations, and, in the presence of heme, all of them produce fluorescent substances with the excitation and emission maxima at 350 nm and 420 nm, respectively, by reaction with amino compound (6). Decomposition of monohydroperoxides of methyl linolenate forms dimeric or monomeric compounds and many kinds of volatile breakdown products including monoaldehydes such as propanal, 2-pentenal or 2,4-heptadienal (21). Although these monoaldehydes also produce fluorescent substances through reaction with amino compounds in vitro (22,23), Frankel et al. (24) have reported that monomeric compounds, other than these volatile aldehydes prepared from methyl linolenate HPO, produce a higher level of fluorescence. We also have demonstrated that secondary oxidation products prepared from autoxidized ML are directly involved in the formation of fluorescent substances (14).

PUFA in biological tissues are mainly localized in membrane phospholipids and are converted to HPO without release from their glycerol backbone (7,8). Miyazawa et al. (25) recently succeeded in confirming the presence of phosphatidylcholine HPO in normal human blood. These results seem to imply that phospholipid HPO are involved in the formation of fluorescent substances in biological tissues. As a model system, when PLPC-HPO was incubated with 1-AP after decomposition by heme, PLPC-HPO also produced a fluorescent substance having the same fluorescence spectrum as that obtained from ML-HPO, which was attached to PLPC without being released from its glycerol backbone (9). Nielsen (26) also reported that peroxidized cardiolipin produced a fluorescent substance through reaction with albumin. Moreover, Shimasaki et al. (27) have reported that the fluorescent substances formed from oxidized liposomes containing rat liver phosphatidylcholine and phosphatidylethanolamine remain in the liposome membranes. The results obtained in the present study also strongly suggest that peroxidized PUFA substituted at the 2-glycerol position in phospholipid are directly involved in the formation of fluorescent substances through reaction with amino compounds without hydrolysis.

It is well known that phospholipase A_2 release PUFA from the 2-glycerol position in membrane phospholipids. Moreover, it has been shown recently that membrane-associated phospholipase A_2 displayed significantly greater activity against acylated fatty acid peroxides in phospholipids (10-12). The elimination of peroxidized fatty acids from membrane phospholipids was shown to protect membranes from peroxidation damage, and then, phospholipase A_2 was necessary for the detoxification of the lipid peroxides (12). Moreover, Jung et al. (28) reported that phosphatidylcholine, oxygenated at the carbon-15 position of the arachidonic acid moiety by 15-lipoxygenase in human polymorphonuclear leukocytes, was hydrolyzed by phospholipase A_2 at a faster rate than nonoxygenated phosphatidylcholine. Ozawa et al. (29) also suggested that phospholipase A_2 played a key role in releasing leukotoxin in lung lavages from rats.

Based on these reports of the preferential hydrolysis of peroxidized phospholipids with phospholipase A_2, we now provide additional support for the concept of phospholipase A_2 having an important role in the regulation of fluorescent substances as they accumulate as end products of lipid peroxidation and cause membrane damage. As revealed by HPLC and shown in Figure 2B, FS-III attached to PLPC was hydrolyzed with phospholipase A_2 and released the resulting fluorescent substance at the same retention time (8.5 min) as that of FS-II formed from ML-HPO. These results suggest that the fluorescent substance (FS-III) formed from oxidized phospholipid is retained at the 2-glycerol position, and that the fluorescent moiety may be gradually released from phospholipid by hydrolysis with phospholipase A_2. On the other hand, FS-I formed from both oxidized ML and PLPC with 1-AP may be derived from breakdown products (e.g., reactive carbonyls) of linoleic acid by iron and ascorbate, because FS-I was not affected with phospholipase A_2.

Lipid peroxides are derived mainly from PUFA attached to phospholipids of biomembranes, and Palmer et al. (30) have reported that liver lipopigments in sheep contain substantial quantities of phospholipid and linoleate. This result also indicates that peroxidized phospholipids may be involved in the formation of fluorescent chromolipids in lipofuscin pigments. Moreover, it is suggested that, with aging, the accumulation of fluorescent lipofuscin pigments in biomembranes may be related to the changes occurring in peroxidized phospholipid content, and phospholipase A_2 may play a role in controlling the formation and accumulation of fluorescent lipofuscin pigments in animal tissues. Kuijk et al. (11) have discussed the novel role of phospholipase deficiency as a causal factor in degenerative diseases such as neuronal ceroid lipofuscinosis.

Arachidonic Acid Uptake by Phospholipids and Triacylglycerols of Rat Brain Subcellular Membranes

Teng-Nan Lin[a], Ronald MacQuarrie[b] and Grace Y. Sun[a,*]

[a]Sinclair Comparative Medicine Research Farm and Department of Biochemistry, University of Missouri, Columbia, MO 65203, and [b]School of Basic Life Sciences, University of Missouri-Kansas City, Kansas City, MO 64110

In the presence of ATP, $MgCl_2$ and CoASH, different subcellular membrane fractions isolated from rat cerebral cortex exhibited characteristic profiles for the incorporation of [1-^{14}C]arachidonic acid into phospholipids and triacylglycerols. In general, uptake of label by phosphatidylcholines was higher in the synaptic membranes, and that by phosphatidylinositols was higher in the microsomes and somal plasma membranes. A substantial amount of the labeled arachidonate was also incorporated into triacylglycerols, especially in the somal plasma membranes and microsomes. Enzymes mediating the transfer of arachidonic acid to phospholipids were unstable with respect to sample storage and exposure to elevated temperatures. In contrast, the acyltransferase for triacylglycerols was more stable to these factors. Washing the membranes with bovine serum albumin resulted in an enhancement of the incorporation of label into phosphatidylinositols without affecting that of phosphatidylcholines, but the incorporation into triacylglycerols was inhibited. Treatment of synaptosomes and plasma membranes with saponin resulted in an enhancement in the labeling of phospholipids, but the labeling of triacylglycerols was inhibited. Thus, although labeled arachidonic acid was incorporated into phospholipids and triacylglycerols in brain subcellular membranes, these two types of acyltransferases exhibited different properties and responded differently to membrane perturbing agents. *Lipids 23,* **942-947 (1988).**

Not only are the phospholipids in brain important in providing the structural stability of neuronal membranes, they also are actively engaged in metabolic activities essential for maintaining the proper functioning of the membranes. A characteristic feature of this metabolism is the presence of enzymes for the deacylation-reacylation of phosphoglycerides, through which acyl groups may be modified (1). In brain membranes, arachidonic acid is specifically involved in deacylation-reacylation activity (2), and active uptake by phosphatidylinositols (PI) and phosphatidylcholines (PC) has been reported (3). More recent studies have shown that each of these acyltransfer processes is catalyzed by a separate acyltransferase (4). There is also evidence that fatty acid ligase is present in most subcellular membranes in conjunction with acyltransferases, so that fatty acids can be effectively activated and transferred to the lysophospholipid within the same membrane domain (5).

Baker and Chang (6) reported that the uptake of fatty acids by triacylglycerols (TG) is a specially active process in neuronal nuclear membranes. Furthermore, the diacylglycerol (DG) acyltransferase in these membranes showed a high selectivity for arachidonoyl-CoA (7). In neuroblastoma cells, the active uptake of arachidonic acid by TG is regarded as an important cellular mechanism for conserving fatty acids in the culture medium for the biosynthesis of phospholipids (8,9).

Our previous studies with respect to arachidonic acid metabolism in brain subcellular membranes have been confined mainly to examining its incorporation into phospholipids (3,10,11). In view of the increasing attention to understanding the arachidonic acid metabolism among brain phospholipids as well as TG, the main objective for this study is to examine these transfer processes among different brain subcellular membrane fractions. In addition, some factors that may differentially alter the uptake of arachidonic acid by phospholipids and TG also are described.

MATERIALS AND METHODS

[1-^{14}C]Arachidonic acid (specific radioactivity 54.9 mCi/mmol) was purchased from New England Nuclear Corp. (Boston, MA). ATP, dithiothreitol, $MgCl_2$, saponin and bovine serum albumin (BSA) were obtained from Sigma Chemical Co. (St. Louis, MO). Organic solvents were high performance liquid chromatographic (HPLC) grade obtained either from Taylor Chemical Co. (St. Louis, MO) or Fisher Scientific (St. Louis, MO).

Animals and brain subcellular fractionation. Male Sprague-Dawley rats weighing 100-200 g were originally purchased from Taconics Farm, Inc. (Germantown, NY) and were maintained at the Sinclair Comparative Medicine Resarch Farm facilities until time of experiment. Rats were killed by decapitation, after which the cerebral cortices were quickly removed and homogenized in 20 vol of 0.32 M sucrose with 50 mM Tris-HCl (pH 7.4) and 1 mM EDTA. Brain tissue was homogenized in seven up-and-down strokes using a glass Potter-Evehjem type homogenizer with Teflon pestle.

Brain homogenate was subjected to a series of differential and sucrose gradient centrifugation steps, according to the recently improved procedure as described by Sun et al. (12). Part of this procedure had incorporated the method of Booth and Clark (13) for the separation of myelin, synaptosomes and mitochondria fractions by sucrose-Ficoll gradient centrifugation. Furthermore, the procedure also included the isolation of a somal plasma membrane (PM) fraction by centrifugation of the post-mitochondrial supernatant at 48,000 × *g* for 20 min. This membrane fraction has been extensively characterized and was found to contain marker enzymes different than microsomes and synaptic plasma membranes (SPM) (12). The final membrane pellets resulting from the fractionation procedure were suspended in 0.32 M sucrose with 50 mM Tris-HCl (pH 7.4). An aliquot of the suspension was routinely taken for protein determination, according

Abbreviations: BSA, bovine serum albumin; DG, diacylglycerol(s); PC, phosphatidylcholine(s); PI, phosphatidylinositol(s); PM, somal plasma membrane(s); SPM, synaptic plasma membrane(s); TG, triacylglycerol(s); HPLC, high performance liquid chromatograph(ic,y); TLC, thin layer chromatograph(ic,y).

to the procedure of Lowry et al. (14), using BSA as the standard.

Assay of arachidonate uptake activity. The incorporation of [1-^{14}C]arachidonic acid into membrane lipids was evaluated by incubation of membranes (200 μg protein) in the presence of [1-^{14}C]arachidonic acid (0.1 μCi), CoASH (0.1 mM), dithiothreitol (0.3 mM), ATP (2.5 mM), $MgCl_2$ (10 mM) and 50 mM Tris-HCl (pH 7.4) in a total volume of 1 ml. The incubation was carried out at 37°C for 10 min. Because this assay procedure was designed to examine the uptake of labeled arachidonic acid by various phospholipids and TG among different subcellular membrane fractions, no exogenous lysophospholipids or cold arachidonic acid was added to the incubation system.

Lipid extraction and analysis. The reaction was terminated by adding 4 vol of chloroform/methanol (2:1, v/v) followed by vigorous mixing and centrifugation to separate the aqueous and organic layers. The organic layer was removed and the upper phase was further extracted by 2 vol of chloroform/methanol/12 N HCl (4:1:0.013, v/v/v). The acidified organic extract was removed and neutralized with 4 N NH_4OH (1 drop) before combining with the first organic extract. After evaporation of the organic solvents under nitrogen, the samples were redissolved in chloroform/methanol (2:1, v/v) and kept at −20°C until further use.

Separation of phospholipids as well as neutral lipids was carried out by thin layer chromatography (TLC), as described by Sun (15). Initially, a portion of the lipid extract was spotted on 20 × 20 cm Silica Gel G TLC plates (250 μ thick, Analtech, Newark, DE). The solvent system for development of the TLC plates in the first dimension was chloroform/methanol/18 M NH_4OH (135:60:10, v/v/v). After development, the lipid area at the solvent front was removed and transferred to test tubes. The TLC plates were then exposed to concentrated HCl fumes for 3 min to hydrolyze the alkenylether bond of plasmalogens (16). After removing the excess HCl fumes from the plate, by blowing with an air gun, the TLC plates were developed in the second dimension with chloroform/methanol/acetone/acetic acid/0.1 M ammonium acetate (140:60:55:3.5:10, v/v/v/v/v). The lipid spots were visualized by exposing the TLC plates to iodine vapor. They were subsequently scraped and transferred to scintillation vials containing 10 ml of a toluene-base cocktail (Taylor Chemical Co.). Radioactivity was measured by a Beckman LS5800 scintillation spectrometer (Beckman Instrument, Inc., Fullerton, CA).

The neutral lipids from the solvent front area of the TLC plate were separated from the Silica Gel G by eluting with chloroform/methanol (5:1, v/v). The lipids were concentrated and applied to TLC plates that were developed in a solvent system containing hexane/diethylether/acetic acid (85:15:2, v/v/v). Because brain membranes contain very small amounts of these neutral lipids (except for cholesterol), appropriate standards were added in order to identify the lipid bands. Lipid bands were visualized through exposure to iodine vapor and were similarly transferred into scintillation vials for the counting of radioactivity.

RESULTS

Using the procedure described by Sun et al. (12), brain homogenate was fractionated into eight membrane fractions. The purity of these subcellular fractions has been assessed previously by assays of marker enzymes, analysis of their lipid profiles, as well as ultrastructural examination under electron microscope (12). In order to compare the extent of arachidonic acid transfer to various phospholipids and TG among the subcellular fractions, the protein concentration of each membrane fraction was adjusted to 2 mg/ml and 200 μg of protein was taken for each assay. When these subcellular membranes were

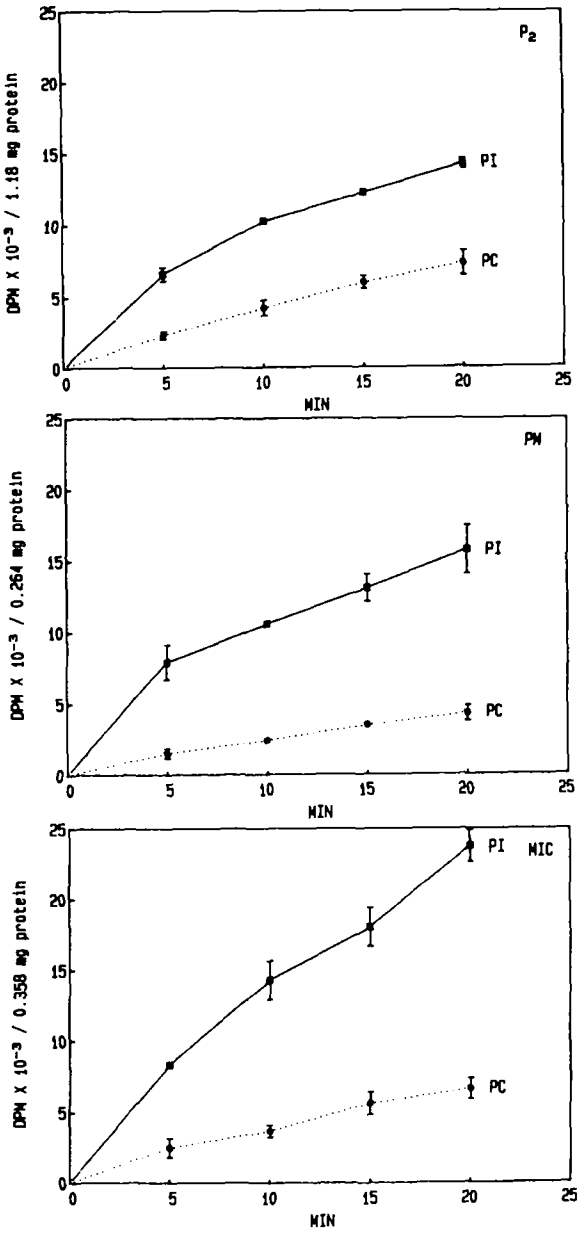

FIG. 1. Time course for the incorporation of [1-^{14}C]arachidonic acid into PI and PC of brain subcellular fractions. The incubation mixture contained: [1-^{14}C]arachidonic acid (0.1 μCi), ATP (2.5 mM), $MgCl_2$ (10 mM), CoASH (0.1 mM), membranes (protein indicated) and Tris-HCl buffer (pH 7.4) in a total volume of 1 ml. Incubation of samples was carried out in triplicates at 37°C for 10 min. The reactions were terminated by adding 4 vol of chloroform/methanol (2:1, v/v) and lipids were extracted as described in the text. Radioactivity of the lipids (DPM) is expressed as the means ± SD from triplicate determinations.

incubated with [1-^{14}C]arachidonic acid in the presence of ATP, $MgCl_2$ and CoASH, radioactivity was incorporated mainly into PI, PC and TG. Under this incubation condition, labeled arachidonic acid was most actively utilized by microsomes that corresponded to 35% within a 10 min incubation time. Examination of the uptake pattern with time indicated a steady increase in labeling of the phospholipids among all three subcellular fractions examined (Fig. 1).

Different subcellular membranes showed different profiles in the distribution of radioactivity among PC, PI and TG (Fig. 2). In this regard, the uptake of arachidonate by PC was enhanced in the synaptic fractions (i.e., synaptosomes, SPM and synaptic vesicles) and was very low in myelin (Fig. 2a). On the other hand, the uptake of arachidonate by PI was highest in microsomes followed by PM (Fig. 2b). Similar to the labeling of PI, the uptake by TG was highest in PM followed by microsomal fractions (Fig. 2c). These results indicate that brain subcellular membrane fractions are different in their ability to take up arachidonic acid.

Because a considerably high level of radioactivity was incorporated into the glycerolipids of PM, an experiment was carried out to examine the pH profile for these acyltransfer processes. As shown in Figure 3, the transfer of arachidonate to PC and PI showed a similar pH profile that was more active towards the alkaline pH range. On the other hand, the transfer to TG showed a more restricted pH profile with peak activity between 7 and 7.5.

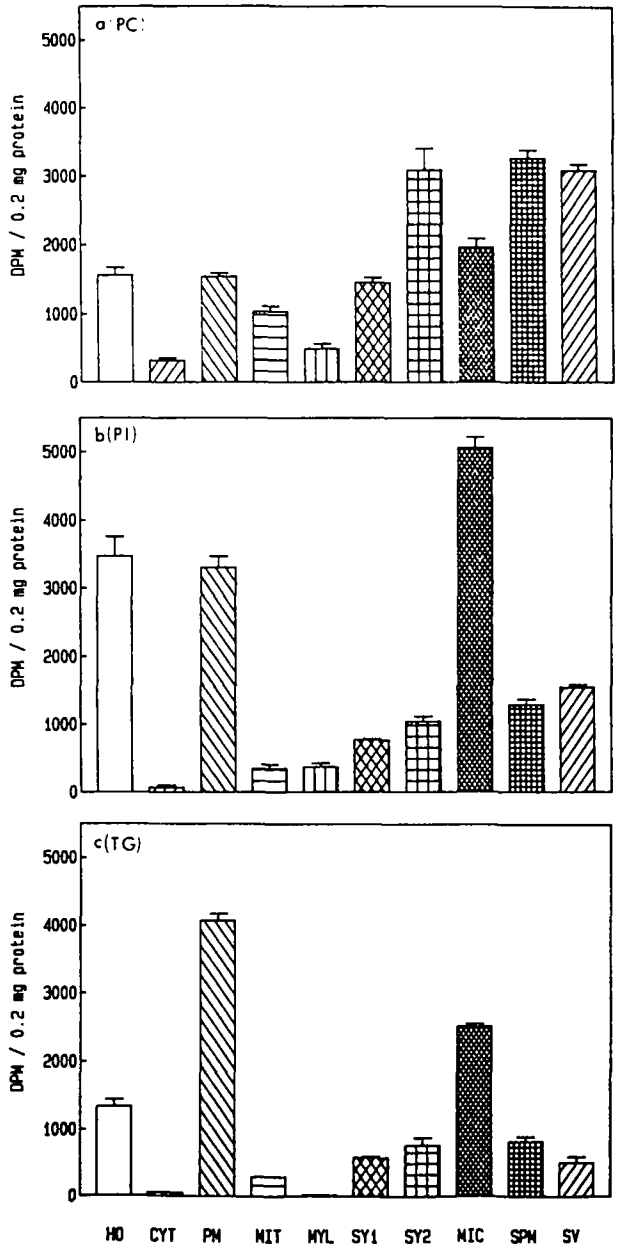

FIG. 2. A comparison of arachidonate uptake by PC (a), PI (b) and TG (c) among different brain subcellular fractions. Brain homogenate was subjected to the subcellular fractionation procedure as described by Sun et al. (12). Incubation of subcellular membranes was the same as described in Fig. 1, except that 0.2 mg of protein was used for each fraction and incubation was carried out at 37°C for 10 min. Radioactivity of the lipids (DPM) are expressed as means ± SD from triplicate determinations. Similar patterns were obtained in two different preparations. HO: homogenate. CYT: cytosol. MIT: mitochondria. MYL: myelin. SY1: intact synaptosomes. SY2: synaptosomes after shock. MIC: microsomes. SV: synaptic vesicles.

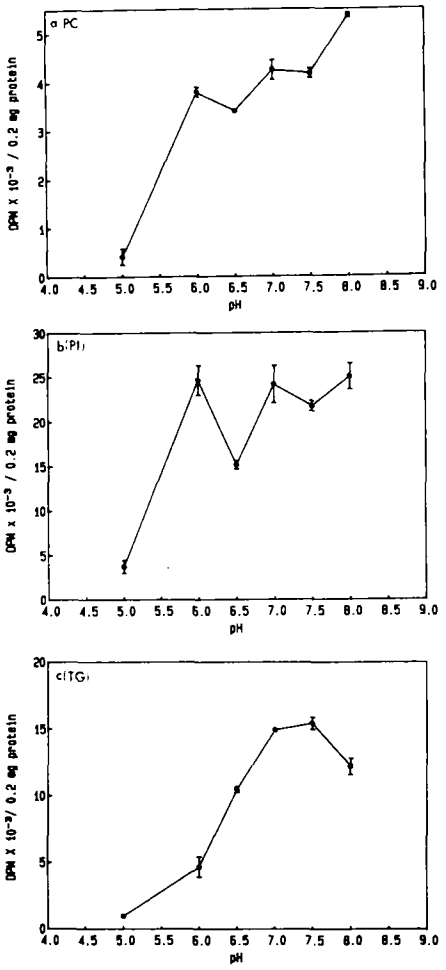

FIG. 3. The pH profile of arachidonate uptake by PC (a), PI (b) and TG (c) in PM fractions. The incubation procedure was the same as described in Fig. 1. Sodium acetate buffer was used for assays in the pH 5-6 range and Tris-HCl buffer was used for pH 7-8.

Results in Figure 4 show the effects of BSA (1 mg/ml) on labeling of the glycerolipids in PM. In agreement with the results from our previous study (10), BSA increased the labeling of PI without affecting that of PC. In addition, results here also show that BSA inhibited the transfer of labeled arachidonic acid to TG. In order to test for enzyme stability, PM were preincubated at 37°C for different time periods prior to assay of the arachidonate incorporation activity. The data in Figure 5 show a decline in labeling of both phospholipids on preincubation of membranes at 37°C. Furthermore, the decline in labeling of PI was more rapid than that of PC. In another study, PM were assayed for arachidonate uptake activity immediately after isolation (ca. 2 hr after homogenization of brain tissue) and after storage of sample at 4°C for 19 hr. Results indicated that the labeling of TG was not affected by sample storage although a substantial decrease in the labeling of phospholipids was observed (Fig. 6).

Because synaptosomes are pinched off nerve ending particles, the low acyltransferase activity in this fraction may be due to a limitation of ATP and CoASH to interact with enzymes present in the intrasynaptic sites. Frequently, saponin is used to facilitate permeability of cell plasma membranes by negatively charged compounds. Consequently, an experiment was designed to test whether pretreatment of synaptosomes with saponin (0.1%) would enhance the acyltransfer process. In addition, testing the effect of saponin with the PM fraction would allow us to discern whether its action on the acyltransferase is due to membrane permeability or due to its presence as a detergent. As shown in Figure 7, both subcellular fractions indicated an increase in arachidonoyl transfer activity to PI and PC after saponin treatment. On the other hand, saponin treatment resulted in a decrease in the labeling of TG.

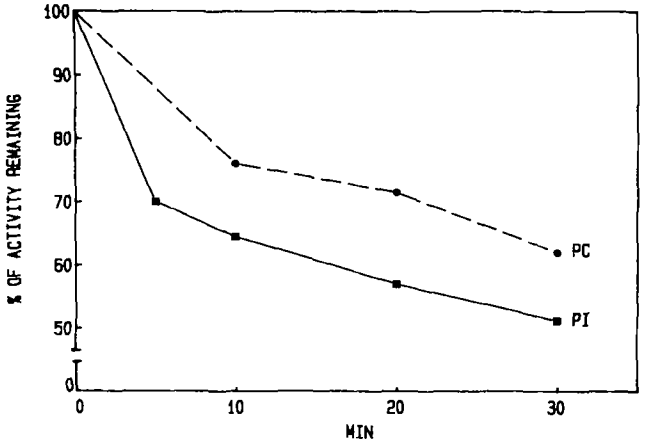

FIG. 4. The effect of BSA (1 mg/ml) on arachidonate incorporation into PM lipids. Conditions for incubation of PM was the same as that described in Fig. 1. Results are presented as the means ± SD from triplicate determinations.

DISCUSSION

In this study, we have taken advantage of our recently improved procedure for the isolation of brain subcellular fractions (12) to further investigate the ability of these membrane fractions to activate arachidonic acid and transfer it to various glycerolipids. With the exception of myelin, most membrane fractions were able to activate the arachidonic acid to its acyl-CoA in the presence of ATP, $MgCl_2$ and CoASH, and transfer the acyl-CoA to phospholipids and TG. In agreement with our earlier data (3), labeled arachidonic acid was preferentially transferred to PI and PC in most brain subcellular fractions. In addition, data from this study showed that arachidonic acid was also incorporated into TG. Because no exogenous lysophospholipids were added to the incubation mixture, it is reasonable to conclude that the uptake activity by different subcellular membranes reflects both activity of

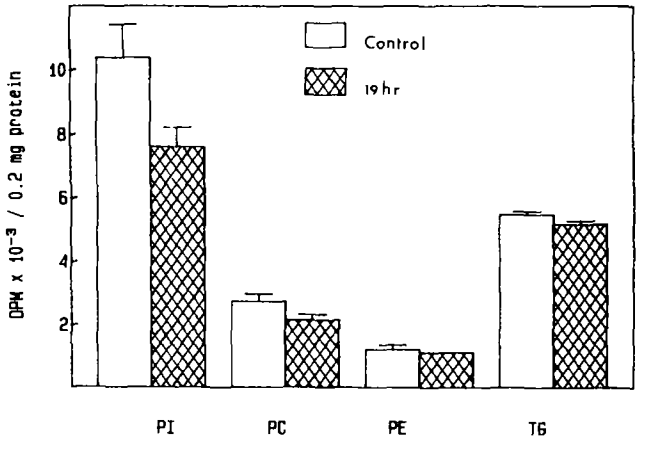

FIG. 5. Effect of preincubation on arachidonoyl transfer activity. Synaptosomes were preincubated at 37°C for the times specified, during which aliquots were taken for assay of the arachidonic acid uptake activity according to procedure described in Fig. 1. Values are the mean from triplicate determinations expressed as percentage of control.

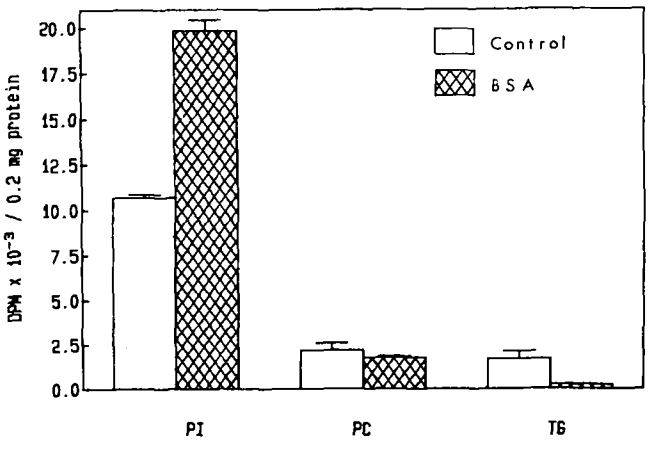

FIG. 6. The effect of sample storage on arachidonoyl transfer activity in the PM fraction. After isolation (ca. 2 hr), the PM fraction was suspended in buffer and placed in an ice bath for 0 and 19 hr. Aliquots were taken for measurement of the arachidonoyl transfer activity according to the procedure described in Fig. 1. Values are the mean ± SD of radioactivity in individual lipids obtained from triplicate determinations.

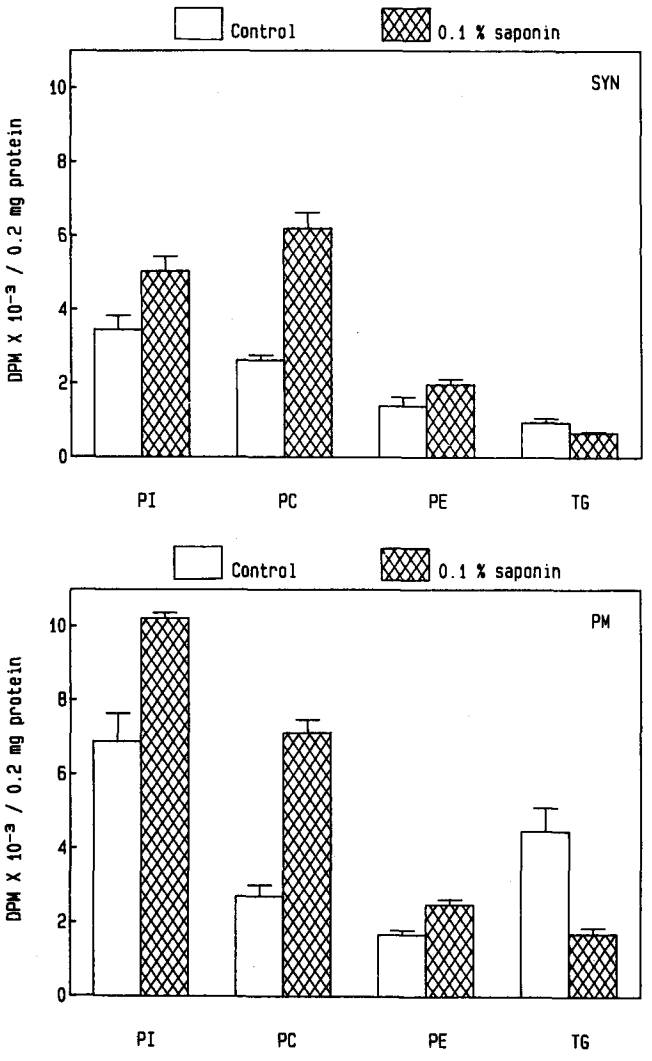

FIG. 7. The effect of saponin (0.1%) pretreatment on arachidonate incorporation into phospholipids and TG in synaptosomes and PM. Incubation condition was the same as described in Fig. 1, except that saponin was added to membranes prior to assay of the uptake activity. Values are the mean ± SD of radioactivity in PC, PI and TG obtained from triplicate determinations.

the acyltransferases and the level of endogenous lysophospholipids and DG in the membrane.

Different subcellular membrane fractions exhibit different uptake profiles for the transfer of arachidonic acid to PI, PC and TG. Of special interest is the active transfer of arachidonoyl group to PI and TG in PM and the differences in the labeling of phospholipids and TG between PM and SPM. Since the PM fraction is likely to include a large portion of plasma membranes from glial cells, it is tempting to conclude that the synthesis of TG through DG acyltransferase may be a characteristic property of glial plasma membranes. This process may be important in transporting and remodeling the TG from blood prior to entering the brain cells.

It is well recognized that the fatty acid profile of TG in brain is quite different from that in blood plasma. Fatty acids of TG in brain are enriched with C20:4 and C22:6, but lacking the C18:2 (17,18), whereas the TG in blood are high in C18:2, but contain little C20:4 and C22:6. Although TG in brain is maintained at a very low level, its unique acyl group profile suggests that the molecules must be engaged in some specific functions in brain. In addition to the PM fraction, high DG acyltransferase activity was also reported in neuronal nuclei membranes (6,7). In cultured neuroblastoma and glioma cells, labeled fatty acids added to the culture medium are readily taken up by phospholipids as well as TG (8,9). There is further evidence that the active uptake of fatty acids by TG in these cells is important for consolidating fatty acids for phospholipid biosynthesis.

The PI in brain is enriched in stearic and arachidonic acids (18), and this acyl group profile is probably attained through an active deacylation-reacylation mechanism (1). This modification is probably most active in microsomes and PM. Because most previous studies on this acyltransfer process were carried out with the crude microsomal fraction in which PM were included, information regarding the ability of PM to remodel phospholipids through the deacylation-reacylation mechanism has not been well substantiated. In a recent study with cultured neuroblastoma cells, plasma membranes isolated from these cells also showed the ability to remodel phospholipids through the deacylation-reacylation cycle as well as the de novo mechanism (19).

It is interesting to find that labeled arachidonate was more actively incorporated into PC than PI in the synaptic membrane fractions (SPM and synaptic vesicles). The exact physiological significance for this labeling pattern is not known. It is possible that these membranes contain a higher endogenous level of lysophosphatidylcholines that resulted in greater acylation to PC. Because these membranes have limited ability to synthesize phospholipids through the de novo route, it is not surprising that an active deacylation-reacylation mechanism is present in these membranes for generation of a metabolically active PC pool for synaptic function.

Ahtough acyltransferases are, in general, sensitive to membrane perturbing agents (11), uptake of arachidonate by membrane phospholipids and TG is also dependent on other factors such as the endogenous free arachidonate levels, acyl-CoA ligase activity and the acyl acceptor levels. Results here indicate that uptake of labeled arachidonate by phospholipids and TG in brain subcellular membranes is affected due to sample storage, exposure to elevated temperature and the effects of BSA and saponin. This type of variance has been well-discussed by Baker and Chang (20) as additional factors, such as the use of pH buffers and exogenous fatty acids, may also affect the acyl-transfer activity. However, because incubation of subcellular membranes in this study was carried out in a well-defined condition using the same buffer, these factors would not have affected the comparison of acylation profiles exhibited by these membranes. The effect of saponin on enhancing the acyltransfer to phospholipids and inhibiting the transfer to TG, again indicates that these two types of acyltransferases have different properties. The fact that both synaptosomes and plasma membranes respond similarly to saponin further suggests that along with its membrane permeability properties, this compound also alters the membrane microenvironment resulting in a change in acyltransferase activity.

The comparative effects of high-fat diets (20%, w/w) on eicosanoid synthesis during mammary tumor promotion in 7,12-dimethylbenz(a)anthracene (DMBA)-induced rats were studied using diets containing 20% primrose oil (PO), 20% menhaden oil (MO) or 20% corn oil (CO). Sprague-Dawley rats fed the PO or MO diet had 21% or 24% fewer adenocarcinomas, respectively, than rats fed the CO diet. Histologically (i.e., mitotic figures, inflammatory cell infiltration and necrosis), the CO-fed rats exhibited the highest frequency of changes within tumors. Plasma fatty acid composition was significantly altered by diet, reflecting the composition of the oils which were being fed. Only the plasma of PO-fed rats contained detectable levels of gamma-linolenic acid (GLA). Arachidonic acid (AA) levels were significantly higher ($p < 0.05$) in PO-fed than in CO- or MO-fed rats. MO-fed rats had significantly higher levels of plasma palmitic acid, while palmitoleic, eicosapentaenoic (EPA) and docosahexaenoic (DHA) acids were detected only in MO-fed rats. As expected, linoleic acid (LA) and AA levels were lower ($p < 0.05$) in the MO-fed rats than in PO- or CO-fed groups. The plasma of the CO-fed rats contained significantly higher levels of oleic acid. Eicosanoid synthesis in mammary carcinomas of rats fed the 20%-fat diets was 2–10 times higher than in mammary fat pads of control rats. The synthesis of PGE_1 and LTB_4 was significantly ($p < 0.05$) higher in PO-fed rats than in CO-fed or MO-fed rats, although PGE values were significantly ($p < 0.05$) higher in CO-fed rats than in MO or PO groups. The synthesis of eicosanoids in both mammary fat pads and mammary carcinomas of MO-fed rats was lower ($p < 0.05$) than in tissues of rats fed either CO or PO diets due to less AA precursor being fed and/or to competition between n-6 and n-3 fatty acids for cyclooxygenase and lipoxygenase. The ratios of monoenoic to dienoic eicosanoids in both mammary fat pads and mammary carcinomas were higher in the PO group than in the MO or CO groups. These results suggest that inclusion of GLA (PO feeding) or EPA and DHA (MO feeding) in the diet may decrease malignancy by altering eicosanoid profiles.

***Lipids 23,* 948–954 (1988).**

The development of carcinogen-induced, spontaneous and transplantable mammary tumors is enhanced by the ingestion of diets containing elevated levels of polyunsaturated fats, especially *cis*-linoleic acid (1–4). Laboratory evidence suggests that the major influence of diets rich in polyunsaturated fat occurs during the promotional phases of chemically induced carcinogenesis. However, the exact mode of action for these effects has not been established. It has been suggested that the effect of dietary fat could be mediated by a change in the host defense system. One mechanism by which this could occur is via an increased synthesis of dienoic eicosanoids, i.e., PGE_2 (5). Vegetable oils such as corn oil (CO) or primrose oil (PO) contain high levels of linoleic acid (LA) (18:2n-6), the precursor of arachidonic acid (AA) (20:4n-6) and ultimately of the dienoic eicosanoids (prostaglandins and thromboxane) and tetraene leukotrienes. Moreover, some inhibitors of prostaglandin synthesis have been shown to prevent the growth-promoting effect of dietary polyunsaturated fatty acids on 7,12-dimethylbenz(a)anthracene (DMBA)-induced mammary tumorigenesis in rats (6).

Eicosapentaenoic acid (EPA) (20:5n-3), found in most fish oils and marine lipids, is the precursor of trienoic eicosanoids (prostaglandins and thromboxane) and pentaene leukotrienes. The EPA structure is similar to arachidonic acid (AA), except for one additional double bond at the 3-position relative to the terminal methyl of the chain. EPA has been shown to competitively inhibit AA metabolism by cyclooxygenase and lipoxygenase and give rise to its own products, some of which have attenuated activity (7).

A number of recent reports (8–11) have indicated that 20% or 10% menhaden oil (MO)-supplemented diets containing 0.34% or 0.09% LA, respectively, reduced tumor incidence and growth in the pancreas and mammary glands. Braden and Carroll (12) showed decreased DMBA-mammary tumor incidence and an increased tumor latency in rats fed 20% and 10% MO diets containing 0.4% and 0.2% LA, respectively, compared with rats fed either a 20% (11.2% LA) or a 10% (5.6% LA) corn oil diet. It has been suggested (13,14) that diets containing high levels of n-3 fatty acids should contain additional essential fatty acid (EFA) because the n-3 and n-6 fatty acids compete for the same enzymes, therefore requiring a higher EFA intake.

Primrose oil, in addition to 75% LA, contains 9% gamma-linolenic acid (GLA) (18:3n-6) that is rapidly converted to dihomogamma-linolenic acid (DGLA) (20:3n-6), the precursor of monoenoic eicosanoids. Data from our laboratory (15) and from others (16,17) have shown that a PO diet inhibits the growth of mammary adenocarcinomas in rats. Changing the ratio of DGLA/AA to shift eicosanoid synthesis toward monoenoic eicosanoids has been suggested as a mechanism for that inhibition (15).

This study was conducted to determine the effect of diets containing 20% PO, 20% MO or 20% CO on

eicosanoid synthesis during tumor promotion in DMBA-induced mammary carcinomas, as well as in mammary fat pads of control rats.

MATERIAL AND METHODS

Diets, feeding and tumor induction. Female Sprague-Dawley rats, 40 days old, were purchased from Harlan (Madison, WI). All animals were housed in suspended metal cages in a temperature-regulated (23 ± 0.5°C) and light-controlled (12 hr light and 12 hr dark) room and were fed standard rat chow (Ralston Purina Co., St. Louis, MO). At 50 days of age, each rat was given a single intragastric 10 mg dose of DMBA (Sigma Chemical Company, St. Louis, MO) in 0.5 ml corn oil. Sham-treated rats received 0.5 ml corn oil. After DMBA administration, the animals were placed in 10 × 16-inch plastic cages on Absorb Dri litter and housed two per cage for the duration of the experiment. At 21 days post-DMBA administration, the rats were randomly divided into three groups of 26 rats each and fed diets containing either 20% CO, PO or MO. Sham-control rats were divided into three groups of 10 rats each and fed the same diets.

Ten- or 20-kg batches of the 20%-fat diets were prepared by ICN Nutritional Biochemical (Cleveland, OH), cold pressed into jumbo pellets and sealed under nitrogen. The diets were shipped second-day delivery by United Parcel Service at two-week intervals. Upon arrival, 1-kg bags of pellets were placed in Seal-N-Save bags, flushed with nitrogen, sealed and stored frozen at −20°C until used. Measured amounts of frozen diet were placed in the rat-cage food dispenser each morning. Uneaten pellets were discarded. The formulation of the diet was based on the AIN 76 semipurified rat diet and has been reported previously (15). Alpha-tocopherol was added with the AIN vitamin mix so that each diet contained 110 IU of vitamin E/kg of diet. All diets were isocaloric and contained the recommended level of nutrients with a constant amount per kilocalorie of casein, fat, carbohydrate, salts, vitamins and fiber. The fatty acid composition of the oils in the diets is given in Table 1. The 20%-CO or PO diet contained 12% (LA) or 16.8% (LA + GLA) EFA, respectively. The 20%-MO diet contained 0.8% EFA (1.81% LA plus 2.3% AA). The National Research Council (18) recommends, for maximum growth in the male rat, the level of EFA should be 0.6% of the diet and, in the female rat, the level of EFA should be 0.22% of the diet. However, when the diet contains high levels of n-3 fatty acids, the EFA requirement may be higher due to competition of n-6 and n-3 fatty acids for the same enzymes (13,14). The primrose oil was provided by Dr. David Horrobin of the Enfamol Research Institute (Kentville, Nova Scotia) and the menhaden oil by Dr. Tony Bimbo (Zapata Haynie Corp., Reedville, VA). The corn oil was purchased from Seaway Foods, Inc. (Cleveland, OH).

The rats were weighed weekly and palpated for the presence of tumors. The size and location of each tumor was noted. One rat fed CO and one rat fed MO were found dead before termination of the experiment. At 16 weeks post-DMBA, all surviving rats were killed using CO_2 gas and weighed, had blood drawn from the heart and then, the weight of the livers was recorded. The tumors were counted, location was noted and then, they were excised and weighed. Sections of each tumor were quickly frozen on dry ice and stored at −80°C for eicosanoid analysis. Two sections from each tumor were placed in 10% buffered formalin for histological examination. The blood was centrifuged at 2,000 rpm and the plasma stored briefly at 4°C.

[a]The corn oil analysis was provided by ICN Nutritional Biochemical, Cleveland, OH.

[b]The primrose oil analysis was provided by Efamol Research Corp., Kentville, Nova Scotia, Canada.

[c]The menhaden oil analysis was provided by Zapata Haynie Corp., Reedville, VA.

Lipid profiles. Total plasma lipids were extracted in chloroform/methanol (2:1), after the method of Folch et al. (19). Methyl esters of fatty acids were prepared with boron trifluoride, as described by Morrison and Smith (20). These procedures have been described in detail by Abou-El-Ela et al. (15).

The fatty acid methyl esters were analyzed using a Hewlett-Packard Model 402 gas chromatograph equipped with a flame ionization detector and connected to a Spectra-Physics Model 4270 recording integrator. Chromatography was performed on a 6 ft × 2 mm glass column containing 10% SP-2330 on 100/120 chromosorb W AW (Supelco Inc., Bellefonte, PA).

Eicosanoid analyses. Malignant mammary tumors from DMBA-treated rats and fat pads of control animals were finely minced and an appropriate tissue aliquot was incubated in 1 ml ice-cold Krebs buffer (containing 2.4 M NaCl, 0.1 M KCl, 0.01 M $MgSO_4$, 0.06 M $CaCl_2$, 0.02 M KH_2PO_4, 0.03 M $NaHCO_3$ and 0.01 M dextrose, pH 7.4) for 1 hr at 37°C under 95% O_2/5% CO_2. The reaction was stopped by acidification to pH 3 with 0.8 M phosphoric acid and the tissue-buffer mixture was extracted once with 4 volumes of ethyl acetate by vigorous shaking (21). The organic phase was removed, and 50 μl of 0.1 M Tris-HCl buffer (pH 7.4) was added. The organic phase was evaporated under nitrogen, and the residue was stored, sealed under nitrogen at −80°C. The samples were appropriately diluted in assay buffer and the stable metabolites of prostacyclin; 6-keto-$PGF_{1\alpha}$ of prostaglandin E;

bicyclic PGE and LTB_4 were analyzed by radioimmunoassay (RIA) using kits purchased from Amersham Corp. (Arlington Heights, IL). The sensitivities of these kits are 12.5, 43 and 14 pg for LTB_4, PGE, and 6-keto-$F_{1\alpha}$, respectively. The PGE_2 antibody from Amersham showed 100% cross-reactivity with PGE_1; thus, PGE_2 is designated as PGE, indicating that both PGE_2 and PGE_1 were assayed in the tissue extracts when the Amersham PGE_2 kit was used. RIA kits for PGE_1 were purchased from Chemical Assays Labs (Cambridge, MA). The lowest detectable level of PGE_1 is 8 pg. PGE_1 antibody cross-reactivity with PGE_2 was 31%. Eicosanoid values are expressed as ng of eicosanoid synthesized per gram of tissue per hour.

Histopathology. A complete necropsy examination was performed on each rat and gross lesions were evaluated. Mammary tumors were fixed in 10% buffered formalin, embedded in paraffin, sectioned at 6 microns and stained with hematoxylin and eosin. Each tumor was described histologically and a diagnosis of each tumor was ascertained, according to the criteria of van Zwieten (22). Histologic descriptions included notations of necrosis, inflammation and anaplasia, and when possible, the invasive or noninvasive nature of the tumor was given.

Statistical analysis. Statistical differences in tissue eicosanoid levels, plasma lipids, body and liver weights and tumor latency were determined by one-way analysis of variance at 0.05 level of significance. Among groups, comparison of tumor burden per tumor-bearing rat involved one-way analysis of variance following square root transformation.

RESULTS

Effect of 20% PO, CO and MO diets on mammary tumorigenesis. Although the number of rats with tumors was similar in the animals fed the three different diets (Table 2), the histopathological data indicate that there was an effect of fat type on the malignancy of those tumors (Table 3). Rats receiving the 20%-PO diet had 21% fewer malignant tumors (64 tumors in 26 rats compared with 78 tumors in 25 rats for CO), and rats fed 20%-MO had 24% fewer malignant tumors (59 tumors in 25 rats compared with 78 for CO) than rats fed the 20%-CO diet. The latent period for tumor development (calculated by averaging the week of tumor appearance for all palpable tumors within a group) was significantly longer ($p < 0.05$) and tumor burden per tumor-bearing rat was significantly ($p < 0.05$) lower in rats fed the PO diet compared with CO-fed rats (Table 2). In the other histopathological parameters measured (mitotic figures, inflammatory cell infiltration and necrosis), the 20%-CO-fed rats exhibited the highest frequency of these changes within tumors (Table 3). The classification of tumors revealed similar diagnoses in all groups.

The animals were thoroughly examined at necropsy; there were no gross signs of EFA deficiency, i.e., hair loss, scaly skin, necrosis of the tail or low body weight.

TABLE 2

The Effect of Feeding 20%-CO, PO or MO Diets On Mammary Tumorigenesis Induced by DMBA

Diet	No. of surviving rats	No. of rats with tumors	Total no. of tumors[a]	Total no. of malignant tumors	Latent period[b] (wks)	Tumor burden/ tumor bearing rat[b] (g)
20% PO	26	21	68	64	10.6 ± 0.5[c]	2.0 ± 0.33[c]
20% CO	25	22	83	78	9.3 ± 0.3[d]	3.2 ± 0.40[d]
20% MO	25	21	64	59	10.1 ± 2.3[c,d]	2.3 ± 0.42[c,d]

[a]These values include both malignant and benign tumors.

[b]Values are mean ± SEM.

[c,d]Means which are significantly different ($p < 0.05$) are followed by a different superscript.

TABLE 3

Histopathological Classification of DMBA-induced Mammary Tumors in Rats Fed 20%-CO, PO, or MO Diets and Killed at 16 Weeks Post-DMBA

	Diagnosis of tumors[a] (number of tumors)					Number of tumors with mitotic figures (avg/hpf)		Tumors with stromal inflammatory cell infiltration	Number of tumors with necrosis
Diet	TPC	CTC	TA	FA	AL	<3	3 to 5+		
20% PO (26[b])	59	5	3	1	0	61	7	62	6
20% CO (25)	75	3	4	1	0	67	16	80	8
20% MO (25)	57	2	3	1	1	57	7	59	2

[a]Malignant tumors = Tubulopapillary carcinoma (TPC) and compact tubular carcinoma (CTC). Benign tumors = Tubular adenoma (TA), fibroadenoma (FA) and adenolipoma (AL).

[b]No. in ( ) = no. of rats/diet group.

Although the EFA content of the PO diet was higher than that of the CO diet, the body weights (Table 4) of PO-fed rats were significantly ($p < 0.05$) lower than those fed CO or MO diets. The liver weights of the MO-fed rats were significantly higher than those of the CO- or PO-fed rats. Therefore, liver to body weight ratios for the MO-fed rats were significantly higher than those for CO-fed rats (TAble 4). In a separate study on these animals (23), we reported that feeding a 20%-MO diet induces liver mixed function oxidases and glutathione-S-transferase.

Effect of 20% PO, CO or MO on eicosanoid synthesis in mammary fat pads of control rats and mammary tumors of DMBA-treated rats. In sham-treated animals, synthesis of PGE_1 and LTB_4 (ng/g wet wt/hr) in mammary fat pads was significantly ($p < 0.05$) higher in PO-fed rats (Table 5) than in MO- or CO-fed rats. Although PGE was significantly ($p < 0.05$) higher in CO-fed animals than in MO or CO groups, eicosanoid synthesis (PGE, 6-keto-$PGF_{1\alpha}$ and LTB_4) was significantly lower ($p < 0.05$) in MO-fed rats. Even though eicosanoid profiles in the mammary fat pads followed the same trends as the profiles in the malignant mammary tumors, rates of synthesis of all eicosanoids were 2–10 times higher in mammary tumors than in mammary fat pads of control animals (Table 5). However, the ratios of PGE_1/PGE, PGE_1/6-keto-$PGF_{1\alpha}$, as well as PGE_1/LTB_4, which were elevated in rats fed the PO diet, were similar in both control and DMBA-treated animals. In mammary tumors, PGE and 6-keto-$F_{1\alpha}$ synthesis rates were significantly ($p < 0.05$) higher in tumors of CO-fed rats than in tumors of PO- or MO-fed rats, and PGE_1 values were significantly ($p < 0.05$) higher in PO-fed rats. PGE_1, PGE, 6-keto-$PGF_{1\alpha}$ and LTB_4 synthesis rates were lower in MO-fed rats than in CO or PO groups.

Effect of dietary fat on plasma fatty acid profile of control and tumor-bearing rats. The plasma fatty acid profile of control and tumor-bearing rats (Table 6) indicated that the quantitative and qualitative differences in the dietary fatty acid content of PO, CO and MO produced relatively selective alterations in the fatty acid content of the plasma that reflected the diet being fed. The plasma levels of palmitic acid (16:0) were elevated significantly ($p < 0.05$) in rats fed the MO diet and reduced in rats fed PO, relative to levels in rats fed CO for both DMBA-treated and control animals. Palmitoleic acid (16:1) was detected only in the plasma of MO-fed animals, and stearic acid (18:0) was high in the plasma of PO-fed control animals. Oleic acid (18:1) was significantly ($p < 0.05$) higher in the CO-fed, lowest in PO-fed and intermediate in MO-fed animals. As expected, plasma LA concentrations from rats fed PO and CO diets were significantly ($p < 0.05$) higher than that of rats fed the MO diet. GLA and AA levels were significantly ($p < 0.05$) higher in rats fed PO compared with those fed CO or MO. On the other hand, EPA and DHA (22:6n-3) levels were detectable only in MO-fed rats.

TABLE 4

The Effect of Diet on Body and Liver Weights in Tumor-Bearing Rats

Diet	Final body weight[a] (g)	Liver weight[a] (g)	Liver/body weight Ratio (%)
PO	258.8 ± 2.81[b]	10.58 ± 0.28[b]	4.1 ± 0.09[b,c]
CO	275.5 ± 5.73[c]	10.68 ± 0.40[b]	3.9 ± 0.14[b]
MO	281.8 ± 3.6[c]	12.8 ± 0.48[c]	4.5 ± 0.2[c]

[a]Values are mean ± SEM.

[b,c]Means which are significantly different are followed by a different superscript ($p < 0.05$).

DISCUSSION

Although tumor incidence was similar in rats fed the MO, PO and CO diets, the number of malignant tumors was reduced by 24% and 21% in the MO- and PO-fed rats, respectively, compared with malignant tumors recovered from rats fed the 20%-CO diet. Moreover, the frequency of mitosis and the extent of necrosis and inflammation within tumors were higher in CO-fed rats compared with

[a] Values are expressed as mean ± SEM (n = 10).

[b,c,d] Means which are significantly different are followed by a different superscript ($p < 0.05$). Control values were compared with other controls, and values from tumor-bearing rats were compared with values from other tumor-bearing rats.

ND, Not detected.

MO- or PO-fed rats. These changes denote a more rapid tumor growth and a greater, although altered, immunologic reactivity than was present in tumors from PO- or MO-fed rats. Feeding a 20%-PO diet significantly extended tumor latency and reduced tumor burden compared with feeding the 20%-CO diet. Although tumor incidence was unchanged with any of the three diets in this study, in a previous study in our laboratory (15), rats fed a 20%-PO diet had significantly decreased incidence of DMBA-induced mammary tumors compared with those fed a 20%-CO diet. Ip et al. (2) showed that mammary tumorigenesis was very sensitive to linoleate intake and increased proportionately in the range of 0.5% to 4.4% of dietary linoletate. The 20%-MO diet contained 0.8% EFA, and the 20%-CO or PO diets contained 12% or 16.8% EFA, respectively. The 20%-PO diet contained 4.8% more EFA than the CO diet, yet rats fed PO diet had 21% fewer malignant tumors, longer latency and reduced tumor burden. On the other hand, the 20%-MO diet with 0.8% EFA had 24% fewer malignant tumors than CO-fed rats. Karmali (24) showed that MO provides greater inhibition of tumorigenesis, when up to 8% CO is present in the diet. In a recent study in our laboratory (unpublished data), when a combination of 15% MO and 5% CO (3.62% EFA) was fed to the rats, mammary tumor incidence was reduced by 27% and the number of malignant tumors was reduced by 37% compared with results from rats fed a 20%-CO diet. It is important to note that the n-3/n-6 fatty acid ratio for 15%-MO + 5%-CO diet was 1.2, but the n-3/n-6 ratio in the 20%-MO diet was 7.0. Thus, it appears from our data and others (24) that optimal dietary ratios of n-3/n-6 fatty acids must be maintained to obtain significant inhibition of tumorigenesis by omega-3 fatty acids. Moreover, it seems possible that tumor promotion and malignancy can be reduced by manipulation of both the types and levels of dietary polyunsaturated fatty acids, even in the presence of relatively high linoleate levels.

Dietary fat can play a major role in eicosanoid production and in modulation of the immune system (25). The n-3 fatty acids of MO appear to inhibit both cyclooxygenase and lipoxygenase (7), although PO enhances monoenoic eicosanoid synthesis by bypassing delta-6 desaturase (D6D), the rate-limiting enzyme for the synthesis of DGLA to 1-series PG (Fig. 1). By feeding three kinds of high-fat diet, we have been able to manipulate eicosanoid production that appears to alter tumorigenesis. Feeding a diet containing 20% CO results in high levels of dienoic eicosanoids, but feeding a 20%-MO diet depresses eicosanoid synthesis either by inhibiting both cyclooxygenase and lipoxygenase or because less AA precursor is being fed in the diet. The feeding of PO depressed dienoic eicosanoid synthesis and enhanced monoenoic eicosanoids and leukotriene synthesis compared with CO feeding. Furthermore, the ratios of monoenoic to dienoic eicosanoids or 4-series leukotrienes (PGE_1/PGE, PGE_1/6-keto-$PGE_{1\alpha}$, PGE_1/LTB_4) were increased by feeding PO. This may account for the reduction in malignancy that seemed to accompany the feeding of PO. Honn et al. (26,27) have hypothesized that selective manipulation of the AA cascade could be used to control tumor promotion and metastasis. Furthermore, they postulated that eicosanoid ratios, rather than absolute values of eicosanoids, determine cellular events in promotion and metastasis.

PGE_2 has been shown to induce suppressor T-cell proliferation, activation of natural killer cells and production of lymphokines (28). When released extracellularly, products of both lipoxygenase and cyclooxygenase pathways are postulated to contribute to development of the inflammatory response (28). Although LTB_4 and PGE_2 may act synergistically to increase vascular permeability, LTB_4 and prostaglandins may exert opposing effects on neutrophil function. In stimulated neutrophils, PGE_2, PGE_1 and 6-keto-$PGF_{1\alpha}$ effectively inhibit adherence, aggregation, calcium mobilization, superoxide generation and lysosomal enzyme release (25). Because

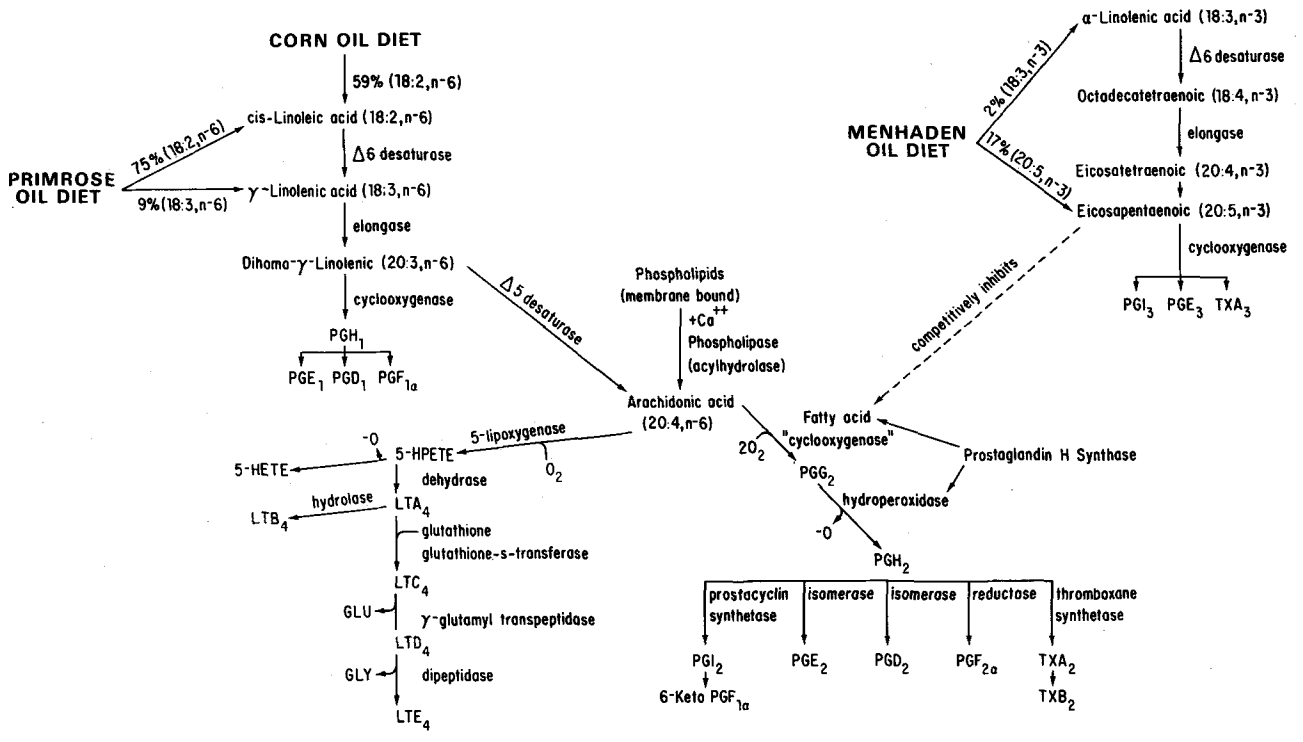

FIG. 1. Scheme for the metabolism of corn oil, primrose oil and menhaden oil to eicosanoids.

LTB_4 increases neutrophil adherence, Ham et al. (29) speculated that production of prostaglandins by endothelial cells will suppress adhesion of neutrophils to the vascular endothelium by inhibiting LTB_4 production, Korchak and Abramson (25) have observed that LTB_4 activation of neutrophils was significantly depressed in the presence of PGE_1. Thus, the reduction in number of malignant tumors observed in PO-fed rats may be mediated by increased synthesis of PGE_1 that may, in turn, alter immune responses by opposing LTB_4. The finding that a MO diet favors the immunologic generation of LTB_5, which has attenuated biological activity compared with LTB_4, suggests that EPA-enriched tissues may exhibit less proinflammatory activity than EPA-poor tissues (30). Feeding 20% MO in this study decreased all dienoic eicosanoid levels, as well as the proinflammatory leukotriene, LTB_4. In order to explain the mechanism of inhibition of tumorigenesis by n-3 fatty acids, optimal trienoic/dienoic eicosanoid ratios should be established. The lack of adequate methodology to measure trienoic eicosanoids is currently the limitation.

In summary, the present study shows that eicosanoid synthesis can be selectively modified by feeding n-3 or n-6 fatty acid precursors. Furthermore, inclusion of GLA or substitution of EPA and DHA for LA in the diet appears to decrease the malignancy of mammary tumors induced by DMBA. Our data suggest that the reduction in malignancy by dietary PO may be accomplished by decreasing the "protumor" dienoic eicosanoids and/or increasing monoenoic eicosanoids in tissues, but the effect of dietary MO may be mediated through depression of the production of dienoic eicosanoids and 4-series leukotrienes. The mammary tumor-promoting effect of dietary fat, specifically CO, may be mediated by overproduction of selective dienoic eicosanoids that modulate the immune response. Further studies are needed to establish the subtle mechanism(s) of fat types and levels in mammary cancer. In particular, the question of the optimal dietary ratios of n-3 to n-6 fatty acids needs to be addressed.

ACKNOWLEDGMENTS

The authors thank Judy Bates for typing the manuscript and Jon Shilstone and Jenella Bellows for technical assistance in collecting the data. This research was presented in part at the FASEB meeting in Washington, D.C. April, 1987, and at the American Oil Chemists' Society Short Course on Polyunsaturated Fatty Acids and Eicosanoids in Biloxi, MS, May, 1987.

[Received August 19, 1987; Revision accepted July 8, 1988]

Esterifications of 1- and *rac*-2-Octanols With Selected Acids and Acid Derivatives Using Lipases

Philip E. Sonnet[a,*] and **Gordon G. Moore**[b]

[a]U.S. Department of Agriculture, Agricultural Research Center, Eastern Regional Research Center, 600 E. Mermaid Lane, Philadelphia, PA 19118, and [b]Pennsylvania State University, Ogontz Campus, Abington, PA 19001

Several aliphatic acids and their ethyl, isopropenyl and 2,2,2-trichloroethyl esters were allowed to react with 1- and 2-octanols catalyzed by commercial lipase preparations of porcine pancreas and the fungi *Candida rugosa*, *Aspergillus niger* and *Mucor miehei*.

Comparisons of reactivity of the acids and esters were made in common organic solvents using the primary alcohol. Reactions of octanoic acid and its esters with 2-octanol in hexane allowed an evaluation of stereoselectivity of the lipases with different substrates that carried the same (octanoyl) residue. A partial resolution of *rac*-2-hexadecanol with *A. niger* lipase is described, and the utility of lipase selectivities (stereo, positional, fatty acid and ester) is discussed with reference to the data presented.

Lipids 23, 955–960 (1988).

Fatty acid selectivities of commercial and purified microbial lipases continue to receive much attention (1,2). Such information would be useful for projected industrial reactions such as the synthesis of fatty acid esters and transformations of natural triglycerides (3–6). The effect of the alcohol or other residue attached to a given acyl substrate on lipase preferences for fatty acids has been studied less frequently, although the accumulated evidence (7–10) indicates that acylation of the enzyme may be promoted, and/or acylation may be made irreversible, by suitable choice of acylating agent. Moreover, the large number of lipase-mediated kinetic resolutions of alcohols (7) and the oft documented triglyceride position preferences of lipases (1) demonstrate the importance of the structure of the alcohol component in reactions that are catalyzed by these enzymes.

We have screened separately and compared several acid derivatives of acetic, octanoic and oleic acids in reactions with 1- and 2-octanol, in order to further assess the potential importance of the nonacyl portion of the substrate in lipase reactions. In the process, we found that a lipase of *Aspergillus niger* (Amano-Lipase K) also is useful for resolving secondary alcohols. In addition, we observed that the degree of stereobias exhibited by lipases can be affected sometimes by the nature of the group associated with the acid residue in the starting material. Lipase selectivities based on the data reported here are evaluated for utility in kinetic resolution of enantiomeric alcohols and in selective transesterification of primary alcohols.

MATERIALS AND METHODS

Gas liquid chromatography (GLC) was performed with a Shimadzu GC-Mini 2 instrument (Columbia, MD) using an SPB-1 column (0.25 mm i.d. × 30 m) fitted with a flame ionization detector and operated at column temperatures indicated herein, with a 50:1 split ratio and with He carrier gas. Chromatograms were recorded with either a Perkin-Elmer Model 023 Recorder (Norwalk, CT) or a Hewlett-Packard 3390 Recording Integrator (Avondale, PA). Infrared spectra (IR) were obtained on a Perkin-Elmer 1310 Spectrophotometer (3% solutions in CCl_4). Nuclear magnetic resonance spectra (NMR) were obtained in $CDCl_3$ using a JEOL JNM-GX 400 FT NMR spectrometer (Piscataway, NJ). Mass spectra (MS) were recorded with a Hewlett-Packard 5995 GC-MS System interfaced with an OV-1 column (0.25 mm i.d. × 12 m). Optical rotations were obtained using a Perkin-Elmer 141 Polarimeter.

Acetic acid was Baker Analyzed Reagent (Baker, Phillipsburg, NJ), all other organic acids were Aldrich Reagent Grade (Aldrich, Milwaukee, WI) and were employed without purification. Hydrocarbon standards for GLC were purchased and used as received, also. Ethyl and 2,2,2-trichloroethyl esters were synthesized in the usual manner from the alcohols and acids (Fisher esterification) or acid halides (triethylamine, CH_2Cl_2). They were distilled and characterized by IR, MS and GLC. Isopropenyl esters were prepared in slightly better yield, and more conveniently than previously reported (11), and an example is given as well. Solvents were purchased "distilled in glass," or were reagent grade and were distilled before use (acetone distilled from $KMnO_4$ and 1,2-dimethoxyethane distilled from lithium aluminum hydride). Diethyl ether was Analyzed Reagent-Anhydrous (Baker) and was used directly. The enzyme preparations by biological source (commercial source; company trade name; initial rate assay on olive oil emulsions given in μmol free fatty acid released, min^{-1}, mg^{-1}) were *C. rugosa* (Enzeco, none, 9.82) (Enzyme Development Corp.; New York, NY), *A. niger* (Amano; Lipase K; 11.2) (Amano, Troy, VA), *M. miehei* (NOVO; Lipase-3A; 5.33) (NOVO, Wilton, CT) and Porcine pancreatic lipase (Sigma; none; 15.6) (Sigma, St. Louis, MO).

Immobilization of lipases. Lipase-3A is on a resin (proprietary), as purchased. For ease in use, greater stability and potential for recovery, the other two fungal lipases were adsorbed onto Duolite, an ion-exchange resin available from Rohm and Haas Co. (Philadelphia, PA). Duolite (50 g) was washed sequentially with 2 × 100 ml of methanol, and then 2 × 100 ml of .05 N phosphate buffer at pH 7.0. The material was then swirled in 100 ml of the same buffer containing 5 g of the commercial lipase powder (30°C, 16 hr). The mixture was suction filtered and washed with 2 × 100 ml of reagent acetone. The granular product was dried under vacuum at 25°C.

Activities of the lipases in organic solvent before and after adsorption were evaluated as follows: 5 ml of wet hexane containing 0.50 mmol of 1-octanol and 0.25 mmol of octadecane, and 5 ml of wet hexane containing 0.50 mmol of octanoic acid were combined. Catalyst

Abbreviations: ee, enantiomeric excess; GLC, gas liquid chromatography; IR, infrared spectra; MS, mass spectra or spectrometry; NMR, nuclear magnetic resonance spectra.

(20 mg of powder or 0.20 g of immobilized enzyme) was added, the reaction mixture was stirred at 30°C and samples were analyzed by GLC (200°C) at 1.0 and 2.0 hr. The measurements were duplicated and averaged. Lipase (powder activity in μmol of ester formed; hr^{-1}, mg; immobilized enzyme activity): *C. rugosa* (1.1, 0.13); *A. niger* (0.33, 0.35). The pancreatic lipase was used as a powder; a useful preparation on Duolite was not obtained. Lipase 3A is immobilized on an ion-exchange resin, as purchased.

Preparation of isopropenyl heptanoate. Heptanoic acid (50 ml), isopropenyl acetate (200 ml) and H_2SO_4 (0.3 ml) were heated under reflux for 5 hr. The mixture was cooled to ca. 25°C, stirred for 0.25 hr with 20 g of sodium acetate and 100 ml of anhydrous ether, and then filtered. The filtrate was concentrated on a rotary evaporator to remove ether and isopropenyl acetate. The concentrate was dissolved in 200 ml of ether and stirred for 2 hr with 25 g of $NaHCO_3$ and 50 ml of water. The organic phase was recovered and dried (Na_2SO_4). The solvent was removed, and the residue was distilled through a Vigreaux column collecting the fraction bp 87–93°C (20 mm): 19.2 g, 32.2% yield, IR 1750, 865 cm^{-1}, GC-MS *m/e* 113 (heptanoyl ion), no molecular ion obtained); ^{13}C NMR 14.09, 19.58, 22.60, 24.91, 29.01, 31.65, 34.37, 101.96, 153.01, 171.02. The product was contaminated with about 3–4% of the acetic heptanoic anhydride. Isopropenyl octanoate and oleate were similarly prepared; the latter was purified by column chromatography, as previously reported (11).

Esterifications of 1-octanol. Reaction mixtures were prepared that contained 0.50 mmol each of 1-octanol and the acylating reagent and 0.25 mmol of the hydrocarbon internal standard in 10 ml of wet solvent. Water-miscible solvents were fortified with 2 μl of distilled water. The enzyme formulation was added, and the reaction mixture was stirred at 30°C. Aliquots were analyzed by GLC—acyl residue (hydrocarbon standard, GLC temperature): acetyl (undecane, 120°C); octanoyl (octadecane, 200°C); oleoyl (tetracosane, 280°C). The amount of catalyst used was adjusted downward, as necessary, to reduce percentage conversion to less than 20% during the first hour and thereby provide a calculated velocity close to an initial rate assay (the rate that would be calculated from the initial linear portion of the rate curve, with an excess of substrate to assure saturation of enzyme active sites). Most reactions proceeded to less than 5% conversion under the conditions employed.

Esterifications of 2-octanol. Reaction mixtures were prepared containing 0.50 mmol each of *rac*-2-octanol and octanoic acid (ester) and 0.25 mmol of octadecane in 10 ml of wet hexane. The enzyme (0.20 g of formulated material or 225 mg of pancreatic lipase powder) was added, and the mixture was shaken at 30°C for 4–6 days. Analysis by GLC provided percentage conversion. The configurational analysis for residual 2-octanol was obtained, as previously described (12), using (S)-α-methylbenzylisocyanate (13) to produce chromatographically separable diastereomers to determine the enantiomeric excess (ee) of the unesterified alcohol.

Resolution of rac-*2-hexadecanol.* 2-Hexadecanol (2.94 g, 10 mmol) was shaken in a solution of wet hexane (50 ml) containing isopropenyl oleate (3.23 g, 10 mmol) and *A. niger* on Duolite (5 g) at 30°C for 14 days. The mixture was suction filtered, and the resin was washed with small portions of hexane. The combined organic phase was concentrated and chromatographed on silica gel, 60–200 mesh, 30 g (Grace Co., Baltimore, MD). The oleate ester was eluted with 2–5% ether-hexane, and the unreacted alcohol was eluted with 7.5–10% ether-hexane (1.36 g, 46.3% of 70.0 ee:S). The ester was saponified (20 ml of 50% 4 N KOH-methanol, reflux overnight) to produce alcohol (1.28 g, 43.5% of 86.6 ee:R). The ester, in other words, was 93.3% (R). The R-alcohol had α_D^{25}-4.0 (C = 4.7, EtOH). A midfraction was recovered with 5% ether-hexane that was mostly alcohol. The chromatographic conditions for the diastereomeric carbamates used to assign configurational purity to the alcohols were: column temperature 280°C, k's 4.167 (R,S-diastereomer), 4.375 (S,S-diastereomer) and a separation factor of 1.050.

RESULTS AND DISCUSSION

Esterification of 1-octanol. Acetic, octanoic and Z-9-octadecenoic (oleic) acids were allowed to react with 1-octanol in wet hexane at 30 ± 0.2°C with the following commercial lipase preparations: Enzeco *C. rugosa,* Amano Lipase K. *(A. niger),* NOVO Lipase 3A *(M. miehei)* and Sigma porcine pancreatic lipase. A hydrocarbon internal standard permitted an evaluation of conversion to 1-octanol ester, from which was calculated a value for reactivity in μmol ester formed, min^{-1}, g^{-1}. Reactivities of ethyl, isopropenyl and 2,2,2-trichloroethyl esters were similarly calculated and the results tabulated as reactivity relative to the corresponding acid as unity (Table 1). A typical chromatogram is given in Figure 1. Under these conditions,

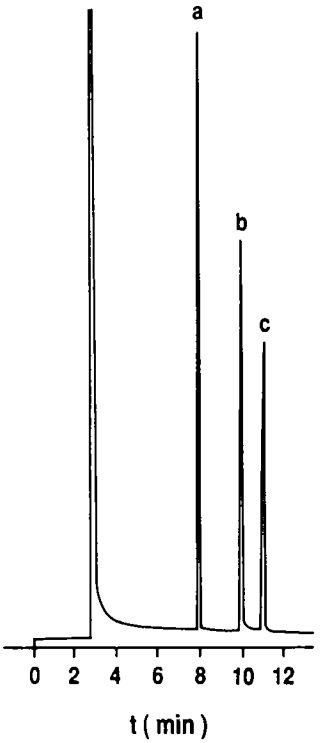

FIG. 1. Gas Chromatogram of a) 2-octanol octanoate, b) 1-octanol octanoate and c) octadecane, in a molar ratio of 1.765:1.797:1.000, using the SPB-1 column at 200°C. Similar chromatograms were used as standards to monitor lipase esterifications.

TABLE 1

Relative Rate of Esterification of 1-Octanol in Hexane[a]

Enzyme	Acid residue	Acid[b]	Ethyl[c]	Isopropenyl[c]	TCE[d]	SH[e]

[a]See Materials and Methods. Reactions were duplicated and GLC analyses were reproducibly ±3%. Activities are in units of μmol of ester formed, min^{-1}, g^{-1}. Figures in parentheses are activities of recovered enzyme measured in hexane.

[b]1,2-Dimethoxyethane.

[c]Methylene chloride.

[d]Less than 0.01.

the ethyl esters were uniformly less reactive than the corresponding free acids. Because the carbonyl groups of the isopropenyl and 2,2,2-trichloroethyl esters render the ester carbonyls electron deficient, however, one might expect that the lipases would be more readily acylated. In fact, the "activated" esters were indeed more reactive with *C. rugosa* lipase, especially the acetates. But these esters were generally less reactive than the free acids using the other lipases. To the degree that an acylated enzyme has no memory of the source of the acyl residue, these relative reactivities suggest that carbonyl polarity in the substrate bears little relationship to the ease of enzyme acylation. It is interesting to note that thiolacetic acid was more reactive than acetic acid. The longer chain acids are favored by the enzymes over acetic acid, as previously established. The counterunit (alkoxy group for an ester) is sometimes more effective in promoting reaction of the shorter acid, perhaps because acetic acid tends to self-associate in hexane, although its esters are monomeric and more hydrophobic.

The reactivity of enzymes in organic media has been reviewed by Klibanov (14), and it is clear that solvent can profoundly influence both stability and reactivity. We conducted esterifications of octanoic acid with 1-octanol, using the same lipase preparations in various organic solvents for 1 hr, and determined reactivities as before. The lipase from such reactions was recovered and used for the same esterification reaction in hexane, in order to determine residual lipase activity (Table 2). In each case, the esterification reaction was fastest in hexane, about

half as rapid in toluene for the lipases of *M. miehei* and porcine pancreas, and very slow otherwise. Evaluations of recovered activity often showed significant losses particularly for *A. niger* and *C. rugosa* lipases, especially in 1,2-dimethoxyethane. The loss in activity for the two aforementioned lipases in acetone is interesting, because that solvent is often used to precipitate crude protein preparations. An exact determination of the nature of these losses in each case is beyond the scope of this investigation, but it is apparent that reactivity in, and recovery of enzyme activity from, organic solvents would have to be uniquely determined and optimized for a particular reaction, enzyme and solvent.

Esterification of 2-octanol. The same lipase preparations were used to catalyze the esterification of 2-octanol with octanoic acid in hexane at 30 ± 0.2°C. Acetic acid and its esters reacted too slowly, and octanoic acid was selected, because the results obtained for octanoic acid were expected to be similar to those that would be obtained for longer chain acids (12). The degree of conversion was obtained by GC (Fig. 1), and the stereobias (enantiomeric excess) in the unreacted 2-octanol was determined by conversion to diastereomeric carbamates with (S)-α-methylbenzylisocyanate that then could be analyzed by GC (Fig. 2). These data permitted the calculation of enantiomeric ratio (E_R), a number that expresses the relative reactivity of enantiomers with an enzyme (15) (Table 3). Although the derivation for E_R was based on pure enzyme, i.e., a single enzymatically active species, a mixture of enzymes such as an impure commercial preparation would, at most, cause the calculated E_R to drift, particularly at greater conversion. Conversions were less than 50% and are offered as a rough indicator of relative reactivity of the enantiomers.

As reported previously, the stereoselection of *M. miehei* lipase was high for octanoic acid; it is also high for the isopropenyl and 2,2,2-trichloroethyl esters. The Amano-Lipase K *(A. niger)* also was high enough to be useful and we partially resolved 2-hexadecanol to show the utility of such a procedure. Previous evaluation of this lipase (12) used the commercial powder that had low activity. Deposition of the *A. niger* lipase powder on Duolite, however, markedly increased its activity and allowed a more accurate determination of its stereobias in this reaction. The increased activity of the immobilized *A. niger* lipase is probably due to improved stability of the enzyme (16). The immobilization process frequently acts to reduce one or another of the denaturation processes, and the assay method that is conducted during a time interval leads to a higher calculated specific activity than did the original enzyme powder. The immobilized *A. niger* lipase was allowed to catalyze the esterification of 2-octanol with oleic acid. At 45% conversion, the residual alcohol was 85% S:15% R (70% ee:S), and the product oleate ester was 87% R (Fig. 2). The E_R would be ca. 29, and a conversion in the vicinity of 58% would assure a pure (S)-2-hexadecanol (17). The *C. rugosa* showed no bias with the octanoic acid and low, opposite biases with the two octanoyl esters. Enzyme recovered from reaction of the isopropenyl ester was used to esterify octanoic acid (no bias for octanoic acid), then recovered and used for the isopropenyl ester (same result for the ester). Thus, the alteration in selectivity is real and reproducible. More striking is the modest bias shown by pancreatic lipase with octanoic acid, and the very strong selectivity with the 2,2,2-trichloroethyl ester. Recently, Deleuze et al. (10) reported

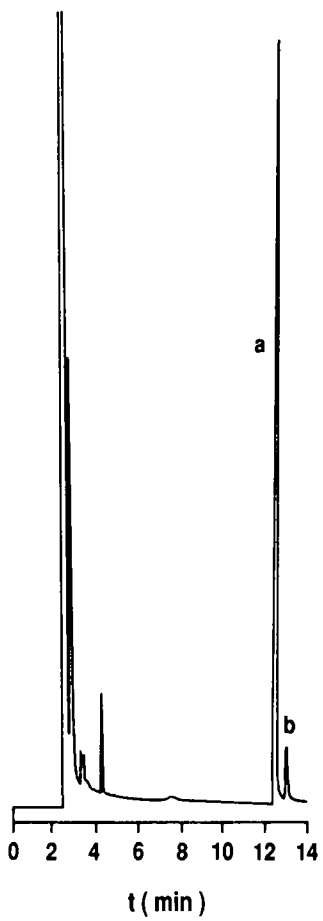

FIG. 2. GLC analysis of α-methylbenzyl carbamates obtained by the reaction of 2-hexadecanol recovered from its oleate ester. The ester had been formed from alcohol and acid using *A. niger* lipase (Amano-Lipase K) on Duolite. Analysis uses an SPB-1 column at 280°C; a) is the R,S-diastereomer (R-alcohol) and b) is the S,S-diastereomer.

TABLE 3

Stereoselectivities of Lipases in Octanoylation of 2-Octanol in Hexane[a]

Enzyme	Acid	Isopropenyl[b]	TCE[c]
C. rugosa	1.0	1.3[d]	1.3
A. niger	>40[e]	>40[e]	>40[e]
M. miehei	>40	>40	>40
Pancreatic	9.6	—[f]	>40

[a] See Results and Discussion for selectivity measurement. The (R)-2-octanol reacts fastest, except as noted.

[b] Ester.

[c] 2,2,2-Trichloroethyl ester.

[d] The (S)-2-octanol reacts slightly faster.

[e] Although calculation gives an exact figure, the analytical technique is insufficiently precise and the error in calculated value increases with higher relative rates. For practical purposes selectivities greater than 40:1 are likely to be useful in kinetic resolution.

[f] Reaction too slow.

the results of competition experiments showing that the relative reactivity of pairs of esters with lipases was independent of the alcohol that was being esterified. Likewise, the relative reactivity of pairs of alcohols with acylated lipases was independent of the source (e.g., structure of the alcohol component of the ester) of acid residue. These observations are consistent with a generally accepted view that lipases first become acylated, and then undergo reaction with an available nucleophile in a discrete second phase of operation. Implicit is an assumption that the nonacyl component of the substrate is shed from the enzyme into the medium, where it becomes a minor component in the pool of available nucleophiles. Our observations do not confound this picture, but merely indicate that substrates and nucleophiles can, perhaps by virture of alternate associations with the protein and their overwhelming presence (compared to enzyme concentration), alter somewhat the delicate balance of stereoselectivity of an acylated enzyme. Similar observations were reported earlier, for example, wherein stereoselectivity involving the esterification of *rac*-2-octanol with octanoic acid using *M. miehei* lipase was reduced significantly in the presence of the much less reactive acetic acid, though the same reaction proceeded at a slower rate with no change in stereoselectivity in the presence of unreactive phenyl(trifluoromethyl)carbinol (18).

Lipase selectivity. Much interest exists in exploring the selectivities of lipases for projected industrial reactions (3–6), and a number of patents have been issued that are based on preferential reactions of various lipases with fatty acids and their derivatives (19). Given the problem of selectively converting one reagent present in a mixture of potential reagents to a product, one is faced essentially with a kinetic problem. With sufficient reaction time, a product mixture would be obtained that is at equilibrium thermodynamically. Therefore, how selective must a catalyst be to be useful?

Competitive reactions were conducted that were chosen based on the data of Table 1. Isopropenyl heptanoate and ethyl octanoate were allowed to transesterify 1-octanol competitively, using *C. rugosa* lipase on Duolite in hexane. Because isopropenyl esters are better substrates for this lipase than ethyl esters and will react irreversibly, one expects to see faster and more complete conversion to octyl heptanoate than to octyl octanoate. The data (Fig. 3) show the general predicament inherent in the use of enzymes as catalysts, when selectivity is modest. The heptanoate product contains only ~2% of the octanoate ester, if the reaction is terminated at ~19% conversion (5 hr). However, at 86% conversion (144 hr), the octanoate component is >17% of the product. In a related experiment that would yield the same two esters as products, but should lead to a mixture richer in octanoate ester (Fig. 4), isopropenyl heptanoate and 2,2,2-trichloroethyl octanoate were allowed to react with 1-octanol. In this case, it was expected that octyl octanoate ester would form more quickly. Indeed, this was so, and then the octyl heptanoate ester began to form. Eventually *trichloroethyl heptanoate* also was observed in the reacting mixture, indicating that trichloroethyl esters do react reversibly.

In summary, several acids and their esters have been evaluated in esterification reactions of 1- and 2-octanol as typical aliphatic alcohols, using several commercially available lipases. Reactions were fastest in hexane, as compared with several other common organic solvents,

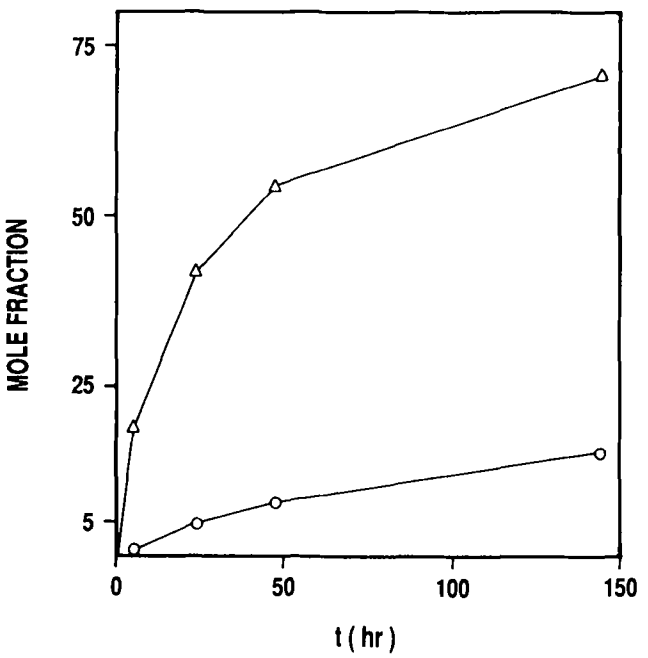

FIG. 3. Reaction of isopropenyl heptanoate (0.01 M), ethyl octanoate (0.10 M) and 1-octanol (0.12 M) in wet hexane with *C. rugosa* lipase (0.300 g/mmol of ester) at 30°C. Δ:1-octanol heptanoate; 0:1-octanol octanoate.

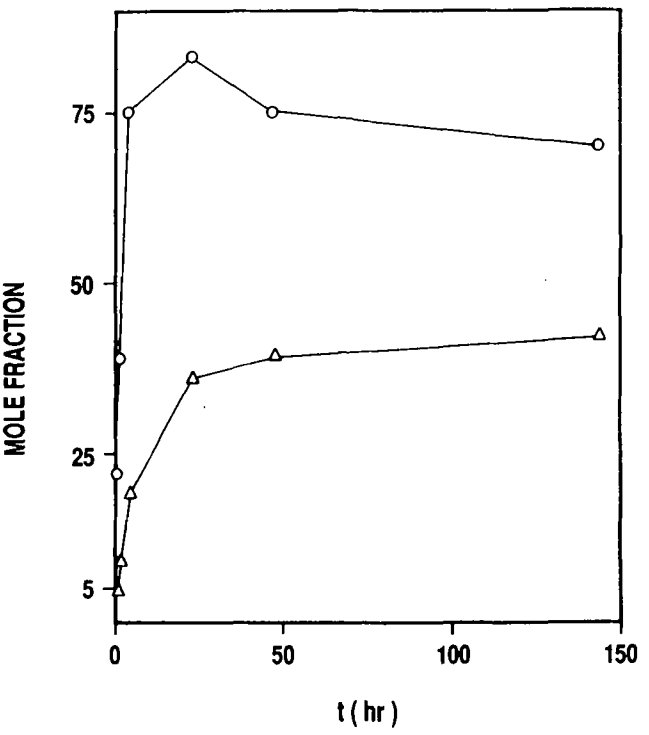

FIG. 4. Reaction of isopropenyl heptanoate (0.10 M), 2,2,2-trichloroethyl octanoate (0.10 M) 1-octanol (0.12 M) in wet hexane with *M. miehei* lipase (0.025 g/mmol of ester) at 30°C. Δ:1-octanol heptanoate; 0:1-octanol octanoate.

and the organic acid itself is usually the best substrate. An exception to this involves the reactions of *C. rugosa* lipase, which reacts more rapidly in hexane with isopropenyl and 2,2,2-trichloroethyl esters. Further evaluation of lipase selectivity using *rac*-2-octanol indicated a previously unobserved high stereoselectivity for the *A. niger* lipase and, unexpectedly, variation in stereobias with source of acyl residue using the lipases of *C. rugosa* and porcine pancreas. Exemplifications of lipase selectivity, based on relative reactivities of esters (Table 1), demonstrate the relationship between selectivity and product purity. Applications of lipase selectivities (as in kinetic resolution of enantiomers [16]) are best applied in the sense of purifying a starting material. Only if the selectivity of a lipase is such, to make the catalyst virtually specific, can it be used to yield a nearly pure product.

ACKNOWLEDGMENTS

The following companies provided samples for these studies: Amano, Enzeco, NOVO (lipase preparations), and Rohm and Haas (Duolite).

Interaction of Rabbit Lipoproteins and Red Blood Cells With Liposomes of Egg Yolk Phospholipids

Armando J. Mendez[a,1], Jin Lin He[a], Hui Sheng Huang[a], Shu Rong Wen[a] and S.L. Hsia[a,b,*]

[a]Lipid Profile Evaluation Laboratory, Department of Dermatology and Cutaneous Surgery and [b]Department of Biochemistry and Molecular Biology, University of Miami School of Medicine, Miami, FL 33101

After intravenous injection of liposomes prepared from egg yolk phospholipids into rabbits, the phospholipids were readily assimilated by the lipoproteins, and there were increases in the circulating levels of cholesterol and phospholipids. The increases in cholesterol level were mainly due to increases of free cholesterol. Gradient ultracentrifugation showed that the lipoproteins decreased in density, and gel filtration chromatography showed that they increased in particle size. Upon electrophoresis, they exhibited slower mobility. Liposomes recovered from rabbits 3 hr after the injection contained free cholesterol, apolipoproteins A-I, E and traces of C. The apolipoprotein may target the liposomes for uptake by hepatocytes. Incubation of the liposomes with rabbit red blood cell membranes in vitro caused a decrease in cholesterol content of the membranes. However, the cholesterol/phosphate ratio in red blood cells isolated from the rabbits after the injection of liposomes did not change significantly, suggesting rapid replenishment of red blood cell cholesterol in vivo, possibly by equilibration with lipoprotein cholesterol or tissue cholesterol. These results suggest that the injection of phospholipid liposomes may have an antiatherogenic effect by the removal of tissue cholesterol and enhancing hepatic disposal of cholesterol through the reverse cholesterol transport mechanism. *Lipids 23,* **961-967 (1988).**

The antiatherogenic effect of intravenous injections of phospholipids has been demonstrated in several experimental animal models. Friedman et al. (1) first reported that the infusion of a suspension of animal lecithin affected a marked resolution of atherosclerotic infiltration and reduced cholesterol deposition in the aorta of rabbits in which atherosclerosis had been induced by a diet containing 1% or 3% cholesterol. These observations were confirmed by others (2,3). Regression of atherosclerotic lesions in baboons after the injection of phospholipids was reported by Howard et al. (4), and similar observations in Japanese quails were reported by Stafford and Day (5).

Recent studies by Williams and Scanu (6) in dogs demonstrated the uptake of apolipoprotein A-I (apo A-I) and cholesterol by intravenously injected phospholipid liposomes, with concomitant uptake of phospholipids by high density lipoprotein (HDL). The authors suggested that the injected liposomes mobilized tissue cholesterol. A possible antiatherogenic mechanism of injected phospholipid liposomes was proposed by Williams et al. (7), based on their observation of liposomes injected into hypercholesterolemic rabbits. They found that the liposomes acquired apolipoproteins E (apo E) from beta-very low density lipoprotein (β-VLDL), and the apo E containing liposomes then competed with β-VLDL for binding to apo E receptors on macrophages, thus, diminishing the uptake of cholesteryl esters from β-VLDL by the macrophages.

To seek further explanation of the antiatherogenic effect of phospholipid liposomes, we injected liposomes of egg yolk phospholipids into normolipidemic rabbits, to assess their effects on cholesterol transport. We found extensive interaction between the liposomes and serum lipoproteins. The injected phospholipids were readily assimilated by serum lipoproteins and the liposomes recovered from rabbit blood contained, in addition to cholesterol, apolipoproteins A-I, E and traces of C. We also examined the effect of the liposomes on cholesterol and phospholipid contents of red blood cells. Taken together, our data support the contention that intravenous injection of phospholipid liposomes may mobilize tissue cholesterol and enhance the reverse cholesterol transport mechanism, thus having an antiatherogenic effect.

MATERIALS AND METHODS

Rabbits. Male New Zealand white rabbits, ca. six months of age, were fed normal rabbit chow and maintained at controlled temperature with a 12-hr dark/light cycle, by the Division of Veterinary Resources at the University of Miami School of Medicine. Food was removed from the rabbits at least 12 hr prior to collection of blood samples or injection of liposomes through the peripheral ear vein.

Liposomes. Injection grade egg yolk phospholipids (lot #VH001V) were a generous gift of Asahi Chemicals (Tokyo, Japan), and contained 98.8% phosphatides, of which 71.0% was phosphatidylcholine; 20.2%, phosphatidylethanolamine; and less than 1%, lysophosphatides. Liposomes were prepared by sonication according to Huang (8). Briefly, phospholipids were suspended in 0.15 M NaCl, pH 7.4, at a concentration of 300 mg/ml, and sonicated for three 10-min intervals at 0°C, with the standard tip of the sonicator (Heat Systems Ultrasonics, Plainview, NY) at a setting of 50 W. The sonicated lipids were then centrifuged at 120,000 × *g* for 30 min to remove Ti particles and nonliposomal lipids. The supernatant was collected and passed through a 0.45 μm pore filter. Liposomes were sized by gel permeation chromatography on BioGel A-5m (BioRad Laboratories, Richmond, CA) using a 1 × 90 cm column. Typical preparations of liposomes contained >90% of the phospholipids in a major peak which corresponded to smooth unilamellar vesicles as previously described (8). The remaining phospholipids that eluted near the void volume were probably composed of multilamelar vesicles and other large lipid aggregates.

Abbreviations: Apo A-I, apolipoprotein A-I; apo E, apolipoprotein E; (β-)(V)LDL, (beta-)(very) low density lipoprotein; HDL, high density lipoprotein; SDS-PAGE, sodium dodecyl sulfate polyacrylamide gel electrophoresis; IEF, isoelectric focusing.

Lipid assays. Cholesterol in serum and serum fractions was determined by the cholesterol oxidase method of Allain et al. (9). Free cholesterol was determined using the same method with the omission of cholesteryl esterase from the reagent.

Triglycerides in rabbit serum were determined using a commercially available kit (Craig Bioproducts Inc., Streamwood, IL) based on the method of McGowan et al. (10).

Serum phospholipids were estimated after precipitation of lipoproteins with 100 volumes of 10% trichloroacetic acid as described by Zilversmit and Davis (11). Phospholipids were determined as inorganic phosphorous after digestion with perchloric acid at 170–180°C for ca. 30 min by the method of Bartlett (12).

Agarose gel electrophoresis. Agarose gel electrophoresis of serum lipoproteins was performed using the Corning (Palo Alto, CA) ACI electrophoresis system according to the manufacturer's procedures. Lipoproteins were stained with Fat Red 7B, and gels were scanned at 510 nm with a Corning model 730 densitometer.

Density gradient ultracentrifugation. Density gradients were prepared by the single spin method of Terpstra et al. (13) with minor modifications. Two ml of serum was adjusted to density 1.21 g/ml by the addition of 0.809 g KBr and 0.050 g sucrose, and placed at the bottom of an ultracentrifuge tube and carefully overlayered with the following KBr solutions: 2 ml d = 1.20 g/ml, 4 ml d = 1.10 g/ml and 4 ml d = 1.006 g/ml. Ultracentrifugation was performed in a SW 40Ti rotor (Beckman Instruments, Palo Alto, CA) at 39,000 rpm using a L5-65 ultracentrifuge (Beckman) for 22 hr at 18°C. Gradients were fractionated using an ISCO (Lincoln, NE) density gradient fractionator, and 0.75-ml fractions were collected.

Gel permeation chromatography. Columns (1.5 × 90 cm) were packed with BioGel A-5m equilibrated in 0.01 M Tris, pH 7.4, 0.15 M NaCl, 0.01% EDTA and 0.02% NaN_3 and kept at 4°C. A flow rate of 6 ml/hr was maintained with the use of a peristaltic pump, and 4-ml fractions were collected.

Electrophoresis. Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) was according to O'Farrel et al. (14), using the discontinuous buffer system of Laemmli (15) in 12% polyacrylamide slab gels. Prior to analysis, samples were delipidated as above and dissolved in 0.01 M Tris, 1 mM EDTA, 1% SDS and 5% β-mercaptoethanol, pH 8.0. Gels were stained with 0.2% Coomassie Bright Blue in methanol/water/acetic acid (5:5:1, v/v/v) and destained in the same solution without dye until a clear background was obtained. Isoelectric focusing (IEF) was performed according to the method of Menzel et al. (16) with minor modifications. A 7.5% polyacrylamide gel containing 1.6% ampholines (Pharmalyte pH 4.5–6.5, Pharmacia Fine Chemicals, Piscataway, NJ) and 5.2 M urea was used. The anode chamber contained 0.01 M H_3PO_4 and the cathode chamber, 0.02 N NaOH. Samples were delipidated with ethanol/ether (3:1, v/v) according to Scanu and Edelstein (17), and dissolved in 0.01 M Tris-HCl, pH 8.2, containing 1% SDS, 2% ampholine, 5% β-mercaptoethanol and 13% sucrose. Electrophoresis was performed at 4°C at 200 V, until the current was zero.

Preparation of red blood cell ghosts. Red blood cell ghosts were prepared by the method of Dodge et al. (18). Blood was collected in tubes containing EDTA (final concentraton 2 mg/ml), and subjected to centrifugation at 1,000 × *g* for 15 min. After removal of the plasma and the buffy coat, the red cells were washed 3 times with 0.15 M NaCl, 0.01 M Tris, pH 7.5. Hemolysis was effected by the addition of 20 volumes of 0.01 M Tris, pH 7.5, with gentle mixing. Red cell ghosts were sedimented by centrifugation at 20,000 × *g* for 45 min, washed 5 times and resuspended in 0.15 M NaCl, 0.01 M Tris, pH 7.5.

RESULTS

Changes in serum lipid levels. Each of eight rabbits was given an IV injection of egg yolk phospholipid liposomes at the dose of 60 mg phospholipid/kg animal weight. There was an immediate rise of serum phospholipid concentration (ca. 2-fold), which was sustained for about 1 hr. The concentration then began to decline, reaching a plateau above baseline 6–8 hr post-injection, and the elevation persisted for at least 72 hr. Approximately 15 min following injection, serum cholesterol levels began to rise, predominantly due to increases in free cholesterol, reaching peak levels between 3 and 4 hr. By the eighth hour, the cholesterol levels reached a plateau above the baseline level in five of the eight animals. Increases in cholesteryl ester concentrations lagged behind increases of free cholesterol by ca. 1 hr and were smaller in magnitude (0–12% above baseline). Serum triglyceride levels varied among the animals. In control animals injected with saline, similar variations in triglyceride levels were observed, indicating that the triglyceride changes could not be attributed to the liposomes. Figure 1 summarizes serum lipid levels of eight rabbits before and 4 hr after liposome injection.

Changes in serum lipoproteins—Agarose gel electrophoresis. Figure 2 shows the results of agarose gel electrophoresis of serum samples before and after liposome injection. Prior to injection (Panel A), the peaks of LDL (beta mobility) and VLDL (pre-beta mobility) are merged, and HDL (alpha mobility) appears as a separate peak. Upon electrophoresis, liposomes gave a single peak with slower migration than LDL (data not shown). Thirty min after injection, two major peaks of lipid-staining material were observable (Panel B) with slower mobilities than the

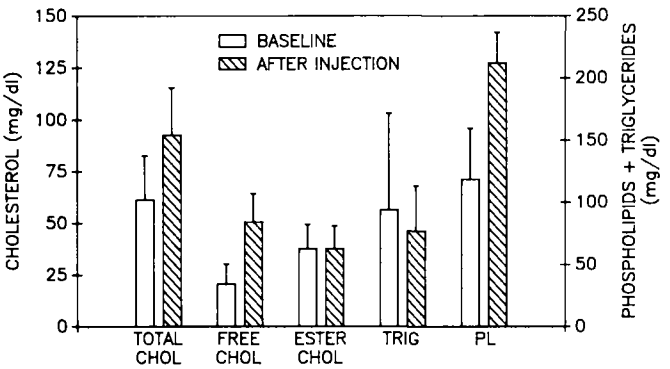

FIG. 1. Changes in rabbit serum lipid levels after injection of egg yolk phospholipid liposomes. Eight rabbits were each injected with egg yolk phospholipid liposomes (60 mg/kg wt). Serum was obtained from blood samples taken before and 4 hr after injection. CHOL, cholesterol; TRIG, triglycerides; PL, phospholipids.

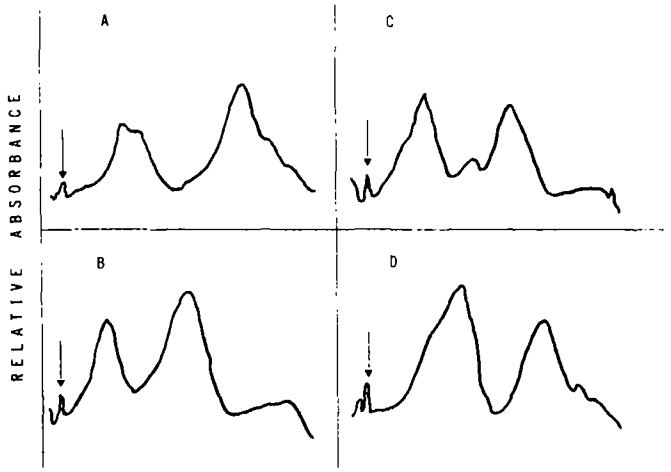

FIG. 2. Agarose gel electrophoresis of rabbit serum. Serum was obtained from blood samples taken before and after injection of egg yolk phospholipid liposomes and subjected to agarose gel electrophoresis. Lipoproteins were stained with Fat Red 7B, and the gels scanned at 510 nm. The origin is marked with an arrow. The cathode is to the left and the anode to the right of the panel. A, before injection; B, 30 min after injection; C, 4 hr after injection; D, 48 hr after injection.

peaks obtained from control serum (Panel A). The first peak from the left represents liposomes in addition to VLDL and LDL, and the second peak corresponds to HDL. Three peaks are observed in Panel C (4 hr after injection). The first one with slower mobility than control LDL contains VLDL, LDL and liposomes, and the large peak to the right represents HDL. Its mobility is faster than that in Panel B, but slower than that in Panel A, indicating partial restoration of HDL. In addition, a small peak is observed between the two major peaks. This peak represents a component of the altered HDL, which was slow to undergo restoration. The electrophoretic pattern of HDL in Panel D (48 hr after injection) is essentially the same as before injection, but a larger pre-beta peak persists. In Panels B, C and D, the liposome and LDL peaks are not distinguishable. However, in control experiments where liposomes and control serum were mixed together and then subjected to agarose gel electrophoresis, the LDL and liposome peaks were separated, although not completely resolved. These data indicate that the LDL peak had lower mobility after injection of liposomes. In addition, electrophoresis of serum mixed with liposomes did not reveal any alteration in the mobility of HDL, indicating that the changes observed in serum after injection were due to changes in the HDL particles and were not an artifact of electrophoresis, resulting from the presence of liposomes in the sample.

Density gradient ultracentrifugation. Serum samples were obtained prior to, 15 min after and 3 hr after injection of 200 mg phospholipid into a rabbit, and subjected to density gradient ultracentrifugation. VLDL at the top of the gradient was removed. Cholesterol and phospholipid contents of the gradient fractions were determined and the results are shown in Figure 3. Panel A shows the results of serum fractions obtained prior to injection, and two distinct peaks of cholesterol and phospholipids, corresponding to LDL and HDL, can be seen with maxima at fractions 4 and 11, respectively. The HDL peak shows

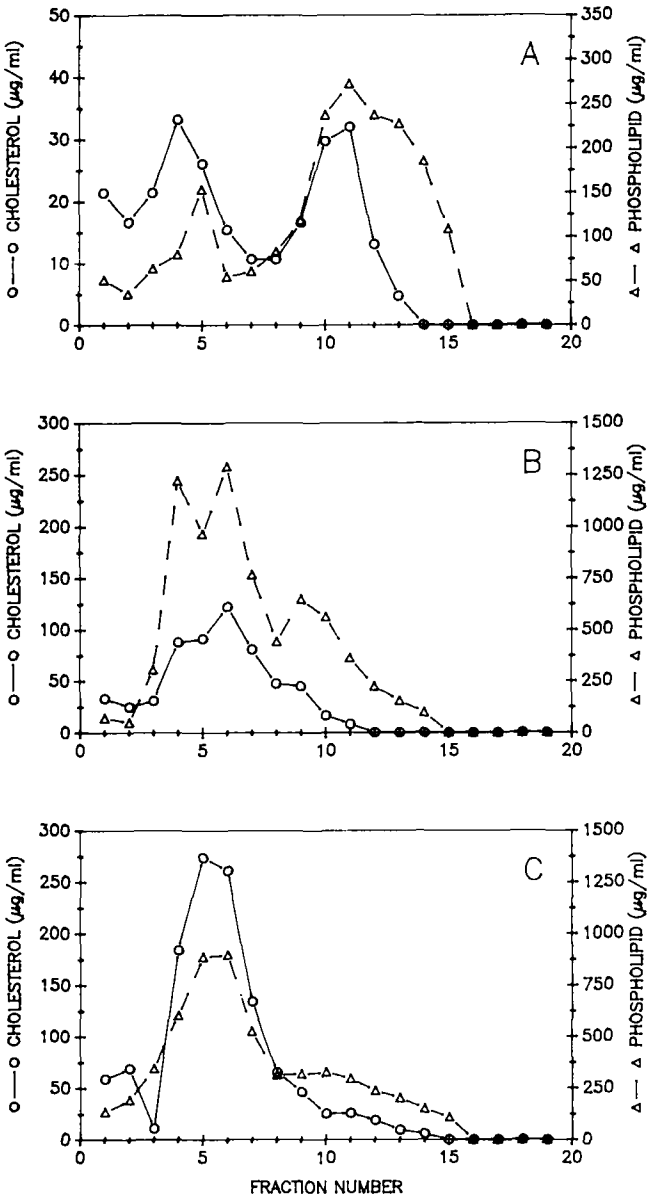

FIG. 3. Density gradient ultracentrifugation profile of rabbit serum. Two ml of serum was subjected to density gradient ultracentrifugation as described in Methods. Fractions of 0.75 ml were collected after tube piercing and displacement of the contents with a dense chase solution. Cholesterol and phospholipid contents of each fraction were assayed. Gradient density increases from left to right. A, before injection, serum cholesterol 28 mg/dl and serum phospholipid 55 mg/dl; B, 15 min after injection, serum cholesterol 42 mg/dl and serum phospholipid 219 mg/dl; C, 3 hr after injection, serum cholesterol 78 mg/dl and serum phospholipid 184 mg/dl.

heterogeneity in the distribution of cholesterol and phospholipids, the less dense fractions having greater contents of cholesterol relative to phospholipids. Panel B shows increases in phospholipids and cholesterol in all fractions, as well as a shift of the HDL peak to lower densities 15 min after injection. In a separate experiment, liposomes were subjected to density ultracentrifugation and were recovered between fractions 2 and 6, with the peak at fraction 3. The increase of phospholipids in the LDL region in Panel B appears to be due to superimposition of the liposomes. In Panel C (3 hr after injection of

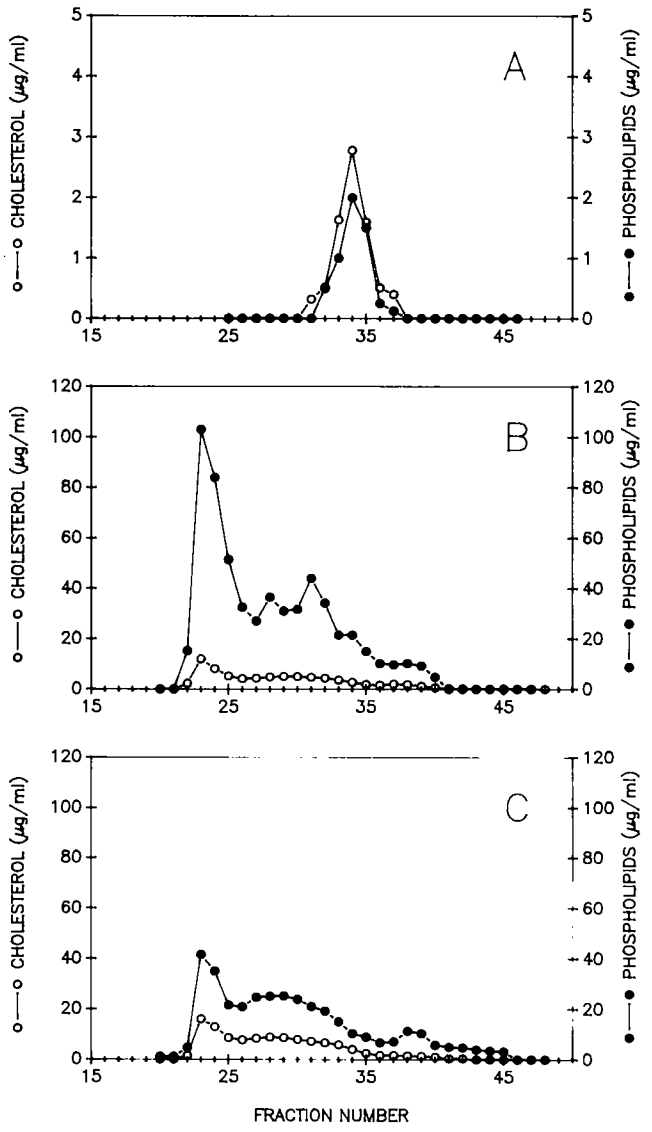

FIG. 4. Gel permeation chromatography of LDL and liposomes isolated by density gradient ultracentrifugation. Density gradient fractions 3 to 7 (Fig. 3) were combined and subjected to chromatography on BioGel A-5m, using a 1.5 × 90 cm column at a flow rate of 6 ml/hr. Fractions of 3 ml were collected and assayed for cholesterol and phospholipid contents. A, density gradient fractions 3 to 7, before injection; B, density gradient fractions 3 to 7, 15 min after injection; C, density gradient fractions 3 to 7, 3 hr after injection.

the liposomes), there is a major peak of phospholipids and cholesterol in the region of LDL. In both regions of LDL and HDL, increases of cholesterol and decreases of phospholipids are observable.

Gel permeation chromatography. Peak fractions from the density gradient ultracentrifugation (Fig. 3) were pooled and further analyzed by gel permeation chromatography to assess particle size and determine contents of cholesterol and phospholipids. Figure 4 shows the profiles of gel permeation chromatography of density gradient fractions 3-7 of Figure 3, corresponding to LDL in control serum. Panel A (control sample) shows only a single peak of cholesterol and phospholipids. Panel B reveals several peaks containing both cholesterol and phospholipids, 15 min after injection. The first peak from the left elutes in the region of control liposomes, and the second is a broad peak encompassing LDL and larger particles. Panel C (3 hr after injection) is qualitatively similar to the profile in Panel B, except for the obvious decrease in phospholipids and the appearance of a more-defined minor peak eluting in the region of control HDL. This peak indicates that a portion of HDL had acquired lower density to the range of LDL (Fractions 3-7, Fig. 3).

There was a decrease in the free cholesterol/phospholipid ratio in the LDL peak 15 min after injection, from 0.47 to 0.08, but an increase to 0.18, three hr after injection. Since the total amount of cholesterol in the LDL peak did not decrease significantly, or actually increased slightly after liposome injection, the decrease in this ratio reflects uptake of phospholipids from the liposomes by the LDL particles.

Similar studies were conducted with density gradient fractions 10 to 15 (HDL) of Figure 3. The results are shown in Figure 5. In each case there was a single peak containing both cholesterol and phospholipid. The rapid uptake of phospholipids by HDL 15 min after injection is evident in Panel B, and the loss of phospholipids thereafter is evident in Panel C.

Identification of liposome-associated apolipoproteins. For the isolation of liposomes from serum, serum samples were subjected to ultracentrifugation at a density of 1.006 g/ml to remove VLDL. The $d > 1.006$ g/ml fraction was then centrifuged at density 1.25 g/ml to separate the total lipoprotein fraction ($d < 1.25$ g/ml). This fraction was subjected to gel permeation chromatography for the separation of individual lipoproteins.

Figure 6 shows typical cholesterol and phospholipid profiles before and after injection of liposomes. Liposomes were recovered in the first peak eluted from the column (fractions 21-25). These fractions were pooled, lyophilized and delipidated. The protein pellet obtained was solubilized in the appropriate buffer (see Methods) and subjected to IEF. Figure 7 shows the liposomes recovered 3 hr after injection to contain the isoforms of apo E as the major protein and smaller amounts of apo A-I. The C apolipoproteins were also observed in trace amounts when gels were subjected to silver staining (data not shown). The isoforms of apolipoproteins E, A-I and C were verified by molecular weight estimations using two-dimensional electrophoresis with SDS-PAGE as the second dimension (data not shown).

Changes in red blood cells in vitro and in vivo. The increase in serum cholesterol found after the injection of liposomes could come from tissues including the arterial wall, the lipoproteins and possibly red blood cells. To test the ability of liposomes to remove cholesterol from red blood cells, we incubated red blood cell ghosts with liposomes and found decreases in the content of membrane cholesterol in a dose- and time-dependent manner (Figs. 8 and 9). Corresponding to the increase of cholesterol associated with the liposomes, was a decrease of cholesterol/phospholipid ratio in the cell membrane.

The above described decrease of cholesterol in red blood cell ghosts was not, however, observed in red blood cells in vivo. Three rabbits were each injected with liposomes (50 mg phospholipid/kg body weight) and blood was collected in EDTA (final concentration: 2 mg/ml blood). The hematocrit was measured and red blood cells were used

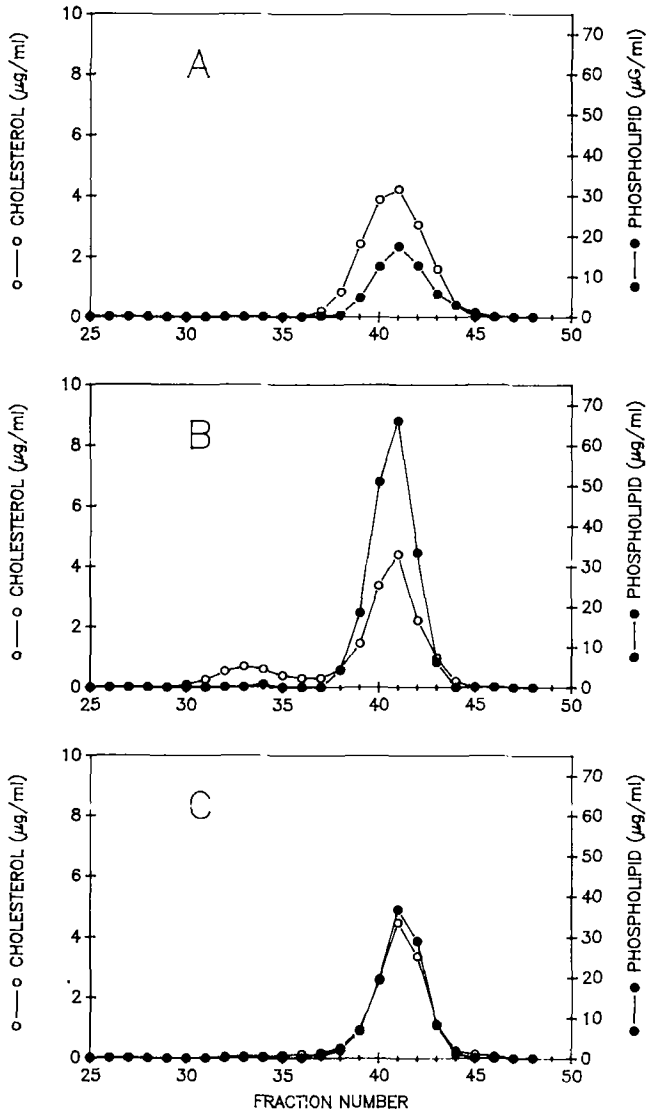

FIG. 5. Gel permeation chromatography of HDL isolated by density gradient ultracentrifugation. Density gradient fractions 10 to 15 (Fig. 3) and subjected to chromatography on BioGel A-5m using a 1.5 × 90 cm column at a flow rate of 6 ml/hr. Fractions of 3 ml were collected and assayed for cholesterol and phospholipid contents. A, density gradient fractions 10 to 15, before injection; B, density gradient fractions 10 to 15, 15 min after injection; C, density gradient fractions 10 to 15, 3 hr after injection.

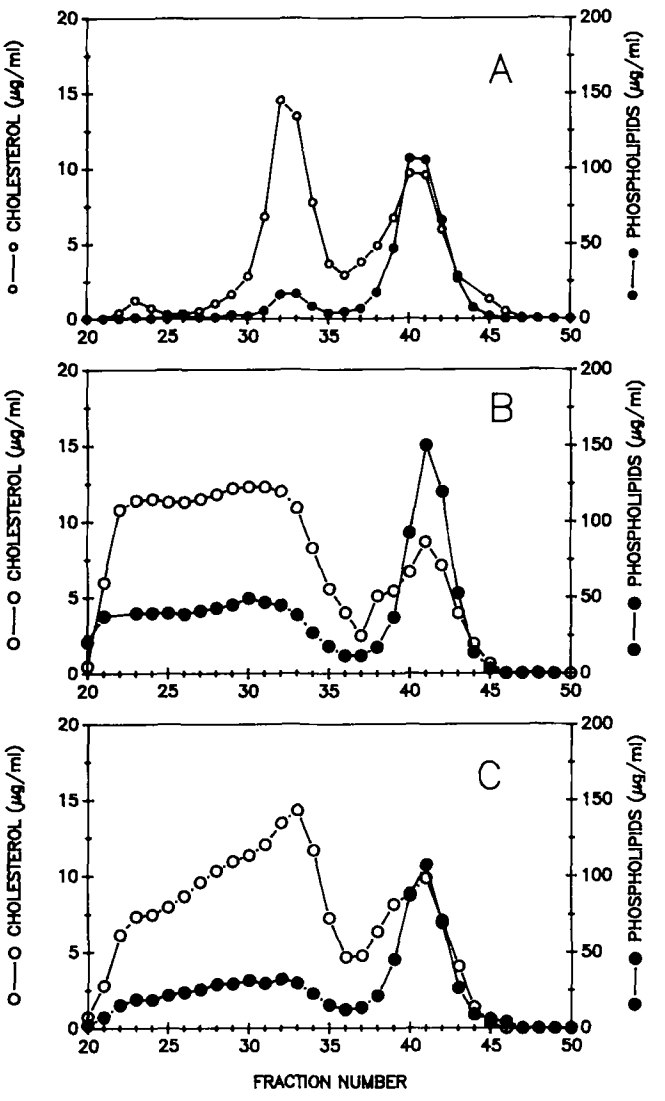

FIG. 6. Gel permeation chromatography of density 1.006 to 1.25 g/ml serum fractions before and after liposome injection. Serum samples were subjected to ultracentrifugation, and the density 1.006 to 1.25 g/ml fraction subjected to gel permeation chromatography on BioGel A-5m using a 1.5 × 90 cm column at a flow rate of 6 ml/hr. Fractions of 3 ml were collected and assayed for cholesterol and phospholipid contents. A, before injection; B, 50 min after injection; C, 3 hr after injection.

to prepare ghosts. The cholesterol and phospholipid contents of the red blood cell ghosts were determined and the cholesterol/phospholipid ratio calculated. Results in Table 1 show that the cholesterol/phospholipid ratio before and after injection did not change significantly, and the variations were within errors of assay (coefficient of variation for the same sample measured in pentuplicate was ±3.1%). Also, there was no appreciable change in the hematocrit value, indicating no loss of red blood cells resulting from the injection of liposomes.

DISCUSSION

Our data show that serum cholesterol and phospholipid levels increase after injection of egg yolk phospholipid liposomes (Fig. 1). Figures 2-5 indicate profound alterations of serum lipoproteins after the injection. There was a rapid assimilation of the injected phospholipids by the lipoproteins and, consequently, there were decreases in the density of LDL and HDL (Fig. 3), with increased particle sizes and decreased electrophoretic mobilities (Fig. 2). These results were qualitatively similar to results obtained after incubation of lipoproteins with liposomes in vitro (recently reviewed in Reference 19). It is of interest that the 2- to 3-fold increase in serum-free cholesterol was associated mainly with the liposomes (Figs. 4 and 6). Similar observations have been reported after infusion of egg yolk phospholipids into dogs (6), except that apo E was not identified in liposomes. It is not likely that the cholesterol taken up by the liposomes was newly

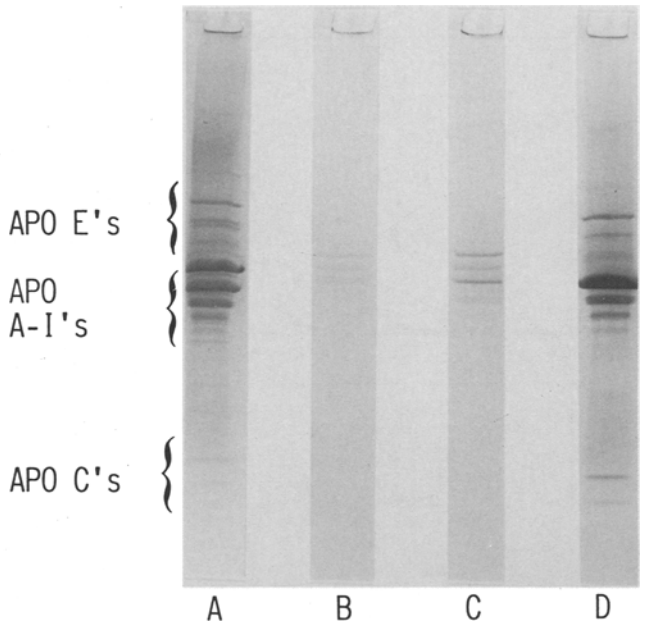

FIG. 7. Presence of apolipoproteins in recovered liposomes. The d > 1.006 to 1.25 g/ml fraction from serum was applied to a BioGel A-5m column as described for Fig. 6. Peak fractions were combined, and after concentration and delipidation were subjected to isoelectric focusing. A, HDL, before injection, column fractions 38–44; B, liposomes, 3 hr after injection, column fractions 21–25; C, liposomes, 3 hr after injection, column fractions 26–29; D, HDL, 3 hr after injection, column fractions 38–44.

synthesized, but was probably from the efflux of tissue cholesterol. Byers and Friedman (20) have shown in the hepatectomized rat that injection of phospholipids caused increased circulating cholesterol levels that could not be attributed to hepatic source.

Although incubation of red blood cell ghosts with liposomes caused removal of membrane cholesterol in vitro, no change in the cholesterol/phospholipid ratio in red blood cells was observed after injection of liposomes in vivo (Table 1). This discrepancy could be explained on the assumption that the cholesterol of red blood cells in vivo is replenished by rapid equilibration with cholesterol in lipoproteins and/or tissues. These data suggest that, if circulating red blood cells incorporate liposome phospholipids, they must also incorporate cholesterol derived from lipoproteins or tissues to maintain a steady cholesterol/phospholipid ratio.

It has been shown previously that incubation of phospholipid liposomes with fibroblasts in culture caused cellular efflux of cholesterol (21,22). In our experience, we found that the cholesterol content of human fibroblasts decreased as much as 30% by incubation with egg yolk phospholipid liposomes (unpublished observation). The data in Figure 5 show that injection of phospholipid liposomes caused the removal of free cholesterol from HDL and an increase in phospholipid content of the HDL. It has been suggested that the free cholesterol/phospholipid ratio of HDL determines its ability to remove cell cholesterol in vitro (23). According to this view, our observed alterations should increase the ability of HDL to remove tissue cholesterol.

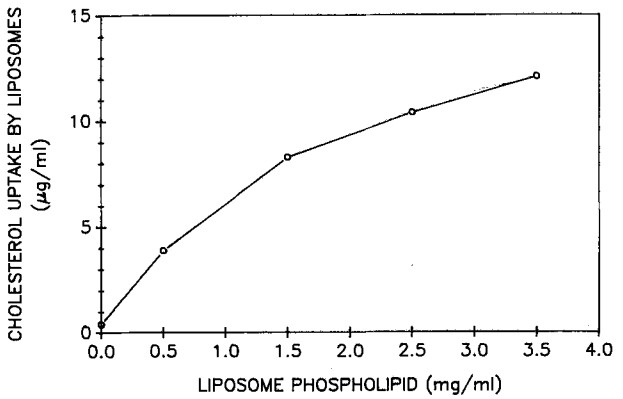

FIG. 8. Cholesterol uptake by liposomes from rabbit red blood cell ghosts. Increasing amounts of egg yolk phospholipid liposomes were incubated with red blood cell ghosts containing 250 μg of phospholipid in 0.15 M NaCl, 0.01 M Tris pH 7.4 for 6 hr at 37°C in a shaking water bath. After incubation membranes were sedimented by centrifugation at 14,000 × *g* for 30 min and cholesterol content in the supernatant was measured.

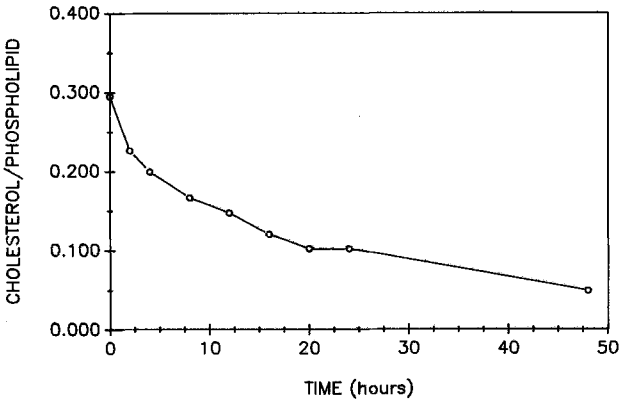

FIG. 9. Time course of cholesterol removal from rabbit red cell ghosts. Red cell ghosts containing 250 μg phospholipids were incubated with 2.5 mg of egg yolk phospholipid liposomes in 1.2 ml of 0.15 M NaCl, 0.01 M Tris, pH 7.4, for various lengths of time at 37°C in a shaking water bath. After incubation, red cell ghosts were sedimented and washed 3 times with buffer at 14,000 × *g*. Cholesterol and phospholipid contents were assayed and the ratio calculated.

TABLE 1

Lack of Change in Red Blood Cells After Injection of Phospholipid Liposomes

	Red blood cell ghosts Cholesterol/phospholipid			Whole blood Hematocrit (%)	
Rabbit	Before	After	% Change	Before	After
1	0.504	0.486	−3.57	38	37
2	0.438	0.423	−3.42	39	38
3	0.462	0.476	+3.03	35	35

Rabbits were injected with 60 mg liposomal phospholipid/kg body weight and blood was collected before and after injection, for measuring hematocrit. Red blood cell ghosts were prepared for measurement of cholesterol and phospholipids.

The fate of cholesterol incorporated into liposomes is not clear. However, many studies have shown that the injected liposomes are preferentially taken up by the liver (24,25). The data in Figure 7 demonstrated that liposomes acquire, in addition to free cholesterol, apolipoproteins E, A-I and traces of C. Because hepatocytes have receptors for apo E and apo A-I (26,27), their presence should target the liposomes for uptake by the liver. Our data support the view that injection of phospholipids has an antiatherogenic effect by enhancing the reverse cholesterol transport mechanism, a hypothesis recently put forth by Williams et al. (28). This enhancement, theoretically at least, may have an antiatherogenic effect.

ACKNOWLEDGMENTS

This work was supported in part by a grant from the Wallace Genetic Foundation and funds from the Dermatology Foundation of Miami. We wish to thank Asahi Chemicals of Tokyo, Japan, for the generous gift of egg yolk phospholipids used in this study.

[Received April 27, 1988; Revision accepted July 18, 1988]

Docosahexaenoic Acid and Other Dietary Polyunsaturated Fatty Acids Suppress Leukotriene Synthesis by Mouse Peritoneal Macrophages

Belur R. Lokesh, J. Mark Black, J. Bruce German and John E. Kinsella*
Lipids Research Laboratory, Stocking Hall, Institute of Food Science, Cornell University, Ithaca, NY 14853

The efficacy of individual ω-3 polyunsaturated fatty acids (PUFA) in altering eicosanoid synthesis in peritoneal macrophages was studied by feeding mice for 10 days a diet containing 2 wt % fat, which included 0.5 wt % ethyl esters of eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA) or linolenic acid (LNA). Upon stimulation with calcium ionophore A23187, macrophages from these animals produced significantly lower amounts of leukotriene C_4, leukotriene B_4 and 12-hydroxyeicosatetraenoic acid, prostaglandin E_2 and 6-keto prostaglandin $F_{1\alpha}$ compared with those obtained from animals on the diets containing olive oil or safflower oil. The decrease in leukotriene synthesis was similar in the animals fed DHA, EPA or LNA diets. This depression of eicosanoids by DHA and EPA was associated with decreased levels of arachidonic acid (AA); however, LA that altered eicosanoids did not have the same effect on AA levels.
Lipids 23, 968-972 (1988).

The role of leukotrienes in inflammatory processes is well documented (1-3). Leukotriene B_4 (LTB_4) is a powerful chemotactic agent, but leukotriene C_4 (LTC_4) and other peptidoleukotrienes enhance vasopermeability and exudation of plasma cells (3-5). Excess or imbalanced production of these leukotrienes may exacerbate pathophysiological states like inflammation, asthma, arthritis and psoriasis (3,4,6,7). Therefore, the regulation of leukotriene production is vital in controlling inflammation and preventing pathophysiological states.

Leukotriene production can be inhibited by agents such as eicosatetraynoic acid, nordihydroguaiaretic acid, BW755C, esculetin or gossypol (3,4,8,9). Certain dietary polyunsaturated fatty acids (PUFA), especially the ω-3 (n-3) PUFA series in fish oils, may modulate leukotriene synthesis and possibly ameliorate inflammatory conditions (10-13). Though fish oils contain both eicosapentaenoic acid (EPA), 20:5n3, and docosahexaenoic acid (DHA) 22:6n3 as the major n-3 PUFA components, the modulating effects of dietary fish oil on eicosanoid synthesis have been generally attributed to EPA, although the effect of DHA is equivocal (13-15). It has been reported that DHA may not affect leukotriene synthesis at the lipoxygenase level in human neutrophils (15) and RBL-1 cell homogenates (12). However, recently we demonstrated that mouse macrophages, enriched with DHA in vitro, produced significantly lower amounts of leukotrienes, compared with the control cells, indicating that DHA can significantly reduce leukotriene synthesis by altering the arachidonic acid (AA) substrate pools utilized for leukotriene synthesis (16).

In order to determine if similar effects can be induced in vivo, mice were fed a diet enriched with DHA. To compare the efficacy of DHA with other unsaturated fatty acids, groups of mice also were fed diets enriched with EPA (20:5n3), linolenic acid (LNA) (18:3n3), olive oil (18:1n9) or safflower oil (18:2n6).

MATERIALS AND METHODS

Materials. Calcium ionophore A23187 (lot 105f-4014), reduced glutathione and cysteine hydrochloride were purchased from Sigma Chemical Company (St. Louis, MO). Ethyl esters of linolenic acid (>99.5% pure) and docosahexaenoic acid (<99.5% pure) and a preparation of eicosapentaenoic acid ethyl esters (53% EPA, 7% docosapentaenoic acid, 13% DHA) were purchased from NuChek Prep (Elysian, MN). Commercial edible olive oil and safflower oil were obtained locally. Leukotriene standards were obtained from Merck Frosst (Montreal, Canada). Radioimmunoassay kits for quantification of prostaglandins (prostaglandin E_2 and 6-keto prostaglandin $F_{1\alpha}$) were purchased from Seragen, Inc. (Boston, MA). Analytical grade solvents were used for the extraction of lipids and eicosanoids.

Animals. Male mice (CD-1 type) weighing 18-20 g were purchased from Charles River (Wilmington, MA) and housed five per cage. A 12 hr light-dark cycle and a temperature of 22°C was maintained in the room.

Diets. Fat-free diet was purchased from ICN Nutritional Biochemicals (Cleveland, OH). All diets were thoroughly mixed with 1.5 wt % olive oil and then supplemented with an additional 0.5 wt % olive oil (Diet A), 0.5 wt % safflower oil (Diet B), 0.5% wt % ethyl ester of LNA (Diet C), 0.5 wt % ethyl ester of EPA (Diet D) and 0.5 wt % DHA (Diet E). The diets were thoroughly mixed after the addition of oils, and small amounts (35 g) were transferred to Whirlpak plastic bags, flushed with nitrogen and stored at 4°C in the dark. The mice received fresh diet every day. There was no oxidation of dietary fats as measured by thiobarbituric acid reactive materials and also by the analysis of fatty acids (17). The fatty acid composition of the diets is shown in Table 1. Mice were fed a fat-free diet for one week to reduce endogenous ω-3 fatty acids and facilitate the rapid uptake of dietary fatty acid esters fed to the animals. The animals on a fat-free diet for one week did not show any symptoms of essential fatty acid deficiency and did not accumulate 20:3n-9 fatty acid. The net production of eicosanoids by macrophage from lab chow-fed animals were: Prostaglandin E_2 (PGE_2) 5.2 ± 0.96 ng/μg DNA and 6 keto Prostaglandin $F_{1\alpha}$ (6 keto $PGF_{1\alpha}$) 32.3 ± 3.16 ng/μg DNA. The corresponding values for macrophages from fat-free-fed animals for one week were PGE_2 5.45 ± 0.9 ng/μg DNA

OO, olive oil; SO, safflower oil; LNA, linolenic acid; EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid.

and 6 keto $PGF_{1\alpha}$ 30.1 ± 2.5 ng/μg DNA. Therefore, the fat-free diet for one week did not exert any deleterious effects on macrophages. Following one week on a fat-free diet, the mice were randomized into cages (5 animals per cage) and fed experimental diets for 10 days. Diet A (olive oil diet) was used as the control diet, as in previous studies (18). Diet B was enriched with linoleic acid (LA), 18:2n6; diet C with LNA; diet D with EPA; and diet E was enriched with DHA. The total fat content (2 wt %) was the same in all diets.

Isolation of peritoneal macrophages. After 10 days on the fat-supplemented diet, the mice were sacrificed by ether inhalation. Peritoneal cells were removed in PBS buffer containing 10 IU heparin/ml. Cells were washed and suspended in Dulbecco's modified Eagle medium containing 10% fetal bovine serum (2.5×10^6 cells/ml). Aliquots (2 ml) were dispensed in Falcon tissue culture wells (35 mm) and incubated for 2 hr at 37°C in a humidified chamber containing 5% CO_2. The adhering cells (1.8×10^6 cells) were washed three times in Dulbecco's medium (19). More than 95% of the cells were identified as macrophages by esterase staining and phagocytosis (20). The protein content of the cells in culture, determined by Lowry et al. (21), was 80 ± 10 ng/10^6 cells and the corresponding DNA content, determined with mitramycin (22), was 56 ± 3.2 ng/mg protein (means ± SD; n = 6).

Leukotriene analysis. Macrophages in 1.5 ml Dulbecco's modified Eagle medium were stimulated by incubation with 0.5 μg/ml calcium ionophore A23187, 5 mM cysteine hydrochloride, 1 mM reduced glutathione for 2 hr at 37°C, as previously described (16,23,24). Reactions were terminated by adding 2 ml methanol, and the cells with the medium were transferred to extraction tubes, sonicated for 30 sec at 4°C and centrifuged for 5 min in a clinical centrifuge. The supernatant was removed and the pH was adjusted to pH 3 with 3% formic acid. This solution was adjusted to contain 20% methanol by adding deionized distilled water. These samples were prepared for high performance liquid chromatography (HPLC) by selective extraction of the eicosanoids/leukotrienes by reverse-phase columns (Sep Pak, Waters, Milford, MA), using the methodology described by Borgeat et al. (25). The leukotriene fractions were quantified by HPLC (Waters, Milford, MA) using a Supelco ODS reverse-phase column and a mobile phase of methanol/water (75:25, v/v) in 5 mM ammonium acetate buffer (pH 5.6) containing 1 mM EDTA. Leukotrienes and hydroxy fatty acids (HETE) were identified by retention time compared with authentic standards, by their UV absorption spectra obtained by a diode array spectrophotometric detector and were quantified by their absorbances using extinction coefficients of authentic standards (16).

Prostaglandin analysis. Macrophages were stimulated with calcium ionophore A 23187 (0.5 μg/ml) for 2 hr at 37°C. Prostaglandins were extracted from the medium in three volumes of ethyl acetate and quantified by radioimmunoassay (26). The PGE_2 antiserum had a cross reactivity of less than 1% with TXB_2, 6-keto $PGF_{1\alpha}$, HETE and AA. The 6-keto $PGF_{1\alpha}$ antiserum had a cross reactivity of 0.6% with PGE_2 and less than 0.1% with TXB_2, HETE and AA.

Fatty acid analyses. Because insufficient macrophage material was available for fatty acid analyses, spleen tissue which changes in a manner similar to macrophages in response to fish oil (26–28), were analyzed to monitor changes after feeding experimental diets.

Mice were killed by ether asphyxiation and the spleens were immediately removed and flushed with a buffer, 0.25 M sucrose containing 10 mM Tris and 1 mM EDTA buffer, pH 7.4. After removing the connective tissues, the spleens were weighed, minced using scissors and homogenized at 4°C in 5 vol of 0.05 M Tris HCl buffer, pH 7.4, in a polytron (Kinematics, Lucerne, Switzerland) for 60 sec in 2 × 30 sec bursts at setting 4, followed by a 20 sec burst with an Ultrasonics Model W-10 ultrasonic sonicator (Ultrasonics, Plainview, NY). The homogenate was collected after centrifuging at 600 *g* for 15 min in a Sorval RC5B to remove cell debris and unbroken cells. Lipids were extracted from spleen homogenates by the method of Bligh and Dyer (29). The phospholipids were separated from neutral lipids on HPTLC plates using chloroform/methanol (80:20, v/v). The lipids were saponified with 0.5 N KOH in methanol and the fatty acids were methylated with diazomethane. The fatty acid methyl esters were separated using a Hewlett-Packard 5880A gas chromatograph (Hewlett-Packard, Avondale, PA) on a 0.75 mm by 60 MSP2330 capillary column (Supelco, Inc., Bellefonte, PA) with hydrogen as carrier gas. Fatty acids were identified by comparing retention times with fatty acid methyl ester standards and quantified using pentadecanoic acid as internal standard (30).

Statistical methods. Results were statistically evaluated by Statistical Analysis System using the General Linear Models procedure and the least significant difference mean-separation determination (SAS Institute, Chapel Hill, NC) (31).

RESULTS AND DISCUSSION

The amounts of diet consumed (ca. 5 g/day/mouse) and the weight gains (6.1 ± 0.3 g/mouse in 10 days, mean ± SD, n = 10 per group) by the animals were similar in all dietary groups.

Fatty acid composition. Spleen is an important site for monocyte/macrophage production and it responds to dietary fatty acids in a way similar to those observed with macrophages (26–28,32). Therefore, the changes induced in spleen phospholipid fatty acid composition by the different dietary fatty acids were determined. The animals on safflower oil diets accumulated significant amounts of LA compared to those on olive oil diets (Table 2). The AA levels in spleens of safflower oil-fed animals, however, were similar to those on olive oil diets, despite the fact that safflower oil diets contained threefold more LA, the precursor of AA (Table 1), indicating that the metabolism of LA to AA is highly regulated. Animals on LNA-enriched diets (Diet C) contained similar amounts of AA, but had significant amounts of 22:5n3 (DPA) and DHA, the elongated and desaturated products of LNA. Significantly, LNA did not accumulate in the spleen phospholipids of animals on LNA-enriched diets. The animals consuming EPA-enriched diets (Diet D) accumulated mostly DPA and DHA, the elongation and desaturation products of EPA. The accumulation of these fatty acids was associated with the displacement of AA from the phospholipids. The animals on the DHA-enriched diet (Diet E) contained significantly higher amounts of DHA in spleen phospholipids, which was accompanied by a decrease of AA (Table 2). A small accumulation of DPA and EPA, the retroconversion product of DHA, was observed in spleen phospholipids of animals on the DHA-enriched diets. These data indicate that the metabolism of PUFA are differentially regulated. While LA (from the safflower oil diet) accumulated in the spleen lipids without any further metabolism, LNA was not accumulated as such but as its elongated and desaturated products. However, EPA accumulated as the parent fatty acid and also as its products, DPA and DHA. A small amount of these fatty acids may have been obtained directly from the diets since EPA-enriched diets also contained small amounts of DPA and DHA (Table 1). However, our studies of the modifications of macrophage in vitro with pure EPA have shown that significant amounts of EPA were elongated to DPA, but not desaturated to DHA by macrophages (16). Similar results have been observed in human polymorphonuclear leukocytes (33,34). Docosahexaenoic acid accumulated mostly as DHA in spleen phospholipids, with only a small amount being retroconverted to DPA and EPA. These results are consistent with those observed in humans, rat liver and endothelial cells (35–37). While LA (from safflower oil) and LNA did not affect AA levels, EPA and DHA displaced AA from spleen phospholipids.

Leukotriene and 12-HETE synthesis. Macrophages are major sources of eicosanoids (38,39) and prostaglandin and leukotriene synthesis is sensitive to the influence of dietary fats (11,26). Therefore, macrophages were analyzed to ascertain the efficacy of different PUFA in modulating eicosanoid production. The resident peritoneal macrophages synthesized negligible amounts of leukotrienes in the absence of a stimulus (23,40,41). Following exposure to calcium ionophore (A23187), the macrophages synthesized significant amounts of LTC_4 and LTB_4 from endogenous substrates (16,23). Upon stimulation, the net production of LTC_4, LTB_4 and 12-HETE, in macrophages isolated from animals on diets enriched in n-3 PUFA, was significantly lowered ($p < 0.05$), compared with the macrophages isolated from animals on safflower or olive oil diets (Fig. 1). These results indicated that n-3 PUFA significantly lowered the net production of leukotrienes in macrophages. The magnitude of the decreases in leukotrienes observed from animals in LNA, EPA or DHA diets was comparable indicating that, irrespective of the chain length and degree of unsaturation, the n-3 PUFA in the diet lowered leukotriene production in macrophages. Significantly, DHA was very effective in reducing leukotrienes. Unlike that in rats (11), the mouse

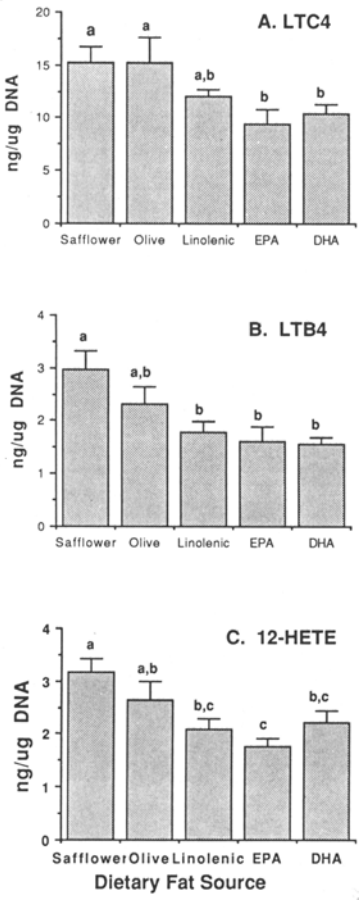

FIG. 1. Histograms showing the relative efficacies of different dietary unsaturated fatty acids in depressing the net production of A) LTC_4, B) LTB_4 and C) 12-HETE by mouse peritoneal macrophages. Macrophages isolated from mice on different dietary fats were stimulated with calcium ionophore A23187 (0.5 μg/ml) for 2 hr at 37°C. The leukotrienes were extracted and analyzed by HPLC as described in methods. Results are mean ± SEM from 5 animals. Means with different letters above the histograms are significantly different ($p < 0.05$) than each other. Histograms with same notation are not different than each other.

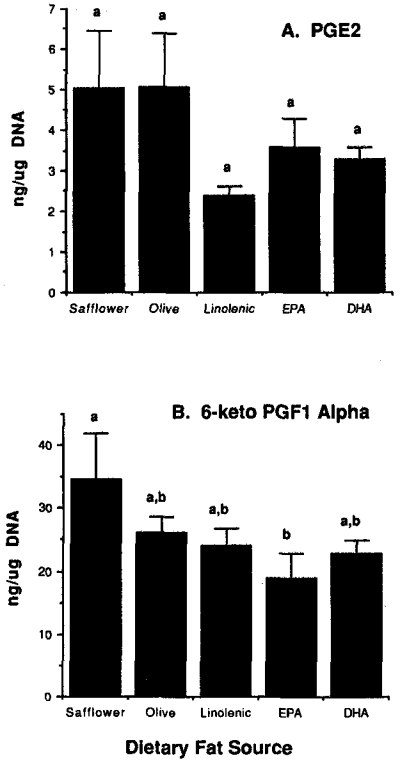

FIG. 2. The effects of different dietary unsaturated acids on the net production of A) PGE_2 and B) 6-keto $PGF_{1\alpha}$ by mouse peritoneal macrophages. Macrophages isolated from mice on different dietary fats were stimulated with calcium ionophore A23187 (0.5 μg/ml) for 2 hr at 37°C. The prostaglandins were extracted in three volumes of ethyl acetate and quantified by radioimmunoassay as described in methods. Results are mean ± SEM from 5 animals. Histograms with different letters are significantly different than each other ($p < 0.05$).

macrophage did not produce 5-series leukotrienes in EPA-enriched cells.

Unlike EPA and DHA, LNA did not displace AA from membrane lipids but, as its elongated products (DPA and DHA), it was still effective in suppressing leukotriene synthesis in macrophages. Therefore, the displacement of AA from tissue pools is not essential, but the incorporation of n-3 PUFA is apparently necessary for suppressing leukotriene production in macrophages. The spleens from animals exposed to EPA-enriched diets contained 50% less n-3 PUFA (ca. 8 mol %) compared with DHA (ca. 16 mol %) or LNA (ca. 18 mol %) diets (Table 1), but caused a similar decrease in leukotriene production. Thus, n-3 PUFA, even as low as 8 mol % in the diet, can suppress leukotriene synthesis. Further studies, to evaluate the minimum amount of n-3 PUFA in the diet needed to suppress leukotriene synthesis in macrophages and to identify the possible role of DPA in this reaction, are in progress.

This study demonstrates that DHA indeed suppresses leukotriene synthesis in macrophages, which agrees with our earlier studies on macrophages modified in vitro with purified DHA (16). Earlier studies with human neutrophils (15) and RBL-1 cell homogenates (12) indicated that DHA is ineffective in modulating leukotriene synthesis in short-term incubations. However, our dietary studies and in vitro studies demonstrated that DHA is as effective as other n-3 PUFA in suppressing leukotriene synthesis, provided a longer time of equilibration with DHA was allowed.

Prostaglandin synthesis. In addition to leukotrienes, macrophages also synthesize prostaglandins upon stimulation with calcium ionophore (38). Macrophages from animals on n-3 PUFA diets produced lower amounts of PGE_2 and 6-keto $PGF_{1\alpha}$ compared with those animals eating a diet containing safflower oil or olive oil (Fig. 2). This is in agreement with our previous results, where n-3 PUFA from a menhaden oil diet or enrichment of macrophages with pure n-3 PUFA lowered prostaglandin synthesis (26,42).

In conclusion by dietary and in vitro modifications, we have demonstrated that DHA, after equilibrating in the cellular lipids, is capable of suppressing leukotriene synthesis in macrophages and its effect is as significant as those observed with EPA. Therefore, in addition to EPA, one should also consider the DHA component of fish oils when evaluating their efficacies in modulating eicosanoid-mediated functions, including inflammatory reactions, cardiovascular functions and perhaps cancer (43–45).

[Received March 7, 1988; Revision accepted July 11, 1988]

Dietary Linoleic Acid and the Fatty Acid Profiles in Rats Fed Partially Hydrogenated Marine Oils

C.-E. Høy* and **G. Hølmer**
Department of Biochemistry and Nutrition, Building 224, The Technical University of Denmark, DK-2800 Lyngby, Denmark

The influence of the linoleic acid levels of diets containing partially hydrogenated marine oils (HMO) rich in isomeric 16:1, 18:1, 20:1 and 22:1 fatty acids on the fatty acid profiles of lipids from rat liver, heart and adipose tissue was examined. Five groups of rats were fed diets containing 20 wt % fat—16% HMO + 4% vegetable oils. In these diets, the linoleic acid contents varied between 1.9% and 14.5% of the dietary fatty acids, whereas the contents of *trans* fatty acids were 33% in all groups. A sixth group was fed a partially hydrogenated soybean oil (HSOY) diet containing 8% linoleic acid plus 32% *trans* fatty acids, mainly 18:1, and a seventh group, 20% palm oil (PALM), with 10% linoleic acid and no *trans* fatty acids.

As the level of linoleic acid in the HMO diets increased from 1.9% to 8.2%, the contents of (n-6) polyunsaturated fatty acids (PUFA) in the phospholipids increased correspondingly. At this dietary level of linoleic acid, a plateau in (n-6) PUFA was reached that was not affected by further increase in dietary 18:2 (n-6) up to 14.5%. Compared with the HSOY- or PALM-fed rats, the plateau values of 20:4(n-6) were considerably lower and the contents of 18:2(n-6) higher in liver phosphatidylcholines (PC) and heart PC. Heart phosphatidylethanolamines (PE) on the contrary, had elevated contents of 20:4(n-6), but decreased 22:5(n-6) compared with the PALM group.

All groups fed HMO had similar contents of *trans* fatty acids, mainly 16:1 and 18:1, in their phospholipids, irrespective of the dietary 18:2 levels, and these contents were lower than in the HSOY group.

High levels of linoleic acid consistently found in triglycerides of liver, heart and adipose tissue of rats fed HMO indicated that feeding HMO resulted in a reduction of the conversion of linoleic acid into long chain PUFA that could not be overcome by increasing the dietary level of linoleic acid.
***Lipids 23,* 973–980 (1988).**

Partially hydrogenated fats used for the manufacturing of margarines and other fats for human consumption are made from vegetable oils in the U.S. (1), but in Europe may include considerable quantities of marine oils (2), particularly in low linoleic acid margarines. The isomeric octadecenoic acids present in partially hydrogenated vegetable oils are incorporated into various tissues of the rat (3–5), as are isomers from partially hydrogenated marine oils (HMO) (6,7). Post mortem studies have also demonstrated presence of isomeric *cis* and *trans* octadecenoates (8,9) in humans.

*To whom correspondence should be addressed.

Abbreviations: EFA, essential fatty acid; HMO, partially hydrogenated marine oil; HSOY, partially hydrogenated soybean oil; OO, olive oil; PALM, palm oil; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PUFA, polyunsaturated fatty acid; SO, sunflowerseed oil; TG, triglyceride; VLDL, very low density lipoprotein; GLC, gas liquid chromatography; SEM, standard error of the mean; TLC, thin layer chromatography.

It has been shown, using liver microsomes from rats raised on essential fatty acid (EFA)-deficient diets, that isomeric octadecenoic acids may competitively inhibit the Δ6-desaturation of 18:2(n-6) into 18:3(n-6) and the Δ5-desaturation of 20:3(n-6) into 20:4(n-6) (10,11). Feeding trials using *trans,trans* 18:2 have also demonstrated a decreased formation of arachidonic acid (12,13).

Partially hydrogenated oils of marine origin differ from those of vegetable origin in their significant contents of 20:1- and 22:1-*cis* and *trans* fatty acids.

Only a few studies on the effects of HMO in EFA-sufficient diets have been published so far. In these studies, a diet with a high level of HMO and a low level of linoleic acid was compared with a reference diet containing a vegetable oil with a much higher linoleic acid level. Using such an experimental design, it was shown that rats fed an HMO + 18:2 diet had reduced levels of 20:4(n-6), but increased levels of 18:2(n-6) and 20:3(n-6), but rats fed a partially hydrogenated peanut oil diet, with similar contents of *trans* fatty acids and linoleic acid as the former, had a smaller decrease in 20:4(n-6) and only accumulated 18:2(n-6) (14,15). This could be explained by reduced Δ6- and Δ5-desaturase activities following intake of HMO, but rats fred partially hydrogenated peanut oil had only reduced Δ6-desaturation (16,17). Also, in accordance with former reports, this study demonstrated that partially hydrogenated fats aggravated the state of EFA deficiency, HMO being more potent in this respect than partially hydrogenated peanut oil (18).

In the present experiment, we used diets with various levels of linoleic acid ranging from 1.9% to 14.5% of the dietary fat, with the dietary level of HMO maintained constant, providing 33% *trans* fatty acids. This design allowed us to study if it was possible to overcome the inhibitory effects of HMO on the conversion of linoleic acid simply by increasing the dietary level of linoleic acid eventually to a level higher than that of the reference group not fed HMO. The effects of chain lengths of isomeric fatty acids were examined in a group fed a diet containing partially hydrogenated soybean oil (HSOY) with an intermediate level of linoleic acid. The fatty acid profiles of major phospholipids and triglycerides (TG) were examined in liver, heart and adipose tissue.

MATERIALS AND METHODS

Animal experiments. Eighty-four weanling male Wistar rats (specific-pathogen-free, Møllegaard Laboratory, Ll. Skensved, Denmark) were divided into seven groups, each with 12 rats of similar average weights. The rats received a diet of the following composition (wt %): casein (Holstebro Maelkekondenserings-fabrik), 20%; fat, 20%; sucrose, 10%; maize-starch (Maizena-Compagniet A/S, Copenhagen), 40%; cellulose powder, MN 100 (Machery Nagel, GFR), 4%; vitamin mixture, 0.5%; choline chloride, 0.5%; and salt mixture (including trace elements), 5.0%. The compositions of the vitamin mixture and the trace elements were as previously described (18). The dietary

fats were partially hydrogenated marine oil (HMO) ("Sandarit," Jahres Fabrikker A/S, Sandefjord, Norway); olive oil (OO) (Pharmacopea Danica 48, Mecobenzon A/S, Copenhagen, Denmark); sunflowerseed oil (SO) (Aarhus Oliefabrik A/S, Aarhus, Denmark); partially hydrogenated soybean oil (HSOY) (Solofabrikken A/S, Sønderborg, Denmark); and palm oil (PALM) (Solofabrikken A/S, Sønderborg, Denmark). The dietary fats were mixed into seven different diets (Table 1).

The rats were caged in pairs at 25°C and a relative humidity of 45%. Diets and water were supplied ad libitum. The rats were examined and weighed weekly. After 10 weeks, the rats were decapitated and liver, heart and a sample of adipose tissue were immediately excised.

Analyses of lipids. Total lipids were extracted from liver or heart, according to Folch et al. (19), and determined gravimetrically. The total phospholipid content was quantitated as inorganic phosphorous (20). Adipose tissue was extracted with chloroform.

Phospholipids were separated by thin layer chromatography (TLC) (21), saponified with 0.5 N NaOH in methanol, followed by methylation of fatty acids with 20% BF_3 in methanol containing 0.02% hydroquinone. Methyl esters were analyzed by gas liquid chromatography (GLC) on a Hewlett-Packard 5830A instrument with FID detector using a 9 ft × 2 mm i.d. silanized glass column packed with GP 10% SP-2330 on Chromosorb W/AW, Supelco Inc., Bellefonte, PA. Initial oven temperature was 190°C for 1 min, followed by temperature programming at 1°C/min to 235°C. Injection was on-column. Carrier gas was helium at an initial flow rate of 16 ml/min. The distributions between *cis* and *trans* isomers were determined by GLC on a 20 ft × 1/8 in. o.d. stainless steel column packed with 15% OV-275 on 100/120 Chromosorb P AW-DMCS, Supelco Inc., at 220°C and a helium flow of 10 ml/min (2).

Triglycerides (TG) of total lipid extracts were prepared by TLC on 0.5 mm Silica Gel G plates using hexane/diethyl ether/acetic acid (80:20:1, v/v/v) as solvent. The triglycerides were methylated, after addition of 15:0 as internal standard for quantitation, and analyzed by GLC as described above.

TABLE 1

Fatty Acid Composition of Dietary Fats (calculated from individual fats)[a]

Determination of catalase activity. As an estimate of the peroxisomal β-oxidation capacity, the contents of peroxisomes in liver fractions were determined by the activity of catalase. The decrease in hydrogen peroxide absorption at 240 nm was monitored as previously described (14).

Statistics. Results were expressed as the mean and the standard error of the mean (SEM). Differences in contents of the major (n-6) fatty acids between the HMO groups, the HSOY group and the PALM group were established by the Newman-Keuls range test (22).

RESULTS

Dietary fats. Partially hydrogenated marine oil (HMO), olive oil (OO) and sunflowerseed oil (SO) were combined (Table 1) to give five dietary fats, groups 1–5, with similar levels of *trans* fatty acids, 33%. The *trans* fatty acids primarily consisted of monoenes as well as small contents of *cis,trans* dienes with chain lengths of C14 to C22. *Trans,trans* dienes were absent. The linoleic acid levels varied from 1.9% to 14.5% of the dietary fats. Group 6 was fed an HSOY diet providing 8% linoleic acid and 32% *trans* acids. Group 7 was a reference group fed unhydrogenated palm oil containing 10% linoleic acid and no isomeric fatty acids. The combinations of dietary fats used in the present experiment allowed for the following comparisons: (1) effect of dietary level of linoleic acid on the formation of polyunsaturated fatty acids (PUFA), groups 1–5; (2) effects of HMO vs HSOY at one dietary level of linoleic acid, group 3 vs group 6; (3) effects of partially hydrogenated fats vs unhydrogenated fats at comparable levels of linoleic acid, groups 3, 6 and 7.

Animal experiments. No significant differences in growth or general performance were detected. The food intakes were similar in all groups.

Liver. In liver phosphatidylcholines (PC) (Table 2), the contents of 20:4(n-6) and 22:5(n-6) were consistently lower in the rats fed HMO, groups 1–5, than in the rats fed PALM. In groups 1–3, this could be explained by a limited dietary supply of (n-6) fatty acids, because in these groups increases in the dietary linoleic acid from 1.9% to 8% were paralleled by increased formation of PUFA. However, a plateau in the contents of (n-6) PUFA was reached at a dietary level of linoleic acid of about 8% and increases in dietary linoleic acid to levels even considerably above that of the reference group could not further elevate the levels of PUFA in liver PC of rats fed HMO. In the rats fed HMO, group 1–5, increased contents of 18:2(n-6) and 20:3(n-6) compared to the PALM group could indicate effects of the diet on the desaturase enzymes. The HSOY diet (group 6) apparently affected the PUFA formation less than did the comparable HMO diet (group 3) and also caused less accumulation of 18:2(n-6), but compared to the PALM diet, an effect on the 20:4(n-6) was still evident in PC.

In the phosphatidylethanolamines (PE) (Table 2), the levels of 20:4(n-6) in groups 1–5 were much less influenced by the dietary contents of linoleic acid than observed for PC. At a dietary content of 8% linoleic acid, a level of 20:4(n-6) similar to that of the PALM group was reached, and further increases were not observed. However, the 22:5(n-6) contents of group 1–5 were significantly lower and the contents of 18:2(n-6) were higher than in the PALM group, still indicating a reduced conversion of linoleic acid in the HMO groups.

Trans fatty acids deposited in HMO fed groups were solely 16:1, 18:1 and 18:2 *cis,trans,* but *trans*-20:1 and 22:1 despite their abundances in the diets, were only detected as traces in PC or PE, indicating that chain shortening of these monoenes had taken place. As the dietary levels of 18:2(n-6) were augmented, the incorporation of *trans* 18:1 also increased, whereas the levels of saturated fatty acids decreased. The total depositions of *trans* fatty acids were considerably higher in the HSOY group, group 6, than in the HMO groups, although the dietary levels were similar.

The TG of liver (Table 3) reflected increasing contents of 18:2(n-6) in the diets, groups 1–5, but the depositions far exceeded the levels in the groups fed HSOY or PALM. In the HMO groups 1–5, the total *trans* fatty acid contents were lower, but the *trans* 16:1 level higher than in the HSOY group.

Heart. In heart PC (Table 4) of rats fed HMO, groups 1–5, the contents of 20:4(n-6) reached a plateau at a dietary level of 18:2(n-6) of 8%, and as in liver PC, further increases in dietary 18:2 did not result in increased formation of 20:4(n-6), which was lower than in the PALM group. Depositions of 18:2(n-6) indicated reduced conversion of linoleic acid.

In PE (Table 4), the contents of 20:4(n-6) seemed little influenced by the dietary 18:2(n-6) levels in HMO-fed rats. The levels of 20:4(n-6), however, were considerably higher in the HMO-fed rats, groups 1–5, than in the HSOY-fed, group 6, or PALM-fed, group 7. Compared to the PALM group, all the HMO- and the HSOY-fed rats had very low contents of 22:5(n-6), pointing to reduced conversion of arachidonic acid when isomeric fatty acids were fed. Also, in PE, the *trans* fatty acid contents were smaller, following intake of HMO, compared with HSOY.

In the HMO-fed rats, groups 1–5, changes in dietary 18:2(n-6) levels were reflected in the heart TG (Table 3), leading to a higher deposition of 18:2 in groups 4 and 5 than in the PALM group.

Adipose tissue. In the HMO-fed rats, more 18:2 was deposited in the adipose tissue (Table 3) than in the HSOY- or PALM-fed rats at similar dietary levels of 18:2. The *trans* fatty acids deposited were *trans*-16:1 and *trans*-18:1 in the HMO-fed groups, but primarily *trans*-18:1 was found in the HSOY group.

Catalase. The rats fed HMO diets had higher catalase activities in liver (Table 5) than rats fed HSOY or PALM diets, indicating an increased peroxisomal activity in accordance with the low levels of liver TG observed in the HMO-fed rats (Table 3).

DISCUSSION

In the formation of long chain PUFA from dietary linoleic acid, the initial Δ6-desaturation of linoleic acid into γ-linolenic acid is rate-limiting (23,24). It has been demonstrated that both the Δ6-desaturation and the subsequent Δ5-desaturation of 20:3(n-6) into 20:4(n-6) can be affected by isomeric fatty acids present in partially hydrogenated fats. This has been shown by Mahfouz et al. (10,11), who found competitive effects of individual *cis* and *trans* octadecenoic acids using microsomes from rats reared on EFA-deficient diets devoid of isomeric fatty acids. Other

investigators (16,17) used microsomes from rats raised on EFA-sufficient diets containing high levels of HMO or partially hydrogenated peanut oil and found reduced conversion of 20:3(n-6) in the HMO group. In these experiments, the microsomal pool of free fatty acids that could act as competitive inhibitors was insignificant. It was thus concluded that the changes in fatty acid profiles of membrane lipids resulting from the long-term dietary treatment could affect the desaturase activities.

Apparently, two effects of isomeric fatty acids may be operative: A direct competitive inhibition of the desaturase by isomeric fatty acids and a membrane effect due

to changes in the fatty acid composition of the microsomal membrane possibly affecting the membrane-bound desaturases or their associated electron transport chain. The importance of the membrane effect is substantiated by the observation that microsomes from rats fed HMO have lower desaturase activities than microsomes from rats fed partially hydrogenated vegetable oils, although the microsomes contain no 20:1 or 22:1 isomers (16).

Previous feeding studies with rats have also established that rats fed partially hydrogenated vegetable or marine fats supplemented with vegetable oils have lower levels of long chain PUFA than rats fed vegetable oils providing either a considerably higher level of dietary linoleic acid (14,15) or similar level of dietary linoleic acid (25,26).

In the present experiment, we investigated if, by increasing the dietary level of 18:2(n-6) relative to the contents of isomeric fatty acids and far above the level of a reference group, it would be possible to increase the levels of 20:4(n-6) in the liver and heart phospholipids to those of the reference group not fed isomeric fatty acids. Furthermore, a group was fed HSOY to compare effects of chain lengths of isomeric fatty acids.

This experiment demonstrates that rats fed partially hydrogenated fats have lower content of 20:4(n-6) in liver PC than a reference group fed unhydrogenated fats with a similar dietary level of 18:2(n-6). Furthermore, it does not seem possible to augment the formation of 20:4(n-6) in the HMO-fed rats to the level of the reference group by increasing the dietary levels of 18:2 within the limits of this experiment. Compared with the HMO groups, the HSOY-fed rats have a higher formation of 20:4, which is consistent with our previous results (14). The lower formation of 20:4(n-6) in HMO-fed animals is paralleled by increased accumulations of 18:2(n-6) in the phospholipids, indicating that the total liver pool of 18:2 is enlarged and pointing to an effect of dietary fats on the desaturation of linoleic acid. This view is supported by the substantial channeling of 18:2 into TG in liver, heart and adipose tissue. However, we find lower incorporation of isomeric fatty acids in the phospholipids of the HMO-fed rats than of the HSOY-fed rats. Furthermore, only isomeric- 16:1 and 18:1 fatty acids are deposited, although the HMO contains large amounts of 20:1 and 22:1 isomers. The absence of these fatty acid isomers from the liver may be explained by the peroxisomal β-oxidation induced by long chain fatty acids. This is evidenced by the increased catalase activity in the HMO groups compared with the HSOY and the PALM group. The significance of peroxisomal β-oxidation in the degradation of 20:4(n-6) appears not to have been elucidated in vivo, but in vitro experiments seem to confirm this pathway (27).

The PUFA contents of PE in liver are less affected by dietary fats than PC, which is in agreement with a recent report (28). Since a higher unsaturation is generally found in PE than in PC, this mainly indicates that the mechanisms for maintaining the unsaturation of PE by selective reacylation of PE formed de novo or by channeling less unsaturated molecular species into PC is also operative in rats fed partially hydrogenated oils. At low dietary levels of 18:2(n-6), the conversion of 18:3(n-3) into 22:5(n-3) and 22:6(n-3) is more efficient in agreement with the findings of Charnock et al. (29).

In the heart, the fatty acid profiles are generally more unsaturated than in the liver. The PUFA may be formed from 18:2 taken from chylomicrons or from 18:2 and 20:4 taken from very low density lipoproteins (VLDL) secreted from the liver. The fatty acid composition of VLDL-TG is similar to liver TG (30). The considerable accumulation of 18:2 observed in liver TG may, in part, explain that even at low dietary linoleic acid levels the HMO-fed rats have high (n-6) PUFA levels in the heart phospholipids. Enhanced activity of lipoprotein lipase following intake of docosenoic acids (31) may accentuate the uptake of fatty acids of hepatic or dietary origin in the extrahepatic tissues. Just as in the liver, the heart phospholipids have low levels of *trans* fatty acids in the HMO-fed rats and only trace amounts of *trans*-20:1 and *trans*-22:1 are found in agreement with the findings of Conacher et al. (6). This reflects the efficiency of peroxisomal β-oxidation of 20:1 and 22:1 fatty acids, as described by Christiansen et al. (32). It thus appears unlikely that the isomeric fatty acids in the organ phospholipids per se constitute the factor that affects the conversion of (n-6) PUFA. In heart PC, the effects of HMO on the formation of 20:4 are significantly smaller than observed for the liver. This agrees with the observation that the heart levels of 18:2 show less dependence on the dietary levels than do the liver levels. Compared with the PALM group, however, a substantial decrease in 20:4 is paralleled by an increase in 18:2, indicating a decreased conversion of 18:2 into long chain PUFA.

Heart PE, as well as PC, is little affected by the dietary levels of linoleic acid in the HMO-fed rats. In the PALM group, however, a substantially higher level of 22:5(n-6) is found in PE, compared with HSOY-fed rats, as found by Royce and Holmes (33). In the HMO groups, the 22:5(n-6) is low and the 20:4(n-6) is high compared with the PALM group, in agreement with a previous report

in which partially hydrogenated herring oil, rich in *cis*-20:1 and *cis*-22:1 relative to *trans*, decreased the formation of 22:5(n-6), but partially hydrogenated capelin oil with a high *trans/cis* ratio did not (15). It is thus possible that the formation of 22:5(n-6) by Δ4-desaturase may be affected by the presence of certain long chain isomers in the heart. Retroconversion of 22:4(n-6) and 22:6(n-3) has been shown to be increased in isolated liver cells from rats reared on HMO diets (34). It is thus possible that this also influences the 22:5 levels.

The linear relationship between the dietary 18:2 levels and that of the heart TG contrasts with the constant levels of (n-6) PUFA in PC and PE of the HMO-fed rats, indicating that the PUFA metabolism, in general, is under extreme control in the myocardium over a wide range of dietary supply of 18:2, as pointed out by Gibson et al. (35), making it especially interesting to note that HMO can perturb the PUFA profiles leading to lower levels of 20:4(n-6) and 22:5(n-6) in HMO- and HSOY-fed rats than in PALM-fed rats. At low dietary and cardiac levels of 18:2, this acid is selectively channeled into a pool available for formation of 20:4(n-6) and incorporated into phospholipids. At high dietary levels of linoleic acid, apparently the 18:2 is stored in TG unavailable for PUFA production, although the levels of long chain PUFA are lower than in the PALM group.

Our comprehension of the physiological implications of a simultaneous incorporation of isomeric fatty acids into biological membranes combined with a reduced formation of long chain PUFA is, so far, quite poor due to the lack of reliable experimental models to evaluate changes in biological membranes by physical or biochemical parameters. It has been demonstrated in vitro (36) that increased fluidity of the microsomal membranes is associated with decreased activity of desaturases, which supports the concept of the microsomal membrane as a self-regulating system based on interaction between "fluidity" and desaturase activity (37), which could be operative under a wide range of dietary conditions (35). On the other hand, numerous investigators have demonstrated that intake of partially hydrogenated fats, even when supplemented with adequate levels of linoleic acid, may reduce the contents of PUFA and, thus, the fluidity, indicating that the regulation of fatty acid composition may be perturbed by external factors such as certain dietary fatty acids. Whether this effect is exerted on the environment of the desaturase or eventually on the synthesis of desaturase remains to be clarified (38). In the evaluation of the possible effects of a prolonged intake of partially hydrogenated fats, it should, however, be pointed out that multigeneration feeding studies with rats so far have not proven any harmful effects of partially hydrogenated vegetable fats, as long as linoleic acid is supplied (39). This could indicate that even major changes in the composition of biological membranes may not significantly affect their biological efficiency. However, similar experiments have not been performed with partially hydrogenated marine oils.

ACKNOWLEDGMENTS

G. Peitersen, L. K. Christensen and E. Kortegaard gave technical assistance. The dietary oils were gifts from Jahres Fabrikker A/S, Aarhus Oliefabrik A/S and Solofabrikken A/S. Grants were received from The MIFU Research Foundation and The Danish Fat Research Foundation.

[Received February 12, 1988; Revision accepted July 13, 1988]

Serum Fatty Acid Proportions Are Altered During the Year Following Acute Epstein-Barr Virus Infection

Because abnormal serum fatty acid (FA) proportions had been found at three months after infectious mononucleosis (IM) in a pilot study, serum total FA profiles of 20 normal college students were measured at monthly intervals for one year following an acute Epstein-Barr virus (EBV) infection. Below normal proportions of arachidonic acid and a reversal of the usual serum ratio of linoleic and oleic acids were maximal during the third month after acute IM. These FA abnormalities coincided with the symptom of increased physical malaise, despite apparent clinical recovery, common after IM. Persistence of low linoleic acid content beyond six months postinfection occurred in all seven students who showed continued clinical symptoms. Estimation of FA enzyme activities over the post-IM year suggested that FA elongation function was normal, but that FA desaturation enzyme activities were lower than normal, particularly early after EBV infection. An inability of the host to normalize the serum total linoleic/oleic acid ratio may parallel a delayed recovery from EBV infection and may offer insight into its pathogenesis.

Lipids 23, 981-988 (1988).

Common intermittent fatigue after acute primary Epstein-Barr virus (EBV) clinical infection, termed infectious mononucleosis (IM), suggests that host systems are severely stressed by the infection (1). A temporal relationship between altered serum fatty acid (FA) patterns, described after acute and chronic illnesses (2-6), confirms a relationship between altered lipid metabolism and disease. Maintenance of normal serum-FA content is essential to homeostasis and health. The ratio or percentage of individual FA in normal fasting serum remains fairly constant within age boundaries (7). Serum FA are substrates for many cellular systems in the body. For example, serum polyunsaturated arachidonic acid is a precursor for important immunoregulatory substances, prostaglandins and leukotrienes that increase dramatically in disease (8). Long-chain polyunsaturated FA have additional roles in maintaining fluidity and stability of membranes, particularly in the vascular system (9). FA serve also as substrates for red-muscle mitochondrial oxidative phosphorylation, and neuronal (10) metabolism. Serum-FA measurements may reflect an imbalance or inadequacy of FA amounts available for lipoprotein synthesis. Measurements over time may indicate possible metabolic FA-tissue turnover events. Recent characterization of desaturation and elongation metabolic pathways of FA have led to understanding the multiple roles of FA in health and disease (11-15).

Abbreviations: FA, fatty acid; Ig, immunoglobulin; ANOVA, analysis of variance; EBV, Epstein-Barr virus; GLC, gas liquid chromatography; IM, infectious mononucleosis; L/O ratio, linoleic to oleic acid ratio.

Acute EBV infection, as any acute illness, alters host lipid metabolism by direct utilization of host lipids and by destruction of host cells (6,16). Host lipid-related metabolic systems can be directly affected in production of endotoxins, in activation of lipase or other host macrophage lysosomal enzymes, or in release of host mediators such as pyrogens, interferons and other immunoregulatory substances (10,13,16). Secondary or indirect effects of acute illness on host lipids may include decreased dietary intake of fats from anorexia, possible decreased intestinal absorption of fats, and increased rates of host lipolysis for the metabolic demands of fever and replacement of tissues. The acute toxic state with prostration also leads to altered rates of liver lipid synthesis and lowered fat utilization by peripheral tissues (6,16). Although important in understanding the immediate response to EBV and other infections, the majority of these stresses on host lipid metabolism appear to resolve after the first month of infectious mononucleosis illness, as fever disappears and clinical recovery occurs.

EBV infection appears rather unique among acute viral infections in that it leads frequently to a delayed return to robust health (1,8,12,13). Because we wished to focus on the prolonged period of weakness and malaise after IM, we began our study near the end of the first month after acute IM. The "onset" of EBV infection was considered to be the date of a positive monospot test with a characteristic acute IM-type of illness in healthy college students. Although it is possible that a subset of more severely-affected post-IM students was selected by our method, sample bias was minimized by a payment and by the encouragement of cooperation in the study by health clinic personnel. At our first fasting blood sampling, the student was afebrile, ambulatory, again able to eat a normal diet and had recovered sufficiently to return to classes. We report here total FA profiles of 20 normal students followed monthly thereafter for one year.

METHODS

Patient selection and sample preparation. Normal college students, 10 male and 10 female, aged 18-23, with an acute illness characterized by severe pharyngitis, generalized lymphadenopathy, fever, prostration and a positive heterophile antibody test, voluntarily participated. An elevated white blood cell count with lymphocytosis containing greater than 10% atypical mononuclear cells confirmed the diagnosis of Epstein-Barr virus (EBV) mononucleosis in all (1). Because we were interested in long-term results of EBV after the acute illness, the first blood specimen was drawn after confirmation of the diagnosis and agreement for enrollment in the program. Fasting blood samples were drawn at a regularly scheduled clinic visit occurring 2-4 wk after the positive heterophile test. Each subsequent visit was planned for 1 mo after the previous visit. No treatments were being given at the time of sampling. A dietary and systems review was taken at

each visit to monitor eating patterns and the possibility of physical complications. Age and sex-matched normals (20) who had no evidence of EBV infection for at least 4 yr were similarly followed. All laboratory personnel were blinded to the clinical diagnosis. Guidelines of the Human Subjects Research Committee of The Ohio State University were followed. No drugs, including aspirin, cortisone or similar products, were being taken 48 hr prior to blood drawing. Serum, separated immediately, was frozen at −20°C until extraction.

Serum total esterified fatty acid extraction for gas liquid chromatography (GLC). For extraction of total serum fatty acids, we adapted the method of Love et al. (2). Overnight stirring of 0.5 ml serum in 19 ml chloroform:methanol (2:1) containing BHT (1 μg/20 ml) was followed by adding 30 μg of 15:0 standard and 4 ml 0.1 M KCl. The lower phase was washed with 8 ml of upper phase solvents (containing chloroform:methanol:0.1 M KCl, 3:48:47, v/v/v). After drying the lower phase under N_2, the extract was hydrolyzed with 2 ml of 1 M KOH in 90% ethanol for 30 min, acidified with 5 ml H_2O containing 1.5 ml of 2 M HCl, extracted with 10 ml diethyl ether and taken to dryness under N_2. Methylation was accomplished by heating to 60°C in a dry bath for 10 min with 0.5 ml BF_3-methanol (Alltech Assoc., Deerfield, IL). After transfer to a separatory vial with hexane, and washing twice with 12 ml saturated NaCl, the methylated FA were dried with Na_2SO_4 crystals, dried under N_2 and kept until use at −20°C (2).

Detection of methylated lipid fractions and standards was performed on a Hewlett-Packard 5840-A Gas Liquid Chromatograph equipped with a dual hydrogen flame-ionization detector and an automatic integrator. A 30-m SP 2330 fused silica capillary column with a 0.20-μm-film thickness and 0.25 mm i.d. (Supelco, Bellfonte, PA) was used. The column was temperature programmed from 180°C to 240°C at 2°/min. The injection port temperature was 250°C, the detection temperature was 250°C, and the linear flow velocity was 10 ml/min, with the carrier gas being He and the split ratio being 1:100. Peaks on the chromatogram were identified by comparing retention times with reference standards (Supelco and Nuchek Prep, Elysian, MN). The percentage of each FA in each sample was calculated by the ratio of each FA area to the total area of the sample. The actual amount (mg/ml) of total FA in the sample was calculated from the amount of 15:0 standard (added at the onset of extraction) remaining in the final chromatogram and the dilution of the sample. Normal controls were included in daily runs. Variation in FA proportions among duplicate samples was less than 2%.

Detection of EBV-specific antibodies. Indirect immunofluorescence was used to examine the sera of the 7 post-EBV patients with linoleic:oleic acid (L/O) ratios of less than 1.20 for specific antibody content. To detect Immunoglobulin A with EBV specificity (EBV-IgA) and early antigens of EBV in the Immunoglobulin G (EBV-EA IgG) antibody fraction, the standard indirect immunofluorescent test was employed (16).

Statistical analyses. Average proportions of 20 patient serum FA, known as the FA profile, were compared with serial samples of fasting age-matched normals, drawn over the year. Analysis of variance (ANOVA) was used to calculate significant differences between the FA contents and estimated FA enzyme activities of the two groups at monthly intervals. The Bonferonni correction for multiple comparisons was made. A P value of <0.01 was considered significant (14). Metabolic indices, calculated according to the formulae of Holman and Johnson (15), estimated the activities of fatty acid elongation and desaturation enzymes at each month post infection. The average amount of FA products of each enzyme pathway in post-EBV serum was compared to the normal average amount to estimate enzyme activity in specific pathways.

RESULTS

Systems and dietary review. All patients expressed marked degrees of fatigue, exhaustion and mental discouragement during the first 3–5 mo after primary EBV infection. Unusual need for extra sleep was a common complaint which led to dropping classes by several students, and appeared more prominent in 4 of the 20 who had experienced slight jaundice during the acute illness. However, there were no specific clinical or physical signs uniquely characteristic during this period. Five of the 20 students required additional treatment for infections at ca. 3 mo post-IM, including acute pharyngitis in 2, non-specific diarrhea in 2 and urinary tract infection in 1. No differences could be found between males and females in clinical responses.

A regimen of adequate rest and balanced diet without alcohol intake had been stressed by the clinic personnel in an initial handout and was reinforced at each visit. Because this group's intellectual level was higher than average and good performance in school was a priority, serious effort toward establishing good dietary habits appeared in all students by the first clinic visit and was continued thereafter. However, sufficient rest was usually not achieved during the first 3–6 months.

Individual clinical variations were more prominent after 6 months. The majority of students were very aware that they were still unable to perform as well as prior to acute IM, but felt "well." In contrast, 9 of 20 at 7–8-mo- and 7 at 12-mo-post-IM continued to feel exhausted and distinctly "not well." One of these had a reoccurrence of a psychiatric illness. Four were forced by their unusual malaise and fatigue to leave school for a semester.

Total serum FA proportions post-EBV infection. In Tables 1 and 2, post-EBV average serum values of total FA present in the serum of all 20 students are compared with the values of age-matched students without EBV at monthly intervals. Proportions of the shorter-chain FA (10-13:1 and 16:1) were significantly higher ($p < 0.001$), but the essential FA, linoleic acid (18:2ω6) and the highly polyunsaturated docosahexaenoic acid (22:6ω3) were lower than normal ($p < 0.001$) during the entire year. A significant increase in the percentage of oleic acid (18:1ω9) occurred during the early post-IM period, but arachidonic acid (20:4ω6) showed phasic lowered proportions ($p < 0.001$). Figure 1 demonstrates the percentage of total FA of arachidonic acid during the year (horizontal axis) in relationship to the normal mean (solid center line) and first standard deviation of normal (dotted lines). This format is carried through subsequent figures.

Proportions of major fatty acids: Oleic acid, linoleic acid and their ratios. Figures 2 and 3 demonstrate the proportions of total FA by percentage of the major fatty acids

[a]The average percentage distribution of serum FA of post-IM students is compared with normal range at 7–8 and at 12 months. The averages of the students with low L/O ratios (>1.20) (7–8 and 12 mo) are also compared with averages of students with normal L/O ratios (>1.20) at each time period.

[b]With separation by the linoleic/oleic acid ratios (L/O ratio) compared with normal range.

[c]Student sample number; at 7–8 months, 9 had low L/O ratios; at 12 months, 7 students had low L/O ratios.

[d]The percentage of each individual FA in the total FA ± SD.

[e]The ratio of linoleic to oleic acid; the L/O ratio.

[f]The average total serum FA mg/ml.

[g]The sum of the percentages of linoleic and oleic acids.

*Significantly different than normal, $p < 0.001$.

**Significantly different than normal, $p < 0.01$.

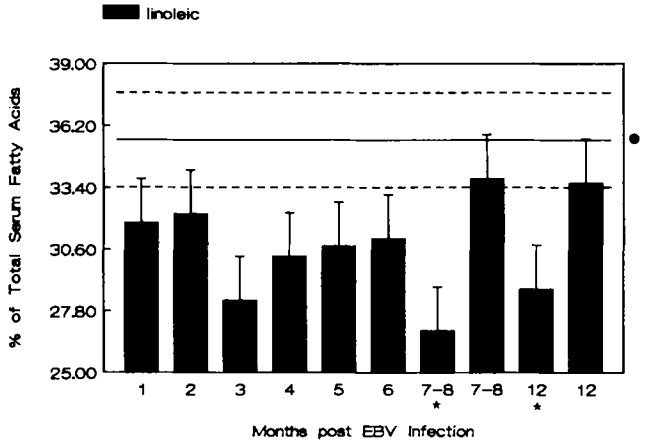

FIG. 3. Average serum proportion of linoleic acid following acute EBV infection. The average proportion of linoleic acid of 20 post-IM students is compared with normal mean (solid line) and first SD (dotted lines) for the first 6 months after IM. At 7–8 and 12 months, averages of students with low L/O ratios* (<1.20) are compared with averages of students with normal L/O ratios (<1.20).

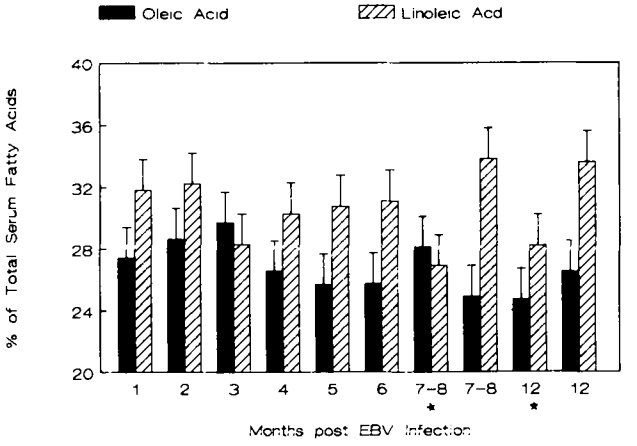

FIG. 4. Average serum proportion of oleic and linoleic acid after EBV infection. Oleic (filled) and linoleic (shaded) acid proportions in serum of post-IM students are shown together to suggest the possible reciprocal relationship between their proportions. Averages of 20 post-IM students occur for the first 6 months; at 7–8 and 12 months, averages are separated by a low L/O ratio* (<1.20) as before.

(oleic and linoleic) at monthly intervals for 1 yr after primary EBV. Marked differences from normal—increased for oleic acid (Fig. 2) and decreased for linoleic acid (Fig. 3) during the first 6 months after EBV—led us to examine their relationship by developing a ratio between them. In normal students throughout the year, the ratio of linoleic to oleic, termed the L/O ratio, was surprisingly steady at 1.44 ± 0.20. In sharp contrast, during the first 6 mo of the post-IM period, the serum L/O ratio was significantly lower than normal (Table 1, Fig. 4). In addition, although the sum of these major FA varied only slightly over the year (Tables 1 and 2), the change in their proportions was marked (Fig. 5).

We found that this ratio had returned to normal in the majority (11 of 20) of students by 6 mo, but still remained below the normal range in 9 by 7–8 mo and in 7 students at the end of the year (Table 2, Fig. 4). To evaluate whether the ratio of these major fatty acids might have a clinical significance, possibly correlating with symptoms, the clinical courses of the 7 patients with low L/O ratios at 1 yr were examined. Clinical complications during the first 6-mo-post-EBV had been experienced by 5 of these students, requiring additional treatment at the health center, and 3 of them had shown mild clinical jaundice in the acute phase of their EBV infection.

To further examine our data in the light of altered L/O ratios, the FA average proportions of the students with a L/O ratio lower than 1.20 (the first SD of normal) were separated from the remainder with L/O ratios in the normal range. Table 2 and Figures 1–3, 5 and 7–10 list these values for 9 of 20 post-IM students at 7–8 mo, and 7 of 20 post-IM students at 12 mo separately from the averages of the remaining students with normal L/O ratios.

Arachidonic acid proportion. Although the percentage of total FA of arachidonic acid (20:4ω6) was significantly lower than normal ($p < 0.005$) during the first month after EBV infection (Table 1, Fig. 1), a slight increase during the second month was followed by a second decrease during the third month ($p < 0.005$). In only 8 students was a normal proportion reached at the 6-mo period. However arachidonic acid values of clinically recovered students (normal L/O ratios) and those with low L/O ratios at 7–8 mo or at 1 yr after acute EBV were not very different. These alterations suggest the possibility of several metabolic influences on serum arachidonic acid proportions (Table 2).

Fatty acid elongation and desaturation enzyme pathways. Figure 6 demonstrates FA pathways of elongation and desaturation from the essential FA. Elongation is carried out at the COOH moiety by mitochondrial acetyl CoA enzyme, and desaturation is accomplished at specific C positions by specific cytochrome b5 oxygenases with NADPH under configurational restraints (7,11–13). Essential FA, linoleic (18:2ω6) and α-linolenic (18:3ω3) acids, and also oleic acid are initially desaturated by the key enzyme Δ6-desaturase. Elongation, normally a reversible process occurring between desaturation steps, can operate in excess when desaturase enzymes are unavailable due to overuse or lack of function (11–13). As indicated in Figure 6, Δ5-desaturase forms 20:5ω3 (eicosapentaenoic acid) from 20:4ω3, and 20:4ω6 (arachidonic acid) from 20:3ω6. Δ4-Desaturase accomplishes the final hydrogen removal from 22:4ω6 and 22:5ω3 to form 22:5ω6 and 22:6ω3.

Estimated desaturation enzymes activities. Figures 7–9 compare the average estimated post-EBV activities of three desaturase enzymes with average estimated normal activity (central line), according to the calculations of Holman and Johnson (15). The Δ6-desaturase nadir at 3 mo post-infection corresponds to the maximal alterations found in FA profiles (Fig. 7). Low values of both Δ5- (Fig. 8) and Δ4- desaturases (Fig. 9) may reflect lack of substrates due to apparent defective activity of Δ6-desaturase enzyme, because these desaturase enzymes are further steps in the same metabolic pathways. For comparison, students with L/O ratios of lower than 1.2 (as indicated by asterisk) after 6 mo are shown by separated average bars at the 7–8- and 12-mo periods (Figs. 7–9).

Estimated elongation enzymes activities. Elongation enzyme activities, estimated by Holman and Johnson Metabolic Indices (15), are compared with estimated normal activity in Figures 10 and 11. Although essential α-linoleic acid (18:3ω3) is slightly elevated during the first 6 mo (Table 1), in contrast, all ω3 elongation products are

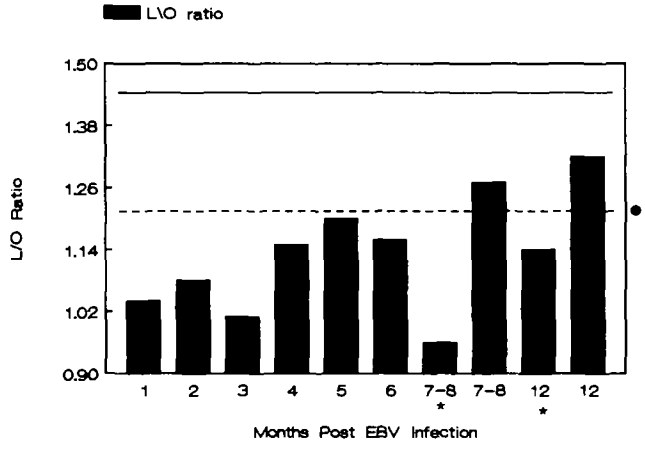

FIG. 5. Linoleic to oleic acid ratio; L/O ratio, following acute EBV infection. The L/O Ratio, determined by dividing the percentage of linoleic acid in the total serum FA by the oleic acid percentage, after acute IM is compared with the normal and mean and first SD. Averages of 20 post-IM students are shown from 1–6 months, and at 7–8 and 12 months, students with low L/O ratios* (<1.20) are shown separately from other post-IM students with normal L/O ratios.

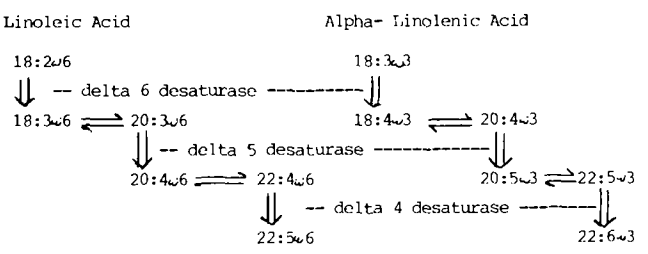

FIG. 6. Desaturation and elongation pathways of the essential fatty acids: Linoleic and α-linolenic acids. The metabolic pathways of the essential fatty acids, linoleic (ω6 series) and α-linolenic (ω3 series) are depicted schematically, with desaturation shown vertically and elongation horizontally. Specific FA configurations serving as substrates for individual desaturase enzymes are shown by dotted lines.

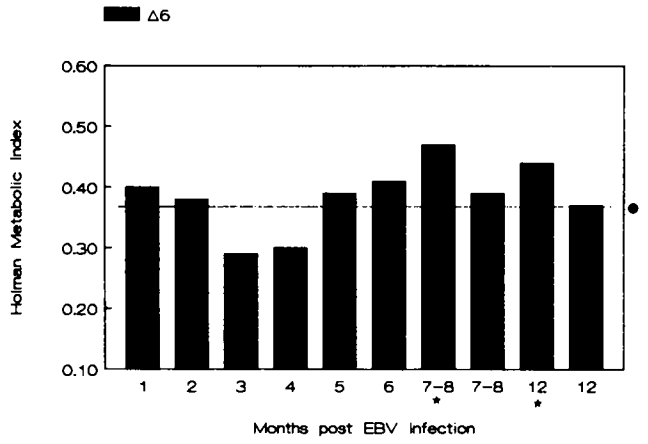

FIG. 7. Estimated Δ6-desaturase activity after EBV infection. Metabolic indices of Holman and Johnson (15) have been calculated from individual FA averaged percentage at each month for 1 year to estimate the metabolic activity of Δ6-desaturase. Averages of 20 students from 1–6 months post-IM, and averages of students separated by L/O ratio are compared with the normal mean (solid line). Low L/O ratio (<1.20) averages are noted by an asterisk (*).

lower than normal during that time (Fig. 10), possibly because their precursor, 18:3ω3, is not available as a suitable substrate for further action. Estimated activities of C20 and C22 elongation enzymes (Fig. 11), however, suggest they are functioning in excess intermittently, possibly storing elongated FA until desaturation processes can normalize pathway flow (Fig. 6). A representative GLC FA chromatograph of a 3-months-post-IM patient's total FA profile shows accumulations of unusual peaks (marked by arrows on Fig. 12) at the expected retention times of "elongation stop-point products" (12,13). Similar unusual chromatograph peaks were commonly found in the FA profiles during the first 3 mo after EBV infection, but were usually absent from later serum samples.

EBV-specific serum antibodies. One-year-post-EBV infection serum samples from each of 7 post-IM students with persistent clinical symptoms and altered linoleic/oleic acid ratios (<1.20) were negative for EBV-IgA and EBV-early-antigen-IgG antibodies.

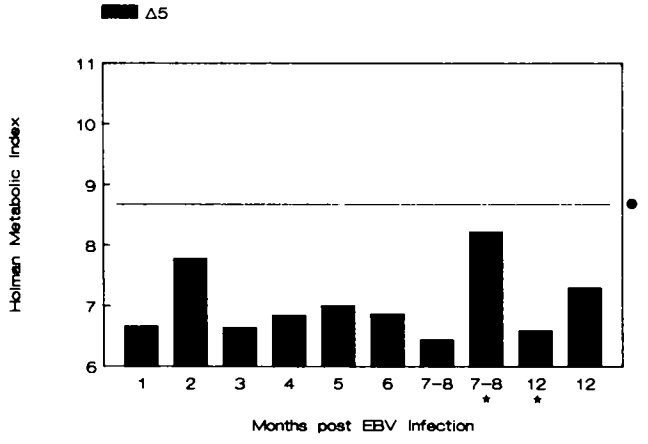

FIG. 8. Estimated Δ5-desaturase activity after EBV infection. Format as described in Figure 7 with Δ5-desaturase enzyme activity estimated by metabolic index calculations (15).

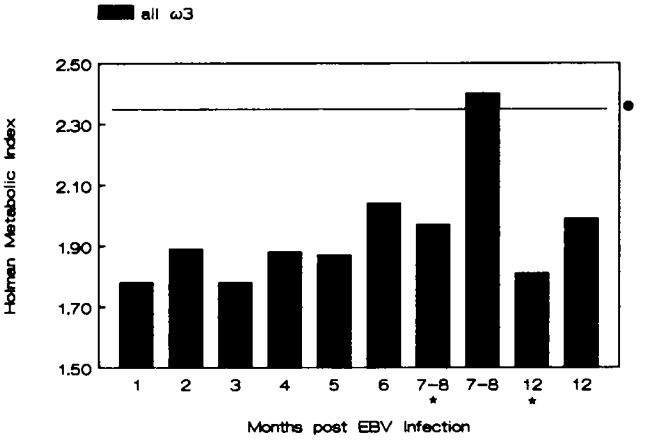

FIG. 10. Estimated ω3 elongation enzyme activities after EBV infection. Format as described in Figure 7 with all ω3 elongation enzyme activities estimated by metabolic index calculations (15).

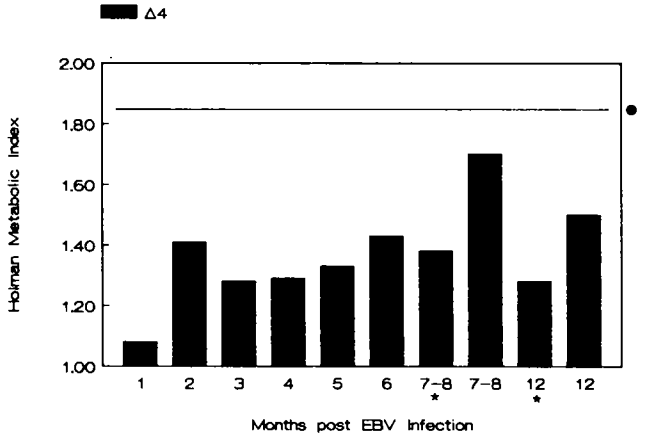

FIG. 9. Estimated δ4-desaturase activity after EBV infection. Format as described in Figure 7 with Δ4-desaturase enzyme activity estimated by metabolic index calculations (15).

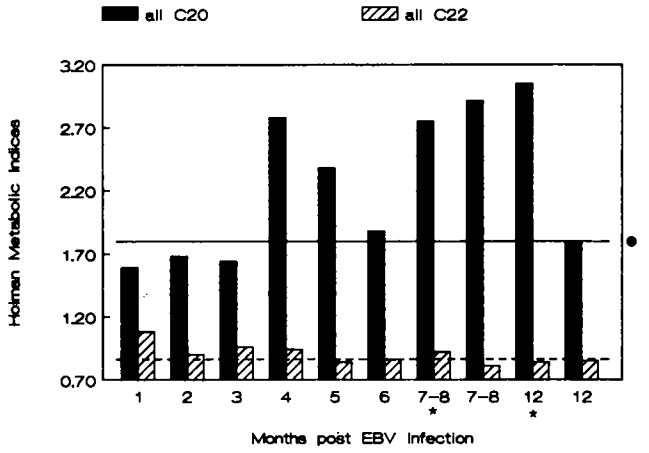

FIG. 11. Estimated C20 and C22 elongation enzyme activities after EBV infection. Format as described in Figure 7, with C20 and C22 elongation enzyme activities estimated by metabolic index calculations (15).

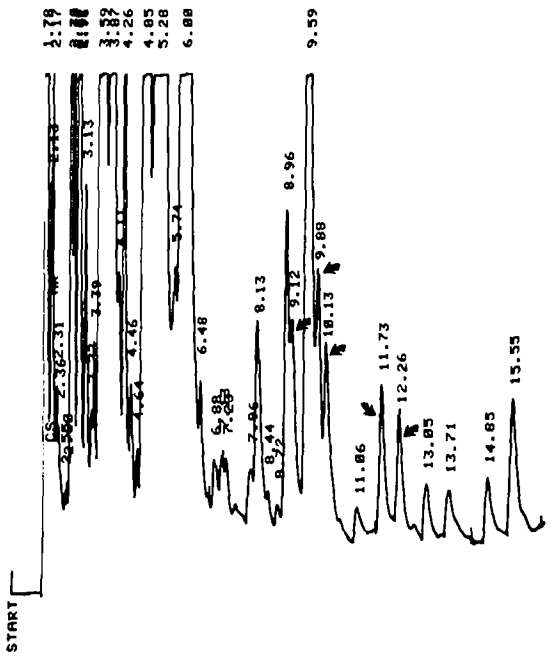

FIG. 12. Gas liquid chromatograph record of total fatty acid proportions of a post-IM student at 3 months after acute EBV infection. Methyl esters of fatty acids, visualized by flame-ionization technique are shown in the sequence of their carbon length, beginning with the shortest (10:0–12) at 2.13 min, and continuing to the longest, 22:6ω3 at 15.55 min. Altered proportions of particular note are oleic acid (5.28 min) = 21.55% of total FA; linoleic (6.0 min) = 23.4%, or 64.8% of the normal mean; arachidonic acid (9.59 min) = 4.54%, or 52.3% of the normal mean; and docosahexaenoic acid (15.55 min) = 0.66% of the total FA, or 53% of the normal mean. The L/O ratio is 1.09, significantly below normal ($p < 0.001$). "Unusual" chromatography peaks marked by arrows occur at C20 (9.12, 9.88 and 10.13 min) and C22 (11.73 and 12.26 min) elongation product positions. These peaks were absent the following month in this student's serum.

DISCUSSION

Alterations in FA composition, measured during months after acute EBV infection—IM—suggest that changes in host lipid metabolism may persist after the primary illness has apparently terminated. By beginning after clinical recovery, our study plan bypassed the known confounding effects of acute illness on serum FA that may be due to inadequate diet, fever, prostration and tissue necrosis (2-6). FA serum profiles of normal college students during the entire year after apparent remission from acute IM showed that serum proportions of the major serum FA, oleic, linoleic, palmitic and arachidonic acids are markedly affected. The following common pattern emerged: Initial values obtained at 1-mo-post acute IM reflected the severe effects common to a primary infection. Then, during the second mo-post-IM, FA profiles appeared to be returning to normal. However, surprisingly, the most significant alterations of FA profiles occurred at 3-4-mo-post-IM, when clinical recovery appeared underway. A slow recovery of FA ratios toward normal usually followed during the subsequent 6 mo. A lack of differences among male and female responses in either biochemical or clinical findings suggested that the severity of the EBV-disease process may have obscured this possibility (7).

Individual patient variations in this pattern, particularly a lower than normal linoleic to oleic acid ratio (<1.20), led us to evaluate individual clinical courses. It appeared that the 7 of 20 students whose FA values had not returned to normal at 1 yr had also experienced more fatigue and difficulty in returning to full activity than the remaining 13 students. Secondary infections that required treatment in 5 of those 7 students shortly after acute IM may have possibly contributed to their slower recovery. Alternatively, a low L/O ratio prior to IM may have led to the development of disease susceptibility. However, none of these students retained IgG or IgA antibody titers to early EBV antigens at 1-yr-post-IM that might suggest a chronic EBV state (16).

To test for a possible clinical association, we separated the FA profiles of the 9 students who had retained low L/O ratios at 7-8 mo and the 7 with low L/O ratios at 1 yr. This selection clearly identified students who expressed more "fatigue" than those with normal L/O ratios, and who had altered their life pattern because of their continuing "malaise." To examine this effect on their entire FA profiles, average FA proportions of students with normal L/O ratios were separated from averages of those with lowered L/O ratios (Table 2, Figs. 1-3 and 7-11). We found that abnormal proportions of other FA and altered FA enzyme activities were also detected in the low L/O ratio group when compared with those having normal L/O ratios post-IM and normals without EBV. We could conclude from these clinical and biochemical correlations that the L/O ratio might be effective as a predictive marker for slow recovery from acute EBV infection, or possibly in other chronic illnesses (2-6). Superimposed infection in the post-IM period, found in several of thes students, also may have prolonged recovery by causing an additional burden on FA metabolism (4,5).

Oleic acid, normally 25.4% and linoleic acid, 35.6%, comprise approximately 60% of serum total-lipoprotein FA (7). Hepatic microsomes are the metabolic source of the large quantities of these FA necessary to sustain normal serum-lipoprotein content. Therefore, major alterations in total serum-FA composition suggest the possibility that liver may continue to be a site of host-viral interaction even after the acute viral hepatic phase. Despite the return to normal values found in the usual panel of liver enzymes after acute IM (1,17,18) and the absence of jaundice, hepatic enlargement or abdominal tenderness in the students of our study, an EBV-related intrahepatic cellular abnormality of FA enzyme activity appears present for at least 4 mo after EBV infection. However, metabolic turnover studies in liver tissue would be necessary to resolve this possibility. EBV latency, known to occur in a subset of B lymphocytes and epithelial tissues, has not been reported in hepatic tissue (20). Although a reciprocal relationship has not been proposed between these FA, it is interesting that the contribution of the total portion of the FA profile by linoleic and oleic acids together did not change appreciably during the year despite marked variations in their individual proportions (Tables 1 and 2; Fig. 5).

We estimated the activities of FA elongation and desaturation enzymes post-IM (15). Because specificity of individual FA enzymes for a particular FA double-bond configuration limits its utilization, specific sequential processing of individual FA can be followed (Fig. 5) (11-13,15). Enzyme activities of elongation and desaturation can be estimated from their proportions. Comparison

of values with normals allows evaluation of FA metabolism in disease states (15). Post-EBV FA elongation enzymes appeared to be functioning normally or in excess after EBV infection (Figs. 6,7). In contrast, activities of the Δ6-, Δ5- and Δ4-desaturases appeared lower than normal, particularly at 3-mo-post infection (Figs. 8–10). The possibility of low FA-desaturase activity was supported by the frequent finding of unusual accumulations of FA at the retention times consistent with C20 and C22 elongated FA compounds (Fig. 11) (13). It is known that, during low activity of desaturase enzymes, reversibly elongated "stop-point" FA can be held temporarily until further enzyme availability (13). Eventually, after reversal of elongation or truncating of the carbon chain, the "stop-point" FA reenter the metabolic pool for further desaturation steps (12,13). Although these FA occur in minute amounts (~1%) in normal blood samples, the majority of post-EBV patients showed noticeable accumulation of apparent "stop-point" FA at some time during the first 2–4 mo, at the time when estimated FA-desaturation activity appeared low (Fig. 11).

Lower serum proportions of other FA may be of clinical significance following acute EBV infection. Low total arachidonic acid, as the FA precursor of immunoregulatory metabolites, has been associated with increased amounts of prostaglandin and leukotriene formation (10,20). Although increases in these immunoregulatory compounds have been measured during the acute phase of EBV-illness (21), they have not been evaluated during the longer postinfection period examined here. In addition, because our method also extracts shorter-chain FA (2,20), the significantly high proportions of 10:0–14:1 FA may represent breakdown products of longer-chain FA (10). Another long-chain polyunsaturate, docosahexaenoic acid (22:6ω3), was present in less than normal proportion in serum after EBV infection. A possible deficit in supply of this FA for red-muscle metabolism, specifically the slow phase of muscle contraction (7), may be a factor in the common post-EBV complaint of "weakness." Moreover, rare neurological complications following EBV infection such as Guillain-Barré and Horner's syndromes or deafness (22,23) may have been augmented by a possible lack of 22:6ω3, an essential neuronal substrate (10). Low serum-lipoprotein arachidonic and docosahexaenoic acid proportions suggest that these FA stores are being rapidly depleted by specific metabolic needs (21), that they are being formed poorly, or both. Our data cannot distinguish among these possibilities.

Although clearly not specific for EBV infection (2–6,20), an abnormally low ratio of serum linoleic to oleic acid appears after clinical recovery in IM. Abnormal proportions of these major FA appear to be associated with increased clinical symptoms in some post-IM patients and other chronic diseases (2,3,20). Abnormality in this FA ratio may reflect a transient but crucial phase of recovery post-IM. Whether this marker can be used as a diagnostic tool in evaluating the EBV-recovery process remains to be determined.

ACKNOWLEDGMENT

Gratitude is expressed to the nursing and medical staff of the Wilce Student Health Center who referred students and facilitated examinations, and to the students, themselves. Epstein-Barr virus specific serum titers were performed by Ronald Glaser, Department of Medical Microbiology and Immunology, Ohio State University. Helpful discussions were held with Dwight Powell and Michael Brady. We thank Priscilla Powers, Barbara Meyer and Gilliard Moghadam for laboratory assistance.

METHODS

Thiophosphoester Analogs of Phosphatidic Acids: Spectrophotometric Substrates for Phosphomonoesterases[1]

David A. Nyquist
Department of Biochemistry, The University of Kansas Medical Center, 39th and Rainbow Boulevard, Kansas City, KS 66103

Thiophosphoester analogs of dioctanoyl and didecanoyl phosphatidic acids were synthesized for use as substrates in spectrophotometric assays. These substrates are easily dispersable in aqueous media and release thiodiacylglycerols after phosphomonoesterase catalyzed hydrolysis. The free sulfhydryl of these thiodiacylglycerols reacts with the colorimetric reagent 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB), allowing the reaction to be followed. These analogs were shown to be good substrates for calf intestine alkaline phosphatase (highest activity at alkaline pH) and phosphomonoesterases of partially purified beef brain cytosol (highest activity at physiologic pH). Cationic amphiphilic drugs inhibit the actions of alkaline phosphatase on the dioctanoyl analog, but did not inhibit enzymatic hydrolysis of *p*-nitrophenyl phosphate. In contrast, the beef brain cytosolic fraction *p*-nitrophenyl phosphate hydrolysis was mildly inhibited, and the phosphatidic acid analog hydrolysis was increased slightly. Tetramisole inhibited all enzyme activities with *p*-nitrophenyl phosphate, but was inhibitory only to the alkaline-phosphatase activity with the phosphatidic acid analog. *Lipids 23,* 989–992 (1988).

Alkaline phosphatase (EC 3.1.3.1) catalyzes the hydrolysis of many water soluble substrates (1) and of the phospholipid phosphatidic acid (PA) (2,3). Phosphatidic acid phosphohydrolase (EC 3.1.3.4) catalyzed hydrolysis of PA is thought to be distinct and to differ from alkaline-phosphatase activity on the basis of substrate specificity, pH requirements and enzyme response to various ions (4). Phosphatidic acid phosphohydrolase activity is usually determined by substrate radiolabeling or orthophosphate release (4). Some common radiolabeled substrates, or substrate precursors, are [^{32}P]PA, [^{32}P]ATP and a novel PA analog, 1-*O*-hexadecyl-*rac*-[2-^{3}H]glycerol-3-phosphate (4). The thiophosphate PA analog presented here has potential for use in determining the activity of various phosphomonoesterases, including alkaline phosphatase and phosphatidic acid phosphohydrolase, in crude and purified preparations.

MATERIALS AND METHODS

Synthesis of thiodiacylglycerols. The method of Snyder (5) was used to synthesize dioctanoyl and didecanoyl thiodiacylglycerols from octanoyl and decanoyl chlorides (Aldrich, Milwaukee, WI), respectively. Products were further purified by thin layer chromatography (TLC).

Synthesis of thiophosphatidic acids. Dioctanoyl and didecanoyl thiodiacylglycerols were reacted in dry pyridine with methyl dichlorophosphate (Aldrich), by a modification of the method of Smrt and Catlin (6), to form dioctanoyl and didecanoyl thiophosphatidic acids (S-PA-8 and S-PA-10). Three hundred mg of thiodiacylglycerol were dissolved in 3 ml of dry pyridine. In a separate 100 ml three-necked round bottom flask, fitted with a $CaCl_2$ drying tube and rubber septum, were placed 8 ml of dry pyridine. A pasteur pipette was run through a rubber septum into the flask so that the tip reached into the reaction mixture. A flask was equipped with a magnetic stirrer and a stream of nitrogen was bubbled through the mixture. One ml of methyl dichlorophosphate was added, with a 2 ml glass syringe through the septum, while stirring. The thiodiacylglycerol solution was added dropwise 10 min later. After 3 hr, no thiodiacylglycerol was detected by 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB) spray on thin layer chromatograms. The white precipitates were suction filtered, followed by addition of 3 ml of 0.2 M Na_2HPO_4/NaH_2PO_4, pH 8.4 buffer, for 15 min with magnetic stirring. The pyridinium salts were extracted with $CHCl_3$ and the lower phase rotary evaporated at 47°C to dryness. Residues were dissolved in $CHCl_3$ and passed through Whatman PS-1 paper. After further rotary evaporation, the solids were dissolved in a small amount of $CHCl_3$ and purified by silica gel (Unisil, 100–200 mesh) column chromatography. S-PA comigrated with dipalmitoyl PA (Sigma, St. Louis, MO) on silica gel TLC plates at R_f 0.10, solvent system $CHCl_3/CH_3OH/NH_4OH$ (60:35:5, v/v/v). Phospholipids were detected by iodine vapor and a phospholipid spray (7). S-PA also were identified by ^{31}P and ^{1}H NMR (IBM WP-200SY 200 MHz FT-NMR), IR (Sargent Welch 3-200 IR spectrophotometer), and C, H, N elemental analysis (Perkin-Elmer Elemental Analyzer). Lipid phosphorus was determined by the method of Ames (8). S-PA released thiodiacylglycerols after enzymatic hydrolysis with alkaline phosphatase as indicated by TLC with DTNB spray (7) and comigration with starting thiodiacylglycerols. IR (film on NaCl) 2970 and 2860 (broad; C–H stretching), 1740 (sharp, strong; ester bonds), 1480 and 1390 (broad; C–H bonds), 1100–1250 (broad; ester bonds), 750 and 687 (sharp, weak; PO_2^-), 1540 and 1630 (sharp, weak; pyridinium). ^{1}H NMR (tetramethylsilane, ppm) 0.9 (terminal-CH_3), 1.3 (-CH_2-chains), 1.6 (CH_2-C-CO), 2.3 (triplett; CH_2-CO), 2.9, 3.0, 5.3 (C–H of glycerol backbone), 4.1 and 4.4 (C-CH-S-), 7.8, 8.2, 8.9 (pyridine ring), 12.2 (H-N^+). ^{31}P NMR (phosphoric acid standard, ppm) dipalmitoyl PA, 1.88, S-PA, 23.50. Elemental analysis (S-PA-10, pyridinium salt) ($C_{28}H_{50}O_7NPS$)—calculated: C, 56.83; H, 8.52; N, 2.37; P, 5.32; and found, C, 56.75; H, 8.62; N, 2.28; P, 5.37.

[1]This research was completed as partial fulfillment of the Ph.D. degree, awarded August, 1987, at Northern Illinois University, DeKalb, IL.

Abbreviations: DTNB, 5,5′-dithiobis(2-nitrobenzoic acid); PA, phosphatidic acid; S-PA-8, *rac*-1-phospho-2,3-*O*-dioctanoyl-1-mercapto-2,3-propanediol; S-PA-10, *rac*-1-phospho-2,3-*O*-didecanoyl-1-mercapto-2,3-propanediol; TLC, thin layer chromatography.

Alkaline phosphatase catalyzed hydrolysis. Immediately before use, substrates were prepared from stock solutions by silica gel TLC (Sigma, 250 μm glass plates). Residues were removed from the silica gel with $CHCl_3$, rotary evaporated and further dried by a stream of N_2 gas. Twenty ml of 10 mM Tris-HCl, pH 7.7, were added, followed by 3 min of rapid stirring with a Biospec handheld high-speed homogenizer set at 10,800 rpm. This treatment gave optically clear and stable solutions. Assays were carried out in 1 × 1 cm quartz cuvettes with 9.6 μM DTNB, 8.8 μM substrate and varying amounts of calf intestine alkaline phosphatase (Sigma, Type VII, P5521). A typical assay proceeded first by mixing the buffer and substrate, then adding the enzyme. After 10 rapid strokes with a Teflon strip, the DTNB (in 10 μl) was added and stirring repeated. Because of substrate self-hydrolysis, cuvettes without alkaline phosphatase were treated in a similar manner as above and these values subtracted from rates. This autolysis rate ranged from about 50% of enzymatic rate, for low concentrations of protein, to 5% with higher concentrations. Reactions were monitored with a Spectronic 501 single-beam spectrophotometer (Bausch and Lomb, Rochester, NY) at 412 nm wavelength. All absorbances were transformed to nmol using the molar extinction coefficient of 12,800 (5). Three determinations of each point were obtained and the means of each was used to determine linear regressions.

Beef brain cytosol enzymatic hydrolysis. A partially purified cytosolic preparation from beef brain was prepared similarly to the method of Berglund et al. (9), for rat liver phosphatidic acid phosphohydrolase preparation. Assay conditions were similar to that for alkaline-phosphatase reactions, except the final concentration of DTNB was 17 μM and 40 μM in the substrate. The protein concentration was estimated by the method of Lowry et al. (10).

pH profiles of enzymatic reactions. S-PA-10 was tested over a range of pH's with alkaline phosphatase and beef brain cytosol enzymes. Conditions were those described in the assay sections with the exception of the buffers. Three buffers were used to cover a 5.5–9.0 range of pH's. For 5.5–7.0, 4-morpholineethanesulfonic acid was used. For pH 6.5–8.0, 4-morpholinepropanesulfonic acid was used. For the pH range of 7.5–9.0 , (3-[tris(hydroxymethyl)-methylamino]-1-propanesulfonic) was used. All buffers had a final concentration of 50 mM. Fifty μg of protein was used per cytosolic assay and 32 ng in alkaline phosphatase assays. Each data point was the mean of 3 determinations (6 for 6.5–8.0, because of buffer overlap).

Effects of tetramisole and cationic amphiphilic drugs on alkaline phosphatase activity. A 20 ml dispersion of S-PA-10 was prepared in 10 mM Tris-HCl, pH 7.6, by sonicating the substrate for 45 sec with a Sonic Dismembrator (Artek Systems, Farmingdale, NY) at the 45% setting, using a 1/2 in. diameter horn. Triton X-100 (Sigma) was then added to give a final concentration of 0.1% (v/v). Assay conditions were similar to those presented above, except final concentrations were 21 μM substrate and 48 μM DTNB. Chlorpromazine, DL-propranolol, tetramisole (+/−) and tetracaine (Sigma) were added to each cuvette before alkaline phosphatase addition.

Alkaline phosphatase was also tested in the presence of these drugs with *p*-nitrophenyl phosphate (Calbiochem, La Jolla, CA). Final concentrations in quartz cuvettes were: 50 μM *p*-nitrophenyl phosphate, 1 mM $MgCl_2$, 0.01% Triton X-100 and 11 ng/ml alkaline phosphatase in 10 mM Tris-HCl, pH 7.6, in a total volume of 3 ml. Assays were similar to those for the thiophosphate analogs, except hydrolysis was followed at 410 nm wavelength and DTNB was not used. Concentrations of cationic amphiphilic drugs were: 0.5 mM chlorpromazine, 10 mM tetramisole, 5 mM propranolol, and 5 mM tetracaine.

Beef brain cytosol was tested with these drugs, although chlorpromazine could not be used under these conditions, because of turbidity after addition to partially purified cytosol. Conditions were similar to those for alkaline phosphatase and the linearity studies described already.

RESULTS AND DISCUSSION

These thiophosphate phosphatidic acid analogs are good substrates for calf intestine alkaline phosphatase and beef brain phosphomonoesterases (Figs. 1 and 2). Although evidence exists for alkaline-phosphatase catalyzed hydrolysis of nonlipid thiophosphomonoesterase (1) and phospholipase hydrolysis of thiol-releasing substrates that use DTNB for product quantitation (5,11), analogous thiophosphatidic acid hydrolysis is reported here for the first time. Calf intestine alkaline phosphatase also has been show to stimulate hydrolysis of egg-derived PA in a highly specific manner (2). The data presented here show an alkaline phosphatase specificity toward *p*-nitrophenyl phosphate over S-PA (Table 1). The solution pH requirement for alkaline phosphatase actions on S-PA follows a classical alkaline phosphatase pH curve for nonlipid substrates such as *p*-nitrophenyl phosphate (Fig. 3). Beef brain cytosolic enzymes appear to contain phosphomonoesterases, which are most active at physiologic pH's (Fig. 3). This could be a reflection of brain phosphatidic acid phosphohydrolase, which has been reported to have pH optima in this range (12).

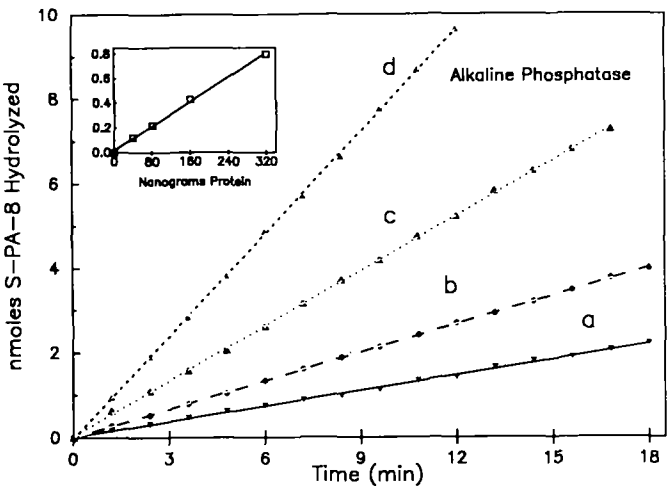

FIG. 1. Alkaline phosphatase catalyzed hydrolysis of S-PA-8 analog. Conditions as described in Methods. a–d, ng Protein in assays: a (40), b (80), c (160), d (320). Inset shows linear relationship of rate of hydrolysis with protein concentration. Correlation coefficients are >0.985.

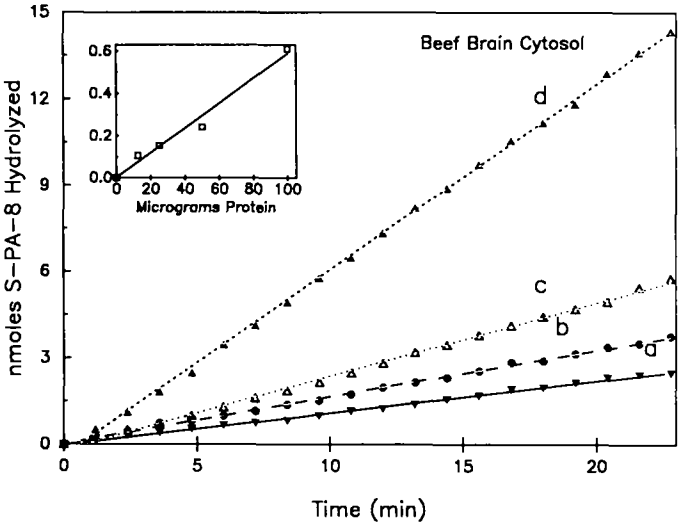

FIG. 2. Beef brain cytosol catalyzed hydrolysis of S-PA-8 analog. Conditions as described in Methods. a–d, μg Protein in assays: a (12.5), b (25), c (50), d (100). Inset shows linear relationship of rate of hydrolysis with protein concentration. Correlation coefficients are >0.985.

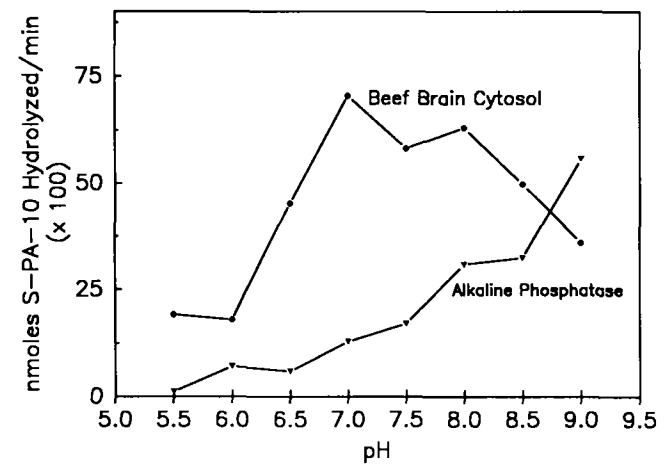

FIG. 3. pH profile of alkaline phosphatase and beef brain cytosol catalyzed hydrolysis of S-PA-10 substrate. Conditions as described in Methods. All correlation coefficients of linear regressions used to plot points are >0.980.

When examining the effects of cationic amphiphilic drugs on alkaline phosphatase catalyzed hydrolysis, substrate types (lipid vs nonlipid) were differentially affected (Tables 2 and 3). Tetracaine, propranolol and chlorpromazine strongly inhibited the enzyme activity towards S-PA-8. With *p*-nitrophenyl phosphate substrate, tetracaine and chlorpromazine had no effect on hydrolytic rate, but propranolol gave a 15% increase. Tetramisole (+/−), a very potent alkaline phosphatase inhibitor (1), inhibited all reactions with both substrates, except with S-PA-8 in brain cytosol (Table 3). Although phosphatidic acid-phosphohydrolase activity was not further purified, the activity towards S-PA-8 in beef brain cytosol is most likely due to this enzyme and not alkaline phosphatase, as seen by the effects of amphiphilic amines and tetramisole. If the activity were to be attributed to alkaline phosphatase, dramatic decreases would be expected, when in fact, the activity is almost unchanged (slight increases). The contrast with tetramisole is most dramatic, because it is a well-defined inhibitor of alkaline phosphatase (1). Cationic amphiphilic drugs have been reported to inhibit phosphatidic acid phosphohydrolase activity with PA substrates (13), and this is seen to be the case with alkaline phosphatase and S-PA. This inhibition is thought to be the result of the amphiphilic amine's ability to prevent the relatively inactive cytosolic phosphatidic acid phosphohydrolase from interacting with microsomal membranes, where activity is much higher (14).

TABLE 2

Actions of Amphiphilic Amines and Tetramisole on Alkaline Phosphatase

Actions of Amphiphilic Amines and Tetramisole on Beef Brain Enzymes

	Substrate	
	S-PA-8	*p*-Nitrophenyl phosphate
Tetramisole	+8	−25
Tetracaine	+15	−13
Propranolol	+16	−13

Values are percentage of the rate of hydrolysis without added compound.

Conditions described in Methods.

The slight stimulation seen in the cytosol is consistent with Koul and Hauser (15) and Martin et al. (16), who reported similar increases with chlorpromazine. It is interesting to note that Koul and Hauser (15) found that sonicating PA preparations caused an increase, but emulsions as substrate preparation lead to amphiphilic amine-induced decreases in activity. The thiophosphate PA is readily dispersable by sonication or high-speed stirring and prepared, by this method, for assays.

In conclusion, these analogs are readily and economically synthesized, excellent substrates for phosphomonoesterases, and are more sensitive to enzymes requiring physiological pH's. They are poor alkaline phosphatase substrates in the presence of cationic amphiphilic drugs. Partially purified beef brain cytosolic fraction is apparently weak in alkaline phosphatase activity, and hydrolysis of S-PA-8 is probably a result of phosphatidic acid-phosphohydrolase activity.

ACKNOWLEDGMENTS

The advice of William Snyder, regarding synthesizing thiodiacylglycerols, is appreciated. For the assistance and advice of Paulann Rider, Northern Illinois University; George Helmkamp Jr., the University of Kansas; Grace Sun, the University of Missouri, Columbia; and Ron McQuarrie, the University of Missouri, Kansas City; I am indebted.

Increased Amounts of Cholesterol Precursors in Lipoproteins After Ileal Exclusion

Pekka V.I. Koivisto and **Tatu A. Miettinen***
Second Department of Medicine, University of Helsinki, SF-00290 Helsinki, Finland

Serum cholesterol precursor sterols reflect the activity of cholesterol synthesis. In this study, squalene, methyl sterol and lathosterol contents were studied in very low density lipoprotein (VLDL), low density lipoprotein (LDL) and high density lipoprotein (HDL) of heterozygous familial hypercholesterolemia patients without and with ileal bypass. The contents of lathosterol and all methyl sterols (lanosterol, $\Delta^{8,24}$-dimethylsterol, Δ^{8}-dimethylsterol, Δ^{8}-methostenol and methostenol), but not of squalene were increased in all lipoproteins by ileal bypass. The increase in the free methyl sterols was more marked than that in the esterified ones. The percentage esterification of the methyl sterols was highest in HDL and lowest in VLDL. Lipoprotein methyl sterol contents were positively correlated with each other and with cholesterol synthesis. The methyl sterols were slightly concentrated in LDL, and squalene strongly concentrated in VLDL. It is concluded that long-term stimulation of cholesterol synthesis increases the methyl sterols in all lipoproteins. *Lipids 23,* **993–996 (1988).**

Serum cholesterol precursor sterols reflect the activity of cholesterol synthesis (1,2), as also evidence by the correlation between the precursors and the hepatic hydroxymethylglutaryl coenzyme A (HMG CoA) reductase activity (3). Therefore, the measurement of these precursors in serum can be used in the detection of clinical states with cholesterol or bile acid malabsorption (4,5) and in the evaluation of changes in different steps of cholesterol synthesis even during short-term processes (6,7).

The bulk of the precursors is transported in low density lipoprotein (LDL). In normal man, the precursor concentrations show a diurnal variation in all three major lipoproteins (6,8). Chronic stimulation of cholesterol synthesis by ileal bypass or resection increases the serum total and LDL precursors (2,5,8–11). It is not exactly known, however, if the changes are similar in the different lipoproteins. Therefore, we studied the effect of the ileal bypass operation (12) on lathosterol, methylated cholesterol precursor sterols and squalene in the different lipoproteins of patients with heterozygous familial hypercholesterolemia.

Abbreviations: Cholesterol (cholest-5-en-3β-ol); Δ^{8}-dimethylsterol (4,4-dimethyl-5α-cholest-8-en-3β-ol); $\Delta^{8,24}$-dimethylsterol (4,4-dimethyl-5α-cholest-8(7), 24-dien-3β-ol); HDL, high density lipoprotein; HMG-CoA, hydroxymethylglutaryl coenzyme A; lanosterol (4,4,14α-trimethyl-5α-cholest-8,24-dien-3β-ol); lathosterol (5α-cholest-7-en-3β-ol); LDL, low density lipoprotein; methostenol (4α-methyl-5α-cholest-7-en-3β-ol); Δ^{8}-methostenol (4α-methyl-5α-cholest-8-en-3β-ol); VLDL, very low density lipoprotein; GLC, gas liquid chromatography; TLC, thin layer chromatography.

PATIENTS AND METHODS

Patients. Thirteen patients with heterozygous familial hypercholesterolemia, as judged clinically (lipid profiles, xanthomas, family history), were studied as outpatients on their habitual home diet. None of them was taking hypolipidemic drugs. Seven patients (3 men, 4 women) had undergone an ileal bypass operation (12), 6–12 years earlier. Six unoperated control patients (3 men, 3 women) had entered the follow-up of our lipid clinic during the same period of time. Both patient groups were of similar age. Preoperatively, the serum cholesterol concentration and body weight had been similar in both groups, but the control patients were slightly more obese during the present study (data not shown). The purpose and design of the study were explained to the patients and they participated as volunteers. The studies have been approved by the ethics committee of the hospital.

Methods. During the seven-day study period, the patients kept a food record for the calculation of cholesterol intake (13). Similar methods have been shown to give a reasonably valid estimate of dietary cholesterol intake (14). The stools of the final three days were collected for the measurement of fecal bile acids (15) and neutral steroids (16). Cholesterol synthesis was calculated as the difference between cholesterol intake and the sum of fecal neutral steroids and bile acids.

Very low density lipoprotein (VLDL) ($d < 1.006$ g/ml) was isolated by ultracentrifugation (17). High density lipoprotein (HDL) was separated from the infranatant with heparin-manganese precipitation (18). LDL values were calculated as the difference between those of the infranatant and HDL. Separation of squalene, free and esterified cholesterol and methyl sterols by thin layer chromatography (TLC) and the subsequent quantitation with gas liquid chromatography (GLC) have been described earlier (6).

The packed GLC column used in the present study caused difficulties in the detection of lathosterol in patients with normal cholesterol synthesis because, unlike the method sterols, lathosterol could not be concentrated by TLC, separately from cholesterol. In patients with ileal bypass, however, the lathosterol contents of all lipoproteins could be quantitated easily. Therefore, lathosterol values are given only for the operated patients (Table 1). Triglycerides were measured with a fluorometric method (19). The squalene and methyl sterol values are expressed in terms of μmol/mol cholesterol to indicate the lipoprotein precursor content.

Statistical analysis of the data was performed using BMDP Statistical Software (BMDP Statistical Software Inc., Los Angeles, CA).

RESULTS

Ileal bypass had lowered serum total and LDL cholesterol and increased HDL cholesterol (Table 1). Squalene was

Mean ± SEM. Squalene and VLDL cholesterol were similar, but other values were changed by ileal bypass ($P < 0.05$ at least, t-test). Lathosterol was not quantitated in the control patients (see the Methods section).

accumulated in VLDL, but the lipoprotein squalene contents were unaffected by the ileal bypass.

The free methyl sterols were up to 10 times increased in all three lipoprotein fractions of the operated subjects. The increases of free Δ^{8}-dimethylsterol and methostenols were higher than those of the esterified ones, resulting in a lowered percentage esterification in the patients with ileal exclusion (Fig. 1). The percentage esterification of the methyl sterols was highest in HDL followed by LDL and VLDL. Compared with the up to 20-fold differences in the sterol concentrations between the different lipoproteins, the contents in terms of μmol/mol cholesterol were remarkably similar in the different lipoproteins. Analysis of variance showed, however, that the methyl sterol contents were slightly higher in LDL than HDL ($P < 0.05$), and tended also to be higher than in VLDL, especially in the control patients. The lathosterol content was markedly increased in the operated patients, and was slightly higher than the sum of the methyl sterols.

Squalene was unassociated with cholesterol synthesis, whereas the methyl sterol contents of all lipoproteins were positively correlated with cholesterol synthesis (Table 2, Fig. 2), especially when the two groups were combined. Methyl sterols of different lipoproteins also were positively associated with each other, and LDL squalene was related to VLDL squalene (Table 3).

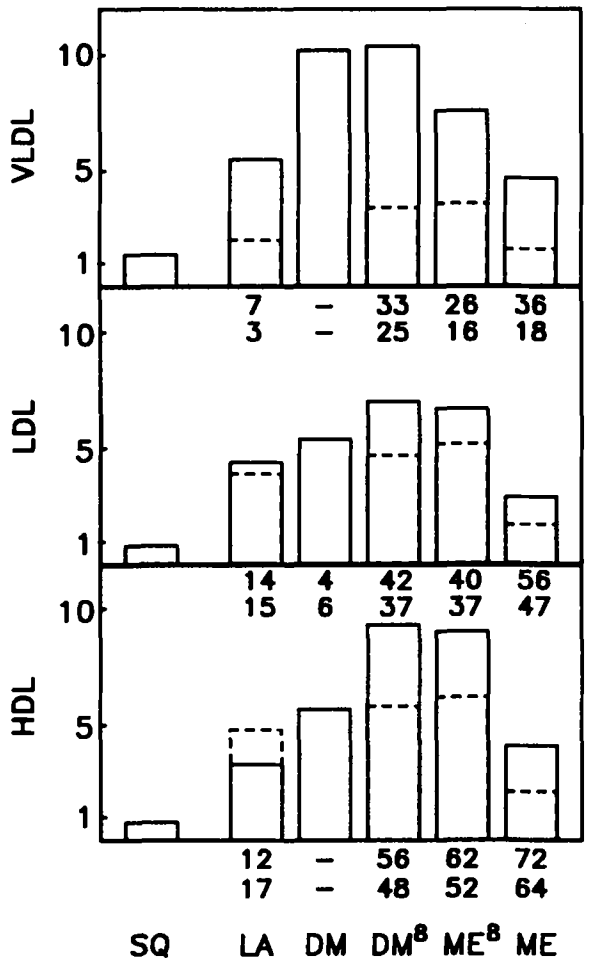

FIG. 1. Relative increases in lipoprotein content of squalene and free (continuous bars) and esterified (broken bars) methyl sterols in patients with ileal exclusion (mean value of the operated patients divided by the mean value of the control patients). Esterified $\Delta^{8,24}$-dimethylsterol was too low for exact detection in controls. Esterification percentage presented below bars for controls (upper rows) and operated (lower rows) patients. SQ = squalene, LA = lanosterol, DM = $\Delta^{8,24}$-dimethylsterol, DM^{8} = Δ^{8}-dimethylsterol, ME^{8} = Δ^{8}-methostenol and ME = methostenol.

DISCUSSION

The present study shows that (a) chronic stimulation of cholesterol synthesis leads to an increase in methyl sterols in all three major lipoprotein classes, (b) that the methyl sterol contents of different lipoproteins are closely correlated and (c) that the distribution of the methyl sterols among the major lipoprotein fractions is quite similar to that of cholesterol, although these sterols are somewhat concentrated in LDL. In addition, the lack of association between the squalene content of any lipoprotein and cholesterol synthesis confirms earlier reports that the serum squalene content is not a reliable index of cholesterol synthesis activity (2,11,20,21).

Earlier studies on the effect of stimulation of cholesterol synthesis by different methods have revealed an

increment in VLDL and LDL methyl sterols, less so in HDL (8,11). The present study shows that the methyl sterol content of HDL also is increased in these patients. The finding that the diurnal variation in the methyl sterol content of LDL is similar to that of HDL (6) fits to the present ones, namely that the methyl sterol content of LDL is more closely correlated with that of HDL than that of VLDL.

The turnover of the methyl sterols and the diurnal changes in lipoprotein methyl sterol content are faster than the turnover of the lipoprotein particles (2,6,11). Therefore, it has been proposed that the methyl sterols might be released to the different lipoprotein particles directly from the hepatocyte cellular membrane, and may be taken up by the liver from the bypassing lipoprotein particles (11). This hypothesis could explain the similarities among the methyl sterol contents of the different lipoproteins seen in the present study. The finding on methyl sterol release on and off lipoproteins is interesting evidence that lipoprotein sterols, probably including cholesterol, can be metabolized without the catabolism of whole lipoprotein particles.

The percentage esterification of the methyl sterols was highest in HDL and lowest in VLDL. The reason for this finding is not obvious. Unlike cholesterol, the methyl sterols are not esterified in serum (22). Therefore, the methyl sterol esters seem, for some reason, to be preferentially concentrated in the heavier lipoprotein particles.

23rd Annual Hugh Lofland Conference on Arterial Wall Metabolism (May 24–27, 1989, Welches, Oregon). Requests for information should be sent to M. R. Malinow, M.D., Chairman, Hugh Lofland Conference, Oregon Regional Primate Research Center, 505 NW 185th Avenue, Beaverton, OR 97006, (503) 690-5258.

10th Anniversary Meeting of the European Association for Cancer Research (University College, Galway, Ireland, September 11–13, 1989). For further information, contact Dr. S. M. Lavelle, Experimental Medicine, University College, Galway, Ireland; or in North America, contact Dr. J. H. Weisburger, American Health Foundation, Valhalla, New York, NY 10595-1599. The program involves plenary lectures, workshops, symposia and poster sessions.

REVIEW

Absorption and Transport of Fat in Mammals With Emphasis on n-3 Polyunsaturated Fatty Acids

Gary J. Nelson[a,*] and **Robert G. Ackman**[b]

[a]Biochemistry Research Unit, Western Human Nutrition Research Center, ARS, U.S. Dept. of Agriculture, P.O. Box 29997, San Francisco, CA 94129; and [b]Canadian Institute of Fisheries Technology, Technical University of Nova Scotia, P.O. Box 1000, Halifax, Nova Scotia, Canada B3J 2X4

The current state of knowledge concerning the absorption and transport of dietary fat with emphasis on long-chain polyunsaturated n-3 fatty acids in mammals is reviewed. It is apparent that long-chain polyunsaturated n-3 fatty acids, either as free acids or as part of triglycerides, are readily absorbed in the gut and transported by the circulatory system. Indeed, it would appear that long-chain polyunsaturated n-3 fatty acids are digested, absorbed and transported similarly to other long-chain fatty acids with only minor variations, although there is much that is still not understood about these processes. The main unresolved issues in the area of the absorption and transport of long-chain polyunsaturated n-3 fatty acids appear to be: 1) If they, when located in the 2-position of triglycerides, have unique metabolic pathways; and 2) whether the unnatural forms, i.e., methyl or ethyl ester derivatives, are suitable vehicles for administration as dietary supplements. The effect in man of dietary, long-chain polyunsaturated n-3 fatty acids on blood serum lipid and lipoprotein levels, particularly the low density lipoproteins, remains controversial, except for the well-documented reduction in serum triglyceride levels. Also, there is uncertainty regarding their distribution and metabolism in tissues. Finally, if the consumption of long-chain polyunsaturated n-3 fatty acids has beneficial health consequences, what is the appropriate therapeutic dose? In view of these important, unresolved issues and uncertainties, it would seem prudent to direct additional research toward a better understanding of the overall process by which fat is digested, absorbed and transported.
Lipids 23, **1005–1014 (1988).**

Within the last two decades, an intense interest has developed in the biochemistry, physiology and metabolism of the family of polyunsaturated fatty acid derived from alpha-linolenic acid, the so-called omega-3, or n-3 or, simply, n3 family (1–4). This interest was stimulated largely by the report of Bang and Dyerberg (5), stating that Eskimos in Greenland had a much lower rate of heart disease than people living in Denmark, despite the very high fat consumption by the Eskimos. Dyerberg (6,7) suggested that the n-3 fatty acids, particularly eicosapentaenoic acid (EPA), may be the primary protective agent in the Eskimo diet. Although this assumption has not been proven valid in some animal models to the satisfaction of all investigators (8,9), it has been established that EPA and other n-3 fatty acids do prolong bleeding times in humans (10–13) and some other animal species (9,14), reduce the tendency of platelets to aggregate (14–22), as well as influence blood viscosity (23–25) and platelet fluidity (26). Monkeys, when fed fish oil diets, show a marked decrease in cardiac arrhythmias (27). Other investigators have reported protective effects of dietary n-3 fatty acids in experimental atherosclerosis (21,28–30). Kromhout et al. reported that individuals who consumed fish in modest amounts had less heart disease than nonfish eaters in a free-living population (31). Storlien et al. reported in 1987 that a diet containing fish oil prevented the development of insulin resistance in rats consuming a high-fat diet (32).

The human dietary requirement for n-3 fatty acids, if indeed they are an essential dietary nutrient (1,2,33–37), is not known at present, although a recent study by Bjerve et al. (38) suggested that the human requirement of alpha-linolenic acid is ca. 0.2% of the total energy intake per day.

Fatty acids of the n-3 series are part of natural foods and are usually eaten in the form of triglyceride (39). The assumption of most investigators has been that n-3 fatty acids are digested, absorbed and transported through normal digestive processes (40,41) and similarly to other types of long-chain fatty acids in the diet. However, although there has been little or no specific experimentation to test this hypothesis, a body of experimental work is developing that allows a critical look at this assumption (42–47).

This area of research includes the use of ethyl esters of menhaden-oil fatty acids, or of a concentrate (ca. 80% total n-3 fatty acids from menhaden-oil fatty acids, also in ethyl ester form). These are provided gratis to NIH or similar peer-review projects by the National Marine Fisheries Service of the Department of Comerce (J. D. Joseph, private communication). At the popular or consumer level, the enriched natural triglyceride oils include 300 mg/g of EPA + docosahexaenoic acid (DHA), as well as higher concentrations in the form of ethyl and methyl esters and/or free acids (48). It can be assumed that more concentrated oils will probably be triglycerides produced from enriched acids or esters, presumably by direct enzyme transesterification. These will be abnormal triglycerides in the context of the structures of either fish oils and lipids, or of the fatty tissues of marine mammal ingested by the Eskimos (46).

To our knowledge, the subject of absorption and transport of n-3 polyunsaturated fatty acids has not been reviewed previously. Indeed, the paucity of investigations of the specific absorption and transport of all long-chain fatty acids is a serious deficiency in modern nutritional science. Thus, it is timely to briefly review this area for

*To whom correspondence should be addressed.

Abbreviations: DHA, docosahexaenoic acid; DPA, docosapentaenoic acid; EPA, eicosapentaenoic acid; FABP, fatty acid binding protein(s); HDL, high density lipoprotein; IDL, intermediate density lipoprotein; PUFA, polyunsaturated fatty acid(s); (V)LDL, (very) low density lipoprotein.

the benefit of the many investigators engaged in feeding fatty acids, particularly n-3 fatty acids, to humans and/or animals.

This review will be limited to a discussion of the digestion and absorption processes of long-chain fatty acids and their transport in the circulatory system of mammals. Metabolic interconversion and utilization or health effects will not be covered, as these areas have been reviewed extensively elsewhere (1–3,36,39,49–53). Indeed, as this review cannot be totally comprehensive, it is intended to be more of an overview, highlighting specific topics and calling attention to areas where opinions are divided or significant gaps in knowledge currently exist.

OUTLINE OF BIOCHEMISTRY AND PHYSIOLOGY OF FAT ABSORPTION AND TRANSPORT

Fat absorption is a multistage metabolic process, the complexity of which is compounded by the insolubility of most lipids in aqueous medium (54). When fat is consumed, either in natural foods or in a purified form (in experimental dietary protocols), a series of physiological events are activated that last for 16 to 24 hr, if no other food is consumed after the initial meal (55). The majority of the fatty acids in the human diet, whether of vegetable or animal origin, is of the C_{18}-chain length, with lesser quantities of C_{16}-chain length, almost invariably palmitic acid (16:0). Butter fat with 10 mol % butyric acid is an exception.

Coconut oil, with 70–80% (w/w) fatty acids of C_8–C_{14}-chain length, is an important dietary element to some population groups. Mustardseed oil and the older, high-erucic acid rapeseed oils are also still important in some regions and have 10–20% of 20:1 and 20–50% of 22:1. Fish oils span the chain-length range from C14 to C22. Unfortunately, some researchers have used the term "medium-chain length" for the C_8–C_{14} group, so that, by implication, the common C_{16}–C_{18} fatty acids became long-chain length. In keeping with the need to distinguish the longer-chain polyunsaturated fatty acids (PUFA), such as arachidonic (20:4n-6), EPA (20:5n-3) and docosapentaenoic (DPA) (22:5n-3) acids, from the C_{18} PUFA, such as 18:2n-6 or 18:3n-3, our terminology will assume that C_4–C_{12} = short chain, C_{14}–C_{18} = medium chain and C_{20}–C_{24} = long chain.

Initially, the fatty food, if consumed orally (rather than as capsules or by stomach tube), is mixed with lingual lipase and hydrolysis of the triglycerides begins in the stomach (56,57). There is also a gastric lipase (57,58) that, particularly in humans, may be more important than lingual lipase in the initial hydrolysis of fat. DeNigris (58) has reported that lingual lipase is not a major source of fat hydrolysis in humans, but is important in other species. Conversely, Moreau et al. (57) indicated in a recent report that gastric lipase is the major enzyme in human gastric juice. It is possible that the gastric lipase is more specific for short- and medium-chain triglycerides, or those with mixed chain lengths (59).

Very short-chain (C < 8 or 10) fatty acids are absorbed directly from the stomach into the venous circulation (60–62); C_{14}- to C_{18}-chain-length fatty acids, as free or esterified fatty acids, are passed mainly into the intestinal lumen where pancreatic lipase, colipase and bile are added to the digestive ferment, and further lipolysis takes place. It is not clear if any significant portion of the free fatty acids liberated, e.g., those with chain lengths greater than 14 carbons, are absorbed into the venous circulation from the stomach. The studies of Chen and coworkers (42–45) would suggest, however, that the majority of the n-3 fatty acids are passed into the small intestine from the stomach, where absorption takes place.

Lingual lipase and pancreatic lipase liberate fatty acids from the 1 and 3 positions of natural triglycerides, leaving the 2-monoglyceride intact (63,64). The positional specificity of gastric lipase has not been elucidated yet (57). Phospholipids are also hydrolyzed by pancreatic enzymes to free fatty acid and their derived lysocompounds (64,65). Pancreatic phospholipase A_2 acts on the 2 position of phospholipids to produce 1-lysocompounds. Pancreatic lipase (1,3-acylglycerol ester hydrolase) will act on the 1 position of phospholipids also (63,64); however, it is generally assumed that most phospholipids are absorbed by the enterocyte as the 1-lysocompound after being hydrolyzed by phospholipid A_2 (64,66). Cholesteryl esters, if present, are hydrolyzed completely (66) to free cholesterol and free fatty acids. Sphingomyelin, usually a minor component of the diet, can be absorbed intact (66).

It should also be noted that some long-chain free fatty acids are absorbed by the portal circulation (60,61,67,68), but the amount absorbed by this route may vary with types and amounts of other nutrients being digested concurrently (69). There is, as yet, no evidence to suggest that significant quantities of the n-3 polyunsaturated fatty acids enter the circulation through the portal vein system (43,44,70), but experiments have not yet included entry by this route for fatty acids from ethyl or methyl esters.

Once the normally ingested fats have been hydrolyzed to free fatty acids, monoglycerides, lysophospholipids and free cholesterol, the hydrolysis products are absorbed by the enterocytes of the intestinal wall. The process of absorption from the intestinal lumen into the enterocyte is by passive diffusion (69). Free fatty acids, lysophospholipids and 2-monoglycerides can be absorbed almost completely in the absence of bile salts (70), although the presence of bile is necessary for the absorption of free cholesterol (71).

In the enterocyte, the lipolysis products are reesterified (72). Cholesterol can be synthesized de novo, if there are inadequate dietary quantities, but even if no cholesterol is supplied by the diet, the bile supplies appreciable quantities to the enterocyte during fat absorption (70,71). The newly synthesized triglycerides, phospholipids and cholesteryl esters are combined with de novo synthesized apolipoproteins, mainly apo B-48, with some apo AI, AII, and AIV, and apo E, to form nascent chylomicrons (73). The chylomicrons are then secreted into the lymphatic system and carried by the thoracic lymphatic duct to the vena cava where they enter the circulation (73). The chylomicrons interact with the serum lipoproteins, absorbing additional apoproteins and albumin and exchanging phospholipids and free fatty acid (74–76). This process produces the mature chylomicron that interacts with circulating lipoprotein lipase which is released from the capillary endothelial cells (77). Lipoprotein lipase initially hydrolyzes chylomicron triglycerides to free fatty acids and 2-monoglycerides.

The liver does not clear chylomicrons directly (78). Rather, their core lipids are hydrolyzed first by the

lipoprotein lipase-colipase system to form chylomicron remnants that are then cleared from the circulation by the apo E receptor (79). Apo B-48 does not bind to the low density lipoprotein (LDL) receptor (80). The chylomicron remnant consists of apo B-48, apo E, phospholipids, cholesterol, cholesteryl ester and some triglyceride (81).

Lipoprotein lipase is activated by apo C-II (77). It has positional specificity for the primary ester bonds of acylglycerols (82) and hydrolyzes the triglycerides to 1,2[2,3]-diacylglycerols and free fatty acids. It also hydrolyzes 1,2[2,3]diacylglycerol to 2-monoacylglycerol and 1,[3]-monoglycerides to free glycerol and fatty acids (83). Lipoprotein lipase has no effect on 2-monoglycerides (78); 2-monoglycerides are hydrolyzed by lipases in the liver (74). This observation may have important implications for absorption, transport and metabolism of n-3 fatty acids as the long-chain n-3 fatty acids may be preferentially distributed in certain positions of the triglyceride molecules (48,84,85). Lipoprotein lipase also hydrolyzes the primary acylester bond of phosphatidylcholine to the 2-acyl lyso-compound and a free fatty acid (86).

The lipoprotein lipase hydrolysis takes place in the peripheral tissues in contact between the chylomicron and the endothelial cells, and the free fatty acids released are taken up by the proximal tissue (76). Some of the free fatty acids released by lipoprotein lipase undoubtedly become bound to albumin and are cleared by the liver (87). As the size of the chylomicron is reduced through hydrolysis of its triglycerides, the apoprotein-phospholipid-cholesteryl coat forms "buds" which apparently split off to form nascent high density lipoprotein (HDL) particles (88). There is no triglyceride or cholesterol ester in these particles that consists exclusively of apo E, apo AI, apo AII and apo C, along with phospholipid and unesterified cholesterol. These nascent HDL particles then acquire cholesteryl esters through the action of the lecithin-cholesterol acyl transferase in blood (89). HDL particles, probably HDL_2, are cleared by the liver (89,90), although there is still controversy over this hypothesis (74,89,90).

In the eucaloric or excess caloric condition, the liver catabolizes chylomicron remnants, synthesizes triglycerides from carbohydrate, and forms very low density lipoproteins (VLDL) that are released into the circulation (74). VLDL is also a substrate for endothelial lipoprotein lipase. VLDL loses triglycerides by hydrolysis and is transformed to intermediate density lipoproteins (IDL) and LDL. LDL is taken up by the LDL receptor (91) of peripheral tissue and the liver. LDL primarily transports cholesteryl esters to the peripheral tissues, where they are hydrolyzed to free cholesterol and then reacylated (92).

ABSORPTION OF N-3 FATTY ACID

The foregoing was a brief overview of normal fat absorption and transfer in mammals, with the exception of ruminants, that absorb fat somewhat differently (93,94). However, in the above discussion, the dietary fatty acids were treated as if all were physiologically equal. This is obviously not true, yet it is an implicit assumption made in most discussions of the subject. First, digestive lipases may not hydrolyze triglycerides containing n-3 fatty acids as efficiently as triglycerides not containing this type of fatty acid (84,85,95–97). Second, there may be differential absorption of n-3 long-chain polyunsaturated fatty acids liberated by the digestive lipases, compared with either saturated, monounsaturated or n-6 polyunsaturated fatty acids. This will be discussed later.

More than twenty years ago Brockerhoff (84,95), Yurkowski and Brockerhoff (96) and Bottino et al. (85) demonstrated that triglycerides containing EPA, DPA (n-6 isomer) and DHA in the 1 and 3 position were resistant to lipolysis by pancreatic lipase in vitro. Brockerhoff (97) later found that the inhibition was specifically produced by the introduction of a double bond in the delta-2 through delta-5 position of the fatty acid chain. Introduction of additional double bonds towards the methylene end of the chain did not increase the inhibition, contrary to the hypothesis of Bottino et al. (85). However, all these investigators reported results obtained primarily with short-term incubations (usually 15 minutes or less) and partial hydrolysis of triglycerides using purified porcine pancreatic lipase and nonphysiological conditions. Although the conditions used in the in vitro experiments bore little resemblance to the in vivo lipolysis of dietary fat, Chen et al. (43) reported that the recovery of fatty acids in the lymph of rats with thoracic cannulas was less complete (57% and 47%, respectively), when fish oil and fish oil concentrates were given, instead of corn oil. Although there have been no direct studies of the efficiency of lipolysis of triglycerides containing n-3 fatty acids in humans, Harris and Connor (98) reported the reduction of postprandial of hypertriglyceridemia in subjects fed a fatty meal, where the source of fat was salmon oil, a result compatible with a slower rate of lipolysis of the n-3–containing triglycerides in the intestine. However, the work of Chen et al. (43–45), El Boustani et al. (47) and Lawson and Hughes (99) suggests that once triglycerides containing n-3 fatty acids are hydrolyzed, the n-3 fatty acids liberated are totally absorbed in vivo. Once absorbed, the n-3 fatty acids appear to be metabolized similarly to other fatty acids. Chen et al. (44,45) found no apparent resistance to hydrolysis of chylomicron triglycerides containing n-3 fatty acids by lipoprotein lipase in rats. Thus, as the digestion of fat may go on for hours in vivo (63,64, 69–71), the rate of lipolysis may have little influence on the ultimate amount of fat absorbed, but the rate of lipolysis could effect the route, i.e., the lymphatic or venous systems, by which the liberated fatty acids enter the circulation (see the discussion of n-3 fatty acid absorption). Although triglycerides containing fatty acids (with double bonds within 5 carbons of the carboxyl end of the molecule, i.e., most n-3 fatty acids) resist pancreatic lipase digestion, further investigation of the action of lipases in vivo on these compounds may be warranted, particularly because it is not known if triglycerides containing n-3 fatty acids are resistant to hydrolysis by lingual or gastric lipases.

It is known that the route of absorption of fatty acids is affected by the length of the carbon chain. Short-chain fatty acids of fewer than 8–12 carbons in chain length are absorbed and pass into the portal vein (61,62). Thus, they go directly to the liver without ever being incorporated into chylomicrons. About one-third to one-half of the fatty acids with carbon-chain lengths of 12 or longer must normally go through the lymphatic-chylomicron route, because only half of the 1- and 3-position fatty acids come

from endogeneous sources (99). The n-3 polyunsaturated fatty acids can be assumed to use this latter route of absorption (100), as they are mainly 18 carbons or longer in chain length (39). The portion absorbed through the portal system (60,61,67,68) seems to profoundly affect liver function and probably explains the well-documented reduction in serum triglycerides in humans (2,98).

The degree of molecular unsaturation has a profound effect on absorption, at least regarding the saturated n-9 and n-6 series of long-chain fatty acids (101–104). In the rat, the saturated fatty acids are poorly absorbed compared with the unsaturated analogs of equivalent chain length (101). Early work by Carroll (101), confirmed by others (61, 102–106), indicated that palmitic acid was absorbed better than stearic acid, and oleic acid was absorbed more completely than either of the saturated acids. Little data are available on this topic in man. Although the poor absorption of the longer-chain saturated fatty acids is presumed due to the higher melting point and great insolubility in an aqueous medium, this has not been explored extensively (54,69). The absorption of fatty acid in the gut does not appear to depend on the bile, because animals with ligated bile ducts appear to absorb fatty acids efficiently (70).

Feeding intact triglycerides in rodents indicate that stearic acid is better absorbed when it is fed as a mixed triglyceride than when fed as tristearin (107,108). Tomarelli et al. reported that an increased stearic acid content of fat decreased the amount of total fat absorbed (109). These authors (109) also found that the amount of palmitic acid in the 1 and 3 positions of the triglyceride reduced total fat absorption. Human infants have been reported to absorb 88% of the stearic acid when fed lard, but only 40% of the stearic acid from lard that had been randomized (110). Recently, Bonanome and Grundy (111) reported essentially complete absorption of stearic acid (>98%) in men fed synthetic triglycerides in a formula diet containing approximately 40% stearic acid, and that the absorption of stearic acid was equivalent to that observed for palmitic and oleic acids incorporated into synthetic triglycerides.

Reports by Chen et al. (42,45) indicate that EPA is absorbed as efficiently as oleic acid in rats and that the absorption of both oleic acid and EPA was equivalent to arachidonic acid. Carroll (101) compared the absorption of saturated and more unsaturated fatty acids and found that longer-chain monounsaturated fatty acids are less well absorbed than those with 18 carbons or less. The work of Chen et al. (42,45) and others (101,105,106) then suggests that additional double bonds in the molecule increase absorption, but that lengthening the chain will decrease the percentage absorbed, compared with a shorter chain having the same number of double bonds.

There is relatively little known about the effect of nutrients such as carbohydrates and proteins on fatty acid absorption. The recent review of physicochemical mechanisms of fat absorption by Carey et al. (69) implied that the presence of other nutrients should enhance absorption compared with a sample of pure fat given as a bolus or by gastric tube. Vallot et al. (61) found that the intestinal pathway of decanoic acid absorption was effected by the presence of other lipids. Vahouny (112) indicated that dietary fiber reduced the absorption of dietary fat. Thus, experiments in which pure fat samples have been used to test absorption may not reflect the situation when natural foods are eaten.

In experimental feeding studies, natural (or synthetic) fats (triglycerides) (102,107–111) are often used as the source of dietary fat, but equally common is the use of purified fatty acid esters, such as the ethyl or methyl ester (7,47,113,114). Although the methyl ester was used in older work (104), it has been replaced, in most instances, by the ethyl ester (42,47,114–120). Occasionally the free fatty acid (120,121) or the arginine salt (47,122) has been used as a delivery vehicle for dietary supplement of the n-3 fatty acids. However, there has been no assurance that the ethyl ester is hydrolyzed by pancreatic lipase as efficiently as natural fats. Indeed, some evidence suggests that ethyl esters are hydrolyzed to a lesser degree than triglycerides or methyl esters (47,99), however, recent work in Japan (114,123), Canada (124), the USA (42) and France (47) shows that ethyl esters of n-3 fatty acids certainly are absorbed by man and rats. Ethyl and methyl esters are relatively rare in natural foods and are most often associated with flavor components (125), although they can be found in small amounts in processed food and alcoholic beverages (126). Thus, assuming absorption and transport identical to that of natural fats may not be correct. There are reports also indicating that fatty acid ethyl esters may be toxic to mitochondria (127,128). The report by El Boustani et al. (47) suggested that ethyl esters of n-3 fatty acids are differentially absorbed in humans, when compared with 2-acyl glycerol EPA, free EPA or its arginine salt. This confirms an earlier report by Nagakawa et al. (212) citing differences in the absorptive biochemistry of free acids or ethyl esters of EPA.

The existing literature on absorption of fats containing n-3 fatty acids suggests they can be readily absorbed as free acid or from triglycerides after hydrolysis by pancreatic, gastric or sublingual lipase (42–45,47,56). Vahouny et al. (129) showed that only half of dietary free EPA appears in the lymph lipids, as similarly reported by El Boustani et al. (47) for ethyl esters. Possibly for ethyl esters, the other half passes through the portal system as a result of in situ hydrolysis after absorption by the brush border in the gut wall. However, EPA as the ethyl ester, although probably absorbed (47) by two different routes, is absorbed totally (123). Selecting which form of EPA is the optimal vehicle (46) for specific n-3-fatty acid supplementation remains equivocal. Although the 2-monoglyceride is absorbed from the lumen and reesterified to triglyceride by the enterocyte without deacylation, it is reported that the ethyl ester does not reach the lymph or circulation intact (121). This suggests that the enterocyte has an esterase or transesterase that can hydrolyze the ethyl ester, allowing incorporation of the liberated fatty acid into de novo synthesized triglycerides in the enterocyte. El Boustani and coworkers's data suggest that this could be the case (47). If pancreatic lipase action on ethyl esters is delayed, then some ethyl ester could be hydrolyzed by intestinal microflora farther down the tract.

As Ackman recently pointed out (46), when n-3 fatty acids are ingested, their molecular structure could have a profound effect on lipid production and its rate, if not the total quantity absorbed. Hence, the physiological and pharmacological properties of n-3 fatty acids could be influenced by the molecular form in which they are ingested.

Although a lot has been written about the effect of dietary n-3 fatty acids on the fatty acid composition of human and other mammalian body fluids and organs (130–136), as well as on eicosanoid metabolism (20,27,39, 115,131,137,138), this review only refers to the data related to absorption and transport of n-3 fatty acids.

The transport of fatty acids from the intestinal lumen is by passive diffusion (63) and takes place in the absence of bile salts. It is likely, but not certain if the 2-monoglyceride is also transported by passive diffusion. Once the free fatty acid has entered the enterocyte, it is rapidly converted by an energy-dependent process to triglycerides and secreted, by another active, energy-dependent process, in the form of nascent chylomicrons. The formation and synthesis of triglycerides takes place in the endoplasmic reticulum (139,140). The free fatty acids are activated to their CoA derivative and the "triglyceride synthetase" complex then incorporates the fatty acid moiety of acyl-CoA unit into triglycerides (139,141). Alternatively, the d-glycerophosphate pathway can also be active in the synthesis of mucosal triglycerides and phospholipids (139,142). The nascent chylomicron particles are formed in the Golgi apparatus (52,139,143). There is reason to believe that apo B-48 is being continuously synthesized in enterocytes, but that its synthesis is stimulated further by dietary fat intake (144). Apo B is not synthesized in the Golgi apparatus but in the rough endoplasmic reticulum (144) and transported to the Golgi apparatus by an undefined mechanism. Thus, only assembly and secretion of the chylomicrons takes place in the Golgi apparatus. However, some glycosylation of the nascent chylomicrons takes place in the Golgi apparatus (145). Actual secretion of the chylomicrons into the lymph takes place by exocytosis from chylomicron-filled vesicles that "bud-off" from the Golgi-cisternae.

Dietary n-3 fatty acids lower serum triglyceride levels (12,19,146–150) apparently by reducing liver triglyceride production and VLDL secretion (151–154). It is not known if n-3 fatty acids also inhibit triglyceride synthesis in the enterocyte, but it is known that fat meals high in n-3 fatty acids do not usually produce the hyperlipemia characteristic of meals high in saturated fat (2,98). Marine mammals do, however, exhibit chylomicronemia when consuming food rich in n-3 fatty acids (155).

Thus, a simplified scheme for the absorption, processing and excretion of fat in the enterocyte is as follows: 1) Fatty acids, 2-monoglycerides, lysolecithin and free cholesterol are passively absorbed into the enterocyte by the microvilli of the brush border; 2) triglycerides, cholesteryl esters and lecithin along with apolipoproteins (apo B-48, apo AI and apo AII, apo AIV and apo C) are synthesized in the endoplasmic reticulum; 3) the lipids and apoproteins are combined into prechylomicron particles either before or in the Golgi apparatus; and 4) nascent chylomicrons are secreted into the lymph by exocytosis.

TRANSPORT OF N-3 FATTY ACIDS

The above description ignores the role of specific fatty acids in this process. Indeed, the tacit assumption has been made that, because a wide variety of fatty acids are encountered in the natural state and are necessary for normal metabolism, the absorption process ideally should be independent of the particular variety of fatty acid being consumed. This would be evolutionarily conservative and prudent. As noted above, there is evidence to the contrary (61,101–106). Long-chain saturated fatty acids are poorly absorbed, perhaps due to calcium soap formation and, at high concentrations, linolenic acid may also be poorly absorbed (Nelson, unpublished observations). At lower intake levels, however, alpha-linolenic acid is readily absorbed and may cause a significant enrichment in the n-3 fatty acid content of tissue lipids, as reported recently by O'Dea et al. (156). It is not clear why the longer-chain saturated fatty acids are not absorbed except that, being very hydrophobic, they would not be expected to readily form micelles. Also, they may not penetrate the membrane of the enterocyte, again due to their hydrophobic characteristics (51,157). However, there is good reason to believe that the absorption phenomena is dose-dependent and, under normal physiological circumstances, during the consumption of natural foods, long-chain saturated fatty acids are not discriminated against during the absorption process (69,70,111).

It is also possible that n-3 fatty acids may be asymmetrically distributed in triglycerides and phospholipids of chylomicrons formed during fat absorption (158–160). They appear to be asymmetrically distributed in tissue phospholipids and, perhaps, triglycerides. It is equally possible that this asymmetry is extended to the distribution and metabolism in the liver (161) and other target organs (124,162,163), as well as in the circulating lipoproteins (164,165).

However, Chen et al. (44) have shown that eicosapentaenoic acid and chylomicrons formed when this n-3 fatty acid is given to rats are cleared from the circulation with the same time curve as oleic acid. The same group has reported (43) similar findings when menhaden oil, fish oil concentrates and corn oil are fed to rats. This would indicate that the extrahepatic lipoprotein lipase does not discriminate against n-3 fatty acids, nor is the uptake of the free fatty acids, liberated by lipoprotein lipase, influenced by the degree of unsaturation or the position of the double bonds in the molecule (44,45). This does not rule out, however, the possibility that fatty acids in the 2-position of monoglycerides have a different metabolic fate than those in the 1,3 position. The data of Chen et al. (43,44) also suggests that the positional specificity of lipoprotein lipase for the 1 and 3 position of triglyceride molecules is not influenced by the type of fatty acid occupying the 1 or 3 position.

Data from Chen et al. (42–45) and El Boustani et al. (47), as well as other investigators (124,164,166–169), indicate that n-3 fatty acids are not randomly distributed in the lipid classes, once hepatic and cellular metabolic processes take over from the absorption and initial transport phenomena. Indeed, the extensive literature on the n-3 fatty acid composition of platelets supports this contention (137,170–175).

The reported distribution of absorbed n-3 fatty acids indicates a slight enrichment of n-3 fatty acids in the phospholipid and mono- and diglyceride fractions of chylomicrons and a concomitant decrease in the triglyceride fraction, when compared to oleic acid in rats (45). In addition, there does not seem to be any major differences between the redistribution of eicosapentaenoic acid and oleic acid to the serum lipoproteins from chylomicrons after four hours in the rat (44). This is a somewhat

unexpected finding, because the distribution of triglyceride, cholesteryl ester and phospholipids is quite different among the various lipoprotein classes (176). Hence, one would expect oleic acid and eicosapentaenoic acid to be distributed in the IDL, LDL and HDL fraction with respect to the lipid class distribution, given the known preference for polyunsaturated fatty acids to be found in the phospholipids and for oleic acid to be incorporated into triglycerides (176,177). However, phospholipids in serum lipoproteins are mainly phosphatidylcholine, lysophosphatidylcholine and sphingomyelin (178). With the known preference of n-3 fatty acids for phosphatidylethanolamine and a lesser preference for phosphatidylcholine, this could simply reflect the phospholipid class composition in the lipoprotein fractions (178). Serum lipoproteins revert to a characteristic fatty acid composition in periods when no dietary fat is being absorbed (179). This is influenced only slightly by the fatty acids in the tissue body pools (180). Indeed, even in long-term feeding studies, the serum fatty acid composition is remarkably constant and characteristic of the species (181–184) during fasting periods, despite large and enduring changes in the tissue fatty acid composition. This suggests that there is a strong genetic determinate of the fatty acid composition of serum lipoprotein and probably reflects the character of the enzymes in the fatty acid metabolic pools in the liver of each species. These enzyme systems were probably evolved to adapt to the usual pattern of intake of dietary fat over evolutionary time spans and, therefore, should be unresponsive to temporary dietary alteration.

If this supposition is true, it could explain many of the purported pharmacological and pathological effects of dietary fatty acids. Unlike proteins or carbohydrates that are digested to common precursor molecules, i.e., simple amino acids or monosaccharides, and absorbed as such, each fatty acid retains its unique chemical properties during the digestion process. Thus, the source of protein or carbohydrate matters little to an organism, assuming the protein contains all the essential amino acids, but an unusual source of fat in the diet may provide very different fatty acids. These fatty acids may profoundly alter the physiology of the organism, if such fat is very different in its fatty acid composition from the animal's usual source of dietary fat.

It is probable that both the amount of fat calories and the type of fatty acids in the diet are responsible for many of the adverse metabolic changes found in fatty-acid-feeding studies. The main reason for this is the genetic basis of intermediary metabolism, which itself is a consequence of evolutionary adaptation to available food supplies (39). Omnivores have obvious evolutionary advantages over those less flexible in their dietary habits, but even omnivores have established dietary patterns, deviations from which can have adverse consequences on health. It may take an equivalent evolutionary time span to adapt to such dietary changes, if they are to become permanent.

Thus, incorporation of exogenous fatty acids into lipid classes, the uptake of fatty acids and lipids by organ systems in the body, and the composition and resident time of fatty acids in body pools are all probably under genetic control. Environmental factors only have a limited influence on these processes.

In most mammalian systems, linolenic acid is strongly discriminated against (1). It does not accumulate in tissue when normal diets are consumed (181,185) and is rapidly eliminated from tissue pools after feeding diets containing large amounts of this compound (Nelson, unpublished observations). Only in a few terrestrial plants (in contrast to marine flora which produce abundant amounts of n-3 fatty acids) does this particular fatty acid become a major component of the total fatty acids present (1). Yet, it could hardly be that it is too unsaturated or not susceptible to further metabolic manipulation, as many more unsaturated fatty acids are common in most tissue (186) and linolenic acid is converted slowly to eicosapentaenoic and docosahexaenoic acids in mammalian tissues (156,187–189). Obviously, the evolutionary pattern in animals has been to eliminate use of linolenic acid in favor of linoleic acid. Although readily converted to arachidonic acid and, in some cases, n-6 docosapentaenoic acid, linoleic acid itself is a major fatty acid of most body tissue pools (186). The evolutionary basis for discrimination against linolenic acid is an interesting but unexplained phenomenon, the elucidation of which awaits a greater understanding of lipid metabolism and adaptation processes.

SUMMARY AND CONCLUSIONS

Most of the data on the absorption and transport of n-3 polyunsaturated fatty acids has been obtained through studies with experimental animals. Some caution should, therefore, be exercised in extrapolating such results to humans. However, fat absorption studies are difficult to conduct in humans, so the animal experiments will remain the foundation of our knowledge in this area for some time.

The major unresolved issues regarding n-3 fatty acid absorption and transport appear to fall into two categories: 1) Are long-chain, n-3 polyunsaturated fatty acids, attached to the 2 position of triglycerides, metabolized similarly, and are they as functionally effective as those in the 1-3 position? 2) Are methyl or ethyl ester acceptable vehicles for the administration of n-3 polyunsaturated fatty acids?

It is clear that as far as absorption is concerned, long-chain n-3 polyunsaturated fatty acids in triglycerides, with the possible exception of linolenic acid, are not absorbed differentially. The absorption of linolenic acid needs further study. All 2-monoglycerides, regardless of which specific fatty acid is incorporated into the molecule, are equally well-absorbed, but their fate once reesterified to triglycerides in the enterocyte also needs further study.

The use of methyl or ethyl esters of n-3 fatty acid to deliver fatty acids to tissue would appear feasible, although it is clear that ethyl esters are poorly hydrolyzed by pancreatic lipase. Ethyl esters, not hydrolyzed in the intestinal lumen, may be carried farther in the intestinal tract to be hydrolyzed by the intestinal flora. It is possible that some ethyl esters of fatty acids may enter the enterocyte unhydrolyzed (47). They must then be rapidly hydrolyzed or transesterified in the cell, because none can be found in human circulation, after ingestion of ethyl ester fatty acids (114,121).

Recent evidence shows that plasma phospholipids and cholesteryl esters respond to EPA as the ethyl esters and to the same extent as from other administered forms

(123). This suggests that absorption is total, but may reflect EPA entering two lipid pools, one in chylomicron form and one possibly through the portal vein. The fate of the ethanol moiety is unknown, but presumedly it is converted to ethyl alcohol.

An interesting, but unstudied, facet of n-3 fatty acid digestion is the composition and fate of bile lecithin. The amount of exogenous phospholipid consumed is relatively small on a daily basis, estimated to be 1-2 g a day for humans (69,70). Bile, however, contributes about 20 g of phospholipid per day (63,69,70) and almost all of this is reabsorbed as free fatty acid and lysolecithin. Bile lecithin has a characteristic fatty acid composition (63,190), but the composition can be influenced by diet (191). In an acute feeding study, the fatty acid composition of the bile will not be influenced by the exogenous fatty acids, but in long-term fatty acid feeding studies, the bile lecithin fatty acid composition will change to reflect the dietary fatty acid composition to some degree. This, in turn, may influence the absorption of the dietary fat and, perhaps, cholesterol absorption.

Other major areas that need additional investigation are: 1) The lipolysis of triglycerides containing n-3 fatty acids by the lipases of the digestive tract—it is known that such triglycerides are relatively resistant to porcine pancreatic lipase (84,85,95-97) in vitro, but this phenomenon has been investigated only indirectly in vivo (43,98, 192); 2) the influence of dietary fatty acids on the distribution of lipoproteins in serum—there is preliminary evidence that n-3 fatty acids may raise LDL levels compared with n-6 fatty acids (8,193); and 3) the partitioning of n-3 fatty acids in the tissues. The specific metabolism of linolenic acid needs more investigation. There is no assurance that feeding linolenic acid will produce the same results as feeding eicosapentaenoic acid or docosahexaenoic acid. Furthermore, little or nothing is known about the metabolism or physiological action of n-3-series docosapentaenoic acid. It also would be interesting to determine how various dietary n-3 fatty acids affect intestinal and liver synthesis of apolipoproteins.

In summary, n-3 fatty acids are digested and absorbed in the mammalian digestive tract in ways similar to other saturated and unsaturated fatty acids. One notable difference in their digestion, however, is their resistance to lipolysis by pancreatic lipase, but this appears to effect more their rate of absorption into the circulation rather than the amount ultimately absorbed. They are incorporated into the chylomicrons and VLDL in the enterocyte. Chylomicrons containing n-3 fatty acids are appropriate substrate for lipoprotein lipase. These fatty acids are taken up by the liver and incorporated into all lipoprotein classes for transport to peripheral tissues where they are incorporated into the tissue fatty acid pools.

The methyl and ethyl esters of n-3 fatty acids are less readily hydrolysed by pancreatic lipase; hence, their absorption is slower when fed in this form (47,99), but may be equally complete. There are no balance studies where fecal excretion was measured comparing EPA or DHA ethyl ester absorption with that of triglyceride or free fatty acids.

Evidence has appeared recently (193) to suggest that, like saturated fatty acids, n-3 fatty acids can raise LDL levels which n-6 fatty acids depress, but more research is needed to confirm this result. However, if the observation proves to be true, then interesting questions are raised, in view of the epidemiological data suggesting that fish consumption reduces cardiovascular disease risk, concerning the mechanism by which n-3 fatty acids reduce the risk of cardiovascular disease. It should be noted, however, that the current evidence suggesting that n-3 fatty acids raise serum cholesterol conflicts with older data of Peifer et al. (194,195) and others (196-199) indicating that n-3 fatty acids markedly depressed serum cholesterol level. Some of the confusion may result from species dependent phenomena or the cholesterol content of fish oil (200), which is nominally 5 to 10 mg/g, but in fish oil concentrates the cholesterol content may not be known, although recent label claims for capsule products usually indicate < 1 to 5 mg/g (48). Further investigations will be needed to resolve this important issue.

Overall, it is clear that the absorption of fatty acids from the diet is still a subject not thoroughly understood. A lot of work has been accumulated in the past thirty years illuminating fundamental pathways of fat absorption and transport, but the mechanisms underlying the absorption and transport of specific fatty acids, with respect to chain length and degree of unsaturation, remain unclear. Recently, molecular biology has contributed considerable data on the fatty acid binding proteins (FABP) of the enterocyte, but the actual role of the FABP in fatty acid absorption and chylomicron formation is unknown (201). It could be that FABP show a fatty acid specificity that provides the mechanism by which the asymmetric distribution of fatty acids in tissue lipid is achieved. Currently, however, this is simply interesting speculation.

In view of the uncertainties establishing the necessary therapeutic intake-level of longer-chain n-3 polyunsaturated fatty acids (202), it seems appropriate to direct additional research toward a better understanding of the overall processes by which fat is digested, absorbed and transported.

cis-9,10-Epoxystearic Acid in Human Leukocytes: Isolation and Quantitative Determination

Per Fahlstadius
Department of Physiological Chemistry, Karolinska Institutet, S-104 01 Stockholm, Sweden

Racemic *cis*-9,10-epoxystearic acid was isolated from total lipids of human leukocytes. Identification of the epoxy acid was based mainly on gas liquid chromatographic-mass spectrometric analysis and on its chemical conversion into *threo*-9,10-dihydroxystearic acid. A mass spectrometric method for quantitative determination of *cis*-9,10-epoxystearic acid using the tetradeuterated compound as internal standard was developed. Using this method, nonstimulated human leukocytes were found to contain 5.1 ± 2.2 μg (SD) of *cis*-9,10-epoxystearic acid per 10^9 cells (n = 8). More than 90% of the epoxy acid occurred in its esterified form in leukocyte lipids.
Lipids 23, 1015–1018 (1988).

Recently, human leukocytes incubated with linoleic acid were reported to produce 9,10-epoxy-12-octadecenoic acid (1,2). The epoxy acid, which served as an uncoupling agent in mitochondrial respiration and caused relaxation of rat stomach smooth muscle, was named "leukotoxin." Biosynthesis of leukotoxin was enhanced in the presence of either calcium ion or the divalent ion ionophore, A 23187 (2). The presence of endogenous leukotoxin in unstimulated cells was also reported (2).

A study was initiated in our laboratory to examine the possible presence and formation of saturated epoxy acids in leukocytes. Such compounds might have easily escaped detection by the ultraviolet absorption method used in the previous work (1,2). The present paper is concerned with isolation and quantitative determination of one such saturated fatty acid epoxide in human leukocytes, i.e., *cis*-9,10-epoxystearic acid.

MATERIALS AND METHODS

Materials. Oleic and linoleic acids were purchased from Sigma Chemical Co. (St. Louis, MO). [1-^{14}C]Linoleic acid was obtained from Amersham (Amersham, UK). Methyl *cis*-9,10-epoxystearate was prepared by epoxidation of methyl oleate by *m*-chloroperbenzoic acid (3). Methyl [1-^{14}C]*cis*-9,10-epoxystearate was obtained by monoepoxidation of [1-^{14}C]linoleic acid followed by catalytic hydrogenation and preparative thin layer chromatography (TLC) (methyl *cis*-9,10-epoxystearate, R_f = 0.37; methyl *cis*-12,13-epoxystearate, R_f = 0.43). The specific radioactivity of the specimen was $137*10^9$ cpm/mol.

threo-9,10-Dihydroxystearic acid was prepared by treatment of methyl *cis*-9,10-epoxystearate (5 mg) with formic acid (1 ml) at room temperature for 2 hr, followed by 1.2 ml of 0.17 M sodium hydroxide in 83% aqueous methanol at room temperature overnight. An aliquot of the dihydroxy acid was converted into the methyl ester-trimethylsilyl (Me_3Si) derivative and analyzed by gas chromatography-mass spectrometry (GC-MS). The mass spectrum showed prominent ions at *m/e* 332 (M-142; rearrangement with loss of $OHC-(CH_2)_7CH_3$), 259 ($Me_3SiO^+=CH-(CH_2)_7-COOCH_3$) and 215 ($Me_3SiO^+=CH-(CH_2)_7-CH_3$). This is in agreement with data published earlier (4).

erythro-9,10-Dihydroxystearic acid was prepared by osmium tetroxide hydroxylation of methyl oleate (5) followed by saponification. The mass spectrum of the methyl ester-Me_3Si derivative was virtually identical to that of the corresponding derivative of *threo*-9,10-dihydroxystearic acid (see above).

Human leukocytes in calcium-free phosphate buffered saline (PBS), pH 7.4, were prepared as previously described (6). The cell count was adjusted to 10^8/ml.

Methyl [9,10,12,13-$^2H_4$]cis-9,10-epoxystearate. Methyl [9,10,12,13-$^2H_4$]linoleate (10 mg) (7) was stirred with 50 μl of 100% hydrazinium hydroxide and 3 mg of cupric diacetate in 1 ml of methanol for 6 hr at room temperature. Gas liquid chromatographic (GLC) analysis of the product demonstrated the presence of methyl stearate, methyl 9- and 12-octadecenoates, as well as methyl linoleate. Epoxidation by *m*-chloroperbenzoic acid afforded a mixture of deuterated methyl 9,10- and 12,13-epoxystearates, as well as methyl 9,10,12,13-diepoxystearate. Pure methyl [9,10,12,13-$^2H_4$]*cis*-9,10-epoxystearate was obtained following preparative TLC. The isotopic composition was 7% trideuterated and 93% tetradeuterated molecules, as determined by mass spectrometry using the unlabeled compound as reference.

Methods. TLC was carried out with Merck Fertigplatten (Kieselgel 60, 0.25 mm). The solvent system used was ethyl acetate/hexane (15:85, v/v). Spots were visualized by spraying with 2,7-dichlorofluorescein and viewed under UV light.

Gas liquid chromatography was carried out with an F&M Biomedical Gas Chromatograph Model 402. The stationary phase used was 3% SE 30 on Supelcoport, except for analysis of menthoxycarbonyl derivatives, in which case the stationary phase was 5% QF-1 on Supelcoport. The column lengths were 1.8 m. Analysis of cyclic carbonate derivatives was performed with a Carlo Erba Strumentazione HRCG 5300 gas chromatograph. A 25-m fused silica capillary column of 007 methyl silicone was used. The column temperature was 250°C.

Mass spectrometry was carried out with an LKB 9000S instrument equipped with column of 1% SE 30 on Chromosorb W, except for the analysis of synthetic and biologically derived methyl 9,10-epoxystearate, in which case a column of 3% OV-210 on Supelcoport was used. The carrier gas was helium in all gas liquid chromatographs. In all mass spectras, the electron energy was 22.5 eV and the trap current 60 μA.

Abbreviations: PBS, phosphate buffered saline; GC-MS, gas chromatography-mass spectrometry; GLC, gas liquid chromatograph(ic,y); TLC, thin layer chromatography.

Radioactivity was determined with a Packard Tri-Carb series 4000 instrument. Methods for catalytic hydrogenation (8) and oxidative ozonolysis (9) and for preparation of Me_3Si (8), (−)-menthoxycarbonyl (9) and cyclic carbonate (5) derivatives were as previously described.

RESULTS

Isolation and identification of cis-*9,10-epoxystearic acid.* Suspensions of human leukocytes in calcium-free PBS (10^8 cells/ml) were added to 20 vol of chloroform/methanol (2:1, v/v). The mixture was kept at room temperature for 30 min. Precipitated protein was removed by filtration, and the clear filtrate was shaken with 0.9% saline (0.2 vol with respect to the volume of filtrate). The chloroform layer was taken to dryness, and the residue was treated with 10 ml of 0.5 M sodium hydroxide in 80% aqueous methanol at room temperature overnight. The solution was extracted with one portion of hexane and subsequently acidified and extracted with two portions of diethyl ether. The combined ether phases were washed until neutral and then taken to dryness. The residue was treated with diazomethane and subjected to preparative TLC using authentic methyl *cis*-9,10-epoxystearate as reference. The zone corresponding to the reference spot (R_f = 0.37) was scraped off and extracted with ethyl acetate. Material thus obtained was analyzed by GC–MS. A peak with a C value identical to that of authentic methyl *cis*-9,10-epoxystearate (C-22.0) appeared. The mass spectrum (Fig. 1) was identical to that of the reference compound and showed prominent ions inter alia at *m/e* 294 (M-18; loss of H_2O), 281 (M-31; loss of $^{\bullet}OCH_3$), 214 (M-98; elimination of $CH_2{=}CH{-}C_5H_{11}$ or its equivalent by cleavage of the 11–12 bond and rearrangement of one hydrogen atom), 199 (M-113; loss of $^{\bullet}(CH_2)_7{-}CH_3$) and 155 (M-157; loss of $^{\bullet}(CH_2)_7{-}COOCH_3$). This is in agreement with data published earlier (10,11). In addition, a minor peak appeared in the gas chromatogram. The retention time and mass spectrum of this material were identical to those of authentic methyl 9,10-epoxy-12-octadecenoate.

An aliquot of the epoxy ester isolated from leukocytes was treated with formic acid followed by sodium hydroxide. This treatment resulted in the formation of 9,10-dihydroxystearic acid as judged by GC–MS. The C value of the methyl ester-Me_3Si derivative was 21.4 (references, corresponding derivatives of *threo-* and *erythro*-9,10-dihydroxystearates, C-21.4 and C-21.5, respectively). The mass spectrum recorded on the Me_3Si derivative of the biologically derived dihydroxyester (Fig. 2) was identical to those of the Me_3Si derivatives of authentic methyl *threo-* and *erythro*-9,10-dihydroxystearates. Methyl 9,10-dihydroxystearate (≈20 μg) prepared from the biologically derived 9,10-epoxystearate was converted into the cyclic carbonate derivative (5) and analyzed by GLC using the cyclic carbonate derivatives of methyl *threo-* and *erythro*-9,10-dihydroxystearates as references. The derivative of the biologically derived 9,10-dihydroxystearate cochromatographed with the cyclic carbonate derivative of methyl *threo*-9,10-dihydroxystearate (retention time, 17.2 min; retention time of cyclic carbonate derivative of methyl *erythro*-9,10-dihydroxystearate, 18.1 min).

On the basis of these data, the epoxy acid isolated from human leukocytes was assigned the structure *cis*-9,10-epoxystearic acid. To determine the absolute configuration of biologically derived methyl 9,10-epoxystearate, a sample (≈20 μg) was converted into a mixture of methyl 9-hydroxy-10-octadecenoate and methyl 10-hydroxy-8-octadecenoate using a modification of a previously described procedure for conversion of epoxy derivatives into allylic alcohols (12). The (−)-menthoxycarbonyl derivaties of the allylic hydroxy esters were subjected to oxidative ozonolysis. The esterified product was analyzed by GLC.

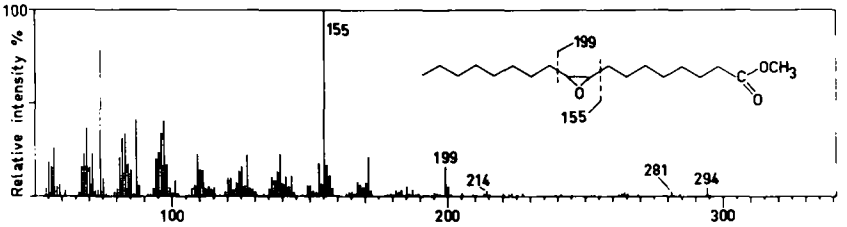

FIG. 1. Mass spectrum of methyl 9,10-epoxystearate derived from endogenous 9,10-epoxystearic acid in human leukocytes.

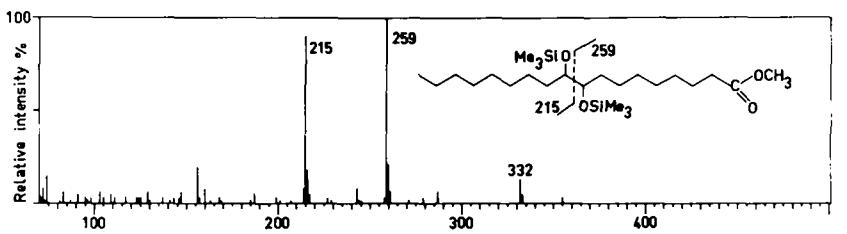

FIG. 2. Mass spectrum of the Me_3Si derivative of methyl 9,10-dihydroxystearate prepared by hydrolysis of endogenous 9,10-epoxystearic acid in human leukocytes.

This analysis showed that dimethyl 2-hydroxysebacate (derived from methyl 9-hydroxy-10-octadecenoate) and methyl 2-hydroxydecanoate (derived from methyl 10-hydroxy-8-octadecenoate) were both racemic. Accordingly, the parent methyl *cis*-9,10-epoxystearate was also racemic.

Quantitative determination of cis-*9,10-epoxystearic acid.* Methyl *cis*-9,10-epoxystearate, 0, 01, 0.2, 0.4 and 1.0 μg, was added to 2 μg of methyl [9,10,12,13-$^2H_4$]*cis*-9,10-epoxystearate. The mixtures of unlabeled and deuterated 9,10-epoxystearates were converted into methyl *threo*-9,10-dihydroxystearates by successive treatments with formic acid, sodium hydroxide and diazomethane, as described above. The Me_3Si derivatives were subjected to GC–MS. The mass region 207–225 was scanned repeatedly (ca. 10 spectra). Intensities of the ion at *m/e* 215 (protium form, $Me_3SiO^+=CH-CH_2-CH_2-CH_2-C_5H_{11}$) and of the ion at *m/e* 218 (deuterium form, $Me_3SiO^+=C^2H-CH_2-CH^2H-CH^2H-C_5H_{11}$) were summed, and the ratio of total intensities of ions 215/218 was calculated. Figure 3 shows a plot of the ratio of ion intensities vs the ratio of protium/deuterium forms in the samples analyzed. The slope was 1.06, and the y-intercept was 0.01.

For quantitative determination of *cis*-9,10-epoxystearic acid, suspensions of human leukocytes (5 ml; 10^8 cells/ml) were added to 20 vol of chloroform/methanol (2:1, v/v) containing 10 μg of deuterated methyl *cis*-9,10-epoxystearate. Extraction and alkaline hydrolysis were carried out as described above. The esterified material was subjected to TLC and the purified 9,10-epoxystearate was converted into methyl *threo*-9,10-dihydroxystearate. Analysis of the Me_3Si derivative by mass spectrometry was carried out as described above. The amount of non-deuterated dihydroxystearate, corresponding to endogenous 9,10-epoxystearate, was calculated from the ratio of intensities of ions 215/218 using the standard curve (Fig. 3). The results of eight such determinations using different batches of leukocytes gave a mean content of *cis*-9,10-epoxystearic acid in human leukocytes of 5.1 ± 2.2 μg (SD) per 10^9 cells. In another set of experiments, saponification of the leukocyte lipids was omitted. In this case, the amount of 9,10-epoxystearic acid detected was 0.4 μg (range 0.1–1.1) per 10^9 cells (n = 5). Thus, the amount of unesterified *cis*-9,10-epoxystearic acid was less than 10% of the esterified epoxy acid. In agreement with this finding, incubation of human leukocytes with *cis*-9,10-epoxystearic acid led to incorporation of the epoxy acid in leukocyte lipids. As seen in Table 1, the recovery of added *cis*-9,10-epoxystearic acid was 51% when the leukocyte lipids were hydrolyzed, as compared with 7% when hydrolysis was omitted.

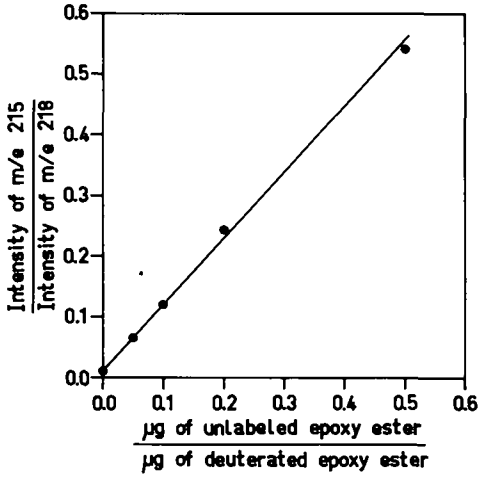

FIG. 3. Plot of the ratio of ion intensities, *m/e* 215/218 vs the ratio of protium/deuterium forms. The slope was 1.06, and the y-intercept was 0.01.

DISCUSSION

The presence of optically active 9,10-epoxystearic acid, 9,10-epoxy-12-octadecenoic acid (coronaric acid) and 12,13-epoxy-9-octadecenoic acid (vernolic acid) in certain plant oils is well documented (13). Recently, leukocytes from different animal species including man were found to produce 9,10-epoxy-12-octadecenoic acid and 12,13-epoxy-9-octadecenoic acid. The 9,10-epoxy acid was the predominant one and was named "leukotoxin" (1–2). In addition, guinea pig peritoneal leukocytes were reported to release large amounts (1.7–6.8 fmol/cell) of leukotoxin (free acid) when treated with aqueous ethanol (2).

In the present study, the occurrence of 18-carbon monoepoxy acids in lipids of human leukocytes was examined. Total leukocyte lipids were saponified, and the product was esterified by treatment with diazomethane and subjected to TLC. The TLC fraction containing monoepoxy esters was analyzed by GC–MS, either directly or following conversion of the epoxide function into the vicinal diol. The major epoxy acid was identified as 9,10-epoxystearic acid by GC–MS using the authentic compound as reference. Hydrolysis of the epoxy acid afforded *threo*-9,10-dihydroxystearic acid, thus showing that the epoxide group had the *cis* configuration. Steric analysis using a recently developed method (Fahlstadius, P. and Hamberg, M., to be published) demonstrated that the biologically derived 9,10-epoxystearate was largely racemic, i.e., a mixture of methyl 9(*S*),10(*R*)- and 9(*R*),10(*S*)-epoxystearates.

TABLE 1

Incorporation of Exogenous *cis*-9,10-Epoxystearic Acid into Leukocyte Lipids

Condition	Amount of 9,10-epoxy-stearic acid (μg)	Recovery of added 9,10-epoxy stearic acid (μg)	(%)
I	0.1	—	—
II	0.4	0.3	7
III	3.4	—	—
IV	5.3	1.9	51

Human leukocytes (5 ml, 10^8 cells/ml) were incubated either with or without 3.8 μg of *cis*-9,10-epoxystearic acid for 30 min at 37°C. The incubate was worked up and 9,10-epoxystearic acid was quantified, as described in the text. Mean values of the amounts of 9,10-epoxystearic acid in 3 experiments are shown.

I = no hydrolysis of total leukocyte lipids, no 9,10-epoxystearic acid added. II = no hydrolysis of total leukocyte lipids, 3.8 μg of 9,10-epoxystearic acid added. III = hydrolysis of total leukocyte lipids as described in the text, no 9,10-epoxystearic acid added. IV = hydrolysis of total leukocyte lipids, 3.8 μg of 9,10-epoxystearic acid added.

In addition to 9,10-epoxystearate, human leukocyte lipids were found to contain small amounts of 9,10-epoxy-12-octadecenoic acid or "leukotoxin" (1,2). The ratio of 9,10-epoxystearic acid to 9,10-epoxy-12-octadecenoic acid was 5-10:1.

A mass spectrometric method for quantitative determination of *cis*-9,10-epoxystearic acid in human leukocytes was developed. With this method, the content of ester-bound *cis*-9,10-epoxystearic acid in human leukocytes was found to be 5.1 ± 2.2 μg (SD)/10^9 cells. On the other hand, much smaller amounts of nonesterified epoxystearic acid could be detected (0.4 μg [range 0.1-1.1]/10^9 cells). This result was in agreement with the finding that *cis*-9,10-epoxystearic acid incubated with leukocyte suspensions was rapidly incorporated into leukocyte lipids. An undefined linoleic acid hydroperoxide was recently suggested to be the precursor of 9,10-epoxy-12-octadecenoic acid (2). However, it seems more likely that formation of monoepoxy acids in leukocytes occurs by a monooxygenase-catalyzed epoxidation of the appropriate unsaturated fatty acid. Conversions of oleic acid (14), linoleic and α-linolenic acids (15), as well as arachidonic acid (16,17) into monoepoxy acids in the presence of liver microsomes have been well-documented. The reaction involves cytochrome P-450 and results in the formation of a mixture of regio- and stereoisomeric (18) epoxy derivatives. The pathway in the biosynthesis of ester-bound *cis*-9,10-epoxystearate in leukocytes may consist of a monooxygenase-catalyzed epoxidation of free oleic acid followed by incorporation of the fatty acid epoxide in leukocyte lipids. Alternatively, oleate esterified in leukocyte lipids may be directly epoxidized.

Effects of Dietary Palm Oil on Arterial Thrombosis, Platelet Responses and Platelet Membrane Fluidity in Rats

Margaret L. Rand[a,1], Adje A.H.M. Hennissen[b] and Gerard Hornstra[a,*]
Departments of [a]Biochemistry and [b]Human Biology, State University of Limburg, P.O. Box 616, 6200 MD Maastricht, The Netherlands

Wistar rats were fed a control diet containing 5 energy % (en %) sunflowerseed oil or diets containing 50 en % of either palm oil, rich in saturated fatty acids, or sunflowerseed oil, high in linoleic acid, for at least eight weeks. Arterial thrombosis tendency, measured by the aorta loop technique, tended to be lowered by the palm oil diet and was lowered significantly by the sunflowerseed oil diet, compared with the control. Aggregation of platelets in whole blood activated with collagen was not altered by palm oil feeding, but was enhanced in the sunflowerseed oil group, compared with the control. The concomitant formation of thromboxane A_2 was decreased by palm oil feeding, although formation of prostacyclin did not change; the ratio of thromboxane/prostacyclin formed was decreased significantly in the palm oil group. Compared with the control diet, platelet membrane fluidity, measured by fluorescence polarization, was not altered in the palm oil group and was significantly increased only by sunflowerseed-oil feeding. Thus, although palm oil contains about 50% saturated fatty acids, it did not increase arterial thrombosis tendency and tended to decrease platelet aggregation, as compared with highly polyunsaturated sunflowerseed oil.
Lipids 23, 1019–1023 (1988).

The type of fat in the diet has been shown to influence arterial thrombosis (1,2). Using an in vivo model for arterial thrombogenesis in rats, we have previously demonstrated that, in general, diets high in saturated fats promote arterial thrombosis, but dietary polyunsaturated fatty acids of the n-6 and n-3 families have antithrombotic effects (2,3).

Sunflowerseed oil contains large amounts of linoleic acid [18:2(n-6)], and diets enriched in this oil have a consistent antithrombotic effect, significantly increasing the obstruction time of aortic loops in rats (2). In contrast with this observation, dietary sunflowerseed oil enhances, in vitro, collagen-induced aggregation of blood platelets (4,5), cell fragments that play important roles in arterial thrombosis (6,7). This increased platelet aggregability may be due to the relatively increased production of the proaggregatory prostanoid thromboxane A_2 (TXA_2), a greater production than can be explained on the basis of the platelet phospholipid content of the thromboxane precursor, arachidonic acid (8). We have recently reported that platelets from rats fed diets high in sunflowerseed oil have an increased overall membrane fluidity (5) and, as a result, an extracellular "message," brought about by the interaction between collagen and the platelet membrane, may be transmitted more efficiently across the membrane to create a higher intracellular response (formation of TXA_2). Consequently, feedback amplification upon platelet stimulation may be enhanced.

This study describes investigations into the effects of another dietary fat, palm oil, that also has been shown to have antithrombotic properties (2). Palm oil is unusual in having an antithrombotic effect, as it contains a low ratio of polyunsaturated to saturated fatty acids; it consists of about 10% linoleic acid and 50% saturated fatty acids (mainly palmitic acid [16:0]). We have examined the effects of dietary palm oil on rat platelet aggregation and prostanoid production in response to stimulation with collagen in whole blood, and on fatty acid composition and membrane fluidity of the platelets, in an attempt to account for the antithrombotic effect of palm oil.

MATERIALS AND METHODS

Animals and diets. Male Wistar rats (specific-pathogen-free), aged five weeks, were fed, ad libitum, one of the following three diets for at least eight weeks: a diet containing 5% of its digestible energy (en %) as sunflowerseed oil—the control diet; a diet containing 50 en % sunflowerseed oil—the sunflowerseed oil diet (which is high in polyunsaturated fatty acids); or a diet containing 50 en % palm oil—the palm oil diet (which is high in saturated and monounsaturated fatty acids). All diets contained 23 en % casein; the remaining calories were contributed by corn starch. Other dietary components (minerals, vitamins, and cellulose) were added, as previously described (2). The diets were freshly made at least once a week, and were stored at 4°C. The rats were given tap water, ad libitum.

The fatty acid compositions of the dietary fats, determined by gas liquid chromatography (GLC) after methylation (See *Lipid analyses* in this section.), are given in Table 1.

All dietary components, except the palm oil (from the Palm Oil Research Institute of Malaysia, Kuala Lumpur, Malaysia), were provided by Unilever Research, Vlaardingen, The Netherlands.

Abbreviations: DPH, 1,6-diphenyl-1,3,5-hexatriene; TXA_2, thromboxane A_2; TXB_2, thromboxane B_2; GLC, gas liquid chromatography; OT, obstruction time.

Measurement of arterial thrombosis tendency. After a feeding period of eight to nine weeks, the arterial thrombosis tendency of the rats was measured using the aorta loop technique, as previously described (9). The time between insertion of the loop and complete obstruction of blood flow through the loop, indicated by a change in the color of the blood from red to dark blue or black, is defined as the obstruction time (OT).

Platelet aggregation in whole blood. During insertion of the aorta loop, blood (1.35 ml) was collected via the loop into a prewarmed syringe containing 3.8% trisodium citrate (0.15 ml) (5). This anticoagulated blood was transferred to an aggregometer cuvette in the thermostated (37°C) cuvette holder of a whole blood aggregometer (Model 500, Chrono-log Corp., Havertown, PA). Five min after blood collection, collagen (3.3 μg/ml, final concentration; Hormon Chemie, Munich, FRG) was added, and the change in impedance, which reflects platelet aggregation around platelets adherent to the electrodes (10,11), was recorded for 15 min.

Measurement of prostanoid formation in collagen-activated whole blood. At completion of an aggregation measurement, the blood was immediately transferred to a small tube and centrifuged at 9,600 × *g* for 2 min. The platelet-free plasma was collected and stored at −20°C until the measurement of thromboxane B_2 (TXB_2), the stable breakdown product of TXA_2, using a radioimmunoassay kit (NEK-007, New England Nuclear, Dreieich, FRG) (5), and measurement of 6-keto-$PGF_{1\alpha}$, the stable metabolite of prostacyclin, also using a radioimmunoassay kit (NEK-008, NEN).

Platelet preparation. Suspensions of washed platelets were prepared from blood obtained by abdominal aortic puncture of rats that had been anesthetized with ether. The animals were exsanguinated at least three weeks after insertion of the aorta loop, that is, after a feeding period of at least 12 weeks. Six parts of blood were collected into one part of the anticoagulant acid-citrate-dextrose (12) and suspensions of washed platelets were prepared essentially according to the method of Ardlie and coworkers (13), as described previously (5). The final resuspension medium of the platelets was Tyrode solution containing 5 mM HEPES, pH 7.35; a portion of the final platelet suspension was used for fluidity measurements and, in some cases, the remainder was centrifuged at 1,300 × *g* for 10 min. The platelet pellet was resuspended in 0.5 ml of 139 mM NaCl, 8 mM Na_2EDTA, and the suspension was stored under N_2 at −20°C until lipid analyses were done.

Fluidity measurements. Platelet membrane fluidity was determined by the method of fluorescence polarization using the hydrophobic probe 1,6-diphenyl-1,3,5-hexatriene (DPH) (Molecular Probes Inc., Junction City, OR) (5,14, 15). One volume of DPH dispersion (1 μM) was added to one volume of platelet suspension (10^8 platelets/ml) and the mixture was incubated at 37°C for 1 hr. Steady-state fluorescence-polarization measurements were done at 37°C using an Aminco-Bowman spectrofluorimeter equipped with Glan-Thompson prism polarizers in the excitation and emission beams and r_s (steady-state fluorescence anisotropy) was determined, as described previously (5). Corrections were made for scattering of polarized exciting light. To correct for slight day-to-day variations in the absolute values of r_s, results are expressed as comparisons with the control diet.

Lipid analyses. EDTA (0.5 ml of a 1% solution) was added to thawing platelet preparations (0.5 ml). A tracer amount of tritiated cholesterol ([1,2,6,7-^{3}H(N)]-cholesterol; NEN) was added to the samples to enable monitoring of recovery, and lipids were extracted according to the method of Bligh and Dyer (16). Butylated hydroxytoluene (0.005%, final concentration) was added to all organic solvents used in the lipid analyses. The phosphorus content of 5% of the total lipid extract was quantitated in duplicate, using a modification of the Fiske/Subbarow technique (17), and total platelet phospholipid content was calculated.

Cholesterol and total phospholipids were separated from other lipids by thin layer chromatography and free cholesterol was determined as described previously, correcting for recovery of tritiated cholesterol (5).

Total platelet phospholipids were eluted and transmethylated with boron trifluoride. Methyl esters of the fatty acids from the phospholipids were extracted with pentane and were analyzed by GLC with a Hewlett-Packard 5840A gas chromatograph using columns packed with 5% DEGS on Chromosorb WHP, 100/120 mesh (Chrompack, Middelburg, The Netherlands) and 2% Apiezon L on Chromosorb WHP, 100/120 mesh, as previously described (5).

Using computer-assisted analysis, chromatograms were corrected for blank runs originating from extraction of platelet-suspending medium and were adjusted with respect to the internal standard, the methyl ester of 15:0. Results are expressed as area percentage of total fatty acids. Identifications were made by comparison of retention times with those of standard mixtures of fatty acid methyl esters (from Unilever Research and Chrompack).

Analysis of data. Because OTs of aorta loops show a log-normal pattern of distribution (2), logarithmic transformation of these values was necessary for statistical analysis. The same was found to be true for TXB_2 and 6-keto-$PGF_{1\alpha}$ formed in whole blood in response to collagen. Analysis of variance, Bonferroni inequality test, Student's t-test or paired t-test were used as indicated in the Results and Discussion section to determine significance of differences. Two-tailed tests were performed.

RESULTS AND DISCUSSION

At the time of insertion of the aorta loops, that is, after a feeding period of eight to nine weeks, there was no difference in mean body weights (approximately 370 g) of the rats fed the three different diets.

Increasing the amount of sunflowerseed oil in the diet from 5 en % to 50 en % was associated with a significant prolongation of the mean log OT of the aorta loops ($P < 0.05$) (Fig. 1), indicating a decreased arterial thrombosis tendency. Rats fed the palm oil diet tended to have longer mean log OTs also, but this difference did not reach statistical significance ($P = 0.10$). Thus, palm oil feeding again tended to lower arterial thrombosis tendency. That a significant lowering of arterial thrombosis tendency was not observed in the present study may have been due to factors other than diet. For example, the variability in OTs of aorta loops is quite high and depends on the skill of the surgeon who inserts the loops. In an earlier study (3), feeding of 50 en % palm oil significantly lowered arterial thrombosis tendency compared with feeding

high-fat (50 en %) diets containing two different types of saturated triglycerides, whale oil or hydrogenated coconut oil. Further confirmation of the antithrombotic effect of palm oil was obtained in a later study (18) in which palm oils again prolonged the OT, compared with a low-fat control group (5 en % sunflowerseed oil), but no significant difference was observed in comparison with the OT of animals on a 50 en % sunflowerseed-oil diet. When results from more recent, as yet unpublished, experiments are included, arterial thrombosis tendency of rats fed a high-fat palm oil diet has been compared with that of rats fed a high-fat sunflowerseed oil diet in 10 studies, and that of rats fed control diets of low-fat (5 en %) sunflowerseed oil or 5 en % sunflowerseed oil + 45 en % hydrogenated coconut oil (This contains a high proportion of saturated fatty acids.) in five studies each. The mean OT (± SEM) of the palm oil groups was 92 ± 3.8% of that of the high sunflowerseed-oil groups ($P > 0.10$), but those of the low-fat and high-fat control groups were 65 ± 3.8% and 63 ± 2.5%, respectively ($P < 0.001$). This clearly demonstrates that dietary palm oil has a distinctive antithrombotic effect when compared with a low-fat or a high-saturated-fat diet.

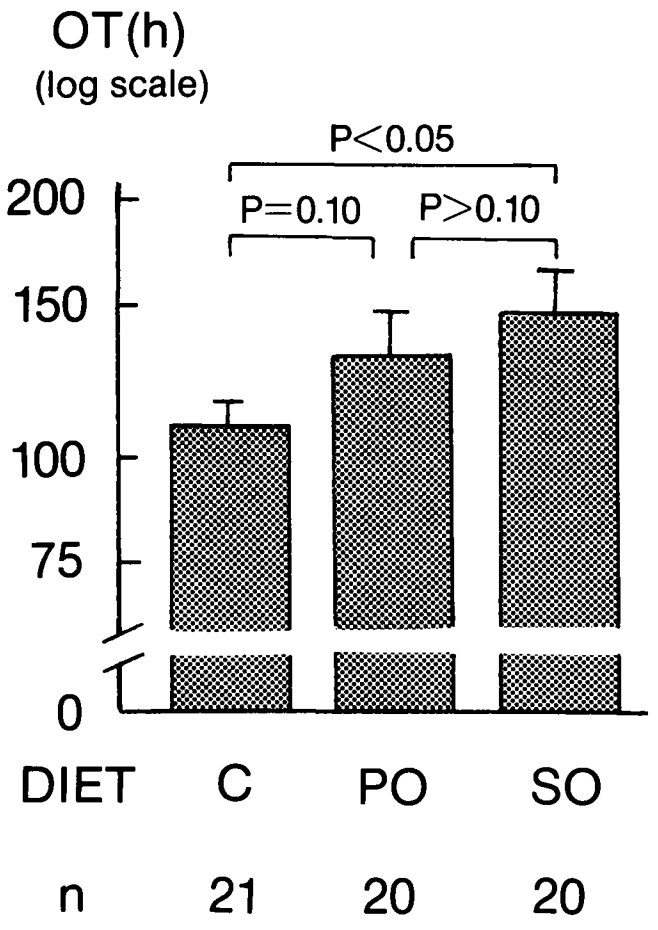

FIG. 1. Arterial thrombosis tendency, as determined by obstruction time (OT) of aorta loops of rats fed the control diet (C), the palm oil diet (PO) or the sunflowerseed oil diet (SO). See Materials and Methods for further details of the diets and aorta loop technique. Values are geometric means ± SEM. Analysis of variance and the Bonferroni inequality test (2-tailed) were used to determine significances of differences.

As measured by the maximum change in impedance, in ohms, there was a significantly greater extent of platelet aggregation in whole blood in the sunflowerseed-oil group (6.8 ± 0.81, n = 19), compared with the control group (4.25 ± 0.55, n = 19) ($P < 0.01$). There was no difference in the extent of platelet aggregation in the palm oil group (4.59 ± 0.65, n = 20), compared with the control group. The values tended to be lower than those observed for the sunflowerseed-oil group ($0.1 > P > 0.05$, means ± SEM, analysis of variance and Bonferroni inequality test).

The present study confirms earlier results (2,4,5) demonstrating that dietary sunflowerseed oil has a distinct antithrombotic effect that is associated, unexpectedly, with enhanced platelet aggregability in vitro in response to collagen. Palm oil feeding was associated with a tendency towards an antithrombotic effect, but no change in platelet aggregability, as compared with the control group. Consequently, no relationship was observed between arterial thrombosis tendency in vivo and platelet aggregability to collagen in vitro.

While sunflowerseed-oil feeding had no effect on the production of immunoreactive thromboxane or prostacyclin in collagen-activated whole blood, dietary palm oil significantly reduced thromboxane formation, leaving production of prostacyclin unaffected (Table 2). This

	Control	Palm oil	Sunflowerseed oil
TXB_2 (log ng/ml)	1.70 ± 0.066(20)	1.55 ± 0.041(20)[b]	1.64 ± 0.082(19)
(ng/ml)	50.1	35.5	43.7
6-keto-$PGF_{1\alpha}$ (log pg/ml)	2.95 ± 0.027(20)	2.99 ± 0.039(16)	3.05 ± 0.030(14)
(pg/ml)	891	977	1122
TX/PG ratio[c]	64.3 ± 7.32(20)	40.2 ± 4.34(13)[b]	61.8 ± 11.40(14)

[a] Values are means ± SEM. Number of determinations is given in parentheses.

[b] Significantly different than control ($P < 0.01$, Bonferroni inequality test).

[c] Calculated on the basis of nontransformed data.

resulted in a significantly lower thromboxane/prostacyclin ratio (Table 2), which has been suggested to determine platelet reactivity and thrombosis tendency (19). It is unlikely that the reduced thromboxane formation by collagen-stimulated platelets from rats fed the palm oil diet was due to a lower platelet count in these animals, because similar numbers of platelets were recovered from the rats fed the different diets (data not shown).

The formation of 6-keto-$PGF_{1\alpha}$ in collagen-activated whole blood most likely reflects prostacyclin production by monocytes (20). Whether these cells are activated themselves and use endogenous arachidonic acid for prostanoid formation or whether they "steal" arachidonic acid or endoperoxides from activated platelets (21) remains to be determined. Activated platelets were most likely the main source of thromboxane produced by collagen-activated whole blood.

Although thromboxane production in vitro has been demonstrated to be positively related to the arachidonic acid content of platelet phospholipids (8), the lower thromboxane production in activated whole blood of palm oil-fed animals cannot be explained on the basis of this relationship, because the arachidonic acid content of platelet phospholipids was not detectably affected by dietary palm oil (Table 3).

Lipid fluidity has been defined as the reciprocal of the lipid structural order parameter, and lower values of r_s (steady-state fluorescence anisotropy), measured using fluorescence polarization, indicate decreased structural order parameters and increased membrane fluidity (22). As observed earlier (5), the administration of a diet rich in sunflowerseed oil significantly enhanced the overall fluidity of platelet membranes, measured with the hydrophobic probe DPH (Table 4). It has been suggested that this greater fluidity promotes stimulus-response coupling, and, as a result, platelet aggregation is increased and TXA_2 production in relation to arachidonic acid availability is enhanced (5). If this is true for palm oil also, then the lower TXA_2 formation by collagen-activated platelets observed after palm oil feeding should be associated with a reduced fluidity of platelet membranes. Compared with the control, however, palm oil feeding did not modify the overall fluidity of platelet membranes (Table 4).

Parameters that are known to modulate membrane fluidity, the cholesterol/phospholipid molar ratio (C/P ratio) and the fatty acid composition of the membrane phospholipids (23,24), were determined in platelets from rats fed the control, palm-oil and sunflowerseed-oil diets. There were no significant differences among the C/P ratios of platelets from rats fed the control diet (0.60 ± 0.01, n = 3), the sunflowerseed-oil diet (0.54 ± 0.02, n = 4) or the palm-oil diet (0.56 ± 0.01, n = 5) (means ± SEM, analysis of variance). We have previously shown that the C/P ratio of platelets from rats fed the control diet and sunflowerseed-oil diet are essentially identical (5).

Feeding of the highly polyunsaturated sunflowerseed-oil diet, compared with the control diet, was associated with differences in the fatty acid composition of the total platelet phospholipids (Table 3) that reflected the fatty acid composition of the sunflowerseed oil (Table 1). For example, as shown previously (5), significantly higher levels of 18:2(n-6) (linoleic acid) and of its elongation product 24:2(n-6) were found in the sunflowerseed-oil group

TABLE 3

Fatty Acid Composition (%) of Phospholipids of Platelets from Rats Fed the Control, Palm Oil and Sunflowerseed Oil Diets[a]

Fatty acid[b]	Diet		
	Control (n = 3)	Palm oil (n = 4)	Sunflowerseed oil (n = 5)
14:0	0.6 ± 0.04	0.4 ± 0.04	0.5 ± 0.05
16:0	27.3 ± 0.15	27.5 ± 0.63	24.6 ± 0.37[e]
16:1(n-7)	1.3 ± 0.02	0.7 ± 0.08	0.9 ± 0.31

20:3(n-6)	0.6 ± 0.01	0.5 ± 0.07	0.7 ± 0.03[f]
20:4(n-6)	25.3 ± 0.89	25.5 ± 0.57	22.7 ± 1.34
20:5(n-3)	NS	—	0.3 ± 0.05[e]
22:0	0.6 ± 0.02	0.7 ± 0.02[e]	0.7 ± 0.03[d]
22:1(n-9)	1.0 ± 0.03	1.1 ± 0.01[f]	0.8 ± 0.04[e]
22:4(n-6)	5.3 ± 0.24	6.0 ± 1.05	5.4 ± 0.50
22:6(n-3)	0.2 ± 0.02	NS	—[d]
24:0	0.8 ± 0.03	0.7 ± 0.09	0.9 ± 0.04
24:1(n-9)	1.8 ± 0.15	2.3 ± 0.20	1.2 ± 0.03[e]
24:2(n-6)	1.0 ± 0.09	0.6 ± 0.12[d]	2.4 ± 0.16[f]
UI[g]	150.2 ± 3.5	148.3 ± 3.8	148.6 ± 4.3

[a] Values are means ± SEM. A line (—) indicates that the fatty acid was not detected, and NS indicates that the mean value was not significantly different than zero.

[b] 18:3(n-3) was not detected in the samples.

Significance of difference compared with control (Bonferroni inequality test):

[c] $P < 0.05$;

[d] $P < 0.025$;

[e] $P < 0.005$;

[f] $P < 0.001$.

[g] UI, the unsaturation index, is calculated by summing the percentage of each fatty acid in a sample multipled by the number of double bonds contained in that fatty acid (24).

(Table 3). However, feeding of the highly saturated/monounsaturated palm-oil diet was not associated with any major differences in fatty acid composition of total platelet phospholipids, compared with the control diet (Table 3).

There were no significant differences among the unsaturation indices calculated from the fatty acid compositions of total phospholipids of platelets from rats fed the three different diets (Table 3). Membrane unsaturation was also calculated in several other ways, by determining the total proportion of unsaturated fatty acids, the ratio of the unsaturation index to the proportion of unsaturated fatty acids, and the ratio of the proportion of unsaturated fatty acids to saturated fatty acids (data not shown) (24–26). There were no significant differences among the unsaturation of the membranes of the platelets from rats fed the different diets calculated in these ways. We agree with the conclusion of Lands (27), that it is difficult to correlate membrane fluidity with unsaturation of the phospholipids of membranes, calculated by means of simple formulae.

TABLE 4

Effect of Dietary Fat on Steady-State Fluorescence Anisotropy, r_s, of DPH-labeled Rat Platelets[a]

	Diet		
	Control	Palm oil	Sunflowerseed oil
Mean r_s	0.218 ± 0.0035	0.218 ± 0.0039	0.212 ± 0.0033
Paired difference than control	—	0.001 ± 0.0018	0.007 ± 0.0018[b]
Paired difference than palm oil	0.001 ± 0.0018	—	0.006 ± 0.0015[b]

[a]Means ± SEM are of 9-10 values. Paired differences are mean paired differences ± SEM of 9-10 values.
[b]Significantly different than zero ($P < 0.01$; paired t-test).

Thus, on the basis of the C/P ratios and the fatty acid data, it is not surprising that differences were not observed in membrane fluidity between the control and palm oil diets. It must be noted, however, that the membrane fluidity measured in these studies is an average membrane fluidity, as DPH partitions equally well into solid and fluid lipid domains of membranes (28), and that the membrane lipid composition that was determined is an overall composition. No information can be obtained from our studies about fluidity or lipid composition of domains of lipids that exist in the membranes (29). It remains possible that compositional and fluidity shifts occur in specific lipid domains and that such shifts were not detected with the methodology used in these studies.

This study demonstrates that palm oil, although it contains a high content of saturated fatty acids, does not promote arterial thrombus formation but, rather, tends to inhibit it. This beneficial antithrombotic effect is associated with a reduced formation of TXA_2 by activated blood platelets, although prostacyclin formation in whole blood is not affected. Collagen-induced platelet aggregation in citrated whole blood and platelet membrane fluidity are not altered in palm oil-fed animals. Upon sunflowerseed-oil feeding, however, collagen-induced platelet aggregation is enhanced and this is associated with an increased fluidity of platelet membranes. The unexpected antithrombotic effect of dietary palm oil, as well as its effect on inhibiting platelet thromboxane formation, requires further investigation.

Formation of Red Pigment by a Two-Step 2-Thiobarbituric Acid Reaction of Alka-2,4-dienals. Potential Products of Lipid Oxidation

Hiroko Kosugi[a,*], Tetsuta Kato[b] and Kiyomi Kikugawa[b]

[a]Ferris Women's College, 4-5-3 Ryokuen, Izumiku, Yokohama 245, Japan; and [b]Tokyo College of Pharmacy, 1432-1 Horinouchi, Hachioji, Tokyo 192-03, Japan

Reaction of 2,4-hexadienal, 2,4-nonadienal and 2,4-decadienal with 2-thiobarbituric acid (TBA) in aqueous acetic acid produced a 532-nm absorbing red pigment. While the 1:1 reaction of the aldehyde and TBA produced little pigment, reaction of the aldehyde with an excess amount of TBA produced significant amounts. Instant heating of the reaction mixture did not produce the pigment. However, initial reaction at 5°C and subsequent heating to 100°C produced the pigment efficiently (two-step reaction). Pigment formation required water and dissolved oxygen. The yield of the pigment from the alka-2,4-dienals was 1/10–1/20 of that from malonaldehyde. In the first step of the reaction at 5°C, the 1:1 adducts of the aldehydes at the *5*-position of TBA and several other unidentified adducts were formed. In the second step, these adducts were converted at 100°C, in the presence of water and oxygen, into the red pigment. The structure of the red pigment from 2,4-hexadienal was elucidated to be the 1:2 adduct of malonaldehyde and TBA. 2-Hexenal and *t*-butylhydroperoxide showed marked synergistic effects on the pigment formation from the alka-2,4-dienals. Red pigment formation due to the alka-2,4-dienals may be enhanced by the presence of other aldehydes and hydroperoxides.

***Lipids 23,* 1024–1031 (1988).**

The 2-thiobarbituric acid (TBA) test has been widely used to measure lipid oxidation (1). Red pigment with an absorption maximum at 532 nm formed in the TBA test of oxidized lipids has been regarded as the 1:2 adduct of malonaldehyde and TBA (2–4).

Recent studies have shown that the TBA test is not specific to malonaldehyde. Malonaldehyde content in oxidized lipids determined by alternative methods are usually lower than those determined by the TBA test (5–11). It is known that monofunctional aldehydes that can be formed in oxidized lipids produce a similar red pigment (12–18). A large part of the red pigment produced by the TBA test of oxidized lipids may be due to these monofunctional aldehydes. However, the contribution of these monofunctional aldehydes to the red pigment formation has not yet been established.

In our investigations of the TBA reaction of monofunctional aldehydes, it was found that alkanals (17) and alk-2-enals (18) produce the red pigment, depending on the reaction conditions. The pigment formation from alkanals is restricted to the reactant ratio of aldehyde: TBA = 1:1 (17). Alk-2-enals produce the pigment at the reactant ratio of 1:1 in maximal yields, but significant amounts of the pigment are produced with an excess amount of TBA (18). The yield of the pigment from alk-2-enals is 1/100–1/500 of that from malonaldehyde with an excess amount of TBA.

We have now investigated the red pigment formation in the reaction of alka-2,4-dienals with TBA in aqueous acetic acid under various conditions. We found that the reaction conditions for alka-2,4-dienals to produce the pigment were greatly different from those for alkanals and alk-2-enals, and that alka-2,4-dienals produced much greater amounts of the pigment by reaction with an excess amount of TBA under the two-step reaction conditions.

MATERIALS AND METHODS

Materials. TBA and 1-butanal were obtained from Wako Pure Chemical Industries (Osaka, Japan). Malonaldehyde bis(dimethylacetal) and 2-hexenal were from the Tokyo Kasei Kogyo Co. (Tokyo, Japan). 2,4-Hexadienal, 2,4-nonadienal and 2,4-decadienal were from Aldrich Chemical Co. (Milwaukee, WI). *t*-Butylhydroperoxide (70% in water) was from Nakarai Chemicals (Kyoto, Japan). The red pigment between malonaldehyde and TBA was prepared according to the method previously reported (2,4).

Analyses. Absorption spectra were measured on a Shimadzu UV-240 or a Hitachi U-2000 spectrophotometer. Fluorescence spectra were measured with a Hitachi 650-60 fluorescence spectrophotometer. ^{1}H and ^{13}C nuclear magnetic resonance (NMR) spectra were recorded on a Bruker AM-400 NMR spectrometer. Signals in ^{13}C NMR spectra were assigned by distortionless enhancement by polarization transfer (DEPT) experiments. Analytical high performance liquid chromatography (HPLC) was carried out with a Shimadzu LC-5A or LC-6A liquid chromatograph equipped with a stainless steel column (4.6 mm × 25 cm) of YMC A-303 ODS (Yamamura Chemical Laboratories Co., Kyoto, Japan). The chromatograph was operated by elution with acetonitrile/0.025 M phosphate buffer (pH 3.0) (2:8, v/v) or methanol/0.04 M acetate buffer (pH 5.5) (4:6, v/v) at a flow rate of 0.8 ml/min. The peaks were detected with Shimadzu SPD-1, SPD-2A or SPD-6A spectrophotometers. Preparative HPLC of the red pigment was carried out with a Hitachi 655-11 liquid chromatograph equipped with a stainless steel column (20 mm × 25 cm) of YMC S-343 ODS, and the chromatograph was operated by elution with methanol/0.04 M acetate buffer (pH 5.5) (4:6, v/v) at a flow rate of 5.0 ml/min.

Reaction of the aldehydes with an excess amount of TBA in aqueous acetic acid. The TBA solution (0.4%) in aqueous acetic acid (4.9 ml) was placed in a screw cap tube (13 ml-content). For the two-step reaction, the tube was precooled to 5°C and 0.1 ml of the aldehyde solution in acetic acid was added. The mixture was kept at 5°C for 1 hr and then heated at 100°C for 20 min. For the one-step reaction, the tube containing the TBA solution was preheated at 100°C, followed by addition of the aldehyde solution. The mixture was then heated at 100°C for 20 min.

Abbreviations: TBA, 2-thiobarbituric acid; DEPT, distortionless enhancement by polarization transfer; HPLC, high performance liquid chromatography; NMR, nuclear magnetic resonance.

Isolation of 1:1 adducts X between the alka-2,4-dienals and TBA. Seven mmol of 2,4-hexadienal, 2,4-nonadienal or 2,4-decadienal was added to a solution of 0.5 g (3.47 mmol) of TBA in 35 ml of 50% acetic acid. A yellow precipitate that appeared during 30–60 min was collected by filtration. The precipitate from 2,4-hexadienal was dissolved in 50 ml of hot glacial acetic acid and filtered. An equal amount of water was added to the filtrate and the mixture was cooled. The precipitate was collected and washed with water to produce X_{HD} (261 mg, yield 33.2%). The precipitates from 2,4-nonadienal and 2,4-decadienal were recrystallized from ethanol to yield pure samples, X_{ND} (351 mg, yield 32.7%) and X_{DD} (295 mg, yield 30.0%), respectively.

Isolation of the red pigment formed in the reaction of 2,4-hexadienal and TBA. A 1.5 liter of 2% acetic acid containing 0.4% TBA and 2 mM 2,4-hexadienal was kept at 5°C for 1 hr and then heated at 100°C for 20 min. The mixture was extracted twice with 50 ml of 1-butanol. The extract was evaporated to dryness and the residue was dissolved in 15 ml of dimethylsulfoxide. The resulting solution was subjected to preparative HPLC. The 532-nm-absorbing peak fractions that appeared at a retention time of 24 min were combined and evaporated to a small volume. A red-violet precipitate was collected by centrifugation at 3,000 rpm for 1 min and washed well with water. The precipitate was dried at 50°C over P_2O_5 in vacuo and yielded 12.2 mg.

RESULTS

Reaction of alka-2,4-dienals with an equivalent amount of TBA. When 0.5 mM 2,4-hexadienal, 2,4-nonadienal or 2,4-decadienal was allowed to react with an equivalent amount of TBA in 15% acetic acid at 100°C for 0.25–6 hr, the reaction mixture turned slightly orange, exhibiting absorption maxima at 495 nm. The spectra from reaction mixtures of alkanals (17) and alk-2-enals (18) heated under the same conditions exhibited absorption maxima at 532 nm. The amount of red pigment formed from alka-2,4-dienals, estimated by absorbance at 532 nm, was lower than that from alkanals (17) and alk-2-enals (18).

Two-step reaction of alka-2,4-dienals with an excess amount of TBA. Treatment of alka-2,4-dienals with an excess amount of TBA in aqueous acetic acid at 100°C produced a red pigment with an absorbance at 532 nm, but the results were not reproducible. After studying the reaction conditions, it was found that allowing the reaction mixture to stand at a relatively low temperature prior to heating (two-step reaction) effectively produced the pigment.

Figure 1A shows absorption spectra of the reaction mixtures of 0.1 mM 2,4-hexadienal and 0.4% (28 mM) TBA in 2% acetic acid. Although instant heating of the reaction mixture at 100°C did not exhibit any significant absorbance at 532 nm, treatment at 5°C prior to heating gave markedly greater absorbance. The reaction of 2,4-nonadienal and 2,4-decadienal under these conditions also yielded a pigment with the same absorption spectrum. Absorption spectra of the reaction mixtures of the alka-2,4-dienals were identical with that of the reaction mixture of malonaldehyde, which was not pretreated (Fig. 1B). Absorption spectra of the reaction mixture of 2-hexenal, showing absorption maxima at 455, 495 and

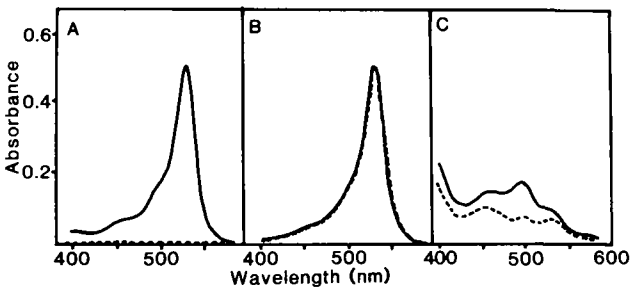

FIG. 1. Absorption spectra of the reaction mixtures of 0.1 mM 2,4-hexadienal (A), 0.0038 mM malonaldehyde bis(dimethylacetal) (B), and 2 mM 2-hexenal (C) with 0.4% (28 mM) TBA in 2% acetic acid. The reaction mixtures were instantly heated at 100°C for 20 min (– – – –), or treated at 5°C for 1 hr and subsequently heated at 100°C for 20 min (——).

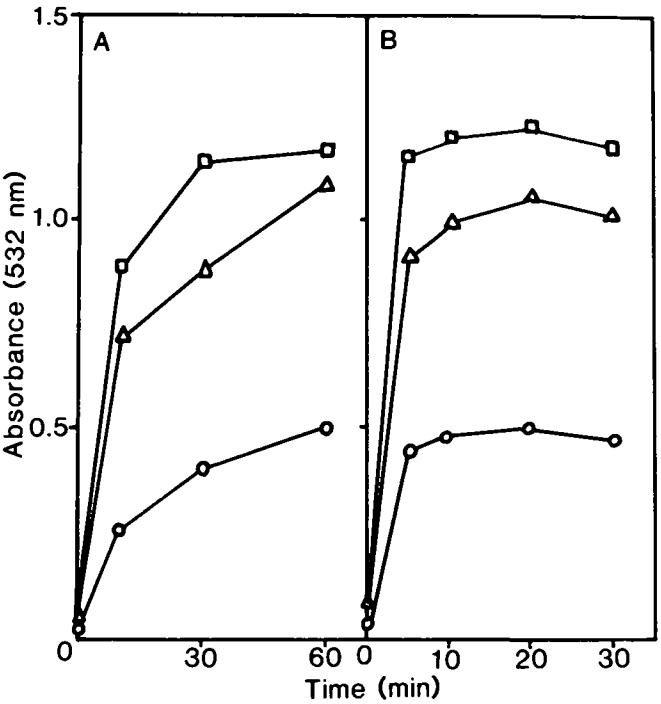

FIG. 2. Time courses of absorbance at 532 nm of the reaction mixtures of 0.08 mM 2,4-hexadienal (○), 2,4-nonadienal (△) and 2,4-decadienal (□), with 0.4% TBA in 2% acetic acid. A: Time courses in the treatment at 5°C prior to heating at 100°C for 20 min. B: Time courses in the heating at 100°C after treatment at 5°C for 1 hr.

532 nm (18), were slightly but not excessively influenced by the pretreatment (Fig. 1C).

Figure 2 shows the time courses of the pigment formation in two-step reaction of the alka-2,4-dienals. The absorbances of the reaction mixtures heated at 100°C for 20 min increased with the pretreatment time (Fig. 2A), and those treated at 5°C for 1 hr increased with subsequent heating (Fig. 2B). Treatment of the reaction mixtures at 5°C for 1 hr and subsequent heating at 100°C for 20 min produced the pigment effectively. When the temperature of the pretreatment was raised from 5°C to 25 or 37°C, formation of the pigment was retarded but still greater than that without the pretreatment. When

the temperature was lowered to 0°C, reproducible absorbance could not be obtained because of precipitation of the TBA into the reaction mixtures.

The pigment formation in the two-step TBA reaction of the alka-2,4-dienals depended on the water content of the reaction mixture. For instance, absorbance of the reaction mixture of 0.08 mM 2,4-hexadienal at 532 nm in 2, 20, 40 and 60% acetic acid was 0.50, 0.15, 0.07 and 0.05, respectively. Formation of the pigment increased progressively with the water content. The pigment formation required dissolved oxygen in the reaction mixtures. Thus, the absorbance did not increase when oxygen in the reaction mixtures was removed by bubbling nitrogen gas prior to the reaction. Water and oxygen were also necessary for the pigment formation from alkanals (17) and alk-2-enals (18). Certain hydrolytic and oxidative mechanisms may be involved in the red pigment formation from these monofunctional aldehydes.

Calibration curves of the absorbance of the two-step TBA reaction of the alka-2,4-dienals (Fig. 3) were not linear but concave. Efficacy for the pigment formation was greater as the carbon number of the aldehydes increased. The absorbance of the two-step TBA reaction mixtures of malonaldehyde and 2-hexenal linearly increased with their concentrations. The concentrations of the aldehydes that gave absorbance 1.0 was 0.1–0.2 mM for the alka-2,4-dienals, 0.007 mM for malonaldehyde and 20 mM for 2-hexenal. Thus, the potency of the pigment formation was in the order of malonaldehyde > alka-2,4-dienals > alk-2-enals under the two-step reaction conditions.

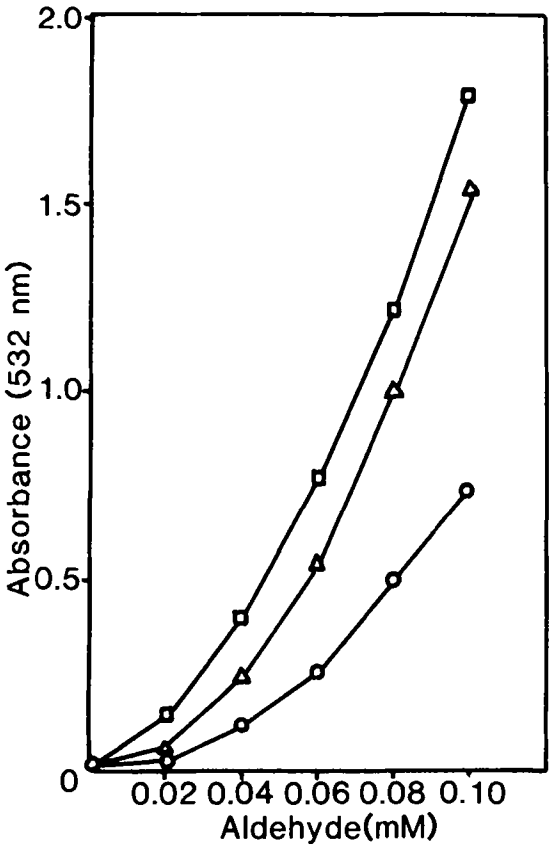

FIG. 3. Calibration curves of absorbance at 532 nm of the reaction mixtures of 2,4-hexadienal (○), 2,4-nonadienal (△) and 2,4-decadienal (□), with 0.4% TBA in 2% acetic acid. The reaction mixtures were treated at 5°C for 1 hr and subsequently heated at 100°C for 20 min.

Presence of intermediary adducts for the red pigment in the first step reaction of alka-2,4-dienals. When a 200 mM mixture of alka-2,4-dienal and 100 mM TBA in 50% acetic acid was allowed to stand at room tempeature, adduct X precipitated. Adduct X_{HD} from 2,4-hexadienal, X_{ND} from 2,4-nonadienal and X_{DD} from 2,4-decadienal were isolated, and their structures were elucidated to be the 1:1 adducts of the aldehyde at the *5*-position of TBA. Physico-chemical properties of these adducts are listed in Table 1. The mass spectra of these adducts revealed the molecular ion peaks corresponding to the indicated formulas. In the ^1H NMR spectrum of each of these adducts, one proton at ca. 8.1 ppm, one proton at ca. 7.9 ppm, one proton at ca. 7.2 ppm and two protons at ca. 6.5 ppm were assignable to the conjugated triene system *(a–e)*. Protons appearing in the higher fields indicated the presence of alkyl residue R. In the ^{13}C NMR spectrum of X_{DD}, signals at 179.6, 161.9 and 161.4 ppm were assignable to the carbons at the *2, 4* and *6*-positions of the TBA ring, five signals between 128 and 156 ppm were to the conjugated triene system *(a–e)*, a signal at 115.8 ppm was to the carbon at the *5*-position of the TBA ring, four signals between 23.3 and 34.2 ppm were to the alkyl chain *(f–i)*, and a singal at 14.3 ppm was to the terminal methyl group *(j)*.

Absorption spectra of these adducts in chloroform revealed maxima at ca. 410 nm. The adducts were unstable in methanol and aqueous acetic acid. For instance, the absorption maximum of X_{HD} in methanol shifted from 385 to 348 nm with an isosbestic point at 359 nm at room temperature for 70 min. The absorbance at the maximum wavelength (409 nm) of X_{HD} in 50% acetic acid was lowered to a half value at room temperature for 4 hr.

Intermediates for the red pigment produced in the first step of the reaction of 2,4-hexadienal were analyzed by HPLC. Thus, a mixture of 0.5 mM 2,4-hexadienal and 2 mM TBA in 50% acetic acid was kept at 5°C and subjected to HPLC (Fig. 4A). The peak corresponding to TBA decreased and the new peaks corresponding to unidentified adducts S, T, U and V appeared after 2 hr. No significant peak corresponding to X_{HD} was observed. A mixture of 0.5 mM X_{HD} and 2 mM TBA was kept at 5°C and subjected to HPLC (Fig. 4B). The peaks due to TBA and X_{HD} decreased and the peaks due to S, T, U and V appeared after 2 hr. Unstable adduct X_{HD} may be initially produced which, in turn, reacted with TBA to form other adducts S, T, U and V. These adducts may be converted into the red pigment in the second step reaction at 100°C.

Involvement of adduct X_{HD} as an intermediate for the red pigment was demonstrated. When a mixture of 0.1 mM X_{HD} and 0.4% TBA in 2% acetic acid was heated at 100°C for 20 min, the red pigment with an absorbance 0.34 was formed. Control two-step TBA reaction of 0.1 mM 2,4-hexadienal yielded the pigment with an absorbance 0.65 (Fig. 3).

Isolation and identification of the red pigment formed in the two-step TBA reaction of 2,4-hexadienal. The reaction mixture of the two-step TBA reaction of 2,4-

hexadienal was subjected to HPLC (Fig. 5). The retention time of the peak due to the red pigment was identical with that of pigment derived from malonaldehyde. The red pigment was purified and isolated by preparative HPLC. ^{1}H and ^{13}C NMR spectra (Table 2) of the pigment confirmed that the structure was the 1:2 adduct of malonaldehyde and TBA. The ^{13}C NMR spectrum showed three signals at 176.5, 162.8 and 161.4 ppm assignable to the carbons at the *2, 4 and 6*-position of the TBA ring, two signals at 157.4 and 117.5 ppm assignable to vinyl carbons (*a* and *b*) and a signal at 101.4 ppm assignable to the carbon at the *5*-position of the TBA ring. The ^{1}H NMR spectrum revealed the presence of vinyl protons (*a* and *b*) as a doublet at 7.69 ppm and a triplet at 8.55 ppm. The data coincided with that of the 1:2 adduct of malonaldehyde and TBA (3). The absorption spectrum of the pigment showed maxima at 532, 305 and 245 nm (Fig. 6A), which were similar to those of the 1:2 adduct of malonaldehyde and TBA (2–4). The fluorescence spectrum of the pigment showed an excitation maximum at 532 nm and an emission maximum at 553 nm (Fig. 6B), which were similar to those previously reported (19).

It is interesting that the reaction of 2,4-hexadienal and TBA gave the 1:2 adduct of malonaldehyde and TBA.

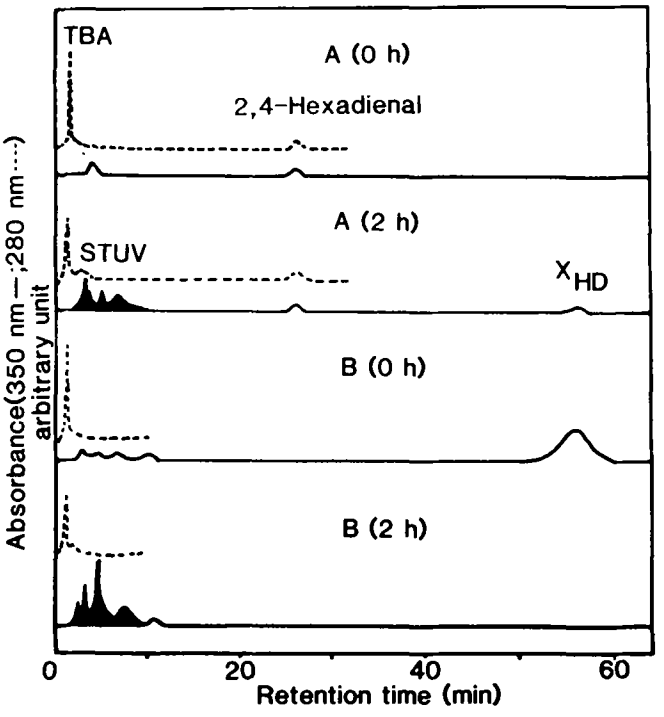

FIG. 4. HPLC patterns of the intermediates for the red pigment in the reaction of 2,4-hexadienal and TBA. A mixture of 0.5 mM 2,4-hexadienal with 2 mM TBA (A), and 0.5 mM X_{HD} with 2 mM TBA (B) in 50% acetic acid was kept at 5°C for 2 hr. The mixture was subjected to a column of YMC A-303 ODS and eluted with acetonitrile/0.025 M phosphate buffer (pH 3.0) (2:8, v/v) at flow rate of 0.8 ml/min. TBA appeared at a retention time of 1 min when detected at 280 nm, and 2,4-hexadienal and X_{HD} at a retention time of 31 min and 56 min, respectively, when detected at 350 nm. X_{HD} was kept stable under HPLC conditions.

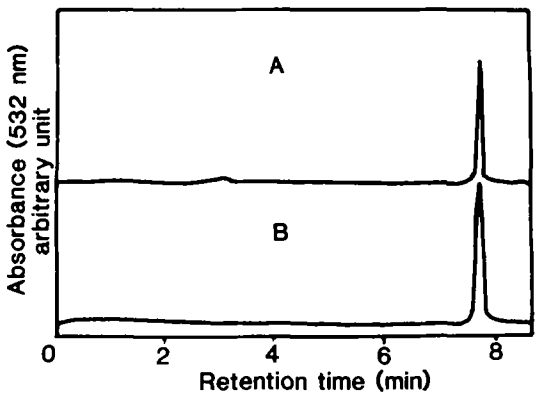

FIG. 5. HPLC patterns of the red pigment derived from 2,4-hexadienal and malonaldehyde. A mixture of 0.1 mM 2,4-hexadienal (A) and 0.05 mM malonaldehyde bis(dimethylacetal) (B) with 0.4% TBA in 2% acetic acid was kept at 5°C for 1 hr and then heated at 100°C for 20 min. The mixture was subjected to a column of YMC A-303 ODS and eluted with methanol/0.04 M acetate buffer (pH 5.5) (4:6, v/v) at a flow rate of 0.8 ml/min.

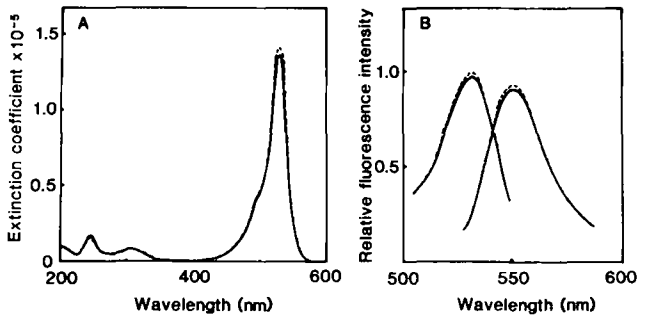

FIG. 6. Absorption spectra (A) and fluorescence spectra (B) of the red pigment derived from 2,4-hexadienal (solid line) and malonaldehyde (dotted line) in water. The red pigment from malonaldehyde was prepared according to the method previously reported (Refs. 2 and 4). Fluorescence excitation (monitored at 565 nm) and emission (monitored at 515 nm) spectra were obtained at a concentration of 0.4 μg/ml.

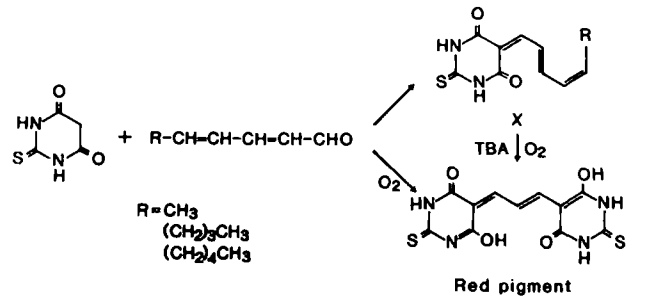

SCHEME 1

Hydrolysis and oxidation of the intermediary adducts may be involved in the red pigment formation in the second step of the reaction (Scheme 1).

Synergistic effects of 2-hexenal and t-butylhydroperoxide on the red pigment formation in the two-step TBA reaction of alka-2,4-dienals. The two-step TBA reaction of 2,4-hexadienal was performed in the presence of malonaldehyde, 1-butanal, 2-hexenal and *t*-butylhydroperoxide (Fig. 7). These components or functions may be involved in the oxidized lipids. Malonaldehyde (0.05 mM) which produced an absorbance of 0.80, 1-butanal (1 mM) with no absorbance, and 2-hexenal (2 mM) with an absorbance of 0.10 were added to the reaction mixtures of 2,4-hexadienal (0–0.1 mM) (Fig. 7A). The rate of increase in absorbance with the dose of 2,4-hexadienal was not influenced by malonaldehyde and little by 1-butanal. In contrast, 2-hexenal markedly potentiated the rate of increase in absorbance. Addition of 1 mM *t*-butylhydroperoxide to the reaction mixtures of 2,4-hexadienal potentiated the rate of increase in absorbance, whereas the hydroperoxide alone did not produce any red pigment (Fig. 7B). These results indicated that there were little or no interactions between 2,4-hexadienal and malonaldehyde/1-butanal but there existed dramatic synergism between 2,4-hexadienal and 2-hexenal/*t*-butylhydroperoxide.

Figure 8 shows the synergistic effects of 20 equivalent amounts of 2-hexenal on the red pigment formation in the two-step TBA reaction of three alka-2,4-dienals. In

the pigment formation due to the alka-2,4-dienals and also abolished the synergism with 2-hexenal.

DISCUSSION

The TBA test is generally used for measurement of lipid oxidation, and the 532-nm absorbing red pigment has been widely used as an excellent index in medical and food science fields (1). The pigment is produced by the reaction of not only malonaldehyde (1-4), but also other aldehydes (12-18). Previously, we have shown that alkanals and alk-2-enals produce the red pigment, depending on the reaction conditions (17,18). It has been shown that alka-2,4-dienals produce the red pigment (13) and the yield of the pigment is very low in comparison with malonaldehyde (15). However, characteristics and contribution of the red pigment from alka-2,4-dienals have not yet been elucidated. We examined the TBA reaction of alka-2,4-dienals in aqueous acetic acid at 100°C under various conditions. It was found that there were many factors which influenced the pigment formation. The factors were the ratio of the reactants; presence of water, oxygen, other aldehydes and hydroperoxides; and time and temperature of pretreatment.

Although the pigment formation from alkanals and alk-2-enals is the highest at the aldehyde:TBA ratio 1:1 (17,18), that from alka-2,4-dienals was very low at that ratio. The pigment formation from alka-2,4-dienals was the highest in the reaction with an excess amount of TBA. The characteristics of the red pigment formation from alkanals, alk-2-enals and alka-2,4-dienals by reaction with an excess amount of TBA in aqueous acetic acid at 100°C are summarized in Table 3. Alkanals, alk-2-enals and alka-2,4-dienals all required water and dissolved oxygen for effective pigment formation, which may indicate the involvement of certain hydrolytic and oxidative mechanisms. The effective pigment formation from alka-2,4-dienals required pretreatment at 5°C, whereas that from other aldehydes did not. Thus, the two-step reaction of alka-2,4-dienals at 5°C and 100°C effectively produced the pigment. In the first step of the reaction, 1:1 adducts X may be initially formed which may be converted into other adducts such as S, T, U and V. These adducts may be converted into the red 1:2 adduct of malonaldehyde and TBA (2-4) in the second step heating (Scheme 1).

Although the calibration curves of alk-2-enals are linear (18), the calibration curves of alka-2,4-dienals were concave. Alka-2,4-dienals produced the red pigment in an amount 1/10-1/20 of that from malonaldehyde at concentrations that gave an absorbance of 1.0. This value was much higher than that from alk-2-enals. It was found that 2-hexenal had pronounced synergistic effects on the pigment formation in the two-step TBA reaction of alka-2,4-dienals, suggesting that alk-2-enals had synergistic effects with alka-2,4-dienals. *t*-Butylhydroperoxide also increased the pigment formation from alka-2,4-dienals. The hydroperoxide may act as an oxidant for the intermediary adducts.

Limitation of the TBA test of oxidized lipids has been claimed since the test is nonspecific to malonaldehyde. It has been shown that the malonaldehyde content in oxidized lipids is much lower than expected (5-11). If the two-step reaction conditions are considered in the TBA test of lipid oxidation, the TBA test may be a useful method for measuring lipid oxidation products such as alka-2,4-dienals.

[Received May 2, 1988; Revision accepted July 18, 1988]

Investigations of the Origin of the Furan Fatty Acids (F-Acids)

Charles P. Gorst-Allman[a], Volker Puchta[b] and G. Spiteller[b,*]

[a]National Chemical Research Laboratory, Council for Scientific and Industrial Research, P.O. Box 395, Pretoria 0001, Republic of South Africa; and [b]Lehrstuhl für Organische Chemie I der Universität Bayreuth, Postfach 10 12 51, Universitätsstrasse 30, De8580 Bayreuth, Federal Republic of Germany

The possible role of linoleic acid as a biogenetic precursor of the furan fatty acids (F-acids) was investigated in in vivo experiments in the rat, using a C_{19} analogue of linoleic acid and gas chromatography–mass spectrometry. No evidence of incorporation of this compound into the F-acids was found. Using an improved analysis procedure by converting F-acids into their tetrahydrofuran derivatives (enabling a separation from the large amounts of normal fatty acids), F-acids (F_3, F_4 and F_6) were detected in rat food, correcting earlier results.

Quantification of F-acid intake with food and excretion of furandicarboxylic acids in the urine, suggested the possibility that the F-acids are not produced de novo in the rat, but instead accumulate in tissue after nutritional intake.

***Lipids 23,* 1032–1036 (1988).**

The F-acids are a group of furanoid fatty acids detected in extremely small quantities in a variety of animal (1–4) and, to a lesser extent, plant sources (5). The most common members of this family, the so-called F_0–F_6 [1 (a)–(g)], can be subdivided into a group bearing a propyl side chain (F_1 and F_4) and a group with a pentyl side chain (F_0, F_2, F_3, F_5 and F_6). Investigations of these compounds have focused on their synthesis (6–17) and on the isolation of new members of the family (18–23), but their biological significance, if any, remains undetermined.

[a]Synthetically produced unnatural furan fatty acids.

SCHEME 1

Relatively little information is available on the biogenesis of these compounds. Schlenk et al. (24) tried to incorporate [^{14}C]acetate into the F-acids in in vivo experiments with fish. However, the only detectable incorporation occurs via chain extension of unlabeled F-acid metabolites. It has also been shown that the F-acids may be further degraded to the urofuranic acids [2] in human feeding experiments, by correlating F-acid intake with urofuranic acid excretion (25). However, the origin of the F-acids themselves is still not known.

SCHEME 2

It seems, on inspection of the structure of the F-acids, that the pathway presented in Scheme 1 provides a plausible route for these compounds. The initial step involves a lipoxygenase type reaction at C-13 to produce 13-peroxy-9,11-octadienoic acid. Subsequent ring closure is followed by double bond rearrangement and methylation to give the F-acids. Similar processes occur in prostaglandin biosynthesis (26), and the final methylation step has been demonstrated as possible in beef liver homogenates (27).

The feasibility of such a route is supported by results on the biosynthesis of the furanoacetylenic phytoalexin wyerone [3] (28,29). This compound has been shown to arise from acetate via a fatty acid-type precursor.

The lack of incorporation of acetate into the F-acid nucleus, as demonstrated by Schlenk for fish (24), may be rationalized by an assumption that fish cannot synthesize F-acids from acetate de novo, but may metabolize nutritionally derived linoleate and linolenate to F-acids. Alternatively, F-acids may not only be produced in mammals and fish, but may be accumulated in the body after additional intake with the food. We have attempted to resolve these questions by in vivo biosynthetic studies in rats and by elaborate examination of the rat food. The probable content of F-acid intake could be calculated from the amount of furan metabolites excreted.

MATERIAL AND METHODS

Gas chromatography (GC) and gas chromatography–mass spectrometry (GC–MS). GC was carried out with a United

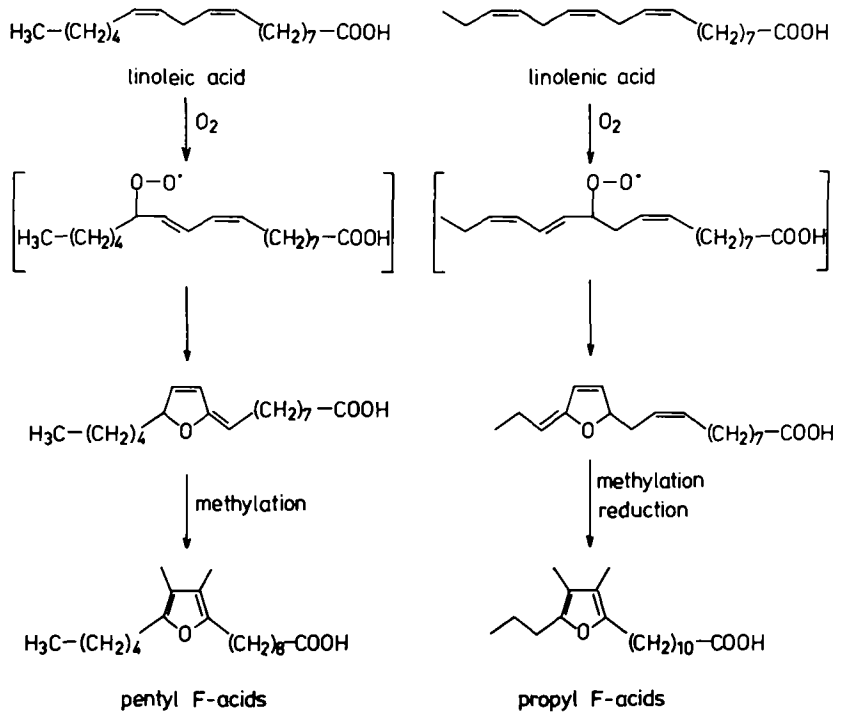
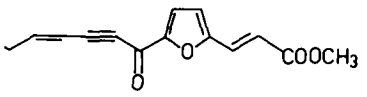


SCHEME 3. Putative biogenesis of the F-acids.



SCHEME 4

Technological Packard Model 438S with an FID, on a WCOT-glass capillary (30 m × 0.3 mm) OV-101 column, programmed from 150°C to 240°C at 2°C/min. The temperature of injector and detector was held at 270°C. Peak area integration was done by a Shimadzu C-R3A integrator. Carrier gas was hydrogen. The split ratio was 1:10.

GC–MS was performed on a Finnigan MAT 312 GC–MS system with a MAT-SS-300 data system, ionization energy 70 eV. The GC column was a 25 m × 0.3 mm i.d. OV-101 WCOT-glass capillary column. The carrier gas was helium (2 ml/min, the temperature program was the same as used for GC and the probes were injected in the splitless mode.

High performance liquid chromatography (HPLC) separation. HPLC was carried out using a Beckman 421 controller, two Beckman 114 M pumps, a Beckman 165 UV detector at 215 nm and a Beckman 156 RI detector. The column was a Serva Si100 (250 mm × 1.6 mm, 3 μm). The solvent was *n*-hexane/methyl-*t*-butyl ether (Merck, 97:3, v/v) at a flow rate of 1.7 ml/min^{-1}.

Synthesis of nonadeca-10,13-dienoic acid. The preparation of this compound from linoleic acid was as described by Marcel and Holman (30).

In vivo rat experiments. Four Wistar rats were kept on a linoleic acid-deficient diet (Altromin; No. C1058; 20 g/day) for 12 days. After this period, the food of three of the rats was supplemented with nonadeca-10,13-dienoic acid (40 mg/rat/day) for 33 days. The rats were killed and the liver, kidney, muscle, fat and blood fractions obtained. Typical work-up procedure for all fractions and the feces is as described for the liver fraction. To the liver fraction (15.6 g) was added [1j] (20 μg), methanol (60 ml) and chloroform (30 ml). The material was homogenized in a Waring blender at high speed for 4 min and then centrifuged at 3,000 rpm for 10 min. The supernatant was carefully removed and the homogenization and centrifugation repeated with chloroform (30 ml). Water (35 ml) and potassium chloride solution (0.88%, 60 ml) was added to the combined supernatants. After partition, the chloroform layer was evaporated to dryness under reduced pressure and the residue transesterificated with sodium methoxide in methanol (0.5 N, 30 ml) and tetrahydrofuran (15 ml) at 50°C for 1 hr under nitrogen. After cooling and acidification (concentrated HCl), most of the tetrahydrofuran was removed under reduced pressure and water (50 ml) was added. The solution was extracted with chloroform (3 × 50 ml), the chloroform removed under reduced pressure and the residue esterified with ethereal diazomethane.

Excess solvent and reagent wre removed in a stream of nitrogen. The residual oil was purified by column chromatography on SiO_2 (Merck, No. 7734, 50 g), collecting the fraction that eluted with cyclohexane/ethylacetate (98:2, v/v). This material was hydrogenated for 2 hr at 1.5 bar in the presence of a rhodium on alumina catalyst (5%, 20 mg). After filtration, the F-acid fraction was concentrated by thin layer chromatography (TLC) on SiO_2 (31), before final purification of the F-acid fraction by HPLC using *n*-hexane/methyl-*t*-butylether/2-propanol (97:3:0.05, v/v/v) as eluant. This material was used for GC–MS.

Examination of rat food. A portion of 20 g rat food (Altromin, No. C 1058) was crumbled in a grain mill (Braun, FRG). Internal standard [1j] 20 μg, methanol (160 ml), chloroform (80 ml) and water (60 ml) were added. The mixture was homogenized in a Waring blender at high speed for 4 min. After stirring the mixture for 3 hr, a second homogenization was done. Centrifugation at 3,000 rpm for 10 min gave a clear supernatant that was carefully removed. The residue was homogenized with chloroform (80 ml) and centrifuged. To the combined supernatants, potassium chloride solution (0.88%, 80 ml) was added. After partition, the lower chloroform layer was evaporated to dryness under reduced pressure. The remainder of the workup was as described for the rat liver fraction above.

Quantification of furandicarboxylic acids (4) in the rat urine. Twenty-four hr urine was collected with at least 0.3% NaN_3. Ten μg 3-carboxy-4-methyl-5-pentyl-furan-2-acetic acid was added as an internal standard. The urine was diluted with a 10-fold amount of cold (−20°C) acetone and left at −20°C overnight, to precipitate protein. The clear solution was decanted and the acetone was removed under reduced pressure. The residue was added, after dilution with 20 ml of water and acidification (concentrated HCl), to a C_{18} bonded-phase extraction column (Chromabond-C_{18}, 500 mg; Macherey & Nagel; D-5160 Düren, FRG; preconditioned with 5 ml methanol and 5 ml water) and drawn through the column under vacuum. The C_{18}-column was washed with 4 ml of 1 mol/l sodium acetate buffer (pH 5) and 4 ml water. Excess water was removed by suction and the final elution was achieved by aspirating 2 ml of methanol. Esterification of the methanol elute was done with excess ethereal diazomethane. After evaporation in the nitrogen stream, the residue was purified by column chromatography (150 mm × 8 mm) on 3 g SiO_2 (Merck No. 7734) in cyclohexane. Two fractions were collected. The first fraction with 20 ml cyclohexane/ethyl acetate (94:6, v/v), and a second fraction with 15 ml cyclohexane/ethyl acetate (8:2, v/v). The second fraction was concentrated to about 3 μl and 1 μl aliquots was used for GC and for GC–MS analyses. The amount of furandicarboxylic acids was calculated by peak area integration in comparison with the internal standard.

RESULTS AND DISCUSSION

The study of F-acid biosynthesis is complicated by the extremely small quantities of the compounds found in most living systems. Beef liver contains ca. 4.5 mg/kg of a mixture of F-acids (32), and a typical rat liver contains less than 10 μg of a similar mixture that will be discussed later. Separation of such extremely small quantities of F-acids from accompanying large amounts of fatty acids is neither practical nor possible even by the use of urea fractionation (3,32). Therefore, hydrogenation of F-acids to the corresponding tetrahydrofuran derivatives was done by using Rh/Al_2O_3 as a catalyst, because separation of tetrahydrofuran acids from fatty acids can be easily achieved by TLC (31). Thus, the F-acids are detected in the form of their tetrahydrofuran compounds in extremely small quantities (31), and analyzed structurally, using GC–MS. Moreover, all the F-acids naturally detectable in rat contain an even number of methylene groups in the carboxyl side chain [1, n = 6, 8, 10]. Consequently, if a C_{19} analog of linoleic acid containing an additional methylene group in the portion of the molecule between the carboxyl group and the first double bond is provided as precursor, the resultant F-acid after metabolism [1h] should contain a carboxyl side chain with an odd number of methylene groups (n = 9) and should be easily detectable and structurally distinguishable from naturally-occurring metabolites.

The substrate specificity of the enzyme system affecting the transformation from fatty acid to F-acid should, by analogy with investigations on prostaglandin biosynthesis (33,34), be tolerant of this chain elongation. For the prostaglandin, the initial sequence also involves a lipoxygenase-type reaction.

In vivo rat experiments. Before initiating in vivo rat-feeding experiments, it was necessary to confirm that F-acids were indeed present in the rat. Previous studies had shown the presence of the F-acid degradation products [4] in rat urine (35), but no investigation of the constituent F-acids had been made (36). A study of rat liver, kidney, muscle, fat and blood showed the F-acids F_3 [1d], F_4 [1e] and F_6 [1g] to be present in the approximate amounts shown in Table 1. It appears that F_3 and F_4 are the major F-acids present in the rat, as opposed to F_6 in beef.

Assuming that unsaturated fatty acids are precursors, this would suggest more efficient metabolism of a C_{18} precursor in the rat, as opposed to C_{20} in cattle, or more efficient chain elongation of a C_{18} derivative in cattle.

In the feeding experiments, rats were subjected to a diet deficient in linoleic acid for a period of two weeks before supplementation of the food with the C_{19} precursor was initiated. In this way, the daily intake of linoleic acid per rat was fixed at ca. 60 mg. After two weeks, the precursor (40 mg/day) was added to the food of each rat, and

TABLE 1

F-Acids Present in Rat

F-acid	Amount (μg/rat)[a]

SCHEME 5

feeding was continued for 33 days. At the end of this period, the liver, kidney, muscle, fat and blood fractions were once more examined. The results are presented in Table 2.

The natural F-acids, F_3 [**1d**], F_4 [**1e**] and F_6 [**1g**], are present in generally reduced quantities, but there is no evidence for the unnatural metabolite [**1h**]. In terms of the experimental design, this would suggest that, in the rat, linoleic acid is not a precursor of the F-acids. The natural metabolites are detectable at a level of ca. 0.1 μg, so even minimal conversion of the C_{19} precursor to [**1h**] should be apparent. Moreover, the metabolite [**1h**] has been synthesized in this laboratory ("unpublished results"), so that its retention index by GC is known, enabling extremely accurate analysis.

The fact that neither acetate (24) nor linoleate appear to be implicated in F-acid biosynthesis is surprising. However, an additional possibility is that the F-acids are not produced in animals, but instead originate in plants and are taken nutritionally into animal systems, whre they accumulate in various organs. However, earlier studies on fish food (37) and cattle food (36) have shown an absence of F-acids in these commodities. Methodology for F-acid detection has improved since these studies were made, and it could be that very small quantities of these metabolites were not detected. In the study of fish meal, detection is only claimed to be 0.2%. Recent work in this laboratory has confirmed the presence of F-acid transformation products in, e.g., soya bean oil ("unpublished results"), and they have been detected previously in seed oil (38). To clarify if previously undetectable amounts of F-acids may be introduced into the rats with their food, the rat food deficient in linoleic acid used in the above study was reexamined using the improved method for the detection of F-acids by hydrogenation to tetrahydrofuran acids. The results are presented in Table 3.

As can be seen, all three F-acids isolated from the rat are present in rat food in significant quantities. The amount of F_3 cannot be determined due to overlap of interfering peaks, but appears to be at least equal to the amount of F_4. It would seem possible, therefore, that the F-acids detected in the rat are not only produced in vivo, but also accumulate in the body via nutritional intake. It would explain the higher amounts of F-acids found in fatty tissue, where obviously no mechanism exists for their immediate removal from the body. In order to remove these F-acids [1], they are metabolized to dicarboxylic acids [4], which are then excreted in the urine.

TABLE 2

F-Acids Present in Rats Fed Food Supplemented with [1h] for 33 Days

F-acids	Amount (μg per rat)[a]				
	Liver	Kidney	Muscle	Fat	Blood
F_3	2	7	7	3	—
F_4	3	3	—	11	—
F_6	1	—	7	1	—

F-Acids Present in Rat Food

F-acids	Amount (μg/100$_g$)[a]	Daily intake per rat
F_3	*b*	*c*
F_4	15	3 μg ≙ 8.8 nmol
F_6	25	5 μg ≙ 13.6 nmol

[a]The values were determined by GC. Peak area was compared with the area of the unnatural F-acid [1j] added at a level of 20 μg to each sample. The results are estimated accurately to ±20%.

[b]Detectable, but not quantifiable because of overlapping peaks.

[c]Not determinable.

TABLE 4

Furandicarboxylic Acids in Rat Urine

Compound	Daily excretion per rat[a]
4b	1.3 μg = 5.0 nmol
4d	3.0 μg = 10.2 nmol

[a]The values determined by GC. Peak area was compared with the area of 3-carboxy-4-methyl-5-pentyl-furan-acetic acid added at a level of 10 μg to each sample. The results are estimated accurate to ±10%.

To elucidate the quantity of F-acids delivered by the food and to compare it with the quantity originating from de novo synthesis, it is necessary to quantify the urinary metabolites of the F-acids. The results are presented in Table 4. In addition, the feces were examined, but no F-acids could be detected. The amount of F-acids found in the rat food is sufficient to explain the origin of the amount of furandicarboxylic acid [**4b,4d**] in the rat urine, and the origin of the F-acids in the tissue.

Therefore, there is no need to assume a de novo synthesis of F-acids by the rat. This would account for the failure of biosynthetic experiments in both rat and fish.

Metabolism of supplementary F-acids to furandicarboxylic acids in rats has been shown to be relatively fast (35), thus explaining the low quantities of these compounds in organs such as liver and kidneys, but metabolism in fish is much slower (24), which accounts for the correspondingly larger quantities of F-acids found in this species.

F-acids present in rat tissue originate, therefore, from rat food and are metabolized to furandicarboxylic acids found in the rat urine.

Obviously, additional work, including a reexamination of different food, is necessary to further elucidate the origin of F-acids in other organisms. This is presently underway.

ACKNOWLEDGMENTS

We thank D. von Holst for assistance in the rat feeding experiments, and the Alexander von Humboldt-Stiftung for a 1987-88 research stipend to C.P.G.-A.

[Received June 7, 1988; Revision accepted July 26, 1988]

Localization of Long-Chain Fatty Acids and Unconventional Sterols in Spherulous Cells of a Marine Sponge[1]

Mishelle P. Lawson, Janice E. Thompson and **Carl Djerassi***
Department of Chemistry, Stanford University, Stanford, CA 94305

The first direct evidence is provided for the presence of unconventional lipids in a particular subcellular membrane system of a sponge. Spherulous cells were isolated from the variety of cell types present in the marine sponge *Aplysina fistularis* by density gradient centrifugation. Spherulous cell plasma membrane was subsequently isolated by cell rupture followed by differential centrifugation and sucrose, or Percoll, density gradient ultracentrifugation. Plasma membrane isolates were identified and assessed for purity using [^{3}H]concanavalin A plasma membrane marker, sodium dodecyl sulfate polyacrylamide gel electrophoresis and ratios of protein, sterol and phosphate. Plasma membrane isolates could not be assessed for purity by traditional enzymatic means. Spherulous cell plasma membrane was found to contain unusual lipids, including long-chain (C_{24}–C_{30}) fatty acids (16.8–27.2%) and unconventional 26-alkylated sterols (66.4–72.6%), in addition to more conventional fatty acids and sterols. Spherulous cell intracellular membranes were also found to contain long-chain fatty acids and unconventional sterols, although the relative importance of these unusual lipids apparently varies between intracellular membranes, with some containing approximately 50% long-chain acids.
***Lipids* 23, 1037–1048 (1988).**

Unusual lipids, including long-chain fatty acids (LCFA) (C_{24}–C_{30}) and unprecedented sterols, have been identified from mixed membrane isolates of whole marine sponges, raising intriguing questions about the structure and function of sponge membranes, as such lipid content contrasts with the shorter-chain fatty acid (C_{14}–C_{22}) and simple sterol (cholesterol) content of other animal cell membranes (1–3). Since the mixed membrane isolates examined to date have consisted of a mixture of subcellular membranes from the entire diversity of cell types present within the adult sponge, the lipid composition of any specific sponge subcellular membrane system is unknown. Moreover, it is also unknown whether LCFA co-occur with unconventional sterols in the cellular membranes of these animals. Such knowledge is critical to an understanding of sponge-membrane structure and function.

Therefore, the purpose of the present study was to isolate and chemically characterize the lipid composition of a specific subcellular membrane (plasma membrane) from one type of sponge cell that was known to contain both unusual fatty acids and sterols. Spherulous cells of the marine demosponge *Aplysina fistularis* were chosen for this study for the following reasons: (A) In our preliminary studies, spherulous cells were found to contain large quantities of LCFA extending to at least C_{30}-chain lengths (unidentified fatty acids with equivalent chain lengths [ECL] corresponding to C_{31}–C_{33} also were detected) and 26-alkylated sterols (Fig. 1) as previously reported for the whole sponge (4–6). (B) Spherulous cells in this sponge are present in large numbers and can be

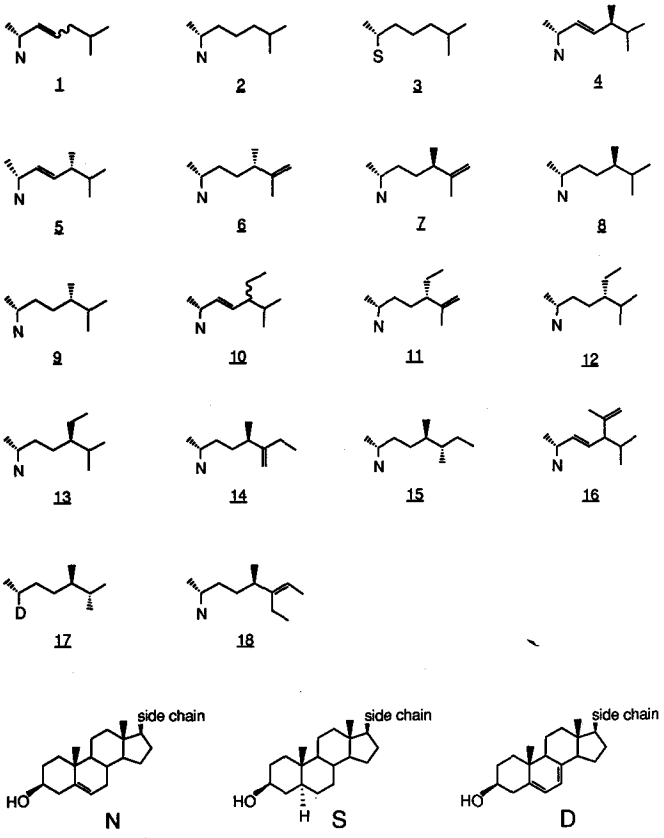

FIG. 1. Major sterols (≥0.5%) present in *Aplysina fistularis*: E/Z-cholesta-5,22-dien-3β-ol (1); cholest-5-en-3β-ol (cholesterol) (2); 5α-cholestan-3β-ol (3); E-(24S)-methylcholesta-5,22-dien-3β-ol (crinosterol) (4); E-(24R)-methylcholesta-,22-dien-3β-ol (brassicasterol) (5); (24S)-methylcholesta-5,25-dien-3β-ol (codisterol) (6); (24R)-methylcholesta-5,25-dien-3β-ol (epicodisterol) (7); (24R)-methylcholest-5-en-3β-ol (8); (24S)-methylcholest-5-en-3β-ol (9); (24E)-ethylcholesta-5,22-dien-3β-ol (10); (24S)-ethylcholesta-5,25-dien-3β-ol (clerosterol) (11); (24S)-ethylcholest-5-en-3β-ol (12); (24R)-ethylcholest-5-en-3β-ol (13); (24R)-24,27-dimethylcholesta-5,25-dien-3β-ol (25-dehydroaplysterol) (14); (24R,25S)-24,26-dimethylcholest-5-en-3β-ol (aplysterol) (15); (24S[or R])-isopropenylcholesta-5,22-dien-3β-ol (16); (24R,25S)-24,26-dimethylcholesta-5,7-dien-3β-ol (7-dehydroaplysterol) (17); E-(24R)-24,26,27-trimethylcholesta-5,25-dien-3β-ol (verongulasterol) (18).

readily and efficiently isolated from other sponge cells and abundant matrix microorganism symbionts (7). (C) Spherulous cells are comparatively large (ca. 10 μm dia.), highly refractile cells that can be readily differentiated from other sponge or symbiont cells due to the presence of large organelles termed spherules (1-3 μm dia.) that contain distinctive, yellow-colored, globular inclusions (8); thus, spherulous cells can be easily observed unaided by light microscopy for rapid verification of spherulous cell isolate purity and cell rupture. (D) Apart from spherules, spherulous cells contain few other intracellular organelles with membranes that could contaminate plasma membrane isolates from these cells (7,9). Finally, the basic histology and behavior of these cells is well known (8,9), including the fact that spherules contain brominated secondary metabolites (7), possibly for use in chemical defense or offense (10). Also abundant in the whole sponge are bacterial symbionts and archaeocyte, pinacocyte and choanocyte sponge cells. Research is currently underway in our laboratory to isolate these cell types.

This study is the first to apply traditional methods of density gradient ultracentrifugation for the purification of plasma membrane from sponge cells. The traditional enzyme assay method for characterization of subcellular fractions, however, could not be considered conclusive for this poorly understood animal system (as discussed further in Results). Therefore, additional methods for the detection of spherulous cell plasma membrane and assessment of its purity were also employed, including radioactive labeling ([^{3}H]concanavalin A) of spherulous cell plasma membrane prior to cell rupture, sodium dodecyl sulfate (SDS)-polyacrylamide gel electrophoresis (PAGE), and ratios of protein, phosphate and sterol.

EXPERIMENTAL

Collection. Aplysina fistularis (Pallas, 1776) *(Verongia thiona, Verongia aurea, Spongia fulva)* (O. Verongida) was collected in March (Experiment 1) and June 1986 (Experiment 2), from the low intertidal (1-3 m below mean lower, low water) at Casa Cove, La Jolla, CA. Sponges were maintained in aerated seawater (6°C) for no longer than 3 days prior to use.

Chemicals and materials. Density gradient chemicals included Ficoll (Type 400 DL) and grade 1 sucrose (Sigma; St. Louis, MO), and Percoll (Pharmacia Inc.; Uppsala, Sweden). Other supplies were: concanavalin A (N-[acetyl-^{3}H] acetylated; 30-90 Ci/mmol; Pharmacia Inc.); methyl α-D-mannopyranoside (Sigma); AcrylAide and GelBond (FMC Corporation, Princeton, NJ); Aquasol (NEN Research Products universal cocktail); and Fiske-Subbarrow reducing agent (Sigma). Bovine serum albumin (BSA) and cholesterol (Sigma) were standards for protein and sterol quantification, respectively. SDS gel electrophoresis standards (Sigma) consisted of 3 kit samples with molecular weight ranges of: 14-70K (product no. MW-SDS-70L), 30-200K (MW-SDS-200) and a prestained selection of 27-180K (MW-SDS-BLUE) proteins. Electron microscopy reagents, reference lipids and other chemicals and materials used in lipid analysis were those listed in Lawson et al. (2).

Tissue samples were held on ice throughout all procedures, unless otherwise stated.

Isolation of spherulous cells. Spherulous cells were isolated from whole sponge tissue according to methods modified after Thompson et al. (7). To dissociate cells, sponges (1 kg, wet wt) were cleaned of macroscopic debris and epibionts, cut into pieces (1 cm^3), washed in calcium-magnesium-free artificial seawater (CMF-ASW) (6 l, 10°C), left in CMF-ASW (25°C) for 1-2 hr and finally forced through cheesecloth. Residual tissue (300 g, wet wt) was retained for lipid analysis. To isolate spherulous cells, the dissociated cells (2 g, wet wt) were concentrated by centrifugation (650 × *g*/5 min/10°C; Sorvall RC-5 centrifuge, GSA rotor), resuspended in CMF-ASW/10°C to a total volume of 20 ml and placed on top of several discontinuous Ficoll gradients (10°C). The gradients were produced by layering from bottom to top the following concentrations of Ficoll in CMF-ASW in 40 ml transparent centrifuge tubes: 23.1% (10 ml), 20% (10 ml), 16.7% (5 ml) and 9.1% (5 ml). The gradients were centrifuged (2,000 rpm/5 min/25°C; International clinical benchtop centrifuge Model CL, rotor #211) and spherulous cells were recovered from the 23.1-20% Ficoll interface by aspiration with a truncated Pasteur pipette. Spherulous cells were washed free of Ficoll in CMF-ASW (250 ml; 600 × *g*/15 min/10°C), resuspended in CMF-ASW (1 ml) and applied to a second Ficoll gradient that consisted from bottom to top of 20% (10 ml), 16.7% (10 ml) and 9.1% (10 ml) Ficoll in CMF-ASW/10°C for further purification. Centrifugation was repeated as for the first gradient, and spherulous cells were collected from the 20-16.7% Ficoll interface and washed as before. Homogeneity of cell fractions was assessed by light and electron microscopy.

[^{3}H]Concanavalin A ([^{3}H]con A) labeling of plasma membrane. Spherulous cells (0.5 g, wet wt) isolated in June were: A) washed free of Ficoll in CMF-ASW/10°C, B) stabilized in 3.5% formaldehyde/CMF-ASW/10°C (20 min) to prevent reaggregation of dissociated cells (9,11), C) washed free of formaldehyde in CMF-ASW/10°C (3×) and finally incubated with [^{3}H]con A (200 nCi/ml) in labeling buffer (LB) (800 mM sorbitol/50 mM Tris-HCl/0.2 mM ethylene glycol bis[β-aminoethyl ether] N,N'-tetraacetic acid [EGTA]/1mM $MgCl_2$/1 mM $CaCl_2$/1 mM $MnCl_2$/BSA [3 g/ml]/CMF-ASW/10°C; pH 7.4; 5-10 ml) for 40 min on ice with gentle shaking every 10 min (12). Cells were centrifuged (2,000 rpm/25°C/5 min) and the supernatant was discarded. Pelleted cells were washed (3×) in LB lacking EGTA (150 ml) (12) and used for Experiment 2, as described below.

The saturation point of [^{3}H]con A labeling to spherulous cell plasma membrane was determined by a standard kinetic study involving subsampling at 0, 10, 30 and 60 min (13). The effects of Ficoll on labeling with [^{3}H]con A were examined by comparing the labeling efficiency in the absence and presence of Ficoll (30%). Possible internalization of the [^{3}H]con A label was investigated by incubating spherulous cells in 200 nCi/ml [^{3}H]con A in LB 10°C/40 min/pH 7.4 according to Sorimachi (13) and was determined to be the proportion of cell-associated radioactivity (lectin binding) remaining after removal of the externally-bound ligand by methyl α-D-mannopyranoside (13). Enrichment of [^{3}H]con A radioactivity was calculated as a ratio of the [^{3}H]-radioactive count per mg protein in subcellular isolates from Percoll gradients compared with that of parent [^{3}H]-labeled cells used in the

experiment (12). Data were corrected for nonspecific binding of [^{3}H]con A, which was assessed by conducting parallel assays with the haptan monosaccharide, methyl α-D-mannopyranoside (100 mM) being present either from t = 0 or t = 60 min, during the course of [^{3}H]con A labeling according to the methods of Cuatrecasas (14), Juliano and Li (15), Emerson and Juliano (16) and Chicken and Sharom (17).

Isolation of spherulous cell plasma membrane. Experiment 1. Subcellular fractionation of spherulous cells was modified after Lawson et al. (2). Spherulous cells were resuspended and homogenized in homogenizing medium (HM) (HM1 = 250 mM sucrose/50 mM Tris-HCl/5 mM EDTA/0.1 mM phenylmethylsulfonylfluoride/CMF-ASW/10°C, pH 7.4) with a Brinkman Polytron homogenizer (setting 1, 30 sec). The homogenate was filtered (0.5 × 0.1 mm mesh nylon) and subjected to successive centrifugation at 1075 and 15,000 × *g* (10 min/10°C; Sorvall RC-5 centrifuge, SS-34 rotor), and 100,000 × *g* (1 hr/4°C; Beckman L2-65B centrifuge, SW-28 rotor) to produce P1, P2 and P3 pellets (see Abbreviations) and a final supernatant, respectively. P1 and P2 pellets were each washed once in HM1 and lyophilized for lipid analysis. The P3 pellet was resuspended in buffer (8.5%, w/w = 250 mM sucrose/50 mM Tris-HCl/CMF-ASW/4°C; pH 7.4; 5 ml) and placed on top of a sucrose density gradient, which consisted of (from bottom to top): 45% (1.32 M, 5 ml), 42.8% (1.25 M, 7 ml), 37.7% (1.1 M, 7 ml), 34.1% (1.0 M, 7 ml), 30% (0.88 M, 7 ml) sucrose/50 mM Tris-HCl/CMF-ASW/4°C with respective densities of 1.21, 1.19, 1.17, 1.16, 1.13 and 1.03 g/ml at 0°C (18). The sucrose gradient was centrifuged (131,000 × *g*/2 hr/4°C; Beckman L2-65B ultracentrifuge, SW-28 rotor) and visually-distinct fractions were collected by aspiration with a Pasteur pipette.

Experiment 1. [^{3}H]Con A-labeled spherulous cells (described above) were resuspended and homogenized (HM2 = 800 mM sorbitol/50 mM Tris-HCl/1 mM $MgCl_2$/1 mM $MnCl_2$/1 mM $MnCl_2$/5 mM β-mercaptoethanol/CMF-ASW/10°C; pH 7.4; 5 ml; hand-held Biospec Biohomogenizer; low speed—10,000 rpm/2 min; on ice) (12,13,19) and fractionated according to methods modified after Fauvel et al. (12). The homogenate was centrifuged (1,000 × *g*/15 min/4°C; Sorvall RC-5 centrifuge, SS-34 rotor), and the supernatant (containing subcellular organelles and microsomal membranes) was mixed with twice-concentrated HM2 in Percoll/CMF-ASW (6:12:10.32:1.68, v/v/v/v) at pH 7.4 and centrifuged (79,000 × *g*/15 min/4°C; Beckman L2-65B ultracentrifuge, SW-28 rotor) to produce a continuous Percoll gradient according to modified methods of Fauvel et al. (12). Fractions of 2 ml were successively collected from the top of the gradient with Pasteur pipettes. Fractions 2–4, which characteristically contain subcellular membranes (12), were combined and mixed with twice-concentrated HM2/Percoll (6:12:10.32, v/v/v) (pH 9.6, adjusted with 1 M NaOH), with a final pH adjustment to 9.6. This mixture was centrifuged (79,000 × *g*/15 min/4°C) and fractions were collected for analysis from the top of the gradient with Pasteur pipettes.

Microscopy. Foramalin-fixed, spherulous cell isolates were examined by light microscopy, utilizing toluidine blue as a staining reagent. Samples of whole sponge, spherulous cells and subcellular isolates were examined by electron microscopy as in Lawson et al. (2). The purity of the mixed membrane isolate, in terms of it being free from subcellular lipidic contaminants such as small vacuoles, lipid droplets and osmiophilic granules (that are characteristically found in spherules), was determined by electron microscopy (2).

Enzyme assays. A coupled enzyme assay, in which formation of ADP by ATPase is coupled to NADH oxidation with the intermediate enzymes pyruvate kinase and lactic dehydrogenase and with the intermediate substrate phosphoenolpyruvate present in excess, was employed to determine membrane-associated Na^+K^+-ATPase activity in aliquots of subcellular isolates according to the methods of Scharschmidt et al. (20).

Determination of radioactivity. Samples of [^{3}H]con A-labeled spherulous cells and subcellular fractions from Experiment 2 were digested in 1 ml household bleach to reduce quenching and the mixture was sonicated (1 min) before the addition of scintillation fluid (Aquasol) to aid in suspension of subcellular tissue. Suspensions were shaken immediately prior to counting radioactivity (Beckman LS 7500 microprocessor controlled liquid scintillation system with external standardization and quench correction).

SDS-Polyacrylamide gel electrophoresis. Samples of whole spherulous cells, homogenates, P1 and P2 pellets, membrane bands and intermediate fractions from Experiment 1, and membrane bands and intermediate fractions from Experiment 2, were analyzed for protein content by SDS-polyacrylamide gel electrophoresis (PAGE) (21). Samples containing 10–20 μg protein were solubilized in buffer (55 mM Tris-HCl/1.8% SDS/8.8% glycerol) (1 part protein:1 part buffer), to which 0.002% bromophenol blue tracking dye was added, at 100°C/2 min. Samples (50 μl) were applied to SDS-polyacrylamide-discontinuous-slab gels containing 10% AcrylAide (4.5% stacking gel, 7% running gel/backed with GelBond) (22,23) and run at 27 mA. Gels were stained with Coomassie Brilliant Blue R and/or silver stained. To detect nonspecific staining, controls of buffers and suspension media were simultaneously run.

Chemical analyses. Lipids were extracted from lyophilized (Experiment 1) or wet/frozen (Experiment 2) tissue, cells and subcellular fractions and were examined by thin layer chromatography (TLC) for lipid class content according to Lawson et al. (2).

The majority of the total lipid extract from the Experiment 1 whole sponge sample and the Experiment 2 whole spherulous cell isolate (60 mg) was separated by column chromatography (7 × 0.7 cm dia. column; SIL-R 100–300 mesh silicic acid, Sigma Co.) into fractions that usually contain triacylglycerols and sterol esters (Fraction 1), free sterols and diacylglycerols (Fraction 2), glycolipids (Fraction 3) and phospholipids (Fraction 4). Fraction 1 was eluted with hexane/ether (2:1, v/v, 20 ml), Fraction 2 with acetone (40 ml), Fraction 3 with methanol (50 ml) and Fraction 4 with chloroform/methanol (2:1, v/v, 20 ml). The composition of eluates was monitored by TLC that utilized codeveloped reference compounds and spray reagents according to Lawson et al. (2). The remainder of the total lipid extracts were used for total lipid fatty acid and total sterol analysis.

Fatty acid composition of all samples, including Experiment 1 whole sponge sample total lipid and lipid

Fractions 1-4, Experiment 1 spherulous cell subcellular fractions and Experiment 2 whole sponge tissue, spherulous cells and spherulous cell subcellular fractions, was determined by temperature-programmed gas chromatography (GC) as described in Lawson et al. (2). Major (≥0.5%) individual fatty acid methyl esters were identified by GC-mass spectrometry (MS) of N-acylpyrrolidide derivatives of the acids (24) according to Lawson et al. (2).

Sterols from Experiment 1 whole sponge tissue Fraction 1 sterol esters were obtained by: A) dissolution in methanol/water (99.5:0.5, v/v), B) addition of KOH (15 mg), C) heating (95°C/5 min) with stirring, D) concentration in vacuo, E) extraction in hexane and F) purification through a Pasteur pipette column of silica gel with hexane/ether (2:1, v/v). Total sterols were obtained from the Experiment 1 whole sponge tissue and subcellular fractions, and the Experiment 2 whole sponge tissue, spherulous cells and spherulous cell subcellular fractions total lipid extracts, according to the same methods. Free sterols were isolated from Experiment 1 whole sponge tissue Fraction 2 by column chromatography in hexane/ether (2:1, v/v). Sterol composition of these samples, for sterols present in amounts of >0.5% of the total, was determined by high performance liquid chromatography (HPLC), GC and GC-MS, as in Lawson et al. (3).

Phospholipid composition was determined by two-dimensional TLC of Experiment 2 whole spherulous cells and P1 pellet, and Experiment 1 whole sponge tissue, P1 and P2 pellets, as described in Lawson et al. (2). Insufficient sample was available for phospholipid analysis of membrane isolates.

Total sterol, protein and phosphorus was quantified in subsamples of A) Experiment 2 spherulous cells, B) Experiment 2 Mixed Membrane Isolate, C) Experiment 1 spherulous cell P1 fraction, D) Experiment 1 intracellular membrane bands 2 and 3 and E) plasma membrane isolates from both experiments. Free sterol content was quantified using the fluorometric procedure of Heider and Boyett (25), with cholesterol as standard. Total protein was determined using a modified Lowry procedure (26), with BSA as standard. Total phosphorus was determined according to Johnson (27), using monobasic potassium phosphate as standard. Inorganic phosphate obtained after digestion was estimated by the high temperature Fiske-Subbarow method as in Bartlett (28). Phospholipid content was estimated assuming 770 g/mol as the average molecular weight of the phospholipids (29).

RESULTS

Isolation of spherulous cells. Intact *A. fistularis* spherulous cells were isolated at greater than 98% purity by volume, as determined by electron microscopy. The isolated spherulous cells were observed to contain multiple lipophilic spherules (2-7 μm), few mitochondria and small amounts of endoplasmic reticulum, in accordance with previous results (7,9). It was necessary to repeat the cell fractionation procedure (with a reduced number of density layers) on the primary spherulous cell isolate to achieve such purity, however, as the primary spherulous cell isolate was contaminated by noticeable aggregations of smaller, weakly refringent cells and organic debris.

[3H]Con A-labeling of plasma membrane. Maximum radioactive labeling of the spherulous cell plasma membrane with the plant lectin [3H]con A was achieved after 30-40 min, with 20% labeling efficiency; 88% of the [3H]con A-labeling at 0-40°C was found to be due to specific membrane binding. High concentrations of Ficoll (30%) diminished labeling efficiency by ca. 10%, but residual Ficoll that remained after washing spherulous cells did not have a significant effect on labeling. Less than 6% of the [3H]con A-radioactive label was internalized under the conditions used; this small amount of internalization of the label, although demanding consideration, did not significantly influence the experiment.

Isolation of spherulous cell plasma membrane. Experiment 1. Homogenization and differential centrifugation of unlabeled spherulous cells produced a relatively pure P3 mixed-membrane isolate, as evidenced by the almost exclusive presence of membrane vesicles in electron micrographs. Substantial P1 and P2 isolates were also produced that included many intact, membrane-bounded spherules, suggesting that these intracellular organelles largely were not disrupted during homogenization.

Subsequent centrifugation of the P3 mixed membrane pellet on a sucrose density gradient resulted in three discrete cloudy-white bands and a very small brown-colored pellet. The uppermost band, Band 1, contained most visible material and banded isopycnically at a sucrose density of 1.03-1.13 g/ml. The sedimentation density of this band corresponds to that reported for plasma membranes (18) in accordance with the proportionately larger size of this band; hereafter, this band will be referred to as the Plasma Membrane Band 1. Band 2 was faint and occurred at a density of 1.16-1.17 g/ml, and Band 3 was less faint and occurred at 1.17-1.19 g/ml. The sedimentation densities of Bands 2 and 3 correspond to those reported for endoplasmic reticulum and mitochondria, respectively (18), although spherule membranes were likely also included in Band 2 and/or 3; hereafter these bands will be referred to as Intracellular Membrane Bands 2 and 3. The pellet mainly consisted of membrane-bound debris.

Because we could not isolate [3H]con A-labeled plasma membrane on a sucrose density gradient because of competition for the radioactive label between sucrose and the carbohydrate residues in the plasma membrane, the following method was used for this purpose.

Experiment 2. Homogenization and differential centrifugation of [3H]con A-labeled spherulous cells produced a supernatant fraction that contained microsomal membranes. Density gradient ultracentrifugation of this supernatant on Percoll at pH 7.4 resulted in a low-density, cloudy-white band at 4-10 ml (as measured from the top), a region expected to accumulate a mixture of subcellular membranes (12); the tritiated radioactivity of this band, hereafter referred to as the Mixed Membrane Isolate, was enriched 2.8 times. A second discreet band, which banded at a higher density (14-16 ml) and was light brown in color, consisted of unidentified cellular material with a 1.2 times enrichment in radioactivity; hereafter this band will be referred to as the Unidentified Cellular Material Isolate. A pellet consisting of spherules and unidentifiable cellular debris also possessed a relatively high radioactivity level.

Upon recentrifugation of the Mixed Membrane Isolate on Percoll at pH 9.6, a single band was observed at 4-10 ml, the same position as the Mixed Membrane

Isolate on the first Percoll gradient. This suggests that the Mixed Membrane Isolate of the previous centrifugation (pH 7.4) was largely plasma membrane, in accordance with the observation of only a slight enrichment in radioactivity of this band after recentrifugation at pH 9.6. Because some purification of the plasma membrane isolate was achieved, nonlabeled intracellular membranes must have been present on the gradient; however, they were not visually apparent, which is probably due to the small amount present. This band, hereafter referred to as the Plasma Membrane Isolate, was enriched 3.1 times in radioactivity, indicating slightly greater purity.

Enzyme assays. Attempts to measure levels of membrane-associated Na^+ K^+-ATPase activity in the above membrane isolates, spherulous cells and related whole sponge tissues were unsuccessful, eliminating the most widely used method for characterization of subcellular isolates and determination of membrane purity. The presence of cytotoxic, brominated natural products in the spherulous cells of *A. fistularis* (7) may act to inhibit this enzyme in vitro as such compounds are powerful inhibitors of Na^+ K^+-ATPase (30,31). An alternative enzyme system, 5′-nucleotidase, which is also frequently used to characterize plasma membranes (32), similarly yielded poor levels of activity; hence, further investigation of enzyme activities was discontinued. Although disappointing, these results were not surprising, as the enzyme composition of sponge cell membranes has not been characterized and there are few studies that report on sponge enzymatic activity. Subsequent unpublished experiments by Lucinda Cordeiro in our laboratory have also failed to utilize the following enzymes as potential sponge membrane markers: K^+-stimulated ATPase, acid phosphatase, NADPH cytochrome c reductase, NADH cytochrome c reductase, which were assayed in the sponge *Microciona prolifera*.

SDS-PAGE. SDS-PAGE of spherulous cell homogenates and membrane fractions obtained from Experiments 1 and 2 produced protein profiles containing 10–14 different bands. The principal bands occurred at 225 K, 175 K, 109 K, 101 K, 93 K, 66.2 K, 64.9 K, 48 K and 46.5 K, with a broad unresolved cluster of bands consisting of several proteins between 33.4–37 K, 24 K, 15 K and 10 K.

Three proteins appeared characteristic of particular subcellular isolates. A high molecular weight protein (225 K) was exclusively present in those isolates that were enriched in plasma membrane (Plasma Membrane Band 1 of Experiment 1 and both the Mixed Membrane Isolate and the Plasma Membrane Isolate of Experiment 2). In contrast, proteins of 175 K and 93 K only were exclusively present in the Intracellular Membrane Bands 2 and 3 of Experiment 1 and the Unidentified Cellular Material Isolate of Experiment 2.

Chemical analyses—whole sponge lipid content. Total lipid extracts of whole sponges collected in March (Experiment 1) and June (Experiment 2) were yellow/brown and yielded identified fatty acids to 30 carbons and unconfirmed fatty acids to C_{31}–C_{33} carbons (Table 1), with two main groupings of fatty acids constituting greater

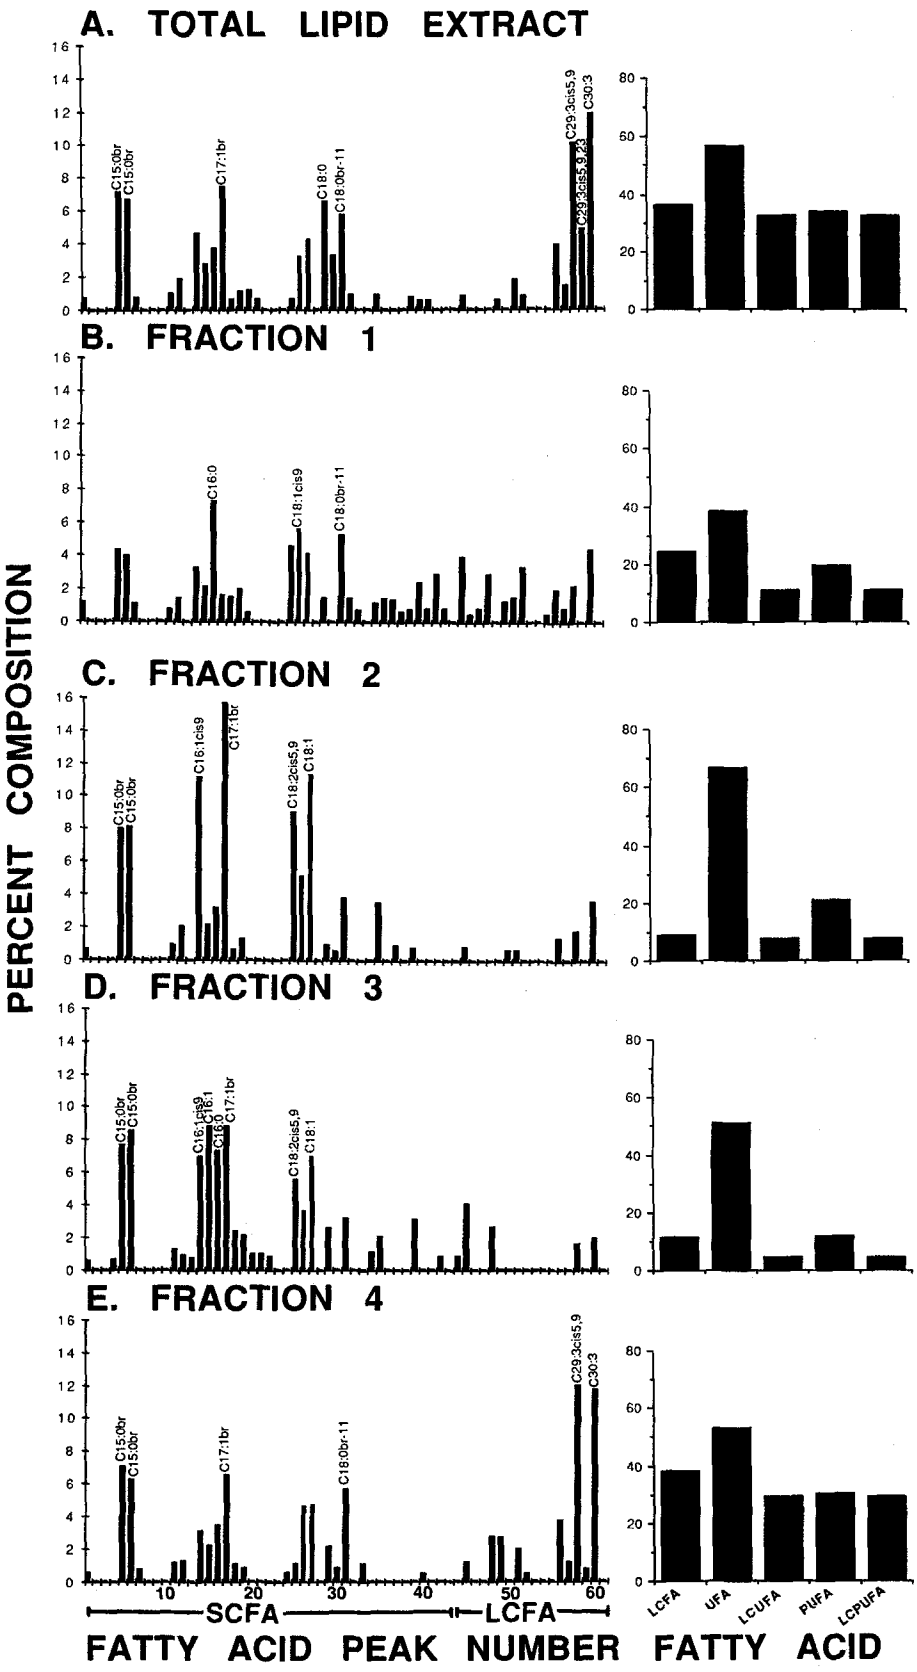

FIG. 2. The distributions of fatty acids as total lipids (A) and in various lipid fractions (B–E) according to fatty acid chain length and saturation for a total lipid extract of *A. fistularis* whole sponge tissue (June collection, Experiment 2). Lipid fractions were expected by convention to contain the following: (B) Fraction 1, triacylglycerols and sterol esters; (C) Fraction 2, free sterols and diacylglycerols; (D) Fraction 3, glycolipids; and (E) Fraction 4, phospholipids. Fatty acids that were ≥5% of the total are labeled; all acids are described in Table 1. SCFA, short chain fatty acids; LCFA, long chain fatty acids (ECL ≥ 23.0); UFA, unsaturated fatty acids; LCUFA, long chain unsaturated fatty acids; PUFA, polyunsaturated fatty acids; LCPUFA, long chain polyunsaturated fatty acids.

than 95% of the acids: C_{15}-C_{18} acids accounted for 63% of the total and C_{28}-C_{30} acids accounted for 32% of the total (Fig. 2). Fatty acids with chain lengths between C_{18} and C_{28} were present in minor amounts (<2% total), suggesting that these acids are either biosynthetic intermediates or dietary acids yet to be processed by the sponge. Most shorter-chain fatty acids in the C_{15}-C_{18} range were found to be branched C_{15}, C_{16} and C_{17} acids, in accordance with previous results for this sponge (5) and for other demosponges (33-37). Fatty acid distribution patterns within each of the two *A. fistularis* collections (March and June) differed (Figs. 2A, 4A) and this is possibly due to seasonal factors, as has been suggested for other sponges (38-40).

Column chromatography of Experiment 1 whole sponge total lipid extract yielded fractions which, according to TLC R_f values, spot characteristics on TLC plates, reference lipids and specific spray reagents, and in accordance with data for other sponges (2,5), were expected to contain the following: Fraction 1—sterol esters (TLC R_f = 0.79 in hexane/ether, 1:1, v/v) and triacylglycerols (0.74); Fraction 2—free sterols and diacylglycerols (0.23); Fraction 3-glycolipids (0.14); and Fraction 4—phospholipids (0). Unidentified lipids were also present at R_f = 0.48.

Of these four lipid fractions, only the phospholipid Fraction 4 contained appreciable levels of long-chain fatty acid (LCFA) (38.4%) (Fig. 2E) and paralleled the levels of LCFA in the total lipid extract (36.3%) (Fig. 2A), although all fractions contained some LCFA (Fig. 2). The major long-chain acids, $C_{28:2cis5,9}$ and $C_{30:3}$, were present at a ratio of 1:1 in the phospholipid fraction, suggesting they co-occur in certain phospholipids or occur singly in phospholipids that complement each other in cell membranes (Fig. 2E). The phospholipid, Fraction 4, was also characterized by high levels of unsaturation (53.3%), especially polyunsaturation in LCFA (Fig. 2E). The similarity of proportions in both LCFA and unsaturated fatty acids between the total lipid extract and the phospholipid, Fraction 4, is common for this (5) and other sponges (1,2), and can be accounted for by the high proportions of phospholipids in sponge tissue (2,5).

Eighteen sterols were detected in the whole sponge total lipid extract described above (Fig. 1). The unconventional sterols 25-dehydroaplysterol (14) and aplysterol (15) accounted for 67.1% of the total sterols, in agreement with the results of Walkup et al. (5), and similar amounts within the sterol esters (64%) and free sterols (65.3%) (Fig. 3). Cholesterol (2) and 5α-cholestan-3β-ol (3) at 13.5-15.3% of the total were the only other sterols present in significant proportions. The sterol composition of free sterols, sterol esters and total sterols was similar (Fig. 3).

Spherulous cell lipid content. The total lipid extract of a subsample of the spherulous cells isolated for Experiment 2 was similar in color to that of the related whole sponge tissue, but differed substantially in lipid composition (Fig. 4A,4B). The spherulous cells lacked several fatty acids that were present in the whole sponge, noteably the $C_{18:0\ br\text{-}11}$ and $C_{18:1}$ (peak no. 28) acids. Moreover, the spherulous cells contained greatly elevated levels of the $C_{16:0}$ acid. It was significant that branched-chain fatty acids were still present in relatively high amounts (12.2%) in spherulous cells, as these acids have been proposed to be bacterial in origin (5).

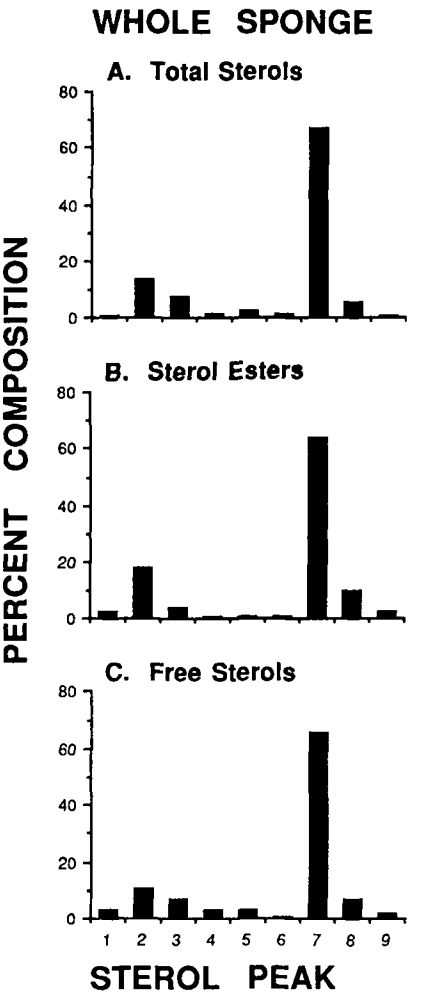

FIG. 3. Relative percent composition of sterols as total sterols (A), sterol esters, (B) and free sterols (C) in *A. fistularis* whole sponge tissue from Experiment 1 (March sample). Sterol peaks: peak 1 = sterol 1; peak 2 = sterols 2 and 3; peak 3 = sterols 4 and 5; peak 4 = sterols 6 and 7; peak 5 = sterols 8-10; peak 6 = sterols 11-13; peak 7 = sterols 14 and 15; peak 8 = sterols 16 and 17; peak 9 = sterol 19. Sterols are identified by number in Figure 1.

Although whole spherulous cell tissue was not analyzed for lipid content for both collections, the P1 pellets, which contained predominantly undisrupted and partially disrupted spherulous cells and organelles, obtained from both subcellular fractionation procedures were analyzed and were found to differ dramatically. The P1 pellet from Experiment 2 contained more than twice as many (ca. 15% more) LCFA, ca. 17% more polyunsaturated fatty acids (PUFA), of which most (~15%) were among LCFA, but lower levels of total unsaturation (~10% less) than the P1 pellet obtained from Experiment 1 (Figs. 4, 5). Also, without exception, the fatty acids that dominated (>5% total) each experimental group were different (Figs. 4C, 5A). Noteably, $C_{22:0}$ occurred at 20.1% in the P1 sample of Experiment 2 spherulous cells, but it was not detected in that of Experiment 1. In contrast, $C_{20:0}$ was present at 8.4% in Experiment 1 P1, but it was not detected in Experiment 2 P1. Long-chain C_{28} to C_{30} acids of Experiment 2 P1 were present in higher proportions (25%) than those of Experiment 1 P1 (10.9%). It was

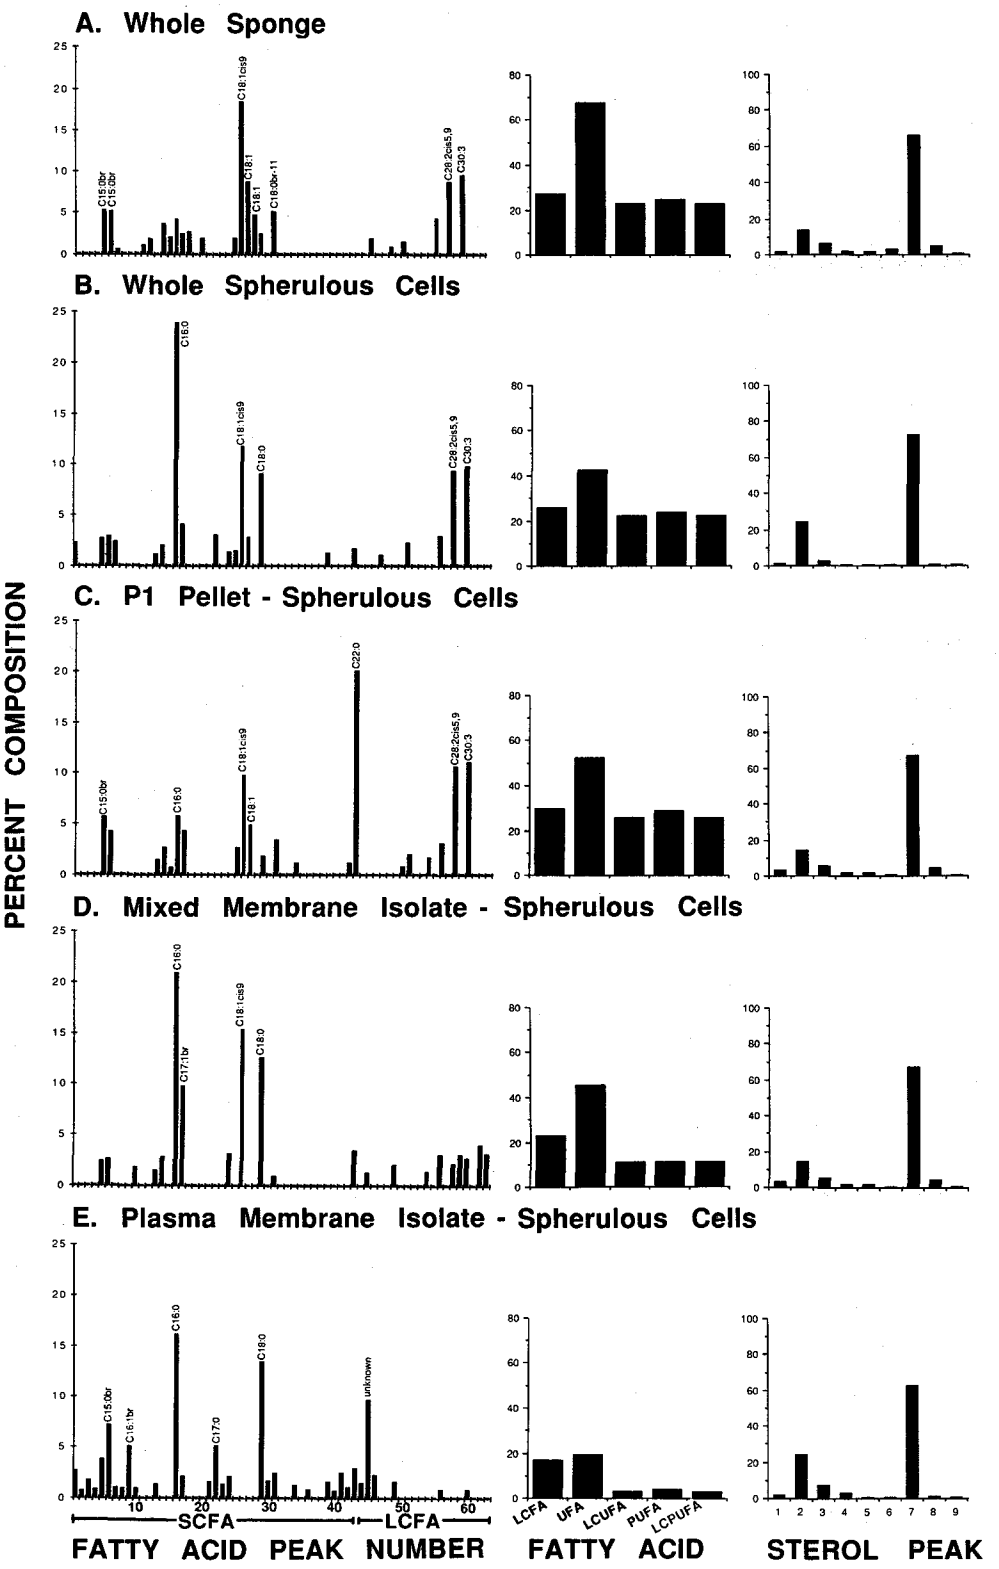

FIG. 4. The distribution of fatty acids, according to fatty acid chain length and saturation, and free sterols in total lipid extracts of whole sponge tissue (A), whole spherulous cells (B), the P1 pellet (C) produced in the course of subcellular fractionation of the spherulous cells, and the two resulting spherulous cell subcellular fractions—i.e., the spherulous cell Mixed Membrane Isolate (D) and the spherulous cell plasma membrane isolate (E), as determined from Experiment 2. Fatty acids that are ≥5% total are labeled; all acids are described in Table 1. Abbreviations and sterol peaks are described in Figures 2 and 3 (captions), respectively.

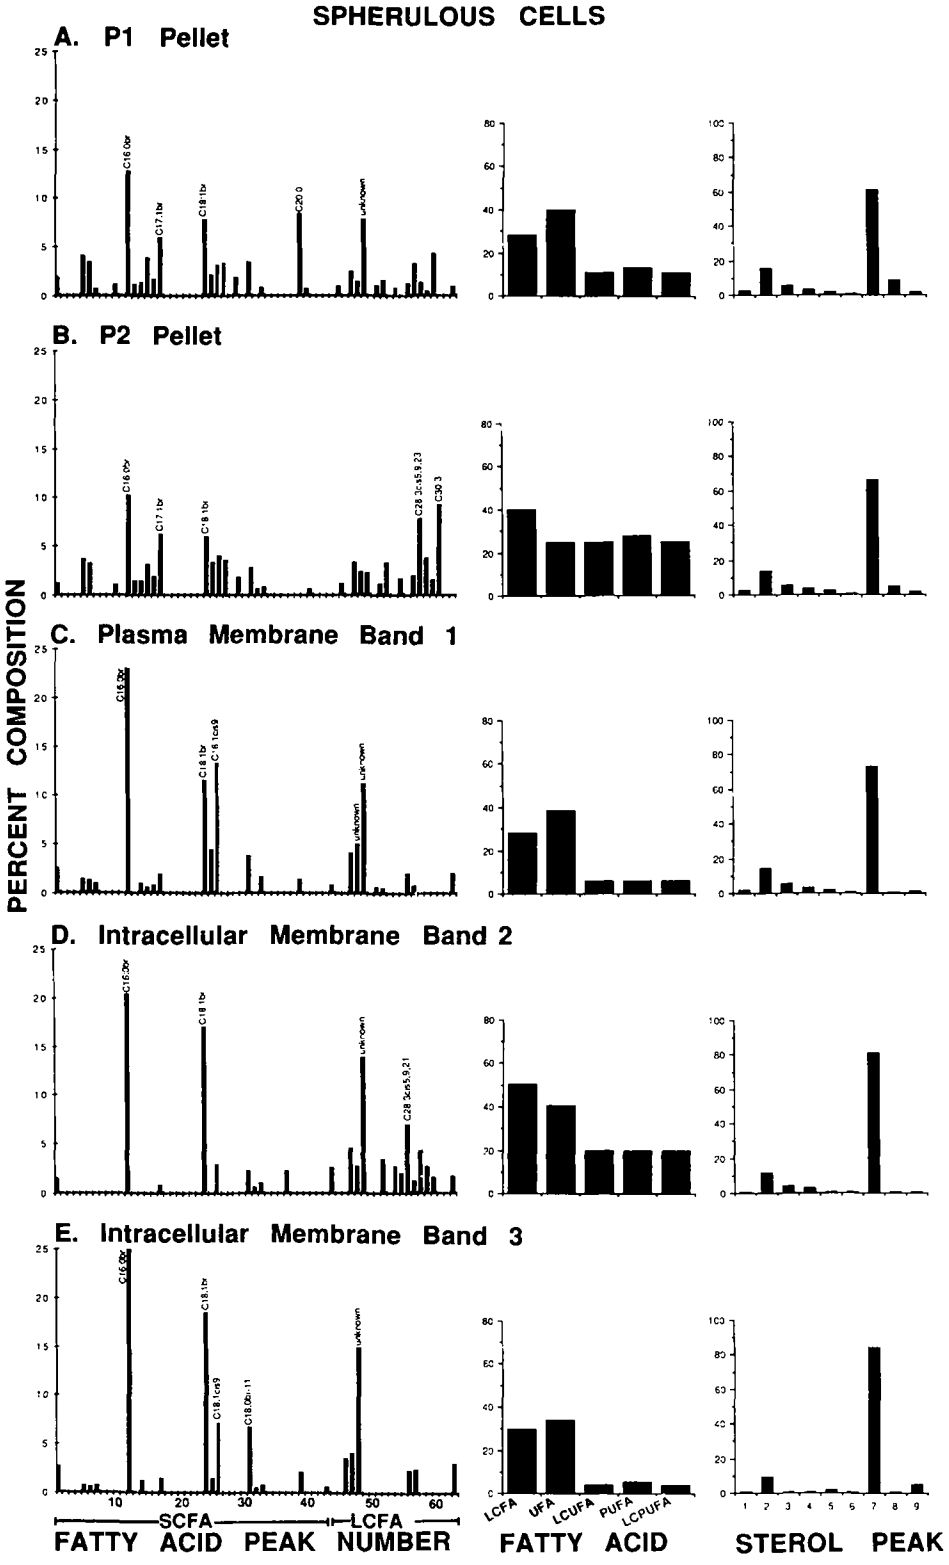

FIG. 5. The distribution of fatty acids, according to fatty acid chain length and saturation, and free sterols in total lipid extracts of spherulous cell subcellular fractions including the P1 (A) and P2 (B) isolates, plasma membrane (C) and intracellular membranes (D and E) as determined from Experiment 1. Fatty acids that are ≥5% total are labeled; all acids are described in Table 1. Abbreviations and sterol peaks are described in Figures 2 and 3 (captions), respectively.

interesting that levels of $C_{28:2cis5,9}$ in Experiment 2 P1 (10.7%) paralleled the level of $C_{30:3}$ (11.2%) in Experiment 2 P1, and $C_{28:3cis5,9,23}$ (3.4%) paralleled the level of $C_{30:3}$ (4.4%) present in Experiment 1 P1. An unknown acid (ECL = 25.479) was present in significant amounts (7.9%) in the P1 sample of Experiment 1, but was absent in that of Experiment 2. Also, the Experiment 1 spherulous cell pellet contained higher levels of branched-chain fatty acids—specifically $C_{16:0br}$, $C_{17:1br}$ and $C_{18:1br}$ acids. Such differences in lipid composition are possibly due to seasonal factors, as mentioned for whole sponge tissue.

Similarities in the fatty acid composition were observed between the P2 pellet (Fig. 5), which was found to consist largely of spherules, and that of Intracellular Membrane Band 2 in Experiment 1 (Fig. 5D) suggesting that Intracellular Membrane Band 2 represents spherule membranes. For example, Intracellular Membrane Band 2 of Experiment 1 had high LCFA (48.1%) and PUFA (19.7%) levels which were reminiscent of the P2 'spherule' pellet where LCFA and PUFA totaled 39.8% and 27.8%, respectively.

The principal phospholipids of the spherulous cells were phosphatidylethanolamine, phosphatidylcholine, phosphatidylserine and phosphatidylinositol, with a minor content of phosphatidylglycerol and diphosphatidylglycerol, in accordance with data for whole tissue (5).

All sterols detected in the whole sponge were also detected in the related spherulous cells, but the relative proportions of the sterols were different (Figs. 3, 4B). 25-Dehydroaplysterol (14) and aplysterol (15) were enriched in the spherulous cells (72.2%), as compared with whole sponge tissue (67.1%); and cholesterol (2) and 5α-cholestan-3β-ol (3) amounted to 24.2% of the total in spherulous cells and 13.8% in the whole sponge. The sterol composition of the P1 samples from both Experiments were similar except that there was slightly more (24S[or R])-isopropropenylcholesta-5,22-dien-3β-ol (16) and 7-dehydroaplysterol (17) (peak 8, Fig. 5A) in the P1 isolate of Experiment 1 than in that of Experiment 2.

Membrane isolate lipid content. Membrane lipids were transparent and mainly consisted of phospholipid and sterol, but sterol esters and an unidentified lipid (R_f = 0.48 in hexane/ether, 1:1) also were present in lesser amounts. It was not determined whether these lipids were situated totally or partially within the membrane bilayer, or whether they were peripheral molecules adherent to the exterior/interior membrane surface(s).

The spherulous cell plasma membrane isolates produced by both experimental methods contained appreciable levels of LCFA: 27.2% of the fatty acids from the Experiment 1 Plasma Membrane Band 1 and 16.8% of the fatty acids from the Experiment 2 Plasma Membrane Isolate were LCFA. For Experiment 1, this plasma membrane LCFA content (27.2%) mirrored that observed for the corresponding P1 pellet (28.2%, Fig. 5), but for Experiment 2, this LCFA content (16.8%) was significantly below that observed for the corresponding P1 pellet (29.5%) or whole tissue (27.3%) (Fig. 4). Spherulous cell plasma membrane LCFA were predominantly of shorter chain lengths (with the measured ECL equaling 24.75-25.48 [$\sim C_{25}$, peak nos. 44-49; 21.21%—Experiment 1; 15.1%—Experiment 2]) than were found in whole spherulous cells or in intracellular membranes (Figs. 4,5), and longer LCFA (peak nos. 50-63, chain lengths C_{26}-?C_{33}) occurred in comparatively low levels (6.8%—Experiment 1; 1.7%—Experiment 2).

The intracellular membrane isolates also contained appreciable levels of LCFA, but the relative fatty acid compositions differed greatly, suggesting different intracellular membranes may differ substantially in composition. One of the Experiment 1 Intracellular Membrane Isolates contained a higher level of LCFA than did the corresponding Plasma Membrane Isolate: Intracellular Membrane Band 2 contained 48.1% LCFA (Fig. 5D), and the corresponding Plasma Membrane Band 1 contained only 27.2% LCFA (Fig. 5C). The Experiment 2 Mixed Membrane Isolate of Percoll gradient 1, which contained a mixture of intracellular membranes and plasma membrane of which the proportions are unknown, contained 22.8% LCFA (Fig. 4D), as compared with 16.8% in the plasma membrane (Fig. 4E). The Experiment 1 Intracellular Membrane Band 3, however, contained 29.8% LCFA—approximately the same as the corresponding Plasma Membrane Band 1 (Fig. 5). Also, Intracellular Membrane Band 3 isolate contained principally shorter LCFA (ECL = 24.75-24.84; C_{24}-C_{25}), and the Intracellular Membrane Band 2 contained more longer acids (ECL = 24.75-28.68; C_{25}-C_{29}). The Experiment 2 Mixed Membrane Isolate likewise contained longer range acids (ECL = 27.49-32.70). The spherulous cell plasma membrane isolate of Experiment 2 had a lower LCFA (16.8%), unsaturated (19.1%) and polyunsaturated (4.1%) fatty acid content and different individual fatty acid composition to that of the parent Mixed Membrane Isolate where LCFA, unsaturated and polyunsaturated fatty acids amounted to 21.5%, 35.5% and 10.9%, respectively.

Further differences in the fatty acid composition between plasma membrane isolates and their corresponding P1 pellets were observed. For example, in Experiment 1, the $C_{18:1cis9}$ acid was greatly enriched in the Plasma Membrane Band 1 although it was barely detectable in the related spherulous cell P1 pellet. Also, P1 had a higher content of the longer LCFA (peak nos. 50-63, chain lengths C_{26}-C_{33}) at 29.5% for Experiment 2 P1 and 15.3% for Experiment 1 P1, although not necessarily of total LCFA, which amounted to 29.5% for Experiment 2 P1 and 28.2% for Experiment 1 P1, compared with a total LCFA content of 27.2% for the Experiment 1 plasma membrane isolate and only 3.4% for the Experiment 2 plasma membrane isolate.

It is not expected that spherulous cell plasma membrane reflects the fatty acid composition of parent spherulous cells (or the P1 pellet) because: 1) other subcellular membranes within spherulous cells (e.g., spherule boundary membranes with high surface areas) are expected to contribute more than plasma membrane to the total fatty acid pool and 2) fatty acids may be stored in subcellular organelles within spherulous cells.

Plasma membrane isolates from both experiments exhibited variable levels of unsaturation (38.5% in Experiment 1; 19.1% in Experiment 2) (Figs. 5C, 4E). Intracellular Membrane Bands 2 and 3 of Experiment 1 exhibited high levels of unsaturation at 40.4% and 34.1%, respectively (Fig. 5D, 5E). The Experiment 2 plasma membrane isolate also exhibited a lower level of LCFA unsaturation (16.8%), relative to the Mixed Membrane Isolate (22.8%) (Fig. 4). In all cases, virtually all polyunsaturation occurred in the LCFA (Figs. 4, 5).

Spherulous cell plasma membrane from each experiment also exhibited major differences in the composition of individual fatty acids (Figs. 4C, 4E, 5A, 5C). Again, this may be due to environmentally or seasonally induced differences in fatty acid content.

All sterols detected in whole sponge tissue were also detected in the spherulous cell plasma and intracellular membranes, and in the P1 and P2 isolates (Figs. 4, 5), although there were some differences in the relative contributions of each sterol in these samples. All samples were dominated by cholesterol (2) and 5α-cholestan-3β-ol (3) (peak no. 2) and 25-dehydroaplysterol (14) and aplysterol (15) (peak no. 7), which represented 9.4–24.2% and 60.9–80.8%, respectively. Spherulous cell plasma membrane contained 72.6% (Experiment 1) and 66.4% (Experiment 2) of the unconventional sterols 25-dehydroaplysterol (14) and aplysterol (15) (Figs 5C, 4E). For Experiment 1 spherulous cell plasma membrane, this was ca. 10% less than that found in the intracellular membranes, although no such difference could be observed between the plasma membrane and Mixed Membrane Isolate of Experiment 2 (Figs. 4, 5), supporting our earlier claim that the Mixed Membrane Isolate was largely plasma membrane. Differences in the proportions of minor sterols between subcellular fractions also were observed. (24S[or R])-Isopropropenylcholesta-5,22-dien-3β-ol (16) and 7-dehydroaplysterol (17) (peak no. 8) occurred at 8.6% in P1, but about half this amount in P2 (4.8%) and at only trace levels (<1%) in all membrane isolates of Experiment 1 (Fig. 5). In Experiment 2, sterols 16 and 17 were present at about twice the amount in P1 (4.1%) as in the Mixed Membrane (1.3%) and plasma membrane isolates (1.4%), although only half that of Experiment 1 P1 (Fig. 4). Crinosterol (4) and brassicasterol (5) (peak 3) were present in trace amounts in Intracellular Membrane Band 3, compared with higher levels (4.3–5.8%) in all other subcellular samples of Experiment 1 (Fig. 5). In Experiment 2, these sterols occurred at 7.7% in the Mixed Membrane Isolate, but in lower proportions in the plasma membrane (2%) and P1 pellet (5.8%) (Fig. 4). E/Z-Cholesta-5,22-dien-3β-ol (1) (peak no. 1) was observed in lower levels in Intracellular Membrane Bands 2 and 3 (trace amounts) than in plasma membrane (1.8%) of Experiment 1 (Fig. 5). Similarly, in Experiment 2, the Mixed Membrane Isolate contained lower levels of this sterol (1.9%) compared with the plasma membrane (3.7%) and P1 pellet (3.3%) (Fig. 4). Verongulasterol (18) (peak 9) occurred at 4.9% in Intracellular Membrane Band 3, but at less than half this in the plasma membrane and the remaining subcellular isolates in Experiment 1 (Fig. 5). Differences in the proportions of sterols for the two experiments may be attributable to seasonal factors, such as environmental temperature or the sponge diet, but the significance of these differences is unknown.

Sterol:phospholipid:protein ratios of subcellular isolates. Fractions identified as spherulous cell plasma membrane by other methods were found to possess greater sterol:phospholipid and sterol:protein ratios than other subcellular membrane systems isolated in this study (Table 2), in concordance with sterol:phospholipid and sterol:protein ratios reported for other plasma membranes (18).

DISCUSSION

This study presents the first definitive evidence for the presence of unconventional lipids in a subcellular membrane system of a marine sponge and thereby supports earlier proposals that unconventional sponge lipids are membrane constituents (1–3,5,33,39,41–44). Conventional subcellular fractionation methods were successfully used to produce highly pure plasma membrane from *A. fistularis* spherulous cells; the purity of these plasma membrane isolates was established by: (1) the enrichment of a radioactive plasma membrane marker, (2) the presence and absence of specific polypeptides and (3) the existence of characteristic protein:sterol:phospholipid ratios. Long-chain fatty acids (LCFA) and the unique sponge sterols, aplysterol (15) and 25-dehydroaplysterol (14), were confirmed as major components of spherulous cell plasma membrane in *A. fistularis*, in contrast to the short-chain (C_{14}–C_{22}) fatty acids (SCFA) and comparatively simple sterol molecules that are exclusively present in the cell membranes of most living organisms.

This study also documents that more conventional lipids co-occur with the unconventional lipids in the *A. fistularis* spherulous cell plasma membrane. The unconventional sterols aplysterol (15) and 25-dehydroaplysterol (14) were found to constitute 66.4–72.6% of the sterols, but the bulk of the remaining sterols were the conventional sterols cholesterol (2) and 5α-cholestan-3β-ol (3). LCFA were found to only constitute 16.8–28.0% of the total fatty acids; the remainder of the fatty acids were C_{14}–C_{22} lengths, including substantial quantities of branched C_{15}–C_{18} fatty acids, which are typical of bacterial cell membranes, but not of animal membranes. This does not necessarily mean that branched acids are synthesized de novo by the sponge. Given our own biosynthetic studies (37,45), short-chain (<C_{22}) branched acids are obtained either through the diet or from the abundant

TABLE 2

The Sterol:Phospholipid:Protein Ratios (mg/mg) of Spherulous Cells, Plasma Membrane and Subcellular Isolates From *A. fisturalis*

	Plasma membrane		Subcellular membranes			Experiment 1 Spherulous cells	
	Experiment 1	Experiment 2	Experiment 1 Intracellular Membrane Band 2	Experiment 1 Intracellular Membrane Band 3	Experiment 2 Mixed Membrane Isolate	Whole	P1 pellet
Sterol:Phospholipid	0.491	0.514	0.131	0.118	0.445	0.296	0.163
Sterol:Protein	0.327	0.392	0.104	0.159	0.300	0.064	0.096

symbiotic bacteria present in the sponge tissue, and their long-chain counterparts are synthesized by the sponge by chain elongation and desaturation of the shorter precursors.

Further investigations are required to establish the lipid contents of the intracellular membranes present within *A. fistularis* spherulous cells, but examination of undefined intracellular membrane isolates produced from spherulous cells during the course of this study indicates that there is considerable variability among the various types of membranes in this sponge. For example, although spherulous cell plasma membrane contained appreciable quantities of LCFA, the highest observed quantities of LCFA occurred in one unidentified intracellular membrane isolate.

Although it is certain that the plasma membrane lipid composition documented for *A. fistularis* spherulous cells does not reflect that of all sponge plasma membranes, as there is considerable variability in the lipid contents of different sponges (not all sponges contain unconventional sterols [46] and some species contain very low levels of LCFA [47]), it is not known if plasma membrane composition varies between cell types in *A. fistularis*. The fact that isolated spherulous cells differ from the corresponding whole tissue, however, suggests there may be variation according to cell type within this sponge. Moreover, it is uncertain whether plasma membrane composition varies between individual spherulous cells (e.g., according to size or age).

Further chemical characterization of additional sponge cell membranes is required to answer basic questions concerning the structures and functions of these membrane systems. Progress will be most quickly made if membrane isolates can be prepared from single cell types that are of a similar life history stage. Ideally, this might be achieved through in vitro culturing of particular sponge cell types, but so far this has proven impossible to achieve because of sensitivity of sponge cells to alien environments and their susceptibility to differention into varying cell types.

ACKNOWLEDGMENTS

We thank Fran Thomas for preparation of electron micrographs; Robin Anderson for assistance with sterol quantification and enzyme assays; Ivan Stoilov for advice on lipid analysis; Wray Huestis and Linda Brunauer for assistance with SDS-PAGE; Mary-Anne Stevenson for advice on concanavalin A plasma membrane labeling; Robert Simoni for guidance and for provision of facilities; Lucinda Cordeiro, Mary Zimmerman and Eser Ayanoglu for advice and guidance. Support for this research was provided by NIH (Grant No. GM-06840) and Hewlett-Packard Inc. (equipment grant).

[Received May 2, 1988; Revision accepted July 19, 1988]

Fatty Acid Composition of Fats of Differing Melting Points Extracted From Ram Subcutaneous Tissue

Cecil B. Johnson[a,*], **Roger W. Purchas**[b] and **E. John Birch**[a]

[a]Biotechnology Division, Department of Scientific and Industrial Research, Private Bag, Palmerston North, New Zealand; and [b]Animal Science Department, Massey University, Palmerston North, New Zealand

The observation that the subcutaneous fat of pasture-fed Southdown rams consists of two distinct regions is reported. Fatty acid composition of fat from the outer and inner regions of subcutaneous tissue taken from the rib region of eight Southdown rams fed pasture were determined. Relative to the harder inner regions (mean melting point 43.1°C), the softer outer regions (mean melting point 31.8°C) were shown to contain more 9:0-, 15:0-, 17:0-, 17:1-, 18:1-*cis* and total 18:1 fatty acids; less 14:0-, 16:0-, 18:0- and 18:1-*trans* fatty acids; and a greater variety and a greater concentration of branched-chain components. Proportions of medium chain-length fatty acids, other than 9:0, did not differ between the layers.

The fatty acid contents of serial samples taken at 1-mm intervals through these tissues were determined. Changes in concentrations of components among samples were gradual through the tissues. There was no clear connective tissue sheet, as has been reported for pigs. The inner region of the tissues contains apparently nonrandom fluctuating changes in fatty acid composition.

Lipids 23, 1049–1052 (1988).

The composition of ovine subcutaneous fat may be influenced by what the animals are fed (1). Diets containing high levels of cereals fed to ewes and wethers may result in the animals having softer subcutaneous fats compared to those fed pasture (2). Subcutaneous fats from the cereal-fed animals may contain higher concentrations of saturated branched-chain, n-saturated odd-carbon and monoenoic acids, and lower concentrations of n-saturated even-carbon chain acids than the corresponding fats from pasture-fed animals (2–6). Similar dietary effects on the fats from rams have also been reported (7,8).

One of us (RWP) observed that the subcutaneous fat of pasture-fed Southdown rams consisted of two distinct regions, the outer of which was very soft—almost oily. Among the animals studied, the soft region varied in thickness from being barely discernible to about 5-mm thick. Investigations of this phenomenon have not been previously reported. To ascertain the chemical reason for their differences, the fatty acid compositions of these regions were determined. Both medium and long chain-length acids were analyzed. Results of these analyses are reported here.

MATERIALS AND METHODS

A group of eight Southdown rams that had been fed on pasture (swards containing ca. equal amounts of white clover and perennial ryegrass) for about 18 months from weaning were slaughtered and the two distinct regions of subcutaneous tissue were separated from an area over ribs 8–12. Samples from the two regions were extracted with chloroform and the solvent then removed under reduced pressure. The extracts accounted for ca. 90% of the original tissues. They were shown by thin layer chromatography (9) to be principally triglycerides. Melting points of the fats were determined by AOCS Method Cc 1-25 (10).

Acylglycerols were converted into methyl esters by treatment with methanolic KOH followed by BF_3/methanol (11). Saturated long chain-length methyl esters were separated from unsaturated esters by adsorption of mercuric acetate adducts of the latter compounds on Amberlite CG-50 type 1 weak cation exchange resin (Johnson, C.B., unpublished data). Esters thus fractionated, as well as the original mixtures, were analyzed by gas chromatography using a Hewlett-Packard Model 5840 chromatograph. Unsaturated esters were separated on a 7 m × 2.3 mm i.d. stainless steel column containing silicone OV-275 (15% on Chromosorb P) at 220°C with a carrier gas (nitrogen) flow rate of 10 ml/min. The original mixtures of esters and the saturated esters were separated on a 2 m × 2.3 mm i.d. stainless steel column containing EGSS-X (10% on Chromosorb W) at 180°C with a carrier gas flow rate of 30 ml/min. A similar column containing Apiezon L grease (3%) at 200°C was also used for the separation of saturated esters.

Medium chain-length acids in the fats were isolated by steam distillation, esterified and analyzed on a 3.7 m × 2.3 mm i.d. stainless steel column containing 10% silicone OV-101 on Gas Chrom Q, as previously reported (12).

Cube samples (ca. 10 mm^3) of the intact adipose tissues from 2 animals were placed on aluminum discs and cooled to −15°C. The discs were placed in a cooled microtome and slices 1-mm thick were then cut sequentially parallel to the outer surfaces from the mounted samples. In addition, from two more animals, the hard and soft regions from the two samples were separated and sliced as described. Fat extracted from the slices was analyzed as described above.

RESULTS

The composition of the fatty acids from the inner and the outer regions of subcutaneous fat from the eight Southdown rams is given in Table 1. Also presented are the melting points of the fats. Fats from the outer regions melted at temperatures between 25.1°C and 39.8°C (mean 31.8°C) and, thus, felt oily. The inner regions were hard, having melting points between 41.4°C and 45.1°C (mean 43.1°C), similar to that of normal ewe or wether fats (13).

Most outer fats contained more 4-methyloctanoic acid and 9:0 than the inner fats. These levels were much higher than those found previously and, thus, may have implications for flavor of the cooked meat (12).

Relative to the inner regions of fat, the outer regions had a significantly greater quantity of n-saturated acids containing odd numbers of carbon atoms and a lesser quantity of the corresponding acids with even numbers of carbon atoms. The outer regions also contained a

greater proportion of anteiso and other branched-chain acids (labeled br in Table 1 [5,14]). Overall, there were significantly more branched-chain acids in the outer, than in the inner fats.

A noticeable feature of the gas chromatograms of methyl esters derived from the outer fats was the large number of small peaks (most <0.5%) between the solvent peak and that of 14:0. These peaks did not shift when the methyl esters were treated with hydrogen and Adam's catalyst (13). Thus, most of them probably were saturated branched-chain compounds. The total concentrations of these compounds were in the ranges 0.96–3.23% (mean 1.87%) in the outer fats and 0.13–0.65% (mean 0.32%) in the inner fats. Position location of the branches and determination of their chain-lengths were not undertaken.

The proportions of the monoenoics 17:1-*cis* and 18:1-*cis* were greater in the outer fats. Inner fats contained a greater proportion of 18:1-*trans* compared with the outer fats. *Cis*-polyunsaturated acids did not differ between the layers, but there was a consistently higher level of 18:2-*cis,trans* isomers in the inner fats.

Slides prepared from the subcutaneous fat tissue that had two clear regions differing in softness and color did not reveal a clear connective tissue sheet separating the layers, as has been reported for pigs (15). The connective tissue present (as shown by van Gieson's stain [16]) was spread throughout the subcutaneous tissue, forming numerous layers and lobules.

Analyses of 1-mm samples taken sequentially through the subcutaneous tissue showed that the fats in the two regions of differing hardness were not homogeneous mixtures of acylglycerols. The concentrations of branched-chain, *cis*-unsaturated and n-saturated components containing an odd number of carbon atoms decreased across the soft region from the outer slice. Concentrations of these components also tended to decrease across the harder inner region. However, the apparent nonrandom distribution of points on either side of a quadratic regression line for each component indicate that there were regular fluctuations in composition of the fat across the inner region. This is illustrated in Figure 1 (for a single animal) for n-heptadecanoate and the methyl branched-chain pentadecanoate (other than the iso and anteiso isomers) designated br-15:0. Concentrations of n-saturated components containing an even number of carbon atoms and *trans*-unsaturated components increased throughout the tissues from the outside to the inside. In most instances, the increase across the hard inner region was less than that across the soft outer region. However, for some samples, the increase in concentration of n-octadecanoate (Fig. 1) was almost linear throughout the subcutaneous tissue.

DISCUSSION

The subcutaneous fats of sheep are more unsaturated and of lower melting point than their perinephric and other internal depot fats (17). Differences in melting points among these fats may also be attributed to differences in the proportions of palmitate and stearate (18). Gradients of decreasing levels of unsaturated acids in the subcutaneous fat between the skin and muscle tissue have been observed in cattle, sheep and goats (19), as well as in pigs (15). However, pig subcutaneous fat consists of two layers of different composition on either side of an interface (15,20). The current paper records the first observation and analysis of two regions of different softness (or oiliness) in pasture-grazed ovine ram fats.

Melting points of the fats from the two layers are controlled principally by the levels of their main components,

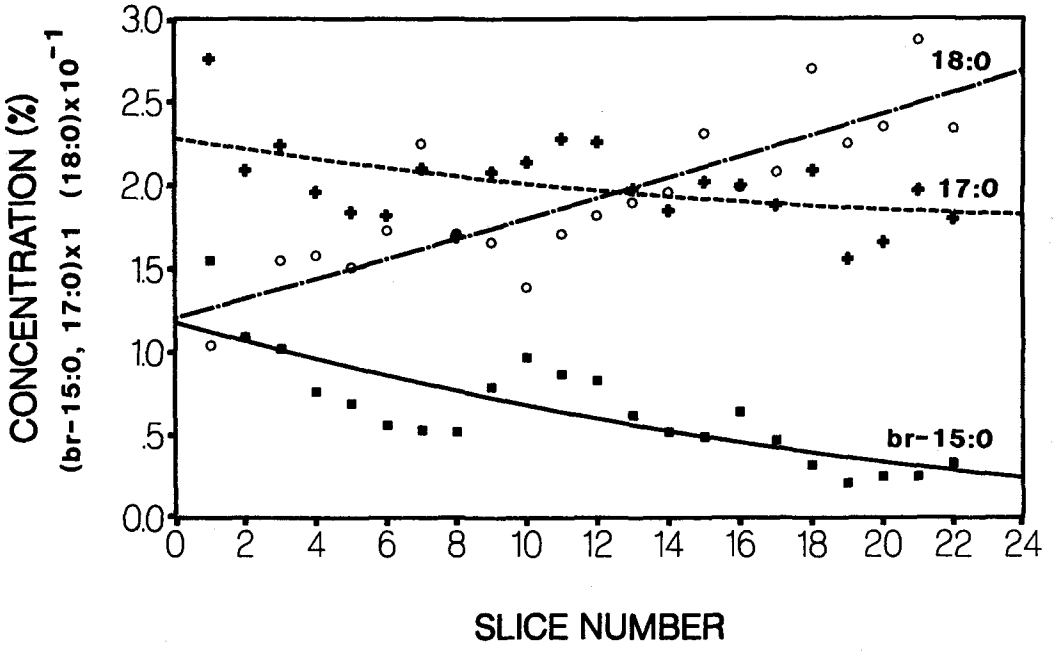

FIG. 1. Changes in fatty acid concentrations with distance into a subcutaneous tissue from surface (slice). Data for each 1-mm slice are shown together with quadratic regression lines for 18:0 (○, —·—·—), 17:0 (+, – – – –) and br-15:0 (■, ——). The visually soft region was 4-mm thick.

namely the 16:0-, 18:0- and 18:1-*cis* and *trans* moieties. These constituted 59–74% (mean 68%) of the outer fat and 79–84% (mean 81%) of the inner fat in the eight animals studied. Decreased melting points of the fats were associated with lower proportions of 16:0-, 18:0- and 18:1-*trans* and higher proportions of 18:1-*cis*.

Other acylglycerol moieties are individually present in small amounts (0.01–5.0%) and, thus, would have little effect on the melting point of the resulting fat. However, their cumulative effect could be important.

Fatty acids and esters containing an odd number of carbon atoms have lower melting points than the corresponding compounds having one less methylene group in their chain (21,22). Likewise, *cis*-unsaturated and branched-chain saturated acids have lower melting points than the corresponding *trans*-unsaturated and n-acids, respectively. Enhanced amounts of 15:0, 17:0, branched-chain saturated and *cis*-unsaturated moieties in the outer fats compared with the inner fats is consistent with the lower melting points of these fats.

Triacylglycerols from the outer layer of pig subcutaneous fat contain more unsaturated acids, less saturated acids and have a lower melting point than triacylglycerols from the inner layer (15). The ram fats in this study showed similar differences, although of greater magnitude for 18:0 and 18:1, to those of the pig. However, the ram fats contained appreciable amounts of branched-chain acids that were not present in the pig fats, possibly reflecting the different digestive systems of these two animals. These acids arise from the biosynthetic incorporation of methylmalonate (derived from propionate), rather than malonate (derived from acetate), into the growing fatty acid chains (5).

In sheep (23) and in pigs (24), both the liver and adipose tissue are considered as important sites for the synthesis of fatty acids from acetate. The formation of the soft outer subcutaneous fat layer in pigs has been suggested to involve desaturation of saturated components in this layer, rather than transport of unsaturated components from some other site (18). Similarly, an enhanced synthesis of unsaturated and branched-chain acids may take place in the soft outer region of the subcutaneous fat of rams.

Effect of Various Steroids on the Biosynthesis of Arachidonic Acid in Isolated Hepatocytes and HTC Cells

Carlos A. Marra*, María J.T. de Alaniz and Rodolfo R. Brenner
Instituto de Investigaciones Bioquímicas de La Plata (INIBIOLP), CONICET-UNLP, Facultad de Ciencias Médicas, 60 y 120, (1900) La Plata, Argentina

The effect of various steroids on the incorporation and desaturation of eicosa-8,11,14-trienoic acid in normal hepatocytes and HTC cells was investigated. After 3 hr incubation with 11-deoxycorticosterone, both kinds of cells showed an increase in the incorporation of eicosatrienoic acid. In contrast, progesterone, cortexolone, 17-β-estradiol, testosterone, estriol, aldosterone, corticosterone, dexamethasone, dehydroepiandrosterone, 11-β-hydroxyandrosterone, 11-ketoaetiocholanolone, epiaetiocholanolone and 5-β-pregnane-3α,20α-diol, provoked no significant changes in the uptake of the exogenous acid. Of all the steroids tested, only 11-dexycorticosterone, dexamethasone and 17-β-estradiol evoked a significant inhibition on the arachidonate biosynthesis in both kinds of cells. Testosterone, estriol, aldosterone and corticosterone provoked a significant inhibition of Δ5-desaturase in HTC cells. In dexamethasone, this effect was dose-dependent (0 to 10^{-4} M). Simultaneous incubation with 17-β-estradiol or 11-deoxycorticosterone with dexamethasone led to an extent of inhibition on arachidonate biosynthesis that did not surpass the effect of each drug. Pretreatment of isolated hepatocytes with the antiglucocorticoid, cortexolone, prevented the dexamethasone-induced inhibition of arachidonate biosynthesis. Normal rat liver microsomes preincubated in vitro with dexamethasone, 11-deoxycorticosterone, 17-β-estradiol, corticosterone or estriol (10^{-6} or 10^{-4} M concentration), showed no significant changes in the Δ5-desaturase activity. The results obtained suggest that the effect of the steroids on arachidonic acid biosynthesis in normal hepatocytes and HTC cells requires receptor occupancy and probably is mediated through a common biochemical mechanism.
***Lipids 23,* 1053–1058 (1988).**

Previous works have demonstrated that oral administration or intraperitoneal injection of glucocorticoid hormones in rats produced a decrease in the activities of Δ6- and Δ5-liver-microsomal desaturases (1,2). In addition, recent studies performed in our laboratory have revealed that the incubation of isolated hepatocytes or HTC cells (the permanent cell-culture line, hepatoma tissue culture 7288c) with dexamethasone also produced a decrease in the conversion of eicosa-8,11,14-trienoic acid to arachidonic acid (3). The mechanism by which dexamethasone exerts this biological effect is still unknown. However, as previously reported (3), the modulatory action of this class of hormone on desaturase activity would be expected to be produced through a mechanism similar to that mediating the other known metabolic effect of glucocorticoids (4–9), namely through induction of the biosynthesis of a regulatory protein. Classically, steroid hormones trigger their effects after combining with a high-affinity cytosolic receptor (6). A property common to all steroid receptors is their ability to recognize subtle differences in steroidal molecular structure. Within this context, the aim of the present work was to test the effect of different steroid hormones on the incorporation and conversion of eicosatrienoic acid in isolated cells. In this system, we have studied four different classes of steroid hormones: glucocorticoids, mineralocorticoids, estrogens and androgens. Also tested was cortexolone that competitively inhibits the action of glucocorticoids, and it is known as an antiinducer (10–13).

MATERIAL AND METHODS

Chemicals. [1-^{14}C]Eicosa-8,11,14-trienoic acid (54.9 mCi/mmol, 98% radiochemically pure) was provided by New England Nuclear Corp. (Boston, MA). Unlabeled eicosa-8,11,14-trienoic acid was supplied by Nu-Chek Prep (Elysian, MN). Bovine serum albumin, essentially fatty acid-free bovine albumin, N-2-hydroxy-ethyl-piperazine-N-2-ethanol sulphonic acid (HEPES), collagenase type IV and trypsin soybean inhibitor type I were provided by Sigma Chemical Company (St. Louis, MO). Dexamethasone was obtained from Merck, Sharp & Dohme Laboratories (Buenos Aires, Argentina). Dehydroepiandrosterone was purchased from Merck Laboratories (Darmstadt, Germany). 17-β-Estradiol was provided by Gador Laboratories (Buenos Aires, Argentina) and 11-deoxycorticosterone was supplied by Schering Laboratories (Buenos Aires, Argentina). All other steroids were purchased from Sigma Chemical Company (St. Louis, MO).

Animals. Adult female Wistar rats weighing 160–180 g fed on a standard pelleted diet (Cargill, Rosario, Argentina) were used. In calories, this standard diet consisted of 56.7% carbohydrates, 10.4% lipids and 32.9% protein, vitamins and minerals. Water was given ad libitum. In order to avoid individual differences among the animals, in all the experiments the rats were fasted for 24 hr, refed for 2 hr and then killed 12 hr after the end of the feeding period.

Isolation of microsomes. Livers were rapidly excised and immediately placed in ice-cold homogenizing medium (14). They were homogenized in 3 ml of homogenizing solution for each gram of liver tissue and then centrifuged for 30 min at 10,000 × *g*. The pellet was discarded and the supernatant fraction was centrifuged again for 60 min

at 110,000 × *g* in a Spinco L-2 ultracentrifuge. The pellets were resuspended in cold homogenizing solution up to a final protein concentration of 50 mg per ml and were used immediately for fatty acid desaturase activity assay.

Incubation of rat liver microsomes with different steroid hormones. A possible direct effect of different steroidal compounds on the microsomal Δ5-desaturation system was examined. The microsomal suspension was preincubated for 15 min at 37°C with dexamethasone, 11-deoxycorticosterone, 17-β-estradiol, corticosterone or estriol at 10^{-6} and 10^{-4} M concentrations. Control tubes were preincubated with the vehicle in which steroid hormones were dissolved (ethanol 20 mM). At the end of the preincubation period, Δ5-desaturase activity was measured by estimation of the percentage conversion of [1-^{14}C]eicosa-8,11,14-trienoic acid to arachidonic acid. Five nmol of the labeled acid and 95 nmol of unlabeled acid were incubated with 5 mg of microsomal protein in a shaker at 37°C for 10 min. The composition of the incubation medium, the procedure to obtain the fatty acid methyl esters and the quantitative analysis of radioactive fatty acid methyl esters, have been described elsewhere (15).

Isolated cells. Liver parenchymal cell isolation from Wistar rats was carried out according to Seglen (16), except that the operational temperature was maintained at 37°C. To minimize glycogenolysis, 0.2% glucose was added to all media used during perfusion and isolation (17). The liver cells were suspended in oxygenated Hank's buffer (18) containing 1.0 g % of bovine albumin. After 30 min, the cells were centrifuged and resuspended in IMEM-Zo medium (19), minus linoleic acid and containing HEPES (5 mM). HTC cells were established in culture from an ascites tumor originally derived from a solid hepatoma (7288 c) (20). The cells were grown in surface culture at 37°C, under sterile conditions, in Swim's 77 medium (S-77) supplemented with 10% (v/v) calf serum (21) and were harvested at confluence. The suspensions of HTC cells were obtained from surface cultures as described elsewhere (22). Cell viability (90%) was assessed by the criterion of trypan blue dye exclusion (23).

Experimental procedures with isolated cells. HTC cells and isolated liver cells were counted in a hemocytometer. Aliquots (3.0×10^6 cells) were incubated with 5 ml of modified IMEM-Zo medium in 25-ml siliconized Erlenmeyer flasks under an atmosphere of 95% oxygen and 5% carbon dioxide in a metabolic shaker (70 rpm) at 37°C. To measure the incorporation and conversion of exogenous eicosa-8,11,14-trienoic acid in both kinds of cells after treatment with different steroid hormones, we performed four types of experiments.

In the first series, HTC cells or normal hepatocytes were incubated for 3 hr with different steroid hormones at a concentration of 0.1, 1.0 or 10 mM. Twenty min before the end of the incubation period, all media were supplemented with a mixture of labeled eicosa-8,11,14-trienoic acid at a final concentration of 80 μM (0.5 μCi per flask). The acid was added as its sodium salt bound to albumin delipidated according to Spector et al. (24).

In the second experiment, incubation of the cells was carried out in an identical manner, but with dexamethasone (0.1 mM) as the active glucocorticoid either alone or in combination with 11-deoxycorticosterone (0.1 mM) or 17-β-estradiol (10 mM).

In the third set of experiments, isolated normal hepatocytes were incubated with dexamethasone (10^{-6} or 10^{-4} M) either alone or in combination with cortexolone (10^{-6} or 10^{-4} M). Here, after 1 hr incubation with cortexolone, dexamethasone was added to some flasks and the cells were incubated with the two hormones for another 3 hr. Then, eicosa-8,11,14-trienoic acid was added to all the flasks, as in the first experiment.

To determine the dose-response curve for inhibition of arachidonate biosynthesis in HTC cells, another type of experiment was carried out. HTC cells were incubated for 3 hr with dexamethasone phosphate at different concentrations (ranging from 0 to 10^{-4} M). Then, eicosatrienoic acid was added to all the flasks, as in the first experiment.

At the end of the incubation periods, cell suspensions were transferred to ice-cold tubes and centrifuged. Each pellet was washed three times with 0.85 g % NaCl (3 ml each time) and resuspended (5 ml) in the same solution. An aliquot of the suspension was used to determine cell viability (23) and the amount of cellular protein (25), and the rest was centrifuged at 2000 × *g* for 5 min. The saline solution was decanted and the cell pellets were saponified for 45 min at 85°C with 2.0 ml of 10% (w/v) KOH in ethanol plus 500 μl of methanol to facilitate lipid extraction. The free fatty acids were extracted from the acidified solution with light petroleum (bp 30–40°C) and esterified with 3 N HCl in methanol for 3 hr at 65°C.

Chromatographic measurements. The radioactivity of the recovered methyl esters (usually 96–98%) was measured in a Beckman liquid-scintillation counter (model LS-3133 P) with 96% efficiency for ^{14}C. The distribution of radioactivity among the fatty acid methyl esters was determined by gas-liquid radiochromatography using an Acromat CG-100 equipped with a Packard proportional counter. Percentage conversion of eicosa-8,11,14-trienoic acid to arachidonic acid was calculated from the distribution of radioactivity between the substrate and product measured directly on the radiochromatogram (26). The column was packed with 10% SP-2330 coated on 100–200 chromosorb WAW (Supelco, Bellefonte, PA). Identification of methyl esters was made by comparison with known standards. Results were calculated as mean ± 1 SEM; statistical analyses were made using the Student-t-test.

RESULTS

We first examined the effect of different steroid hormones on the incorporation and desaturation of eicosa-8,11,14-trienoic acid in isolated rat liver cells (Fig. 1). After 3 hr incubation in the presence of 11-deoxycorticosterone (0.1 mM), a significant increase in the incorporation of the acid was observed (ca. 40% over control values). The uptake of the exogenous eicosatrienoic acid was not modified by incubating the cells in the presence of the other steroid hormones (dexamethasone, progesterone, cortexolone or 17-β-estradiol).

Of all the hormones tested and indicated in Figure 1, only dexamethasone, 11-deoxycorticosterone and 17-β-estradiol had a significant effect on the conversion of eicosatrienoic acid to arachidonic acid in isolated hepatocytes. The inhibition of arachidonic acid biosynthesis produced by dexamethasone was less potent (48% at 0.1 mM) than those produced by 11-deoxycorticosterone (61% at

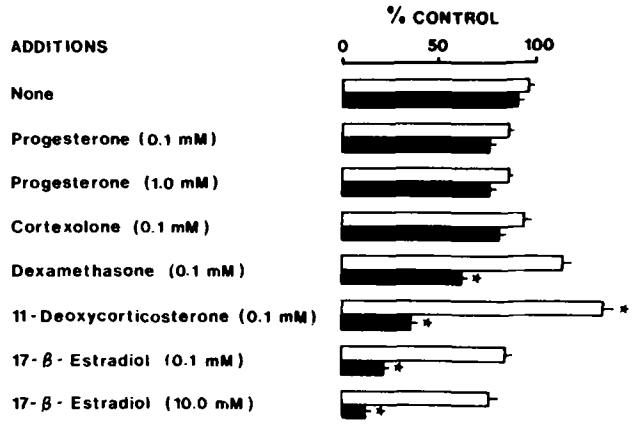

FIG. 1. Effect of different steroid hormones on the incorporation (□) and desaturation (■) of [1-^{14}C]eicosatrienoic acid in isolated rat hepatocytes. Cell suspensions were incubated for 3 hr with or without each of the steroid hormones at the concentrations listed in the figure. The results were expressed as percentage change from control flasks incubated for 20 min with labeled acid 80 μM concentration (42.5 ± 1.3 nmol of eicosatrienoic acid incorporated and 3.0 ± 0.2 nmol of arachidonic acid formed, per mg of cellular protein). Conditions of incubation are described in experimental procedures. Values are the mean of 3 incubation flasks. Vertical lines represent 1 SEM. Results significantly different, $P < 0.01$, are indicated with a star.

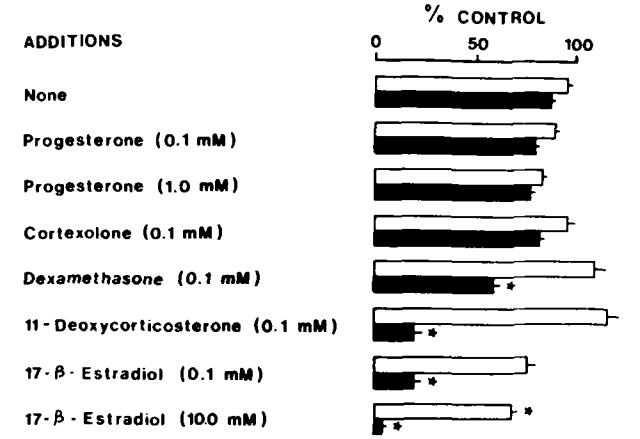

FIG. 2. Effect of different steroid hormones on the incorporation (□) and desaturation (■) of [1-^{14}C]eicosatrienoic acid in HTC cells. Cell suspensions were incubated for 3 hr with or without each of the steroid hormones at the concentrations listed in the figure. The results were expressed as percentage change from control flasks incubated for 20 min with labeled acid 80 μM concentration (25.2 ± 0.8 nmol of eicosatrienoic acid incorporated and 4.3 ± 0.1 nmol of arachidonic acid formed, per mg of cellular protein). Conditions of incubation are described in experimental procedures. Values are the mean of 3 incubation flasks. Vertical lines reprsent 1 SEM. Results significantly different, $P < 0.01$, are indicated with a star.

0.1 mM) and 17-β-estradiol (75% and 88% at 0.1 to 10.0 mM, respectively.

Similar results were obtained by incubating HTC cells in the presence of the same steroid hormones (Fig. 2). In this experiment, however, 11-deoxycorticosterone had no significant effect on the incorporation of eicosatrienoic acid, but 10.0 mM 17-β-estradiol caused a marked decrease in both the incorporation of the acid (30%) and its conversion to arachidonic acid (94%).

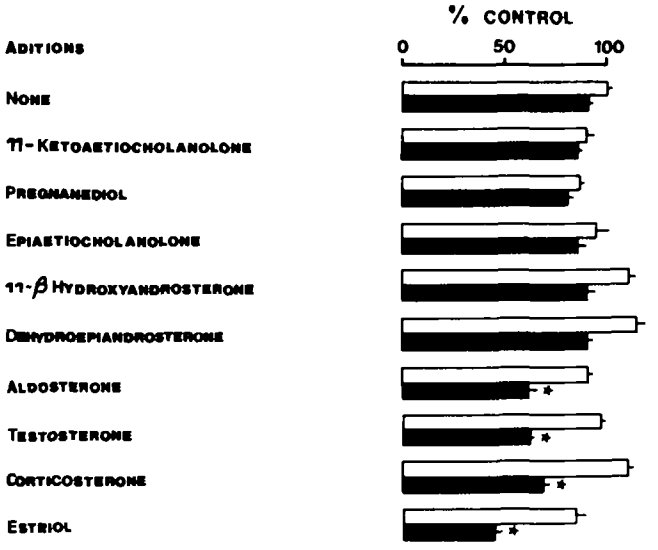

FIG. 3. Effect of different steroid compounds on the incorporation (□) and desaturation (■) of [1-^{14}C]eicosatrienoic acid in hepatoma cells. HTC cell suspensions were incubated for 3 hr with or without each of the steroid hormones at 0.1 mM concentration. The results were expressed as percentage change from control flasks incubated for 20 min with labeled acid 80 μM concentration (24.7 ± 0.9 nmol of eicosatrienoic acid incorporated and 4.8 ± 0.3 nmol of arachidonic acid formed, per mg of cellular protein). Conditions of incubation are described in experimental procedures. Values are the mean of 3 incubation flasks. Vertical lines represent 1 SEM. Results significantly different, $P < 0.01$, are indicated with a star.

We also examined the effect of other steroids on the uptake and desaturation of eicosatrienoic acid in the hepatoma cells (Fig. 3). None of the hormones studied (11-ketoaetiocholanolone, 5-β-pregnane-3α,20α-diol, epiaetiocholanolone, 11-β-hydroxyandrosterone, dehydroepiandrosterone, aldosterone, testosterone, corticosterone and estriol) affected the incorporation of the acid, although the biosynthesis of arachidonate was significantly depressed by aldosterone, testosterone, corticosterone and estriol at a concentration of 0.1 mM.

In order to reveal a possible competitive effect between different steroid hormones, 11-deoxycorticosterone or 17-β-estradiol was added to the incubation medium at the same time as dexamethasone. The results obtained with dexamethasone in combination with either of the other two steroids in isolated hepatocytes (Fig. 4) or HTC cells (Fig. 5) were similar to earlier observations made with those hormones alone in the corresponding cell types (Figs. 1 and 2, respectively).

Short-term treatment of isolated hepatocytes with either progesterone or cortexolone failed to modify either of the parameters studied (Fig. 6). Moreover, pretreatment of the cells for 1 hr with antiglucocorticoid (10^{-4} M) prevented the subsequent inhibition by dexamethasone (10^{-4} or 10^{-6} M), otherwise seen in this system.

A final experiment with HTC cells (Fig. 7) demonstrated that the dexamethasone effect on arachidonate production was dose-dependent.

When rat liver microsomal fractions were preincubated at 37°C for 15 min with dexamethasone, 11-deoxycorticosterone, 17-β-estriol, aldosterone or estriol (10^{-6} or 10^{-4} M concentration) and compared to microsomes

preincubated in hormone absence, no significant changes in the Δ5-desaturation activity were observed (Table 1)

DISCUSSION

At the time of these studies, little was known about the role of different steroid hormones in the regulation of polyunsaturated fatty acid metabolism. Previous studies

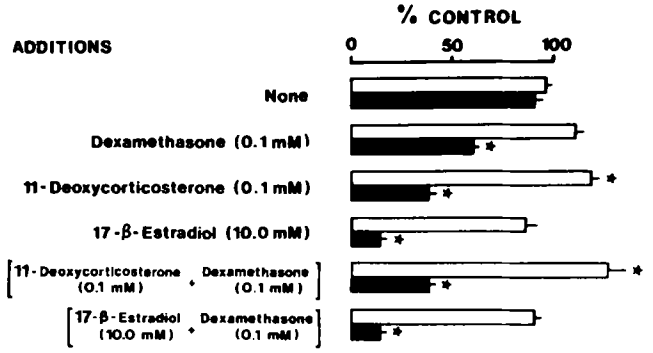

FIG. 4. Competitive effect of steroid hormones on the incorporation of [1-^{14}C]eicosatrienoic acid (□) and its conversion to arachidonate (■) in isolated hepatocytes of rats. Normal liver cells were incubated for 3 hr with dexamethasone (0.1 mM) either alone or in combination with 11-deoxycorticosterone (0.1 mM) or 17-β-estradiol (10.0 mM). Some flasks were also supplemented with the latter two steroid hormones at the concentrations indicated in the figure. Twenty min before the end of the incubation period, all media were supplemented with labeled eicosatrienoic acid (80 μM) as it was described in experimental procedures. The results were expressed as percentage change from control flasks incubated for 20 min with the acid (39.4 ± 1.1 nmol of eicosatrienoic acid incorporated and 2.8 ± 0.1 nmol of arachidonic acid formed, per mg cellular protein). Bars and vertical lines represent means and SEM of 3 experiments. Results significantly different, $P < 0.01$, are indicated with a star.

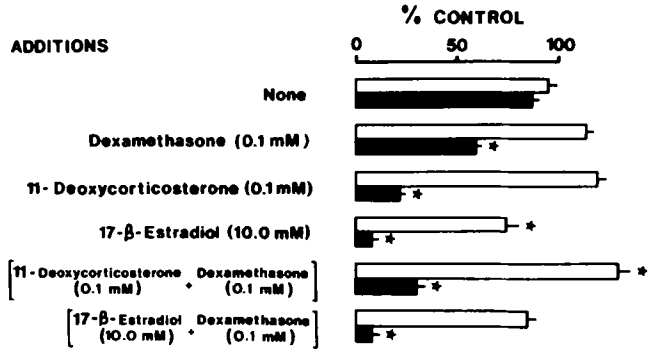

FIG. 5. Competitive effect of steroid hormones on the incorporation of [1-^{14}C]eicosatrienoic acid (□) and its conversion to arachidonate (■) in HTC 7288c cells. The cells were incubated for 3 hr with dexamethasone (0.1 mM) either alone or in combination with 11-deoxycorticosterone (0.1 mM) or 17-β-estradiol (10.0 mM). Some flasks were also supplemented with the latter two steroid hormones at the concentrations indicated in the figure. Twenty min before the end of the incubation period, all media were supplemented with labeled eicosatrienoic acid (80 μM) as it was described in experimental procedure. The results were expressed as percentage change from control flasks incubated for 20 min wth the acid (25.1 ± 0.6 nmol of eicosatrienoic acid incorporated and 3.9 ± 0.1 nmol of arachidonic acid formed, per mg of cellular protein). Bars and vertical lines represent means and SEM of 3 experiments. Results significantly different, $P < 0.01$, are indicated with a star.

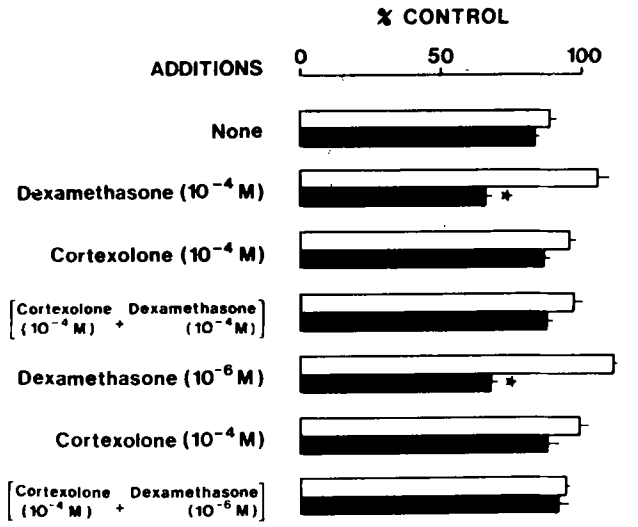

FIG. 6. Effect of pretreatment of isolated liver cells with antiglucocorticoids on the action of dexamethasone on eicosatrienoic acid incorporation (□) and desaturation (■). Normal isolated hepatocytes were incubated for 4 hr with dexamethasone (10^{-6} or 10^{-4} M) either alone or in combination with cortexolone (10^{-6} or 10^{-4} M). In these experiments, after 1 hr of incubation with the antiglucocorticoid cortexolone, dexamethasone was added to some flasks and the cells were incubated with the two hormones for another 3 hr. Labeled eicosatrienoic acid (80 μM final concentration) was added to all the flasks 20 min before the end of the incubation period. The results were expressed as percentage change from control cells incubated for 20 min with the acid (37.5 ± 0.9 nmol of eicosatrienoic acid incorporated and 3.1 ± 0.2 nmol of arachidonic acid formed, per mg of cellular protein). Bars and vertical lines represent means and SEM of 3 experiments. Results significantly different, $P < 0.01$, are indicated with a star.

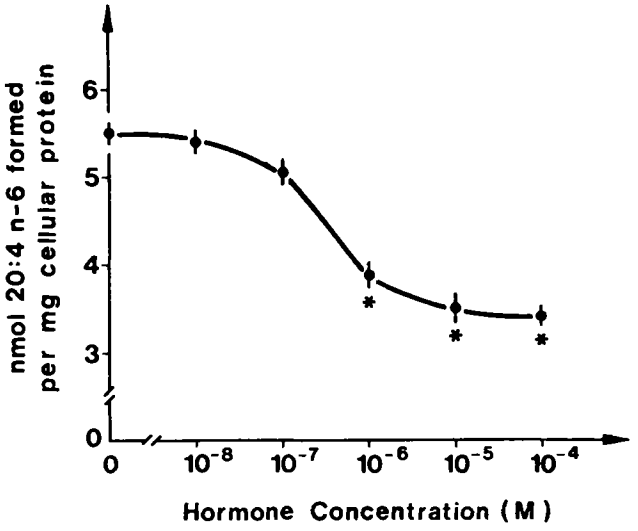

FIG. 7. Dose-response curve for inhibition of arachidonate biosynthesis in HTC cells by dexamethasone phosphate (0 to 10^{-4} M concentration). The cells were incubated at 37°C for 3 hr with the steroid hormone. Twenty min before the end of incubation period, the media were supplemented with labeled eicosatrienoic acid (80 μM concentration) as it was described in experimental procedure. The results were expressed as nmol of arachidonic acid formed per mg of cellular protein. Vertical lines represent SEM of 3 experiments. Results significantly different, $P < 0.01$, are indicated with a star.

TABLE 1

Direct Effect of Steroids on Microsomal Rat Liver Δ5-Desaturase Activity

Treatment	% Conversion 20:3 n-6 to 20:4 n-6
None	40.9 ± 1.3
Dexamethasone (10^{-6} M)	38.2 ± 0.4
Dexamethasone (10^{-4} M)	37.7 ± 0.2
11-Deoxycorticosterone (10^{-6} M)	39.1 ± 1.2
11-Deoxycorticosterone (10^{-4} M)	38.4 ± 0.5
17-β-Estradiol (10^{-6} M)	42.4 ± 2.3
17-β-Estradiol (10^{-4} M)	37.8 ± 0.8
Aldosterone (10^{-6} M)	39.7 ± 1.8
Aldosterone (10^{-4} M)	38.1 ± 1.7
Estriol (10^{-6} M)	41.4 ± 0.5
Estriol (10^{-4} M)	39.5 ± 1.5

Five mg of microsomal protein were preincubated at 37°C for 15 min with the steroids indicated. Control tubes were preincubated with ethanol 20 mM. At the end of the preincubation period, Δ5-desaturase activity was determined as it was stated in Materials and Methods. The results correspond to the percentage conversion of eicosa-8,11,14-trienoic acid to arachidonic acid and they are the mean ±1 SEM of 3 experiments.

from this laboratory had shown that the administration of natural or synthetic glucocorticoids to rats (hydrocortisone, dexamethasone or triamcinolone) produced a decrease in liver microsomal Δ6- and Δ5-desaturase activities (1). In reports by others, the injection of 17-β-estradiol to ovariectomized rats had depressed Δ6-desaturase (27), but the treatment of roosters with the same hormone had stimulated Δ9-desaturase (28).

In this paper, we have demonstrated that, among a variety of steroid hormones of widely different structures (glucocorticoids, mineralocorticoids, androgens and estrogens), only 11-deoxycorticosterone was able to increase significantly the incorporation of eicosatrienoic acid to cells, and 17-β-estradiol evoked a depressive effect. The effect of 11-deoxycorticosterone on the incorporation of eicosatrienoic acid and its conversion to arachidonic acid were opposite, as a significant increase in the incorporation of the acid was seen with a simultaneous decrease in the biosynthesis of arachidonic acid (Fig. 1).

The inhibition of the Δ5-desaturase was more pronounced with 11-deoxycorticosterone and 17-β-estradiol than with dexamethasone, aldosterone, testosterone, corticosterone and estriol. We also found no additive effect between dexamethasone and either 11-deoxycorticosterone or 17-β-estradiol with respect to the inhibition of eicosatrienoic acid desaturation in either isolated hepatocytes (Fig. 4) or HTC cells (Fig. 5). The mechanism through which glucocorticoids modify the desaturation of fatty acid can be explained in different ways. It could be genomic or nongenomic. A possible nongenomic mechanism of dexamethasone action could be evoked by direct binding of the hormone to the microsomes, as already reported for rat liver (29). This effect of the hormone could be produced directly on the Δ5-desaturation system or mediated through changes of the physicochemical properties of the biomembrane that, as we know, may modulate desaturase activity (30,31). However, the preincubation of rat liver microsomes with dexamethasone, 11-deoxycorticosterone, 17-β-estradiol, corticosterone or estriol (10^{-6} or 10^{-4} M concentration) did not produce any significant and specific effect on the Δ5-desaturase activity (Table 1). Therefore, we may discard rather confidently a direct effect of steroids on Δ5-desaturation system.

Regarding the classical mechanism of action generally accepted, steroids enter the cells by simple diffusion and combine with a high affinity receptor (32,33). That the dexamethasone inhibition of eicosatrienoic acid desaturation was blocked by pretreatment of the isolated hepatocytes with antiglucocorticoid (Fig. 6) is consistent with the hypothesis that the effects of the steroid in this biological and biochemical system are mediated through receptor occupancy. The fact that dexamethasone phosphate produced an inhibition of arachidonic acid biosynthesis in HTC cells in a dose-dependent fashion (Fig. 7) also suggests that glucocorticoid receptor structures would be involved.

Based on the above observations together with other evidence obtained in our laboratory (3,34), we can now conclude that the inhibition by steroid hormones of arachidonate biosynthesis does not result from a direct interaction with the Δ5-desaturase enzymatic machinery, but rather requires initial cytoplasmic-receptor occupancy, as well as likely subsequent changes in gene transcription and/or translation. Moreover, these data would also suggest that, despite their differing molecular structures, several steroid hormones inhibit eicosatrienoic acid desaturation probably through a common biochemical mechanism. Further research, however, is needed to evaluate the possible role of these hormones in controlling the activity of desaturases other than the Δ5.

[Received February 18, 1988; Revision accepted July 26, 1988]

A Diet Containing n-3 and n-6 Fatty Acids Favorably Alters the Renal Phospholipids, Eicosanoid Synthesis and Plasma Lipids in Nephrotic Rats

U.O. Barcelli*, D.C. Beach, B. Thompson, M. Weiss and V.E. Pollak
Departments of Internal Medicine and Pathology, University of Cincinnati Medical Center, Cincinnati, OH 45267-0585

The nephrotic syndrome was induced in rats by intravenous adriamycin (3 mg/kg). The rats were then divided into four groups which, for six weeks, were pair-fed diets containing beef tallow (BT), fish oil (FO), a source of n-3 fatty acids, evening primrose oil (EPO), a source of n-6 fatty acids, or a combination of evening primrose oil and fish oil, 75:25 (EPO:FO). The fat content of the diets was 15%. Significant incorporation of the fatty acids into kidney phospholipids was demonstrated. Diets containing FO, EPO and EPO:FO lowered plasma triglycerides and total cholesterol levels as compared with diets containing BT. Only EPO:FO raised high density lipoprotein (HDL) cholesterol levels, as compared with BT. The combination EPO:FO prevented the tenfold suppression of aortic 6-keto-$PGF_{1\alpha}$ caused by FO. These changes in plasma lipids and eicosanoid production are potentially antiatherogenic and may prevent glomerular sclerosis. The combination of EPO and FO, containing n-6 and n-3 fatty acids may offer advantages over either family of fatty acids in this model of nephrotic syndrome.
Lipids 23, 1059–1063 (1988).

Diets containing fish oil (FO) and rich in n-3 polyunsaturated fatty acids (PUFA), lower plasma lipids and preserve kidney function and histology in adriamycin-induced nephrotic rats (1,2). Fish oil suppresses platelet and glomerular thromboxane A_2 (TXA_2), a beneficial effect, but also suppresses aortic production of the vasodilatory prostaglandin I_2 (PGI_2) and glomerular production of PGE and PGI_2. This is an undesirable action. Evening primrose oil (EPO) contains the n-6 PUFA gammalinolenic and linoleic acids; both are precursors of monoenoic and dienoic eicosanoids through the cyclooxygenase pathway. We tested the hypothesis that the addition of n-6 PUFA to a fish-oil diet may prevent suppression of beneficial PG by increasing their precursors in the cell phospholipids. The effect of a mixture of EPO and FO (75:25) was studied. The results were compared with those in animals fed beef tallow (BT), EPO or FO alone as dietary fats. In contrast with previous studies, we used a dose of adriamycin of 3 mg/kg instead of 7.5 mg/kg, to prevent development of advanced renal disease and renal failure, which could interfere with the variables measured.

MATERIAL AND METHODS

Animals and diets. Forty-one Sprague-Dawley female rats (Harlan, Indianapolis, IN) weighing 220–270 g received a single dose of adriamycin (3 mg/kg) (Adria Laboratories, Columbus, OH) into the tail vein, under ether anesthesia. Seven days later (week 0), matched by weight and urinary protein excretion, groups of rats were allocated to four isocaloric diets, containing 14% BT, 14% FO, 14% EPO and 14% of a mixture of EPO and FO, 75:25 (EPO:FO). Soybean oil (SBO) 1% was added to all diets to supplement essential fatty acids. EPO, FO and EPO:FO were supplied by Efamol, Inc. (Kentville, Nova Scotia, Canada). The diets were prepared by Teklad (Madison, WI), who also provided BT and SBO fats. All experimental diets contained 200 g/kg protein as vitamin-free casein, 3 g/kg DL methionine, 382 g/kg sucrose, 150 g/kg maltodextrin, 150 g/kg fat, 70 g/kg cellulose, 35 mg/kg mineral mix (Teklad AIN-76), 10 g/kg vitamin mix (Teklad #40060) that provides 0.24 g/kg diet of dry vitamin-E acetate, and 26 mg/kg of BHA (an antioxidant). The fatty acid composition of the dietary lipids, analyzed by gas chromatography (GC) is shown in Table 1. Pair-feeding was used throughout, with the rats in three groups being pair-fed against the rats in the group with the lowest food intake.

Rats were weighed periodically and kept without food but with free access to water. Urine was collected for 23 hr, at weeks 0 and 4. Systolic blood pressure was measured by the tail cuff method at week 5. At week 6, after a 15 hr fast, rats were killed under ketamine-xylazine anesthesia by exsanguination via cardiac puncture. Plasma creatinine, lipids and platelet TXA_2 production were measured. Kidney tissue was obtained for fatty acid composition, light microscopy and eicosanoid production.

Glomeruli were isolated to measure production of PGE, 6-keto-$PGF_{1\alpha}$ and TXB_2; the latter two are stable metabolites of PGI_2 and TXA_2, respectively. Thoracic aortic

TABLE 1

Fatty Acid Composition of the Dietary Lipids

Fatty acid	BT	FO	EPO	EPO:FO
14:0	3.4	8.2	—	2.0
16:0	24.9	18.7	6.4	9.2
16:1	2.6	9.4	—	2.4
18:0	18.7	4.3	1.7	2.4
18:1	40.0	14.6	7.5	9.5
18:2n-6	4.5	2.1	74.9	56.6
18:3n-6	—	—	9.0	7.0
18:3n-3	—	2.4	—	0.6
20:4n-6	—	1.8	—	0.4
20:5n-3	—	16.5	—	4.3
22:5n-3	—	2.5	—	0.6
22:6n-3	—	11.1	—	2.9

Diets contained 150 g fat/kg. Numbers represent percentage of the total fatty acid content.

*To whom correspondence should be addressed.

Abbreviations: BSA, bovine serum albumin; BT, beef tallow; EBSS, Earls Balanced Salt Solution; EPO, evening primrose oil; FO, fish oil; HDL, high density lipoprotein; PG, prostaglandin; PUFA, polyunsaturated fatty acid; SBO, soybean oil; TXA_2, thromboxane A_2; (V)LDL, (very) low density lipoprotein; GC, gas chromatography; HPLC, high-performance liquid chromatography; PAS, periodic acid-Schiff; RIA, radioimmunoassay.

strips, 5–20 mg dry weight, were incubated and the media assayed for 6-keto-$PGF_{1\alpha}$ production.

Kidney phospholipid fatty acid composition. For this analysis, tissue samples were selected randomly from each dietary group. Kidney tissue was homogenized in saline and extracted with chloroform/methanol (3). Total lipids were separated using a silica SEP PAK cartridge (Waters, Milford, MA); the phospholipid fraction eluted with methanol (4). Phospholipids were methylated in boron trichloride in methanol at 90°C for 1 hr under a stream of nitrogen. Methyl esters of fatty acids were separated on a Supelcowax 10 wide-bore capillary column, using prepurified helium at 12 ml/min as the carrier gas. A 5790A Hewlett-Packard gas chromatograph was used with an injection temperature of 210°C. The GC was interfaced with a 3390A Hewlett-Packard integrator. Fatty acids were identified with a combination of PUFA 1 and PUFA 2 standards (Supelco, Bellefonte, PA) and #68A standard, along with 18:3, 24:0 and 24:1 (NuChek Prep., Elysian, MN). All reagents were high-pressure liquid chromatography (HPLC)-grade (Fisher, Cincinnati, OH).

Glomerular eicosanoids. Five rats in each group were selected randomly for this assay. Kidneys were perfused in vivo with Earls Balanced Salt Solution (EBSS) and heparin (2 U/ml). Glomeruli were isolated using a previously reported sieving technique (5); microscopically, they were at least 80% pure and about 95% decapsulated. Glomeruli were incubated in a total volume of 0.5 ml in EBSS, containing 0.1% bovine serum albumin (BSA) (Fraction V, Sigma, St. Louis, MO), pH 7.4, at 37°C for 1 hr. Samples were then centrifuged immediately, and supernatants saved for eicosanoid radioimmunoassay (RIA) (6). Glomerular pellets were saved for protein determination by the Lowry method (7) after solubilization in 1 M NaOH. For RIA, tritiated eicosanoids and scintillation cocktails were purchased from New England Nuclear (Boston, MA), and standards and antibodies were obtained from Seragen, Inc. (Boston, MA). The smallest detectable doses of eicosanoid standard on the linear portion of the standard curves wre 4.7 pg for PGE, 12.0 pg for 6-keto-$PGF_{1\alpha}$ and 5.2 pg for TXB_2. Nonspecific binding was always less than 3.0%. Intra- and interassay coefficients of variation were 2.7% and 5.5%, respectively, for all assays.

Aortic 6-keto-$PGF_{1\alpha}$ production was measured in the incubation media by RIA after segments of aorta were incubated in EBSS and 0.1% BSA (pH 7.4) at 37°C for 1 hr in a total volume of 1.0 ml. Tissue was air-dried and weighed, and the results wre expressed as ng/mg tissue.

Platelet TXA_2 production was measured after clotting whole blood at 37°C for 30 min with subsequent centrifugation. TXB_2, the stable metabolite of TXA_2, was measured in serum by RIA.

Plasma lipids. HDL cholesterol was measured after precipitation with dextran sulfate-magnesium chloride (Abbott, South Pasadena, CA). Plasma triglycerides, HDL and total cholesterol were measured by enzymatic methods on an ABA100 Bichromatic Analyzer (Abbott Labs.).

Urinary protein was measured using the Bradford reagent (Bio Rad, Rockville Center, NY) and plasma creatinine was determined colorimetrically using the Jaffe reaction.

Light microscopy. Kidney tissue was fixed in Mossman's solution, stained with periodic acid-Schiff (PAS), and coded sections were examined "blinded." In each rat, between 50 and 250 glomeruli were studied. In the glomeruli, particular attention was paid to enlargement with endocapillary swelling, to hyalinosis (capillary protein insulation) and to segmental and global sclerosis. The number of glomeruli with each abnormality was counted, and the results expressed as percentages of total glomeruli studied. The tubular changes evaluated semiquantitatively (0–4+) were dilatation, intraluminal protein, protein reabsorption droplets and nephrocalcinosis.

Statistics. The Kolmogorov-Smirnov test was applied to groups of data to assess whether they were normally or log-normally distributed. For log-normally distributed data, statistical analysis was performed in logarithmically transformed values. Comparisons among groups were tested by one-way ANOVA. Differences between individual groups were established by the Duncan's test.

RESULTS

Weight, blood pressure and renal function (Table 2). In spite of pair-feeding, there were some differences in weight. The lowest weight was in the BT group; weights were significantly higher in each of the FO and EPO, but not in the EPO:FO groups. The mean blood pressures of rats in all groups were normal and did not differ among groups. All rats had nephrotic range proteinuria, with no differences among groups. Mean plasma creatinine in the oil mixture group (EPO:FO) was significantly lower than that of the BT group; but, that of rats in groups fed either FO alone or EPO alone were not different.

Plasma lipids. The results of plasma triglycerides, total cholesterol and HDL cholesterol are shown in Table 3. In the FO, EPO and EPO:FO groups, plasma triglycerides were reduced equally to ca. 50% of that of the BT group. Total cholesterol was reduced by 47% and 20% in the FO and EPO:FO groups, respectively, when compared with BT animals. No difference was observed in the EPO group. Compared with the BT group, HDL levels were significantly increased in the EPO:FO group, but not in the FO or EPO groups.

Fatty acids in kidney phospholipids. The kidney phospholipid fatty acid composition was clearly different in each dietary group (Table 4). The most striking change was in 18:2n-6, which was increased in the FO group, and greatly increased in EPO and EPO:FO groups. There was a marked reduction of 20:4n-6 in the FO group, and a significant but less marked reduction in the EPO:FO group. There was significant incorporation of 20:5n-3 and 22:6n-3 into the FO group. In the EPO:FO group, 22:6n-3 was significantly incorporated, but only small amounts of 20:5n-3 were detectable in 5 of 9 rats. In the groups fed the diets containing EPO, only very small amounts (<1%) of 18:3 n-6 and 20:3 n-6 were detected, indicating a poor incorporation of gammalinolenic acid, although the incorporation of linoleic acid was good.

Eicosanoid production (Table 5). In isolated glomeruli from rats in the FO group, there was a very significant reduction of PGE, 6-keto-$PGF_{1\alpha}$ and TXB_2 production. There was a less marked reduction in these eicosanoids in the EPO:FO group. In the EPO group, TXB_2 production was reduced to about 50% of the BT values.

In aorta, there was a marked reduction in 6-keto-$PGF_{1\alpha}$ production in the FO group, when compared with

[c] $p < 0.05$ vs EPO.

all other groups. In the EPO:FO group, 6-keto-$PGF_{1\alpha}$ production was not significantly different than that of the BT group, although it was lower than that of the EPO group.

Platelet TXB_2 production was significantly lower only in rats in the FO group compared with all other groups. No significant difference was found among EPO, EPO:FO and BT groups.

Light microscopy. There were minor to moderate tubular changes of dilatation and intraluminal protein, but no differences were found among groups. No glomerular alterations were observed in any of the rats.

DISCUSSION

The primary purpose of this experiment was to study the value, compared with saturated fat, of dietary n-6, n-3 PUFA and a mixture of both, on various lipid classes in rat plasma, kidney, aorta and platelets. We hoped that the combination of n-6 and n-3 would eliminate the disadvantages of n-3 PUFA, but preserve the beneficial effects. The dose of adriamycin used induced a slowly progressive renal disease permitting assessment of early lipid changes. In previous experiments (1,2), a dose of 7.5 mg/kg adriamycin induced a very severe nephrotic syndrome, with renal failure, marked renal histologic abnormalities and extreme increases in plasma cholesterol and triglycerides. Adriamycin given at 3 mg/kg induced a fully developed nephrotic syndrome, but renal function and histology were largely preserved and the elevations of plasma lipids were not as marked. This may also explain why, in the present experiment, the diets containing FO did not have an effect on plasma creatinine, because the BT group had a mildly elevated creatinine (0.76 mg/dl), and in our previous report using the adriamycin dose of 7.5 mg/kg, the mean plasma creatinine of the BT group was 0.98 mg/dl (2). Differences in renal function and blood pressure among dietary groups were not anticipated and were not found. We did see a significant decrease in plasma creatinine in the EPO:FO group, suggesting that the combination diet may best preserve renal function, compared with the FO and EPO diets, even at an early stage. The differences in creatinine cannot be explained by differences in weight (Table 2). A long-term experiment with serial measurement of renal function would help to clarify the potential importance of these differences in plasma creatinine. The FO and EPO groups had significantly higher weights than the BT group, in spite of the pair-feedings. The possible influence of these differences on the variables studied is unknown.

The combination of EPO and FO (75:25) lowered plasma triglycerides by 50%, compared with the BT group, and was not different from that of FO or EPO alone. n-6 PUFA have been reported to have beneficial effects on the hypertriglyceridemia of patients with Type IIb hyperlipidemia (8) and patients with chronic renal failure (9). n-3 PUFA feedings reduce plasma total triglycerides, low and very low density lipoprotein (LDL and VLDL) levels in normal (10) and hyperlipidemic patients (8). In normal rats, fish oil reduces plasma triglycerides, but not cholesterol (11); in nephrotic rats (1), fish oil reduces serum triglycerides, total cholesterol and LDL cholesterol. Many investigators attribute the hypolipidemic effect of fish oil in humans to reduction of VLDL triacylglycerol (12), and VLDL apoprotein-B synthesis in the liver (13), leading to a reduction in LDL formation.

The combination of EPO and FO significantly lowered plasma total cholesterol, although not as markedly as FO. Unexpectedly, EPO alone did not have a significant effect on total cholesterol, although the hypocholesterolemic effect of n-6 PUFA has been reported in some human studies (10,12). The rise in HDL in the EPO:FO group was unexpected in view of the lack of effect observed in the FO and EPO groups. In humans with Type

II hyperlipidemia, those who were fed vegetable oil rich in n-6 PUFA had a small but significant increase in plasma HDL (8). The HDL:cholesterol ratio increased in chronic renal failure patients during n-6 PUFA feeding (9). Literature on the effects of fish oil on HDL levels report variable results. The depression of plasma-HDL levels by a fish-oil diet has been documented in humans (8,12,13) and monkeys (14), although others report no change in humans (10,15) or rats (1). Conversely, other investigators report an increase in HDL in patients with chronic renal failure who were fed a fish oil diet with a higher HDL_2:HDL_3 ratio (16). In a study of patients having angina, hyperlipidemia or previous myocardial infarctions (17) and chronic ambulatory peritoneal dialysis patients (18), those fed fish oil showed increased HDL_2 and total HDL. Because HDL is thought to be protective against atherosclerosis, the effect on HDL by the EPO:FO combination is potentially important. A more detailed study of the lipoprotein classes and apoprotein levels is clearly indicated.

There was good incorporation of most of the dietary PUFA into kidney phospholipids. Compared with the BT group, 18:2n-6 levels increased in all three diets, but were the highest in the EPO:FO group. In the groups fed the diets containing EPO, the incorporation of 18:3n-6 was very small, suggesting that the biological effects of the EPO were due mainly to its very high content of 18:2n-6. 20:5n-3 and 22:6n-3 were increased and 20:4n-6 was reduced in the FO and EPO:FO groups, compared with the BT and EPO groups. Our data are in agreement with studies in normal rats (20) and also exemplify the interaction of various PUFA modifying their rates of desaturation, chain elongation and esterification (21) in phospholipids and neutral lipids. What the contributions of n-3 and n-6 PUFAs to this model are speculative. PUFA substitution in phospholipids presumably would have a direct effect on cell membrane fluidity and lipoprotein structure. These may, in turn, affect receptor response to lipoproteins and prostaglandin synthesis upon stimulation.

A potentially beneficial effect of the combination diet was the preservation of aortic synthesis of PGI_2. The FO diet markedly inhibited PGI_2, yet the EPO:FO and EPO diets maintained PGI_2 at levels not significantly different than those of the BT group. The eicosanoid data in isolated glomeruli showed decreased levels of TXB_2 in EPO, FO and EPO:FO groups, and decreased levels of 6-keto-$PGF_{1\alpha}$ and PGE in the FO and EPO:FO groups. Both aortic 6-keto-$PGF_{1\alpha}$ and platelet TXB_2 levels in the rats fed the EPO:FO diet were ca. 70% of those from rats fed EPO, suggesting that FO added to the diet suppresses the synthesis of PG and TX to the same extent. The magnitude of the suppression probably depends on the relative amounts of n-3 and n-6 PUFA in the diets. It would be desirable to formulate a diet that preserves the vasodilatory effects of PGE and PGI_2, while decreasing the vasoconstriction and platelet aggregatory effects of TXA_2. In the nephrotic rat, we believe that a combination of EPO:FO may contribute to preservation of renal function. We have previously reported the protective effects of PUFA on the progression of renal disease in the rat with nephrotic syndrome induced by adriamycin 7.5 mg/kg (1,2) and in other nonimmunologic models of renal disease (22,23). Glomerulosclerosis may be the result of similar pathogenic events to those that lead to atherosclerosis (24). In the model of chronic aminonucleoside nephrosis in the rat, glomerulosclerosis is accelerated by dietary cholesterol supplementation (25). The reduction of atherosclerotic risk factors could also prevent long-term renal deterioration. The combination of n-6 and n-3 PUFA needs to be tested further in models with progressive chronic renal disease.

[Received March 3, 1988; Revision accepted July 26, 1988]

The Composition of Red Cell Membrane Phospholipids in Canadian Inuit Consuming a Diet High in Marine Mammals

Sheila M. Innis[a,*], **Harriet V. Kuhnlein**[b] and **David Kinloch**[c]

[a]Department of Paediatrics, University of British Columbia, Vancouver; [b]MacDonald College, McGill University, Montreal; [c]Medical Services Branch, Health and Welfare Canada, Yellowknife, N.W.T., Canada

A study of the fatty acid composition of red cell phosphatidylcholine and phosphatidylethanolamine and serum cholesterol was undertaken in 185 Canadian Inuit (age 2 months–82 years). Samples from 24 Canadian men and women (21–50 years) living in Vancouver were also analyzed as a reference for the Inuit in this age range. Dietary survey of the Inuit community (325 Inuit) demonstrated a diet based on traditional foods in which the principal source of n-3 fatty acid was marine mammal flesh (mean intake: 164 g/person/day) rather than fish (mean intake: 13 g/person/day). Compared to the Vancouver samples, the Inuit phosphatidylethanolamine had higher 20:5n-3 and 22:6n-3 and lower 20:4n-6, but similar 18:2n-6 levels. The level of 20:5n-3 was higher and 20:4n-6 was lower in the Inuit than in the Vancouver red cell phosphatidylcholine. Despite these differences in percentage content of C20 and C22 n-6 and n-3 fatty acids, the mean chain length and unsaturation index of the Inuit and Vancouver red cell phosphatidylcholine and phosphatidylethanolamine were very similar. Serum cholesterol concentration showed no sex difference within the Inuit, and no difference from Vancouver men and women of similar age. The analyses suggest that the fatty acid composition of the Inuit red cell phospholipids are primarily a reflection of their diet-fat composition.

***Lipids 23,* 1064–1068 (1988).**

Considerable interest has been focused on the n-3 fatty acids, eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3), since the studies by Bang et al. showed a relationship in Greenland Eskimo between a high dietary intake of n-3 fatty acids and a disease pattern characterized by a particularly low incidence of ischemic heart disease (1–5). Clinical studies utilizing fish-oil concentrates, or addition of fatty fish to Western diets, have since suggested that the beneficial effect of n-3 fatty acids may involve several mechanisms including altered platelet function and platelet and vessel wall eicosanoid biosynthesis (6–8), as well as increased red cell deformability and reduced blood viscosity related to the incorporation of dietary C20 and C22 n-3 fatty acids into the red cell membrane (9–11). Despite these biochemical changes in trials with fish oils, the efficacy of dietary fish in reducing mortality from ischemic heart disease is uncertain as both a reduction (12,13) and no reduction (14–16) in disease incidence has been reported in free-living populations consuming fish-rich diets.

During the early 1970s, the major portion of the fat in the Eskimo diet was from marine mammals, rather than from fish (2,4). Although marine mammal fat contains high levels of n-3 fatty acids, the relative quantities of 20:5n-3, 22:5n-3 and 22:6n-3 (17) differ from that in fish (18,19). Further, the preferential acylation of n-3 fatty acids to the glycerol *sn*-2 position in fish rather than to *sn*-1 and *sn*-3 in the triacylglycerols of marine mammals has recently been emphasized, and may be expected to lead to potentially important differences in absorption and metabolism of n-3 fatty acids from these two diet lipid sources (20).

In September 1985, a dietary survey with collection of blood samples, for serum assays not related to fatty acids, was conducted in the Canadian Arctic community of Broughton Island, Northwest Territories. This island, which lies off the East coast of Baffin Island, has ca. 400 residents and was selected for study because previous hunting and fishing surveys indicated a high-potential per capita consumption of native foods, marine foods are abundantly available and the high cost of air transportation continues to be a barrier to the extensive use of other foods. Red cell fatty acids are known to reflect diet fat composition (21,22) and, through modulation of membrane properties, may contribute to the low incidence of ischemic heart disease (9–11) in Eskimo (1,3). Thus, the opportunity was taken to analyze the fatty acid composition of red cell phospholipids (PL) of Broughton Island Inuit in order to document the composition of these cell membranes in a population that continues to consume a largely traditional diet high in marine mammals.

METHODS

Dietary surveys were conducted by direct interview in the native language (Inuktitut) to collect data on patterns of traditional food usage and quantitative food intake data for each household. A summary of the per capita intake of native foods for 325 Inuit who participated in the diet survey is given in Table 1. Further details on the survey are not part of this report, but can be obtained from author HK. The fatty acid composition of marine mammals caught by the Inuit hunters during the survey has been reported (17).

Blood sampling. A venous blood sample was drawn into Venoject (Terume Med. Corp., Elkton, MD) serum separation tubes. The tubes were centrifuged and all but 100–200 μl serum removed for other analyses. The tubes containing the red cell pellet were immediately frozen and shipped to Vancouver where they were transferred to storage at −80°C until analyzed. Samples from 185 Inuit were received and grouped by age and sex for subjects over 11 yrs; children of both sexes were grouped together, 0–5 or 6–10 yrs (Table 2). For comparative purposes, blood samples from 12 men and 12 women consuming a mixed diet and working in the Research Centre in Vancouver were drawn, stored and processed to resemble the handling of the Inuit samples as closely as practically possible.

Red blood cell and plasma cholesterol analyses. Immediately upon removal from frozen storage, the glass tubes containing the red cells were broken and 1 cm^2 of cells was sliced from the bottom of each pellet. The cells were lysed (21), the membranes pelleted, washed three times and the lipids extracted (22,23). The PL were separated from other lipid classes (24), then further resolved into their individual PL classes (25) by thin layer chromatography (TLC) identified on the basis of R_f by cochromatography of known standards. The bands corresponding to phosphatidylcholine (PC) and phosphatidylethanolamine (PE) were recovered, the fatty acid components converted to their respective methyl esters with methanolic HCl and analyzed by capillary-column gas liquid chromatography (GLC). Details of the GLC and data handling have been reported earlier (17). The unsaturation index (UI) and mean chain length of the fatty acids were calculated as described previously (24).

Total cholesterol was assayed in 10 μl of serum using an enzymatic kit (Biopacific diagnostics Inc., North Vancouver, British Columbia).

RESULTS AND DISCUSSION

The dietary survey conducted during September 1985 confirmed a high intake of traditional foods by the Broughton Island Inuit. The average intake of fish (char) was ca. 13 g, but the intake of total marine mammal tissue was ca. 164 g per person per day (Table 1). The extensive use of marine mammals in the diet of these Inuit is similar to the higher intake of seal and whale (higher than fish) by the Greenland Eskimo during the Spring of 1970 (2,4).

The fatty acid composition of PE and PC from the Inuit and Vancouver PE and PC is shown in Tables 3 and 4, respectively. The Vancouver reference data is similar to previous reports for apparently healthy adults consuming mixed Western diets (26,27). The data for the Inuit red cells demonstrate the incorporation of dietary C20 and C22 n-3 fatty acids in all age groups into the membrane PE and PC, and the higher level of these fatty acids in PE than PC. No differences were found in the composition of PE between male and female Inuit (Table 3); PC was also similar between the sexes, except for a higher 20:0 in the 11-15 yr old girls than in the boys (Table 4).

When compared with Vancouver residents of similar age (21-50 yrs), the Inuit had a higher n-3 series 18:3, 18:4, 20:5 and 22:6, and a lower n-6 series 20:4, 22:4 and 22:5 in the red cell PE (Table 3). The most pronounced difference in the n-6 series was in 22:4n-6; the level in the Inuit was ca. 27% of the amount in the Vancouver samples. The total C20 plus C22 n-6 and n-3 fatty acids were lower and higher, respectively in the Inuit; however, the UI and the mean chain length remained similar to the Vancouver samples.

The analyses of PC from the Inuit males showed lower n-6 series 20:3 and 22:5 and higher n-3 series 18:3, 18:4, 20:5 and 22:6 than in Vancouver males (Table 4). The Inuit females had lower n-6 series 18:2 and 20:3 and higher n-3 series 18:3, 18:4 and 20:5 than their Vancouver counterparts. The apparently higher 22:6n-3 in Inuit is explained by the low 22:6n-3 in the Vancouver group. The reason for this is unknown. The total C20 and C22 n-6 and n-3 fatty acids, UI and mean chain length of PC was similar between the Inuit and Vancouver groups, except for a higher C20 plus C22 n-3 series in the Inuit males. The latter was also due to the low 22:6n-3 in the Vancouver men.

The levels of 20:5n-3 and 22:6n-3 in the Inuit PE in this study are higher than those found following supplementation with fish oil concentrates, e.g., containing ca. 19%, 3%, 12% or 31%, 6% and 19% 20:5n-3, 22:5n-3, 22:6n-3, respectively (9,11). The seal and whale caught by the Inuit during the study contained 9-12%, 20:5n-3, 5-6% 22:5n-3, 9-10% 22:6n-3 (17), indicating that, like human red cell PL (26,27, Tables 3 and 4), these mammals contain less 20:5n-3, particularly when related to the content of 22:5n-3 and 22:6n-3, than fish (18,19). The effect of these differences in fatty acid composition, and in the triglyceride structure between mammals and fish (20), on tissue fatty acid composition has not been studied.

TABLE 5

Serum Cholesterol Levels

Age yrs	Inuit Male (mg/dl	Inuit Female mg/dl	Vancouver Male mg/dl	Vancouver Female mg/dl
0-5	118 ± 8			
6-10	147 ± 11			
11-15	161 ± 12	148 ± 20		
16-20	177 ± 17	174 ± 15		
21-50	180 ± 42	183 ± 25	197 ± 22	185 ± 15
>50	184 ± 43	201 ± 28		

Data are given as means ± SE by age and sex for Inuit and Vancouver residents (Table 2). No statistically significant ($p \leq 0.05$) differences were found between male and female Inuit or Inuit and Vancouver residents in a similar age group.

The plasma PL of Greenland Eskimo has been reported to contain greatly decreased levels of 18:2n-6 and increased 20:5n-3 and 22:6n-3 compared with Eskimo living in Denmark (5). Similar analyses of Japanese who consumed diets high in fish found levels of 20:5n-3 ca. 2-fold higher, and 22:6n-3 ca. 2-fold lower, than in Greenland Eskimo (28). These differences between the Eskimo and Japanese may reflect, at least in part, their dietary n-3 fatty acid sources. Important differences have been shown in plasma PL n-6 and n-3 series fatty acids between Eskimo living in Denmark and Danes (5), Japanese and North Americans (28) and West Coast Canadian Indians and Europeans and North Americans (29), and may suggest that important racial variations exist in essential fatty acid metabolism (29,30). In the Broughton Island Inuit, red cell 20:4n-6 was reduced in PE; however, the level of this fatty acid in PC, and of 18:2n-6 in male and female PE and male PC was similar to the Vancouver reference group. Thus, diet rather than racial differences in fatty acid metabolism, appears to be the major determinant of red cell composition in the Canadian Inuit.

The serum cholesterol analyses found no difference in the Inuit due to sex, and no difference from Vancouver residents of similar age (Table 5). Values for the Inuit serum cholesterol concentrations are lower than in previous studies of Alaskan Eskimo adults (31) and Eskimo adults and children (32). The latter study also noted no difference between Eskimo males and females.

[Received April 4, 1988; Revision accepted August 17, 1988]

Formation of Fluorescent Substances From Degradation Products of Methyl Linoleate Hydroperoxides With Amino Compound

Toshihiro Iio and Kazuaki Yoden*
Showa College of Pharmaceutical Sciences, 1-8, Tsurumaki 5-chome, Setagaya-ku, Tokyo, Japan

The degradation products formed from methyl linoleate hydroperoxides by reaction with heme were fractionated by Sephadex LH-20 column chromatography and by reverse-phase high performance liquid chromatography, and the ability of each compound to form fluorescent substances through reaction with amino compound was compared. Maximum formation of fluorescent substances was obtained from monomeric degradation products with amino compound, but low molecular weight aldehydes such as hexanal, 2-hexenal and 2,4-decadienal, formed only a small amount of fluorescent substances. However, the major monomeric degradation products described previously, the hydroxy-, keto- and epoxy-derivatives, do not significantly contribute to the formation of fluorescent substances through reaction with amino compound. It was suggested that formation of fluorescent substances from lipid peroxides with amino compound may originate from a precursor present in monomeric degradation products formed from hydroperoxide of methyl linoleate during lipid peroxidation, and that low molecular weight aliphatic aldehydes are not involved in fluorescent substance formation. Moreover, the majority of TBA-reactive substances in secondary oxidation products prepared from autoxidized methyl linoleate are also unrelated to the formation of fluorescent substances through reaction with amino compound.
Lipids 23, 1069–1072 (1988).

Lipid peroxides of polyunsaturated fatty acids (PUFA) play an important role in the formation of fluorescent lipofuscin pigments, which are associated with aging in animal tissues. Reviews on the formation and characterization of fluorescent lipofuscin pigments in vivo or in vitro have been reported recently by Kikugawa (1) and Tsuchida et al. (2).

The degradation products of methyl linoleate (ML)-hydroperoxide (HPO) produce fluorescent substances (FS) with spectra similar to lipofuscin pigments, exhibiting excitation and emission maxima at 320–360 nm and 410–430 nm upon reaction with glycine or DNA (3,4). We have also reported that both 9- and 13-positional ML-HPO produce FS having the same fluorescence spectra upon reaction with 1-aminopentane (1-AP) as a model amino compound in the presence of heme (5). The degradation of PUFA-HPO by catalysis of heme compounds, metals or ascorbic acid leads to the production of very complicated compounds, including monomeric hydroxy-, keto- or epoxy-derivatives (6–9) and low molecular weight aldehydes such as alkanals, 2-alkenals, 2,4-alkadienals or malondialdehyde (10,11). It is well known that these low molecular weight aldehydes form FS by reaction with various amino compounds (12–16). However, Frankel et al. have recently reported that methyl linolenate HPO is readily decomposed thermally at 150°C and catalytically with ferric chloride-ascorbic acid at room temperature, producing dimeric or monomeric compounds and volatile compounds including low molecular weight monoaldehydes (17). Also, monomeric compounds were shown to exhibit marked formation of FS through reaction with DNA (18). We recently reported that secondary oxidation products (SP) prepared from autoxidized ML, which is a complex mixture of various oxidized products converted from ML-HPO, also produce similar FS directly through reaction with 1-AP (19).

These results suggest that oxidative degradation of PUFA-HPO is necessary for formation of FS through reaction with various amino compounds. However, the direct precursor available for formation of FS has not yet been determined from among the many kinds of degradation products of PUFA-HPO. In this study, therefore, the degradation products formed from ML-HPO by reaction with heme were fractionated by Sephadex LH-20 column chromatography and by reverse-phase high performance liquid chroamtography (HPLC). The results obtained regarding the characterization of the precursor available for formation of FS through reaction with amino compound are discussed.

MATERIALS AND METHODS

Materials. Linoleic acid, dilinolein, hemin and soybean lipoxygenase were purchased from Sigma Chemical Co. (St. Louis, MO). 1-AP, ML and hexanal were purchased from Tokyo Kasei Kogyo Co., Ltd. (Tokyo, Japan). 2-Hexenal and 2,4-decadienal were obtained from Aldrich Chemical Co. (St. Louis, MO). Heme methyl ester (heme) was prepared by the method of Ortiz de Montellano et al. (20).

Preparation of HPO and SP from ML. ML (3.0 g) was autoxidized by stirring at 30°C for 5 or 14 days by methods described previously (19). ML-HPO reached a maximum at 4–5 days and was prepared by silica gel column chromatography (2 × 40 cm, Wako gel C-200, Wako Pure Chemical Industries Ltd., Osaka, Japan) with hexane/ethyl ether (7:3) according to the method of Terao and Matsushita (21). Crude SP, including the precursor available for formation of FS, was also prepared from ML autoxidized for 14 days by the same method as that described above (19). [1-^{14}C]ML-HPO was prepared from [1-^{14}C]linoleic acid (New England Nuclear, Boston, MA) by autoxidation. Each HPO was estimated using a molar absorbance value of 24,500 at 233 nm (22).

Fractionation of degradation products of ML-HPO or crude SP. ML-HPO (100 μmol) was incubated with or without heme (1 μmol) in 100 ml of methanol at 37°C for 30 min. The degradation products were subjected to Sephadex LH-20 column chromatography (1 × 40 cm,

Abbreviations: HPO, hydroperoxide; ML, methyl linoleate; 1-AP, 1-aminopentane; TBA, thiobarbituric acid; HPLC, high performance liquid chromatography; FS, fluorescent substance; GC, gas chromatography; MS, mass spectrm or spectrometry; PUFA, polyunsaturated fatty acids; SP, secondary oxidation products.

Pharmacia Fine Chemicals, Uppsala, Sweden) according to the method of Kanazawa et al. (23) and were eluted with ethanol. Two-ml fractions were collected and monitored at 233 nm and 278 nm. Crude SP (50 mg) was also subjected to the same column chromatography and the effluents were monitored by measuring the thiobarbituric acid (TBA) values. The degradation products from labeled or nonlabeled ML-HPO were also subjected to reverse-phase HPLC on a μ-Bondapak FAA (3.9 × 300 mm, Waters Associates, Milford, MA) using acetonitrile/methanol/water (20:45:55) for the first 30 min followed by methanol as the mobile phases at a flow rate of 1.0 ml/min. The effluents were monitored by absorbance at 254 nm and by ^{14}C radioactivity. Each fraction was collected and the components extracted with chloroform/methanol (2:1) were used for formation of FS and structural analysis. The electron ionization mass spectrum (MS) was measured with a JEOL-D300 mass spectrophotometer using a 30-eV ionization voltage. Gas liquid chromatography was carried out using a glass column packed with 5% silicon SE-52 on celite 545 SK DMCS (Gasukuro Kogyo Inc., Tokyo) at a column temperature of 250°C. The UV absorption spectra were measured with a Hitachi 200-10 spectrophotometer.

Formation of fluorescent substances. ML-HPO (1 μmol) preincubated with or without heme (10 nmol) was incubated with 1-AP (2 μmol) in 3 ml of methanol at 37°C for 20 hr. Hexanal, 2-hexenal or 2,4-decadienal was also incubated with 1-AP in 3 ml of methanol at 37°C for 20 hr. Formation of FS from ML-HPO or these aldehydes with 1-AP was observed to be marked under these conditions. The degradation products in each fraction from HPLC were also incubated with 1-AP under the above conditions. Fluorescence spectra were measured with a Hitachi MPF-3 fluorescence spectrophotometer and fluorescence intensities were expressed as a percentage of that of a quinine sulfate standard (0.1 μg/ml of 0.1 N H_2SO_4). HPLC was carried out on a μ-Bondapak FAA (3.9 × 300 mm, Waters) preceded by a packed guard column (4 × 50 mm, Unisil C_{18}, 10 μm, Gasukuro Kogyo Inc.) with tetrahydrofuran/acetonitrile/water (15:45:50) at a flow rate of 1.0 ml/min. An aliquot of each FS was subjected to the same HPLC conditions and was monitored at excitation and emission maxima of 350 nm and 420 nm with an Hitachi 650-10LC fluorescence spectrophotometer.

RESULTS AND DISCUSSION

ML-HPO produced FS by reaction with 1-AP in the presence of heme, and the same two major fluorescence peaks (FS-I and FS-II) were eluted on reverse-phase HPLC as those formed from SP with 1-AP (5). The degradation products formed from ML-HPO by reaction with heme were fractionated by Sephadex LH-20 column chromatography and then the ability to form FS through reaction with 1-AP in each fraction was studied. The absorption peaks monitored at 233 nm and 278 nm, respectively, were detected in nearly the same fraction, 12–15, but maximum formation of fluorescent substances was obtained from Fr. 9–13. Based on the report by Kanazawa et al. (23), Fr. 9–13 contains mainly polymer- and endoperoxide-rich components, and Fr. 14–18 contains low molecular weight components. Marker compounds, 2-hexenal, 2,4-decadienal, ML-HPO and dilinolein (molecular weight: 617) were eluted at the positions shown by arrows in Figure 1. Oarada et al. (24) separated autoxidized ML by gel chromatography on Bio Beads S-X3 into polymeric, monomeric and low molecular weight compounds. In our study, the elution profiles of the degradation products produced from ML-HPO showed that the precursor available for formation of FS is contained in Fr. 9–13 (Fig. 1) and that it is one of the monomeric degradation products rather than a low molecular weight compound.

When the degradation products produced from [1-^{14}C]ML-HPO by reaction with heme were subjected to reverse-phase HPLC, seven radioactive peaks were detected (Fig. 2). From the UV spectral analysis and gas chromatography–mass spectrometry (GC–MS) fragmentations of the major degradation products described in a previous report (5), the structures produced from 13-HPO of ML were found to be methyl 9-hydroxy-12,13-epoxylinoleate and methyl 11-hydroxy-12,13-epoxylinoleate (17.2%, Fr. II) having no UV absorption, methyl 9-keto-12,13-epoxylinoleate (13.4%, Fr. III), methyl 13-hydroxylinoleate (3.3%, Fr. IV), 13-HPO (9.7%, Fr. V) and methyl 13-ketolinoleate (4.6%; Fr. VI). Similarly, each fraction also contained the analogous derivatives produced from 9-HPO of ML. The major degradation products have been described previously by Hamberg (7) and Dix and Marnett (8). In this experiment, 2-hexenal and 2,4-decadienal as marker compounds were detected at fraction numbers 5 and 10, respectively. When the fractions (Fr. I–VII) detected by HPLC were compared for their ability to form FS by reaction with 1-AP, the most marked formation of FS-II was shown in Fr. VII. This

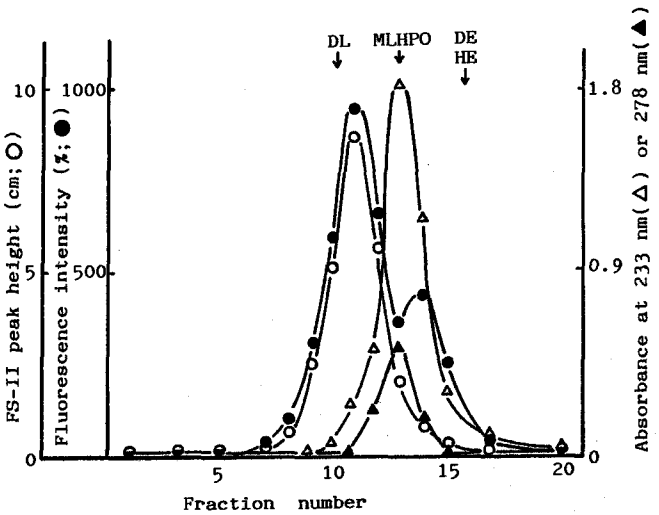

FIG. 1. Sephadex LH-20 column chromatography of the degradation products produced from ML-HPO by reaction with heme. The degradation products of ML-HPO were obtained from reaction of ML-HPO (100 μmol) with heme (1 μmol) at 37°C for 30 min. Sephadex LH-20 column chromatography was carried out according to the experimental method. The effluents were monitored at 233 nm (△) and 278 nm (▲). An aliquot of each fraction was incubated with 1-AP at 37°C for 20 hr and then total fluorescence intensity (●) and FS-II peak height (O) were measured as described in Materials and Methods. 2-Hexenal (HE), 2,4-decadienal (DE), ML-HPO and dilinolein (DL) as marker compounds were eluted at the positions shown by arrows.

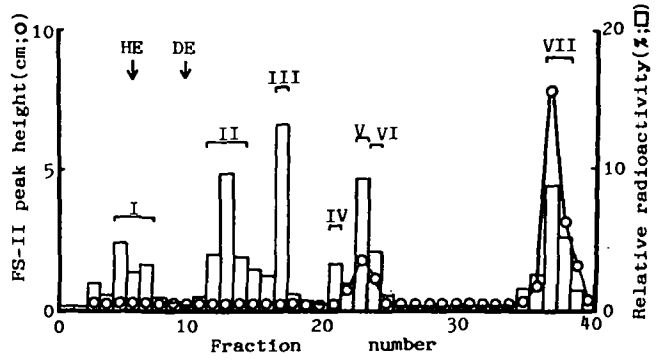

FIG. 2. HPLC of the degradation products produced from ML-HPO by reaction with heme. The degradation products from [1-^{14}C]ML-HPO by reaction with heme were subjected to reverse-phase HPLC. The effluents were monitored by radioactivity (□) and each fraction was incubated with 1-AP for formation of fluorescent substances. FS-II peak height (○) was measured by HPLC analysis as described in Materials and Methods. The structure of each component was identified by a combination of UV analysis and GC-MS fragmentation by the methods described in the previous report (5).

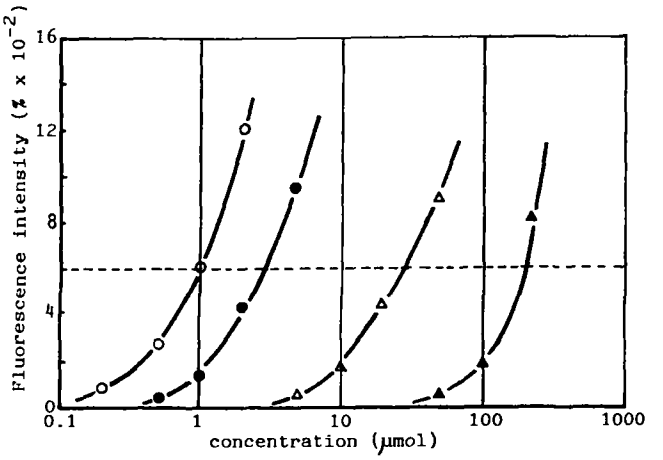

FIG. 3. Comparison of the ability for formation of fluorescent substances by ML-HPO and aldehydes through reaction with 1-AP. ML-HPO (○) was preincubated with heme and then incubated with 1-AP for formation of fluorescent substances in 3 ml of methanol at 37°C for 20 hr. 2,4-Decadienal (●), 2-hexenal (△) or hexanal (▲) also was incubated with 1-AP under the same conditions. Total fluorescence intensity and fluorescence spectrum of each reaction mixture were measured as described in Materials and Methods.

result suggests that the major monomeric degradation products, hydroxy-, keto- and epoxy-derivatives in Fr. II-VI, are not significantly related to the formation of FS through reaction with amino compound. Moreover, monofunctional aldehydes such as 2-hexenal and 2,4-decadienal also do not form FS. The direct precursor available for most of the formation of FS was included in Fr. VII. This fraction accounted for about 13.3% of the total degradation products produced from radioactive ML-HPO. We were unable to identify the components in Fr. I (10.8%) and VII (13.3%) in this study. Fukuzawa et al. (25) reported the formation of FS from 12-keto-oleic acid with amino acids in 0.1 M phosphate buffer (pH 7.4). In our study, methyl 13-keto-linoleate (Fr. VI) also formed a slight FS, but this compound was not the direct precursor for formation of FS. 11-Methoxy-12,13-epoxylinoleate was formed from ML-HPO by acid catalysis (26), but this compound also showed slight formation of FS (data not shown).

We next compared the ability to form FS through reaction with 1-AP between the degradation products of ML-HPO and aliphatic monofunctional aldehydes (Fig. 3). One μmol of ML-HPO showed marked fluorescence intensity (600%) with 1-AP in the presence of heme, but hexanal and 2-hexenal produced only very small amounts of FS at the same concentration. 2,4-Decadienal was more active than 2-hexenal and hexanal, but still less active than ML-HPO. 2,4-Decadienal, 2-hexenal and hexanal subsequently required 2.7-, 28.8- and 175-fold larger amounts, respectively, to obtain the same fluorescence intensity (600%) as that from ML-HPO (Table 1). Although it has been reported that monofunctional aliphatic aldehydes produce FS through reaction with various amino compounds at a high molar concentration (15,16), the amounts of these aldehydes derived from PUFA-HPO account for only a few percent of the degradation products formed from their HPO (17). These results indicate that the aliphatic aldehydes described in this study and the structurally related monomeric degradation products are not direct precursors available for formation of FS through reaction with amino compounds.

TABLE 1

Relationship Between Fluorescence Intensity Formed From ML-HPO or Aldehydes With 1-AP and Their Concentration

Compound	μmol	Fluorescence maxima (nm) Excitation	Emission	intensity (%)
ML-HPO	1.0	348	420	600.0
2,4-Decadienal	1.0	340	416	140.0
	2.7	346	422	600.0
2-Hexenal	1.0	—	—	ND
	28.8	344	408	600.0
Hexanal	1.0	—	—	ND
	175.0	366	442	600.0

ML-HPO was preincubated with heme and then incubated with 1-AP at 37°C for 20 hr. Each aldehyde also was incubated with 1-AP at 37°C for 20 hr.

ND, fluorescence not detected.

When SP prepared from autoxidized ML was subjected to the same Sephadex LH-20 column chromatography, a high TBA value was detected in Fr. 10–15. Therefore, each of the fractions was incubated with 1-AP at 37°C for 20 hr to form FS, and the total fluorescence intensity was observed in Fr. 8–14, whereas a major FS (FS-II) was detected in Fr. 8–10 (Fig. 4). This result suggests that the greater proportion of the TBA-reactive substances (Fr. 10–15) are not related to formation of major FS from SP with amino compound. We have also demonstrated that large amounts of TBA-reactive substances prepared from crude SP using a Sep-pak C_{18} cartridge were not related to the formation of FS (19). Similarly, when SP was subjected to the same reverse-phase HPLC, marked formation of FS-II was observed in Fr. VII eluted with methanol (data not shown). These results indicate that SP also contains a precursor available for the formation

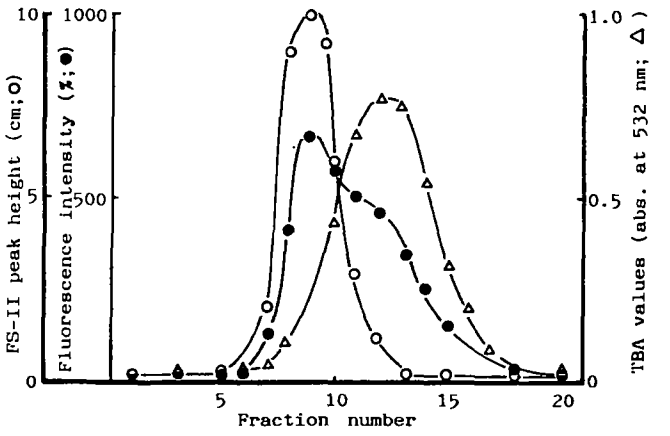

FIG. 4. Sephadex LH-20 column chromatography of SP. SP (50 mg) prepared from autoxidized ML was subjected to Sephadex LH-20 column chromatography. The effluents were monitored by measurement of TBA values (△) and an aliquot of each fraction was incubated with 1-AP for formation of fluorescent substances in 3 ml of methanol at 37°C for 20 hr. Total fluorescence intensity (●) and FS-II peak height (○) were measured using the same methods as described in Figure 1. Marker compounds were eluted at the same positions shown in Figure 1.

of FS through reaction with amino compound, similar to that from ML-HPO described above.

Each FS (FS-II) formed from SP or ML-HPO with 1-AP in methanol solution was shown to have an empirical formula $C_{24}H_{41}NO_4$, with a molecular weight of 407 (data not shown). The other characteristic fragmentation ions ($M^+ - 31$, $M^+ - 57$, $M^+ - 71$, $M^+ - 143$ and $M^+ - 157$) indicate the presence of a pentyl group and methyl octanoate in FS-II. This suggests that the direct precursor available for formation of FS may be a monomeric 19-carbon compound having a methyl ester group produced from ML without cleavage into low molecular weight compounds. We also demonstrated that HPO of 1-palmitoyl-2-linoleoyl-phosphatidylcholine and trilinolein produced FS through reaction with 1-AP after degradation by heme and that the FS (FS-II) was released from their fluorescent lipids after transmethylation (27). This result also suggests that the direct precursor available for formation of FS is a monomeric degradation product attached to a phosphatidylcholine glycerol backbone without breakdown into low molecular weight compounds.

PUFA are converted into very complicated oxidative degradation products, including dimeric or monomeric compounds and low molecular weight aldehydes during the peroxidation process (10,11). Malondialdehyde and aliphatic aldehydes are known to produce FS by reaction with amino compound (12–16). Moreover, Benedetti et al. (28) and Yoshioka and Kaneda (29) have reported that 4-hydroxy, 4,5-dihydroxy or 4-hydroperoxy alkenals show marked toxic effects on the enzyme activities of animal tissues. Esterbauer et al. have suggested the possible involvement of 4-hydroxynonenal in the formatio of fluorescent chromolipids (30). These reports suggest that various aldehydes may be related to the formation of FS through reaction with amino compound during the process of peroxidation. However, our present results strongly indicate that the direct precursor available for formation of FS from lipid peroxides with amino compound is a monomeric degradation product formed from PUFA-HPO rather than low molecular weight aliphatic aldehydes. Moreover, the major monomeric degradation products produced from 9- and 13-HPO of ML described previously (6–9) do not directly produce FS through reaction with amino compound. The identity of this direct precursor is now under investigation.

Predicting Coordinated Lipid Biosynthesis: Application to the Surfactant-accommodated Epidermis

Howard Y. Ando*, Gary G.G. Gazdick, Edwin T. Sugita and Roger L. Schnaare
Department of Pharmaceutics, Philadelphia College of Pharmacy and Science, Philadelphia, PA 19104

Factorialized correlation analysis is proposed as a method for predicting the coordination of multiple enzyme pathways. The approach can be used potentially to find new relationships and to predict relationships that have been established in other tissues. However, careful tracer studies are needed to verify the cause-and-effect relationships between precursor and products. In this study, guinea pigs that were chronically treated with an anionic, a nonionic and a cationic surfactant passed through an irritation stage to a clinical state that appeared normal. The method was used to examine binary coordination of lipid biosynthesis in the epidermis by using a factorialized table of regression coefficients. Coordinated lipid relationships that have been reported in other tissues were predicted between sphingomyelin and cholesterol, as well as between phosphatidylcholine, phosphatidylserine and phosphatidylethanolamine. A new inverse relationship was found between triglycerides and both sphingomyelin and cholesterol, using this method. These data are discussed with respect to a membrane fluidization model for the accommodated state.
Lipids 23, 1073–1078 (1988).

Mechanistic interpretations of biosynthetic coordination are often confounded by an abundance of analytical information. We propose that the degree of coordination between two different components can be estimated from correlation analysis. The only requirement is that reproducible conditions must be found for changing the components in the tissue so that at least three different levels are found for each component.

In this study, the lipid levels were changed in the epidermis of guinea pigs by treating the animals with three different surfactants until an accommodation response was found. An accommodation response is an increased local resistance to a primary irritant after a period of irritation. Repeated contact with the irritant is necessary to maintain this condition (1,2). The lipids in the accommodated epidermis were altered so that the surfactant-and-water-control treatments provided four different levels of each lipid for comparison. Correlation analysis was carried out between pairs of lipids with respect to the different treatments.

MATERIALS AND METHODS

Surfactants. Three different classes of surfactants were used in this study: anionic—sodium lauryl sulfate (Henkel Inc., Fort Lee, NJ), nonionic—laureth-1 (Lipo Chemicals Inc., Paterson, NJ) and cationic—laurtrimonium chloride (Henkel Inc.). The same alkyl chain was chosen so that any adaptive differences that might occur would be due to the surfactant head group.

Animals. Male Hartley guinea pigs, 250–300 g, were accommodated by treating them daily with an aqueous surfactant solution according to the method of Opdyke and Burnett (3). The adaptive concentration used for sodium lauryl sulfate (SLS) and laurtrimonium chloride (LTC) was 0.15%. A much higher concentration of 1.2% was necessary for laureth-1 (L-1). The water bath was maintained at 40°C as recommended. At this temperature, the animals are calm and tolerate the treatment well. Each animal was treated for 2 hr a day for 4–6 wk. After a treatment, the animals were thoroughly rinsed with warm tap water and toweled dry. At the time the animals were killed, they weighed 500–800 g.

Epidermal cell suspension. A modified version of the method of Stanley et al. (4) was used to obtain an epidermal cell suspension from abdominal and back skin. After 1-cm-wide strips of epidermis were separated from the dermis by trypsinization, the epidermis was placed in 10 ml of 0.9% saline with 0.005% soybean-trypsin inhibitor and vortexed for 5 min on a Vortex Geni. These cells were then filtered through a 500-μm nylon mesh and centrifuged at 200 × *g* for 20 min in a 35 ml round-bottom centrifuge tube fitted with a teflon-lined cap. The cell pellet was washed, centrifuged twice more and finally suspended in 1.6 ml of saline.

Lipid extraction. Extraction was carried out by the method of Bligh and Dyer (5) using their recommended volume ratios of chloroform, methanol and aqueous solution. The final chloroform layer was obtained from a 25-ml separatory funnel after the extract had been centrifuged at 200 *g* for 15 min to reduce the emulsified layer.

Lipid separation and quantitation. The chloroform extract was evaporated to dryness under a gentle stream of nitrogen and reconstituted to 100 μl. A 10-μl TLC syringe was then used to spot 1-μl aliquots onto Silica Gel G plates (250 μm × 20 cm × 20 cm) that had been previously predeveloped in solvent A (chloroform/methanol/glacial acetic acid/water, 25:15:4:1.9, v/v/v/v) and solvent B (hexane/diethyl ether/glacial acetic acid, 83:16:1, v/v/v) to reduce charring background. Plates were developed to 12 cm in solvent system A. After they were dried, they were developed to the top of the plate in solvent system B. The first solvent system separated phospholipids. The second separated neutral lipids. Commercially available lipids were used to construct standard curves and to provide an R_f comparison for native lipids. Chloroform stock solutions of lysophosphatidylcholine, sphingomyelin, phosphatidylcholine, phosphatidylserine, phosphatidylethanolamine, oleic acid, stearic acid, triolein, tripalmitin, tristearin, cholesteryl oleate, cholesteryl palmitate, cholesteryl stearate and cholesterol were used for these purposes.

Quantitation was carried out using the liquid scintillation counter to assay charred lipids (6). After the plates were sprayed with a 10% (w/v) cupric sulfate 8% (w/v)

orthophosphoric acid solution, they were placed in a forced-draft hot air oven for 30 min at 180°C. Charred lipid spots were scraped into 7-ml scintillation vials and vortexed in 800 μl of water to disperse the particles. Five ml of ScintiVerse II liquid scintillation cocktail (Fisher Scientific, Fair Lawn, NJ) was added, and the vial was then vortexed to achieve a uniform dispersion in the formed hydrogel. A brief centrifugation period was used to remove any bubbles. Samples were counted on a Packard Tri-Carb Model 3309 liquid scintillation spectrometer using the automatic external standard channels ratio number for quantitation (7–11).

Correlation analysis. If normal precursor-product relationships between different lipids occur independent of the stress placed on the epidermis, a linear regression analysis between different lipid pairs for the four different treatments (water, anionic, nonionic and cationic) should show a high degree of correlation. On the other hand, a poor correlation would indicate a lack of synchrony. For example, a linear regression was carried out between sphingomyelin and phosphatidylserine with respect to the four different treatments. The correlation coefficient, r, for this pair was +0.24, a poor positive correlation. This indicates that mutual changes between these two lipids did not occur in a highly synchronous manner. For perfect synchrony, a correlation coefficient of 1.0 is needed. Thus, an increase (or decrease) in sphingomyelin, for every treatment, is matched by an exact proportional increase (or decrease) in phosphatidylserine. It is this degree of linear proportionality between these changes that governs the strength of the correlation coefficient.

Negative correlations, on the other hand, occur when the treatments cause paired lipid changes to be inversely proportional to one another. For example, the correlation between sphingomyelin and triglycerides gave a correlation coefficient of −0.98. This means that increases (or decreases) in sphingomyelin occurred in synchrony with decreases (or increases) in triglycerides in a nearly exact inversely proportional manner.

RESULTS

Accommodative irritation. Initial studies showed that the degree of irritation caused by the nonionic surfactant L-1 was much less than either SLS or LTC, the anionic and cationic surfactants, respectively. By using a 1.2% solution of L-1, it was found that the degree and duration of irritation was visually equivalent to that caused by a 0.15% solution of SLS or LTC. During the irritation phase of the treatment, the skin turned red and started to crack after 2–3 days. This phase was followed by 2–3 days of dry and flaky skin. Finally, after 2 or 3 wk, the skin and fur appeared normal for all three surfactants.

Histologically, however, there were great differences. These are apparent in Figure 1. In comparison with a water-treated control, the SLS-accommodated skin appeared the most normal. A slight acanthosis and minor granular layer activity were apparent. In contrast, the nonionic- and cationic-accommodated skin was hyperplastic, the prickle-cell layer being 2–4 times as thick as the SLS-adapted skin. However, the hyperplasia, in all cases, showed no neoplastic changes because it was general and diffuse and not focal. An absence of mutagenesis of the tissue or cell-type transformation was apparent from a lack of irregular nuclei or large cells and from the presence of a regular orderly basal layer. A few mitotic figures and lymphocytes were present in the basal layer of the epidermis and in the dermis, respectively, of the L-1- and LTC-treated animals, indicating some residual inflammation. In addition, the dermis of these animals had sebaceous glands that were enlarged and engorged with cells.

Lipid quantitation. The thin layer chromatographic (TLC) system separated 4 polar lipids (phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine and sphingomyelin), as well as 2 neutral lipid groups (cholesteryl esters and triglycerides). The extract also resolved a lipid that was more polar than sphingomyelin. This lipid was presumed to be a lysophospholipid. The

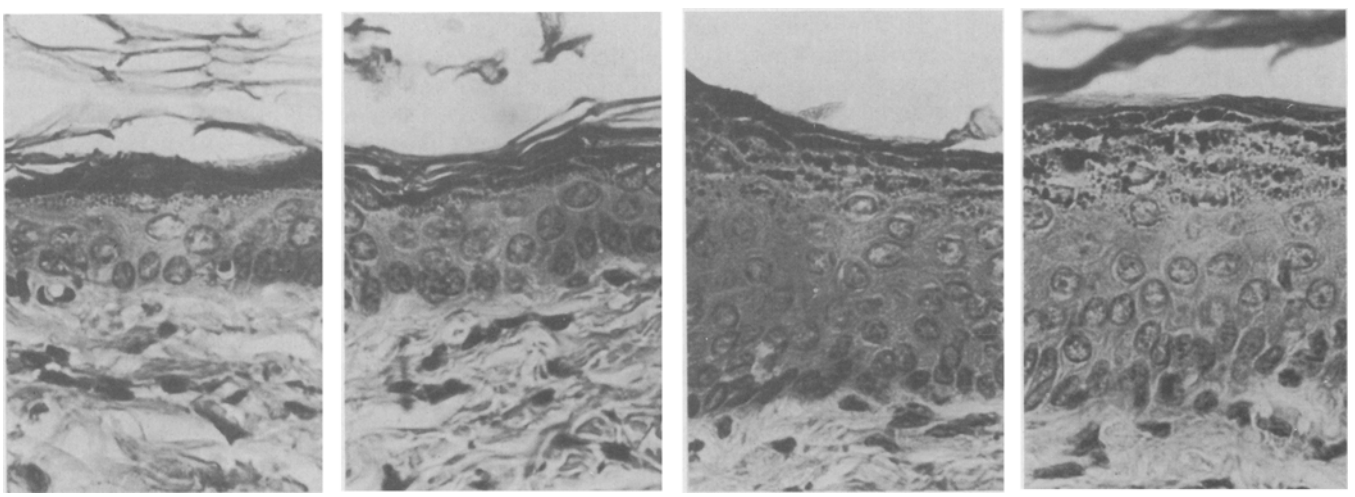

FIG. 1. Adapted epidermises of guinea pigs treated at 40°C for 4–6 weeks. A = water treatment, B = 0.15% sodium lauryl sulfate, C = laureth-1, and D = laurtrimonium chloride. H and E stain at 126× magnification.

ceramide spots were not quantified because they could not be separated from the glycosphingolipids.

The precision of the quantitation methodology was estimated from triolein. Ten 20-μg spots of triolein gave an automatic external standard channels ratios (AEC) mean and standard deviation of 0.0984 ± 0.0055. This represents the combined error due to the AEC methodology and the spotting error of the 10-μl-TLC syringe.

Surfactant induced lipid changes. In Table 1, the epidermal lipids that were extracted from the accommodated guinea pigs and the water controls are given. Phosphatidylcholine was the dominant polar lipid, but triglycerides and cholesteryl esters were the most prevalent neutral lipids. Lipid changes due to treatments that were significantly different than control are also indicated. Two types of changes were apparent. For the anionic and nonionic treatments, sphingomyelin, cholesterol and fatty acids were elevated; for the cationic surfactant, phosphatidylserine, phosphatidylethanolamine and phosphatidylcholine were elevated 371%, 170% and 150%, respectively, above control. In addition, for all three treatments, triglycerides were significantly lower than control.

Correlation analysis. Linear regression analysis of the data in Table 1 was carried out between all possible pairs of lipids (see Materials and Methods). These values are tabulated in the correlation Table 2. Although the table is symmetrical about the main diagonal, the lower triangular portion of the table is shown for ease of comparing rows and columns. In addition, to facilitate the comparison of the stronger correlations, numerical values of the correlation were given only when the correlation coefficient was 0.70 or higher. The symbols 0, + and − were used to indicate ranges of correlations below this arbitrary cutoff value.

TABLE 1

Variation in Lipid Composition after Surfactant Accommodation[a]

Lipid	Water control	Surfactant treatment[b]		
		Anionic	Nonionic	Cationic

FA	++	−−	−−	−−	+0.82	−−	+0.80	

[a]Linear correlation coefficient, r, for two different lipids with respect to their mean lipid compositions in Table 1 (for water control, anionic treatment, nonionic treatment and cationic treatments).

[b]Lipids: S = sphingomyelin, PS = phosphatidylserine, PE = phosphatidylethanolamine, PC = phosphatidylcholine, C = cholesterol, TG = triglycerides, CE = cholesteryl esters, FA = fatty acids.

0, r ranges from 0 to ±0.20.

±, r ranges from ±0.20 to ±0.40.

±±, r ranges from ±0.40 to ±0.70.

An examination of the sphingomyelin row shows that this lipid was positively correlated with all lipids except triglycerides. The very high correlations with respect to cholesterol (+0.93) and the triglycerides (−0.98) indicate, with a high degree of reliability, that as sphingomyelin levels increase, cholesterol levels also increase, but levels of the triglycerides decrease (see Materials and Methods). The cholesterol column shows a similar trend with respect to sphingomyelin and the triglycerides. In addition, a very poor correlation between cholesterol and the phosphatidylethanolamine-based phospholipids is evident.

For the phospholipids, phosphatidylethanolamine shows a very strong correlation with both phosphatidylserine (+0.98) and phosphatidylcholine (+0.96). These latter two lipids also show a strong mutual relationship for each other (+0.90).

Cholesteryl esters and fatty acids show weaker correlations with the other lipids, but interact moderately with one another (+0.80).

DISCUSSION

In this study, it is proposed that predictions can be made regarding the coordinated enzyme synthesis of various biosynthetic components in a given tissue provided that these components can be assayed and that their levels can be altered. Such an analysis can never replace precursor-product tracer studies as an absolute means of understanding enzyme mechanisms. However, we believe it can be used as an initial screen to map out a research strategy in a new tissue. The method of analysis that is proposed is a systematic examination of binary correlation coefficients between all possible pairs of components in the tissue of interest, i.e., a factorialized correlation analysis. The guinea pig epidermis was examined in this study.

When these animals are topically treated with an irritating surfactant at a concentration that is powerful enough to elicit a strong irritation response but weak enough to be sublethal, they are able to somehow adapt to the irritant and enter a clinical phase, under continual surfactant treatment, in which their skin returns visually to a seemingly normal state. McOsker and Beck (12) were the first to describe the histological characteristics of the anionic surfactant accommodation by skin of the guinea pig.

In this study, guinea pigs were chronically treated with lauryl derivatives of anionic, nonionic and cationic surfactants and with water. Thus, four different treatment groups were obtained for lipid analysis. Because the treatments were carried out until an accommodation response was elicited, it was assumed that the lipid biosynthetic apparatus in the skin had adjusted to a new steady-state characteristic of that particular accommodated condition.

We believe two different types of inferences might be gleaned from the factorialized correlation table, Table 2: one regarding established biosynthetic relationships and one regarding unexpected or new relationships. Established relationships concerning sphingomyelin:cholesterol and regarding phosphatidylethanolamine:phosphatidylserine:phosphatidylcholine will now be examined.

Strong correlations were observed between sphingomyelin and cholesterol in the guinea pig epidermis ($r = +0.93$). This appears to parallel observations of sphingomyelin and cholesterol biosynthesis in other tissues. The relationship is related to the fact that, in cells, these two lipids are found exclusively in membranes. Patton found a strong correlation between cholesterol and sphingomyelin in a variety of organelle membranes (13). An increasing gradient of these lipids exists from the nuclear, mitochondrial, endoplasmic reticular and Golgi to the plasma membrane (14,15). There is also some evidence that the coordinated biosynthesis of these lipids is due to a sphingomyelin regulation over cholesterol (16–18).

Regarding the phospholipids, it was found that phosphatidylethanolamine was highly correlated with phosphatidylcholine ($r = +0.96$) and phosphatidylserine ($r = +0.98$). This appears reasonable because phosphatidylethanolamine can serve as a precursor for both of these lipids. Phosphatidylcholine is formed from phosphatidylethanolamine in plasma membranes by the successive action of two different methyltransferases (19,20). As phosphatidylethanolamine is methylated, it moves from the inner leaflet of the membrane to the outer. Thus phosphatidylethanolamine and phosphatidylcholine are only found on the inner and outer leaflets, respectively. Phosphatidylserine, like phosphatidylethanolamine, is found exclusively on the inner leaflet. It can only be synthesized from preformed phospholipids (21)—primarily phosphatidylethanolamine—by the base exchange reaction (22–24). The higher correlation of phosphatidylserine with phosphatidylethanolamine ($r = +0.98$), compared with phosphatidylcholine ($r = +0.90$), may reflect the greater accessibility of the former substrate to the inner leaflet synthetic site.

One of the unexpected lipid changes that occurred in this study regards triglycerides. Triglyceride levels were lower than in the water control for all surfactant treatments (Table 1). At the same time, for the anionic and nonionic treatments, cholesterol, sphingomyelin and fatty acids were elevated. For the cationic treatment, the serine, ethanolamine and choline phospholipids are elevated and fatty acids are lowered. We are not certain why these changes occur.

Because cholesterol and sphingomyelin are highly correlated ($r = +0.93$), one might expect that the strong negative correlation between sphingomyelin and triglycerides ($r = -0.97$) would also imply an equally strong negative correlation between cholesterol and triglycerides. The fact that the actual correlation between these two lipids is somewhat lower ($r = -0.87$) seemed to indicate that one of the four treatments breaks the normal proportional relationships between the lipids. The cationic treatment appears to be such a treatment. When the cationic treatment is omitted from the regression, water, the anionic and the nonionic treatments give nearly a perfect correlation ($r = -0.99$). Similarly, correlations between cholesterol:fatty acids and sphingomyelin:fatty acids improve from $r = +0.82$ to $+0.96$ and from $r = +0.61$ to $+0.96$, respectively. New correlations omitting the cationic treatment from the regression are given in Table 3.

A comparison of the correlation Tables 2 and 3 shows how the influence of the cationic treatment affects the correlations. Because the sphingomyelin:cholesterol correlation now becomes exactly +1.00, Table 3 shows complete symmetry with respect to these two lipids, i.e., the

[b]Lipids: S = sphingomyelin, PS = phosphatidylserine, PE = phosphatidylethanolamine, PC = phosphatidylcholine, C = cholesterol, TG = triglycerides, CE = cholesteryl esters, FA = fatty acids.

0, r ranges from 0 to ±0.20.

±, r ranges from ±0.20 to ±0.40.

±±, r ranges from ±0.40 to ±0.70.

S row equals the C column. The symmetry of phosphatidylserine and phosphatidylcholine with phosphatidylethanolamine is also evident. Moreover, the removal of the cationic treatment influence from the regression now reveals the strong negative correlation of triglycerides with fatty acids (r = −0.98). This may reflect a catabolism of epidermal triglycerides to fatty acids or it may relect the fact that the triglycerides are more readily extracted from the cells and are slow to recover their pretreatment levels. Only precursor-tracer studies can elucidate this point.

One of the unexplained reactions to chronic epidermal irritation is the accommodation phenomenon. Suskind has recommended that cellular and biochemical factors should be investigated to explain this "turning off" of the inflammatory response (25). A speculative mechanism that might begin to explain the observed lipid changes is an adaptive response by the cell to reduce surfactant-induced fluidization of plasma membrane lipids (26-29). This could reduce inflammation by decreasing the release of chemotactic factors in L-1- and SLS-accommodation skin.

In summary, factorialized correlation tables provide a systematic method for examining binary relationships between the different lipids in a tissue. Two different types of correlation response patterns emerged: one that agreed with established lipid couplings (sphingomyelin: cholesterol, phosphatidylethanolamine:phosphatidylserine:phosphatidylcholine) and one that reflected new lipid patterns unique to the accommodation process (cholesterol:triglyceride, sphingomyelin:triglyceride). Such a strategy might be useful in two different ways. First, it might be used as a method for quickly estimating whether relationships that have been established in other tissues hold in the tissue of interest. Secondly, it could be used to search for new relationships that have not been previously discovered. Potentially, this approach can be used to improve the efficiency of a research effort by isolating the established from the new. Although, precursor-product relationships between lipids cannot be inferred from these types of procedures, the analysis may provide the basis for defining the most fruitful tracer experiments. These studies could then be carried out in a prioritized manner.

METHODS

Quantification of Oxysterols in Dutch Foods: Egg Products and Mixed Diets

Peter van de Bovenkamp, Truus G. Kosmeijer-Schuil and **Martijn B. Katan***
Department of Human Nutrition, Wageningen Agricultural University, P.O. Box 8129, 6700 EV HD Wageningen, The Netherlands

A sensitive and specific method is described for quantifying various cholesterol oxidation products in foodstuffs, including 7β-hydroxycholesterol, cholesterol-α-epoxide, cholestane-triol, 7-ketocholesterol and 25-hydroxycholesterol. A chloroform-methanol extract of the food was fractionated over two successive silica columns. Two fractions containing different classes of oxysterols were then analyzed as trimethylsilyl derivatives by capillary gas liquid chromatography, using on-column injection and a temperature gradient from 70 to 200°C. The detection limit was about 0.5 μg/g dry weight for egg yolk powder. Fresh egg yolk contained only 1.2 μg/g of total oxides per g dry weight, showing that artifactual oxidation during the procedure was minimal. Recovery of 5 pure oxysterols added to egg yolk at levels of 6.5 and 10 μg/g was between 93 and 102%. In commercial egg yolk and whole egg powder stored for one year, total amounts of oxysterols ranging from 21 to 137 μg/g dry weight were found. In duplicates of mixed Dutch diets, total amounts ranged from 3.6 to 6.2 μg/g dry weight. Duplicates containing mostly fried and baked foods did not have higher levels than duplicates in which foods had been prepared by boiling or left raw. We conclude that a normal mixed diet provides only minor amounts of cholesterol oxidation products.
Lipids 23, 1079–1085 (1988).

Cholesterol oxidizes spontaneously in air, yielding a variety of oxidation products. At least 30 oxidation products of cholesterol have been reported (1). Many of these have potent biological effects (2). Some are cytotoxic and angiotoxic and may play a role in atherogenesis (3). Certain oxysterols may also be carcinogenic or mutagenic (4–6).

Foods containing cholesterol, particularly those that have been exposed to heat and air during processing or have been stored at ambient temperature, might contain autoxidation products of cholesterol. However, little information is available on the actual presence of cholesterol oxidation products in foods. In egg products, cholestanetriol (7), 7-hydroxycholesterol isomers (8,9) and cholesterol-α-epoxide (10) have been found, but often only after irradiation with UV light. A recent paper (11) reported that no oxysterols could be detected in fresh egg yolk. Spray-dried egg yolk powder contained traces of oxysterols when fresh or stored for 2 months at 4°C, but prolonged storage gave lipids extracts that contained variable levels (0–12 ppm) of various oxidation products. Variable amounts of cholesterol oxidation products have also been found in lard (12), in anhydrous milk fat and nonfat dry milk stored for 2 years at ambient temperature (13) and in heated beef tallow (14,15).

This paper describes a method for the quantitative determination of some cholesterol oxidation products in foods. It employs an isolation and prefractionation step using silica column chromatography. Oxysterols from food products containing high amounts of lipids and a relatively low cholesterol level can thus be purified and enriched in an adequate way before capillary gas liquid chromatography. The levels of some cholesterol oxidation products in fresh egg yolk, dehydrated egg and milk products stored for various periods of time, and in some mixed Dutch diets were estimated with this method.

METHODS AND MATERIALS

Overview. The food is extracted with chloroform-methanol, and lipids other than sterols are removed by column chromatography on silica column I. The sterol fraction is then applied to silica column II, which serves to separate cholesterol (usually present to excess) from oxysterols. The latter are collected in two fractions of different polarity, each of which is then analyzed by capillary gas chromatography. Analysis of two samples in duplicate, plus appropriate standards and controls, takes one technician about two days.

Food samples. Whole egg powder, egg yolk powder, desugared whole egg powder and desugared egg yolk powder were obtained from four different companies in the Netherlands. Because not all companies could provide all four products, the total number of samples analyzed was only 11. Samples were stored in polyethylene bags in a refrigerator at 4°C for approximately one year. In addition to these products, an egg yolk powder stored for four years at ambient temperature was also available. A subsample of this egg yolk powder was irradiated with UV light (254 nm) with a Camag universal UV-lamp (type TL-900) at a distance of 10 cm for three weeks. During this period the powder was mixed with a spatula once a day.

Two samples of dry full-fat milk stored for two and seven years, and three mixed human diets prepared for a study on the carcinogenicity of different diets in rats were also analyzed for cholesterol oxidation products. This latter study aimed at determining the effects on tumor incidence of baking, frying and grilling, and of adding extra fruits and vegetables to the diet. The diets were duplicates of the average diet consumed in The Netherlands. They were kitchen-prepared in batches of several hundred kg and then freeze-dried and pelleted. For the first diet, all foods were left raw; for the second diet,

products were fried, baked or grilled when appropriate. The third diet was equal in composition to the second one, but contained added fruits and vegetables of supposedly anticarcinogenic action. A commercial pelleted rat chow was also analyzed.

Solvents, reagents and column materials. Chloroform (99.5%, v/v) from Janssen Chimica (Brussels, Belgium) (No. 15.821.10) with 0.75% (v/v) ethanol was used for chromatography on column I (Fig. 1). For the fractionation on column II, HPLC grade chloroform stabilized with 2-methyl-2-butene was used from Merck (Darmstad, West Germany) (no. 2444), as were methanol (No. 6009), and acetone (No. 14). Hexane (No. RH 1002) was obtained from Rathburn (Walkerburn, Scotland). Silylation reagents, hexamethyldisilazane (No. 84770) and trimethylchlorosilane (No. 88530) were from Pierce Eurochemie (Oud-Beijerland, The Netherlands) and dried pyridine (No. 7463) was from Merck. The purity of all solvents was checked by chromatography and found to be satisfactory.

Silica gel 60 (Merck) (No. 7734) of particle size 63–200 μm was used for column I. It was purified and activated by suspending 500 g in 1 liter 3 M HCl for 60 min and then washed with deionized water until neutral, dried overnight at 110–120°C and stored in a polyethylene bottle.

For column II, silica gel for low-pressure column chromatography from Baker Chemical B.V. (Deventer, The Netherlands) (No. 7024-1) was used as purchased. The average particle size was 40 μm (30–60 μm) and the average pore diameter 6 nm. Cholestane-triol (No. 4700), 7β-hydroxycholesterol (No. 6430), 7α-hydroxycholesterol (No. 6420), cholesterol-α-epoxide (No. 4130), 7-ketocholesterol (No. 6970) and 25-hydroxycholesterol (No. 6510) were from Steraloids Inc., Wilton, NH; 5α-cholestane (No. 17060) was from Pfaltz and Bauer, Inc., Stanford, CT; and betulin (No. B-9757) was from Sigma Chemical Co., St. Louis, MO.

Saponification. Saponification followed by extraction of the unsaponifiable fraction has often been used in the determination of sterols in foods (16–18). It has been reported (10), however, that up to 75% of the cholesterol-α-epoxide was lost during saponification. Therefore we subjected a cholesterol sample dating back to 1963, a UV-irradiated egg yolk powder and a mixture of pure oxysterols to two degrees of saponification. The oxysterol mixture contained 7-ketocholesterol, 25-hydroxycholesterol and cholestane-triol. Mild saponification with 100 ml 2 M ethanolic NaOH per l to 2 g of each sample was carried out at ambient temperature for one night, and normal saponification was done under reflux in a boiling water bath for 30 min under conditions, as have been reported elsewhere (19).

Extraction of lipids. An aliquot of dry sample containing 1–1.5 g lipids was transferred to a 150 ml wide-mouth conical flask and 100 ml Folch reagent (chloroform/methanol, 2:1, v/v) was added. The mixture was then homogenized with a Polytron Model PT 10/35 homogenizer (Kinematica, GmbH, Lucerne, Switzerland) at speed 5 for about 15 sec. After 10 min of equilibration, the extract was filtered through a defatted folded filter paper (MN 615¼, Macherey-Nagel, Düren, Germany). The residue was washed three times with Folch reagent and the combined filtrate was dried under vacuum with a rotary film evaporator. The vacuum of the evaporator was released with nitrogen gas. The lipids were redissolved in 5 ml of chloroform.

Silica gel column chromatography. For the isolation of cholesterol and oxysterols, a glass column (length 150 mm, o.d. 40 mm) equipped with a teflon stopcock and connected by a glass joint to a glass solvent reservoir was used (column I). The column was packed using a slurry of 50 g activated and purified Silica Gel 60 in chloroform. After settling of the adsorbent, the bed was vibrated with a hand vibrator to remove remaining air bubbles. Then the silica gel was washed with 75 ml chloroform, at a flow rate of 2–3 ml/min. The lipid extracted was transferred to the column, and two portions of 5 ml of chloroform were used for rinsing the flask and then added to the column.

The neutral lipids were eluted with 175 ml of chloroform and the sterols and their oxidation products were then eluted with 150 ml of acetone. The phospholipids remained on the column. The acetone eluent was collected into a flat-bottom extraction flask and evaporated to dryness under vacuum with a rotary evaporator. The vacuum of the evaporator was released with nitrogen gas and the residue was redissolved immediately in a 3-ml chloroform-acetone mixture (98:2, v/v).

For the prefractionation of oxysterols, a 10 g silica gel column (column II) was prepared as follows. In a separation funnel, 10 g of silica for flash chromatography was mixed with chloroform acetone (98:2, v/v) to form a slurry and was left at room temperature for 15 min. Then it was shaken again and the slurry poured into a glass column of length 250 mm and o.d. 13 mm, which was connected by a ball joint to a solvent reservoir. The column contained a small plug of glass wool covered by a thin layer of sea sand in chloroform-acetone mixture (98:2, v/v) on top of the teflon stopcock at the bottom of the tube. After settling of the adsorbent, the column was vibrated with a hand vibrator and rinsed with 50 ml chloroform-acetone solvent mixture (98:2, v/v). A flow rate of 2–3 ml/min was maintained by a nitrogen pressure of about 50 kPa on the solvent reservoir. The solvent level was allowed to descend to the top of the bed, and the sterols were layered on top of the adsorbent, using 3 ml rinsing aliquots of the chloroform-acetone (98:2, v/v) mixture. The column was then successively eluted with 100 ml of three different chloroform-acetone mixtures: A (98:2, v/v), B (80:20, v/v) and C (50:50, v/v).

Cholesterol eluted in fraction A. So did cholestanol and, therefore, quantification of this compound was not possible. Cholesterol-α-epoxide, 7-ketocholesterol, 25-hydroxycholesterol and the major part of the 7β-hydroxycholesterol eluted in fraction B. The cholestane-triol and a minor part of 7β-hydroxycholesterol eluted in fraction C. Common plant sterols eluted in the cholesterol fraction (fraction A) and, thus, did not interfere with the later gas-chromatographic separation of oxysterols (data not shown).

Fraction A was discarded, and fractions B and C were collected separately in extraction flasks. Then 1 ml of an internal standard solution containing 20 μg of each standard component (5α-cholestane and betulin) was added to both fractions. The solvents were evaporated under vacuum with a rotary thin-film evaporator. The vacuum was released with nitrogen gas, and the residues were redissolved in chloroform and transferred to a 1 ml conical vial for derivatization.

Derivatization. The residue was dried under nitrogen. Then 0.5 ml of pyridine hexamethyldisilazane trichloromethylsilane (10:2:1, v/v) was added. The vial was closed with a screw top sealed with teflon. It was left to stand for 30 min at ambient temperature. After removal of the excess of pyridine under a stream of nitrogen, 400 μl of hexane was added. The vial was shaken and centrifuged, and 0.5 μl of the hexane solution was injected into the gas chromatograph.

Gas liquid chromatography. A Packard Instruments (Delft, The Netherlands) gas liquid chromatograph Model 433 with a flame ionization detector, a digital integrator and a capillary on-column injector from Chrompack (Middelburg, The Netherlands) was used. It was equipped with a 25 m × 0.22 mm fused silica capillary WCOT column CP Sil5CB (Chrompack), with a film thickness of 0.12 μm and a coating efficiency of about 90%. The oven temperature program was: initial temperature 70°C for 2 min followed by a rise to 200°C at a rate of 15°C/min and, then, by another rise at a rate of 10°C/min to an upper temperature of 295°C. The oven was held at this upper temperature for various lengths of time until all components were eluted. Other conditions were: carrier gas, hydrogen; pressure, 150 kPa; make-up gas, nitrogen with flow rate 15/min; and detector temperature, 325°C.

Prior to the analysis of samples, the system was calibrated with a mixture of pure compounds, and response factors relative to the average response of betulin and 5α-cholestane were calculated. If the betulin or 5α-cholestane peaks could not be identified due to interference from other unknown compounds, then response factors were calculated relative to only one of these compounds.

Mass spectrometry. To confirm the tentative gas chromatographic identification, some samples were also analyzed on a Finnigan-MAT 8200 mass spectrometer (Finnigan Corp., Cincinnati, OH) equipped with a Finnigan-MAT ss200 data system.

A Varian 3700 gas chromatograph (Varian Associates Inc., Sunnyvale, CA) fitted with a 25 m × 0.5 mm i.d. CP-Sil5 glass capillary column (Chrompack, 4330 EW Middelburg, The Netherlands) was attached to the mass spectrometer through an open split interface. Helium was used as carrier gas at a flow rate of 6 ml/min. The initial oven temperature was 200°C and was increased to 320°C at a rate of 40°C/min. The injector and interface temperatures were 250°C.

Spectra were obtained by electron impact ionization within a mass range of 20–700 m/e. The scan speed was 1 sec/decade. Background subtraction and renormalization to the most intense peak were performed. Peaks were identified by comparing their mass spectra with those of the pure compounds.

RESULTS AND DISCUSSION

Effect of saponification. The results of normal and mild saponification of the old cholesterol sample, the UV-irradiated egg yolk powder and the mixture of pure oxysterols showed that 7-ketocholesterol is very sensitive to alkaline hydrolysis. Only 11–40% of the original amount was recovered under mild saponification conditions, but saponification at 100°C caused a total disappearance of 7-ketocholesterol. 25-Hydroxycholesterol was not very sensitive to alkaline hydrolysis (recovery range, 89–121%), while cholestane-triol was somewhat sensitive to both mild and normal saponification (recovery range, 78–90%). Tsai et al. (17) reported that up to 75% of the cholesterol-α-epoxide was lost during saponification. Therefore, no saponification was used. The error introduced by not saponifying is probably small, as only some 10% of the cholesterol in foods is esterified (20).

Silica chromatography. Silica gel column I served to remove the nonsterol lipids. From an egg yolk powder containing 62.5% of weight as lipid, 79.7% of these lipids were recovered in the chloroform fraction, and the acetone fraction contained 3.7% of the lipids and 80–90% of the total amount of cholesterol.

Column II was used to remove the bulk of cholesterol and to prefractionate the oxidation products. For samples with a highly complex composition such as egg yolk such prefractionation proved necessary, as certain oxysterols could not be separated by only gas chromatography.

Gas liquid chromatography. In Figures 1 and 2 a gas chromatogram of an egg yolk sample is shown. In between the two internal standard peaks, 5α-cholestane and betulin, a large number of peaks was present. Various constituents were first identified tentatively by their retention time relative to 5α-cholestane and betulin. The retention times and response factors are given in Table 1. The mean standard deviation of 0.009 for response factors relative to betulin is smaller than the standard deviation of 0.027 found for response factors relative to 5α-cholestane, because for some samples, the 5α-cholestane was not separated well from other unknown components. The separation of 7-ketocholesterol and 25-hydroxycholesterol was also critical. Due to changes of the capillary column with time, these two components sometimes could no longer be separated after the column had been in use for a prolonged period. The problem could be solved by inserting a 5-min halt at 270°C into the final part of the temperature program.

As for oxysterols not listed in Table 1, 20-hydroxycholesterol was never detected in foods and was therefore not studied extensively. We were unable to quantitate 7α-hydroxycholesterol, because this peak partially coincided with that of cholesterol. In addition, the number of oxysterols that we could quantitate was limited to those for which pure standards were available. Therefore, we could identify the 5,6α-, but not the 5,6β-isomer of cholesterol

TABLE 1

Retention Times of Various Cholesterol Oxidation Products Upon GLC and Response Factors[a]

Cholesterol oxidation product	Retention time	Relative response factor[a]	
		5α-cholestane	Betulin
5α-Cholestane	19.80	1.000	–
7β-Hydroxycholesterol	23.33	0.926 ± 0.022	0.906 ± 0.005
Cholesterol-α-epoxide	23.48	1.234 ± 0.037	1.207 ± 0.015
Cholestane-triol	26.90	1.074 ± 0.026	1.038 ± 0.013
7-Ketocholesterol	25.15	1.100 ± 0.025	1.077 ± 0.005
25-Hydroxycholesterol	25.50	0.931 ± 0.025	0.911 ± 0.008
Betulin	27.50	–	1.000

[a]The relative response factor equals (concentration of component/peak area of component)/(concentration of internal standard/peak area of standard); mean ± SD of 3 measurements is given. Factors are relative to the two internal standards, 5α-cholestane and betulin.

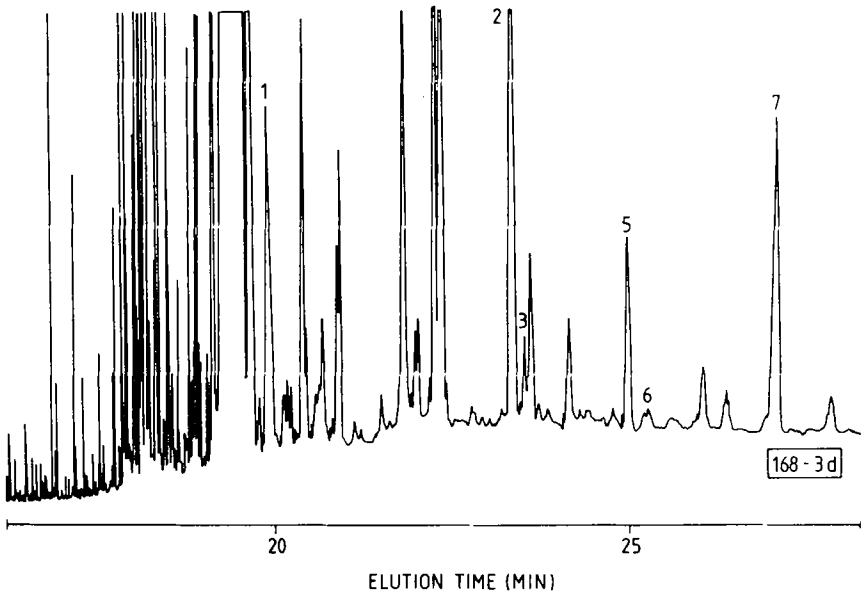

FIG. 1. Gas chromatogram of cholesterol oxidation products in egg yolk powder: fraction B, containing the less polar oxysterols. 1, 5α-cholestane (internal standard); 2, 7β-hydroxycholesterol; 3, cholesterol-α-epoxide; 5, 7-ketocholesterol; 6, 25-hydroxycholesterol; 7, betulin (internal standard).

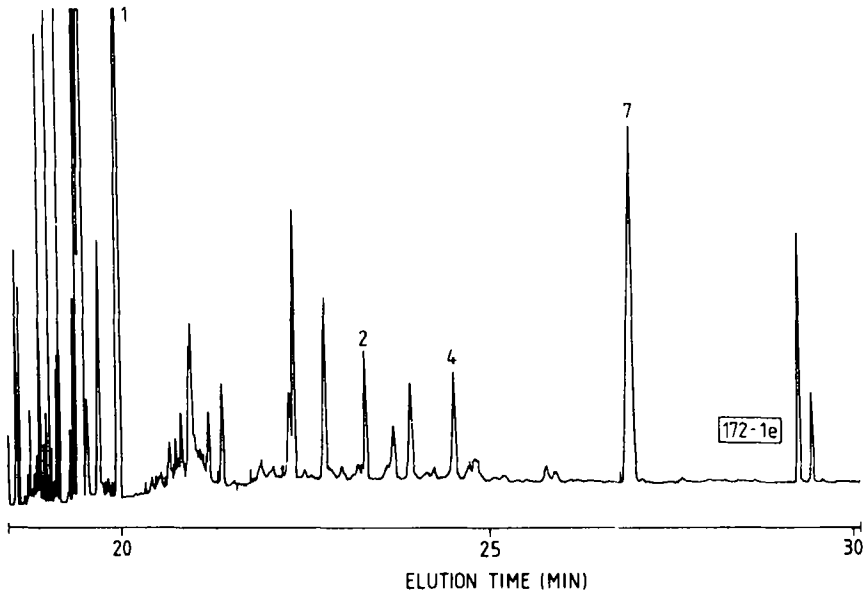

FIG. 2. Gas chromatogram of cholesterol oxidation products in egg yolk powder: fraction C, containing the more polar oxysterols. 1, 5α-cholestane (internal standard); 2, 7β-hydroxycholesterol; 4, cholestane-triol; 7, betulin (internal standard).

epoxide. As the gas chromatography column separated mainly by boiling point, there is a possibility that the α and the β isomer of cholesterol epoxide eluted as one peak. Alternatively, the unidentified peaks in the oxysterol region of the chromatogram (Figs. 1 and 2) could contain this or other unidentified oxysterols.

The stability of the various oxidation products on the column was very good, as indicated by the low standard deviations of the relative response factors. Low standard deviations were obtained only if the sample was injected directly on the column at a temperature of 70°C. If we used a more conventional splitless flash heater at 280–300°C for sample, injection we found large standard deviations, possibly caused by variable decomposition of oxysterols in the flash heater (data not shown).

Recovery, precision and detection limit. A standard mixture containing 20 μg each of cholesterol-α-epoxide, cholestane-triol, 25-hydroxycholesterol and 200 μg of cholesterol

was taken through the full procedure. Recoveries were between 86 and 98% (Table 2). The same oxysterols were added in known amounts (6.5 and 10 μg/g) to egg yolk powder. Recoveries (Table 2) varied between 93 and 98% at the 6.5 μg/g level and between 94 and 102% at the 10 μg/g level.

The reproducibility for independently worked-up samples is given in Table 3. The coefficient of variation tended to be lower, the higher the level of the analyte. For 25-hydroxycholesterol, a concentration of 0.3 μg/g with a coefficient of variation of 72% was found. Thus, this is about the lowest level of oxysterol that can be detected with our method in samples with highly complex matrices such as egg yolk.

Identification. Both the gas chromatographic separation and the detector response were poorer for the GC–MS analyses than for the routine gas chromatographic analyses. The use of splitless on-column injection in the latter was probably a major factor in providing a high yield and good separation.

The m/e values of typical fragments in the mass spectra of pure compounds and of oxysterol fractions from egg yolk powder were compared with published data (1). This provided identification of the trimethylsilylether of cholesterol-α-epoxide (m/e 474, 456 and 384), of cholestane-triol (m/e 546, 456, 403, 367 and 321) and of a 7-hydroxycholesterol (m/e 546, 456, 233 and 208); the geometry of the latter (7α or 7β) could not be determined. The quality of the GC–MS analyses proved insufficient to confirm or reject the identifications of the other oxysterols in egg yolk powder.

Levels of oxysterols in foods. Table 4 gives the levels of oxidation products in egg yolk and whole egg powder, and in dry milk. The very low content of oxysterols in fresh egg yolk indicates that artifactual oxidation of cholesterol during sample work up was minimal; the oxysterol concentration of 1 μg/g should be contrasted with the total cholesterol content of about 12,000 μg present in 1 g of egg yolk. A similar result was found by Nourooz-Zadeh and Appelqvist (11). The levels of 7β-hydroxycholesterol (12.8 to 78.0 μg/g) and cholesterol-α-epoxide (4.2 to 46.0 μg/g) found by us in nonirradiated samples of egg yolk and whole egg powder stored one to four years prior to analysis were higher than those found by Nourooz-Zadeh and Appelqvist (11) who found concentrations between 0 and 9.8 μg/g (7β-hydroxycholesterol) and between 0 and 2.5 μg/g (cholesterol-α-epoxide) in samples stored up to one and a half years, and concentrations of 46.8 μg/g (7β-hydroxycholesterol) and of 9.4 μg/g (cholesterol-α-epoxide) in a sample stored for eight years. The levels of cholestane-triol, 7-ketocholesterol and 25-hydroxycholesterol found by us in egg yolk and whole egg powder were generally low (below 15 μg/g), although these too were higher than those of Nourooz-Zadeh and Appelqvist (11). The effect of storage on the concentrations

TABLE 2

Recovery of Cholesterol Oxidation Products From a Mixture of Pure Compounds and From Egg Yolk Powder[a]

Cholesterol oxidation product	Mean percentage recovery		
	Standard compounds	Added to egg yolk powder	
	20 μg each (n = 5)[b]	6.5 μg/g (n = 2)[c]	10 μ/g (n = 4)[b]
7β-Hydroxycholesterol	86 ± 12	95 (85–105)	102 ± 7
Cholesterol-α-epoxide	92 ± 6	98 (92–103)	99 ± 6
Cholestane-triol	90 ± 5	95 (91–99)	94 ± 3
7-Ketocholesterol	98 ± 9	98 (95–101)	96 ± 4
25-Hydroxycholesterol	94 ± 7	93 (92–94)	97 ± 1

[a]To which pure compounds had been added at two different levels. The samples underwent the entire extraction and column chromatography procedure prior to gas chromatography. The standard mixture also contained 200 μg cholesterol.

[b]Mean ± SD.

[c]Mean (range).

TABLE 3

Reproducibility of the Determination of Cholesterol Oxidation Products in Commercial Whole Egg and Egg Yolk Powder

Cholesterol oxidation product	n	Mean (range) (μg/g)	SD (μg/g)	Coefficient of variation (%)
7β-Hydroxycholesterol	12	36.8 (11.9–78.0)	2.18	5.9
Cholesterol-α-epoxide	11	4.4 (1.8–11.2)	0.75	17.0[a]
Cholestane-triol	12	2.8 (0.3–13.9)	0.48	17.2
7-Ketocholesterol	12	16.9 (4.2–46.0)	1.31	7.7
25-Hydroxycholesterol	12	0.3 (0.0–0.5)	0.21	71.8

[a]If one outlier was excluded, the coefficient of variation was 8.6%.

[d]After irradiation of sample c with UV light for three weeks.

[e]After 7 years of storage.

[f]After 2 years of storage.

of oxysterols was unclear. In egg yolk powder the concentrations increased upon long-term storage, but in whole egg powder they decreased. It might be that differences in storage temperature at the manufacturers are responsible for this (11). UV-irradiation considerably increased the concentrations of all oxysterols studied.

The total concentration in dry full-fat milk stored between two and seven years did not exceed 10 μg/g. Levels of cholesterol oxidation products in commercial rat chow were also very low (Table 4).

In duplicates of the average diet eaten in the Netherlands, oxysterol levels ranged from 0.0–0.2 μg/g for 25-hydroxycholesterol to about 2 μg/g for 7β-hydroxycholesterol. The levels were not higher in duplicate diets made up of fried, baked and grilled products than in duplicate diets made up of the equivalent raw foods. Thus, the amount of cholesterol oxidized during the frying, baking or grilling of foods appears to be very small. As the daily food intake for an average person is about 500 g, the average Dutchman will ingest about 1 mg of 7β-hydroxycholesterol and 0.5 mg of cholesterol-α-epoxide per day. The diets to which fruits and vegetables of supposedly anticarcinogenic activity had been added, contained somewhat higher levels of 7-ketocholesterol (2.0 μg/g compared with 1.1 and 1.0 μg/g for the other two mixed diets without the extra fruits and vegetables added). In view of the freeze drying and pelleting that our samples had undergone these figures may be considered upper limits. On the other hand, the chromatograms of these duplicate diets did contain quite a few peaks that escaped identification, and one could theorize that normal foods might contain appreciable amounts of oxysterols other than those identified. However, the oxysterols studied by us are those naturally formed from cholesterol under a range of conditions, and it seems unlikely that the reaction of oxygen with cholesterol in foods would produce an entirely different range of products. Therefore we suggest that the most plausible load of oxysterols in the average Dutch diet is at most a few mg per day. Whether such amounts contribute to the development of chronic diseases is at present not known.

ACKNOWLEDGMENTS

The authors wish to thank J. van der Greef, A. Tas and G. R. La Vos, Central Institute for Food and Nutrition Research (CIVO/TNO), Zeist, The Netherlands, for the mass spectrometric analysis, and J. T. Knuiman for his assistance in writing this paper. We are grateful to G. Alink, Department of Toxicology, Wageningen Agricultural University, for making available the duplicates of human diets.

A previously uncharacterized fatty acid found in *Corynebacterium sepedonicum* was analyzed by gas chromatography-mass spectrometry and infrared spectrometry and determined to be 12-methyl-*cis*-4-tetradecenoic acid. This fatty acid represents nearly 6% of the total fatty acids of *C. sepedonicum*, but it is present at significantly lower levels in other *Corynebacterium* species. Therefore, 12-methyl-*cis*-4-tetradecenoic acid provides a useful marker in distinguishing *C. sepedonicum* from other microorganisms.

Lipids 23, 1086–1088 (1988).

Fatty acid analysis of cellular components has been used extensively for the determination of taxonomic relationships and for the rapid identification of medically and clinically important bacteria (1,2). However, few examples of fatty acid analyses of plant pathogenic bacteria have been reported (3,4). Some preliminary studies have been performed in our laboratory involving the use of fatty acid analysis for the identification and differentiation of plant pathogenic *Corynebacteria* (4). During these studies, a fatty acid was detected in saponified extracts of *Corynebacterium sepedonicum* (Spieck. and Kotth.) Skapt. and Burkh. that was previously unidentified. In this paper, we report on the characterization of the unknown fatty acid, and have identified it as 12-methyl-*cis*-4-tetradecenoic acid. The fatty acid was a significant component (>5%) of *C. sepedonicum*, but constituted substantially less in all other plant pathogenic *Corynebacteria* tested (4).

MATERIALS AND METHODS

Bacterial strains were obtained from the American Type Culture Collection (Rockville, MD), Plant Disease Division Culture Collection (Auckland, New Zealand), from individual researchers in the U.S. and Canada, and from isolates recovered by us in our laboratory from samples brought in by area potato growers. Identities of all strains were confirmed by biochemical and physiological methods (5) and by indirect immunofluorescent antibody staining according to De Boer and Weiczorek (6).

Bacterial cultures were harvested according to Suzuki and Komagata (7), and the methyl esters prepared (8). Briefly, the cells were centrifuged and washed twice under aseptic conditions. After lyophilization, 5 mg of bacteria was saponified with 1 ml of 3.75 N NaOH in 25% aqueous methanol at 100°C for 30 min in a water bath, with occasional mixing. The mixture was methylated by adding 2 ml of 3.25 N HCl in 45% methanol and heating for 10 min at 80°C. The fatty acid methyl esters were extracted with 1.25 ml of hexane/diethyl ether (1:1, v/v). The organic phase was washed once with 3 ml of 0.3 N NaOH.

Pyrrolidide derivatives were prepared by the method of Andersson and Holman (9). Hydrogenation was accomplished by adding a small amount of platinum oxide catalyst (ca. 5 mg) to a solution of the fatty acid methyl ester mixture in 2 ml of methanol, then directing a stream of hydrogen gas through the solution for 5 min. Fatty acid methyl esters were separated by thin layer chromatography using a Whatman $LKC_{18}F$ thin layer chromatography plate. The solvent was acetonitrile/water (95:5, v/v). Fatty acid methyl ester components were visualized by exposure of a portion of the plate to iodine. Fatty acid composition was determined with a Hewlett-Packard model 5790 gas chromatograph equipped with a 30 m × 0.25 mm i.d. SPB-1 methylsilicone capillary column (Supelco, Bellefonte, PA). The temperature was programmed from 150°C to 250°C at 4°C/min. Mass spectra were obtained with a Hewlett-Packard model 5992 gas chromatography–mass spectrometry (GC–MS) equipped with a 30 m × 0.22 mm i.d. methylsilicone capillary column. Infrared spectra were obtained with a Nicolet 5-MX Fourier transform spectrometer. Spectra were determined on the sample prepared in a KBr pellet.

Most fatty acids could be identified by comparing the equivalent chain lengths (ECL) of their methyl esters with those of a fatty acid methyl ester standard (Supelco 4-7080, Bacterial Acid Methyl Ester Mix CP). Their identifications were further confirmed from their molecular weights which were determined by GC–MS. Fatty acid methyl esters not identified by this method were converted to pyrrolidide derivatives and analyzed by GC–MS to determine the location of unsaturation and branching.

RESULTS AND DISCUSSION

The acyl components of most plant and animal glycerolipids are usually composed of saturated or unsaturated, straight-chain fatty acids. In contrast with plants and animals, certain bacteria such as *Bacillus* (10) and *Staphylococcus* (11) utilize iso and anteiso methyl-branched fatty acids as the predominant acyl constituents of glycerolipids. The genus *Corynebacterium*, however, differs from *Bacillus* and *Staphylococcus* in that it is heterogenous with respect to fatty acid types. *C. sepedonicum* of this genus belongs to the type II group, which is composed predominantly of iso and anteiso branched-chain fatty acids (7).

In our studies of the fatty acid composition of *C. sepedonicum*, we observed that extracts of the bacteria contained five fatty acids that were each present in

[c]Equivalent chain length of methyl ester on an SPB-1 methylsilicone capillary column.

amounts greater than 2% of the total fatty acid content (Table 1). These five fatty acids constituted >95% of the total fatty acids present. Of these five major fatty acids, the latter four were tentatively identified by comparison of the ECL of their methyl esters with those of a standard. These fatty acids have previously been characterized as components of coryneform bacteria by Bousfield et al. (12) and Suzuki and Komagata (7). We further confirmed their identities by the determination of their molecular weights by GC-MS.

The unidentified fatty acid methyl ester (ECL, 14.47) had a molecular weight of 254 by GC-MS analysis, indicating that it contained 15 carbons with either one double bond or a ring structure. Other characteristic fragments were present at *m/z* 225 $[M - CH_3CH_2]^+$, 222 $[M - CH_3OH]^+$ and 193 $[225 - CH_3OH]^+$. When the methyl ester of this fatty acid was isolated by reversed phase thin layer chromatography and then hydrogenated, the resulting product matched the retention time of 12-methyl-tetradecanoic acid, and its molecular weight was increased by 2 amu. This demonstrated that a double bond, and not a ring structure, was present in the nonhydrogenated compound. GC-MS data from the pyrrolidide derivative of the unknown compound (Fig. 1) showed an interval of 12 amu between *m/z* 126 and *m/z* 138, indicating that the double bond was at the fourth carbon (9). The interval of 28 amu between the C-11 and C-12 fragments (*m/z* 236 and *m/z* 264) confirmed the location of the branched methyl group at carbon 12.

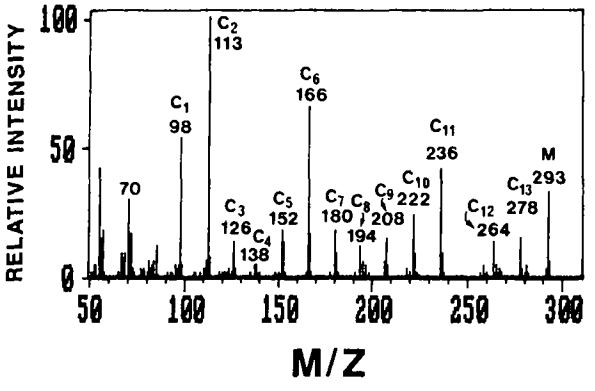

FIG. 1. Mass spectrum of the pyrrolidide derivative of 12-methyl-*cis*-4-tetradecenoic acid, extracted from *Corynebacterium sepedonicum*.

The infrared spectrum of the compound showed absorptions characteristic of unsaturated fatty acids: 3010 cm^{-1} (unsaturation), 2920 and 2860 cm^{-1} (C-H stretch), and 1745 cm^{-1} (ester carbonyl). No infrared absorption was observed at 965 cm^{-1}, due to *trans* double bonds. Therefore, the double bond at carbon 4 was determined to have the *cis* configuration, and the fatty acid was identified as 12-methyl-*cis*-4-tetradecenoic acid, a-15:1(4).

Bousfield et al. (12) alluded to the presence of a-15:1 in some bacteria, but did not report on the position of unsaturation. The characterization of this anteiso fatty acid is of interest because monounsaturation at carbon 4 is unusual among fatty acids from any source. This fatty acid is most likely the product of a Δ4-desaturase. Other possible biosynthetic routes include chain elongation or β-oxidation of other monounsaturated precursors. However, we could not detect the presence of the most probable monounsaturated precursors, 10-methyl-*cis*-2-dodecenoic acid or 14-methyl-*cis*-6-hexadecenoic acid, which might be converted to a-15:1(4) by elongation or β-oxidation, respectively.

The esterification reaction used in these experiments was conducted on whole extracts of saponified *C. sepedonicum* and not on isolated, individual lipid classes. Therefore, no conclusions can yet be drawn regarding the distribution of the various fatty acids among phospholipids, acylglycerols or free fatty acids. The extraction and esterification procedures used in these studies are widely used by clinicians and researchers for the rapid identification of bacteria and for determining their taxonomic relationships (1-4,7,8,12).

On the average, the a-15:1(4) content of *C. sepedonicum* was 5.9% of the total fatty acids (Table 1). We recently compared the fatty acid compositions of several *Corynebacteria* species and showed that the level of a-15:1(4) was significantly higher in *C. sepedonicum* than in the other species (4). Thus, the level of a-15:1(4) could serve as a useful marker to differentiate *C. sepedonicum* from other bacterial species.

Esterification of 8,11,14-Eicosatrienoate and Arachidonate Into Alkylacyl- and Diacylglycerophosphocholine by Vascular Endothelial Cells

Miriam D. Rosenthal*, Morris E. Brown III and Janet E. Jones
Dept. of Biochemistry, Eastern Virginia Medical School, Norfolk, VA 23501

Agonist-stimulated phospholipases release arachidonate, but not 8,11,14-eicosatrienoate, from human endothelial cells. One source of the arachidonic acid is deacylation of 1-alkyl-2-arachidonoyl-glycerophosphocholine, with subsequent conversion of some of the resultant lysophospholipid to platelet-activating factor. This study has compared the distribution of incorporated 8,11,14-[^{14}C]-eicosatrienoate in alkylacyl-GPC and diacyl-GPC with that of [^{14}C]arachidonate synthesized endogenously by desaturation of the 8,11,14-[^{14}C]eicosatrienoate. Cells were incubated for 24 or 48 hr with 8,11,14-[^{14}C]eicosatrienoate, and the resultant mixture of ^{14}C-fatty acids in the cellular lipids was characterized by gas chromatography. The choline phospholipids were then separated, hydrolyzed with phospholipase C and derivatized to diradylbenzoates. Gas chromatographic analysis indicated extensive incorporation of [^{14}C]eicosatrienoate, as well as [^{14}C]arachidonate, into alkylacyl-GPC. Although the ratio of esterified [^{14}C]arachidonate to [^{14}C]eicosatrienoate was greater in alkylacyl-GPC than in diacyl-GPC, the enrichment with [^{14}C]arachidonate was far less than the ratio of arachidonate/eicosatrienoate released from these cells. These results thus support the hypothesis that the acyl specificity of polyunsaturated fatty acid release is provided by the agonist-stimulated phospholipase A_2 rather than the composition of the alkylacyl-GPC.
Lipids 23, **1089–1092 (1988).**

Vascular endothelial cells are among the many types of cells that can synthesize 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine or platelet-activating factor (PAF), a potent hypotensive agent, as well as an active stimulant, of aggregation and degranulation of both platelets and neutrophils (1,2). The agonist-stimulated synthesis of PAF involves phospholipase A_2 activity on 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholine (alkylacyl-GPC), followed by the action of acetyltransferase on the lyso-PAF (1–3). In vascular endothelial cells, synthesis of PAF is initiated by agents such as histamine, bradykinin, thrombin and the calcium ionophore A23187 that also initiates mobilization of free arachidonic acid and synthesis of prostacyclin (4). These processes thus appear similar to those in human polymorphonuclear leukocytes, where 1-*O*-alkyl-2-arachidonoyl-GPC serves as a common source of PAF and arachidonate (5,6).

Our laboratory has recently demonstrated that the agonist-stimulated mobilization of arachidonic acid from endothelial phospholipids exhibits a high degree of acyl-group structural specificity (7–9). Polyunsaturated fatty acids which, like arachidonate, have a double bond in the delta-5 position are released in response to thrombin, histamine and the calcium ionophore A23187; 8,11,14-eicosatrienoate (20:3n-6), docosatetraenoate (22:4n-6) and other C_{20} and C_{22} polyunsaturated fatty acids without a delta-5 double bond are not released. Our working hypothesis has been that the specificity of agonist-stimulated fatty acid release is provided by the substrate specificity of the activated phospholipase A_2.

To further elucidate the mechanisms of arachidonate mobilization in vascular endothelial cells, we have investigated the incorporation of arachidonate and 8,11,14-eicosatrienoate in both diacyl- and ether-linked species of choline phospholipids. We postulated that 8,11,14-eicosatrienoate, like arachidonate, would be extensively esterified into 1-alkyl-2-acyl-GPC. Because 8,11,14-eicosatrienoate is not released from membrane phospholipids by agonists that mobilize arachidonate, extensive synthesis of 1-alkyl-2-eicosatrienoyl-GPC would be consistent with the proposed role of the phospholipase, A_2, in providing the requisite acyl specificity for agonist-stimulated release of polyunsaturated fatty acids. By contrast, a high ratio of arachidonate/8,11,14-eicosatrienoate in 1-alkyl-2-acyl-GPC relative to diacyl-GPC would provide evidence for specificity in the loading of this particular phospholipid pool.

MATERIALS AND METHODS

Radiolabeling of endothelial cells. Endothelial cells were obtained from human umbilical veins (10) and cultured in gelatin-coated 25 cm^2 flasks in HEPES-buffered Medium 199 plus 10% fetal bovine serum, 30 μg/ml Endothelial Cell Growth Supplement and 90 μg/ml heparin, as described previously (7,8). The experiments used confluent monolayers of second passage cells. 8,11,14-[^{14}C]Eicosatrienoate (55 mCi/mmol) was obtained from New England Nuclear (Boston, MA) and stored in hexane under nitrogen at −20°C. For each experiment, an aliquot of the ^{14}C-fatty acid solution was evaporated to dryness under N_2 and redissolved in 95% ethanol; the ethanol solution was added directly to fetal bovine serum. The endothelial cells were radiolabeled by incubation for 24 or 48 hr in complete growth medium supplemented with 5.0 μM 8,11,14-[^{14}C]eicosatrienoate; final concentration of ethanol in the culture medium was less than 0.2% (7,8). The cells were then washed with saline and harvested by rapid trypsinization (7).

Lipid extraction and analysis. Cellular lipids were extracted with acetone/ethyl acetate (11) and the extracts from 10–15 flasks pooled for analysis. Phospholipids were separated by one-dimensional thin layer chromatography (TLC) on Silica Gel H plates that were developed in chloroform/methanol/acetic acid/water (50:30:8:4, v/v/v/v). Lipid spots were visualized with iodine and scraped for quantitation of radioactivity by liquid scintillation

*To whom correspondence should be addressed at Dept. of Biochemistry, Eastern Virginia Medical School, P.O. Box 1980, Norfolk, VA 23501.

Abbreviations: GPC, glycerophosphocholine; PAF, platelet-activating factor; TLC, thin layer chromatography.

spectrometry. For preparative separations, only the standard lanes, spotted with a mixture of phospholipids, were visualized with small drops of tincture of iodine. The choline phospholipids were then scraped and extracted from the silica gel (12).

Choline phospholipids were converted to diradylglycerobenzoates (diacyl, alkylacyl and alkenylacyl), as described by Blank et al. (13). This procedure involves hydrolysis with phospholipase C (14) and derivatization of the diradylglycerols with benzoic anhydride and 4-dimethylaminopyridine in benzene. The diradylglycerobenzoates were then separated by TLC on Silica Gel H plates developed with benzene/hexane/diethyl ether (50:45:4, v/v/v) (13). Standards prepared by hydrolysis and derivatization of diacyl-, alkyl- and plasmalogen or alkenylacyl phospholipids were chromatographed in adjacent lanes and visualized with iodine. The areas containing the diacyl and alkylacyl fractions were scraped and extracted from the silica gel with chloroform/methanol/diethyl ether (1:1:1, v/v/v).

Gas chromatography. Cellular lipid extracts, choline phospholipids and diradylglycerobenzoates were transesterified using methanolic base (12). The resultant ^{14}C-fatty acid methyl esters were separated by gas liquid chromatography and on-line radioactivity detection, as described previously (8,12).

RESULTS

In these studies, the endothelial cells were incubated with 5.0 μM 8,11,14-[^{14}C]eicosatrienoate (20 nmol/4 ml) for 24 or 48 hr. The relatively long incubation times were selected to examine the results of metabolic labeling of phospholipid pools rather than rapid fatty acyl turnover. Total incorporation of ^{14}C-fatty acyl groups into cellular glycerolipids was 64.5% after 24 hr and 57.3% after 48 hr. Because vascular endothelial cells actively desaturate [^{14}C]-eicosatrienoate to [^{14}C]arachidonate (12), long-term incubation with [^{14}C]eicosatrienoate results in a mixture of cellular ^{14}C-acyl groups. Cells incubated for 24 and 48 hr with [^{14}C]eicosatrienoate contained 38.8 and 51.4%, respectively, of the incorporated ^{14}C-acyl groups as [^{14}C]arachidonate. There was also substantial elongation of the synthesized [^{14}C]arachidonate to [^{14}C]docosatetraenoate (Table 1).

TABLE 1

Percentage Distribution of Incorporated ^{14}C in Cellular Fatty Acyl Groups of Endothelial Cells Incubated With 8,11,14-[^{14}C]Eicosatrienoate

	Incubation time	
Fatty acid	24 hr	48 hr
16:0	1.2[a]	1.6
20:3n-6	44.6	29.3
20:4n-6	38.8	51.4
22:3n-6	2.9	1.9
22:4n-6	12.6	15.8

[a]Values are means of triplicate determinations in one of two similar experiments; standard errors were <5% for larger peaks and <10% for smaller ones.

The choline-phospholipid fractions contained 39.0 and 33.6%, respectively, of the total cellular ^{14}C-fatty acyl groups in the 24 and 48 hr samples. As shown in Table 2, ca. 85% of the ^{14}C-fatty acids esterified in choline phospholipids were in diacyl-GPC and 10–11% in alkylacyl-GPC. These values are quite similar to those reported by Blank et al. (15) after a 4 hr incubation with [^{3}H]arachidonate; there was somewhat more incorporation into the alkylacyl fraction and less into the alkenylacyl fraction in the present study.

Table 3 shows the distribution of ^{14}C-fatty acyl groups in the diacyl- and alkyacylglycerobenzoate fractions. Both the diacyl- and alkylacyl-GPC fractions contained a mixture of ^{14}C-fatty acids. After both 24 and 48 hr of incorporation, the alkylacyl-GPC fraction contained sizable amounts of [^{14}C]eicosatrienoate. Thus, human endothelial cells readily incorporate 8,11,14-eicosatrienoate into alkylacyl-GPC. These cells also esterified substantial amounts of the [^{14}C]arachidonate and [^{14}C]docosatetraenoate synthesized from the incorporated 8,11,14-[^{14}C]eicosatrienoate into alkylacyl-GPC.

The results shown in Table 3 indicate some modest enrichment of alkylacyl-GPC with arachidonate, relative to diacyl-GPC, as shown by the higher ratios of [^{14}C]arachidonate/[^{14}C]eicosatrienoate in alkylacyl-GPC. Comparable results were obtained from a replicated 24 hr

TABLE 2

Percentage Distribution of Incorporated ^{14}C-Fatty Acids in Diradylglycerobenzoates Prepared From Endothelial Choline Phospholipids

	Incubation time	
Lipid class	24 hr	48 hr
Diacyl	84.4[a]	86.9
Alkylacyl	11.3	9.8
Alkenylacyl	4.3	3.8

TABLE 3

Percentage Distribution of ^{14}C-Fatty Acyl Groups in Diradylglycerobenzoates Prepared From Diacyl- and Alkylacylglycerophosphocholines of Endothelial Cells Incubated With 8,11,14-[^{14}C]Eicosatrienoate

	Incubation time			
	24 hr		48 hr	
Fatty acid	Diacyl	Alkylacyl	Diacyl	Alkylacyl
16:0	9.1[a]	4.7	14.3	4.3
20:3	61.4	49.2	29.8	26.7
20:4	26.3	36.2	44.5	59.0
22:3	0.8	4.6	2.5	0.8
22:4	3.2	5.3	8.9	9.5
Ratio 20:4/20:3	0.43	0.73	1.49	2.21

[a]Values are means from three independent derivatizations and analyses.

incubation, with ratios of 0.59 and 0.43 for the alkylacyl and diacyl fractions, respectively. In the replicated 48 hr experiment, the ratios were 1.24 and 0.85, respectively, for the alkylacyl and diacyl fractions; these values are lower than those in Table 3 due to less extensive desaturation of the incorporated [^{14}C]eicosatrienoate. Statistical analysis of the combined data (n = 4) using the Student's t-test for paired samples indicated that the ratio of [^{14}C]20:4/[^{14}C]20:3 in alkylacyl-GPC was significantly greater ($p < 0.05$) than that in diacyl-GPC.

DISCUSSION

This study has demonstrated extensive incorporation of 8,11,14-[^{14}C]eicosatrienoate, as well as [^{14}C]arachidonate, into alkylacyl-GPC of vascular endothelial cells. Although 8,11,14-eicosatrienoate is normally a minor component of endothelial phospholipids, the labeling procedure permits direct comparison of the patterns of esterification of 8,11,14-[^{14}C]eicosatrienoate with those of [^{14}C]arachidonate, synthesized endogenously by desaturation of the [^{14}C]eicosatrienoate. The results indicate quite similar patterns of utilization of 8,11,14-eicosatrienoate and arachidonate. Examination of [^{14}C]20:4/[^{14}C]20:3 ratios in alkylacyl-GPC and diacyl-GPC indicated a small but significant enrichment of alkylacyl-GPC with [^{14}C]arachidonate. Although substantially more [^{14}C]eicosatrienoate had been desaturated to [^{14}C]arachidonate by 48 hr than 24 hr, the extent of enrichment of alkylacyl-GPC with arachidonate was similar at 24 and 48 hr. This finding suggests that remodeling of the alkylacyl-GPC through deacylation-reacylation does not result in substantial replacement of 8,11,14-eicosatrienoate with arachidonate.

The modest enrichment of endothelial alkylacyl-GPC with arachidonate relative to other polyunsaturated fatty acids observed in the present study is consistent with findings in other cells. Compositional data from many cell types including neutrophils (16), macrophages (17,18) and mastocytoma cells (19) indicate that the alkylacyl-GPC fraction, although enriched with arachidonate, contains a mixture of *sn*-2 acyl groups. Indeed, loss of arachidonate from the *sn*-2 position of stimulated neutrophils is accompanied by rapid reacylation of some of the resultant lysophospholipid with linoleate and oleate (6). In contrast, inactivation of exogenous PAF through the sequential activities of acetylhydrolase and transacylase and incorporation of exogenous lyso-PAF is highly specific for reacylation with arachidonate in neutrophils (20), platelets (21–23) and macrophages (24). Recent results by Blank et al. indicate that endothelial cells may be somewhat limited in their ability to reacylate lyso-PAF and may thus synthesize alkylacyl-GPC primarily by the de novo route (25).

Our previous studies have demonstrated that the release of [^{14}C]arachidonate from endothelial cells stimulated with thrombin, histamine or the calcium ionophore A23187 is 8- to 12-fold more extensive than that of 8,11,14-[^{14}C]eicosatrienoate (7,8). The present study provides data which indicate extensive incorporation of 8,11,14-[^{14}C]eicosatrienoate into alkylacyl-GPC. There is some selectivity for esterification of [^{14}C]arachidonate, as opposed to 8,11,14-[^{14}C]eicosatrienoate into alkylacyl-GPC, as evidenced by higher ratios of [^{14}C]20:4/[^{14}C]20:3 in alkylacyl-GPC than diacyl-GPC at both 24 and 48 hr. The extent of enrichment of alkylacyl-GPC with [^{14}C]arachidonate relative to [^{14}C]eicosatrienoate is, however, not sufficient to provide the 10-fold acyl specificity observed in the agonist-stimulated release of arachidonate relative to eicosatrienoate (8,9). These results are thus consistent with the hypothesis that the fatty acyl specificity of arachidonate mobilization in endothelial cells is provided by the agonist-stimulated phospholipase A_2 activity. It is likely that the agonist-stimulated deacylation of endothelial phospholipids, like that in macrophages (5) and neutrophils (26), involves mobilization of arachidonate from both alkylacyl- and diacyl-GPC. Furthermore, stimulation of human umbilical-vein endothelial cells results in net loss of arachidonate from inositol-, as well as choline-phospholipids (27). There may also be contributions from ethanolamine-phospholipids and even triacylglycerols, as well (28). Indeed, recent evidence suggests that porcine endothelial cells (29), like neutrophils (30), mobilize substantial amounts of arachidonate from alkenylacyl-GPE, as well as from choline phospholipids.

23rd Annual Hugh Lofland Conference on Arterial Wall Metabolism (May 24–27, 1989, Welches, Oregon). Requests for information should be sent to M. R. Malinow, M.D., Chairman, Hugh Lofland Conference, Oregon Regional Primate Research Center, 505 NW 185th Avenue, Beaverton, OR 97006, (503) 690-5258.

10th Anniversary Meeting of the European Association for Cancer Research (University College, Galway, Ireland, September 11–13, 1989). For further information, contact Dr. S. M. Lavelle, Experimental Medicine, University College, Galway, Ireland; or in North America, contact Dr. J. H. Weisburger, American Health Foundation, Valhalla, New York, NY 10595-1599. The program involves plenary lectures, workshops, symposia and poster sessions.

REVIEW

Recent Advances in the Purification, Characterization and Structure Determination of Lipases

Edna Antonian
Roche Diagnostic Systems, Inc., 340 Kingsland St., Nutley, NJ 07110-1199

Recently, lipases have been purified from mammalian, bacterial, fungal and plant sources by different methodologies. Purified lipases subsequently have been characterized for molecular size, metal binding capabilities, glycoside and phosphorus contents, and substrate specificities. Primary structures of several lipases have been determined either from amino acid or nucleic acid sequences. Lipases sequenced to date share sequence homologies including a significant region, Gly-X-Ser-X-Gly, that is conserved in all. The Ser residue is suspected to be essential for binding to lipid substrates.
Lipids 23, **1101-1106 (1988).**

Lipases are enzymes that catalyze the hydrolysis of triacylglycerols of animal fats and vegetable oils. The rapid development of lipase structure determination and application is coincident with a renewed interest in developing new domestic markets for U.S. surplus fats and oils. Recent reviews dealing with the potential for using lipases and other enzymes for industrial purposes abound (1-8). Because of this interest, a review of lipase purifications, characterizations and structure determinations to update the existing literature (9-11) seemed valuable.

ISOLATION AND PURIFICATION OF LIPASES

Mammalian lipases. Mammalian lipases from rat liver (12-14) and porcine and human pancreas (15-18) were recently investigated. Rat hepatic lipase was purified to homogeneity by two independent groups (12,13). The purification involved a multistep procedure including chromatography with heparin-Sepharose affinity chromatography, DEAE-Sephacel anion exchange chromatography, and gel filtration on Ultrogel AcA 34 by the former group (12), and octyl-Sepharose 4B, heparin-Sepharose 4B, hydroxyapatite and gel filtration by the latter (13). Twu et al. (13) also reported a purification using an immunoadsorbent column that had been prepared with rabbit anti-lipase antibodies coupled to Sepharose 4B. A yield of 10% lipase activity was obtained with any of the methods of purification. The native enzyme had M_r of 200,000, although when it was denatured it had M_r of 53,000, suggesting that the active enzyme is composed of four subunits. The native protein was shown to be a single enzyme molecule of broad substrate specificity toward triacylglycerols, monoacylglycerols and phosphoglycerols. The enzyme was devoid of free sulfhydryl groups at the active site because the use of *p*-chloromercuribenzoate, an alkylating agent for the -SH group, did not change the enzyme activity as assayed using triolein, monoolein and dipalmitoylphosphatidylcholine. However, diisopropylfluorophosphate, a serine inhibitor, did lead to loss of hydrolytic activity with all three substrates. Evidently serine residues are involved in the catalytic process.

Bacterial lipases. A lipase of *Staphylococcus aureus* was isolated and purified by a sequence involving ammonium sulfate precipitation, hydrophobic interaction chromatography with Phenylsepharose CL-4B, and gel filtration through Sepharose CL-4B (19). The enzyme had a M_r of 300,000 in the native state and 45,000 when it was denatured, suggesting subunit association in the native state. Amino acid analysis by acid hydrolysis indicated the presence of 31% hydrophobic residues (leucine, isoleucine, phenylalanine and valine), not very different from other proteins, but the absence of cysteine and methionine. Analysis of the nonprotein content indicated the presence of about 2% glycosidic residues, 0.05% of phosphorous and traces of lipids. The presence of phosphorous may be due to phospholipids bound to the hydrophobic amino acid residues of the lipase. The lipase showed both esterase activity with Tween 20 (a water soluble ester) and lipase activity with olive oil. The lipase preparation was stable within a pH range of 5.0 to 9.0 and exhibited maximal activity at pH 8.0. Chelating agents and metals such as Ca^{2+}, Cd^{2+} and Mn^{2+} had little effect on the activity of this enzyme, implying that the lipase is not a metalloenzyme.

A lipase from this same bacterial species, but from a different strain, has been sequenced very recently (20). From this sequencing study, Lee and Iandolo found that the molecular weight of their denatured enzyme was about 70,000 both by deduction from the DNA sequence and by SDS-polyacrylamide gel electrophoresis. In addition to the molecular weight difference between the two lipases, there were major differences in amino acid compositions that showed two quite different lipases were isolated from the same species of bacteria.

A lipase from *Pseudomonas aeruginosa,* a pathogenic bacterium, was purified by electrophoresis (21). This research group had been interested in characterizing that enzyme to determine whether the lipase made any contribution to the pathogenic properties of the bacteria. The lipase is extracellular and was present as high molecular weight aggregates (M_r = 500,000) that may be caused by association of lipopolysaccharides with the lipase. The lipopolysaccharides were, in fact, separated from the lipase by solubilization of the concentrated culture supernatant with the zwitterionic detergent CHAPS, 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate. The solubilized enzyme was then separated on an isoelectric focusing gel, and a lipase band was subsequently eluted from the gel. The purified enzyme had a molecular weight of 29,000 and a pI value of 5.8. Lipase activity was measured photometrically with *p*-nitrophenylpalmitate or titrimetrically with olive oil as substrate. The

Abbreviations: CHAPS, 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate; HPLC, high performance liquid chromatography.

lipolytic activity appeared to depend on the presence of either the lipopolysaccharides or nonionic or zwitterionic detergents in the medium. In addition, lipase activity was stimulated by the presence of Ca^{2+} ions. Characterization of the properties of this lipase is in progress to determine possible contributons to the bacterial pathogenesis.

Fungal lipases. Two lipase isozymes (I and II) were isolated and purified from *Aspergillus niger* (22) by a combination of DEAE-Trisacryl M ion exchange chromatography, Sephadex G-50 gel filtration and hydrophobic chromatography using Phenylsepharose CL-4B. The motivation for these studies originated from the industrial use of the original lipase preparation, namely as a flavor developer in milk by-products. Technological lipase applications in the food industry can be more accurately guided once enzymatic properties are clearly established. The results of these characterizations are shown in Table 1.

The isozymes had somewhat different substrate specificities. Lipase I gave high rates of hydrolysis with nitrophenyl esters of C6-C12 fatty acids, while lipase II hydrolyzed esters of shorter chain fatty acids. The presence of $CaCl_2$ and $MgCl_2$ increased the activity of lipase I, but not of lipase II. Lipase I was inhibited by Ag^+ and iodoacetamide, while lipase II was inactivated by Ag^+ and Hg^{2+}. It is well established that metal binding sites can play a key role in the activity of an enzyme by influencing the conformation of the active site. The significance of these metals on the activation (inhibition) of these isozymes will be a matter for study. Inhibition of activity of Lipase I by reaction with iodoacetamide suggested the presence of a free sulfhydryl group at its active site. In addition to the differences already enumerated, the authors have also detected differences in the results from using lipases I and II in the development of compositions related to flavor.

A great deal of information was gathered on this enzyme. Unfortunately, the validity of the substrate and metal binding data are questionable. The lipase catalyzed hydrolysis of nitrophenyl esters of fatty acids is a two-step reaction. Initially a fatty acyl-lipase intermediate is formed, which then undergoes hydrolysis at a rate that is too fast to be measured by ordinary techniques (23).

Additionally, Tahoun et al. (24) report the isolation of an intracellular lipase of M_r 45,000, also from *A. niger.* Characterization of this protein was limited, but preliminary study revealed that the catalyst selected for short chain and unsaturated fatty acids and was able to esterify glycerol at both primary and secondary positions. On the other hand, the enzyme preferentially hydrolyzed acid residues from the primary glycerol position.

In pioneering work, Iwai and Tsujisaki (25) isolated and characterized three lipolytically active components from the fungus, *Rhizopus delemar.* In our own research, we have developed a preparative high performance liquid chromatography (HPLC) method (gel filtration) to affect a partial purification of crude *R. delemar* lipase (Miles Laboratories, Inc., Elkhart, IN). We observed 10 microheterogeneous proteins using two dimensional SDS-polyacrylamide gel electrophoresis of M_r = 38,900 with pI's ranging from 4.6 to 7.0. Amino acid analysis of this material revealed that the composition found for the *R. delemar* lipase is similar to that reported for *Rhizopus arrhizus* (26), except for the amount of Glx, which is higher in the former. Similarities observed among lipases from various sources can be of great value in understanding the catalytic mechanism of action of crucial amino acids, and the evolutionary relatedness of lipases. However, the existence of several differentially charged proteins casts doubt on previous reports of lipase purifications from *Rhizopus* species. More detailed structural studies on *R. delemar* lipase are in progress at the U.S. Department of Agriculture in Philadelphia, PA.

A lipase preparation from the fungus, *Mucor miehei* (recently classified as *Rhizomucor miehei* [27]) has received attention as a potentially useful catalyst for 1,3-positional interesterification (28,29). Recently, Huge-Jensen et al. (27,30) isolated two lipolytically active glycoproteins from this fungus that differed in degree of glycosylation. The steps in purification included chromatography of a crude precipitated powder on an anion-exchange column followed by either affinity chromatography (Con A-Sepharose) or hydrophobic interaction chromatography (Phenyl-Sepharose). Two lipase forms were obtained by independent sub-routines in the initial purification by anion exchange. The more highly glycosylated protein was converted to the less glycosylated variant in purification steps performed at low pH. Amino acid composition of both forms showed a similar protein backbone (27). Although the lipase forms differed in other properties, they both exhibited strong selectivity for the primary glycerol position in hydrolysis, favored longer (>C-10) fatty acid chains, and lacked triacylglycerol stereospecificity. The DNA sequence of both forms was very recently elucidated (27); they had the same primary structure.

Other lipase sources. Germinating oilseeds have been investigated by Hassanien and Mukherjee (31) as sources for lipases. Seeds generally contain a considerable amount of triacylglycerols that are processed by these lipases. Crude lipase preparations were isolated from seedling of rape *(Brassica napus)* and mustard *(Sinapis alba)* and cotyledons of lupine *(Lupinus albus)*; each showed

TABLE 1

Properties of Two Isozymes from *Aspergillus niger*

	Lipase I	Lipase II

specificity for the *sn*-1,3 positions of triacylglycerols with maximum activity between pH 8 and 9. In this work, crude lipase preparations were obtained by acetone or buffer solution extractions from easily grown seedlings. Locating active and stable lipases from plant sources has spurred interest in possible applications of plant lipases in enzymatic processing of fats and oils.

LIPASES: MOLECULAR STRUCTURE—MOLECULAR BIOLOGY

Mammalian lipases. The structural work on lipases is limited, and it seemed useful to consider a few of the earlier efforts in order to place the most recent research in perspective. The complete primary structure of a lipase was first determined by De Caro et al. (15) from the porcine pancreas. Earlier, partial lipase sequence data had been published by the same group (16,17). Amino acid sequencing by automated or manual Edman degradation was done on the cyanogen bromide fragmented enzyme. The porcine lipase was composed of a single chain of 449 amino acids. The calculated molecular weight of the protein moiety was about 50,000, and glycosidic residues gave a total molecular weight of 52,000 as observed by sedimentation equilibrium analysis. The glycan moiety of the lipase was bound to Asn-166 (16,32). Partial digestion of the glycopeptide ^{165}Thr-Asn-Gly-Thr-Ile-Glu-Arg^{171} yielded a glycopeptide containing only the ^{166}Asn-Gly-Thr^{168} fragment. Based on glycoprotein linkages determined previously, the oligosaccharide may be bound either to Asn or Thr. The oligosaccharide was not hydrolyzed by 0.5 N NaOH, which suggested that the site of glycosidation was Asn 166. The modification of an unidentified histidine residue by diethyl pyrocarbonate, forming carbethoxyhistidine, inactivated the lipase though the protein was able to adsorb on siliconized glass beads intact. This suggested that this residue was situated at, or close to, the active site (32). A serine residue that is located at position 152 was derivatized by reaction with diethyl *p*-nitrophenyl phosphate. This amino acid may be involved in substrate binding (33,34). Ser-152 occurs in the amino acid sequence **Gly-His-Ser-Leu-Gly**, a region that is homologous with other lipases; the bold-faced amino acids are highly conserved (Table 2).

The primary structure of human hepatic lipase was reported very recently (35). The lipase gene was mapped to the long arm of human chromosome 15. The amino acid sequence derived from the cDNA predicted a protein of 476 residues with calculated molecular weight of 53,249; it was preceded by a signal peptide of 23 residues. The lipase showed conservation of two hydrophobic domains in common with mammalian hepatic, lipoprotein and pancreatic lipases; **Gly-Tyr-Ser-Leu-Gly** and Ser-$(X)_6$-Ser regions were putative lipid-binding regions (35).

Human lipoprotein lipase was sequenced from a cDNA clone coding for a mature protein of 448 amino acids with

a calculated molecular weight of 50,394 (36). Lipoprotein lipase regulates the metabolism of plasma cholesterol and triacylglycerols. This lipase was 28% homologous to porcine pancreatic lipase, 46% to rat hepatic lipase and almost completely homologous to bovine lipoprotein lipase (Table 2).

Human lecithin-cholesterol acyltransferase cDNA-derived protein sequence was determined to have extensive homologies to mammalian lipases (37). This enzyme catalyzes the transfer of acyl groups from the *sn*-2 position of lecithin to the 3-OH of cholesterol. Physiologically, absence or malfunction of this enzyme results in the accumulation of cholesterol in the tissues. The mature protein contained 416 amino acids with a signal sequence of 24 residues. The calculated molecular weight of the amino acid backbone was 47,090. The enzyme contained the putative lipid binding region Gly-His-Ser-Leu-Gly that was present in different enzymes of lipid metabolism (Table 2).

Human pancreatic lipase was found to be a single polypeptide chain with M_r of 48,000 and has been partially sequenced (18). Specifically, amino acid residues at the N-terminus were sequenced; 21 of the residues showed homology with the N-terminus of porcine pancreatic lipase; 4 residues were not identical and 4 residues remain unidentified. Human lipase was also glycosylated. Complete primary structure of the human pancreatic lipase remains to be elucidated so that comparisons of functionality or structural homologies may be made with lipases of other origins.

Bovine lipoprotein lipase was another lipase investigated for its structure and function relationship. Sequences of NH_2-terminal and tryptic peptides were analyzed, revealing close homology of bovine lipoprotein lipase to porcine pancreatic lipase (38). One year later the complete primary structure was reported from the cDNA clone for lipoprotein lipase (39). The primary structure consisted of 450 amino acids in the unglycosylated form having a predicted molecular weight of 50,548. The enzyme had two hydrophobic regions, Gly-Tyr-Ser-Leu-Gly and Ser-$(X)_6$-Ser, that were present in other mammalian lipoprotein, hepatic and pancreatic lipases as well (Table 2) (35).

The complete sequence of canine pancreatic lipase mRNA was revealed (40). The enzyme was translated as a preenzyme with 467 amino acids, of which 17 residues compose the signal peptide. The mature lipase was calculated to have a molecular weight of 49,686. It showed 75.6% homology with porcine pancreatic lipase. The potential substrate binding site found in the other lipases was conserved here as well (Table 2).

Docherty et al. (41) have cloned and sequenced a rat lingual lipase. A preparation from the tongue serous glands was purified by chromatography on a carboxymethyl Sepharose CL6B column followed by gel filtration on Sephadex G100. The molecular weight of the partially deglycosylated enzyme (Endoglycosidase H) was ca. 41,000, and that of the glycosylated material was ca. 52,000. The purified lipase was used to produce rabbit polyclonal antibodies for the preparation of an immunoaffinity column for large scale purification of the lipase. These antibodies were also used for screening libraries.

A cDNA library was constructed in plasmids from mRNA isolated from the serous glands of rat tongue. Polyclonal antibodies against the purified lipase were used to identify the clone carrying the rat lipase gene. Subsequently, partial sequence analysis was done on the purified lipase to elucidate the N-terminal region. This sequence pinpointed the location of the signal peptide and that of the mature protein. A hydrophobic signal sequence of 18 residues cleaved to yield the mature lipase consisting of 377 residues.

This lipase shares sequence homology with porcine pancreatic lipase over a short region including a Ser-153 that coincides with the porcine pancreatic lipase Ser-152, that is essential for binding to lipid substrates (Table 2). A second and shorter segment of homology with porcine pancreatic lipase included an Asn-166, a putative glycosylation site in porcine pancreatic lipase as discussed previously and predicted to be such a potential site in the rat lingual lipase.

Rat hepatic lipase was purified, and partial amino acid sequence was determined by gas-phase microsequence analysis of proteolytic fragments (14). The enzyme had a molecular weight of ca. 52,700 obtained from SDS-polyacrylamide gels. The complete cDNA-derived amino acid sequence was obtained later with the help of an oligonucleotide probe synthesized on the basis of a partial sequence (42). The protein backbone was predicted to have a 53,222 molecular weight and was composed of 472 amino acids. The lipase was preceded by a hydrophobic leader sequence of 22 amino acids. The native lipase had an 8% (w/w) carbohydrate content (43). One of the two hydrophobic regions in common with other enzymes of lipid metabolism is shown in Table 2. The second hydrophobic sequence found in mammalian hepatic, lipoprotein and pancreatic lipases, Ser-$(X)_6$-Ser, was also present here.

cDNA-derived amino acid sequence of mouse lipoprotein lipase was also reported (44). The mature protein contained 447 amino acids with a predicted molecular weight of 50,314. Lipoprotein lipase is conserved extensively among mouse, human and bovine species. One of the putative substrate binding regions in homology with other enzymes of lipid metabolism is shown in Table 2.

Bacterial lipases. The lipase gene from *Staphylococcus hyicus hyicus* has been cloned and its sequence determined by Gotz et al. (45). The gene was cloned in plasmids, expressed in *S. carnosus,* and subcloned in *E. coli.* The DNA sequence yielded a preprotein of 641 amino acids. The authors predicted the location of the signal sequence based on homology with signal sequences from various organisms. The signal sequence was an N-terminal hydrophilic segment that was followed by a hydrophobic sequence ending in Ala-X-Ala that, finally, was followed by the sequence for the mature protein. Interestingly, the *S. hyicus hyicus* lipase also contained the sequence Phe-Ile-Gly-His-Ser-Met-Gly-Gly; the bold-faced region is homologous with lipase sequences from porcine pancreas and rat tongue (Table 2).

The lipase gene expressed in recombinantly transformed *S. carnosus* yielded an extracellular lipase with M_r value of 86,000, as determined by SDS-polyacrylamide gel electrophoresis. However, lipase excreted from donor strain *S. hyicus hyicus* showed a M_r of only 50,000. The authors attributed this molecular weight difference to an identified extracellular proteolytic activity in *S. hyicus hyicus.* The molecular weight calculated from

the preprotein amino acid sequence, including the signal sequence, is 71,000. The authors assumed the M_r 86,000 form enzyme may have hydrophilic or lipophilic contaminants leading to a reduced mobility in SDS gels and a high relative molecular weight.

The lipase gene from *S. aureus* was cloned and sequenced (19) as mentioned above. Detection of lipase activity in the cloned gene was on an egg yolk medium. A positive lipase activity was observed as a halo surrounding the colony upon accumulation of hydrolyzed fatty acids. To localize the lipase gene, various plasmids containing deletions at either end of the sequenced DNA fragment were generated. Deletions of DNA fragments allowed pinpointing the location of the gene. The DNA sequence revealed the presence of a signal sequence with the classical characteristics of a hydrophilic region followed by hydrophobic amino acids and ending in Ala-X-Ala prior to the mature protein. The predicted mature protein had a calculated basic pI of 9.3 and a M_r of 70,000 as determined by SDS-polyacrylamide gel electrophoresis. Comparison of the nucleotide sequences of the *S. aureus* and *S. hyicus hyicus* lipases revealed 46% homology, a significant amount. The amino acid sequences conserved between the two enzymes included the hydrophobic amino acid-rich region (residue 310 to the C terminus) that appeared to be associated with enzyme activity as observed by inactivation of the enzyme upon insertion of a lysogenic phage near the carboxyl end.

Finally, the sequence Leu-Val-Gly-His-Ser-Met-Gly-Gly was found in *S. aureus* lipase, and it contained the homologous region (boldface) found in all the lipases sequenced to date (Table 2).

Kugimiya et al. (46) cloned the lipase gene from *Pseudomonas fragi* in a plasmid. The lipase is known to have 1,3 positional specificity. The tributyrine diffusion agar method was used for the detection of lipase activity. DNA sequencing yielded a preprotein of 135 amino acids with a predicted M_r of about 15,000. A signal sequence composed of mostly hydrophobic amino acids was identified. Comparison of the lipase amino acid sequence with those from other organisms sequenced to date again showed the presence of the short homologous region Gly-His-Ser-X-Gly that is shared by porcine pancreatic, rat lingual, *S. hyicus* and *S. aureus* lipases, as seen in Table 2. In addition, another segment of amino acid sequence composed of five residues, falling in the signal portion, is homologous to the lipase from rat tonge.

Fungal lipases. The lipase gene from *Rhizomucor miehei* was cloned and sequenced (27) as mentioned above. The mature lipase was composed of 269 amino acids having a molecular weight of 29,472. The lipase was synthesized as part of a 363 residues-long precursor from which 24 amino acids were the signal sequence and 70 residues were the propeptide. The native enzyme was modified to two forms taking up either 11% (w/w) or 4% (w/w) carbohydrates. This lipase also showed sequence conservation in the vicinity of one Ser residue, located in a stretch of hydrophobic amino acid residues (27) (Table 2).

Finally, all sequenced lipases except those from *P. fragi* and *R. miehei* contain potential glycosylation sites (Table 2), N-X-T or N-X-S, where X cannot be proline (35). Oligosaccharides may link either through N-acetyl-D-glucosamine to the amide nitrogen of an Asn or through N-acetyl-D-galactosamine to the hydroxyl group of Ser or Thr.

CONCLUSION

We have entered an era in which the availability of protein sequence information, emerging data for substrate binding sites and the relationship of catalytically active residue(s) to the binding site direct us toward protein engineering. Site selective transformations through molecular biology techniques may increase greatly our understanding of lipase mode of action, and could provide semi-synthetic lipases having improved stability and/or desired substrate specificities. The prognosis for the immediate future appears to be continued research into the nature of lipases as an industrially important class of enzymes. A base of information currently is being generated that will stimulate and encourage old industries into evaluating new applications.

ACKNOWLEDGMENT

I thank Philip E. Sonnet at the U.S. Department of Agriculture for his critical review of the manuscript.

ARTICLES

Effect of Host Sterols on the Sterol Composition and Virulence of a Nuclear Polyhedrosis Virus of *Heliothis zea*

Dorothy L. Mac Donald[1] and **Karla S. Ritter***
Department of Bioscience and Biotechnology, Drexel University, Philadelphia, PA 19104

The type of sterol in the diet of *Heliothis zea* affected not only the sterol composition of the insect larva but also the virulence and/or sterol composition of a single-nucleocapsid nuclear polyhedrosis virus (HzSNPV). This baculovirus, which was purified by differential and sucrose density gradient centrifugation, had a sterol content of 40 ng per 10^6 polyhedra. When the sterol composition of HzSNPV was characterized by gas liquid chromatography, reversed phase-high performance liquid chromatography, mass spectrometry, proton nuclear magnetic resonance spectrometry and/or ultraviolet spectroscopy, the sterols in the virus were similar to those of the host. The HzSNPV isolated from larvae fed Δ^5-, Δ^0- or $\Delta^{5,7}$-sterols contained primarily cholesterol, cholestanol or 7-dehydrocholesterol, respectively. Changes in the sterol composition of HzSNPV affected its LD_{50}, but not LT_{50}, in larvae containing Δ^5-sterol. The LD_{50} of virus isolated from larvae containing Δ^0-, Δ^5- and Δ^7-sterols decreased from 275,423 to 32,359 to 5,012 polyhedra/larva, respectively. The latter virus was also more virulent than the one that was isolated from larvae containing $\Delta^{5,7}$-sterol and had an LD_{50} of 58,884 polyhedra/larva. In contrast, the LD_{50} of an HzSNPV (Sandoz, Inc.) containing Δ^5-sterols was not affected by the presence of Δ^5-, Δ^0- or $\Delta^{5,7}$-sterols in the tissues of the host (1,413; 1,288 and 355 polyhedra/larva, respectively). The results of this study indicate that the sterol composition of *H. zea* can affect the sterol composition of HzSNPV and therefore may affect the ability of this biological control agent to control its economically important insect host. *Lipids 23,* 1107-1113 (1988).

The functional role of sterols in viruses is still poorly understood. The sterols in the envelope of viruses probably function as important structural components, just as they do in the membranes of cells (1). Sterols may be necessary in the envelope to assure that the virions are released from the host cell and/or can enter other susceptible cells (2). Interestingly, the depletion of cholesterol from vesicular stomatitis virus caused a substantial loss of infectivity of the virions (3,4). Although the sterol composition of some viruses has been determined (5), the quantity and type of sterol in many other enveloped viruses (e.g., baculoviruses of insects) is unknown.

Viruses are not known to carry the genes responsible for the synthesis of enzymes involved in lipid synthesis (1). Therefore, the lipids such as sterols in the envelope appear to be derived from the host cell. This suggests that if the sterol composition of an organism changed, the sterol composition of the virus might be affected. Bates and Rothblat (6) found that when vesicular stomatitis virus was grown in L cells, which were different from normal cells grown in tissue culture because they contained desmosterol instead of cholesterol, the virus contained only desmosterol and no cholesterol. The stability, growth and plaquing efficiency of the virus, however, was not affected by the presence of this $\Delta^{5,24}$-sterol. In contrast, the fusion of certain viruses (e.g., Semliki Forest virus [SFV] [7], Sindbis virus [8] and Sendai virus [9]) to liposomes was dependent on the quantity or structure of the sterol present in the liposome. When androstanol, cholestanol, coprostanol or sterols lacking a 3β-OH group were used in place of cholesterol in the liposome, the percentage of fusion of SFV with the liposome was reduced to 88.5, 53, 40 and $\leq$13% of that of cholesterol, respectively (7). Therefore, further studies of the effect of host sterols on the sterol composition and infectivity of viruses are warranted.

Many animals contain cholesterol as their tissue sterol, because they can synthesize this molecule from acetate (10), and so their enveloped viruses also usually contain this sterol (11). However, some invertebrates, such as insects, cannot synthesize sterols de novo and so obtain them exogenously in order to synthesize membranes and hormones (e.g., ecdysteroids) (12). Thus, the sterol composition of an insect may vary depending on its ability to utilize and/or metabolize different exogenous sterols (e.g., phytosterols) in its tissues. For example, the principal tissue sterols in the larva of the corn earworm, *Heliothis zea,* are cholestanol, cholesterol, 7-dehydrocholesterol or lathosterol when various Δ^0-, Δ^5-, $\Delta^{5,7}$- or Δ^7-24-alkyl- and desalkylsterols are its dietary sterols, respectively (13,14). Therefore, it is of interest to know whether changes in the sterol composition of insects can affect the sterol composition and/or virulence of their enveloped viruses, particularly those that are biological control agents of insect pests or are vectored by them.

Abbreviations: a_c, k' for the test sterol/k' for cholesterol; TMS, $Si(CH_3)_4$; χ^2, chi-square; df, degrees of freedom; EM, electron microscopy; GLC, gas liquid chromatography; ^{1}H-NMR, proton nuclear magnetic resonance spectrometry; HzSNPV, single-nucleocapsid nuclear polyhedrosis virus of *H. zea*; k', $(V_t - V_0)V_0$; LD_{50}, median lethal dose; LT_{50}, median lethal time; MS, mass spectrometry; NPV, nuclear polyhedrosis virus; RP-HPLC, reversed phase-high performance liquid chromatography; RRT, retention time relative to cholesterol; TLC, thin layer chromatography; UV, ultraviolet spectroscopy; V_0, void volume; V_t, retention volume of the sterol.

The systematic nomenclature for the sterols referred to by their trivial names is: cholestanol, 5α-cholestan-3β-ol; cholesterol, cholest-5-en-3β-ol; 7-dehydrocholesterol, cholesta-5,7-dien-3β-ol; desmosterol, cholesta-5,24-dien-3β-ol; 22-dihydroergosterol, 24β-methylcholesta-5,7-dien-3β-ol; ergosterol, 24β-methylcholesta-5,7,22-trien-3β-ol; lathosterol, cholest-7-en-3β-ol; 24ξ-methylcholesterol, 24ξ-methylcholesta-5-en-3β-ol; sitosterol, 24α-ethylcholest-5-en-3β-ol; stigmasterol, 24α-ethylcholest-5,22-dien-3β-ol.

Cholesterol is the only sterol that has been reported from those enveloped insect viruses which have been studied (e.g., *Chilo* iridescent virus [15]). Although the nuclear polyhedrosis viruses (NPV) of *Bombyx mori* (16), *Lymantria dispar* (17) and *Pseudaletia unipuncta* (18) are known to contain lipids (e.g., phospholipids), the sterol composition of this type of virus has never been investigated.

Consequently, the purpose of the present study was: (a) to determine the quantity of sterol in a single-nucleocapsid nuclear polyhedrosis virus of *H. zea* (HzSNPV); (b) to investigate whether infection with HzSNPV alters the normal metabolism of sterols in *H. zea* larvae; (c) to determine how the sterol composition of the insect affects the sterol composition of the baculovirus; and (d) to study how the sterol composition of HzSNPV affects its virulence.

MATERIALS AND METHODS

H. zea. A disease-free colony of *H. zea* was established from eggs kindly provided by Dr. N. C. Leppla (USDA, Gainesville, FL) and maintained as described previously (19). The experimental larvae were fed a variety of artificial diets which affected their sterol composition. Some larvae were reared on medium that contained cholesterol (recrystallized twice from ethanol; 50 mg/100 ml diet; J. T. Baker Chemical Co., Phillipsburg, NJ) and was supplemented with wheat germ and Mazola corn oil (19); the principal tissue sterol in these larvae was cholesterol (20). Other larvae were fed diets which contained ergosterol (recrystallized twice from ethanol; ICN Pharmaceuticals, Inc., Cleveland, OH), cholestanol (Applied Science Laboratories, State College, PA) or lathosterol (Research Plus Steroid Laboratories, Bayonne, NJ) (20 mg/100 ml diet) and were supplemented with linoleic and linolenic acid (21); the principal tissue sterols in these larvae were 7-dehydrocholesterol (14), cholestanol or lathosterol, respectively (13).

Propagation, isolation and purification of HzSNPV. HzSNPV, a gift from Dr. T. R. Shieh (Sandoz, Inc., Homestead, FL), was propagated in larvae of *H. zea*, which contained a variety of tissue sterols. The 5th-instar larvae were inoculated per os (22) with 1.0×10^5 to 1.0×10^7 polyhedra/4 μl H_2O, using a blunt 30-gauge needle attached to a 1/4 ml syringe mounted on a microburet (Micro-Metric Instrument Co., Tampa, FL). Five days later, the moribund larvae were collected and frozen until the HzSNPV was isolated from the tissues and purified by differential and sucrose density centrifugation. The larvae were thawed, triturated in H_2O, the homogenate filtered through cheesecloth and the filtrate centrifuged at 11,872 *g*. The pellet was resuspended in H_2O and centrifuged at 475 *g* for 10 min. The supernatant containing the HzSNPV was then centrifuged at 11,872 *g* for 20 min to pellet the polyhedra. The virus was layered onto sucrose step gradients (consisting of equal amounts of 50 and 80% sucrose) and centrifuged at 54,000 *g* for 2 hr. The band containing the polyhedra was then collected and the polyhedra washed and lyophilized.

Electron microscopy of HzSNPV. Fat body and tracheae from infected larvae containing cholesterol were prepared for electron microscopy (EM) and examined using a Philips EM 300 electron microscope, as described previously (23), in order to confirm that the virus was a single-nucleocapsid NPV.

Quantitation of insect tissue sterol associated with HzSNPV. The amount of exogenous sterol from the host tissues, which was associated with the purified HzSNPV, was determined by combining an equal weight of infected larvae (fed unlabeled cholesterol) with noninfected larvae (fed radiolabeled cholesterol) and measuring the amount of radioactivity associated with the HzSNPV isolated from the mixture. The infected larvae were reared on diet that contained unlabeled cholesterol (15 mg/100 ml) and was supplemented with linoleic and linolenic acid (19). The noninfected larvae were reared on a similar diet that also contained [7-^{3}H]cholesterol (37 Ci/mmol; New England Nuclear, Boston, MA). The radiolabeled sterol was diluted with the unlabeled cholesterol so that the final specific activity of cholesterol in this diet was 2.58 mCi/mmol. The polyhedra were isolated from the tissues, as described above, and the number of polyhedra/ml calculated using a bacteria counter (C.A. Hausser and Son, Philadelphia, PA). The amount of exogenous sterol associated with the virus was determined by solubilizing the purified polyhedra (5.93 to 16.70×10^6) in 0.5 ml Protosol (New England Nuclear), neutralizing the solution with glacial acetic acid to prevent chemiluminescence, suspending it in 10 ml of 3a20 scintillation cocktail (Research Products International Corp., Mount Prospect, IL) and measuring the amount of radioactivity present with an LS 7500 liquid scintillation counter (Beckman Instruments, Irvine, CA). The counts were corrected for quench and background and the $\pm$ values represent the standard deviation of the mean.

Quantitation of sterol in insect tissue. In order to confirm that sterol was present in the insect tissues, samples of fat body (1.0 to 2.8 mg) were isolated from larvae fed the diet containing [7-^{3}H]cholesterol, weighed and digested in 1 ml of Protosol. The solution was then neutralized and the amount of radioactivity/mg of tissue determined by scintillation counting.

Quantitation of sterol in HzSNPV. The total amount of sterol associated with the polyhedra was determined by isolating the virus from infected larvae reared on diet containing [7-^{3}H]cholesterol and measuring the amount of radioactivity associated with the polyhedra (1.35 to 2.03×10^6), as previously described. The proportion of sterol that was probably exogenous was then subtracted from this value in order to determine the amount of endogenous sterol present in HzSNPV.

Bioassays. Fifth-instar larvae that contained various tissue sterols were inoculated per os with HzSNPV, which had been propagated in larvae containing various tissue sterols or obtained from Sandoz Inc., to ascertain the effect of the different sterols on the virulence (i.e., the LD_{50}) of the virus. The various doses of HzSNPV were prepared using the bacteria counter to determine the number of polyhedra/ml. The larvae were examined daily for the signs and symptoms of disease. In each bioassay, the median lethal time (LT_{50}) of the virus was determined from the time course of infection and the median lethal dose (LD_{50}) calculated using probit analysis (24).

Isolation of sterols from HzSNPV. The lipids from HzSNPV (Sandoz, Inc.) were obtained by continuous extraction of the polyhedra with acetone in a Soxhlet apparatus for 24 hr. The lipids from other HzSNPV (isolated

from larvae of *H. zea*) were obtained using a modified Bligh-Dyer technique (25). The lyophilized polyhedra were hydrated, suspended in chloroform-methanol, incubated at 60°C for 15 to 20 min and the filtrates from 3 extractions pooled. The lipids in both the acetone and chloroform-methanol extracts were saponified in 5% KOH in 90% ETOH during refluxing for 1 hr or at 60°C overnight. The neutral lipids were then extracted with diethyl ether. Due to the small sample size, the 4-desmethylsterols were rapidly isolated by preparative thin layer chromatography (TLC) on Silica Gel G using a solvent system of benzene and ethyl acetate (9:1, v/v). Some of the isolated 4-desmethylsterols from the Sandoz HzSNPV were then separated from one another via preparative reversed phase-high performance liquid chromatography (RP-HPLC) using a Perkin-Elmer Series 1 liquid chromatograph, equipped with a variable wavelength UV detector and a Perkin-Elmer preparative C_{18} column at 30°C. The mobile phase was 100% acetonitrile at a flow rate of 10 ml/min. The sample was injected in 2 ml of isopropanol and the sterols collected in 10 ml fractions.

Isolation of sterols from infected larvae. Larvae of *H. zea* were homogenized with a Sorvall Omni-Mixer (Dupont Instruments, Newtown, CT), the lipids extracted with chloroform-methanol and saponified, as previously described. The neutral lipids were extracted with diethyl ether and the 4-desmethylsterols isolated by TLC or column chromatography on silicic acid (10 mg lipid/g adsorbent; Unisil, Clarkson Chemical Co., Inc., Williamsport, PA). The latter procedure utilized an elution scheme of increasing amounts of ether in hexane and the eluent was monitored by TLC and gas liquid chromatography (GLC). Some or all of the isolated 4-desmethylsterols were then separated from one another via preparative RP-HPLC, as previously described.

Identification of sterols. The sterols isolated from HzSNPV and infected larvae were characterized by GLC, RP-HPLC, ultraviolet spectroscopy (UV), mass spectrometry (MS) and/or proton nuclear magnetic resonance spectrometry (^{1}H-NMR) and identified after comparing their characteristics to those of the dietary sterols and standards (e.g., cholestanol, cholesterol, 7-dehydrocholesterol [Sigma Chemical Co., St. Louis, MO], desmosterol [Sigma Chemical Co.], ergosterol, lathosterol, 24ξ-methylcholesterol [Research Plus Steroid Laboratories], sitosterol [Sigma Chemical Co.], and stigmasterol [Sigma Chemical Co.]) and/or the published descriptions of sterols (e.g., 22-dihydroergosterol [26], Δ^7-24ξ-methylcholestenol, and $\Delta^{7,22}$-24ξ-methylcholestenol [27]).

GLC was performed using a Perkin-Elmer Sigma 3B chromatograph and a 1% SE-30 and/or a 3% QF-1 column at 230 to 235°C. Rates of movement of the sterols were expressed as retention times relative to cholesterol (RRT) ± the actual range of the results. Analytical RP-HPLC was performed on a Perkin-Elmer Series 3B liquid chromatograph equipped with a variable wavelength UV detector, stopflow capabilities and a Zorbax ODS (C_{18}) column at 45°C. The mobile phase was acetonitrile/isopropanol (80:20, v/v) at a flow rate of 2 ml/min. The k′ value ($[V_t - V_0]/V_0$ where V_t is the retention volume of the sterol and V_0 is the void volume) for cholesterol was determined and used to calculate the α_c values (k′ for the test sterol/k′ for cholesterol) of the experimental peaks. The ± values associated with the α_c's represent the actual range of the results. Ultraviolet absorption spectra were obtained by scanning the individual peaks from analytical RP-HPLC between 200 and 300 nm. MS was performed via direct probe on a model 4000 Finnigan instrument with electron impact ionization at 70 eV. The ± values associated with the percentage of the ions present represent the actual range of the results. ^{1}H-NMR was performed at 360 MHz at ambient temperature on a Bruker instrument, model WH360; up to ca. 1 to 2 mg of sterol was dissolved in $CDCl_3$ and $Si(CH_3)_4$ (TMS) was the internal standard.

RESULTS

Identification of sterols. The characteristics of the sterols isolated in this study are summarized below:

Cholestanol. The RRTs in GLC were 1.09 ± 0.02 on QF-1 and 1.00 ± 0.02 on SE-30. The *m/e* of the ions in MS were: 388 (M^+, 22%), 373 (M^+-CH_3, 11%), 355 ($M^+-CH_3-H_2O$, 4%), 273 (M^+-SC-2H, 1%), 257 (M^+-SC-H_2O, 2%), 233 (M^+-SC-C_3H_6, 79%), 231 (M^+-SC-C_3H_8, 7%) and 215 (M^+-SC-$C_3H_6-H_2O$, 100%). The chemical shifts, in ppm from TMS, of protons in ^{1}H-NMR were: C-18, 0.64 (s); C-19, 0.80 (s); C-21, 0.90 (d, J = 7 Hz); C-26 and 27, 0.86 and 0.86 (d, J = 6 Hz).

Cholesterol. The RRTs in GLC were 1.00 ± 0.01 on QF-1 and SE-30. The α_c in RP-HPLC was 1.00 ± 0.01 with an UV absorption maximum at 208 nm. The *m/e* of the ions in MS and the chemical shifts, in ppm from TMS, of protons in ^{1}H-NMR were similar to published values (27).

7-Dehydrocholesterol. The RRTs in GLC were 1.12 ± 0.01 on QF-1 and 1.08 ± 0.01 on SE-30. The α_c in RP-HPLC was 0.77 ± 0.01 with UV absorption maxima at 208, 273, 283 and 295 nm. The *m/e* of the ions in MS and the chemical shifts, in ppm from TMS, of protons in ^{1}H-NMR were similar to published values (27).

Desmosterol. The α_c in RP-HPLC was 0.69 ± 0.01 with a UV absorption maximum at 208 nm. The *m/e* of the ions in MS were: 384 (M^+, 78%), 369 (M^+-CH_3, 44%), 273 (M^+-SC-2H, 100%) and 253 (M^+-SC-H_2O-2H, 11%).

22-Dihydroergosterol. The α_c in RP-HPLC was 0.86 ± 0.01 with UV absorption maxima at 208, 272, 283 and 294 nm. The *m/e* of the ions in MS were: 398 (M^+, 37 ± 21%), 383 (M^+-CH_3, 7%), 380 (M^+-H_2O, 6 ± 6%), 365 ($M^+-CH_3-H_2O$, 41 ± 33%), 339 ($M^+-C_3H_5-H_2O$, 23 ± 19%), 337 ($M^+-C_3H_7-H_2O$, 5 ± 1%), 271 (M^+-SC, 59 ± 11%), 253 (M^+-SC-H_2O, 37 ± 22%), 211 (M^+-SC-$C_3H_6-H_2O$, 52 ± 30%) and 209 (M^+-SC-$C_3H_8-H_2O$, 12 ± 5%). The chemical shifts, in ppm from TMS, of protons in ^{1}H-NMR were: C-18, 0.62 (s); C-19, 0.94 (s); C-21, 0.93 (d, J = 7 Hz); C-26 and 27, 0.79 and 0.78 (d, J = 7 Hz); C-28, 0.86 (d, J = 6 Hz).

Ergosterol. The RRTs in GLC were 1.21 ± 0.01 on QF-1 and 1.20 ± 0.01 on SE-30. The α_c in RP-HPLC was 0.72 ± 0.01 with UV absorption maxima at 208, 272, 283 and 294 nm. The *m/e* of the ions in MS and the chemical shifts, in ppm from TMS, of protons in ^{1}H-NMR were similar to published values (27).

24ξ-Methylcholesterol. The RRTs in GLC were 1.29 ± 0.01 on QF-1 and 1.30 ± 0.05 on SE-30. The α_c in RP-HPLC was 1.12 ± 0.02 with a UV absorption maximum at 208 nm. The *m/e* of the ions in MS were: 400 (M^+, 100%), 385 (M^+-CH_3, 26%), 382 (M^+-H_2O, 30%),

367 (M^+-CH_3-H_2O, 22%), 315 (M^+-85, 26%), 289 (M^+-C_7H_{11}, 26%), 273 (M^+-SC, 9%), 255 (M^+-SC-H_2O, 17%), 231 (M^+-SC-C_3H_6, 9%), 229 (M^+-SC-C_3H_8, 9%) and 213 (M^+-SC-C_3H_6-H_2O, 22%). The chemical shifts, in ppm from TMS, of protons in ^{1}H-NMR were: C-18, 0.68 (s); C-19, 1.00 (s); C-21, 0.90 (d, J = 7 Hz); C-26 and 27, 0.77 and 0.84 (d, J = 6 Hz); C-28, 0.79 (d, J = 7 Hz) for 24α-methylcholesterol and C-18, 0.68 (s); C-19, 1.00 (s); C-21, 0.91 (d, J = 7 Hz); C-26 and 27, 0.85 and 0.78 (d, J = 7 Hz); C-28, 0.79 (d, J = 7 Hz) for 24β-methylcholesterol.

Sitosterol. The RRTs in GLC were 1.53 ± 0.02 on QF-1 and 1.63 ± 0.02 on SE-30. The α_c in RP-HPLC was 1.25 ± 0.02 with a UV absorption maximum at 208 nm. The *m/e* of the ions in MS and the chemical shifts, in ppm from TMS, of protons in ^{1}H-NMR were similar to published values (27).

Stigmasterol. The RRTs in GLC were 1.29 ± 0.01 on QF-1 and 1.44 ± 0.09 on SE-30. The α_c in RP-HPLC was 1.08 ± 0.00 with a UV absorption maximum at 208 nm. The *m/e* of the ions in MS and the chemical shifts, in ppm from TMS, of protons in ^{1}H-NMR were similar to published values (27).

Sterols from infected larvae. The principal sterols present in infected insects in this study were similar to those found previously in noninfected larvae (13,14,20). The sterols isolated from 25.1 g of infected larvae-fed diet containing cholesterol (Table 1) were 95% cholesterol, <1% 24α- and 24β-methylcholesterol, 3% sitosterol, <1% stigmasterol (characterized by GLC, RP-HPLC, UV, MS and ^{1}H-NMR with the exception of stigmasterol which was characterized by MS and ^{1}H-NMR, only) and <1% desmosterol (characterized by RP-HPLC and MS).

The sterols isolated from 20.4 g of infected larvae-fed diet containing cholestanol (Table 1) were >95% cholestanol (characterized by GLC, MS and ^{1}H-NMR) and <5% cholesterol (characterized by RP-HPLC).

The sterols isolated from 56.7 g of infected larvae-fed diet containing ergosterol (Table 1) were 8 ± 4% cholesterol, 50 ± 8% 7-dehydrocholesterol, 37 ± 7% ergosterol (characterized by GLC, RP-HPLC, UV, MS and ^{1}H-NMR), 6 ± 3% lathosterol plus Δ^7-24ξ-methylcholestenol plus $\Delta^{7,22}$-24ξ-methylcholestenol, <1% 22-dihydroergosterol (characterized by RP-HPLC, UV, MS and ^{1}H-NMR), and <1% unidentified component(s). The lathosterol was characterized by the unique C-18 peak at 0.53 ppm in ^{1}H-NMR (its GLC values corresponded to those of 7-dehydrocholesterol, and its RP-HPLC and MS values corresponded to those of cholesterol). The Δ^7-24ξ-methylcholestenol was characterized by the α_c of 1.15 ± 0.02 in RP-HPLC, M^+ of 400 in MS, and the C-18 peak at 0.54 ppm in ^{1}H-NMR. The $\Delta^{7,22}$-24ξ-methylcholestenol was characterized by the α_c of 0.94 ± 0.01 in RP-HPLC, the M^+ of 398 in MS and the C-18 peak at 0.54 ppm in ^{1}H-NMR.

Sterols from HzSNPV. The sterols present in HzSNPV (observed to be a single-nucleocapsid virus by EM), isolated from 38.1 g of infected larvae-fed diet containing cholesterol (Table 1), were 70% cholesterol and 18% sitosterol (characterized by GLC, RP-HPLC, UV, MS and ^{1}H-NMR), 11% 24ξ-methylcholesterol and 2% stigmasterol (characterized by GLC and MS). The latter 24-alkylsterols were probably derived from the plant material in the diet.

The sterols isolated from 120 g of HzSNPV (Sandoz, Inc.) (Table 1) were 56% cholesterol, 12% 24α- and 24β-methylcholesterol, 28% sitosterol and 5% stigmasterol (characterized by GLC, RP-HPLC, UV, MS and ^{1}H-NMR).

The sterols present in HzSNPV isolated from 31.8 g of infected larvae fed a diet containing cholestanol (Table 1) were 99% cholestanol (characterized by GLC, MS and ^{1}H-NMR) and 1% cholesterol (characterized by GLC).

The sterols present in HzSNPV, isolated from 16.6 g of infected larvae-fed diet containing ergosterol (Table 1), were <2% cholesterol, 67% 7-dehydrocholesterol, <2% 22-dihydroergosterol and 30% ergosterol. These sterols were characterized by RP-HPLC and UV.

Quantity of insect tissue sterol associated with HzSNPV. When infected larvae (reared on a diet containing unlabeled cholesterol) were homogenized in a 1:1 ratio with noninfected larvae (reared on a diet containing [7-^{3}H]-cholesterol), the average amount of radioactivity

TABLE 1

Sterol Composition of Infected Larvae of *H. zea* and Their HzSNPV

	% Total sterol in:						
	Infected larvae-fed diet containing:			HzSNPV from larvae-fed diet containing:			HzSNPV
Sterol	Cholestanol	Cholesterol	Ergosterol	Cholestanol	Cholesterol	Ergosterol	(Sandoz Inc.)
Cholestanol	>95	—	—	99	—	—	—
Cholesterol	<5	95	8	1	70	<2	56
7-Dehydrocholesterol	—	—	50	—	—	67	—
Desmosterol	—	<1	—	—	—	—	—
22-Dihydroergosterol	—	—	<1	—	—	<2	—
Ergosterol	—	—	37	—	—	30	—
24ξ-Methylcholesterol	—	<1	—	—	11	—	12
Sitosterol	—	3	—	—	18	—	28
Δ^7-Sterols[a]	—	—	6	—	—	—	—
Stigmasterol	—	<1	—	—	2	—	5
Unidentified	—	—	<1	—	—	—	—

[a]Lathosterol, Δ^7-24ξ-methylcholestenol and $\Delta^{7,22}$-24ξ-methylcholestenol.

associated with the purified nonlabeled polyhedra was 125 ± 115 dpm/10^6 polyhedra. Therefore, the average number of exogenous cholesterol molecules contaminating the polyhedra preparation was $2.63 \times 10^{13} \pm 2.41 \times 10^{13}$ molecules/10^6 polyhedra.

Quantity of sterol in HzSNPV. The average amount of radioactivity associated with polyhedra isolated from larvae (reared on a diet containing [7-^{3}H]cholesterol) was 903 ± 349 dpm/10^6 polyhedra. Therefore, the average number of cholesterol molecules associated with the polyhedra was $9.52 \times 10^{13} \pm 3.7 \times 10^{13}$ molecules/10^6 polyhedra. Consequently, because the percentage of the total cholesterol that was actually associated with the virus, and not due to tissue contamination, was 72.4%, the amount of endogenous cholesterol present in the virus was 6.89×10^{13} molecules/10^6 polyhedra or 40 ng/10^6 polyhedra.

Quantity of sterol in insect tissue. Dietary sterol was present in insect tissue. The average amount of radioactivity present in the fat body from uninfected larvae-fed diet containing [7-^{3}H]cholesterol was 16,104 ± 3,755 dpm/mg tissue. Therefore, the average number of cholesterol molecules in the insect fat body was $1.69 \times 10^{15} \pm 3.9 \times 10^{14}$ molecules/mg of insect tissue or 1.09 μg/mg of insect tissue.

Effect of different host sterols on the virulence of HzSNPV. The effect of various host sterols, on the virulence of HzSNPV obtained from Sandoz, Inc., was determined via bioassays of this virus in larvae-fed diets containing various sterols. The presence of Δ^0-sterol in the tissues of the host did not affect the virulence of the virus because there was no significant difference between the LD_{50}'s of the virus (1,413 and 1,288 polyhedra/larva) in the larvae-fed cholesterol and cholestanol, respectively. Although the larvae-fed ergosterol, and so containing $\Delta^{5,7}$-sterols in their tissues, appeared to be more susceptible to the virus (LD_{50} of 355 polyhedra/larva), this difference may not be significant due to overlapping 95% confidence intervals (Table 2 and Fig. 1).

Effect of different virus sterols on the virulence of HzSNPV. The effect of various viral sterols on the virulence of HzSNPV was determined via bioassays of HzSNPV (propagated in larvae-fed various sterols) in larvae-fed diet containing cholesterol. The presence of Δ^5- versus Δ^0-sterols in the virus affected its virulence because there was a difference in the LD_{50}'s of the viruses (32,359 and 275,423 polyhedra/larva, respectively) in the larvae-fed cholesterol. Because of overlapping 95% confidence intervals (Table 3), the virulence of the virus containing $\Delta^{5,7}$-sterol (LD_{50} of 58,884 polyhedra/larva) may not be different from that of the viruses containing Δ^5- and Δ^0-sterols. However, the HzSNPV propagated in larvae containing the Δ^7-sterol, lathosterol, in their tissues, was the most virulent of all the viruses (LD_{50} of 5,012 polyhedra/larva) (Table 3 and Fig. 2).

The LD_{50} of the laboratory-prepared HzSNPV, containing Δ^5-sterol, was much larger than that of the commercially-obtained HzSNPV (32,359 versus 1,413 polyhedra, respectively). This difference may have occurred because the laboratory virus was always collected from larvae which were moribund, not dead.

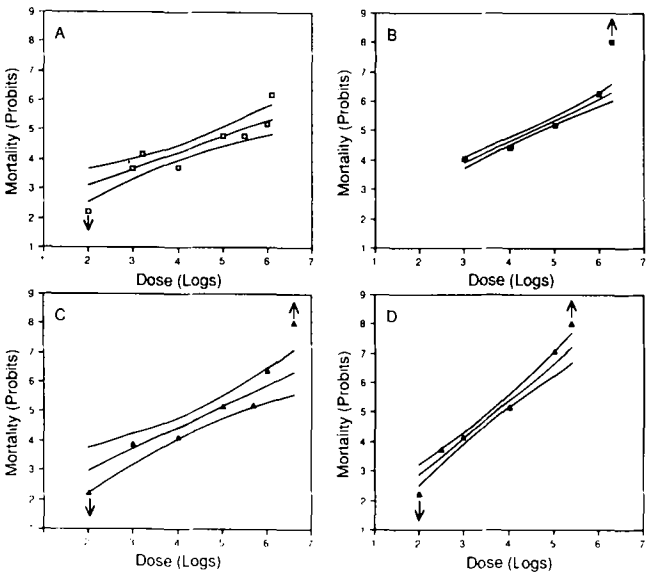

FIG. 2. Dosage-mortality responses of *H. zea*, fed diet containing cholesterol, to HzSNPV isolated from larvae fed cholestanol (A), cholesterol (B), ergosterol (C) or lathosterol (D). Fiducial bands represent 95% limits. Arrows indicate mortality of 0 or 100%, for which the probit value is ∞.

Effect of different virus sterols on the LT_{50} of HzSNPV. The presence of different sterols did not appear to affect the overall course of virus infection because the LT_{50} of the virus in larvae-fed cholestanol, cholesterol, ergosterol or lathosterol ranged from: 6 to 8, 5 to 8, 5 to 7 and 5 to 9 days, respectively.

DISCUSSION

These studies indicate that the sterols present in a host can affect the sterol composition of HzSNPV. When the larvae of *H. zea* contained Δ^5-, Δ^0- or $\Delta^{5,7}$-sterols, primarily, the HzSNPV also contained principally Δ^5-, Δ^0- or $\Delta^{5,7}$-sterols, respectively. This is the first report of an insect or animal virus containing sterols other than cholesterol (11) or desmosterol (6). Only the plant viruses, sonchus yellow net virus (28) and northern cereal mosaic virus (29), are known to contain campesterol, stigmasterol and sitosterol, in addition to cholesterol. (The relative amounts of these phytosterols in the two viruses are: 15 and 13%, 30 and 26%, 34 and 50%, and 21 and 11%, respectively [2].)

Although the major sterols found in the host were the same as those in the virus, some of the minor host sterols (e.g., Δ^7-sterols that were metabolites of ergosterol) were not isolated from the virus. Perhaps the virus selectively utilized certain sterols, which may or may not have been uniformly distributed in the host tissues (e.g., in the membranes), or the amounts of minor sterols in the virus were too small to be detected in this study.

Because the sterols were isolated from whole polyhedra of HzSNPV, it is not known where the molecules were located in the inclusion bodies. However, the envelope associated with the surface of the polyhedra may not be a unit membrane (30) and probably does not contain lipid (31), therefore, the sterol was probably associated with the envelope of the occluded virions. Whether the occluded virion codes for the synthesis of its envelope de novo (32), and then incorporates the host sterols into this structure, or whether it utilizes the host cell membrane (and therefore its sterols) directly, as the non-occluded ones apparently do (33), is not clear.

The results of the present study indicate that the sterol composition of the host not only affects the sterol composition of the virus but also its subsequent infectivity in larvae containing cholesterol as their tissue sterol. The most virulent form of the virus was that isolated from larvae-fed lathosterol followed by the virus isolated from larvae-fed cholesterol, ergosterol and then cholestanol (i.e., the LD_{50} of the virus was 5,012; 32,359; 58,884 and 275,423 polyhedra/larva, respectively). The sterol composition of the virus did not seem to affect the rate of virus replication because there was no significant difference in the LT_{50} of the virus when its sterols were altered. Instead, the sterol composition of the virus may have affected its ability to enter cells, such as midgut cells, via fusion and/or adsorptive endocytosis (viropexis) (32) by changing the fluidity of the envelope (3).

On the other hand, the results of the bioassays in this study indicated that the presence of cholestanol, cholesterol or ergosterol as the principal tissue sterols in the larva, did not affect the infectivity of the virus that was obtained commercially and contained Δ^5-sterols. The slightly higher susceptibility of the larvae-fed ergosterol to the virus (i.e., the LD_{50} of the virus in the larvae-fed cholesterol or cholestanol versus ergosterol was 1,413; 1,288 and 355 polyhedra/larva, respectively) may have been due to the presence of $\Delta^{5,7}$-sterol, per se, in the tissues. However, it is also possible that because the development of uninfected 5th-instar larvae reared on

ergosterol was much slower than on cholesterol and cholestanol (21) (they required 5–6 days longer to reach the 6th instar), such physiologically younger larvae may have been more susceptible to HzSNPV. Ignoffo (34) found that the susceptibility of *H. zea* to NPV decreased as the larvae matured.

The results of this study suggest that if the sterol composition of *H. zea* changed naturally under field conditions (e.g., if the larva consumed a plant with an unusual sterol composition), this might affect the sterol composition and subsequent virulence of HzSNPV. Therefore, further studies on how the sterols of HzSNPV affect the success of this biological control agent in integrated pest management programs are warranted.

ACKNOWLEDGMENTS

We thank Mrs. J. R. Landrey for obtaining the MS and ^{1}H-NMR spectra and for reading the manuscript. This study was partially supported by NSF Grant: PCM-8206541.

Long Chain Fatty Acid Deficits in Brain Myelin Sphingolipids of Undernourished Rat Pups

Yu-Yan Yeh[1]
Department of Biochemistry, St. Jude Children's Research Hospital, Memphis, Tennessee 38101; and Nutrition Department, The Pennsylvania State University, University Park, Pennsylvania 16802

A restricted maternal dietary intake (40% of ad libitum intake) is known to cause myelin deficit that is accompanied by decreased amounts of individual phospholipids and sphingolipids in brain myelin of suckling rats. This communication reports the effects of the same nutritional stress on the fatty acid composition of brain myelin lipids. In myelin of 19-day-old normally fed rats, palmitate (16:0), stearate (18:0) and oleate (18:1) accounted for 80–90% of all fatty acids in phosphatidylcholine, phosphatidylethanolamine and phosphatidylserine. Maternal dietary restriction resulted in deficits of total fatty acid content, but did not affect the proportional distribution of individual fatty acids among phospholipids. By contrast, longer chain (22- and 24-carbon) fatty acids accounted for more than half the fatty acid content of myelin cerebroside and sulfatide from the 19-day-old control rat pups. In undernourished rats of that age, proportions of lignocerate (24:0) and nervonate (24:1) in cerebroside and sulfatide were 40–50% lower than those in control rats. This, together with higher proportions of 16:0, 18:0 and 18:1 and a higher ratio of C_{16}–C_{20} to C_{22}–C_{24} in undernourished than in control rats, suggests an impairment in fatty acid chain elongation. Ten days of nutritional rehabilitation failed to restore the fatty acid imbalances; however, after an additional 5 days of ad libitum feeding, the experimental and control values were similar. The undernutrition results in hypomyelination, which is characterized by a proportional decrease in lignoceric and nervonic acids of sphingolipids.
Lipids 23, 1114–1118 (1988).

Postnatal undernutrition induced by various nutritional stresses leads to myelin and lipid deficits in the developing brain (1–8). The severity of the lipid insufficiency depends not only on the type of undernutrition imposed, but also on the time of onset and duration of the stress (3). The maternal dietary intake restriction known to reduce milk production (9) serves as a reliable model for producing consistent growth retardation of offspring (10). A recent study from this laboratory demonstrates that such a dietary restriction caused proportionally similar decreases in amounts of individual phospholipids, spingolipids and cholesterol in the brain myelin of offspring (11). Consequently, the mole ratios of these lipids did not change, suggesting that undernutrition of this type does not selectively affect the accumulation of any particular lipids in myelin. These observations, however, do not exclude the possibility of changes in fatty acid composition of the lipids.

In the mature brain, myelin phospholipids are rich in 16- and 18-carbon fatty acids, whereas sphingolipids contain a greater proportion of 22- and 24-carbon fatty acids (12–15). Earlier studies have shown that the distribution of fatty acids in brain phospholipids and sphingolipids undergoes a marked shift in the presence of severe nutritional insufficiency (3,16). The lipid composition of the brain differs quantitatively and qualitatively from that of myelin (6). Therefore, the changes observed in the brain of undernourished rat pups cannot be extrapolated reliably to myelin. Because a reduction in lipid content and changes in fatty acid composition may lead to hypomyelination (3,17,18), an attempt was made to determine if restriction of maternal dietary intake during the lactating period alters the proportional distribution of fatty acids in the myelin lipids of offspring. The results show substantial reductions in lignocerate (24:0) and nervonate (24:1) in cerebroside and sulfatide, but not in phospholipids.

MATERIALS AND METHODS

Sprague-Dawley rats were used in all experiments. Pregnant rats purchased in early pregnancy (13 to 14 days of gestation) were kept in separate cages and fed a nonpurified diet (Purina Rat Chow, Ralston Purina, St. Louis, MO) ad libitum. Litters of newborn rats were culled to 12 pups each, within 12 hr after birth, and the pups were allowed to be suckled by their dams. All dams were placed in normally fed control or diet-restricted groups. Controls were fed the nonpurified diet ad libitum throughout the lactating period, whereas dams in the experimental group were fed 40% of the same balanced diet consumed by controls until the pups were 19 days of age (11,19). The food intake of the control group was measured daily. The amount of the feed given to the experimental group was adjusted according to feed consumption of the control dams measured on the preceding day.

Undernourished pups were those suckled by dams fed a restricted amount of diet; control pups were suckled by normally fed dams. At the age of 19 days, undernourished pups became hyporeflexive and nearly motionless. Nutritional rehabilitation consisted of providing diets of dams ad libitum when the pups were 19 days old. Control and postnatally undernourished pups were fed the nonpurified diet ad libitum after weaning on day 22.

Myelin was isolated and purified from whole brain according to established sucrose gradient centrifugation procedures (20). The purity and yield of the myelin were determined as described previously (11).

Lipid extraction (21) and chromatographic separation of phospholipids and sphingolipids (22,23) have been described in detail (11). The isolated phospholipids and sphingolipids were transmethylated by the method of Morrison and Smith (24), and the methylated fatty acids were analyzed by gas chromatography (Hewlett-Packard, Model 5880 A, Avondale, PA). Fatty acids were identified by comparing with standards. For measurement of the total fatty acid content in phospholipids, heptadecanoate

Abbreviations: PC, phosphatidylcholine; PE, phosphatidylethanolamine; PS, phosphatidylserine; Cr, cerebroside; Su, sulfatide.

was added as an internal standard during transmethylation (25). Weights of fatty acids were calculated by the following equation:

$$\frac{\text{Peak area of fatty acid}}{\text{Peak area of heptadecanoate}} \times \text{weight of heptadecanoate added during transmethylation}$$

Student's *t*-test was used in all statistical comparisons.

RESULTS

Earlier studies demonstrated that undernourished pups produced by the present nutritional manipulation had body weight 60% and brain weight 20% lower than that of controls during the third week of life (11,19). Myelin concentrations of undernourished pups were 60–70% lower than those of normally fed controls (11). The stunted growth was noted as early as 1 week after birth (11). Despite these findings, maternal diets were restricted until the pups were 19 days old in the present study, because at that age active myelination takes place (26), and myelin can be isolated in sufficient quantities for lipid analysis (20).

Phosphatidylcholine (PC), phosphatidylethanolamine (PE) and phosphatidylserine (PS)—the major components of myelin phospholipids (22)—were analyzed for their fatty acid composition at 19 days of age. In myelin of control pups, palmitic (16:0), stearic (18:0), plus oleic (18:1) acids accounted for 89%, 80% and 78% of total fatty acid in PC, PE and PS, respectively (Table 1). The proportional distributions of the major fatty acids were 16:0 > 18:1 = 18:0 for PC; 18:1 = 18:0 > 16:0 for PE and 18:0 > 18:1 > 16:0 for PS. Relatively lower proportions of arachidonic acid, ranging from 0.6% to 1.3%, were found in the phospholipids. The total longer chain fatty acids (22–24 carbon) accounted for 4.3% in PC, 5.6% in PE and 11.2% in PS. Postnatal undernutrition did not alter the proportional distribution of fatty acid in the three phospholipids. Nevertheless, the total fatty acid content of myelin PC, PE and PS, expressed as μg/g brain tissue, was 50%, 35% and 57% lower, respectively, in undernourished than in control rats.

Unlike the fatty acid profile of phospholipids, longer chain fatty acids (22- and 24-carbon) accounted for 57% of the total fatty acids in myelin cerebroside (Cr) from 19-day-old control rats (Table 2). At that age, undernourished rats had 40% less lignoceric acid (24:0) and 50% less nervonic acid (24:1) than normally fed rat pups. Behenic acid (22:0) was also lower in undernourished than in control rats. The reduction in longer chain fatty acids was accompanied by proportional increase of 16- and 18-carbon fatty acids, resulting in a higher ratio of C_{16}–C_{20} to C_{22}–C_{24} in undernourished, compared with control, rats. The decreased percentages of lignocerate and nervonate and total longer chain fatty acids persisted in postnatally undernourished rats after 10 days of nutritional rehabilitation; however, with an additional 5 days of corrective feeding, the fatty acid composition of Cr in postnatally undernourished rats no longer differed from that of the control group. The sum of C_{22}–C_{24} acids accounted for 55% of the fatty acid content in Cr from 34-day-old rehabilitated rats. This value was similar to

that of control rats. Thus, extended nutritional rehabilitation yielded a C_{16}-C_{20} to C_{22}-C_{24} ratio that was comparable with the ratio for normally fed rats.

The fatty acid composition of myelin sulfatide (Su) resembled that of Cr in 19-day-old normally fed animals (Tables 2 and 3). Su contained a high percentage (56%) of total fatty acids as C_{22}-C_{24} with a C_{16}-C_{20} to C_{22}-C_{24} ratio of 0.77 (Table 3). Postnatally undernourished rats had reduced lignocerate and nervonate percentages with a concomitant increase in palmitate, stearate and oleate. Despite nutritional rehabilitation for 10 days, the deficits of lignocerate and nervonate persisted; when combined with the high percentages of palmitate, stearate and oleate they resulted in a higher ratio of C_{16}-C_{20} to C_{22}-C_{24} than was found in the control group (1.82 vs 0.77). Extending the period of nutritional rehabilitation to 15 days (i.e., until 34 days of age) corrected the deficits in longer chain fatty acids and restored the fatty acid profile to normal.

DISCUSSION

PC, PE and PS are the dominant phospholipids in purified myelin isolated from rat pups (11). The analysis of the fatty acid composition of myelin from normally fed pups disclosed that palmitate, stearate and oleate constitute 80–90% of all fatty acids in PC, PE and PS, consistent with findings reported by Fishman et al. (13) for rat brain and by O'Brien and Sampson (12) for human brain. Arachidonate is a minor component of myelin phospholipids, accounting for less than 2% of total fatty acids. Fishman et al. (13) have shown that undernutrition induced by increasing the litter size does not alter the fatty acid composition of myelin PC and PE in rat pups during the first 21 days of life. Similarly, restriction of maternal dietary intake in the present study did not affect the fatty acid composition of myelin PC, PE and PS in offspring. By contrast, undernutrition due to an increased litter size was associated with decreased proportions of arachidonate and polyunsaturated fatty acids in brain phospholipid in a study by Srinivasa Rao (16). One explanation for the different reported effects of undernutrition on fatty acid composition is that in the latter study total phospholipids instead of individual phospholipids were analyzed and brain tissue rather than myelin was used for extraction of phospholipids. It should be stressed that the phospholipid compositions of brain tissue and myelin differ widely in normally fed rats (13,16,27). In particular, brain phospholipids contain five- to eightfold more arachidonic acid than do myelin lipids (13,16,27). Hence, if one expects to identify subtle effects of undernutrition on myelin development, the analysis should be directed to the phospholipids of myelin and not to those of brain.

*Significantly different from the control value at $p < 0.05$.

The most important finding of the present study is that undernutrition imposed for 19 days sharply reduces the proportional distribution of lignocerate and nervonate in the myelin-specific cerebroside and sulfatide. As a result, the ratio of C_{16}-C_{20} to C_{22}-C_{24} was higher in myelin from undernourished rats than from that of the controls. This contrasts with the unaltered fatty acid composition of Cr and Su found by Fishman et al. (13) in large litters at 21 days of age. However, in their study, deficits of lignocerate and nervonate were apparent if the postnatal undernutrition produced by larger litters was continued through the postweaning period. One interpretation of these variable results is that different nutritional stresses affect myelin lipid in different ways depending on the duration of the stress (3,5). When increased litter size was combined with a low protein diet after weaning to produce undernutrition, Srinivasa Rao (16) observed reductions of lignocerate and nervonate of cerebroside in brain. Because cerebroside, a myelin-specific lipid, is found exclusively in myelin (6,26), it is reasonable to assume that cerebroside analyzed in the brain by this investigator could represent myelin lipids. Nevertheless, this is consistent with the present study showing that changes in fatty acid composition by postnatal undernutrition is specific for sphingolipids.

The metabolic activity of myelin lipid, such as its membrane-stabilizing action, depends on fatty acid composition (12,28). Increased amounts of longer chain fatty acids, particularly 24:0 and 24:1 in cerebroside and sulfatide (12,15), coincide with periods of rapid synthesis (23) and accumulation (29) of cerebroside and sulfatide during brain maturation. Thus, deficits of 24:0 and 24:1 in sphingolipids (Tables 2 and 3), together with the insufficiency of cerebroside and sulfatide (11), may be important contributing factors of the hypomyelination commonly observed in undernourished pups (3,17,30).

Whether the reduced proportions of 24:0 and 24:1 in cerebroside and sulfatide reflect lower amounts of these fatty acids in myelin remains uncertain. Nonetheless, the 50–60% reduction in concentrations of cerebroside and sulfatide (11) are likely to reduce the amounts of 24:0 and 24:1. In fact, this notion is strongly supported by the observation that myelin of undernourished rat pups had a reduced amount of fatty acids of phospholipids (Table 1), primarily due to low concentration of the lipids (11). Brain shorter chain fatty acids (e.g., 16- and 18-carbon acids) are derived from de novo synthesis and diet (31,33), whereas longer chain fatty acids (e.g., 22- and 24-carbon acids) arise from chain elongation (32–34). Hence, the deficits of 24:0 and 24:1 observed in postnatally undernourished rat pups are best explained by an impairment in fatty acid chain elongation, consistent with the higher ratios of C_{16}-C_{20} to C_{22}-C_{24} in undernourished vs control rats.

Not 10 but 15 days of nutritional rehabilitation by ad libitum feeding corrected the 24:0 and 24:1 deficits in

both cerebroside and sulfatide. The same regimen also restored concentrations of cerebroside and sulfatide to levels comparable with those in normally fed rats (11). The reversibility of these compositional changes suggests that timely nutritional intervention can prevent permanent biochemical lesion of the brain in offspring that are poorly nourished during lactation period.

Lignocerate (24:0) and nervonate (24:1) are the marker fatty acids of brain myelin (16) and the increases in the myelin content of these nonhydroxy fatty acids coincide with brain maturation and development (28). However, it should be noted that, although 24:0 and 24:1 constitute the major proportion of the longer chain fatty acids in sphingolipids (28), these lipids also contain α-hydroxy fatty acids (15,35). Undernutrition induced by increasing the litter size has been shown to increase the amount of 24:1 hydroxy fatty acid in Cr (13), whereas that induced by feeding a low protein diet reduced the 24:1 hydroxy fatty acid content but had no effect on 24:0 hydroxy fatty acid content in Cr (16). A further investigation on the effects of the present model of undernutrition on the α-hydroxy fatty acid composition in myelin sphingolipids is warranted.

[a]Faculty of Pharmaceutical Sciences, The University of Tokyo, Tokyo 113; [b]Department of Bacteriology, Juntendo University School of Medicine, Tokyo 113; and [c]Faculty of Pharmaceutical Sciences, Teikyo University, Kanagawa 199-01, Japan

When guinea pig bone marrow cells were incubated in the presence of 10^{-8} to 10^{-6} M platelet activating factor (PAF) for 24 to 72 hr, microbicidal activity against *Candida parapsilosis* of cells was augmented. This augmentation was inhibited by PAF-specific antagonists, CV6209 or FR900452. PAF-specific binding sites with a high affinity were found on guinea pig bone marrow cells. Carrageenan or 2-chloroadenosine, reagents known to be preferentially cytotoxic to macrophages, abolished the microbicidal activity of PAF-treated bone marrow cells. Macrophages prepared from the peritoneal cavity, however, acquired no appreciable microbicidal action by treatment with PAF. These observations suggest that PAF may affect a class of guinea pig bone marrow cells through binding to receptors specific to PAF, resulting in activation and/or induction of differentiation of monocyte-macrophage lineage cells.
Lipids 23, 1119-1124 (1988).

Platelet activating factor (PAF) was first identified as a potent platelet aggregating agent released from antigen-stimulated, IgE-sensitized rabbit basophils (1). It was later shown to be generated, when appropriately stimulated, by various inflammatory cells (2) such as monocytes (3), macrophages (4), neutrophils (5), eosinophils (6), platelets (7) and endothelial cells (8). It was also revealed that PAF-induced hypotension (9), neutrophil activation (10), monocyte aggregation (11), macrophage activation (12), eosinophil chemotaxis (13), smooth muscle constraction (14) and vascular permeability increased (15).

Besides being involved as a potent mediator in various pathological and physiological reactions, evidence recently accumulated suggests that PAF is a component in the regulation of cellular immune responses (16). It was shown that, when PAF was added to human peripheral blood lymphocyte cultures stimulated with mitogen, lymphocyte proliferation was inhibited (17). Natural killer cell-mediated lysis of leukemia cells was revealed to be enhanced by picomolar concentrations of PAF (18). Berdel et al. (19) showed that intravenous injection of bone marrow macrophages pretreated with a weak PAF agonist, ET18-OMe (1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine), inhibited the development of metastasis of 3-Lewis lung carcinoma in C57B1/6 mice. We recently reported that the antitumor activity of synthetic alkyl-ether lipid analogs might be partly by activation of bone marrow macrophages in vivo, and that the activation is by their binding to PAF receptors on these cells (20). For the present paper, we examined the effect of PAF on guinea pig bone marrow cells and found that PAF induced candidacidal activity.

MATERIALS AND METHODS

Chemicals. Fetal bovine serum was obtained from Hy Clone Laboratories, Logan, UT. RPMI 1640 Medium was from MA Bioproducts, Walkerville, MD. K-Carrageenan was obtained from Sigma Chemical Co., St. Louis, MO.

PAF, PAF agonists and PAF antagonists. PAF, PAF agonists (12) and PAF antagonists CV6209 (21) used in the present study were provided by Takeda Chemical Ind. Ltd. (Osaka, Japan). Their structures are listed in Table 1. A PAF antagonist FR900452 (22) was provided by Fujisawa Pharmaceutical Co. Ltd. (Osaka, Japan). [^{3}H]-PAF was obtained from Amersham (Buckinghamshire, U.K.).

Animals and microorganisms. Female Hartley guinea pigs (body weight 250-500 g) were obtained from the Japan Bio-supply, Tokyo, Japan. *Candida parapsilosis,* isolated and identified in the laboratory of one of the authors (23,24), was used for a microbicidal test. They were cultured on Sabouraud dextrose agar plates.

Preparation of bone marrow cells. Bone marrow cells were prepared from femurs of guinea pigs. After exsanguination, femurs were cut at one end and bone marrow cells were flushed out by injecting 5 ml of Hank's balanced salt solution into the end. After standing in ice for 5 min, the supernatant was collected and centrifuged at 150 × *g* for 5 min. Sedimented cells were hemolyzed by adding 10 ml lysing buffer (140 mM NH_4Cl, 17 mM Tris-HCl, pH 7.2) and incubated for 5 min at 37°C. Cells were then washed with RPMI 1640 medium supplemented with 10% fetal bovine serum, penicillin (50 U/ml) and streptomycin (50 μg/ml).

Assay method for microbicidal activity of bone marrow cells. Microbicidal activity was determined by the methods previously described (24). In brief, bone marrow cells (1×10^5 cells) were seeded in each well of flat-bottomed 96-well plates (Falcon 3072) with 0.2 ml of the RPMI 1640 medium with 10% fetal bovine serum. After 1 to 2 days incubation at 37°C under 5% CO_2 atmosphere, cells were treated with PAF or its agonists for 72 hr, and then infected with 10 μl of 2-fold serially diluted *C. parapsilosis* suspensions. The number of microbes present in the suspension was initially determined by subcultivation onto Sabouraud's agar. In subsequent experiments, turbidity was routinely monitored by measuring the absorbance at 650 nm, because there was good correlation between turbidity and cell number. After incubation for 48 hr at 37°C in a 5% CO_2 incubator, outgrowth of candida cells in each well was determined under a microscope. Microbicidal activity of bone marrow cells (the maximum number of microbes killed [MNMK]) was evaluated as the maximum number of

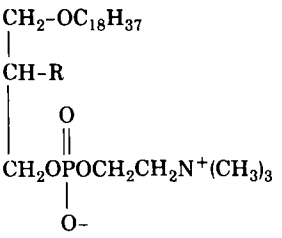
Abbreviations: MNMK, maximum number of microbes killed; PAF, platelet activating factor.

TABLE 1

Structures of PAF, PAF Agonists and PAF Antagonists



Systemic names	Abbreviation	Structure R
1-*O*-Octadecyl-2-*O*-acetyl-*sn*-glycero-3-phosphocholine	PAF	$-OCOCH_3$
1-*O*-Octadecyl-2-*O*-(*N,N*-dimethyl-carbamoyl)-*sn*-glycero-3-phosphocholine	Compound I	$-OCON(CH_3)_2$
3-*O*-Octadecyl-2-*O*-(*N,N*-dimethyl-carbamoyl)-*sn*-glycero-1-phosphocholine	Compound II	$-OCON(CH_3)_2$
racemic 1-*O*-Octadecyl-2-*O*-methyl-glycero-3-phosphocholine	Compound III	$-OCH_3$
1-*O*-Octadecyl-*sn*-glycero-3-phosphocholine	lysoPAF	$-OH$

candida was added to the wells where the growth was completely suppressed. The relative increase of MNMK in the treated sample compared with the control was also calculated as follows: Activation Index = $\log_2$ (MNMK of treated sample/MNMK of control sample).

Quantitation of PAF binding. To a 200 μl of bone marrow cell suspension (1.25×10^7 cells per ml) in calcium- and magnesium-free Hank's balanced salt solution with 0.1% bovine serum albumin (binding buffer) in an Eppendorf tube (1.5 ml), a 50 μl radioactive PAF solution with or without a 1000-fold molar excess of unlabeled PAF was added. After incubation at 22°C for 5 min, a 200 μl cell suspension was filtered through a Whatman GF/C glass-fiber filter with a vacuum apparatus (Saltorius, SM16547) attached to an aspirator. Each filter was washed quickly with 5 ml ice-cold binding buffer four times and dried. Radioactivity bound on the filter was then measured.

TABLE 2

Induction of Candidacidal Activity of Guinea Pig Bone Marrow Cells by PAF

Treatment	Maximum numbers of microbes killed			
	Exp. 1	Exp. 2	Exp. 3	Exp. 4
PAF 10^{-6} M	2350	2680	2180	>5360
10^{-7} M	1180	670	1090	5360
10^{-8} M	147	670	34	670
Control (0.25% BSA)	37	42	9	42

Bone marrow cells seeded at 10^5 cells per well were cultured for 2 days before treatment. They were incubated for 3 days in the presence of PAF and infected with *C. parapsilosis*. After 2 days incubation, MNMK was determined as described in Materials and Methods.

RESULTS

Effect of PAF on candidacidal activity of cultured bone marrow cells. Guinea pig bone marrow cells were placed in each well of 96-well plates and were examined for candidacidal activity. When 10^{-8} to 10^{-6} M PAF was added 3 days prior to infection with *C. parapsilosis*, the MNMK values were significantly larger than those observed with control culture (Table 2). The samples in wells, where microbes were not microscopically found, were properly diluted and subcultured onto the agar. No colony formation was observed, which suggests that no viable microbes remained.

In addition to PAF, synthetic PAF agonists, Compounds I and III, both of which were resistant to deacetylation (12), also showed appreciable activity (Fig. 1). Compound I was more active than PAF; the effective dose of Compound I ranged between 1/100 to 1/1,000 of that of PAF. Compound III showed only weak activity, and lysoPAF showed no appreciable activity (data not shown).

This candidacidal activity increased during incubation of cells with a PAF agonist, before microbial infection; MNMK values of bone marrow cells incubated with 10^{-7} M of Compound I for 1 and 2 days prior to microbial infection were 400 and 1,450, respectively. No significant induction of candidacidal activity was observed when Compound I and the microbe were simultaneously added.

Induction of candidacidal activity through specific PAF binding sites. Compound I has the same configuration as natural PAF. The induction of candidacidal activity was stereospecific; Compound II, an *sn*-1 enantiomer of Compound I, induced no appreciable microbicidal activity (Fig. 1). An enantiomer of PAF did not induce any activity even at 10^{-5} M (data not shown). Specific PAF antagonists, CV6209 and FR900452, suppressed the augmentation of candidacidal activity induced by 10^{-6} M PAF in a dose-dependent manner (Fig. 2).

Guinea pig bone marrow cells were examined to see if they carry specific binding sites for PAF. A total amount of radioactive PAF bound to the cells increased when

greater quantities of radioactive PAF were added to the cell suspension. Nonspecific binding, the binding of radioactive PAF in the presence of a 1,000-fold molar excess of unlabeled PAF, was not saturable, whereas specific binding (the total binding minus nonspecific binding) seemed saturable (Fig. 3A). Two distinct binding sites for PAF were tentatively determined by Scatchard plot analysis of the binding (Fig. 3B). One site exhibited a high affinity with a Kd = 1.1×10^{-10} M and a capacity of 8.8×10^3 binding sites per bone marrow cell (mean, n = 3). The other site, with a substantially lower affinity and greater binding capacity, probably corresponds to nonreceptor uptake of PAF into the lipid bilayer.

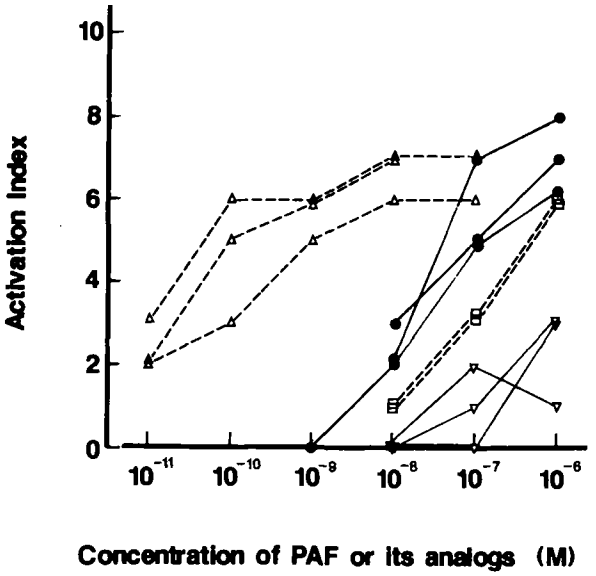


FIG. 1. Induction of candidacidal activity of guinea pig bone marrow cells by PAF (●) and its agonists, Compound I (△), Compound II (▽) and Compound III (□). The experiments were carried out as described in Table 2. Activation Index was determined as described in Materials and Methods. Each line represents experimental result independently performed.

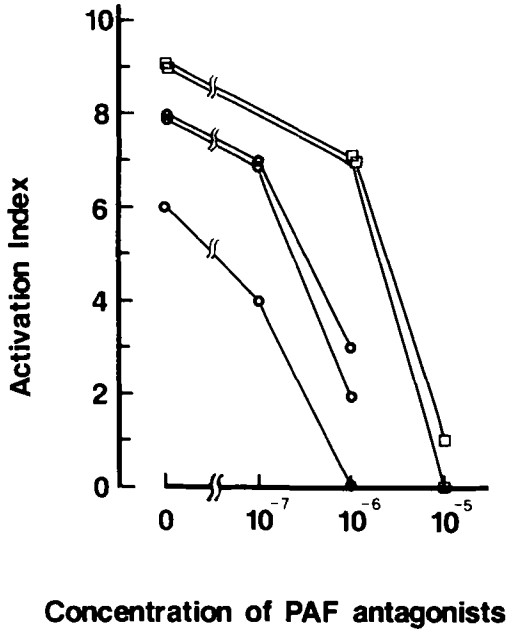

FIG. 2. Effect of antagonists on PAF-induced candidacidal activity of bone marrow cells. Candidacidal activity of bone marrow cells was induced by 10^{-6} M PAF as described in Table 2. PAF antagonists, CV6209 (○) or FR900452 (□), were added to the culture 30 min prior to treatment with PAF and were present throughout the experiment. Each line represents experimental result independently performed.

Possible effector cells in the candidacidal action. It was of great interest to clarify what kind of bone marrow cells were responsible for the microbicidal action. When cultivated without PAF in vitro, the number of viable bone marrow cells present in each well decreased gradually. Addition of 10^{-6} M PAF into the culture medium significantly restored or even increased the number of viable cells (Fig. 4). These observations may suggest that PAF induced prolification of some bone marrow cells.

It was shown that carrageenan taken up by macrophages in vitro (25) was cytotoxic to them (26). On the other hand, either the number or bacteriocidal activity of polymorphonuclear cells was not significantly impaired by carrageenan (27). Bone marrow cells cultured in the presence of PAF were treated with carrageenan prior to microbial infection and examined for the effect against candida. Treatment with carrageenan abolished the induction of candidacidal activity (Table 3).

The inhibitory effect was also observed with 2-chloroadenosine (Table 3), which also was reported to be specifically cytotoxic to macrophages (28). These findings indicated that effector cells for candidacidal activity might belong to monocyte-macrophage lineage cells.

It should be noted here that mature peritoneal macrophages derived from guinea pig injected with mineral oil acquire no appreciable candidacidal activity when treated in vitro with PAF or PAF agonists (Table 4).

DISCUSSION

Guinea pig bone marrow cells were treated with PAF and were examined for action on *C. parapsilosis*. Compared

TABLE 3

Effect of Carrageenan and 2-Chloroadenosine on PAF-induced Candidacidal Activity of Bone Marrow Cells

	Maximum number of microbes killed			
	72 hr incubation		3 hr incubation	
Treatment	Exp. 1	Exp. 2	Exp. 3	Exp. 4
Control (0.25% BSA)	<8	164	<8	<8
PAF 10^{-5} M	4080	5350	4080	4720
PAF 10^{-5} M, K-carrageenan 0.1 mg/ml	64	<20	128	128
K-Carrageenan 0.1 mg/ml	<8	<20	<8	<8
PAF 10^{-5} M, 2-chloroadenosine 0.1 mM	<8	<20	<8	<8
2-Chloroadenosine 0.1 mM	<8	<20	<8	<8

Experiments were carried out essentially identically to that described in Table 2. Bone marrow cells were treated with PAF (10^{-5} M) for 72 hr before *C. parapsilosis* infection. In Exp. 1 and 2, drugs were added to the culture simultaneously with PAF. In Exp. 3 and 4, drugs were added to the culture 3 hr prior to the infection.

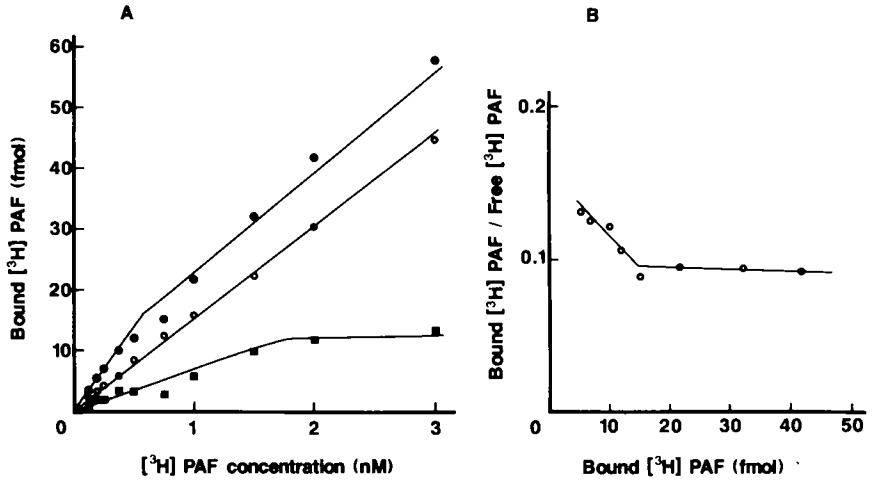

FIG. 3. Binding of [^{3}H]PAF to guinea pig bone marrow cells. A) Bone marrow cells were used for binding assay on the any of collection. Experiments were performed as described in Materials and Methods. Total binding, ●; nonspecific binding, ○; specific binding, ■. Each point is the mean of triplicates and standard deviation is less than 10% of the counts. Under conditions employed, no appreciable PAF degradation was observed. B) Scatchard plot of specific [^{3}H]PAF binding data.

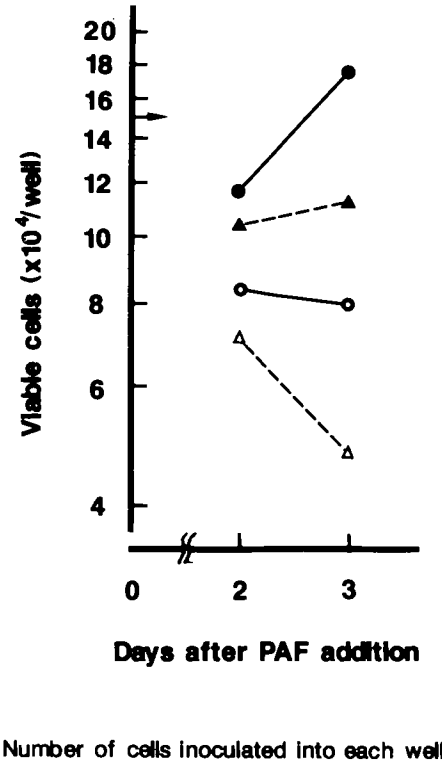

FIG. 4. Time course of the number of viable cells incubated in the presence or absence of PAF. Bone marrow cells were seeded at 1.5 × 10^6 cells per dish (30 mm diameter) 24 hr prior to addition of PAF. After 2 or 3 days incubation with (●▲) or without (○△) 10^{-5} M PAF, number of viable cells were calculated by dye exclusion method. Results of two independent experiments (Exp. 1, ○●; Exp. 2, △▲) were shown.

TABLE 4

Effect of PAF and Its Agonists on Candidacidal Activity of Guinea Pig Peritoneal Macrophages

Treatment		Maximum numbers of microbes killed		
		Exp. 1	Exp. 2	Exp. 3
PAF	10^{-6} M	19	168	
	10^{-7} M	19	168	
Compound I	10^{-6} M			88
	10^{-7} M			44
Compound III	10^{-6} M			22
	10^{-7} M			44
Control (0.25% BSA)		38	83	44

Peritoneal macrophages were prepared as adherent cells from peritoneal exudated cells harvested from guinea pig treated with mineral oil and were cultured with either PAF or its agonists for 24 hr. They were then infected with *C. parapsilosis*, and MNMK was determined after 2 days incubation as described in Materials and Methods.

to nontreated cells, PAF-treated cells caused growth inhibition of candida. The effect of PAF-treated bone marrow cells on candida was not cytostatic but cytocidal, because no viable microbes were detected in wells where microbes were incubated with PAF-treated bone marrow cells.

Among PAF agonists tested, Compound I had the most potent effect on bone marrow cells. The relative activity of compounds to induce candidacidal activity was similar to their relative potency to activate peritoneal macrophages of guinea pig in vitro (12). Unlike the activity to platelets, the activity of PAF to induce candidacidal activity in bone marrow cells, as well as the activity to augment glucose consumption in macrophages (12), was rather poor as compared with Compound I. However, Compound I, opposite to PAF, is resistant to metabolic inactivation (29). Poor activity of PAF toward both bone marrow cells and peritoneal macrophages could be due to its rapid degradation to its inactive form, lysoPAF, by a potent acetylhydrolase in serum, because

a relatively longer period of incubation of cells with PAF was required for showing these activities.

The similarity of the present structure-activity relationship to that observed with macrophage activation, together with inhibition by PAF antagonists of inducing augmentation of candidacidal activity, suggests that the activity may be through a specific mechanism via binding to receptors on some cell populations in bone marrow. Consistently, specific binding sites for PAF were detected on bone marrow cells. They showed high affinity and were saturable.

Longer incubation of bone marrow cells after addition of PAF caused more effective induction of candidacidal activity. On the other hand, relatively brief stimulation with PAF might be sufficient to induce microbicidal activity because of a rapid degradation of PAF in fetal bovine serum containing medium. The total number of viable cells observed in the incubation mixture containing PAF was significantly larger than that of control cultivation. The effect of PAF could not be due simply to an activation of cells preexisting in bone marrow but, at least partly, due to induction of prolification and/or differentiation of immature cells. It was previously reported that Compound III induced in vitro cell differentiation of human (HL-60) and mouse (M1) myeloid cells (30). Unlike the induction of candidacidal activity by PAF agonists, the induction of differentiation of M1 cell was not stereospecific; both *sn*-3 and *sn*-1 enantiomers of Compound III were found to equally induce M1 cell differentiation. Differentiation of M1 cells induced by Compound III may be through a different mechanism than that involved in activation of bone marrow cells.

Effector cells responsible for killing candida are either polymorphonuclear leukocytes or monocyte-macrophage lineage cells. Precursor cells of polymorphonuclear leukocytes, such as myelocytes or metamyelocytes, make up a substantial amount of fresh bone marrow cells and greatly outnumber the precursors of macrophages (31). In the present study, we cultured bone marrow cells 1–2 days prior to PAF addition. Mature polymorphonuclear leukocytes were not expected to participate in this response, considering the life span of this type of cell. We have reported that PAF augmented glucose consumption of guinea pig peritoneal macrophage through binding itself to specific binding sites (12). Hartung reported that PAF stimulated oxidative burst in macrophages (32). However, no significant augmentation of candidacidal activity was observed with mineral oil-induced peritoneal macrophages, even when cells were incubated with PAF or its agonists. Peripheral cells may no longer be susceptible to PAF for inducing their microbicidal activity. The effector cells that mature during the cultivation could be precursor cells of macrophages. The suppressive effect on the induction of candidacidal activity by carrageenan or 2-chloroadenosine, reagents known as inhibitors against macrophages, further supports this idea. Natural killer cells present in bone marrow might be an alternative candidate for the responsible cell, because it has been recently reported that PAF modulated functions of natural killer cells (18). In our preliminary experiment, after 72 hr incubation with PAF, nonspecific esterase positive cells increased from 11% to 33%. The increased cell population could be monocytes and macrophages. Further study must be carried out to clarify the responsible cells.

So far, we do not know if PAF directly affects the induction of maturation of precursor cells into functionally mature cells. Production or secretion of some soluble factors, such as colony stimulating factors, would be triggered by PAF, and those factors affect the immature macrophages.

Lipid Composition of Normal Male Rat Islets

Graciela B. Díaz*, Ana María Cortizo, María Elisa García and Juan José Gagliardino
Centro de Endocrinología Experimental y Aplicada (UNLP-CONICET), Facultad de Ciencias Médicas, Universidad Nacional de La Plata, Calles 60 y 120 (1900)-La Plata, Argentina

Lipid composition was studied in fresh isolated islets from normal male rats. Extractable lipids represent 1856 μg per mg islet protein. In such extracts, phospholipids and neutral lipids represent 13.5% and 86.5%, respectively. Phosphatidylcholine (45.8%) and phosphatidylethanolamine (20.6%) were the major components of the phospholipid fraction, and phosphatidylinositol (8.9%) was the minor component. Esterified cholesterol (38.5%), cholesterol (25.5%) and free fatty acids (24.4%) were the major components of the neutral lipid fraction. Fatty acids esterified to phospholipids account for 619.7 pmol/islet, and 2710 pmol/islet were esterified to neutral lipids. In the phospholipid fraction, saturated and unsaturated fatty acids were in a similar proportion. Conversely, in the neutral lipids, two-thirds of the fatty acids were unsaturated. The ω6 family was the main component of the phospholipid unsaturated fatty acids. In the ω6 and ω3 families, the long-chain fatty acids represent the main components. In the neutral lipid fraction, a different percentage of each family was found: ω3 > ω6 > ω9. The long-chain polyunsaturated fatty acids were also predominant species in the ω6 and ω3 families. Further studies on the lipid composition of islets, obtained from rats with normal and altered islet functions, could provide new insights into the knowledge of the mechanism of insulin secretion.
Lipids 23, 1125–1128 (1988).

The ultrastructural and biochemical changes that occur in the pancreatic β-cell plasma membrane during emiocytosis, suggest that this organelle plays an active role in the last step of insulin secretion (1–3). However, several experimental evidences demonstrate that the cell membrane also participates in the earlier steps of this process, as a source of intracellular signals for the stimulus-secretion coupling (4). These signals would be released after the activation of several islet phospholipases (5). In this regard, the early release of arachidonic acid and its eicosanoid derivatives (6,8), diacylglycerol (9), inositol-1,4,5-triphosphate (IP_3) (10) and other phosphoinositides components (11), as well as phosphatidic acid (12), were reported by several authors. Moreover, the increment in the total islet-phospholipid turnover in response to several insulin secretagogue agents has also been demonstrated (4,13). All these data suggest that islet lipids, and particularly their phospholipid fractions, play an important role in the regulation of insulin secretion. Despite the large number of reports on this matter, little attention has been paid to the normal composition of islet lipids. This work was performed to provide such information through the quantitative determination of the different lipid fractions of fresh isolated islets from normal male rats.

Abbreviations: (F)FA, (free) fatty acid; IP_3, inositol-1,4,5-triphosphate; NL, neutral lipid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PL, phospholipid; PS, phosphatidylserine; SPH, sphingomyelin; DBI, double bond index; (HP)TLC, (high performance) thin layer chromatography; R, DBI/saturated FA ratio.

MATERIAL AND METHODS

Adult normal male Wistar rats of ca. 200 g were fed ad libitum Purina Rat Chow (CABECA R N'3, Buenos Aires, Brazil). This chow contained 33% protein and 10% fat, and the following fatty acid composition: 16:0 (21.4%), 16:1 (2.1%), 18:0 (8.2%), 18:1 (24.9%), 18:2ω6 (37.7%) and 20:4ω6 (0.2%). The animals had free access to drinking water. In the morning of the experiment, nonfasted rats were killed by cervical dislocation without anaesthesia and the tail of the pancreas was carefully dissected. Pancreatic islets were isolated from the pancreas by collagenase (Serva Feinbiochemica, Heidelberg, Germany) digestion (14). After such digestion, separation of the islets from the acinar tissue was achieved by several washings with cold buffer, sedimentation and hand-picking under a stereomicroscope. Total lipids were extracted from groups of 150 islets with 19 ml of a mixture of chloroform/methanol (2:1, v/v) (15) and the washed lower phase was used for the analysis of the different lipid fractions. All solvents were of chromatographic grade. The total lipid content was determined by weighing the dry lipid extract resuspended in a small volume of chloroform. Neutral lipids (NL) were separated from phospholipids (PL) by thin layer chromatography (TLC) on plates of Silica Gel G-60, developed with chloroform/methanol/acetic acid/water (90:6:1.0:0.75, v/v/v/v) (16). The spots were identified by iodine staining, scraped and the NL were eluted with chloroform/methanol (2:1, v/v), and the Arvidson's method, chloroform/methanol/acetic acid/water (50:39:1:20, v/v/v/v) (17) was used for the elution of the PL. The extracts were evaporated to dryness under a stream of N_2. Recovery control was performed at every step using an islet-lipid extract labeled with [^{14}C]palmitic acid and appropriate standards labeled with [^{3}H]glycerol. Final values were adjusted to the corresponding percentage recovery. A double control was used to assess the percentage composition of islet PL and neutral lipids, i.e., a scanner measurement performed directly on the thin layer plates and the determination of radioactivity in the samples eluted from those plates. Identical percentage values were obtained using either method.

Different fractions of NL or PL were separated on HPTLC plates (Silica Gel 60 F254 precoated for HPTLC, E. Merck, Darmstadt, Federal Republic of Germany). A developing solvent mixture consisting of petroleum ether/diethyl ether/acetic acid (80:20:1, v/v/v) (18) was used to identify the different NL fractions. A solvent mixture of chloroform/methanol/30% aq. ammonia/water (140:50:7:3, v/v/v/v) and of chloroform/methanol/acetic acid/water (160:20:4:1.5, v/v/v/v) (19) was used to separate the PL fraction into its different constituents. Appropriate standards (P-L Biochemicals, Inc., Milwaukee, WI) were simultaneously run to identify each PL component. After chromatography, the lipids were charred for densitometry.

Plates were dipped into a 3%-cupric-acetate (w/v)-8%-phosphoric-acid (v/v) solution and heated at 180°C for 15 min (20). The plates were later scanned using a Shimadzu scanning densitometer in the reflectance mode.

Fatty acid (FA) methyl esters from PL or NL were obtained by refluxing the extracts for 3 hr at 65°C with HCl/methanol as described by Stöffel et al. (21). The methyl esters were then separated in a gas liquid chromatograph (GC-RIA Shimadzu) with a Supelco column (1-1851), 10% SP 2330 on 100/120 chromosorb AW Zog) and dual flame ionization detectors using a programmed temperature procedure.

The peaks obtained in the chromatograms were identified running appropriate standards of the purest available grade (P-L Biochemicals, Inc., Milwaukee, WI) and quantitatively estimated using the Δ11-20:1 FA (P-L Biochemicals, Inc., Milwaukee, WI) as internal standard.

Protein concentration was determined according to Lowry's method (22), using bovine serum albumin (Sigma Chemical Co., St. Louis, MO) as standard.

Statistical analysis of the data was performed using the Student's t-test for independent samples.

RESULTS

Fresh isolated rat islets comprised 1856 μg per mg of protein of total extractable lipids. Either the sum of the different islet-lipid fractions or the direct weight of the total islet-lipid extract gave similar figures for this parameter. From this total, the PL fraction represented 13.50%, and the remaining 86.5% corresponded to NL. Table 1 shows the different species identified in the PL islet fraction. The largest percentage corresponded to phosphatidylcholine (PC) (45.8%), followed by phosphatidylethanolamine (PE) (20.6%), phosphatidylserine (PS) (14%), sphingomyelin (SPH) (10.7%) and phosphatidylinositol (PI) (8.9%).

The different species identified in the islet-NL fraction are listed in Table 2. The major component was the esterified cholesterol (38.5%) followed by cholesterol and free fatty acids (FFA) (25.5% and 24.4%, respectively), and the triacylglycerol fraction, the minor component.

The different FA identified in the islet-PL NL fractions are presented in Table 3. The amount of FA esterified to PL was 619 ± 50.8 pmol/islet (n = 6), and 2710 ± 188 pmol/islet (n = 6) corresponds to the NL fraction.

TABLE 1

Phospholipid Composition of Fresh Isolated Islets

Phospholipids	ng/Islet	μg/mg Protein	%
Phosphatidylserine	22.9 ± 1.4	35.2	14.0
Phosphatidylinositol	14.4 ± 1.4	22.2	8.9
Sphingomyelin	17.5 ± 1.9	26.9	10.7
Phosphatidylcholine	74.6 ± 5.2	114.8	45.8
Phosphatidylethanolamine	33.5 ± 4.1	51.5	20.6
Total	162.9 ± 11.10	250.6	

Phospholipid fractions were separated by HPTLC and the different species identified and quantitatively measured, as described in Material and Methods. Each value represents the mean ± SEM of four different islet homogenates.

A similar percentage of saturated and unsaturated FA was found in the phospholipid fraction. Conversely, in the NL fraction, two-thirds of the FA were unsaturated. Accordingly, the double bond index (DBI) and the DBI/saturated FA ratio (R) were larger in the NL than in the PL fraction.

The ω6 family represents the main component of the PL-unsaturated FA. In this family, the largest components were those with 20 and 22 carbons. A similar composition has been described in the outer acrosomal membranes of mammalian sperm (23). The long-chain polyunsaturated fatty acids also represent the main components of the ω3 family. A different percentage of each family was found in the NL fraction, namely ω3 > ω6 > ω9. As

TABLE 2

Neutral Lipid Composition of Fresh Isolated Islets

Lipid	ng/Islet	μg/mg Protein	%
Cholesterol	266 ± 22	409	25.5
Free fatty acids	254 ± 10	391	24.4
Triacylglycerol	122 ± 12	188	11.7
Esterified cholesterol	401 ± 13	618	38.5
Total	1043 ± 29	1606	

Lipids were fractioned and quantitatively measured as described in the text. Each value represents the mean ± SEM of four different islet homogenates.

TABLE 3

Fresh Islet Fatty Acids Composition

Fatty acid	Phospholipis	Neutral lipids
12:0	0.8 ± 0.2	0.8 ± 0.1
14:0	3.3 ± 0.5	3.3 ± 0.2
15:0	1.5 ± 0.3	2.7 ± 0.4
16:0	22.5 ± 2.6	14.4 ± 1.0
16:1	6.1 ± 0.9	5.0 ± 0.5
18:0	15.1 ± 1.7	7.1 ± 0.7

20:1ω9	0.2 ± 0.0	1.5 ± 0.3
20:3ω9	0.3 ± 0.1	0.6 ± 0.2
18:2ω6	4.2 ± 0.4	1.9 ± 0.1
18:3ω6	0.7 ± 0.3	1.0 ± 0.1
20:2ω6	0.1 ± 0.0	1.0 ± 0.2
20:3ω6	0.7 ± 0.3	1.8 ± 0.1
20:4ω6	4.6 ± 0.6	3.9 ± 0.3
22:2ω6	5.6 ± 1.1	4.0 ± 0.9
22:4ω6	4.5 ± 0.7	5.4 ± 0.5
22:3ω6	3.2 ± 0.7	4.3 ± 0.6
18:3ω3	1.3 ± 0.2	2.4 ± 0.3
20:5ω3	0.3 ± 0.2	3.4 ± 0.3
22:3ω3	4.8 ± 0.9	7.9 ± 0.9
22:4ω3	3.2 ± 0.7	5.0 ± 0.6
22:5ω3	2.9 ± 1.1	7.0 ± 1.2
22:6ω3	0.7 ± 0.5	8.4 ± 1.2
Sat FA	43.3	28.5
DBI	141.7	240.8
R	3.3	8.5

The lipids were interesterified and the resulting fatty acid methyl esters were analyzed as described in the text. Each value represents the mean percentage ± SEM of four determinations; DBI = double bond index; R = DBI/saturated FA ratio.

in the PL fraction, long-chain polyunsaturated FA were the predominant species found in the ω6 and ω3 families.

DISCUSSION

It is well known that the lipid composition of animal tissues, even among a given species, varies from one tissue to another, being affected by several factors such as diet composition, sex, age, circadian rhythms and environmental conditions (24). In our experimental model, the effect of the enzymes from the exocrine pancreas released during the isolation of islets, could also represent another source of variation. In islets isolated from normal nonfasted male Wistar rats, such composition shows an uneven proportion of polar (13.5%) and neutral lipids (86.5%).

The total content of PL currently described, expressed on a per-islet basis, agrees with the values reported by Hallberg (25) in Wistar rats. Conversely, they are significantly lower than the values reported by Montague and Parkin (26) in guinea pig islets. According to Hallberg (25), this difference probably reflects species variations of the total PL content of islets. Hallberg stated also that the total content of PL is not affected by different conditions like 48-hr starvation, the culture of the isolated islets for one week, the addition of leucine and gliclazide to or the removal of Ca^{2+} from such medium (25). We have previously shown that the PL content was significantly lower in islets isolated from hypothyroid rats (27). Hence, those results might indicate that chronic rather than acute conditions (or effects) can modify the total content of islet PL, which could affect the release of insulin.

PL fractions identified in the islets are similar to those described in other rat tissues. PC and PE are their major components, as in normal liver (24,28) with PS instead of PI being the minor component in the islets. Otherwise, the percentages of PC and PE are lower in the islets, but PS and SPH are higher than in the liver. The relative content of the different PL classes currently described in the islets isolated from normal nonfasted Wistar rats, with PC and PE as major components, coincides with the data reported from obese hyperglycemic (29) or NMRI mice (25) and Sprague-Dawley rats (30). This islet PL composition is significantly altered in some pathological conditions such as hypothyroidism (27), which is accompanied by a decrease in the insulin secretory response to glucose. These data suggest that the normal islet-PL composition might be a condition necessary to achieving an adequate β-cell secretory response.

The amount of NL per mg of protein was similar in liver and isolated islets (31). However, the esterified cholesterol, the cholesterol and the FFA fractions were larger, but the triacylglycerol fraction was lower in the islets compared to liver.

The islets, like other rat tissues, present a complex composition of esterified FA, with a clear predominance of even-numbered acids (32). Berne has concluded that the major source for these FA is their extracellular uptake rather than their biosynthesis (33). Palmitic acid was the largest component of the saturated FA as in the heart (34). This fact could, at least in part, explain: a) the high and concentration-dependent oxidation rate of palmitic acid measured in islets (35) and b) the large incorporation of labeled palmitate into the islet lipids by islets incubated in the presence of different insulin secretagogue agents (36).

Turk et al. have already reported on the FA composition of the major glycerolipids from Sprague-Dawley-rat islets cultured overnight and then incubated with glucose (30). No references are given in this paper on the FA composition in freshly untreated islets. As shown in our Table 3, they also found that palmitate and stearate were the predominant saturated FA esterified to PL. Conversely, some discrepancies were found in the composition of unsaturated FA. We have previously reported that the percentage composition of polyunsaturated FA changed significantly in islets incubated with high glucose (37). This effect was attributed to a possible effect of glucose on the activity of islet desaturases and the FA chain-elongation process (37). Hence, the different metabolic conditions of the islets used in the current report and those mentioned above could, at least in part, explain the apparent discrepancies in the percentage distribution of polyunsaturated FA. The different number of FA considered in Turk's study compared with our own (11 vs 22), could also contribute to such a difference. However, we do not have a plausible explanation for the particular lower percentage of arachidonic acid found in our experiments.

A large number of a long-chain polyunsaturated FA was found in the islets, mainly esterified to the neutral lipids. The richness of polyunsaturated FA is a characteristic of the lipid composition found in very active tissues, such as heart and liver (38). Such composition explains the large DBI and R (DBI/saturated acid ratio) found in the islets (37). The degree of unsaturation of the phospholipid acyl chains has been considered one of the main determinants of the microviscosity of lipid regions (39). Assuming that the PL content grossly represents the islet membrane composition, the values obtained for such a parameter would suggest that, in the islets, the microviscosity of the membrane lipids is lower than in the liver membranes.

It has already been reported that the oxidation of endogenous FA accounts for about 30% of islet basal respiratory rate (40). The large amount of endogenous islet FA, mainly esterified to the neutral lipid fraction, could easily provide such an oxidizable substrate. In addition, the FA also represent the source of intracellular signals for the stimulus-secretion coupling. The change in the mass of FA esterified to PC (30), the release of arachidonic acid (6,7) and its eicosanoid derivatives (6-8,36) under the glucose stimulus are clear examples of such function.

Further, more detailed studies on the composition and metabolism of islet lipids in normal and pathological conditions would provide important evidence for a more comprehensive knowledge of the insulin secretion mechanism.

Oxidation of the α-tocopherol model compound 2,2,5,7,8-pentamethyl-6-chromanol (*1*) by *t*-butyl hydroperoxide in chloroform, to which an alcohol has been added, produces 5-alkoxymethyl-2,2,7,8-tetramethyl-6-chromanol as the major product. In the present study, *1* was oxidized by *t*-butyl hydroperoxide in water-saturated chloroform to determine whether water would influence product formation in the same way as alcohols.

In addition to the usual products of oxidation such as 2-(3-hydroxy-3-methylbutyl)-3,5,6-trimethyl-1,4-benzoquinone (*9*), 5-formyl-2,2,7,8-tetramethyl-6-chromanol (*11*), the spirodimer and spirotrimer of *1*, three new products have been identified—2,2,7,8-tetramethyl-5-(2,2,5,7,8-pentamethyl-6-chromanoxy)methyl-6-chromanol (*4*), 5-hydroxymethyl-2,2,7,8-tetramethyl-6-chromanol (*5*) and 3-hydroxymethyl-2-(3-hydroxy-3-methylbutyl)-5,6-dimethyl-1,4-benzoquinone (*7*).
***Lipids 23,* 1129–1131 (1988).**

Oxidation of α-tocopherol by *t*-butyl hydroperoxide in purified chloroform, to which ethanol has been added, produces 5-ethoxymethyl-7,8-dimethyltocol in amounts which vary with the concentration of ethanol (1). In the absence of ethanol, oxidation does not occur.

More recent work has shown that, when the α-tocopherol model compound 2,2,5,7,8-pentamethyl-6-chromanol (1) is oxidized by *t*-butyl hydroperoxide in chloroform, to which various alcohols have been added, the predominant product in all cases, in fair to good yield, is the 5-alkoxymethyl-2,2,7,8-tetramethyl-6-chromanol (C. Suarna and P. T. Southwell-Keely, unpublished data). The 5-alkoxymethyl derivatives are formed by oxidation of the chroman to the quinone methide to which the alcohol is then added. Because this was a very facile reaction, it was decided to examine whether water would behave in the same way as an alcohol.

MATERIALS AND METHODS

IR spectra were determined on a Perkin Elmer 580B spectrometer, UV spectra on a Perkin Elmer 124 double beam spectrophotometer and ^1H and ^{13}C NMR spectra on a Bruker AM 500 spectrometer. NMR spectra were taken in $CDCl_3$ and are reported in parts per million downfield from tetramethylsilane as internal standard. Electron impact mass spectra were determined at 70 ev on an A.E. I MS12 spectrometer. High resolution molecular weights were determined on a Bruker Spectrospin Fourier Transform Ion Cyclotron Resonance spectrometer.

Chloroform was purified by washing with 18 M sulfuric acid, distilled water until the washings were neutral, drying (Na_2SO_4) and distilling immediately before use.

t-Butyl hydroperoxide (70%, EGA CHEMIE, Steinheim, West Germany) was purified by the sodium salt method (2). Purity (iodometrically) was 95%.

1 together with its spirodimer and spirotrimer, 5-hydroxymethyl-2,2,7,8-tetramethyl-6-chromanol (5), 2-(3-hydroxy-3-methylbutyl)-3,5,6-trimethyl-1,4-benzoquinone (9) and 5-formyl-2,2,7,8-tetramethyl-6-chromanol (11) were prepared as reference compounds by known methods (3–8).

Oxidation of 1 by t-butyl hydroperoxide in the presence of water. To 1 (200 mg, 0.91 mmol) in chloroform (30 ml, saturated with water) was added *t*-butyl hydroperoxide (82 mg, 0.91 mmol) and the solution was heated under reflux for 3 hr at 60°C. The solution was washed with 5% ferrous sulfate (3 × 20 ml), water (3 × 20 ml), dried (Na_2SO_4) and the solvent removed in vacuo. The residue was chromatographed on thin layers of Silica Gel GF_{254} (solvent: light petroleum (bp 60–80°C)/ethyl acetate (9:1)), the spots were located under ultraviolet light, eluted with purified chloroform, and the solvent was removed under a stream of nitrogen and weighed. Major bands with the following R_f's were isolated: 0.00 (5.5 mg), 0.06 (15 mg), 0.09 (0.9 mg), 0.23 (1.6 mg), 0.30 (2.4 mg), 0.37 (3.1 mg), 0.42 (128 mg; 1), 0.47 (2.3 mg), 0.49 (1.6 mg; 11), 0.52 (8.5 mg; spirodimer of 1) and 0.55 (16.4 mg; spirodimer of 1 plus unknown).

Major band R_f 0.00 was rechromatographed on Silica Gel GF_{254} (solvent: light petroleum (bp 60–80°C)/ethyl acetate (8:2)/benzene (9:1)) yielding 3 minor bands with R_f's 0.03, 0.15 and 0.24.

Minor band R_f 0.15 (4.7 mg) was identified as (7a*S*,11a*R*)-1*H*-2,3-dihydro-7a-(3-hydroxy-3-methylbutyl)-3,3,5,6,9,10,11a-heptamethylpyrano [2,3-a]xanthene-8,11(7a*H*,11a*H*)-dione (12) (9) and minor band R_f 0.24 (0.8 mg) was identified as 9.

Minor band R_f 0.03 (0.5 mg) was identified as 3-hydroxymethyl-2-(3-hydroxy-3-methylbutyl)-5,6-dimethyl-1,4-benzoquinone (7) and had UV λ_{max} 260 nm; IR (KBr) 3422 (OH), 2972, 2929, 2858, 1704, 1649 (C=C-C=O), 1458, 1383, 1306, 1279, 1223, 1150, 1127, 1021, 937, 912, 732 cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.28 (s, 6 H, 2 × CH_3), 1.59 (m, 2 H, =C-CH_2-CH_2-), 2.027 (s, 3 H, =C-CH_3), 2.031 (s, 3 H, =C-CH_3), 2.66 (m, 2 H, =C-CH_2-), 4.57 (s, 2 H, =C-CH_2-OH); irradiation of the singlet at 4.57 ppm gave a Nuclear Overhauser Enhancement (NOE) on the multiplet at 2.66 ppm, thus proving that the hydroxymethyl and the methylene groups were attached to adjacent carbon atoms of the quinone ring; ^{13}C NMR ($CDCl_3$) δ 12.17, 12.47, 21.09, 29.24, 29.24, 43.24, 57.27, 71.05, 140.08, 140.71, 141.36, 145.96, 187.58, 188.59. MS (ei) *m/z* (rel. intensity) 252 $[M]^+$ (6), 234 $[M^+ - H_2O]$ (33), 221 $[M^+ - CH_2 - OH]$ (34), 216 $[M^+ - 2 \times H_2O]$ (29), 201 (44), 191 (35), 176 (100). Exact mass (self ci) calc. for $C_{14}H_{21}O_4$ 253.143436; Found 253.1496650.

Major bands R_f's 0.06 and 0.09 were combined and rechromatographed on Silica Gel GF_{254} (solvent: light petroleum (bp 60–80°C)/ethyl acetate (8:2)/benzene (9:1)) to yield minor bands with R_f's 0.03 (7), 0.22 (9; 10 mg), 0.34 (see below), 0.39 (unknown), 0.45 (unknown), 0.60 (1), 0.69 (11), 0.72 (unknown), 0.76 (unknown).

Minor band R_f 0.34 (3.7 mg), identified as 5-hydroxymethyl-2,2,7,8-tetramethyl-6-chromanol (5), was identical with the synthetic material and had UV λ_{max} 300 nm; IR

Abbreviation: NOE, Nuclear Overhauser Enhancement.

(KBr) 3387 (OH), 2978, 2932, 2861, 1685, 1639, 1624, 1585, 1455, 1386, 1372, 1273, 1230, 1171, 1127, 1093 (C-O-C), 976, 929, 902, 852, 699, 656, 603 cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.28 (s, 6 H, 2 × CH_3), 1.77 (t, 2 H, 3-CH_2, J = 6.9 Hz), 1.98 (t, 1 H, -CH_2-*OH*, J = 5.66 Hz), 2.11 (s, 3 H, Ar-CH_3), 2.16 (s, 3 H, Ar-CH_3), 2.65 (t, 2 H, 4-CH_2, J = 6.9 Hz), 4.875 (d, 2 H, Ar-*CH_2*-OH, J = 5.5 Hz), 7.03 (s, 1 H, -OH); irradiation of the doublet at 4.875 ppm gave an NOE on the singlet at 7.03 ppm and on the triplet at 2.65 ppm, thus confirming that the hydroxymethyl group was on the 5-position of the chroman ring; ^{13}C NMR ($CDCl_3$) δ 11.77, 11.99, 20.18, 26.70, 26.70, 32.90, 60.07, 72.57, 114.99, 118.85, 123.08, 125.83, 145.10, 147.34. MS (ei) *m/z* (rel. intensity) 236 $[M]^+$ (34), 218 $[M^+ - H_2O]$ (95), 203 (84), 189 (28), 175 (100). Exact mass calc. for $C_{14}H_{20}O_3$ 236.140696; Found 236.1422894.

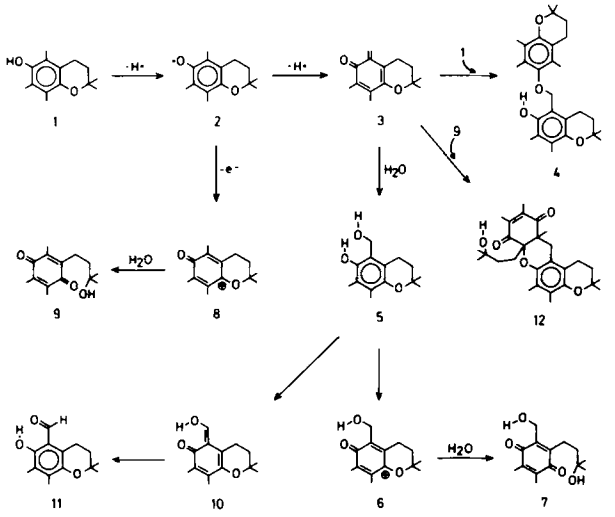
Major band R_f 0.55 was rechromatographed on Silica Gel GF_{254} (solvent: light petroleum (bp 60–80°C)/ethyl acetate (8:2)/benzene (0.5:9.5)) to yield minor bands with R_f 0.00 (**9**), 0.36 (spirodimer of **1**), 0.50 (spirotrimer of **1**; 8 mg), 0.61 (see below) and 0.72 (unknown).

Minor band R_f 0.61 (3 mg) was identified as 2,2,7,8-tetramethyl-5-(2,2,5,7,8-pentamethyl-6-chromanoxy)-methyl-6-chromanol (**4**) and had UV λ_{max} 291 nm; IR (KBr) 3408 (OH), 2978, 2932, 2874, 1457, 1385, 1371, 1273, 1228, 1171, 1128, 1091 (C-O-C), 974, 928, 902, 855, 760 cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.28 (s, 6 H, 2 × CH_3), 1.31 (s, 6 H, 2 × CH_3), 1.74 (t, 2 H, 3-CH_2, J = 6.9 Hz), 1.80 (t, 2 H, 3′-CH_2, J = 6.9 Hz), 2.10 (s, 3 H, Ar-CH_3), 2.13 (s, 3 H, Ar-CH_3), 2.18 (s, 3 H, Ar-CH_3), 2.20 (s, 3 H, Ar-CH_3), 2.22 (s, 3 H, Ar-CH_3), 2.50 (t, 2 H, 4-CH_2, J = 6.9 Hz), 2.61 (t, 2 H, 4′-CH_2, J = 6.9 Hz), 4.92 (s, 2 H, Ar-*CH_2*-O-), 7.8 (s, 1 H, -OH); irradiation of the singlet at 4.92 ppm gave an NOE on the singlet at 7.8 ppm and on the triplet at 2.50 ppm, thus proving that the second chroman was attached at the 5-position of the first chroman ring; ^{13}C NMR ($CDCl_3$) δ 11.92, 12.00, 12.00, 12.27, 13.13, 20.17, 21.05, 26.68, 26.68, 26.82, 26.82, 29.74, 32.87, 71.77, 72.44, 73.01, 114.65, 116.20, 117.69, 123.39, 123.59, 125.76, 125.89, 127.78, 144.95, 147.41, 147.79, 148.65. MS (ei) *m/z* (rel. intensity) 438 $[M]^+$ (45), 421 (6), 232 (6), 220 (74), 219 (100), 218 (17), 203 (13). Exact mass calc. for $C_{28}H_{38}O_4$ 438.276461; Found 438.2778098.

RESULTS AND DISCUSSION

Oxidation of **1** occurs in two single electron steps leading first to the chromanoxyl radical (**2**) (10–13), and then to the quinone methide (**3**) or phenoxylium species (**8**) (Scheme 1) (14,15). Neither **3** nor **8** is stable and both react further either by nucleophilic addition or, in the case of **3**, by polymerization.

Addition of water to **8** produces **9**, the first recognized oxidation product of **1** (7). It would be expected that water would also add to **3** to produce **5** (Scheme 1). This compound, although known as a product of synthesis (6), does not appear to have been reported as an oxidation product. The yield of **5** is much less than that of 5-alkoxymethyl-2,2,7,8-tetramethyl-6-chromanols formed by addition of alcohols to **3** under similar conditions (C. Suarna and P. T. Southwell-Keely, unpublished data). There are probably several reasons for this. First, the much greater solubility in chloroform of alcohols than of water would produce



SCHEME 1

a homogeneous rather than a heterogeneous reaction and lead to a much higher concentration of alcohol in the reaction. Second, **5** is an unstable product (see below) and reacts further, but the 5-alkoxymethyl-2,2,7,8-tetramethyl-6-chromanols are relatively stable.

7 could be formed by two routes. The first route involves oxidation of **5** to the corresponding phenoxylium species **6** followed by addition of water to form the hemiketal and ring opening to the quinone **7** (Scheme 1). The second route (not shown) involves the enolization of **9** to a quinone methide (16), addition of water to form a hydroxymethyl hydroquinone followed by oxidation to the hydroxymethyl quinone. The first route is considered the more likely because **5**, on exposure to air at room temperature, oxidizes to a mixture of **7** and **11**, plus several minor unidentified products (C. Suarna and P. T. Southwell-Keely, unpublished data). By contrast, **9** was completely stable to oxidation by *t*-butyl hydroperoxide at 60°C for 6 hr in water-saturated chloroform.

It is worth noting that when **5** oxidizes spontaneously to a mixture of **7** and **11**, **11** is the major product. The reason for this may be that, although **10** and **6** are of equivalent oxidation state, **10** is merely the enol of **11**, into which it readily converts, but formation of **7** from **6** requires additional reaction with water.

The identification of **4** brings to four—the number of characterized dimers from the oxidation of **1**. The mode of formation of each of these dimers is different. **4** is undoubtedly formed by the nucleophilic addition of a second molecule of **1** to **3** and is a logical expectation, given the ease with which a variety of alcohols adds to **3** to form 5-alkoxymethyl derivatives (1; C. Suarna and P. T. Southwell-Keely, unpublished data). The dihydroxy dimer is formed by free-radical dimerization (4). The spirodimer is formed by Diels-Alder cycloaddition involving two molecules of **3**, one of which acts as diene and the second as dienophile (4,17), and **12** is formed by Diels-Alder cycloaddition of one molecule of **3** to one molecule of **9** (9).

Molecular Species of Mycolic Acid Subclasses in Eight Strains of *Mycobacterium smegmatis*

T. Baba[a,c], K. Kaneda[b], E. Kusunose[c], M. Kusunose[c] and I. Yano[d,*]

[a]Shoin Women's College, Nada, Kobe; [b]Department of Bacteriology, Niigata University School of Medicine, Asahimachidori, Niigata; [c]Toneyama Institute for Tuberculosis Research; and [d]Department of Bacteriology, Osaka City University Medical School, Asahimachi 1, 4-54, Abeno-ku Osaka 545, Japan

Thin layer chromatographic and gas chromatographic separation and mass spectrometric identification of mycolic acid subclasses and molecular species from eight strains of *Mycobacterium smegmatis* were established. Two major adjacent spots and a lower minor one were detected on silica gel thin layer chromatograms of methyl esters. The most abundant subclass showing the highest R_f value on TLC was that of α-mycolic acids (M_1), the second was that of α′-mycolic acids (M_1'), a shorter homologue than α-mycolates, and the third was the hydroxy mycolic acids (M_4) derived from epoxy mycolic acids. They were identified by gas chromatography–mass spectrometry as their trimethylsilylether derivatives. α′-Mycolic acids were monoenoic acids ranging from C_{60} to C_{66} and possessing an α-unit of $C_{24:0}$. Such profiles of α′-mycolic acids were common in eight strains. α-Mycolates were dienoic acids ranging from C_{75} to C_{79} and possessing an α-unit of $C_{24:0}$. In most strains, the major molecular species of α-mycolates were odd-carbon-numbered, centering at C_{77} and C_{79}, possessing a methyl branch in the even-carbon-numbered straight chain. The average carbon number of α-mycolates, from seven strains examined, was about 78, but that of the Takeo strain was 76.3. The profiles of epoxy mycolic acid molecular species composition from eight strains ranging from C_{75} to C_{81} were very similar to their M_1 subclass profiles.
***Lipids 23,* 1132–1138 (1988).**

Mycolic acids, high-molecular weight β-hydroxy, α-branched fatty acids, are the most characteristic components found in the cell wall lipids of mycobacteria (1–7) and related groups such as nocardiae (8–10), rhodococci (11,12) and corynebacteria (13–15). They differ from species to species in their structure and composition. The structures of mycolic acids contribute to the physicochemical properties of the cell walls in these bacteria (16–19). Nocardiae, corynebacteria and rhodococci have one subclass of mycolic acids (α-mycolic acids) that can be separated by thin layer chromatography (TLC). On the other hand, the composition of mycobacterial mycolic acids is much more complex and specific to each species. In recent years, we have developed an analytical method for the determination of individual molecular species of mycolic acids using gas chromatography (GC) and gas chromatography–mass spectrometry (GC–MS) of trimethylsilylated (TMS) derivatives (12,20–26). Analysis of the mycolic acid composition appears to be very useful for the chemotaxonomy of mycobacteria.

Mycobacterium smegmatis, a species of rapidly growing mycobacteria, is widely distributed in nature. This species has been most frequently used as the source for studies on mycobacterial metabolism and enzyme systems (27–30). However, Tsukamura and coworkers reported that *M. smegmatis* was taxonomically heterogenous (31). Moreover, there are only a few reports about the mycolic acids of *M. smegmatis* (4,6,32–36). The present paper describes the detailed analysis of mycolic acid molecular species in eight strains of *M. smegmatis* using our GC–MS method.

Abbreviations: TMS, trimethylsilyl; GC, gas chromatography; MS, mass spectrometry; TLC, thin layer chromatography.

MATERIALS AND METHODS

The *M. smegmatis* strains used in the present work were Takeo, Nishino, PM-5, SN-2, Jucho, Butyricum, Rabinowitch and Sekiguchi. The latter seven strains were donated by Dr. Tokunaga, Department of Tuberculosis, National Institute of Health, Tokyo. Cells were grown in a medium containing 1% glucose, 1% peptone and 0.5% yeast extract, with the pH adjusted to 7.4, on a rotary shaker at 37°C. After 6 days, the cells were harvested by centrifugation and washed with distilled water. The packed cells were suspended in a solution of 10% KOH in 80% aqueous methanol and heated under reflux for 5 hr. After acidification of the aqueous phase, the total fatty acids were extracted with hexane and converted to the methyl esters by refluxing with benzene/methanol/H_2SO_4 (10:20:1, v/v/v) for 2 hr, taking care because benzene is a potent carcinogen. The methyl esters of mycolic acids were separated into three subclasses on a thin layer plate of Silica Gel G (Analtec Inc., Newark, DE) with a solvent system of hexane/diethyl ether (4:1, v/v). The subclasses were then visualized with iodine vapor and recovered from the gel with chloroform. The methyl esters of mycolic acids were trimethylsilylated with N,O-bistrimethylsilyltrifluoroacetamide/pyridine (2:1, v/v) at 80°C for 30 min, as described earlier (12,22). Hydrogenation of mycolic acid methyl esters was performed with PtO_2 in chloroform with or without acetic acid for 3 hr at room temperature. Gas chromatography of the trimethylsilylated derivatives of mycolic acid methyl esters was carried out with a Shimazu GC-6A apparatus equipped with a hydrogen flame ionization detector. GC–MS was performed on a Hitachi M-80B Double Focusing apparatus. The glass column (0.4 m × 3 mm) was packed with 2% OV-101, and maintained isothermally at 315°C or 330°C. The injection port and the flame ionization detector were maintained at 390°C. The molecular separator was kept at 365°C. The ion source energy was 20 eV, and the accelerating voltage was 3 kV. The mycolic acid composition of each subclass was determined by gas chromatography or mass chromatography peaks. The mass spectra of mycolic acid esters were recorded repeatedly at appropriate intervals, the data were compiled in a data processing system (Hitachi M-0101), and then the bar graphs were reproduced as mass spectra of each top component of the total ion current peak or as the average values of several scans. The mass chromatograms

were obtained by continuously monitoring the mass number of each $[M-15]^+$ ion produced from the molecular species of TMS methyl mycolate possessing certain carbon and double bond numbers and those of $[B-29]^+$ ions derived from the α-units.

RESULTS

Figure 1 shows the thin layer chromatographic profiles of fatty acid methyl esters from eight strains of *M. smegmatis*. The total fatty acid methyl esters from each strain gave three major and one minor spots. The upper spot corresponded to nonpolar fatty acid esters. The lower spots, designated as M_1, M_1' and M_4, corresponded to α-, α'- and hydroxy (or hydroxymethoxy) mycolic acid esters in their mobilities, respectively (35–37). Each subclass of these mycolic acid esters was converted to its TMS derivative and analyzed by gas chromatography.

The profiles of gas chromatograms of TMS derivatives of M_1' from eight strains of *M. smegmatis* were very similar to each other and showed four major peaks corresponding to C_{60}, C_{62}, C_{64} and C_{66} acid esters, as judged from the relationship between log retention time vs carbon numbers (Fig. 2a). Each peak was further identified by mass spectrometry. Figure 3 shows bar graphs of mass spectra of TMS-derivatives of α'-mycolic acid methyl esters from one of the strains of *M. smegmatis* (Takeo). As shown in Scheme 1, the general fragmentation of TMS-methyl mycolates on electron impact MS yielded characteristic ions useful for identification. The abundance of the $[M-15]^+$ ion (loss of methyl) and the $[M-90]^+$ ion (loss of trimethylsilanol) rather than molecular ion $[M]^+$, aided in determining the carbon and double bond number of whole molecules. Furthermore, the fragment ion $[A]^+$ (cleavage between the C_2–C_3 bond) and the ion $[A-90]^+$ (loss of trimethylsilanol) was prominent and

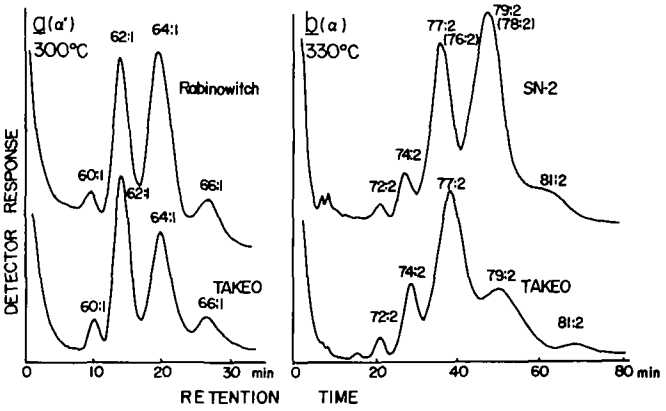

FIG. 2. Representative gas chromatograms of trimethylsilyl ether derivatives of methyl α' (a) and α (b)-mycolates from *M. smegmatis*. Numbers on each peak represent the carbon and double bond numbers as determined by GC–MS. Gas chromatography conditions are described in the text.

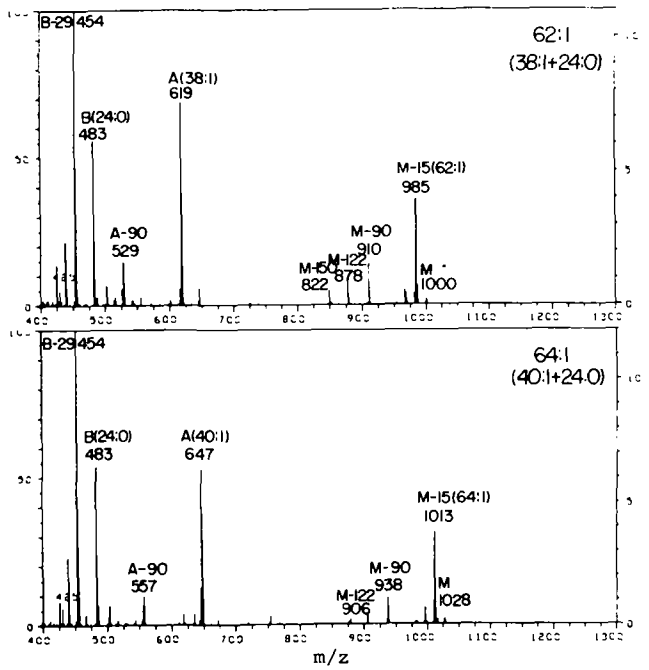

FIG. 3. Mass spectra of trimethylsilyl ether derivatives of methyl α'-mycolates of *M. smegmatis* (Takeo): $C_{62:1}$ (upper) and $C_{64:1}$ (lower), respectively.

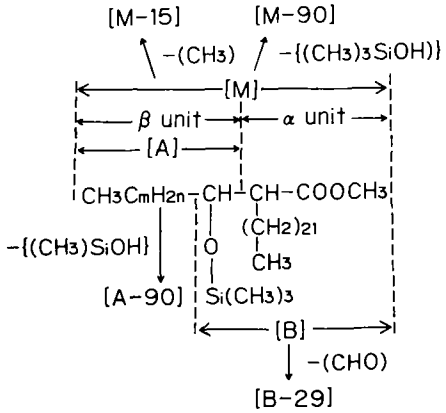

SCHEME 1. General structure and mass fragmentation pattern of trimethylsilyl ether derivatives of methyl mycolates.

useful for the determination of the straight-chain alkyl moiety of the original mycolic acids. On the other hand, fragment ion $[B]^+$ (fission of C_3–C_4) and $[B\text{-}29]^+$ (probably loss of CHO) were very intense and useful for the identification of the α-branched-chain structure of mycolic acids. From the fragment ions $[M]^+$, $[M\text{-}15]^+$ and $[M\text{-}90]^+$, the original structure of α′-mycolates was determined as $C_{62:1}$ and $C_{64:1}$. Fragment ions $[A]^+$ and $[A\text{-}90]^+$ varied in the individual peaks of the gas chromatogram, which indicated that the straight-chain units varied from $C_{36:1}$ to $C_{42:1}$. On the other hand, the α-unit was $C_{24:0}$ among all molecular species of α′-mycolates because the fragment ions $[B]^+$ and $[B\text{-}29]^+$ were distinctively observed at *m/z* 483 and *m/z* 454, as shown in Table 1. After catalytic hydrogenation of methyl α′-mycolates with PtO_2, the sample was trimethylsilylated and analyzed again by GC–MS. The results are shown in the lower portion of Table 1. Each mass number of $[M\text{-}15]^+$, $[M\text{-}90]^+$ ions and the fragment ion $[A]^+$ of the straight-alkyl-chain (β) unit shifted up by two mass numbers. It was therefore confirmed that the α′-mycolic acids, up to C_{66}, from *M. smegmatis* had only one double bond in the straight-alkyl chain (β-unit). The fragment ions and straight-chain and α-alkyl-chain structures of individual molecular species of α′-mycolates are summarized in the upper part of Table 1. Table 2 shows the percentage composition of α′-mycolic acids from eight strains of *M. smegmatis* calculated from the peak areas in the gas chromatograms. Although there is minor quantitative variation in the percentage composition among the strains, the main components of α′-mycolates are $C_{62:1}$ and $C_{64:1}$ in all eight strains of *M. smegmatis*. The average carbon number of each strain was usually about 63, determined by the sum of the multiplication of carbon numbers by the percentages of the composition (carbon number × percentage).

The gas chromatographic pattern of the TMS-derivatives of methyl α-mycolates (M_1) from *M. smegmatis* is shown in Figure 2b, and similar patterns were found in seven strains. Typically, M_1 had two major peaks corresponding to C_{77} and C_{79} such as in the SN-2 strain. On the other hand, the Takeo strain had one large (C_{77}) and two small (C_{75} and C_{79}) peaks in the gas chromatogram. The mass spectra of individual TMS-methyl-mycolates on GC were recorded, and two are shown in Figure 4. As

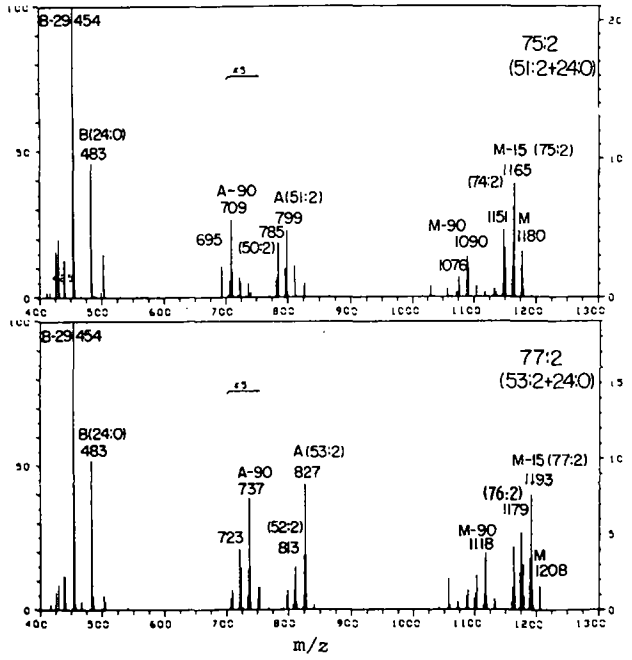

FIG. 4. Mass spectra of trimethylsilyl ether derivatives of methyl α-mycolates of the strain Takeo: $C_{75:2}$ (upper) and $C_{77:2}$ (lower), respectively.

previously described, the carbon and double bond number of the whole molecules, the straight-alkyl-chain and α-branched-chain unit were determined. In the α-mycolic acids of *M. smegmatis*, the total carbon number varied from C_{74} to C_{81} and two double bonds were located in the straight-alkyl chain (Table 3). We also confirmed the existence of two double bonds on the straight-alkyl-chain unit (β-unit) by mass spectrometric analysis before and after hydrogenation, as in the case of the α′-mycolates. When α-mycolates were analyzed after hydrogenation in neutral solvent, the mass spectrum showed four mass number increases in $[M-15]^+$ and $[A]^+$ ions (Table 3), indicating the presence of two double bonds in the straight-alkyl-chain unit. Moreover, mass chromatography of TMS methyl α-mycolates revealed that the odd-carbon-numbered mycolic acids overlapped with the one-less-(even-) carbon-numbered species in a single peak on the gas chromatogram. Judging from the relationship between log retention times and carbon numbers, the odd-carbon-numbered α-mycolates seemed to have one methyl branch in the straight-alkyl-chain unit. The odd-carbon-numbered acids were relatively higher than those of the even ones, as shown in Figure 5. These GC-MS results are summarized in Table 3. The molecular species composition of α-mycolates was calculated from the area percentages on the gas chromatograms (Table 4). Most strains had mainly odd-carbon-numbered mycolic acids, especially with C_{77} and C_{79}. On the other hand, only the Takeo strain possessed mainly a C_{77}-mycolic acid. The average carbon number of the α-mycolic acid of the Takeo strain was 76.3, differed from other strains that were close to 78.

The gas chromatographic profiles of TMS-derivatives of the polar mycolic acid TLC subclass (M_4) from two strains of *M. smegmatis* are shown in Figure 6. This sublcass of mycolates (M_4) occupies 2 to 5% of the total

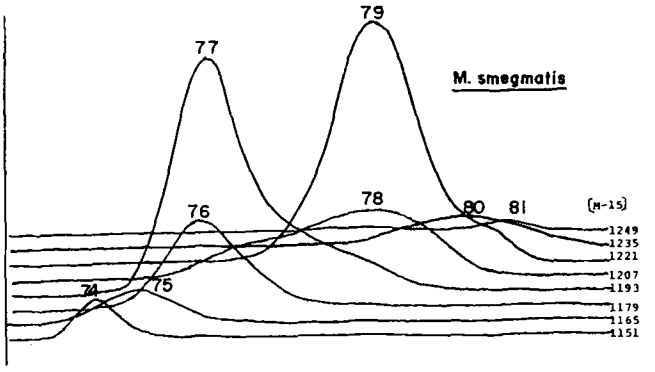

FIG. 5. Mass chromatograms of trimethylsilyl ether derivatives of methyl α-mycolates of *M. smegmatis*. $[M-15]^+$ ions corresponding to each carbon-numbered trimethylsilyl ether derivatives of dienoic methyl α-mycolates were monitored.

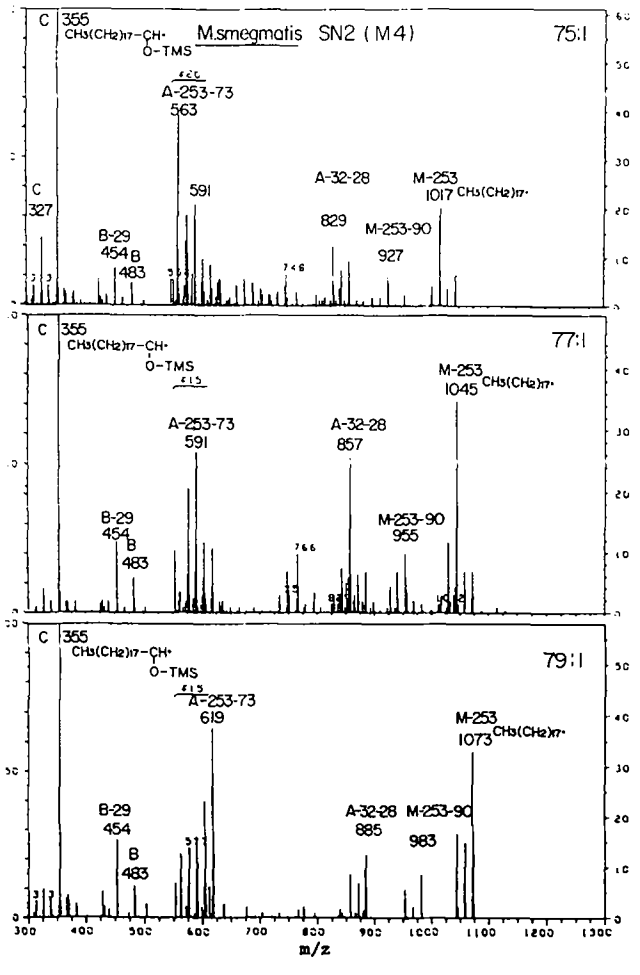

FIG. 7. Mass spectra of trimethylsilyl ether derivatives of methyl hydroxy mycolates (M_4) of the strain SN-2: from top to bottom, $C_{75:1}$, $C_{77:1}$, and $C_{79:1}$.

and is formed by acidic methylation after alkaline hydrolysis of the cellular lipids. Each GC profile of M_4 was similar to that of α-mycolates (Fig. 2b) in which only the Takeo strain had one major peak (C_{77}) and other strains had two major peaks (C_{77} and C_{79}). Mass spectra of three M_4-molecular species from the SN-2 strain are shown in Figure 7. Although the molecular ions cannot be detected, a very intense and characteristic mass ion was observed at *m/z* 355, due to the cleavage at the carbon atom, including O-TMS group, as shown in Figure 7. The other mass fragmentation patterns of polar mycolic acids were basically the same as those of α- or α'-mycolates. Therefore, these species were proposed as hydroxy mycolic acids with one double bond in the straight chain, ranging from C_{73} to C_{81}. The α-unit of M_4 was $C_{24:0}$, which was consistent again with those of the α- and α'-mycolates.

DISCUSSION

M. smegmatis is one of the representative species belonging to the rapidly growing, nonpathogenic and nonchromogenic group (31,38,39). *M. fortuitum* and *M. chelonae* also belong to the same group, but they are human pathogenic (40). Therefore, it is important to distinguish *M. smegmatis* from *M. fortuitum* and *M. chelonae*.

First, we attempted to identify the mycolic acids from eight strains of *M. smegmatis* by our TLC and GC-MS methods. The mycolic acids from all eight strains of *M. smegmatis* were separated by TLC into three subclasses, diunsaturated α-mycolates (M_1), lower molecular-weight monounsaturated α'-mycolates (M_1') and monounsaturated hydroxy mycolates (M_4) derived from epoxy mycolates. A similar pattern was reported by Minnikin et al. (35,36), who used repeated two-dimensional TLC for the analysis. Moreover, we examined the detailed structure and the composition of individual molecular species of mycolic acids by GC-MS analysis of TMS derivatives of mycolic acid methyl esters.

α'-Mycolates from *M. smegmatis* have 60, 62, 64 and 66 carbon atoms with one double bond, predominantly C_{62} and C_{64}. This result is consistent with the report of Wong and Gray (33). α-Mycolic acids commonly exist in all mycobacterial species, but α'-mycolates are the specific component in rapidly growing mycobacteria, such as *M. parafortuitum* (22), *M. chelonae* (41), *M. vaccae* (22) and *M. fortuitum* (22,36), but are absent in slow growing mycobacteria. α'-Mycolates from *M. vaccae, M. parafortuitum* and *M. chelonae* (41) were centered at $C_{58:1}$ and $C_{60:1}$, respectively. On the other hand, those from *M. fortuitum* were diunsaturated. The composition of α'-mycolates was essentially consistent among eight strains of *M. smegmatis*, but not among other species.

α-Mycolates from *M. smegmatis* were in common with other species of rapidly growing nonchromogenic mycobacteria, with respect to the general formulas $C_nH_{2n-4}O_3$ (n = 68-86) containing two double bonds in the straight-alkyl chain, and an α-unit of $C_{24:0}$ (22). It is characteristic in α-mycolates from *M. smegmatis* that the major carbon number is odd-numbered centering at C_{77} or C_{79}, which is due to the existence of one methyl branch in the even-carbon-numbered straight-alkyl chain. Wong and Gray (33) and Danielson and Gray (34) reported the presence of methyl-branched-chain α-mycolates in *M. smegmatis*, but they did not examine the relative quantity of odd- and even-carbon-numbered mycolates. In our previous paper (22), we found through mass chromatography that two types of odd-carbon-numbered-mycolic acids existed

in mycobacterial species. The first type appeared just between the even-carbon-numbered straight-alkyl-chain mycolates on gas chromatograms which was due to the presence of odd-carbon-numbered straight-alkyl chain or one or two cyclopropane rings. The other had almost the same retention time as that of the one-less-even-carbon-numbered molecules, as seen in *M. smegmatis, M. fortuitum, M. chelonae* and *M. chitae.* This would be due to the existence of one methyl-branch in the even-carbon-numbered straight-alkyl chain. We confirmed by mass spectrometry before and after hydrogenation, under very mild conditions with neutral solvents, that the main alkyl chain of α-mycolates from *M. smegmatis* had two double bonds and no cyclopropane ring because there was an increase of four mass numbers in the $[M\text{-}15]^+$ and $[A]^+$ ions. In contrast, when the α-mycolates of *M. vaccae,* which had two cyclopropane rings in the main alkyl chain, were hydrogenated in the same neutral solvent, no change was observed in the mass spectrum and the shift of mass ions and retention times was observed after hydrogenation in acetic acid (42). Because *M. fortuitum, M. chelonae* and *M. chitae* also have no cyclopropane rings in the skeleton structure of α-mycolates (42), one of the characteristics of nonchromogenic and rapidly growing mycobacteria would be likely to have one methyl branch and two double bonds without cyclopropane rings in α-mycolates. The average carbon number of α-mycolates from seven strains of *M. smegmatis* examined was about 78, but that of the Takeo strain was 76.3. Although the Takeo strain is close to *M. chitae* rather than *M. smegmatis* in molecular species of α-mycolates, we believe that the Takeo strain belongs to *M. smegmatis* and not to *M. chitae* because the composition of M_1' is essentially different than that of *M. chitae* (42).

The occurrence of epoxy mycolates in *M. fortuitum* was first reported by Daffe et al. (43). Successively, their characterization and distribution has been reported by Minnikin et al. (36,37) and Lévy-Frébault et al. (44), mainly using spectroscopic analyses, chemical transformations and degradations. However, epoxy mycolates are unstable under acidic conditions and it was shown (37) that epoxy mycolates are converted to dihydroxy or hydroxymethoxy mycolates through diol-type intermediates by acid methanolysis. We speculate that the oxygenated mycolates (M_4) in *M. smegmatis* are hydroxy mycolates produced from epoxy mycolates by the acidic methylation. The compositional profile of hydroxy mycolic acids (M_4) from eight strains of *M. smegmatis* is very similar to that of α-mycolic acids (M_1) from each strain. Although M_4 is a minor component in the mycolic acid subclass in some strains of *M. smegmatis,* it may be an important clue to clarify the biosynthesis or metabolism of this type of mycolate.

Table 5 summarizes the biological properties and mycolic acid subclasses of rapidly growing, nonchromogenic mycobacteria. *M. smegmatis* is closely related to *M. fortuitum, M. chelonae* and *M. chitae* in its physiological characteristics, and the profiles of chemical structures (subclass composition) of mycolic acids are shared. However, there is no species that has essentially the same profile of mycolic acid molecular species or subclass composition as *M. smegmatis.*

Using our TLC and GC–MS method for the analysis of mycolic acids, we can clearly distinguish *M. smegmatis* from *M. fortuitum, M. chelonae* and *M. chitae.*

Fatty Acids as Biological Markers for Bacterial Symbionts in Sponges[1]

Francis T. Gillan[a], Ivan L. Stoilov[b], Janice E. Thompson[a,b], Ronald W. Hogg[a], Clive R. Wilkinson[a] and Carl Djerassi[b,*]

Analyses of fatty acids with carbon numbers between C_{12} and C_{22} are reported for five Great Barrier Reef sponges. These analyses indicate that phototrophic cyanobacterial symbionts (blue-green algae) present in three of the sponges are chemically distinct, whereas the other two sponges do not contain cyanobacterial symbionts. All the sponges contain other, nonphototrophic bacteria. The fatty acid analyses indicate that the nonphototrophic bacterial populations present in the different sponges are distinct in both their chemical compositions and their abundances. Nonphototrophic bacteria are estimated to account for between 60 and 350 μg/g (extractable fatty acids:tissue wet weight), whereas cyanobacteria account for between 10 and 910 μg/g. One sponge (*Pseudaxinyssa* sp.) contains a relatively large amount of the isoprenoid acid, 4,8,12-trimethyltridecanoic acid; this acid is presumed to be derived from phytol, a degradation product of chlorophyll. This sponge also contains relatively large amounts of the nonmethylene interrupted fatty acid, octadeca-5,9-dienoic acid. Analyses of interior and cyanobacteria-rich surface tissues of this sponge indicate that these two acids are probably not associated with the symbiotic cyanobacteria.

***Lipids 23,* 1139–1145 (1988).**

Marine sponges are rich sources of C_{24}-C_{30} fatty acids (1–3), in addition to the shorter C_{14}-C_{22} fatty acids typically found in other organisms. Marine sponge phospholipids also include numerous branched fatty acids, where extra methyl groups can appear either at a middle or terminal position (4,5) (Fig. 1). Litchfield and coworkers have demonstrated that sponges synthesize these long fatty acids primarily by the extension of the short fatty acids, based on their incorporation of labeled acetate into such acids (1), in the manner in which we have shown branched short chain acids serve as primers for long-chain branched acids in the sponge *Jaspis stellifera* (6). Bacteria are the only organisms commonly reported to produce large amounts of iso-, anteiso-, cyclopropyl and monomethyl branched fatty acids (7,8), although some bacteria biosynthesize only straight-chain fatty acids. These latter bacteria have been divided into four chemical groups characterized solely by the presence of the acids 16:1(9), 18:1(11), 16:1(9t) and 18:1(11t), respectively (9).

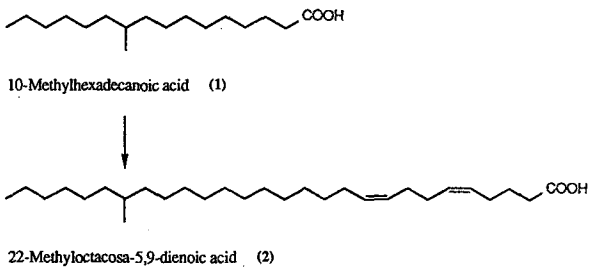

FIG. 1. A short-chain, branched fatty acid 1 assumed to be the precursor of the long-chain, $\Delta^{5,9}$-branched acid 2 in the marine sponge *Aplysina fistularis* (4).

The origin of such bacterial-type fatty acids within sponge tissue is presumed to be of microbial origin, and can be either dietary, from their diet of planktonic microorganisms (<50 μm), or acquired from the large populations of microorganism symbionts found within the sponge body. The intercellular matrix of most terrestrial animals is sterile; in contrast, many marine organisms such as sponges and ascidians often have cyanobacteria (blue-green algae), nonphototrophic bacteria, prochlorophytes and algae associated with this matrix (10–14). Some sponges have been observed to contain very few nonphototropic bacterial symbionts (15–17), whereas in others such bacteria may occupy 40% or more of the whole sponge volume, including as many as seven morphologically different bacterial species (16,18). Similarly, cyanobacterial symbionts can be absent, present or very abundant in sponges (13,14). The presence of cyanobacteria within a particular sponge can readily be inferred by the detection of undegraded chlorophylls in a lipid extract of the sponge tissue where algal epibionts are not present; no such simple procedure is available for the detection and estimation of nonphototrophic bacterial symbionts.

Geochemical studies by Johns and coworkers have demonstrated the usefulness of fatty acids as biological markers for algae and bacteria in marine sediments (7,19,20) and for prochlorophyte symbionts in an ascidian (21). Extensive studies of the fatty acids present in sponges have been reported by Bergquist and coworkers (2,3); however, these reports were not sufficiently quantitative to be useful for biological marker identification. Early studies suggested that certain fatty acids present in sponges originate only from bacteria (4,22). Recent studies demonstrate that bacteria isolated either mechanically or by culture from several host sponges contain short-chain fatty acid precursors (C. Djerassi and coworkers, unpublished data) that can be efficiently utilized for the biosynthesis of long-chain fatty acids (6,23,24). In the present study, we extend the previous microorganism biological marker work (21) and adapt a recently developed bacterial biological marker technique based on fatty acid content (9) to the estimation of cyanobacterial and nonphototrophic bacterial abundance in sponges.

EXPERIMENTAL

Collection and extraction of sponge tissues. Small samples (0.5–2 g fresh weight) of five sponges were collected in the central portion of the Australian Great Barrier Reef

[1]This manuscript is Part 21 in the Stanford series "Phospholipid Studies of Marine Organisms." For Part 20, see reference 42.

Abbreviations: TMTD, 4,8,12-trimethyltridecanoic acid; ECL, equivalent chain length; GC-MS, gas chromatography-mass spectrometry.

(Davies Reef), including three phototrophic, cyanobacteria-containing species (*Dysidea herbacea* [O. Dictyoceratida], *Phyllospongia papyracea* [O. Dictyoceratida] and *Pseudaxinyssa* sp. [O. Axinellida, Australian Museum specimen Z4988]) and two nonphototrophic species (*Phakellia aruensis* [O. Axinellida] and *Rhopaloeides odorabile* [O. Dictyoceratida, previously referred to as *Spongia* sp {25}]) (26,27).

Samples were immediately placed in solvent (chloroform/methanol, 1:1, v/v, plus 0.05% pyridine), with static lipid extraction (24 hr) proceeding in the dark at room temperature. Decantation was followed by reextraction of the sponge residue by grinding in two further changes of solvent. The combined extracts contained >95% of the lipid content of the sponges. An aliquot of this lipid extract was saponified and the resultant fatty acids were converted to methyl esters by standard procedures (28,29).

In the later examination of the distribution of fatty acids between interior and cyanobacteria-rich surface tissues, a sample of *Pseudaxinyssa* sp. was collected from nearby Rib Reef. This sample was dissected into two portions: surface tissues to a depth of 0.5 mm, including exopinacoderm and a distinct reddish-brown band of cyanobacteria, and interior tissues (cream colored). Each portion was lyophilized prior to extraction and the isolated phospholipids were converted to methyl esters, followed by subsequent gas chromatographic analysis. Electron microscopy was used to confirm the large volume of cyanobacteria within the surface tissue fraction and the almost complete absence of cyanobacteria within the interior tissue fraction.

Fatty acid analyses. Fatty acid methyl esters were analyzed on both apolar (50 m × 0.2 mm, SP2100, Hewlett-Packard, Palo Alto, CA) and polar (50 m × 0.2 mm, Superox 0.1, S.G.E. Australia) capillary columns, and the raw data from electronic integration were interpreted using our previously reported computer programs (30). Structures were confirmed by chromatographic comparison with authentic standards where available, by comparison of equivalent chain lengths (ECL) for the methyl esters with those of secondary standards and by capillary gas chromatography–mass spectrometry (GC–MS) (HP 5970A ion selective detector coupled to an HP 5790B gas chromatograph). Long-chain ($\geq C_{24}$) demospongic acids, including previously identified nonmethylene interrupted di- and triunsaturated fatty acids (characteristic of certain sponges) (4,22,31–38) were also identified for these sponges, but are not considered in the present study.

Bacterial community structure analysis. The respective contributions of symbiotic bacteria were determined according to the methods of Johns et al. (21) and Gillan and Hogg (9), wherein the fatty acids extracted from sponge tissue are assumed to originate primarily from three sources—cell membranes of the sponge, nonphototrophic bacteria or cyanobacteria. The minimum abundance of any specific acid in a suite of sponge samples was used as an estimation of the sponge contribution to the abundance of that acid in the other sponges. This method should be especially accurate for estimation of cyanobacterial contributions for our suite of sponge samples as two of these species do not contain cyanobacteria. This method, however, requires that one assumption be made, namely that sponge membrane fatty acid compositions vary within a limited range. Work in our Stanford laboratory currently seeks to test this assumption via the laborious procedure of isolating pure sponge membranes in sufficient quantity for fatty acid analyses (39–42).

RESULTS AND DISCUSSION

Lipids extracts. Three of the five sponges yielded green extracts on treatment with chloroform/methanol. Visible spectroscopy and thin layer chromatography confirmed the presence of chlorophyll-a in these extracts. As expected, the neutral lipid fraction from saponification of the extracts from these three sponges (*D. herbacea, P. papyracea* and *Pseudaxinyssa* sp.) contained appreciable amounts of phytol (3, Fig. 2), indicating the presence of chlorophyll, presumably largely of cyanobacterial origin. In contrast, lipid extracts from the other two sponges (*P. aruensis* and *R. odorabile*) did not exhibit a visible absorption maximum in the 600–700 nm region of their spectra and did not yield phytol (3) on saponification, indicating the absence of cyanobacteria.

In *Pseudaxinyssa* sp., the chlorophyll was almost exclusively associated with the surface tissues of the sponge, as contrasted to the interior tissues of the sponge, in accordance with our microscopic observations. Electron microscopy indicated that cyanobacteria were present in appreciable amounts only in the surface tissues of the sponge.

Fatty acid compositions. The fatty acid compositions of the five sponges are reported in Table 1 where double bonds for diunsaturated and polyunsaturated fatty acids are methylene-interrupted unless specifically stated otherwise. In general, only the position of the carboxyl terminal double bond is stated in these cases. None of the samples examined were markedly similar to any of the others. The three cyanobacteria-containing sponges (*D. herbacea, P. papyracea* and *Pseudaxinyssa* sp.) yielded relatively much

[a]For diunsaturated and polyunsaturated fatty acids, all double bonds are methylene interrupted unless specifically stated otherwise. In general, only the position of the carboxyl terminal double bond is stated in these cases. TMTD = 4,8,12-trimethyltridecanoic acid; Me16:0 and Me18:0 refer to mixtures of monomethyl-branched C_{17} and C_{19} acids, respectively; abbreviations for iso, anteiso and cyclopropyl acids are i, a and cy, respectively.

larger amounts of fatty acids on extraction, particularly straight-chain saturated and monounsaturated fatty acids. Indeed, these three sponges contained, on average, ca. 900 μg/g (wet wt) of these acids compared to only 150 μg/g in the two nonphototrophic sponges (*P. aruensis* and *R. odorabile*). In contrast, no such clear distinction in branched-chain fatty acid distribution was observed for these sponges according to cyanobacterial content. The cyanobacteria-free sample of *R. odorabile* yielded the greatest amount of branched-chain fatty acids, whereas the sample of cyanobacteria-rich *D. herbacea* yielded the least. Only one sponge, *Pseudaxinyssa* sp., contained an appreciable amount of the isoprenoid fatty acid, 4,8,12-trimethyltridecanoic acid (TMTD) (4).

The fatty acid compositions of the interior and cyanobacteria-rich surface portions of *Pseudaxinyssa* sp. are reported in Table 2. The surface tissues were enriched in the 16:1(9), 16:0, 18:3(6), 18:1(9) and 18:1(11) acids,

suggesting that these acids are of cyanobacterial origin.

Cyanobacterial symbionts. Cyanobacteria have been reported to biosynthesize fatty acids in the range C_{14} to C_{18}, with varying degrees of unsaturation (up to tetraenoic acids) (43,44). In addition, it has been shown that the 18:1 isomer produced by cyanobacteria is 18:1(9) (45). Table 3 lists the residual abundances of potential cyanobacterial acids calculated by subtraction of the minimum observed abundance in any of the five specimens. The three species noted for the presence of cyanobacteria, as indicated by the presence of chlorophyll-a, yielded large residual amounts of these acids, whereas the two species without cyanobacterial symbionts yielded very low residual acid abundances. The 16:1(9) acid was found to be the major cyanobacterial acid present in these three cyanobacteria-rich sponges.

Studies employing electron microscopy reveal that *D. herbacea* contains a colonial (multicellular) cyanobacterium similar to *Phormidium spongeliae,* whereas *P. papyracea* and *Pseudaxinyssa* sp. yield a solitary (unicellular) cyanobacterium similar to *Aphanocapsa feldmanni* (10,46). The presence of linoleic (18:2(9)) and γ-linolenic acids (18:3(6)) in the residual acids of *D. herbacea,* but not the other sponges, is thus consistent with the earlier observation that colonial cyanobacteria usually produce polyenoic acids, whereas solitary species usually do not (8,43,44). This result also indicates that fatty acid analyses can potentially be used to screen sponge tissue samples for the presence of different cyanobacterial symbionts; for example, *P. papyracea* and *Pseudaxinyssa* sp. have different residual acid compositions likely indicating the presence of different cyanobacterial populations. The cyanobacteria from *P. papyracea* contain predominantly 16:0 (53%), 16:1(9) (24%), 14:0 (8%) and 18:0 (6%) fatty acids, but the cyanobacteria from *Pseudaxinyssa* sp. contain much more 18:1(9) (35% cf. 2% for *P. papyracea*) and relatively much less 14:0 (3%) and 18:0 (2%). This marked chemical difference cannot be explained solely by compositional variation within a cyanobacterial species; rather, different cyanobacterial species must be present.

The summed fatty acid contribution from cyanobacteria listed in Table 3 is a direct measure of the cyanobacterial biomass present in the sample of sponge tissue analysed. Indeed, because the abundance of fatty acids in cyanobacteria typically varies within the limited range of 3–5% (dry wt basis) (47) during one season, the fatty acid contribution can be used to calculate the biomass of cyanobacteria present. However, most studies on sponges report symbiont biomasses in terms of percentage tissue volume, because this is relatively easily

[a]Cyanobacterial fatty acids are considered to be the residual abundance of acids calculated by subtraction of the minimum observed abundance of each acid in any of the five specimens. Only those acids with residual concentrations greater than 10 μg/g are listed.

estimated by electron microscopy. Although not advocating this practice, the data in Table 3 can be converted to this format with an assumption of the cyanobacterial water content; if the cyanobacterial water content is assumed to be 80%, then the symbiotic cyanobacteria volume contribution to the whole sponge volume can be calculated to vary from 3.4 to 9.1% (w/w) for each of the three cyanobacteria-containing sponges considered in this study.

Nonphototrophic bacterial symbionts. In an earlier study, Gillan and Hogg (9) proposed a method for nonphototrophic bacterial biomass estimation based on the abundances of characteristic bacterial acids. In this study, we cannot use the 16:1(9) abundance to estimate the biomass of the nonphototrophic bacterial group that produces this acid due to major production of this acid by cyanobacteria. In addition, we did not detect the *trans* acids, 16:1(9t) and 18:1(11t), in the sponge analyses. However, several isomers of both the C_{16} and C_{18} mid-chain, monomethyl-branched fatty acids (principally, 9- and 10-methyl 16:0, and 11- and 12-methyl 18:0) were present in most of the sponges. These latter acids have been reported in bacteria, especially sulfate-reducing bacteria (48). As in the case of cyanobacterial estimation, we have estimated the abundances of nonphototrophic bacterial acids due to in situ bacterial symbionts as the residual acid abundances (Table 4).

Two sponges, *P. papyracea* and *R. odorabile*, yielded much larger abundances of nonphototrophic bacterial acids than the other three sponges. However, the predominant bacteria in these two sponges are markedly different: *R. odorabile* contains mainly monomethyl-branched 16:0 and 18:0 acid-producing bacteria and iso/anteiso acid-producing bacteria, whereas *P. papyracea* contains largely bacteria with vaccenic acid (18:1[11]) (Table 4). *Pseudaxinyssa* sp. contained a mixture of these bacteria, but the total abundance was approximately one-fourth less, whereas *D. herbacea* and *P. aruensis* contained only traces of bacteria. The distribution of bacterial acids in *D. herbacea* was similar to that observed in *P. papyracea*.

Because branched acid-producing bacteria also produce small amounts of straight-chain acids, the summed abundances in Table 4 are an underestimate of the actual bacterial fatty acid contribution. A better estimate can be obtained by application of the equations published recently (9); these equations do not, however, account for methyl branched 16:0 and 18:0 producing bacteria. The estimated bacterial symbiont fatty acid contribution reported in Table 4 is based on the value derived by application of the equations plus twice the combined abundance of methyl branched 16:0 and 18:0 (as a first approximation it is assumed that methyl branched acids account for 50% of the total acids in these chemotypes). This calculated, nonphototrophic bacterial contribution varies between 50 μg/g wet wt and 350 μg/g wet wt for the tissue samples examined in this study. For comparison with electron microscopy studies, the approximate tissue volume contributions for bacteria in each of the five specimens can be calculated with the assumption that fatty acids represent 1% wet wt of the sponge (8). In this way, nonphototrophic bacteria represent ca. 1% (for cyanobacteria-containing species) or 3.5% (for cyanobacteria-free species) of the tissue volume of the host sponge, suggesting possible competition for tissue space between these two types of bacteria.

TABLE 5

Calculated Tissue Volumes Contributed by Cyanobacteria and Nonphototrophic Bacteria for Five Great Barrier Reef Sponges

Sponge	Fatty acid contribution μg/g wet wt (% Tissue Volume)		
	Cyanobacteria	Other bacteria	Total
Dysidea herbacea	913 (9.1)	56 (0.6)	969 (9.7)
Phakellia aurensis	35 (0.0)	64 (0.6)	99 (0.6)
Phyllospongia papyracea	825 (8.3)	347 (3.5)	1172 (11.8)
Pseudaxinyssa sp.	335 (3.4)	100 (1.0)	435 (4.4)
Rhopaloeides odorabile	11 (0.0)	343 (3.4)	354 (3.4)

4,8,12-Trimethyltridecanoic acid. Pseudaxinyssa sp. was readily distinguishable from the other sponges due, among other factors, to the presence of a large abundance of the fatty acid 4,8,12-trimethyltridecanoic acid (TMTD) (4) (Fig. 2). This acid is an isoprenoid acid that is derived by degradation of phytol (3), which, in turn, is derived from chlorophyll. The high concentration of this acid in the interior, cyanobacteria-free tissues of this sponge (16.0%) vs that observed for surface tissues (6.7%) suggests that this phospholipid acid is one of the major sponge cell membrane components. In fact, recent work has established that TMTD (4) is present in the membranes of *Pseudaxinyssa* sp. (40). The TMTD in the sponge cells may be derived from degradation of the cyanobacterial chlorophyll phytol (Fig. 2), possibly with the assistance of other bacterial species, but a dietary origin cannot be excluded. It is unlikely that the sponge ingests live symbiotic cyanobacteria because sponges apparently have mechanisms to avoid ingestion of bacterial symbiont species (49).

This is the first case in which such a highly branched fatty acid appears to function within cell membranes, raising further questions about the structure and function of sponge membranes that are already noted for exceedingly long phospholipid fatty acids that are theoretically incompatible with normal membrane function (39,50). The presence of this highly branched acid as a major acid in the sponge cell membrane may be related to the extremely unusual sterol composition of *Pseudaxinyssa* sp. (41,42, 51-54), as suggested by Walkup et al. (4) for another sponge. Over 98% of the sterol mixture consists of the highly branched C_{30} sterols, 24-isopropyl cholesterol (5) and its 22-dehydro- analog (6) (Fig. 2). TMTD also occurs as a major fatty acid in the sterol esters within the interior portions of the sponge, whereas the cyanobacterial fatty acids predominate in the surface portion of the sponge. It should be noted, however, that the whole sponge *Spheciospongia vesparium* also contains large amounts of TMTD, but has a very simple sterol composition of mainly cholesterol and sitosterol (55).

Biosynthesis of fatty acids. The high amount of the 18:2($\Delta^{5,9}$) acid, a nonmethylene interrupted fatty acid unknown in bacteria, suggests that the $\Delta^{5,9}$-dehydrogenase enzyme of the sponge is not only specific for the long demospongic acids, but that the typical $\Delta^{5,9}$-unsaturation pattern (1) can be introduced into shorter fatty acid analogs as well. Thus, the 18:1(Δ^{9}) acid, contributed by symbiotic cyanobacteria, may be further desaturated to the 18:2($\Delta^{5,9}$) acid. This latter fatty acid has been isolated from at least two sponges (5,34); its lower homolog, 16:2($\Delta^{5,9}$), which has never before been reported for bacteria, was recently reported as a major constituent of the sponge *Chondrilla nucula* (56).

CONCLUSIONS

Fatty acid analyses have been shown to distinguish different symbionts present in marine sponges and to provide estimates of the bacterial symbiont abundances. According to fatty acid content, three of the sponges examined in this study were shown to contain cyanobacterial symbionts, whereas all the sponges contained nonphototrophic bacteria; Table 5 summarizes the estimated biomass data for each bacterial class in the five sponge species examined. Although this method sheds light on the contributions of fatty acids by bacterial symbionts in sponges, this method should be cautiously applied for estimation of fatty acid contributions by symbionts because a detailed analysis of the fatty acid composition of isolated (and possibly also cultured) bacterial symbionts and pure isolated sponge cell membranes should be used to unambiguously solve the problem. Some work along these lines has recently been reported (42).

ACKNOWLEDGMENTS

This paper is dedicated to the memory of the senior author, the late Frank Gillan. We thank Frances C. Thomas for electron microscopy and James Stoddart and Mishelle Lawson for review of an early version of this paper. METHODS

Rapid Separation of Neutral Lipids, Free Fatty Acids and Polar Lipids Using Prepacked Silica Sep-Pak Columns

James G. Hamilton[1] and **Karen Comai**[2,*]
Department of Pharmacology, Hoffmann-La Roche Inc., Nutley, NJ 07110

A method is described for the separation of neutral lipid, free fatty acid and polar lipid classes using small (600 mg), prepacked silica Sep-Pak columns. Combinations of hexane and methyltertiarybutylether were used to progressively elute cholesteryl ester first then triglyceride from the column. After column acidification, fatty acids were eluted followed by cholesterol. Recoveries of these lipids were 96% or greater. Polar lipids were eluted from the column using combinations of methyltertiarybutylether, methanol and ammonium acetate. Phospholipid classes could not be separated completely from each other. Phosphatidylethanolamine and phosphatidylinositol eluted together, whereas the more polar phosphatidylcholine, sphingomyelin and lysophosphatidylcholine were eluted as a second fraction. Recoveries of each phospholipid was greater than 98%.
Lipids 23, 1146-1149 (1988).

Methods to separate and isolate neutral and polar lipids have largely depended on preparative thin layer chromatography (TLC) and column chromatography using silicic acid, florisil or alumina and more recently on high performance liquid chromatography (HPLC) (1-4). Significant problems are associated with each of these methods. Preparative TLC is sensitive to sample overload, is cumbersome and time-consuming. Traditional column chromatography is time-consuming and requires large quantities of solvents. HPLC requires expensive equipment. Therefore, the need for rapid, efficient, high recovery methods are needed, especially for use with small and medium sample sizes.

In previous work, it was demonstrated that small silica Sep-Pak columns (600 mg) could be used to separate neutral and polar lipids with a greater than 98% recovery of the following lipid classes: cholesteryl esters, triglycerides, fatty acids, cholesterol, phosphatidylethanolamine and phosphatidylcholine (5). Others have reported the successful use of this and similar methods (6,7).

This report describes in detail the use of the disposable silica Sep-Pak columns to separate cholesteryl esters, cholesterol, free fatty acids and triglycerides from each other and from polar lipids using a novel solvent system containing methyltertiarybutylether (MTBE). The data were generated using radiolabeled and unlabeled lipid standards and lipids extracted from human serum or rat livers. Recoveries for each lipid class were excellent, as in the previous work (5). The processing of 10 samples can be accomplished in less than 1 hr. The use of MTBE instead of chloroform, which was used with the previous method, has allowed us to separate cholesteryl esters from triglycerides and to completely separate phosphatidylethanolamine from phosphatidylcholine.

MATERIALS AND METHODS

Lipids were extracted from human serum using the method of Bligh and Dyer (9). Extracts were stored under nitrogen at −20°C.

Radiolabeled rat liver phosphatidylcholine and phosphatidylethanolamine were prepared by intraperitoneal injection of either 5 mCi of [^{3}H]choline chloride or 5 mCi [^{14}C]ethanolamine (New England Nuclear, Boston, MA) into rats as described previously (5). After 24 hr, the rats were killed and the livers were extracted using the Bligh and Dyer method (8). The phospholipid fraction was obtained by separation from neutral lipids and fatty acids using a silica Sep-Pak column procedure (5). Radiolabeled sphingomyelin was prepared by a modification of the procedure of Dawson (9) using the lipids from the rat liver labeled with [^{3}H]choline chloride. Briefly, liver lipid was dissolved in 5 ml of 2% potassium hydroxide in 95% ethanol and heated at 37°C for 20 min. Chloroform (5 ml) was added to the mixture followed by 8 ml of distilled water. The upper water layer containing choline was discarded. The chloroform (lower) layer was washed twice with 55% methanol. The radioactivity contained in the chloroform layer was almost exclusively sphingomyelin (9). A small amount of additional radioactivity was removed by treating the sample with hydrochloric acid under mild conditions, indicating that plasmalogens were minimally labeled (9).

Neutral lipid standards were purchased from NuChek Prep (Elysian, MN) and stored in sealed vials at −20°C. Polar lipid standards were purchased from Avanti Polar Lipids (Birmingham, AL) and stored in sealed vials at −20°C. All solvents were HPLC grade and were purchased from Burdick and Jackson (Muskegon, MI). Silica Sep-Pak columns (600 mg silica) were purchased from Waters Associates (Milford, MA). The column void volume is 1.5 ml and the column capacity is greater than 1 mg lipid. Tri[^{14}C]oleylglycerol, [^{3}H]oleic acid, cholesteryl[^{3}H]oleate, [^{14}C]cholesterol, [^{3}H]phosphatidylinositol and [^{14}C]lysophosphatidylcholine were purchased from New England Nuclear (Boston, MA). The radiolabeled lipids were purified by HPLC prior to recovery experiments (5). Radiolabeled counting was performed using a Searle Analytic Mark III Scintillation Counter. Samples were mixed with 10 ml Aquasol (New England Nuclear, Boston, MA). For quantitative recovery experiments, the following radiolabeled lipids were added to lipids extracted from human serum (equivalent to 100 μl human serum): 0.02 μCi of [^{3}H]cholesteryl oleate, 0.1 μCi of [^{14}C]cholesterol, 0.02 μCi of [^{3}H]oleic acid, 0.02 μCi of tri[1-^{14}C]oleyl glycerol, 0.04 μCi of [^{3}H]phosphatidylinositol and 0.02 μCi of [^{14}C]lysophosphatidylcholine. Addi-

tionally, 0.04 μCi of [^{14}C]phosphatidylethanolamine, 0.04 μCi of [^{3}H]phosphatidylcholine and 0.02 μCi [^{3}H]sphingomyelin were used without dilution as isolated from rat liver lipids. The column separations described below were performed three to six times for each individual radiolabeled lipid added to serum lipids and for combined radiolabeled lipids in serum lipids.

RESULTS

Separation of neutral lipids. Separation of neutral lipids and free fatty acids from polar lipids was accomplished using prepacked silica Sep-Pak columns as described previously (5), but replacing chloroform with MTBE in the elution solvent. Prior to use, each Sep-Pak column was washed with 4 ml of hexane/MTBE (96:4) followed by 12 ml hexane. This washing procedure removed substances that interfere with HPLC procedures used to monitor lipids (5,10).

Serum lipids from the Bligh and Dyer extraction equivalent to 100 μl of human serum were evaporated to dryness under nitrogen, dissolved in 2.0 ml of hexane/MTBE (200:3) and applied to the Sep-Pak column. The vessel containing the lipid extract was washed once with 2 ml hexane/MTBE (200:3) and the solvent added to the column. The 2 ml eluted solvent was saved.

Cholesteryl esters and triglycerides were eluted with combinations of hexane/MTBE. Hexane/MTBE (200:3, 10 ml) was added to the column, which resulted in the elution of cholesteryl esters in a total volume of 12 ml. The recovery of cholesteryl ester based on [^{3}H]cholesteryl oleate was 95.9% (Table 1). Using 12 ml of hexane/MTBE (96:4), the triglycerides emerged. The recovery of triglyceride based on added tri[1-^{14}C]oleylglycerol was 99% (Table 1).

After removal of triglycerides, the column was acidified with 12 ml hexane/acetic acid (100:0.2). This fraction contained no lipid and was discarded. Fatty acids were then eluted using 12 ml of hexane/MTBE/acetic acid (100:2:0.2) with a 98.2% recovery based on added [^{3}H]oleic acid (Table 1). Cholesterol was eluted using 12 ml of MTBE/acetic acid (100:0.2). Recovery based on added [^{14}C]-cholesterol was 99.1% (Table 1).

Separation of polar lipids. After the neutral lipids and fatty acids were eluted, polar lipids were eluted from the column using combinations of MTBE/methanol/ammonium acetate (pH 8.6). The aqueous ammonium acetate was prepared by adding 2 volumes of 0.001 M ammonium hydroxide to 1 volume of 0.001 M acetic acid. Approximately 50% of the phosphatidylinositol was eluted with MTBE/methanol/ammonium acetate (pH 8.6) (25:4:1, 8 ml) and the remaining 50% with MTBE/methanol/ammonium acetate (pH 8.6) (10:4:1, 12 ml) for a total recovery of 98.6% (Table 2). Phosphatidylethanolamine was quantitatively eluted in the 12 ml of MTBE/methanol/ammonium acetate (pH 8.6) (10:4:1) with a 98.7% recovery. Using 12 ml MTBE/methanol/ammonium acetate (pH 8.6) (5:4:1), 69% of the phosphatidylcholine, 50% sphingomyelin and 2% lysophosphatidylcholine were eluted (Table 2). By increasing the polarity of the eluting solvent to MTBE/methanol/ammonium acetate (pH 8.6) (5:8:2), an additional 22% phosphatidylcholine, 50% sphingomyelin and 93.3% lysophosphatidylcholine eluted (Table 2). An additional 12 ml of this solvent resulted in minor additional recoveries of lysophosphatidylcholine (Table 2). Overall recoveries were 91.6% for phosphatidylcholine, 100% for sphingomyelin and 99.9% for lysophosphatidylcholine based on recoveries of the radiolabeled standards.

Bulk separation of neutral and polar lipids. Bulk separation of all neutral lipids and fatty acids from polar lipids was accomplished with the Sep-Pak column using MTBE/acetic acid (100:0.2) as the eluting solvent. Lipids were dissolved in 2.0 ml of MTBE/acetic acid (100:0.2), applied to the column and washed once with an additional 2.0 ml of the solvent. The elution of all (98+%) neutral lipids and fatty acids was achieved with an additional 10 ml of the solvent. No polar lipdis were removed with MTBE/acetic acid (100:0.2). The polar lipids were then eluted using the solvent systems described above with recoveries identical to those in Table 2. The polar lipids were quantitatively separated into two fractions. The less polar lipids, e.g., phosphatidylethanolamine, phosphatidylinositol, phosphatidylserine and phosphatidylglycerol, were eluted with MTBE/methanol/ammonium acetate (pH 8.6) (10:4:1) followed by the elution of more polar

TABLE 1

Separation and Percent Recovery of Neutral Lipids and Fatty Acids on Silica Sep-Pak Columns[a]

Lipid class	Fraction 1	Fraction 2	Fraction 3	Fraction 4
Cholesteryl ester	95.9 ± 0.7	0	0	0
Triglyceride	0	99.0 ± 0.2	0	0
Fatty acid	0	0	98.2 ± 0.7	0
Cholesterol (and partial glycerides)	0	0	0	99.1 ± 0.3
Phosphatidylethanolamine	0	0	0	0
Phosphatidylcholine	0	0	0	0

[a]Lipids were extracted from fasted human serum using the method of Bligh and Dyer (8). Radiolabeled lipid standards purified by HPLC (5) were added separately to an equivalent of 100 μl of human serum lipid to determine recovery. Results are expressed as the percentage mean ± SE for a minimum of 4 separate determinations of each lipid class. Combinations of lipids were also separated with the same recoveries. Fraction 1 solvent is hexane/MTBE (200:3, 12 ml); fraction 2 solvent is hexane/MTBE (96:4, 12 ml); fraction 3 solvent is hexane/MTBE/acetic acid (100:2:0.2, 12 ml); fraction 4 solvent is MTBE/acetic acid (100:0.2, 12 ml).

TABLE 2

Separation and Percent Recovery of Polar Lipids on Silica Sep-Pak Columns[a]

Lipid class	Fraction 1	Fraction 2	Fraction 3	Fraction 4	Fraction 5
Phosphatidylethanolamine	0	98.7 ± 1.5	0	0	0
Phosphatidylinositol	51.5 ± 0.8	47.1 ± 1.0	0	0	0
Phosphatidylcholine	0	0	69.7 ± 1.1	21.9 ± 0.8	<0.1
Sphingomyelin	0	0	50.1 ± 1.4	49.8 ± 1.3	<0.1
Lysophosphatidylcholine	0	0	2.4 ± 1.0	93.3 ± 0.9	4.2 ± 1.0

[a]Lipids were extracted from fasted human serum using the method of Bligh and Dyer (8). Radiolabeled lipid standards purified by HPLC (5) were added separately to an equivalent of 100 μl of human serum lipid to determine recovery. Results are expressed as the percentage mean ± SE for a minimum of 4 separate determinations for each lipid class. Combinations of lipids were also separated with the same recoveries. The Sep-Pak column was washed with 12 ml MTBE/acetic acid (100:0.2), no radioactivity emerged. The solvent system was composed of MTBE/methanol/ammonium acetate (pH 8.6) in the following proportions and amounts: fraction 1, 25:4:1, 8 ml; fraction 2, 10:4:1, 12 ml; fraction 3, 5:4:1, 12 ml; and fraction 4 and 5, 5:8:2, 12 ml.

lipids, e.g., phosphatidylcholine, sphingomyelin and lysophosphatidylcholine, with MTBE/methanol/ammonium acetate (pH 8.6) (5:8:2). All phospholipids could be eluted with 10 to 20 ml of the latter solvent. Using this solvent is better than methanol alone because the phospholipids emerge in a minimum of solvent.

DISCUSSION

We have developed a rapid highly reproducible method to separate the major neutral lipid classes and polar lipids. By including the appropriate internal lipid standards prior to separation, excellent quantitative data was obtained. Radiolabeled lipids were used in the present work. However, quantitation can be achieved using chemical determination, gas chromatography or HPLC. The method described in this report can be used as an alternative to thin layer chromatography.

The separations obtained on the small disposable silica Sep-Pak columns were a function of lipid polarity and of solvent strength and polarity. The solvent proportions determined empirically were critical for complete separations. The elution volumes could be varied from 10 to 25 ml without contamination from the more polar lipids. A compromise volume of 12 ml was sufficient for complete elution of each lipid in the current work. The neutral lipids (cholesteryl esters and triglycerides) were eluted by solvent strength using combinations of hexane/MTBE; 200:3 for cholesteryl esters followed by 96:4 for triglycerides. A combination of 200 μg of cholesteryl ester and 100 μg of triglyceride separated readily. If present, methylesters of fatty acids and simple alkyl esters would not separate from cholesteryl esters and would elute with hexane/MTBE (200:3). Both short and long chain triglycerides elute with hexane/MTBE (96:4). After acidification of the column with hexane/acetic acid (100:0.2), fatty acids were eluted using hexane/MTBE/acetic acid (100:2:0.2). The elution of cholesterol was achieved with MTBE-acetic acid 100:0.2. Monoglycerides, 1,2- and 1,3-diglycerides emerged in the cholesterol fraction as measured by lipid standards and HPLC chromatography, but they were not quantitated using radiolabeled standards for this report.

Phospholipid classes could not be separated completely from each other. However, phosphatidylethanolamine and phosphatidylinositol were separated completely from phosphatidylcholine, sphingomyelin and lysophosphatidylcholine with excellent (98+%) recoveries. Separations of phosphatidylethanolamine from phosphatidylinositol or phosphatidylcholine from sphingomyelin and lysophosphatidylcholine were not achieved. However, after partial separation on the silica Sep-Pak column, these polar lipids can be separated by HPLC with excellent recovery (10).

This rapid, simple method lends itself to enzymic and other assays where measurement of a lipid as an endpoint is necessary. It is particularly useful for radiolabeled methods. Incorporation of cholesterol precursor into cholesterol, incorporation of fatty acid into cholesterol ester where separation of cholesterol, cholesteryl ester and fatty acid is desired and the separation of fatty acids and triglycerides during lipolysis are a few examples of potential applications of this methodology. Additionally, the cartridge can be reused if washed with methanol (20 ml), MTBE (20 ml) and then hexane (20 ml) making the separations more economical.

In addition to human serum lipids, rat serum and liver lipids, as well as lipids from cultured smooth muscle cells, have been separated quantitatively, as in previous work (5).

The most difficult separation of the neutral lipids proved to be the separation of cholesteryl esters from triglycerides. Numerous combinations of hexane and more polar solvent mixtures were tried. MTBE and diethylether proved to be better than others such as ethyl acetate, chloroform or dichloromethane. MTBE was preferred to diethylether because diethylether is much less stable than MTBE and many of the stabilizers interfered with the analysis. It was surprising to find that the separation of phosphatidylethanolamine from phosphatidylcholine was better using MTBE than chloroform.

Separation of Neutral Lipid, Free Fatty Acid and Phospholipid Classes by Normal Phase HPLC

James G. Hamilton[1] and **Karen Comai**[2,*]
Department of Pharmacology, Hoffmann-La Roche Inc., Nutley, NJ 07110

Normal phase high performance liquid chromatography methods are described for the separation of neutral lipid, fatty acid and five phospholipid classes using spectrophotometric detection at 206 nm. Separations were accomplished in less than 10 min for each lipid class. A mobile phase consisting of hexane/methyltertiarybutylether/acetic acid (100:5:0.02) proved effective in separating cholesteryl ester and triglyceride with recoveries of 100% for radiolabeled cholesteryl oleate and 98% for radiolabeled triolein. Free fatty acid and cholesterol were separated by two different mobile phases. The first, hexane/methyltertiarybutylether/acetic acid (70:30:0.02) effectively separated free fatty acids and cholesterol, but did not separate cholesterol from 1,2-diglyceride. A mobile phase consisting of hexane/isopropanol/acetic acid (100:2:0.02) effectively separated free fatty acid, cholesterol, 1,2-diglyceride and 1,3-diglyceride. Recoveries of oleic acid and cholesterol were 100% and 97%, respectively. Five phospholipid classes were separated using methyltertiarybutylether/methanol/aqueous ammonium acetate (pH 8.6) (5:8:2) as the mobile phase. The recoveries of phosphatidylinositol, phosphatidylethanolamine, phosphatidylcholine, sphingomyelin and lysophosphatidylcholine were each greater than 96%.
Lipids 23, 1150–1153 (1988).

The development of mobile phases for separations of lipids using high performance liquid chromatography (HPLC) has improved despite the lack of adequate detection techniques (1–3). Mobile phases have been developed so that the ultraviolet absorbing properties of lipids in the range of 190 to 210 nm can be used to monitor separations (2–4). Solvents such as methyltertiarybutylether (MTBE), hexane, isopropanol, acetonitrile and methanol, which do not absorb appreciably in the ultraviolet range of 190 to 210 nm, have been used successfully in both normal and reversed phase HPLC separations of lipids (2–5).

This report describes in detail normal phase HPLC techniques for quantitative separation of neutral lipid classes, fatty acids and five major phospholipid classes. Separations were complete for all lipids with the exception of a 15% cross contamination of phosphatidylcholine and sphingomyelin. Each isocratic HPLC separation is completed in less than 10 min with recoveries of greater than 96% for each lipid.

MATERIALS AND METHODS

Lipids were extracted from human serum and rat liver using the method of Bligh and Dyer (6). Extracts were stored under nitrogen at −20°C. Radiolabeled rat liver [^{3}H]phosphatidylcholine, [^{14}C]phosphatidylethanolamine and [^{3}H]sphingomyelin were prepared as previously described (4,7,8). Tri[1-^{14}C]oleylglycerol, [^{3}H]oleic acid, cholesteryl [^{3}H]oleate, [^{14}C]cholesterol, [^{3}H]phosphatidylinositol and [^{14}C]lysophosphatidylcholine were purchased from New England Nuclear (Boston, MA). These radiolabeled lipids were purified by HPLC prior to performing recovery experiments (4). For quantitative recovery experiments, the following amounts of radiolabeled lipids were used: 0.02 μCi of [^{3}H]cholesteryl oleate, 0.1 μCi of [^{14}C]cholesterol, 0.02 μCi of [^{3}H]oleic acid, 0.02 μCi of tri[1-^{14}C]oleylglycerol, 0.04 μCi of [^{3}H]phosphatidylinositol and 0.02 μCi of [^{14}C]lysophosphatidylcholine. Additionally, 0.04 μCi of [^{14}C]phosphatidylethanolamine, 0.04 μCi of [^{3}H]phosphatidylcholine and 0.02 μCi of [^{3}H]-sphingomyelin were used without dilution as isolated from rat liver lipids. Radiolabeled counting was performed using a Searle Analytic Mark III Scintillation Counter. Samples for counting were suspended in 10 ml Aquasol (New England Nuclear, Boston, MA).

Neutral lipid standards were purchased from NuChek Prep (Elysian, MN) and stored in sealed vials at −20°C. Polar lipid standards were purchased from Avanti Polar Lipids (Birmingham, AL) and stored in sealed vials at −20°C. All solvents were HPLC grade and were purchased from Burdick and Jackson (Muskegon, MI).

HPLC was performed using a Waters Associates (Milford, MA) Model 840 HPLC work station which includes a Digital Professional 350 Computer, a Digital LA 50 printer, a Waters 481 Spectrophotometer operated at 206 nm, two Waters Associates model 510 pumps and a Waters Associates U6K injector. Prepacked μPorasil columns (30 cm × 3.9 mm) were obtained from Waters Associates (Milford, MA). As much as 1 mg of each lipid standard was used without effect on column performance. The column capacity for lipid mixtures is greater than 2 mg. The mobile phase flow rate was 2.0 ml/min. All injections for quantitative measurements were made with a TP#5250 syringe (Unimetrics Corporation, Anaheim, CA). All samples for HPLC separations were dissolved in the solvent that was used as the mobile phase. The HPLC system was maintained at room temperature, ca. 22°C.

RESULTS

Separation of neutral lipid classes and free fatty acids by HPLC. Several mobile phases were developed to separate neutral lipids and free fatty acids by normal phase HPLC.

Figure 1 shows the HPLC chromatogram of serum lipids containing [^{3}H]cholesteryl oleate and tri[1-^{14}C]-oleylglycerol standards. The mobile phase consisting of hexane/MTBE/acetic acid (100:5:0.02) (mobile phase 1)

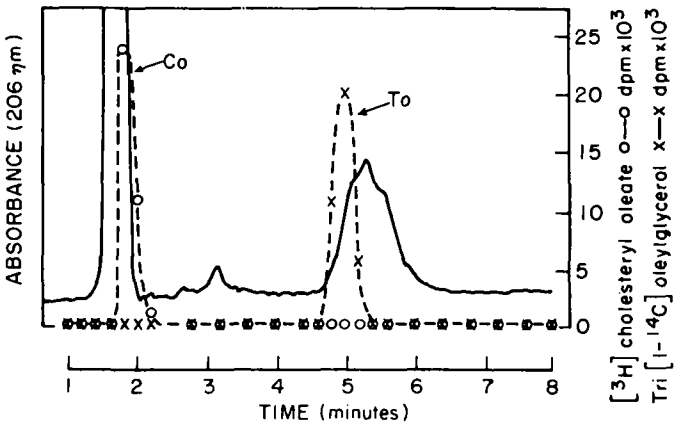

FIG. 1. HPLC separation of serum lipids equivalent to 100 μl serum containing [^{3}H]cholesteryl oleate and tri[1-^{14}C]oleylglycerol. Column: 30 cm × 3.9 mm μPorasil; flow rate: 2.0 ml/min; detection 0.05 AUFS at 206 nm; mobile phase (1): hexane/MTBE/acetic acid (100:5:0.02). [^{3}H]cholesteryl oleate (O———O). Tri[1-^{14}C]oleylglycerol (X———X).

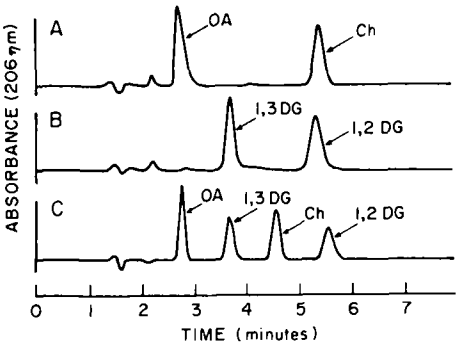

FIG. 2. HPLC separation of neutral lipids. Column: 30 cm × 3.9 mm μPorasil; flow rate: 2.0 ml/min. A and B: detection 0.05 AUFS at 206 nm; mobile phase, hexane/MTBE/acetic acid (70:30:0.02). C: detection 0.15 AUFS at 206 nm; mobile phase, hexane/isopropanol/acetic acid (100:2:0.02). Peak identity: OA, oleic acid, 50 μg; 1,3DG, 1,3-dioleylglycerol, 20 μg; Ch, cholesterol, 5 μg; 1,2DG, 1,2-dioleylglycerol, 20 μ.

effectively separated cholesteryl esters from triglycerides. The radiolabeled standards emerged as sharp peaks at 2.0 min for [^{3}H]cholesteryl oleate and 5.2 min for tri[1-^{14}C]oleylglycerol with excellent recoveries of each (Table 1). However, mobile phase 1 was not sufficiently polar to separate cholesterol and free fatty acids in a reasonable period of time (less than 20 min). Increasing the flow rate of mobile phase 1 to 4.0 ml/min did not appreciably improve the chromatographic profile. The polarity of mobile phase 1 was increased by the addition of more MTBE. The HPLC chromatogram of cholesterol and free fatty acids using hexane/MTBE/acetic acid (70:30:0.02) (mobile phase 2) is shown in Figure 2A. Fatty acids and cholesterol were clearly separated from each other within 7 min. The radiolabeled oleic acid standard emerged at 2.7 min with a 95.9% recovery and the [^{14}C]-cholesterol standard emerged at 5.8 min with a recovery of 98.9% (Table 1). Using mobile phase 2, another neutral lipid, 1,3-dioleylglycerol, separated from both oleic acid and cholesterol (Fig. 2B). However, 1,2-dioleylglycerol did not separate from cholesterol (Fig. 2B). Consequently, a third mobile phase consisting of hexane/isopropanol/acetic acid (100:2:0.02) was developed which effectively separated oleic acid, 1,3-dioleylglycerol, cholesterol and 1,2-dioleylglycerol (Fig. 2C). Oleic acid emerged at 2.7 min, 1,3-dioleylglycerol emerged at 3.7 min, cholesterol at 4.6 min and 1,2-dioleylglycerol at 5.6 min. The recoveries of oleic acid and cholesterol based on the added radiolabeled standards was greater than 98% for each lipid (Table 1). Radiolabeled 1,2- and 1,3-dioleylglycerols were not available and thus recoveries were not determined.

Separation and recoveries of phospholipid classes by HPLC. Phospholipid standards were chromatographed separately and in combination as shown in Figure 3. The solvent system that had been successful in separating phospholipids on small silica Sep-Pak columns (4) was used as the mobile phase for the HPLC separations. This mobile phase consisted of MTBE/methanol/ammonium acetate (pH 8.6) (5:8:2) (4). The ammonium acetate was prepared by adding 2 volumes of 0.001 M ammonium hydroxide to 1 volume of 0.001 M acetic acid.

Within 10 min, the separation of the five phospholipid

Recovery of Neutral Lipids and Free Fatty Acids from HPLC

Lipid class[a]	% Recovery		
	Mobile phase 1[b]	Mobile phase 2[c]	Mobile phase 3[d]
Cholesteryl ester	100.2 ± 0.6	—	96.9 ± 1.0
Triglyceride	98.2 ± 0.7	—	97.8 ± 0.7
Free fatty acid	—	95.9 ± 0.3	100.0 ± 0.5
Cholesterol	—	98.9 ± 0.7	97.4 ± 1.4

[a]Lipids were extracted from human serum using the method of Bligh and Dyer (6). Radiolabeled lipid standards were added separately to an equivalent of 100 μl of human serum lipid. Radiolabeled lipid standards were also added in combination.

[b]Mobile phase 1: hexane/MTBE/acetic acid (100:5:0.02). The results are the mean ± SE for 5 determinations of each lipid class.

[c]Mobile phase 2: hexane/MTBE/acetic acid (70:3:0.02). The results are the mean ± SE for 6 determinations of each lipid class.

[d]Mobile phase 3: hexane/isopropanol/acetic acid (100:2:0.02). The results are the mean ± SE for 7 determinations for each lipid class.

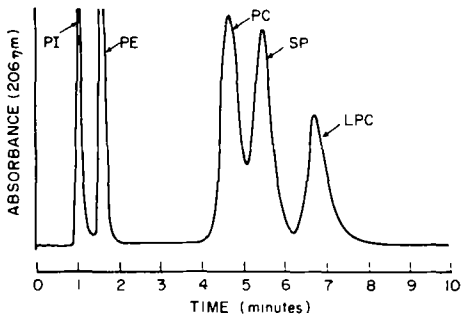

FIG. 3. Separation of phospholipid classes. Column: 30 cm × 3.9 mm μPorasil; flow rate: 2.0 ml/min; detection 0.3 AUFS at 206 nm. Mobile phase (4): MTBE/methanol/ammonium acetate (pH 8.6) (5:8:2). Peak identity: PI, phosphatidylinositol (liver), 25 μg; PE, phosphatidylethanolamine (liver), 125 μg; PC, phosphatidylcholine (egg), 100 μg; SP, sphingomyelin (egg), 100 μg; LPC, monoleyllysophosphatidylcholine (synthetic), 400 μg.

classes was complete (Fig. 3), with recoveries of greater than 06% for each (Table 2).

TABLE 2

Recovery of Phospholipids from HPLC

Lipid[a]	% Recovery[b]
Phosphatidylinositol	98.7 ± 0.9
Phosphatidylethanolamine	98.3 ± 1.1
Phosphatidylcholine	96.1 ± 0.9
Sphingomyelin	100.0 ± 0.8
Lysophosphatidylcholine	96.5 ± 0.2

[a]Radiolabeled lipid standards were combined with unlabeled lipid standards: 25 μg unlabeled + 0.04 μCi of phosphatidylinositol; 125 μg unlabeled + 0.04 μCi of [^{14}C]phosphatidylethanolamine; 100 μg unlabeled + 0.04 μCi of [^{3}H]phosphatidylcholine; 100 μg unlabeled + 0.02 μCi of [^{3}H]sphingomyelin; 400 μg unlabeled + 0.02 μCi of [^{14}C]lysomonoleylphosphatidylcholine. For each individual phospholipid and for the combination, the solvent was evaporated to dryness under nitrogen and taken up in 100 μl of the HPLC mobile phase; MTBE/methanol/aqueous ammonium acetate (pH 8.6) (5:8:2).

[b]The results are the mean ± SE for a minimum of 5 determinations for each individual phospholipid. The recoveries from independent determinations were similar to recoveries from mixtures of these phospholipids.

DISCUSSION

Although there are several very good reversed phase HPLC methods for the separation of the individual species of cholesteryl esters and triglycerides (2,9), few HPLC methods are available for the separation and quantitative recovery of the classes of cholesteryl esters and triglycerides (4,10). The method currently reported is substantially improved over the previously published method in that the silica column step can be omitted and the separation of cholesteryl ester from triglyceride is complete (4). An important aspect of this method is that the elution schemes are isocratic and thus require a single pump rather than a costly gradient system. Additionally, the mobile phases were selected to give complete separations in short periods of time. The cholesteryl ester fraction of serum emerged at 1.4 to 2.0 min, when hexane/MTBE/acetic acid (100:5:0.02) was used as the mobile phase (Fig. 1). Serum triglycerides emerged between 4.8 and 6.0 min with this procedure (Fig. 1). The radiolabeled cholesteryl oleate and triolein used as standards, emerged as sharp peaks when plotted on the HPLC chromatogram. The recoveries were excellent, 100% for cholesteryl oleate and 98% for triolein (Table 1). This method allows for an easy, rapid and quantitative separation of cholesteryl esters from triglycerides. The volumes of solvents used were not critical, However, the proportions of solvents were key to complete separation of cholesteryl ester from triglyceride. Once these lipid classes have been separated, separation into their respective molecular species can be achieved by reversed phase HPLC methods (1).

A second mobile phase, hexane/MTBE/acetic acid (70:30:0.02), effectively separated free fatty acids and cholesterol with quantitative recovery of each (Fig. 2A, Table 2). However, if 1,2-diglycerides are present in the lipid mixture, they will not be separated from cholesterol (Figs. 2A and B). A third mobile phase consisting of hexane/isopropanol/acetic acid (100:2.0:0.02) was used to effectively separate fatty acids, 1,3-diglycerides, cholesterol and 1,2-diglycerides. With this solvent system, carbon chain length and double bonds have little influence on separation, i.e., all fatty acids emerge as a single peak and are separated from alcohols which also emerge as a single peak (Fig. 2C) (4). This mobile phase has the advantage of collecting several individual lipid classes from a single chromatographic run. It has the disadvantage that cholesteryl esters and triglycerides emerge (quantitatively) in the void volume (Table 1).

A number of excellent methods exist for the separation of phospholipid classes using HPLC (3,5,10). The advantage of the current method is that the separation is completed in less than 10 min compared to the 60 to 120 min in most other published work (3,5,10). There is a 15% cross contamination of sphingomyelin and phosphatidylcholine. However, an excellent (98+%) recovery of each phospholipid class is achieved. Although not shown in Figure 3, phosphatidylglycerol and cardiolipin emerge in the phosphatidylinositol fraction.

We have used a combination of the above procedures to separate lipids from serum, liver and cultured cells. It has become routine to use prepacked silica columns to separate neutral lipids and fatty acids from polar lipids (7) and then to use mobile phases 2 and 3 to separate and collect the neutral lipids and mobile phase 4 to separate and collect the phospholipids of interest.

It should be of interest to the potential user of these methods, that the HPLC columns remain stable at the pH of the solvent systems used. To reequilibrate the column after collection of the phospholipids, 3 to 5 column volumes of MTB/acetic acid (100:0.2) were used, followed by 10 to 15 column volumes of the neutral lipid solvent such as hexane/MTBE/acetic acid (100:5:0.02). The HPLC columns were good for at least 50 separations.

ACKNOWLEDGMENT

The authors wish to thank the Pharmacology and Chemotherapy Word Processing Unit (M. Johnson, P. Lotito, N. Manion, C. Muscara and L. Zielenski) for their expertise in typing this manuscript.

Erythrocyte Contamination of Leukocyte Populations Following Density-Gradient Centrifugation Results in Artificially High Levels of Human Leukocyte HMG-CoA Reductase Activity

H. James Harwood Jr.*, Donna M. Bridge and Peter W. Stacpoole
Departments of Medicine and Pharmacology, University of Florida, Gainesville, FL 32610

When measuring human leukocyte HMG-CoA reductase activity, special care must be taken to prevent erythrocyte contamination of the leukocyte layer during isopycnic centrifugation. Contamination during leukocyte isolation and subsequent erythrocyte lysis during NH_4Cl treatment results in increased leukocyte microsomal HMG-CoA reductase activity. Increased enzyme activity is not due to enzyme dephosphorylation, thiol-disulfide reduction or increased enzyme protein concentration. Leukocyte populations containing granulocytes appear to be most sensitive. Prevention of erythrocyte contamination during isopycnic centrifugation should aid in accurate measurement of human leukocyte HMG-CoA reductase activity.
Lipids 23, 1154–1158 (1988).

Measurement of human leukocyte HMG-CoA reductase (reductase) has been complicated by the low activity of the enzyme and the large number of leukocytes required for direct measurement of enzyme activity. This has led many investigators to rely on rates of conversion of acetate into cholesterol as an indirect measure of enzyme activity (1–6). Estimation of rates of cholesterol synthesis requires a smaller number of leukocytes than direct measurement of enzymatic activity, but does not always accurately reflect reductase activity. For example, in mononuclear leukocytes, only about 50% of the acetate converted into mevalonate is converted into cholesterol (7,8). Furthermore, granulocytes are unable to synthesize sterols, due to the absence of squalene epoxidase (2,9), and thus convert all mevalonate formed into nonsterol products.

Direct measurement of leukocyte reductase activity in mitochondria-free whole cell extracts (7,10–12) provides a better estimate of enzyme activity than acetate conversion to sterols (12). However, such extracts contain high concentrations of HMG-CoA cleavage enzymes that preclude accurate measurement of reductase activity by producing nonmevalonate products that comigrate with mevalonate during thin layer chromatography (12). We recently described methods for isolating human leukocyte microsomes and for measuring leukocyte microsomal reductase activity (8) that eliminate the HMG-CoA cleavage activity present in whole cell extracts (8) and thus afford a more accurate determination of enzyme activity than measurement in whole cell extracts (8,13–17).

All three methods described above for estimating human leukocyte HMG-CoA reductase activity, however, rely on density gradient centrifugation methods for separation of leukocytes from plasma and erythrocytes. We recently discovered that when this separation is poor, and erythrocytes contaminating the leukocyte population are lysed during subsequent NH_4Cl treatment, artifactually high levels of reductase activity result.

Abbreviation: BSS, Balanced Salts Solution.

MATERIALS AND METHODS

Chemicals. Escherichia coli alkaline phosphatase was from Sigma Chemical Co. (St. Louis, MO). All other chemicals were from previously listed sources (8,13,14, 17,18). Monospecific, polyclonal, rabbit, antirat liver reductase antiserum was a generous gift from Dr. G. C. Ness (University of South Florida, Tampa, FL).

Isolation of peripheral blood leukocytes. Blood samples ranging from 40 ml to 120 ml were obtained using tourniquet pressure from an antecubital vein with a 19-ga needle and 60-ml syringes. After removing the needle from the syringe, the blood was discharged into 50-ml conical plastic centrifuge tubes containing 1.0 ml of 250 mM EDTA (pH = 7.4) and the tubes were inverted several times. Care was taken to empty the syringe over 5 to 10 sec, with a jet of blood coursing along the side of the tube to minimize hemolysis. Within 10 min of blood drawing, the sample was diluted with an equal volume of room temperature Hank's Balanced Salts Solution (BSS). For isolation of mononuclear leukocytes, 20 ml aliquots of the diluted blood sample were immediately added to 50 ml plastic conical centrifuge tubes, underlayered with 20 ml of room temperature Histopaque 1077 and centrifuged for 40 min at 400 × *g*. To isolate total leukocyte populations (mononuclear leukocytes plus granulocytes), 20-ml aliquots of the diluted blood sample were underlayered with 20 ml of room temperature 70% isoosmotic Percoll (70 ml Percoll, 0.62 g NaCl and 30 ml 0.15 M NaCl) and centrifuged at 400 × *g* for 40 min. Isolated leukocyte populations were washed twice in Hank's BSS and then treated with 0.87% NH_4Cl for 10 min to lyse contaminating erythrocytes. The erythrocyte lysate was then removed from the leukocytes by centrifugation at 400 × *g* for 15 min. Isolated leukocyte populations were then washed and stored frozen in liquid N_2 as previously described (8). Further fractionation of total leukocyte populations into mononuclear leukocyte and granulocyte fractions was accomplished using an isoosmotic Percoll gradient, as described by Harwood et al. (8).

Isolation of plasma-free erythrocytes. Two additional ml of blood from samples used for leukocyte isolation were centrifuged for 5 min in a clinical centrifuge. Following centrifugation, the plasma and buffy coat were discarded. The erythrocyte pellet was washed twice in 4.0 ml Hank's BSS and resuspended to a final volume of 2.0 ml with Hank's BSS. Microsomal reductase activity of this fraction was negligible (data not shown).

Measurement of leukocyte microsomal reductase activity. Leukocyte microsomes were isolated and reductase activity was measured, as described by Harwood et al.

METHODS

(8). Frozen cell suspensions were incubated at room temperature until just thawed, diluted to 1.0 ml with fresh assay buffer (50 mM tris (pH = 7.5, 1.0 mM EDTA, 5.0 mM dithiothreitol, 50 mM KCl) and homogenized 15 times manually with a ground glass Potter-Elvehjem tissue homogenizer. Homogenates were next diluted to 3.0 ml with assay buffer and homogenized 10 times with a motor-driven Teflon pestle. The resulting homogenates were diluted to 8 ml with assay buffer and centrifuged, first at 2,000 × *g* to remove unbroken cells and cell debris, and then at 172,000 × *g* to sediment microsomes. Following centrifugation, the microsomal pellet was resuspended in assay buffer and assessed for reductase activity.

To assay leukocyte reductase activity, 150 μg leukocyte microsomal protein were incubated at 37°C for 30 min in a final volume of assay buffer containing 67 μM [3-^{14}C]HMG-CoA (specific activity 30 cpm/pmol), [5-^{3}H]-mevalonolactone (11,000 cpm; 629 Ci/mol) as an internal standard, 3.4 mM $NADP^+$, 30 mM glucose-6-phosphate, 0.2 U glucose-6-phosphate dehydrogenase and 68 mM EDTA to prevent conversion of mevalonate to phosphomevalonate during incubation. Following incubation, 10 μl of 6 M HCl were then added to terminate the reductase-catalyzed reaction and to convert newly formed mevalonate to mevalonolactone. The mevalonolactone was then separated from unreacted substrate by silica gel thin layer chromatography. Following development in toluene-acetone 1:1 (v/v), the region of the chromatogram from R_f 0.5 to R_f 1.0 was removed and counted in 4.0 ml of Scintelene liquid scintillation fluid.

Radioactivity contained in this region of the silica gel chromatogram comigrated in a 1:1 relationship with authentic [^{3}H]mevalonolactone on three separate thin layer chromatographic systems and was converted into phosphomevalonates, following incubation with MgATP and rat liver mevalonate kinase (data not shown; for similar results using cultured human leukocyte microsomes, see Ref. 8). No other radiolabeled reaction products were detectable in this region of the chromatogram. Thus, as was previously shown using cultured human leukocyte microsomes (8), HMG-CoA cleavage activity is apparently absent from these microsomal preparations. Taken together, these data indicate that mevalonate, the product of the reductase-catalyzed reaction, is the only radiolabeled reaction product migrating in this region of the chromatogram.

Reductase activity is expressed as pmol of mevalonate formed per min of incubation at 37°C per mg microsomal protein. Generally, triplicate determinations of enzyme activity (150 μg of microsomal protein per measurement) could be made from a 40-ml blood sampling.

Measurement of reductase protein concentration. Leukocyte microsomal reductase protein concentration was measured in 1.5 μg of microsomal protein using a noncompetitive, solid-phase enzyme immunoassay recently described by Harwood et al. (18). Purified, proteolytically modified human liver reductase (>94% homogeneous, as judged by scanning transmission densitometry [18]) was used as the source of purified enzyme protein standard. Reductase protein concentration is expressed as μg of immunoreactive protein per mg microsomal protein.

Analysis of protein. Microsomal protein concentration was determined by the method of Bradford (19) using bovine serum albumin as standard.

RESULTS AND DISCUSSION

Mononuclear leukocyte reductase activity from 31 healthy, normocholesterolemic individuals averaged 10.3 ± 0.8 (SE) pmol/min/mg. This value was not significantly different from that measured in isolated lymphocytes (10.1 ± 0.8 pmol/min/mg; n = 8), monocytes (13.0 ± 1.8 pmol/min/mg; n = 7), granulocytes (8.8 ± 0.5 pmol/min/mg; n = 3) or total leukocyte populations (9.3 ± 0.9 pmol/min/mg; n = 2). However, total leukocyte populations, visibly contaminated with erythrocytes following density-gradient centrifugation, but uncontaminated following NH_4Cl treatment (lyses erythrocytes), possessed enzyme activities exceeding 120 pmol/min/mg (Table 1). In one individual (subject 2), leukocytes from one portion of a single blood draw were contaminated with erythrocytes following density-gradient centrifugation, whereas two other portions were uncontaminated. The contaminated sample, which was uncontaminated following NH_4Cl treatment, contained ca. 7 times the microsomal reductase activity of the uncontaminated leukocytes (Table 1). Increased reductase activity was not due to the presence of residual erythrocytes during leukocyte homogenization and microsomal isolation, however, because all erythrocytes were lysed during NH_4Cl treatment and the lysate was removed prior to leukocyte homogenization. Furthermore, because erythrocytes do not contain significant amounts of microsomal reductase activity (data not shown), increased leukocyte reductase activity was not due to contamination of leukocyte microsomal reductase with erythrocyte microsomal reductase.

Increased enzyme activity was not the result of elevated reductase protein concentration (Table 2) but was due to increased enzyme catalytic efficiency (Table 2). Increased catalytic efficiency, however, was not due to enzyme dephosphorylation or thiol-disulfide reduction (Table 3), because addition of *E. coli* alkaline phosphatase or 20 mM dithiothreitol to leukocyte microsomes from a leukocyte sample, not contaminated during density-

TABLE 1

Increased Leukocyte Reductase Activity With Erythrocyte Contamination

Subject	Reductase activity (pmol/min/mg)		Fold increase
	Uncontaminated leukocytes	Contaminated leukocytes	
1	5.9 ± 0.2	124 ± 6	21.0
2	19.3 ± 0.3	135 ± 21	7.0
3	—	135 ± 15	—

Total leukocyte populations were isolated from 40 ml of peripheral blood using 70% isoosmotic Percoll. Data are the average of triplicate determinations of reductase activity ± S.E. For subjects 1 and 3, data are for two separate blood samplings, one which was grossly contaminated with erythrocytes following density-gradient centrifugation, but free from contamination following NH_4Cl treatment (lyses erythrocytes), and one which was uncontaminated (normal intrasubject variation <10%; [8]). For subject 2, data are for a single blood sample in which one of three portions showed gross erythrocyte contamination following density-gradient centrifugation, but not following NH_4Cl treatment, whereas the other two showed no contamination.

gradient centrifugation, failed to produce enzyme levels comparable with those generated in a second portion of the same leukocyte sample, contaminated by erythrocytes during density-gradient centrifugation, but uncontaminated following NH_4Cl treatment (Table 3).

TABLE 2

Increased Leukocyte Reductase Activity is Due to Increased Enzyme Catalytic Efficiency

	Reductase activity (pmol/min/mg)	Reductase protein concentration (μg/mg)	Reductase catalytic efficiency (pmol/min/mg)
	(A)	(B)	(A/B)
Uncontaminated (a)	19.3 ± 0.3	61.7 ± 3.7	347
Contaminated (b)	135 ± 21	85.0 ± 1.5	1,590
b/a	7.0	1.4	4.6

Reductase activity and enzyme protein concentration of the microsomes isolated from the leukocyte populations of subjects 1-3 (Table 1) were measured, as previously described. The data obtained for the leukocyte populations of subject 2 are presented above. Data are the average of triplicate determinations ± SE. Reductase catalytic efficiency, calculated by dividing enzyme activity by enzyme protein concentration, is expressed as pmol/min/mg immunoreactive protein.

Similar increases in catalytic efficiency were observed for the contaminated samples from subjects 1 and 3 (4,560 and 2,250 pmol/min/mg immunoreactive protein, respectively). As previously reported (18,21), the catalytic efficiency obtained from 31 uncontaminated mononuclear leukocyte populations averaged 313 ± 34 pmol/min/mg, a value consistent with the catalytic efficiencies obtained for the uncontaminated total leukocyte populations isolated from subjects 1 and 2.

TABLE 3

Increased Leukocyte Catalytic Efficiency is Not Due to Dephosphorylation or Thiol-Disulfide Reduction

Additions	Reductase activity (pmol/min/mg)
None	19.3 ± 0.3
Alkaline phosphatase	23.5 ± 1.1
20 mM dithiothreitol	21.7 ± 0.5
Erythrocyte contamination	135 ± 21

Peripheral blood leukocyte microsomes (150 μg) isolated from leukocyte populations of subject 2 (Table 1) were incubated at 37°C for 20 min in 50 μl of either buffer (50 mM tris (pH = 7.5), 1.0 mM EDTA, 5.0 mM dithiothreitol, 70 mM KCl), buffer containing 10 U *E. coli* alkaline phosphatase or buffer containing 20 mM dithiothreitol. Enzyme activity was subsequently measured in a second 30-min incubation at 37°C. Data are the average of triplicate determinations ± SE and are compared with the value obtained from a population of the same leukocytes contaminated with erythrocytes following density-gradient centrifugation, but not following NH_4Cl treatment.

As previously reported (21), following isolation, the mononuclear leukocyte enzyme is fully active with respect to dephosphorylation and thiol-disulfide reduction. For example, for a series of mononuclear leukocyte populations for which activity was measured in the presence and absence of either dithiothreitol of alkaline phosphatase, enzyme activity averaged 8.6 ± 1.2 pmol/min/mg microsomal protein in the absence of both agents and was 105% of control in the presence of dithiothreitol and 88% of control in the presence of alkaline phosphatase. Similar results (109% of control and 100% of control, respectively) were observed for total leukocyte populations.

To determine whether increased enzyme activity was due to the presence of and/or lysis of contaminating erythrocytes during NH_4Cl treatment, we subjected whole blood samples to repetitive treatment with 0.87% NH_4Cl until all erythrocytes were lysed. Total leukocyte populations isolated in this way had 6-16 times the reductase activity of either uncontaminated mononuclear leukocyte populations from the same blood sample or uncontaminated total leukocyte populations from alternate blood samples (Table 4). When total leukocyte populations, isolated by this method, were separated into mononuclear leukocyte and granulocyte fractions by isoosmotic Percoll gradient centrifugation, reductase activity in the granulocyte fraction (>90% granulocytes, as determined by Wright's staining) was found to be increased 3-13-fold, when compared with either uncontaminated mononuclear leukocyte populations from the same blood sample or uncontaminated granulocyte populations from alternate blood samples (Table 5). However, reductase activity in the mononuclear fraction (77% lymphocytes, 23% monocytes, <4% granulocytes [8]) was found to be stimulated to a lesser degree than the granulocyte fraction (data not shown), suggesting that granulocytes may be more sensitive to this phenomenon. This suggestion is further supported by the observation that addition of plasma-free erythrocytes to uncontaminated mononuclear leukocyte populations following density-gradient centrifugation, and subsequent erythrocyte lysis during NH_4Cl, treatment, had relatively small effects on activity of the mononuclear leukocyte enzyme (Table 6).

The data presented above describe a potential problem associated with measurement of leukocyte HMG-CoA reductase activity that may result from poor separation of leukocytes and erythrocytes and subsequent erythrocyte lysis. Furthermore, if erythrocyte lysis is the event responsible for aberrant reductase activity, then hemolysis prior to density-gradient centrifugation could also lead to increased HMG-CoA reductase activity. Because all methods for measuring leukocyte reductase activity involve separating leukocytes from erythrocytes, artificial stimulation of leukocyte reductase activity, either by hemolysis prior to separation, or by lysis of contaminating erythrocytes following density-gradient centrifugation, presents a problem whether enzyme activity is measured in isolated microsomes (8,13-18), whole cell extracts (7,10-12) or in whole cells by means of acetate conversion to cholesterol (1-6).

Erythrocyte contamination and/or lysis-induced stimulation of enzyme activity may be minimized in several ways. In obtaining blood samples, vacutainers should be avoided, because their use increases the likelihood of hemolysis. Instead, large gauge needles and syringes should be used and the blood expelled slowly into plastic containers to minimize hemolysis. Processing of blood samples through density-gradient centrifugation should be as rapid as possible to avoid storage-induced hemolysis. Hank's BSS and separation medium should be at room temperature and density-gradient centrifugation should be conducted at room temperature to permit optimal erythrocyte and leukocyte separation (20). Other methods for optimizing separation of mononuclear leukocytes from erythrocytes and granulocytes have been outlined by

TABLE 4

Leukocyte Reductase Activity is Increased by Erythrocyte Lysis

Subject	Reductase activity (pmol/min/mg)			Fold increase
	Uncontaminated mononuclear leukocytes	Total leukocytes isolated over Percoll	Total leukocytes isolated by erythrocyte lysis	
1	8.2 ± 0.01	8.3 ± 0.6	—	1.0
2	9.3 ± 0.1	10.2 ± 1.4	—	1.1
3	9.3 ± 1.0	—	146 ± 7	15.7
4	11.1 ± 1.6	—	69 ± 0.6	6.2
5	9.9 ± 0.3	—	63 ± 1.4	6.4

Leukocyte populations from 40 ml of peripheral blood were isolated by density-gradient centrifugation over Histopaque 1077 (mononuclear leukocytes) or 70% isoosmotic Percoll (total leukocytes) or by total erythrocyte lysis with NH_4Cl (total leukocytes). For leukocyte populations isolated by erythrocyte lysis, blood samples were separated into four 10-ml portions and centrifuged to remove plasma. Each pellet was then resuspended in 50 ml of 0.87% NH_4Cl and permitted to stand for 10 min at room temperature. About 50% of the erythrocytes were lysed by this treatment. Following centrifugation, each cell pellet was resuspended in 50 ml of 0.87% NH_4Cl and remaining erythrocytes were lysed during a second 10-min incubation. Further processing of the leukocyte pellets were as previously described. Data are the average of triplicate determinations of reductase activity ± SE.

TABLE 5

Granulocyte Reductase Activity is Increased by Erythrocyte Lysis

Subject	Reductase activity (pmol/min/mg)		
	Uncontaminated mononuclear leukocytes	Uncontaminated granulocytes	Contaminated granulocytes
1	8.8 ± 0.5	8.0 ± 0.5	—
2	11.5 ± 0.5	9.1 ± 0.4	—
3	7.4 ± 0.4	9.4 ± 1.4	—
4	6.9 ± 1.1	—	92
5	5.9 ± 1.0	—	76
6	9.9 ± 2.1	—	32

For subjects 1-3, mononuclear leukocytes and granulocytes were isolated from a single blood sampling by isoosmotic Percoll-gradient centrifugation, as previously described (8). For subjects 4-6, peripheral blood samples of 120 ml were separated into two fractions. Mononuclear leukocytes were isolated from one fraction (40 ml), whereas total leukocyte populations were isolated from the remaining portion (80 ml) by erythrocyte lysis (see Table 4). Following erythrocyte lysis, granulocyte populations were isolated from the total leukocyte populations by discontinuous density-gradient centrifugation. Where indicated above, the data presented are the average of triplicate determinations of leukocyte microsomal reductase activity ± SE.

TABLE 6

Variable Increase in Mononuclear Leukocyte Reductase Activity Produced by Erythrocyte Addition

Subject	Reductase activity (pmol/min/mg)		Fold increase
	No added erythrocytes	Added erythrocytes	
1	12.8 ± 0.2	38.9 ± 1.8	3.0
2	3.9 ± 0.2	6.0 ± 0.2	1.5
3	5.7 ± 0.7	5.5 ± 0.4	1.0
4	6.0 ± 0.7	10.0 ± 0.4	1.7
5	8.2 ± 0.01	8.8 ± 0.2	1.1
6	9.2 ± 0.1	11.0 ± 1.6	1.2
7	15.7 ± 2.5	14.0 ± 3.6	1.0
8	10.5 ± 0.3	16.6 ± 1.0	1.7
9	12.8 ± 0.9	12.9 ± 0.6	1.0

Peripheral blood mononuclear leukocytes were obtained by leukapheresis and subsequent density-gradient centrifugation, as previously described. Mononuclear leukocytes equivalent to that present in a 40-ml blood sample were mixed with 40 ml Hank's BSS or 40 ml Hank's BSS containing 80 μl of a plasma-free erythrocyte fraction (an amount sufficient to provide a homogeneously red leukocyte pellet). Following centrifugation, the cell pellets were washed in Hank's BSS and the erythrocytes lysed in 0.87% NH_4Cl. Further processing of the leukocyte pellets was as previously described. Data are the averages of triplicate determinations of reductase activity ± SE. For subjects 8 and 9, lysed erythrocytes were used in place of whole erythrocytes.

Boyun (20). When isolating total leukocyte populations by Percoll density-gradient centrifugation, the possibility of significant erythrocyte contamination is greater than during mononuclear leukocyte isolation, however, because some erythrocyte aggregates remain suspended in the Percoll layer following centrifugation. Care must be taken not to include these aggregates in the leukocyte layer.

When these precautions are followed, reproducible determination of leukocyte reductase activity may be achieved (8,13–17). However, any undue time required for processing blood samples or suspected hemolysis or visual erythrocyte contamination of the leukocyte fraction following density-gradient centrifugation should be noted and the validity of subsequent reductase activity determinations questioned.
