Attempts were made to develop an animal model for phytosterolemia. Infusion of Intralipid containing 0.2% sitosterol in rats gave circulating levels of sitosterol of about 2.5 mmol/l, which is similar to or higher than those present in patients with untreated phytosterolemia. In addition, the infusions gave serum levels of cholesterol nearly twice those obtained in rats infused with Intralipid alone or Intralipid containing 0.2% cholesterol. The hepatic HMG-CoA reductase activity was unaffected or slightly increased by the sitosterol infusions (not statistically significant). The cholesterol 7α-hydroxylase activity was slightly depressed (ca. 30%). In the case of 7α-hydroxylation of endogenous cholesterol, the depression reached statistical significance ($p < 0.05$). The microsomal content of sitosterol in the sitosterol-infused rats was about 30% of that of microsomal cholesterol. The effect of sitosterol on 7α-hydroxylation of cholesterol was investigated by incubations of acetone powder of rat liver microsomes with mixtures of cholesterol and sitosterol. Sitosterol mixed with cholesterol to a composition similar to that found in the above microsomal fraction had a depressing effect on 7α-hydroxylation of cholesterol. This degree of depression was of the same magnitude as that found in the sitosterol infusion experiments. The possibility is discussed that the hypercholesterolemia obtained in the β-sitosterol-infused rats is due to the inhibitory effect of sitosterol on the cholesterol 7α-hydroxylase.
Lipids 24, 9–12 (1989).

Phytosterolemia (sitosterolemia) is an inborn metabolic disease characterized by increased absorption of phytosterols and premature atherosclerosis (1). Some patients with sitosterolemia have moderately elevated plasma cholesterol levels (1). The reason for and significance of this finding is unknown.

The primary defect is most probably located in the intestine, and thus the hypercholesterolemia and atherosclerosis may be secondary to the high levels of circulating phytosterols. Studies of the effect of sitosterol and other plant steroids on cholesterol metabolism and turnover have hitherto been hampered by the lack of a suitable animal model. Because plant sterols are absorbed only to a very small degree in the normal intestine, feeding with phytosterol-enriched diet does not give levels of circulating phytosterols sufficiently high to simulate the condition in human phytosterolemia. In addition, sitosterol inhibits cholesterol absorption, thus interrupting the enterohepatic circulation of this sterol and thereby lowering the serum cholesterol. Sitosterol has, in fact, been used as an antihypercholesterolemic agent in patients with mild hypercholesterolemia, giving 10–20% reduction of plasma cholesterol (1). From the above information, one would expect a depressing effect on circulating cholesterol by dietary sitosterol and an increasing effect by administrations bypassing the restricted intestinal absorption. Results hitherto obtained from animal studies are, however, confusing and difficult to interpret. Administration of sitosterol intraperitoneally to rats and subcutaneously to chickens has been reported to lead to depressed levels of plasma cholesterol (2,3). Bhattacharyya and Lopez (4), however, found that sitosterol given orally to rabbits led to a 60% increase in plasma cholesterol concentration. There was no accumulation of cholesterol in the tissues of these animals, and the mechanism behind the increased plasma cholesterol levels could not be explained. Attempts in our laboratory to confirm the results by Bhattacharyya and Lopez have not been successful.

In the present study, we have infused rats intravenously with sitosterol and obtained circulating concentrations of this sterol similar to or higher than those seen in patients with phytosterolemia. Thus, we have an animal model suitable for studies on possible interactions of sitosterol on cholesterol metabolism.

MATERIALS AND METHODS

Unlabeled compounds. Sitosterol (24-ethyl-5-cholesten-3β-ol) (98% pure) was obtained from Alltech Assoc. Inc. (Deerfield, IL). The purity of the material was ascertained by HPLC prior to use. Cholesterol (CH-USP), epicoprostanol(5β-cholestan-3α-ol), mevalonic acid as well as all cofactors were purchased from Sigma Chemical Co. (St. Louis, MO). 3-Hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) was obtained from Pharmacia (Uppsala, Sweden). Other chemicals were commercial products of high purity.

Labeled compounds. [4-^{14}C]Cholesterol and [3-^{14}C]hydroxymethylglutaryl-CoA with specific activities of 55–60 mCi/mmol were obtained from New England Nuclear Corp. (Boston, MA). [$^{2}H_3$]-Labeled 7α-hydroxycholesterol was synthesized as described previously (5).

Animals. Male Sprague-Dawley rats, weighing ca. 250 g, were used. A polyethylene tube (Intramedic PE-50) was introduced into a jugular vein during ether anesthesia. The animals were given an infusion of sitosterol or cholesterol dissolved in soybean oil by sonication and mixed with Intralipid 10% (KabiVitrum AB, Stockholm, Sweden). The mixture was treated with Ultraturax to produce a stable emulsion. The added soybean oil constituted 10% (v/v) of the mixture, and the final sterol concentration was 2 mg/ml. The infusion was continuous for 38 hr at a flow rate of 0.8 ml/hr. A control group of rats received the same amounts of soybean oil and Intralipid without added sterol. The animals were kept in restraining cages with free access to water and ordinary pelleted food.

The animal operations were approved by the local ethical committee for animal experiments.

Abbreviations: DTT, dithiothreitol; HMG-CoA, 3-hydroxy-3-methylglutaryl-coenzyme A; TMS, trimethylsilyl; TLC, thin layer chromatography.

Preparation of liver microsomes. A 10% (w/v) homogenate of the rat livers was prepared in 50 mM Tris-HCl buffer (pH 7.4) containing 0.3 M sucrose, 50 mM NaCl, 10 mM EDTA and 10 mM DTT (dithiothreitol). The microsomal fraction was prepared by centrifugation of the homogenate at 20,000 *g* for 15 min and recentrifugation of the supernatant at 100,000 *g* for 60 min. Half of the microsomal fraction was resuspended in the homogenizing medium and recentrifuged at 100,000 *g* for 60 min. The resulting fraction was suspended in 20 mM imidazol/HCl buffer (pH 7.4) containing 10 mM DTT and used for assay of HMG-CoA reductase. Half of the original microsomal fraction was suspended in a homogenizing medium lacking DTT and recentrifuged at 100,000 *g* for 60 min. This fraction was resuspended in 0.1 M potassium phosphate buffer and used for assay of cholesterol 7α-hydroxylase.

Protein was determined by a method of Lowry et al. (6).

Preparation of acetone powder of liver microsomes. Liver microsomes were prepared as above from rats fed a diet supplemented with 5% cholestyramine (Questran, Bristol-Myers, New York, NY) for six days. The microsomal fraction was washed in a 20 mM phosphate buffer containing 10 mM EDTA and resuspended in this buffer corresponding to 2 g original liver tissue per ml. Of the resulting suspension, 2 ml was added dropwise to 80 ml acetone at −10°C (7). After 30 min, this mixture was passed through an OOA filter and washed with 40 ml acetone and 40 ml ether. The acetone powder was dried in a desiccator and then dissolved in the phosphate buffer to a concentration of 14 mg per ml. For the assay of cholesterol 7α-hydroxylase activity, 1 ml of the acetone powder solution was fortified with 3 mg NADPH in 1.7 ml phosphate buffer and sterol dissolved in 0.3 ml Tween. The cholesterol concentration was varied from 26 to 130 μM. In a parallel series of incubations, sitosterol was added to the incubation in increasing amounts, constituting from 10 to 80% of the total sterol content. [$^2H_3$]-Labeled 7α-hydroxycholesterol was used as internal standard as described below.

Assay of HMG-CoA reductase activity. This assay was performed essentially as described by Brown et al. (8). Forty μl of the microsomal fraction was preincubated for 15 min at 37°C in a total volume of 200 μl, containing 0.1 M phosphate buffer (pH 7.4), 10 mM imidazole buffer (pH 7.4), 5 mM DTT, 10 mM EDTA, 1.5 mM NADP, 6 mM glucose-6-phosphate and 1 unit of glucose-6-phosphate dehydrogenase. The reaction was initiated by adding 95 nmol (0.5 μCi) of [3-^{14}C]HMG-CoA, dissolved in 25 μl of distilled water. The total substrate concentration was 475 μM. The incubation was run for 15 min and terminated by addition of 25 μl 6 M HCl. [^{3}H]Mevalonic acid (0.01 μCi) together with 3 mg of unlabeled mevalonic acid lactone was added as internal standard. The incubation mixture was further lactonized, subjected to thin layer chromatography (TLC) and analyzed for radioactivity.

Assay of cholesterol 7α-hydroxylase activity. Incubation of the microsomal fraction with [4-^{14}C]cholesterol was carried out as described previously (5). In this procedure, the conversion of [4-^{14}C]-labeled cholesterol into 7α-hydroxycholesterol is measured by radioscanning after separation of the product from the substrate by TLC. The conversion of the endogenous microsomal cholesterol into 7α-hydroxycholesterol is measured by isotope dilution-mass spectrometry after isolation of the product by TLC. It should be pointed out that in the latter procedure [4-^{14}C]-labeled 7α-hydroxycholesterol is not detected. For assay of unlabeled 7α-hydroxycholesterol by isotope dilution-mass spectrometry, [$^2H_3$]-labeled 7α-hydroxycholesterol is used as an internal standard, which is added to the incubation mixture prior to the extraction step. After isolation of 7α-hydroxycholesterol by preparative TLC, the material is converted into trimethylsilyl (TMS) derivative prior to determination of the ratio between labeled and unlabeled molecules by combined gas chromatography-mass spectrometry (5). In the latter analysis, the ions at *m/z* 456 and *m/z* 459 are used (corresponding to the M-90 ion in the mass spectrum of derivative of unlabeled and [$^2H_3$]-labeled 7α-hydroxycholesterol, respectively).

Conversion of unlabeled sitosterol into 7α-hydroxysitosterol was assayed as for conversion of cholesterol into 7α-hydroxycholesterol with the exception that the ion at *m/z* 484 was used in the mass fragmentography.

Determination of sterols in blood serum and liver microsomes. Epicoprostanol was added as internal standard before alkaline hydrolysis and lipid extraction twice with *n*-hexane, as described previously (9). The lipid extracts were taken to dryness under nitrogen. The sterols were converted to their TMS ether derivatives before quantitation by gas chromatography, using a Hewlett-Packard 5880A gas chromatograph with a 25 m capillary column (0.32 mm i.d.) CP-WAX 52 CB.

Student's t-test was used for statistical analysis.

RESULTS

Infusion of sitosterol led to an increase in serum levels of this sterol from 0.2 to 2.5 mmol/l, as shown in Table 1. Serum cholesterol concentration in the sitosterol-treated group was significantly elevated to almost twice the level of the control group ($p < 0.001$). Even compared with the rats infused with corresponding amounts of cholesterol, sitosterol infusion resulted in a significantly higher cholesterol concentration ($p < 0.025$). The total plasma sterol concentration in the sitosterol-treated rats was 10.3 mmol/l, of which 24% was attributed to the plant sterol.

Infusion of sitosterol resulted in an increase of microsomal sitosterol concentration from 1.2 to 5.8 μg/mg protein ($p < 0.001$). The microsomal cholesterol content decreased by approximately the same amount, resulting in an unchanged total microsomal content of sterol compared to the control group. Sitosterol constituted 22% of the microsomal sterols. Cholesterol infusion led to a significant increase in cholesterol concentration.

Table 2 shows the activity of hepatic HMG-CoA reductase and cholesterol 7α-hydroxylase. HMG-CoA reductase activity was slightly increased in the sitosterol-treated rats. This increase was, however, not statistically significant ($p > 0.05$). As expected, cholesterol treatment led to a significantly depressed activity of HMG-CoA reductase.

7α-Hydroxylation of endogenous microsomal cholesterol was significantly reduced in the sitosterol-treated rats ($p < 0.05$). The total 7α-hydroxylation of both endogenous- and exogenous-labeled substrate was also

apparently reduced, but this reduction was not significant ($p > 0.05$).

Experiments with delipidated rat liver microsomes. The depressing effect of the sitosterol treatment on the 7α-hydroxylation of cholesterol may be due to the replacement of part of the microsomal cholesterol with sitosterol. Under normal conditions, the microsomal cholesterol 7α-hydroxylase is saturated or almost saturated with substrate (10). If sitosterol has no effect per se on 7α-hydroxylation of cholesterol, a replacement of 20% of the microsomal cholesterol would be expected to lead to about 20% reduction in formation of 7α-hydroxylated product. To study this, delipidated rat liver microsomes (acetone powder) were incubated with increasing amounts of substrate cholesterol (Table 3). In agreement with previous studies (10), saturation was achieved at about 120 μM, and the K_m was about 50 μM. With a cholesterol concentration corresponding to about 80% saturation, the cholesterol 7α-hydroxylase activity was about 70% of V_{max} (Table 3). Addition of sitosterol to yield a mixture of cholesterol and sitosterol in the ratio 4:1, similar to that found in liver microsomes from sitosterol-treated animals (Table 1), further reduced the cholesterol 7α-hydroxylase activity to about 60% of V_{max}. Thus, this degree of depression of the cholesterol 7α-hydroxylase is similar to that obtained in the experiments with infusion of sitosterol (Table 2). As shown in Table 3, addition of increasing amounts of sitosterol, together with decreasing amounts of cholesterol, depressed the 7α-hydroxylase activity to a level 10–60% lower than that expected if sitosterol has no effect per se on 7α-hydroxylation of cholesterol. In separate experiments, it was shown that the rate of 7α-hydroxylation of sitosterol by rat liver microsomes or acetone powder of such microsomes was about 2% of that of cholesterol. This finding is in agreement with a previous report (11).

TABLE 3

Rate of 7α-Hydroxylation of Cholesterol in the Presence of Increasing Concentrations of Cholesterol and Cholesterol + Sitosterol by Delipidated Rat Liver Microsomes

Cholesterol concentration (μM)	Sitosterol concentration (μM)	Rate of 7α-hydroxylation of cholesterol[a] (% of V_{max})

104	26	60
78	0	57
78	52	47
52	0	56
52	78	42
26	0	50
26	104	22

[a]The absolute rate of conversion was 26 pmol/min/mg microsomal protein.

DISCUSSION

The circulating levels of sitosterol obtained in the present animal model, about 2.5 mmol/l, are of the same magnitude as those reported for patients with phytosterolemia (up to 1.6 mmol/l) (12). The hypercholesterolemic effect

of the sitosterol infusion is of interest in relation to the fact that patients with phytosterolemia often have elevated serum cholesterol. It is tempting to suggest that the hypercholesterolemic effect of sitosterol is due to the demonstrated inhibitory effect on the rate-limiting enzyme in cholesterol degradation, the cholesterol 7α-hydroxylase. According to the present investigation, the inhibition is, in part, due to decreased availability of substrate cholesterol because of its replacement with sitosterol and, in part, due to an inhibitory effect of sitosterol on enzyme activity. Shefer and Salen (13) have recently reported, in preliminary form, that sitosterol is a competitive inhibitor of the cholesterol 7α-hydroxylase. It is well documented that sitosterol is a poor substrate for the cholesterol 7α-hydroxylase (11) and, under the present conditions, the rate of 7α-hydroxylation of sitosterol was only about 2% of that obtained with cholesterol as substrate.

The depressing effect of the sitosterol infusion on the cholesterol 7α-hydroxylase was relatively small—about 30%. Evidence has been presented previously, however, that even such a moderately depressing effect on the cholesterol 7α-hydroxylase may significantly increase circulating levels of cholesterol. Andersson and Boström (14) showed that disulfiram is a potent inhibitor of cholesterol 7α-hydroxylase and that treatment of rats with this drug gives a dose-related depression of the cholesterol 7α-hydroxylase. This depression of the choiesterol 7α-hydroxylase was paralleled by increasing serum concentrations of cholesterol. A depression of the cholesterol 7α-hydroxylase by 29% (statistically significant) was associated with an increase in serum cholesterol level by 86%. These effects are almost identical to those obtained here in the infusion experiments with sitosterol. It may be mentioned that Shefer and Salen (13) have assayed cholesterol 7α-hydroxylase activity in a liver biopsy from a patient with phytosterolemia and found it to be about 50% of normal. In view of the great interindividual variations (15), however, no firm conclusions can be drawn from this finding. A reduced cholesterol 7α-hydroxylase activity in patients with phytosterolemia would be expected to lead to reduced bile acid biosynthesis. Miettinen (16), however, found that quantitatively, bile acid synthesis was normal or even higher in a phytosterolemic subject than in controls.

The activity of HMG-CoA reductase, the rate-limiting enzyme in cholesterol synthesis, was slightly increased in the sitosterol-infused rats. This increase was, however, not statistically significant. Most probably the increase is related to the effect of sitosterol on intestinal absorption of cholesterol. Part of the infused sitosterol must be secreted by the liver into the bile and may then reduce cholesterol reabsorption and thereby the feed-back inhibition of the hepatic HMG-CoA reductase by chylomicron cholesterol.

ACKNOWLEDGMENT

The skillful technical assistance of Ulla Andersson is gratefully acknowledged. This work was supported by a grant from The Swedish Medical Research Council (Project 03X-3141) and The Norwegian Council on Cardiovascular Diseases.

Phosphatidylinositol 4,5-Bisphosphate Phospholipase C Activity in Particulate Preparations From Rat Brain

Mieke Bergers*, Sonja Lendi and **Paul D. Mier**
Department of Dermatology, University Hospital, Ph. van Leydenlaan 25, 6525 EX Nijmegen, The Netherlands

We describe the hydrolysis of phosphatidylinositol 4,5-bisphosphate by a particulate rat brain preparation in the presence of the cationic detergent, cetrimide. The optimum cetrimide concentration was in the range 0.2–0.4 mg/ml; at higher or lower concentrations, the reaction rate diminished abruptly, suggesting that the electrical charge density of the micelle is critical for enzymatic attack. In other respects, such as its partial requirement for Ca^{++} and its pH optimum of about 7.0, the particulate enzyme seems similar to soluble preparations which have been reported previously. Interestingly, the particulate preparation could be stimulated about fourfold by a soluble brain extract in the presence of 1 mM guanosine triphosphate, confirming that the enzyme is the catalytic subunit in a membrane-bound signal-transduction system.
Lipids 24, 13–16 (1989).

The receptor-mediated breakdown of PIP_2 to diacylglycerol and inositol trisphosphate is now recognized to be of major importance in the transduction of signals across the plasma membrane of eukaryotic cells (1–4). The enzyme which catalyzes this reaction (EC 3.1.4.10) may be named either as a phospholipase C or as a phosphodiesterase; here, the former term is used. It is now clear that the membrane-bound system requires a guanosine triphosphate (GTP)-binding protein in addition to the receptor and the catalytic subunit (5).

The majority of early workers investigating this pathway used intact cells. Following prelabeling (e.g., with [^{3}H]-inositol) and stimulation with an appropriate "first messenger," the cells were disrupted and changes were demonstrated in the ratio of inositol phosphates (water-soluble) to the inositol-containing phospholipids (lipid-soluble). More recently, several workers have shown receptor-mediated release of inositol phosphates from prelabeled membrane fragments (6–8). In addition, a number of reports have appeared describing soluble preparations that catalyze the hydrolysis of exogenous PI, PIP or PIP_2. These include extracts from brain (9,10), heart muscle (11), seminal vesicles (12) and platelets (13).

We have now applied this last approach to particulate preparations from rat brain. Using the commonly used anionic detergents (such as deoxycholate), all attempts to demonstrate phospholipase C activity were uniformly negative; surprisingly, however, very high activity could be obtained using micelles prepared with a cationic detergent. Here, we describe the technique and report some properties of the particulate enzyme.

*To whom correspondence should be addressed.

Abbreviations: GTP, guanosine triphosphate; PI, phosphatidylinositol; PIP, phosphatidylinositol 4-phosphate; PIP_2, phosphatidylinositol 4,5-bisphosphate.

MATERIALS AND METHODS

Materials. Radioactive [inositol-2-^{3}H(N)]-PIP_2 was obtained from New England Nuclear, Doorn, The Netherlands. Unlabeled PIP_2, GTP and alkyltrimethylammonium bromide ("cetrimide," cat. no. M 7635) were purchased from Sigma Chemical Co. (St. Louis, MO). All other chemicals were of analytical reagent grade and were purchased from Merck (Darmstadt, Federal Republic of Germany).

Preparation of samples and phospholipase C assay. All samples were weighed and homogenized in assay medium (20 mM tris, 1 mM $CaCl_2$ and 100 mM KCl, pH 7.4) using an ice-cooled all-glass Potter-type grinder. The homogenate was centrifuged (30 min, 40,000 *g*), the pellet washed twice by centrifugation in assay medium and the washed particles resuspended in the medium at an appropriate concentration ("crude membrane preparation").

PIP_2 stocks (hot and cold) were stored in chloroform/methanol (1:1) and cetrimide, as a solution, in ethanol. Immediately prior to assay, appropriate volumes of the stock solutions were mixed to yield a "cocktail" containing 50 nmol/ml (total) PIP_2, 0.5 μCi/ml [^{3}H]-PIP_2 and 0.4 mg/ml cetrimide. The solvent was removed in a stream of nitrogen, an equal volume of assay medium added and the preparation sonicated for 30 sec at 0°C.

The reaction was initiated by the addition of 10 μl of this reagent to 10 μl of the crude membrane preparation, usually at a concentration equivalent to 5 mg/ml fresh weight brain. After incubation for 10 min at 37°C, the reaction was stopped by the addition of 500 μl 1 N HCl and 500 μl chloroform/methanol (1:1). The mixture was agitated vigorously, the phases separated by a brief centrifugation and 500 μl of the upper (aqueous) phase removed for scintillation counting. All samples were measured in duplicate, and appropriate reaction blanks were included with each batch of assays. After correction for the blank, activity was calculated as pmol PIP_2 hydrolyzed/min/mg fresh weight of brain.

Preliminary experiments showed that siliconization of glassware was essential to avoid serious loss of PIP_2 by surface absorption. Using the technique described above, solubilization of [^{3}H]-PIP_2 (i.e., percentage of the radioactivity in the "cocktail" which was present in the aqueous micelle preparation) was usually better than 90%; at other concentrations of substrate or detergent, much lower figures were observed.

Alternative procedures for substrate solubilization. Other methods tested for solubilization of the PIP_2 in the reaction mixture included (a) anionic detergents (deoxycholate and taurodeoxycholate) with final concentrations in the range 0.02–5 mg/ml; (b) a neutral detergent (Triton X-100) with a final concentration in the range 0.02–2% v/v; (c) absorption onto bovine serum albumin; and (d) absorption onto a suspension of glass particles (diameter less than 1 μm). In certain experiments using cetrimide, the final concentration of the detergent varied from 0.04 to 0.6 mg/ml.

Kinetic studies. Experiments were carried out to investigate the effects of various parameters on the rate of hydrolysis of PIP_2. These included the incubation time (range 1–30 min), tissue concentration (up to 20 mg/ml), Ca^{++} concentration (0–2 mM) and pH in the range 6.5–9.0. In all experiments, the reaction conditions, other than the variable being studied, were as described in the standard protocol above.

Stimulation experiments. Because the crude membrane preparation may be expected to contain receptors for a range of different neurotransmitters, the supernatant from the original brain homogenate (at 100 mg/ml) was used as a source of mixed "first messengers." This was heated to 100°C for 5 min prior to use to destroy any soluble phospholipase C activity present, and appropriate dilutions prepared in assay medium.

A series of assays was set up containing crude membrane preparation (5 mg/ml), GTP (final 1 mM) and boiled supernatant at various concentrations. Reagent was added, the mixture incubated for 5 min and the measurements completed in the usual way. Blanks containing boiled supernatant but omitting the membrane preparation were included in addition to the normal reagent blank.

RESULTS

General. Attempts to demonstrate particulate phospholipase C using systems in which the substrate was "solubilized" with different concentrations of anionic or neutral detergents, by absorption onto protein or by absorption onto the surface of dispersed glass particles, were uniformly negative. By contrast, the use of micelles stabilized with a cationic detergent (cetrimide) resulted in high levels of enzymatic activity. The effects of different cetrimide concentrations are illustrated in Figure 1A.

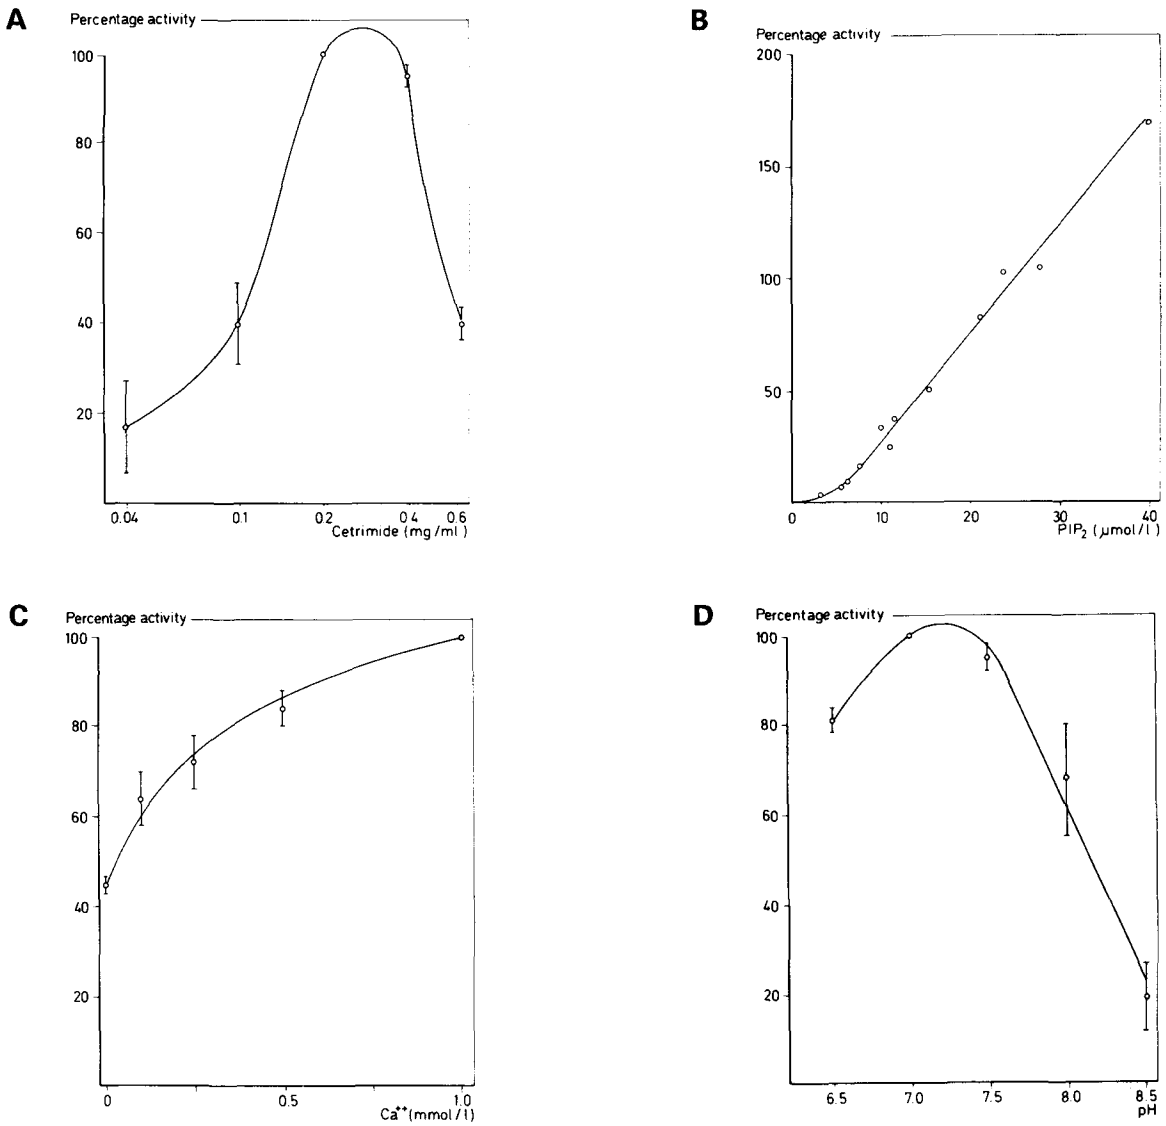

FIG. 1. Kinetics of the hydrolysis of PIP_2 by particulate preparations of rat brain in the presence of cetrimide. In all cases, the conditions, other than the variable being studied, were as described in the standard assay procedure. The absolute value obtained using the standard protocol (mean 165 $pmol.min^{-1}.mg^{-1}$) corresponds to 100%. In general, points represent the mean ± SE of 4–6 experiments; in (B), each point represents a single assay. (A) Cetrimide concentration; (B) PIP_2 concentration; (C) Ca^{++} concentration; (D) pH.

It is clear that maximum activity occurs around 0.2 mg/ml (final concentration in the reaction mixture).

The observed phospholipase C activity of rat brain, using the standard protocol, was 165 ± 39 pmol substrate hydrolyzed/min/mg fresh weight (mean ± SD, 23 different preparations).

Reaction kinetics. Regardless of the concentration of the tissue preparation, the reaction was reasonably linear until about 20% of the substrate had been cleaved, after which a sharp reduction in the rate of reaction occurred. Thus, using a rat brain preparation corresponding to 5 mg/ml fresh weight tissue, the time-curve was linear for 10–15 min; at lower concentrations, linearity was maintained for longer periods.

The variation of reaction rate with PIP_2 concentration is illustrated in Figure 1B. The reaction does not obey Michaelis-Menton kinetics, there being a distinct lag phase at low substrate concentrations. The curve appears to saturate above about 50 μM PIP_2 (not shown), but the reproducibility here became very poor, presumably because of the difficulty in maintaining a uniform micelle preparation. Ca^{++} dependence is shown in Figure 1C; there is clear stimulation, the activity at 1 mM being about double that observed in the absence of Ca^{++} (no added Ca^{++}, 1 mM EDTA). The incremental activity followed Michaelis-Menton kinetics, a Lineweaver-Burke plot showing an apparent K_m of 0.2 mM. Variation of activity with pH is shown in Figure 1D; optimum activity occurs in the range 7.0–7.5.

Stimulation experiments. The addition of 1 mM GTP to the particulate brain preparation resulted in a slight but definite reduction in activity (mean activity remaining 79%, 6 experiments). The further inclusion of "boiled supernatant" gave a clear concentration-dependent stimulation, illustrated in Figure 2. It is seen that addition of supernatant at a final concentration equivalent to 50 mg/ml brain increased the basal activity of the particulate preparation about fourfold. In the absence of particles, the "boiled supernatant" had no detectable phospholipase C activity.

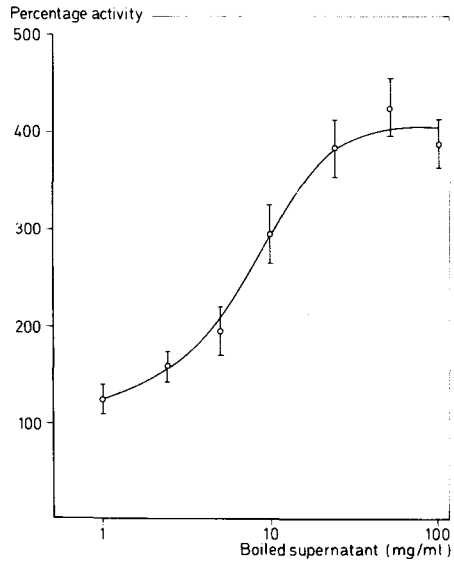

FIG. 2. Stimulation of particulate rat brain phospholipase C activity by the addition of a soluble brain extract ("boiled supernatant"). Points represent the means ± SE of 6 experiments; activity in the absence of the soluble preparation is taken as 100%. All assays contained GTP at a final concentration of 1 mM.

DISCUSSION

We show here that the use of a cationic detergent at an appropriate concentration permits direct measurement of the phospholipase C activity of particulate preparations using an exogenous substrate. Presumably, the critical factor which determines the rate of hydrolysis of the substrate under our conditions is the electrical charge density at the surface of the micelle. The PIP_2 molecule will, of course, carry a strongly negative charge at neutral pH, and it seems that a partial neutralization of this charge by the alkyltrimethylammonium ion is necessary for attack at a significant rate. It is not possible to calculate the net charge density from the data available, because we do not know the distribution of the cetrimide between the micelle and the aqueous phase.

The relationship between the particulate enzyme(s) and the various soluble preparations which have been described remains unclear. Brain has been shown to contain at least two immunologically distinct forms of soluble PI-specific phospholipases C, both of which may exist in different oligomeric forms (10). Further, the degree of phosphorylation of the substrate (PI, PIP or PIP_2) and the precise manner in which it is presented (for example, admixture of other phospholipids) seem to have a profound effect on the observed properties of the enzyme, such as its behavior with respect to pH and its requirement for metals (9). These latter workers reported that a soluble rat-brain preparation showed a major peak of activity against PIP_2 at pH 5.5 together with a minor peak around pH 7.5. Using pure PIP_2 as substrate and a low ionic strength buffer, they also demonstrated a threefold stimulation of this preparation by submicromolar concentrations of Ca^{++}; however, this shifts to the millimolar region in the presence of Mg^{++} and at higher ionic strength (9,14). Thus, the possibility of identity between the particulate enzyme and previously described soluble preparations cannot be excluded.

Nonetheless, the marked stimulation of activity obtained by the addition of a soluble extract to the particulate preparation in the presence of GTP strongly suggests that the enzyme reported here is, in fact, the rate-limiting step in this signal-transduction pathway. Our approach may well be of value in situations where speed, simplicity and sensitivity are of paramount importance, such as measurement of phospholipase C in human biopsy material. We are currently applying this technique to our investigations into the skin disease psoriasis, where an abnormality in the phosphoinositol cycle has been speculated (15).

ACKNOWLEDGMENTS

We thank P. Spaan and Wilma Janssen (Animal Laboratories, University of Nijmegen) for their technical assistance and Waltraud Verbeeck for preparation of the manuscript.

Dietary N-6 and N-3 Fatty Acids and Salt-induced Hypertension in the Borderline Hypertensive Rat

David E. Mills*, Ron P. Ward, Marvin Mah and Linda DeVette
Department of Health Studies, University of Waterloo, Waterloo, Ontario N2L 3G1, Canada

This study examined the effects of salt-loading on blood pressure (BP) development in the borderline hypertensive rat (BHR) and its modification by dietary n-3 and n-6 fatty acids. In experiment 1, 4 groups (n = 10/group) of male BHR receiving 1% NaCl as a replacement for tap water were placed on chow enriched with either olive oil (OL), sunflower oil (SUN), evening primrose oil (EPO) or fish oil for 6 weeks. BP, heart rate, body weight, water, Na^+ and K^+ intake and urinary output were measured weekly. SUN and fish oil reduced the pressor response to salt seen vs the OL group by 50%, and EPO abolished the pressor response, reducing BP below control levels. The BP response was unrelated to either food intake or water and electrolyte intake and excretion. In experiment 2, male BHR received water +/− 18:3n-6 (0.04 mg/hr in OL via ip pump) or 1% NaCl +/− 18:3n-6 (n = 12/group) for 12 weeks, followed by 2 weeks recovery on tap water. Salt increased BP, and 18:3n-6 decreased this response, but had no effect on animals receiving tap water. In experiment 3, effects of 3 doses of 18:3n-6 (0.04, 0.08, and 0.12 mg/hr) on the pressor response to 1% NaCl were examined. All doses reduced the BP response to salt vs controls with no dose-response. These data suggest that the BHR is genetically salt-sensitive, and that dietary n-3 and n-6 fatty acids can attenuate the cardiovascular response to salt in this model.
Lipids 24, 17-24 (1989).

The borderline hypertensive rat (BHR) is produced by backcrossing the spontaneously hypertensive rat (a genetically hypertensive animal) with its normotensive parent strain, the Wistar Kyoto rat. The offspring of this mating typically demonstrate a gradual increase in systolic blood pressure (BP), which stabilizes at maturity at 140-150 mm Hg (1,2). Certain types of chronic stressors have been demonstrated to act as neurogenic triggers in this animal, producing an irreversible hypertension similar to that of its genetically hypertensive parent, with BP in excess of 180 mm Hg (1-3). We have recently demonstrated that administration of 18:3n-6 is capable of diminishing the pressor and tachycardic response to chronic isolation stress in this animal model (4).

The BHR has recently been demonstrated to be salt-sensitive, developing a more severe hypertension when placed on chow containing 8% NaCl (2). The goals of the present study were to verify the salt-sensitivity of the BHR and to assess the effects of dietary supplementation with oils rich in various n-3 and n-6 fatty acids on the pressor response to salt-loading in this animal. Oils used were rich in 18:1n-9 (olive [OL]), 18:2 (sunflower [SUN]), 18:3n-6 (evening primrose oil [EPO]) and 20:5n-3/22:6n-3 (fish).

Abbreviations: EPO, evening primrose oil; OL, olive oil; PL, phospholipid; SUN, sunflower oil; TG, triglyceride; BHR, borderline hypertensive rat; BP, blood pressure; ip, intraperitoneally.

METHODS

Experiment 1: Effects of dietary oils and salt-loading on BP and electrolyte excretion.

Diet and salt-load. Individually housed adult male BHR (n = 40), 9 wk of age, were used in the study. All animals received standard chow containing 5% vegetable oil (Master Feeds, London, Ontario), until the start of the test period. One wk following a pretest measure, all animals were placed on 1% NaCl, as a replacement for drinking water, for a 6-wk period. Concurrently, animals were randomly assigned to one of four diet groups receiving supplementary OL, SUN, EPO (Efamol) or fish oil (Maxepa), which was mixed into their food at a level of 10% total calories (n = 10/group). All animals remained on the supplemented diets and saline for the 6-wk period.

Measures. Weekly measures of BP and heart rate were made on conscious animals using the tail cuff technique, previously described (5). Body weight was also measured. In addition, animals were placed in metabolic cages at weekly intervals for 24-hr assessment of saline and food intake and urine output. From this information, weekly assessments of Na^+, K^+ and water intake and urinary excretion were made. Electrolyte analysis was performed by flame photometry (Corning 405). During measurements the experimenters were blind to the treatment grouping of the animals. Following the week-6 measures animals were killed with CO_2, and livers were removed and flash frozen in liquid nitrogen for fatty acid analysis of the phospholipid (PL) and triglyceride (TG) fractions.

Experiment 2: Effects of salt-loading and 18:3n-6 on BP and electrolyte excretion.

Treatment and salt-load. Forty-eight male BHR, bred at the University of Waterloo, were individually housed for a 9-wk post-weaning acclimation period. All animals received chow (Master Feeds) and tap water ad libitum during this period. Animals were then implanted ip with either 8-wk, constant flow (1.3 μl/hr) osmotic pumps (Alza Corp., Palo Alto, CA), releasing 0.04 mg 18:3n-6 (Sigma Chemical, St. Louis, MO)/hr in OL vehicle, or dummy pumps (n = 24/group) under halothane anesthesia, as previously described (4). Dummy pumps were used because OL administered by pump has been demonstrated to have no effect on BP in the Wistar Kyoto rat (6), and supplementation of the chow diet of 4 BHR rats with OL (10% cal) over 4 wk produced changes in BP of less than 4 mm Hg (unpublished), which approximates the reproducibility of the method in this laboratory. One week following surgery 12 rats/group were placed on 1%-NaCl solution as a replacement for tap water, whereas 12/group remained on tap water for a 12-wk experimental period. Weekly measures of BP, heart rate and body weight were taken, as described above.

Experiment 3: Dose-response of 18:3n-6 on BP and water and electrolyte excretion during salt-loading in BHR.

Treatment. Following a 5-wk acclimation period, 40 individually housed male BHR were rank-ordered by body

weight, distributed to 1 of 4 treatment groups, then implanted ip with either dummy pumps or 8-wk osmotic pumps releasing 0.04, 0.08 or 0.12 mg 18:3n-6/hr in OL (10/group). Following a 2-wk control period on tap water, all animals were placed on 1% NaCl, as previously described, for 6 wk. Weekly measures of BP; heart rate; body weight; food, water and NaCl intake; and urinary water and electrolyte excretion were made, as previously described. At the end of the salt-loading period, all animals were killed and their livers, kidneys and adrenals were removed and frozen for fatty acid analysis.

Lipid analysis. Lipids were extracted from ca. 1 g of tissue (except for the adrenals, in which lipids were extracted from the paired glands), which had been homogenized in chloroform/methanol (2:1, v/v) with 0.02% BHT at a ratio of 20:1 (v/w). One ml 0.9% saline was added to the homogenate, and it was allowed to stand overnight. The lower phase was then extracted and evaporated under nitrogen at 40°C, the residue was suspended in 750 μl chloroform and 300 μl was spotted on silica gel GF plates (Analtech Inc., Newark, DE) for separation of the fractions. Plates were then placed in a solution of hexane/diethyl ether/glacial acetic acid (90:10:1). Following separation, 2 ml BF_3 was added to the PL and TG fractions, which were then tightly capped and heated at 90°C for 30 min. Next, 5 ml hexane and 2 ml saline were added, the tubes vortexed and then centrifuged at 1,500 rpm for 2 min. The top layer was then removed and evaporated under nitrogen at 40°C, and the residue dissolved in 500 μl hexane. This was then transferred to a gas chromatograph autosampler vial, capped under nitrogen and analyzed on a 15-m Supelcowax 10 column.

Statistics. Blood pressure, heart rate, body weight and fluid and electrolyte data were analyzed using a 2-way analysis of variance with repeated measures. Where a significance of $p < 0.05$ was demonstrated, specific points of difference were compared using the Newman-Keuls test. Fatty acid data were analyzed using a 1-way ANOVA. Again, where significance of $p < 0.05$ was demonstrated, further comparisons were made using the Newman-Keuls test.

RESULTS

The fatty acid composition of the lab diet and dietary oil supplements are shown in Table 1.

20:4	—	—	—	0.5	—
20:5	—	—	—	—	18.4
22:6	—	—	—	0.3	11.5

Experiment 1—blood pressure, heart rate and body weight. Systolic BP responses to variations in dietary fat during salt-loading are illustrated in Figure 1. Salt-loading produced a significant increase in BP in animals receiving OL ($p < 0.001$), SUN ($p < 0.01$) and fish ($p < 0.01$) oil vs presalt levels. However, the BP response to salt-loading was reduced by SUN and fish oil in comparison to OL ($p < 0.001$). In contrast to the above, supplementation with EPO abolished the pressor response to salt-loading and lowered BP vs presalt levels ($p < 0.001$). There were no differences in heart rate or body weight gain among treatment groups in the study (data not shown).

Urinary sodium and potassium excretion. Weekly measures of 24-hr water, Na and K intake and urinary excretion are illustrated in Figures 2 and 3. Replacement of drinking water with 1% NaCl resulted in a significant increase in both Na and water intake/unit body weight in all of the dietary groups vs control period values. Furthermore, Na and water intake in the EPO group alone was significantly greater than in the OL group for the duration of salt-loading. In contrast, K intake/unit body weight fell significantly in all groups during salt-loading, with no consistent differences among the dietary groups. The drop in K intake was a direct reflection of the decrease in food consumption during the experimental period (data not shown).

Urinary Na excretion increased ca. 5-fold during salt-loading vs the presalt condition. There were no significant differences in Na excretion among the various dietary groups, with the exception of the EPO group, which had a greater Na excretion than the OL group at week 1, and SUN, which had a lower Na excretion than the OL group at week 2. Urinary K excretion fell significantly during salt-loading in all groups except the SUN group, in which excretion was significantly elevated, vs

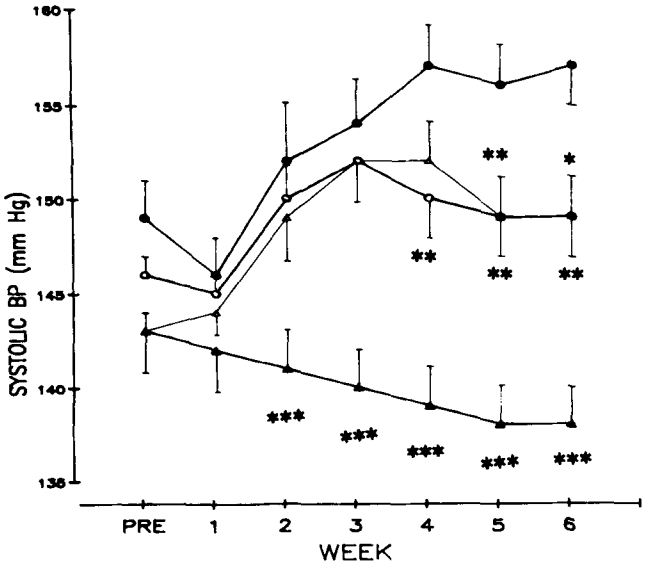

FIG. 1. Systolic BP ($\bar{X} \pm$ SEM) prior to (PRE) and during salt-loading with 1% NaCl as a replacement for drinking water in male BHR (n = 10/group) receiving chow plus 10% (cal) olive oil (OL), sunflower oil (SUN), fish oil (Maxepa) or evening primrose oil (EPO, Efamol). *, $p < 0.05$ vs olive oil. **, $p < 0.01$ vs olive oil. ***, $p < 0.001$ vs olive oil. △, Maxepa; ●, olive oil; ▲, evening primrose oil; ○, sunflower oil.

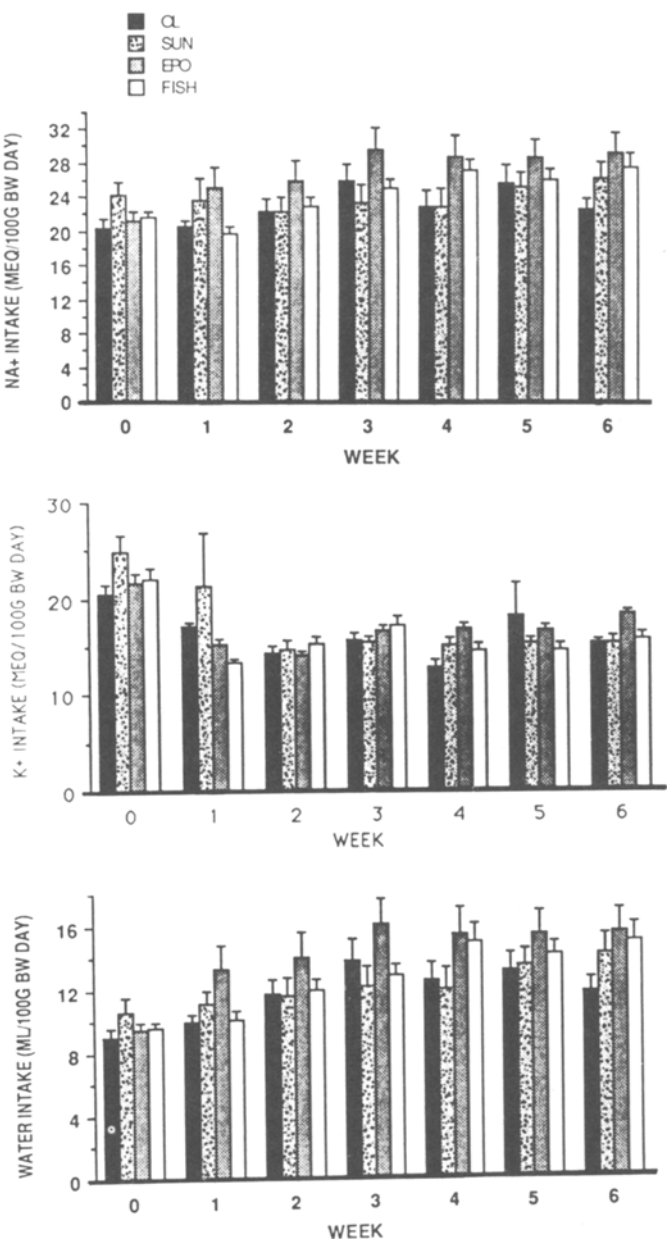

FIG. 2. Twenty-four-hr water, Na^+ and K^+ ($\bar{X} \pm$ SEM) intake prior to (week 0) and during salt-loading in BHR receiving chow plus OL, SUN, EPO or fish oil. Details as in Figure 1.

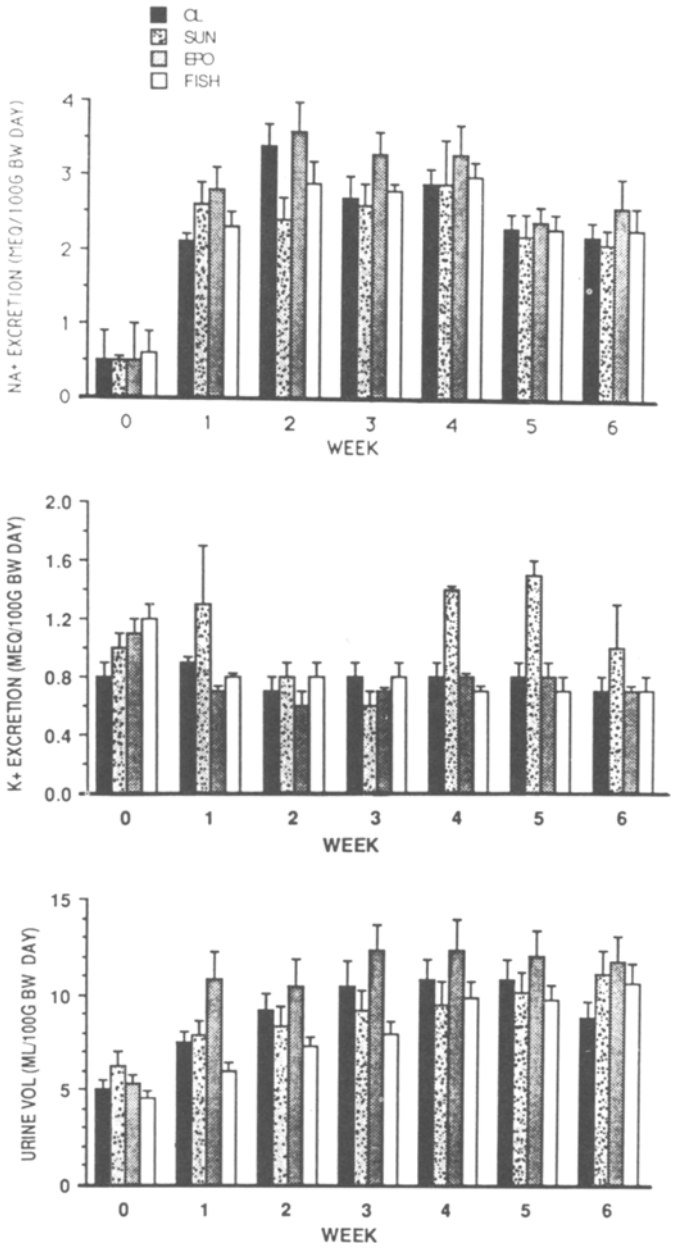

FIG. 3. Twenty-four-hr urinary Na^+, K^+ and water excretion ($\bar{X} \pm$ SEM) prior to (week 0) and during salt-loading in BHR receiving chow plus OL, SUN, EPO or fish oil. Details as in Figure 1.

that of the OL group at weeks 1, 4 and 6, as well as vs the presalt value in the SUN group.

The increase in Na excretion seen during salt-loading was accompanied by an increase in urine volume/unit body weight in all diet groups. In addition, the urine volume of the EPO group was significantly higher than that of the OL group at weeks 1 and 6, and that of the SUN group was elevated vs the OL group at week 6. In contrast, the group receiving fish oil had a reduced urine volume vs OL at weeks 1, 2 and 3.

Liver fatty acid composition. Fatty acid composition of liver PL and TG fractions are shown in Table 2. In liver PL 16:0 was increased by EPO and fish oil and decreased by SUN, whereas 18:0 was increased by SUN and EPO. Olive oil supplementation led to greater 18:1 levels than in all other groups. SUN, EPO and fish increased 18:2 vs OL, and SUN and EPO increased 18:3n-6 and 22:4, whereas fish oil decreased 22:4 vs OL. Liver PL 20:3 was increased by fish oil and was decreased by SUN vs OL, and both EPO and fish oil lowered 20:4 vs OL, although the fish oil effect was more pronounced. Fish oil alone reduced 22:5n-6 vs OL. SUN increased the proportion of 18:3n-3 and 20:5 in liver PL, and fish oil increased 22:5n-3 and 22:6n-3 vs OL. EPO, in contrast, reduced 22:6n-3 vs OL.

Liver TG were also altered by diet. Fish oil elevated both 16:0 and 18:0 vs OL, and EPO decreased 16:0. As in the PL, 18:1 was higher in the OL group than in the

Details are as in Figure 1. All values represent $\bar{X}$ ± SEM.

other diet groups. Groups receiving SUN and EPO demonstrated higher levels of 18:2, 18:3n-6, 20:3, 20:4 and 22:4 vs OL, whereas the fish oil group demonstrated less 18:3n-6, 20:4 and 22:4. Levels of 22:5n-6 were also increased by EPO. The only change seen in liver TG was an increase in 22:6n-3 by the fish oil group.

Experiment 2—blood pressure, heart rate and body weight. The systolic BP response to salt loading with and without 18:3n-6 is shown in Figure 4. Administration of 18:3n-6 had no effect on BP in the absence of salt-loading, with the exception of week 2, when it increased BP vs animals with dummy pumps. In BHR with dummy pumps, BP increased significantly within 2 weeks of salt-loading vs BHR on tap water and remained significantly higher than animals on tap water at weeks 5, 6, 7 and 10, with BP not significantly different than that of animals on tap water during recovery. Furthermore, BP in the salt-loaded BHR receiving 18:3n-6 was significantly lower than in salt-loaded BHR without 18:3n-6 at weeks 3, 7, 8, 9, 10, 11 and at week 1 of recovery. Neither salt-loading nor 18:3n-6 administration significantly affected heart rate or body weight gain in this study.

Experiment 3—blood pressure, heart rate and body weight. The effects of various doses of 18:3n-6 on the systolic BP response to salt-loading are shown in Figure 5. Control animals receiving OL responded to salt-loading with a significant increase in BP within 1 week. Administration of 18:3n-6 during salt-loading, although not completely eliminating the pressor response, significantly diminished the BP increase vs control animals throughout the entire period of salt-loading. Generally, all doses of 18:3n-6 had similar effects on BP, with the exception that the BP response to salt was reduced to a greater extent by administration of 18:3n-6 at 0.12 mg/hr than 0.04 mg/hr at weeks 4 and 5 of salt-loading.

Changes in body weight gain from the end of the control (presalt) period are shown in Figure 6. Body weight rose linearly throughout the control and experimental period in the control group. In contrast, all doses of 18:3n-6 led to a decline in body weight during the control period, which differed significantly from the response of the control animals. No dose response was seen in this parameter. The body weight gain during salt-loading was reduced vs controls in groups receiving 0.04 and 0.08 mg 18:3n-6/hr, but not in those receiving 0.12 mg 18:3n-6/hr. Heart rate declined throughout the salt-loading period in all groups, with no significant treatment effects (data not shown).

Food, water and electrolyte regulation. During salt-loading, 24-hr urine volume and Na excretion significantly increased, and 24-hr K excretion decreased vs the presalt-loading values (data not shown). However, no differences

FIG. 4. among treatment groups were seen in either total or weight-adjusted daily food, saline or electrolyte intake, urine production or Na and K excretion (data not shown).

Tissue fatty acid composition. The composition of selected liver, adrenal and kidney PL fatty acids is shown in Table 3. Liver composition was unaffected by fatty acid administration, with the exception that 18:3n-6 and 20:3n-6 were significantly increased in the groups receiving 0.08 and 0.12 mg 18:3n-6/hr, respectively. In the kidney PL, all doses of 18:3n-6 increased 18:1n-9 and decreased 22:5n-6 vs controls. In addition, 0.08 mg/hr increased 20:3n-6 and 22:4n-6, and both 0.08 and 0.12 mg/hr increased 18:0 and decreased 20:4n-6 vs controls. In the adrenal PL, all doses of 18:3n-6 increased 18:2n-6 and decreased 18:3n-6, 20:3n-6 and 22:5n-6. In this tissue, 0.04 mg/hr alone increased 20:4n-6 vs controls.

DISCUSSION

In a preliminary report, Lawler and Cox observed that salt-loading with chow containing 8% NaCl significantly increased BP in the BHR by 19 mm Hg over a 6-wk period (2). The results of the present study, in which salt-loading was achieved via the replacement of drinking water with 1%-saline solution, confirm the salt-sensitivity of the cardiovascular system in this animal model and suggest that salt-induced hypertension in the BHR may be achieved by lower levels of salt than previously believed. In addition, the failure of BP to return to control levels during the recovery period, following 12 wk of 1% saline, suggests that the hypertension produced by chronic salt-loading may be irreversible, due to a neurogenic triggering effect which has been described previously (1-3). However, additional work is needed to verify this hypothesis, as the hypertension observed in the

recovery period of the present study was monitored for only two wk and was of a modest degree. More severe salt-loads for longer exposures and longer follow-up periods must be examined in order to confirm the ability of this stimulus to act as a neurogenic trigger.

The results of the present study also suggest that the pressor response to salt is modifiable by dietary fatty acid manipulation. Specifically, the present data suggest that EPO, at a level of 10% of total calories, is capable of completely abolishing the pressor response to salt-loading with 1% saline in the BHR. Furthermore, SUN and fish oil, at a level of 10% of total calories, are ca. 50% as effective as EPO in reducing the pressor response to salt. The greater effectiveness of EPO vs SUN may be due to the additive effects of 18:2 (ca. 72% in both SUN and EPO) and 18:3n-6 (ca. 8% in EPO). Although SUN and fish oil appeared to be equally effective in this model, one may not conclude from these results that 18:2 and 20:5/22:6 are of equal potency in this model, because the dose of 18:2 in SUN was ca. 3-fold that of 20:5/22:6 in the fish oil used. Further studies are required in which the individual fatty acids contained in these oils are directly compared on an equimolar basis.

The present data also suggest that administration of

18:3n-6 per se attenuates, but does not eliminate, the pressor response to salt-loading in the BHR, with no significant dose-response relationship demonstrable over the range studied. Possible explanations for the absence of a dose-response are: (1) the threshold dose of nonesterified 18:3n-6 administered ip is ≤0.04 mg/hr, (2) the fatty acid may exert a permissive action in the system which does not demonstrate a dose response or (3) the dose range examined was not broad enough to detect a dose-response relationship. The reduced effect of ip 18:3n-6 on the BP response to salt in comparison with that of EPO may result from: (1) the additive effect of 18:2 and 18:3n-6 in EPO, (2) the greater dosage of 18:3n-6 associated with dietary EPO (ca. 50-fold that of the pump study) or (3) the differences in bioactivity of the TG form of 18:3n-6 found in EPO vs the nonesterified form administered by pump.

The absence of an effect of 18:3n-6 on baseline BP in the BHR is in agreement with an earlier report (4) and supports the concept that 18:3n-6 acts via modifying BP regulation in the perturbed system. In contrast, the current observation that EPO leads to a modest, but significant reduction in baseline BP in the BHR suggests that, at a higher dose and/or in combination with 18:2, 18:3n-6 may alter basal BP regulation.

The present observation that administration of 18:3n-6 by osmotic pump does not alter resting HR is in contrast to an earlier report (5). This difference in effect may be due to the use of the normotensive Wistar-Kyoto strain in the earlier study vs the BHR in the present or the use of a fat-free diet during the experimental period in the earlier study vs chow in the present.

The reduction of BP seen following fatty acid manipulation in the present study was not associated with any consistent alterations in food, water, Na or K intake or urinary water, Na or K excretion. The only suggestion of an alteration in either food or water and electrolyte metabolism was the altered body weight gain seen in animals receiving 18:3n-6 in OL. However, similar body weight changes were not observed in animals receiving EPO. This inconsistency between experiments 1 and 2, and experiment 3 can be explained, in part, by the fact that the animals in experiment 3 were rank ordered by weight prior to assignment to treatment groups, whereas animals in experiments 1 and 2 were randomly assigned to groups. This variation in procedure resulted in a reduction of the body weight variance in experiment 3 vs 1 and 2, and allowed for a more sensitive discrimination of body weight changes resulting from treatment in the final experiment. However, the relationship between body weight regulation and pressor response to salt is unclear, as the weight gain and BP response do not closely coincide. These indicate that the cardiovascular actions of SUN, EPO and fish-oil supplements in this model act via mechanisms other than the alteration of salt and water metabolism.

Dietary 18:2 has been previously shown to diminish the pressor response to salt-loading that occurs in genetically normotensive rats raised on an essential fatty acid-deficient diet (7,8). Several mechanisms of action have been proposed for 18:2 in this model, including suppression of circulating epinephrine and angiotensin, altered vascular reactivity to pressor agents and increased excretion of Na, K and water (7–9). Although the salt-loaded BHR of the present study were maintained on an essential fatty acid-repleted diet, 18:2, 18:3n-6 and 20:5/22:6 supplementation may utilize mechanisms similar to those of 18:2 in the essential fatty acid-deficient normotensive rat to reduce BP during salt-loading in the BHR. In support of this are the observations that 18:3n-6 and 20:5 reduce vascular reactivity to circulating angiotensin in both animals (4–6) and humans (10) and that EPO, SUN and linseed oil decrease sympathetic activity in the spontaneously hypertensive rat (11).

In the present study, dietary supplementation with various vegetable and marine oils rich in n-3 and n-6 fatty acids produced significant changes in liver PL and TG fatty acids, reflecting the major constituents of the oils and the effects of these constituents on fatty acid elongation and desaturation. Specifically, OL increased 18:1, and SUN, EPO and fish oil increased 18:2 (vs OL). Fish oil also increased long-chain n-3 fatty acids vs the other groups. In addition, both EPO and fish oil reduced 20:4, and fish oil reduced long-chain n-6 fatty acids. The levels of 18:3n-6 and 20:3 were unchanged by EPO in liver PL, but 22:4 and 22:5 increased, suggesting that 18:3n-6 was elongated in this group. In liver TG, OL increased 18:1 vs other groups, and SUN and EPO elevated 18:2. In addition, EPO increased 18:3 and 20:3 levels. Again, fish oil elevated long-chain n-3 fatty acids and reduced long-chain n-6 fatty acids. In animals receiving 18:3n-6 ip, there were no consistent changes in tissue PL fatty acids, with the exception of an increase in 18:2 and a reduction in 18:3n-6 and 20:3n-6 in the adrenal PL of all groups receiving 18:3n-6, possibly reflecting an inhibition of desaturation of 18:2.

The proposal that dietary n-3 and n-6 fatty acid-induced changes in BP in both salt-loaded and control animals are related to endogenous prostanoid synthesis, particularly those derivatives of 20:4 (prostaglandins E_2 and I_2), 20:3 (prostaglandin E_1) and 20:5 (prostaglandin I_3), is controversial (12–15). Support for this relationship is often found in the proportion of these fatty acid precursors in tissue PL or actual prostanoid production/excretion (12,13). A commonly proposed mechanism for the physiological effects of dietary 18:3n-6 is that it is incorporated into tissue PL and subsequently metabolized to prostaglandin E_1 (16,17), which can subsequently reduce BP via peripheral vasodilation (18) or diuresis (19,20). However, there appears to be no relationship between tissue fatty acid composition and the pressor responses to salt, as might be predicted, based on the prostaglandin E_1 theory. This suggests that in this model, (1) the levels of prostanoid synthesis are not reflected in the levels of PL or TG fatty acid precursors, (2) some tissue other than the liver, kidney or adrenals is the site of relevant increases in 20:3 or (3) the effects of dietary n-3 and n-6 fatty acids on BP are mediated through processes that do not involve altered prostanoid synthesis. This last proposal is consonant with several other reports in the literature (14,15). It appears from the data that changes in PL fatty acid composition are not prerequisite for a physiologic effect. As levels of dietary supplementation are often decided because of their effect on tissue PL composition, these data suggest that physiologically significant changes may be achieved at lower levels of fatty acid supplementation than commonly believed.

The BHR is a useful model in the investigation of the

relationship between genetic and environmental factors in the regulation of BP. The results of this study suggest that the BHR is salt-sensitive and that dietary n-3 and n-3 fatty acid modification, particularly with 18:3n-6, may attenuate the triggering of deleterious cardiovascular effects of salt in this genetically predisposed model.

Serum Lipoprotein and Apoprotein Concentrations in 4-(4-Chlorophenyl)-2-Hydroxytetronic Acid and Clofibrate-treated Cholesterol and Cholic Acid-fed Rats

Vaijinath S. Kamanna[1,a], Howard A.I. Newman[a,*], Suman T. Patel[a,2], Ahsok K. Tehim[b], Donald T. Witiak[b] and Dennis R. Feller[c]

Influence of clofibrate and an aci-reductone, 4-(4-chlorophenyl)-2-hydroxytetronic acid (CHTA) on lipoproteins and apoproteins was studied in cholesterol- plus cholic acid-fed rats. CHTA (0.4 mmol/kg body wt, twice daily) significantly lowered serum total cholesterol and triglyceride concentrations at both 10 and 16 days, whereas clofibrate at the same dose did not alter serum cholesterol levels, but elevated serum triglyceride concentrations at 16 days. The abnormal cholesterol-rich very low density lipoproteins (VLDL), intermediate density lipoproteins (IDL) and low density lipoproteins (LDL) produced by cholesterol plus cholic acid were significantly reduced in their cholesterol content by treatment with CHTA, a compound having an oxidation reduction potential. Conversely, clofibrate administration increased VLDL-cholesterol with concomitant decreases in IDL- and LDL-cholesterol concentrations. Administration of CHTA to cholesterol- plus cholic acid-fed rats significantly increased concentrations of VLDL and IDL, but had no effect on HDL protein. Both CHTA and clofibrate administration to cholesterol- plus cholic acid-fed rats significantly lowered IDL protein concentrations.

Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) studies of apoproteins revealed that clofibrate treatment significantly reduced apoC-III and C-II in VLDL, C-II in IDL, and apoA-IV and A-I in HDL. Rats treated with CHTA significantly raised apoC-II and C-III in HDL.

Isoelectric focusing (IEF) of VLDL apoproteins showed a significant decrease in apoC-II, C-III-0 and apoC-III-3 in clofibrate-treated animals. Thus, the mechanism for antilipidemic action of the oxidation reduction compound, CHTA, which differs markedly from the prototype drug, clofibrate, is independent from major apoprotein modification.

Lipids 24, 25–32 (1989).

Clofibrate and related analogues are among the most widely used hypolipidemic drugs for treating "Broad Beta" hyperlipidemic patients (1). We have been involved for many years with investigating the synthesis (2), effects on lipid and lipoprotein parameters (3), modes of action (2,3) and metabolism (4) of these substances. In this article, we discuss the antilipidemic activity of 4-(4-chlorophenyl)-2-hydroxytetronic acid (CHTA), an aci-reductone [-C(OH)=C(OH)-C=O] having a proposed (5) biologically relevant oxidation reduction potential that may modify lipogenesis oxidation reduction enzyme systems. We have reported both the hypocholesterolemic and platelet anti-aggregatory properties of this compound and found that CHTA was superior to clofibrate as a hypocholesterolemic drug and modifier of the heparin-$MnCl_2$ precipitated lipoprotein cholesterol to alpha-lipoprotein cholesterol ratio (5).

Rats (6), swine (7), rabbits (8) and dogs (9) fed cholesterol have been shown to induce β-migrating very low density lipoprotein (β-VLDL), intermediate density lipoprotein (IDL) and high density lipoprotein (HDL)-cholesterol (C) with a marked increase in arginine-rich peptide (apoE). We employed the cholesterol- plus cholic acid-fed rat model to determine the antilipidemic activity of CHTA, a compound related to clofibrate by its chlorophenyl group, but unrelated because of its aci-reductone characteristics. Clofibrate administration to rats fed a chow diet has been reported to cause a decrease in plasma triglycerides, cholesterol, HDL-C and apoAI, B and C-III (10). Recently, Krause and Newton (11) observed decreased plasma cholesterol, cholesterol in apoB-containing lipoprotein and apoB without alteration of HCL-C, apoA-I and apoE concentrations in cholesterol-fed rats treated with clofibrate.

Because apoproteins are considered to play a major role in lipid and lipoprotein metabolism, we compared clofibrate and CHTA for effects on lipoprotein and apolipoprotein distribution in rats fed cholesterol plus cholic acid. We specifically evaluated CHTA to determine if the oxidation-reduction portion of the molecule would confer greater hypolipoproteinemic effects, because this compound might integrate into cellular membranes and modify receptors which may, in turn, alter enzymatic activity necessary for lipid metabolism.

In view of the altered apoprotein distribution in cholesterol-induced hypercholesterolemia and in an attempt to further our knowledge of the role of clofibrate and CHTA with apoproteins, we have analyzed and now report the apoprotein distribution in this model.

MATERIALS AND METHODS

Chemicals. Acrylamide, N-N'-methylene-bis-acrylamide, riboflavin-5-phosphate, urea, ampholines, Coomassie Brilliant Blue R-250 and sodium dodecylsulfate were obtained from Bio-Rad Laboratories (Rockville Center, NY). A-Gent Cholesterol and A-Gent Triglyceride reagents

Abbreviations: β-VLDL, beta-very low density lipoprotein; C, cholesterol; CHTA, 4-(4-chlorophenyl)-2-hydroxytetronic acid; HDL, high density lipoprotein; IDL, intermediate density lipoprotein; (V)LDL, (very) low density lipoprotein; ANOVA, analysis of variance; dl, deciliters; hsd, honestly significantly different; IEF, isoelectric focusing; PI, pH at isoelectric point; SDS-PAGE, sodium dodecylsulfate-polyacrylamide gel electrophoresis.

were obtained from Abbott Laboratories, Diagnostic Division (Chicago, IL). Rat semisynthetic diet and high-cholesterol fortified diets were obtained from U.S. Biochemicals (Cleveland, OH). Clofibrate [2-(*p*-chlorophenoxy)-2-methylpropionic acid ethyl ester] was purchased from Sigma (St. Louis, MO). CHTA was synthesized in our laboratory, as described earlier (5).

Animals and experimental protocol. Male Sprague-Dawley rats (250–260 g) were maintained on a semisynthetic diet (dextrin, 48%; casein, 18%; sucrose, 11%; coconut oil, 10%; USP X VII salt mixture, 4%; celufil, 2%; liver concentrate NF, 0.4%; choline chloride, 0.2%; D-methionine, 0.2%; vitamin supplements, 4%) or a high-cholesterol diet (semisynthetic diet ingredients plus cholesterol USP, 1% and cholic acid, 0.5%) for a period of 1 wk prior to vehicle or drug-plus-vehicle treatment. Rats were housed in a vivarium at 25–26°C with an alternate 12-hr light and dark cycle with food and water provided ad libitum. After 1 wk of feeding with semisynthetic diet (8 rats, group I) and high-cholesterol diet (24 rats), blood was withdrawn from the orbital plexus of all ether-anesthetized animals. Serum cholesterol was determined in these blood samples and, on the basis of cholesterol levels, rats fed high-cholesterol diet (24 rats) were distributed into three groups (II, III and IV; 8 rats in each group) by a stratified random sampling to minimize variations in the initial cholesterol values (mean serum cholesterol concentrations in these three groups were 238,237 and 236 mg/dl, respectively). Groups III and IV received either 0.4 mmol/kg body wt twice daily of CHTA or clofibrate through intragastric administration with 0.25% methylcellulose as a vehicle, for 16 days. Groups I (control) and II (CH-control) were administered the same amounts of vehicle only and, during drug treatment, rats were maintained on the respective diets.

All rats were fasted 16–18 hr before blood collection. Blood was drawn from the orbital plexus under light ether anesthesia on the day before (Day −1) and 10 days after drug treatment (Day +10). After 16 days of drug treatment, blood was collected by exsanguination from the abdominal aorta. All blood samples were kept for 2–3 hr at 4°C and, after coagulation, serum was separated by centrifugation at 2000 *g* for 10 min.

Lipoprotein isolation and characterization. Serum samples were combined to obtain 3 pools from each group of animals (two rat sera in each pool), and these samples were used for lipoprotein isolation. Serum was fractionated into VLDL (d < 1.006 g/ml), IDL (d 1.006–1.019 g/ml), low density lipoprotein (LDL) (d 1.019–1.063g/ml) and HDL (d 1.063–1.21 g/ml) classes by differential ultracentrifugation according to the procedure of Havel et al. (12). Lipoprotein fractions were collected with a Spinco tube slicer and were dialyzed against 0.15 M NaCl–0.005 M EDTA, pH 7.5 at 4°C. Cholesterol recovery based on total serum cholesterol concentrations ranged from 65–70%. All reported values have been normalized to 100% recovery. The purity of the lipoprotein fractions was checked by agarose gel electrophoresis. In cholesterol-fed rats, contamination of HDL-C in LDL fractions occurs because both float at similar densities (6). Thus, the LDL fraction was not used for sodium dodecyl sulfate-polyacrylamide electrophoresis (SDS-PAGE) or isoelectric focusing (IEF) studies. The protein content of purified VLDL, IDL and HDL was measured by the method of Lowry et al. (13), as modified by Sata et al. (14). Apoprotein B concentrations of both VLDL and IDL were calculated to be the difference in protein concentration found before and after 2-propanol precipitation (15). Appropriate amounts of VLDL, IDL and HDL (400 μg for IEF and 150 μg for SDS-PAGE) were lyophilized and delipidated according to the procedure of Brown et al. (16) and Scanu and Edelstein (17).

Apoprotein electrophoresis. Apoproteins of VLDL, IDL and HDL were separated by SDS-PAGE, as described by Shore et al. (18). In all SDS-PAGE of apoproteins, a distinct band was observed having a molecular mass similar to bovine serum albumin. We observed similar IEF patterns in VLDL, IDL and HDL fractions at the albumin isoelectric points. The gels were stained with 0.2% Coomassie Brilliant Blue R-250 (18) and scanned at 570 nm in a Gilford model 240 spectrophotometer equipped with a Gilford Model 2410-S linear transport system connected to an Apple II computer. The percentage of the total area under each peak was computed by the ADALAB Chromatochart program. Apolipoproteins were identified on the basis of molecular mass (18).

IEF of apoVLDL, IDL and HDL was carried out at 4°C in 7.5% polyacrylamide gel containing 8 M urea and 2% ampholines, pH 3.5–10 (19). Amounts of protein used for IEF with respect to the linearity of the dye binding and chromogenicity of apoCs have been established in our laboratory (20). For the present study, appropriate amounts of apoprotein and corrections were used. For each set of gels, one IEF gel was run without applying any sample to monitor pH gradient. Following electrophoresis, gels were stained with Coomassie Brilliant Blue R-250 and destained as described by Vesterberg and Hansen (21). The gels were scanned at 570 nm, and areas under each peak and apoprotein proportions were computed as described above. The gel, without the sample applied to monitor pH gradient, was sliced into 2 mm segments. Each of these segments was transferred to an Eppendorff tube containing 1.2 ml of distilled water. The tubes were left in the cold room overnight. The pH was measured at room temperature on a Beckman Model 3550 digital pH meter (22). Apoproteins were characterized on the basis of pI values (20,22,23).

Analyses. Serum cholesterol and lipoprotein-cholesterol levels were determined by the method of Allain et al. (24) with A-Gent cholesterol reagent on the Abbott Biochromatic analyzer (ABA-100). Serum triglycerides were measured on the ABA-100 with A-Gent triglyceride reagent according to the procedure of Sampson et al. (25).

Statistical analyses. Cholesterol and triglyceride concentration values were analyzed by a two-way analysis of variance (ANOVA). Significance of cholesterol distributions among lipoproteins and apoprotein concentrations were analyzed by a one-way analysis of variance. On those ANOVAs that demonstrated significance due to groups, post-hoc Tukey (hsd) tests for significance among groups were performed.

RESULTS

Serum total cholesterol levels in control, CH-control and drug-treated rats are recorded in Table 1. Feeding a cholesterol-rich diet for 1 wk (Day −1) significantly increased serum cholesterol levels which remained stable

TABLE 1

Effect of CHTA and Clofibrate on Serum Cholesterol Concentrations in Cholesterol-fed Rats[a]

	Serum cholesterol (mg/dl)[b]		
	Day −1	Day +10	Day +16
I. Control	119 ± 6.5[c]	103 ± 8.4	98.5 ± 10.2[d]
II. Cholesterol-rich (CH)	238 ± 72.1	195 ± 36.6[e]	221 ± 67.4[e]
III. CH + CHTA	237 ± 69.8	137 ± 19.2[f]	155 ± 36.5[f]
IV. CH + Clofibrate	236 ± 65.2	186 ± 33.1[g]	218 ± 58.5[g]

[a]Groups III and IV received either 0.4 mmol/kg body wt twice daily of CHTA or clofibrate through intragastric administration with 0.25% methylcellulose as a vehicle for 16 days. Day +10 and Day +16 represent 10 and 16 days of drug treatment. Day −1 represents initial values before drug treatment.

[b]Mean ± SD, N = 8 rats per group.

II. Cholesterol-rich (CH)	126 ± 30.0	128 ± 13.0[d]	130 ± 17.3[d]
III. CH + CHTA	130 ± 33.7	100 ± 7.13[e]	97 ± 16.0[e]
IV. CH + clofibrate	131 ± 26.3	136 ± 37.0[f]	162 ± 39.1[f]

[a]Drug administration is the same as described in Table 1.

[b]Mean ± S.D., n = 8 rats per group.

[c]N = 5.

[d]$p < 0.005$, Group II vs I, III.

[e]$p < 0.005$, Group III vs II, IV.

[f]$p < 0.005$, Group IV vs III, I.

at Day +10 and Day +16. Intragastric administration of CHTA (0.4 mmol/kg body wt, twice daily) to hypercholesterolemic rats significantly lowered serum cholesterol levels at 10 and 16 days compared with CH-controls, whereas clofibrate treatment did not alter serum cholesterol levels at either Day +10 or Day +16.

Serum triglyceride concentrations in control, cholesterol-fed and drug-treated animals are listed in Table 2. Cholesterol feeding did not significantly alter serum triglyceride levels. Administration of CHTA to CH-controls, however, significantly decreased serum triglyceride concentrations when compared with initial values before drug treatment or with those of the CH-control group. Clofibrate treatment for 10 days did not alter serum triglycerides, but, following 16 days of drug treatment, serum triglyceride concentrations were elevated when compared with either initial values or with CH-control rat serum triglyceride concentrations.

Cholesterol feeding to rats markedly increased VLDL-, IDL- and LDL-C and decreased HDL-C levels when compared with those of the semisynthetic diet-fed group (Table 3). CHTA treatment significantly lowered VLDL-, IDL- and LDL-C concentrations. No change was observed in HDL-C levels. Similarly, clofibrate treatment also lowered IDL- and LDL-C levels, but there was a marked increase in VLDL- and a modest rise in HDL-C concentrations when compared with CH-controls. VLDL-apoB concentrations were increased with CHTA treatment when compared with CH-controls (Table 4). Inclusion of cholesterol in the semisynthetic diet increased VLDL and IDL protein concentrations (Table 5).

The SDS-PAGE pattern of VLDL apoproteins exhibited apoE, apoC-III and C-II as major and apoA-IV and A-I as minor bands. A faint unknown band with a molecular mass of about 21,000 was also observed. Cholesterol feeding significantly increased apoE concentrations compared with CH controls (Table 6). None of the apoprotein proportions changed in CHTA-treated animals, whereas clofibrate treatment produced smaller proportions of both ApoC-II and apoC-III. With SDS-PAGE of IDL apoproteins (Table 7), apoC-II was decreased with clofibrate treatment, but no other apoprotein proportions were altered with drug treatment. A distinct unknown band, similar to one found in total lipoproteins (26) and having a molecular mass of about 21,000 (similar to the unknown VLDL apoprotein band), was detected in IDL apoproteins.

Separation of apoA-IV, E, A-I, C-III and C-II from HDL was obtained. Whereas cholesterol feeding significantly increased the proportion of ApoA-IV, A-I and E in HDL with proportional decreases in apoC-II, clofibrate reduced both A-I and A-IV toward control values, but had no effect on ApoE (Table 8). CHTA treatment increased apoC-II, but had no effect on other apoproteins.

With IEF, VLDL ApoC peptides were focused in the pI range 4.42–4.73, and had four bands, which are characterized as apoC-II (pI 4.73), apoC-III-0 (pI 4.66), apoC-III-2(-1) (pI 4.49) and apoC-III-3 (pI 4.42). ApoE peptides showed 4–5 isoforms characterized as E-4 (pI 5.52), E-3 (pI 5.47), E-2 (pI 5.40), E-1 (pI 5.33) and at pI 5.26. In CH-controls, a distinct band appeared at pI 5.07 and a faint band at pI 4.92, which together accounted for 4–6% of the total apoprotein. Clofibrate treatment did not alter the ApoE isoform concentration compared with that of CH-controls (Table 9), whereas CHTA administration caused a small but significant reduction in $apoE_2$. ApoC-III-2(1) concentrations were significantly decreased with clofibrate treatment compared with CH controls and CHTA (Table 10). ApoC-II in clofibrate-treated animals was only significantly decreased when compared with CHTA.

IEF of IDL apoproteins showed faint bands in the apoA-I region characterized as apoA-I-1 (pI 5.91), A-I-2 (pI 5.89), A-I-3 (pI 5.64) and A-I-4 (pI 5.57). Similar to apoE isoforms in VLDL, apoE isoforms in IDL were focused in the pI range of 5.52–5.26. In CH-controls, IEF produced two unidentified peaks at pI 5.07 and 4.92, a result similar to that observed for apolipoproteins in VLDL. Apo A-I-1 was significantly increased with clofibrate administration (Table 11). Decreased proportions of apoC-III-2 were observed in clofibrate-treated rats (Table 12) when compared with CH controls and CHTA-

treated rats, whereas apoC-III-0 concentrations were only significantly decreased when compared with CH controls.

IEF-analyzed HDL apoprotein revealed separated isoforms of apoA-I, apoC-III and apoE + A-IV. CHTA treatment did not alter any of these apoprotein concentrations (Table 13). The IEF pattern of HDL apoprotein of clofibrate-treated animals did not indicate any measurable bands in pI regions of apoA-I, apoE and apoCs due to insufficient sample sizes. However, cholesterol feeding did increase apoAI-1 and AI-3 (Table 14).

DISCUSSION

Although the rat, which is resistant to hypercholesterolemia and atherosclerosis, has limited use as an experimental model, cholesterol feeding (6) provides a lipoprotein pattern resembling that in miniature swine and rabbit models (7,8). Features include: (a) presence of β-VLDL, (b) increase in IDL, a remnant composite resulting from chylomicron and VLDL metabolism (27-30), (c) increase in LDL and (d) measurable concentrations of HDL-C (6-8). Additionally, in these models, higher concentrations of apoE were observed in VLDL, IDL and HDL (6-8). We also observed an increase in VLDL apoE proportions in cholesterol- plus cholic acid-fed rats when compared with controls (Controls, 32.7 ± 3.81%; CH-control, 43.7 ± 1.72%). In our studies with CH-controls compared with animals on a basal diet, VLDL cholesterol concentrations increased 12.2 times, whereas protein increased 1.7-fold. Additionally, with CHTA treatment, the ratio for cholesterol in VLDL became 8.18, whereas the protein ratio became 1.31. Our observations are compatible with the rat cholesterol feeding studies of Mahley and Holcombe (6), DeLamatre and Roheim (26) and Lasser et al. (31).

Nonetheless, clofibrate has no effect on serum total cholesterol or triglyceride in this cholesterol-fed rat model at +10 and +16 days of treatment. Concurrent studies wherein cholesterol concentrations were measured at 4, 7 and 14 days showed that clofibrate administration caused a transient lowering of total cholesterol levels on days 4 and 7 (Day +4, 164 ± 51.5; Day +7, 204 ± 77.4; Day +14, 171 ± 72 mg/dl). This transient effect (not observed with CHTA) may be due to offsetting changes in VLDL, LDL and HDL. At Day +16 the following changes were observed: VLDL and HDL cholesterol concentrations were significantly higher, and IDL- and LDL-cholesterol levels were significantly lower than those of CH-controls. The elevation in VLDL-cholesterol levels may be attributed to a decreased catabolism of the particles leading to lower IDL- and LDL-cholesterol concentrations. Decreased catabolism of VLDL in clofibrate-treated cholesterol-fed rats may be due to the decreased apoC-II concentrations because this apoprotein enhances lipoprotein lipase activity (32). Alternatively, there may be inhibition of lipoprotein lipase activity with no reduction in the usual transfer rates of apoC-III to HDL and apoE to VLDL. Our findings of no effect on total serum cholesterol concentration at +10 and +16 days are similar to those of Seri et al. (33) who observed no reduction in serum cholesterol levels in rats fed a chow diet supplemented with 2% cholesterol, 1% sodium cholate and 5% coconut oil for 4 days. However, in some studies with clofibrate treatment of rats fed cholesterol-containing diet, there was a decreased serum cholesterol concentration with no alteration in HDL-cholesterol levels, but this change did not result in an increased proportion or an absolute increase in apoA levels. In fact, we observed a significant decrease in the proportions of apoA-I with a concomitant increase in apoC-III in contrast to the usual finding of a direct relationship of ApoA-I and HDL-C, as was observed with other drugs in both rats (11,34) and human subjects (35). However, Kitazacki et al. also observed a significant decrease in apoA-I levels (36) in cholesterol-fed EXHC rats. In contrast, Krause and Newton (11) observed no alteration in apoA-I concentration.

CHTA is more effective than clofibrate in reducing total serum cholesterol levels in this model. The action of this aci-reductone appears to differ markedly from that of clofibrate because CHTA lowers the concentration of VLDL-, IDL- and LDL-cholesterol without altering C apoprotein proportions when compared with CH-controls. Clearly, in contrast to the action of clofibrate in this model, CHTA does not inhibit, but appears to enhance, VLDL catabolism. Interestingly, absence of alteration in the apoC-II to apoE ratios by CHTA treatment suggests that this oxidation reduction compound acts by a mechanism independent of apoprotein regulation of triglyceride hydrolysis.

Cardiac Membrane Vitamin E and Malondialdehyde Levels in Heart Muscle of Normotensive and Spontaneously-hypertensive Rats

David R. Janero* and **Barbara Burghardt**
Department of Pharmacology and Chemotherapy, Roche Research Center, Hoffmann-La Roche Inc., Nutley, NJ 07110-1199

The vitamin E (α-tocopherol) and free and bound malondialdehyde (MDA) in ventricular heart muscle and myocardial membrane from Wistar-Kyoto (W/K) normotensive and spontaneously hypertensive (SH) rats have been measured directly by high performance liquid chromatography (HPLC). Thiobarbituric acid-reactive substance (TBA-RS) in the myocardium and heart-muscle membrane of the two strains was also quantified by a colorimetric TBA test. It was found that SH-rat myocardium and myocardial membrane contained more than 3-fold less α-tocopherol than did heart muscle and cardiac membrane of the normotensive rat. Coincident with this relative vitamin E deficiency were several-fold greater amounts of MDA and TBA-RS in SH-rat myocardium and myocardial membrane. Most (87%) of the MDA in SH-rat heart muscle, but only 40% in W/K-rat heart muscle, was free (i.e., unbound). These results offer direct evidence that SH-rat myocardium is vitamin E-deficient and highly peroxidative, relative to cardiac muscle of the normotensive W/K parent strain. The lower vitamin E content of SH-rat myocardium is particularly striking, because SH-rat myocardial membrane was found to contain ~35% more phospholipid than myocardial membrane in the W/K rat. Although the amounts of myocardial TBA-RS are greater in the SH strain, they do not reflect the actual MDA profiles of the heart muscles or the heart membranes and cannot be used as a quantitative index of cardiac oxidative-injury status due to non-MDA TBA-RS in both strains.
Lipids 24, 33-38 (1989).

Peroxidation of polyunsaturated fatty acid (PUFA) moieties in membrane phospholipids is a causal contributor to the pathophysiology of many diseases (1). The heart muscle damage associated with cardiac ischemic and reperfusion injury may result, at least in part, from radical-mediated myocardial membrane lipid peroxidation, perhaps through superoxide-dependent, iron-promoted oxygen chemistry (2). Vitamin E (α-tocopherol), an essential antioxidant nutrient (3), is present in cardiac muscle (4) and may help prevent myocardial oxidative injury from free radicals produced in both the normal and diseased heart (3,5). Clinical data suggest that increased cardiac-membrane tocopherol tone effectively protects the heart from irreversible necrosis: Dietary supplementation with vitamin E is associated with a reduced risk of human mortality from cardiovascular disease (6), and vitamin E has been used therapeutically in ischemic heart-disease patients (7).

Despite such evidence, quantitative information on the relationship between myocardial membrane vitamin E content and cardiac membrane oxidative stress is lacking. The male spontaneously hypertensive (SH) rat appears to be a particularly suitable study-object in this regard. The SH rat, derived from the Wistar-Kyoto (W/K) normotensive strain, is an accepted model of human cardiovascular disease (8), because it displays a progressive, postweaning increase in systolic blood pressure (9). Although the plasma vitamin E concentration in both strains (when fed the same diet) is identical (10), whole-heart homogenate from the SH rat contains ~25% less vitamin E than does normotensive W/K-rat heart homogenate. Furthermore, recent methodological advances for direct quantification of MDA (11-13), a secondary end product of lipid hydroperoxide decomposition (1), have obviated reliance on the thiobarbituric acid (TBA) test (14) to estimate tissue and membrane oxidative-injury status.

We report here investigation of the relationships among cardiac membrane vitamin E level, TBA-reactivity and MDA content in the myocardial membrane of SH and W/K normotensive rats. The membrane data are placed within the context of the vitamin E, TBA-reactive substance (TBA-RS), and bound and free MDA levels in the myocardium of each strain.

EXPERIMENTAL PROCEDURES

Materials. N-2-hydroxyethylpiperazine-N'-2-ethanesulfonic acid (HEPES), tris(hydroxymethyl)aminomethane (Tris), hydroxylamine hydrochloride, TBA, and tetramethoxypropane were from Sigma Chemical Co. (St. Louis, MO). Catalase (hydrogen-peroxide:hydrogen-peroxide oxidoreductase, EC 1.11.1.6; thymol-free analytical preparation from beef liver; 260,000 units/mg) and superoxide dismutase (SOD; superoxide:superoxide oxidoreductase, EC 1.15.1.1; analytical preparation from bovine erythrocytes; 5000 units/mg) were from Boehringer-Mannheim (Indianapolis, IN). Desferal (desferrioxamine B methanesulphonate) was a gift from Ciba A.G. (Basle, Switzerland). Chelex 100 was from Bio-Rad (Richmond, CA). Vitamin E (*d*-α-tocopherol) and [3,4-^{3}H]vitamin E (297 μCi/mg, sp. act.) were synthesized and purified by Hoffmann-La Roche. All organic solvents were of analytical grade (Burdick and Jackson, Muskegon, MI).

Animals. SH and W/K rats (10-wk-old) were purchased from Charles River Breeding Labs (Wilmington, MA) and maintained on Purina Rodent Chow (Ralston Purina, St. Louis, MO) and tap water ad libitum on a 12-hr light/dark cycle. When 12 wk of age, the rats were decapitated. Just prior to sacrifice, blood pressures and heart rates of conscious animals were taken by the indirect tail-cuff method (15), and body weights were recorded. The systolic blood pressures of the rats used in the studies described were: SH, 214 ± 2.9 mm Hg; W/K, 120 ± 3.9 mm Hg. Their

Abbreviations: HEPES, N-2-hydroxyethylpiperazine-N'-2-ethanesulfonic acid; MDA, malondialdehyde; PUFA, polyunsaturated fatty acid; SOD, superoxide dismutase; TBA-RS, thiobarbituric acid-reactive substance; TCA, trichloroacetic acid; Tris, tris(hydroxymethyl)aminomethane; HPLC, high performance liquid chromatography; SH, spontaneously hypertensive; W/K, Wistar-Kyoto.

heart rates were: SH, 420 ± 16 beats/min; W/K, 397 ± 9 beats/min. Their body weights were: SH, 273 ± 12 g; W/K, 282 ± 14 g (means ± S.D.; n ⩾ 30).

Isolation of myocardial membrane. The procedure was carried out in a dehumidified cold room (3°C) under amber lighting. Hearts of SH and W/K rats were rapidly excised, perfused ex vivo via the aorta with 50 ml ice-cold 10 mM HEPES buffer, pH 7.4, and trimmed. The ventricular myocardium from each strain was homogenized (100 mg tissue/ml HEPES) for 3 × 5 sec with a Tissuemizer (Tekmar, Cincinnati, OH) at "maximal" setting. The respective homogenates were filtered through 4-ply cheesecloth, and a portion of each filtrate was set aside for immediate lipid, vitamin E, TBA-RS, MDA and protein analyses (below). The remainder of each filtrate was subjected to salt extraction and differential centrifugation for myocardial membrane isolation, as detailed (11). The washed, purified membranes were resuspended in 10 mM HEPES buffer, pH 7.4, and used immedidately.

Extraction and quantification of lipid and vitamin E. During lipid and α-tocopherol extractions, care was taken to avoid sample exposure to air; only solvents purged with highly purified argon were used. Lipids were extracted from myocardial homogenate and membranes by a modified (16) Bligh-Dyer procedure (17). Lipid recovery was quantitative by the chemical criteria detailed (18): >98% of the radioactivity associated with the organic fraction obtained by direct saponification (18) of membrane metabolically labeled in vivo from [^{14}C]acetate, sodium salt (54.0 mCi/mmol, sp. act. [New England Nuclear, Boston, MA]), was recovered in the saponified fraction from the lipid extracted out of an identical amount of labeled lmembrane. Lipid ester was quantified by the hydroxamate reaction with L-α-phosphatidylcholine dipalmitate (Avanti Polar Lipids, Birmingham, AL) as standard (19).

Vitamin E was extracted into acetone according to procedures developed for rat liver (20). Tissue samples and extracts for vitamin E analysis were exposed to amber lighting only. In preliminary experiments, extraction efficiency was estimated by adding a known amount of [^{3}H]vitamin E to the myocardial suspension prior to homogenization and extraction and likewise supplementing the myocardial membrane prior to extraction. Because >96% of the ^{3}H-labeled vitamin E was recovered in the final tissue and membrane acetone extracts, the procedure was considered quantitative for vitamin E extraction from myocardium. Vitamin E determination was carried out fluorometrically by reverse-phase high performance liquid chromatography (HPLC) on a μBondapak C_{18} 3.9 mm × 30 cm column preceded by a radially-packed C_{18} precolumn (Waters/Millipore, Bedford, MA). A ternary-gradient HPLC system (Beckman Instruments, Palo Alto, CA) with flourescence detector (Perkin-Elmer, Norwalk, CT) was used. The mobile phase was methanol/water (97:3, v/v) at a flow rate of 2.0 ml/min (10). Calculation of vitamin E content in the experimental samples was by computer-assisted regression analysis from a standard peak-area response curve of varying amounts of pure *d*-α-tocopherol.

TBA test. TBA-reactivity as MDA-equivalents was determined colorimetrically (11). In brief, myocardial homogenate or membrane was acidified with 0.15 ml ice-cold 76% trichloroacetic acid (TCA)–2.3 N HCl/1.0 ml tissue suspension. Next was added 0.35 ml of a mixture of H_2O/7.14 M butylated hydroxytoluene in ethanol/1.51% TBA in 0.2 M Tris, pH 7.0 (1:1:5, v/v/v). After thorough mixing, the samples (pH = 2.4) were incubated in an 80°C shaking water bath for 30 min. The tubes were then chilled, and 0.5 ml ice-cold 91% TCA, followed by 2.0 ml $CHCl_3$, was added. After centrifugation for 30 min at 2000 × *g*, 4°C, the absorbance of the upper phase was read at 532 nm. MDA standard, prepared by hydrolysis of 1,1,3,3-tetramethoxypropane with 76% TCA-2.3 N HCl, was subjected to the identical TBA-test procedure to generate a standard curve of TBA-reactivity as MDA-equivalents. The molar amounts of TBA-RS (as MDA-equivalents) in the biological samples were calculated by computer-assisted regression analysis of the standard curve.

Isolation and quantification of MDA. MDA was isolated as its enolate anion by ion-pair HPLC with spectrophotometric detection at 267 nm (11). The myocardial homogenate or membrane suspension was prepared for HPLC analysis by rapid ultrafiltration through a YM2 membrane (Amicon, Danvers, MA) to exclude high mol-wt (>1000) molecules and particulates. The clear filtrate was then subjected to HPLC for "free" (unbound) MDA quantification.

In order to liberate any bound tissue MDA prior to HPLC analysis, samples were hydrolyzed in base (NaOH) at pH 12.0, 60°C, for 30 min (11,21). The hydrolysis reaction mixtures were then subjected to ultrafiltration (as above), and the clarified filtrates were neutralized (pH ~7.4) with HCl prior to HPLC analysis for "total" MDA. The difference in sample MDA prior to and after hydrolysis (i.e., between 'free" and "total" MDA) was considered "bound" MDA. Recovery of standard MDA in these procedures was >96%.

MDA for HPLC calibration chromatograms was prepared by hydrolysis of malonaldehyde-bisdiethylacetal (Merck, Darmstadt, West Germany) with H_2SO_4 and purification of MDA product as described (22). Absolute MDA concentration in the solution was checked by UV spectrophotometry at 267 nm with the extinction coefficient 34,000 M^{-1} cm^{-1} (22) in a Beckman DU-7 spectrophotometer.

Protein determination. Protein was quantified by a dye-binding microassay (23).

Statistical analysis. Comparisons of two group means were made by Student's *t*-test (24). Unless otherwise noted, differences between SH-rat and W/K-rat group means were significant ($p \leqslant 0.01$).

RESULTS

Biochemical characteristics of SH and W/K rat myocardial membrane. The properties of the membrane isolated from SH and W/K rat ventricular myocardia are summarized in Table 1. For both strains, ~70% of the total cardiac-muscle homogenate lipid was recovered in the isolated myocardial membrane. Because the phospholipid is localized almost exclusively in heart-muscle membrane (25), these data demonstrate an equivalent, high myocardial membrane recovery from both strains. The dramatically lower protein content of the membrane with respect to starting homogenate illustrates the efficiency of soluble myocardial (particularly contractile) protein extraction

TABLE 1

Biochemistry of SH and W/K Rat Myocardial Membrane[a]

Fraction	Lipid				Protein		Lipid ester: protein
	Ester		Phosphate				
	(%)	(mEquivalents/heart)[b]	(%)	(μg/heart)[b]	(%)	(mg/heart)[b]	
Heart muscle homogenate							
SH	100	9.9 ± 0.3	100	536.3 ± 31.4	100	53.2 ± 2.7[d]	0.18 ± 0.01
W/K	100	6.8 ± 0.6	100	367.7 ± 28.7	100	49.6 ± 2.4[d]	0.14 ± 0.01
Myocardial membrane							
SH	74.8 ± 3.2[d]	7.4 ± 0.4[c]	76.5 ± 4.4[d]	410.3 ± 23.4	23.1 ± 1.3[d]	12.3 ± 0.8[d]	0.60 ± 0.04
W/K	69.1 ± 4.5[d]	4.7 ± 0.2[c]	68.0 ± 4.9[d]	250.1 ± 16.3	24.2 ± 1.4[d]	12.0 ± 0.7[d]	0.40 ± 0.02

[a]Myocardial membrane was isolated from cardiac venticular muscle homogenates of SH and W/K rats by salt extraction and differential centrifugation, as described (11). Results are means ± S.D. ($n \geq 7$).

[b]One heart-equivalent represents ~1.0 g tissue wet-weight.

[c]89.9 ± 3.2% of the lipid ester was found in membrane phospholipid; the remainder was associated with neutral lipid.

[d]Difference between respective SH and W/K group means not statistically significant ($p > 0.01$).

during membrane isolation. The high proportion of lipid recovered in the myocardial membrane and the ~3-fold greater lipid ester:protein ratio of the membrane over the respective source homogenate indicate that the isolated membrane is representative of the myocardial membrane in situ. Further support for this conclusion rests with the finding that, after density-gradient centrifugation of either the isolated SH-rat or W/K-rat myocardial membrane, the resultant distribution of membrane types (~90% mitochondria, ~7% sarcoplasmic reticulum, ~3% sarcolemma) approximates the relative membrane areas of the three organelles in the intact heart-muscle cell (26). The present state of development of myocardial subfractionation procedures does not allow isolation of rat-heart sarcoplasmic reticulum and sarcolemma to purity and with high yield (27). Consequently, the washed particulate total-membrane fraction from SH and W/K myocardia was used for the studies herein.

Myocardial membrane of the SH rat contained ~35% more lipid ester and phospholipid, but not more protein, than did the membrane of W/K rat-heart muscle (Table 1). From the high tissue (phospho)lipid recovery in the isolated membrane and the similar (phospho)lipid enrichment in SH-rat myocardial homogenate relative to W/K-rat myocardial homogenate, the greater heart-muscle membrane (phospho)lipid content of the SH rat would appear to reflect the situation in situ.

Vitamin E contents of SH and W/K rat myocardia and myocardial membranes. SH and W/K rat-heart muscle and myocardial membrane were analyzed for their vitamin E content (Table 2). The isolated membrane from both strains represented a high proportion (~70%) of starting homogenate vitamin E, as was the case with tissue (phospho)lipid (Table 1). The ventricular cardiac muscle of the W/K normotensive rat contained some threefold more vitamin E than did the myocardium of the SH strain. A similar relative vitamin E deficit in SH-rat heart-muscle membrane was underscored by normalizing vitamin E mass to lipid mass: Because SH-rat myocardial membrane contains ~35% more lipid than W/K-rat myocardial membrane (Table 1), the vitamin E content of heart-muscle membrane from the SH rat is about fivefold less than that of the W/K-derived membrane, when normalized to lipid mass.

TBA-RS in SH and W/K rat myocardia and myocardial membranes. The content of TBA-RS in heart muscle and muscle membrane of SH and W/K rats is given in Table 3 as MDA-equivalents. Normalized to protein, the amount of TBA-RS in the ventricular myocardium in the SH rat was ~4-fold greater than in the normotensive W/K strain. Likewise, SH-rat myocardial membrane contained ~3-fold more TBA-RS (normalized to membrane protein) than did the membrane in the W/K rat. Between the two animal strains, the amounts of heart-muscle protein and myocardial membrane protein were equivalent, but SH-rat myocardium had the greater lipid content (Table 1). Consequently, when normalized to lipid mass, the differences in homogenate and membrane-associated TBA-RS between the two strains were diminished slightly, but not eliminated. The TBA-RS appears to be an endogenous tissue/membrane constituent, for it was present even when myocardial homogenization and membrane isolation were carried out in the presence of a battery of anti(per)oxidants and metal chelators, including SOD (10 nM, final conc.), catalase (20 μM, final conc.) and Desferal (100 μM, final conc.), demonstrated to inhibit TBA-RS formation from peroxidized heart lipids (11). Buffer ultrapurification with Chelex resin to remove trace metals likewise did not influence the TBA-RS content.

MDA contents of SH and W/K rat myocardia and myocardial membranes. The nonspecificity of the TBA test would appear to prohibit its use in the quantitative analysis of tissue or membrane MDA (11,13). Consequently, the MDA contents of ventricular muscle and myocardial membrane were determined by direct chromatographic MDA isolation (11). Myocardial homogenates and membrane samples were hydrolyzed to release any MDA bound to biomolecules such as proteins and nucleic acids (28), and the contents of MDA after hydrolysis ("total" MDA) were compared to those of parallel samples

TABLE 2

Vitamin E Contents of SH and W/K Rat-Heart Muscle and Myocardial Membrane

Fraction	Vitamin E[a] (%)	(μg/heart)	(μg/g protein)	(μg/mEquivalents lipid ester)	(μg/mg lipid phosphate)
Heart muscle homogenate

[b]nd, not detected.

not hydrolyzed ("free" MDA), the difference considered 'bound" MDA.

As normalized to protein, the amount of myocardial MDA in the SH rat was ~2-fold greater than in the W/K normotensive animal, and the amount of myocardial membrane MDA was ~5-fold greater (Table 4). Most (87%) of the MDA in SH-rat heart muscle, but only ~40% of the total W/K-rat myocardial MDA, was free MDA. All membrane-associated MDA in both strains was bound and could be released only upon hydrolysis. When MDA contents were normalized to lipid mass, the inter-strain differences diminished slightly, because SH-rat myocardium is relatively enriched in (phospho)lipid (Table 1), but the ratio of bound MDA:free MDA in each strain's heart muscle or myocardial membrane did not change. As was the case with TBA-RS, the endogenous myocardial and membrane MDA amounts were not influenced by the presence of anti(per)oxidants during

tissue homogenization and membrane isolation or by buffer ultrapurification.

DISCUSSION

The present study offers direct evidence that heart muscle membranes in the SH rat are vitamin E-deficient relative to the myocardial membranes of the parent normotensive strain. Furthermore, the lower membrane vitamin E content is accompanied by greater amounts of endogenous membrane (and muscle tissue) MDA, an index of oxidative PUFA damage in biological systems and foods (29). This coincidence between low vitamin E status and high MDA content strongly indicates that SH-rat myocardium is highly peroxidative relative to W/K normotensive-rat myocardial tissue.

Bound MDA predominates in W/K-rat myocardium, whereas almost all of the MDA in SH-rat heart muscle is free MDA. The ~10-fold greater free MDA:bound MDA ratio in SH-rat myocardium indicates that the intrinsic capacity for MDA production in the heart muscle of the SH rat far exceeds the capacity for MDA condensation and cross-linking with tissue biomolecules (28,30).

The net amounts of myocardial and myocardial membrane MDA may be influenced to some extent by oxidative catabolism. Although mouse heart has been shown to convert ^{14}C-labeled MDA to $^{14}CO_2$ (and other products) (31), the relative abilities of SH- and W/K-rat myocardia to oxidize MDA are not known. The slightly (~1.8-fold) greater amount of bound MDA in SH-rat myocardium relative to the W/K-rat tissue, in spite of the ~5-fold greater free-MDA content in SH-rat heart muscle, demonstrates that SH-rat myocardium contains the larger MDA pool readily available for metabolic and/or excretory clearance (32). The relative sizes of the free MDA pools may reflect a greater efficiency of MDA clearance in the W/K rat relative to the SH strain. These data imply that, even though total myocardial MDA binding capacity is ~8-fold greater in the SH myocardium, net MDA production in the relatively vitamin E-deficient SH-rat myocardium is far greater than in the W/K-rat heart.

Lee and Csallany (21) have demonstrated that livers from Sprague-Dawley rats fed a vitamin E-deficient diet for 43 wk contained ~10-fold less α-tocopherol and ~3-fold more MDA than did livers from rats fed a normal diet. After 10 weeks on a vitamin E-deficient diet, rats are in a severe negative nitrogen and food balance (10,33). The SH and W/K rats used in this study were not in a wasting state. These physiological and metabolic differences notwithstanding, the association between depressed tissue α-tocopherol levels and enhanced tissue MDA content in a dietary animal model of vitamin E-deficiency (21) and in the SH rat (Tables 2 and 4) implies that a dynamic balance exists in situ between vitamin E level and tissue peroxidative status.

Alterations in this balance may have profound effects on membrane function, as our data at the membrane level, demonstrating an inverse correlation between myocardial membrane tocopherol tone and membrane-bound MDA, would suggest. It is known that reactivity of MDA with membrane constituents changes membrane properties (34), and the resistance of hepatomas to peroxidative damage is a reflection of their high α-tocopherol content relative to normal liver tissue (35). We have recently demonstrated, in fact, that the low membrane vitamin E content in the SH-rat heart enhances the susceptibility of cardiac membrane phospholipid to oxidative injury when exposed to oxy-radical chemistry (36).

The amounts of TBA-RS in SH-rat myocardium and myocardial membrane are significantly higher than in normotensive W/K-rat heart tissue. However, TBA-reactivity was not a true indicator of the peroxidative state of the myocardium. Neither the absolute amounts of TBA-RS nor the magnitudes of the relative inter-strain differences in TBA-RS quantitatively reflect the actual MDA profiles of the heart muscle or its membrane. These findings support our previous contention (11) that the TBA test cannot be used as anything other than an empirical indicator of membrane oxidative injury and extend our conclusion to the tissue level. Therefore, the TBA test may not be able to measure rat-heart MDA as a pathophysiological index of oxidative injury (cf. 37,38) or to quantify changes in liver and brain lipid peroxidation with dietary α-tocopherol (cf. 21,39).

ACKNOWLEDGMENTS

We thank A. Higgins, L. Klevans and A. C. Sullivan for support of this work; the Pharmacology Word Processing Unit (M. Johnson, P. Lotito, S. Maloney, N. Manion and L. Zielenski), C. Muscara and B. Kinback for secretarial assistance; C. Gerenz, A. Liebman, R. Lopez, J. Pittman and S. Urbano for technical assistance; and A. Bendich, C. Burghardt and S. Burghardt for comments.

Effect of Dietary *trans* Fatty Acids on Some Membrane-associated Enzymes and Receptors in Rat Heart

Syed Q. Alam*, Yun-Fang Ren and **Bassima S. Alam**
Department of Biochemistry and Molecular Biology, Louisiana State University Medical Center, 1100 Florida Ave., New Orleans, LA 70119

Three groups of male weanling Sprague-Dawley rats were fed diets containing 20% corn oil, 20% partially hydrogenated soybean oil (PHSBO) or 18% PHSBO + 2% corn oil. PHSBO contained about 48% of its total fatty acids as *trans*-octadecenoate. Rats were killed after 16–18 weeks of feeding the various diets, hearts were dissected and crude sarcolemma was prepared by differential centrifugation. The activities of ouabain-sensitive (Na^+ + K^+)ATPase were significantly lower in membranes of rats fed 20% PHSBO than the control rats fed 20% corn oil. The feeding of 2% corn oil with 18% PHSBO resulted in partial restoration of the enzyme activity. The maximum number of [^{3}H]ouabain-binding sites (B_{max}) was also lower in cardiac membranes of rats fed 20% PHSBO than those fed 20% corn oil. Similar to (Na^+ + K^+)-ATPase activity, some restoration of the number of [^{3}H]ouabain-binding sites was observed when 2% corn oil was fed with 18% PHSBO-containing diet. There was no difference in the binding affinity of the radioligand for the receptor among the 3 dietary groups. Adenylate cyclase activities (fluoride-, isoproterenol- and forskolin-stimulated) were lower in membranes of rats fed 20% PHSBO or 18% PHSBO + 2% corn oil than in the control group fed 20% corn oil. Density of the β-adrenergic receptor was the lowest in cardiac membranes of rats fed 20% PHSBO. The feeding of 2% corn oil with 18% PHSBO resulted in partial restoration of the maximum number of [^{3}H]dihydroalprenolol (DHA)-binding sites. The affinity of the binding sites was, however, not affected by the type of the dietary fat. The results of this study suggest that dietary *trans* fatty acids can affect the activities of (Na^+ + K^+)ATPase and adenylate cyclase and the density of digitalis and β-adrenergic receptors in rat heart.
Lipids 24, 39–44 (1989).

Because the type and the level of dietary fat is known to affect cardiovascular health and disease, there is a great deal of interest in understanding the mechanism of action of the dietary fats at the cellular level. Some of the cellular effects of dietary lipids on heart function may be exerted by their ability to induce changes in the structural lipids of cardiac sarcolemma. A number of studies have shown that the dietary lipids can influence the lipid composition of cardiac membranes (1–7). The diet-induced structural changes in membrane lipids were associated with modification of membrane-associated enzymes and receptors (1,4–8).

(Na^+ + K^+)ATPase and adenylate cyclase are membrane-associated enzymes, the activities of which have been shown to be dependent on the nature of the membrane lipids. Diet-induced changes in membrane lipids have been correlated with alterations in the activities of (Na^+ + K^+)ATPase (9–14) and adenylate cyclase in several tissues (1,4–8,15,16–18). However, there are few studies on the diet-induced changes in cardiac adenylate cyclase system. In one study, Wince and Rutledge (7) reported a decrease in adenylate cyclase activity in atrial homogenates of rats fed sunflower oil relative to the coconut oil. The K_D and B_{max} of [^{3}H]dihydroalprenolol (DHA)-binding sites were also decreased in atrial homogenates from rats fed sunflower oil. We have shown that the activity of adenylate cyclase was reduced and the characteristics of β-adrenergic receptors were altered in essential fatty acid (EFA) deficiency in rat heart (19). In another study (20) we found that the feeding of diets containing 10% menhaden oil, a rich source of ω3 fatty acids, resulted in an increase in adenylate cyclase activity and in the density of [^{3}H]forskolin-binding sites. In both of the above studies, there were changes in the fatty acid composition of cardiac membranes. An increase in catecholamine-stimulated adenylate cyclase activity with dietary cholesterol-supplementation and a reduction in the number of β-adrenergic receptors in rat heart also have been reported (4). The adenylate cyclase activity and β-receptor concentration was not affected by the dietary lipids (sunflowerseed oil vs sheep kidney fat) in this study. A similar increase in cardiac adenylate cyclase activity with a concomitant decrease in β-adrenergic receptor content has been reported recently in marmoset monkeys as a result of feeding diets supplemented with sheep kidney fat (6). These changes in adenylate cyclase system were attributed to alterations in the membrane cholesterol to phospholipid ratios.

trans Fatty acids, the geometric isomers of naturally occurring *cis* fatty acids, can also induce changes in membrane lipids. We have reported their incorporation into the exocrine gland membrane lipids (21–23) and changes in adenylate cyclase system (22,23). The purpose of the present study was to determine the effects of feeding diets containing *trans* fatty acids on cardiac adenylate cyclase and (Na^+ + K^+)ATPase activities and on β-adrenergic and digitalis receptors.

MATERIALS AND METHODS

All the dietary ingredients were purchased from TEKLAD (Madison, WI). Partially hydrogenated soybean oil (PHSBO) was supplied by Kraft, Inc. (Glenview, IL). All organic solvents were of nanograde and were obtained from Mallinckrodt (Paris, KY). All the biochemical reagents were purchased from Sigma Chemical Co. (St. Louis, MO). Cyclic [^{3}H]AMP (41 Ci/mmol), 1-[propyl-2,3-^{3}H]dihydroalprenolol (55 Ci/mmol) and [^{3}H]ouabain (42 Ci/mmol) were purchased from Amersham (Arlington Heights, IL). α[^{32}P]ATP (619–650 Ci/mmol) was obtained from ICN (Cleveland, OH).

Three groups of male weanling Sprague-Dawley rats (Holtzman Co., Madison, WI) were fed ad libitum semipurified diets containing 20% corn oil, 20% PHSBO or

Abbreviations: DHA, dihydroalprenolol; EFA, essential fatty acid; FAME, fatty acid methyl ester; PHSBO, partially hydrogenated soybean oil; A-TLC, argentation-thin layer chromatography.

18% PHSBO + 2% corn oil. The diets were similar to the AIN-76A (24,25), except for high fat and sucrose content. Composition of the diets, including the fatty acid composition of the dietary lipids, has been reported (23). PHSBO contained about 48% of the total fatty acids as *trans* octadecenoic acid (t-18:1).

Rats were decapitated after 16–18 wk of feeding the various diets, hearts were dissected, washed several times with ice-cold physiological saline, chopped into small pieces with scissors and homogenized in a Potter-Elvejhem homogenizer with 9–10 volumes of a buffer containing 0.32 M sucrose, 0.05 M Tris-buffer, pH 7.4 and 1 mM $MgCl_2$. The homogenates were filtered through four layers of cheese cloth, and crude sarcolemmal membranes were prepared by differential centrifugation (26). The purity of the membrane preparations was determined by monitoring 5′-nucleotidase activity using the method of Aronson and Touster (27). The mitochondrial contamination was measured by succinic dehydrogenase activity (28) and microsomal contamination by glucose-6-phosphatase activity (27).

The crude cardiac sarcolemma prepared by the above method was used for all the studies (adenylate cyclase activity, β-receptor, fatty acid analyses and $Na^+ + K^+$-ATPase activities) except those for [^{3}H]ouabain binding studies. The latter were conduced in membranes prepared in an identical manner, except the tissues were homogenized in the presence of 0.1% Na-deoxycholate. The purpose of including 0.1% Na-deoxycholate in the homogenization medium was to expose all the potentially available binding sites in membranes which otherwise remain masked (29,30). In addition to measuring the [^{3}H]-ouabain-binding sites, ($Na^+ + K^+$)ATPase activities were also measured in membranes prepared in the presence of 0.1% deoxycholate.

Adenylate cyclase activity was measured in triplicate samples of the membranes (50 μg protein) by monitoring the conversion of α[^{32}P]ATP to cyclic-[^{32}P]AMP using the procedure of Sinensky et al. (31). The product, cyclic [^{32}P]AMP, was isolated by sequential column chromatography using Dowex and Alumina columns (32). Cyclic [^{3}H]AMP was added prior to column chromatography to monitor the recovery of cyclic [^{32}P]AMP. Details of the assay procedure have been described (18).

Beta-receptor-binding assays were performed by incubating 150–350 μg of the membrane protein (in duplicate) with 0.5 to 20 nM [^{3}H]DHA in a final volume of 0.5 ml of the incubation buffer (50 mM Tris-HCl, 10 mM $MgCl_2$, pH 7.4) for 15 min, followed by a rapid filtration on Whatman GF/A glass fiber filters, washing the filters three times, each with 4 ml of ice-cold buffer. Filters were dried and counted in a Liquid Scintillation Spectrometer (Beckman LS6800). The specific binding of [^{3}H]DHA is defined as the difference between the total binding and the amount bound in the presence of 1 mM alprenolol. The average ratio of the specific bound vs the nonspecific bound was about 2.8. The dissociation constants (K_d) and the receptor number of the binding sites (B_{max}) were determined using Scatchard plots (33) which were compiled from the specific binding data, with lines being fitted by linear-regression analysis.

($Na^+ + K^+$)ATPase activity was determined in homogenates and membranes by measuring the release of inorganic phosphate after incubation of the membranes (20–50 μg protein) in the presence of 3 mM Tris-ATP, 130 mM NaCl, 20 mM KCl and 3 mM $MgCl_2$, with and without 1 mM ouabain. Ouabain-sensitive activity was calculated by subtracting the amount of Pi released in the presence of 1 mM ouabain (Mg^{2+}-ATPase activity) from the total activity measured in the absence of ouabain. Homogenates or membranes were preincubated in the presence of all other reagents for 5 min at 37°C. Then Tris-ATP was added and the incubation carried out for 10 min. The reaction was stopped by adding 0.2 ml of 50% cold TCA. The protein precipitate was removed by centrifugation at 4000 × *g* for 10 min at 4°C. The supernatant was used for measuring the concentration of Pi by colorimetric assay, which was a modification (27) of the method of Fisk and Subbarow (34). The reaction was linear with respect to the time of incubation and the concentration of the protein.

The characteristics of digitalis receptor were studied by measuring the binding of [^{3}H]ouabain to the cardiac membranes prepared with 0.1% Na-deoxycholate, according to the method of Lin and Akera (35). Assays were initiated by adding 100–300 μg of the membrane protein to an incubation mixture containing 1 mmol Tris-inorganic phosphate (orthophosphoric acid titrated to pH 7.4 with Tris-base), 1 mM $MgCl_2$, 10 mM Tris-HCl buffer (pH 7.4) and [^{3}H]ouabain in a final volume of 500 μl. Nonspecific binding was measured in the presence of 6 mM nonlabeled ouabain. All samples were assayed in duplicate or triplicate. The incubation was carried out for 5 min at 37°C with gentle shaking and terminated by immersing the reaction mixture in ice-water followed by rapid vacuum-filtration of the contents through GF/A glass fiber filters. The filters were washed 3 times with the 4-ml portions of the ice-cold incubation buffer, dried and counted. The dissociation constants and the maximum number of the binding sites were calculated by Scatchard analysis, as described above for DHA binding.

Protein was measured by the method of Lowry et al. (36) using bovine serum albumin as a standard.

Lipids were extracted from aliquots of homogenates and membranes with chloroform-methanol by the method of Bligh and Dyer (37). Phospholipids were separated from the neutral lipids by column chromatography on Bio-Sil A columns. Aliquots of total lipids and phospholipids were transesterified with boron trifluoride methanol (38), and the fatty acid composition of the methyl esters was determined by argentation-thin layer chromatography (A-TLC) and gas chromatography (GC) as described (21). Fatty acid methyl esters (FAME) were identified by comparison with the retention times of known standards using 2 different columns, a packed column, 15% Silar 10 C on Gas chrom Q (12 ft × 2.0 mm i.d.) and a megabore capillary column, DBWAX (12 m × 0.53 mm i.d., J and W Scientific, Folsom, CA). The former was run at 220 and 230°C, whereas the latter was temperature programmed from 60–220°C at 8°C/min and held at this temperature for 20 min.

RESULTS

Body weight gains of rats fed the diet containing 20% PHSBO were lower than those fed the control diet, 20% corn oil. The feeding of 2% corn oil with 18% PHSBO

restored most of the weight gain to the control levels. These data have been reported (23).

There was a 6-8-fold enrichment in 5′-nucleotidase activity in the membranes over that of the homogenates. There was no significant difference in the relative purity of the membranes among the 3 dietary groups. No mitochondrial contamination was detected, as shown by the absence of succinic dehydrogenase activity. The microsomal contamination, as evaluated by glucose 6-phosphatase activity, was 3-4%. Similarly, there was no difference in the yield of membrane protein among the 3 dietary groups.

The feeding of diets containing PHSBO resulted in the incorporation of *trans*-octadecenoate, the main geometric isomer in PHSBO, in the cardiac membrane phospholipids (Table 1). This fatty acid constituted 9-11% of the total fatty acids in the total phospholipids of membranes. A similar degree of incorporation of t-18:1 was observed in total lipids of the membranes (data not shown).

There were changes in the fatty acid patterns of total phospholipids of cardiac membranes of rats fed 20% PHSBO and of those fed 20% corn oil. Increases in the levels of 16:1 and *cis* 18:1 and decreases in the levels of 16:0 DMA, 16:0, 18:0 and 18:2 were generally observed in cardiac membranes of rats fed 20% PHSBO compared to those fed 20% corn oil. Also, 20:3 ω9 constituted 4.4% of the total fatty acids in membranes of the 20% PHSBO group, whereas it made up less than 1% of the total fatty acids in the other 2 groups. The inclusion of 2% corn oil with the 18% PHSBO diet resulted in restoring most of the fatty acid levels to those of the control group fed 20% corn oil. The levels of 20:4 were higher in cardiac membranes of rats fed 18% PHSBO + 2% corn oil than the other two groups. The double bond index of the total fatty acids in the membrane phospholipids was not significantly different among the 3 dietary groups.

TABLE 1

Fatty Acid Composition of Total Phospholipids of Cardiac Membranes of Rats Fed Diets Containing PHSBO and Corn Oil

Fatty acid	20% Corn oil	20% PHSBO	18% PHSBO + 2% corn oil
16:0 DMA	2.7 ± 0.4[a]	1.5 ± 0.3[b]	1.9 ± 0.1[a,b]
16:0	17.4 ± 1.4[a]	10.4 ± 0.6[b]	12.2 ± 0.7[b]
16:1	0.7 ± 0.1[a]	1.7 ± 0.3[b]	1.9 ± 0.2[b]
18:0 DMA	1.6 ± 0.3[a]	1.5 ± 0.3[a]	2.1 ± 0.1[a]
18:0	21.8 ± 0.6[a]	18.5 ± 1.2[b]	17.8 ± 0.7[b]
c-18:1	7.4 ± 0.7[a]	19.2 ± 1.0[b]	12.7 ± 0.8[c]
t-18:1	—[a]	9.4 ± 0.6[b]	10.8 ± 0.7[b]
18:2	19.5 ± 0.6[a]	14.1 ± 0.7[b]	13.5 ± 0.5[b]
20:2	0.5 ± 0.2[a]	0.2 ± 0.1[a]	0.3 ± 0.2[a]
20:3 ω9	0.7 ± 0.1[a]	4.4 ± 0.5[b]	0.9 ± 0.2[a]
20:3 ω6	0.2 ± 0.1[a]	0.7 ± 0.2[a]	0.4 ± 0.2[a]
20:4	14.7 ± 0.5[a]	14.0 ± 0.8[a]	19.3 ± 1.1[b]
22:4	1.1 ± 0.1[a]	0.8 ± 0.3[a]	0.7 ± 0.3[a]
22:5	2.2 ± 0.3[a]	1.5 ± 0.4[a]	1.8 ± 0.1[a]
22:6	2.1 ± 0.3[a]	0.8 ± 0.1[a]	1.6 ± 0.4[a]
Double bond index	136.6 ± 4.8[a] (136.6 ± 4.8)[a]	135.3 ± 5.4[a] (144.7 ± 5.4)[a]	144.6 ± 8.0[a] (155.4 ± 8.0)[a]

Values are in area percentage, mean ± SE of 3 analyses/group; — indicates trace. Values with different superscripts in the same row are significantly different ($P < 0.05$) from each other using Newman-Keul's test.

Double bond index = sum of (% fatty acid × number of double bonds). Values in parentheses designate double bond index calculated with t-18:1 as an unsaturated fatty acid.

DMA, dimethylacetal.

The activities of ouabain-sensitive $(Na^+ + K^+)$ATPase, Mg^{2+}-ATPase and 5′-nucleotidase in cardiac homogenates and membranes of rats fed the 3 diets are shown in Table 2. $(Na^+ + K^+)$ATPase activity in homogenates and membranes of rats fed 20% PHSBO was only 35-40% of that in the control group fed 20% corn oil. The feeding of 2% corn oil with 18% PHSBO resulted in partial restoration of the enzyme activity. A similar trend, but to a lesser degree, was also observed in Mg^{2+}-ATPase activity in cardiac homogenates. An opposite trend in Mg^{2+}-ATPase activity was observed in membranes of rats fed 20% corn oil vs those fed PHSBO. Due to a large variation, however, these differences in Mg^{2+}-ATPase activities were not significant. There was no significant difference among the 3 dietary groups in 5′-nucleotidase activity in homogenates or membranes. Similar differences were observed in $(Na^+ + K^+)$ATPase and Mg^{2+}-ATPase activities of cardiac homogenates and membranes prepared in the presence of 0.1% Na-deoxycholate (data not shown).

The results of receptor-binding studies are shown in Table 3. There was no significant difference in binding affinity of [^{3}H]ouabain in the cardiac membranes among the 3 groups. The maximum number of the binding sites, however, was the lowest in membranes of rats fed 20% PHSBO. The feeding of 2% corn oil with 18% PHSBO resulted in partial restoration of the B_{max} to that of the control group. There was a decrease in the density of β-receptors as evaluated by [^{3}H]DHA binding in membranes of rats fed 20% PHSBO compared with those fed 20% corn oil. The inclusion of 2% corn oil with the PHSBO diet resulted in partial restoration of the β-adrenergic receptor concentration to that of the control levels. Due to large variations in B_{max} from one experiment to another, the results of the combined experiments do not show a significant difference among the 3 dietary groups. However, in each experiment, the B_{max} was lower in the membranes of rats fed 20% PHSBO than those fed 20% corn oil. If the value for B_{max} in the control (20% corn oil) group is set at 100%, the comparative values for the 20% PHSBO group were 59 ± 9%, and those for 18% PHSBO + 2% corn oil group were 88 ± 7%. This type of consistent trend was not observed in the affinity of the binding sites.

Data on adenylate cyclase activity are presented in Table 4. There was no significant difference in the basal activity. However, fluoride-, isoproterenol- and forskolin-stimulated adenylate cyclase activity was generally lower in cardiac membranes of rats fed 20% PHSBO than those fed 20% corn oil. Unlike the $(Na^+ + K^+)$ATPase activity, however, the feeding of 2% corn oil with the 18% PHSBO did not restore the adenylate cyclase activity, which was still lower than that in cardiac membranes of the control rats fed 20% corn oil.

DISCUSSION

The incorporation of *trans* fatty acids into animal and human tissues (39), their metabolism, biological and nutritional effects have been extensively studied (40). Most of the studies show that *trans* fatty acids, which are

TABLE 2

ATPase and 5′-Nucleotidase Activities in Cardiac Homogenates and Membranes of Rats Fed Diets Containing Corn Oil and PHSBO

	$(Na^+ + K^+)$ATPase[a]		Mg^{2+}-ATPase		5′-Nucleotidase	
Diet fed	Homogenate	Membrane	Homogenate	Membrane	Homogenate	Membrane
20% Corn oil	3.5 ±0.5	25.6 ±2.4	34.8 ±0.4	103.1 ±17.4	2.3 ±0.1	14.3 ±1.4
20% PHSBO	1.4[b] ±0.4	9.1[c] ±3.0	31.4[b] ±0.7	168.6 ±36.0	2.0 ±0.1	16.0 ±0.7
18% PHSBO + 2% corn oil	2.4 ±0.3	18.8 ±3.0	32.9[b] ±0.2	143.6 ±27.6	2.2 ±0.1	16.4 ±2.4

[a]Ouabain-sensitive activity which represents the difference between the total activity (measured without ouabain) and the activity measured in the presence of 1 mM ouabain. PHSBO, partially hydrogenated soybean oil.

Values are mean ± SEM of 4 enzyme assays/group; each assay was done in duplicate. Values with superscripts are significantly different from the control group, 20% corn oil, [b]$P < 0.05$, [c]$P < 0.01$, using Student's t test. The specific activities are given as μmol Pi/mg protein/hr.

TABLE 3

Effect of Feeding Diets Containing Corn Oil and PHSBO on the Characteristics of [^{3}H]Ouabain Binding and [^{3}H]DHA Binding Sites in Rat Heart

	K_D		B_{max}	
Diet fed	Ouabain (nM)	DHA (nM)	Ouabain (pmol/mg protein)	DHA (fmol/mg protein)
20% Corn oil	36.7 ± 2.2[a]	5.0 ± 0.7[a]	1.22 ± 0.08[a]	203 ± 31[a]
20% PHSBO	35.4 ± 5.1[a]	3.4 ± 0.7[a]	0.77 ± 0.05[b]	124 ± 32[a]
18% PHSBO + 2% corn oil	33.2 ± 7.0[a]	5.0 ± 1.5[a]	0.99 ± 0.12[a,b]	178 ± 28[a]

Values are mean ± SEM of 4 preparations/group; each was assayed in duplicate or triplicate. Values with different superscripts in the same column are significantly different ($P < 0.05$) using analysis of variance, Newman-Keul's test. PHSBO, partially hydrogenated soybean oil.

TABLE 4

Adenylate Cyclase Activities in Cardiac Membranes of Rats Fed Diets Containing Corn Oil and PHSBO

Diet fed	Basal	+Fluoride	+Isoproterenol	+Forskolin
20% corn oil	23 +1.0	200 ± 6.6	55 ± 2.3	248 ± 22
20% PHSBO	25 ± 1.0	154 ± 5.8[b]	44 ± 2.3[a]	212 ± 10
18% PHSBO + 2% corn oil	20 ± 1.3	161 ± 12.5[a]	45 ± 3.3[a]	178 ± 17[a]

The enzyme activity is shown as pmol cAMP/mg protein/min. The values are mean ± SE of 4 experiments, each done in triplicate. Values with superscripts are significantly different ([a]$P < 0.05$, [b]$P < 0.01$ using Student t test) from the corresponding values in the control group (20% corn oil). The basal activity was measured in the absence of any exogenous activator. Stimulated activity was measured in the presence of 15 mM NaF, 10 μM isoproterenol or 33 μM forskolin. PHSBO, partially hydrogenated soybean oil.

commonly present in foods, do not have any adverse effects on human health, provided the diet contains sufficient amounts of the essential fatty acids. *Trans* fatty acids, like their naturally occurring *cis* isomers, can be incorporated into cell membrane lipids. Therefore, the focus of our study was to determine if some of the membrane properties, such as the activities of membrane-associated enzymes and receptor characteristics, are altered as a result of the incorporation of *trans* fatty acids. $(Na^+ + K^+)$ATPase was chosen in view of its role in cardiac muscle as a receptor for digitalis. Similarly, β-adrenergic-stimulated adenylate cyclase system in heart regulates a variety of physiological processes crucial for heart function.

The feeding of a diet containing 20% PHSBO may have caused a marginal EFA deficiency as shown by an accumulation of 20:3 ω9 and 20:3 ω9/20:4, which was 0.3. A ratio higher than 0.4 is a commonly used biochemical index of an EFA deficiency (41). There was no biochemical evidence of an EFA deficiency in terms of fatty acid patterns in cardiac membranes of rats fed 18% PHSBO + 2% corn oil.

Because the double bond index of total fatty acids in membrane phospholipids was the same in the 3 dietary

groups, the decrease observed in $(Na^+ + K^+)$ATPase and adenylate cyclase activity in cardiac membranes of rats fed diets containing *trans* fatty acids cannot be attributed to the membrane fluidity. We have observed a similar lack of correlation between membrane fluidity and cardiac adenylate cyclase activity, both in EFA deficiency (19) and by feeding diets containing different oils (20). In other tissues, such as salivary glands (23) and lacrimal glands (22), we found that membrane fluidity was decreased by feeding diets containing 20% PHSBO. It appears, therefore, that the heart differs from other tissues in terms of having a greater ability to regulate the fluidity of its membranes. There is also some evidence that arachidonic acid levels in the heart, as opposed to the kidney, were not significantly decreased in EFA deficiency (42), which is also consistent with our findings in a marginal EFA deficiency (19) and in the present study by feeding a 20% PHSBO-containing diet.

The decrease in $(Na^+ + K^+)$ATPase activity which was observed in cardiac homogenates and membranes of rats fed 20% PHSBO may be attributed partly to a reduced number of the enzyme molecules as shown by lower B_{max} values for [^{3}H]ouabain-binding and no change in the affinity constants. It is known that, under these experimental conditions, the specific binding of ouabain represents the concentration of the enzyme (43). Whether the synthesis of $(Na^+ + K^+)$ATPase or its degradation was affected by feeding diets containing 20% PHSBO cannot be determined and will need further investigations.

There are two types of ouabain-binding sites, high affinity and low affinity, which have been shown to exist in the heart (44-46). In the present study, we have measured mainly the high affinity binding sites by using the rapid filtration method which has been used to measure [^{3}H]ouabain-binding sites in rat cardiac microsomes (45).

$(Na^+ + K^+)$ATPase is a lipid-dependent enzyme, and the nature of the acyl group, as well as the polar head groups, has been shown to alter its activity (9-14). Therefore, the question is whether the decrease in its activity in membranes of rats fed 20% PHSBO may be due to the diet-induced incorporation of the *trans* fatty acids into membrane phospholipids or by some other mechanism such as the changes in the concentration of the enzyme. Our data on receptor binding using [^{3}H]ouabain would suggest that the number of enzyme units was decreased. Abeywardina et al. (47) have shown that different dietary lipids induced changes in the fatty acid composition of cardiac membranes. However, the specific activity nor the Arrhenius plots for $(Na^+ + K^+)$ATPase were changed. The characteristics of [^{3}H]ouabain-binding sites were not measured in this study. Modulation of ATPase (1) and other membrane-associated enzymes (5) in rat cardiac mitochondria has been reported by feeding diets containing different types and levels of lipids. Changes in enzyme activities were correlated with the changes in membrane phospholipid composition. A decrease in 5′-nucleotidase, phosphodiesterase and p-nitrophenylphosphatase activity in cardiac sarcolemma of rats fed for 4 wk, diets enriched with coconut oil, has been reported (2). The changes in enzyme activities were associated with fatty acid compositional changes in membrane phospholipids. The effects of feeding diets containing *trans* fatty acids on $(Na^+ + K^+)$ATPase have not been studied previously.

Adenylate cyclase system consists of the receptor (R), guanine nucleotide-binding regulatory proteins (G_s and G_i) and the catalytic unit of the enzyme (C). Diet-induced changes in any of these components may theoretically account for the decrease in adenylate cyclase activity which was observed in cardiac membranes of rats fed 20% PHSBO or 18% PHSBO + 2% corn oil, as compared with the control group fed 20% corn oil. The decrease in isoproterenol-stimulated activity in membranes of rats fed PHSBO may be due to the lower density of the β-adrenergic receptor as compared to the control group. However, the fluoride- and forskolin-stimulated activities were also lower in membranes of rats fed PHSBO-containing diets. Because fluoride and forskolin activation of adenylate cyclase does not involve the β-receptor, it is possible that other components of the adenylate cyclase system such as the levels of G proteins (G_s and G_i) or the catalytic unit itself may be altered by the feeding of diets containing PHSBO. Although we did not measure the characteristics of the catalytic unit in this study, in a previous study (20) we found that the number of the catalytic units of the enzyme were increased and the sensitivity of adenylate cyclase to forskolin, which directly binds to the catalytic unit (48-50), was higher in cardiac membranes of rats fed 10% menhaden oil compared with those fed 10% corn oil or 8% coconut oil + 2% corn oil. Our finding of lower adenylate cyclase activity and B_{max} for [^{3}H]DHA in membranes of rats fed 20% PHSBO is consistent with the results of our previous study (19) in which we found that a marginal or severe EFA deficiency was associated with lower adenylate cyclase activity and lower concentrations of the β-adrenergic receptor in rat heart. Also, it lends further support to the notion that the observed decrease in adenylate cyclase activity and in β-receptor concentration in heart of rats fed 20% PHSBO may be due to a concomitant EFA deficiency. However, our finding that in the 18% PHSBO + 2% corn oil group which did not cause an EFA deficiency, the adenylate cyclase activity was significantly lower than in the control group fed 20% corn oil, suggests that some of the effects of PHSBO may be due to *trans* fatty acids. This is an important observation because *trans* fatty acids are present in several foods, especially in partially hydrogenated vegetable oils. To maximize their effects, we used rather high levels of *trans* fatty acids (17-19% of the total calories). Therefore, it would be important to study the effects of feeding lower levels of *trans* fatty acids—4-5% of total calories, which is more common in the western diets—on cardiac adenylate cyclase system. It would also be interesting to study the effects of individual *trans* fatty acids. Because the PHSBO contained about 2% of the total fatty acids as c,t-(t,c or t,t) 18:2 (23), it is conceivable that some of the effects of diets containing PHSBO may be due to these isomeric fatty acids.

[Received May 3, 1988; Revision accepted September 19, 1988]

Effect of Dietary n-3 Polyunsaturated Fatty Acids on Cholesterol Synthesis and Degradation in Rats of Different Ages

Yong-Soon Choi, Shoichiro Goto, Ikuo Ikeda and Michihiro Sugano*
Laboratory of Nutrition Chemistry, School of Agriculture, Kyushu University, 46-09, Fukuoka 812, Japan

Male Sprague-Dawley rats four weeks or eight months of age were fed purified diets containing 10% fat, either as a blend of safflower oil and palm olein (polyunsaturated fatty acids, PUFA, 34%), a blend of linseed oil and palm olein (PUFA, 33%) or sardine oil (PUFA, 33%) for four weeks. In other trials, sterol contents were made equivalent by supplementing cholesterol to a blend of corn oil and palm olein (PUFA, 30%) or phytosterol to sardine oil (PUFA, 30%). Fish oil was hypolipidemic in rats of different ages, but it tended to increase liver cholesterol in adult animals and this was not improved by the addition of phytosterol. The age-dependent increase in liver cholesterol was not duplicated in rats fed a vegetable fat blend supplemented with cholesterol. At both ages, liver 3-hydroxy-3-methylglutaryl coenzyme A reductase activity was lower in the sardine oil than in the other groups. There were no significant age- or diet-related differences in the activity of liver cholesterol 7α-hydroxylase. Fecal steroid excretion was comparable in age-matched rats fed diets supplemented either with cholesterol or phytosterol. Sardine oil reduced the Δ6-desaturase activity markedly as compared with linseed oil, and age-dependent reduction of the desaturase activity was observed in all dietary groups examined. Thus, the results showed a specific effect of fish oil on lipid metabolism.
Lipids 24, 45-50 (1989).

Evidence for the beneficial effect of fish oils rich in n-3 polyunsaturated fatty acids (PUFA), compared with vegetable oils, in the prevention of hyperlipidemia has been accumulating in experimental animals as well as humans, although it is still controversial (1-3).

An elevation of the serum cholesterol level with age is one of the major risk factors to atherosclerotic coronary heart disease in aged animals including humans (4,5). In this context, fish oil may be of value in preventing an age-dependent increase in serum lipid levels. Nevertheless, the effect of dietary fish oil on the cholesterol homeostasis in aged animals is not fully understood (6). Previously, we observed that the response of the hepatic cholesterol homeostatic mechanism to dietary cholesterol diminishes with age, whereas the susceptibility to dietary fat type is enhanced (7,8). In order to compare the possible effect of fish oil on lipid metabolism in aged rats, the difference in the fatty acid composition was confined in the present study to that of PUFA.

Abbreviations: CPO, a blend of corn oil and palm olein (4:6); HMG-CoA reductase, 3-hydroxy-3-methylglutaryl coenzyme A reductase; LDL, low density lipoprotein; LPO, a blend of linseed oil and palm olein (3:7); PUFA, polyunsaturated fatty acid; SDO, sardine oil; SPO, a blend of safflower oil and palm olein (3:7); GLC, gas liquid chromatography; TLC, thin layer chromatography.

MATERIALS AND METHODS

Animals. Young (3 wk old) and adult (8 mo old) male Sprague-Dawley rats obtained from Japan Charles River (Kanagawa, Japan) were housed individually in a room with controlled temperature and light (20-23°C and 0800 to 2000 hr). After acclimatization for one week, rats were divided into groups of eight each and fed purified experimental diets ad libitum. After 4 wk, rats were decapitated at night (0200 hr). Feces were collected for 2 days, beginning 5 days before killing, and lyophilized.

Experimental diets were prepared according to the recommendation of the American Institute of Nutrition (9): casein, 20; fat, 10; mineral mixture, 3.5; vitamin mixture, 1.0; choline bitartrate, 0.2; DL-methionine, 0.3; cellulose, 5.0; corn starch, 15; and sucrose, 45.0 (in wt %). Vitamin and mineral mixtures were purchased from Oriental Yeast Co. (Tokyo, Japan). To prevent the oxidation of fats, experimental diets were prepared weekly and were packed in a pouch containing an oxygen absorbent (Ageless S-200, Mitsubishi Gas Chemical Co., Tokyo) and stored at 4°C (5). Diets served were changed every day. Safflower oil and linseed oil were products of the Nissin Oil Co. (Tokyo, Japan). Sardine oil (SDO) and palm olein were provided by the Nippon Oil & Fat Co. (Tokyo, Japan) and the Fuji Oil Co. (Osaka, Japan), respectively. Corn oil was the product of the Ajinomoto Co. (Tokyo, Japan). Safflower oil, linseed oil or corn oil were blended with palm olein (3:7 by weight for SPO [safflower oil + palm olein] and LPO [linseed oil + palm olein]), and 4:6 by weight for CPO (corn oil + palm olein) in order to make the total PUFA content equal to that of sardine oil. In Experiment 1 the sterol content was not adjusted, in order to learn the effect of the fat itself. In Experiment 2, in order to exclude the possible effect of sterols on lipid metabolism, cholesterol was added to CPO and plant sterols (β-sitosterol from soybean) to SDO, so that plant and animal sterol contents were similar in each diet. The crystalline sterols were dissolved in fat at 37°C. By gas liquid chromatographic (GLC) analysis, the content of plant sterols was 0.16% (campesterol, 20; β-sitosterol, 58; and stigmasterol, 22%), 0.22% (campesterol, 25; β-sitosterol, 49; and stigmasterol, 26%) and 0.52% (campesterol, 26; β-sitosterol, 73; and stigmasterol, 1%) for SPO, LPO and CPO, respectively. The cholesterol content of SDO was 0.31 and 0.59% in Experiments 1 and 2, respectively. β-Sitosterol (Sigma Chemical Co., St. Louis, MO) added in SDO was composed of 37% campesterol and 61% β-sitosterol. Fatty acid compositions and sterol contents of dietary fats are shown in Table 1.

Materials. DL-3-Hydroxy[3-^{14}C]methylglutaric (HMG) acid (52 mCi/mmol) and [1-^{14}C]linoleic acid (59 mCi/mmol) were obtained from Amersham International plc. [4-^{14}C]Cholesterol (57.5 mCi/mmol) was purchased from New England Nuclear (Boston, MA). Radioactive HMG-CoA (5,000 dpm/nmol) was prepared as described elsewhere (10). Radioactive cholesterol and linoleic acid were purified by thin layer chromatography (TLC) prior to use (11). All reagents used were analytical grade.

SDO	7.5	17.2	7.1	2.3	14.2	1.3	0.9	3.4	8.1	13.5	6.0	1.6	9.4

Experiment 1: SPO, safflower oil + palm olein (3:7 by weight) containing 0.16% phytosterol; LPO, linseed oil + palm olein (3:7 by weight) containing 0.22% phytosterol; and SDO, sardine oil containing 0.31% cholesterol. The sterol content was not adjusted in Experiment 1. Experiment 2: CPO, corn oil + palm olein (4:6 by weight) containing 0.52% phytosterol and SDO, sardine oil containing 0.59% cholesterol. The sterol content of each fat was adjusted in Experiment 2.

Analyses. The activities of HMG-CoA reductase, cholesterol 7α-hydroxylase and Δ6-desaturase in liver microsomes were measured as described previously (7,8). Serum, liver and microsomal lipids were extracted, and cholesterol, triglyceride and phospholipid were measured (10). The fatty acid composition of microsomal phosphatidylcholine was analyzed by GLC (8). Fecal neutral (12) and acidic steroids (13,14) were analyzed by GLC using 5α-cholestane (Nakarai Chemicals, Kyoto, Japan) and 23-nor-deoxycholic acid (Steraroids Inc., Wilton, NH) as an internal standard, respectively. Sterol contents in dietary fats were also analyzed by GLC (12). Microsomal cholesterol was determined enzymatically (8) and protein by the method of Lowry et al. (15).

Data were analyzed by Student's t-test to examine the age-effect between the same dietary group or a one-way analysis of variance followed by Duncan's multiple range test to inspect all differences within the same age group (16).

RESULTS

In both experiments, food intake and weight gain were comparable in age-matched rats. Relative liver weight (g/100 g body weight) was also comparable in Experiment 1, although in Experiment 2, it was slightly (but significantly) higher in the SDO groups of young, but not adult, rats (Table 2).

Table 3 shows concentrations of serum lipids. No significant age-dependent increase in the lipid level was found in both experiments, except for serum cholesterol in rats fed SDO in Experiment 2. In Experiment 1, the concentration of serum cholesterol was lower in the SDO than in the SPO and LPO groups regardless of age. The effect of fat type on the triglyceride level was more marked in adult than in young rats; it was significantly higher in adult rats fed fat rich in n-6 PUFA than in those fed fats rich in n-3 PUFA. A similar response was observed in phospholipid. These trends were essentially duplicated even when sterol contents were made equivalent (Experiment 2).

Table 4 shows concentrations of liver lipids. In Experiment 1, the liver cholesterol level was comparable among the groups of young rats, whereas it was considerably higher in the SDO than in the SPO and LPO groups among adult rats. In Experiment 2, the liver cholesterol level was significantly lower in young rats fed SDO than in those fed CPO, whereas no fat-dependent difference was found in adult rats due to an age-dependent increase in the former. The increase in liver cholesterol was attributable mainly to that of esterified cholesterol. In Experiment 1, there was no significant fat- or age-effect in esterification of liver cholesterol. However, in Experiment 2, a significant fat-dependent response was observed in esterification of liver cholesterol in young rats (young, 56.3 $\pm$ 3.2 and 34.2 $\pm$ 3.8 and adult, 49.5 $\pm$ 2.7 and 42 $\pm$ 3.6% of total liver cholesterol, for CPO and SDO, respectively). The concentration of triglyceride, especially in young rats, was low in the SDO group. An age-dependent increase in liver triglyceride was marked in rats fed n-3 PUFA fats in both experiments. There was a slight but significant difference in the concentration of phospholipid due to dietary fats. A significant age-related reduction of phospholipid was observed only in the SDO group in Experiment 1.

Table 5 shows the specific activity of HMG-CoA reductase, cholesterol 7α-hydroxylase and Δ6-desaturase of liver microsomes. In Experiment 1, there was a trend toward decreasing the HMG-CoA reductase activity with age, although the difference was not significant. In both ages, the reductase activity tended to be lower in the SDO than in the other groups. Cholesterol 7α-hydroxylase activity was comparable regardless of age or diet. There was a significant age-dependent decrease in the activity of Δ6-desaturase in all groups of rats. The desaturase activity was markedly higher in the LPO than in the SDO and SPO groups in both ages, that of the latter two groups being comparable. The microsomal cholesterol content was not influenced either by diet or age. In Experiment 2, the activity of HMG-CoA reductase tended to be higher in the CPO than the SDO groups, but no age-associated change was observed. Cholesterol 7α-hydroxylase activity was again comparable regardless of diet or age.

Table 6 shows the fatty acid composition of phosphatidylcholine of liver microsomes in Experiment 1. There was a detectable difference in the composition of PUFA

Values are mean ± SE of eight rats. Fatty acids less than 1% are excluded.

[a,b,c]In age-matched rats, values in the same line without common superscript letters denote significant difference ($p < 0.05$).

*Significantly different ($p < 0.05$) than the corresponding young rats. 18:2 metabolites include 20:3, 20:4 and 22:5n-6. See Table 1 for abbreviations.

due to the source of dietary fats, both the ratio of n-3 to n-6 PUFA and of the linoleate metabolites to linoleate being markedly different. In the SDO group percentages of n-6 PUFA increased, whereas those of n-3 PUFA decreased with age. A similar tendency was observed in the LPO group. On the contrary, in the SPO group, the percentage of 18:2n-6 and 22:6n-3 increased and that of 22:5n-6 decreased in relation to age. The ratio of linoleate metabolites to linoleate decreased significantly with age in rats fed SPO or SDO, but not in those fed LPO.

As Table 7 shows, the weight of dried feces was higher in the CPO than in the SDO groups, especially in young rats. Fecal weight increased with age, reflecting the amount of the diet ingested. Although there was no dietary fat-dependent difference in fecal excretion of neutral steroids, it tended to decrease with age, especially in rats fed a CPO diet. There was no significant difference in the excretion of phytosterol due to diet or age (young, 9.11 ± 0.46 and 7.42 ± 0.93 and adult, 9.61 ± 1.12 and 8.48 ± 0.60 mg/day, for CPO and SDO, respectively). Acidic steroid excretion per day was markedly larger in adults than in young rats, and in the former, it was significantly higher in the CPO than the SDO groups. However, when acidic steroid excretion was expressed as

TABLE 7

Fecal Steroid Excretion in Young and Adult Rats Fed Different Fats (Experiment 2)

	Young		Adult	
(mg/day)	CPO	SDO	CPO	SDO
Fecal weight (g/day)	1.71 ± 0.08[a]	1.40 ± 0.09[b]	2.29 ± 0.05*	1.99 ± 0.1*
Neutral steroids	10.0 ± 0.8	9.95 ± 0.65	8.05 ± 0.37*	7.63 ± 0.86
Acidic steroids	3.60 ± 0.32	3.86 ± 0.39	9.66 ± 0.64[a,]*	6.86 ± 0.31[b,]*
Total steroids	13.6 ± 0.7	13.2 ± 1.1	17.7 ± 0.9*	14.5 ± 1.5

Values are mean ± SE of eight rats.

*Significantly different ($p < 0.05$) than the corresponding young rats.

See Table 1 for abbreviations.

mg/day/kg body weight, there was no significant age- or fat-effect (young, 12.1 ± 1.1 and 13.0 ± 1.6 and adult, 13.9 ± 0.9 and 10.8 ± 1.6 mg/day/kg body weight for CPO and SDO, respectively).

DISCUSSION

Numerous studies have shown a hypocholesterolemic effect of fish oil compared with vegetable oil in rats (1,6, 17–19). Recently, Roach et al. (19) showed that there was no significant difference in the low density lipoprotein (LDL) receptor activity in the liver between rats fed fish oil and safflower oil, and suggested that reduced production rather than reduced uptake from the plasma of LDL cholesterol is responsible for the cholesterol-lowering effect.

In the present study, SDO reduced the serum cholesterol level both in young and adult rats even when compared with a linseed oil blend containing α-linolenic acid. In Experiment 1, aging did not influence the concentration of serum cholesterol in all groups, whereas in Experiment 2 it increased significantly in rats fed SDO. The age-dependent increase might be attributed in part to a higher cholesterol content of fish oil used in this trial than in the preceding experiment. It has been reported that cholesterol homeostatic mechanism in response to dietary cholesterol operates efficiently in young but not in adult rats (7). Although the serum triglyceride level increased with age (4), the triglyceride-lowering effect of SDO seemed to be more efficient in adult than in young rats. LPO exerted an intermediate effect on the serum lipid profile, in agreement with the observation by Suzuki et al. (6), but not with our previous study (8). These results at least indicate an importance of the dietary level of α-linolenic acid in manifesting a desirable effect, especially in adult rats (20).

Conflicting data are available with respect to the concentration of liver cholesterol of young rats fed fish oil (17,18). In the present study, the liver cholesterol level in young rats was comparable among dietary groups in Experiment 1, although SDO contained a small amount of cholesterol. In Experiment 2, in which the dietary cholesterol level was adjusted, the concentration of liver cholesterol remained normal in young rats fed SDO, but increased in young rats fed CPO. In adult rats, however, the liver cholesterol level was comparable in two groups due to the rise in the SDO group with age. These results indicated that the liver cholesterol-lowering ability of SDO is age-dependent. The effect of plant oils was not influenced by aging. Therefore, it is evident that dietary fat and aging interact each other in regulation of hepatic cholesterol homeostasis. Although there was no significant dietary fat- or age-effect in esterification of liver cholesterol (Experiment 1), n-6 fatty acid supplemented with cholesterol provoked a higher esterification of liver cholesterol than did fish oil (Experiment 2), suggesting that n-6 PUFA supplemented with cholesterol increases esterification of liver cholesterol more than fish oil increases it. The low liver triglyceride level in rats fed fish oil may, in part, be attributable either to the low absorption rate (21), reduced lipogenesis (22) or an increased β-oxidation (23), regardless of a low serum triglyceride level.

Fecal steroid excretion appeared to be independent of fat type and age (Table 6). N-3 as well as n-6 PUFA have been reported to enhance biliary steroid excretion compared with saturated fatty acids (8,24). The hypocholesterolemic effect of fish oil, compared to n-6 PUFA, appears at least to be not relevant to the change in fecal steroid excretion (17). Although the age-dependent increase in the bile acid excretion did not parallel the change in the activity of liver cholesterol 7α-hydroxylase, no age-effect was observed on the bile acid excretion when expressed per kg body weight.

Fatty acids of n-3 series, particularly those in fish oil, reduced the activity of liver HMG-CoA reductase compared with the n-6 counterparts irrespective of the addition of cholesterol. The results are consistent with the observation reported by Roach et al. (19). When the diets contained cholesterol, age-related reduction of the reductase activity was not observed, probably due to the feedback regulation by dietary cholesterol. The results suggest the possibility that the hypocholesterolemic effect of fish oil may at least be manifested by the decrease in cholesterol synthesis without largely influencing steroid excretion. It has been reported that there was no close relationship between HMG-CoA reductase activity and bile acid metabolism in rats fed different fats (25).

The significant dependence of Δ6-desaturase on dietary fat type or age was consistent with other reports (8,20,26). The desaturase activity in rats fed a SDO diet was lower

than in those fed diets rich in linoleic or linolenic acid. It has been reported recently that in rats 20:5n-3 and/or 22:6n-3 may act as an analogue of 20:4n-6 in inhibiting Δ6-desaturation by a feedback mechanism (27). The higher desaturase activity in rats fed α-linolenic acid than in those fed linoleic acid may reflect the preference of this type of n-3 PUFA as a substrate (8,20). In fact, a significant proportion of n-3 PUFA such as 20:5, 22:5 and 22:6 was detected in rats fed LPO.

The fatty acid profile of microsomal phosphatidylcholine indicated an alteration of the desaturation systems depending on fat type. Although the ratio of linoleate metabolites to linoleate might reflect the various desaturation systems, Δ6-desaturation seems to be primarily responsible for the change in the ratio (8). Fish oil inhibits liver Δ6- and Δ5-desaturation of n-6 PUFA (28). In the present study, the change in the proportion of 22:5n-6 and 22:6n-3 in the various groups might also imply an inhibition of Δ4-desaturation of both the linoleate and linolenate series, thus suggesting an inhibition of overall desaturation of PUFA.

In summary, the hypolipidemic effect of n-3 PUFA, particularly those in sardine oil, was confirmed even in aged rats, but fish oil exaggerated an accumulation of liver cholesterol with age. Cholesterol occurring in fish oil appeared to influence its metabolic effect. PUFA of the n-3 series inhibited the overall desaturation of n-6 PUFA. These results suggest an interplay among dietary fat, cholesterol and age in maintaining the cholesterol homeostasis.

Mechanisms of Linoleic Acid Uptake by Rabbit Small Intestinal Brush Border Membrane Vesicles

Kit-Yin Ling, Hsin-Yi Lee and **Daniel Hollander***
Division of Gastroenterology, Department of Medicine, University of California, Irvine, California

We examined the initial transport of a long-chain unsaturated fatty acid, linoleic acid, by brush border membrane vesicles isolated from rabbit small intestine. This preparation allowed us to examine the transport of linoleic acid across the brush border membrane without the effect of the unstirred water layer or cytosol binding proteins. Linoleic acid was solubilized in a 2 mM taurocholate solution which did not compromise the functional integrity of the vesicles. Linoleic acid uptake in the range of 1 to 100 μM followed passive diffusion kinetics. Time course study showed that linoleic acid uptake reached maximal levels during the initial 15 seconds. Although the amount of linoleic acid accumulated in the vesicles diminished over the next 30 minutes, the molar quantity was still twentyfold higher than that of D-glucose (6.5 vs 0.33 nmol/mg protein). Uptake of D-glucose by the vesicles demonstrated typical osmotic responsiveness. We found no osmotic effect on linoleic acid uptake. Hypotonic lysis of membrane vesicles loaded with linoleic acid released 40% of the fatty acid. We concluded that a major portion of the accumulated fatty acid was bound to or incorporated into the membrane itself while ca. 40% did traverse the membrane and accumulated in the intravesicular space as nonmicellar aggregates. The known inhibitors of anion transport, diisothiocyanatostilbene and isothiocyanatostilbene did not change the transport of linoleic acid. We conclude that, in the absence of an unstirred layer or cytosol proteins, linoleic acid transport at up to 100 μM concentration is passive with rapid accumulation both by the cell membrane and the lumen of vesicles.
Lipids 24, 51-55 (1989).

Linoleic acid is a major dietary essential fatty acid. Aside from being incorporated into cellular and membrane phospholipids (1), linoleic acid is an important source of energy and is the molecular precursor of dihomo-gamma-linoleic acid and arachidonic acid, which are precursors of prostaglandins synthesis (2,3). Because of the importance of prostanoids in normal physiological functions, the consequences of dietary deficiency or malabsorption of linoleic acid can involve many organs and systems (3). Prostanoid metabolites of linoleic acid may also play a major role in the prevention of peptic disease as seen in the recent decline in incidence and virulence of peptic ulcer disease which has been linked to the marked increase in consumption of linoleic acid-containing vegetable oils in the western world (4).

Very limited information is available regarding the initial mechanism of linoleic acid transport across the lumenal brush border membrane of the small intestine. Most previous studies of intestinal transport of fatty acids in vivo and in vitro have demonstrated that simple diffusion is the main mechanism of absorption which is modified by the resistance of the unstirred water layer and a number of other lumenal factors (5-9). Chow and Hollander (10,11) have shown that the absorption of linoleic acid by either everted gut sacs or perfused small intestinal segments is a concentration-dependent dual transport mechanism. That is, carrier-mediated diffusion and simple diffusion are predominant at low and high lumenal concentration of the substrate, respectively. To bypass the interference of the unstirred water layer, cytosol binding proteins and other physiological variables, Proulx and coworkers have isolated brush border membranes from small intestinal segments to study the uptake of fatty acids, cholesterols and phospholipids in vitro (12-15). They found that lipids were taken up by simple diffusion and were either bound to or incorporated into the membrane bilayers with little accumulation in the vesicular lumen.

In the present study, we used an established membrane vesicle filtration technique (16) to examine the initial transport of linoleic acid across intestinal brush borders using brush border membrane vesicles isolated from rabbit small intestine.

MATERIALS AND METHODS

Chemicals. 1-[^{3}H]-D-glucose was purchased from ICN Radiochemicals (Irvine, CA), and [^{14}C]linoleic acid was purchased from NEN (Boston, MA). Phloridzin, phloretin, 4,4′-diisothiocyananostilbene-2,2′-disulfonic acid (DIDS), 4-acetamido-4′-isothiocyanatostilbene-2,2-disulfonic acid (SITS) and all chemicals for various enzyme assays were obtained from Sigma Chemical Co. (St. Louis, MO). All other chemicals used in the present study were reagent grade.

Isolation of brush border membrane vesicles (BBMV). BBMV were prepared from frozen jejunal and ileal mucosal scrapings of New Zealand white rabbits by a calcium precipitation method described by Stevens et al. (17) with some modifications developed in the laboratory of E. M. Wright (personal communication). All steps were performed at 4°C. Briefly, each gram of thawed mucosal aliquot was suspended in 20 vol of an isolation buffer I (300 mM D-mannitol in 10 mM Tris-HCl buffer, pH 7.0) and homogenized with a Polytron homogenizer (Brinkmann Instruments, Westbury, NY) set at #9 for 30 sec. The mucosal homogenates were centrifuged at 500 g for 5 min. The supernatant was aspirated and saved. Each of the pellets was homogenized again at the same setting for 15 sec in 20 ml of fresh buffer I. After centrifugation at 500 *g* for 5 min, the supernatant was aspirated and pooled with that collected from the previous step. The combined supernatant was then homogenized in a loose-fitting glass/Teflon homogenizer using a Stirrer RZR1 (Wiarton, Ont., Canada) set at #2 for 5 strokes. The pooled

Abbreviations: DIDS, 4,4′-diisothiocyanatostilbene-2,2′-disulfonic acid; LLA, linoleic acid; SITS, 4-acetamido-4′-isothiocyanatostilbene-2,2-disulfonic acid; BBMV, brush border membrane vesicles.

homogenate was then stirred vigorously, while a sufficient amount of 0.1 M CaCl was added to give a final concentration of 10 mM. After continuous stirring for 45 min, the turbid mixture was centrifuged at 4,000 *g* for 5 min. Most organelles except a good portion of the brush border members were discarded in the pellets. The supernatant was then subjected to another centrifugation at 7,500 *g* for 20 min. The supernatant that contained brush border membranes was recentrifuged at 28,000 *g* for 45 min. The pellets were resuspended in an isolation buffer II (300 mM D-mannitol in 10 mM Hepes-Tris, pH 7.4). The suspension was homogenized in a tight-fitting glass/Teflon homogenizer set at #2 for 10 strokes. The brush border homogenate was centrifuged at 30,000 *g* for 60 min. The final BBMV pellets were resuspended in buffer II at a final concentration of 10–12 mg protein per ml. These BBMV were used fresh or stored in 1 ml aliquots in liquid nitrogen (18). The D-glucose and linoleic acid transport activities of these BBMV changed little upon storage.

The purity of BBMV was routinely monitored by marker enzyme assays. Brush border alkaline phosphatase and lysosomal acid phosphatase were determined using *p*-nitrophenyl phosphate as substrate (19). Basolateral membrane Na^+/K^+ ATPase (20) and mitochondrial succinate dehydrogenase (21) were determined according to standard methods. Protein was determined by a modification of Lowry et al. (22) using bovine serum albumin as standards. The BBMV preparation was consistently enriched in alkaline phosphatase, at activity of 10- to 13-fold over that of the mucosal homogenate. It was relatively free of all other subcellular organelles, except a 2- to 5-fold contamination of lysosomal acid phosphatase of that of the mucosal homogenate.

Preparation of linoleic acid incubation media. For the present studies, we solubilized linoleic acid in a taurocholate solution by sonication, as described by Proulx et al. (12), with some modifications. Briefly, the amount of unlabeled linoleic acid that will give a final concentration of 0.5 mM in a 10 ml volume was sonicated with 1 ml of transport buffer (100 mM NaCl, 100 mM D-Mannitol, 1 mM $MgCl_2$, 2 mM $CaCl_2$ and 10 mM Hepes-Tris, pH 7.4) for 2 min in a water-bath sonicator (Laboratory Supplies Co. Inc., Hicksville, NY). The turbid solution cleared up when enough powdered sodium taurocholate was added to give a final concentration of 10 mM in the final volume of 10 ml. After adding another 9 ml of transport buffer, the mixture was sonicated for another 2 min. This sonicated preparation stayed in a clear micellar solution for at least 4 hr and was used as the unlabeled linoleic acid-taurocholate stock solution. The [^{14}C]labeled linoleic acid in ethanol was dried under N_2 and sonicated with an appropriate amount of the unlabeled linoleic acid-taurocholate stock stolution to formulate the final incubation medium. When transport of D-glucose was measured simultaneously, appropriate amounts of [^{3}H]-D-glucose and unlabeled D-glucose were also included.

Transport assays. The uptake of substrate by BBMV at 20°C was determined by the filtration technique described by Hopfer et al. (16). To measure Na^+-dependent D-glucose uptake in the absence of linoleic acid, the transport buffer described in the above section was used. To measure Na^+-dependent D-glucose uptake in the presence of taurocholate, the transport buffer plus specified concentration of the bile acid was used. Uptake assay was initiated by the addition of 100 μl of the radioisotope-labeled incubation medium to 10 μl of BBMV. Incubation was stopped with 2 ml of ice-cold stopping buffer (0.15 M KCl, 2 mM Hepes. Tris, pH 7.4) and 0.6 mM phloridzin for D-glucose uptake (16) and 0.2 mM phloretin for linoleic acid uptake (23). The mixture was rapidly filtered through an HA nitrocellulose 0.45 μm filter (Millipore Corp., Bedford, MA). The filter was rinsed twice with 2 ml of the stopping buffer. The radioactivity associated with the filter was measured in Ultrafluor (National Diagnostic, Manville, NJ) using a Beckman LS9000 liquid scintillation counter (Beckman Instruments, Inc., Palo Alto, CA). Each data point presented in this report was the average value of duplicate samples. The value of each sample was the net radioactivity after subtraction of the nonspecific linoleic acid binding to the filter.

To study the effect of sodium ion on transport activities, either KCl or choline chloride were used in place of NaCl. To study the effect of osmolarity on the accumulation of D-glucose or linoleic acid by BBMV, we added various concentrations of D-mannitol to the final incubation medium. The data presented in the figures represented individual values from a typical experiment as some minor variations do exist between preparations of membrane vesicles.

RESULTS

Effect of taurocholate on D-glucose uptake in BBMV. In the intestinal lumen, dietary fatty acids are present either in mixed bile acids micelles or as free monomers. To mimic these physiological conditions and to ensure that linoleic acid in the incubation medium was in solution, we used taurocholate as the micellarizing agent at a concentration that is well below the intralumenal bile salt concentration of 10–40 mM. Taurocholate is the main component of rat bile and, by comparison with other bile acids, it has been shown to exert the mildest damaging effect on brush border membranes (14).

The ability of BBMV to accumulate D-glucose in the presence of a Na^+-gradient deteriorated with time as the concentration of taurocholate was increased (Fig. 1). For 1 min incubation, taurocholate at 2 mM did not have a

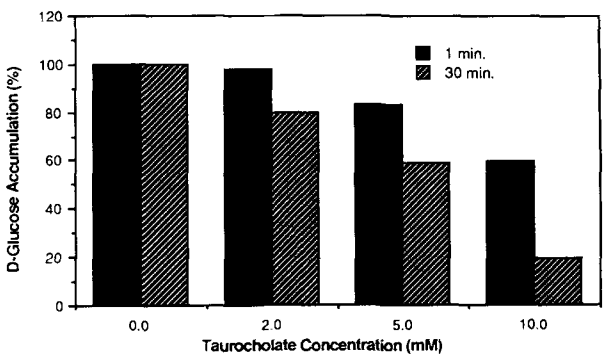

FIG. 1. Effect of taurocholate on D-glucose uptake. BBMV were preloaded with 300 mM D-mannitol in 10 mM Hepes-Tris buffer, pH 7.4. They were incubated at 21°C in a transport medium containing 0.1 mM D-glucose (unlabeled and [^{3}H]labeled), 100 mM NaSCN, 100 mM D-mannitol, 1 mM $MgCl_2$ and 10 mM Hepes-Tris buffer, pH 7.4, plus various concentrations of traurocholate.

detectable effect on D-glucose up to 40%. A 30 min incubation in 2 mM and 10 mM taurocholate caused a decrease of 20% and 80% in D-glucose accumulation in BBMV. These results indicate that taurocholate does affect brush border functions, at least D-glucose transport in a time- and dose-dependent way. We, therefore, limited our studies to linoleic acid concentrations that produced optically clear solutions in a 2 mM taurocholate solution. We also found that the addition of linoleic acid at a concentration of 100 μM had no effect on the uptake of D-glucose by BBMV in the presence of 2 mM taurocholate.

Time course of linoleic acid and D-glucose uptake. When isolated membrane vesicles were incubated simultaneously with labeled linoleic acid and D-glucose, the familiar "overshoot" of D-glucose uptake by brush border membrane vesicles in the presence of sodium gradient was observed (Fig. 2). There was a rapid uptake of D-glucose during the first 90 sec, followed by efflux of D-glucose, which eventually came to equilibrium across the membrane. The initial uptake of linoleic acid was extremely fast and the amount of fatty acid accumulated was much greater than that of D-glucose (Fig. 2). Over the 30 min incubation period, the amount of linoleic acid accumulated in the vesicles diminished, but the value was still 25- to 30-fold greater than the D-glucose accumulation. When the sodium ion in the incubation medium was replaced by potassium or choline, the Na^+-dependent D-glucose overshoot disappeared, but linoleic acid uptake remained unchanged (data not shown). Also, lowering the incubation temperature from 21° to 4°C wiped out D-glucose overshoot and yet did not affect linoleic acid transport.

Uptake of linoleic acid and D-glucose under different osmotic conditions. To determine if the accumulated linoleic acid is bound to the membrane or is being transported into the vesicular lumen or both, two types of experiments were performed. In one, uptake of linoleic acid and D-glucose was measured in incubation media with increasing osmolarity. The uptake of D-glucose after 30 min of incubation decreased linearly with the increase in osmolarity from 200 mOsm to 820 mOsm (Fig. 3A). Extrapolation of the data to conditions of infinite osmolarity demonstrated that little of the accumulation represented binding to the membranes. The amount of D-glucose accumulated changed linearly with the osmolarity in the medium demonstrating that the BBMV we used were sealed and osmotically reactive. Therefore, the D-glucose accumulation can be used for calculating the intravesicular volume by using the concentration of D-glucose in the incubation medium as a reference (24). Based on an accumulation of 329 pmol/mg protein at an initial D-glucose concentration of 0.1 mM after a 30 min incubation, the BBMV have an intravesicular volume of 3.3 μl/mg protein (Fig. 2). This value is well within the range of vesicle size reported for transport studies. Uptake of linoleic acid after 10 min incubation under similar conditions (240 mOsm to 820 mOsm) did not vary with the osmolarity (Fig. 3B). Furthermore, if we used the amount of linoleic acid accumulation after a 30 min incubation (Fig. 2) to calculate the theoretical intravesicular volume, the calculated value was 65 μl/mg protein, a value which is far too large. These results suggest that the observed linoleic acid accumulation was to a large degree due to binding to the membrane rather than intravesicular lumenal accumulation.

In the second experiment, membrane vesicles incubated with linoleic acid were deliberately lysed with ice-cold distilled water (25). Lysis of the vesicles releases the linoleic

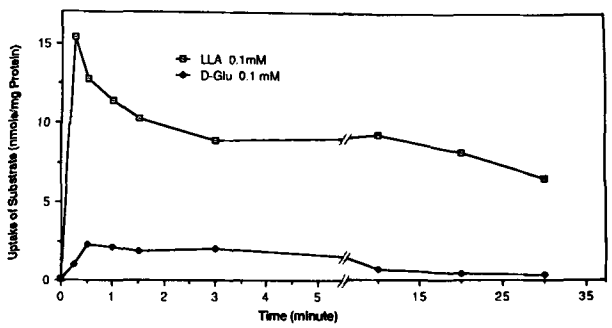

FIG. 2. Time course of D-glucose and linoleic acid (LLA) uptake. BBMV were preloaded with 300 mM D-mannitol in 10 mM Hepes-Tris buffer, pH 7.4. They were incubated at 21°C in transport medium containing 0.1 mM D-glucose (unlabeled and [^{3}H]labeled), 0.1 mM linoleic acid (unlabeled and [^{14}C]labeled), 100 mM NaSCN, 100 mM D-mannitol, 1 MM $MgCl_2$, 2 mM $CaCl_2$, 2 mM taurocholate and 10 mM Hepes-Tris buffer, pH 7.4.

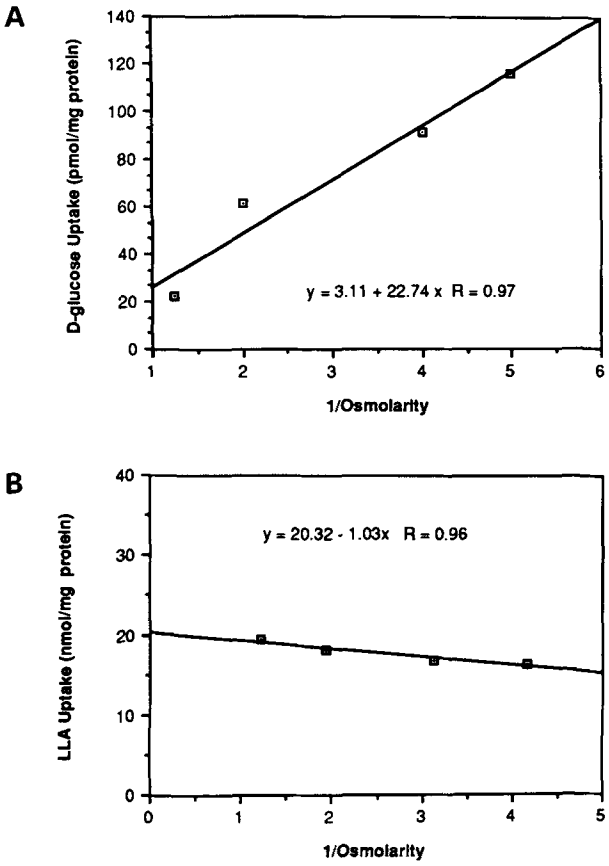

FIG. 3. Effect of increasing osmolarity on the uptake of D-glucose (panel A) and linoleic acid (panel B). BBMV were preloaded with 300 mM D-mannitol in 10 mM Hepes-Tris buffer, pH 7.4. The membrane vesicles were incubated for 30 min at 21°C in uptake media containing either 0.1 mM D-glucose (unlabeled and ^{3}H labeled) or 0.1 mM linoleic acid (unlabeled and ^{14}C labeled) in 100 mM NaSCN, 1 mM $MgCl_2$, 2 mM $CaCl_2$, 2 mM taurocholate, 10 mM Hepes-Tris buffer, pH 7.4, with an appropriate amount of D-mannitol to give the indicated osmolarity.

acid which had accumulated in the lumen of the vesicles. In these experiments, we found a loss of ca. 40% of the accumulated linoleic acid, indicating that 60% of the total linoleic acid is firmly attached to the brush border membranes. Such attachment could be due to tight adsorption to the outer or inner surfaces of the membrane or incorporation into the membrane itself.

Kinetics of uptake of linoleic acid. The rate of linoleic acid uptake increased linearly with increasing concentrations from 10 to 100 μM (Fig. 4). Thus, transport at this range of concentrations was compatible with simple passive diffusion. Although linoleic acid uptake at 25 μM and 100 μM was not affected by DIDS or SITS at inhibitor concentrations up to 5 mM, it was inhibited by 23%, following the addition of 0.2 mM phloretin to the incubation medium.

DISCUSSION

We investigated the initial absorption of linoleic acid by intestinal BBMV isolated from rabbit small intestine. The linear relationship between linoleic acid concentrations and its transport rates (Fig. 4) suggests that linoleic acid absorption in the range of concentrations we studied is a simple diffusion process. This conclusion is further supported by our observation that lowering the incubation temperature had no effect on the transport rate, nor did the inhibitors DIDS and SITS.

Chow and Hollander (10,11) previously demonstrated saturation kinetics of linoleic acid transport in vivo and in vitro, and recently, Stremmel (26) reported a saturable oleate transport in isolated rat jejunal mucosal cells. The study of linoleic acid absorption in everted small intestinal sacs had a reported Km of 0.967 mM (10) in the presence of 10 mM taurocholate. Accordingly, it is only reasonable that we did not observe saturation kinetics in the present experiments, because the highest concentration of linoleic acid we were able to solubilize in the taurocholate solution is much lower than the apparent affinity constant of linoleic acid transport. Others have used 7.2 mM taurocholate in their membrane vesicle uptake study of cholesterol and fatty acids (15). At 7.2 mM, taurocholate caused membrane solubilization and the loss of 5% membrane proteins in 20 min (14,15). In our studies, we found that taurocholate at concentrations greater than 2 mM is damaging to the membrane, as reflected by its effect on glucose transport (Fig. 1). Therefore, we restricted the concentration of taurocholate to 2 mM, which is well below the normal intralumenal concentration of bile acid (10–40 mM) or the critical micellar concentration (2.5 mM), and studied only the concentrations of linoleic acid that can be solubilized in it. If it were not for this limitation in the concentrations of taurocholate and linoleic acid, we perhaps could have also demonstrated saturation kinetics in our present experiments. It is possible that taurocholate could inhibit a carrier-mediated transport system for linoleic acid. Furthermore, inhibition of a possible linoleic acid carrier-mediated transport system could also occur by the incorporation of linoleic acid within the lipid bilayer of the membrane. We found that the addition of 0.2 mM phloretin to the uptake medium inhibited linoleic acid uptake by 20–25%. Phloretin has been shown to inhibit specific membrane transport proteins (27). The partial inhibition of linoleic acid uptake by phloretin suggests that membrane protein could play some role in the initial uptake of linoleic acid, in addition to passive diffusion of the fatty acid across the lipid cell membrane. Thus, the absorption of linoleic acid in vivo could be partly due to a carrier-mediated, facilitated transport mechanism.

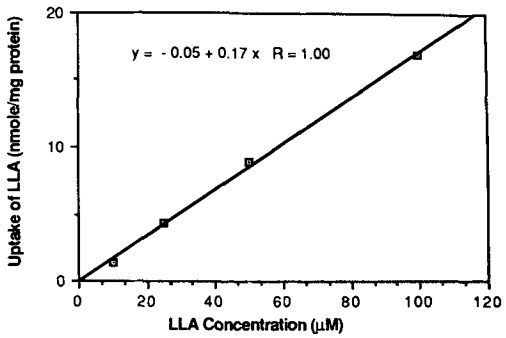

FIG. 4. Effect of linoleic acid concentration on its uptake. BBMV were preloaded with 300 mM D-mannitol in 10 mM Hepes-Tris buffer, pH 7.4. The incubation media were 100 mM NaSCN, 1 mM $MgCl_2$, 2 mM $CaCl_2$, 2 mM taurocholate, 10 mM Hepes-Tris buffer, pH 7.4, plus the specified concentration of linoleic acid (unlabeled and [^{14}C]labeled) and a sufficient amount of D-mannitol to give a final osmolarity of 330 mOsm.

Using D-glucose accumulation in the BBMV as a reference, we calculated that our vesicles have an intravesicular volume of 3.3 μl/mg protein, which is in the same range of vesicle sizes reported in other uptake studies. But using linoleic acid accumulation values gave an apparent vesicular volume of 65 μl/mg protein. This calculation suggests that the majority of the linoleic acid could not have accumulated in the lumen of the vesicles at the same concentration as in the incubation mixture and must have been partly bound to the membrane of the vesicles. The results in Figure 3B showing the lack of response of linoleic acid uptake to changes in osmolarities in the incubation medium also support the idea that a great deal of the linoleic acid is bound to the vesicular membrane.

Although it is not impossible for fatty acids to bind only to the outside surface of membrane vesicles, a variety of fatty acids and lipids had been demonstrated to be incorporated into the lipid bilayer itself (12,13,15,28). Fatty acid transport occurs very rapidly (29). Thus, rapid intercalation of linoleic acid into the membrane, itself, could be substantial enough to compenstate for any reduction in intravesicular accumulation and, hence, account for the lack of measurable osmotic response in total vesicular accumulation of linoleic acid (Fig. 4).

In order to determine how much of the linoleic acid actually accumulates in the vesicular lumen vs how much is bound or incorporated into the membrane, we lysed the vesicles at the end of incubation with ice-cold distilled water to release any fatty acid that did accumulate in the vesicular lumen (25). We found at least 40% of the linoleic acid was released when the vesicles were lysed. These data indicate that 40% of the linoleic acid must have traversed the lipid bilayer of the brush border membrane and accumulated in the vesicular lumen. Because the average intravesicular volume can only accommodate 5–10% of the accumulated linoleic acid if its concentration in the intravesicular compartment had remained the same as in

the incubation medium, the quantity of linoleic acid we found in the vesicular lumen is much higher than expected. One possible explanation for this finding is the formation of linoleic acid aggregates within the vesicular lumen. Taurocholate has a relatively low apparent affinity constant (0.59–0.66 mM) for brush border membranes and is transported by a relatively slow Na^+-dependent active transport mechanism (30). Therefore, even at very high exogenous concentrations, a very limited quantity of taurocholate will traverse across the membrane. The fact that we did not observe any differences in the uptake of linoleic acid whether sodium or potassium ion was present in the incubation medium indicates that, even in the presence of Na^+, the amount of taurocholate entering the vesicular space would not be sufficient to solubilize the linoleic acid accumulated in the vesicular lumen. Therefore, we propose that, once linoleic acid penetrates across the membrane into the vesicular lumen, it does not stay in solution but could precipitate as aggregates in the presence of calcium which accumulated in the lumen (31). The possibility that the vesicular linoleic acid is entrapped as nonsoluble aggregates is in accord with the report by Proulx et al. (15) and Merrill et al. (28) that fatty acids transported into BBMV are not exchangeable with exogenous fatty acids.

By using BBMV, we were able to study the initial uptake of linoleic acid by the cell membrane. This preparation is devoid of unstirred water layer effects and cytosolic proteins that can bind fatty acids. Previously, we demonstrated that fatty acids are absorbed in vivo by a saturable process compatible with a facilitated transport mechanism (10,11). In our in vivo experiments, we were unable to conclude whether saturation was due to unstirred layer effects or, perhaps, due to cytosolic binding proteins. The present experiments allow us to propose that the considerable degree of linoleic acid binding to the brush border membrane could be due in part to binding to membrane proteins. Further studies are needed in order to explore the possibility that brush border membrane proteins could play a role in the absorption of lipids.

ACKNOWLEDGMENTS

We are grateful to E. M. Wright for his help in membrane vesicle isolation, to J. K. Lanyi for discussion and to M. Garner and J. K. Lanyi for critical review of the manuscript. This study was supported by the National Institute of Aging Grant AG-2767 and by the Goldsmith Family Foundation.

Effect of Alcohols on the Oxidation of the Vitamin E Model Compound, 2,2,5,7,8-Pentamethyl-6-chromanol

C. Suarna and **P.T. Southwell-Keely***
Department of Organic Chemistry, University of New South Wales, P.O. Box 1, Kensington, NSW 2033, Australia

The vitamin E model compound, 2,2,5,7,8-pentamethyl-6-chromanol, has been oxidized with *t*-butyl hydroperoxide in chloroform in order to simulate in vivo oxidations due to lipid hydroperoxides. In the presence of a variety of alcohols, ranging from methanol to cholesterol, the corresponding 5-alkoxymethyl-2,2,7,8-tetramethyl-6-chromanols were formed in fair to good yield and were the major products in each reaction.
***Lipids* 24, 56-60 (1989).**

Recent work has shown that, when α-tocopherol (**1a**) (Scheme 1) and its model compound, 2,2,5,7,8-pentamethyl-6-chromanol (**1b**) are oxidized by *t*-butyl hydroperoxide in chloroform to which a small amount of ethanol has been added, the major products are 5-ethoxymethyl-7,8-dimethyltocol (**7a**; R′ = CH_3-CH_2-) and 5-ethoxymethyl-2,2,7,8-tetramethyl-6-chromanol (**7b**; R′ = CH_3-CH_2-), respectively (1). It appears that these products are formed by the oxidation of **1a** and **1b** to a quinone methide intermediate which then adds ethanol. The aim of the present work was to determine whether this reaction was general for all alcohols.

MATERIALS AND METHODS

IR spectra were determined on a Perkin Elmer 580B spectrometer, UV spectra on a Perkin Elmer 124 double beam spectrophotometer, ^{1}H NMR spectra on a Bruker AM 500 spectrometer and electron impact mass spectra on an A.E.I MS 12 mass spectrometer. NMR spectra were taken in $CDCl_3$ and are reported in parts per million downfield from tetramethylsilane as internal standard.

Chloroform was purified by washing with 18 M sulfuric acid, distilled water until the washings were neutral, drying (Na_2SO_4) and distilling immediately before use.

Phytol (Sigma Chemical Co., St. Louis, MO) was used without purification.

t-Butyl hydroperoxide (70%, EGA CHEMIE, Steinheim, West Germany) was purified by the sodium salt method (2). Purity (iodometrically) was 95%.

Cholesterol (E. Merck, Darmstadt, West Germany) was purified by a bromination-debromination procedure (3).

Compound **1b** together with its spirodimer (**5b**) and spirotrimer (**6b**) and 2-(3-hydroxy-3-methylbutyl)-3,5,6-trimethyl-1,4-benzoquinone (**9b**) were prepared as reference compounds by known methods (4-7).

Oxidation of **1b** *by* t-*butyl hydroperoxide.* To **1b** (220 mg, 1.0 mmol) in chloroform (24 ml, containing the respective alcohol (6.0 g) (Table 1) was added *t*-butyl hydroperoxide (91 mg, 1.0 mmol) and the solution refluxed for 3 hr. The solution was then washed with 5% ferrous sulfate solution (2 × 30 ml), distilled water (3 × 30 ml), dried (Na_2SO_4) and the solvent removed in vacuo. The residue was chromatographed on thin layers of Silica Gel GF_{254} (solvent: light petroleum (bp 60-80°C)/ethyl

The reaction mixtures containing 2,2,5,7,8-pentamethyl-6-chromanol (220 mg; 1.0 mmol), *t*-butyl hydroperoxide (91 mg; 1.0 mmol), chloroform (24 ml) and respective alcohol (6 g), were heated at 60°C for 3 hr, washed with 5% ferrous sulfate to destroy unreacted hydroperoxide (2 × 30 ml), water (3 × 30 ml), dried (Na_2SO_4) and the solvent removed in vacuo. The residue from each reaction was chromatographed on thin layers of Silica Gel GF_{254} (solvent: light petroleum (bp 60-80°C)/ethyl acetate (9:1), the products located under UV light, eluted with chloroform, and the solvent removed under a stream of nitrogen and weighed.

*These reactions were performed on half of the above scale.

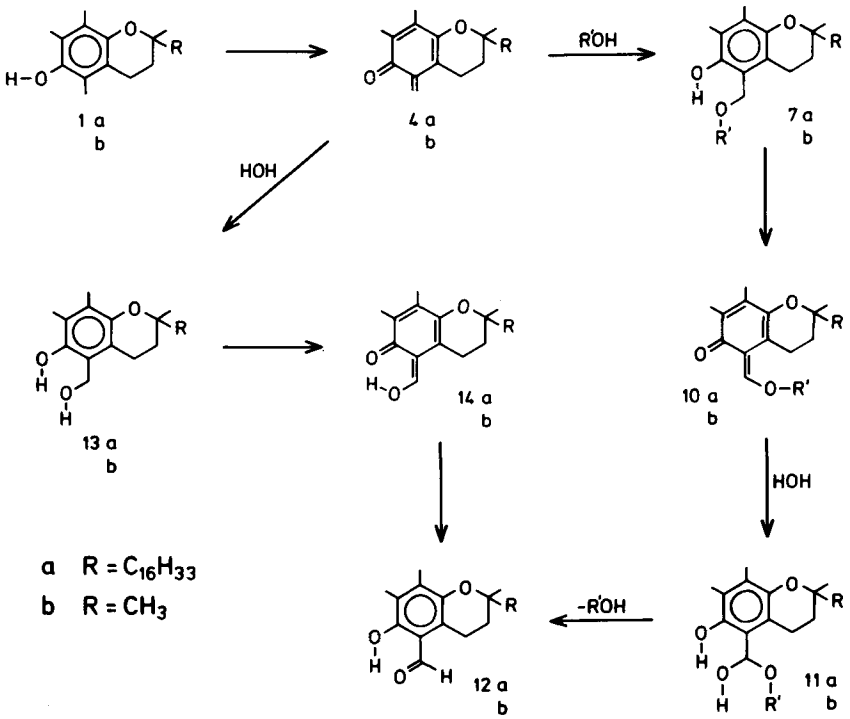
acetate (9:1)), the products located under ultraviolet light, eluted with purified chloroform, the solvent removed under a stream of nitrogen and weighed. The following products were identified by comparison of their ultraviolet and ^1H NMR spectra with those of the prepared reference compounds: **1b** R_f 0.44; **9b** R_f 0.08.

5-Formyl-2,2,7,8-tetramethyl-6-chromanol (**12b**) (Scheme 2) R_f 0.68 was identified by comparison of its UV and ^1H NMR spectra with literature values for the authentic compound (8,9). An additional band was noted at R_f 0.90, which is still under investigation. The following 5-alkoxymethyl adducts of **1b** were identified (Table 1).

5-Methoxymethyl-2,2,7,8-tetramethyl-6-chromanol had UV λ_{max} (hexane) 303 nm (log 3.70); IR (KBr) 3313 (OH), 2982, 2933 (CH_3), 1624, 1455, 1387, 1368, 1276, 1230, 1175, 1132, 1099 (C-O-C), 938, 902, 854, 678 cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.28 (*s*, 6H, 2 × CH_3), 1.77 (*t*, 2H, 3-CH_2, J = 6.9 Hz), 2.11 (*s*, 3H, Ar-CH_3), 2.15 (*s*, 3H, Ar-CH_3), 2.62 (*t*, 2H, 4-CH_2, J = 6.9 Hz), 3.43 (*s*, 3H, CH_3-O-), 4.66 (*s*, 2H, Ar-CH_2-O-), 7.42 (*s*, 1H, OH) ppm; irradiation of the singlet at 4.66 ppm gave a Nuclear Overhauser Enhancement (NOE) on the singlet at 7.42, on the singlet at 3.43 and on the triplet at 2.62 ppm, thus proving that the methoxy group was on position 5 of the chroman ring; MS (ei) *m/z* (rel intensity) 250 $[M]^+$ (34), 218 (100), 203 (75), 189 (24), 175 (78).

5-Propoxymethyl-2,2,7,8-tetramethyl-6-chromanol had UV λ_{max} (hexane) 303 nm (log 3.71); IR (KBr) 3325 (OH), 2974, 2942 (CH_3), 1623, 1463, 1386, 1370, 1277, 1231, 1172, 1130, 1104 (C-O-C), 973, 944, 903, 854, 652 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.96 (*t*, 3H, $\underline{CH_3}$-CH_2-, J = 7.4 Hz), 1.28 (*s*, 6H, 2 × CH_3), 1.67 (m, 2H, CH_3-$\underline{CH_2}$-CH_2-), 1.77 (*t*, 2H, 3-$\underline{CH_2}$, J = 6.9 Hz), 2.11 (*s*, 3H, Ar-CH_3), 2.15 (*s*, 3H, Ar-CH_3), 2.61 (*t*, 2H, 4-CH_2, J = 6.9 Hz), 3.51 (*t*, 2H, -CH_2-$\underline{CH_2}$-O-, J = 6.6 Hz), 4.70 (*s*, 2H, Ar-$\underline{CH_2}$-O-), 7.73 (*s*, 1H, OH) ppm; irradiation of the singlet at 4.70 ppm gave an NOE on the singlet at 7.73, on the triplet at 3.51 and on the triplet at 2.61 ppm, thus proving that the propoxy group was on the 5-position of the chroman ring; MS (ei) *m/z* (rel intensity) 278 $[M]^+$ (22), 218 (100), 203 (63), 189 (18), 175 (61).

5-n-Butoxymethyl-2,2,7,8-tetramethyl-6-chromanol had UV λ_{max} (hexane) 303 nm (log 3.71); IR (KBr) 3320) (OH), 2960, 2925 (CH_3), 1620, 1455, 1380, 1360, 1270, 1225, 1160, 1120, 1095 (C-O-C), 935, 895, 855 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.93 (*t*, 3H, $\underline{CH_3}$-CH_2-, J = 7.4 Hz), 1.28 (*s*, 6H, 2 × CH_3), 1.41 (m, 2H, CH_3-$\underline{CH_2}$-CH_2-), 1.63 (m, 2H, CH_2-$\underline{CH_2}$-CH_2-), 1.77 (*t*, 2H, 3-CH_2, J = 6.9 Hz), 2.11 (*s*, 3H, Ar-CH_3), 2.15 (*s*, 3H, Ar-CH_3), 2.61 (*t*, 2H, 4-$\underline{CH_2}$, J = 6.9 Hz), 3.55 (*t*, 2H, -CH_2-$\underline{CH_2}$-O-, J = 6.5 Hz), 4.70 (*s*, 2H, Ar-$\underline{CH_2}$-O-), 7.73 (*s*, 1H, OH) ppm; irradiation of the singlet at 4.70 ppm gave an NOE on the singlet at 7.73, on the triplet at 3.55 and on the triplet



SCHEME 2

at 2.61 ppm, thus proving that the butoxy group was on the 5-position of the chroman ring; MS (ei) *m/z* (rel intensity) 292 $[M]^+$ (14), 218 (100), 203 (64), 189 (19), 175 (60).

5-(2-Methyl-1-propoxy)methyl-2,2,7,8-tetramethyl-6-chromanol had UV λ_{max} (hexane) 303 nm (log 3.71); IR (KBr) 3330 (OH), 2974, 2945 (CH_3), 1623, 1464, 1387, 1370, 1277, 1231, 1173, 1131, 1101 (C-O-C), 1024, 945, 903, 855, 653 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.95 (d, 6H, 2 × CH_3, J = 6.7 Hz), 1.28 (*s*, 6H, 2 × CH_3), 1.77 (*t*, 2H, 3-CH_2, J = 6.9 Hz), 1.94 (m, 1H, CH), 2.11 (*s*, 3H, Ar-CH_3), 2.15 (*s*, 3H, Ar-CH_3), 2.60 (*t*, 2H, 4-CH_2, J = 6.9 Hz), 3.32 (d, 2H, -CH-$\underline{CH}_2$-O-, J = 6.5 Hz), 4.70 (*s*, 2H, Ar-$\underline{CH}_2$-O-), 7.75 (*s*, 1H, OH) ppm; irradiation of the singlet at 4.70 ppm gave an NOE on the singlet at 7.75, on the doublet at 3.32 and on the triplet at 2.60 ppm, thus proving that the 2-methyl-1-propoxy group was on the 5-position of the chroman ring; MS (ei) *m/z* (rel intensity) 292 $[M]^+$ (20), 218 (100), 203 (48), 189 (14), 175 (48).

5-(2-Methyl-2-propoxy)methyl-2,2,7,8-tetramethyl-6-chromanol had UV λ_{max} (hexane) 303 nm (log 3.75); IR (KBr) 3298 (OH), 2980, 2942 (CH_3), 1639, 1456, 1367, 1270, 1230, 1198, 1169, 1129, 1094, 1044, 999, 931, 894, 858, 820 cm^{-1}; ^1H NMR ($CDCl_3$) δ 1.28 (*s*, 6H, 2 × CH_3), 1.33 (*s*, 9H, 3 × CH_3), 1.76 (*t*, 2H, 3 - $\underline{CH}_2$, J = 6.9 Hz), 2.09 (*s*, 3H, Ar-CH_3), 2.14 (*s*, 3H, Ar-CH_3), 2.58 (*t*, 2H, 4 - $\underline{CH}_2$, J = 6.9 Hz), 4.66 (*s*, 2H, Ar-CH_2-O-), 8.30 (*s*, 1H, OH) ppm; irradiation of the singlet at 4.66 ppm gave an NOE on the singlet at 8.30 and on the triplet at 2.58 ppm, thus proving that the 2-methyl-2-propoxy group was on the 5-position of the chroman ring; MS (ei) *m/z* (rel intensity) 292 $[M]^+$ (16), 218 (100), 203 (48), 189 (14), 175 (48).

5-n-Heptoxymethyl-2,2,7,8-tetramethyl-6-chromanol had UV λ_{max} (hexane) 303 nm (log 3.71); IR (KBr) 3322 (OH), 2972, 2935 (CH_3), 1623, 1464, 1387, 1370, 1279, 1232, 1171, 1130, 1104 (C-O-C), 1024, 945, 903, 854, 650 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.88 (*t*, 3H, $\underline{CH}_3$-CH_2-, J = 6.8 Hz), 1.28 (*s*, 6H, 2 × CH_3), 1.22 – 1.38 (broad m, 8H), 1.63 (m, 2H, -CH_2-$\underline{CH}_2$-CH_2-O-), 1.76 (*t*, 2H, 3 - $\underline{CH}_2$, J = 6.9 Hz), 2.10 (*s*, 3H, Ar-CH_3), 2.15 (*s*, 3H, Ar-CH_3), 2.60 (*t*, 2H, 4 - $\underline{CH}_2$, J = 6.9 Hz), 3.54 (*t*, 2H, -CH_2-$\underline{CH}_2$-O-, J = 6.6 Hz), 4.69 (*s*, 2H, Ar-CH_2-O-), 7.73 (*s*, 1H, OH) ppm; irradiation of the singlet at 4.69 ppm gave an NOE on the singlet at 7.73, on the triplet at 3.54 and on the triplet at 2.60 ppm, thus proving that the *n*-heptoxy group was on the 5-position of the chroman ring; MS (ei) *m/z* (rel intensity) 334 $[M]^+$ (10), 218 (100), 203 (37), 189 (10), 175 (35).

5-n-Undecoxymethyl-2,2,7,8-tetramethyl-6-chromanol had UV λ_{max} (hexane) 303 nm (log 3.70); IR (KBr) 3317 (OH), 2973, 2961, 2929 (CH_3), 1623, 1463, 1387, 1370, 1278, 1232, 1172, 1130, 1104 (C-O-C), 1013, 946, 902, 855, 653 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.88 (*t*, 3H, $\underline{CH}_3$-CH_2-, J = 6.9 Hz), 1.28 (*s*, 6H, 2 × CH_3), 1.22 – 1.38 (broad m, 16H), 1.63 (m, 2H, -CH_2-$\underline{CH}_2$-CH_2-O-), 1.77 (*t*, 2H, 3-CH_2, J = 6.9 Hz), 2.11 (*s*, 3H, Ar-CH_3), 2.15 (*s*, 3H, Ar-CH_3), 2.60 (*t*, 2H, 4-CH_2, J = 6.9 Hz), 3.54 (*t*, 2H, -CH_2-$\underline{CH}_2$-O-, J = 6.6 Hz), 4.70 (*s*, 2H, Ar-CH_2-O-), 7.73 (*s*, 1H, OH) ppm; irradiation of the singlet at 4.70 ppm gave an NOE on the singlet at 7.73, on the triplet at 3.54 and on the triplet at 2.60 ppm, thus proving that the undecoxy group was on the 5-position of the chroman ring; MS (ei) *m/z* (rel intensity) 390 $[M]^+$ (7), 218 (100), 203 (22), 189 (7), 175 (22).

5-Phytoxymethyl-2,2,7,8-tetramethyl-6-chromanol had UV λ_{max} (hexane) 303 nm (log 3.68); IR (KBr) 3377 (OH), 2954, 2931 (CH_3), 1747, 1674, 1622, 1462, 1384, 1370, 1274, 1231, 1172, 1127, 1095 (C-O-C), 1051, 1016, 935, 903, 852 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.87 (m, 12H, 4 × CH_3), 1.29 (*s*, 6H, 2 × CH_3), 1.03 – 1.57 (broad m, 19H),

1.65 (*s*, 3H, =C-CH_3), 1.77 (*t*, 2H, 3-CH_2, J = 6.9 Hz), 2.02 (m, 2H, =C-CH_2-), 2.11 (*s*, 3H, Ar-CH_3), 2.16 (*s*, 3H, Ar-CH_3), 2.61 (*t*, 2H, 4-CH_2, J = 6.9 Hz), 4.09 (d, 2H, =CH-$\underline{C}\underline{H}_2$-O-, J = 6.9 Hz), 4.70 (*s*, 2H, Ar-CH_2-O-), 5.39 (*t*, 1H, =CH-, J = 6.8 Hz), 7.68 (*s*, 1H, OH) ppm; irradiation of the singlet at 4.70 ppm gave an NOE on the singlet at 7.68, on the doublet at 4.09 and on the triplet at 2.61 ppm, thus proving that the phytoxy group was on the 5-position of the chroman ring; MS (ei) *m/z* (rel intensity) 514 $[M]^+$ (7), 296 (8), 294 (30), 278 (27), 264 (28), 236 (31), 218 (100), 203 (67), 189 (23), 175 (82).

5-Cholesteroxymethyl-2,2,7,8-tetramethyl-6-chromanol had UV λ_{max} (hexane) 303 nm (log 3.69); IR (KBr) 3382 (OH), 2940 (CH_3), 1623, 1457, 1384, 1370, 1274, 1231, 1171, 1127, 1095 (C-O-C), 1074, 1058, 1021, 943, 931, 903, 854, 803 cm^{-1}; ^1H NMR ($CDCl_3$) δ 0.68 (*s*, 3H, CH_3), 0.86 (d, 3H, CH_3-CH-, J = 6.6 Hz), 0.866 (d, 3H, CH_3-CH, J = 6.6 Hz), 0.91 (d, 3H, CH_3-CH, J = 6.5 Hz), 1.00 (*s*, 3H, CH_3), 1.27 (*s*, 6H, 2 × CH_3), 0.95 – 1.20 (broad m, 9H), 1.22 – 1.42 (broad m, 4H), 1.42 – 1.61 (broad m, 8H), 1.76 (*t*, 2H, 3-CH_2, J = 6.9 Hz), 1.8 – 1.9 (m, 2H), 2.00 (m, 3H), 2.10 (*s*, 3H, Ar-CH_3), 2.14 (*s*, 3H, Ar-CH_3), 2.30 (m, 1H), 2.44 (m, 1H), 2.60 (*t*, 2H, 4-CH_2, J = 6.9 Hz), 3.34 (m, 1H, -CH-O-), 4.75 (*s*, 2H, Ar-CH_2-O-), 5.35 (m, 1H, =CH-), 7.86 (*s*, 1H, OH) ppm; irradiation of the singlet at 4.75 ppm gave an NOE on the singlet at 7.86, on the multiplet at 3.34 and on the triplet at 2.60 ppm, thus proving that the cholesteroxy group was on the 5-position of the chroman ring; MS (ei) *m/z* (rel intensity) 604 $[M]^+$ (5), 602 (8), 386 (74), 368 (51), 353 (37), 301 (42), 275 (53), 255 (31), 247 (18), 231 (31), 219 (97), 218 (100), 213 (43), 203 (64), 189 (29), 175 (82).

RESULTS AND DISCUSSION

Oxidation of **1a** and **1b** is believed to proceed in two single electron steps leading first to the tocopheroxyl (**2a**) and chromanoxyl radicals (**2b**) (10-12) and, subsequently, to the phenoxylium (protonated quinone methide, **3a, 3b-3c, 3d**) or quinone methide (**4a,4b**) (13,14) species (Scheme 1). In the absence of other reactants, the quinone methide can dimerize to **5a,5b** and trimerize to **6a,6b** (15,5,6) in reactions typical of the species (16,17). Good yields of **5a**, in particular, are obtained in these reactions (5,15). Oxidations of simpler phenols have given very good yields of trimer (17). However, the present work shows that, if a nucleophile is present, an alcohol in this case, 1-4 addition to the quinone methide to form 5-alkoxymethyl derivatives (**7b**) is clearly preferred to polymerization. Indeed, only traces of the dimer **5b** and trimer **6b** were observed in these reactions.

Table 1 shows that the 5-alkoxymethyl derivatives of **1b** are formed in moderate to good yield in all cases except that of cholesterol and are, in each case, the major products of reaction. The reason for the lower yield of the cholesterol adduct was probably due to steric hindrance of the secondary alcohol group of cholesterol and to the much lower molar ratio of alcohol to chroman used in this reaction than in the other reactions. However, steric hindrance can be overcome by a sufficient concentration of alcohol as was the case with the more hindered, but much more compact 2-methylpropanol-2. NOE studies revealed that, in all cases, the alcohol had added exclusively to the 5-position of the chroman ring. No sign of substitution in other positions of the chroman ring was observed.

The second most plentiful product in almost all reactions was **12b** (Scheme 2). It has been demonstrated previously that 5-ethoxymethyl-7,8-dimethyltocol (**7a**; R′ = CH_3-CH_2-) may be oxidized to 5-formyl-7,8-dimethyltocol (**12a**), probably by formation of an intermediate quinone methide (**10a**), addition of water to form a hemiacetal (**11a**) and loss of ethanol (18). It seems likely that further oxidation of all 5-alkoxymethyl derivatives (**7b**) to **12b** may occur in the same manner. An alternative way in which **12b** may arise is by the addition of water to the first formed quinone methide (**4b**) to form 5-hydroxymethyl-2,2,7,8-tetramethyl-6-chromanol (**13b**) (C. Suarna and P.T. Southwell-Keely, unpublished observations) followed by oxidation to another quinone methide (**14b**) which is the enol of **12b**.

α-Tocoquinone (**9a**) and **9b** (Scheme 1) were the first oxidation products of **1a** and **1b**, respectively, to be characterized (7). These compounds were formed in very high yield by oxidation of the parent materials with silver nitrate or ferric chloride in alcoholic solvents. Their route of formation is believed to involve an intermediate phenoxylium species (**3a-3d**), evidence for which exists (19,20), followed by addition of water to form the quinone hemiketal (**8a,8b**) (21,22) and then ring opening to the quinone. In the present reactions, which were performed in chloroform, **9b**, although always present, was formed only in small amounts.

This, it may be inferred that, when oxidations are carried out in nonpolar solvents such as chloroform or light petroleum, the neutral intermediate quinone methide (**4a,4b**) determines the products. However, when oxidations are performed in polar media such as alcohols, the positively charged phenoxylium ion is the favored intermediate, due to solvent stabilization of the charged species, and determines the products.

Both **9b** and **7b** are formed by 2 electron oxidation of the starting material. However, **9b** has no antioxidant activity, whereas such 5-alkoxymethyl-2,2,7,8-tetramethyl-6-chromanols, as have been tested, have quite good antioxidant activity (23). In view of the relative ease with which the 5-alkoxymethyl adducts form, it is tempting to speculate that, if such reactions occurred in membranes (with cholesterol, phosphatidylinositol, phosphatidylglycerol, cardiolipin, etc., serving as the alcohol), they would extend the antioxidant activity of α-tocopherol by forming oxidation products which also contained this activity. If, as has been suggested earlier, the 5-alkoxymethyl adducts are further oxidized to **12b**, this would represent an additional means of retaining antioxidant activity (23).

Incorporation of *trans*-8- and *cis*-8-Octadecenoic Acid Isomers in Human Plasma and Lipoprotein Lipids

E.A. Emken*[a], **R.O. Adlof**[a], **W.K. Rohwedder**[a] and **R.M. Gulley**[b]

[a]Northern Regional Research Center, ARS/USDA, 1815 N. University St., Peoria, IL 61604, and [b]St. Francis Medical Center, Peoria, Illinois

Mixtures of deuterium-labeled *trans*-8-, *cis*-8- and *cis*-9-octadecenoic acids (8t-18:1, 8c-18:1, 9c-18:1) were fed as triglycerides (TG) to two adult male subjects. Blood samples were collected sequentially over a 48-hour period. Plasma and lipoprotein lipids were separated by thin layer chromatography and analyzed by gas chromatography–mass spectroscopy. Results indicate (i) absorption of the 8t- and 8c-18:1 isomers were similar to 9c-18:1; (ii) the 8t-18:1 isomer was cleared approximately 30% faster than 9c-18:1 from plasma TG; (iii) cholesterol ester samples contained 8.4 times less 8t-18:1 than 9c-18:1; (iv) incorporation at the 1-acyl phosphatidylcholine (PC) position was higher for 8t-18:1 and 8c-18:1 (2.2 and 1.7 times) than for 9c-18:1; and (v) discrimination at the 2-acyl PC position was 4.6-fold against 8t-18:1 and 1.3-fold against 8c-18:1 compared with 9c-18:1. Discrimination against uptake of the Δ-8 isomers in both neutral and phospholipid classes suggests that both 8t- and 8c-18:1 may be preferentially oxidized relative to 9c-18:1. Except for triglycerides, data for each of the lipid classes from total plasma and individual lipoprotein samples were similar. These data indicate that differences for incorporation and turnover of the 8t- and 8c-18:1 isomers relative to 9c-18:1 are not substantially influenced by the lipoprotein classes. The maximum isotopic enrichment detected in the chylomicron triglycerides fractions was 60%, which indicates that a substantial amount of endogenous triglycerides was mobilized during absorption of the deuterated fats.

***Lipids 24,* 61-69 (1989).**

Isomers of *cis* and *trans* octadecenoic acid with double bonds in the 8 to 14 positions have been identified in a variety of human tissues (1,2). The main dietary sources of these isomeric structures are partially hydrogenated vegetable oils, which supply a significant portion (ca. 6.5%) of the total dietary fat consumed in the U.S. (3).

A number of human studies have been conducted to investigate the effect of diets containing hydrogenated oils on serum cholesterol and triglyceride (TG) levels (4,5). In general, the results of these studies indicate that hydrogenated oils do not increase TG or cholesterol levels sufficiently to merit major concern regarding their nutritional impact in healthy individuals. Because these human studies provide no actual metabolic data for individual 18:1 isomers the effect of isomeric fatty acids on health problems is still questioned. Except for human tissue composition data, existing biochemical data for the 8t- and 8c-18:1 isomers are based on in vitro studies and animal data.

*To whom correspondence should be addressed.

Abbreviations: CE, cholesterol ester; CHYLO, chylomicron; FFA, free fatty acid; HDL, high density lipoprotein; LCAT, lecithin:cholesterol acyltransferase; LDL, low density lipoprotein; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PS, phosphatidylserine; TG, triglyceride; VLDL, very low density lipoprotein; GC–MS, gas chromatography–mass spectroscopy; TLC, thin layer chromatography.

The main objective of this study was to compare the metabolism of the 8t- and 8c-18:1 isomers to 9c-18:1 in "normal" young adult male subjects in order to determine if there is a biochemical basis for suspecting that the Δ-8 isomers might have adverse nutritional or physiological impact on health. A second objective was to validate in human subjects the results reported for in vitro and animal studies. A third objective was to gain further insight into the absorption and transport of dietary fat in man.

EXPERIMENTAL

Preparation of the deuterium-labeled fatty acids and sampling schedule. The composition of the deuterium-labeled fatty acids in the mixtures of monoacid triglyceride (TG) fed are summarized in Table 1. The number of deuterium atoms used to label the 8t- and 8c-18:1 isomers was reversed in the two studies to permit detection of unanticipated systematic analytical errors and isotope effects. Synthesis of the labeled fatty acids (8t-18:1-17,18-$^2H_2$, 8t-18:1-12,12,13,13-$^2H_4$, 8c-18:1-17,18-$^2H_2$, 8c-18:1-12,12,13,13-$^2H_4$ and 9c-18:1-14,14,15,15,17,18-$^2H_6$) and their monoacid triglycerides has been described previously (6,7).

The mixture of deuterated TG (27.5 g, subject 1, and 24.0 g, subject 2) was heated to ca. 70°C and emulsified in a blender with 30 g calcium-sodium caseinate, 30 g dextrose and 15 g sucrose in 200 ml of water, which had also been heated to 70°C. The mixture was fed at 8 a.m., in place of the subject's normal breakfast, following a 10–12-hr fast. The subjects ate a light lunch at ca. 12:30 p.m. and a normal evening meal at ca. 6:30 p.m.

Blood samples (ca. 22 ml each) were obtained by venipuncture at 0, 2, 4, 6, 8, 12, 15, 24 and 48 hr for plasma lipid class fatty acid analysis. Samples (ca. 30 ml) were collected at 2, 4, 6, 8, 12, 15 and 24 hr for lipoprotein lipid class analysis. Standard preparative ultracentrifuge

TABLE 1

Deuterium-labeled Fatty Acids Used in Triglyceride Mixtures Fed

	Total fed	24.0			

methods were used to separate chylomicron (CHYLO), very low density (VLDL), low density (LDL) and high density (HDL) lipoprotein fractions (8). Samples were analyzed by electrophoresis to confirm the purities of the lipoprotein fractions.

Subjects. The subjects were two Caucasian males, ages 26 and 23. Medical histories, physical examinations and clinical blood profile data indicated that the subjects were in excellent health, had no history of congenital ailments and had not taken any medication for at least 3 wk before the study. Dietary histories confirmed that food selection was typical of American diets reported in the Hanes and USDA surveys (9,10). The subjects' height/weight ratios (195 cm/88.5 kg and 178 cm/70.4 kg), blood pressure (120/75 and 120/80), and serum cholesterol (133 mg/dl and 171 mg/dl), and fasting TG (65 mg/dl and 83 mg/dl) were within normal ranges.

The subjects were requested to follow, for 1 wk prior to feeding, the standard diet for diabetics recommended by the American Diabetic Association. The purpose was to help the subjects select diets of ca. 40% fat, 40% carbohydrate and 20% protein. No significant changes in the subjects' weights were observed during this period, which indicated a stable energy balance. The subjects fasted for 12 hr before the experimental meals were fed. This protocol was approved by the ARS/USDA Human Studies committee, and informed consent was obtained prior to feeding the mixture of deuterium-labeled fats.

Lipid class separation. Total lipids were extracted with 2:1 chloroform/methanol (11). Known weights of triheptadecanoin, cholesteryl heptadecanoate, heptadecanoic acid (17:0) and diheptadecanyl-L-α-phosphatidylcholine were added as internal standards to the total lipid extract to allow calculation of the concentrations (mg/ml) of the deuterated fatty acids in these plasma lipid classes. The concentrations of the other plasma lipid classes were calculated from known weights of the free acid of 17:0 added after their isolation by thin layer chromatography (TLC). Internal standards were not added to the chylomicron extracts from subject 1.

Preparative TLC was used for isolation of TG, cholesterol ester (CE), free fatty acid (FFA), phosphatidylethanolamine (PE), phosphatidylcholine (PC) and phosphatidylserine (PS) lipids (12,13). Methyl esters of the isolated lipids were prepared by heating with a 5% HCl-methanol solution (14). To determine the distribution of the deuterium-labeled fatty acids in the 1- and 2-acyl position of PC, a portion of the isolated PC was treated with phospholipase A_2 (15), and the reaction products were separated by TLC and esterified.

Analytical methods. Quantitation of deuterium-labeled fatty acids incorporated into plasma and lipoprotein lipids was achieved by gas chromatography-mass spectroscopy (GC-MS) analysis of their methyl esters. Fatty acid percentages and concentrations for both labeled and unlabeled fatty acid esters were obtained by analysis with a Finnigan model 4500 quadrupole mass spectrometer operated in a chemical ionization mode with isobutane as the ionization reagent. The gas chromatograph-mass spectrometer was equipped with a Supelcowax 10 fused silica column (30 m × 0.32 mm; Supelco Inc., Bellefonte, PA) and was temperature programmed from 165°C to 265°C at 5°C/min with a 20-min final hold. The MS methodology included selected-ion monitoring of each GC peak, followed by integration of the peak areas at appropriate mass numbers. The specific operating conditions and computer-assisted storage and processing of the MS data have been described previously (16).

Quantitation and absolute weight data for both the isotope-labeled and nonlabeled fatty acid methyl esters in the plasma lipid samples were based on the known weight of heptadecenoic acid added as an internal standard prior to conversion of the lipid classes to their methyl esters. Response factors were determined by analysis of standard mixtures containing weighted amounts of pure fatty acid methyl esters purchased from Nu-Chek Prep Inc. (Elysian, MN) and Applied Science (State College, PA). The accuracy of the GC-MS data was estimated at 2% relative standard deviation from analysis of various standard mixtures of known composition that simulated the composition of actual samples.

A Varian model 3400 gas chromatograph, equipped with a 100-m × 0.25-mm SP2560 fused silica capillary column (Supelco Inc., Bellefonte, PA) and a flame ionization detector, was used to analyze many of the samples to confirm the quantitation of the methyl ester data obtained by GC-MS. Operating conditions were: split ratio, 1:100; linear velocity of helium, 21 cm/sec; detector and injection temperature, 235°C. The column oven temperature was programmed from 165 to 220°C at 3 c/min with an initial hold of 15 min and a final hold of 30 min. Methyl ester GC peaks were identified and quantitation was confirmed by analysis of authentic standards and mixtures of known composition and by MS data.

Selectivity values. Selectivity values were calculated by dividing the experimental ratio by fed ratio where the experimental ratio equals the ratio of labeled 8t- or 8c-18:1 to labeled 9c-18:1 in the sample and the fed ratio equals the ratio of the corresponding fatty acids in the fed mixture. If the value obtained for the selectivity value is less than 1.0, the reciprocal is calculated and the value given a negative sign. Because calculation of values by this procedure results in values either greater than 1 or less than −1, the values were adjusted to a zero basis by adding or subtracting −1 as appropriate. The use of the reciprocal for selectivity values less than 1.0 avoids the problem of compressing negative values between 0.0 and 1.0, which facilitates comparison of negative values with positive values. Thus, a selectivity value less than 0.0 denotes discrimination against incorporation of the deuterium-labeled fatty acid in the numerator, and a value greater than 0.0 indicates preferential incorporation. Expression of the data as selectivity values compensates for the small differences in the percentage of labeled fatty acids in the fed mixtures.

Area selectivity values are calculated by the same procedure as for selectivity values for individual samples, except the experimental ratio is obtained from the area under the curves after the data is plotted, for example, as in Figure 1. Thus, area selectivity values are a "weighted" average of all the samples analyzed for an individual plasma or lipoprotein lipid class.

RESULTS

Digestion. Absorption and clearance of the deuterium-labeled 8t-, 8c- and 9c-18:1 acids are reflected in the plasma and CHYLO TG data plotted in Figure 1. The

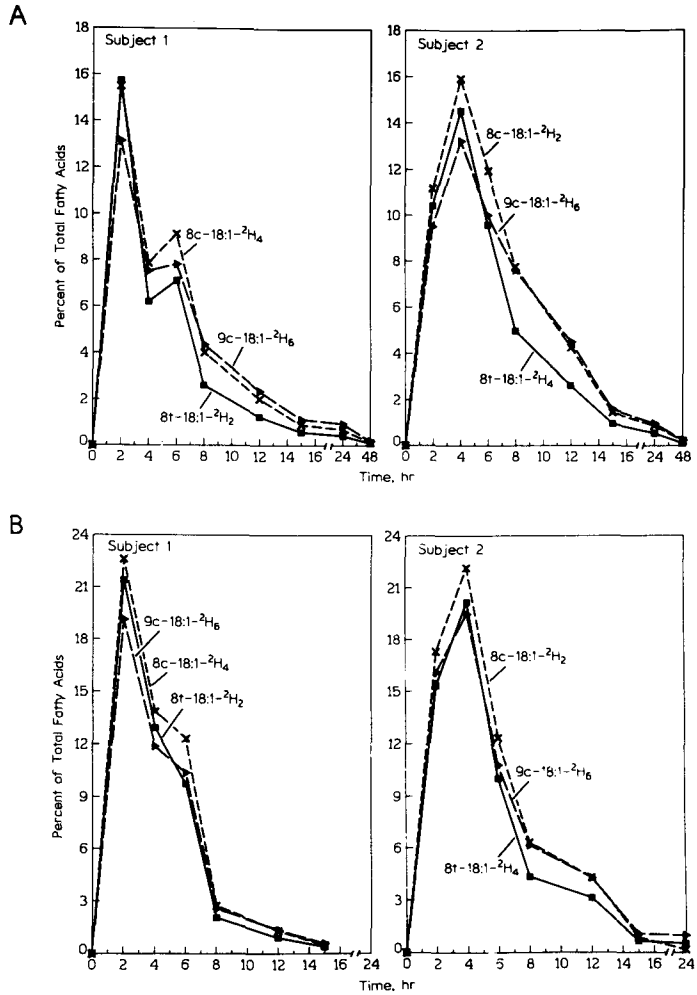

FIG. 1. Incorporation and turnover of deuterium-labeled 8t-, 8c- and 9c-18:1 in (A) plasma triglycerides and (B) chylomicron triglycerides.

profiles of the CHYLO and plasma TG curves are similar because the CHYLO TG contribute the majority of deuterated TG in the plasma TG samples. For example, the distribution of the total deuterated fatty acids in the 6-hr lipoprotein sample from subject 2 was CHYLO TG, 161 μg/ml (67.7%); VLDL TG, 34.2 μg/ml (14.4%); LDL TG, 29.7 μg/ml (12.5%); and HDL TG, 12.8 μg/ml (5.3%). The percentages for each of the deuterated fatty acids incorporated into the lipoprotein TG fractions collected over a 24-hr period from subject 2 are plotted in Figure 1B and Figure 2. The VLDL and HDL TG samples (Fig. 2) contain slightly smaller percentages for 8t-18:1-$^2H_4$, but the 6- to 15-hr LDL TG samples contain about 25% less 8t-18:1 than 8c- and 9c-18:1. This difference probably reflects a higher rate of removal of 8t-18:1 during formation of LDL from VLDL.

Comparison of the shape of the curves for 9c-18:1 to the curves for 8t- and 8c-18:1 (CHYLO TG data, Fig. 1B) indicates similar absorption of both Δ8-18:1 isomers and 9c-18:1. Calculated selectivity values for the plasma TG fraction show the absorption of the Δ8-18:1 isomers varied from 8% higher to 12% less than 9c-18:1. The maximum percent of total deuterated fatty acid in the CHYLO TG samples was similar for both subjects. The only major difference between CHYLO TG data from the two subjects was the 2-hr offset for the time of maximum absorption.

Incorporation in plasma and lipoprotein lipids. Uptake and turnover of the labeled fatty acids in plasma CE samples are illustrated in Figure 3. These data show large differences between the percentages of 8c-, 8t- and 9c-18:1 incorporated into plasma CE samples. The area selectivity values (Table 2) indicate that esterification of cholesterol with 9c-18:1 was 35–50% greater than for 8c-18:1 and about 8.5 times higher than for 8t-18:1.

Plots of the plasma PC data are shown in Figure 4. Variation between the curves for the two subjects is due to a high deuterated fatty acid content in the 8-hr sample from subject 1 and to a small general discrimination against 8c-18:1 for samples from subject 2. Determination of the deuterated fatty acid distribution at the 1- and 2-acyl positions of PC shows strong preferential incorporation of 8t-18:1 at the 1-acyl position, which is balanced by a preferential incorporation of 9c-18:1 at the 2-acyl position. Maximum percentage deuterated fatty acids incorporated, time of maximum incorporation and selectivity values for the plasma lipids are presented in

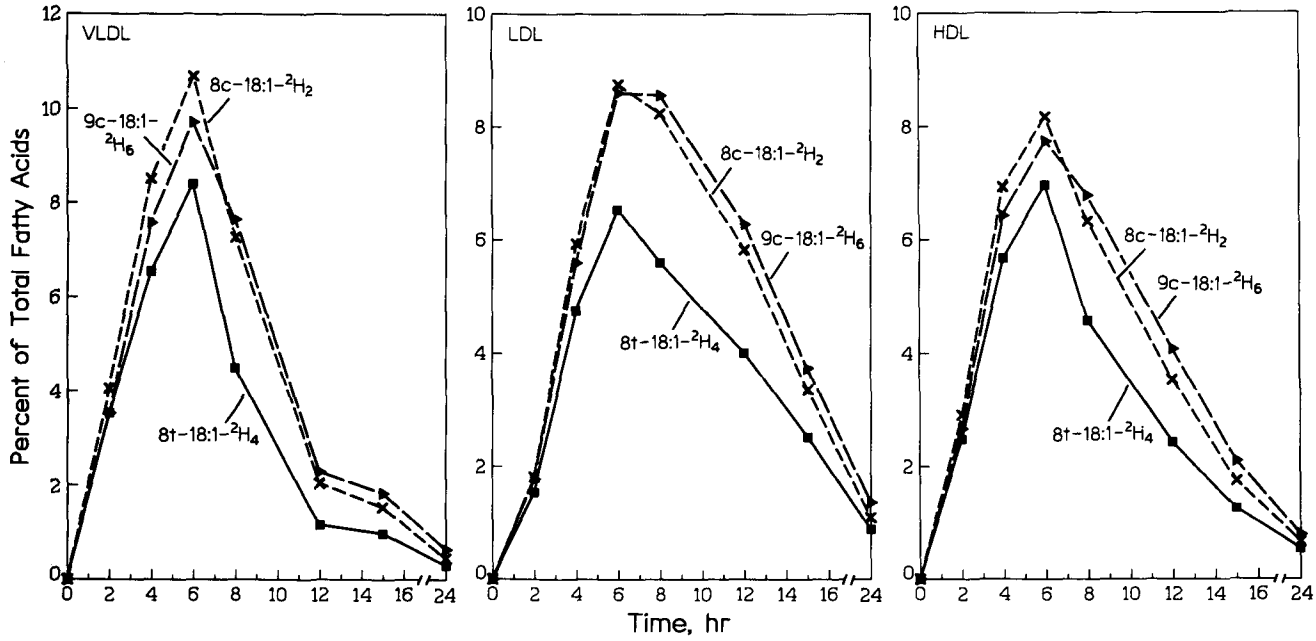

FIG. 2. Incorporation and turnover of deuterium-labeled 8t-, 8c- and 9c-18:1 in very low, low and high density lipoprotein triglycerides from subject 2.

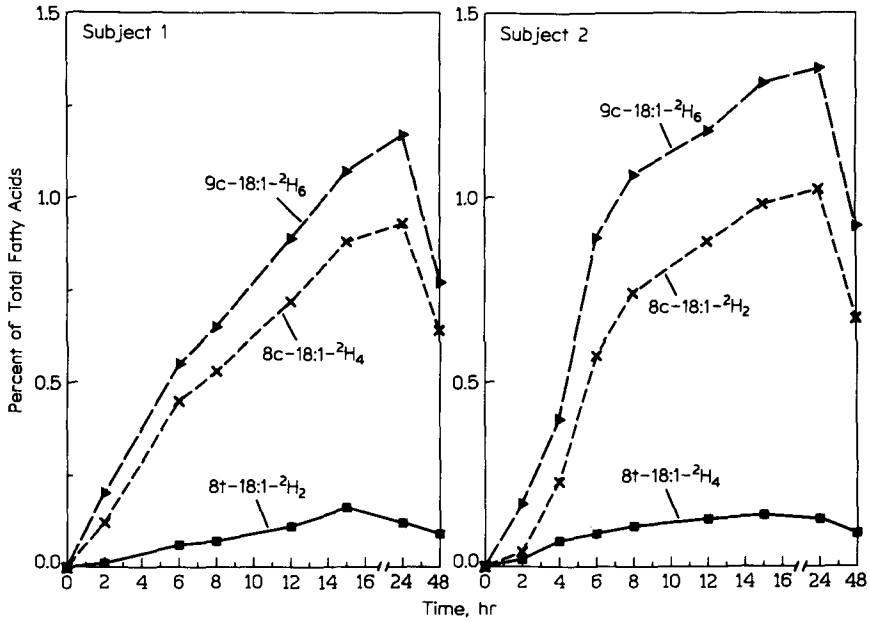

FIG. 3. Uptake and turnover of deuterium-labeled 8t-, 8c- and 9c-18:1 in plasma cholesterol ester samples.

Table 2. The selectivity values are negative for nearly all the lipid fractions. The exception is the positive selectivity value for the 1-acyl PC fraction.

Area selectivity values and the maximum percentages for the deuterated fatty acids incorporated into lipoprotein TG, CE, PE and PC fractions are summarized in Table 3. The selectivity values for CE, PE and PC followed the same trends in both the plasma and lipoprotein samples. The negative selectivity values for VLDL, LDL and HDL TG samples indicate discrimination against 8t- and 8c-18:1 incorporation. These values probably reflect reduced amounts of the 8c- and 8t-18:1 isomers available for incorporation into these fractions due to more rapid removal of these isomers rather than differences in enzyme specificities involved in TG synthesis.

Chain-shortened and elongated fatty acids. Chain-shortened deuterium-labeled 16:1 fatty acids were detected in the TG, CE, FFA and PC plasma lipid classes with the

[b]Area selectivity values are the average of two subjects, data from Ref. 23.

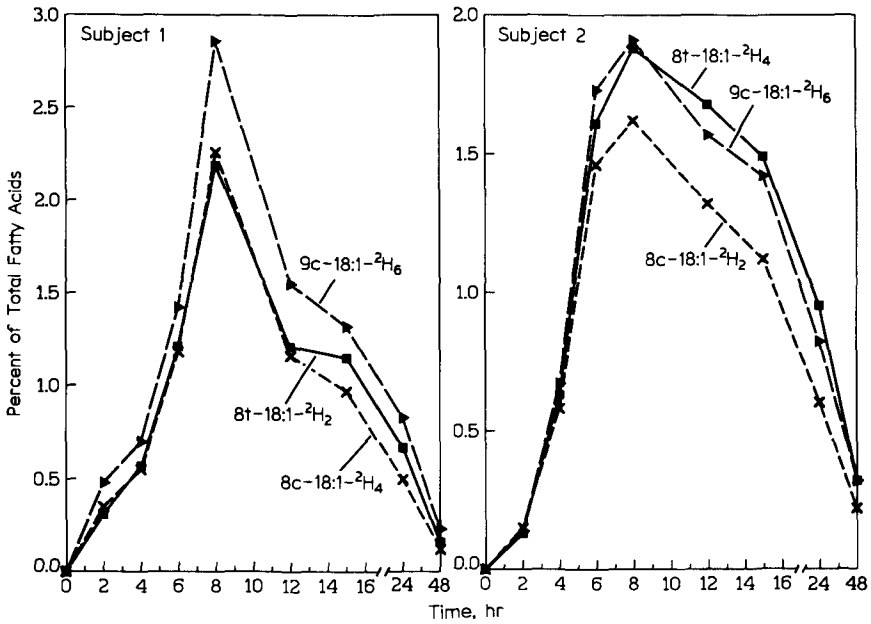

FIG. 4. Uptake and turnover of deuterium-labeled 8t-, 8c- and 9c-18:1 in plasma phosphatidylcholine samples.

TG fractions containing the highest amounts. The maximum percentages for deuterium-labeled 16:1 acids in the plasma TG and FFA fractions (based on total fatty acid content) were: TG (0.95-0.86% 6t-16:1; 0.12-0.17% 6c-16:1; 0.07-0.06% 7c-16:1) and FFA (0.29-0.17% 6t-16:1; 0.07-0.06% 6c-16:1, 0.0-0.03% 7c-16:1. Percentages for deuterium-labeled 16:1 in the VLDL, LDL and HDL TG samples are plotted in Figure 5. The amount of 6t-16:1 chain-shortened product from 8t-18:1 was 5 to 6 times higher than the 6c-16:1 product from 8c-18:1, and chain-shortened 9c-18:1 was detected at very low levels. Deuterated 10t-20:1, 10c-20:1 and 11c-20:1 were found in trace (.01 to .05%) amounts in only the TG fractions.

DISCUSSION

The variability between the results from each subject was evaluated on the basis of total percentage deuterated fatty acid incorporated, mg/ml of deuterated fatty acid incorporated, selectivity values, overall curve shape or profile and time of maximum deuterated fat incorporated for each lipid class. Based on these five criteria, the overall variability between results from each subject was small and indicates that the results were not influenced by the lack of rigorous control of the diet before or after the deuterated fat mixtures were fed.

The percentages of deuterated 9c-18:1 incorporated into

[a]Weight percent of deuterium-labeled fatty acid in total lipid fraction.

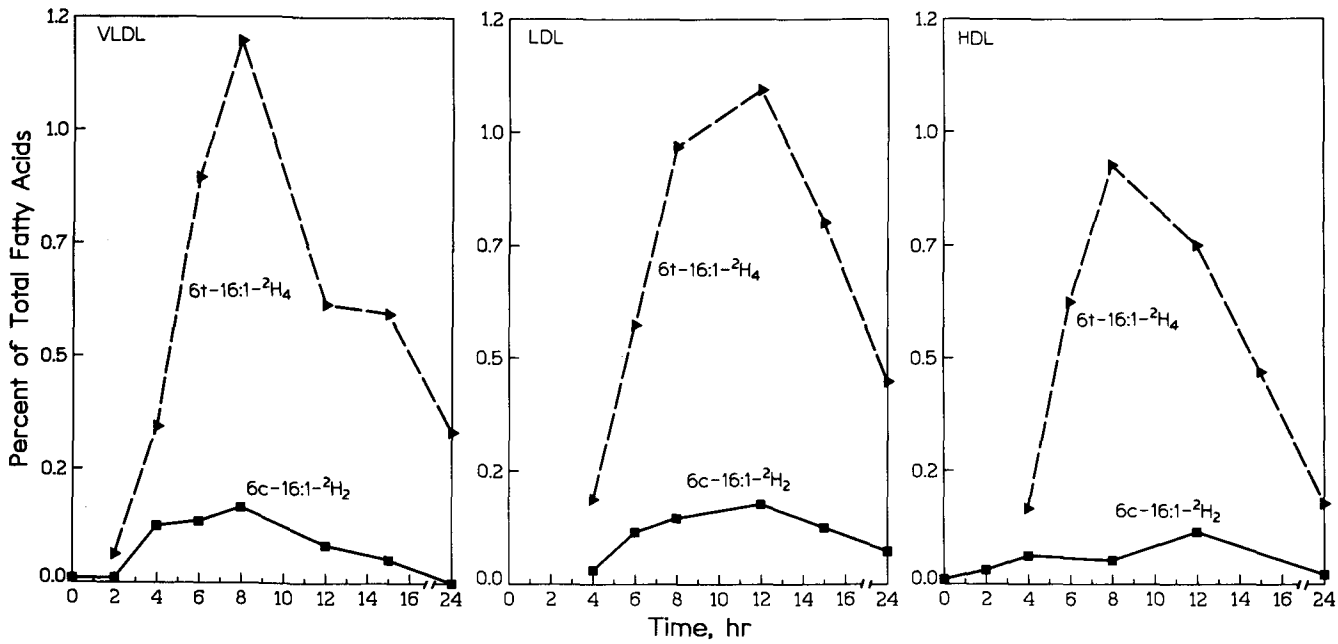

FIG. 5. Percentage of deuterium-labeled 6t- and 6c-16:1 incorporated into plasma triglycerides.

the various lipid classes from subjects used in this study were consistent with 9c-18:1 data from 11 subjects fed deuterated 9c-18:1 as a control in previous studies (17-21). Medical histories did not identify any health problems, and clinical data and fatty acid composition of individual lipid classes were within ranges reported as normal for the U.S. population. Based on these combined data, the metabolism of the Δ8-18:1 fatty acids in these subjects

[a]The percentages for the 4 fatty acids listed represented about 95% of the total unlabeled fatty acids. Data normalized to 100%.

is considered to be representative of normal young adult males.

Absorption. The plasma and CHYLO TG data in Figure 1 and the TG selectivity values in Tables 2 and 3 are clear evidence that absorption of the 8t- and 8c-18:1 isomers was similar to 9c-18:1, which is about 95% absorbed by normal subjects. These data are consistent with the nonselectivity of pancreatic lipase for positional 18:1 isomers (22). The maximum total isotopic enrichment in the CHYLO TG samples was ca. 60%. The presence of ca. 40% unlabeled TG in these fractions is a very consistent feature that we have observed in previous human studies (18,19,21,23).

The fatty acid composition of the four major unlabeled fatty acids present in the 2- to 12-hr CHYLO TG fractions (Table 4) was relatively constant. The increase in total weight of unlabeled fatty acids (subject 2) in the 6- and 8-hr fraction is likely due to fat consumed at lunch. The consistency in both the unlabeled fatty acid composition of the CHYLO TG and the isotopic enrichment data suggests that mobilization of stored fat provides a portion of the fatty acids incorporated into CHYLO particles during digestion of dietary fat. This suggestion for mobilization of a pool of stored fat is based on the fact that subjects who fasted for 12 hr have low levels of CHYLO TG, and that dietary fat from previous meals has been removed from the digestive system and the maximum isotopic enrichment of the fatty acids in the CHYLO-TG samples is about 60%. This combination of experimental data indicates some source of unlabeled endogenous fat must have been incorporated during formation of the CHYLO TG particles, because none is present in the experimental mixture fed. In fact, the unlabeled fatty acids in the 6- and 8-hr CHYLO TG samples, which should contain fatty acids from the noon meal, have a composition that is similar to the unlabeled fatty acids in the 2- and 4 hr-samples. These data suggest that the body has a mechanism for attempting to maintain the CHYLO TG fatty acid composition within certain limits by mobilization of an endogenous pool of stored fat.

Based on the isotopic enrichment of the CHYLO TG samples, we calculate that ca. 16.1 g (subject 1) and 14.8 g (subject 2) of unlabeled fat was incorporated into the CHYLO TG during absorption of the labeled fats. These data agree with results from rat studies which reported that endogenous fat supplied up to 50% of the fat in CHYLO particles (24). The source of the endogenous fat in the chylomicrons is unclear. The liver parenchymal and fat-storing cells (25) are possible sources of endogenous fat because of their high TG content. The amount of residual TG and FFA in the plasma and intestinal cells, following a 10- to 12-hr fast, is too small to supply 15–16 g of endogenous fat. The turnover rate for CHYLO TG was calculated from the weight of the total labeled fatty acids fed plus the calculated weight (16.1 g and 14.8 g) of unlabeled endogenous fatty acids incorporated into the CHYLO TG during absorption of the labeled fatty acids. The calculated turnover rates for CHYLO TG were 4.1 and 4.6 mg/min/kg of body weight for subjects 1 and 2, respectively. These data are consistent with values of 3.9 and 4.7 mg/min/kg for mixtures containing the 11c and 11t-18:1 isomers and 5.2 mg/min/kg for a mixture of 10c-, 10t- and 9c-18:1 (18,19).

Oxidation. Plasma TG data indicate that the 8t- and 8c-18:1 isomers are removed slightly more rapidly than 9c-18:1, but neither isomer is selectively incorporated into PC or CE fractions (Figs. 3 and 4, Tables 2 and 3). Thus, the 8t- and 8c-18:1 isomers must be either selectively oxidized or deposited into tissue lipids. Because analysis of tissue lipids does not provide evidence for preferential incorporation of the Δ8-18:1 isomers (1,2), a higher rate of β-oxidation is left as the most plausible explanation for the plasma TG data. This explanation is consistent with in vitro rat and human data which have shown that the *trans* isomers are oxidized more rapidly than 9c-18:1 (26–28) and with the higher conversion of 8t- and 8c-18:1 to 16:1 isomers (see following section). It does not agree with in vitro rat liver studies which have reported that the 8t- and 8c-18:1 isomers are oxidized more slowly than 9c-18:1 (29) and with rat liver peroxisome studies that found similar rates for the oxidation of *cis* and *trans* fatty acids (30).

Interconversion. The 8t- and 8c-18:1 isomers have been reported to be retroconverted to 14:1 (31), desaturated to 6c,8t-18:2 (32,33) and elongated to 20:1 (34). Retroconversion of deuterated 8t- and 8c-18:1 to deuterated 6t- and 6c-16:1 (but not 14:1) and elongation to deuterated 10t- and 10c-20:1 (trace amounts) were observed. The higher percentage of 6t-16:1 compared with 6c-16:1 (Fig. 5) was similar to the pattern for chain-shortened products from the Δ 10 and 11 *cis*- and *trans*-18:1 isomers (18,19). Desaturation of 8t- and 8c-18:1 to 18:2 isomers was not detected.

Transfer times. Lipoprotein LDL and HDL TG data (Fig. 2 and Table 3) indicate maximum isotope enrichment occurred 6 hr after feeding. The times of maximum enrichment indicate that about a 2-hr period is necessary for transfer of fatty acids from CHYLO TG to LDL and HDL TG. The time of maximum enrichment for lipoprotein and plasma PC (Fig. 4 and Table 3) is 4–6 hr after maximum CHYLO-TG enrichment. These data suggest cell uptake and excretion of a portion of the deuterated fatty acids occur before they are incorporated into TG and PC associated with lipoprotein fractions. Much of the 2- to 4-hr time delay observed for the incorporation of deuterated chain-shortened 16:1 fatty acids into TG (Fig. 5) is

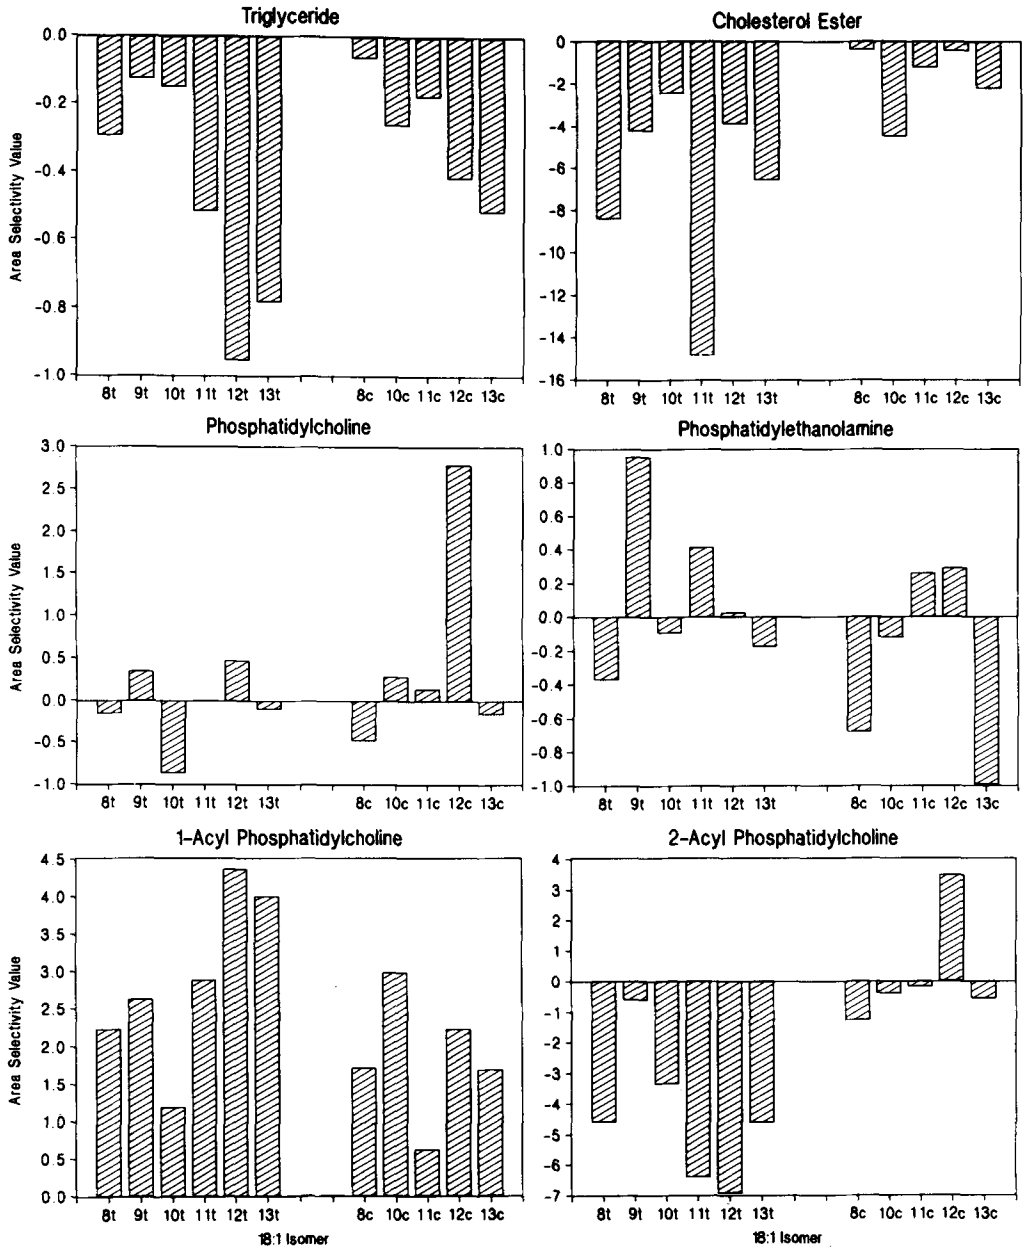

FIG. 6. Comparison of plasma triglyceride, cholesterol ester, phosphatidylcholine, phosphatidylethanolamine, 1-acyl phosphatidylcholine and 2-acyl phosphatidylcholine area selectivity values for the 8 through 13 *trans*- and *cis*-18:1 positional isomers. All area selectivity values are relative to 9c-18:1. Data for isomers other than 8t- and 8c-18:1 are from references 17–21.

probably due to the time required for the fatty acids to be internalized into the liver cells and then excreted into the plasma. Liver cells are probably responsible for much of the PC synthesized, but cells other than liver cells may be involved in TG synthesis. The maximum enrichment for the 24-hr LDL CE sample is more difficult to understand. The LDL CE data suggests the possibility that transfer of deuterated fatty acids from the 2-acyl position of PC is responsible for most of the deuterated LDL CE and that the newly synthesized CE remains associated with the LDL particles for a comparatively long time period.

Enzyme specificity. The deuterated fatty acid content and selectivity values for the plasma CE and PC-2 fractions (Table 2) indicates the 8t-18:1 isomer is a poor substrate for lecithin:cholesterol acyltransferase (LCAT) and 2-acyl phosphatidylcholine acyltransferase. The PC-1 data indicates that 8t-18:1 is preferred over 9c-18:1 for acylation of the 1 position of phosphatidylcholine. This selectivity for incorporation of 8t-18:1 at the 1-acyl position is balanced by discrimination against incorporation of 8t-18:1 at the 2-acyl PC position and is similar to results reported for rat liver PC (35). The PC-1 and PC-2 selectivity values for the 8c-18:1 isomer were intermediate between 8t- and 9c-18:1.

The specificities of LCAT and acyltransferase enzymes for 8t- and 8c-18:1 resemble the pattern reported for 18:0

vs 9c-18:1 (Table 2), but the 18:0/9c-18:1 CE- and PC-selectivity values (23) are much larger than the 8t- and 8c-18:1/9c-18:1 values. The relative incorporation of the 8t- and 8c-18:1 isomers into plasma TG, CE and PC are compared with data for other 18:1 isomers in Figure 6. These data indicate the Δ-8 bond position does not have a unique effect on metabolism when compared with other positional 18:1 isomers. The data compared in Figure 6 are from similar designed studies, and 9c-18:1 was used as an internal control in all experiments. Possible trends in selectivity values within lipid classes appear to be associated with the position of the double bond as it is moved away from the center of the fatty acid chain or toward the methyl end of the chain. There are no consistent correlations with known physical properties. Each 18:1 isomer has its own "individuality," but the difference between the metabolism of the *cis*- and *trans*-positional 18:1 isomers and 9c-18:1 is much less than the differences between 9c-18:1 and 18:0, 16:0 or 9c,12c-18:2 (23). Thus, the 18:1 isomers should not be regarded as equivalent to saturated fatty acids or oleic acid. In general, human plasma lipid selectivity values validate in many many of the results reported for various tissue lipids from rat (36,37), laying hen (38,39) and in vivo studies (40-42). Given the wide variation in diets, species and experimental designs, the similarity between results from different species is closer than expected. The structural features of the 8t- and 8c-18:1 isomers obviously influence the binding constants of some of the enzymes involved with fatty acid metabolism, but it is unknown if this sensitivity to the structure of these isomers extends to other enzymes and alters cell metabolism.

[Received April 28, 1988; Revision accepted September 21, 1988]

Eskimo Plasma Constituents, Dihomo-γ-linolenic Acid, Eicosapentaenoic Acid and Docosahexaenoic Acid Inhibit the Release of Atherogenic Mitogens

Donald L. Smith*, Anthony L. Willis, Ngoc Nguyen, Debra Conner, Shaye Zahedi and Judy Fulks
Atherosclerosis and Thrombosis Section, Institute of Experimental Pharmacology, Syntex Research, Palo Alto, CA 94303

Studies in man and laboratory animals suggest that ω3 polyunsaturated fatty acid constituents of fish oils have antiatherosclerotic properties. We have studied the effects of several such polyunsaturated fatty acids for ability to modify the in vitro release of mitogens from human platelets. Such mitogens may produce the fibroproliferative component of atherosclerotic plaques. Both 5,8,11,14,17-eicosapentaenoic acid (20:5ω3) and 4,7,10,13,-16,19-docosahexaenoic acid (22:6ω3), major constituents of fish oils, inhibited adenosine diphosphate-induced aggregation of platelets and the accompanying release of mitogens. These effects are dose dependent. Linolenic acid (18:3ω3), the biosynthetic precursor of eicosapentaenoic acid, also inhibited platelet aggregation and mitogen release. Eicosapentaenoic acid also inhibited mitogen release from human monocyte-derived macrophages, which, in vivo, are an additional source of mitogens during atherogenesis.

Potent inhibition of human platelet aggregation and mitogen release was also seen with dihomo-γ-linolenic acid (8,11,14-eicosatrienoic acid 20:3ω6), whose levels are reportedly elevated in Eskimos subsisting on marine diets.

We conclude that diets that elevate plasma and/or tissue levels of eicosapentaenoic acid, docosahexaenoic acid and dihomo-γ-linolenic acid precursor γ-linolenic acid (18:3ω6) may exert antiatherosclerotic effects by inhibiting the release of mitogens from platelets and other cells. *Lipids 24,* **70-75 (1989).**

Marine lipid diets rich in 5,8,11,14,17-eicosapentaenoic acid and 4,7,10,13,16,19-docosahexaenoic acid seem to exert antiatherosclerotic effects in both man and experimental animals (1-12). However, there is no definitive description of the mechanisms involved. There is a mild cholesterol-lowering effect and marked triglyceride-lowering effect of such diets (4-6). However, these effects, alone, may not be sufficient to inhibit atherosclerosis.

The principal feature of human atherosclerosis is the development of fibroproliferative plaque, probably in response to mitogens released from platelets, macrophages and other cells resident in or adhering to the vascular wall (13,14). By contrast, lipid accumulation per se may result in development of fatty streaks composed of only foam cells. In previous studies, we have shown that some of the eicosanoids derived from polyunsaturated fatty acids can inhibit some or all of these processes. For example, prostacyclin (PGI_2; derived from arachidonic acid), some stable prostacyclin mimetics and prostaglandin E_1 (PGE_1; derived from dihomo-γ-linolenic acid) inhibit not only platelet aggregation, but also release of mitogens from platelets and macrophages and accumulation of cholesterol in macrophage foam cells (13,15,16). In the present study, we examined effects of dihomo-γ-linolenic, eicosapentaenoic and docosahexaenoic acids on platelet aggregation and mitogen release and compared them with those of several fatty acids that have varying degrees and positions of unsaturation.

METHODS

Materials. Arachidonic acid, dihomo-γ-linolenic acid, α-linolenic acid, γ-linolenic acid, eicosapentaenoic acid, docosahexaenoic acid, 11,14,17-eicosatrienoic acid, Ficoll (histopaque-1077) and adenosine diphosphate (ADP) were all obtained from Sigma Chemical Company (St. Louis, MO). Adrenic acid was from NuChek Prep (Elysian, MN). Mead acid was supplied by Dr. Howard Sprecher (Ohio State University). Toluene (reagent grade; Mallinckrodt, Paris, KY) was redistilled before use. All fatty acids were dissolved as stock solutions of 10 mg/ml in toluene and stored at −20°C under nitrogen for not more than two months. Hank's balanced salts solution, Dulbecco's phosphate buffered saline (PBS), Dulbecco's modified Eagle's medium (DMEM), L-glutamine, sodium pyruvate, HEPES buffer and trypsin-EDTA (0.5 mg/ml trypsin, 0.2 mg/ml EDTA) were from Gibco (Grand Island, NY). Fetal calf serum was purchased from Irvine Scientific (Santa Ana, CA). Pooled human hyperlipemic serum (>250 mg/dl cholesterol) was provided by the Lipid Research Laboratory at Stanford University Medical School. All serum was heat inactivated (56°C, 30 min). Kits for radioimmunoassay of platelet factor 4 (PF4) were from Abbott Labs (N. Chicago, IL). A Diff-Quik differential staining kit was obtained from American Scientific Products (McGaw Park, IL).

Cell cultures. Human preputial skin fibroblasts were originally obtained from Dr. C. Fielding (University of California, San Francisco, CA) and maintained at 37°C (in an atmosphere containing 5% CO_2, 95% air) in culture medium (DMEM with 25 mM HEPES buffer, pH 7.3), L-glutamine and sodium pyruvate (Gibco #380-2320) supplemented with 100 μg/ml gentamicin and 10% fetal calf serum).

Human monocytes were prepared by modification of previously described methodology (17) from 100 ml of human blood from one male volunteer, age 37, or one female volunteer, age 25. In both cases, no drugs had been ingested during the previous 14 days. The blood was collected into 20 ml vacutainer tubes containing 1 ml heparin (final concentration 10 Units/ml), mixed with an equal volume of PBS; and 20 ml were carefully layered on 15 ml of Ficoll-sodium metrizoate (density = 1.077 g/l) in 50 ml conical polypropylene centrifuge tubes. This preparation was centrifuged for 30 min at 400 × *g* at room temperature. After aspiration of the top (diluted plasma) layer,

Abbreviations: ADP, adenosine diphosphate; PRP, platelet-rich plasma; PF4, platelet factor 4; PFP, plataelet-free plasma; PFPDS, platelet-free plasma-derived serum; DMEM, Dulbecco's minimum essential medium; PBS, Dulbecco's phosphate-buffered saline.

mononuclear cells at the interface were collected, washed twice in PBS, and resuspended and cultured in DMEM with autologous serum (10%), as described by Fogelman et al. (18), except that insulin was not present in the medium. Cells were plated at approximately 10^6 cells per well into 16-mm diameter culture wells of 24-well plates and allowed to adhere for 2 hr at 37°C and 5% CO_2. Nonadherent lymphocytes were then removed, by aspirating supernatant after gentle rocking of the plates, and the adherent monocytes were washed and incubated in fresh culture medium with 10% autologous serum. The adherent cells were kept in culture for seven days (and the medium changed every two days), allowing the monocytes to become macrophage-like cells (18).

Monocyte purity (absence of lymphocytes) of adherent cells was verified by standard differential staining methodology, using a Diff-Quik differential staining set.

Platelet aggregation and release of mitogens. Human blood (50–100 ml) from each of six healthy, drug-free volunteers of either sex, and in an age range of 21–50 years, was withdrawn by venipuncture via a 19-gauge butterfly infusion set into a plastic syringe containing 0.1 volume of 3.8% sodium citrate. Platelet-rich plasma (PRP) was then prepared by centrifugation of 10 ml aliquots at 1,500 × *g* for 4 min at room temperature, ca. 25°C. Fifteen microliters of a stock solution of arachidonic acid in toluene vehicle, or toluene vehicle alone, were dried under nitrogen gas at room temperature in a siliconized aggregation cuvette (0.312 in. diam.). A stirring bar was inserted, followed by 600 μl of human PRP. Mean platelet count (± SEM) was 551,100 ± 47,900/μl. Contents were stirred (1,000 rpm at 37°C) for a minimum of 3 min, while aggregation was recorded as maximal increase in light transmission. Control response to ADP (1.6 μg/ml; 3.75 μM) was also measured for comparison. Aggregation response to arachidonic acid was expressed as percentage of the response to ADP.

When inhibitory effects of fatty acids were examined, 15 μl of the appropriate stock solution or toluene vehicle was added to the cuvette, the toluene evaporated (as previously described), and the PRP was added and stirred (1,000 rpm at 37°C) for 20 min, to allow the fatty acid to dissolve and exert maximal effects on the platelet response. Aggregation was then induced by addition of 6 μl of a solution containing ADP (1.6 μg/ml, 3.75 μM, final concentration). Aggregation was recorded for 3 min, as change in light transmission of the PRP, and response reported as percentage inhibition of maximum amplitude from the control (without fatty acid).

Immediately after each sample of PRP had aggregated for 3 min, platelets were removed by centrifuging at 15,000 × *g* for one min, and supernatants again centrifuged under the same conditions. A portion of the resulting platelet-free plasma (PFP) was clotted by an adaptation of the method of Weiss et al. (19), i.e., 0.1 volume of 0.5 M $CaCl_2$ was added and samples were incubated at 37°C for 1 hr. This procedure eliminated clotting of the plasma during the subsequent mitogenesis assay, which sometimes interfered with accurate cell counting. Clots were removed with a sterile plastic rod, and the resulting platelet-free plasma-derived serum (PFPDS) was frozen at −20°C (or used immediately) for platelet mitogen assay. It was essential to remove all platelets before freezing, to avoid the artifact of freeze-thaw release of mitogens. Background samples (with no induced release of platelet mitogens) were prepared in an identical manner, except that PFP samples were used in place of PRP samples. When measured, PF4 was determined by competitive radioimmunoassay using a commercial kit (see Materials section).

Because there was a remote possibility that mitogens and/or PF4 might be trapped within the matrices of the clot, PFP and PFPDS were tested to see if they would give equivalent results in the mitogenesis assay. Mitogens in the serum produced a net increase from initial cell number (mean ± SEM) of 12,500 ± 1340 cells for PFP and 13,200 ± 1660 cells for PFPDS ($p > 0.1$, $n = 18$ in each case). Similar data were obtained in measurements of PF4: Values of 3.07 ± 0.16 μg/ml for PFP and 2.95 ± 0.16 μg/ml for PFPDS (mean ± SEM) were obtained ($p > 0.1$, $n = 7$ in each case). It is concluded that the use of PFPDS is both convenient and valid in the mitogenesis assay.

Mitogenesis assay. PFPDS, prepared during aggregation studies, was examined for its ability to support growth of human fibroblasts in culture. Cells were seeded at 8,000 cells/well into 16-mm diameter culture wells of 24-well plates. After 24 hr, culture medium was replaced with serum-free culture medium containing thawed, sterile-filtered (0.2 μm pore size) PFPDS, at a final concentration of 10% PFPDS. Cells were incubated at 37°C, 5% CO_2 for two days. The medium was then removed and the cells released with trypsin-EDTA. Cells were counted at appropriate settings in a Coulter counter (model ZBI, Coulter Instruments, Hialeah, FL), and percentage inhibition of growth was determined from counts corrected for PFP background samples (typically 35–65% of control counts).

Direct effects on cell proliferation. Fifteen microliters of a stock solution containing the appropriate fatty acid in toluene vehicle, or toluene alone, were added to tubes and the toluene evaporated under nitrogen gas. Fetal calf serum was added to a final concentration of 250 μg/ml fatty acid in serum. Mixtures were subjected to identical conditions to those used to prepare postaggregation samples for mitogen release. These samples were then diluted to 10% fetal calf serum with culture medium for proliferation assay using human fibroblasts (see Mitogenesis Assay). In this assay, final concentration of fatty acid in the cell incubation medium was thus 25 μg/ml; this is equivalent to a mitogenesis assay, starting with 250 μg/ml of fatty acid in the platelet-rich plasma. After correction for seed number, results were expressed as percentage inhibition from the control (without fatty acid).

Release and estimation of macrophage-derived growth factors. Five microliters of a solution containing eicosapentaenoic acid in toluene vehicle, or toluene alone, were added to tubes and the toluene evaporated under nitrogen gas. Then 500 μl of human hyperlipemic serum were added to stimulate conversion of the macrophages into foam cells that released mitogens. The tubes were gently mixed for 10 min, followed by addition of 4.5 ml of DMEM. The medium of the macrophage-like cells (see Cell Cultures) was replaced with this new medium and the incubation continued for another three days. The medium was then decanted, sterile-filtered (0.2-μm pore size), and examined for ability to support growth of human fibroblasts in culture, as follows: Fibroblast cells were seeded at 8,000

cells/well into 16-mm-diameter culture wells of 24-well plates. After 24 hr, culture medium was replaced with 1 ml of the filtered macrophage-conditioned medium per well. Cells were then incubated at 37°C, 5% CO_2 for two days, the medium removed, and the cells released and counted as described earlier (Mitogenesis Assay). After correction for seed number, results were expressed as percentage inhibition from the control (without fatty acid).

Statistical analysis. Values in the text and figures are expressed as the mean ± SEM. Because of variability in platelet sensitivity of different donors, comparisons among platelet-inhibitory polyunsaturated fatty acids were made within the same group of donors. Overall comparisons of data among inhibitory fatty acids (Fig. 1 and text) were determined by one-way analysis of variance, and comparisons with control group were determined using the Duncan multiple range test. For arachidonic acid (Fig. 2 and text), significance was determined by t-test for a single mean or between groups by two-tailed unpaired Student's t-test. For other studies (Figs. 3 and 4), comparisons with control were determined using two-tailed unpaired Student's t-test. In all cases, statistical significance was assumed at $p < 0.05$.

RESULTS

Eicosapentaenoic acid (20:5ω3), docosahexaenoic acid (22:6ω3), docosahexaenoic acid (22:6ω3) and EPA precursor α-linolenic acid (18:3ω3) inhibited both platelet aggregation and mitogen release at 250 μg/ml (Fig. 1). By contrast, arachidonic acid at 250 μg/ml induced platelet aggregation (percentage transmission = 42.8 ± 12.2) to ca. 79% of that induced by ADP at 1.6 μg/ml examined in direct comparison (Fig. 2a), with a corresponding stimulation of platelet mitogen release (Fig. 2b). Part of the inhibitory effects on mitogen release seen with docosahexaenoic and α-linolenic acids may have resulted from direct antiproliferative effects (hatched bars, Fig. 1b). Significant direct antiproliferative effects were not seen with eicosapentaenoic acid (Fig. 1b) or arachidonic acid (19.0 ± 8.4%, p vs control >0.1, n = 8) under these conditions.

All of the polyunsaturated fatty acids tested at 50 μg/ml were either less active than at 250 μg/ml or inactive in both assays (Fig. 1). Although not shown in Fig. 1, adrenic acid (22:4ω6), examined only at 250 μg/ml (5 donors), inhibited aggregation 30.8 ± 2.6% ($p < 0.05$): Platelet mitogen release was also lower by 28.6 ± 24.0%, but this change was not statistically significant.

Mead acid (5,8,11-eicosatrienoic acid; 20:3ω9) is elevated in many atherosclerotic individuals and in many who are at risk for atherosclerosis (13,20); and low concentrations of Mead acid potentiate the in vitro platelet aggregatory effects of other agents (21). Accumulation of Mead acid is thought to be a hallmark of essential fatty acid deficiency resulting from insufficient dietary intake of ω6 and ω3 fatty acids, as would occur with a high saturated-fat diet (22). By contrast with the strong inhibitory effects of the trienoic ω6 fatty acid dihomo-γ-linolenic acid (8,11,14-eicosatrienoic acid; 20:3ω6) (Fig. 1), Mead acid (not shown in Fig. 1) had little effect on platelet aggregation or mitogen release. In addition to inhibiting the maximum amplitude of ADP-induced platelet aggregation, dihomo-γ-linolenic acid also significantly ($p < 0.05$)

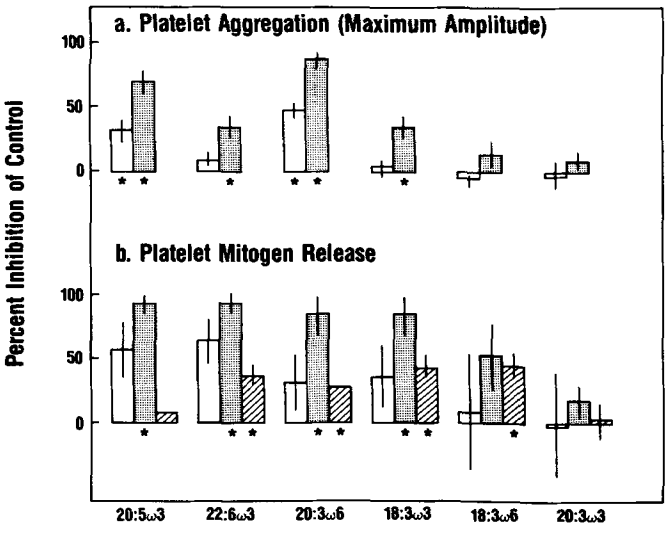

FIG. 1. Effects of several polyunsaturated fatty acids on (a) maximum amplitude of ADP-induced platelet aggregation and (b) mitogen release, at 50 μg/ml (plain bars) and 250 μg/ml (stippled bars). 20:5ω3, eicosapentaenoic acid; 22:6ω3, docosahexaenoic acid; 20:3ω6, dihomo-γ-linolenic acid; 18:3ω3, α-linolenic acid; 18:3ω6, γ-linolenic acid; 20:3ω3, 11,14,17-eicosatrienoic acid. Results are expressed as percentage inhibition of fatty acid-free control adenosine diphosphate-induced aggregation or mitogen release. Cell proliferation results (hatched bars) at 250 μg/ml in serum are expressed as percentage inhibition of fatty acid-free control proliferation. Aggregation and mitogen release values are reported as means ± standard error of 4–6 donors. Proliferation values are reported as means ± standard error of 4–8 incubation wells. *p vs control <0.05.

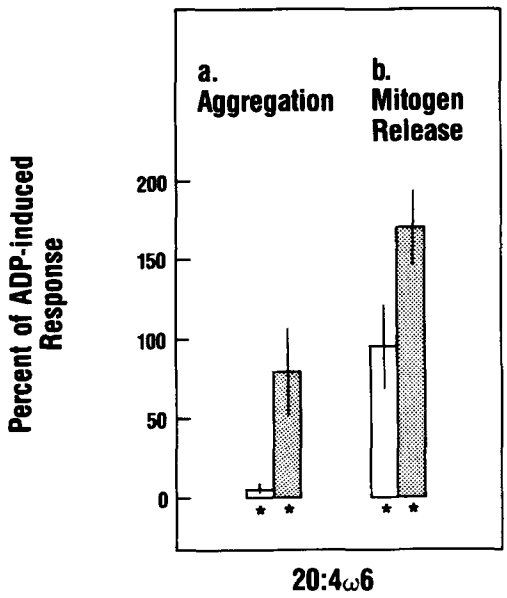

FIG. 2. Effect of arachidonic acid (20:4ω6) on (a) maximum amplitude of platelet aggregation and (b) mitogen release at 50 μg/ml (plain bars) and 250 μg/ml (stippled bars). Results are expressed as percentage of adenosine diphosphate-induced aggregation or mitogen release response. These effects were opposite in direction to those in Fig. 1. Aggregation and mitogen release values are reported as means ± standard error of 6 donors. *p vs control <0.05.

inhibited the initial rate of ADP-induced platelet aggregation at 250 μg/ml (87.0 ± 4.8% inhibition) and at 50 μg/ml (32.1 ± 3.3% inhibition). Significant inhibition of initial rate was not seen with the other fatty acids examined. Values of percentage inhibition of initial rate at 250 μg/ml and 50 μg/ml, respectively, were: 35.0 ± 16.5 and −9.3 ± 5.2 for eicosapentaenoic acid; 9.1 ± 4.3 and −2.3 ± 5.7 for docosahexaenoic acid; 4.9 ± 5.6 and −0.3 ± 4.5 for α-linolenic acid; 2.0 ± 5.3 and −18.1 ± 6.0 (significant stimulation, $p < 0.05$) for γ-linolenic acid; and 7.3 ± 9.9 and −6.1 ± 4.6 for 11,14,17-eicosatrienoic acid.

The dose-response curve for eicosapentaenoic acid on platelet aggregation and mitogen release showed inhibitory ED_{50} values of 45 μg/ml and 30 μg/ml, respectively (Fig. 3). Corresponding ED_{50} values for docosahexaenoic acid were 480 μg/ml and 160 μg/ml, respectively (not shown in Fig. 3).

Eicosapentaenoic acid also inhibited release of mitogens from human monocyte-derived macrophages: ED_{50} = 60 μg/ml (Fig. 4).

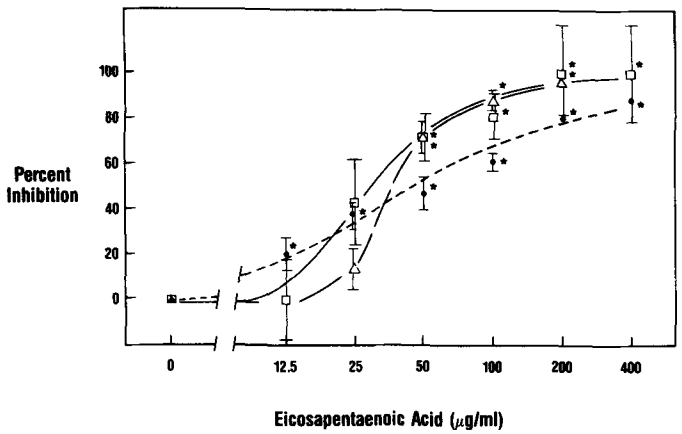

FIG. 3. Platelet effects of eicosapentaenoic acid. (●), Aggregation; (□), Mitogen release; (△), Platelet-factor-4 release. Means ± standard error; n = 6–12 adenosine diphosphate incubations (from 2 donors). *p vs control <0.05. Mean ED_{50} values between donors were within 20% of each other.

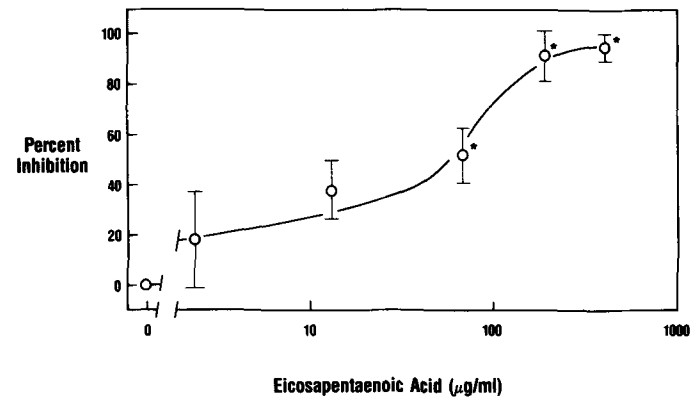

FIG. 4. Effect of eicosapentaenoic acid on release of macrophage-derived growth factors (MDGF). Means ± standard error of ≥5 macrophage incubation wells (from 2 donors). *p vs control <0.05. Mean ED_{50} values between donors were within 20% of each other.

DISCUSSION

Our findings provide the first report on the effects of purified fatty acid eicosanoid precursors on release of platelet or macrophage mitogens.

Unsaturated fatty acids are present in the diet as components of phospholipids, cholesteryl esters and (mainly, in the case of fish oils) as triglycerides. The fatty acid is digestively cleaved from these more complex lipids and then absorbed via the gastrointestinal tract by an apparent active transport mechanism (13,23,24). It is reesterified into triglycerides that are acted upon by lipoprotein lipase to release fatty acids that are then reesterified into adipose tissue or into membrane phospholipids (see ref. 13).

From these sources, the free fatty acid forms of eicosanoid precursors (e.g., arachidonic acid, dihomo-γ-linolenic acid, and eicosapentaenoic acid) are released. This is accomplished by the actions of hydrolytic enzymes including phospholipases, and the free acids are rapidly converted to eicosanoids.

During in vitro cell biology studies, one attempts to mimic the latter part of the above sequence of events by addition of the unsaturated fatty acid in free acid form (The esterified form in foods probably cannot be digested, as in the gastrointestinal tract.). However, sufficiently large concentrations have to be added in order to surmount binding to plasma albumin and allow penetration into appropriate cellular compartments. The relevance of this approach is clearly documented in the case of arachidonic acid. Although, as seen here, high concentrations (ca. 250 μg/ml) of arachidonic acid have to be used to surmount binding to plasma albumin and produce aggregation of the platelets (25) (Fig. 2), concentrations about tenfold lower produce similar effects in the absence of plasma (26). Furthermore, there is little doubt as to the in vivo relevance of in vitro platelet studies with exogenous arachidonic acid. Thus, oral administration of purified arachidonate to human volunteers can markedly increase ex vivo aggregation of platelets (27). Also, the mode of action of aspirin-like drugs via cyclooxygenase (28,29) is attributable to inhibition of conversion of intracellularly released arachidonate to endoperoxides and thromboxanes (13).

In the present studies, addition of exogenous arachidonic acid to PRP induced release of atherogenic platelet mitogens at a concentration (50 μg/ml) that did not induce significant aggregation. This result further underscores our suggestion that dietary arachidonate from meat and dairy constituents of the diet are proatherosclerotic (30).

By contrast to findings with arachidonic acid, we have shown here that eicosapentaenoic acid (≥50 μg/ml), docosahexaenoic acid (250 μg/ml) and dihomo-γ-linolenic acid (250 μg/ml) inhibited both platelet aggregation and mitogen release.The inhibition of platelet mitogen release by eicosapentaenoic acid and docosahexaenoic acid clearly has direct relevance to the antiatherosclerotic potential of marine lipid (Eskimo) diets that are rich in these fatty acids. The similar activity of dihomo-γ-linolenic acid is of considerable interest. Although it is an ω6 fatty acid and is not present in marine lipids to any extent, it is reportedly elevated in Eskimos subsisting on such diets (31) and is the precursor for prostaglandin E_1 that inhibits

platelet function (32). This elevation may be a consequence of impaired Δ^5 desaturation of dihomo-γ-linolenic acid (itself derived from linoleic acid, 18:2ω6) to arachidonic acid. This may be of genetic origin (33) or due to interference by fatty acids of the ω3 series (34).

In people consuming large amounts of fish oil, epidemiological (1,2,35,36) and most (37-45), but not all (46,47), clinical evidence points to reduced platelet aggregation to ADP and collagen, prolonged bleeding times and reduced platelet retention to glass beads (5,48). However, there have been few studies showing direct effects of purified ω3 fatty acids on platelet function either in vivo or in vitro. Early work showed that eicosapentaenoic acid slightly inhibited the second wave of aggregation produced by ADP (2). Oral administration, by humans, of highly purified eicosapentaenoic acid inhibits platelet aggregation induced by epinephrine, collagen or ADP and inhibits ex vivo platelet retention to glass beads (49). Docosahexaenoic acid, an inhibitor of cyclooxygenase (50), has been shown to reduce in vitro aggregation induced by thrombin, epinephrine and collagen (51,52). Also, dihomo-γ-linolenic acid (an ω6 fatty acid) markedly inhibits platelet aggregation when administered in vivo or in vitro (53-57). By contrast, as described earlier, arachidonic acid has the potential prothrombotic effect of inducing platelet aggregation even upon repeated oral administration of arachidonate in human volunteers (27).

Plasma and platelet levels of these complex ω3 fatty acids are barely detectable in people consuming little or no fish oil (38). However, they become markedly elevated (largely at the expense of arachidonic acid) in people consuming marine diets rich in ω3 fatty acids (35,37,58).

In our in vitro studies, analogy with arachidonic acid indicates that the amount of the fatty acids we used was of physiological significance. In confirmation of this assumption, fish oil administration in dogs reduces clotting-induced release of mitogenic activity from platelets (59), and there is a corresponding reduction in experimental atherosclerosis induced by arteriovenous grafting and cholesterol feeding. These recent findings extend earlier in vivo evidence for antiatherosclerotic effects of diets rich in marine oils—i.e., epidemiological evidence showing lower rates of cardiovascular disease in man (1-5,9,35, 60,61) apparently confirmed in prospective studies (62). Antiatherosclerotic effects of fish oils have also been shown in animal models (7,8,10,11).

Macrophage-derived foam cells may be an early source of mitogenic material inducing proliferative lesions (63,64). The ability of eicosapentaenoic acid to suppress mitogen release from both platelets and macrophages, thus, may be important in potential antiatherosclerotic properties of marine lipids.

METHODS

Simple High Performance Liquid Chromatography Methods for Monitoring Lipase Reactions

Françoise Ergan* and **Gérald André**
Biotechnology Research Institute, National Research Council Canada, 6100 Royalmount Ave., Montreal, Quebec H4P 2R2, Canada

This paper describes three simple high performance liquid chromatography methods to separate mixtures of free fatty acids, mixtures of different triglycerides and mixtures of all fat classes (monoglycerides, diglycerides, triglycerides and free fatty acids). It is possible with our methods to identify and quantify each peak of the chromatogram. These methods have been designed to monitor lipase reactions. Using a first set of conditions, we have been able to separate five fatty acids: linolenic, linoleic, palmitic, oleic and stearic, without any specific preparation of the samples. With a second set of conditions, we showed that the same mobile phase and the same column could separate both triglyceride species and fat classes. However, in the latter case, a flow gradient was used. *Lipids 24,* 76–78 (1989).

Modification of fats and oils is a new area for enzyme technology. Not only are triglycerides being hydrolyzed or broken down, they are also rearranged and synthesized. These reactions are carried out with lipases. There are several compounds that have to be measured as a result of these reactions. Very often it is sufficient to follow the appearance or disappearance of free fatty acids (FFA). However, sometimes it is necessary to monitor the levels of monoglycerides (MG), diglycerides (DG) and triglycerides (TG). In the case of flavor development, it may be necessary to profile all of these. Sometimes after a lipolysis treatment, the amounts of all lipid species or classes in the reaction mix are requested, i.e., in addition to the total FFA, the amounts of MG, DG and TG have to be determined. Measuring the content of glyceride compounds such as MG and TG is of interest in reactions other than lipolysis. Examples of these reactions are the synthesis of MG via glycerolysis or the synthesis of cocoa butter substitute from palm oil via transesterification. Sometimes it is desirable to know how much of each FFA or other lipid is in the sample. The many individual components can be resolved using the methods described in this paper to give what is known as a "profile" of a modified fat or oil.

Methods for monitoring lipid enzyme reactions are still being developed. Many of the present methods are time-consuming and are based on procedures used by chemists to characterize fats and oils, e.g., titration or gas chromatography (GC). They involve solvent extractions, sample transfers and, sometimes, chemical modifications. FFA can be monitored using the pH-stat methods or by direct titration. GC can be used provided that FFA are first converted to fatty acid methyl esters (FAME) (1) or acidified with sulfuric mixed with silicic acid and then eluted with 1% butanol in petroleum ether (2). Lipid class profiles can be found by thin layer chromatography (TLC) (3) or high performance liquid chromatography (HPLC), provided that the sample is modified in order to convert the FFA into their respective methyl esters (4) or that a transport-flame ionization detector (T-FID) is used (5). Triglyceride profiles are easily obtainable through HPLC (6,7) and high temperature GC (5).

In this paper, we describe simple HPLC methods in order to easily obtain FFA profiles, TG profiles and lipid class profiles without any previous modification or preparation of the sample. Those methods differ from each other as little as possible, so that it is relatively easy to switch from one type of analysis to another on the same sample.

EXPERIMENTAL PROCEDURES

Reagents. TG standards (POP, POS, SOS) of the highest purity grade were purchased from Supelco Canada (Oakville, Ont.). Free fatty acids, esters of fatty acids, triolein, diolein, monoolein, lipase L-0382 from porcine pancreas, and lipase L-4384 from *Rhizopus arrhizus* were purchased from Sigma Chemical Co. (St. Louis, MO). HPLC-grade acetonitrile, acetone and tetrahydrofuran (THF) were obtained from Fisher Scientific (Pittsburgh, PA). Cocoa butter was donated by General Foods (Montreal, Canada). Lipozyme was a gift from Novo (Lachine, Québec, Canada).

Equipment. HPLC was carried out using the following equipment: Waters M590 solvent delivery systems, WISP 710B sample processor, Waters M481 LC spectrophotometer (Waters Assoc., Milford, MA); refractive index detector 1037A (Hewlett-Packard, Palo Alto, CA) and Professional 350 computer (Digital Equipment Corporation, Concord, MA).

Columns. TG profiles and lipid class profiles. TG, as well as lipid classes, are resolved by a HPLC system equipped with a reverse phase column: CSC-S, Spherisorb ODS-2, 5 μm (25 cm × 4.6 mm).

FFA profiles. The column used for FFA separation was a Supelcosil (octyl bonded spherical silica) LC-8, 3 μm (15 cm × 4.6 mm) to which a guard column Supelcosil LC-8, 5 μm (2 cm × 4.6 mm) was connected.

Standards preparation. FFA. Twenty-five mg of each FFA (linolenic, linoleic, palmitic, oleic and stearic acids) were dissolved in 1 ml of acetonitrile. Three to four drops of THF were added when solubilization was incomplete. More acetonitrile was then added after solubilization, up to a final volume of 5 ml.

*To whom correspondence should be addressed.

Abbreviations: DG, diglycerides; FAME, fatty acid methyl esters; FFA, free fatty acids; MG, monoglycerides; OOO, triolein; POP, *rac*-glyceryl-1,3-palmitate-2-oleate; POS, *rac*-glyceryl-1-palmitate-2-oleate-3-stearate; RI, refractive index; SOS, *rac*-glyceryl-1,3-stearate-2-oleate; TG, triglyceride; THF, tetrahydrofuran; GC, gas chromatography; HPLC, high performance liquid chroamtography; T-FID, transport-flame ionization detector; TLC, thin layer chromatography; CSC, Chromatography Sciences Co., Canada.

TG. Ten mg of POP, POS and SOS were dissolved in 1 ml of acetone. Cocoa butter was prepared at a concentration of 10% in acetone.

Lipid classes. A mixture containing 10 mg of triolein, 10 mg of diolein, 10 mg of monoolein and 10 mg of oleic acid was dissolved in 1 ml of acetone. No pretreatment was required for any of these standards before injection in the column.

Lipase reaction and samples preparation. Two types of reaction were performed with lipase enzymes and monitored by HPLC methods.

Hydrolysis. Triolein (0.5 g) was mixed in an Eppendorf tube with 0.5 ml of 10 mM sodium phosphate buffer, pH 5.8, containing 0.2 mg of lipase from porcine pancreas (10,800 U). The mixture was shaken vigorously at 34°C on a vortex shaker.

Synthesis. Oleic acid (0.5 g) was mixed in an Eppendorf tube with 0.05 g of glycerol in the presence of 5 μl of Lipozyme (10,000 LU/g). The mixture was shaken vigorously at 34°C on a vortex shaker.

For both types of experiments, 5 μl aliquots were taken at preset intervals and diluted in 200 μl of acetone. No pretreatment was necessary before injecting those samples into the HPLC system. Oleic acid, monoolein, diolein and triolein amounts were calculated in each aliquot as percentages of the initial amount of oleic acid, in oleic acid equivalents, taking into account that diolein and triolein contain 2 and 3 mol of oleic acid, respectively.

RESULTS AND DISCUSSION

FFA. The mobile phase is acetonitrile/tetrahydrofuran/0.1% H_3PO_4 (50.4:21.6:28, v/v/v). The flow rate is 1 ml/min. Twenty-five μl are injected and the column is thermostated at 35°C. Figure 1 represents the FFA separation with a refractive index (RI) detector. The response factors are more similar with the RI detector than with the UV detector. A good separation is achieved with the LC-8 column and an isocratic run.

TG. The mobile phase used here is acetone/acetonitrile (50:50, v/v). The flow rate is 2.5 ml/min. Fifteen μl are injected, and the column is thermostated at 35°C. Figure 2 represents the chromatogram of cocoa butter obtained using a UV detector at 220 nm.

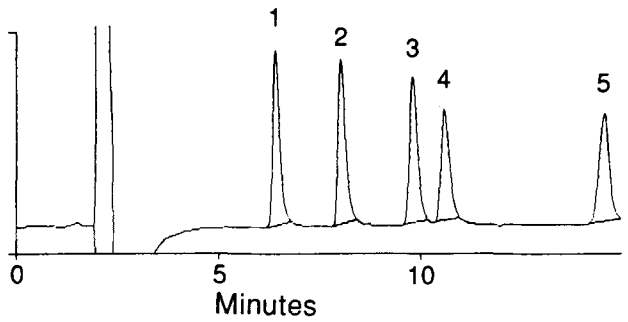

FIG. 1. Chromatogram of FFA (RI detector). 1, linolenic acid; 2, linoleic acid; 3, palmitic acid; 4, oleic acid; and 5, stearic acid. Column: Supelcosil (octyl bonded spherical silica) LC-8, 3 μm, (15 cm × 4.6 mm) + guard column Supelcosil LC-8, 5 μm, (2 cm × 4.6 mm). Mobile phase: acetonitrile/tetrahydrofuran/0.1% H_3PO_4 (50.4:21.6:28). Flow rate: 1 ml/min, T = 35°C, injected volume 25 μl, standard concentrations 5 mg/ml of acetonitrile.

Lipid classes. The mobile phase is the same one as previously described for TG analysis. However, a flow gradient is used: 0.8 ml/min for 6 min, increased in 4 min up to 4 ml/min, held at 4 ml/min for 11 min, decreased back to 0.8 ml/min in 4 min and held for another 5 min at 0.8 ml/min before the next injection. Fifteen μl are injected, and the column is thermostated at 35°C. Figure 3A is the UV chromatogram at 206 nm of a mixture containing 10 mg of monoolein, diolein, triolein and oleic acid/ml of acetone.

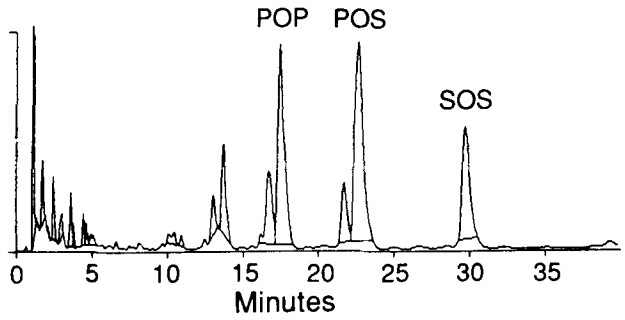

FIG. 2. Chromatogram of the TG of cocoa butter (UV detector 220 nm). P, palmitic acid; O, oleic acid; S, stearic acid. Column: CSC-S, Spherisorb ODS-2, 5 μm (25 cm × 4.6 mm). Mobile phase: acetone/acetonitrile (50:50). Flow rate: 2.5 ml/min, T = 35°C, injected volume 15 μl, sample concentration 10% in acetone.

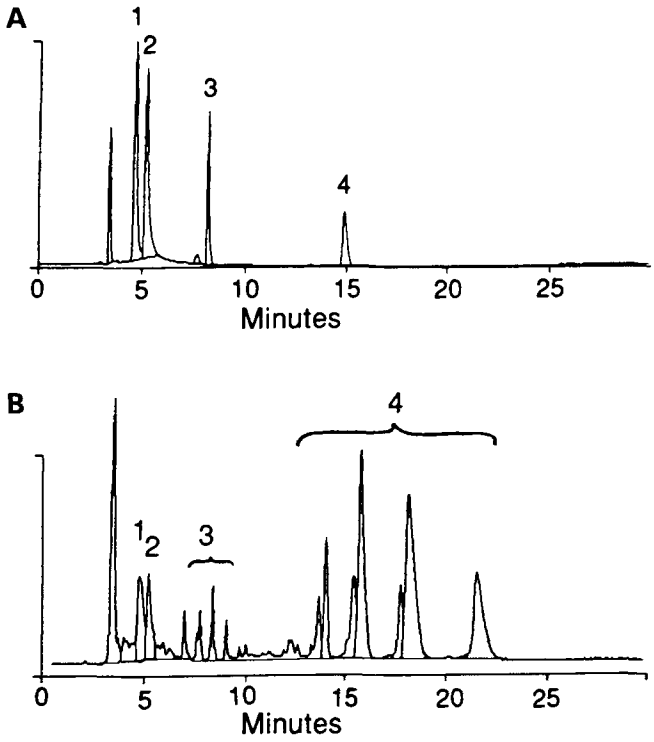

FIG. 3. (A) Chromatogram of lipid classes (UV detector at 206 nm). 1, monoolein; 2, oleic acid; 3, diolein; and 4, triolein. Column: CSC-S, Spherisorb ODS-2, 5 μm (25 cm × 4.6 mm). Mobile phase: acetone/acetonitrile (50:50). Flow rate: see text, T = 35°C, injected volume 15 μl, standard concentrations 10 mg/ml of acetone. (B) Chromatogram of lipid classes contained in cocoa butter (UV detector 206 nm). 1, MG; 2, FFA; 3, DG; 4, TG. Chromatographic conditions as in Figure 3A.

It is possible to separate 1,2-diolein from 1,3-diolein. Actually, the diolein standard used contained 85% of the 1,3-isomer and 15% of the 1,2-isomer. Our lipid class profile shows the separation between the two diolein isomers when using the UV detector.

If the methods have general utility, they must be applicable to real samples. The previous analyses deal only with lipid classes containing a single fatty acid (oleic acid). One problem in applying reversed phase chromatography to lipid class separations is that components containing different fatty acids are also resolved. We show here that the resolution is still adequate when applied to a cocoa butter sample (Fig. 3B). This chromatogram (UV, 206 nm) shows one single peak for MG, another peak for FFA, a series of peaks for DG and another distinct series for TG. DG and TG species containing different FA are resolved; however, there is no overlapping between the different classes.

Lipase reactions. Figures 4A and 4B show two examples of the use of previously described methods as process monitors. Hydrolysis (Fig. 4A) and synthesis (Fig. 4B) of triolein have been followed through HPLC. Both modes of detection have been compared for each type of analysis, and the best one is shown in the figures. In the case of FFA, the UV detector gives very different response factors with the different fatty acids. For this reason, the RI detector is preferred for FFA analysis. For all the other compounds and types of analysis, the sensitivity of the UV detector (at 206 nm) is better than that of the RI detector. Therefore, UV detection is preferred for TG analyses and fat classes analyses.

We have shown in this paper that HPLC techniques are suitable for many analyses of fats without previous modification and treatment of the sample. With only two different columns and two different mobile phases, it has been possible to monitor lipase reactions, not only for substrates and products of the reaction, but also for intermediate products of the reaction. This paper supports the view that HPLC can provide a relatively rapid and reproducible method for monitoring bench scale and pilot-plant scale reactions involving hydrolysis and synthesis of fats using lipases.

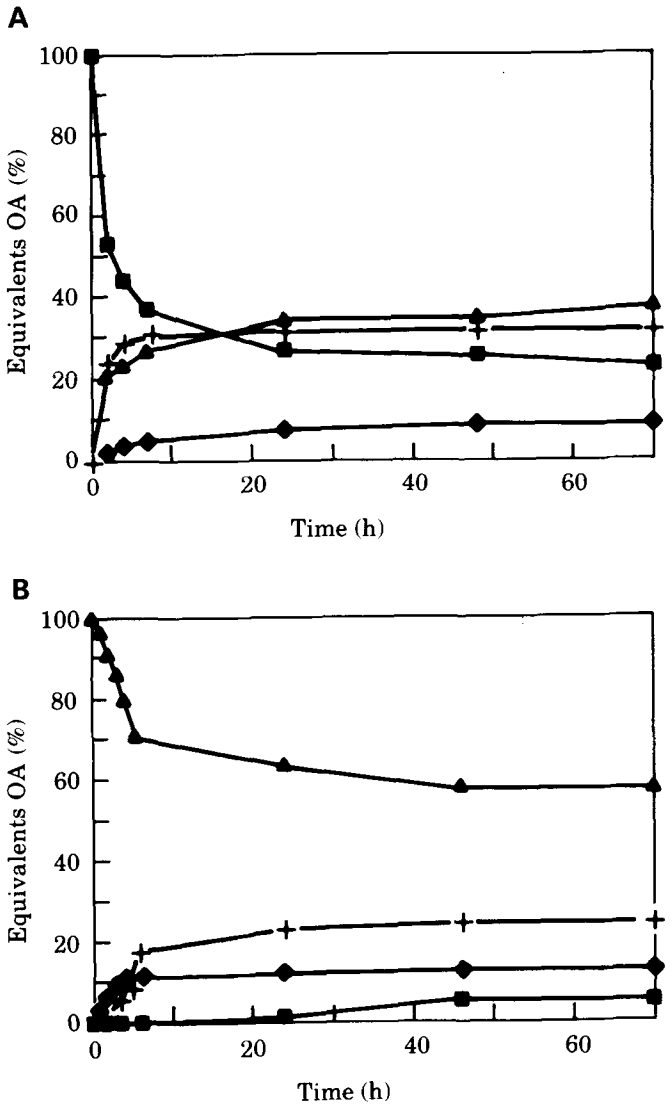

FIG. 4. (A) Hydrolysis of triolein with a lipase from porcine pancreas. The HPLC method described in Fig. 3A was used to monitor the reaction. ■, Triolein, + diolein, ◆ monoolein and ▲oleic acid. (B) Synthesis of glycerides (mono-, di- and tri-) from oleic acid and glycerol using a lipase from *Mucor miehei* (Lipozyme). The HPLC method described in Fig. 3A was used to monitor the reaction. Symbols are similar to those used in Fig. 4A.

Location of Double Bonds in Fatty Acids of Fish Oil and Rat Testis Lipids. Gas Chromatography-Mass Spectrometry of the Oxazoline Derivatives[1]

Q.T. Yu, B.N. Liu, J.Y. Zhang and **Z.H. Huang***
Shanghai Institute of Materia Medica, Chinese Academy of Sciences, 319 Yue-yang Road, Shanghai 200031, China

A new approach to the derivatization and analysis of long chain polyunsaturated fatty acids is described. The method is based on the formation of 2-alkenyl-4,4-dimethyloxazolines by condensation of the starting material with 2-amino-2-methylpropanol. The derivatization method is rapid, efficient and specific with respect to the chain feature of the parent acids. Volatility, comparable with that of the corresponding simple esters, and improved gas chromatographic separation are achieved without difficulty. The derivatives exhibit clear and regular fragmentation patterns that allow easy discrimination of positional isomers and assignment of double bond location in the chain.
***Lipids* 24, 79-83 (1989).**

Determining the location of double bonds in fatty acids (FA) has been a topic of continuing interest in analytical biochemistry. Gas chromatography-mass spectrometry (GC-MS) techniques approach this problem in two different ways, each consisting of a key step involving chemical modification prior to analysis. Derivatization at the double bond ("on-site" modification [2-4]) to oxygenated compounds (e.g., mixtures of carbonyl compounds and vicinal diols) leads to more distinctive fragmentation patterns that allow final determination of the unsaturated points. This approach is often associated with the formation of more polar derivatives and an increase in molecular weights, and is therefore unsuited for the analysis of polyunsaturated fatty acids (PUFA). Another technique, first proposed by Vetter et al. in 1971 (5), is based on the derivatization of the terminal carboxylic acid group ("remote site" modification [2-4]), whereby fatty acids are converted to amides or esters such as N-acylpyrrolidides (6) and picolinyl esters (7) that easily stabilize the ions containing the double bonds. In consequence, spectra are recorded that are frequently characteristic of particular unsaturated fatty acids (UFA).

Pyrrolidides have been studied most often for the analysis of natural samples (8-14). Although distinctive modes of fragmentation can be obtained for UFA, the interpretation of spectra becomes substantially more difficult if the number of double bonds is greater than four (6). A superficially attractive method has been suggested that involves specific deuteration of the double bonds in PUFA using nascent deuteriodiimide (N_2D_4), followed by conversion to pyrrolidides and mass spectrometric analysis of the resulting derivatives (15,16). Although correct assignment was obtained for up to six double bonds under certain circumstances, the results were found variable with different types of instruments (16).

Detailed study of the fragmentation of isomeric unsaturated FA has been accomplished by Christie et al. (17-19) via derivatization to picolinyl esters. It has been demonstrated, in a comparative study using PUFA-rich natural samples, that picolinyl esters are preferred over pyrrolidides because they give more abundant diagnostic ions (20). Furthermore, the picolinyl ester derivatives can be separated by high performance liquid chromatography (HPLC) in the reversed-phase mode before GC-MS analysis. Such a procedure is of value for the detection of minor components in natural samples (21-22).

A somewhat different strategy to increase the power and versatility, so that unusual fatty acids can be studied, would be to develop a method of direct analysis of FA mixtures without prior chromatographic separation. Such analysis is indeed possible by fast atom bombardment (FAB) in combination with tandem mass spectrometry (MS-MS). Gross and coworkers (23) have reported that free FA can be readily desorbed either as anions $(M-H)^-$ or as alkali metal-cationized species $(M + Li)^+$ or $(M - H + 2Li)^+$ (24) and collisionally activated (CA). This technique has been used for the analysis of picolinyl esters of UFA samples (25). Usually, the determination of chain structure based on FAB-CA-MS-MS of these derivatives is possible for PUFA with up to three ethylenic linkages, but becomes more difficult for molecules with higher degrees of unsaturation.

The preparation of 2-substituted 4,4-dimethyloxazolines (DMOX) by condensation of the FA with 2-amino-2-methylpropanol (AMP) and subsequent measurement of their electron impact (EI) mass spectra represents a useful alternative technique for the structure determination of UFA (26). Being different from the commonly used simple esters and amides, such derivatives with their terminal carboxylic acid group incorporated into a heterocycle show improved MS and GC properties due to the enhanced charge stabilization and the reduced tendency of hydrogen bonding in the resulting molecules. DMOX has proved to exhibit clear-cut and regular fragmentation patterns that precisely indicate the double bond position in the chain. To establish the usefulness of this method, the GC-MS of PUFA mixtures from fish oil and rat testis lipids have been studied, and the results are reported in this paper.

MATERIALS AND METHODS

Materials. 2-Amino-2-methylpropanol (AMP) and dicyclohexylcarbodiimide (DCC), with purity over 99% were purchased from Aldrich Chemical Co. (Milwaukee, WI). Fish oil (from *Navodon septentrionalis*) was obtained

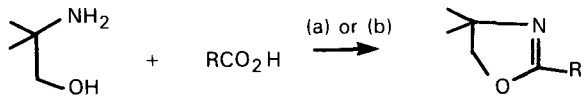
[1]Chemical Modification in Mass Spectrometry, Part 8. For preceding paper, see reference 1.

*Author to whom correspondence should be addressed.

Abbreviations: AMP, 2-amino-2-methylpropanol; DCC, dicyclohexylcarbodiimide; DMOX, 2-alkenyl-4,4-dimethyloxazoline; FA, fatty acid; PUFA, polyunsaturated fatty acid; UFA, unsaturated fatty acid; CA, collisionally activated; EI, electron impact; FAB, fast atom bombardment; GC-MS, gas chromatography-mass spectrometry; HPLC, high performance liquid chromatography; MS-MS, tandem mass spectrometry; TIC, total ion current.

from a local fish-products factory. Rat testes were collected from freshly killed laboratory animals and the lipids were extracted with chloroform/methanol (2:1, v/v). FA were prepared by saponification with aqueous methanolic potassium hydroxide solution.

Derivatization. DMOX were prepared (in μg to mg scale) according to the procedures described earlier (26,27):



(a) The FA fraction was heated with a 2-fold excess of AMP at 170°C for 1–2 hr, or (b) the FA fraction was first allowed to react with equal amount of DCC (in CH_2Cl_2, room temperature, 2 hr) followed by treating with $SOCl_2$ (0°C, 0.5 hr). The conversion (estimated by GC) was better than 90% by either method. To obtain high quality spectra, a critical step is to allow the reaction product to pass through a small column of silica gel, followed by eluting with minimum amount of ethyl acetate before analysis.

GC-MS. All GC-MS analyses were carried out on a Finnigan-MAT 44S gas chromatographer-mass spectrometer equipped with a 18 m × 0.28 mm glass capillary column coated with SE-54 (crosslinked and bonded). Helium was the carrier gas at a flow rate of about 1 ml/min, split ratio 1:10. The samples were injected onto the column at 250°C; oven temperature was programmed at 4°C/min from 150 to 240°C. Spectra were recorded at an ionization energy of 70 eV. Ion source was maintained at 250°C during the analysis. Quantities of individual compounds were determined by percentages of total integrated areas in total ion current (TIC) tracing.

RESULTS AND DISCUSSION

Fish oil and rat testis lipids were chosen as model samples in this study because both were known to contain a number of mono- and polyunsaturated fatty acids. Good separation was developed with the DMOX of each sample. The DMOX were eluted at column temperatures below 240°C with negligible column bleedings from a cross-linked SE-54 glass capillary column. The TIC tracings of FA of fish oil derivatized as methyl esters and DMOX are presented in Figure 1.

Both derivatives provide similar chromatographic profiles, although slightly broader peaks are observed in the latter. With a few exceptions, most of the components derivatized as DMOX were separated with sufficient resolution. Well-interpretable mass spectra were recorded for each peak. Peaks which were not fully resolved such as peaks #9, #10 and #11 in Figure 1b yielded respective mass spectra (Fig. 2) that were still clear enough to permit correct identification of the "unknowns." Under the conditions described above, UFA derivatives are eluted before the saturated ones, whereas monoenoic acid derivatives with double bonds near the carboxylic group emerge before those having a double bond remote from the polar end. This is also the case of UFA derivatives from rat testis lipids, and the chromatogram of the latter is presented in Figure 3.

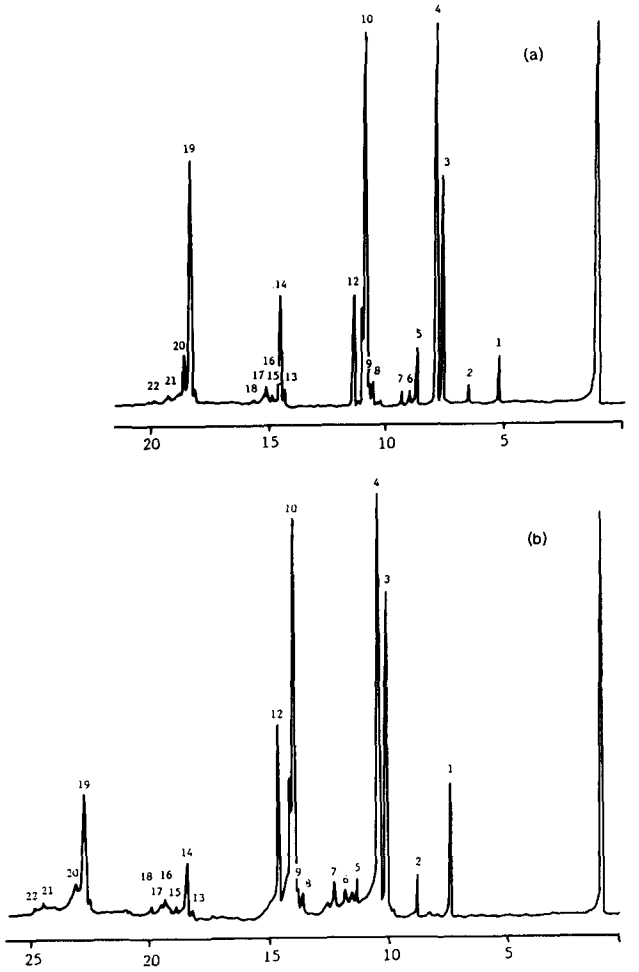


FIG. 1. Gas chromatograms of fatty acid derivatives from fish oil: (a) methyl esters and (b) DMOX. For GC conditions, see Experimental.

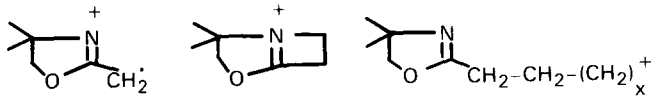
Component fatty acids and characteristic ions of DMOX obtained from the two natural samples are listed in Table 1. The assignment is consistent with the results obtained by other methods (28,29), with small differences in certain minor constituents for species-dependent reasons.

Close resemblance is observed between the mass spectra of DMOX and those of the corresponding N-acyl pyrrolidides in the region above *m/z* 100. One important advantage of the present method is that DMOX furnish much more prominent fragment ions (especially in the high mass end), whereas the interference arising from peaks composed of pure "hydrocarbons" is minimum. The fragmentation is simple. Only three types of ions are present in the spectra—the McLafferty rearrangement product (*m/z* 113, usually as the base peak for 2-unsubstituted FA series), the ion due to cyclization-displacement (*m/z* 126 usually as the second large peak in the spectrum) and a series of homologous ions containing the heterocyclic ring (*m/z* 126 + 14x, x = 1,2,3, ...):



m/z 113 *m/z* 126 *m/z* 126 + 14x

The double bond position can be deduced easily by using the empirical rule formulated in our previous work (26). Considering only the most pronounced ion in each cluster of FA derivatives, an even-mass ion series starting from *m/z* 126 is distributed regularly at intervals of 14 mass units. It turns out that the presence of a double bond at carbon n of the fatty acid is indicated by a gap of 12 mass units in the homologous series instead of the normal 14 units between ions containing n-1 and n carbon atoms of the original acid moiety. For monoenoic acids, additional information is provided by two more intense peaks corresponding to fragments containing n − 2 and n + 2 carbon atoms due to allylic cleavage on both sides of the double bond, hence greatly facilitating the correct determination of this particular site of unsaturation (Fig. 4).

TABLE 1

DMOX of Fatty Acids of Rat Testis Lipids and Fish Oil

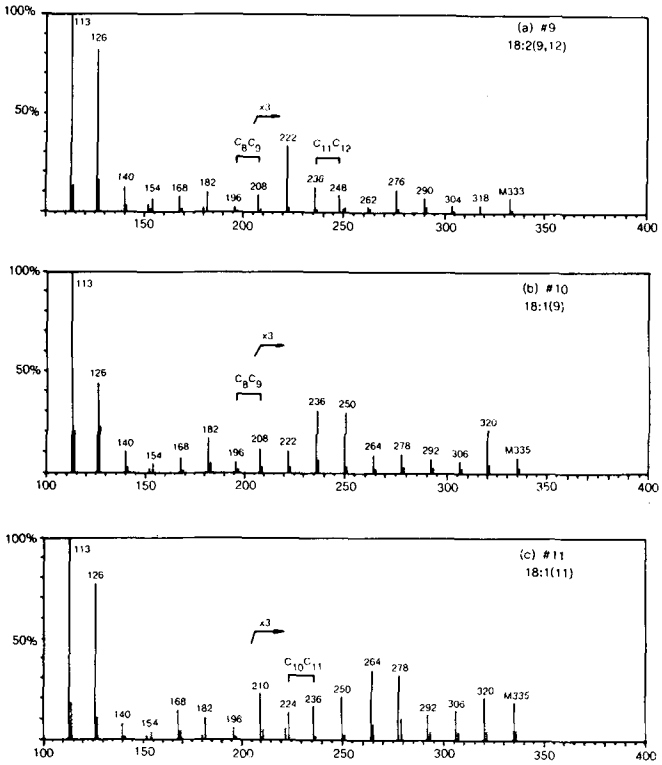

FIG. 2. Mass spectra recorded during GC-MS of DMOX of fish oil products: (a) #9, (b) #10 and (c) #11.

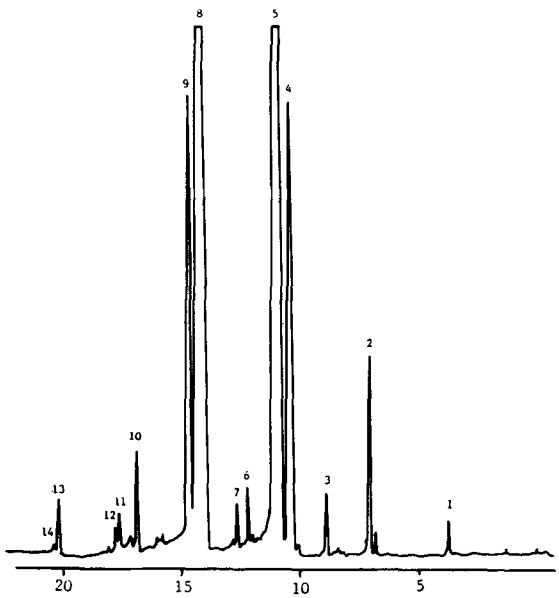

FIG. 3. Gas chromatogram of DMOX derived from fatty acids of rat testis lipids. For GC conditions, see Experimental.

Spectra of PUFA derivatives are depicted in Figure 5, which reveals typical fragmentation for methylene-interrupted acids: the "abnormal" interval of 12 amu (Δ^n) is flanked by two higher homologous peaks (fragments with C_{n-2} and C_{n+1}), thus forming a number of easily

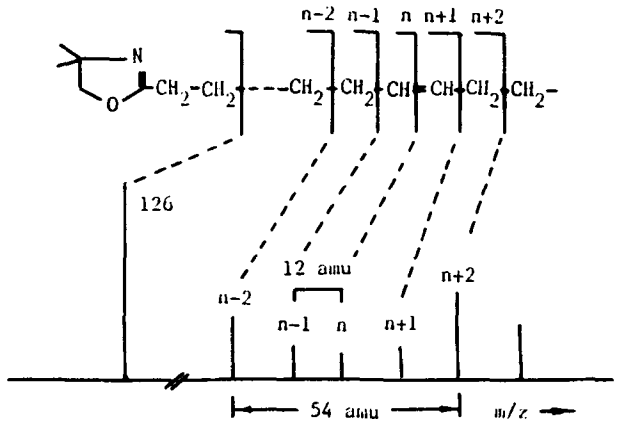

FIG. 4. Schematic presentation of the mass spectral characteristics of monoenoic acid derivatives.

recognizable markers separated by 40 amu in the spectrum profile of the compound in question. As confirmed on model compounds (26), peaks indicating the first double bond in spectra of PUFA derivatives at C_4 (*m/z* 138), C_5 (*m/z* 152) and C_6 (*m/z* 166) are accompanied by a strong odd-mass ion at *m/z* 139, 153 and 167, respectively. Mechanistic aspects of their formation remain unexplored. The empirical rule works well for all compounds in this study.

In summary, this study provides a useful method for simultaneous separation and structure elucidation of UFA. With conversions higher than 90%, the derivatization is easy. It does not require a complicated cleanup procedure, and the GC-MS analysis is usually completed within 30 min. Although the GC of pyrrolidide or picolinyl derivatives necessitates a column temperature approximately 50°C higher than that used for the methyl esters (10,20), it suffices for DMOX to maintain the column temperature only 10°C higher, compared with those of methyl esters (26). This procedure gives more specific results regarding the double bond position and the chain feature as well. Therefore, the DMOX method is potentially of value for the GC-MS of naturally occurring long or very long chain (>22C) PUFA. The encouraging results of extended application to branched acids (30), cyclopropanoid acids (31), cyclopentenoid acids (32) and oxygenated acids (33,34) will be reported elsewhere.

Biosynthesis of (^{14}C)Arachidonic Acid From (^{14}C)Linoleate in Primary Cultures of Rat Sertoli Cells

J.G. Coniglio* and **J. Sharp**
Department of Biochemistry, Vanderbilt University, Nashville, TN 37232

The conversion of [^{14}C]linoleate to [^{14}C]arachidonate by rat Sertoli cells was established by use of primary cultures. Most of the ^{14}C from [1-^{14}C]linoleate was located in C-3 of the synthesized arachidonate, indicating that the labeled tetraene had originated largely by elongation and desaturation of the intact labeled substrate rather than by mere addition of ^{14}C-acetate generated by bio-oxidation of the radioactive substrate to an already existing 18-carbon precursor. Although a relatively small amount of ^{14}C was present in 18:3ω6 and a relatively large amount of ^{14}C was present in 20:2, it was not possible from these data to establish the relative importance of 20:2 in the biosynthesis of arachidonic acid in rat Sertoli cells.
Lipids 24, 84-85 (1989).

Arachidonic acid is a major component of phospholipids in testes of rats and most other animals. Its synthesis from linoleate in intact rat testis has been shown (1), but the testicular cell type(s) responsible for the synthesis is not known.

Sertoli cells are thought to be responsible for supplying nutritive substances to the developing germinal cells. Thus, there is a possibility that rat Sertoli cells utilize dietary linoleate for the synthesis of arachidonate, which can then be transferred to the developing germinal cells or utilized for further conversion to the 22-carbon pentaene which accumulates in rat spermatids and spermatozoa. Intratesticular injection of [^{14}C]linoleate in rats led to significant labeling of arachidonic acid in Sertoli cells separated from other testicular cells at 3-48 hr after injection (2). However, from these in vivo studies, it could not be determined if the Sertoli cells had incorporated the ^{14}C into arachidonic acid or if the labeled arachidonate originated in some other cell type and subsequently was transferred to the Sertoli cell.

In this communication, we report the use of primary cultures of rat Sertoli cells to establish the conversion of [^{14}C]linoleate to [^{14}C]arachidonate in this cell type.

MATERIALS AND METHODS

Primary cultures of Sertoli cells of Sprague-Dawley rats, 20-25 days old, were prepared according to the method of Tung et al. (3). Testes from 5 or 6 animals yielded sufficient cells to plate 4 dishes (10 ml medium per dish). About 5 million cells per dish were harvested (counted only in one experiment). On the fifth day of the culture, 1 μCi [1-^{14}C]linoleic acid (Sp. act. 55.6 mCi/mmole; New England Nuclear Corp., Boston, MA) and 0.50 mg ^{12}C-linoleic acid were provided as the albumin complex (prepared in a 4:1 molar ratio of salt to fatty acid-poor albumin) to each dish of culture in 10 ml medium. The cells were maintained at 31°C for 48 hr, after which they were harvested and digested with KOH using hydroquinone as antioxidant and a nitrogen atmosphere. After acidification, the fatty acids were extracted with petroleum ether. About 2-4 mg carrier, nonradioactive fatty acids (obtained from testes of nonradioactive rats) were added to the extracted ^{14}C-fatty acids before methylation. The preparation of methyl esters and the radio gas chromatographic analysis were done as reported previously (4). About 15-25 μg fatty acid methyl esters were used per radio gas chromatographic analysis. The location of the ^{14}C in the isolated pure arachidonic acid molecule was done by Dauben degradation (5) of the saturated 20-carbon acid obtained by hydrogenation of the polyene.

In some experiments, 10 μCi [1-^{14}C]sodium acetate (Sp. act. 57.7 mCi/mmole; New England Nuclear Corp.) and 0.2 mg ^{12}C-sodium acetate per dish were used as substrate.

RESULTS AND DISCUSSION

Sertoli cells in primary cultures incorporated 7.2% (SD = 1.8, n = 4) of the linoleate-^{14}C substrate into long chain fatty acids in 48 hr. Of the long chain fatty acid ^{14}C in the harvested cells 39% (SD = 5.1) was present as linoleic acid. The distribution of the remaining ^{14}C is shown in Table 1. Over 60% of the total fatty acid ^{14}C (not counting linoleate-^{14}C) was in 20-carbon metabolites (20:2,

20:3, 20:4). The collected fraction identified in Table 1 as 18:3-20:1 from each of the four experiments was pooled into one sample and further purified by preparative gas chromatography. Radio gas chromatographic analysis of the purified fraction showed that only about 5% of the ^{14}C was in the 18:3ω6.

Chemical degradation of the labeled arachidonic acid showed that over 90% of the ^{14}C was in carbon 3 (carboxyl carbon is number 1). The ratio of the specific activity of C-1:average carbon in the fatty acid chain (C1:average carbon) was 3.0 and that of C-3:average carbon in the fatty acid chain (C3:average chain) was 17.0. A ratio of 2.0 indicates complete de novo synthesis, and a ratio of 20 (for a 20-carbon fatty acid) indicates elongation of the immediate precursor. The palmitic acid fraction was also isolated and degraded. The ratio of C1:average carbon was 2.3 and that of C-3 was 3.5, indicating that the palmitate had been synthesized mostly by de novo synthesis using the ^{14}C-acetate generated by cellular oxidation of the radioactive linoleate.

When [^{14}C]acetate was used as substrate, 2.7% (SD = 1.05, n = 3) of the administered dose was incorporated into long chain fatty acids. The distribution of the ^{14}C in individual fatty acids is shown in Table 1. Over 90% of the incorporated ^{14}C was in saturated fatty acids. With the exception of 22:4, which had about 2% of the total ^{14}C, each of the polyenoic acids had less than 1% of the total ^{14}C activity.

Conversion of [^{14}C]linoleate to [^{14}C]arachidonate in these experiments is firm evidence that rat Sertoli cells can synthesize the tetraene from the dietary precursor, linoleic acid. It had previously been shown that rat testes could synthesize arachidonate from linoleate, but it was not determined in which cell type(s) the biosynthesis occurred (1). Because linoleate was metabolized to acetate by the cells in culture, it was of interest to determine whether the ^{14}C-tetraene had been synthesized by mere addition of ^{14}C-acetyl CoA (generated by oxidation of the labeled linoleate) to small amounts of an existing appropriate precursor (18:4) or by utilization of the ^{14}C-linoleate substrate. The results of Dauben degradation of the isolated pure 20:4 clearly demonstrate that the ^{14}C-20:4 had been produced mainly by elongation and further desaturation of the ^{14}C-linoleate substrate. The rather low incorporation of ^{14}C into 20:4, when [1-^{14}C]-acetate was used as substrate, is in agreement with these results. The incorporation of [^{14}C]acetate into arachidonic acid in isolated incubated germinal cells has been reported (6).

The rather large amount of ^{14}C in 20:2 is of interest in that Δ^8 desaturation would provide 20:3, the precursor of arachidonic acid. Although, in most organs, Δ8-desaturase is not present and desaturation of 20:2 yields 5,11,14-20:3 (a dead-end product), there is an active Δ8-desaturase in rat testes (7). However, it remains to be established whether or not this desaturase is active in Sertoli cells. Although the small amount of ^{14}C in the 18:3ω6 fraction may indicate a minor role for this metabolite in arachidonate biosynthesis in Sertoli cells, it is also possible that a high rate of turnover of 18:3 to 20:3 kept the ^{14}C 18:3 from accumulating. Therefore, it is not possible from these data to evaluate the relative importance of these two metabolic pathways in the biosynthesis of arachidonic acid in rat Sertoli cells.

ACKNOWLEDGMENTS

We thank Dr. Michael Skinner, Department of Pharmacology, Vanderbilt University, for helping us with the rat Sertoli cultures. This work was supported in part by NIH grants HD18605 and HD05797.

[Received August 2, 1988; Revision accepted September 14, 1988]

Plasma Esterase-1 (ES-1) Activity is Increased in Rats Fed High-Fat Diets

H.A. Van Lith[a], G.W. Meijer[a], L.F.M. Van Zutphen[a] and A.C. Beynen[a,b,*]

[a]Department of Laboratory Animal Science, State University, Utrecht, and [b]Department of Human Nutrition, Agricultural University, Wageningen, The Netherlands

The question addressed is whether the amount and type of dietary fat affects esterases in plasma. Rats were fed semipurified diets containing 2.0 to 19.4% (w/w) of fat in the form of coconut fat or corn oil. Fat was added to the diets at the expense of isocaloric amounts of carbohydrates. Plasma total esterase activities measured with 4-nitrophenylacetate as substrate were slightly increased with increasing fat intakes. However, an increase in fat concentration of the diet was associated with a pronounced increase in the activity of the so-called ES-1 isozyme in plasma. ES-1, which represents very little plasma total esterase activity, was quantified densitometrically as the high-mobility, anodal esterase band on polyacrylamide gel electrophoresis. The positive association between amount of dietary fat and ES-1 activity was identical for coconut fat and corn oil.
***Lipids 24,* 86–88 (1989).**

The plasma of vertebrate animals contains various enzymes that can hydrolyze artificial fatty acid esters of aromatic alcohols. Although the physiological function of these esterases is obscure, there is some evidence that they are involved in lipid metabolism. The addition of olive oil (5%, w/w), cholesterol (2%) and cholate (0.5%) to the diet of rats and mice caused an increase in plasma total esterase activity, as measured with β-naphthylpropionate as substrate (1,2). The increase in plasma total esterase activity was associated with an increase in the activity of an anodal, fast-moving esterase zone in the plasma zymogram. Lewis and Hunter (3) reported that injection of fat into the stomach produced an increase in the activity of plasma esterases of high electrophoretic mobility. These studies prompted us to investigate whether, under more physiological conditions, the amount and/or type of fat in the diet would affect plasma esterase activities in rats. For this purpose, rats were fed diets with increasing levels of either coconut fat or corn oil, the fats being added at the expense of isocaloric amounts of carbohydrates.

MATERIALS AND METHODS

Male rats, aged 4 weeks, of an outbred Wistar colony (Cpb/WU) were used. The animals were housed individually exactly as described previously (4). On day 0 of the experiment, the rats were divided into 8 dietary groups of 6 animals each. The groups had similar distributions of serum cholesterol concentration and body weight; the mean values were 2.69 mM and 118 g. The groups were fed semipurified diets in meal form which contained either coconut fat or corn oil at various concentrations. The fat concentrations expressed as percentage of weight (and energy) were: 2.0 (5.5), 4.1 (11.0), 8.6 (22.0) and 19.4 (44.0). The low-fat diets contained (g/100 g): casein, 16; corn starch, 25.585; dextrose, 25.585; molasses, 10; corn oil, 2 (or corn oil, 1 plus coconut fat, 1); cellulose, 15; dicalcium phosphate, 0.61; calcium carbonate, 0.62; magnesium carbonate, 0.07; magnesium oxide, 0.03; potassium bicarbonate, 1.8; sodium chloride, 0.5; vitamin premix, 1.2, and mineral premix, 1.0. The composition of the vitamin and mineral premix has been described (5). All diets contained at least 2.75% of energy as corn oil so as to provide sufficient linoleic acid. This implies that the coconut fat diets actually contained 2.75% of energy less in the form of coconut fat than indicated. Extra fat was added to the diets at the expense of isocaloric amounts of corn starch and dextrose in a 1:1 (w/w) ratio. Food and tap water were provided ad libitum.

At the end of the experiment (day 58), the rats were anesthetized in the nonfasting state (between 10.00 and 13.00 hr) by the intraperitoneal administration of 15 mg of pentobarbital (Nembutal, Sanofi Sante Animale SA, Paris, France). Blood was taken by aortic puncture, and 4.5 ml was mixed with 0.5 ml of distilled water containing 3.8% (w/w) of sodium citrate. Plasma was collected by low speed centrifugation.

Plasma cholesterol was measured enzymatically using the kit (Monotest) supplied by Boehringer-Mannheim GmbH (Mannheim, FRG). Plasma triglycerides were determined enzymatically as described (6). Total esterase activity in plasma, which had been stored for 3 days at −20°C, was measured with 4-nitrophenylacetate as substrate. The final reaction mixture was incubated at 37°C and consisted of 2.5 mM 4-nitrophenylacetate, 0.5% (w/w) Triton X-100 and 0.5% (w/w) acetone in 50 mM Tris buffer (pH 7.1). The release of product, 4-nitrophenol, was monitored spectrophotometrically at 410 nm. The absorption of a solution of 0.1 mM 4-nitrophenol (dissolved in the same buffer as the substrate) served as a standard. Reaction conditions were chosen so that the amount of 4-nitrophenol formed was linear with time and enzyme concentration. Enzyme activity was calculated after correction for spontaneous hydrolysis of the substrate.

Plasma esterase patterns were determined by vertical 7.6–15.0% (w/v) polyacrylamide gradient slab gel electrophoresis using a multiphasic buffer system. The gel buffer was a 37.5 mM Tris buffer (pH 8.9). The electrode buffer consisted of 5 mM Tris and 38.5 mM glycine (pH 8.3). To each slot of the slab gels, 25 μl of a mixture containing 67.5% (v/v) of plasma, 0.285% (w/w) sodium citrate and 10% (w/w) glycerol was added. After electrophoresis, the gels were stained for esterase activity with α-naphthylacetate, α-naphthylpropionate and Fast Blue BB (Merck, Darmstadt, FRG). Of both esters, 100 mg was dissolved in 2 ml of Triton X-100/acetone (1:1, w/w), and this solution was mixed with 25 ml of 50 mM Tris buffer (pH 7.3). Immediately before use, this mixture was added to 175 ml of 50 mM Tris buffer (pH 7.3) containing 100 mg of Fast Blue BB. The gels were

TABLE 1

Effect of Dietary Fat on Lipid Concentrations and Total Esterase Activities in Plasma of Rats

Measure	Type of fat	Amount of fat in the diet (%, w/w) 2.0	4.1	8.6	19.4	Sign.[a]
Body wt (g)	Coconut fat	365 ± 9	349 ± 12	370 ± 21	382 ± 12	
	Corn oil	341 ± 10	375 ± 10	349 ± 15	364 ± 16	
Feed intake (g/d)	Coconut fat	26.4 ± 0.5	24.4 ± 0.9	23.9 ± 0.7	22.5 ± 0.5	A
	Corn oil	25.2 ± 0.5	25.3 ± 0.4	22.3 ± 0.8	20.6 ± 1.0	
Plasma cholesterol (mM)	Coconut fat	2.76 ± 0.09	2.52 ± 0.19	2.54 ± 0.18	2.65 ± 0.09	
	Corn oil	2.79 ± 0.06	2.84 ± 0.07	2.72 ± 0.13	2.75 ± 0.22	
Plasma triglycerides (mM)	Coconut fat	1.21 ± 0.12	1.19 ± 0.20	1.67 ± 0.27	2.20 ± 0.36	T,AXT
	Corn oil	1.74 ± 0.41	1.52 ± 0.18	0.98 ± 0.18	0.72 ± 0.12	
Plasma esterase activity (μmol/min/ml)	Coconut fat	1.42 ± 0.05	1.83 ± 0.23	1.63 ± 0.08	1.91 ± 0.11	A
	Corn oil	1.57 ± 0.07	1.55 ± 0.14	1.73 ± 0.11	1.83 ± 0.09	

The diets were fed for 58 days. Results expressed as means ± SE for 6 animals/group, except for the group on the diet containing 2% coconut fat, which consisted of 5 animals (on day 30, one animal in this group died).

[a]Significance ($P < 0.05$) was calculated by analysis of variance. A, effect of amount of fat; T, effect of type of fat; AXT, effect of interaction.

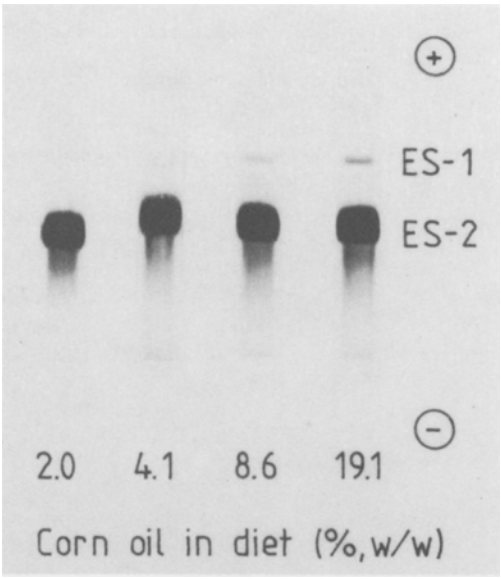

FIG. 1. Electrophoresis on polyacrylamide gradient gels of esterases in plasma of individual rats fed diets containing various levels of corn oil.

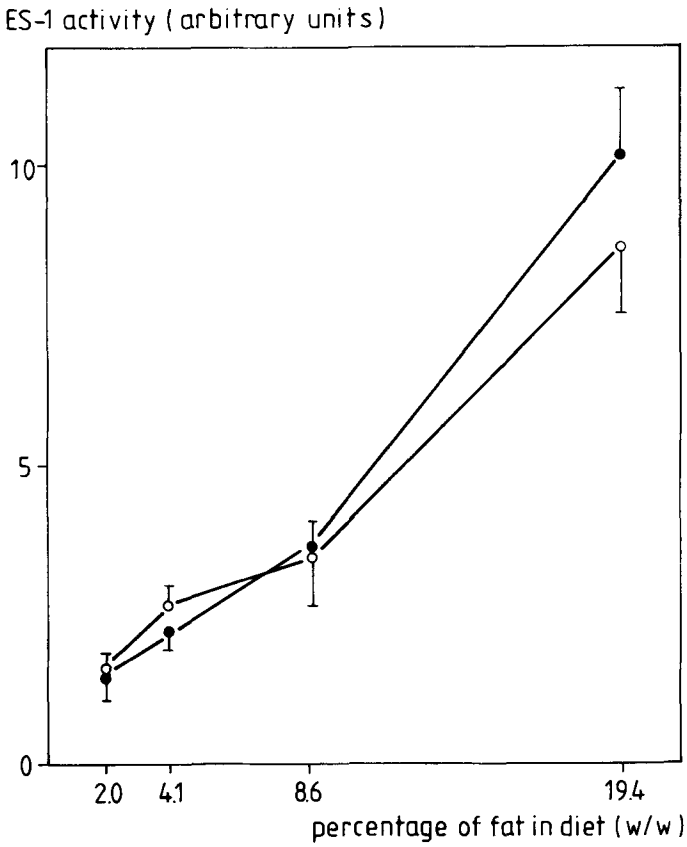

FIG. 2. Relationship between the activity of ES-1 and amount of fat in the diet. Results, expressed as means ± SE; ○ = corn oil; ● = coconut fat. There was a significant ($P < 0.05$, analysis of variance) effect of amount of dietary fat, but no effect of fat type and no interaction.

incubated with this solution at room temperature, under slow shaking, for exactly 10 min. After staining, the gels were fixed in 5% (w/v) trichloric acid and photographed. The intensity of the ES-1 band was measured by densitometric scanning of the stained gels at 530 nm.

RESULTS AND DISCUSSION

Dietary coconut fat vs corn oil did not systematically affect body weight of the rats (Table 1). Likewise, the amount of fat in the diet did not clearly influence body weight. This is explained by the significant reduction of feed intake with increasing fat concentrations. In this way caloric intake remained essentially similar in rats fed the various experimental diets.

There was no significant effect of the amount and type of fat on plasma cholesterol levels. However, at dietary fat levels higher than 2.0% (w/w), corn oil produced higher group mean plasma cholesterol concentrations than did coconut fat. This corroborates earlier work using rats fed cholesterol-free, semipurified diets (7,8). Above dietary fat levels of 4.1% (w/w), plasma triglyceride concentrations increased with increasing amounts of coconut fat in the diet, but with corn oil the opposite was seen (Table 1). Thus, there was an interaction of amount and type of fat. The triglyceride lowering action of corn oil, when compared with coconut fat, agrees with other investigations (8,9).

The amount of fat in the diet significantly influenced plasma total esterase activities. However, this effect was relatively small (Table 1). Plasma total esterase activities represent the sum of the activities of a number of different esterases. In rats, the so-called ES-2 isozyme is most abundant. This is illustrated by the separation of these enzymes on polyacrylamide gradient gel electrophoresis and visualized with α-naphthylacetate and α-naphthylpropionate as substrates (Fig. 1). It is also clear that an increase in dietary corn oil caused an increase in the intensity of the most anodal plasma esterase zone (ES-1). This is supported by the data in Figure 2, showing the relationship between the amount of fat in the diet and the activity of ES-1 which was assessed densitometrically. The relationship was almost identical for corn oil and coconut fat.

This study shows that ES-1 in plasma of rats is positively associated with the concentration of fat in the diet. Dietary corn oil and coconut fat had identical effects on ES-1 but influenced plasma cholesterol and triglyceride concentrations differentially. Thus, ES-1 would appear not to be related to these plasma lipids. As to the physiological function of ES-1, we can only speculate. Possibly, this esterase isozyme is involved in fat absorption and released from the intestine during this process. Administration of fat to rats by stomach tube resulted in an increase in the activity of esterases of high electrophoretic mobility in the intestinal lymph (3).

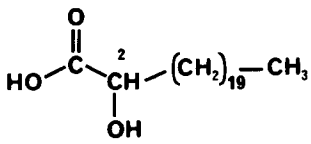
On the Isolation of 2-Hydroxydocosanoic and 2-Hydroxytricosanoic Acids From the Marine Sponge *Amphimedon compressa*

Néstor M. Carballeira* and **Mario R. Lopez**
Department of Chemistry, University of Puerto Rico, Rio Piedras, Puerto Rico 00931

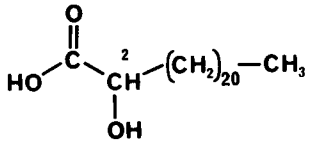
The first α-hydroxy fatty acids from a marine sponge, namely 2-hydroxydocosanoic and 2-hydroxytricosanoic, were identified in the Caribbean sponge *Amphimedon compressa*. These acids were found to occur in phosphatidylethanolamine and phosphatidylserine and constituted 52% of the total fatty acid mixture of this sponge. The long chain fatty acids 5,9,23-nonacosatrienoic (29:3) and 5,9,23-tricontatrienoic (30:3), as well as a new tetratricontatetraenoic (34:4) acid, were also found in *A. compressa*.
***Lipids 24,* 89-91 (1989).**

Sponges have attracted in recent years the attention of marine natural products chemists because they have proved to be rich sources of bioactive and novel secondary metabolites. Unusual and unprecedented phospholipid fatty acids with no terrestrial counterpart have been isolated and characterized from dozens of marine sponges (1). However, one important group of phospholipid fatty acids, the 2-hydroxy acids, has not been recognized to exist in the phospholipids of marine sponges. One piece of work by Ayanoglu et al. (2), in which the phospholipid fatty acids of the marine sponge *Higginsia tethyoides* were analyzed, describes the isolation of a series of closely related 2-methoxy fatty acids, the only example to date of 2-oxa-substituted fatty acids in marine sponges. Unique to the latter work was the observation that these fatty acids were shown to be present in conventional phospholipids like phosphatidylethanolamine and phosphatidylserine (2), when the normal expectation is for these acids to be present in sphingolipids. Four kinds of fatty acid occur in sphingolipids, the saturated long-chain fatty acids like palmitic (16:0), very long chain saturated fatty acids like behenic (22:0), monoenoic fatty acids such as oleic (18:1) and α-hydroxy very long chain fatty acids such as cerebronic (h 24:0). Important in this context is to mention that polyunsaturated fatty acids are conspicuously absent from these lipids.

In this paper we wish to report, for the first time, the isolation of the important fatty acids 2-hydroxydocosanoic (Scheme 1) and 2-hydroxytricosanoic (Scheme 2) from the phospholipids of the marine sponge *Amphimedon compressa*. This is the first time, to our knowledge, that these 2-hydroxy fatty acids have been isolated from conventional sponge phospholipids. Such hydroxylated acids usually are encountered in brain cerebrosides, sphingomyelins and lecithins (3) and in smaller concentrations in the kidney (4).



SCHEME 1



SCHEME 2

EXPERIMENTAL PROCEDURES

Amphimedon compressa was collected May 3, 1988, near La Parguera, Puerto Rico. The sponge was washed in sea water, carefully cleaned of all nonsponge debris and cut into small pieces. Immediate extraction with chloroform/methanol (1:1, v/v) yielded the total lipids. The neutral lipids, glycolipids and phospholipids were separated by column chromatography using the procedure of Privett et al. (5). The phospholipid classes were investigated by thin layer chromatography (TLC) using silica gel and chloroform-methanol-water (75:25:4, v/v/v) as solvent. The ^{31}P-NMR of the phospholipids was performed at 22°C on a GN 300 FT-NMR spectrometer at 121.6 MHz. For the acquisition, 16K data points were used and ca. 1000 accumulations were obtained before Fourier transformation of the free induction decay. In a typical run, phospholipids (20-30 mg) were dissolved in 3 ml of deuterated chloroform-methanol (2:1, v/v) containing, as internal reference, triphenylphosphine (ϕ_3P). The fatty acyl components of the phospholipids were obtained as their methyl esters by reaction of the phospholipids with methanolic hydrogen chloride as described before (6). The resulting methyl esters were analyzed by gas chromatography-mass spectrometry (GC-MS) using a Hewlett-Packard 5995 A gas chromatograph-mass spectrometer equipped with a 30-m × 0.32-mm fused silica column coated with SE-54. For the location of double bonds, N-acylpyrrolidide derivatives were prepared by direct treatment of the methyl esters with pyrrolidine/acetic acid (10:1, v/v) in a capped vial (1 hr at 100°C) followed by ethereal extraction from the acidified solution and purification by preparative layer chromatography (PLC). Hydrogenations were carried out in 10 ml of absolute methanol and catalytic amounts of platinum oxide (PtO_2). Mass spectral data of key fatty acids for this discussion are presented below.

2-Hydroxydocosanoic acid methyl ester. MS *m/z* (rel intensity): 370 (M^+, 88), 348 (6), 338 (M^+ − MeOH, 5), 312 (13), 311 (M^+ − COOMe, 56), 309 (9), 292 (9), 293 (2), 159 (6), 145 (10), 127 (15), 125 (14), 111 (27), 103 (14), 97 (48), 90 (38), 83 (50), 71 (38), 69 (52), 57 (100), 55 (81).

2-Hydroxytricosanoic acid methyl ester. MS *m/z* (rel intensity): 384 (M^+, 80), 370 (4), 352 (M^+ − MeOH, 6), 338 (5), 326 (15), 325 (M^+ − COOMe, 62), 323 (17), 306 (13), 280 (3), 159 (9), 145 (13), 127 (22), 125 (18), 103 (14), 90 (31), 83 (49), 69 (49), 59 (27), 57 (100), 55 (84).

RESULTS

Our results are presented in Table 1 where the fatty acid composition of *A. compressa* is presented. The sponge contained, among others, a series of saturated long chain fatty acids, the most abundant being hexadecanoic (16:0), octadecanoic (18:0), behenic (22:0) and tricosanoic (23:0), which together accounted for 20% of the total fatty acid composition of this sponge. In the fatty acid mixture, the most striking result was the presence of a very long chain fatty acid in an impressive 42% abundance. The mass spectrum of the methyl ester of this acid exhibited a molecular ion peak at *m/z* 370 (88%, $C_{23}H_{46}O_3$) with a higher than usual abundance. The existence of a $M^+ - COOCH_3$ fragment ion at *m/z* 311 with an abundance of 56% strongly suggested α-substitution that was further confirmed by other diagnostic peaks at *m/z* 338 ($M^+ - CH_3OH$) and at *m/z* 292. Lack of peaks at *m/z* 74 and 104, but presence of fragmentation ions at *m/z* 90 and *m/z* 103 arising from the characteristic McLafferty rearrangement (7), suggested immediately the presence of α-hydroxy substitution instead of, for example, α-methoxy. In fact, after a literature comparison (7), it became obvious that we were dealing with 2-hydroxydocosanoic acid (Scheme 1), which is unprecedented in marine sponges.

A second very long chain fatty acid that was also present in the mixture with an abundance of 11.5% presented a very characteristic MS spectrum with a molecular ion peak at *m/z* 384 (80%, $C_{24}H_{48}O_3$). The existence of a $M^+ - COOCH_3$ fragment ion at *m/z* 325 (62%) also strongly suggested α-substitution. The other diagnostic peaks were found at *m/z* 352 ($M^+ - CH_3OH$) and at *m/z* 306, also consistent with α-substitution. Lack of peaks at *m/z* 74 and 104, but presence of fragmentation ions at *m/z* 90 and *m/z* 103 from the characteristic McLafferty rearrangement confirmed again the presence of α-hydroxy substitution (7). In fact, after a detailed literature comparison (7), it became obvious that we were dealing with still another α-hydroxy fatty acid, the 2-hydroxytricosanoic acid (Scheme 2), which is also unprecedented in marine sponges. These two α-hydroxy fatty acids accounted for ca. 52% of the total phospholipid fatty acid composition of this sponge, a rather unusual finding.

Capillary GC and GC-MS analysis of the mixture also revealed the presence of two very long chain phospholipid fatty acids displaying base peaks at *m/z* 81, a value diagnostic of acids possessing the Δ5,9 unsaturation pattern typical of "demospongic acids" (8). On the basis of capillary GC retention times and equivalent chain length (ECL) values, together with mass spectral comparisons, these acids were characterized as 5,9,23-nonacosatrienoic ($\Delta^{5,9,23}$-29:3) and 5,9,23-tricontatrienoic ($\Delta^{5,9,23}$-30:3), which were present in 8 and 15%, respectively. The latter acids already have been reported to occur in marine sponges (8). A third polyunsaturated very long chain phospholipid fatty acid was also detected in trace amounts in this sponge which, by means of GC-MS analysis of its methyl ester, had a molecular weight of 514. A careful analysis of the mass spectrum of the methyl ester of this acid and comparison of ECL values suggested that we were dealing with tetratricontatetraenoic acid methyl ester (34:4), an extremely long chain fatty acid, unprecedented in marine sponges. Unfortunately, the trace amounts of this acid prevented us from locating the double bond positions.

The phospholipids from *A. compressa* were separated and analyzed by preparative thin layer chromatography (TLC), and the acids reported in this work are major constituents of phosphatidylethanolamine (PE) and phosphatidylserine (PS). To our surprise, not even traces of phosphatidylcholine (PC) or sphingomyelin were observed in the phospholipid mixture of *A. compressa.* In order to verify our TLC results, we decided to run a ^{31}P-NMR spectrum of the total phospholipids from *A. compressa* (Fig. 1). It can be seen that only two phospholipids, namely PE and PS, comprise the total phospholipid mixture of this sponge.

TABLE 1

Identified Phospholipid Fatty Acids From *Amphimedon compressa*

Fatty acid	Abundance (%)
Hexadecanoic (16:0)	2.3
Octadecanoic (18:0)	7.0
Nonadecanoic (19:0)	0.8
Eicosanoic (20:0)	0.3
Heneicosanoic (21:0)	0.9
Docosanoic (22:0)	8.5
Tricosanoic (23:0)	3.1
2-Hydroxydocosanoic (22:0)	42
2-Hydroxytricosanoic (23:0)	11.5
5,9,23-Nonacosatrienoic (29:3)	8.2
5,9,23-Tricontatrienoic (30:3)	15.4
Tetratricontatetraenoic (34:4)	traces

DISCUSSION

The results presented here are interesting because, to the best of our knowledge, this is the first time that 2-hydroxy fatty acids have been isolated from a marine sponge. The high abundance of these acids (53% of the total phospholipid fatty acids) practically excludes any possible microbial symbiont source. These fatty acids have been found before in brain cerebrosides, sphingomyelins, lecithins arising from the cerebral cortex, cerebral white matter, diencephalon and midbrain in amounts ranging between 10–15% (9). The two α-hydroxy acids isolated in this work have also been detected in monohexosylceramides, lactosylceramides and oligohexosylceramides from A_2-Asia and A_2-England Influenza Virus (10). From the above reports, it is assumed that these α-hydroxy fatty acids occur exclusively in sphingolipids.

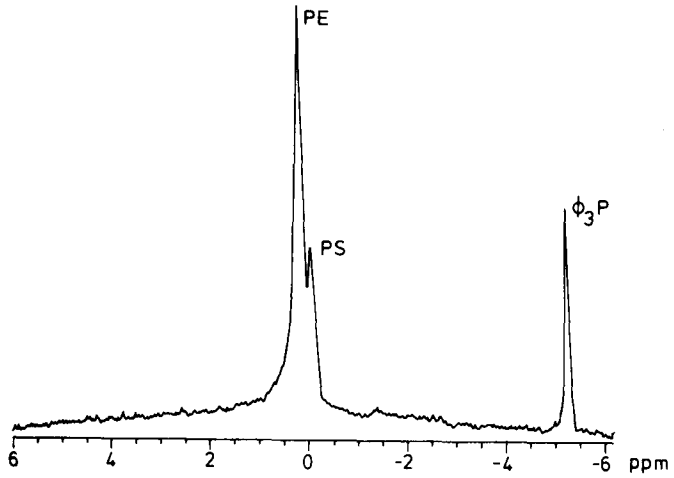

FIG. 1. The complete ^{13}P-NMR spectrum of the total phospholipids from *A. compressa*. The abbreviations are PE, phosphatidylethanolamine; PS, phosphatidylserine; ϕ_3P, triphenylphosphine.

This probably implies that there are mechanisms of compartmentalizing the pools of these fatty acids, or that α-hydroxylation occurs after the regular chain length fatty acids have been introduced into a sphingolipid or some specialized precursor. Naturally occurring 2-hydroxy fatty acids are known to possess the R configuration (11), and we believe that the acids isolated in this work also possess the R configuration at carbon 2.

Our findings with the sponge *Amphimedon compressa* suggest that these 2-hydroxy fatty acids are not only restricted to sphingolipids, but that they can be found, at least in marine sponges, in other phospholipids like PE and PS. Our results are also compatible with previous findings by Ayanoglu et al. (12) that α-methoxy fatty acids from the marine sponge *Higginsia tethyoides* are present in common phospholipids like PE and PS. Interesting to point out is the observation that in these sponges the α-substituted fatty acids seem to occur concomitantly with the very long chain fatty acid 5,9,23-tricontatrienoic (30:3). It will be very interesting to find out if this 30:3 acid and the α-hydroxy fatty acids are related in their biosynthetic origin or if they play special membrane functions, because in sphingolipids polyunsaturated acids are normally absent.

The origin of the α-hydroxy fatty acids presented in this work is worthy of investigation. One good possibility is α-oxidation of the long chain saturated fatty acids docosanoic (22:0) and tricosanoic (23:0), because these are found in relatively large amounts in *A. compressa*. This possibility has been demonstrated in the case of brain sphingolipids by Mead and Levis (13), who demonstrated that α-oxidation is the preferred pathway for the biosynthesis of 2-hydroxytetracosanoic acid.

[Received July 1, 1988; Revision accepted September 21, 1988]

Microsomal Δ5 Desaturation of Eicosa-8,11,14-trienoic Acid is Activated By a Cytosolic Fraction

Alicia I. Leikin[1] and **Rodolfo R. Brenner**[1,*]
Instituto de Investigaciones Bioquímicas de La Plata (INIBIOLP), CONICET-UNLP, Facultad de Ciencias Médicas, 60 y 120, (1900) La Plata, Argentina

Δ5 Desaturation of eicosa-8,11,14-trienoic acid to arachidonic acid was studied in rat liver microsomes. It was shown that Δ5 desaturation of fatty acids in vitro requires the participation of a peripheral component of cytosolic origin. Desaturation of 20:3n-6 to 20:4n-6 decreases in washed microsomes as they lose an adsorbed cytosolic fraction (CF), but the enzymatic activity can be recovered as a function of CF concentration in the incubation medium. Albumin does not substitute for CF. Δ5 Desaturation of 20:3n-6 is inhibited by arachidonic acid by a product inhibition effect, but CF prevents retroinhibition of Δ5-desaturase by 20:4n-6. This ability of CF is eliminated by preincubation of CF with 20:4n-6, but not with γ-18:3n-6, the product of Δ6 desaturation of 18:2n-6, thus indicating that CF impairs the retroinhibitory effect of arachidonic acid on Δ5-desaturase in a specific manner. Δ6 Desaturation of linoleic acid to γ-18:3n-6 is also activated by CF and retroinhibited by γ-18:3n-6. CF activity on Δ6 desaturation is retained after preincubation with 20:4n-6, but it is lost after preincubation with γ-18:3n-6. Activation of Δ6-desaturase by CF is associated with the removal of the reaction product in a specific manner. Chromatography of CF by Sephacryl S-200 separates two major subfractions which show different efficiency in reactivating Δ5- and Δ6-desaturase activities in washed microsomes. Therefore, CF may contain subfractions that can prevent Δ5- and Δ6-desaturase retroinhibition by apparently binding their respective reaction products specifically.
Lipids 24, 101-104 (1989).

Fatty acid desaturase systems involve three integral microsomal components: the desaturase, the NADH cytochrome-b_5 reductase and cytochrome-b_5 (1-11). The requirement of a soluble factor for Δ6 desaturation of fatty acids was first recognized in our laboratory (10,12,13). Some of its characteristics and its cytosolic origin have been described (14,15), as well as the mechanism of its participation in the Δ6-desaturation process (16). It primarily prevents the retroinhibition of the enzyme by apparently binding the reaction product, 18:3n-6, as it is formed. The factor is different from the one described by Jeffcoat et al. (17).

The requirement of a soluble factor by the Δ5-desaturase system has also been proposed by us (18). The importance of the Δ5-desaturase lies in its catalyzing effect in the conversion of eicosa-8,11,14-trienoic acid to arachidonic acid, eicosa-8,11,14,17-tetraenoic acid to eicosa-5,8,11,14,17-pentaenoic acid and, then, in eicosanoid production. The participation of soluble cytosolic fractions in fatty acid Δ5 desaturation could be related to a fine-tuned regulation of arachidonic and eicosa-5,8,11,14,17-pentaenoic acid biosynthesis.

In the present work, we studied the participation of a cytosolic fraction in Δ5 desaturation of 20:3n-6 to 20:4n-6. It was found that washed rat-liver microsomes largely lost their Δ5-desaturase activity, but this activity was recovered by the addition of a cytosolic fraction. The inhibition of Δ5-desaturase by arachidonic acid was eliminated by the addition of the cytosolic fraction. Cross experiments performed with Δ5- and Δ6-desaturases and the addition of the fraction preincubated with either 18:3n-6 or 20:4n-6 indicated that, apparently, definite sites exist that bind 18:3n-6 and 20:4n-6.

EXPERIMENTAL PROCEDURES

Materials. [1-^{14}C]Linoleic (58 mCi/mmol) and [1-^{14}C]-eicosa-8,11,14-trienoic acids (55 mCi/mol) were provided by New England Nuclear (Boston, MA). Linoleic and eicosatrienoic acids (99% pure) were provided by Nu-Chek Prep Inc. (Elysian, MN). ATP, CoA, NADH, N-acetylcysteine were provided by Boehringer Argentina (Buenos Aires, Argentina). Sephacryl S-200 was supplied by Pharmacia Fine Chemicals (Uppsala, Sweden). All other chemicals and solvents, reagent grade, were provided by Carlo Erba (Buenos Aires, Argentina).

Microsomes. Wistar rats of 150-200 g reared on Purina Chow were used to obtain liver microsomes (13). Unwashed microsomes and cytosol were separated by centrifugation at 105,000 *g* for 60 min. The microsomes were then washed at 0-4°C with a low ionic strength solution of 0.25 M sucrose, 0.15 M NaCl, 0.04 M buffer phosphate (pH 7.4), 0.3 mM nicotinamide and 1.5 mM N-acetylcysteine. After centrifugation at 105,000 *g* for 60 min, the extracted microsomes were separated from the adsorbed cytosolic fractions.

Preparation of the cytosolic fraction. NaCl (0.254 g/ml) was added to 0.6 ml of cytosol. This mixture was then placed on top of 3.5 ml NaBr solution (0.44 g/ml) in a 4.2-ml tube and centrifuged at 220,000 *g* for 24 hr at 14°C in a Kontron Centrifuge. The saline gradient formed was monitored by a refractive index of 0.3 ml fractions collected in control tubes where cytosol was replaced by the low ionic strength solution. The fraction isolated from cytosol at density 1.26 g/ml was dialyzed against 0.15 M NaCl, flushed with nitrogen and kept frozen at −80°C until used. The fraction was called cytosolic fraction (CF).

Sephacryl S-200 fractionation. A 56 cm × 1.6 cm Sephacryl S-200 column was used. The cytosolic fraction (0.6 ml) containing ca. 12 mg of protein was applied to a column equilibrated with 0.02 M phosphate buffer (pH 7.4), 0.1 mM EDTA. Fractions of 1.2 ml were collected and their absorption was analyzed at 280 nm in a Zeiss PMQII spectrophotometer (Carl Zeiss, Oberlochen, Württemberg, FRG). Tentative molecular weights were estimated by using different proteins like lactic dehydrogenase, bovine serum albumin and trypsin.

Fatty acid desaturating assay. Δ5- and Δ6-desaturase activities were determined in microsomes by measuring the conversion of 34 μM [1-^{14}C]eicosatrienoic and [1-^{14}C]linoleic acids to arachidonic and γ-linolenic acids, respectively, at 35°C for 15 min in the presence of 2.5 mg (unwashed microsomes) or 2 mg (washed microsomes) of protein in a final volume of 1.5 ml. When the assay was run for the reconstituted system, 0.5 mg of cytosolic fraction or subfractions of Sephacryl S-200 were added to 2 mg of washed microsomes in order to complete 2.5 mg equivalent to whole microsomes. The incubation solution contained 0.25 M sucrose, 0.15 M KCl, 0.04 mM phosphate buffer (pH 7.4), 0.70 mM N-acetyl cysteine, 0.04 M NaF, 1.3 mM ATP, 0.06 mM coenzyme A, 0.87 mM NADH, 5 mM, $MgCl_2$, 0.33 mM nicotinamide. After the incubation time, the reaction was stopped and the products were saponified with 2 ml 10% methanolic KOH, extracted with petroleum ether (boiling point 30–60°C) and methylated. The methyl esters of the obtained fatty acids were analyzed by radiochromatography in an Acromat CG-100 apparatus equipped with a proportional counter.

Analytical procedures. Protein concentration was determined by the method of Lowry et al. (19). Binding of fatty acids to the cytosolic fraction was achieved by incubating either linoleic or eicosatrienoic acid (120 nmol/mg protein) with CF at 25°C for 15 min.

RESULTS

Effect of cytosolic fraction on Δ5 desaturation of eicosatrienoic acid. Unwashed microsomes (M) desaturated eicosatrienoic to arachidonic acid at a rate of 230.0 pmol × min^{-1} × mg^{-1}. When microsomes were washed and centrifuged (Me), the enzymatic activity decreased to ca. 127.0 pmol × min^{-1} × mg^{-1}. Addition of the cytosolic fraction (CF, d = 1.26 g/ml) made it possible to recover Me-desaturating activity (Fig. 1). The addition of increasing amounts of CF to Me brought about a dose-dependent recovery of the desaturation. This recovery was not observed when CF was substituted by bovine serum albumin (Fig. 2). Arachidonic acid, the product of Δ5 desaturation of eicosatrienoic acid, inhibited the reaction (Fig. 3), but free CF was able to revert the inhibition when added to the microsomes. The preincubation of CF with arachidonic acid impaired its ability to reactivate the retroinhibited microsomes (Fig. 3).

On the other hand, Δ6-desaturase activity diminished after washing rat liver microsomes, but it was recovered by the addition of the cytosolic fraction CF (Fig. 1). The product of Δ6 desaturation of linoleic acid (18:3n-6) inhibited the enzyme (Fig. 3), but free CF eliminated the inhibition when added to the incubation medium. Moreover, the preincubation of CF with 18:3n-6 impaired the ability of the factor to reactivate the retroinhibited microsomes.

Therefore, the effect produced by CF on both Δ5- and Δ6-desaturases in the presence of the corresponding reaction products is similar. The crude cytosolic fraction separated by gradient centrifugation at 1.26 g/ml density

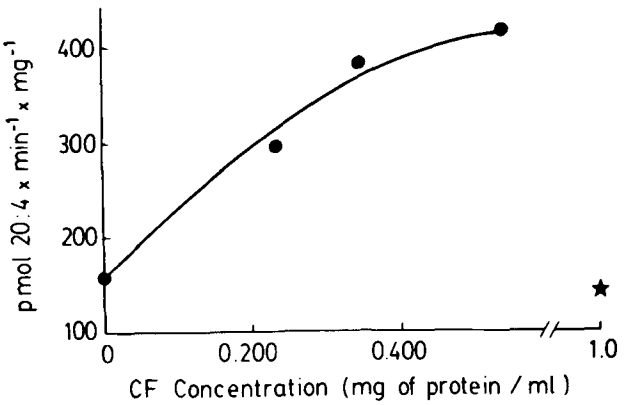

FIG. 2. Δ5-Desaturase activity in washed microsomes (Me) as a function of CF protein concentration in the medium. ★, Effect of 1 mg of albumin.

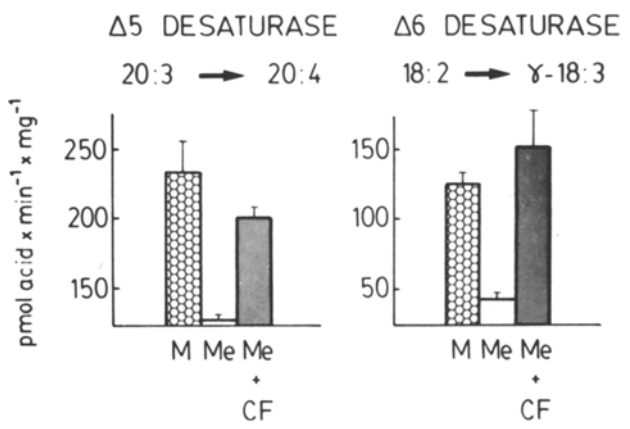

FIG. 1. Δ5-Desaturase activity [20:3n-6 → 20:4n-6] in M, Me and Me + CF; and Δ6-desaturase activity [18:2n-6 → 18:3n-6] in M, Me and Me + CF. The assays were carried out as described in Experimental Procedures.

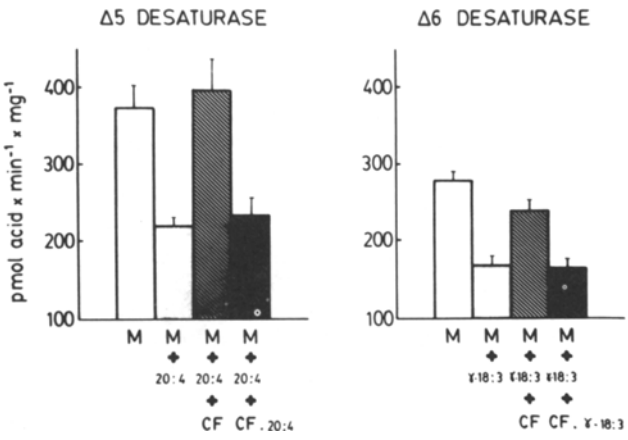

FIG. 3. Δ5-Desaturase activity in M and M plus 20:4n-6; and Δ6-desaturase activity in M and M plus 18:3n-6. 17 nmol of inhibitor acid were added to 0.75 mg of M protein (second bars). 34 nmol of inhibitor acid were added to 0.75 mg M protein simultaneously with 0.25 mg of CF protein (third bars). 34 nmol of inhibitor acid were added to 0.75 mg of M protein simultaneously with 0.25 mg of CF protein preincubated with 30 nmol of inhibitor acid (fourth bars). Final volume was 0.5 ml and the assays were carried out as described in Experimental Procedures.

was able to reactivate the two desaturases eliminating the inhibitions evoked by those products.

Differences in the participation of the cytosolic fraction on Δ5 desaturation of eicosatrienoic acid and Δ6 desaturation of linoleic acid. In another series of experiments, we found that whole microsomes desaturated eicosatrienoic acid to arachidonic acid at a rate of 374.0 pmol × min^{-1} × mg^{-1}. In washed microsomes, that activity decreased to 163.1 pmol × min^{-1} × mg^{-1}. The addition of CF to Me recovered the activity, not only when it was added free, but also after preincubation with 18:3n-6. However, CF preincubated with arachidonic acid did not increase Me Δ5-desaturation rates over 150.0 pmol × min^{-1} × mg^{-1} (Table 1).

Similarly, unwashed microsomes desaturated linoleic acid to γ-linolenic acid at a rate of 284.9 pmol × min^{-1} × mg^{-1} and the Δ6-desaturase activity in Me decreased to 121.2 pmol × min^{-1} × mg^{-1}. CF increased the desaturation activity when it was added free or, in this case, preincubated with 20:4n-6. Conversely, CF preincubated with 18:3n-6 did not increase Me Δ6-desaturation rates over 136.2 pmol × min^{-1} × mg^{-1} (Table 1). Therefore, the mechanism of CF activation of Δ6- and Δ5-desaturases in vitro would be specific for each enzyme and evoked by the binding of the corresponding products to CF eliminating the product inhibition.

TABLE 1

Effect of CF Free or Preincubated With 18:3n-6 and 20:4n-6 Acids and of Sephacryl Subfractions on Δ5- and Δ6-Desaturase Activities

	Δ5-Desaturase pmol 20:4n-6 × min^{-1} × mg^{-1}	Δ6-Desaturase pmol 18:3n-6 × min^{-1} × mg^{-1}
M	374.0 ± 44.2*	284.9 ± 47.1*
Me	163.1 ± 18.0*	121.2 ± 2.0*
Me + CF	326.2 ± 29.0*	262.1 ± 9.0*
Me + CF 18:3n-6	277.0-397.0**	127.2-145.2**
Me + CF 20:4n-6	133.0-167.0**	230.0-234.0**

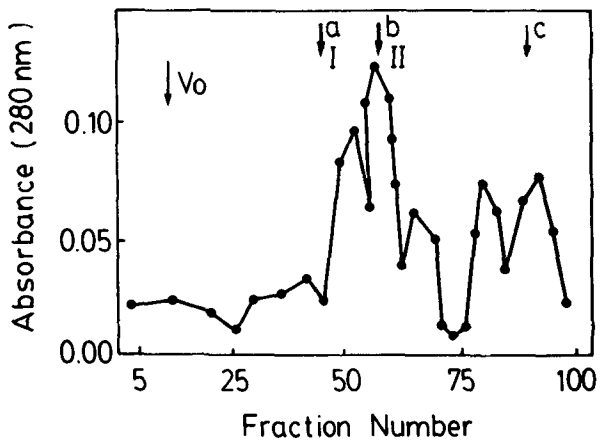

FIG. 4. Sephacryl S-200 chromatographic profile of d = 1.26 g/ml cytosolic fraction. V_o, exclusion volume; (a) elution volume of lactic dehydrogenase, MW: 142,000 daltons; (b) elution volume of bovine serum albumin, MW: 68,000 daltons; (c) elution volume of trypsin, MW: 23,800 daltons; I, CF subfraction of estimated MW = 130,000; and II, CF subfraction of estimated MW = 68,000. The conditions were described in Experimental Procedures.

Cytosolic fraction chromatography by Sephacryl S-200. The differences found in the effects of CF on Δ5- and Δ6-desaturases led us to attempt its further subfractionation by Sephacryl S-200. The CF floating at d = 1.26 g/ml was applied to a 56 cm × 1.6 cm column, and fractions of 1.2 ml were collected. Two main subfractions were obtained (Fig. 4) and added to Me in order to measure Δ5 and Δ6 desaturation. The subfraction CF_I, corresponding to an estimated molecular weight of 130,000 daltons, reactivated Me Δ5-desaturase from 163.1 to 352.0 pmol × min^{-1} × mg^{-1} (Table 1), and recovered Me Δ6-desaturase activity from 121.2 to 303.0 pmol × min^{-1} × mg^{-1}. The subfraction CF_{II}, corresponding to an estimated molecular weight of 68,000 daltons, produced little reactivation of Δ5-desaturase and reactivated Δ6-desaturase of Me from 121.2 to 240.0 pmol × min^{-1} × mg^{-1} (Table 1).

DISCUSSION

The present experiments show that in vitro rat-liver microsomal Δ5 desaturation of 20:3n-6 to 20:4n-6 requires the participation of a cytosolic fraction to reach full activity. This result is similar to that found for microsomal Δ6 desaturation of linoleic acid (16). In both cases, the CF fraction loosely binds to microsomes. The mechanism proposed for CF participation in Δ6 desaturation relates to the specific uptake of the reaction product 18:3n-6 as it is formed and, in this way, avoids its inhibitory effect (16). In the case of Δ5-desaturase, CF reactivates the diminished Me activity in a dose-dependent fashion (Fig. 2). The ability of the fraction to restore the maximal Δ5-desaturase activity could be explained by a similar mechanism associated with a particular interaction with an inhibitory compound. In fact, arachidonic acid produced by Δ5-desaturase from 20:3n-6 inhibits the enzyme, and CF impairs that inhibition in whole M (Fig. 2). To produce this effect, CF must be free, because the preincubation of CF with arachidonic acid impairs its anti-inhibitory ability, as if specific sites were no longer available for the 20:4 produced by Δ5-desaturase (Fig. 3, Table 1). However, CF preincubation with 18:3n-6 does not deactivate the factor, thus, suggesting that CF would apparently bind arachidonic acid in sites different than those for γ-linolenic acid.

Δ6-Desaturase is inhibited by 18:3n-6, as shown in present and previous experiments (16,21-23). When the enzymatic activity was measured in Me, it was lower and the addition of CF, either free or preincubated with 20:4n-6, increased the values up to those of M, whereas the preincubation of CF with γ-linolenic acid impaired its ability to reactivate the enzyme (16) (Fig. 1). Therefore, as in the case of the Δ5-desaturase system, the existence of specific sites for the location of the Δ6-desaturase product in CF, 18:3n-6, can be envisioned. Cross experiments (Table 1) support the idea of the presence of specific sites in CF for Δ5- and Δ6-desaturase products. Moreover, the results suggest that these sites would be different for 20:4

and 18:3n-6. Even more significant are the results obtained by employing the Sephacryl S-200 subfractions of CF. Although there is some overlapping, two partially resolved fractions having different estimated molecular weights and the ability to reactivate Δ5- and Δ6-desaturases were detected. This would imply the existence of two independent cytosolic subfractions able to interact with each enzyme. The aforementioned proteins would apparently bind the corresponding reaction products, thus, avoiding the respective retroinhibition of Δ5 and Δ6 desaturases in a specific mode. CF_{II} would concentrate a fraction specific for Δ6-desaturase reactivation, whereas CF_I would be specific for Δ5-desaturase, but with some overlapping and contamination with CF_{II} activity. Because the subfractions here employed were not pure, further purification will prove useful in defining their true identity.

It has been suggested that catalase would stimulate stearoyl-CoA desaturase (18). However, we have already demonstrated (14) that it is not the catalase activity present in cytosolic fractions that is responsible for the Δ6-desaturase reactivating ability. Moreover, in our experience, albumin does not substitute for CF in desaturase reactions.

Despite the present conclusions, we must take into consideration that desaturases were tested under in vitro conditions, in which these enzymes (but not the elongases) were active. In this case, the fate of the desaturated products is not exactly the same as in the in vivo system, because they are released into the incubation medium instead of being available to the elongating system.

[Received May 23, 1988; Revision accepted September 22, 1988]

Cholesterol Metabolism in Frog (*Rana esculenta*) Liver: Seasonal and Sex-related Variations

G. Bruscalupi, F. Castellano, S. Scapin and A. Trentalance*
Dipartimento di Biologia Cellulare e dello Sviluppo, Universitá di Roma I "La Sapienza," Piazzale Aldo Moro, 5, 00185 Rome, Italy

Many aspects of lipid metabolism have been studied in amphibians, but seasonal lipid modulation in male and female frogs has not been investigated. We describe here the yearlong patterns of hepatic lipid content and enzyme activities related to cholesterol homeostasis, 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase activity and acyl coenzyme A:cholesterol acyltransferase (ACAT) activity in liver of the male and female frog, *Rana esculenta*. Lipid storage follows distinct seasonal patterns, with an increase in June that is more pronounced in the female than in the male frog. Cholesterol content and cholesterol storage as cholesteryl ester in male liver are consistent with the activity of HMG-CoA reductase and of ACAT enzymes. HMG-CoA reductase activity of the female frog shows an extra peak in fall unrelated to cholesterol storage and probably related to the production of essential compound for oogenesis.
***Lipids 24,* 105-108 (1989).**

The frog, as a poikilothermic vertebrate, shows seasonal variations in physiological activities closely reflecting environmental changes. Oxygen consumption, CO_2 production and respiratory quotient vary during the year (1) with fluctuations greater than those normally found in warm blooded animals. The variations suggest a differential utilization of energy reserves depending on the season, viz. glycogen in winter and lipids in summer.

This view is supported by the occurrence of marked changes in weight, composition (2-6) and enzymatic activities (2,7,8) in the liver of these animals. Such changes could be related to the fluctuations of blood hormone levels detectable during the year; actually, glucagon and insulin peak in March and in October (6), respectively, whereas sex hormones show maximal levels between fall and winter (9,10). Sex-related changes in blood sugar level (11), liver and fat body weight and composition (2), and liver content of dolichol phosphate (12) have been reported.

As lipid metabolism is related to membranogenesis and gametogenesis and no data are available on the annual or sex-dependent cholesterol metabolism of the frog, it is of interest to determine whether seasonal behavior and sex-related physiological activities affect lipid content in the liver and production or utilization of cholesterol. For this purpose, lipid and cholesterol content of male and female frogs *(Rana esculenta)* were compared, on an annual basis, to the activity of two enzymes involved in hepatic cholesterol homeostasis: the key enzyme of biosynthesis, 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase, and the enzyme of cholesterol esterification, acyl coenzyme A:cholesterol acyltransferase (ACAT).

*To whom correspondence should be addressed.

Abbreviations: ACAT, acyl coenzyme A:cholesterol acyltransferase; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; TLC, thin-layer chromatography.

EXPERIMENTAL

Animals. Male and female frogs *Rana esculenta* (23.2 ± 5.5 g average body weight) kept in an outdoor terrarium were collected at random every month for one year. Animals were killed after anesthesia with 0.2% MS222 (tricaine methane sulphonate). Livers were removed rapidly and weighed. Chemical and biochemical assays were performed in duplicate on liver from 7-9 frogs for each sex.

Lipid and cholesterol content. Lipids were extracted in chlorophorm/methanol/water (0.8:2:1, v/v/v) according to the method of Bligh and Dyer (13), in the presence of 50 μg/ml BHT (2,6-di-tert-butyl-*p*-cresol) in order to avoid unsaturated fatty acid oxidation. An aliquot of chloroform phase was evaporated to dryness under a stream of N_2 and vacuum desiccated to constant weight over KOH for determination of total lipid content. Total and free cholesterol content in liver lipid extracts was determined on aliquots from the chloroform phase by the cholesterol esterase and cholesterol oxidase method using monotest High Performance and Test Combination reagent kits, supplied by Boehringer (Mannheim, Federal Republic of Germany). A sterol recovery of 82-90% was obtained, as determined by the addition of a known amount of specific compounds during the extraction procedure.

Preparation of microsomes. Liver tissue was homogenized in 5 volumes (w/v) of microsomal buffer (0.1 M sucrose/0.01 M KCl/0.03 M EDTA/0.004 M KH_2PO_4, pH 7.4) with a glass-Teflon Potter-Elvejhem homogenizer (3 strokes at moderate speed). The subcellular fractionation was carried out according to the method described by Erickson et al. (14) for rat liver. Briefly, the homogenate was centrifuged twice for 10 min at 12,000 × *g* and the supernatant centrifuged for 60 min at 105,000 × *g*. The microsomal pellet was resuspended in 1 ml of buffer by homogenization with a loose-fitting Teflon pestle.

Enzyme assays. HMG-CoA reductase was assayed by the radioisotope method reported by Erickson et al. (14), following the formation of mevalonic acid from [^{14}C]-3-hydroxy-3-methylglutaryl-CoA. Essentially, 80-120 μg frog liver microsomes were incubated in 0.2 ml microsomal buffer containing 10 mM dithiothreitol, 30 mM EDTA, 70 mM NaCl, 3 mM NADP and 1 enzyme unit of glucose-6-phosphate dehydrogenase. The mixture was preincubated 7 min at 37°C; 10 nmol [^{14}C]HMG-CoA (24,000 dpm/nmol) was added and the incubation continued for another 20 min. After alkaline hydrolysis of residual [^{14}C]HMG-CoA and addition of [^{3}H]mevalonate as the internal standard (10,000 dpm), labeled mevalonic acid formed was separated by Bio Rad AG1-X8 formate ion-exchange column chromatography (15). Recovery was never less than 60%. ACAT activity of aliquots of microsomes preincubated 90 min at 37°C was assayed by the radioisotope method of Dietschy et al. (16). Labeled cholesteryl oleate formed from 1-^{14}C-oleoyl-CoA (sp. act. 2700 dpm/nmol) during a 4-min incubation at 37°C was

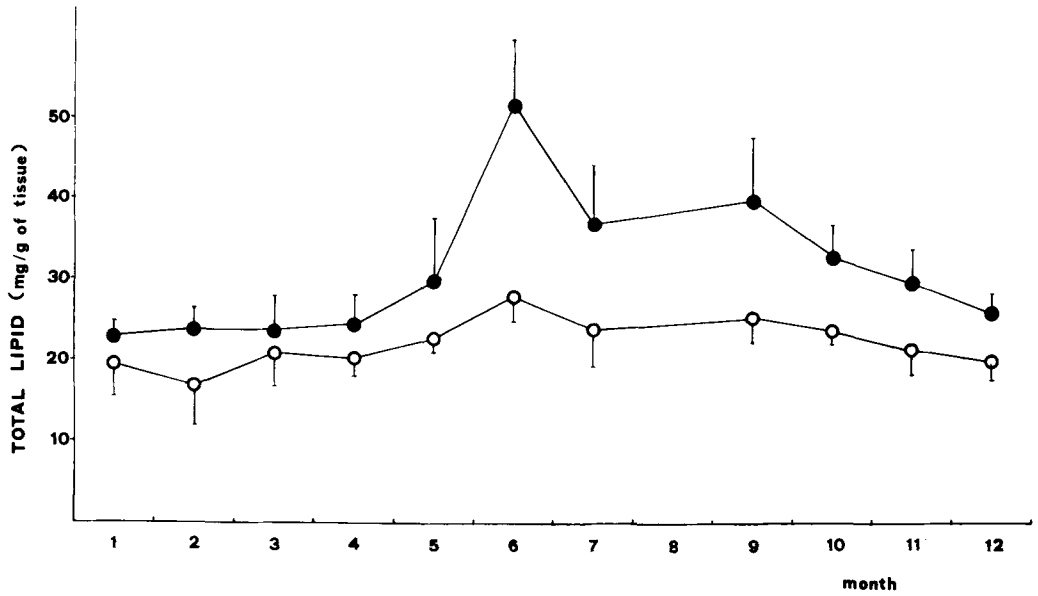

FIG. 1. Yearlong variations of total lipid content of male (○) and female (●) frog liver. Results are expressed as mg of lipids/g of liver wet weight, ± SD. Statistical details in the text.

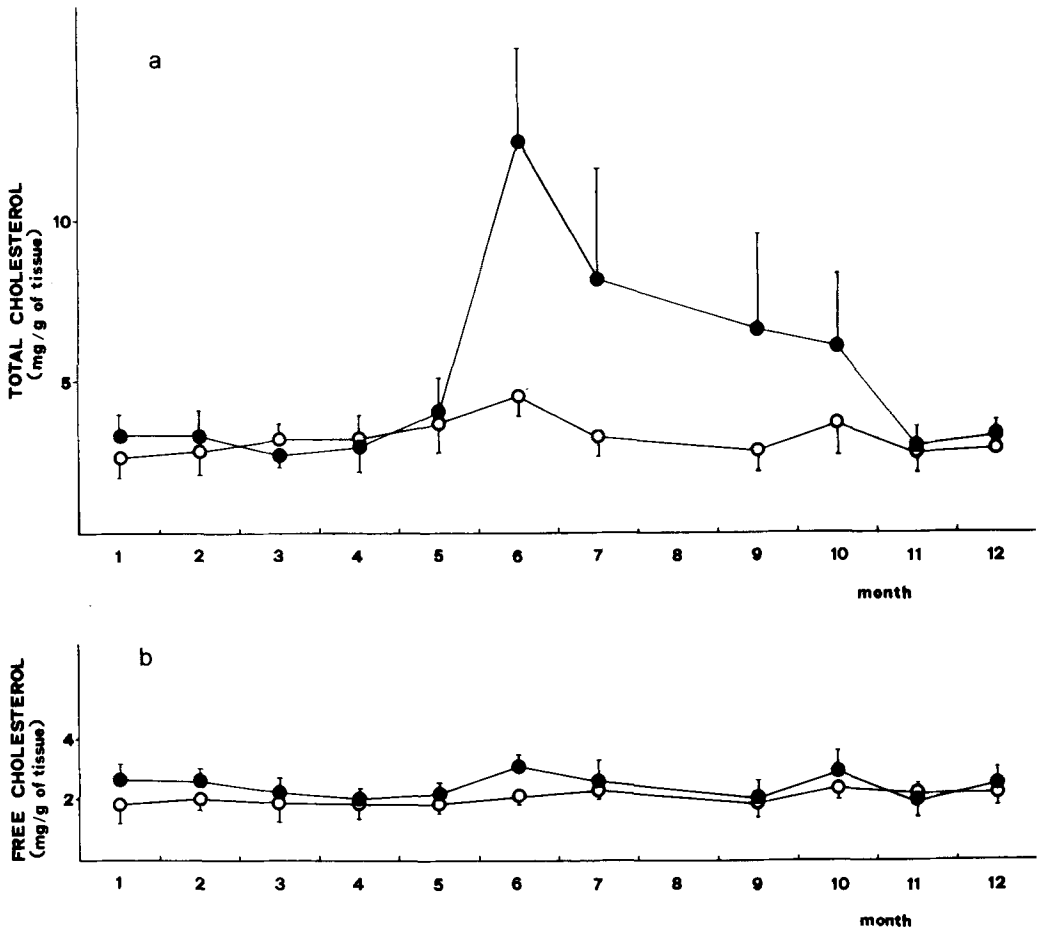

FIG. 2. Yearlong variations of total cholesterol (a) and free cholesterol (b) of male (○) and female (●) frog liver. Results are expressed as mg/g of liver wet weight, ± SD. Statistical details in the text.

extracted in chlorophorm/methanol (2:1, v/v) and separated by thin-layer chromatography in hexane/ethyl acetate (90:10, v/v). [^{3}H]Cholesterol was used as internal standard (8,000 dpm). Recovery was never less than 60%.

Radioactive compounds were obtained from Amersham.

Other assays. Proteins were measured according to Lowry et al. (17) using bovine serum albumin as standard.

Statistical analysis. Significance of data was determined by analysis of variance and Student's t test.

RESULTS AND DISCUSSION

Total lipid content of liver (Fig. 1) varied significantly throughout the year both in male and female frogs ($P < 0.005$ from the analysis of variance); furthermore, the females showed a significantly higher lipid content than males ($P < 0.05$ at least). The maximum lipid content was reached in June with 2.5- and 1.5-fold increases in females and males, respectively.

Total cholesterol content varied in a pattern comparable to that represented by total lipids ($P < 0.005$ from the analysis of variance in both sexes). From June to October, females showed a significantly higher total cholesterol content than did males (Fig. 2a). In contrast, free cholesterol was constant throughout the year in both sexes (Fig. 2b).

To establish whether fluctuations of cholesterol content during the year could be caused by a modified biosynthetic rate, the activity of HMG-CoA reductase, the rate-limiting enzyme in cholesterol biosynthesis, was assayed in liver microsomes on a monthly basis (Fig. 3). HMG-CoA reductase activity showed minimal fluctuations in male frogs, generally reflecting cholesterol content. HMG-CoA reductase activity in females seemed to vary more sharply with seasonal changes ($P < 0.05$ from the analysis of variance). Actually, its level increased in June, slightly decreased during summer, and showed another much higher peak in November. The fluctuation of HMG-CoA reductase activity/g of liver was confirmed by a similar profile of the specific activity (nmol/mg membrane protein) (Fig. 3, inset).

Whereas the June peak was in good correlation with the modification of liver cholesterol content, the later peak seemed unassociated with cholesterol storage.

The activity of the ACAT enzyme that catalyzes

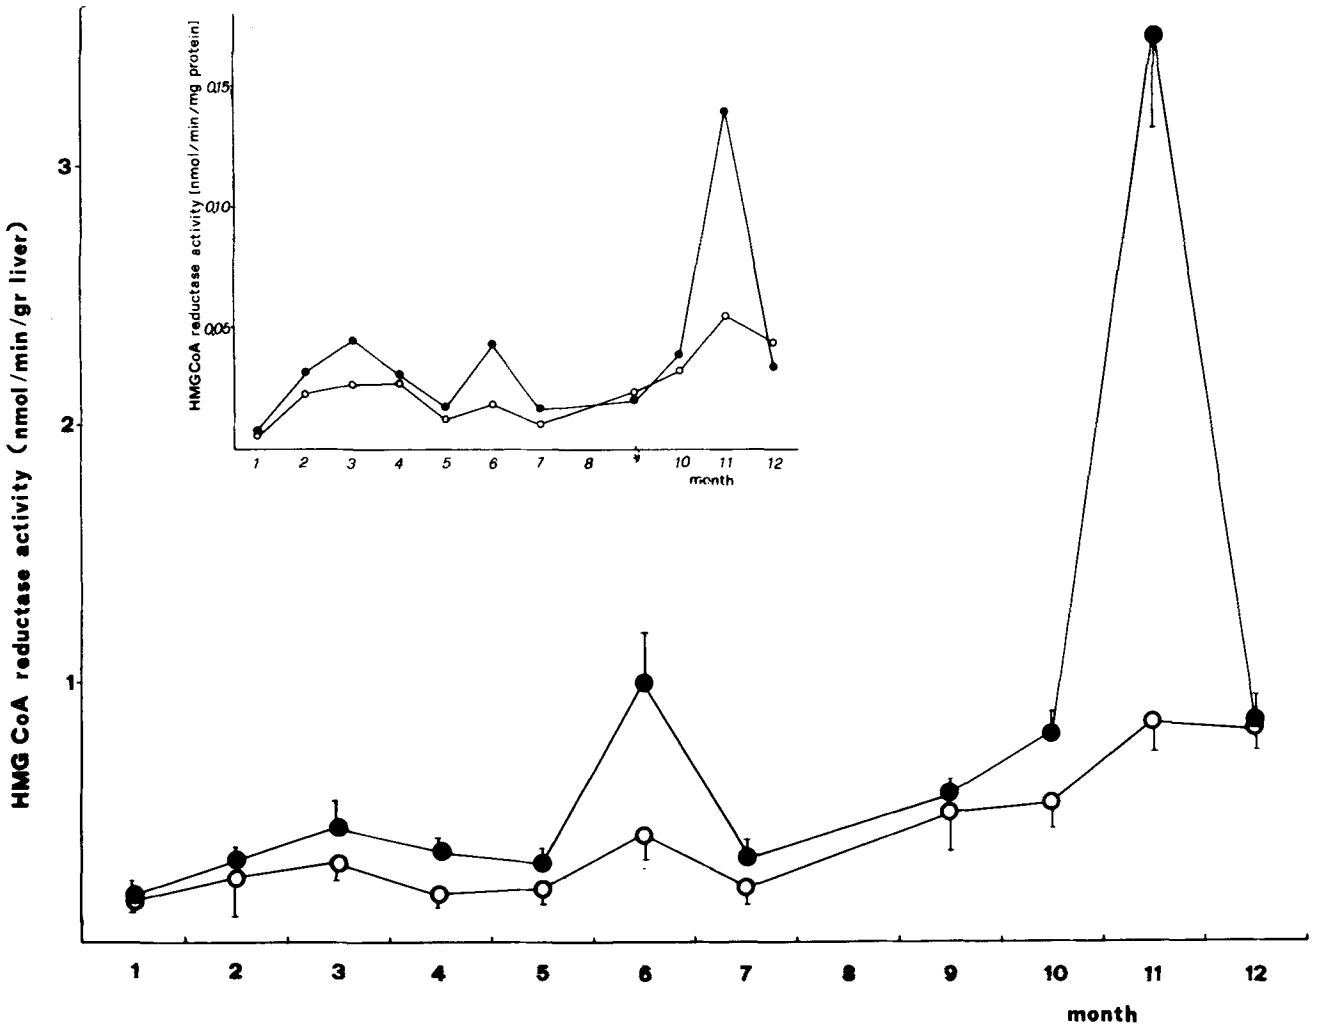

FIG. 3. Yearlong variations of HMG-CoA reductase activity in male (○) and female (●) frog liver. The results (the average of 4 separate preparations) are expressed as nmol mevalonate/min/g of liver wet weight, ±SD. In the inset, specific activity of the enzyme (nmol mevalonate/min/mg membrane protein) is shown. Statistical details in the text.

TABLE 1

ACAT Activity Measured in Male and Female Frog Liver in February, June and July

	Enzyme activity (nmol/min/g liver)	
Month	Female	Male
February	0.35	0.30
June	1.21	0.86
July	0.35	0.51

The results are expressed as nmol cholesteryl oleate/min/g of tissue (representative experiment).

cholesterol esterification, which was assayed during the three months in which cholesteryl ester content changed, showed different values for male and female frogs (Table 1). The activity was higher in females, but the pattern was similar in both. As cholesteryl ester content increased, ACAT showed greater activity.

Annual observations of sex differences have rarely been reported in poikilothermic vertebrates (18), and generally have been related to reproductive function (10).

This study found marked differences between male and female frogs in cholesterol content, biosynthesis and esterification activities during the one-year period of observation.

In male liver, the variations of these parameters were comparable, pointing out an increased synthesis of cholesterol stored as cholesteryl ester in summer. In females, on the other hand, fluctuations of cholesterol metabolism were more complex and two phases could be distinguished. In the first part of the year, cholesterol content, biosynthesis and esterification seemed interrelated, whereas in winter and particularly in November, such correlation was lost.

The high activity of HMG-CoA reductase detected in females in November could be related to the higher concentration of estrogens (10), hormones known to stimulate this HMG-CoA reductase activity (19). The higher reductase activity not accompanied by a high cholesterol content would suggest that the enzyme is producing cholesterol for export. The enhanced liver production of total RNA observed in the female *Rana esculenta* by Brachet et al. (7) in the same period of the year supports the idea that cholesterol is exported from the liver by some newly synthesized protein.

Because estrogens stimulate hepatic synthesis of essential products for oogenesis, such as the lipoprotein vitellogenin (20-22), we suggest that the extra peak of reductase activity could be related to the production of these compounds.

[Received August 1, 1988; Revision accepted September 26, 1988]

Very Low Density Lipoprotein Secretion by Cultured Hepatocytes of Rabbits Fed Purified or Autoxidized Cholesterol

Vladimir A. Kosykh*, Vadim Z. Lankin, Eugeniy A. Podrez, Dmitriy K. Novikov, Sergey A. Volgushev, Alexander V. Victorov, Vadim S. Repin and **Vladimir N. Smirnov**
USSR Cardiology Research Center, Academy of Medical Sciences, 3rd Cherepkovskaya St., 15A, Moscow 121552, USSR

The main objectives of this study were to compare the effects of dietary commercial cholesterol (containing 5% of oxidized cholesterol derivatives) and purified cholesterol on the secretion rate of very low density lipoprotein apolipoproteins and lipids by cultured rabbit hepatocytes and to verify the hypothesis that products of cholesterol autoxidation stimulate the rapid development of hypercholesterolemia. Rabbits fed dietary (old) commercial cholesterol for six weeks showed a fivefold increase in the serum concentration of cholesterol compared with that in purified cholesterol-fed rabbits. The secretion rates of very low density lipoprotein total protein and very low density lipoprotein [^{3}H]apolipoproteins were similar for the hepatocytes of these two cholesterol-fed groups of animals and were two- and threefold greater, respectively, than for cells from control rabbits. Cholesteryl ester content of the hepatocytes from dietary (old) commercial cholesterol-fed rabbits was dramatically increased in comparison with hepatocytes from control and purified cholesterol-fed rabbits. The elevated intracellular cholesteryl ester content is assumed to account for such an increase of very low density lipoprotein-cholesteryl ester secretion by cells prepared from dietary (old) commercial cholesterol-fed rabbits. These effects appear to be caused by activation of cholesterol esterification by oxidized cholesterol derivatives. The rapid development of hypercholesterolemia induced by dietary (old) commercial cholesterol is associated, at least in part, with the stimulated production of hepatic very low density lipoprotein apolipoproteins and cholesteryl esters.
Lipids 24, 109–115 (1989).

Cholesterol-rich diet induces in rabbits a marked elevation in plasma cholesterol level, particularly for cholesteryl esters that are associated with β-very low density lipoproteins (VLDL), which are also enriched in apo-E and apo-B (1). The accumulation of these particles is explained by the combination of a decrease of hepatic clearance (2,3) and hepatic and/or intestinal overproduction (4–7). It has been shown previously that cholesterol-feeding raises the cholesterol pool in the liver (8). The accumulation of hepatic cholesterol leads to a suppression of 3-hydroxy-3-methylglutaryl coenzyme A reductase activity, thus blocking cholesterol synthesis, and to suppressed production of low density lipoprotein (LDL) receptors (3). Recent studies have shown that a cholesterol diet also increases the rate of apo-E synthesis in rabbit liver (9) and that cholesteryl-ester content of VLDL secreted by perfused liver may be increased significantly as well (7).

These hepatic effects of dietary cholesterol are not conclusive evidence that it acts directly as a regulatory molecule (10,11). Oxidized cholesterol derivatives (OCD) may arise from spontaneous, nonenzymatic oxidation of dietary cholesterol (12,13) or may be of natural origin, occurring as a product of hepatic cholesterol catabolism (14–17). Feeding rabbits with purified cholesterol (PCh) caused a substantial delay (1–1.5 months) in the development of high hypercholesterolemia as compared with animals that received an equal dose of cholesterol that contained OCD (18).

Clarification of the mechanism of the development of hypercholesterolemia induced by oxysterol-rich cholesterol is very important, because the isolation of these substances from a variety of foods has been documented (13), and their presence in cholesterol-rich diet has been linked to the aetiology of atheromata (12,19).

In the present study, the secretion rates of lipids and apolipoproteins in the VLDL fraction by hepatocytes from rabbits fed OCh or cholesterol purified from its autoxidation products were compared to estimate the extent to which hepatic VLDL production is responsible for highly elevated cholesterol plasma concentration.

MATERIALS AND METHODS

Materials. All chemicals used were reagent grade. Minimal essential medium (MEM) with Earle's salts, fetal calf serum (FCS), MEM nonessential amino acids, kanamycin, L-glutamine and 35- to 100-mm culture dishes were purchased from Flow Laboratories, Inc. (Zwanenburg, The Netherlands). Collagenase, type IV, was a product of Sigma Chemical Co. (St. Louis, MO). L-[4,5-^{3}H]Leucine (sp. act. 135 Ci/mmol), L-[^{35}S]methionine (sp. act. >800 Ci/mmol) and [1-^{14}C]acetic acid, sodium salt (sp. act. 59 mCi/mmol) were purchased from Amersham International (Amersham, Buckinghamshire, U.K.). PCh was obtained from old USP cholesterol by two crystallizations from ethanol. USP cholesterol was purchased from Sigma Chemical Co. (St. Louis, MO) and stored at room temperature for ca. 5 years. Cholesterol purity was checked by high performance liquid chromatography (HPLC) using a DuPont 8800 (Du Pont Instruments, Wilmington, DE) liquid chromatograph equipped with ultraviolet (209 nm) and refractive index ERC-7510 (Erma Optical Works, Tokyo, Japan) detectors. A reversed-phase column (Altex, Berkeley, CA, Ultrasphere-ODS, 250 × 4.6 mm, 5 μ particles) and an isocratic method with eluting system of 5% H_2O/95% MeOH were used. PCh was stored at −20°C. The purity of samples checked by HPLC before and after each experiment was greater than 99%. Dietary commercial cholesterol (OCh) contained about 5% OCD, the majority being 7α- and 7β-hydroxycholesterol, 7-ketocholesterol, cholestane-3β, 5α, 6β-triol.

Abbreviations: ACAT, acyl coenzyme A cholesterol-acyltransferase; EDTA, ethylenediamine tetraacetic acid; FCS, fetal calf serum; OCD, oxidized cholesterol derivatives; OCh, dietary (old) commercial cholesterol; PCh, purified cholesterol; SDS, sodium dodecylsulphate; (V)LDL, (very) low density lipoprotein; HPLC, high performance liquid chromatography; HPTLC, high performance thin layer chromatography; MEM, minimal essential medium.

PCh and OCh were solubilized in olive oil with a stainless steel paddle for 10 min at room temperature.

Animals. Male rabbits of the Chinchilla breed, weighing 2.5-3 kg, were used. Control animals were maintained on a laboratory rabbit chow and, in addition, received olive oil (0.5 ml/kg body wt) orally each day. One experimental group received a suspension of OCh in olive oil (0.2 g cholesterol/kg body weight); the other experimental group received an analogous suspension of PCh (0.2 g cholesterol/kg). After 1.5 months, the animals were killed and blood was collected on EDTA (0.1%). Plasma was separated immediately by centrifugation.

Cultured hepatocytes. Rabbit hepatocytes were prepared and plated after collagenase digestion by methods described in detail elsewhere (20). The cells were plated in 35-mm dishes at 2×10^5 cells/cm^2 in ME medium containing FCS, kanamycin (100 μg/ml) and nonessential amino acids (1%) and were maintained at 38°C in 95% air/5% CO_2 atmosphere. The cells were incubated for 24 hr under these conditions for measurement of VLDL secretion over the following 18 hr. A percentage viability of hepatocyte monolayer was determined by addition of 0.075 ml 0.4% (w/v) Trypan Blue in 1 ml of cultured medium. Monolayers were incubated for 5 min at room temperature, then Trypan Blue was removed and percentage viability was assessed.

Analytical methods. For studies of secretion rates of de novo synthesized VLDL apolipoproteins, cells were incubated with leucine-free or methionine-free ME media containing 1% of nonessential amino acids and [^{3}H]-leucine (40 μCi/ml) or [^{35}S]methionine (50 μCi/ml), respectively, for 18 hr. Then the medium was removed for analysis. Plasma VLDL and VLDL fractions secreted by rabbit hepatocytes were isolated by preparative ultracentrifugation of the plasma and media in cellulose propionate tubes (Beckman Instruments, Palo Alto, CA) at 40,000 rpm in a LP-42 Ti rotor (Beckman Instruments) for 2.5 hr at 18°C. VLDL were isolated from the centrifugation tubes at d > 1.006 (50 μl from the top) and were recentrifugated. Protein was determined by the method of Lowry et al. (21) using bovine albumin as a reference standard. For sodium dodecylsulphate (SDS)-polyacrylamide gel electrophoresis, aliquots of VLDL fractions were prepared as previously described (22). They were subjected to electrophoresis on polyacrylamide gel that contained 0.1% SDS (3-20% gradient polyacrylamide) and were stained with Coomassie Blue. The relative quantity of VLDL apolipoproteins in two cholesterol-fed groups as compared with control was estimated by scanning using an LKB 2202 Ultrascan laser densitometer. The isotope incorporation into apolipoprotein band was estimated by counting the gel slices. The gels were cut into 2-3 mm slices, placed into separate vials containing 30% H_2O_2 (w/w), incubated overnight at 70°C and 10 ml of scintillation mixture (Ready-Solv EP, Beckman Instruments) were added to the vials. The radioactivity was determined in a scintillation counter Rackbeta 11 1215 (LKB Wallac, Turku, Finland).

For studies of de novo lipid biosynthesis, cells were incubated with ME medium containing [^{14}C]acetate (5 μCi/ml, 0.1 mM) for 18 hr. Sonicated cells and VLDL fractions were extracted twice with 5 ml of a mixture of chloroform/methanol (2:1, v/v) (23). The organic phase was washed 3 times with water to remove ca. 99% of [^{14}C]-acetate and then dried under reduced pressure. In the preliminary experiments, the extraction recovery of [^{14}C]triglyceride added as a standard was 94%. Lipids in an aliquot of the chloroform/methanol extract were separated into classes by high performance thin layer chromatography (HPTLC) using silica gel plates (0.2 mm Merck, Darmstadt, FRG) developed in hexane/diethyl ether/acetic acid (70:30:2, v/v/v). Quantitative determination of neutral lipids was performed by a densitometry of HPTLC plates (24) with an automated Camag HPTLC/TLC Scanner (Muttens, Switzerland) connected with a recording integrator SP 4100 (Spectra Physics, Darmstadt, FRG) (25). Each determination was accompanied by a calibration using cholesteryl oleate, triolein and cholesterol as standards. The spots on silica gel plates containing the certain lipid species were scraped into counting vials and the radioactivity was assayed.

For the determination of a reuptake of secreted lipoproteins, cells were incubated with [^{35}S]methionine (250 μCi/100-mm culture dish) for 18 hr. The medium with labeled lipoproteins was dialyzed for 24 hr against an unlabeled medium and then was administered to hepatocytes or to 35-mm culture dishes without hepatocytes. After an 18 hr incubation, the medium taken from both groups was ultracentrifuged for the isolation of lipoproteins (d < 1.21 g/ml). Following the separation on SDS-polyacrylamide gel, the amount of ^{35}S in apolipoproteins B and E was quantified by a scintillation counting.

Plasma total cholesterol was assayed enzymatically using the Total Cholesterol Kit (Medix, Helsinki, Finland) by chemistry analyzer FP-901 (Labsystems, Oy, Finland). Ten μl of plasma or standard solution were combined with 1 ml of cholesterol enzymatic reagent and incubated at 37°C for 20 min. The absorbance at 500 nm was measured for each sample against a reagent blank.

Statistical analysis. Results were analysed with Student's t test and expressed as mean ±SD. Values of P < 0.05 (doubled-tailed) were considered significant.

RESULTS

Plasma cholesterol and VLDL apolipoprotein analysis. OCh-fed rabbits were characterized by a 15-fold increase of plasma cholesterol concentration (Table 1). On the other hand, PCh-fed rabbits manifested only a 3-fold augmentation of cholesterol level. These results agree well with those previously published (18).

Plasma VLDL apolipoproteins were analyzed by SDS-polyacrylamide gel electrophoresis (Fig. 1). The apolipoprotein qualitative composition of VLDL (d > 1.006 g/ml) for three experimental groups of animals was the same

TABLE 1

Plasma Cholesterol Concentration

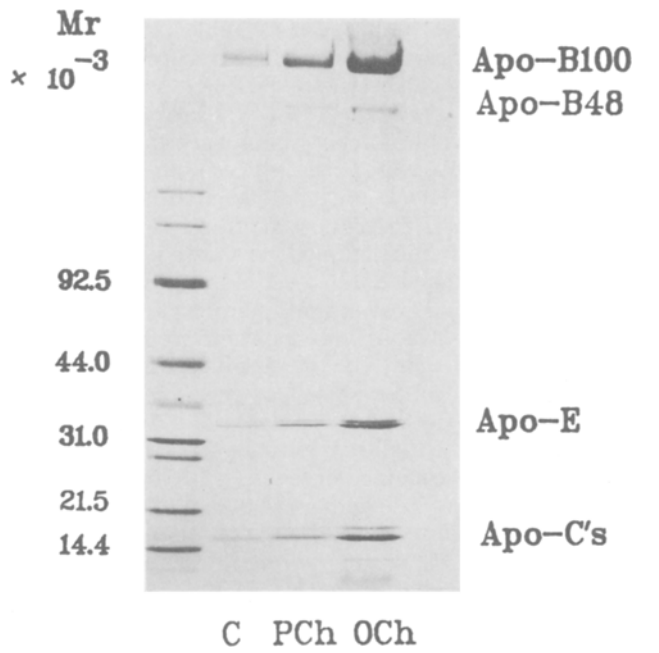

FIG. 1. SDS-polyacrylamide gel electrophoresis of plasma VLDL fractions obtained from control rabbits (C) and animals fed purified (PCh) and old commercial (OCh) cholesterol. The gel (3 to 20% gradient polyacrilamide) was loaded with VLDL (d < 1.006 g/ml) derived from an equal volume of plasma. It was stained with Coomassie Blue. The vertical axis indicates the molecular weights of the marker proteins.

TABLE 2

Plasma VLDL Apo-B-100 and Apo-E Concentrations

	Apo-B-100 (% from control)	Apo-E (% from control)
C	100 ± 12	100 ± 8
PCh	207 ± 15[a]	203 ± 32[a]
OCh	576 ± 104[a,b]	885 ± 127[a,b]

[a] $P < 0.01$, vs control.

[a,b] $P < 0.01$, vs PCh.

C, control; PCh, purified cholesterol; OCh, old commercial cholesterol. Values are means ±SD of 4 rabbits.

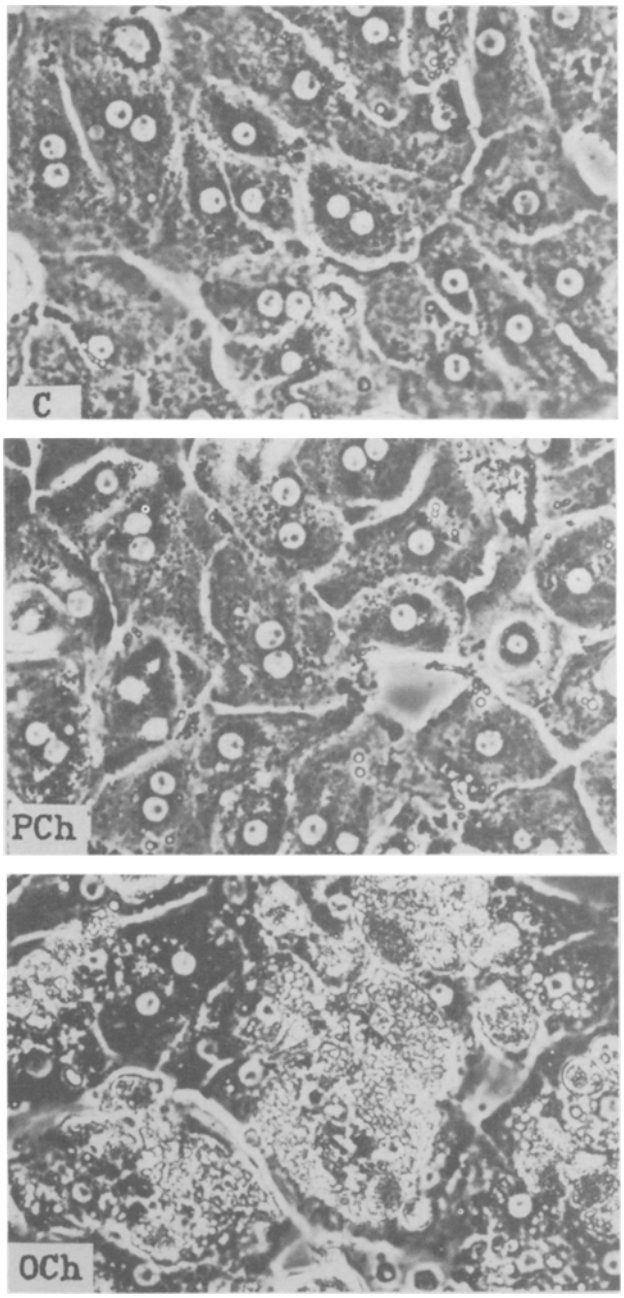

FIG. 2. Phase-contrast microscopy of hepatocytes obtained from control rabbits (C), animals fed old commercial cholesterol (OCh) and purified cholesterol (PCh) which have been cultured for 24 hr.

with respect to general apolipoproteins B-100, E and C. The analysis of polyacrylamide electrophoretic gel by densitometry showed a marked increase (6-to 10-fold, 4 experiments) in the levels of plasma VLDL apo-B-100 and apo-E of OCh-fed rabbits (Table 2). In contrast to this, plasma concentration of VLDL apolipoproteins of rabbits that received PCh was increased only by 2-fold (4 experiments) as compared with control.

Cultured hepatocytes and lipid content. There was no difference in the plating efficiency of the hepatocytes obtained from animals of three experimental groups (55 ± 7%, control; 50 ± 9%, OCh; 60 ± 9%, PCh; five different preparations in each group). The viability of hepatocyte monolayers after 24 hr in culture was greater than 90%. OCh-hepatocytes were loaded with lipids, which was clearly visible via phase-contrast microscopy (Fig. 2). The lipid inclusions in these cells were maintained throughout 5 days in primary culture. Cholesterol ester concentration (Table 3) was elevated in PCh-hepatocytes (230%, $p < 0.05$) and was dramatically increased (24-fold, $p < 0.05$) in OCh-hepatocytes. Triacylglycerol concentration had also risen in hepatocytes from both experimental groups (160%, $p < 0.05$; and 180%, $p < 0.05$).

Incorporation of [^{14}C]acetate into lipids. Cholesterol biosynthesis measured using [^{14}C]acetate was inhibited by 40–50% in hepatocytes from both groups of animals fed cholesterol (Table 4). Consistent with the immense 24-fold increase in cellular cholesteryl ester concentration

TABLE 3

Hepatocyte Cholesterol and Triacylglycerol Concentrations

Hepatocytes	Triacylglycerols	Cholesterol	Cholesterol esters
	μg lipid/mg cell protein		
C	35.4 ± 4.8	25.6 ± 3.1	39.2 ± 5.6
PCh	58.2 ± 6.1[a]	36.1 ± 6.1[a]	91.4 ± 12[a]
OCh	64.9 ± 7.2[a]	117 ± 18[a,b]	949 ± 120[a,b]

[a]P < 0.05, vs control.

[b]P < 0.05, vs PCh.

C, control; PCh, purified cholesterol; OCh, old commercial cholesterol. Values are means ± SD of 3 replicates for 4 experiments from each group.

TABLE 4

Effects of Dietary Purified and Commercial Cholesterol on the Incorporation of Sodium [^{14}C]Acetate into Lipids of Cultured Rabbit Hepatocytes

Hepatocytes	Triacylglycerols	Cholesterol	Cholesterol esters
	10^{-3} × cpm/mg cell protein		
C	340.4 ± 38.5	74.2 ± 7.6	4.1 ± 0.5
PCh	502.2 ± 69.8[a]	41.2 ± 5.2[a]	6.3 ± 0.7[a]
OCh	482.4 ± 64.4[a]	36.2 ± 5.4[a]	16.2 ± 3.1[a,b]

[a]P < 0.05, vs control.

[b]P < 0.05, vs PCh.

C, control; PCh, purified cholesterol; OCh, old commercial cholesterol. Values are means ± SD of 3 replicates for 3 experiments from each group.

(Table 3), OCh-hepatocytes revealed a 4-fold increase of [^{14}C]acetate incorporation (Table 4) into cholesteryl esters. In contrast, PCh-hepatocytes incorporated a relatively low (150% of control) amount of [^{14}C]acetate into cholesteryl ester. The incorporation of the labeled acetate into the triacylglycerol pool of cells obtained from two cholesterol-fed groups was also above control value (by 45%).

Secretion of VLDL lipids and apolipoproteins. The secretion rates of VLDL lipid and protein components were different for hepatocytes obtained from control and both cholesterol-fed rabbit groups (Table 5). PCh-hepatocytes secreted larger amounts of VLDL protein, triacylglycerol and free cholesterol (by 90, 90 and 30%, respectively), whereas cholesteryl ester secretion was not altered. Equal 2-fold increases have been demonstrated for VLDL total protein, triacylglycerol and cholesterol secreted by OCh-cells. Additionally, a 5.2-fold rise in content of released cholesteryl esters was found.

From Coomassie Blue-stained gel shown in Fig. 3 (left), it is readily seen that VLDL secreted by control cells contained apo-B, E and C as major apolipoproteins. Certain quantitative differences are apparent in the material secreted by cells from control animals and from two groups of cholesterol-fed animals. Secretion of all VLDL apolipoproteins by cells from cholesterol-fed animals was highly activated compared with control hepatocytes. Close results were obtained in several experiments. When [^{35}S]methionine or [^{3}H]leucine was added in medium and its incorporation into the various apolipoprotein bands was determined, it became evident that alteration in secretion of newly synthesized VLDL apolipoproteins actually took place (Fig. 3, right; Table 6). Figure 3 (right) shows the autoradiogram of SDS-polyacrylamide electrophoresis gel and the stimulation of [^{35}S]methionine incorporation into apo-B and apo-E for two experimental groups. The secretion rates of apo-B and apo-E as components of de novo synthesized VLDL were similar for PCh- and OCh-cells and surpassed those of control by ca. 3-fold (Table 6).

Reuptake of newly secreted apo-B and E. To examine the possibility that the results obtained may reflect certain changes in the reuptake of secreted VLDL, control and OCh-cells were incubated with [^{35}S]methionine-labeled secreted lipoproteins. After an 18 hr cultivation, the amount of [^{35}S]methionine-labeled apolipoproteins left in the medium was determined. The results shown in Table 7 demonstrate that cultured control and OCh-hepatocytes do not actively (at least not more than 10% of total apolipoproteins added) take up and degrade newly secreted apo-B and apo-E in the culture medium. Thus, the accumulation of VLDL in the medium of the primary culture of rabbit hepatocytes is purely the process of secretion.

DISCUSSION

Recently it was found that rabbits fed OCh during 1.5 months showed a marked (15-fold) elevation in plasma

TABLE 5

Rates of VLDL Protein and Lipid Secretion by Cultured Hepatocytes

Hepatocytes	Total protein	Triacylglycerol	Cholesterol	Cholesterol ester
	μg lipid/mg cell protein/18 hr

cholesterol content, whereas the plasma cholesterol level of rabbits that received PCh was only 3-fold higher than in control animals (18). However, after a 3-month feeding of rabbits with PCh, their plasma level of cholesterol reached the same high values that were registered for OCh-fed animals. An addition of butylated hydroxytoluene to PCh inhibits the development of higher hypercholesterolemia (18). These results can be explained, considering the action of OCD that are present in OCh and might be formed during hepatic metabolism. Indeed, the liver has been shown to compensate for an increase of dietary cholesterol intake by suppressing its own cholesterol synthesis and by secreting more cholesterol in the bile (26). The presence of OCD in cholesterol-rich diet, which was found capable of blocking hepatic secretion of free cholesterol (27) and bile acid synthesis (28–31), can be responsible for the rapid increase in the hepatic cholesterol level and development of hypercholesterolemia in OCh-fed rabbits as compared with PCh-fed animals.

Data presented in this report demonstrate that, in OCh-fed rabbits the plasma concentrations of apo-B and E are increased by 3- to 4-fold as compared with those in PCh-fed animals. These results are in contrast to the changes found in primary cultures. In cultured hepatocytes prepared from PCh- and OCh-fed animals, the VLDL apolipoprotein accumulation rates were similar and elevated ca. 2-fold as compared with control animals. It is noteworthy that the accumulation of VLDL apo-B and E in a primary culture medium is due only to the process of secretion and is not due to a difference between the secretion and reuptake (Table 7). Earlier data procured for a primary culture of rat hepatocytes also demonstrated that only a small turnover of newly synthesized

lipoprotein components occurs and that a measurement of the rates of an accumulation in the medium does provide a reliable indication of the synthetic rates (32). The observed discrepancy between the in vivo and in vitro data could be understood taking into account that the in vivo accumulation of apo-B and E is not caused solely by the hepatic overproduction of β-VLDL, but also by the reduction of their uptake (2). It is well established that, in cholesterol-fed rabbits, the accumulation of cholesterol in the liver leads to a suppression of production of hepatic LDL receptors responsible for the uptake of β-VLDL (3). Although in this work we carried out no comparative studies on the uptake of β-VLDL by hepatocytes isolated from various dietary groups of animals, based on the published data (3), one can infer that hepatocytes overloaded with cholesterol should be characterized by a lower uptake compared with the other two groups of animals.

Our finding is consistent with a previous in vitro observation that dietary cholesterol increases rabbit hepatic secretion of VLDL protein (7). Earlier, Garcia et al. (9) (for rabbits) and Lin-Lee et al. (33) (for rats) have shown that cholesterol diet stimulates synthesis of apo-E in the liver. Such an increase in apo-E content in rats is mediated by an accumulation of translatable apo-E mRNA. Recently it has been reported that cholesterol feeding in rats also resulted in a several-fold increase in the level of apo-B mRNA in the liver (34). Thus, the overproduction of VLDL apolipoproteins may account for the augmentation in plasma VLDL apolipoprotein concentration caused by dietary PCh or OCh.

The significant increase in VLDL apolipoprotein secretion by hepatocytes prepared from OCh-fed rabbits compared with control cells interrelated with stimulation of VLDL neutral lipid secretion so that only an absolute increase in cholesteryl ester secretion occurs. An elevated level of VLDL cholesteryl ester was observed in the presence of the enhanced intracellular cholesteryl ester synthesis and dramatic accumulation of cholesteryl ester in cells. It has been previously reported that cholesterol feeding increases the hepatic acyl coenzyme A cholesterol-acyltransferase (ACAT) activity and stimulates VLDL cholesteryl ester secretion by perfused rabbit liver (7,35). Our data for the primary culture testify that the cholesteryl ester pool within hepatocytes is responsible for the stimulation of VLDL cholesteryl ester secretion. At the same time, we found no differences in the secretion rates of VLDL cholesteryl esters by hepatocytes of PCh-fed rabbits and those of control, although the cholesteryl ester pool in former hepatocytes was 2 to 3 times bigger than in control cells. It is possible that such unaltered cholesteryl ester secretion by these hepatocytes may be due to a relatively small intracellular cholesteryl ester pool and to the absence (under culture conditions) of additional input of free cholesterol derived in vivo from cholesterol-rich lipoproteins. In addition, intracellular cholesteryl ester pool can be utilized also for synthesis of bile acids and for secretion of free cholesterol (29). A profound rise in the rate of formation of cholesteryl esters and their rapid accumulation in hepatocytes from OCh-fed rabbits compared with cells from PCh-fed animals are probably associated with the increase in concentration of substrate cholesterol for ACAT and its stimulation by OCD (11). Earlier, it was shown that 25-hydroxycholesterol activated cholesteryl ester formation in isolated hepatocytes (36,37). The enhancement of this stimulatory effect was observed when cells were incubated with mevalonic acid, which is a substrate for cholesterol synthesis. Moreover, in this case, hepatocytes secreted an augmented amount of VLDL cholesteryl esters (36).

Taking together all the above considerations, we conclude that results presented here indicate that OCD induce rapid intracellular cholesterol and cholesteryl ester accumulation in hepatocytes of rabbits receiving OCh. This, in turn, stimulates the VLDL secretion that, at least partly, could evoke a rapid development of hypercholesterolemia.

Analysis of Seed Oils Containing Cyclopentenyl Fatty Acids by Combined Chromatographic Procedures

William W. Christie[a,*], **Elizabeth Y. Brechany**[a] and **Vijai K.S. Shukla**[b]
[a]The Hannah Research Institute, Ayr, Scotland KA6 5HL; and [b]Aarhus Oliefabrik A/S, M.P. Bruunsgade 27, P.O. Box 50, DK-8100 Aarhus C, Denmark.

The fatty acids of seed oils of the Flacourtiaceae, *Hydnocarpus anthelmintica, Caloncoba echinata* and *Taraktogenus kurzii,* have been examined by a combination of capillary gas chromatography, silver ion high performance liquid chromatography and gas chromatography–mass spectrometry. In addition to the common range of cyclopentenyl fatty acids found in such oils, 13-cyclopent-2-enyltridec-4-enoic acid was a major component of *H. anthelmintica* and was identified by mass spectrometry as its picolinyl ester and dimethyldisulphide adduct. It has not previously been found in nature. In the other seed oils, the isolated double bond in the corresponding fatty acid was in position 6, as expected. Similarly, *cis*-4-hexadecenoic acid and C_{16} and C_{18} cyclopentyl fatty acids were identified for the first time in *H. anthelmintica. Iso-* and *anteiso*-methylbranched fatty acids were present in trace amounts.
Lipids 24, 116–120 (1989).

The seed oils of many species of plants of the family Flacourtiaceae are known to contain fatty acids with terminal cyclopent-2-enyl rings (1–3). They have been used for centuries in traditional medicine as a treatment for leprosy. The analysis of these oils by gas chromatography (GC) on packed columns, especially with polar liquid phases, is not straightforward, because cyclic and straight-chain components overlap, and it is necessary to use silver ion thin layer chromatography as a complementary technique to obtain adequate resolution of all the components (4,5). In this study, three seed oils have been examined and it is confirmed that GC with wall-coated open tubules (WCOT) columns of fused silica with a variety of different liquid phases resolves all the main components without difficulty (cf [3]). Silver ion high performance liquid chromatography (HPLC) of the methyl esters followed by GC–mass spectrometry (MS) of the picolinyl ester derivatives, a combination that has been proven to be of value with other natural lipid samples (6), permitted the identification of the individual fatty acid components including several that were hitherto not known.

MATERIALS AND METHODS

The authenticated seeds of *Hydnocarpus anthelmintica, Caloncoba echinata* and *Taraktogenus kurzii* were obtained from Dr. N. V. Bringi of Bombay and Dr. S. R. Shukla, Pharmacology Department, MLN Medical College, Allahabad, India. They were extracted with hexane.

Methyl ester derivatives of the fatty acids were prepared by sodium methoxide-catalyzed transesterification (7). A portion was hydrogenated with platinum oxide as catalyst (8).

For analytical purposes, a Carlo Erba Model 4130 capillary gas chromatograph (Erba Science, Swindon, U.K.), fitted with split/splitless injection and equipped with a capillary column (0.25 mm i.d. × 25 m in length) of fused silica coated with Silar 5CP (Chrompak Ltd, London, U.K.), was used with the methyl ester derivatives. After holding the temperature at 155°C for 3 min, it was temperature-programmed to 195°C at 4°C/min, then, was held at this point for a further 17 min. Hydrogen was the carrier gas. Components were quantified by electronic integration.

A Spectra-Physics Model 8700 solvent delivery system was used in separations by HPLC (Spectra-Physics Ltd., St. Albans, U.K.), together with an ACS Model 750/14 mass detector (Applied Chromatography Systems, Macclesfield, U.K.). A stream-splitter (ca. 10:1) was inserted between the column and the detector. A column (4.6 mm × 250 mm) of Partisil 10SCX (Hichrom Ltd, Reading, U.K.) was utilized in the silver ion form as described elsewhere (9). One to 2 mg of methyl esters were applied to the column in 10 μl of dichloroethane. Gradient elution was used and the solvent reservoirs contained dichloroethane/dichloromethane (1:1, v/v) (A) and dichloroethane/dichloromethane/acetonitrile/methanol (20:20:1:1, v/v/v/v) (B). The gradient was changed over 40 min from 100% A to 50% A − 50% B; the flow rate was 1 ml/min.

After analysis of the fractions by GC, they were hydrolyzed to the free acids before conversion to the picolinyl ester derivatives as described elsewhere (10). These were submitted to electron-impact GC–MS, as described earlier, on a capillary column coated with a 5% phenylmethylsilicone phase (except that the upper temperature of the column was 10°C lower) (11).

A portion of the final dienoic fraction from each sample was converted to the dimethyldisulphide adduct by reaction with dimethyldisulphide in the presence of iodine as catalyst as described by Francis (12). It was subjected to GC–MS under the same conditions as the picolinyl ester derivatives, although it eluted somewhat later. A further aliquot was subjected to permanganate-periodate oxidation (13), the products were esterified by acid-catalyzed methanolyis and analysed by GC–MS.

RESULTS

The methyl ester derivatives prepared from the seed oil of *H. anthelmintica* were initially examined by GC on a capillary column of fused silica coated with Silar 5CP and the peaks expected from the cyclopentenyl fatty acids were all well resolved from the normal straight-chain components, as shown in Figure 1. The C_{16} cyclopentenyl fatty acid, hydnocarpic acid, elutes before 18:0, whereas the C_{18} cyclopentenyl compounds, chaulmoogric and gorlic acids, elute after 18:2, but well before any C_{20} straight-chain fatty acids. Very similar results were obtained on a column of Carbowax 20M, as reported earlier

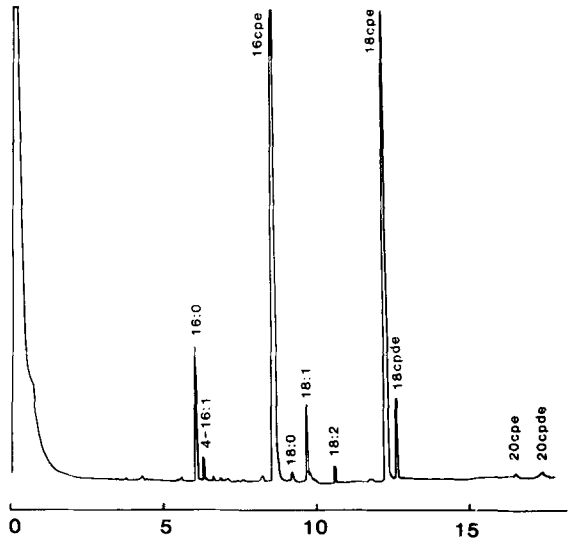

FIG. 1. Separation of the methyl ester derivatives of the fatty acids of *H. anthelmintica* on a WCOT column of Silar 5CP (see Experimental section for conditions). Abbreviations: 16cpe, 11-hendecylcyclopent-2-enoate; 18cpe, 13-tridecylcyclopent-2-enoate; 18cpde, 13-tridec-4-enylcyclopent-2-enoate; 20cpe, 15-pentadecylcyclopent-2-enoate; 20cpde, 15-pentadec-9-enylcyclopent-2-enoate.

by others (3). On a more polar phase, CP-Sil 84 (broadly equivalent in polarity to diethylglycolsuccinate polyester [DEGS]) hydnocarpic acid elutes just after 18:0, but is clearly separated from 18:1. There were a number of minor components (each less than 0.1%) which were not immediately identifiable. In contrast to previous experience with packed columns (4,14), it appears that cyclopentenyl seed oils are readily resolved on polar phases in capillary columns. The three seed oils each seemed to contain similar fatty acids, although the relative proportions in each were very different, and the results of the quantitative analyses are presented in Table 1.

In order to confirm the identities of the various components, the methyl ester derivatives from *H. anthelmintica* were first separated by silver ion HPLC, as shown in Figure 2, from which 5 fractions were obtained. These were each hydrolyzed and converted to the picolinyl ester derivatives for exmination by GC-MS. Prefractionation in this way ensures adequate resolution on the nonpolar GC phase required to elute picolinyl esters in a reasonable time (6). The saturated fraction consists mainly of 16:0, with smaller amounts of 14:0, 15:0, 17:0 and 18:0. In addition and rather surprisingly, small amounts of 13- and 12-methyl-14:0, 14-methyl-15:0 and 15- and 14-methyl-16:0, and two cyclopentyl fatty acids were found. The branched-chain components are rather easily identified as picolinyl ester derivatives, as described by Harvey (15), as a gap of 28 amu is seen in the regular series of ions for successive methylene groups for loss of the carbon containing the methyl group. The spectra compare well with those of authentic standards. 11-Cyclopentylhendecanoate and 13-cyclopentyltridecanoate were recognized from their mass spectra, which have good molecular ions, a gap of 69 amu for the loss of the cyclopentyl ring (together with a substantial ion at m/z = 69), and a regular series of ions 14 amu apart for fragmentations

TABLE 1

Fatty Acid Compositions (wt %) of Cyclopentene-containing Seed Oils

Abbreviations: i, iso-; ai, anteiso; cpa, cyclopentyl ring; cpe, cyclopent-2-enyl ring; cpde, cyclopent-2-enyl ring and a double bond in the aliphatic chain; tr, trace.

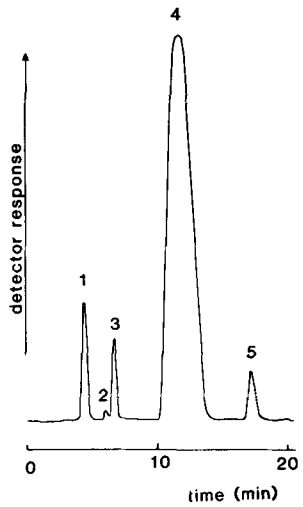

FIG. 2. Silver ion HPLC trace of the methyl esters of the fatty acids of *H. anthelmintica*. See Experimental section for conditions. Fraction 1 = saturated, 2 = 4-16:1, 3 = 9-18:1, 4 = cyclopentenoic fatty acids predominantly, 5 = as last, but with an additional double bond in the alkyl-chain.

between successive methylene groups in the chain. In addition, the spectra of the compounds and their GC retention times are identical to those of authentic derivatives prepared by hydrogenation of the oils.

The second fraction was a minor one and consisted mainly of 4-16:1. It has the *cis*-configuration from its retention time on the silver ion column. This particular isomer is distinguished from others by its mass spectrum

as the picolinyl ester in that it is the only one not to have readily identifiable fragmentations at the double bond and to have its base peak at m/z = 151; there is also a characteristic ion at m/z = 218 (16). The spectrum is very similar to that of authentic 4-18:1 and quite different from that of adjacent isomers. A further trace constituent in this fraction gave too noisy a spectrum for unequivocal identification, but it was consistent with that expected for 4-15:1.

The third fraction was mainly a 9-18:1 fatty acid, but there were also small amounts of 9-16:1, 9-17:1 and 9-19:1. Again, the mass spectral identification of the picolinyl esters is rather simple (15,16).

The fourth fraction contained predominantly cyclopentenyl fatty acids with some 18:2(n-6). The mass spectrum of 11-cyclopent-2-enyl-hendecanoate (hydnocarpate) is illustrated in Figure 3. There is an abundant molecular ion at m/z = 343, and the usual ions containing the pyridine ring at m/z = 92, 108, 151 and 164. The base ion at m/z = 67 presumably is the cyclopentenyl ring, and there is a significant complementary ion, representing $(M - 67)^+$ at m/z = 276. Again, there are ions 14 amu apart representing cleavage between the successive methylene groups. The C_{18} and C_{20} isomers have analogous spectra.

The mass spectrum of the main component of the fifth fraction is illustrated in Figure 4 and was not as expected for "gorlic acid," i.e., 13-cyclopent-2-enyltridec-6-enoate, but could be interpreted as having a double bond in position 4; the molecular ion is at m/z = 369, as expected, and the base peak is at m/z = 67, confirming the presence of the cyclopentenyl ring. There are no ions that can be readily assigned to fragmentation at a double bond in the aliphatic chain, although the ion at m/z = 151 is particularly prominent (60% of the base peak), as in the derivatives of fatty acids with an isolated double bond in position 4 (cf. the 16:1 straight-chain isomer). In contrast, the corresponding fractions from *C. echinata* and *T. kurzii* contained the true 6 isomer, and the mass spectrum of its picolinyl ester derivative is illustrated in Figure 5. Ions for fragmentation at the cyclopentenyl ring at m/z = 67 and 302 are as expected. In addition, there is a substantial ion at m/z = 246, and a gap of 26 amu between m/z = 192 and 218, all characteristic of an isolated double bond in position 6 (16). Similarly in all the oils, the analogous C_{20} homologue, "hormelic" acid, has the isolated double bond in position 9, because the mass spectra of the picolinyl ester derivatives all have a characteristic doublet of prominent ions at m/z = 274 and 288, together with ions expected for fragmentation on either side of the double bond (15,16).

In order to confirm the position of the isolated double bond in the C_{18} dienoic component from *H. anthelmintica*, the methyl ester derivative was converted to the *bis*-dimethyldisulphide adduct, as these are simple to prepare and have excellent mass spectral fragmentation properties (12). The reaction gave several products, when examined by GC-MS, but the last and most abundant component to elute had the correct molecular weight (m/z = 480) and the complete spectrum is illustrated in Figure 6. There is a major fragment (37%) at m/z = 147, representing cleavage between carbons 4 and 5 and containing the carboxyl group, and one at m/z = 115 (147 − methanol), as expected for an adduct of a double bond in position 4 (12). In the high mass range, there were ions at m/z = 432 (M-48, loss of CH_3SH presumably from the ring). Therefore, although an expected ion at m/z = 333 (containing carbon 5 and the remainder of the molecule) is not seen, there is one at m/z = 285 (333 − 48) (43%). If the molecule loses both sulphur moieties from the ring,

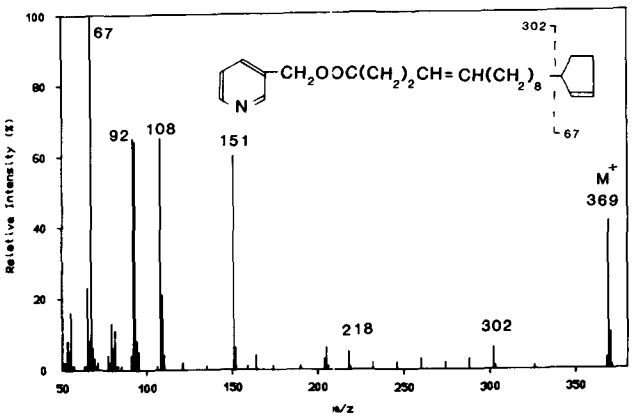

FIG. 4. Mass spectrum of the picolinyl ester derivative of 13-cyclopent-2-enyl-tridec-4-enoic acid.

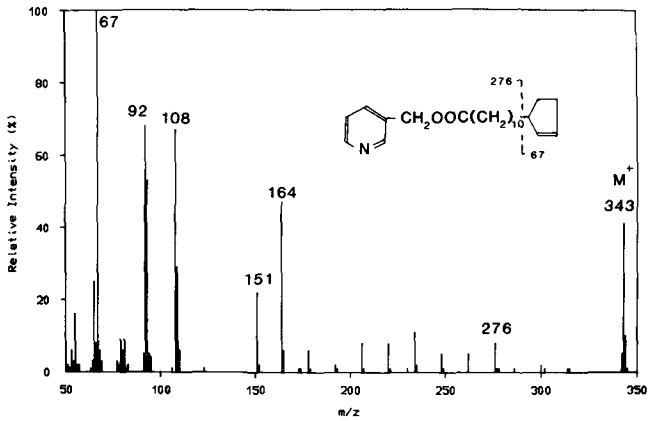

FIG. 3. Mass spectrum of the picolinyl ester derivative of hydnocarpic acid.

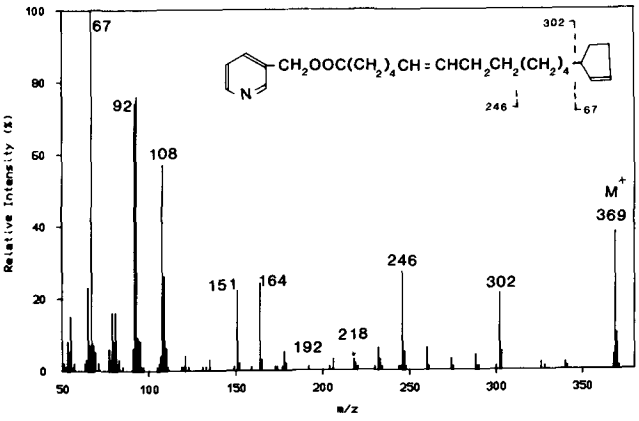

FIG. 5. Mass spectrum of the picolinyl ester derivative of 13-cyclopent-2-enyl-tridec-6-enoic acid (gorlic acid).

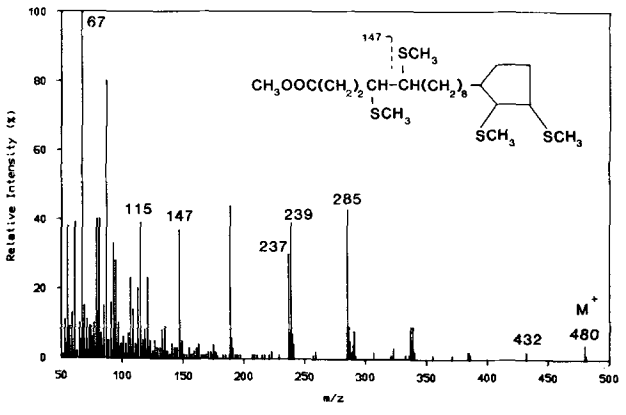

FIG. 6. Mass spectrum of the *bis*-dimethyldisulphide adduct of methyl 13-cyclopent-2-enyl-tridec-4-enoate.

i.e., to $m/z = 384$, loss of 147 gives an ion at $m/z = 237$, and this also is abundant (30%). If the two sulphur atoms are expelled together, an ion at $m/z = 239$ is expected and this is similarly prominent (39%). It is evident that the sulphur atoms are readily lost from the cyclopentenyl ring under electron impact, because the base peak is at $m/z = 67$, as in a nonadducted cyclopentenyl fatty acid derivative. These mass spectral assignments were confirmed by examining the mass spectrum of the dimethyldisulphide derivative of the 6-isomer from *T. kurzii*. In this the ion at $m/z = 147$ is shifted to 175 (37%), i.e., plus 28 amu, and that at 115 becomes 143 (85%). The ions containing the ring at $m/z = 285$ and 237, in the spectrum of the 4-isomer, are shifted to 257 (47%) and 209 (44%) respectively, i.e., a loss of 28 amu. An unidentified ion at $m/z = 189$, in the spectrum of the 4-isomer, is shifted to 161 in that of the 6-isomer, so is presumably derived from the ring portion of the molecule.

Permanganate-periodate oxidation of the diene from *H. anthelmintica* gave a compound with a mass spectrum consistent with that expected from the methyl ester derivative of a C_{14} keto dibasic acid, i.e., a molecular ion at $m/z = 300$ (5%) with $[M-1]^+$ also abundant (30%). There are also substantial ions at $m/z = 128$ (73%), 152 (35%), 160 (66%), 184 (45%), 207 (20%), 225 (20%) and 239 (20%). The spectrum of the corresponding compound from the cyclic diene of *T. kurzii* has a molecular ion at $m/z = 272$ (4%), with $[M-1]^+$ at 271 (26%) and substantial ions also at 128 and 160, among others. A keto dibasic acid can only be formed if the double bond in the ring is in position 2, although the complexities of the spectra are such that the position of the keto group cannot be immediately confirmed. The dibasic acid fragments, which should also be formed during the oxidation, were apparently lost on work-up and were not detected.

It, therefore, appears that the principal cyclic dienoic fatty acids in *H. anthelmintica* is cyclopent-2-enyltridec-4-enoic acid, not the 6-isomer as reported earlier (5).

DISCUSSION

The novelty of much of the data acquired in this study from samples that had been examined to some extent before (5) confirms the value of using silver ion HPLC to provide simplified fractions and GC-MS of the picolinyl esters to determine fatty acid structures. This approach had earlier proven its worth in analyses of lipids from marine invertebrates (6). In particular, it facilitates unequivocal identification of components present in samples at trace levels. Picolinyl esters per se have now been used for identification purposes with a number of natural samples as opposed to model compounds in GC-MS (10,11,17-19). Here, it is shown that they provide the essential structural details for a variety of different cyclopentenyl fatty acids. A double bond in position 4, as was the case in this study, is probably the least easy to locate, but access to authentic models eliminated much of the problem and the alternative approach of preparing chemical adducts provided final confirmation. Previously, mass spectra of methyl esters of cyclopentenyl fatty acids were shown to give valuable information on the nature of the cyclic moiety, but not of double bonds (20). Pyrrolidides gave information on both the position of the double bonds and the ring structure (21), but the spectra are not as easily interpreted as are those of picolinyl esters.

Cyclopent-2-enyltridec-4-enoate does not appear to have been found before in nature, although an analogous C_{16} fatty acid has been detected (5). Presumably there is a biosynthetic relationship to *cis*-4-hexadecenoic acid, with which it occurs in *H. anthelmintica*. This acid also does not appear to have been found in a seed oil, or elsewhere in nature, although C_{10} to C_{14} homologues were detected in seed oils of the Lauraceae (22). Although they were only present in small amounts, the C_{16} and C_{18} fatty acids containing a cyclopentyl (saturated) ring have not previously been reported from plant sources, nor are they known to occur naturally elsewhere, although they can be produced in bacteria supplied with suitable precursors (23,24). Trace levels of five branched-chain (*iso* and *anteiso*) were detected and have only been found in one seed oil previously (25). It is not impossible that the last could be products of bacterial contamination of the seed or fruit.

In *H. anthelmintica*, there is no evidence for a C_{18} monoene with a double bond in position 4, whereas the C_{20} cyclopentenyl fatty acid with the double bond in the aliphatic chain is the 9-enoic isomer ("hormelic" acid).

Capillary Gas Chromatography and Tandem Mass Spectrometry of Paf-acether and Analogs: Absence of 1-*O*-Alkyl-2-propionyl-*sn*-glycero-3-phosphocholine in Human Polymorphonuclear Neutrophils

M.J. Bossant[a,b], R. Farinotti[a], F. De Maack[c], G. Mahuzier[a], J. Benveniste[b] and E. Ninio[b,*]

Fast atom bombardment-tandem mass spectrometry was used to identify molecular species of paf-acether (paf) produced by human polymorphonuclear neutrophils. Using this biological material, normal phase high performance liquid chromatography was necessary prior to the fast atom bombardment-tandem mass spectrometry step. Gas liquid chromatography/electron capture detection after hydrolysis with phospholipase C and conversion to heptafluorobutyrate derivatives was used to confirm the results. The results indicated the presence of mainly 1-*O*-hexadecyl/octadecyl-2-acetyl-*sn*-glycero-3-phosphocholine, acyl analogs of paf and only trace amounts of other alkyl analogs of paf. We did not detect the 2-propionyl analog of paf. Moreover, supplementation of human polymorphonuclear neutrophils with sodium propionate did not result in formation of the 2-propionyl analog of paf.
Lipids 24, 121-124 (1989).

Paf-acether (paf), a mediator of anaphylaxis and inflammation and an antihypertensive agent (1-4) has the following structure: 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (AAGPC) (5-7). It is synthesized by a variety of cells: macrophages, monocytes, polymorphonuclear leukocytes, platelets, exocrine secretory glands, endothelial cells and also in organs such as heart and kidney (2,3,8,9). Its biological activity requires an *O*-alkyl moiety at the *sn*-1 position of the molecule, a short acyl chain at the *sn*-2 position and a phosphocholine at the *sn*-3 position of glycerol (10-19). Advanced separation techniques have demonstrated that paf produced by human polymorphonuclear neutrophils (PMN) is composed of primarily (80%) 1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine (16:0-paf), but also 1-*O*-octadecyl-2-acetyl-*sn*-glycero-3-phosphocholine (18:0-paf) (20%). A least 14 molecular species of phospholipids containing saturated or unsaturated alkyl or acyl chains have been described as paf analogs (7,20,21). Using synthetic compounds, several investigators indicated that the 2-propionyl analog of paf (APGPC) is as active as paf itself in inducing platelet activation (12,14,16-18), PMN degranulation (17) and hypotension (14), whereas the butyryl and hexanoyl analogs are much less active. In 1982, Ninio et al. (22) demonstrated that, when the acetyl-CoA substrate was replaced by propionyl-CoA in lysates from murine macrophages, an ether lipid was produced that was as potent an aggregating agent as paf. Lee (23) confirmed this result showing that the (^{3}H)propionyl-CoA was effectively incorporated into lyso paf in rat spleen microsomes. Tokumara et al. (24) have shown the presence in bovine brain of ten 1-acyl analogs of paf including species having an *sn*-2 propionyl/butyryl or acetyl group. But the presence of paf analogs such as 1-alkyl-2-propionyl/butyryl derivatives in biological systems has not yet been demonstrated.

The aim of this work was the identification of paf elicited from stimulated PMN, and the focus was upon the search for 2-propionyl analogs. Accordingly, direct mass spectrometry analysis of intact native molecular species of paf appeared essential. To eliminate matrix interferences, family members of paf derivatives were isolated by liquid chromatography. Application of fast atom bombardment-mass spectrometry (FAB-MS) resulted in limited fragmentation of compounds, but failed to identify paf derivatives mixed in the chromatographic fractions. The combination of FAB and tandem mass spectrometry (MS-MS) resulted in formation characteristic daughter ions generated from stable and metastable ions (parent ions), thus, increasing the specificity and allowing the identification. In parallel, paf was quantified by gas liquid chromatography-electron capture detection (GC-ECD), after hydrolysis with phospholipase C and conversion to the heptafluorobutyrate derivative (25), and by classical biological methods, as well (1,26).

MATERIALS AND METHODS

Reagents. 1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine (16:0-paf), 1-*O*-octadecyl-2-acetyl-*sn*-glycero-3-phosphocholine (18:0-paf) and 1-*O*-octadecenyl-2-acetyl-*sn*-glycero-3-phosphocholine (18:1-AAGPC) were purchased from Novabiochem (Laùfelchingen, Switzerland). 1-*O*-hexadecyl-2-propionyl-*sn*-glycero-3-phosphocholine (16:0-APGPC) and 1-*O*-octadecyl-2-propionyl-*sn*-glycero-3-phosphocholine (18:0-APGPC) were purchased from Seratec (Epinay/Seine, France). Phospholipase C from *Clostridium welchii,* fatty acid-free bovine serum albumin (BSA), sodium propionate and acetate and heptafluorobutyric anhydride were obtained from Sigma Chemical Co. (St. Louis, MO). Ionophore A 23187 (Io) was purchased from Calbiochem (La Jolla, CA). Ficoll-Hypaque was obtained from Pharmacia (Uppsala, Sweden).

Preparation and stimulation of PMN. Human PMN were purified according to previously described procedures (27). Briefly, venous blood from healthy donors was collected into tubes containing citric acid-dextrose as anticoagulant and sedimented for 30 to 45 min in the presence of gelatin 0.3% final (Plasmagel). Twenty ml of

supernatant were layered onto 10 ml Ficoll-Hypaque (density 1.077) and centrifuged at 400 × *g* for 20 min at 20°C. The cell pellet was resuspended in 500 μl of HEPES buffer (pH 7.4) containing: KCl (2.6 mM), NaCl (137 mM), glucose (5.6 mM) and HEPES (4.2 mM). Contaminating erythrocytes were lyzed by adding 3 volumes of distilled water to the cell suspension for 40 sec and then 1 volume of 3.5% (w/v) NaCl. The cells were then washed twice with HEPES buffer and resuspended at 1×10^6 cells/ml with the same buffer supplemented with 1.3 mM $CaCl_2$, 1 mM $MgCl_2$ and 0.25% (w/v) BSA. The cell suspension contained 98% of PMN as assessed by May-Grünvald Giemsa staining. Replicate tubes with 1×10^7 PMN in 10 ml of HEPES buffer, containing 0.25% BSA were stimulated for 15 min at 37°C with 6 μM ionophore A 23187 and compared with unstimulated controls. In some studies, PMN were preincubated with either 1 mM sodium propionate or 1 mM sodium acetate. All incubations were stopped by the addition of ethanol (to reach a final concentration of 80%) and rapid cooling at 4°C. Tubes were kept at 4°C overnight and were then centrifuged at 3000 × *g* for 10 min at 20°C. The supernatants were brought to dryness under a stream of air at 40°C and were stored at −20°C. In three separate experiments, the supernatants were brought to dryness under a stream of nitrogen at 40°C. The same results were obtained (data not shown), allowing us to consider the use of air as a sufficient method.

Purification and identification of paf by GC-ECD. Paf of the complex lipid fraction recovered in aqueous ethanol was purified by normal phase high performance liquid chromatography (HPLC) using a Microporasil column (3.9 mm i.d. × 300 mm long, Waters Associates, Milford, MA) with a mobile phase of dichloromethane/methanol/water (300:250:25, v/v/v). Samples obtained after HPLC separation were prepared for GC-ECD. Briefly, samples were hydrolyzed to the diglycerides with phospholipase C from *C. welchii,* followed by heptafluorobutyric (HFB) derivatization (25). GC was performed using a Girdel 30 instrument (Delsi, Suresnes, France) and an OV 1 fused silica capillary column (0.25 mm i.d. × 25 m long) maintained at 215°C. The temperature of the capillary injector was kept at 270°C. The capillary head pressure was set at 0.4 bar with helium as carrier gas. For ECD, nitrogen was used as a make-up gas at a flow rate of 30 ml/min and the 10 mCi ^{63}Ni detector was maintained at 300°C (25).

Identification by MS-MS. Lipids were separated by HPLC as described above. Aliquots of HPLC fractions were tested for platelet aggregation activity. Structural identification of these fractions was performed using a Nermag R 30-10 triple quadrupole mass spectrometer (Rueil Malmaison, France) equipped with an FAB source. Samples were introduced in a glycerol matrix with a direct insertion probe fitted with a copper sample stage. Measurements were made with a krypton pressure of approximately 1×10^{-5} Torr. The first quadrupole (Q1) scanned the 100-600 AMU range. The second (Q2) was used as a collision chamber, whereas the third (Q3) analyzed the common daughter ion (*m/z* = 184). When a current ion was measured in Q3, the computer recorded the mass of the parent ions present in Q1.

RESULTS AND DISCUSSION

Tandem mass spectrometry. Spectra of synthetic paf were obtained by FAB-MS. One can observe, in Table 1, that the *m/z* = 184 ion corresponding to the phosphocholine moiety is an intense common ion in paf and related compounds. Consequently, this ion was chosen for further identification of paf synthetized from PMN by FAB-MS-MS. In Figure 1, the parent scan obtained using the HPLC fractions purified from the PMN preparation is shown. To detect the doublets spaced by 2 AMU in paf and analogs, resolution was set below 1 AMU. This explains the abundance of peaks in the spectrum. As previously described, the two major species present were the 1-*O*-alkyl 16:0 (*m/z* = 524) and 1-*O*-alkyl 18:0 (*m/z* = 552) derivatives of paf. In addition, two other compounds with *m/z* = 538 (524 + 14) and 566 (552 + 14) were detected. These ions could be assigned to three different species of molecules: (1) 1-*O*-alkyl 17:0 (*m/z* 538) and 19:0 (*m/z* 566) analogs of paf; (2) analogs of 16:0-paf (*m/z* 538) and 18:0-paf (*m/z* 566) with a propionyl group at the *sn*-2 position (APGPC); or (3) 1-*O*-acyl 16:0 (*m/z* 538) and 18:0 (*m/z* 566) species (acyl-acetyl-GPC). All ions were accompanied by homologous ions that differed by 2 atomic mass units and these presumably corresponded to the unsaturated paf analogs (particularly 18:1-AAGPC). These species were quantitatively negligible in comparison with 16:0-paf and 18:0-paf. Further differentiation among AAGPC, APGPC and acyl-acetyl-GPC species could not be made using FAB-MS-MS, because these three species exhibited similar spectra (data not shown). If MS-MS generally offers the opportunity to study mixtures of

TABLE 1

Fragmentation of Paf and Analogs With FAB Ionization

Compounds	Phosphocholine	Glycerol matrix ions		(MH)+
16:0-paf	184 (96)	277 (100)	369 (20)	524 (50)
18:0-paf	184 (100)	277 (50)	369 (10)	552 (30)
16:0-APGPC	184 (100)	277 (80)	369 (21)	538 (21)
18:0-APGPC	184 (100)	277 (31)	369 (5)	566 (29)

FAB mass spectra of synthetic 16:0-paf, 18:0-paf, alkyl-propionyl-16:0-GPC (16:0-APGPC) and alkyl-propionyl-18:0-GPC (18:0-APGPC) obtained with a 1 μg sample (abundance %).

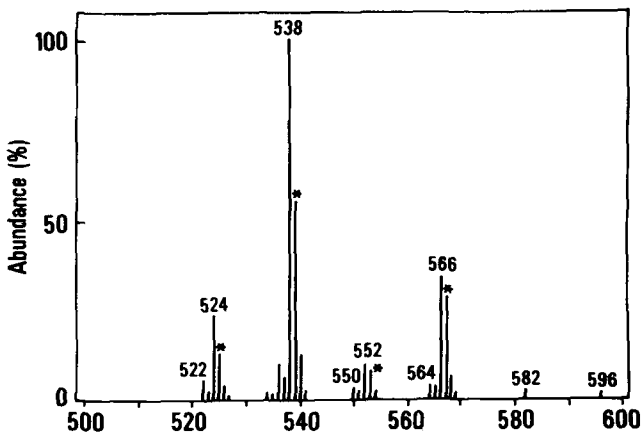

FIG. 1. FAB-MS-MS of paf formed by Io-stimulated human PMN with *m/z* = 184 for parent scans. Abundance (%). *Resolution on Q_1 < 1 AMU.

lipids, for our purpose, it does not appear a straightforward method for identifying isomers. However, this technique allowed us to characterize the molecular species undetectable when using GC-MS. In fact, the sensitivity of the latter method is too low to detect paf and derivatives generated by stimulated PMN.

Capillary GC-ECD and biological assays. Differences in the polarity of paf and derivatives allows separation by capillary GC-ECD. The analysis of synthetic standards: 17:0-AAGPC, 16:0-APGPC, 18:0-APGPC and acyl-acetyl-GPC 16:0 and 18:0 was performed on fused silica capillary column GC as HFB derivatives (25). The capacity factor k' was measured for each compound and is reported in Table 2. Good separations were obtained (Fig. 2) for those of the same molecular weight, i.e., APGPC-HFB, acyl-acetyl-GPC-HFB and AAGPC-HFB. Each peak was identified by GC-MS in the chemical ionization (isobutane) mode (25). The analysis of PMN supernatants by GC-ECD showed the presence of unknown peaks (X). These compounds were also present in extracts from unstimulated PMN, but they were biologically inactive. Thus, we assumed that the presence of these unidentified peaks would not alter the interpretation of our results. As previously described (28), we found 80% of the 16:0 and 20% of the 18:0 species. Small amounts of 17:0-paf-HFB and acyl-acetyl 16:0-HFB were observed (Fig. 2), but no 16:0-APGPC-HFB, 18:0-APGPC-HFB, 19:0paf-HFB or unsaturated paf-HFB was detected.

In the next series of experiments, we added sodium acetate or sodium propionate to Io-stimulated PMN. Five samples in each group were analyzed by GC-ECD. About the same amount of paf (16:0 + 18:0) was formed in Io-stimulated PMN in the absence (257 ± 35 pmol/1 x 10^7 cells, mean ± SEM) or in the presence of sodium acetate (298 ± 70). By contrast, paf formation was decreased by 50% when Io-stimulated PMN were supplemented with sodium propionate (134 ± 24). These results were confirmed using bioassay (data not shown), which ensured that the molecules of interest were not altered or lost during the isolation procedure. In addition, both methods of quantitation gave similar results. The lack of incorporation of the propionyl moiety into paf molecules and an inhibition of paf synthesis (50%) by sodium propionate were also demonstrated.

TABLE 2

GC/ECD Analysis of Paf and Analogs as HFB Derivatives

Compounds	k'	RT (min)
16:0-paf	5.4	26
16:0-acyl-acetyl-GPC	6.6	30
17:0-AAGPC	6.9	32
16:0-APGPC	7.3	33
18:1-AAGPC	9.2	41
18:0-paf	10.3	45

Each synthetic compound was hydrolyzed with phospholipase C followed by heptafluorobutyric derivatization for 10 min at 70°C. The GC analysis of paf and paf analogs was performed on a fused silica OV1 capillary column (0.25 mm i.d. × 25 m) using ECD detection.

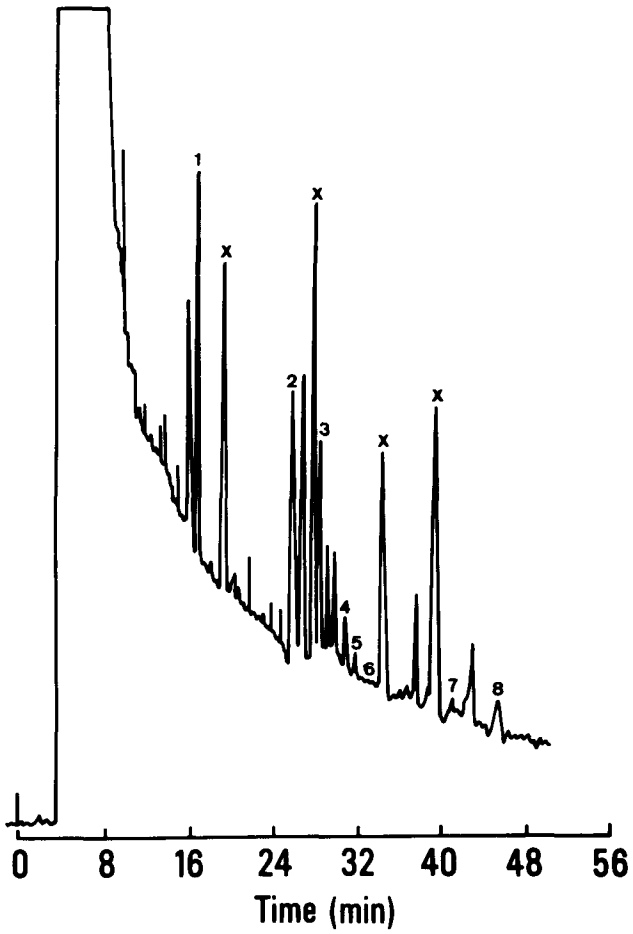

FIG. 2. GC-ECD chromatogram obtained from heptafluorobutyrate (HFB) derivatives of paf formed by Io-stimulated PMN. 1: 16:0-lyso paf, 2: 16:0-paf, 3: 18:0-lyso paf, 4: acyl-acetyl 16:0-GPC, 5: 17:0-AAGPC, 6: 16:0-APGPC, 7: 18:1-AAGPC, 8: 18:0-paf, X: unknown compounds.

The current investigations, together with those of Weintraub et al. (20), Mueller et al. (10) and Ramesha and Pickett (21), demonstrate that stimulated PMN synthesize 16:0-paf and 18:0-paf, as well as several other saturated or unsaturated paf analogs. In contrast with Weintraub et al. (20) and Mueller et al. (10), we did not detect 15:0, 20:0 or 22:0 paf analogs, but we found other molecular forms, such as 19:0- or 17:1-AAGPC, 16:0-acyl-acetyl-GPC or 18:0-acyl-acetyl-GPC with their unsaturated analogs. These apparently conflicting data can be explained by differences in both the purification phase and the sensitivity of analytical measurements utilized. In previous studies (7,20,21,28), a Bligh and Dyer extraction (29) was followed by thin layer chromatography and HPLC separation. According to Jouvin-Marche et al. (30), we used the ethanolic extraction followed by normal phase HPLC purification. This method is equivalent to Bligh and Dyer's (29) extraction, as far as paf is considered. In our studies, thin layer chromatography was not necessary. Our results are in good agreement with those of Kim and Salem (31) who, using thermospray HPLC-MS, did not find 2-propionyl analog of paf in commercial paf preparation from beef heart.

Finally, the combination of the high selectivity in the isolation procedure and the high specificity of the MS-MS

and GC-ECD analysis lead to the unequivocal conclusion that the human PMN produce principally 16:0-paf and 18:0-paf and very limited quantities of 17:0-paf. Analogs of paf, such as 16:0-acyl-acetyl are also formed, but detectable levels (limits of detection: 20 pg) of the 2-propionyl analog of paf were not observed under the conditions of stimulation that were used.

ACKNOWLEDGMENTS

We thank R. L. Wykle for his gift of 17:0-paf; and we thank G. Bessou for the preparation of human neutrophils. This work was supported by a grant from the University of Paris XI, AI 8420.

Thiobarbituric Acid-reactive Malondialdehyde Formation During Superoxide-dependent, Iron-catalyzed Lipid Peroxidation: Influence of Peroxidation Conditions

David R. Janero* and **Barbara Burghardt**
Department of Pharmacology and Chemotherapy, Hoffmann-La Roche Inc., Nutley, NJ 07110

A systematic study of the influence of biological lipid peroxidation conditions on lipid hydroperoxide decomposition to thiobarbituric acid-reactive malondialdehyde is presented. A superoxide-dependent, iron-catalyzed peroxidation system was employed with xanthine oxidase plus hypoxanthine plus ferric iron-adenosine diphosphate complex as free radical generator. Purified cardiac membrane phospholipid (as liposomes) was the peroxidative target, and 15-hydroperoxy-eicosatetraenoic acid was used as a standard lipid hydroperoxide. Exposure of myocardial phospholipid to free radical generator at physiological pH (7.4) and temperature (37°C) was found to support not only phospholipid peroxidation, but also rapid lipid hydroperoxide breakdown and consequent malondialdehyde formation during peroxidation. Under lipid peroxidation conditions, oxidative injury to the phospholipid polyunsaturated fatty acids required superoxide radical and ferric iron-adenosine diphosphate complex, whereas 37°C temperature and trace iron were sufficient for lipid hydroperoxide decomposition to malondialdehyde. Harsh thiobarbituric acid-test conditions following peroxidation were not mandatory for either lipid hydroperoxide breakdown or thiobarbituric acid-reactive malondialdehyde formation. However, hydroperoxide decomposition that had begun in the peroxidation reaction could be completed during a subsequent thiobarbituric acid test in which no lipid autoxidation took place. Iron was more critical than heat in promoting the observed hydroperoxide decomposition to malondialdehyde during the lipid peroxidation reaction at 37°C and pH 7.4. These data demonstrate that the radical generator, at physiological pH and temperature, serves a dual role as both initiator of membrane phospholipid peroxidation and promotor of lipid peroxide breakdown and thiobarbituric acid-reactive malondialdehyde formation. Consequently, peroxidation reaction conditions can directly influence lipid hydroperoxide decomposition, malondialdehyde production and system thiobarbituric acid-reactivity. In vivo, decomposition of lipid peroxides to malondialdehyde during radical-mediated, metal-catalyzed membrane peroxidation may represent an integral component of oxidative tissue injury rather than a mere consequence of hydrolyzing the peroxidized biological sample in a thiobarbituric acid test.

Lipids 24, 125–131 (1989).

Abbreviations: ADP, adenosine diphosphate; BHT, butylated hydroxytoluene; Desferal, desferrioxamine B methanesulphonate; Fe^{3+}, ferric iron; Fe^{3+}•ADP, ferric iron-adenosine diphosphate complex; HEPES, N-2-hydroxyethylpiperazine-N′-2-ethanesulfonic acid; HPETE, hydroperoxy-eicosatetraenoic acid; HX, hypoxanthine; MDA, *malondialdehyde*; NBT, *nitro*-blue tetrazolium; $O_2^{\cdot-}$, superoxide anion radical; PUFA, polyunsaturated fatty acid; SOD, superoxide dismutase; TBA, thiobarbituric acid; TBARS, TBA-reactive substance; Tris, tris(hydroxymethyl)aminomethane; XOD, xanthine oxidase; HPLC, high performance liquid chromatography.

Free radical-mediated, metal-promoted peroxidation of membrane phospholipid polyunsaturated fatty acids (PUFA) is important to the pathogenesis of many diseases (1). Heart muscle damage during myocardial ischemia and reperfusion, for instance, is believed to involve membrane PUFA peroxidation initiated by superoxide anion radical ($O_2^{\cdot-}$) and ferric iron (Fe^{3+}) (2). During such nonenzymatic lipid peroxidation, $O_2^{\cdot-}$ establishes a suitable Fe^{3+}:Fe^{2+} ratio for the initiation of peroxidation through hydrogen atom abstraction from PUFA (3). Rearrangement of double bonds in the resulting lipid radicals yields conjugated dienes that are attacked by molecular oxygen to form peroxy radicals (4). The peroxy radicals may themselves abstract hydrogen atoms from other PUFA, forming new lipid radicals along with lipid hydroperoxides and, thereby, propagating the initiation event (5). Lipid peroxides are known to decompose at high temperature and low pH in the presence of transition metals (6). Some of the many possible decomposition products have pathological effects of their own (7).

The thiobarbituric acid (TBA) test is the most frequently used method for assessing lipid peroxidation in vitro and in vivo (8). This assay is predicated on the formation of a red adduct (absorption maximum 532 nm) between TBA and malondialdehyde (MDA), a colorless end product of lipid peroxide decomposition (9,10). Optimal color response of the TBA test to lipid hydroperoxide necessitates incubation conditions so harsh that they liberate, by sample hydrolysis, "bound" MDA (11). Antioxidant is also required to inhibit spurious PUFA autoxidation (11,12). Consequently, the TBA test is usually conducted by heating (~80–100°C) a biological sample at low (≤3) pH with TBA, one of several possible iron sources, and butylated hydroxytoluene (BHT) (4,12). These acidic hydrolysis conditions drive the breakdown of lipid peroxides to MDA and other small-molecule products (6,11,12). Any difference in the formation of TBA-reactive substance (TBARS) with or without BHT in the TBA test has been presumed to reflect the existence of lipid peroxidation products that can yield TBARS only under TBA-test conditions (3).

On a molar basis, MDA is the lipid peroxide decomposition product that reacts most efficiently with TBA to form red chromogen (10,13). Yet end products of lipid peroxide breakdown, other than MDA, are TBA-reactive and may produce orange or yellow pigments, depending, at least in part, on TBA-test reagents (14), and TBA-positive products are generated through oxidative damage to nonlipid molecules (15). The nature of MDA as a secondary indicator of PUFA peroxidation, dependent on both formation and breakdown of lipid peroxide, and the nonspecificity of TBA chemical reactivity toward MDA complicate the interrelationships among peroxide decomposition, bona fide MDA formation and TBARS generation resulting from biological lipid peroxidation. Some investigators hold that MDA is formed primarily

as a consequence of fatty-hydroperoxide decomposition in the TBA test (16). Yet, others have reported isolation of MDA from lipid peroxidation systems not reacted with TBA (17,18).

The lack of quantitative information on the course of lipid peroxide decomposition to bona fide, TBA-reactive MDA during PUFA peroxidation prompted the following investigations on the operative interrelationships among lipid peroxidation conditions, fatty-peroxide breakdown and MDA and TBARS formation. Purified, PUFA-rich (1,2) membrane phospholipid from myocardium and preformed fatty-acid hydroperoxide (15-*L*-hydroperoxy-5,8,11,13-eicosatetraenoic acid [15-HPETE]) were used as lipid study-objects. Our findings demonstrate that $O_2^{\cdot-}$-dependent, Fe-catalyzed radical reactions at physiological pH and temperature serve not only to initiate PUFA peroxidation, but also to promote the simultaneous, rapid breakdown of lipid hydroperoxide so generated to MDA. Promotion of lipid peroxide decomposition by the radical generator under physiological pH and temperature is in marked contrast to the TBA-test conditions supporting fatty-peroxide breakdown. Exposure of the peroxidized lipid sample to the harsh conditions of a TBA test does not necessarily enhance MDA production above that formed during peroxidation itself, although hydroperoxide decomposition can occur during the TBA test.

EXPERIMENTAL PROCEDURES

Materials. N-2-Hydroxyethylpiperazine-N′-2-ethanesulfonic acid (HEPES), tris(hydroxymethyl)aminomethane (Tris), hydroxylamine hydrochloride, adenosine diphosphate (ADP), TBA, tetramethoxypropane, soybean lipoxygenase (EC 1.99.2.1) and hypoxanthine (HX) were from Sigma (St. Louis, MO). XOD (analytical preparation from bovine milk; 1.0 unit/mg) and superoxide dismutase (SOD; analytical preparation from bovine erythrocytes; 5000 units/mg) were from Boehringer-Mannheim (Indianapolis, IN). Desferal (desferrioxamine B methanesulphonate) was a gift from Ciba A.G. (Basle, Switzerland). Ferrioxamine was synthesized according to Hoe et al. (19). Chelex 100, a chelating resin with high selectivity for Fe^{3+}, was from Bio-Rad (Richmond, CA). Reagent-grade deionized water was produced with a commercial deionizer from Hydro (Research Triangle Park, NC). All organic solvents were of analytical grade and from Burdick and Jackson (Muskegon, MI).

Extraction and quantification of heart-muscle membrane phospholipid. Membranes were isolated from the perfused ventricular myocardium of the adult male Sprague-Dawley rat by differential centrifugation and salt extraction (20). The washed, purified membranes represented >70% of the total myocardial phospholipid and were some 3-fold enriched with respect to starting homogenate (18). Lipids were extracted and purified from the myocardial membranes by a modified (21) Bligh-Dyer procedure (22). The final chloroform phase containing the purified lipid represented quantitative recovery of myocardial membrane lipid by the chemical criteria detailed (18). The myocardial membrane phospholipid was isolated from the total membrane lipid extract by Sep-Pak silica column chromatography (Waters, Milford, MA) (23). All lipids were stored in chloroform under argon at −20°C (24).

The hydroxamate reaction was used to measure lipid ester (25); L-α-phosphatidylcholine dipalmitate (Avanti Polar Lipids, Birmingham, AL) was the standard.

Preparation of cardiac liposomes. A known amount of myocardial membrane phospholipid in chloroform was placed into a rotating glass flask. The solvent was evaporated under argon at room temperature (22°C), and the lipid film was resuspended in 10 mM HEPES-0.145 M KCl, pH 7.4, by indirect anaerobic sonication for 15 min at room temperature. No protein was detectable in the liposome preparation (18).

Peroxidation reaction system. Cardiac membrane phospholiposomes were subjected to $O_2^{\cdot-}$-dependent, Fe-catalyzed peroxidation as detailed (18). In brief, the complete peroxidation reaction contained 10 mM HEPES-0.145 M KCl, pH 7.4; 1.0 mM HX; 0.1 mM Fe^{3+}-1.0 mM ADP complex; 125 μg phospholipid/ml; and 10 mUnits XOD/ml (final concs.) "Free" HEPES was used, and its pH was adjusted with KOH. This concentration of HEPES was minimal for maintaining the pH at ~7.4 through the peroxidation reaction and did not influence the initial rates of peroxidation relative to an unbuffered system, which progressively decreased in pH. The reaction was started by adding the XOD, mixing and heating to 37°C in a shaking water bath. Liposome samples were also incubated in parallel to the same final lipid concentration, but without free radical generator (i.e., without XOD + HX + Fe^{3+}·ADP). Incubations of liposomes with select components of the free radical generator ("incomplete" generator) were also carried out, as specified in the Tables. Incubations were terminated by lipid extraction, acidification or SOD addition, depending on subsequent analysis. In some experiments, Desferal was included in the peroxidation reaction at a 250 μM final concentration.

Determination of conjugated diene and TBARS. For conjugated diene analysis, lipids were extracted (21) out of the peroxidation incubations and dissolved in cyclohexane. Lipid spectra were taken from 190 nm to 400 nm in a Beckman DU-7 spectrophotometer (Beckman, Palo Alto, CA). The spectra were used as detailed (18,26) to calculate net conjugated diene formation.

The TBA test was conducted as described (18). In brief, the peroxidation incubation was terminated on ice by acidification with 0.15 ml ice-cold 76% TCA-2.3 N HCl per 1.0 ml peroxidation reaction mixture. In some experiments, Desferal (250 μM, final conc.) was next added; in others, 0.1 mM Fe^{3+}-1.0 mM ADP complex was added to the specified final concentration. Finally, 0.35 ml of a mixture of H_2O/7.14 M BHT in ethanol/1.51% TBA in 0.2 M Tris, pH 7.0 (1:1:5, v/v/v) was added. After thorough mixing, the samples (pH = 2.4) were incubated in an 80°C shaking water bath for 30 min. The tubes were then plunged into an ice-water bath, and 0.5 ml ice-cold 91% TCA, followed by 2.0 ml $CHCl_3$, was added. After centrifugation for 30 min at 2000 × *g*, 4°C, the absorbance of the upper phase was read at 532 nm. MDA standard, prepared by acidification of 1,1,3,3-tetramethoxypropane with 76% TCA-2.3 N HCl, was subjected to the identical TBA-test procedure in order to construct a standard curve of TBARS as MDA-equivalents. Computer-assisted regression analysis of the standard curve was used as detailed (18) to quantify the molar amounts of MDA-equivalents in the experimental samples. Reactivity between MDA standard and TBA was not affected by

components of the radical generator, Desferal, ferrioxamine or SOD.

Chromatographic MDA isolation and quantification. When a peroxidation reaction was to be analyzed by high performance liquid chromatography (HPLC) for MDA content, peroxidation was stopped by adding SOD to a final concentration of 10^{-7} M and freezing the mixture in dry ice-acetone (18). MDA was isolated from the sample by ion-pairing HPLC with detection at 267 nm and quantified as described (17,18).

Buffer ultrapurification. Buffers were treated with Chelex resin, 100–200 mesh, to eliminate metal content (27). The Chelex column was equilibrated and optimized for divalent cation chelation as detailed (28). This protocol has been demonstrated to be particularly effective in removing divalent cations from HEPES and Tris buffers (29).

Synthesis and purification of lipid hydroperoxide (15-HPETE). Soybean lipoxygenase and 5,8,11,14-eicosatetraenoic acid (arachidonic acid; NuChek Prep, Elysian, MN) were used to synthesize 15-HPETE according to Graff (30). During extraction and purification of 15-HPETE product, sample temperature, glassware and solvents were maintained below 0°C to obviate decomposition of the lipid hydroperoxide. The conversion of arachidonate to 15-HPETE was >96%, as evaluated with [1-^{14}C]arachidonic acid (60 mCi/mmol sp. act.; New England Nuclear, Boston, MA). 15-HPETE purity was verified by thin layer chromatography (31).

Assay for $O_2^{\cdot-}$ production. The $O_2^{\cdot-}$ generated from XOD + HX was reacted with either cytochrome C or nitro-blue tetrazolium (NBT) as detector molecule. The reaction mixture, in a final volume of 3 ml, consisted of: 76 μM cytochrome C or 100 μM NBT, 1.0 mM HX, 30 mUnits XOD and 50 mM K-phosphate buffer, pH 7.4, containing 0.1 mM EDTA. The rate of SOD-inhibitable cytochrome c reduction was monitored at 550 nm (32); the rate of SOD-inhibitable NBT reduction was monitored at 560 nm (33).

RESULTS

Conjugated diene, MDA and TBARS production during myocardial membrane phospholipid peroxidation. Incubation of purified cardiac membrane phospholipid (as liposomes) under $O_2^{\cdot-}$-dependent, Fe-catalyzed peroxidation conditions led to a rapid, net formation of lipid conjugated diene (Fig. 1). Addition of more phospholipid, but not more free radical generator, to the system at 90 min could elicit a subsequent, albeit slight, increase in conjugated diene content (data not shown). The rate of $O_2^{\cdot-}$ production, assessed directly as SOD-inhibitable cytochrome c or NBT reduction, was high for ca. 25 min and was detectable, but insignificant, thereafter. Because the rate of diene formation during the period of maximal $O_2^{\cdot-}$-production was only slightly greater than the rate when $O_2^{\cdot-}$-production had virtually ceased, much of the lipid peroxide formation in Figure 1 may reflect propagatory interactions between PUFA and lipid radicals (4,5). By 90 min of reaction, the level of conjugated intermediates in the peroxidation system was maximal, suggesting that propagation had ended and/or that lipid peroxide decomposition was occurring at a rate approaching the rate of lipid peroxide formation.

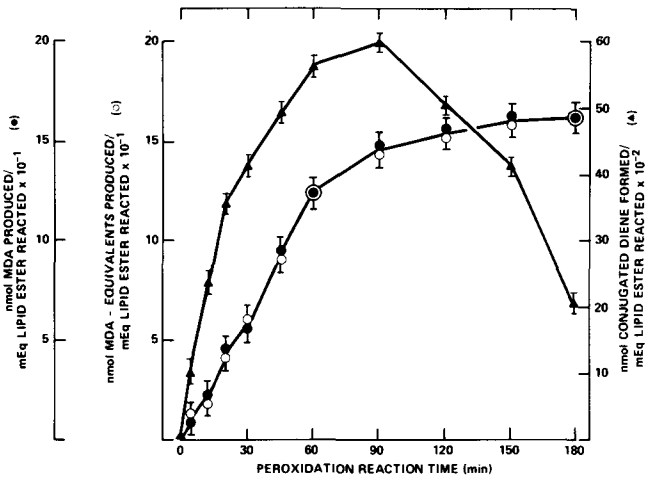

FIG. 1. Conjugated diene, MDA and TBARS formation during myocardial membrane phospholipid peroxidation. Purified rat heart-muscle membrane phospholipid was reconstituted into liposomes and subjected to peroxidative injury in a $O_2^{\cdot-}$-dependent, Fe-catalyzed system with XOD + HX + Fe^{3+}·ADP as radical generator. Liposomes were also incubated without radical generator. Three sets of samples were taken over 180 min of peroxidation reaction at the indicated times: One set of peroxidized and nonperoxidized samples was extracted for lipid, and the isolated lipids were analyzed spectrophotometrically for conjugated diene content. A second set was acidified and subjected to a colorimetric TBA test. A third set was made to 100 nM in SOD and analyzed by HPLC for MDA content. The mean differences between peroxidized and nonperoxidized samples in these three assays were taken as production of the respective lipid peroxidation product: conjugated dienes (▲), MDA enolate anion (●) and MDA-equivalents, i.e., TBARS (○). Data, normalized to the amount of phospholipid ester reacted, were graphed ± SD (n ≥ 6).

The peroxidation system developed TBA-reactivity in parallel with a net increase in MDA content (Fig. 1). No liposome-bound MDA was detected (18). A maximal linear rate of both MDA and TBARS (as MDA-equivalents) formation [2.1 ± 0.1 nmol/mEquivalent phospholipid ester reacted/min (mean ± SD, n = 7)] was maintained through the first 45 min of peroxidation and resulted in ca. 150 nmol MDA and TBARS by 2 hr. As detailed elsewhere (18), the parallelism between MDA formation and TBARS production is due to the fact that negligible nonlipid derived, nonMDA TBARS is produced. The similar yield of MDA enolate anion by HPLC and MDA-equivalents in the TBA test demonstrates that postperoxidative PUFA autoxidation did not take place during the TBA reaction. Furthermore, these kinetics indicate that the radical generator served to initiate PUFA peroxidation and to promote, although peroxidation was ongoing at physiological pH and temperature, the decomposition of lipid hydroperoxide to TBA-reactive MDA.

Influence of lipid peroxidation conditions on conjugated diene, MDA and TBARS formation. We initially studied the influence of peroxidation reaction conditions on MDA formation and TBA-reactivity. A 60-min reaction was adopted, for at that time the amplitude of peroxidation was high and the kinetics reasonably linear (Fig. 1). Parallel samples of purified cardiac membrane phospholipid were incubated for 60 min at physiological (37°C) or ambient (22°C) temperature without free radical generator, with complete generator (i.e., XOD + HX +

Fe^{3+}·ADP) or with "incomplete" generator (i.e., select generator components). The peroxidation system was then either analyzed spectrophotometrically for conjugated diene, subjected to HPLC for MDA quantification or incubated with TBA in acid at 80°C with Fe^{3+}·ADP present for TBARS determination.

Full diene, MDA and TBARS formation (cf. Fig. 1) required phospholipid exposure to complete free radical generator at 37°C (Table 1). The $O_2^{\cdot-}$-dependent, Fe-catalyzed nature of the peroxidation was apparent from the negligible diene formation when either SOD was present with complete generator or Fe^{3+}·ADP was omitted from the generator. Introduction of Fe^{3+}·ADP into the TBA test after incubating the lipid with $O_2^{\cdot-}$ (i.e., with XOD + HX) did not elicit TBARS formation. Physiological (37°C) temperature was not essential to peroxidation or to lipid peroxide decomposition, but a room-temperature (22°C) incubation of phospholipid with complete free radical generator reduced peroxidation by ~20%.

In an attempt to resolve the contributions of lipid hydroperoxide formation and lipid hydroperoxide decomposition to TBA-reactive MDA production during peroxidation, purified lipid hydroperoxide (15-HPETE) was incubated under the same peroxidation conditions as the membrane phospholipid had been. However, 100 μM SOD was included to quench the free radical generator (18). The data (Table 2) demonstrate that, during a peroxidation incubation at physiological or room temperature with complete radical generator or Fe^{3+}·ADP alone, lipid hydroperoxide readily decomposed to MDA, and the system evidenced full TBA-reactivity in a subsequent TBA test. Because 90 nmol 15-HPETE yielded 3 nmol MDA, the efficiency of lipid hydroperoxide conversion to bona fide MDA was low—ca. 3-4%. During a peroxidation incubation at 37°C in the absence of Fe^{3+}·ADP, 15-HPETE decomposition to MDA was ~80% of that when Fe^{3+}·ADP had been present; TBARS formation (with Fe^{3+}·ADP present in the TBA test) was not reduced. Similarly, during a 22°C peroxidation incubation, the absence of Fe^{3+}·ADP resulted in ~40% less MDA being produced, yet TBARS formation during a subsequent TBA test was not reduced. Therefore, lipid hydroperoxide readily decomposed to TBA-reactive MDA under PUFA peroxidation conditions. The iron component of the radical generator and heat were critical determinants of the extent of decomposition. The combined data from Tables 1 and 2 demonstrate that lipid hydroperoxide breakdown begun during peroxidation could be completed in a subsequent TBA test which did not itself elicit lipid autoxidation.

Influence of Trace Fe on MDA and TBARS formation from lipid hydroperoxide decomposition during cardiac phospholipid peroxidation. Cardiac phospholipid peroxidation was negligible without added Fe^{3+}·ADP (Table 1). Yet, without Fe^{3+}·ADP, lipid hydroperoxide decomposed to MDA and TBARS (Table 2). Aqueous, millimolar buffer solutions may contain ca. 0.2–20.0 μM divalent cation contamination (28). These data suggested that trace Fe might be present in the peroxidation reaction system which could not catalyze PUFA peroxidation itself but could promote lipid hydroperoxide decomposition. Accordingly, we investigated the influence of Fe on MDA and TBARS production from cardiac phospholipid peroxidized in the $O_2^{\cdot-}$-dependent, Fe-catalyzed system and from 15-HPETE. For these studies, Desferal was used at a concentration (250 μM) 2.5 times the Fe^{3+} concentration in the radical generator. As detailed elsewhere (18), the stoichiometric nature of Fe^{3+} chelation by Desferal required a minimal Desferal concentration of ~100 μM, the concentration of added Fe^{3+}·ADP, to inhibit peroxidation. This finding indicated that all the Fe^{3+}·ADP in the radical generator was available to peroxidation. Desferal's effects were due solely to Fe chelation; ferrioxamine (i.e., Fe-saturated Desferal [19]) was without effect (data not shown).

At either physiological (37°C) or room (22°C) temperature, excess Desferal blocked phospholipid PUFA peroxidation when complete free radical generator was present (Table 3). In peroxidation incubations containing $O_2^{\cdot-}$

TABLE 1

Influence of Peroxidation Reaction Conditions on Conjugated Diene, MDA and TBARS Formation From Myocardial Membrane Phospholipid[a]

Peroxidation conditions	Conjugated diene (% control)	MDA (% control)	TBA-test conditions	TBARS (% control)
37°C, 60 min:			80°C, 30 min:	
+ XOD; + HX; + Fe^{3+}·ADP	100	100		100
+ XOD; + HX; + Fe^{3+}·ADP + SOD	<1.0	<1.0		<1.0
+ XOD; + HX; no Fe^{3+}·ADP	<1.0	<1.0	+ Fe^{3+}·ADP	<1.0
no XOD; no HX; no Fe^{3+}·ADP	<1.0	<1.0	+ Fe^{3+}·ADP	<1.0
22°, 60 min:			80°C, 30 min:	
+ XOD; + HX; + Fe^{3+}·ADP	86 ± 5	82 ± 4		84 ± 5
+ XOD; + HX; + Fe^{3+}·ADP; + SOD	<1.0	<1.0		<1.0
+ XOD; + HX; no Fe^{3+}·ADP	<1.0	<1.0	+ Fe^{3+}·ADP	<1.0
no XOD; no HX; no Fe^{3+}·ADP	<1.0	<1.0	+ Fe^{3+}·ADP	<1.0

[a]Total myocardial membrane phospholipid (as liposomes, 125 μg/ml) was incubated for 60 min under the described peroxidation conditions. When present, the final component concentrations were: 0.1 mM Fe^{3+} − 1.0 mM ADP complex; 10 mUnits XOD/ml; 1.0 mM HX; 100 nM SOD. After 1 hr, parallel samples were assessed for conjugated diene or MDA content; other samples were subjected to the TBA test at 80°C with Fe^{3+}·ADP. Data are expressed relative to the control incubation, taken as 100%. At 60 min, 100% conjugated diene formation represents 5600 ± 300 nmol conjugated diene/mEquivalent phospholipid ester reacted, and 100% MDA or TBARS formation represents 130 ± 6 nmol MDA/mEquivalent phospholipid ester reacted. Data are means ± SD ($n \geq 6$).

(i.e., XOD + HX), but no Fe^{3+}·ADP (either with or without 250 μM Desferal), no lipid peroxidation occurred, indicating that any trace Fe present could not serve to initiate peroxidation. Fe chelation during the TBA test after lipid peroxidation had occurred did not influence formation of TBARS (Table 3), nor did it affect the TBA-reactivity of MDA standard (data not shown). The results in Table 3 are further support for the conclusion that the lipid hydroperoxide originating from cardiac phospholipid PUFA peroxidation had decomposed during the peroxidation reaction such that full TBA-reactive MDA production preceded and was not dependent on the TBA test.

A role for trace Fe, as promotor of lipid hydroperoxide decomposition and consequent MDA and TBARS production, could be demonstrated by substituting 15-HPETE for phospholipid in these experiments (Table 4). Incubation of 15-HPETE with complete free radical generator or generator without Fe^{3+}·ADP, at either 37°C or 22°C, elicited MDA formation. The peroxidation incubations, without added Fe^{3+}·ADP, produced 20–30% less MDA than did the samples containing Fe^{3+}·ADP. However, if 250 μM Desferal were included in the peroxidation incubation, either with or without Fe^{3+}·ADP present, no lipid hydroperoxide decomposition to TBA-reactive MDA took place. Similarly, buffer ultrapurification with Chelex 100 prevented 15-HPETE decomposition under the conditions of the peroxidation incubation, but had no effect on PUFA peroxidation, if $O_2^{\cdot-}$ and Fe^{3+}·ADP were present (data not shown).

In the TBA test at 80°C, partial (~50% of maximal) lipid hydroperoxide breakdown to TBARS occurred following peroxidation incubations with Desferal in which no MDA had formed (Table 4). This partial TBARS production suggested that thermal decomposition of lipid

TABLE 2

Influence of Peroxidation Reaction Conditions on MDA and TBARS Formation From Lipid Hydroperoxide (15-HPETE)[a]

Peroxidation conditions	MDA (% control)	TBA-test conditions	TBARS (% control)
37°C, 60 min, + SOD:		80°C, 30 min:	
+ XOD; + HX; + Fe^{3+}·ADP	100		100
no XOD; no HX; + Fe^{3+}·ADP	98 ± 3		94 ± 4

[a]Total myocardial membrane phospholipid (as liposomes, 125 μg/sample) was incubated for 60 min under the described peroxidation conditions. The samples were processed and analyzed as detailed in the footnote to Table 1. Data are means ± SD ($n \geq 6$).

hydroperoxide during the TBA test was responsible for the TBA-reactivity. This TBARS appeared to be largely, if not exclusively, MDA: HPLC analysis of 15-HPETE incubated under TBA-test conditions revealed MDA formation to ~50% of maximal.

DISCUSSION

In biological systems, analysis of peroxidative PUFA injury as TBARS depends on both formation and decomposition of lipid peroxides (4,35). This study has identified and examined, in quantitative terms, at least some of the factors operative in the formation of TBA-reactive MDA from membrane-phospholipid PUFA undergoing peroxidation via $O_2^{\cdot-}$-dependent, Fe-catalyzed reactions of the type which cause tissue damage in vivo (1,2). The data highlight a complex functional interrelationship among biological lipid peroxidation and postperoxidative phenomena such as fatty-hydroperoxide decomposition and MDA formation.

Comparative analyses of MDA formation from membrane phospholipid undergoing peroxidation and from purified lipid hydroperoxide (15-HPETE) incubated under peroxidation conditions demonstrated that $O_2^{\cdot-}$-dependent, Fe-catalyzed oxyradical chemistry at physiological pH and temperature leads not only to PUFA peroxidation, but also to lipid hydroperoxide breakdown and TBA-reactive MDA formation. A subsequent TBA test at high temperature and low pH was not required for MDA formation and did not enhance MDA yield. These data define a second function of the radical generator, promoting peroxide decomposition, aside from initiating PUFA peroxidation (3,36). Accordingly, the data do not support the view that exposure of a peroxidized biological sample to the TBA test is critical to, let alone essential for, lipid peroxide breakdown to MDA (16).

Experiments in which peroxidation incubations contained Fe chelator (Desferal) or buffers treated with Fe^{3+}-chelating resin (Chelex 100) indicate that trace Fe, although unable to initiate peroxidation, can promote lipid peroxide breakdown to TBA-reactive MDA during the peroxidation incubation. Trace Fe increases TBA-test coloring (37), but the augmented signal has been taken as indication that trace Fe promotes lipid autoxidation during the TBA test (11,12,38). Our data invite an alternative interpretation, whereby the increased color could be due to enhanced lipid hydroperoxide degradation during the peroxidation reaction itself.

A subphysiological temperature in the peroxidation reaction reduced lipid peroxidation by ~20%, but did not influence lipid hydroperoxide decomposition to MDA. The 80°C heat of the TBA test incubation by itself (i.e., with no Fe^{3+} present) supported partial (~55%) lipid hydroperoxide breakdown to MDA. Thus, although both Fe and heat promote MDA formation from lipid hydroperoxide during peroxidation (Tables 3 and 4) and in the TBA test (11,12), Fe appears to be more critical for peroxide decomposition under lipid peroxidation conditions, whereas Fe and heat are about equally important for MDA formation from fatty-hydroperoxide during the TBA test.

Other studies (18), along with data herein, demonstrate the lack of PUFA autoxidation (but not lipid hydroperoxide breakdown) during the TBA test used. Yet the low (~4%) molar efficiency of lipid hydroperoxide decomposition during the TBA test to bona fide MDA noted here and elsewhere (39) should be borne in mind when using the TBA test or TBA-MDA adduct analysis by HPLC (40) as a quantitative index of lipid peroxidation. This caution is emphasized by our finding that hydroperoxide breakdown to MDA during radical-mediated lipid peroxidation at physiological pH and temperature is similarly inefficient.

Although the conversion of lipid peroxide to MDA is low, the resulting amounts of red-pigmented TBARS (determined colorimetically as MDA equivalents) and bona fide MDA (by HPLC) approximate each other. This correlation supports the view that MDA represents the major (if not sole) TBA-reactive product of biological lipid peroxide formation and decomposition detected colorimetrically at 532 nm (10,13,14). With purified lipid as oxidative-injury target, TBA-reactivity appears to be a good reflection of MDA formation and, hence, of lipid peroxide production and decomposition (Fig. 1). Yet

[a]Lipid hydroperoxide (15-HPETE; 90 nmol/sample) was incubated for 60 min under the described peroxidation conditions. The samples were processed and analyzed as detailed in the footnote to Table 2. Data are means ± SD ($n \geq 6$).

MDA is most certainly not the only decomposition product, for a complex variety of small molecules can be generated from lipid peroxide breakdown (10,13,35). In membrane/tissue systems where purified lipid is not the peroxidative target, bona fide MDA may represent only 20-60% of the total TBARS (18,31,39-42). Therefore, the presence of nonlipid-related, nonMDA TBARS in biological peroxidation samples represents a major limitation to the quantitative use of the TBA test in systems not having purified peroxidative target.

Formation of lipid-derived MDA under peroxidation conditions at physiological pH and temperature implies that MDA is produced locally in tissues during radical-mediated membrane damage. This proposition could help explain the association among Fe overload, oxidative stress and high tissue MDA levels (43). In vivo, local tissue effects of MDA (7,44,45) probably reflect the balance between MDA formation and catabolism (46). Because PUFA hydroperoxides are structurally similar to prostaglandin biosynthetic intermediates (16), hydroperoxide breakdown to MDA, concomitant with biological PUFA peroxidation, could obviate the pathophysiological effects of nonenzymatically produced prostaglandin-like substances. The relationships between lipid peroxide decomposition and TBA-reactive MDA formation during membrane PUFA peroxidation, as described herein, suggest a broader mechanistic outlook of radical-mediated tissue injury to encompass not only lipid peroxide formation, but also sequelae such as peroxide decomposition and the pathophysiological effects of decomposition products at the sites of tissue injury.

[Received March 18, 1988; Revision accepted October 3, 1988]

Effect of Marginal Zinc Deficiency on Lipoprotein Lipase Activities in Postheparin Plasma, Skeletal Muscle and Adipose Tissues in the Rat[1]

Sung I. Koo* and **Christine C. Lee**
Department of Biochemistry, Oral Roberts University, School of Medicine, Tulsa, OK 74171

The activities of lipoprotein lipase in postheparin plasma, retroperitoneal adipose and gastrocnemius muscle tissues were determined in the rats fed 2.8 ppm of dietary zinc for eight weeks, as compared with pair-fed and ad libitum-fed rats given 30.8 ppm of zinc. The postheparin lipoprotein lipase activity, as determined by using a lipid emulsion labeled with [^{3}H]triolein as the substrate, was significantly lower in the first group of rats, relative to that in the second and third groups. Tissue lipoprotein lipase activities were compared using the lipid emulsion and activator serum obtained from the zinc-deficient rats and the ad libitum-fed rats. The activator sera were devoid of very low density and low density lipoproteins, but enriched in high density lipoproteins. Muscle lipoprotein lipase activities were significantly lower when assayed with the activator serum from the zinc-deficient compared with the activities determined with the activator serum from the ad libitum-fed. Similarly, muscle lipoprotein lipase activities were lower in all groups when [^{3}H]-triolein-labeled chylomicrons from the zinc-deficient were used as the substrate, compared with the activities determined using the chylomicrons from the ad libitum-fed. Lipoprotein lipase activities in the adipose tissues were not affected by the different sources of the activator sera and chylomicrons. The results strongly suggest that the decrease in postheparin lipoprotein lipase activity in zinc deficiency is not due to changes in tissue lipoprotein lipase enzyme per se, but to compositional alterations in chylomicrons and high density lipoprotein, particularly, with regard to C apolipoproteins, modulators of lipoprotein lipase activity.
Lipids 24, 132–136 (1989).

Zinc deficiency in experimental animals produces profound alterations in lipid metabolism. Evidence indicates that zinc deficiency in rats impairs the intestinal absorption of triglyceride (1) and cholesterol (2), which may be attributable to the defective formation of chylomicrons in the intestinal mucosa (3,4).

At present, however, little is known about the effect of zinc deficiency on the postabsorptive metabolism of chylomicron-carried lipids. Upon their entry into the circulation, chylomicrons are subjected to peripheral lipolysis by endothelial lipoprotein lipase (LPL), with resultant formation of chylomicron remnants, which are then rapidly taken up via the high affinity apo-E receptor (5). Our recent data (6) demonstrate that the initial plasma clearance of chylomicrons, as labeled with [^{14}C]cholesterol, is significantly delayed in marginally zinc-deficient rats. Such a delay suggests a possible impairment in the peripheral lipolysis and/or hepatic uptake of chylomicrons (remnants).

The present study was designed to specifically investigate the effect of marginal zinc deficiency on the activities of LPL in postheparin plasma, skeletal muscle and adipose tissues. In view of the important role of apo C in modulating LPL activity (7,8) and the observed decrease in chylomicron apo C in zinc deficiency (3), the LPL activities were compared between zinc-deficient (ZD) and control (CT) rats by using a natural substrate (purified chylomicrons) and an artificial substrate with the activator sera, as obtained from the ZD and CT rats.

MATERIALS AND METHODS

Animals and diets. Male Fischer rats (CDF[-344]Crl BR; Charles River Breeding Lab., Inc., Wilmington, MA) were housed individually in plastic cages with stainless-steel wire bottoms and subjected to a light cycle with the light period from 1500 to 0300 and dark period from 0300 to 1500 throughout the experiment. After acclimatization for 1 wk, the rats weighing 159 ± 8 g were divided into 3 treatment groups of 20 each.

The composition of the basal diet was the same as described previously (4). The basal diet contained 0.8 ppm of zinc. The experimental groups consisted of: 1) a zinc-deficient (ZD) group fed ad libitum the basal diet supplemented with 2.0 ppm of zinc. The total zinc content of the ZD diet was 2.8 ppm; 2) a pair-fed (PF) group fed 30.8 ppm of zinc, but with food intake restricted to the amount consumed by ZD; and 3) another control (CT) group fed the same diet ad libitum. Rats were allowed free access to deionized-distilled water delivered via an automatic watering system. All rats were housed in a windowless humidity- and temperature-controlled room in the Biomedical Research Center fully accredited by the American Association for the Accreditation of Laboratory Animal Care, and cared for in accordance with the guidelines of the National Research Council for the care and use of laboratory animals.

Determination of postheparin plasma lipoprotein lipase activity. After 8 wk of dietary treatment, 5 rats from each group were fasted for 18 hr and injected with 150 IU heparin/kg body wt (H-7005, Sigma Chemical Co., St. Louis, MO) via the jugular vein. At 10 min, blood samples were collected via the orbital sinus and plasma was obtained by centrifugation at 1700 × *g* for 1 hr and stored at −80°C in 100-μl aliquots. The substrate mixture, as prepared by the method of Nilsson-Ehle and Schotz (9), consisted of 300 mg triolein (99% purity, Sigma Chemical Co.), 0.5 mCi [^{3}H]triolein (15.4 Ci/mmole, NEN Research Products, Boston, MA), 18 mg phosphatidylcholine and 6.25 mg glycerol. The LPL assay mixture was obtained by vigorously mixing 1.1 ml of the substrate mixture in 4 volumes of 0.2 M Tris-HCl buffer, pH 8.6, containing 0.15 M NaCl and 3% bovine serum albumin (fatty acid-

free; Sigma Chemical Co.). The mixture was then diluted by mixing with 6.38 ml of the buffer without albumin.

For LPL assay, 10 μl of postheparin plasma was preincubated for 10 min at 27°C, with 10 μl of Tris-HCl buffer (0.388 M Tris-HCl and 0.2 M NaCl), pH 8.6, with and without protamine sulfate (10). The protamine concentration of the buffer was 60 mg/ml. To the preincubated mixture, 180 μl of the assay mixture was added and incubated for 60 min at 27°C. The optimal plasma volume and assay durations were predetermined by using a series of plasma dilution and incubation intervals. LPL activity was linear with increasing concentrations of postheparin plasma from 5 to 30 μl and plateaued at 40–70 μl. With 10 μl of postheparin plasma, LPL activity was linear with time up to 90 min. At 60 min of incubation, 3.25 ml of methanol:chloroform:heptane (1.41:1.25:1.0, v/v/v), and 1.0 ml of 0.1 M boric acid and 0.1 M K_2CO_3 (pH 10.5) were added. The mixture was then partitioned by vortexing vigorously for 30 sec and centrifuged at 1500 × *g* for 30 min. One-ml aliquot of the upper phase was used to determine the ^{3}H-radioactivity of oleic acid released. All assays were performed in duplicates. LPL activity was computed by the difference between total postheparin plasma lipase and hepatic lipase (protamine-resistant) activities.

Determination of tissue LPL activities. Five rats from each group were fasted for 18 hr. Under ether anesthesia, the rats were exsanguinated and the retroperitoneal white adipose and gastrocnemius muscle of the left leg were removed. The tissues were homogenized in ice-cold 0.25 M sucrose in 1 mM EDTA buffer, pH 7.4. The soluble fractions of the tissues were prepared by centrifuging the tissue homogenates, as described previously (11).

The LPL activities were assayed by using both an artificial substrate prepared as above and a natural substrate (lymph chylomicrons) obtained from donor rats of both groups. For LPL assays using the artificial substrate, the substrate mixture was prepared as above and the activator sera were prepared by removing very low density lipoprotein (VLDL) and low density lipoprotein (LDL) fractions ultracentrifugally and heating at 62°C for 10 min. This approach was taken to enrich serum with high density lipoprotein (HDL) fraction, which was used as the source of apo Cs, modulators of LPL activity (7,8). Tissue LPL activities were determined by using the HDL-enriched serum fractions (activator sera) from ZD and CT rats, and the effects of the activator sera on the enzyme activity were compared as follows: 1.4 ml of the substrate and 5.6 ml of 0.2 M Tris-HCl buffer containing 3% albumin (pH 8.6) were mixed thoroughly and divided into 2 aliquots of 3.5 ml each. To 1 aliquot, 168 μl of activator serum from ZD rats and 532 μl of 0.15 M NaCl were added and mixed. To the other, the same amounts of activator serum from CT rats and saline were added. To 100 μl of each of the aliquots, 100 μl of the soluble fraction (enzyme source) of the adipose or muscle tissues was added and incubated for 37°C for 60 min. The assay system so prepared contained 4.0 μl of activator serum per 200 μl. The tissue LPL activity was linear with increasing the activator serum from 2 to 16 μl/200 μl of the assay system.

To prepare the chylomicron substrate, chylomicrons were obtained from the donor rats from both ZD and CT groups and purified as reported previously (2,3). The purified chylomicrons were labeled with [^{3}H]triolein by a slight modification of Fielding (12) as follows: Using a syringe with a 25-G needle, [^{3}H]triolein (500 μCi) dissolved in 1.0 ml of dimethylsulfoxide was slowly added to 4.0 ml of 10 mM Tris-HCl buffer, pH 7.4, containing 0.15 M NaCl, 1 mM EDTA and 0.01% NaN_3 and mixed by vortexing. To this mixture, 5.0 ml of purified chylomicrons (500 mg triglyceride) was added, mixed gently and incubated at 37°C for 3 hr. After dialyzing in 4 l of 0.15 M NaCl with 0.1% EDTA (pH 7.4) at 4°C for 18 hr, the mixture was centrifuged in a Beckman 50.3 Ti rotor at 45,000 rpm for 15 min. The top chylomicron fraction was resuspended in 0.15 M NaCl (pH 7.2) and washed. The ^{3}H-radioactivity of the chylomicrons so prepared ranged from 38 to 60 μCi/100 mg triglyceride (TG). The TG concentration of the labeled chylomicrons, as obtained from both ZD and CT rats, was adjusted exactly to 68.5 mg/ml saline. The substrate was prepared by mixing the ^{3}H-chylomicrons (82.2 mg TG) from both sources in 4.8 ml of 0.2 M Tris-HCl buffer with 3% albumin (pH 8.0) and 1.2 ml saline. The LPL activity was determined by incubating 100 μl of the above substrate mixture with 100 μl of the soluble fraction of the tissues at 37°C for 2 hr. LPL activities were linear with chylomicron-TG concentrations from 0.2 to 1.5 mg/100 μl of the substrate mixture. For LPL assay using the chylomicron substrate, no activator sera were used because of the presence of apo Cs in chylomicrons, but the effects of the two chylomicron substrates, as obtained from ZD and CT rats, were compared. All assays were performed in duplicates. The ^{3}H-radioactivity of oleic acid released was partitioned and measured, as described above for plasma LPL assay.

Plasma zinc analysis. Five rats from each group were fasted for 18 hr. Blood samples were collected from the orbital sinus by using heparinized capillary tubes during the mid-dark period (0800–0900) of the light cycle. Plasma zinc was analyzed by atomic absorption spectrophotometry (Perkin-Elmer Co., Norwalk, CT). Zinc standards were prepared from a Fisher-certified reference standard (Fisher Scientific Co., Fair Lawn, NJ).

Statistics. Analysis of variance and Duncan's multiple range test were used for comparisons among three group means, and t-test was used to determine the effect of activator sera on LPL activity. The statistical analyses were performed using a computer software (PC ANOVA, Human Systems Dynamics, Northridge, CA). The level of significance was determined at $p < 0.05$.

RESULTS

General observations. The food intake, body weight, and plasma zinc status of the rats, as affected by dietary treatment, are shown in Table 1. The purpose of supplementing the basal diet containing 0.8 ppm with additional 2 ppm of zinc for ZD rats was to prevent a drastic decrease in food intake and resultant rapid weight loss in these rats and to produce a marginal level of zinc deficiency. For the 8-wk period, no significant difference in body weight was noticed between ZD and PF rats. Significant differences in food intake and body weight between ZD and CT groups were evident during wk 4 and thereafter. Plasma zinc in ZD rats, as determined at wk 8, was significantly lower when compared with PF and CT controls. However, no external symptoms of zinc deficiency such as skin lesions and alopecia were detectable, as

observed in severe zinc deficiency produced with lower dietary zinc in young rats (1).

Postheparin plasma LPL activity. The effect of zinc deficiency on postheparin plasma LPL activity is presented in Table 2. Because the intravenous injection of heparin is known to release both endothelial LPL and hepatic lipase (HL) into plasma (10), LPL activity was measured by subtracting HL activity from the total activity of postheparin TG hydrolase. The total plasma TG hydrolase activity was significantly decreased in ZD, relative to PF and CT controls. The decrease was due to a significant decrease in LPL activity. The plasma LPL activity in ZD rats was 75.6 and 72.9% of that in PF and CT groups, respectively. Postheparin plasma HL activity was not affected by zinc deficiency.

Table 3 compares the effects of zinc deficiency and activator sera from ZD and CT rats on the LPL activity of retroperitoneal adipose and gastrocnemius muscle tissues. Data, as obtained by using the lipid emulsion substrate, showed that zinc deficiency per se did not affect the LPL activity of either the adipose or muscle tissue. The LPL activities of the adipose tissues from all 3 groups did not significantly differ, whether assayed with the activator serum from ZD or CT rats. However, the LPL activities of the gastrocnemius muscles were significantly decreased by the ZD activator serum, compared with the activity determined with the CT activator serum. The muscle LPL activities in ZD, PF and CT groups, as assayed with ZD activator serum, were decreased to 81.0, 80.4 and 76.5%, respectively, of the activity determined with CT activator serum.

[4]Gastrocnemius muscle.

Similarly, the LPL activities of the adipose tissues from ZD, as well as control groups, remained unchanged, regardless of the source of the chylomicrons used as the substrates (Table 4). As with the artificial substrate, the muscle LPL activities were significantly lower in all 3 groups, when measured with the chylomicron substrate from ZD group, compared with the activities assayed with CT chylomicrons. The LPL activities in ZD, PF and CT groups, when measured with ZD chylomicrons as the substrate, were 64.7, 70.3 and 72.8%, respectively, of the activities obtained with CT chylomicrons.

DISCUSSION

Dietary TG is carried primarily by chylomicrons from intestinal mucosa to plasma and is rapidly cleared from the circulation by the action of endothelial lipoprotein lipase (LPL) of extrahepatic tissues and by the subsequent uptake by liver of the chylomicron remnants formed after lipolysis by LPL (13). In this regard, LPL plays a key role in the clearance of chylomicron TG from plasma, as well as in the peripheral utilization of its hydrolytic products (fatty acids). The present data demonstrate that zinc deficiency significantly lowers the postheparin plasma activity of LPL.

In several earlier studies (14–16), significant elevations in plasma (or serum) TG have been observed in zinc-deficient rats, suggesting a possible impairment in the plasma clearance of TG. However, some studies (17,18) have reported decreases in serum TG in zinc-deficient animals. The conflicting observations may be ascribable to the differences in the degree of zinc deficiency produced in different studies and also the well-characterized difference in feeding pattern between zinc-deficient and pair-fed control animals. In a recent study (19), in an effort to overcome such variables, Park et al. have used the method of intragastric force-feeding for both zinc-deficient and pair-fed controls and demonstrated a marked elevation in serum TG in zinc-deficient rats. This finding (19) reaffirms that the hypertriglyceridemia observed in zinc-deficient animals is not related to a difference in food intake or feeding pattern, but due to zinc deficiency.

Whether the increase in serum TG results from endogenous or dietary triglyceride is not presently known. However, the contribution of endogenous synthesis to serum TG may not be significant, considering the general catabolic state induced by zinc deficiency, as characterized by hypoinsulinemia, ketosis and reduction in fat reserves and muscle mass (14,19–21). Therefore, the elevation in serum TG, as demonstrated by intragastric feeding (19), may be due primarily to the impaired removal of TG of dietary origin. This is consistent with the observed low LPL activity and with the significant delay in the initial plasma clearance of [^{14}C]cholesterol-labeled chylomicrons (6) observed in zinc-deficient rats. Under nonforce-feeding conditions, however, the diet-induced hypertriglyceridemia may not be apparent in zinc-deficient rats despite the low LPL activity, because of the decrease in food intake and/or impaired absorption of fat (1,2).

The results obtained by using an artificial lipid emulsion and chylomicrons as the substrates (Tables 3 and 4) demonstrate that the LPL activity of the gastrocnemius muscle was consistently lower, when the assay system contained either the chylomicrons as the substrate or the HDL-enriched serum as the activator derived from ZD rats, compared with those from CT rats. Under the same assay conditions, however, the LPL activity of the retroperitoneal adipose tissue was unresponsive to the change in the substrate or the activator. This suggests that adipose LPL enzyme may be less sensitive to the concentrations of the modulator (activator) apolipoproteins (apo Cs) than muscle LPL. It has previously been shown that LPL enzymes from muscle and adipose tissues are distinct with regard to their molecular weights and kinetic properties (22,23).

The heparin-releasable LPL activity in the plasma represents the composite activity of endothelial-surface LPL from various peripheral tissues. The total endothelial LPL activity in postheparin plasma would, therefore, depend on the total tissue masses and, hence, the degree of tissue vascularization. It might be possible that the lower LPL activity in postheparin plasma is partly related to a general reduction in total tissue mass. However, in the present study, no relationships were found between postheparin LPL activities and body weights of rats. The data on tissue LPL activities from both experiments with activator sera and chylomicrons from the two different sources (Tables 3 and 4) strongly suggest that the decrease in heparin-releasable plasma LPL activity may be attributable, at least partly, to zinc deficiency-induced alterations in the concentrations of LPL-modulator (activator) apolipoproteins (apo Cs) in the chylomicrons and HDL-enriched serum (activator serum). This conclusion is also in line with the significant decreases in the total apo-C contents of lymph chylomicrons (3) and plasma HDL (24) and a reduction in the total plasma concentration of HDL apo C (25) in marginally zinc-deficient rats. Because chylomicrons, upon their release into the plasma, acquire apo C mainly from plasma HDL (26), the decrease in HDL apo C would consequently affect the peripheral lipolysis and removal of chylomicron triglyceride. In view of the evidence that apo C-II activates and apo C-III inhibits LPL activity (7,8), it is suggested that zinc deficiency may lower the circulating level of apo C-II or the ratio of apo C-II to apo C-III. Previously, it has been shown (27) that the ratio of apo C-II to apo C-III was significantly lower in zinc-deficient rats, relative to the ratio in ad libitum-fed controls, although it did not differ from that in pair-fed rats.

In summary, the present study provides evidence that zinc deficiency significantly lowers the LPL activity in postheparin plasma and in the gastrocnemius muscle. The data and earlier observations suggest that the lowering of LPL activity in marginal zinc deficiency may be due to a significant decrease in activator apo C in the plasma, rather than a change in the enzyme. However, in the present study, we examined the total tissue LPL activities. Further studies are needed to determine separately the endothelial-surface (heparin releasable) and cell-associated (nonheparin releasable) LPL activities. The effects of the low LPL activity on the utilization of dietary fat by muscle and adipose tissues, and the clinical implications of a high fat intake and ensuing possible hyperlipidemia in zinc deficiency should be further examined.

ACKNOWLEDGMENTS

This work was supported by NIH Grant HL-27531. The authors wish to thank Steve Duarte for his technical assistance and care of the rats for this study.

Alpha- and Gamma-Tocopherol Levels in Lipoproteins Fractionated by Affinity Chromatography

Beverly A. Clevidence* and **Joanna Lehmann**
Lipid Nutrition Laboratory, Beltsville Human Nutrition Research Center, U.S. Department of Agriculture, Agricultural Research Service, Beltsville, MD 20705

Alpha- and gamma-tocopherol levels of nine women were measured in whole serum and in serum lipoproteins separated by heparin affinity chromatography. Alpha-tocopherol levels (mean ± SD) in whole serum, low density plus very low density lipoproteins and high density lipoproteins were 10.8 ± 2.7, 6.4 ± 1.6 and 4.6 ± 1.4 (μg/ml), respectively. Corresponding values (μg/ml) for gamma-tocopherol were 1.2 ± 0.5, 0.7 ± 0.3 and 0.6 ± 0.2. Recoveries of serum alpha- and gamma-tocopherol from the heparin columns were 102 ± 5% and 105 ± 7%, respectively. Serum alpha-tocopherol was linearly correlated with components of high density lipoprotein (apolipoproteins, high density lipoprotein cholesterol), but not with serum total lipids or indices of low density lipoprotein, even though high density lipoprotein carried less than half of the serum alpha-tocopherol. However, serum gamma-tocopherol was highly correlated with indices of serum lipids, such as serum cholesterol ($r = 0.92$, $p = 0.005$). The coefficient for the correlation of low density lipoprotein (+ very low density lipoprotein) tocopherol with high density lipoprotein tocopherol was $r = 0.66$ ($p = 0.06$) for alpha-tocopherol and $r = 0.84$ ($p = 0.004$) for gamma-tocopherol. These differences in the relationships of the two tocopherols to lipids and lipoproteins support the view that when the two tocopherols are present at normal dietary levels, gamma-tocopherol partitions between lipoproteins based on their relative lipid content, but a portion of the alpha-tocopherol in high density lipoprotein is specifically bound.
Lipids 24, 137-140 (1989).

In plasma, tocopherols are transported primarily by high density lipoproteins (HDL) and low density lipoproteins (LDL). Fasting, normolipemic humans have relatively minor amounts of tocopherol carried by very low density lipoproteins (VLDL) (1,2). It is widely believed that the concentration of alpha-tocopherol in serum is primarily a function of serum lipid levels, and that alpha-tocopherol rides passively and nonspecifically in the lipid medium of lipoproteins (3-5). However, the exact location of tocopherol in lipoproteins is not known. Behrens and Madere (6,7) have recently suggested that alpha-tocopherol concentration in plasma may be controlled by specific carriers or transport proteins that regulate absorption, transport and tissue uptake. They also suggested that sex differences in distribution of alpha-tocopherol among lipoproteins may be related to the parallel sex differences in protein distribution among lipoproteins. Because women generally have higher ratios of HDL protein (predominantly apolipoprotein [apo] A) to LDL protein (apo B) than do men, women would tend to carry greater proportions of alpha-tocopherol in HDL relative to LDL.

Typically, studies to determine the distribution of alpha-tocopherol among lipoproteins or the regulation of alpha-tocopherol within lipoproteins have used ultracentrifugation, sometimes combined with gel filtration, to separate lipoproteins. These techniques are labor intensive and require equipment not readily available to most laboratories. More importantly, substantial losses of both alpha-tocopherol (1,2) and apoproteins (8) occur during isolation of lipoproteins by these techniques. Another approach for lipoprotein separation would be the use of precipitation techniques (9,10), which are commonly used to isolate HDL for cholesterol analysis. However, LDL tocopherol would be calculated by difference and the LDL moiety would be lost for further study.

Affinity chromatography offers an attractive alternative for lipoprotein separation not only because lipoprotein fractions remain in solution, but also because it is a rapid and simple technique. The present study was designed to evaluate tocopherol content of lipoproteins separated on heparin affinity columns. Based on this methodology, some initial findings are reported that relate alpha- and gamma-tocopherol to apoprotein and cholesterol content of lipoproteins.

MATERIALS AND METHODS

Nine women, 20-40 years of age, were randomly selected from a group participating in a controlled diet study (11). All subjects ate a low-fat (20% of calories as fat) diet, which met the Recommended Dietary Allowances. (All procedures were approved by the Human Studies Review Committees of the U.S. Department of Agriculture, Agricultural Research Service and the Georgetown University Institutional Review Board.) Estimated average daily intake of alpha-tocopherol was 15 mg per day and included dl-alpha-tocopheryl acetate from fortified breakfast cereals. Subjects did not take vitamin supplements, estrogens or other medications. Following a 12 hr fast, blood was drawn, cold clotted and serum separated by low speed centrifugation at 4°C.

Serum lipoproteins were fractionated on heparin columns (LDL Direct, Isolab Inc., Akron, OH) according to the manufacturer's instructions. Briefly, after applying whole serum (200 μl) to the column, HDL and LDL (+ VLDL) were eluted with low and high ionic strength buffers, respectively. Volumes were adjusted to exactly 1.2 ml. For comparison, a separate sample of HDL was produced from each serum sample by precipitating non-HDL lipoproteins with phosphotungstate-Mg^{2+} (9). Column eluates (100 μl) containing HDL or LDL (+VLDL) and HDL from the precipitation method (50 μl) were mixed with 1 ml of 100% methanol, and tocopherols from 75 μl of the methanolic extracts were measured by a high performance liquid chromatographic (HPLC) procedure

Abbreviations: HDL, high density lipoprotein; (V)LDL, (very) low density lipoprotein; HPLC, high performance liquid chromatograph(ic,y).

previously described for whole plasma (12). The entire process, including tocopherol analysis, was performed in one day.

Serum triglycerides were assayed by an enzymatic method (13) using a centrifugal analyzer. An enzymatic method (14) was used to determine cholesterol in whole serum and in HDL column fractions. Cholesterol content of LDL (+VLDL) was calculated as the difference between serum total cholesterol and the HDL cholesterol measured from HDL column fractions. Total serum lipids were estimated as (2 × cholesterol) + triglycerides (15). Apo A and apo B were assayed in triplicate from whole serum by electroimmunoassay (16) using rabbit antisera to human apoproteins (Behring Diagnostics, La Jolla, CA). Antisera to apo A was raised against total apo A with apo A-I and A-II present in a ratio of 65:35, the approximate ratio of these apoproteins in human serum (17). Serum samples for apo A analysis were diluted 1:50 (v/v) in electrophoresis buffer, containing (per liter) tris, 2.9 g; sodium barbital, 4.9 g; barbital, 1.2 g; EDTA, 0.1 g and NaN_3, 0.1 g; pH 8.6. These samples were heated at 52°C for 3 hr to expose antigenic sites. For apo B analysis, serum was diluted 1:10 (v/v) in electrophoresis buffer and assayed without delipidation. (In our hands, the within-assay coefficient of variation for the electroimmunoassay was 2.3% for apo A and 2.9% for apo B; both calculated from 26 replicates of a pooled plasma sample. The between-assay coefficient of variation was typically 5% for apo A and 6% for apo B.) Samples for apoprotein analysis were stored at −20°C prior to analysis.

Data were analyzed using the SAS system (SAS Institute, Cary, NC). Correlation coefficients were determined by the Pearson product-moment method, and the paired t-test was used to compare mean values for tocopherols by method of lipoprotein separation.

RESULTS

Heparin affinity chromatography. Recoveries (mean ± SD) of serum alpha- and gamma-tocopherol from heparin affinity columns were 102 ± 5% and 105 ± 7%, respectively. LDL (+VLDL) contained 59 ± 6% of the recovered alpha-tocopherol and 54 ± 8% of the gamma-tocopherol. To assess the accuracy of the column recoveries, HDL tocopherol values from HDL column fractions were compared with tocopherol values from HDL obtained by precipitation of non-HDL lipoproteins. Values (mean ± SD) for HDL tocopherol isolated by affinity columns and by the precipitation technique were, respectively, 4.6 ± 1.4 and 4.4 ± 1.3 μg/ml for alpha-tocopherol; 0.6 ± 0.2 and 0.6 ± 0.3 μg/ml for gamma-tocopherol. These means were not significantly different by method of separation.

Tocopherol levels and relationships to lipoproteins. Table 1 shows means and ranges for tocopherol, lipid and apoprotein values of serum, HDL and LDL (+VLDL). Coefficients for linear correlations of alpha- and gamma-tocopherol in serum, HDL and LDL (+VLDL) with serum lipids, apoproteins and lipoprotein cholesterol are in Table 2. In serum, alpha-tocopherol was linearly associated ($p \leq 0.05$) with apo A and with HDL cholesterol, and gamma-tocopherol was linearly associated with total lipids, serum cholesterol, apo B and LDL (+VLDL) cholesterol. Within HDL, only alpha-tocopherol was linearly

TABLE 1

Tocopherol, Lipid and Apoprotein Levels in Serum, HDL and LDL (+VLDL) of Nine Women

Component	Mean ± SD	Range
Serum:		
Alpha-tocopherol (μg/ml)	10.8 ± 2.7	7.4–14.2
Gamma-tocopherol (μg/ml)	1.2 ± 0.5	0.6–2.1
Total lipids (mg/dl)[a]	462 ± 81	385–613
Cholesterol (mg/dl)	197 ± 36	165–263
Triglycerides (mg/dl)	68 ± 15	43–90
Apo A (mg/dl)	186 ± 42	116–270
Apo B (mg/dl)	83 ± 12	65–99
HDL:		
Alpha-tocopherol (μg/ml)	4.6 ± 1.4	2.5–6.4
Gamma-tocopherol (μg/ml)	0.6 ± 0.2	0.3–1.0
Cholesterol (mg/dl)	53 ± 15	38–76
LDL (+VLDL):		
Alpha-tocopherol (μg/ml)	6.4 ± 1.6	4.7–8.8
Gamma-tocopherol (μg/ml)	0.7 ± 0.3	0.3–1.3
Cholesterol (mg/dl)[b]	144 ± 36	122–223

[a]Calculated: total lipids = (2 × cholesterol) + triglycerides.

[b]Calculated: LDL (+VLDL) cholesterol = serum cholesterol − HDL cholesterol.

TABLE 2

Coefficients (r) for Linear Correlations of Alpha- and Gamma-Tocopherol (α-T, γ-T) in Serum, HDL and LDL (+VLDL) with Serum Lipids, Apoproteins and Lipoprotein Cholesterol

		Serum		HDL		LDL (+VLDL)	
Component		α-T	γ-T	α-T	γ-T	α-T	γ-T
Serum lipids							
Total lipids	r	0.49	0.92	0.30	0.91	0.60	0.84

	p	NS	0.0007	NS	0.007	NS	0.0004

[a]Probability of ≤0.05 indicates that there was a linear correlation between the indicated variables.

NS, not significant at the probability of 0.05 under the Ho: Rho = O/N = 9.

associated with apo A and with HDL cholesterol. Within LDL (+VLDL), only gamma-tocopherol was linearly associated with apo B and LDL (+VLDL) cholesterol. Also, there were linear associations between apo A and HDL cholesterol ($r = 0.85$, $p = 0.004$) and between apo B and both serum total cholesterol ($r = 0.82$, $p = 0.007$) and LDL (+VLDL) cholesterol ($r = 0.74$, $p = 0.02$). The coefficient for the correlation of LDL (+VLDL) tocopherol with HDL tocopherol was $r = 0.66$ ($p = 0.06$) for alpha-tocopherol and $r = 0.84$ ($p = 0.004$) for gamma-tocopherol.

DISCUSSION

Affinity columns. By binding apo B, heparin columns retain VLDL and LDL, whereas HDL passes through. VLDL and LDL are then eluted with a saline solution of increased ionic strength. Values for HDL tocopherols obtained by this fractionation method were comparable to tocopherol values obtained by phosphotungstate-Mg^{2+} precipitation. Although not significantly different, HDL tocopherol values from the precipitation method tended to be slightly lower. That is consistent with reports that HDL cholesterol values by the phosphotungstate-Mg^{2+} precipitation method are about 7% lower than HDL cholesterol values from ultracentrifugation or heparin-Mn^{2+} precipitation techniques (18).

In contrast to the precipitation technique, heparin affinity columns allowed direct determination of tocopherol in both LDL (+VLDL) and HDL fractions, with the added benefit of retaining lipoproteins in a soluble state suitable for subsequent chemical analysis. The lack of separation of VLDL from LDL did not present a problem in this study, because VLDL contribution to total serum alpha-tocopherol is negligible—less than 3% in fasting, normolipemic women (1,2). Similarly, the presence of apo B in both VLDL and LDL did not greatly distract from using apo B as an index of LDL concentration because ca. 90% of apo B is associated with LDL.

Alpha-tocopherol levels in whole serum were similar to those reported by Behrens and coworkers (1,2) for women of similar age (Table 3). Yet, in those studies, alpha-tocopherol content of lipoproteins, isolated by ultracentrifugation and subsequent gel filtration, was 72% (1) and 68% (2) of the original serum value. In contrast, recoveries of alpha-tocopherol from lipoproteins fractionated by the heparin affinity columns were 102%. Our alpha-tocopherol values and recoveries for LDL (+VLDL) were twofold higher than those of Behrens and coworkers, but were strikingly similar for HDL. These observations indicate that tocopherol loss associated with the ultracentrifugation and gel filtration method of isolating lipoproteins was selective for LDL. Our experience has been that once LDL is isolated from serum, tocopherols in this fraction are unstable. The improved recovery of LDL (+VLDL) tocopherol by the affinity column method may be a function of the decreased time lapse (hours rather than days) from blood collection to tocopherol analysis of lipoprotein fractions.

Relationship of tocopherols to lipoproteins. Correlation data have the limitation of only showing strengths of associations and cannot be used to prove cause and effect. However, if there is a cause and effect that has a linear association, then the correlation data must reflect that relationship. For example, if the distribution of tocopherol between lipoproteins is in equilibrium, then the correlation of tocopherol contents of HDL and LDL (+VLDL) should be very strong. Such was the case for gamma-tocopherol. On the other hand, no significant linear relationship between alpha-tocopherol contents of LDL (+VLDL) and HDL was found. These findings are consistent with the concept that alpha-tocopherol distribution among lipoproteins is not solely a function of nonspecific diffusion into a lipid medium. One explanation would be that some portion of the alpha-tocopherol in HDL is not in equilibrium with serum total lipids or serum cholesterol, but instead, is specifically bound by some component of HDL (1).

Gamma-tocopherol content of serum, HDL and LDL (+VLDL) was strongly correlated not only with serum total lipids and cholesterol, but also with LDL cholesterol, which accounts for the majority of cholesterol in serum. It should be noted that correlations of gamma-tocopherol in serum, HDL and LDL (+VLDL) with total lipids was similar to the correlation of these variables with serum cholesterol. (This was because values for total lipids were derived using a formula that largely depends on cholesterol levels and, to a lesser extent, triglyceride levels, which were consistently low in these subjects. Thus, for our subjects, the strong association of gamma-tocopherol with total lipids appears to be due to the correlation with serum cholesterol.) Although our results are consistent

TABLE 3

Distribution of Alpha-Tocopherol (α-T) in Lipoprotein Fractions of Women: Comparison of Values in Literature to Those of Present Study

	Ultracentrifugation and gel filtration				Affinity column	
	Ref. 1, n = 7		Ref. 2, n = 6		Present study, n = 9	
Component	μg/ml (mean ± SD)	% of serum α-T	μg/ml (mean ± SE)	% of serum α-T	μg/ml (mean ± SD)	% of serum α-T
Serum	8.97 ± 2.84	100	10.35 ± 0.86	100	10.8 ± 2.7	100
VLDL	0.09 ± 0.09		0.15 ± 0.03		—	
LDL	2.73 ± 0.72		2.85 ± 0.30		—	
LDL (+VLDL)[a]	2.82	31	3.00	29	6.4 ± 1.6	59
HDL	3.66 ± 1.78	41	4.00 ± 0.71	39	4.6 ± 1.4	43

[a]For Ref. 1 and 2, LDL (+VLDL) is the sum of individual measures of VLDL and LDL tocopherol. For the present study, LDL (+VLDL) was measured from column fractions that included both VLDL and LDL.

with the view that distribution of gamma-tocopherol among lipoproteins is nonspecific, increased alpha-tocopherol intake is known to result in the displacement of gamma-tocopherol by alpha-tocopherol in serum (19), as well as in red blood cells, platelets and lymphocytes (20). Therefore, results may differ when dietary intake of tocopherol is lower than in this study. Also, the fact that subjects consumed a low-fat diet may have bearing on these data.

In contrast to gamma-tocopherol, alpha-tocopherol contents of serum, HDL and LDL (+VLDL) were not generally related to indices of serum lipids. This conflicts with some previous studies that report correlations between serum alpha-tocopherol and either total cholesterol (15,21,22) or serum total lipids (22,23). However, this discrepancy may only reflect a more limited range of total lipid levels in this study.

A strong affinity of alpha-tocopherol for HDL was observed by Granot et al. (24) in their in vitro studies of [H_3] alpha-tocopherol distribution between lipoproteins. The association of alpha-tocopherol with lipoproteins was not a function of lipid mass ratios; in fact, most of the alpha-tocopherol remained associated with HDL even when LDL lipid mass was tenfold that of HDL. Transfer of alpha-tocopherol from HDL to LDL was decreased from 55 to 20%, and transfer from LDL to HDL was increased from 40 to 70%, by decreasing the mass ratio of LDL (the LDL to HDL protein ratio) from 4 to 1. Under physiological conditions, the mass ratio (estimated as the apo B to apo A ratio) would be about 0.5 for normolipemic women. Mass ratios in the physiological range would, therefore, be expected to favor retention of alpha-tocopherol by HDL and donation of alpha-tocopherol by LDL.

Behrens et al. (1,2) have speculated that HDL protein (presumably apo A, which accounts for ca. 90% of HDL protein mass) binds alpha-tocopherol, thus regulating alpha-tocopherol concentrations in HDL. Consistent with their studies, we found evidence that HDL alpha-tocopherol is linearly related to serum apo A, but no such relationship was found between LDL alpha-tocopherol and serum apo B, even though in this study, LDL carried a larger proportion (59 $\pm$ 6%) of the total serum alpha-tocopherol than did HDL. These observations support the concept that HDL contains one or more components specific for binding alpha-tocopherol. However, the HDL component responsible for this postulated alpha-tocopherol binding could not be identified in this study.

Even though some target tissues may acquire alpha-tocopherol as a component of LDL, as suggested by alpha-tocopherol entry into fibroblasts via the LDL receptor (25,26), it may be the alpha-tocopherol in HDL that ultimately reaches other target tissues. In the rat, those tissues with the highest levels of alpha-tocopherol (adrenal and ovary) (27) are also known to selectively bind HDL, the source of cholesterol for steroid synthesis in these tissues (28,29). If some target tissues take up alpha-tocopherol preferentially from HDL, then selective association of tocopherol with HDL would provide a biological advantage to those tissues by ensuring supply when plasma alpha-tocopherol levels are low.

Our data support assertions by Behrens and coworkers (1,2) that gamma-tocopherol may be carried passively in serum lipoproteins, but that alpha-tocopherol content of HDL is, to some degree, regulated. The biological advantage of regulating alpha-tocopherol content in HDL is unknown, but may be related either to the size advantage HDL would have over other lipoproteins in moving from plasma to peripheral tissues, or to the apo A component of HDL, which may allow certain tissues to selectively take up HDL-associated alpha-tocopherol.

[Received March 31, 1988; Revision accepted October 17, 1988]

Fatty Acid Pattern of Tissue Phospholipids in Copper and Iron Deficiencies

Susan B. Johnson[a], Tim R. Kramer[b], Mary Briske-Anderson[b] and Ralph T. Holman[a,*]

[a]The Hormel Institute, University of Minnesota, Austin, MN 55912; and [b]Grand Forks Human Nutrition Research Center, Agriculture Research Service, United States Department of Agriculture, Grand Forks, ND 58202

Because copper and iron have been reported to be essential cofactors in Δ9 desaturation of fatty acids, the effects of different dietary intakes of copper and iron on tissue fatty acids were studied. Male Long-Evans rats (ten per group) were fed diets containing adequate, deficient or excess copper or iron. On day 42 of the dietary regimen, the animals were killed and tissues and blood were removed for analysis of metals and fatty acids of phospholipids. Compared with the copper-adequate rats, the copper-deficient rats showed increased 18:0 in liver and decreased 16:1ω7 in liver, heart and serum. There were no differences for 16:0 or 18:1ω9. Intake of excess copper did not cause an increase in products of Δ9 desaturation. Comparisons between iron-deficient and iron-adequate rats showed that iron deficiency increased 18:2ω6 in liver and serum and decreased 20:4ω6 in serum only. Relative percentages of 16:0, 18:0, 16:1ω7 and 18:1ω9 in liver and serum phospholipids were similar for both groups. Intake of excess iron caused a decrease in 18:2ω6; and 16:0 and 18:1ω9 were higher in the liver of the iron-excess group than the iron-deficient group. This study did not support the requirement for copper or iron in the Δ9 desaturation of fatty acids as expressed in phospholipids of liver, heart and serum.

Lipids 24, 141–145 (1989).

In rats and pigs (1–3), copper was shown to be a cofactor in the Δ9 desaturation of stearic acid (18:0) to oleic acid (18:1ω9). Male rats fed low-copper had decreased oleic acid content in tissue phospholipids (PL); copper supplementation had an opposite effect (4). High-copper intake caused increased tissue 18:1ω9, and subsequently, 20:3ω9, the major polyunsaturated metabolic product of 18:1ω9 and the fatty acid elevated in essential fatty acid (EFA) deficiency. With an increase in 20:3ω9 and because of the competitive inhibition between the ω6 and ω9 metabolic pathways, the amount of arachidonic acid (20:4ω6) decreased and its precursor, linoleic acid (18:2ω6), increased (5). In several species, copper deficiency is accompanied by decreased growth rates, neurological lesions, bone lesions and defects in structure of hair (6), symptoms characteristic of EFA deficiency in humans (7).

Iron has been shown to be a structural component of the Δ9 and Δ6 desaturases (8,9). Rao et al. (10) found decreased 16:1ω7 and 18:1ω9 in liver and in other tissues of iron-deficient (FeD) rats; however, 18:2ω6 and 20:4ω6 were 2- to 3-fold greater in iron-deficient than in iron-adequate (FeA) animals. Decreased desaturation of stearic to oleic acid by Δ9 desaturase was shown in rat liver microsomes from animals fed low-iron diets. This could cause the decreases in 16:1ω7 and 18:1ω9 in tissue lipids (11).

Because copper and iron have been reported to be involved in Δ9 fatty acid desaturation (1,2,10,11) and because similar symptoms are found in deficiencies of copper, zinc and EFA (7), the current study was undertaken to elucidate the involvement of copper and iron in fatty acid metabolism.

MATERIALS AND METHODS

Animals and experimental design. Weanling (age 21 days), outbred male Long-Evans [Crl:(LE)BR] rats were purchased from Charles River Breeding Laboratories, Inc. (Wilmington, MA). Upon arrival, rats were placed in stainless steel cages and fed ad libitum a nonpurified diet (Purina Rodent Laboratory Chow No. 5001, Ralston Purina, St. Louis, MO) and tap water. At age 28 days, the rats were matched by weight (ten animals per group), placed individually in suspended stainless steel cages and given deionized water. In each study, three groups of ten animals each were fed diets containing deficient, adequate or excess copper or iron. Daily food intake and weekly weight changes of the animals were measured. The deficient, adequate and excess groups in both studies were given free access to their diets. Pair-fed (PF) rats were fed the copper-adequate (CuA) or FeA diets in amounts equal to the average amount consumed on the previous day by the corresponding deficient group.

Diets. Purified diets contained 21.3% casein protein, 5% safflower oil, and other nutrients as listed in Table 1. The Cu-deficient (CuD) FeA diet contained 0.5 μg Cu and 41.0 μg Fe per gram; CuA–FeA, 5.4 μg Cu and 38.2 μg Fe per gram; Cu-excess (CuE)–FeE, 94.1 μg Cu and 43.8 μg Fe per gram; CuA–FeD, 5.4 μg Cu and 5.6 μg Fe per gram; CuA–FeA, 5.3 μg Cu and 41.7 μg Fe per gram; and CuA–Fe-excess (FeE), 5.2 μg Cu and 731 μg Fe per gram.

Sampling and measurements. On day 42 of the dietary regimen (age 70 days), between 0800 and 0900 hr, and on each of the next 4 days, equal numbers of rats from each dietary group were anesthetized with ether, bled by cardiac puncture and killed. Two ml of blood were placed in a vacutainer (47 × 10.25 mm, #6384, Becton Dickinson, Rutherford, NJ) for hematocrit determinations and the remainder was placed in Radiac-washed, deionized water-rinsed glass tubes. Hematocrits were determined by centrifuging the blood in microhematocrit tubes (Chase Instrument, Lindenhurst, NY). The remaining blood was allowed to clot for 1 hr at room temperature, followed by 2 hr at 4°C. The serum was collected and diluted 1:5 with deionized water. Copper and iron concentrations were determined by flame atomic absorption spectrophotometry (Model 1250 Atomic Absorption Spectrophotometer, Perkin-Elmer, Norwalk, CT).

[a]Teklad Test Diets, Madison, WI.

[b]Teklad (vitamin fortification mix) cat. no. 40060, Teklad Test Diets, Madison, WI. Composition of vitamin mix was (in grams/kilogram): p-amino-benzoic acid, 11.0132, ascorbic acid, coated (97.5%), 101.6604, biotin, 0.0441, vitamin B-12 (0.1% trituration in mannitol), 2.9736, calcium pantothenate, 6.6079, choline dihydrogen citrate, 349.6916, folic acid, 0.1982, inositol, 11.0132, menadione (vitamin K3), 4.9559, niacin, 9.9119, pyridoxine/HCl, 2.2026, riboflavin, 2.2026, thiamine/HCl,2.2026, dry vitamin A palmitate (500,000 U/g), 3.9648, dry ergocalciferol (500,000 U/g), 0.4405, dry vitamin E acetate (300 U/g), 24.2291 and cornstarch, 466.6878.

Hearts and livers were removed from individual rats, frozen at −10°C, lyophilized, transferred to crucibles (Vycor Brand, Corning Glass Works, Corning, NY) and ashed at 450°C in a muffle furnace. The residue remaining after ashing was dissolved in 2.0 ml concentrated HCl (reagent grade, Fisher Scientific, Fair Lawn, NJ) and then diluted with 0.12 N HCl, as required, to perform copper and iron analyses by flame atomic absorption spectroscopy. Copper and iron contents of the diets were also measured by flame atomic absorption spectroscopy after ashing at 450°C.

Fatty acid analyses. Lipids of liver, heart and serum were analyzed in the copper study. Only liver and serum lipids were analyzed in the iron study. The tissues and serum were frozen immediately and stored at −20°C, until shipment on dry ice to the Hormel Institute, Austin, MN, for lipid analysis.

Lipids were extracted from the samples with chloroform/methanol (2:1, v/v) and the PL separated from the neutral lipids using silicic acid plates developed in petroleum ether/diethyl ether/acetic acid (80:20:1) (12). The PL were converted to fatty acid methyl esters (FAME) and were analyzed on a Packard GC 428 gas chromatograph using a 50 m × 0.22 mm FFAP fused silica capillary column (Scientific Glass Engineering, Austin, TX) and the same operating conditions as described (12). Relative percentage composition was calculated for the FAME, and peak identifications were made by comparing with authentic FAME standards.

Data were evaluated by analysis of variance followed by Tukey's studentized range test (13).

RESULTS

The CuD and FeD rats did not consume less food than CuA and FeA rats, respectively. On day 42 of the dietary regimen, the CuD, CuA and CuE rats consumed equivalent amounts of food (21 ± 1.7, 24 ± 0.8 and 22 ± 0.6, g/day ± SE) and gained equivalent weight (274 ± 15.8, 302 ± 12.9 and 293 ± 9.8, g ± SE), respectively. Similarly, on day 42 of the dietary regimen, FeD, FeA and FeE rats consumed equivalent amounts of food (21 ± 2.5, 22 ± 1.1 and 21 ± 1.0, g/day ± SE) and gained equivalent weight (252 ± 11.8, 281 ± 12.4 and 270 ± 12.4, g ± SE), respectively. Because of equivalent food intake by deficient and adequate rats, data for the PF groups are not presented.

Copper. Copper concentrations were decreased in serum, liver and heart of CuD rats (Table 2). The copper concentration of serum was equivalent for CuA and CuE rats, but increased in liver and heart of CuE rats.

Few differences in fatty acid patterns of PL were found in tissues of CuD and CuA rats (Tables 3-5). Relative percentages of 18:2ω6 and 20:4ω6 were not different in tissues from CuD and CuA rats. In CuD and CuA rats, 16:0 and 18:0 in PL were similar for heart and serum. In liver, 16:0 was unchanged and 18:0 was increased in CuD rats. 16:1ω7, the Δ9 desaturation product formed from 16:0, was significantly lower in liver, heart and serum PL of CuD than CuA rats. 18:1ω9, the Δ9 desaturation product formed from 18:0, was unchanged in tissues of CuD rats. Total Δ9 desaturation products, which include all fatty acids formed by Δ9 desaturation, were lower in liver and serum (but not heart) of CuD than CuA rats. The final metabolic product formed from serial desaturation and elongation of 18:0 (20:3ω9) was not different in tissues from CuD and CuA rats; also, 22:6ω3 was not significantly different in heart or serum.

The total metabolites formed from a single essential precursor showed limited differences in tissues from CuD and CuA rats. Total ω6 metabolites are those formed from serial desaturation and elongation of 18:2ω6. Total ω3 metabolites are those formed from serial desaturation and

TABLE 2

Copper Content in Serum, Liver and Heart of Copper-Adequate (CuA), Copper-Deficient (CuD) and Copper-Excess (CuE) Rats (Mean ± SE)

Tissue	Units	Diet groups CuA (n = 10)	CuD (n = 10)	CuE (n = 10)
Serum	μg/dl	146.0 ± 3.8[a]	1.0 ± 0.0[a,b]	136.5 ± 4.7[b]
Liver	μg/g	13.8 ± 0.2[a]	2.5 ± 0.3[a]	16.2 ± 0.4[a]
Heart	μg/g	21.2 ± 0.2[a]	6.7 ± 0.4[a]	23.4 ± 0.4[a]

Values with similar superscripts are significantly different at $p < 0.05$.

TABLE 3

Fatty Acid Contents in Liver Phospholipids (Relative %, Mean ± SE) in Copper-Adequate (CuA), Copper-Deficient (CuD) and Copper-Excess (CuE) Rats

Fatty acid	Diet groups CuA (n = 10)	CuD (n = 10)	CuE (n = 5)

elongation of linolenic acid (18:3ω3). Total ω9 metabolites are those formed from 18:1ω9. Total ω6 metabolites were not different for CuD and CuA rats. Total ω3 metabolites for liver and heart were not different in CuD and CuA rats, but were elevated in serum of CuD rats. Total ω9 metabolites were not different for liver, heart or serum of CuD and CuA rats.

Intake of excess copper did not cause a significant increase in Δ9 desaturation. Only 16:1ω7 in heart PL was increased. Except for reduced 16:0 in liver of CuE rats, 16:0 and 18:0 were equivalent in tissues of CuA and CuE rats. 18:2ω6 was lower in hearts of CuE than CuA rats, but not in liver or serum. 20:4ω6 did not differ in tissues of CuA and CuE rats. Only in liver, were total ω6 metabolites higher in CuE rats than CuA rats. Total ω3 and ω9 metabolites and Δ9 desaturation products were not different for tissues of CuA and CuE rats.

To illustrate the maximum possible effects of copper, Figure 1 shows the normalcy ratio (NR, ratio of experimental value to the control value) profile of relevant fatty acids in liver PL of CuD compared with CuE rats. In CuD rats, 20:4ω6 and total ω6 metabolites were lower ($p < 0.05$) than in CuE rats; but, in liver of CuD rats, 16:0 and 18:0 were higher ($p < 0.05$) than in CuE rats. The NR profile for heart and serum PL of CuD rats compared with CuE rats showed only a significant decrease ($p < 0.05$) in heart 16:1ω7 (figure not shown).

Iron. Hematocrits and iron concentrations of serum and liver were decreased in FeD rats (Table 6). Only liver iron was increased in rats fed excess iron.

Fatty acid compositions of PL in liver and serum from FeD, FeA and FeE rats are given in Tables 7 and 8. In liver and serum of FeD rats, 18:2ω6 was higher than in FeA rats. FeD rats showed lower serum 20:4ω6 than FeA rats. Liver and serum 16:0, 18:0, 16:1ω7 and 18:1ω9 were similar for FeD and FeA rats. Liver and serum 22:6ω3 were higher in FeD than in FeA. Total ω3 metabolites of liver and serum were higher for FeD rats than FeA rats.

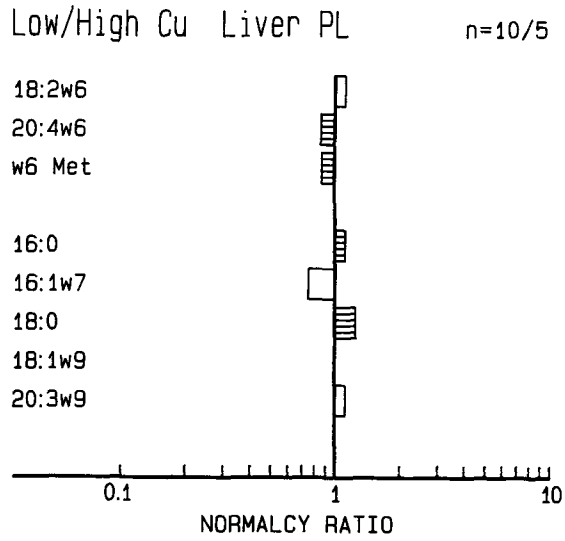

FIG. 1. Normalcy ratio profile of animals fed low-copper diet (CuD) compared with high-copper diet (CuE). Horizontal shading indicates significance at $p < 0.05$; open bars are not significant.

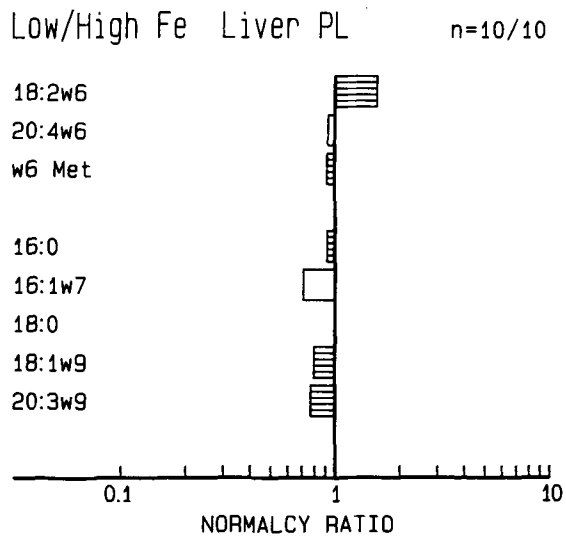

FIG. 2. Normalcy ratio profile of animals fed low-iron diet (FeD) compared with high-iron diet (FeE). Horizontal shading indicates significance at $p < 0.05$; open bars are not significant.

Paris with same superscript are significantly different than each other at $p < 0.05$.

Serum total ω6 metabolites were lower for FeD rats than FeA rats. Liver and serum total Δ9 desaturation products and ω9 metabolites for FeD and FeA groups were not different. Intake of excess iron caused higher liver 20:3ω9 and lower serum 18:2ω6 in FeE than FeA rats (Tables 7 and 8).

To illustrate the maximum possible effects of iron, the NR profile of relevant fatty acids in liver PL of FeD compared with FeE rats is shown in Figure 2. FeD liver had higher 18:2ω6 than FeE liver. Total ω6 metabolites, 16:0, 18:1ω9 and 20:3ω9, were lower in liver of FeD than FeE rats. The NR profile for serum showed higher 18:2ω6, and decreased total ω6 metabolites in FeD compared to FeE rats, but no other differences in serum PL (figure not shown).

DISCUSSION

Wahle et al. (14) reported decreased ratios for monounsaturated to saturated fatty acids of both C_{16} and C_{18} chain lengths in subcutaneous adipose tissue from CuD rats. They also reported decreased desaturation of stearic to oleic acid by liver microsomes from CuD animals (14). The ratio of oleic to stearic acid was higher in the whole back fat of pigs given a copper supplement (15). In the current study, few consistent significant differences in fatty acid composition occurred in the tissues and serum of CuD animals. The ratios were calculated for the product/precursors of 16:1ω7/16:0 and 18:1ω9/18:0. Only a decreased 16:1ω7/16:0 ratio was found in the liver of CuD animals.

When compared with CuA rats, CuD rats showed only elevated liver 18:0 and depressed liver, heart and serum 16:1ω7. When the extremes of copper deficiency and copper excess were compared, CuD rats exhibited elevated liver 16:0 and 18:0 and depressed heart 16:1ω7. If copper was a cofactor for Δ9 desaturation, a larger difference in the precursors and products of Δ9 desaturation, that is, 16:0, 18:0, 16:1ω7 and 18:1ω9, should have occurred between CuD and CuE rats than between either CuD and CuA or CuA and CuE rats, because desaturation in CuD rats would have been inhibited by low copper and enhanced in CuE rats by high copper. However, neither of the studies showing the effect of copper on Δ9 desaturation in the adipose tissue of rats or pigs (14,15) reported the fatty acids of liver or heart. Adipose tissue lipid is largely triglyceride, and oleic acid is the principal fatty acid. On the other hand, polyunsaturated fatty acids are major components of PL which are the major lipids of liver, heart and serum. If copper is a required cofactor for desaturation from stearic to oleic acid, its effect may be more pronounced in the adipose tissue that accumulates the product. Lawrence et al. (16) analyzed the fatty acid composition of rat liver mitochondria and found only slightly less 20:4ω6 and more 22:5ω6 in CuD than CuA rats. They found no increase in 18:0 and no decrease in 18:1ω9 (16). PL synthesis in liver mitochondria was shown to be depressed by copper deficiency (17), which could help explain the minimal changes of fatty acids found in our study of the liver, heart and serum PL. The changes in fatty acids caused by diminished Δ9 desaturation may not be expressed in the membranes of liver and heart because of the depressed synthesis of PL.

Some previous studies of iron deficiency in rats have shown decreased percentages of 16:0, 16:1ω7, 18:0 and 18:1ω9 and increased 18:2ω and 20:4ω6 in tissue lipids (10). Cunnane and McAdoo showed higher linoleic acid in plasma PL and triglycerides of FeD rats and no difference in liver fatty acid composition (18). The present study revealed a significantly higher content of 18:2ω6 in liver and serum PL of FeD than in FeA rats. Excess iron caused reduction of 18:2ω6 in serum of FeE rats. Saturated and monounsaturated fatty acids were generally lower in FeD rats than in FeE rats, but were not significant (Fig. 2). If iron was a required cofactor for Δ9 desaturation, there should have been more consistent, significant differences in the levels of 16:1ω7 and 18:1ω9 between FeD and FeE groups.

The present study did not confirm the requirement for copper or iron in the Δ9 pathway of fatty acid desaturation as indicated in phospholipids. A few significant changes in the saturated and monoenoic fatty acids affected by Δ9 desaturase occurred, but these were inconsistent in the various tissues studied. Possibly, the failure of the present study to show these consistent, significant changes in Δ9 desaturase found previously (14,15,18) could be due to the differences in the tissues and lipid classes chosen for analysis in the various studies.

Bradykinin-Increased Phospholipid Deacylation-Reacylation in Rat Renal Medulla is Inhibited by dBc AMP

Norma Sterin-Speziale*, Verónica L. Kahane, Clara P. Setton and Emir H. Speziale
Departamento de Quimica Biológica, Orientación Quimica Biológica Patólogica, Facultad de Farmacia y Bioquimica, UBA. Junin 956, 1113 Buenos Aires, Argentina

The effect of bradykinin on the mobilization of arachidonic acid was analyzed separately by acylation and degradation.

Acylating activity was determined by the incorporation of [^{14}C]arachidonic acid into the phospholipids at different times. Different concentrations of bradykinin had no effect on the phospholipid acylating activities.

The degradation of the phospholipids was performed on renal medullary slices prelabeled with [^{14}C]arachidonic acid. Treatment with bradykinin produced an initial degradation of phosphatidylcholine, phosphatidylethanolamine and phosphatidylinositol, with a concomitant increase in lysophosphatidylcholine, lysophosphatidylethanolamine and lysophosphatidylinositol within 5 min of incubation. Phosphatidylcholine-, phosphatidylethanolamine- and phosphatidylinositol-labeling increased thereafter and reached the control values after 10 min of incubation.

After 30 min, incubation of prelabeled slices with bradykinin produced a significant concentration-dependent increase in the phospholipid-labeling by reutilization of [^{14}C]arachidonic acid.

The effect of bradykinin on the phospholipid-labeling was blocked by preincubation with increasing concentrations of dBc AMP.

Mepacrine also blocked the bradykinin stimulation in phosphatidylcholine and phosphatidylethanolamine, but had no effect on bradykinin-induced changes in the phosphatidylinositol arachidonic acid moiety.
Lipids 24, 146–150 (1989).

When different cell types are activated, one of the early changes observed is the increased turnover and metabolism of unsaturated fatty acyl moieties of membrane phospholipids. Metabolism of arachidonic acid (AA) to prostaglandins via the cyclooxygenase enzyme system is one of the responses to such triggering stimuli. Because the level of free AA in the cells is generally very low, the synthesis of prostaglandins is limited by the availability of the free AA after it is released from membrane phospholipids (1,2).

The stimulatory effect on renal prostaglandin synthesis exerted by bradykinin (BK) is very important for the renal function modulation (3). It has been postulated that this stimulatory effect is produced by inducing renal phospholipase activity (4–6). Replenishment of phospholipids deacylated by these phospholipases occurs through the reacylation of lysophosphatides (7). This replenishment is essential for the integrity of membrane structure (8), and its efficiency may determine the extent to which the phospholipase mechanism can be utilized for maintaining high levels of prostaglandins. Because arachidonate is an essential fatty acid, the continuous supply for phospholipid replenishment must come from an exogenous source (9).

The precursor of prostaglandins is a part of a cyclic biochemical process that involves three different steps: a) an acylation reaction for the incorporation of plasma AA into phospholipids, b) an active deacylating process that uses these phospholipids as substrate and c) a coupled and efficient reacylating system that maintains membrane integrity.

In the present study, we present evidence of the bradykinin effect on all these processes in rat renal medullary slices.

MATERIALS AND METHODS

[^{14}C]AA (specific activity 52.8 mCi/mmol) was obtained from New England Nuclear (Boston, MA); and phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS), phosphatidylinositol (PI), lysophosphatidylcholine (LPC), lysophosphatidylethanolamine (LPE) and lysophosphatidylinositol (LPI) were obtained from Supelco (Bellefonte, PA). Silica Gel H plates (0.25 mm thick) were purchased from Applied Science (State College, PA) and Silica Gel G plates (0.25 mm thick) from Brinkmann Instruments, Inc. (Westbury, CT). Bradykinin, mepacrine (MP) and dibutyril cyclic adenosine monophosphate (dBc AMP) were provided by Sigma Chemical Co. (St. Louis, MO), and X-ray films for autoradiography were from Eastman Kodak Company (Rochester, NY).

Bradykinin effect on rat renal medullary phospholipid labeling. After decapitation of male Sprague-Dawley rats (250–280 g), both kidneys were removed and maintained on ice-cold Krebs solution. Each kidney was cut in half through its longitudinal axis and the renal medulla was separated by scissor and scalpel dissection (10). The renal medullary tissue was sliced (ca. 0.5 mm thick) using a Stadie-Riggs microtome. For each experiment, 100 mg of tissue slices were collected in 1.25 ml of Krebs Ringer bicarbonate buffer containing 5.5 mM of glucose. The medium was gassed with carbogen (95% O_2, 5% CO_2). Samples were incubated at 37°C with 0.25 μCi of [^{14}C]AA in a metabolic shaking bath under an atmosphere of carbogen for different lengths of time. In some experiments, the influence of BK on this acylation reaction was investigated. In these cases, the slices were preincubated with various concentrations of BK at 37°C for 10 min before the addition of AA. The reactions were stopped by the addition of 4.0 ml of chloroform/methanol (1:2, v/v) (11). The samples were homogenized in glass tubes with Teflon pestles at 3,000–3,500 rpm. Phases were split by adding 1.25 ml of water (12). In the

Abbreviations: AA, arachidonic acid; BK, bradykinin; dBc AMP, dibutyril cyclic adenosine monophosphate; LPC, lysophosphatidylcholine; LPE, lysophosphatidylethanolamine; LPI, lysophosphatidylinositol; MP, mepacrine; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; TLC, thin layer chromatography.

experiments measuring LPI, the extraction was performed using chloroform/methanol/concentrated HCl (50:100:1, v/v), and the phases were separated by adding 0.6 ml of chloroform and 0.6 ml of 2 M KCl (13). The lower chloroform phases were removed. The inorganic phases were washed twice with chloroform and the organic phases were pooled and dried under a stream of nitrogen at 25°C. This extraction procedure ensures 80–85% recovery of the lipids. The extracts were submitted to thin layer chromatography (TLC) and quantitated as will be described.

Effect of BK on deacylation and reacylation of prelabeled slices. The slices prelabeled for 60 min were removed from the tubes and washed three times with ice-cold fresh Krebs' solution containing 10% albumin. The labeled slices were incubated with BK for different lengths of time. However, when the influence of dBc AMP or MP on the degradation of the phospholipids was investigated, the labeled slices were preincubated with these compounds for 10 min. Appropriate control incubations were done in the presence of diluents instead of drug solutions. The reactions were stopped as previously described. Then, the tissues were homogenized and the lipids extracted as described for the acylation. The extracts were separated by TLC.

Chromatographic lipid separation. The labeled phospholipid extracts were redissolved in chloroform, applied onto activated Silica Gel H TLC plates (0.25 mm thick) and developed in a solvent system consisting of chloroform/methanol/acetic acid/water (75:45:12:3, v/v/v/v) (14). In this solvent system, PI and PS migrated as a single spot, whereas PC, PE, LPC, LPE and sphingomyelin were well separated.

Separation of PI from PS was achieved by two-dimensional chromatography on 1% ammonium oxalate-impregnated Silica Gel H plates using the previous solvent system in the first dimension and chloroform/methanol/13.5 N ammonia/water (70:30:0.5:4, v/v/v/v) in the second dimension (15).

The LPI was separated on thin layer Silica Gel G plates impregnated with 1% potassium oxalate containing 2 mM ethylenediaminetetraacetic acid using chloroform/methanol/4 N NH_4OH (45:35:10, v/v/v) (16).

For the separation of neutral lipids and free fatty acids, the upper phase of a mixture of ethyl acetate/2,2,4-trimethylpentane/acetic acid/water (9:5:2:10, v/v/v/v) as a solvent system was used. The migration of the lipids was detected by I_2 vapors or autoradiography, as appropriate.

The positional distribution of the incorporated, labeled fatty acid was analyzed by the degradation of PC, PE or PI with phospholipase A_2. The enzyme activity was evaluated as previously described (14). The amount of radioactivity recovered from the phospholipids and the free fatty acid fraction indicated that the fatty acid was incorporated in position 2 of the phospholipid molecule. The degradation rate exceeded 96%. No spontaneous hydrolysis of the phospholipids was observed in controls under identical conditions without addition of phospholipase A_2.

Quantitation. Zones of the TLC plates corresponding to the various phospholipids fractions were scraped off and added to 5.0 ml of a toluene-omnifluor 0.4% mixture. Quantitation was performed in a liquid scintillation counter. Counting efficiency for ^{14}C was 75%.

For the quantitation of the individual lysophospholipids, specific areas of the plates were digested with 70% of perchloric acid and the resulting inorganic phosphate was assayed (17).

Areas of silica gel were used as blanks for cpm or phosphorus assay and the results were corrected by subtraction of blank values from all samples.

All results were compared by Student's t test, and differences were considered statistically significant when p values were less than 0.05.

RESULTS

[^{14}C]AA incorporation. Effect of BK. Fatty acid incorporation into phospholipids appears to be a rapid phenomenon (Fig. 1), because 35–45% of the maximal radioactivity incorporated into the phospholipids is present within 5 min of incubation. The equilibrium is reached at 60 min of incubation, when the maximal incorporation of radioactivity is achieved. Of the phospholipids studied, PC accounts for most of the radioactivity (60%). A smaller amount of AA is incorporated into PE (19%). PI incorporates 21%, and no radioactivity is associated to PS.

The addition of BK for 10 min prior to labeling does not affect the time course of AA incorporation into the renal medullary phospholipids at any concentration studied 0.5–2.0 μg/ml).

Bradykinin-induced changes in radioactive phospholipids. Figure 2 shows the time course degradation of PC,

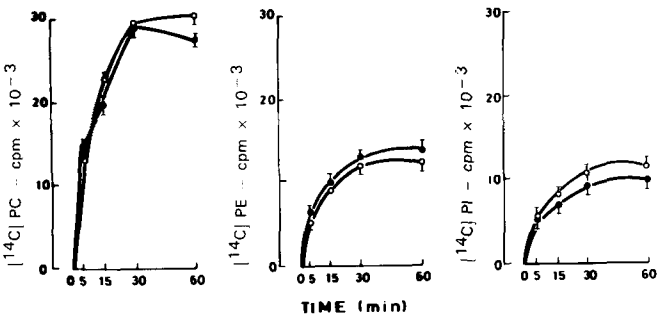

FIG. 1. Time course incorporation of [^{14}C]AA on rat renal medullary phospholipids—the BK effect. Tissue slices were incubated with [^{14}C]AA in the absence (○) and the presence (●) of BK (1 μM) for different lengths of time. Each point represents the mean of 5 experiments ± SE.

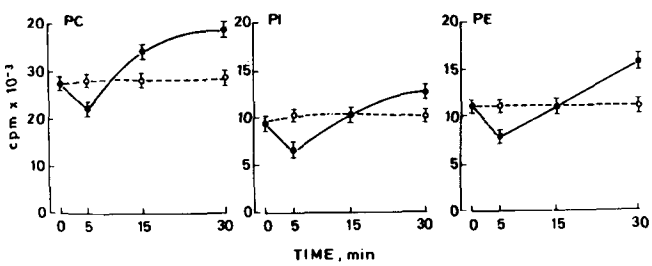

FIG. 2. Effect of BK on prelabeled rat renal medullary phospholipids. The slices prelabeled with [^{14}C]AA during 60 min were incubated in fresh Krebs' solution in the absence (○) and presence (●) of BK for different lengths of time. Each point represents the mean of 5 experiments ± SE.

PI and PE prelabeled with [^{14}C]AA. In the experiments achieved with BK (1.0 μg/ml), a transient decrease of radioactivity was observed within 5 min. This degradation was followed by a considerable increase in the labeling of the phospholipids. The BK action was observed in PC, PE and PI. Phosphatidylserine does not participate in this phenomenon. No change of radioactivity was observed in the absence of BK.

Table 1 shows the increase in the net amount of lysophospholipids as a consequence of the BK-effect. This increase, together with the decrease of radioactivity in the phospholipids, reflects the degradation of phospholipids. No radiolabeled lysophospholipids were detected. Because AA is incorporated into position 2 of the phospholipids, the lack of lysophospholipid radioactivity indicates that no phospholipase A_1 activity was present.

The reacylation of the phospholipids, shown by the increase of the labeling at 30 min of incubation, was analyzed at different concentrations of BK. In Figure 3, a concentration-dependent increase in PC-, PI- and PE-labeling can be observed ($p < 0.05$), with a maximal stimulation up to 39.8%, and 32.7% of the control values in PC, PI and PE, respectively.

Table 2 shows that arachidonate is very efficiently incorporated into triglycerides and, after 60 min of incubation, a considerable amount of radioactive fatty acid remains in a free form in the system. This free fatty acid is not extractable by washing with albumin. After treatment with bradykinin, a decrease of radioactivity in the free fatty acid pool and in the triglycerides was observed.

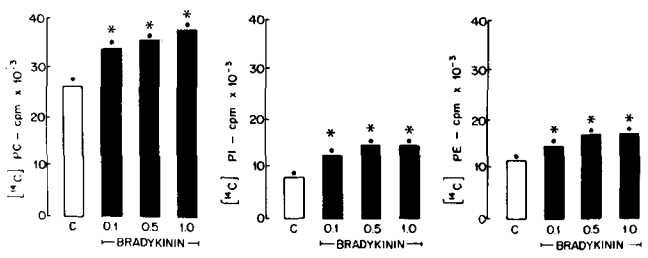

FIG. 3. Effect of BK on prelabeled rat renal medullary phospholipids. The slices prelabeled with [^{14}C]AA were incubated for 30 min in the presence of different concentrations of BK. Each bar represents the mean of 5 experiments ± SE.

MP inhibits the BK effect on PC and PE, but not the effect on PI. MP at 0.1-mM concentration blocks the effect of BK on medullary PC by 72%. At 0.5 mM, a complete inhibition is observed; but at a higher concentration of MP (1.0 mM), a decrease of radioactivity is shown, reaching values even lower than those obtained in the absence of BK. A similar pattern is observed with PE, but the value reached at 1 mM MP is not lower than the one obtained in the absence of BK (Fig. 4). On the contrary, MP (0.1 mM) failed to block the BK increase of radioactivity on PI. Moreover, at higher concentrations, it produced a significant ($p < 0.05$) stimulation of labeling.

dBc AMP blocks the BK effect on medullary phospholipids. Different concentrations of dBc AMP (0.05–0.1 M) prevented the BK-labeling increase of PC, PI and PE.

The dBc AMP lower concentration (0.05 M) exerted a partial blockade, but, at higher concentrations, a total inhibition was observed (Fig. 5). A single concentration of

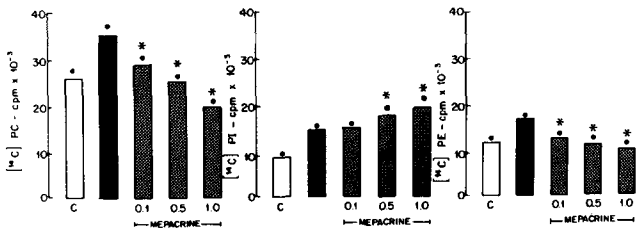

FIG. 4. Effect of MP on BK-stimulation of rat renal medullary phospholipids. The slices prelabeled with [^{14}C]AA were preincubated with different concentrations of MP and then incubated for 30 min in the presence of 1 μg/ml of BK. Each bar represents the mean of 5 experiments ± SE.

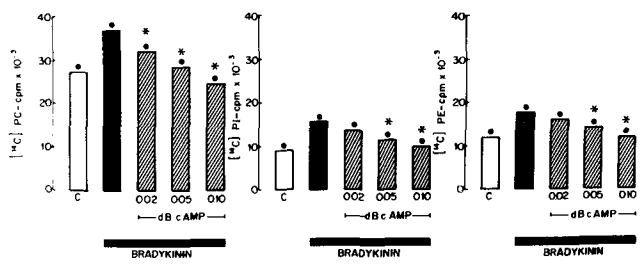

FIG. 5. Effect of dBc AMP on BK-stimulation of rat renal medullary prelabeled slices. The slices prelabeled with [^{14}C]AA were preincubated with different concentrations of dBc AMP and then incubated for 30 min in the presence of 1 μg/ml of BK. Each bar represents the mean of 5 experiments ± SE.

0.1 M dBc AMP also prevented the breakdown of the various phospholipids observed after 5 min of incubation (data not shown).

DISCUSSION

Bradykinin is an important physiological stimulator of the renal prostaglandin synthesis (3), and it has been generally accepted that this hormone exerts its stimulatory effect through phospholipase A_2 activation (4-6,18).

The present paper was aimed at obtaining direct evidence on the ability of BK to influence the mobilization of the prostaglandin precursor, AA. Arachidonic acid is introduced into phospholipids by acylation of the lysophospholipids, rather than by de novo synthesis (18-21).

Our studies of incorporation of AA showed that, under the conditions used, the acylation step is active in rat renal medullary phospholipids, and BK does not influence this enzymatic step (Fig. 1).

To determine the effect of BK on the activation of the deacylation-reacylation cycle, slices prelabeled with [^{14}C]AA were prepared and reincubated in physiological medium. This study demonstrates that BK perturbs the deacylation-reacylation cycle.

We have previously shown (4) that AA is incorporated at position 2 of the phospholipids. Therefore, the transient degradation of the radiolabeled phospholipids promoted by BK (Fig. 2), with the concomitant increase of the corresponding nonradioactive lysophospholipids, can be considered a sign of phospholipase A_2 activation. This result may represent a direct evidence of the generally accepted concept that BK exerts its prostaglandin synthesis stimulatory effect through phospholipase A_2 activation (4-6,18). On the other hand, the breakdown of the phospholipids promoted by BK is followed by what appears to be a compensating resynthesis (Figs. 2 and 3). The most reasonable interpretation of these data encompasses the concept that both components of the deacylation-reacylation cycle, a membrane bound phospholipase A_2 and an acyl-CoA transferase, increase their activities in the presence of BK.

To determine the source of the fatty acid used during the bradykinin stimulation, we explored the mobilization of the arachidonate from the triglyceride and the free fatty acid pool. Under these conditions, a decrease of radioactivity in both of them is observed, perhaps indicating that the free arachidonate and/or the triglyceride pool could act as the source of the fatty acid.

We used MP to ascertain the relative implication of phospholipase A_2 in the reacylation evoked by BK. Although MP is considered to be an inhibitor of phospholipase A_2, and it has been used to differentiate phospholipase A_2 from phospholipase C activities (22), it is not possible to analyze the effect of MP from this exclusive point of view.

The data indicate (Fig. 3) that BK exerts its effects on PI even in the presence of 1 mM of MP and completely blocks the action on PC and PE. One interpretation of these results is the possibility that the BK increase of reacylation on PI occurs through a mechanism distinct from the one that operates on PC and PE. Therefore, MP would produce a selective inactivation of such processes, maybe as the consequence of different phospholipase A_2 activities.

However, this interpretation is only speculative, because in our experience, MP alone exerts mobilization of AA from the kidney phospholipids by a mechanism independent of phospholipases (manuscript in preparation). Moreover, Dise et al. reported a direct interaction of MP with erythrocyte and platelet phospholipids (23).

On the other hand, dBc AMP exerts a concentration-dependent blockade in both effects of bradykinin: the deacylation (a reflection of the phospholipase A_2 activation) and the recomposition of the renal phospholipids. This inhibition is effective on PC, PE and PI. The mechanism by which dBc AMP produces this inhibition could be related to our previous observations that bradykinin induces PI-specific phospholipase C activity in rat renal medulla. The stimulation of this phospholipase C occurs at 2 min and is prevented by dBc AMP (24). From these two observations, we suggest that the bradykinin stimulation of the breakdown and recomposition of the kidney phospholipids, as presented here, could be secondary to the stimulation of phospholipase C. Therefore, in rat renal medulla, BK could stimulate a sequence of reactions that involves both phospholipase C and A_2 activation. Such a sequence of reactions has been described for thrombin in platelets (25).

Of interest, is the absence of BK stimulation in the acylation process.

One adequate explanation could be that the AA incorporated into phospholipid during deacylation-reacylation (Fig. 2) arises from an intermediate pool (such as triglycerides) which has not become sufficiently labeled to show transfer to phospholipids under the conditions of acylation (Fig. 1).

Dietary Induction of Cholesterol Gallstones in Hamsters From Three Different Sources

Bertram I. Cohen*, Naoyuki Matoba, Erwin H. Mosbach and Charles K. McSherry
Departments of Surgery, Beth Israel Medical Center and the Mount Sinai School of Medicine of the City University of New York, New York, NY 10003

Cholesterol gallstones were produced in young male, golden Syrian hamsters, obtained from three different suppliers, by administering a nutritionally adequate, semipurified diet for periods of either 5 or 10 weeks. The major components of the lithogenic diet were casein, cornstarch, butterfat, corn oil and 0.3% cholesterol. The hamsters were obtained from Sesco, Harlan Sprague-Dawley (Engle hamster) and Charles River (Lakeview hamster). There were profound differences among the three groups with respect to gallstone formation and cholesterol metabolism: The highest incidence of gallstones occurred in Sesco hamsters, 44.4% and 63.6% after 5 and 10 weeks on the lithogenic diet, respectively. In the Engle hamster, after a 5-week feeding, cholesterol crystals and gallstones were absent. When the feeding period was extended to 10 weeks, cholesterol gallstones were present in 45.5% of the animals. In the Lakeview hamsters, neither gallstones nor cholesterol crystals were found in the gallbladder after a 5-week period. After 10 weeks, cholesterol gallstones were found in only a single hamster. In all groups, the lithogenic diet produced large increases of liver, serum and biliary cholesterol concentrations and increased liver weights. When the animals were fed for 5 weeks, only the bile of Sesco hamsters became supersaturated. Supersaturated bile was induced in all groups after a 10-week feeding of the lithogenic diet with cholesterol saturation ranging from 1.47 to 1.97. These data indicate that it is possible to induce cholesterol gallstones in hamsters by means of a nutritionally adequate, semipurified diet of moderate cholesterol content. The source of the animals appears to be an important variable, because there were significant differences among the hamsters of differing origins, in cholesterol metabolism and rates of gallstone formation.
Lipids 24, 151-156 (1989).

Cholesterol cholelithiasis has been studied for many years, yet the mechanism of gallstone formation is still not fully understood. In order to elucidate its cause and to produce and evaluate new cholelitholytic agents, several animal models of cholesterol gallstones have been studied, for example, the squirrel monkey (1), prairie dog (2,3), hamster (4,5) and mouse (6). Hamsters are small, easy to handle and have a bile acid composition similar to that of man (7), which makes the hamster a useful model. Two hamster models of cholesterol gallstone disease have been described by Dam and Christensen (4) and by Pearlman et al. (5). The former model used a fat-free, nutritionally inadequate diet that inhibited normal growth of the animals and frequently resulted in premature deaths, whereas the latter was not readily reproducible. It is known, however, that hamsters from different commercial suppliers differ in their susceptibility to gallstone disease and exhibit differences in the metabolism of cholesterol and the other biliary lipids (8,9). The present study was designed to determine whether significant differences in cholesterol gallstone formation and cholesterol metabolism existed among male, golden Syrian hamsters from three suppliers. We now report that a nutritionally adequate semipurified diet of moderate cholesterol content induces cholesterol gallstones at widely divergent rates in these groups of hamsters. This model should prove useful for investigating mechanisms of gallstone formation and for developing and testing new bile acids and bile acid analogs designed to prevent or dissolve gallstones.

MATERIALS AND METHODS

Male, golden Syrian hamsters *(Mesocricetus auratus),* 4 wk of age, were obtained from three different suppliers, namely Sesco Inc., Omaha, NE (Sesco hamster, golden Syrian outbred hamster derived from closed colony from the University of Nebraska Medical Center, Eppley Cancer Institute); Harlan Sprague-Dawley, Indianapolis, IN (Engle hamster, golden Syrian brown and white outbred hamster derived from a nucleus colony obtained from the National Institutes of Health); and Charles River Breeding Labs, Wilmington, MA (Lakeview hamster, golden Syrian outbred hamster descended from two original colonies acquired in 1949 and 1951). During a 1-wk quarantine period the animals were maintained with Purina Rodent Chow and water ad libitum. The animals from each supplier were divided into two groups and maintained with a semipurified diet (SPD) (control diet: groups I, III and V) or SPD containing 0.3% cholesterol (cholesterol diet: groups II, IV and VI) (Dyets Inc., Bethlehem, PA). One kg of diet contained 200 g casein, 20 g corn oil, 40 g butterfat, 434 g cornstarch, 146 g Dyetrose (soluble starch), 100 g fiber (cellulose), 50 g salt mix (modified USP XIV salt mix, #200951), 5 g vitamin mix (#300000), 2 g choline chloride, with or without 3 g cholesterol. Cholesterol was added at the expense of cornstarch. Food and water were given ad libitum, and the animals were kept under an alternating 12-hr light/dark cycle.

After a 5-wk feeding (short-term feeding), a portion of the animals of each group were killed according to the procedure described below. The remainder was continued on the same diets for 10 wk (long-term feeding).

At the end of the experiment, the animals were anesthetized with 20 mg ketamine hydrochloride (Bristol Labs, Syracuse, NY). Blood was withdrawn by cardiac puncture to determine the serum cholesterol concentration, and the animals were killed by exsanguination. The gallbladder was exposed and examined visually. When cholesterol gallstones were present, they could usually be seen through the gallbladder wall as yellowish-white

Abbreviations: GLC, gas liquid chromatography; LD, lithogenic diet; mol %, molar percentage; SPD, semipurified diet.

solids. Gallbladder bile was removed using a 50 μl Hamilton syringe. The gallbladder was excised and stones, if present, were removed and stored in a desiccator until analysis. In a few cases, the cystic duct was obstructed by a concrement and the gallbladder contained little bile. One drop of fresh bile and gallbladder contents were immediately examined under a polarizing microscope (Olympus MCHAP microscope, Olympus Corp., Lake Success, NY) to determine the presence of cholesterol crystals and gallstones (10). Bile samples were centrifuged at 2000 × *g* for 10 min, and aliquots were used for determination of biliary lipids. The liver was excised and weighed, and aliquots were removed for cholesterol determination.

A portion of bile was hydrolyzed with alkali (2 N NaOH), and biliary bile acids were determined as the methyl ester acetates using an SPB-5, 15 m capillary column (Supelco, Bellefonte, PA) attached to a Hewlett-Packard 5830A gas chromatograph (9). Biliary phospholipid concentration was determined by an enzymatic colorimetric procedure using the Wako phospholipid B kit (Wako Pure Chemical Industries, Ltd., Osaka, Japan). Cholesterol concentrations of bile, serum and liver were analyzed by gas liquid chromatography (GLC), using the trimethylsilyl ether derivatives (11). The gallstones were washed with distilled water, desiccated at 100°C in vacuum at least 3 days, then used for the determination of cholesterol content. The stones were placed in 2.0 ml 10% KOH in ethanol using 5α-cholestane as an internal standard and heated at 70°C for 1 hr. After the stones were completely dissolved, cholesterol was extracted with hexane and analyzed by GLC, using the procedure described above for biliary cholesterol.

Cholesterol saturation indices of bile were calculated using published methods (12,13). The data are reported as the mean ±SEM. Statistical differences among the groups were calculated using one-way analysis of variance followed by Student's t-test (14). The significance of differences in gallstone incidence was determined by chi-square (14).

RESULTS

Animals of the 12 experimental groups were fed the diets for 5 wk (short term) or 10 wk (long term). Food intake for each animal averaged 9 g/day. All animals were healthy throughout the experimental period and gained similar amounts in weight: 46.8 ± 1.9 g for the short-term animals and 49.3 ± 4.9 g for the long-term hamsters.

The incidence of gallstones and cholesterol crystals was determined at sacrifice by polarizing light microscopy (Table 1). Neither cholesterol gallstones nor biliary cholesterol crystals were found in any animals fed the cholesterol-free semipurified control diet (groups Ia and b; IIIa and b; and Va and b), irrespective of the duration of the feeding period. The addition of 0.3% cholesterol to the semipurified diet (lithogenic diet, LD) led to the production of cholesterol crystals and stones, but the incidence and course of development was not the same for the three groups. With the short feeding period, cholesterol gallstones were found only in Sesco hamsters (44.4%). In the Engle hamster, gallstones and cholesterol crystals were not detected. Similarly, the Lakeview hamsters had neither gallstones nor cholesterol crystals after a 5-wk feeding of the lithogenic diet.

The longer feeding period produced a higher incidence of gallstones in groups IIb and IVb receiving the lithogenic diet. In the Sesco hamster, there was a higher incidence of cholesterol crystals and stones (63.6%), significantly different in comparison with animals fed no cholesterol (group Ib). In the Engle group, 45% of the hamsters now had cholesterol gallstones. Attempts to

TABLE 1

Incidence of Gallstones and Cholesterol Crystals in Three Groups of Hamsters

Source	Group[a]	Diet[a]	No. of wk on diet	No. of animals	Incidence of biliary CH gallstones	Incidence of biliary CH crystals

	VIb	SPD + 0.3% CH	10	11	1/11	1/11

[a]Animals were fed a semipurified diet (SPD) or SPD plus cholesterol (CH) for 5 wk (short-term feeding; groups Ia–VIa) or 10 wk (long-term feeding; groups Ib–VIb). See Materials and Methods.

[b]Differs from groups IVa and VIa; $p < 0.01$, by chi-square test.

[c]Differs from corresponding control groups; $p < 0.005$, by chi-square test.

[d]Differs from group VIb; $p < 0.01$, by chi-square test.

[e]Differs from group VIb; $p < 0.01$, by chi-square test.

induce cholesterol stones in the Lakeview hamsters failed: only one animal of this group had cholelithiasis.

The size of stones varied from tiny sand-like solids to 2 mm in diameter. All the stones had a yellowish-white color and were hard to crush. To determine the cholesterol content of the stones, several samples were analyzed by GLC. These analyses revealed that the stones contained at least 70% cholesterol by weight.

The effect of the feeding period and dietary cholesterol content on liver weight and tissue cholesterol concentrations are shown in Table 2. In animals fed the lithogenic diet, liver weight, liver cholesterol, serum cholesterol and biliary cholesterol were increased, compared with those of the corresponding control groups; and all of these differences were statistically significant. In all groups, the liver cholesterol concentrations were markedly increased by cholesterol feeding: 8.5 to 27.7 times above that of the corresponding controls. The values for liver cholesterol appear to increase sharply for the first 5 wk (groups IIa, IVa and VIa) and then decline or increase slightly after 10 wk (IIb and IVb vs VIb, respectively). Average food intake did not change during the entire experiment. In comparison with Engle and Lakeview hamsters, the liver cholesterol levels of the Sesco hamster were the highest, both in the groups fed the semipurified diet alone (groups Ia and Ib) and in those fed the lithogenic diet (groups IIa and IIb). Biliary cholesterol levels exhibited changes paralleling those of liver cholesterol. Serum cholesterol levels were increased in animals maintained with the lithogenic diet. In addition, in the Engle hamsters, serum cholesterol levels were increased significantly by the longer feeding of the semipurified diet; there was a significant difference between groups IIIa and IIIb. A similar change was observed when comparing groups IVa and IVb. Lakeview hamsters also showed increasing values of serum cholesterol as the duration of the feeding period was increased.

Biliary lipid compositions and lithogenic indices are shown in Table 3. The total biliary lipid concentrations were, in most instances, not affected by the addition of 0.3% cholesterol to the semipurified diet. Sesco hamsters had greater total lipid concentrations than the other two groups. The molar percentage (mol %) of phospholipid in the Sesco groups seemed low in comparison with the other hamsters. In all groups fed the high cholesterol lithogenic diet, the mol % of biliary cholesterol was increased significantly compared with that of each corresponding control group.

The lithogenic indices were calculated from the total lipid concentration using a computer program and data depicted in Table 3. The cholesterol saturation of bile was below 1.00 in all six control groups (Ia and b; IIIa and b; and Va and b), although in the Engle and Lakeview hamsters, the lithogenic indices on the SPD alone showed a definite dependence on the length of the feeding period. (The values for groups IIIb and Vb were significantly higher than those of groups IIIa and Va, respectively.) After a 5-wk feeding of the lithogenic diet, all the Sesco hamsters had supersaturated bile (mean LI = 1.24). Long-term feeding of the lithogenic diet (10 wk) caused supersaturation of bile in all three groups of hamsters. All animals in groups IIb and IVb had lithogenic indices exceeding unity; 8 out of 10 animals in group VIb had bile with a lithogenic index above 1.0.

Table 4 shows the composition of the biliary bile acids. Total bile acid concentration was highest in the Sesco hamster. The percentages of four bile acids normally found in the hamster (cholic acid, chenodeoxycholic acid, deoxycholic acid and lithocholic acid) were very similar in all groups fed the semipurified diet. Feeding the lithogenic diet caused a decrease in cholic acid and a corresponding increase in chenodeoxycholic acid, although in some groups these differences were not significant.

DISCUSSION

Models of cholesterol cholelithiasis in the hamster have been described by Dam and Christensen (4) and Pearlman et al. (5). Hamster gallstone models are important. The biliary lipid and bile acid composition of the hamster is similar to that of man and, because of their small size, many animals can be studied simultaneously without using excessive amounts of synthetic bile acids or bile acid analogs that are being tested for their cholelitholytic properties. On the other hand, this model presents a disadvantage in that only small quantities of bile and gallstones are available per animal. Dam and Christensen (4) described the induction of cholesterol gallstones in young, growing golden Syrian hamsters by administering a fat-free, semipurified diet for about 6 wk. However, this model had two serious disadvantages: First, because of the lack of essential fatty acids in the diet, the animals did not gain weight and frequently a considerable proportion of the hamsters died from intestinal infections before completion of the experiment. Second, dihydroxy bile acids, chenodeoxycholic acid (15,16) and ursodeoxy-

cholic acid (17), shown to be cholelitholytic in man are ineffective in preventing or dissolving cholesterol gallstones in this model.

The model of Pearlman et al. (5) employed a chow diet supplemented with 0.24% cholesterol and small levels of ethinyl estradiol to obtain a 90% incidence of cholesterol gallstones during a period of 12 wk. (When the estrogen was omitted, the incidence was 50%.) The cholelitholytic dihydroxy bile acids (ursodeoxycholic acid and chenodeoxycholic acid) were effective in preventing or dissolving cholesterol gallstones. Unfortunately, probably because of a genetic change in these hamsters (the source of the hamsters was not reported), this model was not reproducible (18). Our laboratory had similar experiences with a hamster model of pigment lithiasis (9).

During studies designed to elucidate the dietary factors to establish a stable, reproducible model of pigment cholelithiasis in the hamster (9), we used semipurified diets containing various components including casein, cornstarch and butterfat, as exemplified by the cholesterol-free control diet used in the present study. This basal diet produced a 10–20% incidence of pigment stones in the Engle hamster; no pigment stones were found in the other two strains studied (9). However, when 0.3% cholesterol was added to this diet and fed to the hamsters for 5–10 wk, cholesterol gallstones developed in two of the three groups used, namely in the Sesco hamster and, to a lesser extent, in the Engle hamster (Table 1). This new model of cholesterol cholelithiasis has proved to be reproducible, uses a nutritionally adequate diet and does not require the administration of estrogens or other hormones. All of the 104 experimental animals gained weight at a normal rate and did not develop symptoms of disease or die during the feeding period used.

We reported previously that there were apparent strain differences between Lakeview hamsters and the BIO strain (Bio-Research Institute, Cambridge, MA) with respect to cholesterol metabolism (8). In that study, too, the BIO hamster model of prostatic hypertrophy (19) became nonreproducible, although differences in cholesterol metabolism persisted. In the present study, hamsters from three suppliers were used to investigate whether they differed with respect to cholesterol gallstone formation and cholesterol metabolism when a lithogenic diet was administered. Only Sesco hamsters had lithogenic bile at the end of 5 wk and exhibited a higher incidence of gallstones than the other two groups (Table 1). All hamsters had lithogenic bile at the end of 10 wk (Table 3). The lithogenic index, indicating supersaturation of bile with cholesterol, may explain in part the greater incidence of gallstones in the Sesco animals. In the other two strains, it took much longer for the bile to become supersaturated with cholesterol (Table 3). It cannot be concluded that more prolonged feeding of the lithogenic diet alone, particularly in the Lakeview hamsters, would lead to an increased incidence of cholesterol cholelithiasis. Factors other than cholesterol, such as nucleating/antinucleating proteins, gallbladder motility and mucus secretion in the gallbladder, may be involved in gallstone formation.

Sesco hamsters in the control groups (groups Ia and Ib) had higher concentrations of liver and biliary cholesterol than those of the other two strains. When the total weight of cholesterol per liver was calculated for all three groups (liver weight times liver cholesterol concentration), Sesco hamsters clearly accumulated higher amounts of cholesterol than the other hamsters. However, this finding alone does not enable us to conclude that there is a quantitative difference in hepatic cholesterol secretion among the three groups. It will be necessary to measure cholesterol secretion into the bile, before and after cholesterol feeding, to obtain definitive information on this point.

The parameters of cholesterol metabolism examined in the present experiment do not provide clear-cut clues to the differences in gallstone incidence observed in the three groups of hamsters. Tissue cholesterol concentrations and liver weights were all increased in the groups fed the lithogenic diet (Table 2), but the Sesco hamsters that had the highest degree of cholelithiasis did not differ greatly from the other two groups. Other investigators, including our group, have previously reported similar responses to high cholesterol diets in the hamster (20–22), although the intensity of the response appeared to be lower when a basal diet of rodent chow was used. It is noteworthy that in previous studies with the Engle and Lakeview hamsters, marked increases of serum and liver cholesterol were reported with diets similar but not identical to that used in the present experiment (9). The earlier experiments used diets containing cholesterol and ethinyl estradiol, but not butterfat and cornstarch; the former diet also led to high cholesterol saturation of bile, but only pigment stones were produced (9). The control diet used in the present experiment, which contained no cholesterol, nevertheless produced a significant increase of serum cholesterol in the Engle hamster (Table 2). There can be little doubt that the change from sucrose to cornstarch and partial substitution of butterfat for corn oil, plus the added cholesterol, played an important role in producing cholesterol cholelithiasis. Butterfat was reported to produce cholesterol gallstones in hamsters (23); complex carbohydrate (cornstarch) rather than simple carbohydrate was similar to the type of carbohydrate that produced cholesterol gallstones in another hamster model (5). The role of these same dietary components in gallstone formation has been described by Hashimoto (24), but the exact role of individual dietary components in stimulating the production of nucleating/antinucleating factors (mucin, protein) remains to be established.

In summary, cholesterol gallstones can be produced in the hamster, but the incidence seems to depend on the source from which the animals are obtained. This suggests that inherent genetic differences that alter the incidence of cholesterol cholelithiasis may exist in hamsters.

METHODS

Determination of Ethane and Pentane in Free Oxygen Radical-induced Lipid Peroxidation

O.M. Pitkänen[a,*], M. Hallman[a] and S.M. Andersson[a,b]

[a]Children's Hospital, Helsinki University Central Hospital, Stenbäckinkatu 11, 00290 Helsinki, Finland; and [b]Department of Medical Chemistry, University of Helsinki, Siltavuorenpenger 10, 00170 Helsinki, Finland

It has been proposed that ethane and pentane reflect free oxygen radical-induced lipid peroxidation. However, methodological difficulties limit the use of these gases for assessment of free oxygen radical activity. In the present report we describe an improved method for the accurate analysis of picomole quantities (≥1 pmol) of ethane and pentane. They are first quantitatively trapped into an adsorbent and then heat-desorbed directly into a capillary column for gas chromatographic quantitation. During oxidation of linolenic (n-3) and linoleic (n-6) acid, ethane and pentane were formed, respectively. Nonstimulated granulocytes formed pentane. Upon addition of phorbol 13-myristate 12-acetate, the generation of pentane was increased by 540%. Addition of superoxide dismutase plus catalase inhibited lipid peroxidation in both a cell-free system and in isolated cells.

The present method is useful in the evaluation of free oxygen radical induced damage.

Lipids 24, 157-159 (1989).

Free oxygen radicals are produced during normal metabolism and in pathological states (1). Sources include redox-reactions of electron transport chains and certain reactions catalyzed by soluble enzymes like xanthine oxidase (1-3). A burst of free oxygen radical formation takes place during phagocytosis (4). Free oxygen radicals damage lipids, DNA and proteins (1,2). There are several defense systems against free oxygen radicals. Of these, superoxide dismutase catalyzes the autoxidation of superoxide radical, and catalase promotes hydrolysis of the resulting hydrogen peroxide that may form highly reactive hydroxyl radicals in the presence of a transition metal (1).

Because of the transient nature of the free oxygen radicals, direct measurement of these molecules is difficult (1,2). They have been determined by chemiluminescence or by following the reduction of cytochrome c added in vitro (5,6). In vivo assessment of free oxygen radicals is based mainly on analysis of products of lipid peroxidation in extracellular fluid, but the specificity of these methods is low (2,7-9). However, peroxidation of n-3 and n-6 fatty acid families results in the formation of ethane and pentane, respectively (10). In animals, these volatile alkanes are generated only by free oxygen radical-mediated lipid peroxidation that may take place as a result of free oxygen radical activity (11).

Previously published methods for determination of ethane and pentane require large injection volumes or separation of ethane and pentane prior to quantitation by gas chromatography with packed columns (12-15). In the present study, we describe an accurate method for the analysis of ethane and pentane as indicators of lipid peroxidation.

MATERIALS AND METHODS

Standards and reagents. Ethane and propene standard gases were purchased from AGA SpecialGas, Lidingö, Sweden. Pentane was from Rathburn Chemical Ltd. (Walkerburn, Scotland, U.K.). Gas standard bag, gas bulbs for standard dispension and the capillary column were from Chrompack (Middelburg, The Netherlands). Linolenic acid, linoleic acid, phorbol 13-myristate 12-acetate (PMA), superoxide dismutase (SOD) and catalase (CAT) were obtained from Sigma Chemical Company (St. Louis, MO). Porasil-C was purchased from Alltech Associates (Deerfield, IL), and Ficoll-Paque from Pharmacia Chemicals (Uppsala, Sweden). All chemicals were of the highest grade of purity available.

Collection of ethane and pentane. The gaseous samples were collected using acid washed stainless steel columns (5 mm i.d.) packed with 80/100 mesh of Porasil-C packing material for gas chromatography. The headspace of the air-tight reaction vial was flushed into the gas trap with an excess of analytical grade of N_2 containing 0.5 pmol/ml propene as an internal standard. A precolumn of powdered NaOH, for elimination of water, and CO_2 was connected to the gas trap containing from 2.5 to 5 ml of Porasil-C adsorbent. Because of the low boiling point of ethane, the trap was immersed in liquid N_2/ethanol slurry.

Gas chromatography of ethane and pentane. The gases were analyzed using a Hewlett-Packard 5890 gas chromatograph with a Chrompack Al_2O_3/KCl (50 m, 0.4 mm i.d.) capillary column and high purity He as carrier gas. The hydrocarbons were detected with a flame ionizing detector (FID) and quantitated with a Hewlett-Packard 3390A integrator. A shunt with a high-pressure valve on the carrier gas line was connected to the trap. The other end of the trap was connected through a needle to the injector. The sample was eluted into the capillary column by heating the trap to 120°C for 10 min. During the elution, the proximal 30 cm loop of the capillary column was immersed in a liquid N_2 bath. The gas chromatography was started by rapid transfer of the 30 cm loop into the oven. The temperature was programmed from 50 to 200°C at 15°C/min.

Lipid peroxidation in a cell-free system. In the studies of alkane liberation from linolenic and linoleic acid, the fatty acids (10 μmol each) were incubated for 48 hr at room temperature (22°C) in the dark. The headspace of the air-tight 20-ml reaction vessel initially contained clean air.

In another experiment, 1.0 μmol of linoleic acid with 5 μmol palmitic acid was sonicated in 5 ml 200 mM phosphate buffer, pH 7.8, in an ice-cold water bath for 45 min. Lipid peroxidation was induced with 10 mM H_2O_2 and 0.2 mM $FeSO_4$ in 37°C for 18 hr. The headspace (15 ml) initially consisted of N_2.

Isolation and incubation of the granulocytes. Peripheral blood granulocytes were isolated from buffy-coats obtained from the Finnish Red Cross Blood Transfusion Service, by density gradient sedimentation and subsequent Ficoll-Paque centrifugation (16). The viability of the cells was more than 90% by the Trypan-Blue exclusion method (17). Altogether, from 280 to 580 × 10^6 cells were incubated in air-tight silicone-coated vials (100 ml) for 2 hr at 37°C in 50 ml preoxygenated phosphate-buffered saline containing 5 mM glucose, and 0.5 mM $CaCl_2$. (N-2-Hydroxyethylpiperazine-N-2-ethanesulfonic acid [HEPES] should not be used as buffer because it produces ethane in the presence of activated granulocytes.) Constant shaking of the incubation vessels (60 strokes/min) prevented aggregation of the cells.

Before incubation, the headspace was flushed with 100% O_2. During incubation pO_2, pCO_2 and pH were measured in a 0.5 ml specimen taken at the beginning and the end of the experiment. A maximal decrease in pH was from 7.4 to 7.2 and pO_2 decreased from 600 to 200 mm Hg.

Fatty acids were analyzed by gas chromatography as described previously (18).

Statistical method. The results are presented as mean ±SE. Unpaired Student's t-test was used to examine statistical significance.

RESULTS

Method for quantitation of ethane and pentane. The capillary column sharply separated the hydrocarbons under the conditions described. The retention time of ethane was 5.5 ± 0.1 min and that of pentane 10.9 ± 0.2 min (n = 15) (Fig. 1). The detector response to the standard gases compared with the constant amounts of propene as an internal standard proved to be linear (Fig. 2). The detection limit for ethane and pentane was 1 pmol. The recoveries of ethane and pentane were over 90% in the range of 15–140 pmol. With larger concentrations, the saturation of the adsorptive capacity of Porasil-C became evident. This concerned ethane and propene in particular, their boiling points being −89°C and −48°C, respectively.

Experiment with the cell free system. Linolenic and linoleic acid were incubated for 48 hr in clean air. In the headspace of the vial containing 10 μmol linolenic acid, 2.0 nmol of ethane was formed, whereas 2.4 nmol of pentane was detected in the vial containing 10 μmol linoleic acid (Fig. 1). In order to demonstate the free oxygen radical dependence on the lipid peroxidation, linoleic acid in slightly basic phosphate buffer was sonicated in a basin sonicator for 45 min at +4°C. Thereafter, H_2O_2 and ferrous-ion were added. As shown in Table 1, addition of SOD (50 U/ml) and CAT (50 U/ml) inhibited the formation of pentane by 94%.

Experiment with the granulocytes. The pooled granulocytes were divided into three different groups and incubated in pure oxygen. One group was kept as control.

TABLE 1

Formation of Ethane and Pentane from Linolenic and Linoleic Acid

Addition	Form	Gas formed
Linolenic acid (n-3), 10 μmol	Dry[a]	2.0 nmol ethane/48 hr
Linoleic acid (n-6), 10 μmol	Dry[a]	2.4 nmol pentane/48 hr
Linoleic acid, 1 μmol + 10 mM H_2O_2 + 0.2 mM Fe^{2+}	Liposomes[b,c]	1.0 nmol pentane/18 hr
Linoleic acid, 1 μmol + 10 mM H_2O_2 + 50 U/ml SOD + 50 U/ml CAT	Liposomes[b,c]	0.1 nmol pentane/18 hr

[a]Temperature: 22°C.

[b]Temperature: 37°C.

[c]Liposomes were prepared by sonicating the fatty acid for 45 min on ice bath on 200 mM KH_2PO_4-K_2HPO_4, pH 7.8.

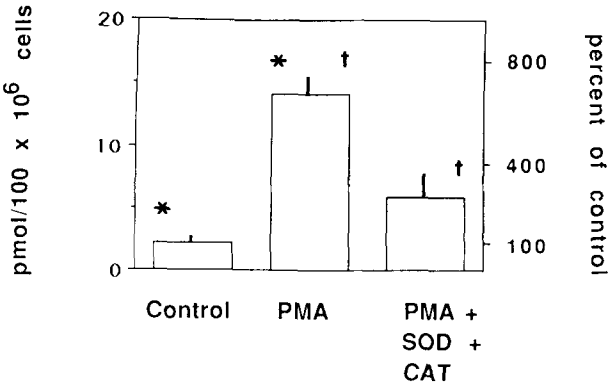

FIG. 3. Production of pentane by granulocytes. The cells were treated with PMA alone and with PMA in the presence of SOD + CAT. Pentane formation in control cells represents 100%. Each group consisted of six separate experiments. Pentane production increased after activation of granulocytes with PMA (*, $p < 0.0005$), and pentane production in PMA-activated cells was decreased by SOD + CAT (†, $p < 0.025$).

The second group of cells was treated with 50 ng/ml PMA to induce oxygen radical formation (19). The third group was incubated with 50 ng/ml PMA, after addition of 200 U/ml SOD and 200 U/ml CAT. The control cells remained in homogenous suspension during the incubation, whereas PMA-induced aggregation and attachment of the cells onto the walls of the reaction vial. However, the cells treated with PMA, SOD and CAT remained homogenously suspended in the incubation medium in a similar way to the controls.

Nonactivated granulocytes produced 2.2 ± 0.3 pmol pentane per 100 × 10^6 cells. Stimulation of granulocytes by PMA increased pentane production to 14.1 ± 1.4 pmol/100 × 10^6 cells (540%, $p < 0.0005$). In the presence of SOD and CAT, the effect of PMA on pentane production was significantly inhibited ($p < 0.025$). Ethane production was close to the detection limit (0.3 ± 0.3 pmol/100 × 10^6 cells), and it was affected by neither PMA nor PMA + SOD + CAT (Fig. 3).

Analysis of nonactivated granulocytes revealed no detectable linolenic acid (n-3).

DISCUSSION

In the present study, we describe a quantitative method for the determination of ethane and pentane with a sensitivity exceeding that of previous methods by at least one order of magnitude (12-15). Because there is also a high recovery, the present method enables measurement of the volatile products of lipid peroxidation both in a chemically well-defined system and in isolated cells.

The present system allowed quantitative measurement of the hydrocarbons ranging from 1 to 150 pmoles. The capillary column enhanced the sensitivity because of distinct resolution of the peaks. The use of an internal standard enabled exact quantitation and monitoring of the recovery of the sample. In this method, special interest was focused on the injection of the enriched specimen into the gas chromatograph. The Porasil-C trap was connected to a shunt built on the carrier gas line of the chromatograph. The sample was desorbed with heat, led directly into the column and concentrated in the proximal loop of the column immersed in liquid N_2. The present technique reduces the sample loss compared with the conventional syringe injection. The problem of saturation of the adsorption capacity at higher than 400 pmole of trapped hydrocarbon can be avoided by adjusting the gas volume.

The nature of the alkanes formed in lipid peroxidation is dependent on the fatty acid composition of the cell membrane. Nonactivation of granulocytes produced pentane, and PMA increased only pentane in the headspace. Therefore, the phagocytic stimulation of granulocytes involving activation of the respiratory burst was associated with selective peroxidation of n-6 fatty acids.

Although it has been proposed that free oxygen radicals are important in pathogenesis of many diseases, direct evidence of their role is often based on unreliable techniques or is missing altogether (2,20). As demonstrated by Dillard et al. (13), ethane and pentane are specific markers of free oxygen radicals that can be measured in expired air. However, measurement of these alkanes has been hampered by low sensitivity of previous gas chromatographic methods. The present method conceivably improves the accuracy of measurement of expired ethane and pentane. It may further enable detection of these peroxidation products in specimens recovered from transcellular space such as cerebrospinal and synovial fluid.

ERRATUM

"Location of Methyl Branchings in Fatty Acids: Fatty Acids in Uropygial Secretion of Shanghai Duck by GC-MS of 4,4-Dimethyloxazoline Derivatives," by Q. T. Yu, B. N. Liu, J. Y. Zhang, and Z. H. Huang, *Lipids 23*, 804-810, 1988. Abstract, lines 8-12, should read:

Continuing our previous study, 66 out of a total of 68 fatty acids obtained from the preen gland wax of Shanghai duck now have been identified by gas chromatography-mass spectrometry (GC-MS) of their oxazoline derivatives.

Table 3, footnote a, should read:

[a]Peaks #3, 64 and 65 represent minor unsaturated acids, which have been identified according to the empirical rule of "12 mass interval" as described (17). These acids were probably originated from contaminations in gland sampling and handling.

Figure 1 should be replaced by the following gas chromatogram:

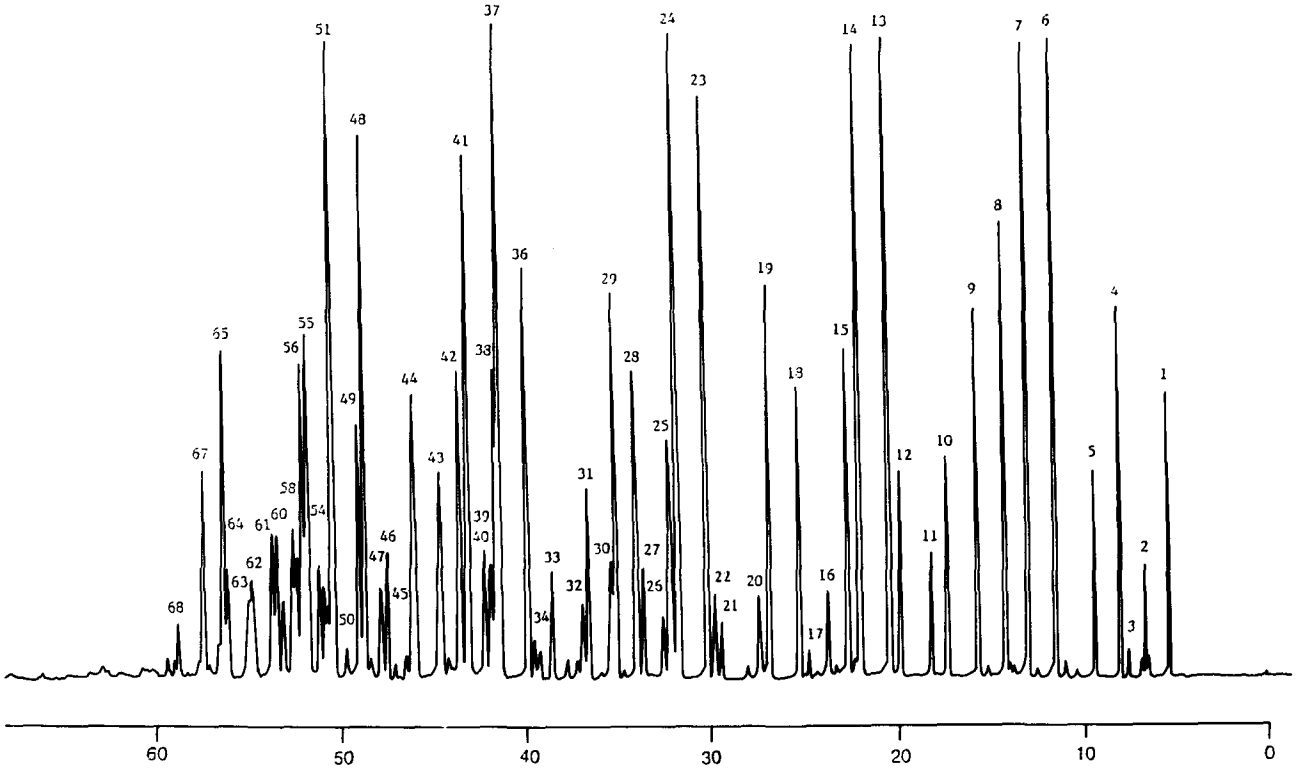

FIG. 1. Gas chromatogram of DMOX of fatty acid mixture obtained from the preen gland secretion of Shanghai white duck *(A. platyrhynchos)*.

Effects of Dietary Casein and Soy Protein on Metabolism of Radiolabelled Low Density Apolipoprotein B in Rabbits

Samir Samman*, Pramod Khosla and Kenneth K. Carroll
Department of Biochemistry, University of Western Ontario, London, Ontario, N6A 5C1, Canada

Rabbits fed semipurified diets containing casein have elevated plasma cholesterol levels compared to those fed soy protein. As part of continuing studies on the mechanism of casein-induced hypercholesterolemia, two groups of six rabbits were fed these diets for 14 to 16 weeks. Animals fed the casein diet were found to have significantly higher plasma concentrations of protein, cholesterol, triacylglycerol, phospholipid and apolipoprotein B (apo B) associated with low density lipoprotein (LDL) than those fed the soy protein diet. Kinetic studies showed that the fractional catabolic rate of LDL-apo B was significantly lower in animals fed casein than in those fed soy protein regardless of whether the tracer LDL was obtained from donors fed casein or soy protein. The production rate of LDL-apo B was higher in casein-fed animals but this was not statistically significant. These results show that the efficiency of removal of LDL is significantly reduced in animals fed casein compared to those fed soy protein, and that the source of LDL did not affect the efficiency of its subsequent removal. The accumulation of LDL in casein-fed animals is consistent with down-regulation of the LDL receptor.
Lipids 24, 169–172 (1989).

The differential effects of dietary casein and soy protein on plasma cholesterol levels in rabbits are well established (1,2). Casein, fed as part of a cholesterol-free semipurified diet, raises plasma cholesterol, while soy protein maintains it at a low level (3,4). Although the overall lipoprotein pattern is similar in both dietary groups, the rise in plasma cholesterol level in casein-fed animals is characterized by a much higher level of low density lipoprotein (LDL) (5).

The rise in LDL in casein-fed animals is accompanied by changes in composition of the lipoproteins. Recent studies in our laboratory have shown that the LDL is enriched in cholesterol at early stages of dietary treatment (6). As part of ongoing studies of the mechanism of casein-induced hypercholesterolemia, LDL apolipoprotein B (apo B) turnover was investigated in rabbits fed diets containing either casein or soy protein.

MATERIALS AND METHODS

Animals and diets. Young, male New Zealand White rabbits (1.5–2.0 kg) were obtained from Riemen's Fur Ranches (Guelph, Ontario), and housed individually in a controlled environment as described previously (5). The animals were maintained on rabbit Chow (Ralston Purina Co., St. Louis, MO) for up to two weeks before being transferred to semipurified diets containing either casein or soy protein, the composition of which has been described (7). The animals, six per group, were fed these diets for 14 to 16 weeks.

Isolation and iodination of LDL. Prior to the metabolic studies, blood was obtained from the marginal ear vein of unanesthetized animals in the fasted state. Plasma was separated and LDL ($1.019 < d < 1.063$ g/ml) isolated from the pooled plasma of six animals from each dietary group by sequential ultracentrifugation (8). The isolated LDL was ultracentrifuged a second time to wash and concentrate it. LDL obtained from animals fed casein and soy protein diets was radiolabeled with ^{131}I and ^{125}I (Amersham, Oakville, Ontario), respectively, as described by Huff and Telford (9), followed by dialysis to remove unbound radioiodine. To determine the intramolecular distribution of the radioiodine, 10 μl aliquots of LDL were added to carrier bovine serum albumin (5% solution) and then precipitated by trichloroacetic acid (TCA, 5% final concentration). In addition, aliquots of the labelled lipoprotein were added to 200 μg of carrier LDL and then precipitated using isopropanol (50% final concentration). The isopropanol pellet yielded the amount of label associated with apo B (10), while the TCA supernatant yielded the free iodine (11). The distribution of label was similar for both groups, with 92% of the label in apo B and less than 2% as free iodine.

In vivo studies. Animals were fasted for 12–16 hr prior to the kinetic studies. Each animal was injected with approximately 3.7 μCi ^{125}I-LDL (obtained from soy protein-fed donors) and 1.9 μCi ^{131}I-LDL (obtained from casein-fed donors). The amount of protein injected amounted to less than 0.01% of the circulating pool of LDL protein. Both tracers were injected simultaneously into the marginal vein of the left ear followed by 1–2 ml of phosphate-buffered saline to flush the cannula. Blood samples were then taken from the marginal vein of the right ear at 3 min, 45 min, 1.5, 3, 4.5, 6, 12, 24, 36, 48, 60 and 72 hr postinjection. Plasma was separated and the radioactivity in apo B determined following precipitation by isopropanol (12). A radioactivity disappearance curve was then constructed for both tracers by taking the radioactivity in apo B at three min as 100% of the injected dose. The curves were analyzed according to the method described by Matthews (13). The fractional catabolic rate (FCR), as defined by Kushwaha and Hazzard (14), was determined for both tracers.

Plasma total cholesterol was assayed enzymatically (CHOD PAP Monotest, Boehringer Mannhein Canada, Dorval, P.Q.) on samples obtained at 3 min and 24, 48 and 72 hr. Aliquots of plasma (0.5 ml) from all time points from each animal were then pooled and ultracentrifuged as described above to obtain the LDL fraction. The cholesterol, triacylglycerol and phospholipid concentrations of LDL were analyzed using enzymatic assay kits (Boehringer Mannheim Canada, Dorval, P.Q.). Total protein concentration was determined using the modification of Markwell et al. (15) of the Lowry method (16). To determine the concentration of apo B, 100 μg of protein was precipitated by isopropanol (10). The supernatant was

*To whom correspondence should be addressed.

Abbreviations: apo B, Apolipoprotein B; FCR, fractional catabolic rate; LDL, low density lipoprotein; VLDL, very low density lipoprotein.

assayed for protein and apo B was calculated as the difference between this value and the total protein concentration. Production rates (or turnover rates) for homologous LDL were calculated as the product of the FCR and the plasma concentration of apo B and expressed as mg/hr/dl.

Statistical analyses. Statistical differences between dietary groups were determined using Student's t test. To determine statistical differences within a group, the paired Student's t test was used.

RESULTS

Both groups of animals maintained equal weight gains throughout the experimental period such that the final weight was 3.4 ± 0.1 kg (SEM) for each dietary group. However, the two dietary proteins had divergent effects on plasma cholesterol concentrations, with casein-fed animals exhibiting a marked hypercholesterolemia (399 ± 62 mg/dl) compared to those fed soy protein (66 ± 16). These concentrations of total cholesterol were maintained throughout the 72 hr of the kinetic experiments consistent with the animals being in a steady state.

All components of LDL were significantly higher in casein-fed animals than in those fed soy protein, with the cholesterol and phospholipid concentrations showing a seven-fold difference (Table 1). In addition, LDL-apo B metabolism in casein-fed animals was slower than in those fed soy protein, with the FCR, or the efficiency of removal, being significantly lower (Fig. 1, and Table 2). The FCR in casein-fed rabbits was low regardless of the source of tracer LDL, that is, whether it came from casein- or soy protein-fed donors had no significant influence on its clearance rate, which was determined by the diet fed the recipient animal. There was a significant relationship between the FCR and plasma LDL-apo B concentrations, the FCR diminishing with increasing concentrations of LDL-apo B in soy protein-fed animals. However, for animals fed casein, there was little or no change in FCR

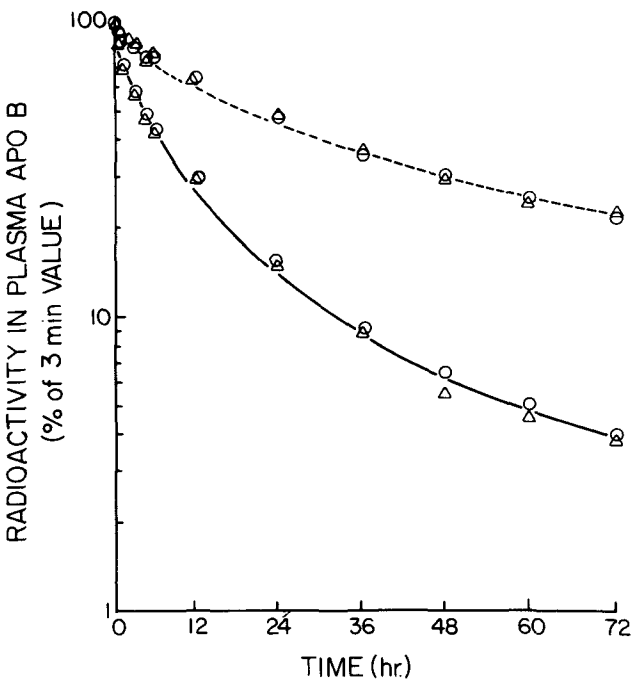

FIG. 1. Decay of radioactivity of plasma apo B obtained using LDL from (△) casein-fed or (○) soy protein-fed donor rabbits injected into (– – –) casein-fed or (—) soy protein-fed recipients. Each data point represents the mean value for 6 animals; SEM did not exceed 8% for any data point.

TABLE 1

The Effect of Dietary Casein and Soy Protein Diets on the Composition of Plasma LDL

Diet	Protein (mg/dl)	Cholesterol (mg/dl)	Triacylglycerol (mg/dl)	Phospholipid (mg/dl)
Casein	74.2 ± 12.7**	144.7 ± 23.1**	10.2 ± 2.7*	69.2 ± 10.2**
Soy protein	15.6 ± 3.1	19.1 ± 2.9	3.2 ± 0.5	10.3 ± 1.6

All values expressed as Mean ± SEM, n = 6.

Protein, cholesterol, triacylglycerol and phospholipid concentrations in the group fed casein diet were significantly higher than their soy protein-fed counterparts, as determined using Student's t test (**P < 0.001, *P < 0.05).

TABLE 2

Effects of Dietary Casein and Soy Protein Diets on the Metabolism of LDL-apo B in Rabbits

Diet	Plasma LDL-apo B (mg/dl)	FCR (per hr)		Production rate (mg/hr/dl)
		Casein-fed donor	Soy protein-fed donor	
Casein	65.4 ± 10.5**	0.023 ± 0.002*	0.023 ± 0.002	1.41 ± 0.38
Soy protein	12.5 ± 2.9**	0.089 ± 0.018	0.079 ± 0.013*	0.82 ± 0.11

All values expressed as mean ± SEM, n = 6.

Mean values sharing a common symbol are statistically different from each other as determined using Student's t test (**P < 0.001, *P < 0.05).

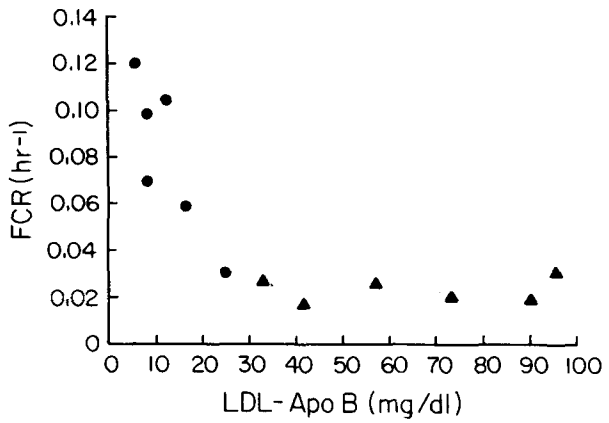

FIG. 2. The relationship between FCR (/hr) and LDL-apo B (mg/dl) in rabbits fed (▲) casein or (●) soy protein diets for 14 to 16 weeks.

over a three-fold increase in LDL-apo B concentration (Fig. 2).

Casein-fed animals had a larger plasma pool and a higher production rate of LDL-apo B than those fed soy protein, but the latter did not reach statistical significance.

DISCUSSION

The results of these experiments show, for the first time, that the hypercholesterolemic effect of dietary casein compared to soy protein is due primarily to the reduced efficiency of removal of LDL. This effect is consistent with the down-regulation of the LDL receptor which determines the metabolic fate of LDL (17).

The LDL particles in casein-fed animals are enriched in cholesterol compared to those fed soy protein diets. From time-course studies of the effect of dietary protein on plasma lipoproteins, these changes occur within 3-7 days of dietary treatment (6,18). It is thus plausible that the cholesterol-enriched LDL particles in casein-fed animals are removed less efficiently than those from animals fed soy protein, which could in turn result in raised levels of LDL. However, results of these experiments showed that the source of LDL, whether it came from a normocholesterolemic soy protein-fed donor animal or a hypercholesterolemic casein-fed donor animal, was unimportant in determining the efficiency of its removal. These results are in contrast to those obtained for the metabolism of very low density lipoproteins (VLDL) and intermediate density lipoproteins which are influenced by diets of both the donor and recipient animals (7).

Thus, our results suggest that the changes seen in the LDL particle do not contribute to any functional abnormality and that the effect is consistent with the down-regulation of the LDL receptor. The in vitro experiments of Chao et al. (19) showing a down-regulation of the receptor in animals fed wheat starch-casein diets lend support to this suggestion.

Another possible explanation of the raised levels of LDL is an increase in its production rate. Our data show a trend for a higher production rate in animals fed casein than in those fed soy protein diet, although large variations and small numbers of animals prevented this from reaching statistical significance. In the rabbit, most of the LDL is derived from a VLDL-independent pathway (20,21). Current work in our laboratory suggests that casein-fed animals produce more LDL by such a pathway than do animals fed soy protein diets (Khosla, P., Samman, S., and Carroll, K.K., unpublished data). This, together with a reduced efficiency of removal of LDL (Fig. 2), contributes toward an increased pool size of LDL in casein-fed animals.

The relationship between FCR and LDL-apo B concentration shown in Figure 2 is of interest because of the role apo B plays in targetting the LDL particle to its receptor in both hepatic and nonhepatic cells (22). The decreased FCR with increasing LDL-apo B concentration reflects the saturation of the removal mechanism, possibly due to the expanded LDL pool.

Beynen et al. (23) have suggested that the casein-induced rise in LDL is a consequence of "primary events" which take place in the intestinal lumen. They suggest that the first step involves stimulation of cholesterol and/or bile acid absorption as demonstrated in our laboratory (24). The subsequent increase in hepatic cholesterol concentrations may elicit down-regulation of the apo B/E receptor and increase the output of cholesterol associated with lipoproteins. However, it remains to be established what component of casein induces increased cholesterol absorption. Thus, further research on the digestibility of the proteins (25), interactions with micronutrients (26) or interference with the enterohepatic circulation (27) may help to determine the primary causes of casein-induced hypercholesterolemia.

[Received July 28, 1988; Revision accepted November 28, 1988]

Incorporation of Arachidonic, Dihomogamma Linolenic and Eicosapentaenoic Acids Into Cultured V79 Cells

Klaus U. Weithmann, Hazel Peterson and **Alex Sevanian***
Institute for Toxicology and Department of Pathology, University of Southern California, School of Pharmacy, 1985 Zonal Avenue, Los Angeles, CA 90033

The uptake and distribution of three common dietary polyunsaturated fatty acids was studied using Chinese hamster lung fibroblasts (V79 cells). Treatment of V79 cells with arachidonic (20:4), eicosapentaenoic (20:5) and dihomogammalinolenic (20.3) acids for 24 hr produced a marked uptake of 20:3 and 20:4, both of which were assimilated to a considerably greater degree than 20:5. All polyunsaturated fatty acids were incorporated primarily into phospholipids; however, there were considerable differences in their distribution into individual phospholipid species. Although 20:4 was incorporated primarily into phosphatidylcholine, 20:3 entered largely into phosphatidylethanolamine and phosphatidylglycerol, and 20:5 was distributed about equally between phosphatidylcholine, phosphatidylethanolamine and phosphatidylinositol. A marked conversion of 20:3 to 20:4 was found after 24 hr and, in several phospholipids, there was as much derived-radiolabeled 20:4 as there was radiolabeled 20:3. There was little evidence of 20:4 and 20:5 metabolism. V79 cells undergo substantial changes in phospholipid fatty acid composition following supplementation with these polyunsaturated fatty acids; however, these fatty acids are assimilated to different degrees and their distribution among cellular phospholipids is distinct, suggesting incorporation via independent mechanisms. ***Lipids 24,*** **173–178 (1989).**

Polyunsaturated fatty acids (PUFA) are most frequently found associated with complex lipids such as phospholipids and triacylglycerols, whereas low cellular levels of these fatty acids in free form are usually maintained by active reacylation reactions. Indeed, there have been numerous reports on the uptake and distribution of fatty acids (1–3) and, more specifically, arachidonic acid (20:4) (1,4) in cell culture systems. It is generally concluded from these and other studies (5) that it is possible to experimentally modify the lipids of cultured cells by addition of fatty acids to the growth media. Release of these PUFA from complex lipids is largely influenced by the action of phospholipases, where, for example, phospholipase A2 hydrolysis represents the first step in the conversion of these PUFA to eicosanoids (6). Phospholipases appear to influence the uptake, distribution and release of 20:4 and related PUFA. Specific phospholipase activities towards different phospholipid species have been reported under in vitro conditions (7). Nakagawa et al. (8) demonstrated that stimulated rabbit alveolar macrophages utilize 20:4 for eicosanoid synthesis mostly from choline glycerophospholipids, leaving the other glycerophospholipids, as well as triacylglycerols, practically unaffected. Similar substrate preferences were shown in other cell systems such as platelets (9), lymphocytes (10) and fibroblasts (11). It has been proposed that different classes of phospholipids serve as sources of arachidonic acid for eicosanoid production (12). Moreover, the release of arachidonic acid can be influenced by its distribution in specific phospholipid pools.

Eicosanoids are synthesized from several 20-carbon PUFA in many cell types where they participate in numerous physiological and pathophysiological reactions (13). Although the most prominent of these fatty acids is 20:4, prostaglandins and leukotrienes are also produced from other 20-carbon n-3 and n-6 PUFA. Replacement of (20:4) by dihomogammalinolenic acid (20:3) or eicosapentaenoic acid (20:5) is known to generate prostaglandins and leukotrienes with an accordingly altered number of double bonds and, in general, these eicosanoids exert weaker or, in some cases, distinct, biological effects compared with 20:4. This suggests that the potential for adverse effects produced by 20:4 metabolism may be circumvented by appropriate substitution with the other eicosanoid precursors (14).

Chinese hamster embryonic lung fibroblasts (V79 cells) were used to investigate the uptake of added 20:4, 20:3 and 20:5 into the different lipid pools. We were specifically interested in determining whether these fatty acids were assimilated into similar or different phospholipid species because this could have a bearing on their subsequent availability for eicosanoid synthesis. V79 cells were selected due to their ease of culture and rapid growth combined with an apparent low level of eicosanoid synthesis.

METHODS

Cell culture. Chinese hamster embryonic lung fibroblasts (V79 cells) were grown in 100-mm petri dishes (Corning Glass Works, Corning, NY, NY) as described previously (15,16). The culture medium in all cases consisted of 5 ml Dulbecco's Minimum Eagles Medium, containing 10% heat-inactivated dialyzed fetal calf serum (Gibco, NY).

Logarithmically growing cell cultures (ca. 5×10^5 cells per dish) were incubated for 24 hr with one of the following radioactively labeled PUFA: [1-^{14}C] 20:4 (n-6) (1.0 μCi/μmol) or [2-^{14}C] 20:3 (n-6) (4.0 μCi/μmol), which were >98% pure, or [1-^{14}C] 20:5 (n-3) (0.55 μCi/μmol), which was 96% pure, as determined by high pressure liquid chromatography (HPLC) according to methods herein described. Radiolabeled lipids were obtained from Amersham (Arlington, IL) and nonlabeled fatty acids were purchased from NuChek Prep (Elysian, MN). Unlabeled 20:5 was found to be only 65% pure and was, therefore, purified further by Prep-HPLC using a 5-μ (9 mm × 25 cm i.d.) RP-18 column (Alltech, Inc., Los Altos, CA) eluted with 20% H_2O in acetonitrile at a flow rate of 6 ml/min.

Abbreviations: CL, cardiolipin; FAME, fatty acid methyl ester; LPC, lysophosphatidylcholine; PA, phosphatidic acid; PBS, phosphate buffered saline; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; PI, phosphatidylinositol; PS, phosphatidylserine; PUFA, polyunsaturated fatty acids; SM, sphingomyelin; GC, gas chromatography; HPLC, high performance liquid chromatography; TLC, thin layer chromatography.

The eluant was monitored by refractive index. The concentrations of fatty acids used varied depending on the experiments performed and are, thus, indicated in the Results section. All fatty acids were dissolved in ethanol and added to the culture medium prior to culture. The final concentration of ethanol was 0.5% (v/v). The cells were then harvested by washing the monolayers with cold PBS (phosphate buffered saline, pH 7.2) three times and then scraping off the plastic into 50-ml PBS. After centrifuging for 15 min at 1000 rpm, the cell pellet was recovered and total lipids extracted.

Extraction of cells. The cells (ca. 10^8 cells in 0.7-ml buffer) were extracted using a modified Bligh & Dyer method (17) by means of freeze-thawing in liquid nitrogen 3 times. The cell homogenate was subsequently mixed with 2 ml of chloroform/methanol/water (2:2:1.8, v/v) and the mixture kept for 14 hr under argon in a refrigerator. After centrifugation, the supernatant was saved and the pellet subjected to brief extraction using the same solvents. Extraction of the pellet was repeated twice and the supernatants pooled. The combined chloroform phases, containing 98–100% of the total radioactivity, were further separated by two chromatographic procedures. In the first system the neutral lipids were separated by thin layer chromatography (TLC) on 0.2-mm thick silica gel G-60 plates (EM Science, Cherry Hill, NJ) using a solvent system containing petroleum ether/diethylether/acetic acid (80:20:1, v/v) (18). Under these conditions the phospholipid fraction remained at the origin. Areas corresponding to triacylglycerols and free fatty acids were identified by comparison with authentic standards as visualized by iodine vapor. The plates were scanned for radioactivity (radio-TLC) (Berthold Instruments, Wildbad, FRG), regions of interest scraped from the plates and isolated lipids recovered by elution with chloroform/methanol (1:1, v/v). After drying, the samples were stored under argon in a −20°C freezer until further analysis. The phospholipid fraction was separated using a second TLC system (19) containing chloroform, methanol, triethylamine, isopropanol and an aqueous solution of 0.25% (w/v) potassium chloride (30:9:18:25:6, v/v). Individual phospholipid species were identified using a standard mixture containing lysophosphatidylcholine (LPC) (0.07), phosphatidylcholine (PC) (0.17), phosphatidylglycerol (PG) (0.47), cardiolipin (CL) (0.56), phosphatidylserine (PS) (0.29), phosphatidylinositol (PI) (0.40), phosphatidylethanolamine (PE) (0.43), phosphatidic acid (PA) (0.77) and sphingomyelin (SM) (0.12) (Rf-values in parenthesis), which were applied to each plate.

The authentic standards, which were developed along the margins of the plates were charred (19,20) in order to identify the location of each phospholipid. The margins were broken away prior to charring and then rejoined to locate the isolated phospholipid. The recovered phospholipid and triacylglycerol fractions were then subjected to transesterification by heating in 1 ml 4 N HCl/methanol at 90°C for 1 hr under argon. The resulting fatty acid methyl esters (FAME) were extracted with 4 ml hexane. The methanol phases were analyzed for phosphorous content according to Bartlett (21), whereas the hexane phases were evaporated and the residues prepared for gas chromatography (GC) by dissolving them in 25 μl acetonitrile, containing 0.01% BHT and 25 μg methylheptadecanoate (GC-standard). This solvent also was used to dissolve the free fatty acid fractions that were methylated using ethereal diazomethane (22).

The FAME composition was determined by GC using a 30 m × 0.53 mm i.d.DB-225 capillary column. Chromatographic conditions were as follows: helium carrier gas at 5.0 ml/min, initial column temperature at 185°C (using on-column injection), temperature gradient of 2°C/min beginning at 8 min postinjection, 220°C final temperature held for 12 min, detector temperature of 250°C. Authentic fatty acid methyl ester standards were obtained from NuChek Prep (Elysian, MN) and used to identify the fatty acids in samples. Chromatography was performed with a Hewlett-Packard 5730A gas chromatograph interfaced to a Perkin-Elmer 3600 chromatographics data station. The FAME were quantified according to their peak areas and individual FAME were calculated as the percentage of total FAME identified in a given sample.

FAME derived from all samples were also analyzed by HPLC using a Perkin-Elmer Liquid Series 4 Chromatograph, connected in series to a liquid scintillation flow-detector (radio-HPLC) (Ramona-LS (IN/US, Fairfield, NY). The radiochromatogram was displayed and analyzed by computer utilizing integrated chromatographics software. UV absorbance at 205 nm was simultaneously recorded. A spherisorb ODS-2, 3-μ (150 mm × 4.6 mm i.d.) column (Chromanetics Corp., Jessup, MD) was eluted with acetonitrile: water (65:35, v/v) at a flow rate of 1.0 ml/min. After 12 min, the composition of the mobile phase was raised to 90% acetonitrile linearly over a 4-min interval and then maintained as such for 15 min. Thereafter, the mobile phase was returned to its original composition over a 4-min interval, thus ending the analytical run.

Data are reported as the mean and standard deviation calculated from 3–5 independent analyses. Statistical analysis, where applicable, was performed using the Students t-test.

RESULTS AND DISCUSSION

The analysis of the various lipid fractions isolated from V79 cells after 24 hr of culture revealed that most of the fatty acids (70%) were present in phospholipids, whereas the free fatty acid and triacylglycerol fractions each contained ca. 15% of the total fatty acids. The high level of free fatty acids, along with high levels of LPC, appear to be due to freeze thawing of samples during the extraction of lipids from cells. When cells were extracted without freeze-thawing, the levels of free fatty acids were reduced to <7%, whereas LPC levels were lowered to 3%. This suggests that the amounts of radiolabel present in these lipid fractions are anomalously high and, as presented in Tables 1 and Figures 1 and 2, likely do not represent incorporation into these lipid pools accurately. The determination of individual FAME derived from phospholipids (Table 1) showed that palmitate (16:0), stearate (18:0) and oleate (18:1) were the predominant fatty acids. 18:1 was the major fatty acid in the free fatty acid fraction (48.8%), whereas 16:0 was predominant in the triacylglycerol fraction (30.6%). PC amounted to 40% of the total isolated phospholipids; PE made up 23%, whereas the contribution of all other phospholipids was <10%. The major fatty acid of the phospholipids was 18:1 (43.9% of total FAME). Considerable amounts of 16:0 (10.6%), 18:0 (13%) and 20:4 (5.5%) were present, whereas other identified fatty acids were <2% each (Table 1).

[a] Percentage composition of fatty acids in total phospholipids as determined by GC.

[b] The values shown are the percentage of total fatty acids found in all phospholipid species. Percentages less than 0.1 are shown as 0. Values are the mean of 3 determinations with variations not greater than 10% of the mean for any component shown.

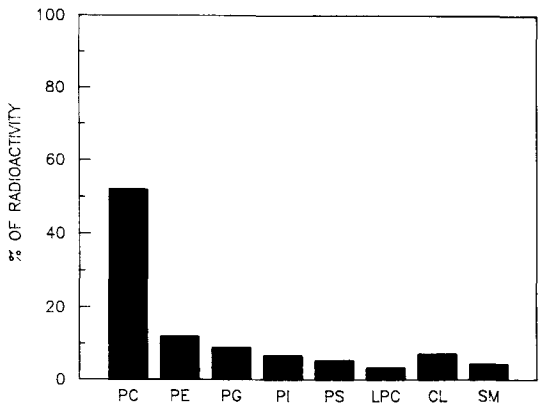

FIG. 1. The uptake and distribution of 10 μM [^{14}C]-20:4 after 24 hr incubation with V79 cells is shown. The incorporation of labeled fatty acid into individual phospholipids is presented as percentage of radioactivity incorporated into total phospholipids.

After 24 hr of culture in presence of 10 μM additions of [2-^{14}C] 20:3, [1-^{14}C] 20:4 or [1-^{14}C] 20:5, most of the radioactivity added to the medium was incorporated into the cells. Uptake of the three labeled fatty acids by V79 cells is shown in Figures 3, 4 and 5. Each fatty acid was incorporated in a biphasic manner over the 24-hr incubation period. A rapid initial phase of uptake occurred during the first 3-5 hr, followed by a more gradual uptake for the remaining incubation period. The initial uptake of fatty acids appeared to be independent of cell division,

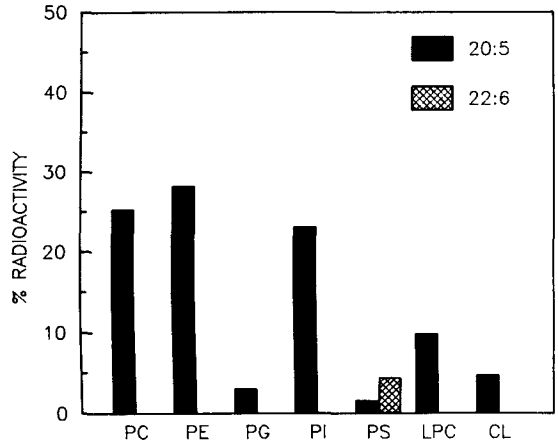

FIG. 2. The uptake and distribution of 10 μM [^{14}C]-20:5 after 24 hr incubation with V79 cells. Data are presented in a manner identical to Figures 1 and 6. Also shown is the extent of radioactivity associated with 22:6, determined by radio-HPLC analysis of the fatty acid methyl esters derived from each phospholipid species as described in the text.

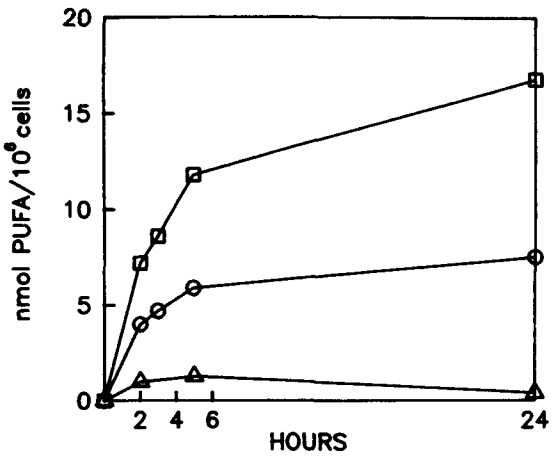

FIG. 3. The uptake of [^{14}C]-20:3 over 24 hr of incubation. The values shown at each time point present the total amount of radioactive fatty acid associated with isolated cells. The extent of incorporation was determined in the presence of 1 μM (△), 5 μM (○) and 10 μ (□) additions of each fatty acid to the culture medium.

as cell numbers were not significantly different during the first 6 hr of incubation. The second phase of uptake was associated with cell division and cell numbers had more than doubled by 24 hr. The uptake of each fatty acid was concentration dependent, where doubling the concentration in the medium approximately doubled the amount of fatty acids assimilated. Both 20:3 and 20:4 were incorporated to nearly equal extents, whereas about half as much 20:5 was incorporated under similar incubation conditions. Radio-TLC measurements showed that only minor amounts (~5%) of the total cellular radioactivity was present in the free fatty acid fraction, whereas negligible amounts of radioactivity (<1%) were detected in the triacylglycerol fraction at 24 hr. The major portion of the extracted radioactivity (~95%) was present in the phospholipid fraction.

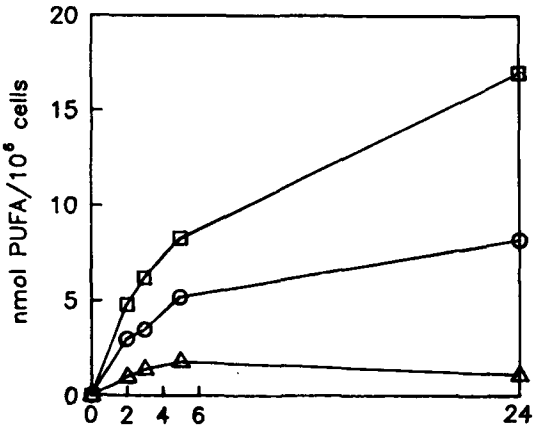

FIG. 4. The uptake of [^{14}C]-20:4 over 24 hr of incubation. See Figure 3 for details.

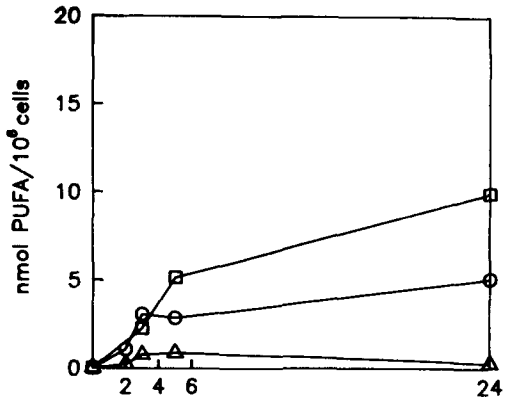

FIG. 5. The uptake of [^{14}C]-20:5 over 24 hr of incubation. See Figure 3 for details.

TABLE 2

Major Fatty Acid Composition in Cells Grown in the Presence of the Indicated Polyunsaturated Fatty Acids

	% composition[a]			
	20:3 ω-6	20:5	20:4	None[b]
16:0	19.3	7.1	17.5	10.6
18:0	18.8	21.9	19.1	13.0
18:1	25.3	33.3	33.8	43.9
20:3 ω-6	3.9	0.7	0.9	0.3
20:4	5.1	5.2	6.9	5.5
20:5	0	3.7	0	0

[a]Fatty acid methyl ester composition of total lipid extracts from V79 cells incubated for 24 hr in the presence of 10 μM of the fatty acids noted. Values are the mean of 3 independent analyses with maximum variation being no greater than 10% of the mean.

[b]Fatty acids methyl ester composition of cells grown under standard conditions in complete medium only. Values shown are the mean of 3 independent analyses with maximum variation being no greater than 10% of the mean.

Table 2 summarizes the data for incorporated radioactive fatty acids after 24 hr. The distribution and proportions of the major fatty acids 16:0, 18:0 and 18:1 were altered after addition of 20:3, 20:4 and 20:5. The most pronounced changes occurred with 18:1 where addition of 20:3 lowered the proportion of 18:1 by ~40%. The changes in saturated fatty acids and 18:1 were least evident after incubation with 20:5. It is conceivable that these responses represent adjustments of lipid composition because PUFA are known to affect membrane fluidity (23). One possible stage of regulation may occur through elongation and desaturation reactions that can be influenced by incorporation of PUFA into cultured cells (24). Increases in saturated fatty acids on addition of PUFA may compensate for the elevated assimilation of unsaturated fatty acids and result from decreased desaturase activity (25).

After cultivation of cells for 24 hr in the presence of 10 μM [^{14}C]-20:3, the levels of this fatty acid increased from 0.3 to 3.9% of total FAME. Cultivation in the presence of 10 μM [^{14}C] 20:5 increased 20:5 content from 0 to 3.7%. The percentage of 20:4 was not significantly altered after addition of 10 μM [^{14}C] 20:4, i.e., it remained in the range of 5-7% of total FAME. The small increase in the proportion of 20:4 upon supplementing V79 cells with this fatty acid may be misleading when considered only in terms of percentage of total FAME composition rather than in terms of absolute amounts of lipid. Considerable amounts of [^{14}C]-20:4 were incorporated into the various phospholipids—with marked uptake into PC. However, these data do not indicate whether preexisting pools of 20:4 were redistributed during assimilation of added 20:4 and preferential uptake into PC (which would serve as a large phospholipid pool). This effect, combined with redistribution of 20:4 from other minor phospholipids, could permit substantial amount of 20:4 to be assimilated with little effect on the overall proportions of 20:4.

It should be noted that the lipid composition of these cells is probably determined in large measure by the serum lipid composition of the culture medium. Therefore, the fatty acid composition of the culture medium was analyzed in order to establish the inherent levels of the PUFA that were under study. GC measurements of derived FAME indicated that 20:4 concentrations were 2.5 μM. Accordingly, the final concentration of 20:4 in supplemental cultures was 12.5 μM. 20:5 and 20:3 concentrations were less than 0.05 μM, suggesting that supplementing the medium with 10 μM concentrations of these PUFA represented marked elevations over standard culture conditions.

Radio-HPLC analysis of the FAME isolated from cellular phospholipids indicated that most of the incorporated [^{14}C]-20:4 was found in the PC fraction, whereas all of the other phospholipids showed markedly less uptake (Fig. 1). Figure 6 describes the distribution of [^{14}C]-20:3 among cell phospholipids. It can be seen that [^{14}C]-20:3 was present mainly in PE and PG. Substantial amounts of 20:3 were converted to 20:4. Conversion of 20:3 to 20:4 was most extensive in PG and least in PS. No further metabolic products of 20:3 were detected (Fig. 7A). Figure 2 shows that 20:5 was incorporated mainly into PC, PE and PI. Conversion of this fatty acid to 22:6 occurred to a some extent where considerable

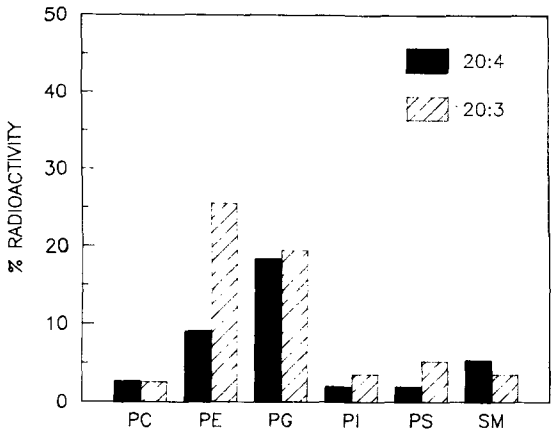

FIG. 6. The uptake and distribution of 10 μM [^{14}C]-20:3 after 24 hr incubation with V79 cells is shown. Data are presented in a manner identical to that described for Figure 1. Also shown is the extent of radioactivity associated with 20:4, determined by radio-HPLC analysis of the fatty acid methyl esters derived from each phospholipid species as described in the text (also, see Fig. 7 for an example).

amounts of [1-^{14}C]-22:6 were associated with PS. The amount of 22:6 formed represented ~2.5% of the total 20:5 incorporated into phospholipids. Included in Figure 7 are sample chromatograms for 20:3 uptake into PE (Fig. 7A), 20:4 uptake into PC (Fig. 7B) and 20:5 uptake into PS (Fig. 7C).

These findings show that V79 cells contain low levels of PUFA under standard culture conditions, however, there is a marked capacity to assimilate these fatty acids on supplementation of the culture medium. After 24 hr, most of these fatty acids were incorporated into phospholipids, but because specific pools were not examined in detail at time intervals less than 24 hr, we cannot ascertain into which lipid pools the fatty acids may have entered during earlier periods of incorporation. The uptake of 20:3 and 20:4 into cell phospholipids was quite similar although the pattern of uptake into specific phospholipid species differed in several respects. This might suggest that 20:3 and 20:4 may use similar binding sites and uptake mechanisms, whereas a distinct pathway may exist for 20:5. However, PC was the major site for 20:4 incorporation, whereas 20:3 was incorporated primarily into PE and PG, and 20:5 accumulated largely into PC, PE and PI. Consequently, the assimilation of different PUFA may be occurring by separate uptake mechanisms in these cells. This suggests that the uptakes of these fatty acids are independent of each other and that each has a preferred incorporation into specific phospholipid pools. The differential uptake of these PUFA into phospholipids may also depend on the degree of unsaturation of the phospholipid pool into which the fatty acids are incorporated. PC, for example, is the most saturated phospholipid (i.e., saturated and monoenoic fatty acids make up >90% of all fatty acids) and 20:4 is incorporated mostly into PC. 20:3 is incorporated largely into PE and PG and 20:5 into PE and PI, all of which are considerably more unsaturated than PC.

It is also interesting to note that these fatty acids are subject to different degrees of metabolic conversion. There was little evidence of 20:4 metabolism, where more than 90% of the added 20:4 was recovered as 20:4 (Fig. 7B). As shown in Figure 7B, there was a small radioactive peak eluting after 20:4, which indicates that some metabolic conversion had taken place. This was seen

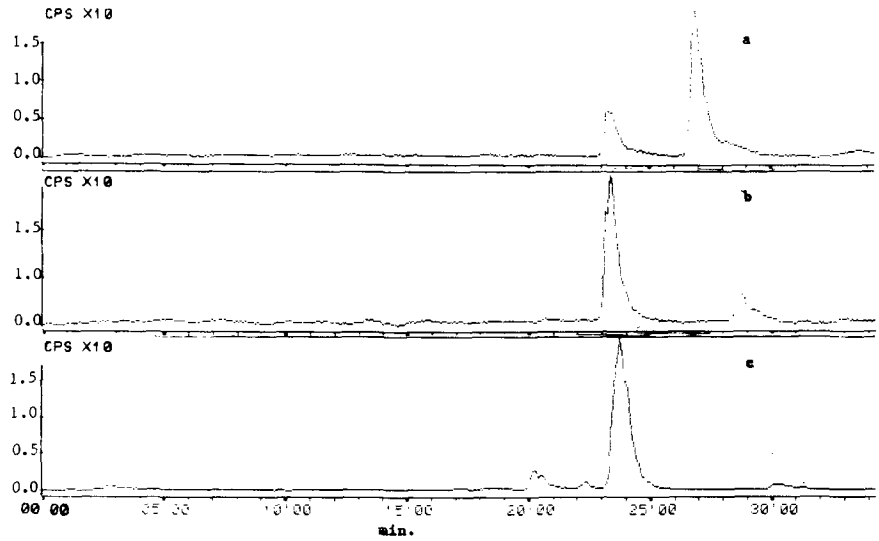

FIG. 7. Radio-HPLC chromatograms characterizing labeled fatty acids isolated from cell phospholipids after 24 hr incubation with 10 μM additions of [^{14}C]-20:3 (A), [^{14}C]-20:4 (B) and [^{14}C]-20:5 (C). A representative chromatogram of radioactivity associated with FAME derived from PE is shown in A. Peaks correspond to authentic standards of 20:4 (23.1 min) and 20:3 (26.5 min). A representative chromatogram of radioactivity associated with FAME derived from PC is shown in B. Peaks correspond to authentic standard of 20:4 (23.1 min) and an unknown component (28.7 min). A representative chromatogram of radioactivity associated with FAME recovered from PS is shown in C. Peaks correspond to authentic standards of 20:5 (20.2 min) and 22:6 (23.8 min).

only in PC and the identity of this product is presently unknown. 20:5 was metabolized to a minor extent where the product was identified as 22:6. On the other hand, 20:3 was extensively converted to 20:4, indicating that these cells possess Δ5-desaturase activity. The metabolic conversions of PUFA have been described in a similar cell line (CHO cells), which also possessed Δ5-desaturase, but lacked Δ-6 desaturase (24). The proportions of 20:3 and derived 20:4 were similar in virtually all the phospholipid species after 24 hr (with the exception of PE), despite the finding that the fatty acids were incorporated differently into the various phospholipid species (Fig. 6). The rather facile conversion of 20:3 to 20:4 may, in part, account for the comparable uptake of these fatty acids into cell lipids and, accordingly, it should be possible to enrich different phospholipid pools with 20:4 by incubating cells with 20:3 instead of 20:4.

These studies indicate that interaction of ω-3 and ω-6 may not be direct because these fatty acids appear to be incorporated into different phospholipid pools. The noted inhibitory effects of 20:5 on 20:4 metabolism and eicosanoid synthesis in some cases, as well as conversion of the former to less active eicosanoid products (2,26,27), suggests that these fatty acids are interacting via common pools. This may also be the case in V79 cells, in so far as PC represents a common depot for 20:4 and 20:5. It may thereby be possible to influence the release and availability of 20:4 by additions of 20:5, thus altering the production of eicosanoids. These findings can be viewed in the light of other reports comparing the uptake of these three fatty acids. For example, Punnonen et al. (28) described the uptake of 20:3, 20:4 and 20:5 into human keratinocytes. In these cells, incorporation into phospholipids was predominant and the extent of uptake was of the order: 20:3 ∼ 20:4 > 20:5. Similar findings have been described by others (29). Nevertheless, there are some clear differences in terms of which phospholipid species incorporated these fatty acids. The most notable difference occurred with 20:4, where Punnonen et al. (28) described uptake primarily into PE along with considerable incorporation into triacylglycerols. Because PE is the major phospholipid in keratinocytes (30) and PC is the major phospholipid in V79 cells, the extent of 20:4 uptake may reflect the pool size of these phospholipids. Other differences in the uptake and distribution of PUFA can be found in the literature, particularly with respect to studies with platelets, fibroblasts and endothelial cells (9,10,29,31). These discrepancies may be due to differences in phospholipid composition or to the utilization of PUFA in events such as eicosanoid synthesis. Differences in uptake and distribution may also be accounted for by the concentrations of fatty acids in the medium. Others have reported that supplementations with high concentrations of fatty acids (>10 μM) increase the proportionate uptake into triacylglycerols and change the distribution of fatty acids among phospholipid species (10-12). This was also found in V79 cells, where concentrations of >10 μM 20:4 resulted in a greater proportion of the fatty acid being incorporated into triacylglycerols (data not shown). These findings suggest that care must be taken during treatment of cells with specific fatty acids, when attempts are made to enrich specific lipid species. Another parameter influencing uptake, subsequent conversion and utilization of PUFA is the phospholipid species into which the fatty acids are incorporated. Accordingly, release of specific fatty acids (e.g., for the purpose of prostaglandin synthesis) could involve different phospholipid pools and, thus, be separately influenced.

In this study, we investigated the effect of various types of fats on heart lipid peroxidation status and on blood lipid parameters. Rats were fed either a low-fat diet (2.2% lard plus 2.2% corn oil), a corn oil diet (17%), a salmon oil diet (12.5%) supplemented with 4.5% corn oil, or a lard diet (15%) supplemented with 2% corn oil. All diets were supplemented with 1% cholesterol. Rats were fed for eight weeks. When compared with the low-fat diet, the salmon oil-diet intake resulted in a lower blood cholesterol, triglyceride and phospholipid concentrations (−50, −56 and −30%, respectively). Corn oil only tended to lower blood lipids; this decrease was significant for triglycerides only (−40%). The hypocholesterolemic effect of salmon oil diet is even more pronounced, if blood cholesterol values are compared with those of rats fed the lard diet. Heart lipid composition was not affected by dietary manipulations. Fatty acid composition of cardiac phosphatidylcholines and phosphatidylethanolamines, however, were altered by high-fat diets. In phosphatidylcholine, salmon oil induced a twelvefold decrease in the n-6/n-3 ratio and a 26% increase in the unsaturation index. For phosphatidylethanolamine, the n-6/n-3 ratio decreased 7.7-fold and the unsaturation index increased by 13%. A 50% decrease of the n-6/n-3 ratio was observed in animals fed the lard diet. Ultramicroscopic examination of ventricles revealed that those of the salmon oil group significantly accumulated lipofuscin-like or ceroid material, whereas this accumulation was barely detectable in hearts of the other groups. Selenium-dependent glutathione peroxidase activity tended to be the highest in hearts of rats fed the salmon oil diet; this increase is significant (+36% and +54% for total and specific activities, respectively), if values are compared with those of the rats fed the lard diet. Liver glutathione peroxidase and heart glutathione S-transferases activities remained unchanged. These results indicate that fish oil did not lower the selenium involved in glutathione peroxidase activity. This rules out that a deficiency in this enzyme was at the origin of heart lipofuscinosis. Also, it is concluded that the n-6/n-3 ratio of the diet is likely more determinant in the alteration of heart lipid peroxidation status than is the polyunsaturated/saturated ratio.
***Lipids 24,* 179–186 (1989).**

Fish consumption is considered as a promising nutritional approach to preventing cardiovascular diseases (1,2). Although fish oils are also expected to give the same effects (3–5), they, however, may induce an increase in sensitivity to membrane peroxidation because of their very high unsaturation degree. Indeed, n-3 polyunsaturated fatty acids (PUFA) comprising fish oils are efficiently incorporated into membrane phospholipids of various organs (6). Among these, the heart has been shown to respond to the dietary n-3 PUFA supplied by fish oils (7–12). This appears largely attributable to cardiomyocytes (13,14). As these n-3 PUFA (20:5 n-3, 22:5 n-3, 22:6 n-3) are oxidatively unstable, a higher sensitivity to membrane peroxidation can be expected in animals fed highly polyunsaturated oils (15–17). Consequently, a higher requirement of vitamin E may be needed (16–18). This could explain why the serum concentration of vitamin E in animals fed fish oils was always less than that in animals fed standard diets or polyunsaturated fats other than fish oils (12,19), although the dietary supply of the vitamin was largely adequate. This subnormal circulating vitamin E level was supposedly responsible for the mild, but significant, accumulation of lipofuscin-like or ceroid material observed in hearts of rats fed fish oil (12,20). This was not the case in hearts of pigs fed mackerel oils (21,22), although lipofuscin accumulated in their livers (21). It is possible that the lower amount of fish oil used or the species of animals tested may account for the differences observed in hearts.

Another component of the defense system against lipid peroxidation is the selenium-dependent glutathione peroxidase (GSH-PX; E.C. 1.11.1.9) (23) that has been reported in various tissues (20). This enzyme reduces hydroperoxides of PUFA, provided they are first released by intracellular phospholipase A_2 (24).

The increase in membrane unsaturation induced by fish-oil intake may lead to a higher requirement of GSH-PX and, consequently, of selenium. If the selenium status is subnormal or near the limit recommended, enzyme activity may be altered, thus resulting in an increase in the peroxidation level. The selenium metabolism is the object of intense studies (25). It is well established that a decrease in GSH-PX activity reflects a selenium deficiency (26,27) and that repletion of the element increases GSH-PX activity (27–29). However, the mechanism of enzyme regulation during repletion appears complex. A recent study (29) has shown that the chemical form of the element, as fed, did not affect enzyme activity, although in tissue cytosol the estimated percentage of selenium associated with the enzyme changed. Also, it has recently been demonstrated (28) that during selenium repletion the rate of increase in rat liver GSH-PX protein was significantly higher than that of its activity. From these results the authors (28) deduced that an active and an inactive form of GSH-PX coexisted. As the increase in activity is hyperbolic, the same authors concluded that the level

Abbreviations: ALAT, alanine aminotransferase; ASAT, aspartate aminotransferase; FAME, fatty acid methyl ester; GSH-PX, selenium-dependent glutathione peroxidase; GST, glutathione S-transferase; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PL, phospholipid; PUFA, polyunsaturated fatty acid; TG, triglyceride; ANOVA, analysis of variance; GLC, gas liquid chromatography; HPLC, high performance liquid chromatography; P/S, polyunsaturated/saturated.

of total selenium is not the primary factor regulating enzyme activity in selenium-adequate animals.

Thus, our purpose was to study the effect of fish oil on the heart selenium status, considering this element as an active component of GSH-PX. To this end, we compared the effects of a salmon oil diet with those of a corn oil, a saturated fat and a low-fat diet. Heart lipid status was studied by investigating lipid composition, GSH-PX and glutathione S-transferase (GST, E.C. 2.5.1.18) activities and ultramicroscopic aspects of myocardium. Some plasma parameters were also analyzed to assess the effectiveness of fish oil in lowering a diet-induced rise in plasma cholesterol and to evaluate cell injury indicated by enzyme release.

MATERIALS AND METHODS

Animals and feeding procedures. Four groups of 6 male Wistar rats (IFFA-CREDO, L'Arbresle, France), weighing 190–210 g, were used. One group was fed a low-fat diet (4.4%, w/w) consisting of an equal amount of lard and corn oil with a polyunsaturated/saturated (P/S) ratio of 1.2. A second group received a corn oil diet (17%, w/w) with a P/S ratio of 5. The third group received a salmon oil diet (12.5%, w/w), supplemented with 4.5% corn oil and a P/S ratio of 1.9, and the last group was fed a 15% lard diet supplemented with 2% corn oil and with a P/S ratio of 0.4. Table 1 presents the composition of the diets. All the diets were supplemented with 1% cholesterol (w/w) and contained ca. 60 μg/kg of selenium. Corn oil contained 45 mg of α-tocopherol per 100 g of oil. Salmon oil was supplemented with 20 mg of α-tocopherol and 20 mg of α-tocopheryl acetate per 100 g of oil. Lard contained 3 mg/100 g of α-tocopherol. Thus, the control diet supplied a total of 171 mg/kg of tocopherol and the lard, corn oil and salmon oil diets supplied 175, 246 and 232 mg/kg, respectively. Peroxide values of corn oil and salmon oil were zero and 3.8, respectively. In the middle of the experimentation period, the daily intake of 20:5n-3 was estimated at 1 g/kg body weight. The low-fat, corn oil and lard diets were prepared to last one month and stored at −20°C in plastic bags. The salmon oil diet was prepared every two weeks and stored at −20°C in sealed containers flushed with nitrogen. The rats were fed for 8 weeks ad libitum, and uneaten food was discarded in the morning. They had free access to tap water.

Detailed information on mineral, vitamin and fatty acid composition of the diets are given elsewhere (12,30). On the basis of the information given by U.A.R., the selenium content was estimated at 60 μg/kg.

UI, Unsaturation Index.

Tissue treatment and blood sampling. At the end of the feeding period, the rats were weighed and guillotined, in the morning and at the same time for each group. Blood was collected in lithium heparin-containing tubes. The heart was quickly excised and a biopsy of ventricular tissue was taken immediately and immersed in a 2.5% solution of glutaraldehyde, with further treatment by ultramicroscopy performed as previously described (12). Hearts were thoroughly rinsed at 4°C in a Tris-HCl buffer 20 mM (pH 7.5) containing 0.22 M mannitol and 70 mM sucrose. Tissue homogenization and lipid extraction were done as previously described (30). All lipid extracts were kept at −20°C under nitrogen until analysis. Livers were excised and homogenized with a Potter-Elvehjem in a buffer consisting of 50 mM KH_2PO_4, pH 7.4, 30 mM EDTA, 70 mM KCl, 1 mM dithiothreitol and 0.1 M sucrose.

Blood was centrifuged at 2,000 *g* for 20 min at 4°C and the plasma was collected for immediate analysis. The biopsies were observed with a Philips EM 300 microscope (Endoven, The Netherlands) at 80 kV. For each heart (2 per group), the frequency of lipid droplets or lipofuscin material was expressed as the ratio of the number of structures/number of unoverlapped fields examined (30 μm^2 each). The total number of fields examined (four grids issued from two hearts) was 214, 197, 184, 233 for low-fat, corn oil, salmon oil and lard diets, respectively. The person who did the observations was not aware of the nature of the samples.

Lipid analysis, plasma parameters and enzyme assays. Choline- and ethanolamine-containing phospholipids (PL) were separated by high performance liquid chromatography (HPLC) using a Waters-Associates liquid chromatograph system (Milford, MA) as previously described (31). Separated phospholipids were quantified by phosphorus determination (32). Fatty acid methyl esters (FAME) of PC and PE were prepared according to a rapid and convenient method used for vegetable oil triglycerides (TG) (33). FAME were separated as previously described (12, 30) using gas liquid chromatography (GLC) (Girdel 3000, Paris, France) equipped with a peak integrator (Girdel Co., Enica 10, Delsi, Suresne, France) and a 50-m capillary column (Spirawax FS 1493, Spiral, Dijon, France).

The TG concentrations of plasma and heart lipid extracts were determined by using the Technicon-Smac analyzer (Technicon, Tarry-Town, NY) according to the method of Bucolo and David (34). For heart-TG measurement, a sample of the heart lipid extract was evaporated to dryness under nitrogen and then dispersed by sonication in 20 mM Tris-HCl buffer, pH 8.0. Cholesterol concentration in the heart was evaluated from the same aqueous lipid dispersion with a cholesterol esterase–cholesterol oxidase kit (Boerhinger Mannheim, Mannheim, FRG) using a two-point kinetic method. Measurements were made with an automatic Multistat III (Instrumentation

Laboratory, Lexington, MA) at 30°C. Plasma cholesterol was determined with the Technicon-Smac analyzer according to the method of Lie et al. (35). Plasma PL were assayed with the Biolyon Kit (Ref. 44711, Wako Chemicals, Neuss, FRG) using the Technicon RA 1000.

Plasma alanine aminotransferase (ALAT) (E.C. 2.6.1.2) and aspartate aminotransferase (ASAT) (E.C. 2.6.1.1) were assayed according to the method of Kessler et al. (36), using the Technicon SMAC analyzer system. Alkaline phosphatase (E.C. 3.1.3.1) was assayed according to the method of Morgenstern et al. (37). Heart (100 μg protein) and liver (20 μg protein) GSH-PX activity (E.C. 1.11.1.9) was assayed, as described by Levander et al. (38), by using t-butylhydroperoxide to initiate the reaction. Heart glutathione S-transferase (E.C. 2.5.1.18) activity (100 μg protein) was assayed according to Habig et al. (39) by using 1-chloro-2,4-dinitrobenzene as substrate. Kinetics were recorded with an automatic DU 40 spectrophotometer (Beckman Instruments, Palo Alto, CA).

Chemicals and statistical analysis. FAME standards were from Interchim (Paris, France). Solvents were of HPLC grade and were filtered through a 0.2-μm Millipore filter before use. Results presented in the tables are means ± SD of 6 animals. Statistical significance of mean differences between dietary groups was investigated by analysis of variance (ANOVA) and by the Sheffé multiple comparison method at $p < 0.05$ or $p < 0.01$.

RESULTS

Over the 8-week feeding period, no significant difference ($p > 0.05$) was observed in body weight gains (in g): 162.0 ± 32.7, 185.0 ± 6.8, 178.0 ± 34.8 and 207.0 ± 34.8 for rats fed low-fat, corn oil, salmon oil and lard diets, respectively. Heart weights were not significantly different (in g): 0.80 ± 0.04, 0.84 ± 0.05, 0.91 ± 0.11 and 0.87 ± 0.07 in rats fed low fat, corn oil, salmon oil and lard diets respectively. Table 2 shows some of the relevant blood parameters. Total protein concentration was not affected by the diets ($p > 0.05$). Alkaline phosphatase, ALAT and ASAT activities remained unchanged ($p > 0.05$). The most striking effect of diets on plasma concerned lipid composition. Compared with the low-fat diet, salmon oil-diet intake resulted in a reduction by a factor of about 2 ($p < 0.01$) of both esterified and free cholesterol; with corn oil, this effect was much less pronounced and not significant. Salmon oil- and corn oil-diet intake led to a significant lower serum-TG concentration (−55% and −38%, respectively). The hypocholesterolemic property of salmon oil is even more pronounced, when comparing plasma cholesterol values of this group with those of the lard-diet group. The same observation was made for plasma-PL concentration.

Heart composition is shown in Table 3. Protein, total PL, cholesterol and TG concentrations were not

Protein, phospholipid, cholesterol and triglyceride concentrations are expressed per g of wet tissue. Phospholipid composition is in molar percentage. Values are means ± SD ($n = 6$).

PC, phosphatidylcholine; PE, phosphatidylethanolamine; SPH, Sphingomyelin.

significantly altered ($p > 0.05$) by the dietary manipulations. Only TG tended to increase in the hyperlipidic groups. The composition of choline- and ethanolamine-containing PL was not modified except for a slight, but insignificant, increase in PC and decrease in PE in the hearts of rats fed salmon oil. The amount of lyso derivatives of PC and PE remained unchanged ($p > 0.05$) in the four groups.

Marked variations were observed in the fatty acid composition of PC and PE (Table 4). In PC and PE, palmitic acid had the lowest levels in the corn oil group, whereas it had the highest level in PE of rats given the salmon oil diet. Monounsaturated fatty acids (18:1, essentially) were affected differently, depending on the nature of the diet and the class of phospholipid. When compared with the low-fat diet, the salmon oil diet lowered 18:1n-9 and n-7 in the two classes of PL, whereas corn oil and lard diets lowered 18:1n-7 in both classes. A drastic drop in arachidonic acid (20:4n-6) was induced by salmon oil in both PC and PE. In the latter, the value was 3.5-fold lower than that in the low-fat diet. In PE, corn oil provoked a slight, but significant, decrease in 20:4n-6. It induced a rise in the 22:4n-6 and 22:5n-6, mainly in PE. The primary feature arising from salmon oil intake was the appearance of eicosapentaenoic acid (20:5n-3) in cardiac PC and PE of rats fed salmon oil. In addition, 22:5n-3 and mainly 22:6n-3 were efficiently incorporated in the cardiac PL. The 22:6n-3 was increased by a factor of 7.9 and 2.8 in PC and PE, respectively. The lard diet also provoked a significant rise in 22:5n-3 and 22:6n-3, especially in PE. As shown in Table 4, the n-6/n-3 ratio of cardiac PC and PE of rats given the salmon oil diet dropped sharply as a consequence of n-3 PUFA incorporation. A decrease in this ratio was also observed in cardiac PL of rats fed the lard diet, but was less pronounced than that observed with the salmon oil diet. The highest increase in the unsaturation index of cardiac PL was provoked by the salmon oil diet (+26% in PC and +13% in PE). Compared with the low-fat diet, the lard diet induced a higher level of cardiac-PL unsaturation (+8% for both classes). This index was slightly increased in corn oil-fed animals: +8 and +3% in PC and PE, respectively.

Ultramicroscopic examination of ventricles revealed that a few lipid droplets were occasionally present in cardiomyocytes of rats fed low-fat as well high-fat diets (Table 5). The most striking feature of the hearts of rats given the salmon oil diet was the significant accumulation (Fig. 1 and Table 5) of dense granules structurally identified as lipofuscin or ceroid material (40).

As shown in Table 6, heart GSH-PX total and specific activities tended to be higher in the salmon oil group than in the other groups. These increases were significant ($p < 0.05$), when compared with those of the saturated lard diet. They were +36% and +54% for total and specific activities, respectively. Heart-GST activity, as well as liver GSH-PX activity, was not significantly modified among the four groups.

DISCUSSION

The high-fat diets were well accepted by the rats, none of which showed any significant difference in body weight at the end of the experiment. The previously mentioned hypocholesterolemic effect of fish oil (3,4,12) is confirmed. It even tended to be more pronounced than that of vegetable oil, if comparison is made with the saturated lard diet. The fact that most of the plasma lipid components were lowered, suggests that a drop in circulating lipoproteins occurred, as has been demonstrated for very low density, as well as low density lipoproteins in man (41). Heart lipid composition was not affected by the dietary manipulations. This is in agreement with previous studies performed in rats fed fish oils (7,8,12,30), but not with another report showing a global increase in heart TG, PL and cholesterol in rats fed higher amount of fish oil (42). However, we observed an average of 2.8%

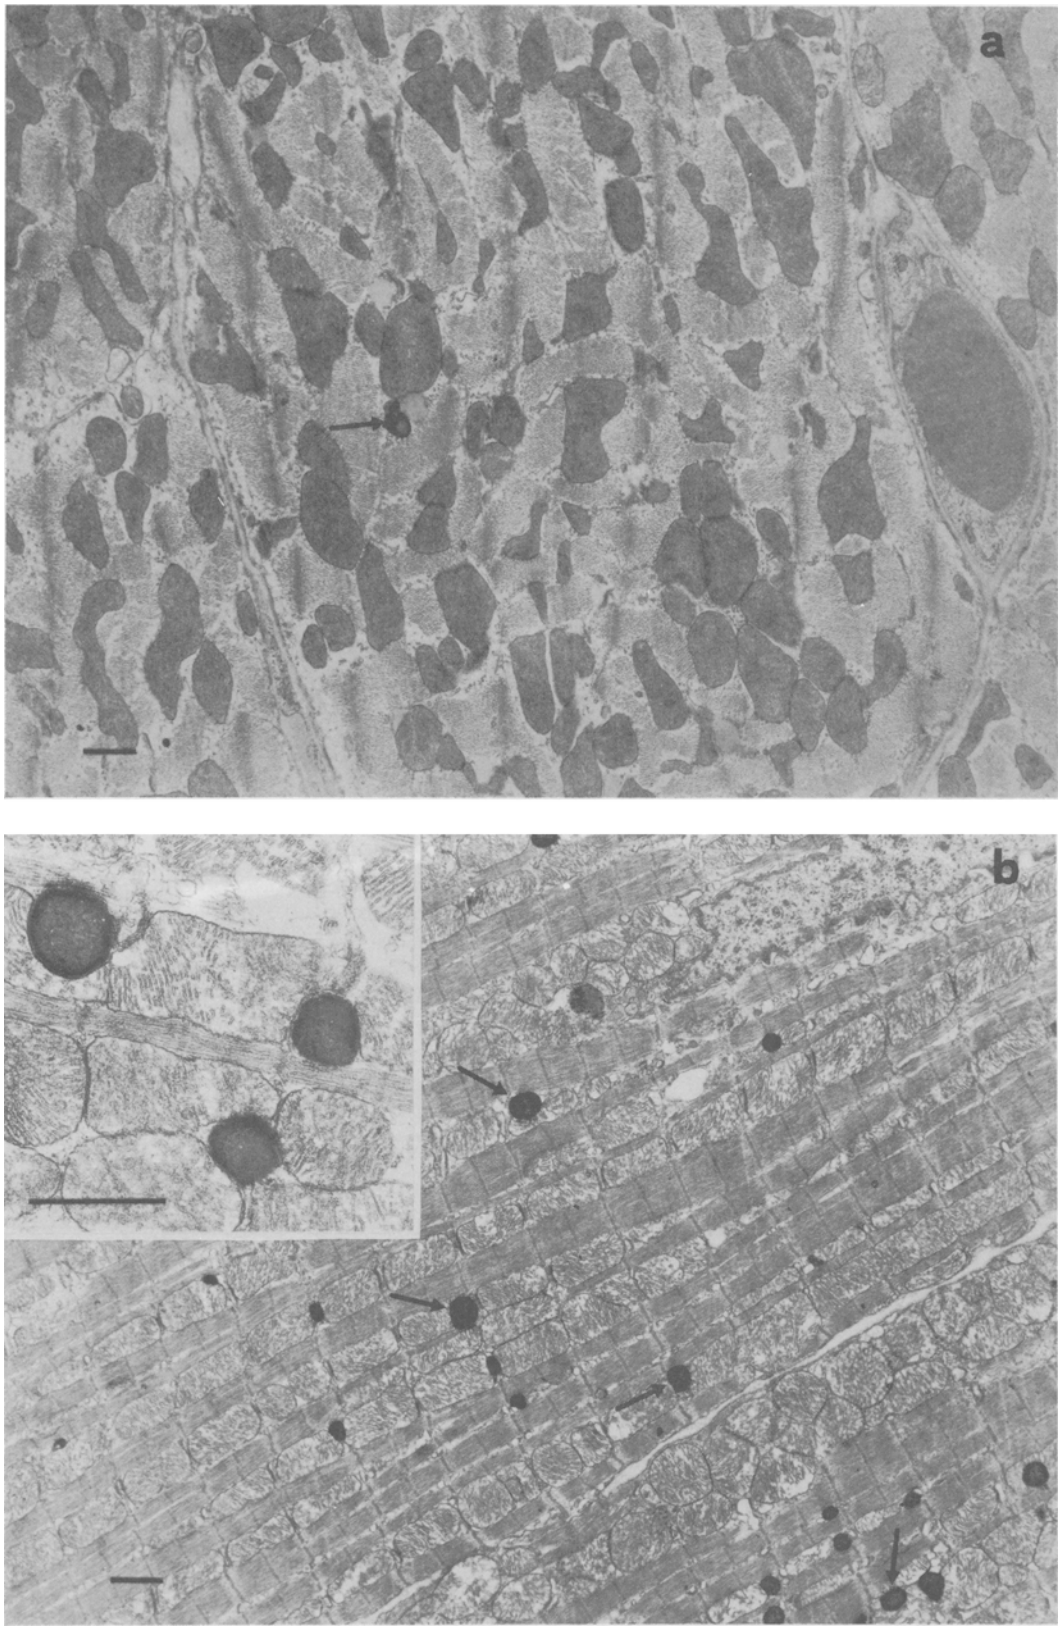

FIG. 1. Ultramicroscopic examination of ventricle of heart of rats fed low-fat (a) or salmon oil (b) diet. Arrows show some examples of lipofuscin or ceroid-like material. The bars indicates 1 μm.

TABLE 5

Estimation of Lipidosis and Lipofuscinosis in Heart Ventricle Myocytes of Rats Fed Various Diets

	Low-fat	Corn oil	Salmon oil	Lard
Intracytoplasmic lipid droplets	0.39 ± 0.10	0.34 ± 0.06	0.16 ± 0.03	0.35 ± 0.00
Lipofuscin-like material	0.11 ± 0.01^{a,**}	0.16 ± 0.09^{a,**}	1.63 ± 0.19^{b,**}	0.11 ± 0.04^{a,**}

Values that represent the frequency of structures (number per 30 μm^2) are means ± SEM; (n = 2). Procedures for counting are detailed in the Materials and Methods section. Values not bearing the same superscript letter are significantly different at $p < 0.01$ (**). Values without superscript letter are not statistically different ($p > 0.05$).

TABLE 6

Activities of Selenium-Dependent Glutathione Peroxidase and Glutathione S-Transferases in Heart and Liver of Rats Fed Various Diets

	Low-fat	Corn oil	Salmon oil	Lard
Heart				
GSH-PX Units/mg	0.40 ± 0.03^{a,b}	0.38 ± 0.04^{a,b}	0.51 ± 0.14^{a}	0.33 ± 0.05^{b}
GSH-PX Units/g	48.9 ± 6.6^{a,b}	47.0 ± 4.6^{a,b}	60.5 ± 10.9^{a}	44.1 ± 3.1^{b}
GSH S-Tr. Units/g	2.8 ± 0.4	2.6 ± 0.3	2.3 ± 0.5	2.2 ± 0.3
Liver				
GSH-PX Units/mg	1.3 ± 0.3	1.2 ± 0.1	1.5 ± 0.2	1.4 ± 0.3

One Unit corresponds to a micromol of substrate catalyzed/min. Activities are expressed either per g of wet tissue (total activity) or per mg of protein (specific activity). Values not bearing the same superscript letter are significantly different at $p < 0.05$; values are means ± SD (n = 6).

of cardiac lysoPE, whereas in our previous reports (12,30) this figure was ca. 1%. Because the percentages of lyso PC were similar, the increase in cardiac lysoPE might be specific and reflect a metabolic change induced by the cholesterol supplementation in the diets.

A more pronounced effect on cardiac fatty acid composition appeared with 12.5% salmon oil than with 17% corn oil. This may reflect different metabolic properties of n-3 and n-6 PUFA (43). It has been shown that n-3 PUFA competitively inhibit n-6 desaturation. Also, n-3 PUFA may be preferred as substrate by the acylCoA: lysoPCacyltransferase for acylation into lysophosphoglycerides. A cardiac cytosolic acyltransferase has been described as being selective towards some n-3 PUFA (44), although data with 22:5n-3 and 22:6n-3 were lacking. So, all these events may converge to enhance incorporation of n-3 PUFA in cardiac-membrane PL, especially the 22:6n-3, which became the predominant fatty acid in PE. A higher level of the 22:6n-3 was also induced by the lard diet in both PC and PE. This is the result of the preferential metabolism of n-3 by desaturases, especially when dietary supply of 18:n-6 is low. Thus, the n-6/n-3 ratio of the diet appears to be a more determinant factor in the modification of cardiac-PL fatty acid composition than is the P/S ratio or the amount of fat. This is in agreement with studies showing that lower (9,22), as well as higher, amounts (7,8,10,12) of dietary fish oils induced significant incorporation of n-3 PUFA in cardiac PL. Comparison of our results with previous studies (12,30) indicates that addition of cholesterol to the diets does not modify the rate of incorporation of either n-6 or n-3 PUFA in hearts. This was also found by others in rat heart and kidney, but not in liver (10).

As a result of n-3 incorporation, the unsaturation index of heart-membrane PL was increased in the salmon oil group. This may increase membrane-PL sensitivity to peroxidation. Indeed, ultramicroscopic examination of the ventricles revealed significant accumulation of lipofuscin-like or ceroid material in the salmon oil group, indicating a higher level of lipid peroxidation. Selenium deficiency is known to generate lipid peroxidation, as measured by pentane production (45). A minimal value of 40 μg of selenium per kg of diet had been recommended for optimal growth of rats (20), but this minimal value should now be around 70 μg/kg. Some authors (22) have supplemented their fish oil diets with selenium to prevent any deficiency induced by a higher demand to neutralize hydroperoxides. As our purpose was to study the effect of dietary PUFA on the GSH-PX activity in selenium basal conditions, no selenium was added. Our basal diet contained ca. 60 μg of selenium/kg, which is near the recommended limit. The specific activities of the GSH-PX measured in heart and liver of rats fed low-fat diet gave values in the range of those reported by Levander et al. (38). This suggests that our basal diet (low-fat) induced no deficiency in the active GSH-PX. However, it may be thought that the fish oil diet induced some deficiency in the selenium available for GSH-PX. This was not the case, because heart GSH-PX activity was not lowered in the salmon oil group and, significantly, was 50% higher than that measured in hearts of rats fed the saturated lard diet. Moreover, liver GSH-PX activity, which is used as an index of selenium status in animals (46), remained unchanged in all the experimental groups. This indicates that selenium availability for GSH-PX was not altered in the salmon oil group. It can be argued that if diets had

been supplemented with selenium, we might have observed a more pronounced activation of heart GSH-PX in rats fed salmon oil. But, on the other hand, if GSH-PX activity had been insufficient in the salmon oil group, we should have observed some activation of the GST, because these enzymes are known to compensate for inadequate activity of the selenium-dependent enzyme (38,47). In fact, GST activities remained unchanged, which again argues against a subnormal level of active GSH-PX in the salmon oil group.

It is interesting to compare the fish oil group with the lard group. In the latter, no significant lipofuscin accumulation was observed in heart, although 22:5n-3 and 22:6n-3 levels were higher than those of the low-fat group. GSH-PX, in this group, was even lower than that of the fish oil group. This would indicate that selenium-dependent enzyme activity is not the most important factor protecting lipids against peroxidation and that it was not involved in heart lipofuscin or ceroid accumulation in the fish oil group.

Deficiency or subnormal level of vitamin E, on the other hand, is well known to increase the level of peroxidation and ceroid accumulation in tissues (12,18,20,21,48–50). An increased P/S ratio in the diet has been proposed as a major factor leading to a higher susceptibility to peroxidation in rats (16). Our previous study (12) suggested that the n-6/n-3 ratio and the unsaturation index of the diets might be a more accurate parameter to investigate their effects on vitamin E status. Indeed, we showed that a salmon oil-enriched diet, more significantly lowered the plasma vitamin E concentration of rats than did a corn oil diet having a higher P/S ratio, but a lower unsaturation index and n-3/n-6 ratio than the salmon oil diet. In the present study, rats were given diets similar to those previously used (12), except they were supplemented with 1% cholesterol. Herein, we can reasonably infer a similar lowering effect of salmon oil on serum vitamin E. Nevertheless, two biological parameters allow us to suggest that vitamin E deficiency was not attained in the salmon oil group. First, blood transaminases were not elevated in this group, which is in contrast to the results in vitamin E and selenium-deficient pigs (50). Second, Cao et al. (51) have recently reported a higher level of lysoPC in the hearts of vitamin E-depleted rats. In our present experimental conditions, no significant increase in heart-lysoPC concentration could be detected in the salmon oil group. This lets us suggest that, although a subnormal vitamin E level was probably induced in this group, a serious deficiency level was not attained.

In conclusion, high intake of fish oil given for 2 months did not affect the enzymatic defense system against fatty acid hydroperoxides. Other factors like vitamin E or phospholipid hydroperoxide glutathione peroxidase (53) have to be considered when explaining heart lipofuscinosis.

ACKNOWLEDGMENTS

The authors are grateful to P. Garzino for the care of animals during the feeding period and to M. Bonneil for typing the manuscript. This work was supported by INSERM.

[Received May 3, 1988; Revision accepted November 4, 1988]

Isolation and Identification of Acetyl-CoA Carboxylase From Rainbow Trout (*Salmo gairdneri*) Liver

J.M. McKim, Jr.[a], H.W. Schaup[b], K. Marien[a] and D.P. Selivonchick[a,*]
[a]Department of Food Science and [b]Department of Biochemistry and Biophysics, Oregon State University, Corvallis, OR 97331

Acetyl-CoA carboxylase is the pivotal enzyme in the de novo synthesis of fatty acids and is the only carboxylase with a biotin-containing subunit greater than 200,000 daltons. The biotin moiety is covalently linked to the active site and has a high affinity ($K_d = 10^{-15}$ M) for the protein avidin. This relationship has been used in previous studies to identify acetyl-CoA carboxylase isolated from mammalian species. However, acetyl-CoA carboxylase has not been isolated and characterized in a poikilothermic species such as the rainbow trout. The present study describes the isolation and identification of acetyl-CoA carboxylase in the cytosol of rainbow trout *(Salmo gairdneri)* liver. The enzyme was isolated using two distinct procedures—polyethylene glycol precipitation and avidin-Sepharose affinity chromatography. Identification of the isolated protein as acetyl-CoA carboxylase was made by the following: (1) sodium dodecyl sulfate-polyacrylamide gel electrophoresis; (2) avidin binding; (3) in vivo labeling with [^{14}C]biotin; and (4) acetyl-CoA carboxylase-specific activity. The subunit molecular weight of the major protein was 230,000 daltons ± 3.3%. This protein was shown to bind avidin (M_r = 16,600) prior to sodium dodecyl sulfate-polyacrylamide gel electrophoresis, indicating the presence of biotin. In addition, protein isolated from fish that had previously received intraperitoneal injections of [^{14}C]biotin, showed the majority of radioactivity associated with the 230,000 dalton protein. The polyethylene glycol precipitation yielded 200 μg protein (4.4 μg/g liver), with a specific activity of 5 nmol malonyl-CoA/min/mg protein, whereas avidin affinity chromatography yielded 1.75 ± 1.1 mg protein (9.0 μg/g liver), with a specific activity of 1.37 ± 0.18 μmol malonyl-CoA/min/mg protein. The enzyme was citrate dependent showing maximum activity between 10 and 20 mM. Acetyl-CoA carboxylase-specific activity decreased by 50% in the presence of 0.2 M NaCl. These findings suggest that the major protein (M_r = 230,000) purified from rainbow trout liver is acetyl-CoA carboxylase with enzyme characteristics comparable to mammalian acetyl-CoA carboxylase.
***Lipids 24,* 187-192 (1989).**

Acetyl CoA-carboxylase (ACC) [EC 6.4.1.2] is a biotin-containing enzyme responsible for the first committed step in the de novo synthesis of fatty acids (1-3). The enzyme has been isolated and characterized from several mammalian tissues, including rat liver (4-7), rat mammary gland (8) and rabbit mammary gland (9,10), as well as from chicken liver (11) and goose uropygial gland (12). These studies reported a subunit (M_r) for ACC that ranged from 225,000 to 260,000 daltons. However, this enzyme has not been characterized or purified to homogeneity in a poikilothermic species.

The rainbow trout *(Salmo gairdneri)* is currently being used as an alternative vertebrate model (13-15) for testing the carcinogenic effects of environmental and dietary toxicants, such as nitrosamines (16,17), aflatoxin B_1 and cyclopropenoid fatty acids (CPFA) (18-20). These studies have shown that the liver is the primary site of toxicity for these compounds. Because the liver is also the principle organ for lipogenesis in fish (21), it is possible that these compounds, as well as others, may adversely affect the primary lipogenic enzymes ACC and/or fatty acid synthetase.

In this laboratory, preliminary studies using rainbow trout identified ACC (M_r = 220,000) from the microsomal fraction of liver homogenates and revealed that the enzyme was closely associated with, but not bound to, liver endoplasmic reticulum. It was also observed that fish exposed to dietary CPFA showed a significant reduction in liver microsomal ACC (22). The presence of this enzyme in the microsomal fraction is of interest, because it is well known that the biochemical pathway involved with lipogenesis occurs in the cytosol of cells. Previous studies (4-12) have, therefore, concentrated on isolating the enzyme from the soluble fraction of tissue preparations. Recently, other workers have reported mammalian ACC to be associated with the mitochondira (23) and endoplasmic reticulum (24). These investigations not only support our earlier findings in trout, but also suggest that fatty acid synthesis and, hence, ACC are not confined to the cytosol.

Before toxicity data obtained from a poikilotherm model can be used to predict similar effects in a homoiotherm model, it is necessary to fully understand the similarities and differences of the enzyme affected in both systems. We report here the first purification of ACC from the cytosol of rainbow trout liver.

MATERIALS AND METHODS

Chemicals. [^{14}C]Biotin and [^{14}C]sodium bicarbonate were purchased from Amersham Inc. (Arlington Heights, IL). Polyacrylamide (99%), protein standards and all other electrophoresis supplies were obtained from Bio Rad (Richmond, CA). All other reagents were purchased from Sigma Chemical Co. (St. Louis, MO) and were of the purest grade available.

Animals and diets. Mt. Shasta strain rainbow trout *(Salmo gairdneri)* were used for all analyses. These were spawned and reared at the Oregon State University Food Toxicology and Nutrition Laboratory. The control diet (diet A) consisted of a dextrose and casein-gelatin mixture containing 10% lipid. The test diet (diet B) contained 20% carbohydrate with no lipid or biotin. All animals were ca. 1 yr of age and weighed 300-700 g.

Isolation of acetyl-CoA carboxylase. Fish were killed by a sharp blow to the head and the livers were excised immediately and placed in ice-cold homogenization buffer

Abbreviations: ACC, Acetyl-CoA carboxylase; CPFA, cyclopropenoid fatty acid; PEG, polyethylene glycol precipitation; SDS-PAGE, sodium dodecyl sulfate-polyacrylamide gel electrophoresis.

(Tris-HCl 100 mM pH 7.4, sucrose 0.25 M, EDTA 2 mM, β-mercaptoethanol 15 mM and phenylmethylsulfonyl fluoride 0.4 mM) as a rinse. After rinsing, the livers were placed in an ice-cold glass blender pitcher that contained a small volume of the homogenization buffer. When all livers had been removed and placed in the pitcher, three volumes of ice-cold homogenization buffer were added and the livers homogenized by pulsating (5-sec intervals) at high speed for 20 sec. The homogenate was allowed to settle and the foam was removed by aspiration. The homogenate was filtered through cheese cloth to remove fibrous materials and then centrifuged at 100,000 × *g* for 1 hr at 4°C. The supernatant was subjected to ammonium sulfate precipitation (35% of saturation) and two 3% polyethylene glycol (PEG) precipitations, as described previously (9). Protein concentrations were determined either by absorbance at 280 nm or the Bradford assay (25).

Acetyl-CoA carboxylase activity. ACC activity was assayed using the [^{14}C]bicarbonate fixation procedure (26,27). The reaction buffer (Tris-Acetate, 70 mM, pH 7.5; potassium acetate, 120 mM; reduced glutathione, 4 mM; potassium citrate, 10 mM; ATP, 1 mM; bovine serum albumin, 0.6 mg/ml; acetyl-CoA, 0.35 mM; and magnesium acetate, 10 mM) was essentially as described by Allred and Roehrig (26), with the following modifications: nonlabeled bicarbonate was omitted to increase sensitivity, and samples were incubated with 7 mM (0.25 μCi) of sodium [^{14}C]bicarbonate (0.1 μCi/μmole) at 37°C for 2–3 min. Final reaction volumes were 0.5 ml and reactions were started by addition of enzyme. Controls were performed in the absence of enzyme or acetyl-CoA.

Binding avidin to PEG-isolated acetyl-CoA-carboxylase prior to sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). Ten fish (45 g liver tissue) were killed and prepared according to the method previously described. Avidin was bound to ACC essentially as described by Goodson et al. (5). ACC (3 μg) was added to 0.15 ml of sample buffer (Tris-HCl, 0.0625 M, pH 6.8; 4% sodium dodecyl sulfate (SDS), w/v; 2% dithiothreitol; 5% glycerol and 0.003% bromophenol blue) and the mixture was heated 2–3 min at 95°C. After cooling, 50 μg of N-acetylated monomeric avidin was added and the mixture was allowed to stand for 5 min. The sample was loaded onto an acrylamide gel (18.0 cm × 16.5 cm × 0.2 cm) consisting of a 3.5% stacking gel and a 5% resolving gel (28). The sample was electrophoresed at 21 mA constant current for 7 hr, stained overnight with Coomassie Blue and destained with a 50% methanol, 10% acetic acid solution for several hours.

In vivo [^{14}C]biotin incorporation into acetyl-CoA carboxylase. Ten fish (450–600 g) were fasted for 1 month, then fed diet B for 5 days. During this feeding period, each fish received daily i.p. injections of 2 μCi [^{14}C]biotin in 0.2 ml distilled water. After sacrifice, ACC was isolated by the PEG procedure run on SDS-PAGE and stained Coomassie Blue, as previously described. The gel was sliced into 2 mm segments, each of which was placed into a 1.5 ml Eppendorf micro centrifuge tube and dried in an oven at 60°C. Following the addition of 0.1 ml 30% hydrogen peroxide, each segment was incubated again at 60°C to solubilize the gel. Once solubilized, each tube received 0.4 ml of water and 5.0 ml ACS scintillation fluid and the radioactivity in each segment was determined using a Beckman model LS 3801 scintillation counter, as previously described (7).

Avidin affinity chromatography. Avidin was cross-linked to the Sepharose according to Thampy and Wakil (4), as modified from Beaty and Lane (11). The biotin binding capacity of the column was 13 nmoles/ml of packed column. Ca. 200 g of liver tissue was removed and prepared as described above, except that the PEG precipitations were omitted. The 100,000 × *g* supernatant was subjected to ammonium sulfate precipitation (35% or 26% of saturation) and the pellet collected by centrifugation at 20,000 × *g* for 20 min. The $(NH_4)_2SO_4$ pellet was resuspended in a minimum volume of column buffer (Tris-HCl, 100 mM, pH 7.5; EDTA 1.0 mM; dithiothreitol 0.1 mM; NaCl 0.5 M; glycerol 5.0% (v/v) and phenylmethylsulfonyl flouride 0.4 mM) and added to the avidin-Sepharose gel, forming a slurry. To prevent settling and ensure uniform mixing, the preparation was gently shaken at 4°C for 4–6 hr. The suspension was then gently poured into a 150-ml glass fritted funnel mounted on a vacuum flask and washed with 4–6 liters of column buffer (precooled to 4°C) to remove unbound protein. The cleaned avidin-Sepharose gel, now containing bound ACC, was transferred to a Bio Rad econo column, 10 cm in length by 2.5 cm in diameter with a 50-ml capacity. ACC was eluted with 0.2 mM biotin in column buffer without the 0.4 mM phenyl-methylsulfonyl flouride. The column was attached to a peristaltic pump and the flow rate set at 3–5 ml/hr. Fractions were collected in 1.0-ml aliquots and analyzed for protein content on a Beckman spectrophotometer at 280 nm. The fractions containing protein were pooled and dialyzed 4–5 hr at 4°C against column buffer without NaCl. This dialysis is important, because NaCl will greatly decrease ACC activity. ACC-specific activity and protein content were then determined. The final preparation was aliquoted, frozen rapidly in liquid nitrogen and stored at −70°C.

RESULTS

ACC was initially isolated and purified using the PEG procedure first described by Hardie and Cohen (9). The protein concentration in the final preparation was 200 g (45 g liver tissue, 4.4 μg ACC/g liver). A portion of the final preparation was subjected to SDS-PAGE and the protein visualized by Coomassie Blue staining. As shown in Figure 1, lanes 2 and 3, the major band detected had an (M_r) of 230,000 daltons ± 3.3%, as determined by its electrophoretic mobility (Fig. 2). Two minor protein components (Fig. 1, lanes 2 and 3, [a,b]) were closely associated with the putative ACC.

Biotin is covalently bound to all known carboxylases. Therefore, to show the presence of biotin in the 230,000-dalton protein, another portion of the PEG-isolated protein was incubated with N-acetylated monomeric avidin. Because the binding affinity between avidin and biotin is high, (Kd = 10^{-13}, for monomeric avidin), the avidin (M_r = 16,600) bound to the putative ACC forms a stable ACC-avidin complex. The molecular weight of this complex was found to be approximately equal to the sum of the two subunits—248,000 daltons (Fig. 1, lane 1; and Fig. 2). In Figure 1, lane 1, both the major 230,000-dalton band and minor component (b) bind to avidin. This results in an increased molecular weight and a decreased

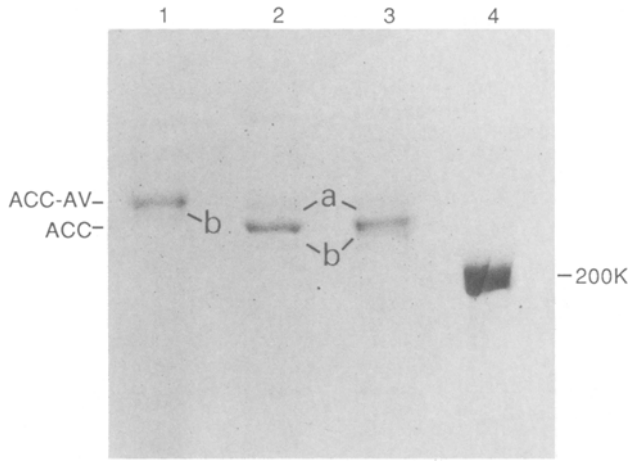

FIG. 1. SDS-PAGE analysis (5% polyacrylamide) and subsequent staining with Coomassie Blue of the putative acetyl-CoA carboxylase (ACC) at 230,000 daltons obtained from the PEG-precipitation procedure. Lane 1 shows the formation of a carboxylase-avidin complex (ACC-AV) and the subsequent increase in mol wt from 230,000 to 248,000. Lane 2 represents 3 μg ACC after 4 hr dialysis. Lane 3 is 3 μg ACC without dialysis. Lane 4 is a myosin standard marker. The bands identified as (a) and (b) are minor components (see Results).

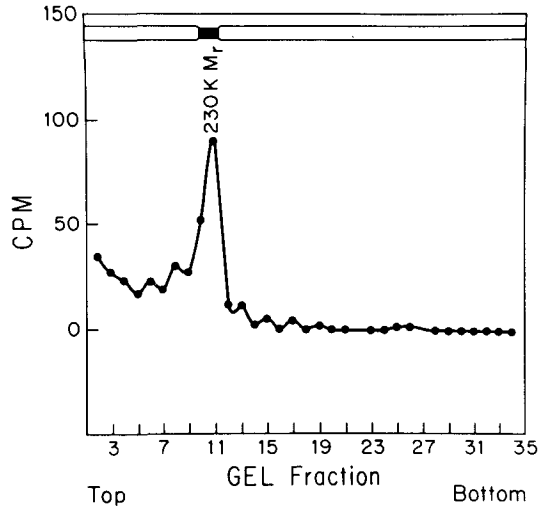

FIG. 3. SDS-PAGE analysis (5% polyacrylamide) of [^{14}C]biotin labeled acetyl-CoA carboxylase, isolated by the PEG procedure. The amount of protein used was 25 μg (12.0 CPM/μg protein). After electrophoresis at 21 mA constant current for 7 hr, the gel was stained with Coomassie Blue (gel not shown) and sliced into 2-mm segments. The radioactivity content of each slice was determined as described in Materials and Methods and the distribution of [^{14}C]biotin plotted. The majority of the radioactivity was observed in the 230,000-dalton region of the gel.

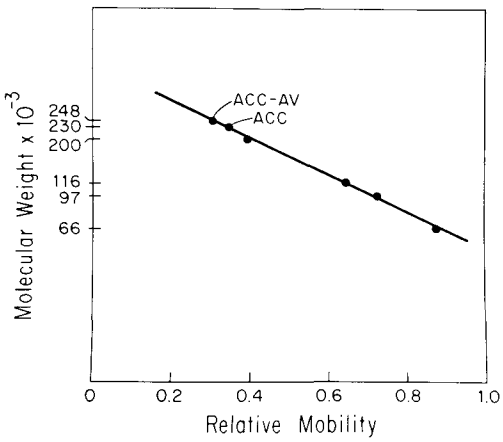

FIG. 2. Mol wt determination for rainbow trout acetyl-CoA carboxylase (ACC). Subunit mol wt (MW) of the Bio Rad protein standards, ($\times 10^{-3}$) were as follows: Myosin (200), β-galactosidase (116), phosphorylase b (97) and bovine serum albumin (66). The putative ACC was (230), and the acetyl-CoA carboxylase-avidin complex (ACC-AV) was (248). The graph was derived by plotting the $\log_{10}$ values of the subunit (MWs) against their relative mobility. Actual MW ($\times 10^{-3}$) are shown for easier evaluation.

electrophoretic mobility. Subsequently, both bands appear above their counterparts in lanes 2 and 3. This evidence suggests that protein (b) also possesses biotin and is most likely a proteolytic fragment of the major 230,000-dalton band. Protein (a) on the other hand did not bind avidin and did not change its position relative to lanes 2 and 3. Therefore, component (a) is not visible in lane 1 (the ACC-AV complex is coeluting with protein [a]), suggesting that it did not react with avidin and, therefore, could not be an active subunit of ACC.

Additional evidence showing the presence of biotin in the 230,000-dalton protein is shown in Figure 3. These data represent the in vivo incorporation of [^{14}C]biotin into the 230,000-dalton protein. The protein was isolated by the PEG procedure and analyzed by SDS-PAGE. The graph depicts the distribution of radioactivity in the gel, showing the majority of activity present in the 230,000-dalton region.

The PEG isolation was adequate for making a preliminary identification of the 230,000-dalton band as ACC. However, the final preparation was not homogeneous and proteolysis was apparent. Several attempts to improve the quality of the isolation were unsuccessful. In addition, the specific activity of citrate-activated (10 mM) ACC (5.0 nmoles/min/mg protein) was extremely low in this procedure.

Therefore, to improve the purification procedure and verify the data obtained from the PEG isolation, fresh liver tissue was extracted, homogenized and centrifuged at 100,000 × *g* and subjected to 26% $(NH_4)_2SO_4$ precipitation, as described previously for the PEG procedure. However, instead of continuing with the PEG purification, the $(NH_4)_2SO_4$ fraction was further purified using avidin-affinity chromatography. Figure 4 shows the elution of ACC from the column, as determined by its absorbance at 280 nm. Total ACC activity (μmol malonyl-CoA/min/ml) in selected fractions showed a single peak that coincided with the protein peak. The amount of protein recovered was 1.75 mg ± 1.1 (9.0 μg ACC/g liver), and the activity in the combined fractions was 1.37 ± 0.18 μmol malonyl-CoA/min/mg ACC. A sample of the column-purified ACC was analyzed by SDS-PAGE (Fig. 5). The Coomassie Blue stained gel revealed a single protein band with a subunit (M_r) of 230,000 daltons. The two minor components observed in the PEG isolation procedure (Fig. 1) were not present.

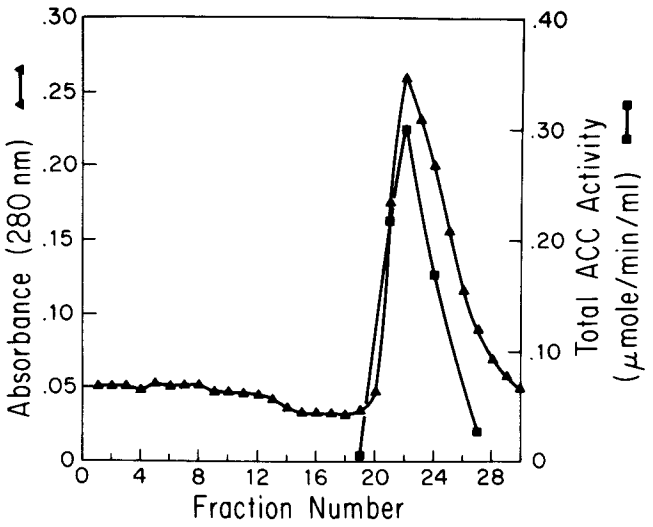

FIG. 4. Elution of ACC from the avidin-Sepharose column using 0.2 mM biotin in column buffer. Fractions were collected in 1.0 ml aliquots at a flow rate of 3–5 ml/hr. ACC total activity coincided with the protein peak. The biotin binding capacity was 13 nmoles/ml packed gel.

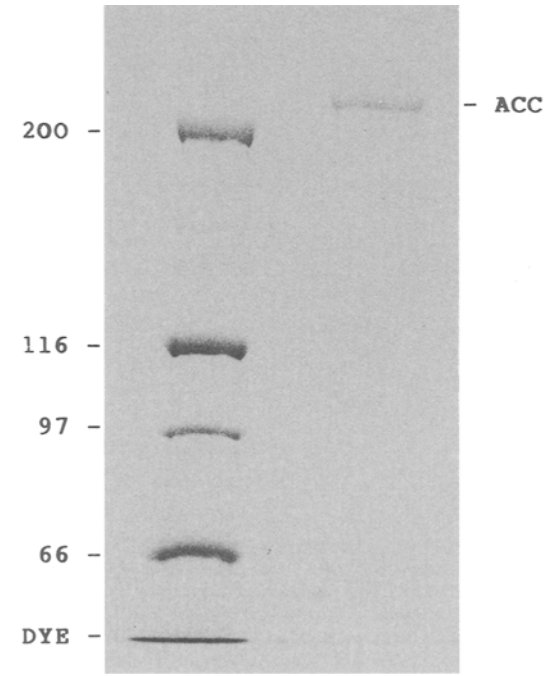

FIG. 5. SDS-PAGE analysis (5% polyacrylamide) and subsequent staining with Coomassie Blue of protein recovered from the avidin-Sepharose column. Lane 1 contains Bio Rad high mol wt standards ($\times 10^{-3}$). Lane 2 received 5 μg protein and shows a single protein (M_r = 230,000) component.

A typical purification using avidin affinity chromatography is shown in Table 1. Data obtained from mammalian and avian species using essentially the same protocol are included for comparison. It is difficult to accurately access ACC activity in crude cell fractions due to interference by malonyl-CoA decarboxylase and contamination by mitochondrial pyruvate carboxylase (29). However, the values are useful as a relative comparison between species and to monitor the success of the purification procedure. Data presented in Table 1 can be summarized as follows: (1) Throughout the purification,

TABLE 1

Purification of Acetyl-CoA Carboxylase (ACC) From Rat, Chicken, Goose and Rainbow Trout Using Avidin-Sepharose Affinity Chromatography

Fraction	Species	Tissue	Total protein (mg)	Total[a] Act. (U)	Specific Act. (U/mg)	Purification (-fold)
100,000 × *g*						
	Rat[b]	Liver	11,169	40.1	.004	1.0
	Chicken[c]	Liver	4,000	400.0	.010	1.0
	Goose[d]	Uropy	2,240	44.0	.020	1.0
	Trout[e]	Liver	11,800	21.0	.002	1.0
$(NH_4)_2SO_4$						
35%	Rat	Liver	1,248	31.2	.025	6.25
25%	Chicken	Liver	360	162.0	.450	45.00
30%	Goose	Uropy	60	35.0	.590	30.00
26%	Trout	Liver	172	3.0	.020	10.00
Avidin-Sepharose column						
	Rat	Liver	20.0	37.10	1.830	458.00
	Chicken	Liver	29.4	153.00	5.200	520.00
	Goose	Uropy	3.0	15.00	5.000	250.00
	Trout	Liver	1.0	1.24	1.240	620.00

[a]Activity in all studies was determined using the [^{14}C]bicarbonate fixation assay at 37°C. One unit (U) equals μmol malonyl-CoA produced per min at 37°C.

[b]From 200 g liver; ACC production was induced by diet (Ref. [6]).

[c]From 500 g liver; citrate was included throughout the isolation (Ref. [11]).

[d]From five uropygial glands; gel filtration preceded the 30% $(NH_4)_2SO_4$ (Ref. [12]).

[e]From 200 g liver; fish received standard diet.

ACC total activity in trout was significantly lower than in the other species; (2) each step in the procedure resulted in a several-fold increase in purity for all species; (3) the specific activity of trout ACC in the final fraction, although lower, was comparable with values obtained in rat, chicken and goose; and (4) the overall recovery of trout ACC per gram of liver was less than in the other species.

Activity assays performed at various citrate concentrations (0, 2, 5, 10, 20 and 40 mM) revealed the enzyme was citrate dependent with optimal citrate levels between 10 and 20 mM. At 40 mM and at higher citrate concentrations, ACC-specific activity decreased. In addition, sodium chloride (0.2M) in the reaction mixture decreased ACC-specific activity by 50%. These findings are all characteristic of ACC isolated from homoiotherms and are consistent with data reported in previous studies (12).

DISCUSSION

ACC has been identified and characterized in several mammalian species. The activity of ACC in various fish species has been studied only in crude cell fractions (30–32). The present investigation provides the first description and characterization of ACC purified from rainbow trout liver cytosol. To accomplish this, advantage was taken of the fact that ACC is predominantly a cytosolic enzyme with a subunit (M_r) greater than 200,000 daltons. The remaining carboxylases are confined to the mitochondria and possess a subunit (M_r) less than 200,000 daltons (3,5). In addition, ACC (as well as the other carboxylases) contains a covalently linked biotin moiety associated with each subunit. Thus, a protein isolated from the soluble fraction that possesses biotin and has a subunit (M_r) greater than 200,000 daltons is consistent with the characteristic properties of ACC.

The subunit (M_r) of the major protein isolated from rainbow trout using two different techniques was determined to be 230,000 daltons. This is in agreement with the (M_r) range of 225,000–260,000 daltons reported for mammals. To establish that this protein also possessed a biotin moiety essential for carboxylase activity, it was incubated with monomeric avidin. The resulting protein-avidin complex showed an increase in the (M_r), as judged by a reduction in its electrophoretic mobility. These data suggest that the entire 230,000-dalton band in Figure 1, lane 1, was composed of the biotinyl protein. The fact that protein (b) also bound avidin, strongly suggests that it is a proteolytic fragment of the larger protein. This proteolytic fragment was also observed by Hardie and Cohen (10). Protein (a) (Fig. 1, lane 1) did not move up relative to its position in lanes 2 and 3. This suggests that (a) did not possess biotin and therefore must be a contaminant. The electrophoretic properties and close association of band (a) with ACC suggests that protein (a) is fatty acid synthetase, which has been shown to electrophorese slightly above ACC (10). To be certain that the observed ACC-avidin complex (Fig. 1, lane 1) was the result of a specific biotin-avidin interaction and not random association of avidin with the 230,000-dalton protein, [^{14}C]biotin was incorporated into the carboxylase in vivo. The results of this experiment confirmed the presence of biotin in the 230,000-dalton band and showed that the observed interaction between avidin and the suspected ACC (M_r = 230,000) was associated with the presence of this moiety.

The PEG-isolation procedure was useful in establishing the presence of biotin in the 230,000-dalton protein. However, ACC-specific activity, as well as the amount of protein obtained (4.4 μg/g liver), was extremely low. Additionally, small amounts of contaminant proteins were apparent. Therefore, avidin-Sepharose affinity chromatography was used to purify trout ACC to homogeneity.

This procedure yielded a homogeneous ACC preparation without the proteolysis observed using the PEG procedure. In addition, ACC-specific activity in the final fraction was substantially higher than the PEG isolation and comparable with ACC activity reported in homoiothermic species. The average amount of ACC recovered per gram of liver increased from 4.4 μg to 9.0 μg.

The data presented here provides good evidence that the 230,000-dalton protein isolated from rainbow trout liver cytosol is ACC, with a subunit (M_r) and enzyme characteristics comparable with mammalian ACC. These similarities are important, because the rainbow trout is being used to study the effects of various toxicants on lipogenesis. The fact that the fish ACC possesses many of the same biochemical properties as rat ACC suggests that toxicants directly affecting this important lipogenic enzyme in trout may also cause the same effects in mammals. Finally, these data provide an important impetus to studies currently underway in our laboratory and aimed at understanding the mechanisms by which xenobiotics affect ACC and the processes involved with lipogenesis in the rainbow trout model.

ACKNOWLEDGMENTS

The authors thank K. G. Thampy and S. J. Wakil for providing information and assistance enabling the preparation of the avidin columns and John Casteel, Ted Will and Sheila Cleveland for feeding and maintaining the fish during this study and for assisting with various procedures. We are also grateful to Roderick Dashwood for his critical review of this article and to Adeline G. McKim for typing this manuscript. This work was supported by NIH Grant R01 CA30087-04 to D.P.S. J. M. McKim is a predoctoral candidate in the Oregon State University Toxicology Graduate Training Program funded by training Grant No. 5T32 ES07060 from the NIEHS. In vivo Incorporation of Lauric Acid Into Rat Adipose Tissue Triacylglycerols

Maurice Bugaut
Laboratoire de Physiologie Animale et de la Nutrition, Faculté des Sciences Mirande, B.P. 138, 21004 DIJON Cedex, France

An in vivo approach was taken to examine fatty acid esterification in adipose tissue using a coconut oil-enriched diet. Rats were fed a diet containing coconut oil (50% lauric acid) for six weeks. Triacylglycerols from perirenal adipose tissue were fractionated by silver nitrate–thin layer chromatography and, then, preparative gas chromatography. The distribution of 169 triacylglycerol types accounting for 97% of total triacylglycerols was determined. There was evidence for a very high content of mixed triacylglycerols composed of intermediate (12:0 and 14:0) and long acyl moieties. No significant differences were observed between the experimental distribution of triacylglycerol types and the random distribution, calculated from the total fatty acid composition. This indicated that most long chain triacylglycerols stored before coconut oil feeding would have been rearranged after the six weeks of coconut oil feeding. The experimental proportion of trilauroylglycerol reached 2%, as expected from its random proportion, and the proportions of dilauroylacylglycerols were slightly higher than the random values. Present results were compared with those previously obtained from triacylglycerols of adipose tissue of rats fed a low-fat standard diet (1,2). From our results and those of other authors, it is suggested that lauric acid is a good substrate for *sn*-glycero-3-phosphate acyltransferase and diacylglycerol acyltransferase in rat adipose tissue.
***Lipids 24,* 193–203 (1989).**

Adipose tissue, as most tissues, is able to synthesize only fatty acids longer than C14 (3), but may incorporate shorter chains (4), if present in the plasma. Lauric acid, probably by passive permeation (5), is transported through the plasma membrane of rat adipocytes; and although this fatty acid is transported less efficiently than longer chain acids (6), it is easily stored in the triacylglycerols of body fat of coconut oil (50% lauric acid)-fed animals, whereas shorter chain acids are not deposited (7). The mechanism of triacylglycerol biosynthesis in adipose tissue has been the subject of some interest (8), but much remains to be learned of the factors (including the chain length of fatty acids) that control intracellular esterification.

In the present study, rats were given CO for 6 weeks, and the distribution of triacylglycerol types in the triacylglycerols of the perirenal adipose tissue (TCO) was determined. The results were compared with those previously obtained from the triacylglycerols of the adipose tissue of rats fed a low-fat standard diet (TC), analyzed under similar conditions (1,2). The present results provide useful information about controlling the chain length of the fatty acids that acylate the glycerol moiety during triacylglycerol synthesis in rat adipose tissue. The results, however, cannot be used to define the precise mechanism of biosynthesis.

Abbreviations: $AgNO_3$, silver nitrate; CO, coconut oil; TC, triacylglycerols from rats fed a standard diet; TCO, triacylglycerols from rats fed a standard diet with 20% CO; VLDL, very low density lipoproteins.

MATERIALS AND METHODS

Source of triacylglycerols. Male Wistar rats of the same age (Lessieux, Sèvres, France) were supplied a low-fat standard diet (UAR, Villemoisson, France) ad libitum for 4 weeks before any experiment. A preliminary study was undertaken to determine the pattern of deposition of intermediate chain fatty acids (12:0 + 14:0) into adipose tissue. Rats weighing 150 g were fed the standard diet supplemented with 20% (w/w) CO for 7 weeks. Three rats were killed each week and perirenal adipose tissue was excised from both sides. Total lipids were extracted according to Delsal (9). Aliquots of total lipids obtained from 3 rats killed at a fixed time were pooled and, then, analyzed by gas chromatography for their fatty acid profiles.

In a second step, 2 groups of 6 rats weighing ca. 285 g each were maintained on either the standard diet or the 20%-CO diet for 6 weeks. All rats were weighed each week and sacrificed after 6 weeks. Perirenal adipose tissue was excised and weighed, and total lipids were extracted. The 6 rats fed the standard diet were only used as control animals to assess body growth, and weight and lipid content of the adipose tissue. Aliquots of total lipids from the 6 CO-fed rats were pooled and fractionated on a column of silicic acid according to Fillerup and Mead's procedure (10) for preparing pure triacylglycerols (TCO). The purity of the triacylglycerols was controlled by thin layer chromatography using a mixture of hexane/diethyl ether/acetic acid (90:30:1, v/v/v) as the solvent system. TCO were then fractionated by $AgNO_3$-thin layer chromatography and preparative gas chromatography to determine the distribution of triacylglycerol types.

The standard diet contained only 3.7% (w/w) lipids made up of 67% triacylglycerols, 15% free fatty acids, 9% phospholipids, 6% diacylglycerols, 2% monoacylglycerols and 0.8% sterol esters (as the mol % of fatty acids for all the lipids). CO (Astra Calvé, Asnières, France) consisted of 96% triacylglycerols and 4% diacylglycerols. The main constituents (wt %) of the standard diet enriched with 20% CO were carbohydrates (46.4%), lipids (23.0%), proteins (13.6%), water (9.0%), cellulose (4.0%), minerals (4.0%) and vitamins. Lipids in the 20%-CO diet, therefore, consisted of CO (87.1%) and long chain lipids (12.9%) originating from the standard diet.

TC (triacylglycerols from perirenal adipose tissue of rats fed a standard diet) have previously been studied (1,2), and some results are used here for comparison. The rats had been fed the same low-fat standard diet as that described above.

$AgNO_3$-thin layer chromatography. Total TCO were fractionated according to the degree of unsaturation on Silica Gel G (Merck, Darmstadt, FRG) impregnated with 10% silver nitrate in three steps using chloroform

(stabilized with 0.4% ethanol) made more or less polar by adding methanol (0–1.5%). The bands were scraped and the triacylglycerols were extracted as previously described (1). The proportions of the bands were determined using two internal standards—tritridecanoylglycerol added at the beginning of the extraction of triacylglycerols from $AgNO_3$-silica powder and pentadecanoic acid added before preparing the butyl esters. The proportions of the bands were eventually corrected of contaminations due to overlapping or tailing. The extent of these contaminations was calculated from the fatty acid composition of the bands.

Gas chromatography. Although triacylglycerols can be resolved by high performance liquid chromatography into numerous peaks, depending on both the degree of unsaturation and chain length, gas chromatography was chosen for several reasons—separation of triacylglycerols according to only one precise characteristic (total carbon number), elution of long chain triacylglycerols in a relatively short time and possible fractionation of minute amounts of triacylglycerols. Resolutions of triacylglycerols were performed, therefore, by a Packard 7400 gas chromatograph equipped with an on-column injector heater. The glass column (0.40 m × 2 mm I.D.) was packed with 3% JXR on 100–120 mesh Gas Chrom Q (Applied Science Laboratories, State College, PA) and operated with a gas (helium) flow of 100 ml/min. Analyses were made by linear-temperature programming from 220 to 350°C at 4°C/min. Weight calibration factors were determined from known composition mixtures of saturated triacylglycerols (Applied Science Laboratories). The factors for a well-conditioned column and for a 1–10 μg/peak range of injected triacylglycerols were: 1.17 for trioctanoylglycerol (C24), 1.07 for tridecanoylglycerol (C30), 1.00 for trimyristoylglycerol (C42), 1.03 for tripalmitoylglycerol (C48), 1.10 for tristearoylglycerol (C54) and 1.35 for triarachidoylglycerol (C60), when the factor for trilauroylglycerol (C36) was equal to 1. The correction factors for intermediate molecular weight triacylglycerols were interpolated from the curve obtained with the standard triacylglycerols.

The micropreparative fractionation of triacylglycerols also was carried out by gas chromatography under similar conditions. However, quantities of triacylglycerols as large as 150–300 μg (about 50 μg for a major peak) dissolved in $CHCl_3$ or CS_2 (100 μg/μl) could be injected into a wider glass column (0.30 m × 4.4 mm I.D.). Helium flow was increased to 200 ml/min, 88% of the column effluent was directed with a stream-splitter to a Packard 852 gas collector modified to maintain its temperature at 335°C. Each peak of the triacylglycerols was trapped at room temperature in a glass cartridge partially filled with glass wool and eluted with pentane. Purity of the collected peaks was checked by gas chromatography under the analytical conditions described above. When the purity was less than 98%, the peaks of the triacylglycerols were purified under the micropreparative conditions.

Fatty acid compositions were determined by gas chromatography of the butyl esters, as previously described (11). When microquantities (0.5–50 μg) of triacylglycerols collected by micropreparative gas chromatography were analyzed, fatty acid butyl esters were prepared in sealed glass tubes (70–100 μl of inner volume), as reported elsewhere (1).

Nomenclature and calculations. When triacylglycerols are fractionated by $AgNO_3$-thin layer chromatography, the bands consist of one or several classes of triacylglycerols. A class is symbolized by a triad of digits, each digit representing the number of double bonds in a constituent fatty acid, without positional reference. Following the separation of triacylglycerols by gas chromatography on apolar phase, each chromatographic peak is equivalent to a group of triacylglycerols characterized by the same total number of carbon atoms of the three acyl moieties. Triacylglycerol types are combinations of three fatty acids, without positional reference.

The experimental distribution of triacylglycerol types, as proposed by Bezard et al. (12), was first calculated in each group as follows: the fatty acids found in one group were combined three by three so that the carbon number of each combination (triacylglycerol type) corresponded to the group. Equations were established from the experimental percentages of the fatty acids in the group and from the unknowns (mol % of the triacylglycerol types, which had to be determined). The solution of the equations was such that the fatty acid composition of the group, calculated from the triacylglycerol type distribution, had to be as close to the experimental fatty acid composition as possible. The distribution of the triacylglycerol types in the total triacylglycerols was calculated by using the experimental proportion of the group in the corresponding class and that of the class in the total triacylglycerols.

The random distribution of triacylglycerol types was calculated according to the method described by Bailey (13) and Baltes (14) and as used by Kuksis et al. (15,16). If a, b and c are the experimental percentages of the fatty acids A, B and C in the total triacylglycerols, the random percentages of the triacylglycerol types AAA, AAB and ABC are equal to $a \times a \times a \times 10^{-4}$, $a \times a \times b \times 3 \times 10^{-4}$ and $a \times b \times c \times 6 \times 10^{-4}$, respectively.

RESULTS

Time course of CO fatty acid incorporation into adipose tissue. Rats were fed a 20%-CO diet for 7 weeks, and total lipids from perirenal adipose tissue were analyzed. Changes in the fatty acid composition are shown in Figure 1. The fatty acid distribution was nearly stabilized within 3 weeks. The intermediate chain fatty acids (12:0 + 14:0), accounting for 2.5% before CO feeding, reached 24% after 1 week and stayed at a plateau (about 37%) during the last 4 weeks.

Total fatty acids and triacylglycerol groups. Rats were fed either a standard diet or a 20%-CO diet for 6 weeks. The growth of CO-fed animals was comparable with that of control animals, as shown in Figure 2. The perirenal adipose tissue of CO-fed rats was 1.3 times as heavy as that of control rats. Total lipids accounted for 96.1% ± 0.3 and 92.5% ± 0.5 ($p < 0.001$) of the fresh perirenal adipose tissue mass in the CO-fed and control rats, respectively. In Table 1, the fatty acid and triacylglycerol group compositions of triacylglycerols from adipose tissue of the CO-fed rats (TCO) are compared with those of triacylglycerols from the standard diet, CO and adipose tissue of rats fed a low-fat standard diet (TC) (1). In CO-fed rats, saturates represented two-thirds of fatty acids and lauric acid was the major fatty acid. The shortest

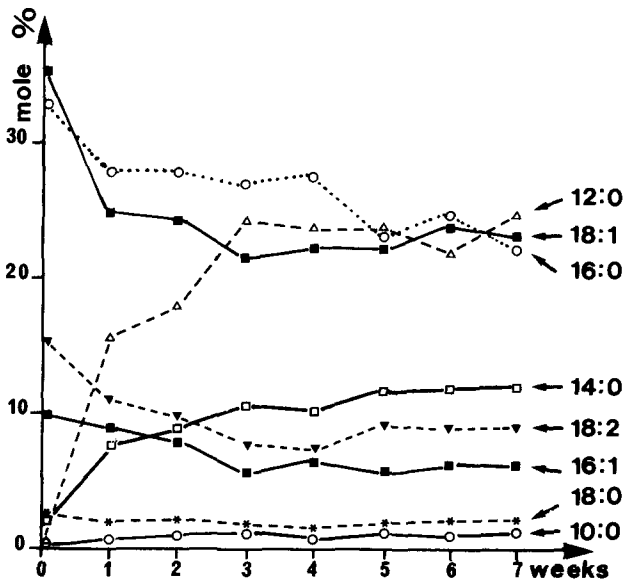

FIG. 1. Time course of CO fatty acid incorporation into total lipids of adipose tissue of rats fed a 20%-CO diet.

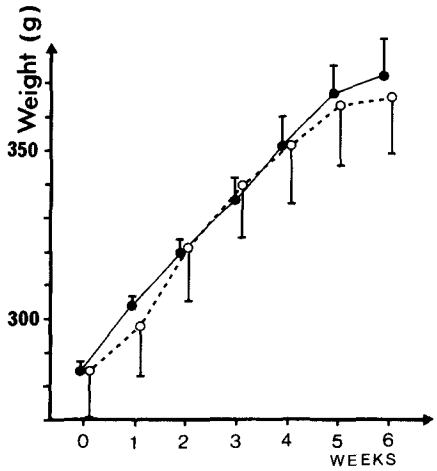

FIG. 2. Growth of rats fed a standard diet supplemented with 20% CO (continuous line) versus rats on a standard diet (dotted line). Means ± SE (n = 6).

chains (6:0 + 8:0) present in CO were not incorporated into TCO. Linoleic acid, an essential fatty acid that is known to have a regulatory action on adipose tissue (17), was still present in TCO, because its content (w/w) in the CO diet was about 1.5%—as much as in the standard diet. In contrast to TCO, three main classes of long chain fatty acids—saturates (35%), monoenes (37%) and diene (27%)—had been observed in adipose tissue triacylglycerols from rats on the low-fat standard diet (TC) (1), like rats on a fat-free diet supplemented with 2% linoleate (17). The distribution of triacylglycerol groups in TCO reflected neither that in the standard diet and in TC (1), nor that in CO. The triacylglycerol groups C42-C48, which represented only 7% in TC (1) and 14% in CO, reached 64% in TCO. This provides evidence for mixed triacylglycerols made up of long and intermediate acyl moieties.

Triacylglycerol classes. Although TC had been fractionated into 13 bands by only one chromatographic run (1), the separation of TCO was made more difficult because of the widening of the bands due to differences

in the R_f values according to triacylglycerol chain length, because R_f increases along with molecular weight of triacylglycerol (18–20). Figure 3 shows the 10 bands obtained by using 3 different developing solvent systems.

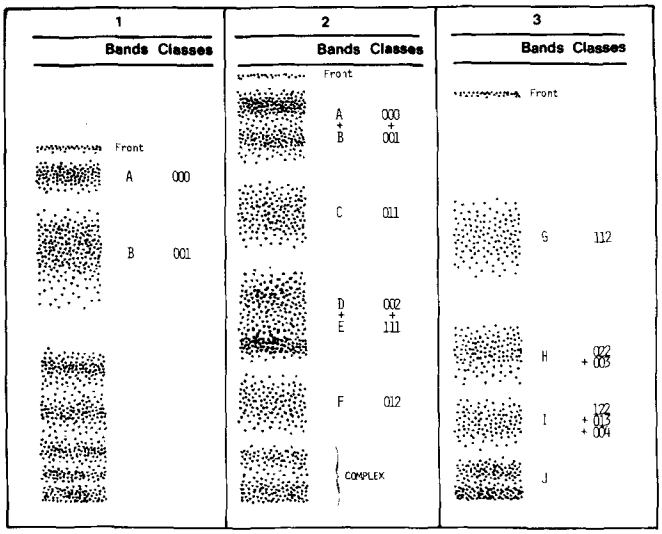

FIG. 3. Separation of triacylglycerols from perirenal adipose tissue of CO-fed rats (TCO) by ascending thin layer chromatography on $AgNO_3$-impregnated Silica Gel G. Plate 1: The classes 000 and 001 were separated using chloroform alone. Plate 2: Total triacylglycerols were fractionated using chloroform/methanol (99.3:0.7, v/v). Plate 3: The complex band isolated on the plate 2 was rechromatographed in chloroform/methanol (98.5:1.5, v/v). The bands were located under UV light after spraying with 0.05% ethanolic dichlorofluorescein.

Bands D and E were collected together, because they were incompletely separated as already observed for TC (1) and other fats (21,22). The bands contained one or several classes, which were identified by gas chromatography of fatty acids as shown in Table 2. The order of elution of the triacylglycerol classes followed that determined experimentally by Gunstone and Padley (23), but some classes were not separated (classes 022 + 003 in band H and classes 122 + 013 + 004 in band I). The triacylglycerol structure of band I was not studied. Triacylglycerol compositions of bands were obtained by gas chromatography under analytical conditions (Table 3). The calculation of average chain length of triacylglycerols shows a good correlation between fatty acid and triacylglycerol compositions for all bands except the complex, polyunsaturated band (J). The experimental triacylglycerol composition of TCO, or that calculated from the triacylglycerol compositions of the bands, too, is very close to the random distribution.

The proportion of a class is the mean of the determinations based on three internal standards, namely tridecanoic and pentadecanoic acids used for fatty acid analyses and tritridecanoylglycerol used for triacylglycerol gas chromatography. Table 4 shows the experimental and random distributions of classes in TCO. The triacylglycerols of the three major classes (000, 001 and 002) accounted for 73.5% and contained at least two saturated acyl moieties as the consequence of the high content of saturates (65%). In contrast with TCO, there was only one major class (012) in TC (1), as the reflection of the three main fatty acids (16:0, 18:1 and 18:2) (see Table 1). The experimental and random proportions of

Others	0.7	1.0	−27

[a] Difference % = (Experimental % − Random %)/(Random %) × 100.

[b] Classes were underlined when the experimental and random proportions were estimated to be significantly different.

this class in TC reached 24.0% and 20.7%, respectively (1). The experimental and random distributions of classes were fairly close in both fats. However, it can be noticed that the experimental proportion (24.7%) of the saturated class (000) in TCO was lower than the random proportion (27.5%). Similar results had been obtained in TC (2.0% and 4.3%, respectively) (1). On the other hand, the mixed classes 001 and 002 in TCO, and 012 in TC (1), showed experimental values higher than the random proportions expected.

Triacylglycerol types. Bands of triacylglycerols were fractionated into groups by micropreparative gas chromatography and fatty acid compositions of groups were determined. Figure 4 shows triacylglycerol chromatograms obtained for the analysis and fractionation of band F (class 012), which accounted for 9.7% in TCO. Under analytical conditions, all the chromatograms of the bands isolated from TCO displayed traces of triacylglycerols having an odd carbon number (Fig. 4A). The separation of peaks under analytical conditions was better than under micropreparative conditions (Figs. 4A and B), because peaks were overloaded for collecting enough triacylglycerol for fatty acid determinations. However, this separation was sufficient enough to obtain a purity greater than 98% for the peaks C46-C52 (Fig. 4C). Peak C54 (4.4%) was purified under the same chromatographic conditions (Fig. 4D). Peaks C42 (0.7%) and C44 (1.2%) were not collected. Peak tailing in chromatograms (Fig. 4) was mainly caused by the void volume of the flame ionization detector. The fatty acid composition of the triacylglycerol groups C46-C54 (collected peaks) of the class 012 (band F) was then determined (data not shown). It was observed that the proportions of fatty acid classes (saturates, monoenes and diene) were close to 33%, showing absence of selective losses during fractionation and purification of triacylglycerols.

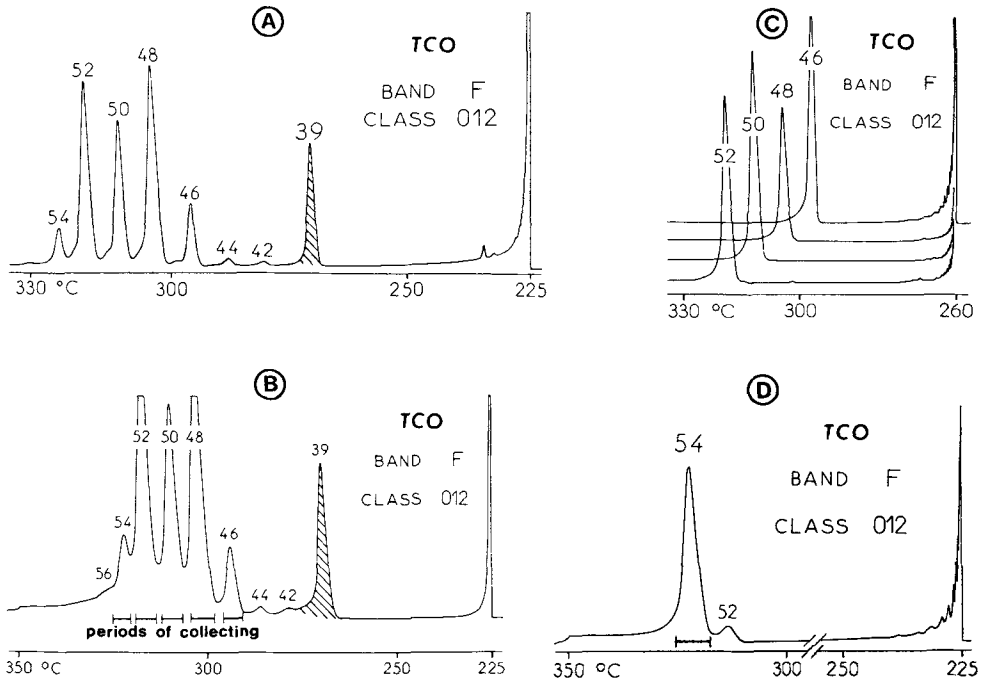

FIG. 4. Gas chromatography of triacylglycerols of band F (class 012) isolated beforehand by $AgNO_3$-thin layer chromatography from triacylglycerols of perirenal adipose tissue of CO-fed rats (TCO). Peaks identified by total number of acyl carbon atoms. Peak C39 corresponds to tritridecanoylglycerol added as an internal standard. Conditions of analytical or micropreparative gas chromatography as given in the Experimental Section. A) Chromatogram recorded under analytical conditions. B) Chromatogram recorded under micropreparative conditions and time of peak collection. C) Chromatogram recorded under analytical conditions for checking purity of peaks C46–C52 first collected by micropreparative gas chromatography. D) Chromatogram recorded during purification of peak C54.

Distributions of triacylglycerol types in groups were calculated from fatty acid compositions of collected peaks. The proportions of types in TCO were calculated from the distributions of types in groups, the distributions of groups in classes (Table 3) and the distribution of classes in TCO (Table 4). The triacylglycerols of bands A–G, accounting for 93.6% in TCO, were fractionated and analyzed. They contained 181 potential triacylglycerol types, and the proportions of most of them were assessed. Only some minor peaks accounting for 0.4% (in total) in TCO were not collected, resulting in 21 types not determined. The bands H and I were more complex and only 9 types accounting for 3.4% in TCO could be estimated. Table 5 shows the proportions of the 94 triacylglycerol types representing at least 0.1% in TCO and accounting for 95.8% in total. The proportions of 75 minor types, each one representing less than 0.1% in TCO, were also assessed, but were not shown in Table 5, because they accounted for only 1.2% in total. The first 10 main types in TCO were mixed triacylglycerols containing one or two lauroyl moieties and accounting for 42.2%. The type 16:0 18:1 18:2, which was the major one in TC (16.7%) and contained the three main fatty acids of TC (1,2), accounted for only 2.6% in TCO.

In Table 5, the experimental values were compared with the random percentages calculated from the fatty acid composition in Table 1. The differences between the two kinds of distribution were generally limited in TCO, as well as in TC (1,2), and often reflected the differences already noticeable in classes. For example, tripalmitoylglycerol accounted for 0.53% in TCO and 1.04% in TC (1,2), whereas the random proportions reached 0.74% and 2.4%, respectively. The experimental proportion of lauroylpalmitoyloleoylglycerol reached 7.0%, but its random proportion did not exceed 5.8%. The experimental and random proportions of palmitoyloleoyllinoleoylglycerol were similar (2.6%) in TCO, but they were different in TC (16.7% and 13.6%, respectively) (1,2). All these differences reflected those of classes 000, 001 and 012 in TCO (Table 4) and TC (1,2). However, sometimes differences were not homogeneous for all the types in a class. Although most of the main types of class 001 in TCO had an experimental proportion higher than the random proportion, two types—14:0 16:0 18:1 and 14:0 14:0 18:1—showed the reverse situation. The comparison of the experimental and random distributions of types in class 000 of TCO, according to the chain length of the component fatty acids, is given in Table 6. It is evident that, when the mean chain length of the saturated TCO increased, the experimental proportions of types became lower than the random proportions. This was not observed in the other classes of TCO, nor in TC (1,2) or CO (Bugaut, M., unpublished data).

DISCUSSION

Effect of CO on growth and perirenal adipose tissue size. Similar weight gain was observed in rats fed the 20%-CO

TABLE 5

[a]Triacylglycerol types are triacylglycerols identified by their three component fatty acids, without positional reference.

diet and the standard diet, as reported by other authors (24,25). Nevertheless, it has been observed earlier that inclusion of hydrogenated CO (26), or saturated triacylglycerols containing C12–C18 acyl moities prepared from CO (17,27–29), depressed growth more than a fat-free diet, but there was no difference in growth when linoleate was added to the diets. On the other hand, addition of CO to the diet enlarged perirenal fatty depot, as described by Kaunitz et al. (17,27,29) in the epididymal fat of rats fed a CO fraction rich in intermediate chain fatty acids (12:0 + 14:0), when compared with rats on a fat-free diet. The enlargement of fat bodies in CO-fed rats, when compared with rats on a standard diet, would be due mainly to an increase in fat cell number in the perirenal site and an increase in adipocyte volume in the epididymal site (25). Moreover, the lipid content of perirenal adipose tissue was significantly higher in CO-fed rats than in rats fed the standard diet. Similar results were obtained by Awad (30) studying the epididymal fat pads. As far as perirenal adipose tissue is concerned, the increase of lipid content in CO-fed rats is difficult to explain, because an expected increase in adipocyte volume has not been observed (25).

Fatty acids. Rats were fed a diet enriched with medium

[a] as a function of the chain length of component fatty acids. saturated TCO are compared with saturated triacylglycerols from adipose tissue of rats fed a standard diet (TC) and from coconut oil (CO) (Bugaut, M., unpublished data). Experimental values for TC were calculated from the experimental percentages of individual triacylglycerol types taken in Ref. 2. Random values were calculated from the fatty acid composition of TC in Table 1 according to Bailey's method (13).

[b] Families of triacylglycerols identified by the chain length of component fatty acids. M, medium chain fatty acids (6:0 + 8:0 + 10:0). I, intermediate chain fatty acids (12:0 + 14:0). L, long chain fatty acids (16:0 + 18:0).

[c] Difference % = (Experimental % − Random %)/(Random %) × 100.

(6:0 + 8:0 + 10:0) and intermediate chain triacylglycerols for 6 weeks, and perirenal adipose tissue was analyzed. The fatty acid composition of adipose tissue triacylglycerols partially reflected that of CO. However, among medium chain fatty acids, only a small amount of decanoate was incorporated in vivo into adipose tissue triacylglycerols, as already observed by other authors (3,7,31-33), in spite of linoleate in the diets. Kaunitz et al. (17,34) found that linoleate supplementation (2%) to a fat-free diet increased the incorporation of medium chain fatty acids into adipose tissue. The low level of medium chain fatty acids in the adipose tissue of the CO-fed rats did not result from the inability of adipocytes to utilize medium chain fatty acids, because octanoate can be activated to its acyl-CoA derivative (35). Octanoate is known to be incorporated in an intact form into triacylglycerols of rat perirenal fat, and its catabolism rate in this tissue is not different from palmitate (4,36,37). In fact, medium chains are absorbed via the hepatic portal vein (38) and quickly taken up by the liver (39). *Sn*-3-glycerophosphate and *sn*-1-acylglycerol-3-phosphate acyltransferases in rat liver have been reported to exclude fatty acids of chain lengths shorter than 12:0 (40). However, *sn*-1,2-diacylglycerol acyltransferase accepts octanoate as a substrate (41). As a result, medium chain fatty acids are incorporated into hepatic triacylglycerols only in a low proportion (42-44) and predominantly in position *sn*-3 (45). Therefore, in contrast to laurate (46), the medium chain fatty acids cannot be secreted at a significant level into the blood as very low density lipoprotein (VLDL). The largest portion of medium chain fatty acids is catabolized to CO_2 and ketone bodies in the liver (47). This catabolism occurs at a high rate in other organs (36,48) including the intestine (49,50). Medium chain fatty acids are cleared from the blood so rapidly that their plasma content remains at a very low level (44,51,52).

Laurate and myristate reached 28% and 14%, respectively, of the adipose tissue triacylglycerol fatty acids after 6 weeks of CO feeding. The high level of the intermediate chain fatty acids observed in the adipose tissue could be the result of the presence of linoleate (1.5% in the CO diet), which "facilitates the laying down of a depot fat more representative of that in the diet" (17). The rate of deposition of the two fatty acids (Fig. 1) was similar to that of undecanoate, which follows an experimental curve with the $t_{1/2}$ = 9 days in young rats (53) and, with increasing age, remains rapid in rats (54,55). The incorporation rate of myristate was higher than that of laurate, because the ratio of laurate to myristate was 3 in CO and only 2 in fat tissue. This could be the result of three factors. First, the proportion of dietary 14:0 drained via the lymph duct is 1.4 times higher than that of 12:0 (56). Therefore, less 14:0 than 12:0 is directly cleared by the liver. Second, intermediate chain fatty acid catabolism in the liver (39) or total organism (57) decreases when chain length increases. Finally, laurate as undecanoate (58-59), is elongated to myristate and to other longer fatty acids in the rat liver (60-62), but not in the adipose tissue (4,51). Myristate deriving from the hepatic elongation is supplied to the adipose tissue via VLDL triacylglycerol.

Because the proportions of long chain fatty acids (≥16 C), except 18:0 and 18:3, were much higher in TCO than in the CO diet, an endogenous origin for the long chain fatty acids has to be considered. Intestinal chylomicrons carry not only exogenous lipids, but also endogenous long chain fatty acids (63). These fatty acids can be synthesized de novo either by the hepatocyte before delivering to VLDL or in situ by the adipocyte (64). Finally, long chain fatty acids such as linoleate could be preferentially recycled inside the fat cell, because the store of essential fatty acid in body lipids is known to be preserved at the expense of other fatty acids (65-68). However, increased linoleate requirement has been observed in rats fed saturated intermediate chain triacylglycerols, when compared with animals fed a fat-free diet

or medium chain triacylglycerols (17,28,29). Therefore, it appears that the animals receiving intermediate chain triacylglycerols preserve their linoleate store less efficiently than the others. It is difficult to transfer these findings to rats receiving CO, which contains both medium (22%) and intermediate (64%) chain triacylglycerols.

Triacylglycerols. The decrease of long chain triacylglycerols observed in the perirenal adipose tissue of CO-fed rats paralleled the changes in the fatty acid composition as described above. The triacylglycerol groups C50-C56, which accounted for 93% in TC (1), decreased to 22% after 6 weeks. This decrease cannot be explained only by an accumulation of triacylglycerols newly synthesized from endogenous long chain and exogenous medium chain fatty acids, even though the relative content of previously stored long chain triacylglycerols is reduced because the perirenal adipose tissue increases in size during aging (69). The analyses of triacylglycerols in groups, classes and types indicated that the experimental and random distributions in TCO were very close on average. The 10 major types of triacylglycerols in TC (1,2), which were mixed combinations of 16:0, 16:1, 18:1 and 18:2 and accounted for 66.1% in total, did not exceed 13.4% in TCO, and these experimental percentages were very close to the random percentages in both fats—65.1% in TC (1,2) and 12.4% in TCO. There appears to be no evidence for a significant remainder of the primitive long chain triacylglycerols, which would not have been rearranged after 6 weeks of CO feeding. Our data suggest that intermolecular rearrangement of triacylglycerol fatty acids in adipose tissue occurs rapidly. This is probably a result of hydrolysis of stored triacylglycerols and reesterification of part of released fatty acids, along with fatty acids synthesized de novo by adipocytes or newly taken up from blood, although the rate of reesterification of lipolyzed free fatty acids (70) is not known in rats fed intermediate chain triacylglycerols. Triacylglycerol fatty acid turnover in adipose tissue through the lipolysis/reesterification cycle seems considerably faster than previous estimates (71-75).

Several authors (24,30,76-84) have shown that administration of a diet containing saturated fat, including CO, which modifies cellular lipid contents and fatty acid compositions, induces alterations in a variety of cellular functions such as enzyme activity (lipolysis and lipogenesis) and nutrient uptake. Furthermore, it has been suggested that exogenous fatty acids could control the relative proportions of the fatty acids entering each position of the triacylglycerols by factors that probably include the acyltransferases of the glycerophosphate pathway and other enzymes (85,86). Indeed, it is well-established that, with rare exceptions, linoleate is predominantly esterified to the position *sn*-2 of animal fats (87). Therefore, TC contained a higher experimental proportion of the triacylglycerol types in class 012 and a lower proportion in classes 022, 122 and 222, than was expected from their random proportions (1,2). However, the differences between the experimental and random distributions of long chain triacylglycerol types in TCO were sometimes less than in TC or disappeared, as in the case of 16:0 18:1 18:2, and even were reversed as for 16:0 16:0 18:1, 16:0 16:1 18:2 and 16:1 18:1 18:2. These results are in agreement with those of Guesnet et al. (54) who have observed a great modification of the distribution of long chain fatty acids among the three positions of rat fat triacylglycerols after CO feeding. These authors pointed out that the long chain fatty acids, except linoleate, tend to be distributed much more equally among each of the three positions than in rats on a stock diet. Though this paralleled the appearance of laurate preferentially esterified in external position, the decrease in linoleate could contribute to these modifications as well. The supply of exogenous intermediate chain fatty acids may control the relative proportions of the fatty acids entering triacylglycerols, as already suggested for exogenous long chain fatty acids (85,88-90).

It is noteworthy that, considered as a whole, the differences between the experimental and random proportions of groups, classes, and types are weak in TCO. This suggests that intermediate and long chain fatty acids could belong to a single homogeneous compartment for triacylglycerol synthesis. Apparently, this conclusion does not agree with those of other authors. It has been suggested that free fatty acids and acylglycerols in the adipocyte would be shared between several semi-independent pools according to their origin, extracellular or intracellular (fatty acids issued from either de novo synthesis or lipolysis) (88,91,92), as observed in liver (93) and intestine (94). Interestingly, Awad and Chattopadhyay (83) reported that the fatty acid composition of intracellular free fatty acids did not reflect that of triacylglycerols of adipose tissue or dietary fat when the rats were fed CO or other fats. This composition with a high level of palmitate, stearate and arachidonate and a very low level of linoleate could correspond instead to that of membrane phospholipids. Therefore, the major part of intracellular free fatty acids would not belong to the pool of triacylglycerol synthesis, which would be small and rapid.

The absence of very significant differences between the experimental and random proportions of triacylglycerol types in TCO could also suggest that there is no obvious evidence for any specificity of acyltransferases towards chain length. Although lauroyl-CoA has been found to be a much less effective substrate than long chain acyl-CoA for *sn*-1-acylglycerol-3-phosphate acyltransferase when assessed in vitro in rat liver (95) and cow mammary gland (96), the esterifying enzymes of adipose tissue would be able to transfer saturated intermediate chain fatty acids into any position of the glycerol skeleton—even into position *sn*-2—as was proven by the presence of trilauroylglycerol in TCO. Myristate has also been found to be distributed equally among the three positions of the adipose tissue triacylglycerols of CO-fed rats (54). However, under the same conditions, laurate was incorporated preferentially into the external position (97-99), especially the position *sn*-3 (54), as observed for medium chain fatty acids as well (34). This is in agreement with the results of Coleman and Bell (100) who found the highest activity of the microsomal 1,2-diacylglycerol acyltransferase from isolated rat fat cells towards decanoyl- and lauroyl-CoA. We observed that the experimental proportions of dilauroyllinoleoylglycerol (3.2%) and dilauroylglycerols (18.6%), in general, in TCO were a little higher than the calculated values of random distribution (2.8% and 15.6%, respectively). Laurate, in the presence of long

chain fatty acids, has been found to be preferentially esterified to the position *sn*-1 (54) probably for reasons of physico-chemical stability of the triacylglycerol, as compared with the position *sn*-2, to which unsaturated fatty acids are predominantly attached (101). Therefore, laurate is probably a good substrate for *sn*-glycerol-3-phosphate acyltransferase.

We also observed that the shorter the chain length of the triacylglycerol types of the class 000 in TCO, the more readily the triacylglycerols were synthesized (Table 6). Furthermore, trilauroylglycerol was largely present (2%) in TCO, as expected from its calculated proportion, whereas the experimental percentage of tripalmitoylglycerol in TC was 2.3 times lower than its random percentage (1,2). These observations agree with the fact that 1,2-dilauroyl- and 1,2-dimyristoylglycerol are better substrates than 1,2-dipalmitoylglycerol for the 1,2-diacylglycerol acyltransferase when assessed in rat (100) and chicken (102) adipose tissue. It can, therefore, be concluded that intermediate chain fatty acids are, in general, slightly better utilized by acyltransferases than saturated long chain fatty acids.

The final pattern of stored triacylglycerols may also depend on the specificities of the two lipolytic enzymes, hormone-sensitive lipase and monoacylglycerol lipase (103), through the lipolysis-reesterification cycle. Whereas, during lipolysis, some authors (73,104) found no preferential release of adipose tissue triacylglycerol fatty acids, others (98,105-107) observed a trend to a preferential release of saturated long chains. This could be the result of the positional specificity of hormone-sensitive lipase that splits external bonds (108). Reesterification by the 2-monoacylglycerol pathway (109) of part of 2-monolinoleoylglycerol, which would escape monoacylglycerol lipase, could contribute to the retention of linoleate in the body fat of animals fed a diet with low levels of essential fatty acid (65-68). Although triacylglycerol lipase activity is higher when using a CO emulsion as substrate, instead of triolein (110), intermediate chain fatty acids from adipose tissue of rats fed a CO diet have been found to be mobilized at the same rate (107) or at a lesser rate (98) than longer chain fatty acids.

In conclusion, our results support the view that lauric acid is a good substrate for adipose tissue acyltransferases in vivo. However, even if the laurate content in adipose tissue triacylglycerols from CO-fed rats is quickly stabilized (ca. 3 weeks), further studies would be necessary to gain more information on the time course of triacylglycerol reshuffle.

Reaction Products of α-Tocopherol With A Free Radical Initiator, 2,2′-Azo*bis*(2,4-dimethylvaleronitrile)

Ryo Yamauchi*, Tomoatsu Matsui, Yasuko Satake, Koji Kato and Yoshimitsu Ueno
Department of Agricultural Chemistry, Gifi University, 1-1, Yanagido, Gifu City, Gifu 501-11, Japan

α-Tocopherol was reacted with an alkylperoxyl radical at 37°C in ethanol. 2,2′-Azo*bis*(2,4-dimethylvaleronitrile) was used to generate the alkylperoxyl radicals. The reaction products of α-tocopherol were isolated by reverse-phase and normal-phase high performance liquid chromatography, and their structures were characterized by infrared, ultraviolet, ^1H and ^{13}C nuclear magnetic resonances and mass spectrometry. They were 8a*S*-hydroperoxy-α-tocopherone, 8a*R*-hydroperoxy-α-tocopherone, a mixure of 7,8-epoxy-8a*S*-ethoxy-α-tocopherone and 7,8-epoxy-8a*R*-ethoxy-α-tocopherone, 8a*S*-(1*R*-cyano-1,3-dimethyl)butylperoxy-α-tocopherone, 8a*S*-(1*S*-cyano-1,3-dimethyl)butylperoxy-α-tocopherone, a mixture of 8a*R*-(1*R*-cyano-1,3-dimethyl)butylperoxy-α-tocopherone and 8a*R*-(1*S*-cyano-1,3-dimethyl)butylperoxy-α-tocopherone, 4a*S*,5*R*-epoxy-8a*R*-ethoxy-α-tocopherone, 4a*R*,5*S*-epoxy-8a*S*-ethoxy-α-tocopherone, 4a*S*,5*R*-epoxy-8a*S*-ethoxy-α-tocopherone and 4a*R*,5*S*-epoxy-8a*R*-ethoxy-α-tocopherone.
***Lipids* 24,** 204-209 (1989).

α-Tocopherol is an important natural antioxidant in food and living cells. The fundamental chemistry of the inhibition of lipid peroxidation by α-tocopherol, both in homogeneous solution (1-3) and in aqueous dispersion (4-7), has been studied extensively. One molecule of α-tocopherol can scavenge two lipid-peroxyl radicals (1). However, the detailed reaction products of α-tocopherol with peroxyl radicals have not yet been satisfactorily elucidated, even in vitro.

α-Tocopherol is very reactive toward a variety of free radicals and active oxygen species and forms various products. For example, α-tocopherol traps radicals generated from certain radical initiators such as benzoyl peroxide (8), 2,2′-azo*bis*(isobutylnitrile) (9) and *t*-butyl hydroperoxide (10-12), and it reacts with alkyl and alkoxyl radicals to give alkylated derivatives (13-16). Free radical oxidation of α-tocopherol takes place via the tocopheroxyl radical as an intermediate (17,18). If a suitable lipid-peroxyl radical is present, a product may be formed from the coupling of the lipid-peroxyl radical with the tocopheroxyl radical. Winterle et al. (19) reported that α-tocopherol formed 8a-alkylperoxy-α-tocopherones via reaction of alkylperoxyl radical with α-tocopheroxyl radical. Matsumoto et al. (20) also reported that the reaction products of an α-tocopherol model compound, 2,2,5,7,8-pentamethylchroman-6-ol, with *t*-butylperoxyl radical were 8a-peroxychroman epoxides.

We have studied the reaction products of α-tocopherol with an alkylperoxyl radical in ethanol. 2,2′-Azo*bis*(2,4-dimethylvaleronitrile) (AMVN) was used as the alkylperoxyl radical-generating source, in which the alkyl radical from the thermal decomposition of AMVN reacts with molecular oxygen to generate the alkylperoxyl radical (2).

*To whom correspondence should be addressed.

Abbreviations: AMVN, 2,2′-azo*bis*(2,4-dimethylvaleronitrile); HPLC, high performance liquid chromatography; TLC, thin layer chromatography; NMR, nuclear magnetic resonance; MS, mass spec(tra, trometry); IR, infrared; UV, ultraviolet.

MATERIALS AND METHODS

Materials. 2*R*, 4′*R*, 8′*R*-α-Tocopherol (Type V) was purchased from Sigma Chemical Co. (St. Louis, MO) and purified by Sephadex LH-20 column chromatography (21). A free radical initiator, AMVN, was purchased from Wako Pure Chemical Ind. (Osaka, Japan) and used without further purification. 8a-Hydroperoxy-α-tocopherone was produced from α-tocopherol by photosensitized oxidation (22). All other chemicals were obtained from common laboratory suppliers. All solvents were distilled in an all-glass still before use.

High performance liquid chromatography (HPLC). HPLC was performed with a Jasco Trirotar V pump equipped with a Model 875 UV detector. Reverse-phase HPLC was done either with a μBondasphere 5μ C18 100Å column (3.9 × 150 mm, Nihon Waters Ltd., Tokyo, Japan) or a Wakogel LC ODS-10H column (7.6 × 250 mm, Wako Pure Chemical Ind., Osaka, Japan) developed with methanol at a flow rate of 0.7 or 3.0 ml/min. Normal-phase HPLC was done with a LiChrosorb Si 60 column (4.6 × 250 mm, Merck, Darmstadt, FRG) developed with hexane/isopropanol (98:2 or 95:5, v/v) at a flow rate of 1.5 ml/min. The eluent was monitored by an absorbance at 250 nm.

Reaction procedure. α-Tocopherol (1.29 g, 3 mmol) and AMVN (3.72 g, 15 mmol) were dissolved in ethanol (500 ml) and incubated at 37°C for 34 hr under air. After the reaction was complete, hexane and distilled water (500 ml each) were added to the reaction mixture and the upper organic phase was washed twice with 100 ml of distilled water to remove ethanol, and the solvent was removed in vacuo. The oily residue obtained was then dissolved in 50 ml of ethanol and allowed to stand at −20°C for 2 hr. The resulting crystals of AMVN were removed by filtration. The filtrate was analyzed by reverse-phase HPLC. The compounds responsible for the peaks that appeared to be the reaction products of α-tocopherol were isolated by reverse-phase and normal-phase HPLC. Both the disappearance of α-tocopherol in the reaction mixture and the purities of isolated compounds were checked by thin layer chromatography (TLC) on precoated silica gel 60 plates (Merck, Darmstadt, FRG) using hexane/ethyl ether (80:20, v/v). The isolated compounds were dissolved in ethanol and stored at −20°C until analysis. The peroxide values were determined by the iodometric method (23). Benzoyl peroxide was used as the standard peroxide.

Spectroscopy. Proton (^1H) and carbon-13 (^{13}C) nu-

clear magnetic resonance (NMR) spectra were recorded on a JEOL JNM-GX-270 FT NMR spectrometer with $CDCl_3$ as the solvent and with tetramethylsilane as the internal standard. NMR spectra were measured at ca. 27°C; ^{13}C NMR at 67.8 MHz with proton decoupling, and ^1H NMR at 270.05 MHz. Mass spectra (MS) were obtained with a Shimadzu GCMS 9020 DF gas chromatograph-mass spectrometer system. Samples were introduced via the direct inlet probe. Electron impact spectra were obtained with an ionizing energy of 70 eV. Infrared (IR) spectra of samples in liquid film were measured on a Jasco A-302 IR spectrometer. Ultraviolet (UV) spectra were measured with a Hitachi Model 200-10 spectrophotometer. Specific rotations were determined with a Yanaco OR-50 automatic polarimeter.

RESULTS

AMVN decomposes at 37°C to form alkyl radicals which, in turn, react with molecular oxygen to form alkylperoxyl radicals. The resulting alkylperoxyl radical reacts with α-tocopherol. The reaction was monitored by TLC; the α-tocopherol (R_f 0.45) disappeared after 34 hr incubation. The reaction products of α-tocopherol with AMVN were analyzed by reverse-phase HPLC (Fig. 1). Eight major peaks, **1**, **2**, **3**, **4**, **5**, **6**, **7** and **8**, in addition to some minor peak, appeared on the chromatogram. Each peak was collected by preparative reverse-phase HPLC. Peaks **1** and **4** could each be separated into two peaks (**1a** and **1b** from **1** and **4a** and **4b** from **4**, respectively) by the normal-phase HPLC using hexane/isopropanol (95:5, v/v for **1** and 98:2, v/v for **4**, respectively) as eluents. The structures of **1a**, **1b**, **2**, **3**, **4a**, **4b**, **5**, **6**, **7** and **8** were determined as described in Scheme 1.

1a and **1b** were obtained as pale yellow oils (**1a**: R_f 0.20, yield 23.5 mg; **1b**: R_f 0.16, yield 23.3 mg). Their spectral data were essentially identical with authentic 8a-hydroperoxy-α-tocopherone (22,24,25). **1a**, 8a*S*-Hydroperoxy-α-tocopherone: MS *m/z* 462 (M^+, 1%); IR (film) ν 3350 cm^{-1} (OOH), 1640; UV (ethanol) λ 240 nm (ε 12000); ^1H NMR ($CDCl_3$) δ 0.86-0.92 ppm (*m*, 12H), 1.05-2.30 (broad *m*, 23H), 1.08 (*s*, 3H), 1.86 (*s*, 6H), 1.97 (*s*, 3H), 2.64 (broad *t*, 2H), 8.16 ppm (*s*, 1H); ^{13}C NMR ($CDCl_3$) δ 10.8 ppm, 11.3, 13.2, 19.7, 19.8, 21.1, 21.9, 22.6, 22.7, 24.5, 24.8, 25.2, 28.0, 31.8, 32.7, 32.8, 37.3 (2 atoms), 37.5 (2 atoms), 39.4, 43.4, 77.2, 98.3, 132.2, 132.6, 145.2, 148.3, 185.4; $[\alpha]_D^{25}$ +23 (*c* 0.47, ethanol). **1b**, 8a*R*-Hydroperoxy-α-tocopherone: MS *m/z* 462 (M^+, 1%); IR (film) ν 3350 cm^{-1} (OOH), 1640; UV (ethanol) λ 240 nm (ε 10200); ^1H NMR ($CDCl_3$) δ 0.83-0.88 ppm (*m*, 12H), 1.05-2.30 (broad *m*, 23H), 1.36 (*s*, 3H), 1.88 (*s*, 3H), 1.89 (*s*, 3H), 1.98 (*s*, 3H), 2.63 (broad *t*, 2H), 7.71 (*s*, 1H); ^{13}C NMR ($CDCl_3$) δ 10.8 ppm, 11.3, 13.4, 19.6, 19.8 (2 atoms), 21.4, 22.6, 22.7, 24.4, 24.8, 26.8, 28.0, 32.6, 32.8 (2 atoms), 37.3 (2 atoms), 37.5 (2 atoms), 39.4, 41.7, 77.2, 98.6, 132.3, 132.4, 145.0, 148.1, 185.4; $[\alpha]_D^{25}$ −2 (*c* 0.09, ethanol).

Compound **2** was obtained as a colorless oil (yield 39.2 mg) that gave two spots on a TLC plate (R_f 0.68 and 0.64). Compound **2** was identified as a mixture of 7,8-epoxy-8a*S*-ethoxy-α-tocopherone and 7,8-epoxy-8a*R*-ethoxy-α-tocopherone: MS *m/z* 490 (M^+, 1%), 447 (36), 445 (37), 430 (14), 417 (58), 265 (45), 225 (100), 182 (62), 165 (39), IR (film) ν 1680 cm^{-1}; UV (ethanol) λ 248 nm (ε 7880); ^1H NMR ($CDCl_3$) δ 0.84-0.88 ppm (*m*, 12H), 1.00-2.60 (broad *m*, 28H), 1.15 (*s*, 3/2H, shielded 2-CH_3), 1.37 (*s*, 3/2H, deshielded 2-CH_3), 1.46 (*s*, 3H), 1.50 (*s*, 3H), 1.80 (*s*, 3H), 2.91 (*q*, 2H); ^{13}C NMR ($CDCl_3$) δ 11.2 ppm, 12.0, 15.5 (2 atoms), 19.7, 19.8, 21.1 and 21.4, 22.3 and 22.5, 22.6, 22.7, 24.5, 24.8, 25.3 and 27.0, 28.0, 31.3 and 31.5, 32.7, 32.8, 37.3, 37.5 (3 atoms), 39.4, 41.6 and 43.4, 58.2 and 58.3, 62.4, 65.0 and 65.1, 75.6 and 75.7, 96.9 and 97.0, 128.6 and 128.7, 143.9 and 144.0, 195.8 and 195.9. The stereochemistry of the epoxy group was not investigated. Compound **2**, in the presence of 0.1 M HCl, decomposed rapidly to α-tocopherylquinone 5,6-oxide: MS *m/z* 462 (M^+, 2%), 444 (4), 419 (11), 402 (16), 237 (47), 195 (100); IR (film) ν 3550 cm^{-1}, 1685; UV (ethanol) λ 274 nm (ε 4500); ^1H NMR ($CDCl_3$) δ 0.83-0.88 ppm (*m*, 12H), 1.02-2.10

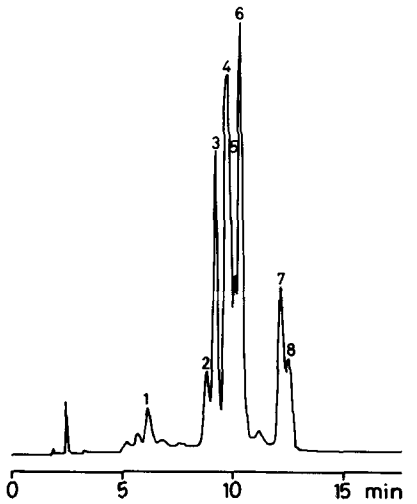

FIG. 1. Reverse-phase HPLC of the products of the reaction of α-tocopherol with AMVN in ethanol for 34 hr. HPLC was done with a μBondasphere 5μ C18 100Å column developed with methanol at a flow rate of 0.7 ml/min. The eluent was monitored by an absorbance at 250 nm.

[a]Shifts in parts per million downfield relative to tetramethylsilane.
[b]Multiplicity: s, singlet; d, doublet; t, triplet; m, multiplet.
[c]A double peak due to epimeric isomers.

(broad m, 24H), 1.21 (s, 3H), 1.60 (s, 6H), 2.00 (s, 3H), 2.38 (m, 1H), 2.60 (m, 1H).

Compounds **3**, **4a** and **4b** were obtained as colorless oils (**3**: R_f 0.54, yield 98.5 mg; **4a**: R_f 0.62, yield 116.3 mg; **4b**: R_f 0.57, yield 82.2 mg). UV spectra of these compounds showed the same absorption maximum at 240 nm in ethanol (**3**: ε 12600, **4a**: ε 12800, **4b**: ε 11600). These spectra are very similar to those of **1a** and **1b** or to the 8a-alkylperoxy-α-tocopherone reported by Winterle et al. (19), which is formed by reaction of alkylperoxyl radicals and α-tocopherol. The ^{1}H NMR spectra of **3**, **4a** and **4b** were consistent with those expected for 8a-(1-cyano-1,3-dimethyl)butylperoxy-α-tocopherones (Table 1). In particular, the geometrical relationship between the compounds can be established by interpretation of the spectra. When the 8a-peroxy group is *trans* to the 2-methyl group (**3** and **4a**), the 2-methyl group (1.11 ppm) is localized in a shielding environment above the plane of the enone system. When the 8a-peroxy group is *cis* to the 2-methyl group (**4b**), deshielding of the 2-methyl group (1.39 ppm) is observed. Furthermore, the stereochemistry of the cyano group in the 8a-(1-cyano-1,3-dimethyl)butylperoxy group was determined. When the cyano group is *S* (**4a**), deshieldings of the 4-methylene (2.82 ppm), 5-methyl (1.87 ppm) and 8a-(1-methyl) (1.60 ppm) groups are observed. When the cyano group is *R* (**3**), deshieldings of the 7-methyl (1.86 ppm) and 8-methyl (2.02 ppm) groups are observed. When the cyano group is a mixture of *R* and *S* (**4b**), the two methyl groups resonate as close double peaks (7-methyl: 1.858 and 1.862 ppm, 8-methyl: 2.01 and 2.02 ppm). The ^{13}C NMR spectra of **3**, **4a** and **4b** show two tertiary ethers (**3**: 77.3 and 77.7 ppm, **4a**: 77.5 and 77.9 ppm, **4b**: 77.2 and 77.7 ppm), a carbon atom bearing two oxy substituents (**3**: 97.9 ppm, **4a**: 97.7 ppm, **4b**: 98.1 ppm), a nitrile carbon (**3**: 120.2 ppm, **4a**: 120.4 ppm, **4b**: 120.2 ppm) and a single carbonyl (**3**: 185.2 ppm, **4a**: 185.2 ppm, **4b**: 185.4 ppm) (Table 2). The peroxide values of **3**, **4a** and **4b** were determined to be 1.10, 0.95 and 1.19 mol/mol of the respective compounds. Thus, each compound contains one peroxy group in the molecule. From these results and other spectral data, the structures of **3**, **4a** and **4b** were identified as follows: Compound **3**, 8a*S*-(1*R*-cyano-1,3-dimethyl)butylperoxy-α-tocopherone: MS *m/z* 471 ([M-100]$^+$, 1%), 445 (9), 430 (62), 417 (14), 221 (18), 178 (16), 165 (100); IR (film) ν 1645 cm^{-1}; $[\alpha]_D^{25}$ +20 (*c* 0.38, ethanol). Compound **4a**, 8a*S*-(1*S*-cyano-1,3-dimethyl)butylperoxy-α-tocopherone; MS *m/z* 471 ([M-100]$^+$, 1%), 445 (7), 430 (65), 417 (15), 221 (18), 178 (17), 165 (100); IR (film) ν 1645 cm^{-1}; $[\alpha]_D^{25}$ −15 (*c* 0.41, ethanol). Compound **4b**, a mixture of 8a*R*-(1*R*-cyano-1,3-dimethyl)butylperoxy-α-tocopherone and 8a*R*-(1*S*-cyano-1,3-dimethyl)butylperoxy-α-tocopherone: MS *m/z* 471 ([M-100]$^+$, 1%), 445 (20), 430 (60), 417 (21), 221 (14), 178 (16), 165 (100); IR (film) ν 1650 cm^{-1}; $[\alpha]_D^{25}$ −22 (*c* 0.29, ethanol).

Compounds **5**, **6**, **7** and **8** were obtained as colorless oils (**5**: R_f 0.71, yield 60.9 mg; **6**: R_f 0.72, yield 132.9 mg; **7**: R_f 0.83, yield 88.3 mg; **8**: R_f 0.76, yield 32.1 mg). Their structures were identified to be geometric isomers of 4a,5-epoxy-8a-ethoxy-α-tocopherone. Compound **5**, 4a*S*,5*R*-epoxy-8a*R*-ethoxy-α-tocopherone: MS *m/z* 475 ([M-CH_3]$^+$, 1%), 445 (40), 430 (6), 417 (100), 265 (13),

Compounds **5, 6, 7** and **8**, in the presence of 0.1 M HCl, decomposed rapidly to α-tocopherylquinone 2,3-oxide (26): MS *m/z* 462 (M^+, 1%), 444 (6), 419 (54), 402 (26), 237 (54), 167 (100); IR (film) ν 3500 cm^{-1}, 1680; UV (ethanol) λ 272 nm (ε 4200); ^1H NMR ($CDCl_3$) δ 0.83–0.88 ppm (*m*, 12H), 1.05–2.05 (broad *m*, 24H), 1.21 (*s*, 3H), 1.63 (*s*, 3H), 1.81 (*m*, 1H), 1.97 (*s*, 6H), 2.29 (*m*, 1H).

DISCUSSION

α-Tocopherol is a chain-breaking antioxidant and reacts with peroxyl radicals to stop autoxidation of polyunsaturated fatty acids. The resulting tocopheroxyl radicals can react with other peroxyl radicals or with each other to form some reaction products. Although Winterle et al. (19) reported that the tocopheroxyl radical reacted with alkylperoxyl radicals to form 8a-alkylperoxy-α-tocopherones and some unknown products, they could not characterize their structures. In the present study, we have succeeded in isolating and characterizing the reaction products of α-tocopherol with the alkylperoxyl radical from AMVN in ethanol. The products are 8a-hydroperoxy-α-tocopherones (**1a** and **1b**), 7,8-epoxy-8a-ethoxy-α-tocopherone (**2**), 8a-alkylperoxy-α-tocopherones (**3, 4a** and **4b**) and 4a,5-epoxy-8a-ethoxy-α-tocopherone (**5, 6, 7** and **8**) (Scheme 1). Compounds **3, 4a** and **4b** correspond to the peroxy ketals reported by Winterle et al. (19). Compounds **1a** and **1b** have been reported to be primary products of the reaction of α-tocopherol, with singlet molecular oxygen (22,24,25) and key intermediates in the superoxide-catalyzed oxygenation of α-tocopherol (27). 4a,5-Epoxy-8a-methoxy-α-tocopherones, with structures that resemble compounds **5, 6, 7** and **8**, were obtained as the reaction products of α-tocopherol with singlet molecular oxygen (26).

The reaction of α-tocopherol (TOH) with AMVN in ethanol can be accomplished by several processes:

$$\text{AMVN} \rightarrow 2\text{R}\cdot \quad (1)$$
$$\text{R}\cdot + \text{O}_2 \rightarrow \text{ROO}\cdot \quad (2)$$
$$\text{ROO}\cdot + \text{TOH} \rightarrow \text{ROOH} + \text{TO}\cdot \quad (3)$$
$$\text{TO}\cdot + \text{ROO}\cdot \rightarrow \text{molecular products} \quad (4)$$

Because the tocopheroxyl radicals produced are resonance stabilized, they do not continue the chain reaction, but are eventually destroyed by reaction with a second peroxyl radical (reaction 4) (28). Our results indicate that the tocopheroxyl radical reacts with the alkylperoxyl radical to form **3, 4a** and **4b** as the products. If the tocopheroxyl radical reacts with a hydroperoxyl radical, **1a** and **1b** might be formed. The hydroperoxyl radical (HOO·) can be produced from the autoxidation of ethanol (29). The essential steps in the process are:

$$\text{ROO}\cdot + \text{CH}_3\text{CH}_2\text{OH} \rightarrow \text{ROOH} + \text{CH}_3\dot{\text{C}}\text{HOH} \quad (5)$$
$$\text{CH}_3\dot{\text{C}}\text{HOH} + \text{O}_2 \rightarrow \text{CH}_3\text{CHO} + \text{HOO}\cdot \quad (6)$$

The ROO· in reaction 5 may be the alkylperoxyl radical (see reaction 2). Presumably, the formation of **1a** and **1b** proceeds by this mechanism.

The formation of 8a-ethoxy compounds **2** and **5–8** must occur via the carbonium ion of α-tocopherol (TO^+) followed by reaction with the ethoxide anion (EtO^-) 30,31):

$$\text{TO}\cdot + \text{ROO}\cdot \rightarrow \text{TO}^+ + \text{ROO}^- \quad (7)$$
$$\text{TO}^+ + \text{ROO}^- \rightarrow \textbf{3, 4a and 4b} \quad (8)$$
$$\text{TO}^+ + \text{EtO}^- \rightarrow \text{8a-ethoxy-α-tocopherone} \quad (9)$$

Electron transfer might be the first step in the tocopheroxyl radical reaction with the alkylperoxyl radical (reaction 7). Collapse of this ion pair would yield **3, 4a** and **4b** (reaction 8), but the ethoxide anion would presumably be perfectly able to compete with ROO^- and it would yield 8a-ethoxy-α-tocopherone (reaction 9). Epoxides can be formed by peroxyl radical addition to double bonds followed by an intramolecular homolytic substitution process. Thus, the observed products **2** and **5–8** require peroxyl radical addition to 8a-ethoxy-α-tocopherone at the 7 and 5 positions, respectively. Matsumoto et al. (20) obtained 4a,5-epoxy-8a-alkylperoxychroman as the reaction product of the α-tocopherol model compound with *t*-butylperoxyl radical. More extensive oxidations of **3, 4a** and **4b** may produce the corresponding epoxy compounds.

The Distribution of Lipids and Sterols in Cell Types From the Marine Sponge *Pseudaxinyssa* sp.[1]

Mary P. Zimmerman[a], Frances C. Thomas[a], Janice E. Thompson[a], Carl Djerassi[a,*], Heidi Streiner[b], Elizabeth Evans[b] and Peter T. Murphy[b,2]

[a]Department of Chemistry, Stanford University, Stanford, California 94305; and [b]Sir George Fisher Centre for Tropical Marine Studies, James Cook University, Townsville 4811, Australia

The sponge *Pseudaxinyssa* sp., unique in sterol and fatty acid composition, was cellularly dissected into fractions enriched in each of the major cell types present in the sponge: microbial symbionts (cyanobacteria), small sponge cells (pinacocytes and choanocytes), and large sponge cells (archeocytes and cyanophytes). Three phototrophic microbial symbionts were also isolated from the cell fractions and grown in culture. An unsymmetrical distribution of fatty acids and sterols was observed for the sponge cells: small cells contained larger quantities of long chain fatty acids (> C24) and smaller quantities of sterols than were present in the larger sponge cells. Moreover, the rare sterols 24-isopropylcholesterol predominated in the smaller sponge cells, whereas its 22-dehydro analog predominated in the larger sponge cells. Long chain fatty acids and sterols were not detected in the cultured microbial symbionts. This constitutes the first report of lipid variability according to cell type for this most primitive group of Metazoa.

Lipids 24, 210-216 (1989).

The logical next subject for the study of lipid biosynthesis beyond the unicellular level (1) is the sponge—an organism limited to only a few cell types which are loosely cohesive without nervous cell control, but with the capacity for developing specialization and derived from the totipotent archeocyte cell. In higher organisms, the ratio of different kinds of polar lipids in membranes is characteristic of the type of membrane system, the organ and the species. Cholesterol, the most prevalent animal sterol, is not found in all membranes, and fatty acid composition varies markedly from one tissue to another (2,3). In contrast, the phylum Porifera with no real tissue development exhibits the widest diversity of sterols (4-10). Further, the major class Demospongiae has been especially noted for unusually long chain (C_{26}-C_{36}) fatty acids (11-22).

It is the common practice in this laboratory (23) and the practice of others to use whole sponges for biosynthetic studies of sterols and fatty acids. Generally included in the whole sponge are inter- and intracellular microbial symbionts. To date, few attempts have been made to assign sterol and lipid chemistry to particular sponge cell types (19,24), and only crude partial cell separations have been performed to investigate the biosynthetic roles of the symbionts (25).

It has long been known (26-28) that sponge cells can be dissociated in a calcium-magnesium-free medium to give a suspension of live cells. DeSutter and Van de Vyer (29) separated a choanocyte-enriched fraction from one enriched in archeocytes of the fresh water sponge *Ephydatia fluviatilis* by using a Ficoll gradient and noted that choanocytes aggregated very rapidly, but never formed functioning sponges. Johns et al. (30) added EDTA to further sequester the calcium and magnesium ions (to slow reaggregation), but noted that cell viability decreased. Lowenstein (31) had already shown that cells exhibited a "leakiness" at low-calcium concentrations and that hypotonically shocked cells failed to aggregate. Finally, DeSutter and Tulp (32) used a Ficoll gradient to purify gram quantities of specific sponge cell types. Hence, sponge cells can be effectively sorted according to size and density; certainly, the less small and dense pinacocytes and choanocytes can be effectively separated from the more large and dense archaeocytes and spiculocytes. In the present work, tandem Ficoll gradients were used to purify microbial symbionts and sponge cells from the demosponge *Pseudaxinyssa* sp.

Separation of sponge cells from microorganism symbionts can be more difficult than that of sponge cells from one another. Whereas eubacteria would be expected to be easily separable due to their small size and low density, cyanobacteria may not have densities much different than sponge cells. Moreover, in some sponges, bacteria are found intracellularly in the vacuoles and even within the nucleus (33). In some species, young sponges begin life with an established bacterial flora (34)—matrix bacteria are transferred into the larvae (35) or into the gemmules (36). Some chemical basis for this association already has been suggested (34,37), but any explicit role of membrane lipids in symbiosis is not known.

The Great Barrier Reef sponge *Pseudaxinyssa* sp. is a long-lived species that contains a considerable population of cyanobacteria (blue-green algae) (25,38). Its sterol composition is quantitatively simple, but structurally unique—99% of the sterols are represented by 22-dehydro-24-isopropylcholesterol (1) and 24-isopropylcholesterol (2) (39). In addition, there are trace sterols with intriguing side chains: triply (1-10) and quadruply (11-14) methylated, including cyclopropyl (14), tert-butyl (10) and 24-dialkylated (6-9, 11-14) sterols (40,31). Conventional sterols, such as cholesterol, are absent. In addition, this sponge is known to contain unusual long chain fatty acids that Lawson (24) identified as cellular membrane constituents. *Pseudaxinyssa* sp. is, therefore, an excellent candidate for the evaluation of cell-specific lipid content.

EXPERIMENTAL

Sponge sample. Pseudaxinyssa sp. (Australian Museum specimen #Z4988) was collected by hand from the John Brewer Reef, Australian Great Barrier Reef (15 M), December 18, 1986.

Chemicals and materials. The protease enzyme (no. P-2143) and Ficoll (type 400) were purchased from Sigma Chemical Co. (St. Louis, MO). The calcium-magnesium-free artificial sea water (CMF-ASW) was prepared from doubly distilled water and contained 462 mM NaCl, 8.4 mM Na_2SO_4, 11 mM KCl and 2.1 mM $NaHCO_3$.

Electron microscopy. For electron microscopy, sponge samples were prefixed in 3% glutaraldehyde/0.1 M sodium cacodylate buffer in Australia and then shipped to the USA where they were postfixed in 1% osmium tetroxide in the same buffer. After alcohol dehydration, they were embedded in epoxy resin according to Spurr (42). Silver sections were stained with 1% uranyl acetate and Reynold's (43) lead citrate and were examined with a Philips 410 electron microscope at 60 or 80 KV. The cultured cyanobacteria were fixed as above except that the prefix (in USA) was 2.5% glutaraldehyde, 4% paraformaldehyde, 2% acrolein in a 0.2 M phosphate buffer at 6.9 pH (prefix time = 18 hr).

Construction of ficoll gradients. Two types of Ficoll gradients were constructed (Fig. 1) by layering the below-designated w/w concentrations prepared from CMF-ASW. For the initial gross separation (I) and the refinement of the lighter cell fractions, Type I and II gradients were prepared by layering 5 mL aliquots of 23, 21.7, 16, 13, 9, 5, 0% and 21.7, 16, 13, 9, 5 and 0% Ficoll solutions, respectively. For the further separation and enrichment of the heavier cell fractions, Type III gradient was prepared by layering 10 mL aliquots of 35, 30, 26, 23, 21.7% Ficoll solutions. The Ficoll gradients were prepared just prior to use and kept at 3-10°C.

Dissociation of sponge cells was according to Thompson et al. (44) with the following modifications: The wet sponge (500 g) was washed 4 times in CMF-ASW, cut into cubes 0.5 cm on a side, soaked in a bath of 500 mL CMF-ASW to which 126 mg of protease enzyme had been added, and left at room temperature (23°C) for 2 hr. The resulting cloudy mixture was then filtered through cheesecloth and centrifuged at 600 *g* (MSE Mistral 41 Rotor GRMS [swing bucket]) for 5 min to produce a dark red, very dense sponge pellet. About 15% of the pellet was reserved for electron micrography (EM) analysis (Fig. 2B) and membrane analysis. The rest was suspended in 75 mL CMF-ASW and applied to the Ficoll gradients as described.

Separation of cells on ficoll gradients. To the top of a type I Ficoll gradient (Fig. 1) was added 10 mL of the resuspended pellet and the system was spun 5 min at 3°C and 600 *g* in the Mistral swing bucket centrifuge. The cells were concentrated between Ficoll layers and at the top of the column and were collected from these locations. The lightest four fractions were combined and washed free of Ficoll in CMF-ASW (250 mL × 2) via centrifugation (10,000 *g*/15 min). These cells were placed on the top of a Ficoll type II gradient and centrifuged as before. The cellular material between the different Ficoll concentrations was collected to yield the cell fractions I, II and III shown in Figure 1. Fractions IV and V were obtained from the original gradient (I) by collecting cells between the Ficoll concentrations 16-21.7 and 21.7-23%, respectively. The remaining pellet, which contained a major fraction of the original cells, was reapplied to the top of a Type III Ficoll gradient and centrifuged as before. Collection of cells between the Ficoll concentrations 22 and 26, 26 and 30, and 30 and 35% produced fractions VIa, VIb and VIc, respectively. Lipid analysis of fraction VIc and the adjacent pellet cells gave the same results, indicating that all cell types had finally been suspended. After this procedure was repeated six times, the following combined fraction weights were realized: I (42.7 mg), II (26.5 mg), III (27.2 mg), IV (19.5 mg), V (14.7 mg), VIa (2.5 mg), VIb (11.0 mg), VIc (9.9 mg), pellet

(bottom cells, 43.3 mg). The cells were then identified by size and morphology.

Chemical analysis of cell fractions. A sample cell fraction was freeze-dried and extracted with 3 × 1 mL of $CHCl_3/CH_3OH$ (1:1, v/v). The soluble material was separated from other cellular debris by filtration through a small plug of glass wool and sand. The extract was dried under a stream of nitrogen; then 1 mL of 1.15 N HCl (CH_3OH) was added and the reaction was heated at reflux for 1 hr. The solvents and reagents were then azeotropically removed with toluene under a stream of N_2. The resulting material was dissolved in 0.25 mL toluene and passed through a 0.5 ml florosil (toluene) column with toluene washes (1 mL × 5). After evaporation of the solvent (N_2), the resulting fatty acid methyl esters and sterols were collectively analyzed by capillary gas chromatography (GC) on a Hewlett-Packard 5790A series gas chromatograph equipped with a 25 m (0.3 mm i.d.) SE-54 coated fused silica column programmed at 170-320°C, 5°C min^{-1}; injector 250°C; detector temperature 300°C; automatic injector system (sampler model 7672A), injector (Model 3392A), sampler/event control module (model 19405A) and a computerized fatty acid system developed in our laboratory and previously used for the fatty acid analysis of *Pseudaxinyssa* sp. (45,46).

Sterol analysis. Under the above conditions of gas chromatography, the two sterols that constitute 99% of the nonsaponifiable lipid of *Pseudaxinyssa* sp., 24-isopropylcholesterol (2) and its 22-dehydro analog (1), were detected after all long chain fatty acids had come off the column. Sterol retention times were confirmed by injections of these known sterols.

Culture of symbionts. Multiple cultures were made from Ficoll fractions I-VI. Plates were inoculated directly from the Ficoll gradient on MN medium made with Difco agar (DIFCO Laboratories, Detroit, MI) as described by Rippka et al. (47). After substantial growth on solid medium, the culture was placed in liquid medium which, after several weeks, gave ~ 100 mg wet material for both chemical and EM analysis

RESULTS

Electron micrographs of the whole sponge *Pseudaxinyssa* sp. (Fig. 2A) show distinct cell types that we would expect to separate (or enrich) via a Ficoll gradient: small cells or choanocytes (a in Fig. 2A) with cell dimensions ~4.25 × 2 μm and a nuclear diameter of 0.87 μm; pinacocytes (b in Fig. 2A) with cell dimensions of 3 × 4 μm; and large cells or cyanophytes (e in Fig. 2A), which are cyanobacteria-containing arachaeocytes, with dimensions of 28.7 × 9.25 μm and nuclear diameters of 3.2 μm. Also found were other archeocytes and spiculocytes.

Dissociation of the whole sponge yielded intact cells independent of the mesophyl matrix; a small number of cells were broken by the dissociation process resulting in the presence of cell fragments (Fig. 2B). The dissociated cells took on a more rounded form, making morphological assignments difficult. The fatty acid and sterol analyses of this cell mixture (Figs. 3-4) agrees qualitatively and quantitatively with that reported from the whole sponge (45). Therefore, the dissociated cell mixture was a valid representation of the

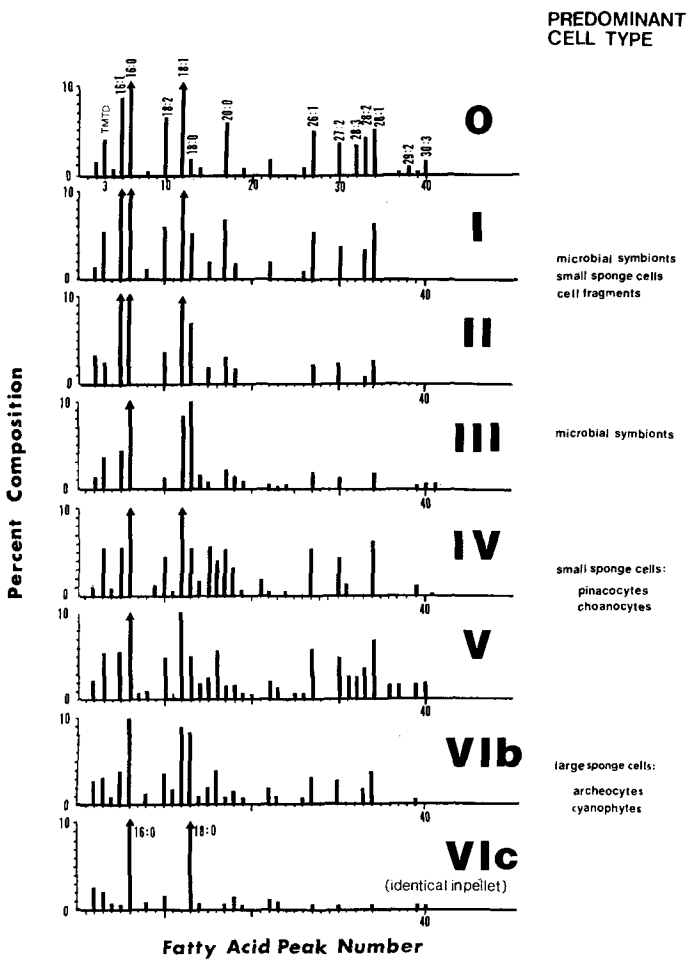

FIG. 3. Fatty acid analysis of Ficoll cell fractions. Fraction 0 represents analysis of dissociated cells from whole *Pseudaxinyssa* sp. prior to fractionation. Arrows indicate fatty acid contributions greater than 10% of total. These values are: 0 (peak 6, 18%; peak 12, 17%); I (5,13; 6,32; 12,30); II (5,12; 6,29; 12,26); III (6,39); IV (6,19; 12,11); V (6,20); IVb (6,23); VIc (6,38; 13,24). The chemical nature of the major fatty acids is indicated in Ficoll cell fraction 0 and in Table 1. (Note the percentage composition is of the fatty acids only.)

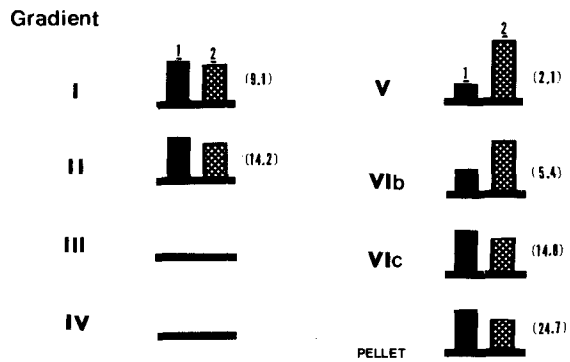

FIG. 4. Distribution of major sterols in Ficoll density gradient fractions. Graphed are the relative amount of each sterol in each cell fraction: 22-dehydro-24-isopropylcholesterol (1) vs 24-isopropylcholesterol (2). In parentheses is the percentage contribution to lipid (sterol + fatty acid) composition of the sterols in each fraction.

whole sponge and our cell separation was focused on obtaining cells of each cell type.

Cell separation. The first observation made from the cell separation was that the lighter fractions (I-III) were green, whereas the heavier fractions were dark red. This suggests a gross separation of phototrophic symbionts (green) from sponge cells. However, the Ficoll separation was refined enough to enrich fractions by cell type. Each fraction, therefore, was used as an inoculum for the culture of cyanobacterial symbionts, and subjected to electrom microscopy and fatty acid analysis.

The lightest four fractions (Fig. 1) were collected, combined and resubmitted to another Ficoll gradient (II). The resulting top three interfaces (between Ficoll concentrations 0-5, 5-10 and 10-14%) were collected to give fractions I, II and III. EM of these fractions (Fig. 2C) showed intercellular microbial symbionts (a), small sponge cells (b) and cell fragments. Both symbiont cells and sponge cells were of relatively small diameters (3-8 μm) compared with those cells found in the last Ficoll gradient (VIc, Fig. 2E), where cells of 15 μm diameter were common. The cells isolated with low density Ficoll appeared to suffer some osmotic shock, which likely explains the minimal observed reaggregation (31). Nonetheless, some of the small cells (b in Fig. 2C) have the gross morphology of a choanocyte (48), although a strict assignment cannot be made. The gross lipid analysis for these light fractions (I-III) is shown in Figure 3. In order to know the fatty acid contribution of the sponge cells, the contribution from the microbial symbionts had to be ascertained.

The major phototrophic symbionts of Pseudaxinyssa sp. Because the Ficoll gradient is a cell enrichment technique, each Ficoll fraction was used as a culture inoculum in order to give the broadest spectrum of phototrophic microbial symbionts. The medium chosen (MN) (47) favored growth of cyanobacteria because chlorophyll-a analysis had indicated large populations of these bacteria in the sponge (25). From this survey, three microbial symbionts were repeatedly isolated and grown in bulk. Their fatty acid content apparently makes a major contribution to the fatty acid analysis of the whole sponge (Table 1), although other microbial symbionts cannot be strictly excluded.

A green cyanobacterium (CBI) was found predominantly in the lighter Ficoll layers I-III; a red cyanobacterium (CBII) was found in all the Ficoll layers; and a green unicellular symbiont (SYMIII) was found predominantly in the lighter layers. The cyanobacteria CBI and CBII are seemingly identical in EM analysis with the red color of the latter lost during fixation. The EM (Fig. 2F) shows cylindrical cyanobacterial cells growing in straight trichomes, many more than 10 cells in length, although all cyanobacteria appear to be unicellular in the sponge, in agreement with previous studies (49). Each cyanobacterium has a dense peripheral thylakoid system surrounding a central nucleoplasm. In culture, the cells grew to 2 μm in length and 0.9 μm in width. The cells are separated from each other by deep constrictions and each cell has one and sometimes more gas vacuoles. Although seemingly identical in morphology, the cyanobacteria CBI and CBII do differ.

The two cyanobacteria CBI and CBII differ both in color and fatty acid composition. The cyanobacterium CBI which was isolated from the lighter Ficoll fractions I-III was green, whereas cyanobacterium CBII, which was present in all fractions, but dominant in the heavier ones (i.e., IVc), was red. The red bacterium CBII likely was present intracellularly, imparting the distinct red color of the cyanophytes. Both cultures contained fatty acids (Table 2) typical of cyanobacteria—primarily, C_{16} and C_{18} acids (50). In addition, both

cyanobacteria have C16/C18 fatty acid ratios greater than one, another common characteristic of cyanobacteria (51). Moreover, Gillan et al. (46) has identified C16:1 *cis*-9 as a marker acid for cyanobacteria, and this is present in both the obvious cyanobacteria (CBI, II) and in the third symbiont (SYMIII) described below.

The third symbiont (SYMIII) is not an obvious cyanobacterium. It is apple green in color with an average cell diameter of 10 μm and with no obvious nucleus (Fig. 2G). Its size and morphology agree closely with another Great Barrier Reef symbiont recently reported (52) which has an ultrastructure resembling that of the chlorophyll-b-containing prokaryote *Prochloron* sp. Moreover, the fatty acid analysis of SYMIII was not typical of a cyanobacterium. The C16/C18 ratio for SYMIII (Table 2) is less than 1, suggesting that SYMIII may be more closely related to the green algae. In general, the unsaturated C18 fatty acids are predominant in all species of green algae, whereas, with some exceptions, C16 fatty acids are predominant in blue-green algae (53).

Nonsaponifiable lipids in symbionts. Sterols are generally considered to be present only in eukaryotic organisms, whereas prokaryotes seem to use carotenoids and other polyterpenoids; however, some crossover is known i.e., one class of prokaryote, Mycoplasma, requires environmental sterols (54). The present analysis ascertained by capillary GC that the major sterols in *Pseudaxinyssa* sp. were not present (to 0.03% of lipid content) in any of the three cultured symbionts.

The lipid analysis (Figs. 3-4) of the less dense Ficoll fractions (I-III) is largely dominated by the symbiont fatty acid contribution (Table 1, Fig. 3). The minor sterol and long chain fatty acid contribution is presumably from small sponge cells and cell fragments. Fraction III exemplifies heavy symbiont population, being composed largely of C16:0, C18:1, and C18:0, with no significant amount of sterols (Fig. 4). Small sponge cells largely comprise fraction IV with very little contamination from symbionts and fragments.

The ficoll gradient fractions mainly containing small sponge cells (IV, V). Progressing in descending order from fraction IV, the Ficoll density gradient contains mainly sponge cells. This is most clearly shown from the EM (Fig. 2D) which shows sponge cells of ~ 4 μm in length and very few cyanocytes or larger cell types. Some choanocytes are visible, but mostly the morphology is obscure. By an extrapolation of DeSutter's Ficoll gradient (32), the cells in fraction IV are likely pinacocytes and choanocytes. According to fatty acid analysis (Fig. 3), these fraction IV cells contain the highest concentration of long chain fatty acids—twice as many as fraction VIb—whereas fraction VIc has almost none. Coupled with this, fractions IV and V have a very low sterol content (Fig. 4). Moreover, the cells in fraction V (Fig. 4) contain a small amount of 24-isopropylcholesterol (2), but far less 22-dehydroisopropyl cholesterol (1). This discrimination favoring the saturated side chain persists into fraction VIb and thereafter is reversed (Fig. 4). (It is known that our sterol isolation procedure would not have separated these sterols.) The ratio of these sterols in the whole sponge is 1:1. Different cell types appear to be using these two sterols selectively, implying a functional dependence on whether the sterol has a double bond at position 22 in the side chain. Fractions IV and V differ from those that follow by containing the smaller sponge cells (pinacocytes and choanocytes), the cells in direct contact with the aqueous environment and those that insulate the interior of the sponge from the environment. Thus, it is not surprising that they differ in lipid constitution from the interior cells.

The ficoll gradient fractions containing mainly large sponge cells (VIb, VIc). Fraction VIc and the pellet (Fig. 1), which together constitute 33% of the dissociated cell mass, were identical in lipid content. These fractions contained large (14.7 μm diam.) cyanobacteria-containing archaeocytes (= cyanocytes). The major fatty acids were saturated C16:0 and C18:0. More than ten times as much sterol was present as was found in the small cell fractions (IV), with the major sterol being the side chain saturated 1 (Fig. 4). This is another deviation from the 1:1 ratio that the sterols exhibit on whole sponge analysis. In these cell fractions, unsaturation in the membrane lipids is predominantly found in the sterols. A fatty acid of nonbacterial origin, 4,8,12-trimethyltridecanoic acid, is present in fraction VIc, which is consistent with the composition of cells internally located in the sponge (46). This fatty acid was not present in any of our cultured symbionts. In terms of cell and lipid content, fraction VIb represents a transition between Fractions V and VIc.

CONCLUSIONS

This study demonstrates that the cells of a sponge can be separated and differentiated by combined EM and fatty acid analysis, while retaining cell viability, thus setting the stage for a new era of biosynthetic studies in sponges. At least in this study, the cells could be separated not only by size, but also by function, because the surface cells were much smaller than the

internal symbiont-infested archeocytes (cyanocytes). The surface cells (choanocytes, pinacocytes) collectively had a higher concentration of long chain fatty acids and a lower concentration of sterols than the internally located archeocytes. This was not surprising because the function of a surface cell, primarily as insulation from the marine environment, is different than that of the internal archeocytes, where growth, reproduction and other regulation are handled. The knowledge that sterols are present in high concentration in these internal cells, and that the sterol nucleus is central to cell regulation in higher forms of life, moves us closer to unlocking the mystifying role that the complex and diverse array of sterol structures present in sponges must play.

ACKNOWLEDGMENT

This work was supported by the National Institutes of Health (Grant No. GM-06840) and the National Science Foundation (Grant No. DMB-8606429). We thank Chris Ireland and Tawnya McKee for their help in initial culturing of symbionts and Mishelle Lawson and Shirley Sorokin for their help in initial separation procedures. We also acknowledge valuable help from Douglas Smith in terms of automated fatty acid analysis.

Effects of Cholesterol Oxidation Derivatives on Cholesterol Esterifying and Cholesteryl Ester Hydrolytic Enzyme Activity of Cultured Rabbit Aortic Smooth Muscle Cells

Robert J. Morin* and **Shi-Kaung Peng**
Department of Pathology, Harbor-UCLA Medical Center, Torrance, CA 90509

The effects of 5 μg/ml of 25-hydroxycholesterol; cholestane-3β,5α,6β-triol; and cholesterol on acyl CoA cholesterol acyltransferase, acid cholesteryl ester hydrolase and neutral cholesteryl ester hydrolase was studied in cultured rabbit aortic smooth muscle cells. After 1 hour incubation, 25-hydroxycholesterol resulted in a fourfold stimulation of acyl CoA cholesterol acyltransferase activity. No stimulation by 25-hydroxycholesterol was noted before 15 minutes or after 5 hours of incubation. Neither cholestane-3β,5α,6β-triol nor cholesterol influenced acyl CoA cholesterol acyltransferase activity at any time interval. No significant effects of any of the sterols were noted on acid cholesteryl ester hydrolase or neutral cholesteryl ester hydrolase activity. The imbalance between acyl CoA cholesterol acyl transferase and hydrolase activities induced by 25-hydroxycholesterol could result in cholesteryl ester accumulation by arterial smooth muscle cells, which may be associated with atherosclerosis.
Lipids 24, 217-220 (1989).

Administration of oxidized derivatives of cholesterol to rabbits has resulted in arterial endothelial injury (1) and, to pigeons, has produced a greater degree of atherosclerosis than cholesterol feeding alone (2). In vitro, these cholesterol oxidation products have been shown to be toxic to arterial smooth muscle cells (3-5) and fibroblasts (6) and to induce a number of alterations in membrane structure and function (7-9). In cultured mouse L fibroblast cells, incubation with 25-hydroxycholesterol (25-OH) or cholestane-3β,5α6β-triol (Triol) resulted in intracellular lipid accumulation (6). The cholesteryl ester content of cultured heptocytes from rabbits fed oxidized cholesterol derivatives was greatly increased as compared with hepatocytes from control or rabbits fed pure cholesterol (10). Atherosclerosis is characterized by a marked increase in the content of cholesteryl esters in the arterial wall. Cholesteryl esters in the cell are in dynamic equilibrium, and are continuously synthesized by esterifying enzymes and degraded by hydrolytic enzymes. The balance between these processes could determine the extent of cholesteryl ester accumulation. Most cholesteryl esters originate from esterification of plasma lipoprotein-derived free cholesterol by the action of the microsomal enzyme acyl CoA:cholesterol acyltransferase (ACAT) (EC 2.3.1.26). The activity of this enzyme is increased up to 70-fold during experimental atherosclerosis (11,12). Hydrolysis of arterial cholesteryl esters by a lysosomal acid cholesteryl ester hydrolase (ACEH) (EC 3.1.1.13) and a cytosolic neutral cholesteryl ester hydrolase (NCEH) (EC 3.1.1.13) may regulate the amounts of cholesteryl esters accumulating in the arterial wall. In the present study, the effects of 25-OH and Triol on ACAT, ACEH and NCEH were studied in cultured rabbit aortic smooth muscle cells to explore the mechanisms for the lipid accumulation and atherogenesis previously induced by these agents.

Abbreviations: ACAT, acyl CoA cholesterol acyl transferase; ACEH, acid cholesteryl ester hydrolase; HDL, high density lipoprotein; HMGCoA, hydroxy methyl glutaryl coenzyme A; NCEH, neutral cholesteryl ester hydrolase; SVE, sucrose containing 1.0 mM EDTA and 1% ethanol; triol, cholestane-3β,5α,6β-triol; 25-OH, 25-hydroxycholesterol.

MATERIALS AND METHODS

Aortas of New Zealand white, young adult rabbits (2-3 kg) were aseptically removed using the ventral approach. After dissection of adventitial fat, aortic segments were immersed in basal culture medium and cut into ca. 1-mm^2 pieces. All fragments were treated with 0.2% collagenase, incubated at 37°C for 15 min to remove endothelium, washed 2× with growth medium and, then, transferred into 30-ml Falcon flasks. These explants were nourished in Eagle's medium supplemented with 10% fetal calf serum and antibiotics. Medium in the flasks was changed 3× a week. After growth to confluence (3 wk), the cells were washed with calcium- and magnesium-free phosphate-buffered saline solution. Two ml of 0.20% trypsin was added to each flask and, then, decanted off 2 min later. After incubation for 10 min, with occasional agitation, all cells were detached from the flasks. The remaining small amount of trypsin was inactivated by the addition of 10 ml of culture medium containing 10% fetal calf serum. The cells were transferred into new 75-cm^2 Falcon flasks. Confluent monolayers of aortic smooth muscle cells developed within 2 wk. Cell cultures were incubated in lipoprotein-deficient media [sera delipidized as described by Brown et al. (13)] for 24 hr prior to ACAT assay. The cell cultures were then incubated with ethanol, cholesterol, 25-OH or Triol at 5 μg/ml final concentration for 15 min, 1 hr or 5 hr. Cells were then washed 3× with media, the media discarded and the cells then scraped with a rubber policeman into 0.15 M Tris-HCl buffer, pH 7.4, containing 0.01 M mercaptoethanol and 0.5 mg/ml defatted bovine serum albumin. Cells were then completed homogenized using a glass Potter-Elvehjem homogenizer (Baxter Scientific Products, McGraw Park, IL).

Assay of ACAT activity was done using a modification of the method described by Hajjar et al. (14), using exogeneous cholesterol and radioactive fatty acyl CoA (50 mCi/mmol, New England Nuclear, Boston, MA) in phospholipid liposomes. Unilamellar liposomes were prepared by mixing 10 μCi 1-^{14}C oleyl CoA, 0.25 μmol cholesterol, 0.47 nmol oleic acid and 25 μmol

egg lecithin (Sigma Chemical Co., St. Louis, MO) in 2.0 ml methanol: methylene chloride. The solvents were removed by evaporation under N_2 followed by lyophilization. The mixture was resuspended by mechanical rotational agitation in 6.0 ml of 100 mM KCl containing 10 mM Tris-HCl buffer, pH 7.0, and 3.1 mM sodium azide. The suspension was then sonicated at 45°C for 12 min at 100 watts in a Branson sonifier, and then centrifuged at 30,000 rpm in a Beckman 50Ti rotor (Palo Alto, CA) to remove particulate matter. For the ACAT reaction aliquots of the cell homogenates were mixed with 0.25 ml of the liposomal substrate, 0.5 ml 0.15M Tris-HCl buffer, pH 7.4, containing 0.01 M mercaptoethanol and 0.05% defatted bovine serum albumin. Incubations were done in a shaking water bath at 37°C for 30 min. The reactions were stopped by addition of chloroform: methanol, 2:1, containing unlabeled cholesteryl oleate as a carrier. The lipids were extracted by the Folch procedure (15) and separated by thin layer chromatography on silica gel 250-μ plates using hexane/ethyl ether/glacial acetic acid (100:8:2) as the developing solvent. The lipids were visualized by spraying with Rhodamine 6G in phosphate buffer, the cholesteryl ester zones scraped into vials containing Aquasol-2/water (10:1) and counted in a Beckman Liquid Scintillation spectrometer (Fullerton, CA). Quenching was corrected by automated external standardization.

Assay of NCEH was done using a mixed micellar substrate (16) prepared as follows: 10 μCi of cholesteryl [1-^{14}C] oleate, (55 mCi/mmol, Amersham, Arlington Heights, IL) was freed of contaminating fatty acids by liquid-liquid partitioning using a methanol/water (1:1) phase and a chloroform/heptane (5:4) phase (17). The purified radioactive substrate was added to chloroform containing 3.8 μmol of phosphatidylcholine and 0.8 μmol of unlabeled cholesteryl oleate. The solvent was evaporated under N_2 at 37°C and the lipids suspended in 8.0 ml of 0.1 M potassium phosphate buffer, pH 7.0, containing 2.0 μmol sodium taurocholate. This was sonicated at 46°C in a Branson Sonifier (Danbury, CT) using 100 watts, then centrifuged at 30,000 rpm for 15 min in a Beckman 50Ti rotor to remove particulate matter. Incubation mixtures were prepared by adding 50 μl of the micellar cholesteryl [1-^{14}C] oleate substrate to 0.8 ml of 0.1 M phosphate buffer, pH 7.0, with 0.05% bovine serum albumin and 0.15 ml cell homogenate in the same buffer. After incubation for 60 min at 37°C, 16.3 ml of methanol/chloroform/heptane (1.4:1.3:1.0) and 5.3 ml of 50 mM potassium carbonate/50 mM potassium borate buffer, pH 10.0, was added. The mixture was agitated by mechanical rotation for 5 min, shaken for 30 min and centrifuged for 10 min at 2500 rpm to separate the phases. Radioactivities in aliquots of the upper aqueous phases containing the 1-^{14}C oleate product were counted in an Aquasol-2 scintillation solution. Micellar 1-^{14}C oleic acid standards were incubated, processed and counted in an identical manner to monitor recovery.

Assay of ACEH was done by a modification of the Haley, et al. method (18) using a micellar cholesteryl [1-^{14}C) oleate substrate, prepared as previously described for the NCEH assay. After sonication, one part of the prepared lecithin dispersion was added to 4 parts 0.125 M Na acetate buffer, pH 3.9, containing 5.0 mM Na taurocholate. Cells were homogenized with a glass mortar and pestle in 0.25 M sucrose containing 1.0 mM EDTA and 0.1% ethanol (SVE) and centrifuged for 10 min at 1,000 rpm. The pellets were rehomogenized in SVE and recentrifuged, and the combined supernatants were used as the enzyme source. These were adjusted to 0.1% digitonin and incubated for 10 min at 0°C. Equal parts of the enzyme and substrate solution were mixed and incubated at 37°C for 60 min. The reactions were stopped and the substrates and products separated, as previously described for the NCEH assay. The radioactivities of the 1-^{14}C oleate in the aqueous phase were counted, also as previously described.

Protein content of the cell homogenates was determined by the Lowry method (19).

RESULTS AND DISCUSSION

Effects of cholesterol oxides on cholesterol esterifying activity. Incubation of rabbit aortic smooth muscle cells for 1 hr with 25-OH at 5 μg/ml resulted in a ca. 4-fold increase in ACAT activity (Table 1). Cholesterol and Triol under similar conditions had no significant effects on ACAT. The effect of incubation time on ACAT enzyme activities as influenced by cholesterol and its oxidation products is indicated in Table 2. The stimulation of ACAT by 25-OH was not manifest at 15 min, was maximal at 1 hr and disappeared after 5 hr of incubation. Incubation with 25-OH for 24 hr also did not result in any stimulatory effect. Cholesterol

NCEH			
Chol	122 ± 61	106 ± 39	112 ± 50
25-OH	81 ± 13	90 ± 15	93 ± 22
Triol	81 ± 21	102 ± 21	112 ± 53

[a]Each value represents mean percentage of control ± S.D. of 4-6 experiments. Abbreviations are defined in Table 1.
[b]Significantly different than controls at $p < 0.01$.

and Triol had no significant effects on ACAT activity at any time interval. Stimulation of ACAT by 25-OH has been observed previously in human fibroblasts (13), mouse L fibroblast cells (20) and in rat hepatocytes (21,22). Cholesteryl ester synthesis in bovine adrenal cortical cells and microsomal preparations was not affected by 25-OH (23).

The influence of 25-OH on ACAT activity in arterial smooth muscle cells has not been studied previously. The time course of 25-OH stimulation of ACAT in this preparation differs from that in previous experiments on other cells. In human fibroblasts, the rate of cholesterol esterification increased linearly from 0 to 24 hr and was correlated with the degree of suppression of hydroxy methyl glutaryl coenzyme A (HMGCoA) reductase activity by 25-OH (13). ACAT activity after 5 hr of incubation with 25-OH was increased 8-fold over control levels. In cultured hepatocytes, stimulation of ACAT by 25-OH was maximal after 15 min, less at 4-6 hr and had disappeared after 18 hr (22). The inhibition of HMGCoA reductase by 25-OH, however, persisted for at least 22 hr. One proposed mechanism of action of 25-OH on ACAT activity is that suppression of HMGCoA reductase leads to decreased microsomal membrane cholesterol content and a reduced cholesterol/phospholipid ratio in these membranes (20). This could make exogenous cholesterol more accessible to the active sites of ACAT. According to this theory, a lag phase in 25-OH action would be expected until HMGCoA had been sufficiently suppressed. This could account for the lack of stimulation observed at 15 min in the present experiments. In arterial smooth muscle cells, suppression of HMGCoA reductase by 25-OH increases exponentially to a maximum of about 80% suppression at 1 hr (4). This time of maximum suppression correlates with the maximum stimulation of ACAT activity observed at 1-hr incubation with 25-OH in the present experiments. At later time intervals, there is possibly an adaptive effect similar to that previously observed in rat hepatocytes (22).

Effects of Cholesterol Oxides on Cholesteryl Ester Hydrolytic Activity. As seen in Tables 1 and 2, there were no significant effects of cholesterol, 25-OH or Triol on either ACEH or NCEH activity after incubation with the arterial smooth muscle cells for 15 min, 1 hr or 5 hr. Previous experiments using acetone-butanol extracts of pig aortas have shown a 4-fold stimulation of ACEH by 26-hydroxycholesterol and a 9-fold stimulation by Triol (24). It was postulated that this was due to a dispersing effect of the added sterols, improving access of the enzyme to the cholesteryl esters. The divergent results of the present experiments may be attributable to the different preparations used (intact cells vs extracts) or to the different sterol concentrations used (5 μg/ml vs 50 μg/ml) in the previous experiment.

The observed 25-OH induced stimulation of ACAT activity in arterial smooth muscle cells without a corresponding increase in cholesteryl ester hydrolase activity may result in a net accumulation of cholesteryl esters, leading to initiation or progression of atherosclerosis. Another effect of 25-OH, however, is to increase high density lipoprotein (HDL) receptor sites on bovine vascular cells (25). This may result in increased reverse cholesterol transport by HDLs, which could modulate the effect of 25-OH on ACAT by decreasing substrate availability. Determination of the net effect of 25-OH on atherogenesis, therefore, will require further experiments using in vivo models.

METHODS

An Improved Procedure for Bile Acid Extraction and Purification and Tissue Distribution in the Rat

Patricia L. Locket[1] and **Daniel D. Gallaher***
Department of Food and Nutrition, North Dakota State University, Fargo, ND 58105

Two bile acid extraction procedures were compared using endogenously radiolabeled tissues and feces. The method of Setchell et al. (*J. Lipid Res. 24,* 1085-1100, 1983) resulted in essential complete extraction, whereas that of Manes and Schneider (*J. Lipid Res. 6,* 376-377, 1971) gave recoveries between 56-82%. The time requirement for the method of Setchell et al. could be drastically reduced with no loss in extraction efficiency. Using extracts from endogenously labeled material, a purification procedure using C18 solid-phase extraction cartridges was developed that recovers >90% of bile acids. The distribution of bile acids within the intestinal tract and liver of the rat was determined.
Lipids 24, 221-223 (1989).

Bile acid metabolism has gained increasing attention in recent years in part due to the purported role of these compounds in the regulation of cholesterol synthesis (1) and the etiology of colon cancer (2), as well as their proven efficacy in gallstone dissolution (3). However, studies of bile acid metabolism have been hampered by the difficulty of extracting and purifying bile acids from biological material quantitatively. Although many extraction procedures have been described in the literature (ref. 4), it has been our experience that few of them result in greater than 80% recovery when recovery is tested by use of an added standard. Previously, one of us (DDG) had found nearly complete recovery of an added bile acid standard from rat intestinal contents using the acidified ethanol extraction procedure of Manes and Schneider (5). However, due to the reported difficulty of extracting bile acids from feces and the possibility of the acidic conditions of this procedure causing structural changes in the bile acids, we chose to explore other bile acid extraction procedures. Our objective was to develop a procedure to extract and partially purify a large number of samples in a minimum amount of time with minimum loss for later analysis of bile acids by high performance liquid chromatography. To test recoveries, we chose to use tissues and fecal material endogenously labeled with bile acids, because it has been reported that fecal samples labeled exogenously do not give an accurate measure of bile acid recovery (6,7).

MATERIALS AND METHODS

Materials. All solvents were of analytical grade and redistilled. [24-^{14}C]Chenodeoxycholic acid (sp. act. 50 mCi/mmol) was obtained from E.I. Du Pont de Nemours & Co., Biotechnology Systems Division (Boston, MA). [24-^{14}C]-Cholic acid (sp. act. 50 mCi/mmol) was obtained from Research Products International Corp. (Mount Prospect, IL). The radiopurity of each bile acid was checked by thin layer chromatography and found to be >98% for chenodeoxycholic acid and >97% for cholic acid. Both bile acids were used without further purification.

Endogenous labeling of tissue and fecal samples. ^{14}C-Cholic and ^{14}C-chenodeoxycholic acid, 0.625 uCi of each, were added to 10 ml of methanol and thoroughly mixed into 15 g of a semipurified diet. The diet was similar to the AIN-76 diet (8), except that cornstarch was the sole carbohydrate source and no cellulose was added. The diet was dried in a vacuum oven at ca. 30°C to evaporate the methanol. Following a 24 hr fast, 3 g of labeled diet was offered to each of 4 male weanling rats for 2 hr. Forty-eight hours after presentation of the labeled meal the rats were anesthesized by exposure to ethyl ether, laparotomized, and the small intestine, cecum, colon, stomach and liver removed and weighed. A blood sample was taken by cardiac puncture and plasma collected after centrifugation. Plasma volume of the animals was taken as 3.28% of body weight (9). Fecal pellets were collected from the time of feeding of the labeled diets. The collected tissues and fecal pellets were homogenized (Tissumizer, Tekmar Co., Cincinnati, OH) in distilled water, freeze-dried, weighed and stored at −20°C until bile acid extraction.

Bile acid extraction. Two different bile acid extraction methods were investigated using the endogenously labeled tissues and feces. Method 1 was the procedure described by Manes and Schneider (5). Two ml of 0.5 N HCl in absolute ethanol was added to 100 mg of lyophilized tissue in screw cap tubes. The mixture was incubated at 37°C in a shaking water bath for 1 hr, with vortexing every 15 min. Tubes were centrifuged at 1500 × *g* for 10 min and the supernatants collected. The pellet was resuspended in 2 ml of the acidified ethanol, incubated and centrifuged as above. Supernatants were pooled and evaporated with nitrogen gas at low heat (55°C).

Method 2 was the procedure of Setchell et al. (6). Two ml of absolute ethanol was added to 100 mg of sample in 20 I.D. × 125 mm screw cap tubes. Tubes were tightly capped and sonicated in a bath sonicator for 30 min. Following sonication, the tubes were placed in a Reactitherm heating block (Pierce Chemical Co., Rockford, IL) and refluxed at 100°C. Reflux times of 2 hr, 1 hr, and 15 min were tested. After refluxing, tubes were centrifuged at 1500 × *g* for 10 min, and supernatants were removed and retained. The pellet was resuspended in 2 ml 80% ethanol, refluxed and centrifuged as before. Supernatants were pooled with the first. The pellet was resuspended a third time in 2 ml chloroform/methanol (1:1, v/v) and again refluxed and centrifuged and the supernatant was decanted and pooled. The pellet was washed once by adding 2 ml of chloroform/methanol (1:1, v/v), followed by

*To whom correspondence should be addressed.

Abbreviations: DPM, disintegration per minute; DW, distilled water.

centrifugation and removal of the supernatant as before.

Pooled extracts and the residues remaining after extraction were quantitatively transferred to liquid scintillation vials and dried under nitrogen gas. One ml of tissue solubilizer (TS-2, Research Products International, Mount Prospect, IL) and 200 μl of distilled water were added to each vial and the vials placed on a rotary shaker for 18 hr. Two drops of glacial acetic acid and 15 ml of liquid scintillation cocktail (Safety-Solve, Research Products International, Mount Prospect, IL) were added to each vial and radioactivity was determined by liquid scintillation, counting with quenching corrected by use of an external standard. Recovery was calculated as the ratio of disintegrations per minute (DPM) in the extract to the DPM in the extract plus residue, and was expressed as a percentage.

Partial purification. Reversed-phase C18 bonded-phase cartridges (Sep-Pak, Waters Assoc., Milford, MA) were used for purification of the bile acid extracts. Recovery of bile acids from various purification procedures was tested using labeled bile acids obtained from the method 2 extraction procedure. Losses at each stage of the purification procedure were evaluated by a counting of the cartridge eluant.

Cartridges were initially solvated with 4 ml of methanol, followed by 4 ml of distilled water. To tubes containing the dried bile acid extract, 0.6 ml of methanol was added and the tubes vortexed to solubilize bile acids. Next, 2.4 ml of distilled water was added, the tubes vortexed and the solution loaded onto the cartridges at a rate of 1 ml/min using a vacuum pump. The tubes containing the extract were washed twice with 4 ml of methanol/water (20:80, v/v), with each wash subsequently loaded onto the cartridges. Combinations of distilled water (DW), hexane and methanol were used to remove water soluble and lipid impurities. Purification procedure 1 was that described (10), which was subsequently modified. The wash sequences (4 ml of each solution) for each purification procedure were as follows: (1) DW, hexane, DW, methanol/DW (40:60) washes; methanol/DW (75:25) to elute bile acids. (2) DW, hexane, methanol/DW (40:60) washes; methanol to elute bile acids. And, (3) DW, hexane washes; methanol to elute bile acids.

Bile acid distribution. One of the animals ate only a small quantity of the labeled diet, expressed almost no fecal material over the following 2 days and acted lethargic. Thus, the results from this animal were not used in determining tissue distribution.

The tissue distribution of endogenously labeled bile acids was calculated by extraction of the bile acids from small intestine, cecum, liver, colon contents and plasma, using the method 2 extraction procedure, and by determining the total amount of radioactivity in each sample.

RESULTS AND DISCUSSION

Bile acid extraction. Table 1 shows a comparison of the two extraction methods used and the effect of reducing the refluxing time in method 2. The results show that with the method of Setchell et al. (method 2) (6), almost complete extraction of bile acids was obtained from all samples tested. In contrast, the procedure of Manes and Schneider (method 1) (5) led to incomplete and variable extraction. In both methods, the poorest recovery of bile acids was from liver.

TABLE 1

Comparison of Bile Acid Extraction Methods Using Endogenously Radiolabeled Rat Tissues and Feces

	% Bile acids recovered[a]			
		Method 2 Minutes of reflux		
Sample	Method 1	120	60	15
Small intestine	81.6[b] (5.2)	99.2 (0.2)	99.2 (0.3)	99.2 (0.3)
Cecum	75.9 (5.7)	98.5 (1.2)	98.2 (0.6)	98.3 (0.9)
Liver	55.7 (4.1)	93.8 (7.5)	96.1 (3.0)	95.1 (2.5)
Feces	79.5 (5.0)	97.9 (2.1)	97.5 (0.5)	97.6 (0.3)

[a] Recovery calculated as radioactivity in extract/radioactivity in extract and residue remaining. Method 1 is that of Manes and Schneider (4); method 2 is that of Setchell et al. (6), with reflux times varied. See text for details of extraction procedure.

[b] Each value is the mean (SD) of duplicate determinations from 4 animals, except for method 2 fecal samples, where samples from 2-3 animals were used.

One of us (DDG) had previously found that recovery of an added taurocholate standard to rat intestinal contents was essentially 100% using method 1 (unpublished results). However, using endogenously labeled small intestinal tissue, we have found recovery, using this procedure, to be only about 80% complete. These results are similar to those of Setchell et al. (6) who found that after sonification and extraction with 90% ethanol, recovery of added standards from human feces ranged between 90 and 100%, whereas the recovery of endogenous radiolabeled bile acids averaged 82%. Thus, the use of a single bile acid standard to represent the entire spectrum of bile acids, which vary considerably in their hydrophobicity and metabolism, cannot be relied on to give an accurate measure of the completeness of extraction of all bile acids.

As bile acids are taken up by the cells of the gastrointestinal tract, sonicating the samples to disrupt these cells would seem important and may partially explain the completeness of the recovery in method 2. However, we questioned the necessity of the long reflux times, as originally described by Setchell et al. (6). As shown in Table 1, it is possible to reduce the refluxing times from 2 hr to 15 min with no loss in recovery. This greatly reduces the time of the method and allows many more samples to be extracted in a day.

Bile acid purification. The effectiveness of three different purification procedures is shown in Table 2. Procedure 1 had previously been found to give 93% recovery from small intestinal contents when added radiolabeled taurocholate was used to measure recovery (10). In the present study, using endogenously radiolabeled samples, this procedure gave only 42% recovery. Considerable losses were found in both the methanol/water wash and upon resolvating the cartridge with methanol. As in procedure 2, using methanol instead of a methanol/water solution to elute the bile acids improved recovery considerably. Most of the losses in these two procedures were

TABLE 2

Comparison of Bile Acid Extract Purification Procedures Using C18 Reversed Phase Cartridges

Procedure[a]	Sample loading	Washes				Eluants		Resolvation
	MeOH:DW (20:80)	DW	Hexane	DW	MeOH:DW (40:60)	MeOH:DW (75:25)	MeOH	MeOH
	% radioactivity recovered in each fraction							
1	4.10[b] (2.08)	1.52 (1.43)	1.56 (1.50)	6.04 (3.71)	27.05 (20.54)	41.93 (5.76)	—	17.79 (22.44)
2	3.33 (0.76)	0.26 (0.24)	0.83 (0.78)	—	23.41 (18.06)	—	72.15 (19.03)	0
3	3.87 (2.34)	1.69 (2.35)	0.38 (0.34)	—	—	—	93.93 (3.71)	0.12 (0.14)

[a]Cartridges were solvated with 4 ml of methanol, followed by 4 ml of distilled water. Four ml of each solution was drawn through the cartridge by vacuum at a rate of 1 ml/min. MeOH, methanol; DW, distilled water.

[b]Each value represents the mean (SD) of 6 determinations.

in methanol/water washes, apparently due to the solubility of certain polar bile acids in this concentration of methanol. Elimination of methanolic solutions as a wash and using it solely to elute the bile acids (as in method 3) increased recovery to ca. 94% and greatly reduced the variability of recovery. Because ca. 4% of the radiolabel is lost during sample loading, some bile acids do not adhere to the C18 packing material of the Sep-Pak even in only 20% methanol.

To our knowledge, this is the first report of a bile acid purification procedure using endogenously labeled material. The finding that a procedure previously thought to give 93% recovery of bile acids (10) in actuality gives a recovery of only 42% during purification indicates that the use of a single bile acid as a marker for all the bile acids is inappropriate. When developing a purification procedure using only a single bile acid as a marker of recovery, it is clear that one can only be confident of the recovery of that single bile acid. Bile acids of greater and lesser polarity may be lost by the procedure. As a result, optimization based on recovery of a single marker may greatly overestimate the recovery of bile acids as a group.

Bile acid distribution. From analysis of the quantity of radiolabel in each tissue sample we have calculated the distribution of bile acids in the intestinal tract and liver. The small intestine contained 73.0 ± 2.8% (mean ± SD) of the bile acids, the cecum 10.4 ± 3.5%, the colon contents 13.4 ± 3.2% and the liver 3.3 ± 0.5%. These results are in general agreement with the finding of Uchida et al. (11) who reported that, of the bile acids in the intestinal tract and liver, 87% were in the small intestinal contents and 10% in the large intestinal contents. Although we find slightly fewer bile acids in the small intestine and more in the large intestine than Uchida et al. (11), the combined amount in these two tissues of 96.7% (SD 0.5%) is virtually identical to that found by Uchida et al. (11). The quantity of bile acids within the plasma was extremely small, accounting for <0.1% of the radiolabel consumed by each rat. Thus, determination of the bile acid content of the intestinal tract would be a good estimate of bile acid pool size.

Fecal excretion over the 2 days was 12.1% (SD 2.4%) of the radiolabel fed. Combining the tissue label with that excreted in the feces, 86.2% (SD 2.6%) of the radiolabel can be accounted for. The remainder is presumably located in other soft tissues. Bile acids have been isolated from several soft tissues in the rat (12). As the ^{14}C-labels were located in the side chain, a position that is refractory to biological removal, it is unlikely that any label was lost due to degradative reactions of the gut microflora.

Comparative Study of Methods For Measuring Cholesterol in Biological Fluids

Franck Cheillan[a,b,*], Huguette Lafont[b], Elise Termine[b], Yolande Hamann[a] and Guy Lesgards[a]

[a]Laboratoire de Chimie des Produits Naturels, Faculté des Sciences de St-Jérôme, Avenue Escadrille Normandie-Niémen, 13997 Marseille Cedex 13, France; and [b]INSERM, Unite 130, 18 Avenue Mozart, 13009 Marseille, France

A method combining enzymatic and electrochemical detection of cholesterol in biological fluids was compared with conventional detection methods: two chromatographic methods—gas chromatography or high performance liquid chromatography—and two enzymatic methods with colorimetric detection either by kinetic measurement or at the end of the reaction. For serum, enzymatic determination is accurate with both colorimetric detection methods; but for bile, colorimetric detection is difficult to perform due to interference from bile pigments. Enzymatic cholesterol determination, combined with electrochemical detection, is simpler and gives results in good agreement with those of chromatographic methods.
Lipids 24, **224–228 (1989).**

Accurate determination of cholesterol levels in biological fluids is of great importance in routine medical testing. The enzymatic method has proven to be an effective technique for measuring cholesterol in serum and plasma (1–4), but few methods have been developed for other fluids such as bile (5,6). This study was undertaken partly in view of this fact.

Quantitative determination of cholesterol level in bile is necessary because of the relationship between this factor and gallstone formation. However, it is difficult for several reasons: Bile is a complex medium containing certain constituents such as bile salts that are structurally analogous to cholesterol. Moreover, bile pigments are dark green, thus causing very high colorimetric interference in the 300–600 nm wavelength zone.

The first techniques used for routine cholesterol determination were chemical methods followed by colorimetric reactions (7). However, because these reactions lack strict specificity, great care was required in applying them to complex media such as plasma or bile.

Use of enzymes in second generation methods has enabled more specific recognition of the substrate, but because the enzyme reaction is followed by colorimetric detection (8), interference is still high (9). The catalytic action of cholesterol oxidase is measured colorimetrically by a coupled system involving oxidation of either methanol in the presence of catalase or phenol and 4-aminoantipyrine in the presence of peroxidase. These reactions present certain disadvantages—lengthy reaction time and interfering substances during H_2O_2 production in the first step of the reaction or during the colorimetric reaction (10). Some authors (9) have also mentioned the potential reaction of bilirubin during procedures using H_2O_2.

Because our aim was to choose a cholesterol determination method applicable to a variety of fluids, the association of an enzyme reaction and electrochemical detection seemed to be a method of choice, to avoid colorimetric interference and take advantage of the specificity of the enzyme. Chromatographic methods—gas chromatography (GC) (11) and high performance liquid chromatography (HPLC) (12,13)—were used to separate cholesterol from the other lipids and allow cholesterol determination using calibration. Chromatographic results were compared with those obtained by enzymatic reaction and electrochemical detection with an O_2 selective electrode.

Electrochemical measurement was performed by voltammetry using an oxygen electrode, and cholesterol level was calculated from the rate of oxygen consumption (14). An O_2 selective electrode was calibrated and the decrease of oxygen level was monitored during the catalytic action of cholesterol oxidase on its substrate. Once the conditions of the use of this electrode in reactive media were determined, the accuracy of the results, obtained with enzymatic determination with electrochemical detection, was evaluated by comparing them with results obtained by four other methods, namely: enzymatic determination combined with two kinds of colorimetric detections, GC on capillary column and HPLC.

MATERIALS AND METHODS

Reagents. Pseudomonas cholesterol oxidase: EC 1.1.3.6, 18 IU/mg protein; pseudomonas cholesterol esterase: EC 3.1.1.13, 400 IU/mg protein; aqueous cholesterol calibrators 2.59 mM, 5.18 mM and 10.36 mM; standards for chromatography: ergosterol, cholestanol, cholesterol and cholesteryl esters were obtained from Sigma Chemical Co. (St. Louis, MO). Serum standard TQC chemistry calibrator 1 from Technicon (Geneva, Switzerland) and all other chemicals and solvents were of at least reagent grade.

Treatment of samples. Human gallbaldder biles were obtained from patients by preoperative puncture of the gallbladder. They were stored at 4°C and used within a few days. Human hepatic biles were obtained by cannulation of the common bile duct.

When enzymatic methods were used, the bile and serum samples were not submitted to any prior preparation. Chromatographic methods required extraction of lipids according to Folch's method (15), followed by a filtration on a Sep-Pak (16) to remove phospholipids from the neutral lipids containing cholesterol. HPLC allowed simultaneous measurement of cholesterol and its esters; on the other hand, with GC, only total cholesterol could be determined, and that, only after hydrolysis of esters using methanolic potassium hydroxide (17).

Enzymatic determination followed by colorimetric detection. The CHOD-PAP method (8) from Boehringer Mannheim (Meylan, France) was used for colorimetric detection. The colorimetric reaction was read at 500 nm with a spectrophotometer (Jobin Yvon 220, Longjuneau, France). This method cannot be applied to bile samples at the end of the reaction step because of the presence

*To whom correspondence should be addressed at INSERM, Unité 130, 18, Avenue Mozart, 13009 Marseille, France.

Abbreviations: GC, gas chromatography; HPLC, high performance liquid chromatography.

of color interference (18). For kinetic measurement, the method described by Deeg and Ziegenhorn (8) was used to obtain quantitative data.

Gas chromatography (11). A Girdel chromatograph (Suresnes, France) was used under the following conditions: carrier gas nitrogen inlet pressure, 0.6 bar; fused silica column, length 30 m, diameter 0.5 mm; stationary phase OV 17., oven temperature: 240°C; Ross evaporator injector temperature: 270°C; flame ionization detector; and internal standard, cholestanol.

The sample is mixed, volume for volume, with the internal standard at 1 g l^{-1}. The same total volume of silylation reagent (1 ml pyridine, 0.9 ml hexamethyl disilazane and 0.6 ml trimethyl chlorosilane) is added and the solution is incubated 10 min at 110°C. After drying and recovery by 1 ml of hexane, 1 or 2 μl are injected.

Liquid chromatography. A Waters chromatograph system (720 system controller, WISP 710A automatic injector and M 6000A pump, Waters, Milford, MA) was employed with a Hibar column (250 mm × 4 mm, Merck, Darmstadt, FRG), packed with a stationary phase (LiChrosorb RP-18 [7 μm]Merck, Darmstadt, FRG).

The chromatographic conditions were optimized in the laboratory. The mobile phase was acetonitrile/isopropanol (50:50, v/v) and the flow rate 1.5 ml/min. The detection wavelength was 214 nm. The internal standard was ergosterol for free cholesterol and cholesterol myristate for esterified cholesterol. Five μl of the internal standard solution at 2 g l^{-1} were added to 50 μl of the sample solution and made up to 200 μl with the mobile phase; 50 μl were injected. The results of chromatographic (HPLC) separation of cholesterol and cholesteryl esters in biological media are given in Figures 1 and 2.

Enzymatic determination, followed by electrochemical detection. A Beckman Cholesterol Analyzer II (Beckman Instruments, Fullerton, CA), modified to measure current intensity after enzymatic reaction, was used. It was equipped with a voltage generator and an amperemeter with a sensitivity of ca. one nanoampere. This instrument was connected to an oxygen electrode coated with a Teflon membrane. The oxygen electrode is a "polarographic" electrode in that it measures current limited by the diffusion of oxygen through the Teflon membrane towards a rhodium cathode (5 mm diam.). This cathode is maintained at a potential of −550 mV in relation to a metallic silver anode. The cathode and the anode were connected via an electrolyte gel containing potassium chloride. A uniform thickness of electrolyte gel was maintained between the membrane toward a rhodium cathode by a nylon mesh disc, inserted whenever the electrode was charged. A Teflon membrane (0.0254 mm diam.) was in contact with the test solution. The amount of oxygen that diffuses through the membrane is proportional to the oxygen concentration in the solution. Free cholesterol is oxidized by cholesterol oxidase to cholest-4-en-3-one with the simultaneous consumption of oxygen. The rate of oxygen consumption measured by the analyzer is directly proportional to the cholesterol concentration in the solution.

The electrode was immersed in a cell with a constant temperature of 37°C and containing 5 ml of phosphate buffer. This cell was placed on a magnetic shaker until the current intensity stabilized, at which time 0.6 Units of cholesterol oxidase in 10 μl distilled water were added, followed 1 min by 40 μl of the test solution. If the sample contained esterified cholesterol, 0.06 IU of

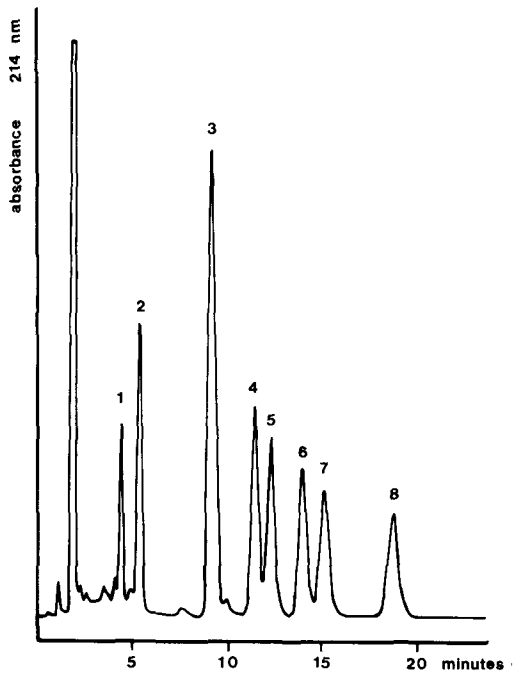

FIG. 1. HPLC separation of cholesterol and cholesteryl esters of serum samples. Chromatographic conditions: column RP 18 (7μ) LiChrosorb Merck; eluent solvent: acetonitrile-isopropanol (50:50); flow: 1.5 ml.min^{-1}. Peaks: 1, ergosterol; 2, cholesterol; 3, cholesterol arachidonate; 4, cholesterol linoleate; 5, cholesterol myristate; 6, cholesterol oleate; 7, cholesterol palmitate; and 8, cholesterol stearate.

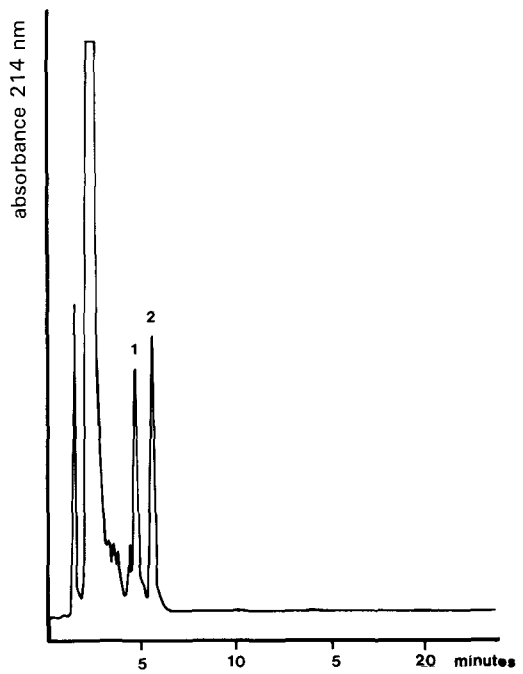

FIG. 2. HPLC separation of cholesterol and cholesteryl esters of bile samples. Chromatographic conditions: column RP 18 (7μ) LiChrosorb Merck; eluent solvent: acetonitrile-isopropanol (50:50); flow: 1.5 ml.min^{-1}. Peaks: 1, ergosterol; 2, cholesterol; 3, cholesterol arachidonate; 4, cholesterol linoleate; 5, cholesterol myristate; 6, cholesterol oleate; 7, cholesterol palmitate; and 8, cholesterol stearate.

cholesterol esterase in 10 µl distilled water were added with cholesterol oxidase. The reaction was complete within 5 min and the response of the instrument was then read. To obtain reproducible results, all solutions were added by a microsyringe.

DEVELOPMENT OF THE EXPERIMENTAL PROCEDURE

Composition of the buffer solution. Trials with phosphate buffer and Tris buffer showed that the response of the oxygen electrode was better with the latter. It was also observed that a surfactant was needed to properly stabilize cholesterol in both standard solutions and biological samples. The effect of Triton X 100 concentration on the response of the oxygen electrode (Fig. 3) was studied. On the basis of these preliminary trials, the following buffer mixture was finally selected: Tris buffer, 0.1 M; sodium cholate, 3 mM; and Triton X100, 0.05% in volume.

Effect of the pH. The buffer was tested at various pH in order to select the level of maximum cholesterol oxidase activity. The pH was adjusted with HCl solutions. Although variations were slight, 7.5 seemed to be the optimal level (Fig. 4).

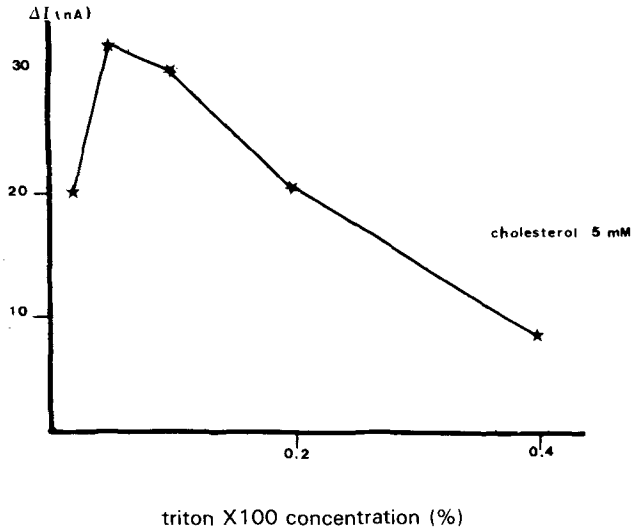

FIG. 3. Effect of Triton X100 concentration on the electrode response.

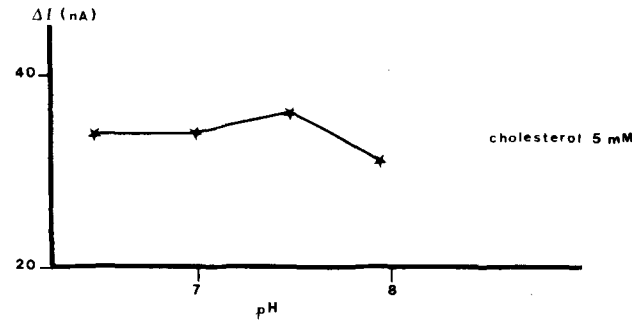

FIG. 4. Effect of the pH on the reaction rate of oxygen consumption.

Effect of temperature. Under identical experimental conditions, measurements were taken at 25°C, 37°C and 40°C. at 37°C (temperature selected), the electrode was appreciably more sensitive, because the measured response was ca. 50% higher. At 40°C, diffusion of O_2 was accelerated, but the enzyme was less stable.

Evaluation of the electrochemical detection—sensitivity. The smallest test sample giving a reliable reading is 100 µl of a solution containing 0.5 mmol l^{-1} cholesterol. This corresponds to the level of cholesterol in rat hepatic bile.

Linearity. Calibration was achieved with aqueous standard solutions of cholesterol (aqueous cholesterol calibrators, Sigma Chemical Co.). For 0.3 IU, the variation in current intensity measured at the end of the reaction was proportional to the quantity of cholesterol up to 8 mmol l^{-1}. For 0.6 IU, the interval increased to 12.5 mmol l^{-1} (Fig. 5).

Reproducibility. The day-to-day reproducibility of the standard curve was checked for a 10 mmol l^{-1} cholesterol standard solution. The variations observed over a 13-day period were identical to those observed in serial measurements on the same day.

The number of determinations performed was 13, the mean was 60 nA, the SD was ±2 nA, and CV was 3%. The lifetime of the electrode was estimated to be 3–4 wk.

Recalibration was necessary every time the electrode was charged and was valid only under the following conditions: Tris/cholate/Triton X100 buffer; pH 7.5; temperature 37°C; and 0.6 IU of cholesterol oxidase.

Solutions higher than 12.5 mmol l^{-1} of cholesterol must be diluted to be in the linear range of the calibration curve.

Because bile is a viscous medium, a microsyringe must be used to inject samples in order to minimize volume error and apply the calibration curve.

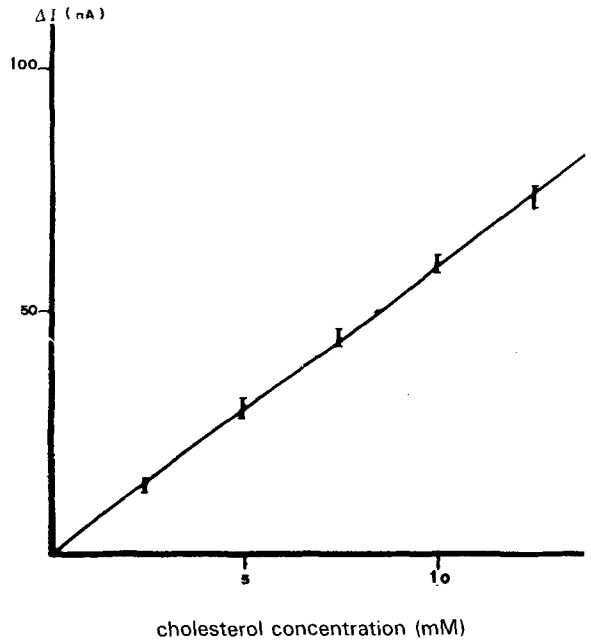

FIG. 5. Calibration curve expressed the variation of the response (ΔI) of the electrode following the consumption of oxygen in the medium due to the cholesterol oxidase activity.

Interfering substances (sodium taurocholate, sodium glycodeoxycholate, sodium cholate). To test their effects on electrode response, bile salts were added to the standard cholesterol solution. These substances had no effect on cholesterol oxidase activity, as shown by Noma et al. (19).

COMPARISON OF THE FOUR METHODS OF DETERMINATION

Using the same serum standard, the results of the electrochemical enzymatic method were compared with those obtained with four other procedures (Table 1). Serum rather than bile was used, because bile standard is not commercially available. Each value is the mean of three measurements. In all cases and especially for the enzymatic methods, the results obtained were very similar and close to the manufacturer's values (4.85 mmol l^{-1} for total cholesterol and 1.20 mmol l^{-1} for free cholesterol). The electrochemical detection method was also tested with different bile samples and the results compared with those obtained with other methods.

One gallbladder bile sample was chosen to compare values obtained by the enzymatic method with electrochemical detection, those obtained by the enzymatic method with kinetic studies and to test HPLC and GC. Because bile pigments perturb the final colored reaction, colorimetric enzymatic methods were inappropriate for measuring cholesterol in gallbladder bile. The dispersion data recorded with four different techniques applied to two biological fluids are presented in Table 2. The variations in results were smaller for enzymatic procedures than for chromatographic techniques. The chromatograms in Figures 1 and 2 are given as examples of HPLC separation.

DISCUSSION AND CONCLUSION

Enzymatic determination in association with electrochemical detection is a reliable and reproducible technique for measuring cholesterol in various biological fluids (serum and bile). Once the calibration curve has been established, measurement is rapid (5 min, as the mean) with no pretreatment of samples.

TABLE 1

Comparison of the Results Obtained With Serum and Bile From Five Techniques

	Enzymatic methods			Chromatographic methods	
Samples	Electrochemical detection	Colorimetric final point	Kinetic detection	GC	HPLC
Serum					
Free cholesterol	1.17	1.24	1.20	1.04	1.09
Total cholesterol	4.79	4.97	4.85	—	5.45
Bile					
1	7.00	—	4.00	7.50	6.50
2	18.20	—	6.10	19.40	17.40
3	6.20	—	6.10	5.70	6.50
4	6.70	—	6.00	5.70	6.50
5	2.85	—	2.10	2.90	2.10

For each sample, three measurements are performed. The mean is expressed in mmol l^{-1}. No value is reported for bile cholesterol in the case of colorimetric final point, because the interference of bile pigments leads to erratic value.

TABLE 2

Reproducibility of Measurements of Free Cholesterol Determination in One Human Bile Sample With the Four Methods

Methods	Number of determinations	Mean mmol l^{-1}	SD mmol l^{-1}	CV%	SEM
Enzymatic electrochemical detection	10	6.20	0.25	4	0.08
Enzymatic kinetic colorimetric detection	14	6.09	0.15	2.5	0.03
GC	10	5.70	0.50	9	0.15
HPLC	10	6.48	0.50	8	0.15

One gallbladder bile was chosen and 10 determinations were performed with the same sample in the case of enzymatic electrochemical detection, GC and HPLC, respectively, and 14 determinations in the case of enzymatic procedure associated with a kinetic colorimetric detection.

The initial difficulties encountered with the electrode were easily overcome. Oxygen diluted in a buffer containing surfactant diffused well in all the fluids studied. Several tests were required to optimize the composition of the buffer solution in which the enzymatic reaction must be carried out. For proper calibration, it is essential that the standard cholesterol be totally solubilized under the same conditions as the sample. Provided this precaution is taken, the method is effective, quick and reliable for routine determination of cholesterol in biological fluids. Comparison of results obtained with those from other techniques showed it to be a particularly high-performance technique that eliminates interferences associated with colorimetric detection.

Besides convenience and rapidity, this method for determining cholesterol is very sensitive. The results obtained by electrochemical detection are readily reproducible and, given its excellent sensitivity, this method can be used for less concentrated samples, e.g., hepatic bile. Either the kinetic rate or the steady state method can be used to assay the free cholesterol. The selectivity of the electrode can be enhanced by a Teflon membrane. The use of electrochemical detection instead of colorimetric determination after enzyme treatment of cholesterol lowers the level of interferences especially with bile samples. Furthermore, under our conditions, bilirubin reaction with H_2O_2 cannot be a source of interferences in electrochemical determination of the cholesterol oxidase activity, because the reaction is estimated from the oxygen consumption rather than from H_2O_2 formation.

These findings contrast with the very marked interferences due to bile pigments observed when colorimetric determination in association with enzymatic reactions is applied to bile. The use of colorimetry after enzymatic reaction is very difficult and only the method described by Deeg and Ziegenhorn (8) has been used effectively, although it requires great caution.

As stated by Noma and Nakayama (10), ascorbic acid does not affect oxygen consumption and may be electrochemically neutral at the potential used. These authors reported comparable results with respect to the range of linearity and the sensitivity threshold for the cholesterol determination in bile and serum. GC and HPLC confirmed, as well, the quantitative results obtained by enzymatic method associated with electrochemical detection in the absence of interferences or inhibition observed in this method.

The lesser accuracy of chromatographic methods, when compared with the other methods (9), may stem from differences in the way that samples are prepared. Pretreatment of samples, especially saponification of esterified cholesterol, and losses during sample injection in the case of GC may be largely responsible for these discrepancies between GC and HPLC. HPLC is the method of choice to separate and identify cholesteryl esters; however, the quantification of these esters is difficult in the case of a sample containing triglycerides that interfere in the quantitative determination. Regardless of the detection procedure, the cholesterol levels measured after enzymatic reaction are similar in both bile and serum. Inaccuracy with these techniques is minimal. In conclusion, it can be said that, given its precision and convenience, electrochemical detection should be considered a valid alternative for determination of cholesterol.

2-Hydroxy Fatty Acids From Marine Sponges 2. The Phospholipid Fatty Acids of the Caribbean Sponges *Verongula gigantea* and *Aplysina archeri*

Néstor M. Carballeira*, Fathi Shalabi and **Vilmary Negrón**
Department of Chemistry, University of Puerto Rico, Rio Piedras, Puerto Rico 00931

The α-hydroxy fatty acids 2-hydroxy-eicosanoic (1) acid, 2-hydroxyheneicosanoic (2) acid, 2-hydroxydocosanoic (3) acid, 2-hydroxytetracosanoic (4) acid, 2-hydroxy-23-methyl-tetracosanoic acid and 2-hydroxypentacosanoic (5) acid were isolated from the Caribbean sponges *Verongula gigantea* and *Aplysina archeri*. The very long chain fatty acids 5,9-nonacosadienoic acid (29:2) and 5,9,23-tricontatrienoic acid (30:3) were also identified together with the *iso*-prenoid fatty acid 3,7,11,15-tetramethylhexadecanoic (phytanic) acid that seems to be common in the Aplysinidae. *A. archeri* contained an extremely long chain fatty acid tentatively characterized as dotricontaenoic (32:1) acid. These acids were found to occur in phosphatidylserine, phosphatidylinositol, phosphatidylethanolamine, phosphatidylcholine and traces of phosphatidylglycerol. *Lipids 24,* 229–232 (1989).

Phospholipid fatty acids from marine sponges have been the subject of numerous research efforts in the search for unique structures with unusual membrane functions (1). One interesting group of fatty acids, namely the 2-hydroxy acids, have not been recognized to exist in the phospholipids of marine sponges until just recently when we reported, for the first time, the isolation of the interesting 2-hydroxydocosanoic and 2-hydroxytricosanoic acids from the Caribbean sponge *Amphimedon compressa* (2). To our surprise, the latter α-hydroxy acids were found in an unusual abundance of more than 50% of the total phospholipid fatty acid composition of *A. compressa*. These α-hydroxy acids have been found to occur mainly in brain sphingolipids and in a few other sources such as influenza virus (3), but our recent report is the first time that these interesting acids have been found to occur in the phospholipids of a marine sponge. Cerebrosides have been quite generally present in marine invertebrates and have also been known to be a rich source of α-hydroxy fatty acids. Karlsson and Björkman (4) have isolated a cerebroside fraction from the sea star *Asterias rubens* and characterized it by degradation. The cerebroside was found to contain glucose, saturated α-hydroxy fatty acids (C16–C26) and uncommon long-chain basis. Schmitz and McDonald (5) reported the isolation of a cerebroside mixture from the marine sponge *Chondrilla nucula*. They reported that these cerebrosides contained a mixture of homologous C16 to C26 saturated straight-chain αhydroxy acids plus traces of saturated C25 *iso* α-hydroxy acid. In light of the above findings, we have undertaken a search for α-hydroxy acids in other marine sponges, to better understand their role in these invertebrates. In this paper we wish to report the isolation of yet another series of α-hydroxy fatty acids from the Caribbean sponges *Verongula gigantea* and *Aplysina archeri*, both belonging to the family Verongidae. Sponges from the family Verongidae have been particularly interesting because they have been shown to possess, as a characteristic feature, the rare sterols aplysterol and 24,28-didehydroaplysterol (6). *V. gigantea* has also been the subject of previous scrutiny by several researchers because, as other members of the Aplysinidae (= Verongidae), it has been found to be a rich source of brominated metabolites, in particular racemic and levorotatory Aeroplysinin-1 (7).

EXPERIMENTAL PROCEDURES

Verongula gigantea and *Aplysina archeri* were collected June 8, 1987, at 75 feet near the Shelf Edge of La Parguera, Puerto Rico. The sponges were washed in sea water, carefully cleaned of all nonsponge debris and cut into small pieces. Immediate extraction with chloroform/methanol (1:1, v/v) yielded the total lipids. The neutral lipids, glycolipids and phospholipids were separated by column chromatography on ammonium hydroxide-treated silicic acid (100–200 mesh) using the procedure of Privett et al. (8). The phospholipid classes were investigated by preparative thin layer chromatography (TLC) using silica gel and chloroform/methanol/water (65:25:4, v/v/v) as solvent. The phospholipid mixture was also studied by means of ^{31}P NMR. In a typical run, phospholipids (20–30 mg) were dissolved in 3 ml of deuterated chloroform/methanol 2:1 (v/v) containing as internal reference triphenyl phosphine. The run was performed at 22°C on a GN 300 FT-NMR spectrometer at 121.6 MHz. Approximately 1000 accumulations were obtained before Fourier transformation of the free induction decay. The fatty acyl components of the phospholipids were obtained as their methyl esters by reaction of the phospholipids with methanolic hydrogen chloride (6) followed by purification on column chromatography eluting with hexane/ether (1:1, v/v). The resulting methyl esters were analyzed by gas chromatography–mass spectrometry (GC–MS) using a Hewlett-Packard 5995 A gas chromatograph–mass spectrometer equipped with a 30 m × 0.32 mm fused silica column coated with SE-54. For the location of double bonds, N-acylpyrrolidide derivatives were prepared by direct treatment of the methyl esters with pyrrolidine/acetic acid (10:1, v/v) in a capped vial (1 hr at 100°C), followed by ethereal extraction from

Dotricontaenoic (32:1)	—	1.5

Most branched acids (denoted by br) are *iso-anteiso* pairs.

RESULTS

Our results are presented in Table 1, where the phospholipid fatty acid compositions of *Verongula gigantea* and *Aplysina archeri* are presented. The phospholipid fatty acid composition of these sponges basically presented a series of saturated fatty acids (70% of the total fatty acid composition of *V. gigantea* and 75% of *A. archeri*) with big amounts of *anteiso* and *iso* acids. Interesting to point out in the mixtures is the presence of the acid 3,7,11,15-tetramethylhexadecanoic (phytanic) in ca. 5.6% abundance in *V. gigantea* and 5% abundance in *A. archeri*. The mass spectrum of phytanic acid methyl ester was very characteristic because it presented a base peak at *m/z* 101 (100%) and peaks at *m/z* 171 (15%) and *m/z* 241 (2%), immediately revealing branching and confirming its identity (10). A series of very long chain α-hydroxy fatty acids were also characterized in these sponges. In *V. gigantea* the α-hydroxy fatty acids identified were 2-hydroxy-eicosanoic (1), 2-hydroxyheneicosanoic (2), 2-hydroxy-docosanoic (3) and 2-hydroxytetracosanoic (4), which together accounted for 18% of the total fatty acids of this sponge. On the other hand, *A. archeri* contained the acids 2-hydroxy-eicosanoic (1), 2-hydroxytetracosanoic (4), 2-hydroxy-23-methyltetracosanoic and 2-hydroxypentacosanoic (5), which accounted for 3.5% of the total fatty acids from *A. archeri*. The characterization of these fatty acids (see below) was achieved by means of capillary GC–MS. Instrumental in their characterization was the presence of, in the mass spectrum of these acids, a prominent M^+-$COOCH_3$ ion strongly suggesting α-substitution, which was further confirmed by other diagnostic peaks. Lack of peaks at *m/z* 74 and 104, but presence of fragmentation ions at *m/z* 90 and *m/z* 103, arising from the characteristic McLafferty rearrangement (11), suggested immediately the presence of α-hydroxy substitution instead of, for example, α-methoxy. In fact, after literature comparison (11), it became obvious that we were dealing with a complete family of 2-hydroxy acids. In Figure 1 we present the gas liquid chromatographic (GLC) region of the α-hydroxy fatty acids methyl esters from *Verongula gigantea*. From the chromatogram it can be readily seen that the α-hydroxy fatty acids had a longer retention time than their analogous nonhydroxylated acids. Figure 2 shows a plot of retention time of α-hydroxy acids methyl esters from *Verongula gigantea* as a function of acid carbon-chain length. The linearity of the acids in question is clear from the plot.

Capillary GC and GC–MS analysis of the mixtures also revealed the presence of two very long chain phospholipid fatty acids displaying base peaks at *m/z* 81, a value diagnostic of acids possessing the Δ5,9-unsaturation pattern typical of "demospongic acids" (12). On the basis of capillary GC retention times and equivalent chain length

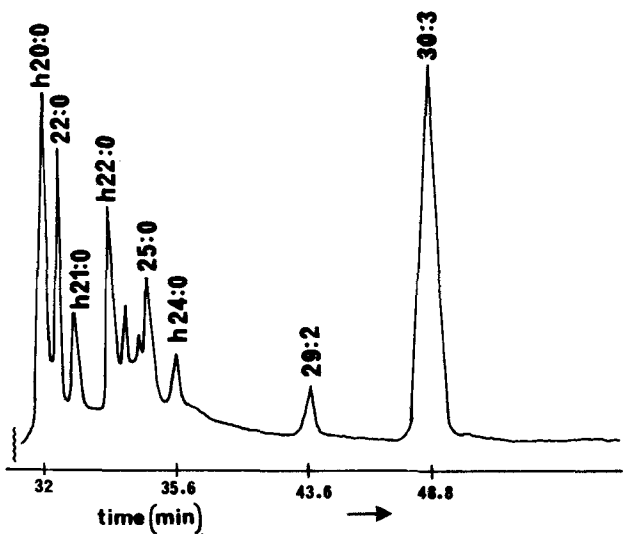

FIG. 1. GLC of the region of the α-hydroxy fatty acids methyl esters from *Verongula gigantea*. Note the longer retention time of the α-hydroxy fatty acids as compared with the analogous nonhydroxylated acids.

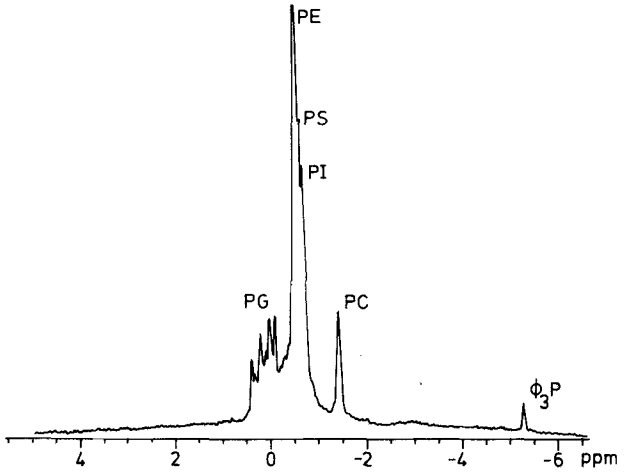

FIG. 3. The complete ^{31}P NMR spectrum of the phospholipids from *Verongula gigantea*. The abbreviations are PE, phosphatidylethanolamine; PS, phosphatidylserine; PI, phosphatidylinositol; PG, phosphatidylglycerol; PC, phosphatidylcholine; ϕ_3P, triphenylphosphine. Some minor peaks were not identified.

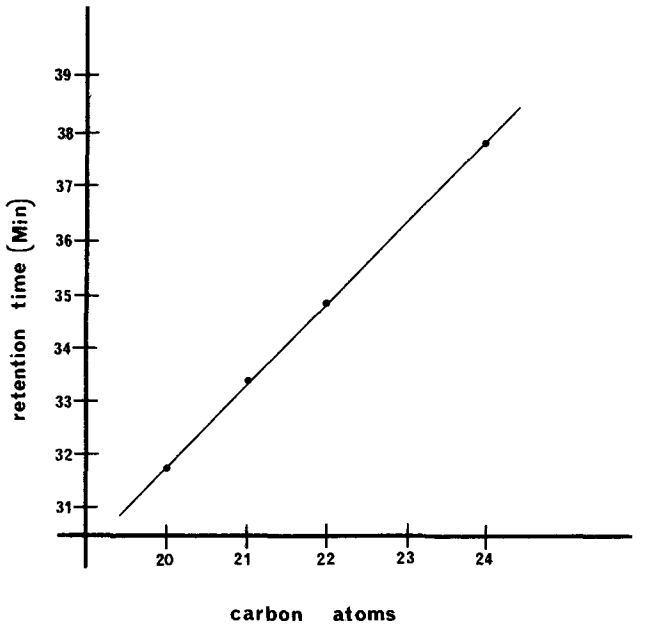

FIG. 2. Plot of retention time of α-hydroxy fatty acid methyl esters from *Verongula gigantea* as a function of acid carbon-chain length.

(ECL) values, together with mass spectral comparisons, these acids were characterized as 5,9-nonacosadienoic ($\Delta^{5,9}$-29:2) with ECL of 28.44 and 5,9,23-tricontatrienoic ($\Delta^{5,9,23}$-30:3) with ECL of 29.43, which were present in *V. gigantea* in 1.4 and 10.8% abundance, respectively, whereas *A. archeri* contained the same acids in 6.2 and 7.5% abundance, respectively (Table 1). These fatty acids have been previously reported to occur in marine sponges (12). *A. archeri* also contained another very long chain unsaturated fatty acid methyl ester that presented a molecular ion peak at m/z = 492, a base peak at m/z = 74 and fragmentation peaks at m/z = 69 and m/z = 55. On the basis of the mass spectrum and ECL values, the isolated compound could only correspond to a dotricontaenoic (32:1) fatty acid methyl ester. However, the small amounts of this acid prevented us from unequivocally locating the double bond position. It is very likely for the double bond of this acid to be located far from the carbonyl group because the base peak at m/z = 74 is still prevailing (Normally, monounsaturated acids with double bonds near the carbonyl group have base peaks at m/z = 55.) and likely possibilities are the familiar ω3 and ω6 types of unsaturation.

The main phospholipids of *Verongula gigantea* and *A. archeri* were separated and analyzed by preparative TLC and these were mainly characterized as phosphatidylserine (PS), phosphatidylinositol (PI), phosphatidylethanolamine (PE) and lesser amounts of phosphatidylglycerol (PG) and phosphatidylcholine (PC). Sphingomyelin was not observed in the mixture. The ^{31}P NMR spectrum of the total phospholipids from *V. gigantea* is presented in Figure 3.

DISCUSSION

The α-hydroxy fatty acids isolated in this work are 2-hydroxy-eicosanoic (1), 2-hydroxyheneicosanoic (2), 2-hydroxydocosanoic (3), 2-hydroxytetracosanoic (4), 2-hydroxy-23-methyl-tetracosanoic and 2-hydroxypentacosanoic (5). Also, taking into account the 2-hydroxytricosanoic acid, which we previously isolated from *Amphimedon compressa*, we can say that, overall, α-hydroxy fatty acids to be found in the phospholipids of marine sponges range in length between C20:0 and C25:0. As the prior case of the marine sponge *A. compressa*, it seems that 2-hydroxy fatty acids tend to exist in the phospholipids of these sponges together with their analogous saturated long-chain acids. However, it is more

interesting to notice that very long chain polyunsaturated fatty acids such as 5,9,23-tricontatrienoic (30:3) and 5,9-nonacosadienoic (29:2) have been found also to be present in these phospholipids when we have isolated the α-hydroxy acids. The latter is a very interesting observation because polyunsaturated fatty acids are conspicuously absent from sphingolipids, but in these marine phospholipids they seem to be a major constituent. It then seems reasonable to assume that these α-hydroxy fatty acids and the 30:3 and 29:2 acids play a significant membrane function in these sponges. The α-hydroxy fatty acids isolated in this work have been previously found to occur in brain cerebrosides, sphingomyelins and lecithins arising from the cerebral cortex, cerebral white matter, diencephalon and midbrain in amounts ranging between 10 and 15% (13). Some of the α-hydroxy acids isolated in this work also have been detected in monohexosylceramides, lactosylceramides and oligohexosylceramides from A_2-Asia and A_2-England Influenza Virus (3). However, the publication more related to our work is the report, by Schmitz and McDonald (5), of the isolation of α-hydroxy acids from cerebrosides isolated from the sponge *Chondrilla nucula.* These investigators reported the presence of α-hydroxy acids ranging in length from C16 to C26. The most interesting α-hydroxy acid in their mixture was the saturated C25 *iso* α-hydroxy acid, because it seems to be present only in marine sponges. In fact, we do not know of any other report for this acid, apart from the publication by Schmitz and McDonald and this report. The interesting observation of our present work is that we have encountered the α-hydroxy acids in the phospholipids rather than in cerebrosides. We discard the presence of cerebrosides in our phospholipid mixtures due to our rigorous isolation procedure. Cerebrosides normally elute in the acetone fraction on column chromatography with silica gel, in contrast to phospholipids that elute with the more polar methanol fraction. Naturally occurring α-hydroxy fatty acids are known to possess the R configuration, and we believe that the acids isolated in this work also possess the R configuration at carbon 2.

It will be interesting to find out the mode of biosynthesis of the α-hydroxy fatty acids in *Verongula gigantea* and *A. archeri.* One good possibility is α-oxidation of their corresponding very long chain saturated fatty acids such as docosanoic (22:0) and tetracosanoic (24:0), because these are found in relatively good amounts in *V. gigantea.* This possibility has been demonstrated in the case of brain sphingolipids, by Mead and Levis (14), who established that α-oxidation is the preferred pathway for the biosynthesis of the 2-hydroxytetracosanoic acid (4), better known as cerebronic acid. Still another interesting question is if the hydroxyl moiety is introduced before the fatty acid is coupled to the phospholipid backbone or if it is introduced once the fatty acid is linked to the glycerol backbone. Work in progress may elucidate the role of α-hydroxy acids in sponges.

ACKNOWLEDGMENT

Vance Vicente from La Parguera, Puerto Rico, did the collection and classification of the sponge. O. Rosario and Isaura Diaz assisted in the mass spectrometry. This material is based on work supported by the National Science Foundation under Grant No. CHE-8715649 and NIH (S06 RR08102-17). The NMR facilities were obtained thanks to an NIH-RCMI Grant (G12 RR 03641). We also thank the University of Puerto Rico (Grant No. 86-100-12-88.0) for support of this work. V. Negrón thanks the MARC program for an undergraduate fellowship.

Effect of Dietary Fat on Individual Long-Chain Fatty Acyl-CoA Esters in Rat Liver and Skeletal Muscle

Denise M. Ney*, John B. Lasekan, Terry Spennetta, Mike Grahn and **Earl Shrago**
Departments of Nutritional Sciences and Medicine, University of Wisconsin, Madison, WI 53706

The effect of dietary fat on the long-chain acyl-CoA ester profile of liver and skeletal muscle was investigated by feeding weanling rats 12%-fat diets composed of high-linoleic safflower oil (73% 18:2n-6), high-oleic safflower oil (70% 18:1n-9) or olive oil (70% 18:1n-9) for six and ten weeks. Approximately 50% of both hepatic and skeletal muscle acyl-CoA esters comprised linoleoyl-CoA or oleoyl-CoA with high-linoleic or oleic feeding, respectively. Total hepatic acyl-CoA ester concentration was 40% higher ($p < 0.05$) in rats fed 12% fat compared with controls fed a 4%-fat diet. These data demonstrate that the long-chain acyl-CoA ester profile of liver and skeletal muscle reflects the dietary fatty acid profile.
Lipids 24, 233–235 (1989).

Long-chain acyl-CoA esters are key substrates for lipid biosynthesis and oxidation and are effectors for many other important enzymatic reactions. Current information demonstrates that they have site-specific interactions with enzyme systems (1), suggesting that long-chain acyl-CoA esters play a role in the regulation of cell metabolism (2). The fatty acid composition of mammalian membranes can be altered by changing the proportion of the different classes of fatty acids in the diet (3), which may subsequently affect the activity of specific lipid enzyme systems and cellular function (4). The effects of dietary fat on the composition of individual long-chain acyl-CoA esters have not been reported. This communication describes the effects associated with ingestion of diets composed predominantly of linoleic acid or oleic acid on the composition of individual long-chain acyl-CoA esters in rat liver and skeletal muscle.

MATERIALS AND METHODS

Male weanling, Sprague-Dawley rats weighing 45–50 g (Sasko King, Inc., Omaha, NE) were fed ad libitum one of three 12%-fat diets composed predominantly of linoleic or oleic acids, or a stock laboratory diet (Wayne Rodent Blox, Chicago, IL) composed of 4% fat. The 12%-fat diets contained (percentage by weight): sucrose, 50.0; casein, 20.0; oil, 12.0; cornstarch, 8.0; cellulose, 5.0; AIN 76 mineral mix, 3.5; AIN 76A vitamin mix, 1.0; DL-methionine, 0.3; choline dihydrogen citrate, 0.2; and butylated hydroxy toluene, 0.02 (5,6). Fat was provided exclusively from high-linoleic safflower oil (U.S. Biochemical Corp., Cleveland, OH), high-oleic safflower oil (California Fats and Oils, Richmond, CA) or 100% pure cold-pressed olive oil (U.S. Biochemical Corp.). The fatty acid composition of the 12%-fat diets was determined by gas chromatography after total lipid extraction (7) and transmethylation of the fatty acids with methanolic HCl (8). The resultant fatty acid methyl esters were separated on a Hewlett-Packard 5830A gas chromatograph equipped with a packed glass column and a flame ionization detector (9), identified by comparison of retention times with standards and expressed as percentage distribution of fatty acid methyl esters. The fatty acid distribution of the diets is given in Table 1.

After feeding for 6 and 10 weeks, 6–9 animals from the 12%-fat dietary groups and 3 animals from the stock-fed 4%-fat control group were fasted overnight and anesthetized with CO_2 before collection of tissues. Samples of liver and hind limb skeletal muscle were removed immediately, frozen in liquid nitrogen and kept at −70°C until analyzed by reverse-phase high performance liquid chromatography (HPLC) for individual long-chain fatty acyl-CoA esters (10,11).

Results were analyzed by two-way analysis of variance (ANOVA) in a 4-diets × 2-lengths-of-feeding design, using the General Linear Model (GLM) technique (12). Means were compared with the least significant difference technique (13) at 5% level of probability and reported with pooled standard error.

RESULTS AND DISCUSSION

Ingestion of diets composed predominantly of linoleic or oleic triacylglycerols resulted in clear differences in the long-chain acyl-CoA ester composition of both liver and skeletal muscle (Tables 2 and 3). The fatty acyl-CoA ester profile reflected the fatty acid profile of the diets such that ca. 50% of total liver or muscle acyl-CoA esters were composed of linoleoyl-CoA in rats fed the high-linoleic safflower oil diet (73% 18:2n-6), or oleoyl-CoA in rats fed the high-oleic safflower or olive oil diets (70% 18:1n-9). This effect is consistent with changes in the fatty acid composition of membranes, serum, adipose tissue or tumors in response to variation in dietary fatty acid intake (3,14,15). In addition, a higher concentration of palmitoleoyl-CoA was noted in both liver and skeletal muscle from animals fed oleic versus linoleic oils, although the palmitic acid content of the diets was not appreciably different (Table 1). Despite wide differences in linoleic acid

TABLE 1

Fatty Acid Distribution of Diets[a]

Fatty acid	High-linoleic safflower oil	High-oleic safflower oil	Olive oil	Control-stock
14:0	0.2	0.2	0.1	1.5
16:0	7.1	5.7	11.8	15.1
16:1	—	—	1.6	2.3
18:0	1.9	2.2	2.4	3.8
18:1n-9	16.3	70.0	70.3	20.8
18:2n-6	72.8	19.3	10.8	44.9

[a]Expressed as % distribution of fatty acid methyl esters. Only the major fatty acids are reported, therefore, the total does not equal 100.

intake, the concentrations of arachidonyl-CoA in liver and skeletal muscle were similar among linoleic and oleic groups, as previously noted in serum and tumors from rats (14). This response may reflect the inhibitory action of excess dietary linoleic acid on the Δ^6-desaturase reaction (16) and subsequent conversion of linoleic acid to arachidonic acid and differences in the selective incorporation of arachidonic acid into membrane phospholipids. Hepatic palmityl-CoA concentrations were similar; but, after 10 weeks of feeding, skeletal muscle palmityl-CoA was higher in rats fed high-linoleic safflower oil compared with both oleic-rich diets. The stearyl-CoA concentration of liver and skeletal muscle was not affected by diet.

The total concentration of long-chain acyl-CoA esters in liver (per g wet wt) was ca. 6-fold higher than in skeletal muscle. In addition, the total concentration of acyl-CoA esters in liver and skeletal muscle differed in response to diet and length of feeding. Hepatic acyl-CoA content was not affected by the length of feeding; however, feeding for 10 weeks resulted in a 50% higher concentration of total acyl-CoA esters in skeletal muscle compared with feeding for 6 weeks. This observation may reflect an increase in the adipose content of skeletal muscle due to aging, whereas hepatic triglyceride content was similar in animals fed for 6 and 10 weeks (17).

Total concentration of liver acyl-CoA esters was 40% higher in animals fed the 12%-fat diets compared with controls fed a stock diet containing 4% fat, although skeletal muscle total acyl-CoA ester levels were not different from controls. This suggests that hepatic tissue

is more responsive to the quantity of dietary fat than skeletal muscle. In addition, total hepatic acyl-CoA ester content is 2- to 3-fold higher with fasting compared with the fed state, reflecting an increase in beta oxidation with fasting (10). Thus, the conditions of fasting and high-fat feeding, as used in this study, both resulted in an increase in hepatic acyl-CoA ester content.

Distinctive changes in the pattern of individual hepatic acyl-CoA esters were noted due to length of feeding in both control and 12%-fat groups, $p < 0.001$ (Table 2). These changes were not observed in skeletal muscle and were independent of the effect of diet. Hepatic concentrations of 12:0, 14:0, 16:0 and 18:0 acyl-CoA esters increased with time, whereas the concentration of 18:1 acyl-CoA was not affected by the length of feeding. The concentration of 18:2 acyl-CoA decreased by ca. 40% from 6 to 10 weeks with a concomitant increase in 20:4 acyl-CoA ester content. A similar decrease in the linoleic acid content of hepatic microsomal and mitochondrial membranes has been noted in aging rats (18). Changes in the proportion of hepatic 18:2 and 20:4 acyl-CoA esters may reflect a greater conversion of linoleic to arachidonic acid (16) with maturation.

These data demonstrate the sensitivity of both hepatic and skeletal muscle long-chain acyl-CoA ester composition to dietary fatty acid intake, and the potential utility of measuring tissue concentrations of individual and total long-chain acyl-CoA esters during different metabolic conditions.

Vitamin E. Deficiency Increases the Synthesis of Platelet-Activating Factor (PAF) in Rat Polymorphonuclear Leucocytes

Kenji Fukuzawa*, Yasuhiro Kurotori, Akira Tokumura and **Hiroaki Tsukatani**
Faculty of Pharmaceutical Sciences, Tokushima University, 1-78 Shomachi, Tokushima 770, Japan

Vitamin E deficiency was found to stimulate FMLP (N-formyl-L-methionyl-L-leucyl-L-phenylalanine)-induced biosynthesis of PAF (1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) in polymorphonuclear leucocytes (PMN) from rat peritoneum. In three separate experiments each, the amounts of PAF synthesized during 6 min and 12 min incubation of PMN cells from control, vitamin E-supplemented, and vitamin E-deficient rats were 129–240, 131–227 and 248–354 pmol/10^6 cells, respectively. The activity of the acetyl-transferase, which transfers the acetyl moiety of [^{3}H]acetyl-CoA to 2-lysoPAF (1-*O*-alkyl-*sn*-glycero-3-phosphocholine) to form [^{3}H]PAF, was higher in PMN homogenates from vitamin E-deficient rats (2.28 ± 0.07 nmol/min/mg protein) than in those from E-supplemented rats (1.06 ± 0.10 nmol/min/mg protein). However, there was no difference between the two groups in the activity of acetylhydrolase (4.26 ± 0.71 and 4.26 ± 0.06 nmol/min/mg protein, respectively), measured as degradation of [^{3}H]PAF to [^{3}H]lysoPAF. *In vitro* addition of α-tocopherol did not inhibit the increased activity of acetyl-transferase in vitamin E-deficient rats, indicating that the enzyme in vitamin E-supplemented rats was not directly inhibited by α-tocopherol. The acetyl-transferases of the two groups showed similar Km values for acetyl-CoA, but different Vmax values (225 μM and 6.4 nmol/min/mg protein in vitamin E-deficient rats, and 216 μM and 3.6 nmol/min/mg protein in vitamin E-supplemented rats), suggesting that the enzyme was not activated but increased in amount in vitamin E deficiency. *Lipids 24,* 236–239 (1989).

Platelet aggregability is reported to be elevated in vitamin E-deficient animals (1,2). Vitamin E, which functions as a physiological membrane lipid antioxidant, has been shown to inhibit platelet aggregation and platelet serotonin release (3), and to reduce endogenous thromboxane and malondialdehyde formation in stimulated platelets (4,5). The mechanism of this effect of vitamin E, however, is not known.

Platelet-activating factor (PAF) is a potent phospholipid mediator that causes stimulation of leukocytes, vascular hypotension and broncho-constriction besides aggregation of platelets (6). However, no evidence has been reported of a biological relation between vitamin E and PAF.

In the present paper we report the influence of dietary and in vitro addition of vitamin E on the biosynthesis and catabolism of PAF in rat polymorphonuclear leukocytes (PMN).

Abbreviations: FMLP, N-formyl-L-methionyl-L-leucyl-L-phenylalanine; lysoPAF, 1-*O*-alkyl-*sn*-glycero-3-phosphocholine; PAF, platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; PMN, polymorphonuclear leucocytes; PMSF, phenylmethylsulfonyl-fluoride.

MATERIALS AND METHODS

Chemicals. [^{3}H]PAF (1-*O*-[^{3}H]octadecyl-2-acetyl-*sn*-glycero-3-phosphocholine, 80 Ci/mmol) was purchased from Amersham Corp. Unlabeled PAF and lysoPAF (1-*O*-octadecyl-*sn*-glycero-3-phosphocholine) were obtained from Feinchemikalien. [^{3}H]Acetyl-CoA (1.6 Ci/mmol) was from New England Nuclear. Unlabeled acetyl-CoA, FMLP (N-formyl-L-methionyl-L-leucyl-L-phenylalanine) and cytochalasin B were from Sigma Chemical Co. PMSF (phenylmethylsulfonyl fluoride) was from Nakarai Chemicals. Percoll was from Pharmacia Co. Silica gel-60 plates were purchased from Merck. α-Tocopherol was supplied by Eisai Co. Ltd.

Animals. Male Wistar strain rats, initially weighing 30–50 g, were divided into a control group, vitamin E-deficient group and vitamin E-supplemented group, and given rat chow described below containing all-*rac*-α-tocopheryl acetate at 2 IU, less than 0.1 IU and 50 IU per 100 g of diet, respectively, for 16–20 weeks. The chow consisted of 36% corn starch, 25% vitamin-free casein, 10% α-starch of wheat, 8% powdered filter paper, 6% salt mixture, 5% granulated sugar, 2% vitamin mixture and 10% stripped corn oil (Eastman Kodak Chemicals). The salt mixture provided Na, 270 mg; K, 692 mg; P, 579 mg; Ca, 411 mg; Mg, 86 mg; Fe, 41 mg; Zn, 0.4 mg; Mn, 1.3 mg, and I, 7.7 mg per 100 g of diet. The vitamin mixture provided vitamin A, 1000 IU; D_2, 200 IU; E, less than 0.1 IU; B_1, 2.4 mg; B_2, 8 mg; B_6, 1.6 mg; B_{12}, 0.001 mg; C, 60 mg; K, 10.4 mg; biotin, 0.04 mg; folic acid, 0.4 mg; Ca-panthenate, 10 mg; para-aminobenzoic acid, 10 mg; niacin, 12 mg; inositol, 12 mg, and choline-Cl, 4000 mg per 100 g of diet. Rats weighing about 230–280 g were used for experiments.

Determination of α-tocopherol content. α-Tocopherol was determined by the method of Abe and Katsui (7) as follows. α-Tocopherol was extracted with 7 ml of water/ethanol/hexane (1:1:5, v/v/v) from 0.2-ml samples of sera, and its content in the hexane layer was measured fluorometrically.

Preparation of PMN cells. Rat peritoneal PMN were obtained from male Wistar rats 15–16 hr after intraperitoneal injection of sodium caseinate as described by Cunningham et al. (8). The cells were separated by centrifugation at 300 g for 5 min, and a highly purified preparation of neutrophils (>95%) was obtained by Percoll gradient centrifugation.

Biosynthesis of PAF in PMN cells. Reaction mixtures containing 1×10^7 PMN cells/ml, Krebs Ringer phosphate buffer (KRP), and 2 mM PMSF, a serine hydrolase inhibitor, were incubated at 37°C for 15 min. The mixture was then centrifuged at 120 g for 2 min at 4°C to remove PMSF, and the PMN were resuspended in the same volume of fresh KRP. Then 3-ml portions (3×10^7 cells) were stirred with 10^{-6} M FMLP, 0.5 μg/ml cytochalasin B, and 1 mM $CaCl_2$ for the indicated times. Reactions were terminated by the addition of 10 ml of chloroform/methanol (1:2), and lipids were extracted by

the method of Bligh and Dyer (9). After evaporation of the solvent, the residues were dissolved in 100 μl of chloroform/methanol (2:1), and subjected to TLC on silica gel-60 plates with chloroform/methanol/water (65:35:7) as solvent. Bands of PAF were scraped off and extracted by the method of Bligh and Dyer (9). The solvent was evaporated, and the concentration of PAF was determined by assay of its ability to aggregate washed rabbit platelets (10). Student's t-test was used to calculate the significance of differences.

Assay of acetyltransferase. The activity of lysoPAF: acetyl-CoA acetyltransferase (EC 2.3.1.67) was assayed by a modification of the method of Albert and Snyder (11). The acetylation reaction was carried out at 37°C in basic medium containing 60 mM Tris-HCl (pH 7.5), 0.2% fatty acid-free bovine serum albumin, 10 μM $CaCl_2$, 2 mM PMSF (an inhibitor of acetylhydrolase), 12 μM lysoPAF, 2 μCi of [^{3}H]acetyl-CoA, 130 μM acetyl-CoA and about 0.2 mg protein of cell lysate in a final volume of 2 ml. The reaction was started by the addition of [^{3}H]acetyl-CoA. After incubation, radioactive PAF was extracted and purified chromatographically using silica gel-60 TLC plates as described above, and its radioactivity was assayed in a liquid scintillation counter.

Assay of acetylhydrolase. The activity of PAF acetylhydrolase (EC 3.1.1.48) was determined by the method of Blank et al. (12) with minor modifications. The reaction mixture consisted of 60 mM Tris-HCl (pH 7.5), 80 μCi of [^{3}H]PAF, 50 μM PAF, 0.8% fatty acid-free bovine serum albumin, 0.1 mM EDTA (to inhibit acetyltransferase) and about 0.2 mg protein of cell lysate in a final volume of 2 ml. The reaction was carried out at 37°C and then radioactive PAF and lysoPAF were extracted, purified and measured in a liquid scintillation counter.

RESULTS AND DISCUSSION

The mean α-tocopherol contents of the serum of the control, vitamin E-supplemented and vitamin E-deficient groups were 8.63 ± 0.6 μg/ml (n = 20), 13.1 ± 0.9 μg/ml (n = 20) and less than 0.2 μg/ml (n = 20), respectively.

PMN are one of the main types of blood cells in which PAF is synthesized. Table 1 shows the effect of the dietary vitamin E level on FMLP-induced biosynthesis of PAF by PMN from rat peritoneum. The amount of PAF production in the vitamin E-deficient group was about twice that in the control and vitamin E-supplemented groups. That is, the only marked difference was in the vitamin E-deficient group.

Acetylation of lysoPAF by acetyl-transferase [1] is the main pathway for the biosynthesis of PAF, and deacetylation of PAF by acetyl-hydrolase [2] is the first step in its conversion to biologically inactive lysoPAF in PMN.

$$\text{lysoPAF} + \text{acetyl-CoA} \xrightarrow{\text{acetyltransferase}} \text{PAF} \quad [1]$$

$$\text{PAF} \xrightarrow{\text{acetylhydrolase}} \text{lysoPAF} + CH_3COOH \quad [2]$$

Next we examined whether the increase of PAF production in vitamin E deficiency was attributable to increased synthesis and/or decreased catabolism of PAF. As shown in Figure 1, when lysoPAF and [^{3}H]acetyl-CoA were incubated with PMN homogenates at 37°C, [^{3}H]PAF production by the preparation from vitamin E-deficient rats was about twice that of the preparation from vitamin E-supplemented rats. However, there was no difference between the activities of acetyl-hydrolase in the two groups, measured as degradation of PAF and formation of lysoPAF on incubation of [^{3}H]PAF with the PMN homogenates (Fig. 2). Little formation of 1-*O*-[^{3}H]-alkyl-2-acyl-*sn*-glycero-3-phosphocholine was observed during 45 min incubation (data not shown). The extent of increase in acetyltransferase activity in homogenates

TABLE 1

Effect of Dietary Vitamin E on PAF Production in FMLP-Activated PMN of Rats

		PAF (pmol/10^6 cell)		
		Control	E-Supplemented	E-Deficient
Exp. 1	6 mn	80	93	280
	12 min	156	153	354
Exp. 2	6 min	78	75	154
	12 min	129	131	248
Exp. 3	6 min	101	136	273
	12 min	240	227	345

PMN obtained from three or four rats in each experiment were preincubated at 37°C for 15 min in 3 ml of KPR solution containing 6 μmol PMSF, and then incubated with 3 nmol FMLP and 1.5 μg cytochalasin B for 6 min and 12 min. After incubation, PAF in the whole incubation mixtures was extracted and analyzed as described under Materials and Methods. The values for vitamin E-deficient rats at 6 min and 12 min were significantly different ($p < 0.01$) from those of the controls.

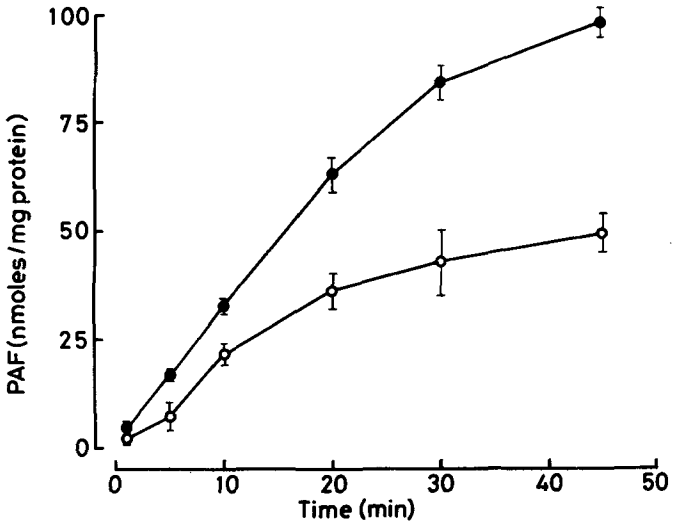

FIG. 1. Time course of incorporation of [^{3}H]acetyl-CoA into lysoPAF by PMN homogenates prepared from vitamin E-deficient (●) and vitamin E-supplemented (○) rats. Cell homogenates were incubated at 37°C for the indicated times in 2 ml of Tris-HCl (pH 7.5) media containing 260 nmol [^{3}H]acetyl-CoA and 24 nmol lysoPAF. Radioactive PAF in the whole incubation mixtures was measured as described in Materials and Methods. Points and bars are means ± S.E. for four experiments. The values for the two groups were significantly different ($P < 0.001$) at all time points.

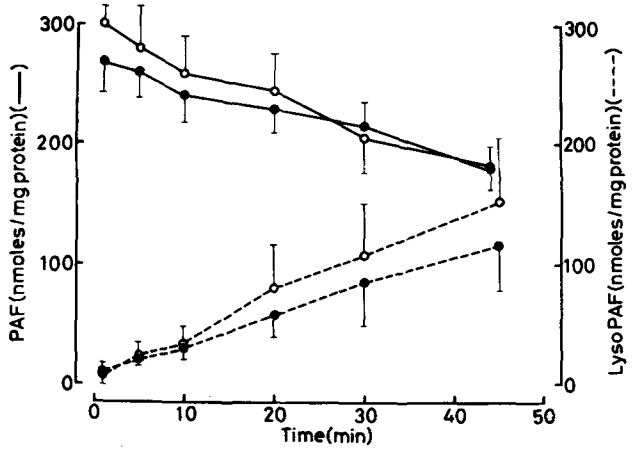

FIG. 2. Time course of conversion of [^{3}H]PAF to [^{3}H]lysoPAF by PMN homogenates from vitamin E-deficient (●) and vitamin E-supplemented (○) rats. Homogenates were incubated at 37°C for the indicated times in 2 ml of Tris-HCl (pH 7.5) medium containing 100 nmol [^{3}H]PAF. Remaining [^{3}H]PAF (—) and [^{3}H]lysoPAF formed (– – –) in the whole incubation mixtures were measured as described in Materials and Methods. Points and bars are means ± S.E. for four experiments.

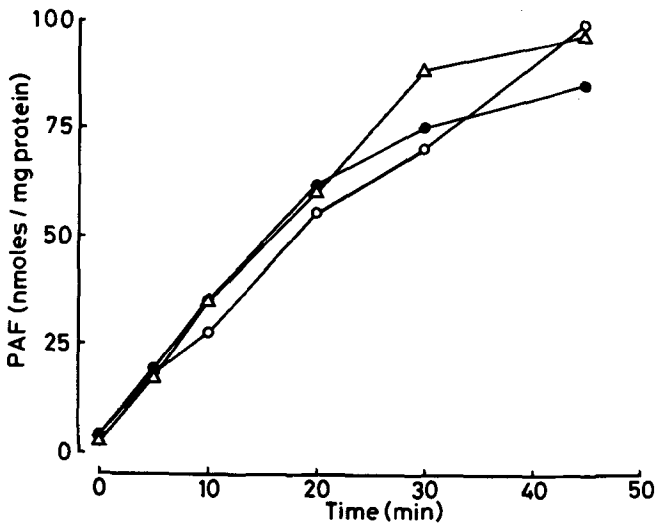

FIG. 3. Effect of in vitro addition of α-tocopherol on the activity of PAF:acetyl-CoA acetyltransferase in PMN homogenates prepared from vitamin E-deficient rats. α-Tocopherol dissolved in 2 μl of DMSO was added to 2 ml of incubation mixtures. The final concentrations of α-tocopherol were 0 ng/ml (△), 40 ng/ml (○) (normal level, and 400 ng/ml (●). Incubation conditions and measurement of radioactive PAF were as for Fig. 1.

of vitamin E-deficient animals was parallel to that of the amount of PAF produced in PMN cells, strongly suggesting that the elevated level of PAF in vitamin E-deficient cells was due mainly to increase in acetyltransferase activity.

Phospholipid metabolism is modulated by the vitamin E status of the animal (13–15). In vitamin E-deficient

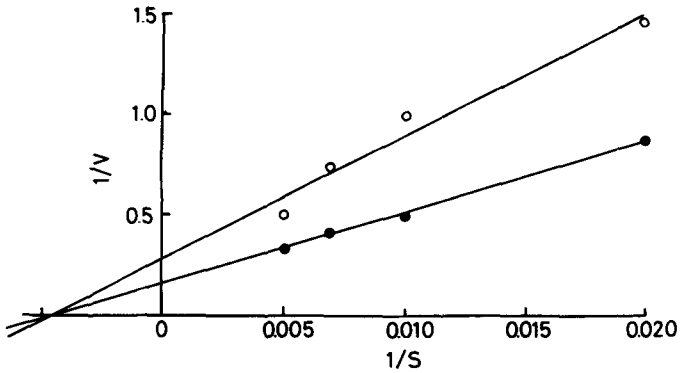

FIG. 4. Double reciprocal plot of PAF:acetyl-CoA acetyl-transferase activity of vitamin E-deficient (●) and vitamin E-supplemented (○) rats. Incubation conditions were as described for Fig. 1. V, PAF (nmol/min/mg protein); S, acetyl-CoA (μM).

rats, both biosynthesis and catabolism of phosphatidylcholine, the major phospholipid in mammalian tissues, are reported to be increased through acylation and deacylation at its *sn*-2 position. The decreased deacylation induced by dietary vitamin E is though to be due to its direct inhibition of phospholipase A_2, because the enzyme is inhibited *in vitro* by addition of α-tocopherol (14,15). As the lower activity of acetyltransferase in vitamin E-supplemented rats could also be attributed to direct inhibition of the enzyme by α-tocopherol, we examined the effect of added α-tocopherol on the activity of acetyltransferase *in vitro*. For this, a physiological concentration of α-tocopherol (40 ng/ml of incubation medium) and a 10-fold higher concentration (400 ng/ml) were added to samples of homogenate of PMN from vitamin E-deficient rats, and incubated with lysoPAF and [^{3}H]-acetyl-CoA. As shown in Figure 3, no difference was found in the time course of [^{3}H]PAF production with and without added α-tocopherol, indicating that the acetyltransferase was not directly inhibited by α-tocopherol.

Kinetic data on the acetyltransferases from the two groups are shown in Figure 4. The Km and Vmax values of the enzymes for acetyl-CoA were determined from double reciprocal plots. The Km values of the vitamin E-deficient and -sufficient groups were similar (225 and 216 μM, respectively), but their Vmax values were different (6.4 and 3.6 nmol/min/mg protein). These results suggest that vitamin E deficiency increased the amount of the acetyltransferase.

PAF was first characterized by its platelet aggregating activity (16), but later it was shown to have a wide spectrum of biological activities on physiological and pathological processes (6). For example, a direct involvement of PAF has been shown in ischemic cellular damage (17,18), which is protected by vitamin E (19,20). Our findings should be helpful in further studies on other effects of PAF besides elevated platelet aggregation in vitamin E-deficient animals.

ACKNOWLEDGMENT

The authors are grateful to Eisai Co. Ltd., Tokyo for control, vitamin E-deficient and vitamin-supplemented rat chow. This study was supported in part by a research grant (62560087) from the Japanese Ministry of Education, Science and Culture.

[Received October 5, 1988; Revision accepted December 30, 1988]

The Effect of Enhanced Intake of Linoleic Acid on the Fatty Acid Composition of Tissue Polar Lipids of Post-Smolt Atlantic Salmon (*Salmo salar*)

J. Gordon Bell,* Arthur Youngson, Alexander I. Mitchell and **Colin B. Cowey**[1]
NERC Institute of Marine Biochemistry, St. Fitticks Road, Aberdeen, AB1 3RA, Scotland

Duplicate groups of Atlantic salmon (*Salmo salar*) post smolts were given diets in which the lipid component was either fish oil or a mixture of corn oil and lard. This difference in the dietary lipid did not significantly affect growth over a period of sixteen weeks.

Proportions of docosahexaenoic acid [22:6(n-3)] and total (n-3) fatty acids in the polar lipids of liver and white muscle were unaffected by this difference in dietary lipid component over the time period used. Fish given the diet containing corn oil and lard had significantly higher levels of 20:2(n-6), 20:3(n-6) and 20:4(n-6) in the polar lipids of these tissues than were present in the tissues of the fish given diets containing fish oil. These results suggest that linoleic acid [18:2(n-6)] undergoes elongation and desaturation to arachidonic acid [20:4(n-6)] in post-smolt Atlantic salmon.
***Lipids* 24, 240-242 (1989).**

Marine fish species such as turbot (*Scophthalmus maximus*) have an absolute requirement for the highly unsaturated fatty acids (HUFA), 20:5(n-3) and 22:6(n-3), (1) and probably 20:4(n-6) as well. This requirement arises because they are unable to elongate and desaturate the 18-carbon precursors of these fatty acids (2). Some freshwater fish, however, can satisfy their HUFA requirement when given an adequate dietary supply of 18:2(n-6) and 18:3(n-3) (3,4). The freshwater parr of anadromous salmonid fish, e.g., rainbow trout (*Salmo gairdneri*) and chum salmon (*Oncorhynchus keta*), are also capable of elongation and desaturation of both (n-3) and (n-6) 18-carbon precursors (5,6). However, very little is known about fatty acid metabolism during the stressful period of parr-smolt transformation in Atlantic salmon (*Salmo salar*) or during the time of marine ongrowing, although Ackman and Takeuchi (7) observed that hatchery-reared fish undergoing this transformation appeared unable to convert 18:2(n-6) to 20:4(n-6).

With sources of marine oil becoming limited due to demands for human pharmaceutical products and a worldwide expansion in aquaculture, there is interest in using increasing levels of cheaper, more readily available plant oils in salmonid feeds (8,9). It is important, therefore, that we know the consequences of this for membrane fatty acid composition and metabolism, as well as overall carcass composition. In this experiment, post-smolt Atlantic salmon were given practical-type diets containing either fish oil (FO) or a mixture of lipids, mainly corn oil and lard (CO/L).

MATERIALS AND METHODS

Six hundred Atlantic salmon S1 smolts (mean wt, ca. 34 g) were obtained from Sea Farm (Kerry) Ltd, Gairloch, Scotland, distributed into 4 tanks of 2000 l capacity each and supplied with sea-water at a rate of 26 l/min. The temperature over the experimental period (July-November) was 12-9°C and the fish were subjected to natural photoperiod. The FO and CO/L diets were given by automatic feeders which were activated for a few seconds every 15 min (during daylight hours) and adjusted to supply 25 g/kg biomass per day, 7 days each week. Fish were bulk weighed every 28 days and the ration adjusted accordingly.

Both the FO and CO/L diets were formulated to meet the nutritional requirements of salmon (10) (Table 1). A quantity of canning oil (a deodorised fish oil) was added to the CO/L diet to provide adequate (n-3) fatty acids. Salmonid fish require ca. 1% of their diet as (n-3) lipid (3). The major fatty acid components of the two diets are shown in Table 2. After 16 weeks, samples of liver and muscle were removed from at least 4 fish per group. Samples were frozen immediately in liquid N_2 and stored at −80°C until analyzed.

Extraction of lipid, separation of polar and neutral lipid and analyses of purified fatty acid methyl esters were carried out as described by Cowey et al. (11). Significance of difference between treatments was determined by Students t-test.

Samples of heart, kidney, liver, gills, pyloric caeca (with pancreas) and red and white muscle were fixed in 8% formaldehyde in buffered saline prior to light microscopy. Parrafin wax-embedded sections were cut at 5 μm and stained with haematoxylin and eosin (H+E).

RESULTS AND DISCUSSION

Good growth was achieved (32-37 g to 150-180 g in 16 weeks) with both experimental diets and no significant differences in weight gain were observed. Tables 3 and 4 show fatty acid compositions from the polar lipid fractions of liver and muscle from one group from each treatment. No significant differences were observed between duplicate groups of the same dietary treatment. No histological lesions were observed.

Polar lipids from the livers of fish given the CO/L diet showed increased proportions of arachidonic [20:4(n-6)], dihomogammalinolenic [20:3(n-6)], eicosadienoic [20:2(n-6)] and linoleic [18:2(n-6)] acids compared with those fish given the FO diet. Compensatory decreases were observed in 14:0, 16:0, 20:1(n-9), 20:5(n-3), 22:5(n-3) and 24:1 fatty acids. The presence of high levels of 20-carbon (n-6) fatty acids in membrane lipids indicates appreciable Δ6- and Δ5-desaturase activity in liver

cells. No further elongation and Δ4-desaturation to 22:4(n-6) and 22:5(n-6) was observed.

The presence of 20:2(n-6) shows significant "dead-end" chain elongation from 18:2(n-6). Hagve et al. (12) had similar findings from experiments in which isolated hepatocytes from rainbow trout were incubated with [1-^{14}C] 18:2(n-6). This dead-end elongation product is normally incorporated preferentially into the neutral lipid of rainbow trout (13).

In white muscle there was a similar fatty acid profile to that in liver polar lipids. The muscle polar lipids of CO/L fish showed increased 18:2(n-6), 20:2(n-6), 20:3(n-6) and 20:4(n-6) with compensatory decreases in 14:0, 16:1(n-7), 20:1(n-9), 20:4(n-3), 22:1(n-11) and 24:1. These results indicate that the flesh content and relative proportions of (n-3) and (n-6) fatty acids may be manipulated to some extent by dietary means.

Recent work by Ackman and Takeuchi (7) on Atlantic salmon, and Dosanjh et al. (9) on chinook salmon (*O. tshawytscha*), both undergoing parr-smolt change, indicated that little or no elongation and desaturation of 18:2(n-6) to 20-carbon (n-6) HUFA occurred although substantial amounts of 18:2(n-6) were present in the tissue. It is possible that at the time of the change to smolts, when body lipids are changing to an even more preponderantly long-chain (n-3) HUFA spectrum, some inhibition by dietary fatty acids of the desaturases that metabolise 18:2(n-6) may occur.

However, Hardy et al. (8), in an experiment in which Atlantic salmon of over 1.5 kg wt were given a diet that provided a level of 18:2(n-6) similar to that used here, did not find any significant increase of 20:3

(n-6) and 20:4(n-6) in muscle lipids. They did observe a significant increase in the dead-end product 20:2(n-6) when compared with diets containing entirely fish oils.

It is of interest that the proportions of 20:4(n-6) and 20:5(n-3) in liver polar lipids sum to 9.1% in both treatments (2.16 + 6.94 for FO; 5.07 and 4.03 for CO/L). The corresponding values for white muscle are 8.25% and 8.65%, again very similar. It seems possible, therefore, that in the structural sense these two fatty acids are interchangeable—one able to substitute for the other. Data from the CO/L diet that contained a sufficiency of both 20:4(n-6) and 20:5(n-3) indicate that dietary 20:5(n-3) is the preferred polar lipid fatty acid, if adequate in amount, but that 20:4(n-6) is an acceptable substitute if some of the 20:5(n-3) is used instead for elongation to 22:6(n-3).

20:3(n-6) is present at ca. tenfold greater proportion in tissue polar lipids of fish given CO/L diet compared with those given FO. Because dietary 20:3(n-6) was very low in both diets it seems likely that this increase must be a result of elongation and desaturation of 18:2(n-6). The accumulation of 20:3(n-6) and 20:2(n-6) reflects the rate limiting activity of the desaturases compared with the much more rapid reaction rates of the elongases. Hagve et al. (12) demonstrated that Δ5-desaturation of 20:3(n-6) in rainbow trout hepatocytes was only a quarter of that in rat hepatocytes.

It may be noted that (n-6) fatty acids cannot be substituted entirely for (n-3) fatty acids in artificial diets for fish (5,14); nor was this the intention. The inclusion of (n-6) fatty acids in feed for salmonids would however reduce the amount of dietary fish oil [(n-3) fatty acids] necessary in culture of these fish without any effects on tissue pathology or growth rate.

ACKNOWLEDGMENT

We thank all DAFS personnel involved in running the Fish Cultivation Unit, Aultbea, for their assistance with this experiment.

Fatty Acid Hydroperoxide Isomerase in *Saprolegnia parasitica*: Structural Studies of Epoxy Alcohols Formed From Isomeric Hydroperoxyoctadecadienoates

Mats Hamberg
Department of Physiological Chemistry, Karolinska Institutet, Box 60400, S-104 01 Stockholm, Sweden

The major part (80%) of the fatty acid hydroperoxide isomerase activity present in homogenates of the fungus, *Saprolegnia parasitica*, was localized in the particle fraction sedimenting at 105,000 × *g*.

13*(S)*-Hydroperoxy-9*(Z)*,11*(E)*-octadecadienoic acid and 9*(S)*-hydroperoxy-10*(E)*,12*(Z)*-octadecadienoic acid were both good substrates for the particle-bound hydroperoxide isomerase. The products formed from the 13*(S)*-hydroperoxide were identified as an α,β- and a γ,δ-epoxy alcohol, i.e., 11*(R)*,12*(R)*-epoxy-13*(S)*-hydroxy-9*(Z)*-octadecenoic acid and 9*(S)*,10*(R)*-epoxy-13*(S)*-hydroxy-11*(E)*-octadecenoic acid, respectively. The 9*(S)*-hydroperoxide was converted in an analogous way into an α,β-epoxy alcohol, 10*(R)*,11*(R)*-epoxy-9*(S)*-hydroxy-12*(Z)*-octadecenoic acid and a γ,δ-epoxy alcohol, 12*(R)*,13*(S)*-epoxy-9*(S)*-hydroxy-10*(E)*-octadecenoic acid.

9*(R,S)*-Hydroperoxy-10*(E)*,12*(E)*-octadecadienoic acid and 13*(R,S)*-hydroperoxy-9*(E)*,11*(E)*-octadecadienoic acid were poor substrates for the *S. parasitica* hydroperoxide isomerase. Experiments with 13*(R,S)*-hydroperoxy-9*(Z)*,11*(E)*-octadecadienoic acid showed that the 13*(R)*-hydroperoxy enantiomer was slowly isomerized by the enzyme. The major product was identified as α,β-epoxy alcohol 11*(R)*,12*(R)*-epoxy-13*(R)*-hydroxy-9*(Z)*-octadecenoic acid.

Lipids 24, 249-250 (1989).

A pathway for sequential degradation of certain polyunsaturated fatty acids in the primitive fungus, *Saprolegnia parasitica*, was identified in recent work (1-3). Thus, arachidonic acid added to homogenates of the fungus was converted into 15*(S)*-HPETE by a lipoxygenase. The hydroperoxide did not accumulate, but was rapidly converted by action of a hydroperoxide isomerase into a pair of epoxy alcohols—11*(S)*,12*(R)*-epoxy-15*(S)*-hydroxy-5*(Z)*,8*(Z)*,13*(E)*-eicosatrienoic acid and 13(*R*),14(*R*)-epoxy-15(*S*)-hydroxy-5(*Z*),8(*Z*),11(*Z*)-eicosatrienoic acid. The two epoxy alcohols possessed an allylic epoxide group and therefore underwent spontaneous hydrolysis into a number of isomeric trihydroxyeicosatrienoates. Interestingly, relatively large amounts of trihydroxyeicosatrienoates and trihydroxyoctadecenoates could be isolated from the culture medium of the fungus, thus showing that the lipoxygenase/hydroperoxide isomerase pathway is active in the growing organism (1).

The present paper describes further studies of the hydroperoxide isomerase of *S. parasitica* using a number of isomeric hydroperoxy-octadecadienoates derived from linoleic acid as substrates.

Abbreviations: 9*(S)*-HPOD, 9*(S)*-hydroperoxy-10*(E)*,12*(Z)*-octadecadienoic acid; 9*(R,S)*-HPOD, 9*(R,S)*-hydroperoxy-10*(E)*,12*(Z)*-octadecadienoic acid; 13*(S)*-HPOD, 13*(S)*-hydroperoxy-9*(Z)*,11*(E)*-octadecadienoic acid; 13*(R,S)*-HPOD, 13*(R,S)*-hydroperoxy-9*(Z)*,11*(E)*-octadecadienoic acid; 15*(S)*-HPETE, 15*(S)*-hydroperoxy-5*(Z)*,8*(Z)*,11*(Z)*,13*(E)*-eicosatetraenoic acid; 8*(R)*-HETE, 8*(R)*-hydroxy-5*(Z)*,9*(E)*,11*(Z)*,14*(Z)*-eicosatetraenoic acid; I_{9S}, methyl 12*(R)*,13*(S)*-epoxy-9*(S)*-hydroxy-10*(E)*-octadecenoate; II_{9S}, methyl 10*(R)*,11*(R)*-epoxy-9*(S)*-hydroxy-12*(Z)*-octadecenoate; I_{13S}, methyl 9*(S)*,10*(R)*-epoxy-13*(S)*-hydroxy-11*(E)*-octadecenoate; II_{13S}, methyl 11*(R)*,12*(R)*-epoxy-13*(S)*-hydroxy-9*(Z)*-octadecenoate; MC, (−)-menthoxycarbonyl; CC, cyclic carbonate; Me_3Si, trimethylsilyl; GC-MS, gas chromatography-mass spectrometry; GLC, gas liquid chromatography; HPLC, high performance liquid chromatography; TLC, thin layer chromatography.

MATERIALS

13*(S)*-[1-^{14}C]HPOD (specific radioactivity, 1.4 kBq/μmol) was prepared by incubation of [1-^{14}C]linoleic acid with soybean lipoxygenase as previously described (4). 9*(S)*-[1-^{14}C]HPOD (specific radioactivity, 1.3 kBq/μmol) was prepared by incubation of [1-^{14}C]linoleic acid with whole homogenates of tomato, essentially as described by Matthew et al. (5). II_{13S} and its diastereomer, methyl 11*(S)*,12*(S)*-epoxy-13*(S)*-hydroxy-9*(Z)*-octadecenoate, were prepared by epoxidation of the methyl ester of 13*(S)*-HPOD using vanadium oxyacetylacetonate as catalyst (6). Methyl *erythro*- and *threo*-12,13-dihydroxyoctadecanoates were prepared by OsO_4- and performic acid hydroxylations, respectively, of methyl 12*(Z)*-octadecenoate (6). Methyl *erythro*- and *threo*-9,10-dihydroxyoctadecanoates were prepared, in a similar way, starting with methyl oleate.

9(R,S)*-Hydroperoxy-10*(E),*12*(E)*-octadecadienoic acid and 13*(R,S)*-hydroperoxy-9*(E),*11*(E)*-octadecadienoic acid.* Linoleic acid (100 mg) was kept under O_2 at 37°C for 15 hr. The product was subjected to silicic acid chromatography (column, 5 g). Elution with diethyl ether/hexane (2:8, v/v) yielded a mixture of hydroperoxyoctadecadienoates (ca. 16 mg, according to UV spectrometric analysis). This material was subjected to preparative reversed-phase high performance chromatography (HPLC) using a column of Polygosil C_{18} 5 μ (300 × 8 mm) and acetonitrile/water/acetic acid (68/32/0.02, v/v/v) at a flow rate of 1.5 ml/min. Three peaks of material showing strong absorption at 230-235 nm appeared, i.e., I (38.9-41.9 ml effluent), II (42.3-44.1 ml) and III (44.6-46.5 ml). The UV spectra of material forming peaks II and III showed an absorption band with λ_{max} = 231 nm, indicating an *E,E* diene structure. Further proof of the presence of one pair of conjugated *E,E* double bonds in compounds forming peaks II and III was provided by the IR spectra which showed an absorption band at 995 cm^{-1} (7). Catalytic hydrogenation of II and III afforded 13-hydroxy- and 9-hydroxyoctadecanoic acids, respectively. Thus, material present in peak II was identical to 13*(R,S)*-hydroperoxy-9*(E)*,11*(E)*-octadecadienoic acid, whereas peak III was due to 9*(R,S)*-hydroperoxy-10*(E)*,12*(E)*-octadecadienoic acid.

9(R,S)*-HPOD and 13*(R,S)*-HPOD.* Material forming peak I was subjected to straight-phase HPLC using a column of Nucleosil 5 μ (250 × 4.6 mm) and isopropanol/

hexane/acetic acid (1.5:98.5:0.02, v/v/v) at a flow rate of 3 ml/min. Two peaks appeared, i.e., 13*(R,S)*-HPOD (23.4–26.1 ml effluent) and 9*(R,S)*-HPOD (34.5–37.2 ml). Catalytic hydrogenation, which afforded 13-hydroxyoctadecanoic acid from the former hydroperoxide and 9-hydroxyoctadecanoic acid from the latter, demonstrated the positions of the hydroperoxy groups. The presence of a conjugated *E,Z* diene structure in the two compounds was shown by UV spectrometry, which showed an absorption band with λ_{max} = 234 nm, and by IR spectrometry, which showed bands at 990 and 955 cm^{-1} (ratio of intensities, 0.9:1) (7).

Methyl 10(R),*11*(R)*-epoxy-9*(S)*-hydroxy-12*(Z)*-octadecenoate.* The methyl ester of 9*(S)*-[1-^{14}C]HPOD (3 mg) was treated for 1 hr at room temperature with 3 ml of hexane saturated with vanadium oxyacetylacetonate. Thin layer radiochromatography showed two peaks of radioactivity due to a pair of diastereomeric α,β-epoxy alcohols (6). The more polar epoxy alcohol (R_f = 0.49; solvent system ethyl acetate/hexane [3:7, v/v]) was collected and characterized as follows: UV spectrometry did not show any specific absorption. The infrared spectrum showed bands at 3620–3350 cm^{-1} (hydroxyl), 1735 cm^{-1} (ester carbonyl) and 890 cm^{-1} (*trans* epoxide). No absorption band appeared in the region 950–1000 cm^{-1}. Thus, the presence of *E* double bond(s) could be excluded. Analysis of the trimethylsilyl (Me_3Si) derivative by gas chromatography–mass spectrometry (GC–MS) showed a peak with a retention time corresponding to C 22.5. The mass spectrum showed prominent ions at *m/e* 383 (M − 15, 4%), 367 (M − 31, 1), 308 (M − 90, 1), 259 (Me_3SiO^+=CH-$[CH_2]_7$-$COOCH_3$, 100), 212 (M − 186, [tentatively ascribed to migration of Me_3Si from C-9 to epoxide oxygen followed by elimination of OHC-$\{CH_2\}_7$-$COOCH_3$], 13) and 155 (OHC-$(CH_2)_7$-C≡O^+, 35), indicating a methyl octadecenoate carrying a hydroxyl at C-9, as well as a second oxygen function (epoxide according to the IR analysis). $KMnO_4$ oxidation performed on the MC derivative yielded the MC derivative of 2*(S)*-hydroxysebacate, demonstrating that the hydroxyl group of the epoxy alcohol had the *S* configuration. Catalytic hydrogenation yielded a major component that was identified as methyl *threo*-9,10-dihydroxyoctadecanoate by thin layer chromatography (TLC) carried out with $NaAsO_2$-impregnated silica gel using the authentic *threo* (R_f = 0.72) and *erythro* (R_f = 0.63) isomers as references. The presence of a hydroxyl group at C-9 (mass spectrometry, $KMnO_4$ oxidation), coupled with the results of the catalytic hydrogenation, located the epoxide group at C-10/C-11. The absolute configurations of C-10 and C-11 followed from the established configuration of C-9 (*"S"*) coupled with the findings that the relative configuration of C-9/C-10 was *threo* and that the configuration of the C-10/C-11 epoxide group was *trans*. On basis of these data, the epoxy alcohol was assigned the structure methyl 10*(R)*,11*(R)*-epoxy-9*(S)*-hydroxy-12*(Z)*-octadecenoate.

METHODS

Enzyme preparation. Homogenates of *S. parasitica* in 0.1 M potassium phosphate buffer pH 7.4 (1:2, w/v) (2) were centrifuged at 750 × *g* for 10 min. The supernatant was further centrifuged at 105,000 × *g* for 60 min. The sediment thus obtained was resuspended in potassium phosphate buffer (if not otherwise indicated, protein concentration was adjusted to 0.16 mg/ml). Protein was determined according to Bradford (8).

Spectrophotometric assay of hydroperoxide isomerase activity. Suspensions of the sediments obtained by centrifugation at 750 × *g* and 105,000 × *g*, as well as the clear 105,000 × *g* supernatant, were diluted with potassium phosphate buffer as needed. Samples of 2 ml were transferred to cuvettes and treated with 10–20 μg of the different hydroperoxides (temperature, 20°C). The absorbance at 236 nm was followed, vs time. The initial slopes (0–30 sec) of the decrease in absorbancy were taken as a measure of hydroperoxide isomerase activity.

Incubations and isolation of epoxy alcohols. [1-^{14}C]-Linoleic acid, 13*(S)*-[1-^{14}C]HPOD and 9*(S)*-[1-^{14}C]HPOD (0.25 mg) were shaken with suspensions of the 105,000 × *g* particle fraction (5 ml; 0.16 mg of protein/ml) at 22°C for 30 min. The mixtures were acidified to pH 3 and rapidly extracted with two portions of diethyl ether. The residue obtained after evaporation of the solvent was treated with diazomethane and subjected to thin layer chromatography (TLC) (solvent system, ethyl acetate/hexane [3:7, v/v]). With the solvent system used, the R_f values of methyl 11*(S)*,12*(S)*-epoxy-13*(S)*-hydroxy-9*(Z)*-octadecenoate, II_{13S}, and II_{9S} were 0.63, 0.54 and 0.49, respectively.

Linoleic acid and 13*(S)*-HPOD were found to yield a common pair (ratio, ca. 3:1) of epoxy alcohols. The R_f values of the methyl esters of the major and minor epoxy alcohols were 0.54 (II_{13S}) and 0.42 (I_{13S}), respectively. Incubation of 9*(S)*-HPOD resulted in the formation of another pair (ratio, ca. 2:1) of epoxy alcohols. The R_f values of their methyl esters were 0.49 (II_{9S}, major epoxy alcohol) and 0.39 (I_{9S}, minor epoxy alcohol). Unlabeled 13*(R,S)*-HPOD (0.25 mg) was incubated in the same way, although in this case 10 ml of enzyme preparation was used. Analysis of the esterified product by TLC showed two major spots, i.e., epoxy alcohols II_{13S} (R_f = 0.54) and II_{13R} (R_f = 0.63), as well as fainter spots of more polar material that was not further characterized.

Methods for structure determination. TLC was carried out with precoated plates (Kieselgel 60, 0.25 mm) from E. Merck (Darmstadt, FRG). Analysis of diastereomeric methyl 9,10- and 12,13-dihydroxyoctadecanoates was carried out using plates coated with silica gel G-$NaAsO_2$ (9:1, w/w) and methanol/chloroform (1:99, v/v) as solvent. Material was located by spraying with 2′,7′-dichlorofluorescein and viewing under UV light. Gas liquid chromatography (GLC) was performed with an F&M Biomedical gas chromatograph model 402 using a column of 5% QF-1 on Supelcoport. GC–MS was carried out with an LKB 9000S instrument equipped with a column of 3% OV—210 on Supelcoport. The electron energy was set at 22.5 eV, and the trap current was 60 μA. Ultraviolet spectra were recorded with a Hewlett-Packard model 8450A UV/VIS spectrophotometer. Radioactivity was determined with a Packard Tri-Carb series 4000 liquid scintillation counter. A Berthold Dünnschichtscanner II was used for determination of radioactivity on TLC plates.

Methods for catalytic hydrogenation (2), oxidative ozonolysis (9), $KMnO_4$ oxidation (3), and preparation and analysis of MC (9) and CC (3) derivatives were as previously described.

RESULTS

Localization and specificity of hydroperoxide isomerase activity. The major part (80%) of the hydroperoxide isomerase activity of homogenates of *S. parasitica* was present in the particle fraction sedimenting at 105,000 × *g*, whereas ca. 10% of the activity remained in the cytosol (Table 1).

13*(S)*-HPOD and 9*(S)*-HPOD were both good substrates for the particle-bound isomerase. No significant difference between the initial rates of isomerization of these hydroperoxides could be detected (Fig. 1). On the other hand, the *E,E* hydroperoxides, 9*(R,S)*-hydroperoxy-10*(E)*,12*(E)*- and 13*(R,S)*-hydroperoxy-9*(E)*,11*(E)*-octadecadienoates, were isomerized slowly (rates relative to those of the *E,Z* hydroperoxides, 10% or less (Fig. 1). 13*(R,S)*-HPOD was incubated in order to examine the stereospecifical requirements of the enzyme. If the enzyme did utilize only the 13*(S)*-hydroperoxide in the mixture of enantiomers it would be expected, with the spectrophotometric assay used, that the decrease in absorbancy at 235 nm would level off at 50% of the starting value. Interestingly, this was not found (Fig. 2). The curve obtained suggested that the 13*(R)*-hydroperoxide acted in a dual way, i.e., as a (poor) substrate for and as a (competitive) inhibitor of the isomerase. That 13*(R)*-HPOD was indeed isomerized by the enzyme was supported by the finding that preincubation with 10^{-4} M *p*-hydroxymercuribenzoate, an inhibitor of the *S. parasitica* hydroperoxide isomerase (2), resulted in complete inhibition of isomerization of 13*(R,S)*-HPOD, and further proved by the isolation of a specific hydroperoxide isomerase product formed from 13*(R)*-HPOD.

TABLE 1

Hydroperoxide Isomerase Activity in Fractions of Homogenates of *S. parasitica*[a]

Fraction	Total activity (%)	Specific activity (μmol/min·mg protein)
750 × *g* sediment	11	0.28
105,000 × *g* supernatant	9	0.06
105,000 × *g* sediment	80	0.45

[a]Fractions indicated were diluted with 0.1 M potassium phosphate buffer pH 7.4. Two ml of the dilutions were transferred to a cuvette and treated with 25 μM 13*(S)*-HPOD (temperature, 20°C). Hydroperoxide isomerase activity was calculated from the initial slopes (0–30 sec) of the decrease in absorbancy at 236 nm.

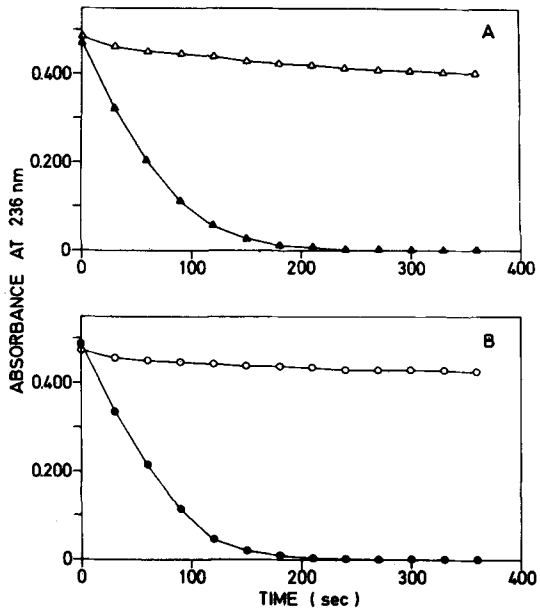

FIG. 1. Spectrophotometric assay of hydroperoxide isomerase activity. The blank and sample cuvettes contained 2 ml of a suspension of the particle fraction sedimenting at 105,000 × *g* (protein concentration, 27 μg/ml). Hydroperoxides (11 μg) were added to the sample cuvette in 5 μl of ethanol. Temperature, 20°C. (A) 9*(S)*-HPOD (-▲-▲-) and 9*(R,S)*-hydroperoxy-10*(E)*,12*(E)*-octadecadienoic acid (-△-△-). (B) 13*(S)*-HPOD (-●-●-) and 13*(R,S)*-hydroperoxy-9*(E)*,11*(E)*-octadecadienoic acid (-○-○-).

Structures of epoxy alcohols formed from linoleic acid and 13(S)-HPOD. II_{13S}, the methyl ester of the major epoxy alcohol formed from 13*(S)*-HPOD and linoleic acid (Fig. 3), was found to be identical to methyl 11*(R)*,12*(R)*-epoxy-13*(S)*-hydroxy-9*(Z)*-octadecenoate as shown by comparison with authentic material prepared by vanadium-catalyzed epoxidation of the methyl ester of 13*(S)*-HPOD. Criteria for identity included identical infrared spectra, identical C values and mass spectra, as well as identical results obtained on $KMnO_4$ oxidation and catalytic hydrogenation. Oxidation of the MC derivative (which yielded the MC derivative of 2*(S)*-hydroxyheptanoic acid) and the mass spectrum recorded on the Me_3Si derivative (which showed a base peak at *m/e* 173 due to $Me_3SiO^+ = CH\text{-}C_5H_{11}$) demonstrated the presence of an alcohol group at C-13, and thus excluded isomeric epoxy alcohols such as 12,13-epoxy-11-hydroxy-9-octadecenoate, 12,13-epoxy-9-hydroxy-10-octadecenoate, 9,10-epoxy-11-hydroxy-12-octadecenoate, and 10,11-epoxy-9-hydroxy-12-octadecenoate.

UV spectrometric analysis of I_{13S}, the methyl ester of the minor epoxy alcohol formed from 13*(S)*-HPOD and linoleic acid (Fig. 3), did not show any specific absorption

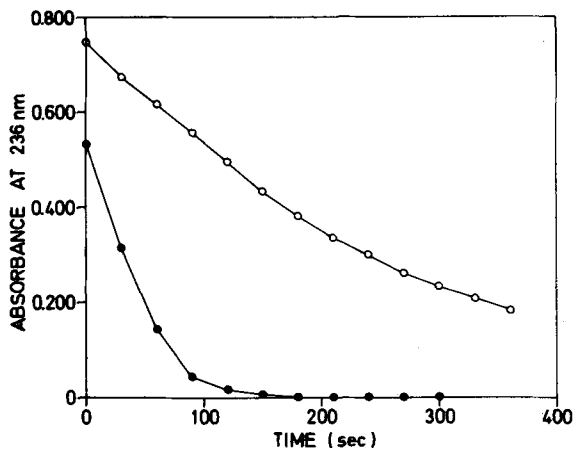

FIG. 2. Spectrophotometric assay of hydroperoxide isomerase activity. The blank and sample cuvettes contained 2 ml of a suspension of the particle fraction sedimenting at 105,000 × *g* (protein concentration, 40 μg/ml). 13*(S)*-HPOD (12 μg; -●-●-) and 13*(R,S)*-HPOD (17 μg; -○-○-) were added to the sample cuvette in 5 μl of ethanol. Temperature, 20°C.

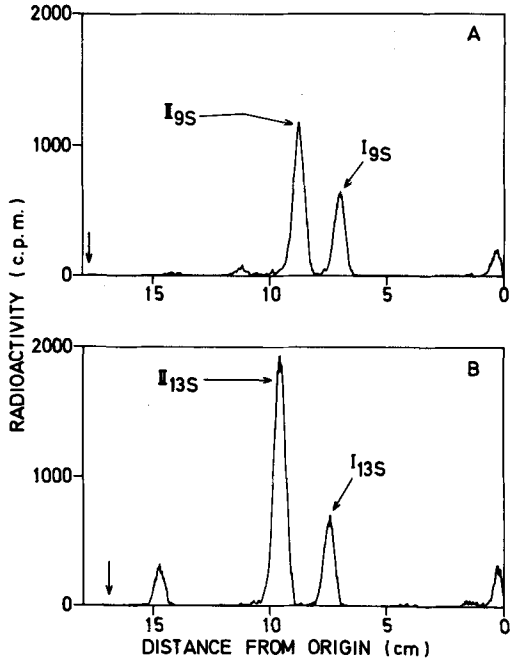

FIG. 3. Thin layer radiochromatograms of esterified products obtained after incubation of 0.25 mg of 9(S)-[1-^{14}C]HPOD (A) and 0.25 mg of [1-^{14}C]linoleic acid (B) with 5 ml of suspension of 105,000 × g particle fraction at 22°C for 30 min. Solvent fronts are indicated by arrows. Solvent system, ethyl acetate/hexane (3:7; v/v).

band. Infrared spectrometry showed bands inter alia at 3620–3350 cm^{-1} (hydroxyl), 1735 cm^{-1} (ester carbonyl) and 970 cm^{-1} (*E* double bond). No absorption band was observed in the region 850–900 cm^{-1}, thus excluding the presence of a *trans* epoxide group. The C-value of the Me_3Si derivative of I_{13S} was 23.9 and the mass spectrum showed prominent ions at *m/e* 398 (M, 1%), 383 (M − 15, 3), 327 (M − 71 [loss of $^{\bullet}C_5H_{11}$], 80), 308 (M − 90, 9), 298 (M − 100 [rearrangement with loss of $OHC-C_5H_{11}$], 17), 241 (M − 157 [loss of $^{\bullet}\{CH_2\}_7-COOCH_3$], 14), 237 (327 − 90, 40), 199 (M − 199 [cleavage at C-10/C-11 with charge retention in the fragment C-1 to C-10 and/or C-11 to C-18], 13), 185 (probably $O^+\equiv C-[CH_2]_7-COOCH_3$, 100) and 173 ($Me_3SiO^+=CH-C_5H_{11}$, 80). This spectrum indicated a methyl octadecenoate carrying a hydroxyl group at C-13, as well as a second oxygen function. Oxidative ozonolysis performed on the MC derivative of I_{13S} yielded the MC derivative of 2(*S*)-hydroxyheptanoic acid demonstrating the presence in I_{13S} of a double bond at Δ^{11} and a hydroxyl group at C-13 (*S* configuration). Catalytic hydrogenation of I_{13S} yielded comparable amounts of three components, i.e., methyl 9,13-dihydroxyoctadecanoate, methyl 9-hydroxyoctadecanoate, and methyl 13-hydroxyoctadecanoate, the identities of which were established by GC–MS. The absence of ketoesters in the hydrogenation product indicated that the nonhydroxylic oxygen function of I_{13S} detected by mass spectrometry was, as expected, an epoxide group.

Conclusive evidence for the presence of an allylic epoxide group at C-9/C-10 was provided by the finding that I_{13S} underwent spontaneous hydrolysis into isomeric trihydroxyesters (2,10–12). Thus, I_{13S} (1 mg) in methanol (0.5 ml) was treated with glass-distilled water (50 ml) at room temperature for 20 hr and the product subjected to thin layer radiochromatography (solvent, ethyl acetate). Two major peaks of radioactivity appeared, i.e., peak I (28%, R_f = 0.35) and peak II (60%, R_f = 0.48). Analysis by GC–MS of the Me_3Si derivatives of material forming peak I showed the presence of comparable amounts of a methyl 9,12,13-trihydroxy-10-octadecenoate (ion due to loss of $^{\bullet}CH_3$ [M − 15] at *m/e* 545, base peak at *m/e* 173 due to $Me_3SiO^+=CH-C_5H_{11}$) and a methyl 9,10,13-trihydroxy-11-octadecenoate (M − 15 ion at *m/e* 545, base peak at *m/e* 259 due to $Me_3SiO^+=CH-[CH_2]_7-COOCH_3$) (see refs. 3 and 6 for detailed mass-spectrometric data of trihydroxyoctadecenoates and trihydroxyeicosatrienoates). Oxidative ozonolysis performed on the MC derivatives of material present in peak I yielded the MC derivatives of 2(*S*)-hydroxysebacate and 2(*S*)-hydroxyheptanoate (from the 9,12,13- and 9,10,13-trihydroxyoctadecenoates, respectively). Ozonolysis of the cyclic carbonate (CC) derivatives of material present in peak I yielded the CC derivative of *erythro*-2,3-dihydroxyoctanoate (from the 9,12,13-trihydroxyoctadecenoate) and the CC derivative of a 2,3-dihydroxyundecanedioate (from the 9,10,13-trihydroxyoctadecenoate). The configuration of the latter product could not be established because of lack of the appropriate reference compounds. From these data it followed that peak I was due to a methyl 9(*S*),12,13-trihydroxy-10-octadecenoate which had the *erythro* configuration at C-12/C-13, and a methyl 9,10,13(*S*)-trihydroxy-11-octadecenoate. In the same way, peak II was found to be due to a methyl 9(*S*),12,13-trihydroxy-10-octadecenoate that had the *threo* configuration at C-12/C-13 (15%), and a methyl 9,10,13(*S*)-trihydroxy-11-octadecenoate (85%).

The two methyl 9(*S*),12,13-trihydroxy-10-octadecenoates present in peaks I and II were formed from I_{13S} by solvent attack at C-12 followed by isomerization of the Δ^{11} double bond into the Δ^{10} position and opening of the epoxide ring (Fig. 4). The fact that the carbon-oxygen bond at C-9 remains intact during this conversion, and the fact that the two trihydroxyesters formed had both the "*S*" configuration at C-9, demonstrated that C-9 of

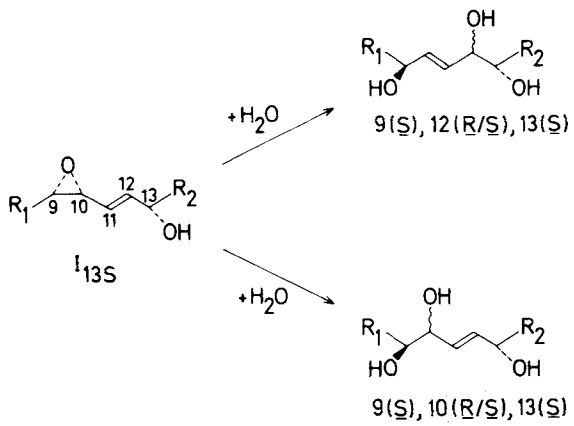

FIG. 4. Stereochemistry in the hydrolysis of γ,δ-epoxy alcohol I_{13S}. Formations of methyl 9(S),12(R,S),13(S)-trihydroxy-10-octadecenoate and methyl 9(S),10(R,S),13(S)-trihydroxy-11-octadecenoate by solvent attack at C-12 and C-10, respectively, are shown. R_1 = $(CH_2)_7-COOCH_3$, R_2 = $(CH_2)_4-CH_3$.

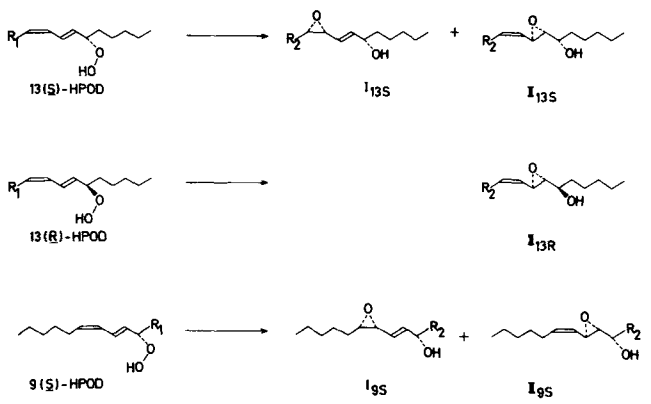

FIG. 5. Structures of epoxy alcohols formed from 13*(S)*-HPOD, 13*(R)*-HPOD and 9*(S)*-HPOD by action of *S. parasitica* hydroperoxide isomerase. $R_1 = (CH_2)_7$-COOH, $R_2 = (CH_2)_7$-$COOCH_3$.

epoxy alcohol I_{13S} had the "*S*" configuration. Furthermore, the absence of an absorption band typical of a *trans* epoxide in the infrared spectrum of I_{13S} showed that the C-9/C-10 epoxide group had the *cis* configuration. Accordingly, epoxy alcohol I_{13S} was assigned the structure methyl 9*(S)*,10*(R)*-epoxy-13*(S)*-hydroxy-11*(E)*-octadecenoate (Fig. 5).

Structures of epoxy alcohols formed from 9(S)*-HPOD.* II_{9S}, the methyl ester of the major epoxy alcohol formed from 9*(S)*-HPOD, was identical to methyl 10*(R)*,11*(R)*-epoxy-9*(S)*-hydroxy-12*(Z)*-octadecenoate, as shown by comparison with the authentic compound by UV and IR spectrometry, mass spectrometry, chemical degradation of the MC derivative, as well as catalytic hydrogenation. Formation of the MC derivative of 2*(S)*-hydroxysebacate upon oxidation with $KMnO_4$, and the mass spectrum of the Me_3Si derivative, showing a base peak at *m/e* 259 (Me_3SiO^+=CH-$(CH_2)_7$-$COOCH_3$), both demonstrated the presence of an alcohol group at C-9. This eliminated possible isomeric epoxy alcohols such as 9,10-epoxy-11-hydroxy-12-octadecenoate, 9,10-epoxy-13-hydroxy-11-octadecenoate, 12,13-epoxy-11-hydroxy-9-octadecenoate and 11,12-epoxy-13-hydroxy-9-octadecenoate.

The UV spectrum of I_{9S}, the methyl ester of the minor epoxy alcohol formed from 9*(S)*-HPOD, did not show any specific absorption band. The IR spectrum showed absorption bands at 3620-3350 cm^{-1} (hydroxyl), 1735 cm^{-1} (ester carbonyl) and 970 cm^{-1} (*E* double bond). The absence of absorption band in the region 850-900 cm^{-1} showed that no *trans* epoxide group was present in I_{9S}.

The C-value of the Me_3Si derivative of I_{9S} was 23.9 and the mass spectrum showed prominent ions at *m/e* 398 (M, 1%), 383 (M − 15, 3), 367 (M − 31, 1), 327 (M − 71 [loss of $^{\cdot}C_5H_{11}$], 3), 308 (M − 90, 4), 285 (M − 113 [cleavage at C-11/C-12 with elimination of C-12 to C-18], 4), 259 (Me_3SiO^+=CH-$\{CH_2\}_7$-$COOCH_3$, 35), 241 (M − 157 [loss of $^{\cdot}\{CH_2\}_7$-$COOCH_3$], 100), 212 (M − 186 [tentatively ascribed to migration of Me_3Si to epoxide oxygen followed by elimination of OHC-$\{CH_2\}_7$-$COOCH_3$], 9), 155 (OHC-$[CH_2]_7$-$C{\equiv}O^+$, 13), 151 (241 − 90, 24), and 99 ($O{\equiv}C$-C_5H_{11}, 82). This spectrum was similar to that of the Me_3Si derivative of a methyl 12,13-epoxy-9*(R,S)*-hydroxy-10-octadecenoate previously isolated in a study of the hemoglobin-promoted degradation of 13*(S)*-HPOD (11).

Oxidative ozonolysis performed on the MC derivative of I_{9S} yielded the MC derivative of 2*(S)*-hydroxysebacate demonstrating the presence in I_{9S} of a hydroxyl group at C-9 (*S* configuration). Catalytic hydrogenation of I_{9S} yielded comparable amounts of three components, i.e., methyl 9,13-dihydroxyoctadecanoate, methyl 13-hydroxyoctadecanoate and methyl 9-hydroxyoctadecanoate.

Thin layer radiochromatographic analysis of the hydrolysis product of I_{9S} showed two major peaks, i.e., peak I (27%, R_f = 0.35) and peak II (65%, R_f = 0.48). GC-MS analysis and steric analysis demonstrated that peak I was due to comparable amounts of a methyl 9,10,13*(S)*-trihydroxy-11-octadecenoate and a methyl 9*(S)*,12,13-trihydroxy-10-octadecenoate, the latter of which had the *erythro* configuration at C-12/C-13. Peak II was due to a methyl 9,10,13*(S)*-trihydroxy-11-octadecenoate (ca. 15%), and a methyl 9*(S)*,12,13-trihydroxy-10-octadecenoate having the *threo* configuration at C-12/C-13 (ca. 85%).

The two methyl 9,10,13*(S)*-trihydroxy-11-octadecenoates present in peaks I and II were formed from I_{9S} by solvent attack at C-10 followed by isomerization of the Δ^{10} double bond into the Δ^{11} position and opening of the epoxide group (Fig. 4). The carbon-oxygen bond at C-13 was not affected by this conversion. This fact, coupled with the finding that the configuration of C-13 of the two trihydroxyesters was "*S*," showed that the parent epoxy alcohol I_{9S} had the "*S*" configuration at C-13. Furthermore, from the fact that the C-12/C-13 epoxide group of I_{9S} had the *cis* geometry (IR spectrometry), the complete structure of epoxy alcohol I_{9S} could be deduced, i.e., methyl 12*(R)*,13*(S)*-epoxy-9*(S)*-hydroxy-10*(E)*-octadecenoate (Fig. 5).

Structures of epoxy alcohols formed from 13(R,S)*-HPOD.* The methyl esters of two epoxy alcohols were isolated following incubation of 13*(R,S)*-HPOD. The more polar one (R_f = 0.54) was identified as II_{13S} by comparison with the authentic compound using IR spectrometry, mass-spectrometric analysis of the Me_3Si derivative, chemical degradation and catalytic hydrogenation.

The methyl ester of the less polar epoxy alcohol (II_{13R}; R_f = 0.63) cochromatographed with authentic methyl 11*(S)*,12*(S)*-epoxy-13*(S)*-hydroxy-9*(Z)*-octadecenoate (6). Analysis by GC-MS showed that the C value (22.5) and mass spectra of the Me_3Si derivatives of the two compounds were identical. The infrared spectra of the compounds were also identical and showed absorption bands at 3620-3350 cm^{-1} (hydroxyl), 1735 cm^{-1} (ester carbonyl) and 890 cm^{-1} (*trans* epoxide). No absorption appeared in the region 950-1000 cm^{-1} demonstrating the absence of *E* double bonds. Catalytic hydrogenation of II_{13R} yielded a major product that was identified as methyl *erythro*-12,13-dihydroxyoctadecanoate by $NaAsO_2$-TLC (references: methyl *erythro*-12,13-dihydroxyoctadecanoate, R_f = 0.69; methyl *threo*-12,13-dihydroxyoctadecanoate, R_f = 0.79). Oxidation of the MC derivative of II_{13R} with $KMnO_4$ gave rise to the MC derivative of 2*(R)*-hydroxyheptanoate, as well as methyl hydrogen azelate. From these data it was apparent that II_{13R} was an 11,12-epoxy-13*(R)*-hydroxy-9*(Z)*-octadecenoate. The absolute configurations of C-11 and C-12 were

both *"R"* as deduced from the *erythro* relationship between C-12/C-13, coupled with the configuration of C-13 (*"R"*) and the geometry of the C-11/C-12 epoxide group *(trans)*.

The stereochemistry of epoxy alcohol II_{13R} was studied in an independent way, i.e., by steric analysis of trihydroxyesters formed by hydrolysis. Thus, II_{13R} (1 mg) in methanol (0.5 ml) was treated with glass-distilled water (50 ml) at room temperature for 20 hr. Analysis of the hydrolysis product by TLC (solvent, ethyl acetate) showed two major peaks in a 1:1 ratio (R_f = 0.36 and 0.45), as well as two minor peaks (R_f = 0.57 and 0.71) (6). The two major compounds were subjected to GC–MS analysis as the Me_3Si derivatives and found to be diastereomeric methyl 9,12,13-trihydroxyoctadecenoates. Their stereochemistry was established in the following way. As was previously shown, e.g., by ^{18}O labeling experiments, hydrolysis of 11,12-epoxy-13-hydroxy-9-octadecenoates into 9,12,13-trihydroxy-10-octadecenoates occurs by solvent attack at C-9, isomerization of the Δ^9 double bond into the Δ^{10} position and opening of the epoxide group (6). Thus, the hydroxyl group at C-13 of the epoxy alcohol does not participate in the hydrolysis and its configuration will remain unchanged in the trihydroxyesters formed (in the present case, *"R"* configuration). Oxidative ozonolysis performed on the CC derivative of the two trihydroxyesters yielded *erythro*-2,3-dihydroxyoctanoic acid. This finding, coupled with the fact that the trihydroxyesters had the *"R"* configuration at C-13, showed that the hydroxyl group at C-12 of the trihydroxyesters had the *"S"* configuration. Oxidative ozonolysis performed on the MC derivative of the two trihydroxyesters yielded the MC derivative of 2*(R)*-hydroxysebacate and 2*(S)*-hydroxysebacate from the more polar and the less polar trihydroxyester, respectively. The two trihydroxyesters could thus be identified as methyl 9*(R)*,12*(S)*,13*(R)*-trihydroxy-10-octadecenoate and methyl 9*(S)*,12*(S)*,13*(R)*-trihydroxy-10-octadecenoate. The former diastereomer, in which the two allylic hydroxyl groups lie on the same side with respect to the plane of the double bond, was the more polar diastereomer, in agreement with results recently obtained with related trihydroxyesters (3,6). The fact that the two major trihydroxyesters obtained from II_{13R} were enantiomeric to the corresponding trihydroxyesters formed by hydrolysis of methyl 11*(S)*,12*(S)*-epoxy-13*(S)*-hydroxy-9*(Z)*-octadecenoate (6) gave further proof for II_{13R} being identical to methyl 11*(R)*,12*(R)*-epoxy-13*(R)*-hydroxy-9*(Z)*-octadecenoate (Fig. 5).

DISCUSSION

Recent experiments showing that trihydroxyeicosatrienoates and trihydroxyoctadecenoates accumulate in the medium of growing cultures of *Saprolegnia parasitica* indicated the presence of a lipoxygenase pathway in this fungus (1). Subsequent studies, in which arachidonic acid was incubated with homogenates of the fungus, led to the identification of a lipoxygenase that catalyzed oxygenation of arachidonic acid into 15*(S)*-HPETE and a hydroperoxide isomerase that catalyzed conversion of the hydroperoxide into two epoxy alcohols (2,3). The mechanism of the latter conversion consisted of an intramolecular epoxidation of either of the two conjugated double bonds by the distal hydroperoxide oxygen and thus differed from that of previously described nonenzymatic and pseudoenzymatic conversions of fatty acid hydroperoxides into epoxy alcohols (10–13).

Parts of the lipoxygenase and hydroperoxide isomerase activities of homogenates of *S. parasitica* remained in the supernatant fraction following centrifugation at 105,000 × *g*. These soluble enzyme activities have been characterized and found to be associated with a common protein having a molecular weight of 145,000–150,000 (14).

In the present study of hydroperoxide isomerase from *S. parasitica* using isomeric hydroperoxyoctadecadienoates as substrates, the particle fraction sedimenting at 105,000 × *g* was used as the enzyme source. This fraction was found to contain the major part (about 80%) of the hydroperoxide isomerase activity present in homogenates of *S. parasitica*. Experiments in which linoleic acid was found to be efficiently converted into epoxy alcohols in the presence of the particle fraction (Fig. 3) showed that this fraction also contained lipoxygenase activity, however, it is not known whether the particle-bound lipoxygenase and hydroperoxide isomerase activities, like the soluble ones, are due to the same protein.

Among the different hydroperoxyoctadecadienoates tested, 13*(S)*-HPOD and 9*(S)*-HPOD both served as good substrates for the particle-bound hydroperoxide isomerase. The product in each case consisted of an α,β-epoxy alcohol, in which the epoxide group had the *trans* configuration, and a γ,δ-epoxy alcohol, in which the epoxide group had the *cis* configuration. The structures and stereochemistry of epoxy alcohols formed from 13*(S)*-HPOD and 9*(S)*-HPOD were analogous to those formed from arachidonic acid (2,3), however, the ratio between α,β- and γ,δ-epoxy alcohols differed. When arachidonic acid and 15*(S)*-HPETE were used as precursors, α,β- and γ,δ-epoxy alcohols were formed in a ratio of 0.5–1:1 (2), whereas the corresponding ratio was 2–3:1 when linoleic acid, 13*(S)*-HPOD and 9*(S)*-HPOD were the precursors.

Incubation of racemic 13-HPOD showed that, in addition to 13*(S)*-HPOD, the unnatural 13*(R)*-hydroperoxy isomer was slowly isomerized by the enzyme. The α,β-epoxy alcohol formed from 13*(R)*-HPOD was identified as 11*(R)*,12*(R)*-epoxy-13*(R)*-hydroxy-9*(Z)*-octadecenoic acid. Stereochemical analysis of α,β-epoxy alcohols formed from 13*(S)*-HPOD, 13*(R)*-HPOD and 9*(S)*-HPOD showed that in each case the configuration of the epoxide group was *R,R*. These results thus indicated that the steric course of the enzymatic epoxidation of the *E* double bond of the substrate was directed by the hydroperoxide isomerase and did not bear any relationship to the position or configuration of the hydroperoxy group of the substrate. The *E,E*-hydroperoxides, 9*(R,S)*- and 13*(R,S)*-hydroperoxy-*E,E*-octadecadienoates, were very poor substrates for the isomerase, indicating that the presence of an *E,Z* conjugated diene structure is an important feature of hydroperoxy acids serving as good substrates for the isomerase.

A number of recent studies indicate the importance of lipoxygenase-derived products for regulation of various cell functions in lower organisms. For example, 10,11,12-trihydroxy-5*(Z)*,8*(Z)*,14*(Z)*,17*(Z)*-eicosatetraenoic acid, a lipoxygenase product derived from 5,8,11,14,17-eicosapentaenoic acid, has been identified as a hatching factor in the barnacle, *Balanus balanoides* (15), and 8*(R)*-HETE in low concentrations has been found to induce starfish

oocyte maturation (16). The existence, in *S. parasitica*, of a lipoxygenase pathway that is in operation during active growth (1) may indicate a role of lipoxygenase products in the regulation of growth and reproduction of the fungus.

Three New and Bioactive Icosanoids from the Temperate Red Marine Alga *Farlowia mollis*

Michele L. Solem, Zhi D. Jiang and William H. Gerwick*
College of Pharmacy, Oregon State University, Corvallis, OR 97331

Three new dihydroxyicosanoids, 12(R),13(R)-dihydroxyicosa-5(Z),8(Z),10(E),14(Z)-tetraenoic acid, 12(R),13(R)-dihydroxyicosa-5(Z),8(Z),10(E),14(Z),17(Z)-pentaenoic acid and 10(R*),11(R*)-dihydroxyoctadeca-6(Z),8(E),12(Z)-trienoic acid, have been isolated from a previously unstudied temperate red marine alga, *Farlowia mollis* (Cryptonemiales, Rhodophyta). The structures of these new metabolites have been deduced from detailed nuclear magnetic resonance and mass spectrometry analyses on stabilized diacetate-methyl esters and stereochemistry deduced by ^{1}H NMR couplings and CD analysis of a dibenzoate derivative. Collectively, these new natural products modulate fMLP-induced superoxide anion generation in human neutrophils, inhibit the conversion of arachidonic acid to lipoxygenase products by human neutrophils, and inhibit the functioning of the dog kidney Na^+/K^+ ATPase.
Lipids 24, 256-260 (1989).

Recently, we have reported on the isolation of several new icosanoids from the red seaweeds *Ptilota filicina, Murrayella periclados* and *Platysiphonia miniata* (1-4). Our continued survey of Oregon seaweeds for new natural products with potential biomedicinal application has now identified another red alga, *Farlowia mollis* (Harv. & Bail.) Farl. & Setch., as a rich source of structurally novel and physiologically active icosanoids. The complete structures of these unstable diols (**1,2,3**) were efficiently solved by application of 2D-nuclear magnetic resonance (NMR) and CD methodologies on stabilized derivatives. Furthermore, a metabolite recently isolated from *P. filicina*, 5(Z),7(E),9(E),14(Z),17(Z)-icosapentaenoic acid, as well as all Z 5,8,11,14,17-icosapentaenoic acid (EPA), were also present in the organic extract of this temperate seaweed.

EXPERIMENTAL METHODS

General. Ultraviolet spectra were recorded on an Aminco DW-2a UV-Vis spectrophotometer and infrared spectra (IR) were recorded on a Nicolet 5 DXB FT 15 spectrophotometer. Circular dichroism was measured on a Jasco 41A spectropolarimeter. NMR spectra were recorded on a Bruker AM 400 NMR spectrometer and all shifts are reported relative to an internal TMS standard. Low resolution mass spectra (LRMS) were obtained on a Varian MAT CH7 spectrometer, whereas high resolution mass spectra (HRMS) were obtained on a Kratos MS 50 TC. High performance liquid chromatography (HPLC) was done using a Waters M-6000 pump, U6K injector and R 401 differential refractometer, whereas thin layer chromatograms (TLC) were made using Merck aluminum-backed TLC sheets (silica gel 60 F_{254}). All solvents were distilled from glass prior to use.

Collection, extraction and isolation. Farlowia mollis was collected from exposed intertidal pools (−0.5 to +0.5 m) at Cape Perpetua on the Oregon coast in August 1986. The seaweed was preserved by freezing until workup, at which time the defrosted alga (103 g dry wt) was homogenized in warm $CHCL_3$/MeOH (2:1, v/v). The mixture was filtered and the solvents were removed *in vacuo* to yield 600 mg of a dark green tar which displayed antibiotic activity to *S. aureus* and *E. coli.* The extract was fractionated by silica gel chromatography in the vacuum mode (10 cm × 9 cm, Merck TLC-grade Kieselgel), and metabolites were progressively eluted with increasingly polar mixtures of isooctane and ethyl acetate. The known compounds, 5(Z),7(E),9(E),14(Z),17(Z)-icosapentaenoic acid and all Z 5,8,11,14,17-icosapentaenoic acid (EPA), eluted in 20-40% EtOAc/isooctane (ca. 2-3% of the lipid extract each) and were identified by comparison of their 400 MHz ^{1}H NMR features with authentic standards. Those eluting with 50% EtOAc/isooctane were a mixture of fatty acids and contained diols **1, 2** and **3**. Treatment of a portion of these fractions with CH_2N_2 afforded a mixture of methyl esters that was subsequently chromatographed on normal phase HPLC (μ-Porasil Z-module, 65% EtOAc/isooctane) which removed residual pigments from the fatty acid mixture. After observations using NMR, the fatty acid mixture was acetylated using excess acetic anhydride/pyridine (1/1) and the resulting mixture was separated by normal phase HPLC (2 × 3.9 mm × 25 mm μ-Porasil, 10% EtOAc/isooctane) to yield 10 mg of **4**, 15 mg of **5** and 4 mg of **6**.

Abbreviations: DMAP, dimethylaminopyridine; EPA, icosapentaenoic acid; SOD, superoxide dismutase; HPLC, high performance liquid chromatography; HRMS, high resolution mass spectra; IR, infrared spectra; LR EIMS, low resolution electron impact mass spectrometry; LRMS, low resolution mass spectra; TLC, thin layer chromatogram.

Methyl 12(R),13(R)-diacetoxy 5(Z),8(Z),10(E),14(Z)-icosatetraenoic acid (4). Compound 4 was a colorless oil showing the following: UV (MeOH) λ_{max} 236 nm (log ε = 4.532); IR ($CHCL_3$) 3022, 3019, 2931, 1734, 1372, 1246, 1222, 1217, 1210, 1026 cm^{-1}; $[\alpha]_D^{25}$ = +2.24° (c = 0.63, CCL_4); low resolution electron impact mass spectrometry (LR EIMS) *m/z* (rel. intensity) 374 (M^+ − AcOH, 9.1), 314 (M^+ − 2 AcOH, 4.4), 265 (26.1), 225 (22.0), 223 (82.7), 205 (36.7), 191 (20.5), 173 (12.8), 169 (22.6), 163 (17.3), 131 (14.5), 127 (62.9), 95 (11.2), 91 (14.4), 83 (15.3), 81 (23.3), 79 (16.6), 67 (20.2), 57 (20.2), 55 (20.6), 43 (100); HR EIMS *m/z* obs. 374.24768 (M^+ − AcOH, $C_{23}H_{34}O_4$ requires 374.24757; for ^1H NMR and ^{13}C NMR data see Table 1.

Methyl 12(R),13(R)-diacetoxy-5(Z),8(Z),10(E),14(Z),17(Z)-icosapentaenoic acid (5). Compound 5 was also isolated as a colorless oil and showed UV (MeOH) λ_{max} 236 nm (log ε = 4.432); IR ($CHCL_3$) 3020, 2965, 2955, 1734, 1434, 1372, 1223, 1220, 1208, 1025 cm^{-1}; $[\alpha]_D^{25}$ = +3.72° (c = 1.13, CCL_4); LR EIMS *m/z* (rel. intensity) 372 (M^+ − AcOH, 6.6), 312 (M^+ − 2AcOH, 4.7), 265 (29.6), 237 (17.0), 224 (15.5), 223 (100), 205 (48.8), 191 (28.0), 173 (21.0), 163 (28.6), 147 (13.7), 145 (20.2), 141 (16.6), 135 (10.1), 131 (28.9), 129 (11.9), 125 (32.5), 121 (13.2), 109 (14.7), 107 (93.0), 105 (19.0), 97 (10.1), 95 (24.0), 93 (20.3), 91 (36.3), 83 (22.8), 81 (35.0), 80 (12.5), 79 (53.2), 77 (13.2), 71 (16.3), 69 (15.6), 59 (13.1), 57 (20.3), 55 (37.1); for ^1H NMR and ^{13}C NMR data see Table 1.

Methyl 10(R),11(R*)-diacetoxy 6(Z),8(E),12(Z)-octadecatrienoic acid (6).* Compound 6 was also isolated as a colorless oil showing the following: UV (MeOH) λ_{max} 234 nm (log ε = 4.224); IR (neat) 3014, 2954, 2930, 2858, 1742, 1457, 1437, 1371, 1241, 1226, 1168, 1114, 1026 cm^{-1}; LR EIMS *m/z* (rel. intensity) 348 (M^+ − AcOH, 13.5), 239 (25.4), 237 (10.7), 223 (15.9), 198 (14.6), 197 (73.5), 180 (12.5), 179 (100), 169 (24.4), 165 (62.4), 147 (25.0), 137 (10.8), 127 (63.1), 119 (19.4), 109 (21.1), 107 (13.7), 105 (11.7), 95 (10.8), 93 (10.6), 91 (14.6), 83 (10.8), 81 (22.4), 79 (14.3), 67 (18.9), 57 (19.4), 55 (16.9), 43 (78.9); for ^1H NMR and ^{13}C NMR data see Table 1.

Formation of methyl 12(R),13(R)-bis(p-nitrobenzoyl)-5(Z),8(Z),10(E),14(Z),17(Z)-icosapentaenoic acid (7) from diol 2. A portion of crude extract (1.2 g) was treated with CH_2N_2 and chromatographed over silica gel in the vacuum mode (EtOAc/isooctane). Fraction 3 (30% EtOAc/isooctane) contained mainly methyl ester derivatives of diols 1-3 and was refluxed overnight with p-nitrobenzoyl chloride in CH_2Cl_2 and pyridine (1:1) with catalytic amounts of dimethylaminopyridine (DMAP). The reaction was terminated with the addition of ice and then H_2O and the products extracted with Et_2O. The Et_2O was sequentially washed with portions of saturated $NaHCO_3$ (2 × 25 ml), 5% HCl (2 × 25 ml), and H_2O (1 × 25 ml). A rapid vacuum chromatography of this material gave a fraction enriched in 7, which was further purified over HPLC (Alltech RSIL 10 μ 50 cm × 10 mm, 15% EtOAc/isooctane, 1.3 mg). Pure derivative 7 showed the following: UV (MeOH) λ_{max} = 240 nm (log ε = 4.874); $[\alpha]_D^{25}$ = +21.0° (MeOH); CD (MeOH) $\Delta\varepsilon$ = −19.8, +34.6 (λ_{max} = 235, 256 nm); ^1H NMR (bz-d-6, 400 MHz) δ 0.97 (t, 3H, J = 7.7 Hz, $C\underline{H}_3CH_2$-), 1.70 (p, 2H, J = 7.4 Hz), 2.09 (m, 4H), 2.31 (t, 2H, J = 7.4 Hz), 2.93 (t, 2H, J = 6.9 Hz), 3.03 (bt, 2H, J = 6 Hz), 3.66 (s, 3H), 5.30-5.49 (m, 5H), 5.52 (m, 3H), 5.88 (dd, 1H, J = 3.8, 8.2 Hz), 6.03 (t, 1H, J = 11.0 Hz), 6.17 (dd, 1H, J = 3.8, 9.5 Hz), 6.80 (dd, 1H, J = 14.7, 11.0 Hz), 8.16 (d, 2H, J = 8.7 Hz, Ar-$\underline{H}$), 8.18 (d, 2H, J = 8.0, Hz, Ar-$\underline{H}$), 8.28 (d, 2H, J = 8.7 Hz, Ar-$\underline{H}$), 8.30 (d, 2H, J = 8.0 Hz, Ar-$\underline{H}$).

Evaluation of superoxide anion production by human neutrophils stimulated with the diols 1-3. Ca. 150 to 200 ml of whole blood (ACD anticoagulant) was drawn from various donors by certified members of the Red Cross or Good Samaritan Hospital (Corvallis, Oregon). The blood was immediately subjected to dextran precipitation (6% Dextran, M.W. = 70,000, Pharmacia). Ca. 60 ml of whole blood were mixed with 40 ml 6% Dextran, and the cells were allowed to stand for 1 hr, undisturbed, in a 100-ml plastic graduated cylinder. After this time, most of the RBCs had settled to the bottom leaving a straw-colored leukocyte-rich plasma on top. This plasma was drawn off and centrifuged at 120 × *g* for 20 min at 4°C. The supernatant was discarded, and the cells were shocked with ice-cold distilled H_2O (ca. 10% the volume of the original plasma suspension), and after 30 sec their isotonicity restored by the addition of 0.6 M NaCl (33% the volume of added H_2O. The cells were washed with PBS (Sigma, w/o Ca^{+2}), and then subjected to a discontinuous gradient centrifugation using Ficoll-Paque (Pharmacia). Ca. 3×10^7 cells in 8 ml PBS were layered onto 4 ml Ficoll-Paque in a 15-ml glass centrifuge tube and then centrifuged at 250 × *g* for 20 min at 4°C. The pellet of cells at the bottom of the tube contained ca. 99% PMNLs by microscopic examination. These cells were washed with PBS and then resuspended using Hank's buffered saline solution (Sigma, with Ca^{+2}, w/o phenol red (HBSS)) at a concentration of 6.0×10^6 cells/ml (5). The cells were counted using a hemocytometer and their viability (>95% for all assays) determined using a trypan blue (0.5% in PBS) exclusion assay in which only damaged cells take up the dye.

The following protocol was used to measure the production of superoxide anion by isolated human neutrophils (6,7). Isolated neutrophils (1-2 hr old, 3-4 × 10^6/0.5 ml Hank's buffered saline solution (HBSS)) were incubated for 10 min at 37°C. Cytochalasin B (5 μg/ml) was added to the cells and the mixture was incubated for 3 min, or if no cytochalasin B was used, the incubation time of 3 min was maintained. Test lipids (0.10-10 μM) were then added to the cells, and the mixture was incubated at 37°C for 2 min. Cytochrome C was then added to the mixture (final conc. 10 mM in HBSS), and followed immediately by fMLP or LTB_4, if they were to be tested. The final assay volume of 2.0 ml was then incubated at 37°C for 15 min and then stopped by the addition of 10 μl of superoxide dismutase (1 mg/0.3 ml HBSS). The cells were pelleted by centrifugation (200 × *g* for 10 min) and the supernatant was measured for absorbances between 500-570 nm (reduced cytochrome C λ_{max} = 550 nm). Blanks were used to obtain baseline values and controls produced by the addition of 10 μl of superoxide dismutase (SOD) before cytochalasin B, fMLP or LTB_4 were added to the cells.

RESULTS AND DISCUSSION

The temperate red alga *Farlowia mollis* was originally collected in our survey efforts from the Oregon coast in 1986 and the lipid extract showed antimicrobial activity to

several human pathogens and the occurrence of potentially novel compounds by TLC (blue char upon acidification at 0.13 R_f). Furthermore, the crude extract of *F. mollis* displayed good inhibitory activity to dog kidney Na^+/K^+ ATPase (IC_{50} = 38 μg/ml) and hog gastric mucosa H^+/K^+ ATPase (IC_{50} = 9.4 γ/ml). Thus, larger collections were made in August 1986, May 1987 and June 1987, all of which contained the same unusual appearing blue-charring compounds. Bioautography against *E. coli* indicated that polar compounds in the extract were responsible for the antimicrobial activity. Hence, the material collected in August of 1986 was vacuum chromatographed over silica gel to rapidly yield mixtures enriched in these polar blue-charring diols (1–3).

In order to stabilize and more easily separate compounds 1-3, they were first treated with CH_2N_2 and later with acetic anhydride in pyridine, to produce diacetate-methyl ester derivatives. This mixture of derivatives was then easily separated by HPLC to yield (in order of their polarity) a purple-charring compound, (4), a blue-charring compound, (5), and a grey-blue-charring compound, (6).

The diacetate-methyl ester derivative of 4 was a colorless and optically active oil which gave a measurable M^+ − acetate peak by HR EIMS affording a molecular formula of $C_{25}H_{38}O_6$ (7° unsaturation). The IR spectrum for 4 showed an intense carbonyl stretch for multiple esters ($\gamma_{C=0}$ = 1734 cm^{-1}), the protonic consequences of which were readily observed in the ^1H NMR (Table 1) and defined two acetates and one methyl ester. By ^{13}C NMR, the remaining four degrees of unsaturation presented as olefinic bonds (Table 1), and two of these formed a conjugated system (λ_{max} = 236 nm).

The overall structure of derivative 4 was readily approachable by ^1H-^1H COSY experiments and lead to the generation of two partial structures which accounted for all of the atoms in the molecule. The first partial structure began with a sharp 2H triplet at δ 2.09, which was readily identified from comparisons with model compounds as belonging to the C-2 protons of a fatty acid, in this case in the form of a methyl ester. Sequential correlations between these C-2 protons and those at C-3, C-4 and C-5 defined a normal Δ 5 unsaturated fatty acid (Table 1). The other proton of the Δ 5 olefin was located at δ 5.29 and was additionally correlated to a bisallylic methylene at δ 2.78 (H_2-7). The C-7 methylene was a triplet and was therefore coupled to one other proton, located at δ 5.38 from the COSY experiment. The C-8 proton was coupled by 11.0 Hz to its olefin partner (δ 5.98) and, thus, defined a *cis* geometry for this double bond. This latter proton was coupled to another olefin proton at δ 6.83 (H-10), which in turn was correlated to its olefin partner (δ 5.78, H-11) by 15.0 Hz and, therefore, was of

trans geometry. The H-11 proton was coupled to a proton α to an acetate located at δ 5.87 (H-12, 75.58 ppm from HETCOR) and this was adjacent to another such α-acetoxy proton at δ 6.20 (H-13, 70.61 ppm). This partial structure terminated with a correlation between the H-13 proton and a two proton olefin multiplet at δ 5.59 (H-14,15).

The second partial structure in derivative 4 began with a poorly defined methyl triplet at δ 0.86 which showed correlations to a 4H multiplet at δ 1.23 (H_2-19, H_2-18). The multiplet was further coupled to a 2H multiplet at δ 1.29 (H_2-17), itself correlated to an allylic doublet of triplets at δ 2.22 (H_2-16). Finally, this latter band was also correlated to the 2H olefin multiplet at δ 5.59 (H-15,14).

Combination of these spin system-derived partial structures accounted for all of the atoms in the molecule and could be put together in only a single manner, thus giving the constitutive structure for diol 4. The stereochemistry of the C5-6 olefin was given by the ^{13}C NMR chemical shift of the adjacent *bis*-allylic methylene. A value of δ 26.43 for this carbon atom (assigned from the HETCOR experiment) defines both adjacent olefins as possessing Z stereochemistries (8,9). Similarly, the shift of δ 28.40 for C-16 defines a Z stereochemistry for the C14-15 olefin. The relative configurations at C-12 and C-13 were defined as threo from the diagnostic couplings (J = 3.7 Hz) between these protons (see discussion which follows for 5) (10). The absolute stereochemistry was deduced as 12R, 13R by virtue of this threo relationship and the comparable optical rotations of derivatives 4 and 5. Determination of the absolute stereochemistry of diol 2 and, thus, of derivative 5, was by CD as will be discussed. Hence, the structure of diol 1 was deduced as 12(R),13(R)-dihydroxyicosa-5(Z),8(Z),10(E),14(Z)-tetraenoic acid.

The spectroscopic features (IR, UV, optical rotation and NMR) of the diacetate-methyl ester derivative 5 were similar to those obtained for the same derivative of diol 4 (Table 1). Further, the LR EIMS of derivative 5 showed a highly analogous pattern of cleavage relative to compound 4. However, several significant peaks (i.e., M+ − HOAc) in the mass spectrum of 5 were 2 amu units less than in 4 and indicated that it contained an additional olefin. All of the proton and carbon resonances ascribable to protons and carbons at C-1 through C-15 were nearly identical in compounds 4 and 5. However, two additional olefin resonances and one additional *bis*-allylic methylene resonance were observed in the ^1H NMR spectrum of derivative 5 relative to derivative 4. Further, the terminal methyl group was slightly further down field and was coupled to an allylic methylene at C-19, positioning the new olefin between C-17 and C-18. This olefin was of the Z stereochemistry as revealed by characteristic carbon shifts of δ 26.75 for C-16 and δ 20.88 for C-19 (1,8,9).

In a simple diol such as 5 (i.e., without the confounding effects of 1–3 interactions from additional substituents at C-10, C-11, C-14 or C-15), the C-12-C-13 rotomer with antioriented alkyl groups will predominate as the lowest energy conformation (10). Hence, a threo arrangement between protons at C-12 and C-13 was indicated by measurement of a diagnostically small coupling constant (J = 3.8 Hz) (10). The *bis*-(p-nitrobenzoate) derivative 7 showed a bisignate CD curve with a positive maximum at 256 nm and a negative maximum at 235 nm and, thus, could be assigned to heterochromophoric exciton coupling between the C-8 to C-11 diene and p-nitrobenzoate at C-12 (11,12). This positive split Cotton effect indicates a right-hand screwness between these groups and defines the stereochemistry at 12 as R (12–15). The 12R, 13R stereoisomer is the only one consistent with (a) the threo arrangement of protons at C-12 and C-13, (b) the anti arrangement of alkyl chains and (c) a righthand screwness between benzoate and diene chromophores (Fig. 1). Hence, diol 2 was the ω-3 analog of compound 1, or 12(R),13(R)-dihydroxyicosa-5(Z),8(Z),10(E),14(Z),17(Z)-pentaenoic acid. The R stereochemistry at C-12 correlates to the same relative arrangement of atoms as found in 12-(S)-HETE and 12-(S)-HEPE, hydroxyicosanoids we have recently isolated from other red marine algae (3,4).

Derivative 6 of diol 3 was isolated from related chromatography fractions and again showed very similar spectroscopic (IR, UV, LR EIMS and NMR) features to derivatives 4 and 5. The mass spectrum of 6 gave analogous peaks as for 4, however, they occurred at 26 amu lower, indicating that it was derived from an 18-carbon fatty acid. Derivative 6 showed nearly identical ^1H and ^{13}C NMR bands for atoms at C-6 to C-18, as assigned to C-8 to C-20 in derivative 4 (Table 1). From ^1H-^1H COSY data, sequential correlations were observed between methylene groups at C-2 to C-5, as well as a correlation from H_2-5 to an olefin proton at δ 5.31 (C-6). Although the threo relative stereochemical relationship between protons at C-12 and C-13 was intact in 6 (J = 3.7), correlation to the absolute stereochemistry in

derivative 5 was precluded as the compound decomposed before rotational data could be recorded. Hence, 3 was an 18-carbon analog (10(R*),11(R*)-dihydroxyoctadeca-6(Z),8(E),12(Z)-trienoic acid) of diol 1, in which the olefin and hydroxy functionalities were in the same positions in the two compounds relative to their methyl termini.

A mixture of diols 1 and 2 (1:1.5) were evaluated for several pharmacological properties expected in analogs of leukotriene, lipoxin and diHETE-type natural products. In Table 2, values are reported for the production of superoxide anion by human neutrophils stimulated under various experimental conditions. The mixture appears to be a weak primary stimulator of superoxide anion production. However, at 10^{-5} M, it inhibited fMLP-stimulated superoxide anion production in ranges between 15% and 34% of control values for three donors. This inhibitory activity is comparable with the activities of the prostaglandins PGE_1 and PGI_2 at equivalent concentrations (7).

The 1:1.5 mixture of diols 1 and 2 showed weak activity in preliminary testing for inhibition of 5-lipoxygenase activity in A23187-stimulated human polymorphonuclear leukocytes (38% inhibition at 10^{-4} M). Other dihydroxy-icosanoids are known inhibitors of lipoxygenase activity (16). Further, the mixture was only moderately inhibitory to the dog kidney Na^+/K^+ ATPase preparation (54% inhibition at 10^{-4} M, 35% at 10^{-5} M).

ACKNOWLEDGMENTS

We thank Rodger Kohnert for help in obtaining NMR data on the OSU Department of Chemistry's Bruker AM 400 spectrometer, purchased in part through grants from the National Science Foundation (CHE-8216190) and the M. J. Murdock Charitable Trust. Brian Arbogast and Don Griffin helped with low and high resolution mass spectra at the mass spectral facility in the OSU College of Agricultural Chemistry. The high resolution instrument, a Kratos MS 50 TC, was purchased with grants from the National Institutes of Health Division of Resources (DRR 1S10RR01409). We thank David Waterbury and Krishna Murthy of Syntex Research for running ATPase and lipoxygenase inhibition assays, respectively. This work was supported by the Oregon Sea Grant Program (R/PD-51).

Polyunsaturated Fatty Acid Changes Suggesting a New Enzymatic Defect in Zellweger Syndrome

Manuela Martinez*
Autonomous University of Barcelona, School of Medicine, Hospital Infantil Vall d'Hebron, 08035 Barcelona, Spain

The fatty acid composition of red blood cells, fibroblasts, forebrain, liver and kidney were studied in a 3-month-old infant who died from Zellweger Syndrome, and the results were compared with those of age-matched controls. Besides a typical increase in the very long chain fatty acids 26:0 and 26:1 and a great reduction in the plasmalogen levels, confirming the diagnosis of Zellweger Syndrome, some striking changes in the polyunsaturated fatty acid patterns were discovered. The most important was a very drastic decrease in the values of 22:6ω3 and 22:5ω6, the two products of Δ4-desaturation. In the kidney, the level of 22:6ω3 fell below that of 26:0. Consequently, the ratio 26:0/22:6ω3 (and 26:1/22:6ω3) was most useful in emphasizing the fatty acid anomalies, especially in renal tissue, where the 26:0/22:6ω3 ratio increased to almost 200 times the normal values. Other significant, although less consistent fatty acid alterations were increases in 18:2ω6, 18:3ω6, 20:3ω6, 18:4ω3 and 20:4ω3, and a decrease in 20:4ω6 in some tissues. The existence is proposed of a new enzyme defect in peroxisomal disorders, involving the desaturase system of long chain polyunsaturated fatty acids.
Lipids 24, 261-265 (1989).

Zellweger Syndrome is a rapidly progressive, rare hereditary disorder that involves the central nervous system, liver, kidney and bones. Affected patients die within the first months of life with severe nervous system dysfunction. A total absence of peroxisomes in hepatocytes and renal proximal tubules has been reported (1) in these patients, in association with severe defects in certain enzymes known to be located in peroxisomes. These include the long chain fatty acid β-oxidation system and dihydroxyacetone phosphate acyltransferase (EC 2.3.1.42), a crucial enzyme in plasmalogen synthesis (2). As a result of these enzyme defects, an accumulation of very long chain fatty acids (3) and a drastic decrease in plasmalogen concentration (4) have been described in tissues of Zellweger patients. No other anomalies in the fatty acid composition of affected tissues have been reported, and no data exist for the polyunsaturated fatty acid (PUFA) patterns of any of the affected tissues (See references 5-7 for recent reviews on the subject.).

This paper reports some hitherto undescribed, very significant changes in the PUFA composition of tissues from a patient with Zellweger syndrome. A preliminary account of this work has appeared elsewhere (8).

Abbreivations: BHT, butyl hydroxytoluene; DMA, dimethyl acetal; EFA, essential fatty acid; EP, ethanolamine plasmalogen; FAME, fatty acid methyl ester; GPC, glycerophosphocholine; GPE, glycerophosphoethanolamine; GPL, glycerophospholipid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PUFA, polyunsaturated fatty acid; FID, flame ionization detector; GLC, gas liquid chromatography; TLC, thin layer chromatography.

MATERIALS AND METHODS

A 2-month-old infant with Zellweger syndrome was studied for the total fatty acid and plasmalogen composition of plasma, red blood cells and cultured fibroblasts. The neurological picture and the X-ray findings were typical of the disease. Biochemically, the patient could be diagnosed in vivo by significant increases in the ratios 26:0/22:0 and 26:1/22:0, most marked in fibroblasts, and by important decreases in total plasmalogens and in the 18:0 dimethyl acetal/methyl stearate ratio and 16:0 dimethyl acetal/methyl palmitate ratio, mainly in red blood cells. After death, which occurred at 3 months of age, the fatty acid and plasmalogen composition of the patient's cerebrum, liver and kidney were studied. The cerebrum, liver and kidney of 5 control infants, neurologically normal and with ages ranging from 30 prenatal weeks to 7 postnatal months, were also studied. Total forebrain homogenates were generally used, but in addition, the cerebral cortices of the patient and one of the controls were studied. The bodies were refrigerated at 4°C immediately after death, and autopsy was carried out within 24 hr postmortem.

All the solvents were of highest commercial quality (Merck, Darmstadt, West Germany) and contained 50 mg/l of butyl hydroxy toluene (BHT) (Fluka, Buchs, Switzerland) to prevent lipoperoxidation. In order to study the total fatty acid and plasmalogen composition of tissues, the fatty acid methyl esters (FAME) and aldehyde dimethyl acetals (DMA) of all the samples (about 100 mg of tissues and packed red blood cells or 1 mg of protein, in the case of fibroblasts) were obtained by direct transesterification without lipid extraction, according to the method of Lepage and Roy (9). Suitable amounts of 13:0 and 19:0 (500 μg for tissues, 100 μg for packed erythrocytes and 50 μg for fibroblasts) were added before transesterification, as internal standards.

Given the enormous alterations found in the total fatty acid patterns, the fatty acid composition of ethanolamine and choline glycerophospholipids was also studied. Total lipids were extracted with 20 volumes of chloroform/methanol/water (50:50:15, v/v/v), and separated into neutral and acidic lipids by DEAE-Sephadex column chromatography (10). Ethanolamine and choline glycerophospholipids (from 15 μg of lipid phosphorus) were separated by thin layer chromatography (TLC) from neutral lipids, with chloroform/methanol/water (60:25:4, v/v/v) as the solvent system. The spots were made visible with bromothymol blue, scraped off, transferred to methanolysis tubes (Corning, New York, NY) and transesterified by the same method (9), after addition of 50 μg of 13:0 and 19:0.

The FAME and DMA were separated by capillary column gas-liquid chromatography (GLC). A Hewlett-Packard 5890 gas chromatograph was used, equipped with a 30 m long, 0.25 mm i.d., SP-2330 fused silica capillary column (Supelco, Bellefonte, PA) and flame ionization detectors (FID). A two-step temperature program was used (140-180°C, at 4°C/min; 180-210°C, at

2°C/min) in order to optimize separation of all the peaks. This program allowed a very clean separation of 26:0 and 26:1 from the two artifactual peaks coming from cholesterol esters (marked 1 and 2 in Fig. 1), without the need for using TLC for methyl ester purification, a step that always leads to losses of PUFA. The carrier gas was helium, at a column pressure of 17 psi (flow rate, about 1 ml/min), and the split ratio varied between 10:1 and 50:1, depending on the amount of FAME injected. Injector and detector temperatures were 200°C and 220°C, respectively.

Identification of the peaks was carried out by comparison with authentic standards, whenever possible, and/or with mixtures of known fatty acid and aldehyde composition. Otherwise, fatty acids were identified by the equivalent chain length approach (11). The peak areas were measured with a Hitachi D-2000 integrator (Hitachi, Ltd., Tokyo, Japan) and quantitated on a molar basis. Because nanomoles of DMA directly gave nanomoles of alkenyl-acyl compounds (plasmalogens), the figures for FAME and DMA were used to calculate the absolute amounts of the corresponding diacyl glycerophospholipids (GPL), phosphatidylethanolamine (PE) and phosphatidylcholine (PC), by using the following formula:

$$\text{nmol of diacyl GPL (PE or PC)} = \frac{\text{nmol FAME} - \text{nmol DMA}}{2}$$

All computations and statistical analyses were carried out with a Compucorp electronic calculator-programmer, Model 445 Statistician (Computer Design Corp., Los Angeles, CA). The values for grouped data were the means ± SEM.

RESULTS

Tables 1 and 2 show the total fatty acid and plasmalogen composition, respectively, of the tissues and cells studied in absolute, quantitative terms. The decreases in total plasmalogens and in the 16:0 dimethyl acetal/palmitic acid (16DMA/16:0) ratio and the 18:0 dimethyl acetal/stearic acid (18DMA/18:0) ratio were evident in all samples, especially in the kidney and red blood cells, whereas the increase in the very long chain fatty acids 26:0 and 26:1 was most pronounced in fibroblasts and

Control values are means ± SEM.

kidney. The most striking and consistent finding, however, was a drastic decrease in the amount of 22:6ω3 (docosahexaenoic acid), as well as 22:5ω6 (docosapentaenoic acid), particularly in the kidney and liver. The decrease in docosahexaenoic acid in renal tissue was such that it fell below that of cerotic acid (26:0), as could be seen by just looking at the chromatogram (Fig. 1). This inversion of the normal situation—in which 26:0 is only a trace constituent at that age, whereas 22:6ω3 accounts for about 2% of the kidney total fatty acids—was much emphasized by using the ratio 26:0/22:6ω3. In all tissues, the ratio 26:0/22:6ω3 (and 26:1/22:6ω3) is normally much less than 0.1, whereas in the patient's kidney, this ratio was 5.3.

The ratios 22:6ω3/22:5ω3 and 22:5ω6/22:4ω6 were clearly decreased in the tissues studied, indicating that the desaturation reactions 22:5ω3 → 22:6ω3 and 22:4ω6 → 22:5ω6 were probably defective in the patient. To a lesser extent, the reactions 20:3ω6 → 20:4ω6 and 20:4ω3 → 20:5ω3 were also diminished in most tissues, as indicated by a decreased 20:4ω6/20:3ω6 ratio, mainly in erythrocytes, and by an augmentation of the minor component, 20:4ω3, in the forebrain and kidney. The main constituent of the ω6 series, arachidonic acid (20:4ω6), was within normal limits in the cerebrum and slightly decreased in erythrocytes, liver and kidney. The parent ω6 fatty acid, linoleic acid (18:2ω6), was very significantly increased in the forebrain and red blood cells; and the minor precursor, 18:3ω6, was only slightly increased in erythrocytes. The trace ω3 precursor, 18:4ω3, was significantly increased in the cerebrum. These small changes suggest that the elongation of fatty acids may also be slightly impaired in some tissues. The two minor ω9 fatty acids, 20:1ω9 and 20:3ω9, tended to increase in most tissues, but only significantly in the forebrain. It is worthwhile noticing that fibroblasts were almost normal in PUFA composition, although the two ratios, 22:6ω3/22:5ω3 and 22:5ω6/22:4ω6, were significantly decreased in the Zellweger fibroblasts compared with controls.

Figure 2 shows the absolute values of glycerophosphoethanolamines (GPE) and glycerophosphocholines (GPC) in the cerebral cortex, liver and kidney of the patient compared with a control. This figure shows that there was no decrease in the absolute amounts of the major two

phospholipids of the patient, but rather an increase. In agreement with data by Heyman et al. (4), the diacyl glycerophosphoethanolamines (GPE) were increased in the Zellweger patient, in contrast to the drastic decrease in alkenylacyl glycerophosphoethanolamines, the ethanolamine plasmalogens (EP).

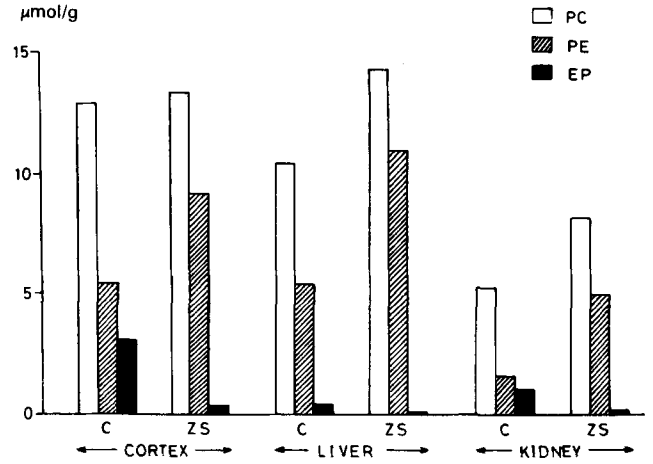

FIG. 2. Absolute amounts of phosphatidylcholine (PC), phosphatidylethanolamine (PE) and ethanolamine plasmalogen (EP) in the cerebral cortex, liver and kidney of the infant with Zellweger Syndrome (ZS), compared with a neurologically normal control (C).

Tables 3 and 4 show the fatty acid patterns of GPE and GPC, respectively, in the three tissues studied, expressed as molar percentages. Again, a very important decrease in the two long chain PUFA, 22:6ω3 and 22:5ω6, can be discerned as the major change in both phosphoglycerides. It can also be seen that the proportion of linoleic acid was significantly increased in GPE of all three tissues. In GPC, the increase in 18:2ω6 was only significant in the cerebrum and liver. The proportion of 20:4ω6 was very significantly decreased in cerebral and renal GPC.

DISCUSSION

The marked decrease in the tissue levels of the two long chain PUFA, 22:6ω3 and 22:5ω6, as reported in this paper, has not been described before in reference to Zellweger Syndrome and simply cannot be explained by an altered distribution and/or a decrease in the lipid content of tissues. Figure 2 shows that the total levels of ethanolamine and choline glycerophospholipids were not decreased in the patient, and the normal amount of total fatty acids excludes any significant loss of lipids, such as is found in PUFA lipidosis (12). Although the total amount of GPE was not decreased in the patient, this very unsaturated phospholipid was remarkably poor in 22:6ω3 and 22:5ω6—a finding consistent with a defect in the synthesis of these two fatty acids.

A dietary effect on the PUFA patterns can be excluded, because even in the most extreme cases of essential fatty acid (EFA) deficiency or imbalance, the proportion of 22:6ω3 never decreases below 50% of the normal values (13,14). The patient had been fed since birth with maternal milk and commercial milk formulas with ω3/ω6 ratios ranging from 1:10 to 1:26. Although these low ω3/ω6 ratios could partly explain the increase in 18:2ω6 and the decrease in 20:4ω6 in some tissues, they could never explain a reduction in the absolute amount of 22:6ω3 by a factor of almost 20 in the liver and kidney and by a factor of 4 in the brain, leading to extremely low proportions of docosahexaenoate in GPE of all tissues. The triene fatty acid, 20:3ω9—a marker for EFA deficiency (15)—

ZS, Zellweger Syndrome. The values are molar percentage (mean ± SEM). Other fatty acids, present in small proportions (16:1ω9, 20:1ω9, etc.) have been omitted from this table but were included in the percentage computation. There wre only trace amounts of 18:3ω3 and the minor precursor 18:4ω3 was present only in the cerebrum of the Zellweger patient, accounting for 0.6% of GPE fatty acids.

ZS, Zellweger Syndrome. The values are molar percentage (mean ± SEM). Only the main fatty acids are listed in this table.

was significantly increased only in the brain, and was within normal limits in the liver and kidney, especially in GPC. Furthermore, it must be taken into account that 20:3ω9 not only increases in EFA deficiency but is higher in the immature than in the mature human brain (16), and it could also be higher in the cerebrum of a patient with a disease producing mental retardation. Last and most

important, the pentaene fatty acid, 22:5ω6—the other product of Δ4-desaturation, together with 22:6ω3—is known to increase in ω3 deficiency (17). However, in the Zellweger patient this fatty acid was, like 22:6ω3, far below normal.

Therefore, the enormous decrease in the two products of Δ4-desaturation, 22:6ω3 and 22:5ω6, found in the Zellweger patient very strongly suggests a Δ4-desaturase defect in this infant. The existence of an enzyme defect in the long chain PUFA desaturase system in a peroxisomal disorder would be consistent with the view that peroxisomes are derived from the endoplasmic reticulum (18). In this connection, it is interesting to point out that smooth endoplasmic reticulum was reported to be very scarce in the original description of peroxisomal defects in Zellweger patients by Goldfischer et al. (1). However, more recent studies have failed to reveal true connections between peroxisomes and endoplasmic reticulum (19), and the polypeptide compositions of these two organelles seem to be substantially different (20). The endoplasmic reticulum anomalies originally described (1) have not been considered a generalized finding in Zellweger Syndrome. Therefore, should the present data be substantiated by enzyme studies, it is probably better to assume that Δ4-desaturase is simply one of the many enzymes that are being considered genuinely peroxisomal.

The fact that the PUFA composition of fibroblasts was nearly normal in the patient deserves some comment and must be further investigated in other patients with Zellweger Syndrome. It must be taken into account that fibroblasts are ex vivo cells, cultured in an artificial medium, and this could partly account for the difference compared with in vivo grown tissues. Cultured cells preferentially use preformed fatty acids (21,22), and fetal bovine serum is relatively rich in 22:6ω3 and 22:5ω3 (23,24), so the exogenous PUFA in the medium could partly mask the enzyme defect. In these conditions, Zellweger fibroblasts, which seem to contain some peroxisomes (25), could display a PUFA composition much nearer the normal than the more severely affected tissues grown in vivo.

Although only one case has been studied so far, the significance of the reported findings is such that it urges investigators of peroxisomal disorders to study the desaturase system in these patients. If confirmed, the existence of the proposed Δ4-desaturase defect would greatly contribute to understanding the pathogenesis of Zellweger Syndrome. Indeed, so drastic a decrease in the long chain PUFA docosahexaenoic acid, a fatty acid mainly enriched in synaptic membranes and the retina, might explain the mental deterioration and visual impairment in Zellweger syndrome, especially when such a decrease cannot be compensated for by any increase in the other long chain PUFA, 22:5ω6.

ACKNOWLEDGMENTS

I thank Ann B. Moser for showing me her techniques for the study of very long chain fatty acids. I also thank Isabel Lorente for providing useful information and the tissues from her patient; Carmen Dominguez for culturing fibroblasts for the study; and Carmen Navarro for helping with the neuropathological diagnosis.

[Received September 27, 1988; Revision accepted November 28, 1988]

Fish Oil Prevents Change In Arachidonic Acid and Cholesterol Content in Rat Caused by Dietary Cholesterol

M.L. Garg, A. Wierzbicki, M. Keelan, A.B.R. Thomson and M.T. Clandinin*
Nutrition and Metabolism Research Group, Department of Foods & Nutrition and Medicine, Division of Gastroenterology, 533 Newton Research Building, University of Alberta, Edmonton, Alberta, Canada T6G 2C2

Rats were fed diets high in either saturated fat (beef tallow) or α-linolenic acid (linseed oil) or eicosapentaenoic and docosahexaenoic acids (fish oil) with or without 2% cholesterol supplementation. Consumption of linseed oil and fish oil diets for 28 days lowered arachidonic acid content of plasma, liver and heart phospholipids. Addition of 2% cholesterol to diets containing beef tallow or linseed oil lowered 20:4ω6 levels but failed to reduce 20:4ω6 levels when fed in combination with fish oil. Feeding ω3 fatty acids lowered plasma cholesterol levels. Addition of 2% cholesterol to the beef tallow or linseed oil diet increased plasma cholesterol concentrations but not when fish oil was fed. Feeding the fish oil diet reduced the cholesterol content of liver, whereas feeding the linseed oil diet did not. Dietary cholesterol supplementation elevated the cholesterol concentration in liver in the order: linseed oil > beef tallow > fish oil (8.6-, 5.5-, 2.6-fold, respectively). Feeding fish oil and cholesterol apparently reduced 20:4ω6 levels in plasma and tissue lipids. Fish oil accentuates the 20:4ω6 lowering effect of dietary cholesterol and appears to prevent accumulation of cholesterol in plasma and tissue lipids under a high dietary load of cholesterol.
Lipids 24, 266-270 (1989).

Consumption of marine oils rich in eicosapentaenoic (20:5ω3) and docosahexaenoic (22:6ω3) acids decreases plasma levels of cholesterol and triacylglycerols in healthy (1-3) and hyperlipidemic subjects (4-6). While the hypotriglyceridemic effect of fish oil exceeds the capacity of most available drugs, the hypocholesterolemic effects are still doubtful except when the excess cholesterol is present in very low density lipoprotein (4,5). Consumption of fish oil also lowers serum levels of thromboxane (TxA_2) and thus has anti-aggregatory effects on the manifestation of thrombosis (7-9). While the exact mechanisms for the fish oil-induced decrease in plasma lipid levels are not clear, the platelet anti-aggregatory effect is most likely mediated via changes in the balance of eicosanoids formed from their common precursor, arachidonic acid (20:4ω6) (7-9). Arachidonic acid is usually prsent in the SN-2 position of membrane phospholipids (10). Eicosapentaenoic acid present in fish oil competes with 20:4ω6 for incorporation into phospholipid (11,12) and subsequently competes with 20:4ω6 at the level of cyclo-oxygenase (13) in the formation of eicosanoids such as prostacyclin, prostaglandins, thromboxane and leukotrienes. In a recent study we demonstrated that fish oil reduces synthesis of 20:4ω6 by inhibiting the Δ^6-desaturase enzyme (14), a rate-limiting enzyme in the 20:4ω6 biosynthetic pathway (15,16).

Abbreviation: ACAT, acyl coenzyme A:cholesterol acyltransferase.

Dietary cholesterol has also been shown to interfere with metabolism of essential fatty acids (17-19). Cholesterol supplementation produces changes in fatty acid composition of plasma and tissue lipids, similar to that found in essential fatty acid deficiency (17-19), i.e., decreases in 20:4ω6 and 22:6ω3 content and increases in monounsaturated fatty acids (16:1ω7 and 18:1ω9) and their long chain polyunsaturated (20:3ω9) metabolites. In the present study we examined the interaction of dietary cholesterol with ω3 fatty acids of linseed oil (18:3ω3) or fish oil (20:4ω6 and 22:6ω3) in the modification of the cholesterol content and fatty acid composition of rat plasma, liver, heart and adipose tissue lipids.

MATERIALS AND METHODS

Fish oil concentrate (S-28GA) was obtained from Nissho Iwai American Corp., New York; beef tallow was supplied by Canada Packers Inc., Edmonton, Alberta, Canada, and linseed oil was purchased from a local health food store. All solvents were redistilled before use.

Animals and diets. Weanling male Sprague-Dawley rats weighing 50-60 g were housed individually in hanging stainless steel cages in a well ventilated room maintained at 22 ± 2°C on a 12/12 hr light-dark cycle. Animals were randomly divided into 3 groups of 12 rats each such that the average weight per group was similar. Experimental diets were prepared by adding one of the following fat mixtures to 800 g of fat-free basal diet mix described previously in detail (20): 180 g beef tallow plus 20 g safflower oil (beef tallow group); 160 g linseed oil plus 40 g beef tallow (linseed oil group); 200 g fish oil (fish oil group). Half of the animals in each group were fed the same diet supplemented with 20 g cholesterol/kg of diet. The fatty acid composition of the diets has been presented (Table 1). The beef tallow diet contained mainly saturated and monounsaturated fatty acids (83% w/w of total fatty acids). Both the linseed oil and fish oil diets were enriched with the same amount of ω3 fatty acids (approximately 40% of total fatty acids), but qualitatively, the linseed oil diet was high in α-linolenic acid (18:3ω3), whereas the fish oil diet was enriched with 20:5ω3 and 22:6ω3. Addition of 2% cholesterol to the fat-supplemented diets had no effect on the fatty acid composition of the diets. Diets were prepared weekly and stored at −20°C. Food and water were provided ad libitum for 28 days.

Lipid analysis. After the 4-week experimental period, the rats were killed by decapitation between 0800 and 1000 hr; livers, hearts and epidydimal fat pads were excised immediately and rinsed with ice-cold physiological saline. Following decapitation, blood was collected with a heparinized funnel and plasma was separated by centrifuging (1500 × g for 10 min). Lipids were extracted from plasma and tissues by homogenizing with chloroform/methanol (2:1, v/v) (21) followed by washing with saline. Total and free cholesterol content were determined using an enzymatic method (22). The difference between

[a] Addition of 2% cholesterol to beef tallow, linseed oil or fish oil diets had no effect on the fatty acid composition of the diets.

[b] At least four random samples from each diet were analyzed.

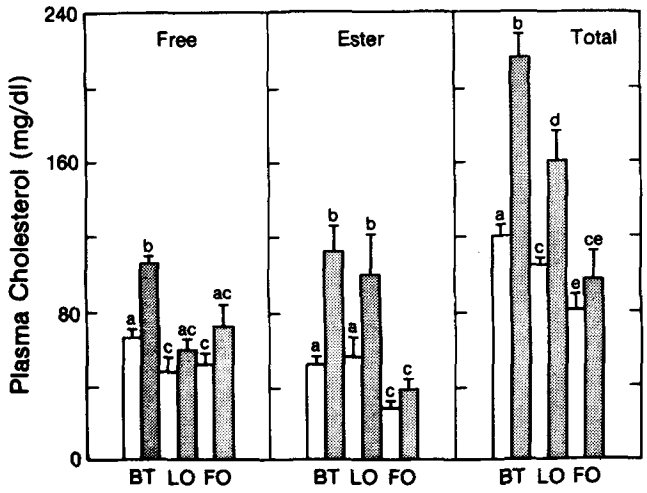

FIG. 1. Effect of dietary cholesterol and/or dietary ω3 fatty acid on cholesterol content of rat plasma. Values are the mean ± standard deviation of 6 animals (n = 6). Values without a common superscript are significantly different ($p < 0.05$). Open bars indicate low cholesterol diets, and shaded bars represent high cholesterol (2%) diets. BT, beef tallow diet; LO, linseed oil diet; FO, fish oil diet.

the total and free cholesterol content gave a measure of the esterified cholesterol content.

Total phospholipids were separated from neutral lipids by thin layer chromatography on Silica Gel G plates using a solvent system comprised of hexane/diethyl ether/acetic acid (80:20:1, v/v/v) (23). The areas corresponding to phospholipids were scraped off the plates and methylated using BF_3-methanol (14%, w/w) reagent, at 100°C for one hr (24). Fatty acid composition was determined by automated gas liquid chromatography (Varian, Model 6000) of methyl esters using a fused silica capillary column (BP20, bonded phase) as reported previously (25).

STATISTICAL ANALYSIS

Results are presented as the mean ± standard deviation. The effect of dietary fat treatments was evaluated by analysis of variance procedures. Comparison between individual diets was made using Duncan's multiple range test (26).

RESULTS

Food consumption, body weight, liver weight, heart weight and liver weight/body weight ratio data for animals fed the lipid-supplemented diets have been presented elsewhere (13). Animals fed the fish oil diet with or without cholesterol supplementation grew at a slower rate than those fed the beef tallow or linseed oil diet. The amount of food consumed per day, liver weights, heart weights and liver weight/body weight ratios remained unchanged with dietary fatty acid and/or cholesterol treatment (13).

Cholesterol content of plasma, liver, heart and adipose tissue. Cholesterol content of plasma was significantly reduced by feeding either the linseed oil or fish oil diet (Fig. 1). The reduction was greater with fish oil (32.8%) than with linseed oil (12.6%). The decrease in plasma cholesterol content was found to be mainly in the free cholesterol content following consumption of the linseed oil diet, whereas the fish oil diet lowered both the free and esterified cholesterol content. Addition of 2% (w/w) cholesterol to the beef tallow or linseed oil diet increased the plasma level of cholesterol; however, cholesterol supplementation with fish oil had no significant effect (Fig. 1). Dietary cholesterol elevated both the free and esterified cholesterol content of plasma when fed with beef tallow, and elevated only the esterified cholesterol content of plasma when the diet containing linseed oil was fed (Fig. 1.).

In liver tissue, feeding the fish oil diet decreased the cholesterol level whereas feeding the linseed oil diet had no significant effect (Fig. 2). The decrease associated with feeding the fish oil diet was observed in the cholesterol ester fraction while the free cholesterol content remained unaffected. Addition of 2% (w/w) cholesterol increased cholesterol concentrations in liver in the following order: linseed oil > beef tallow > fish oil groups. Both the free and esterified cholesterol content was elevated following feeding of cholesterol-enriched diets (Fig. 2). The level of cholesterol in heart and adipose tissue was not affected by dietary fatty acid and/or cholesterol treatments (data not shown).

Fatty acid composition of plasma and tissue lipids. Feeding either the linseed oil or fish oil diet, without added cholesterol, decreased the 20:4ω6 content of rat plasma, liver and heart phospholipids (Fig. 3). In liver and heart the decrease was greater after feeding the fish oil than after feeding the linseed oil diet when compared with the control animals fed diets containing beef tallow. Feeding diets containing linseed oil increased the proportion of 18:3ω3, 20:5ω3, 22:5ω3 and 22:6ω3 in liver, heart and adipose tissue lipids (Table 2, Fig. 3). Animals fed the diet containing fish oil exhibited larger increases in

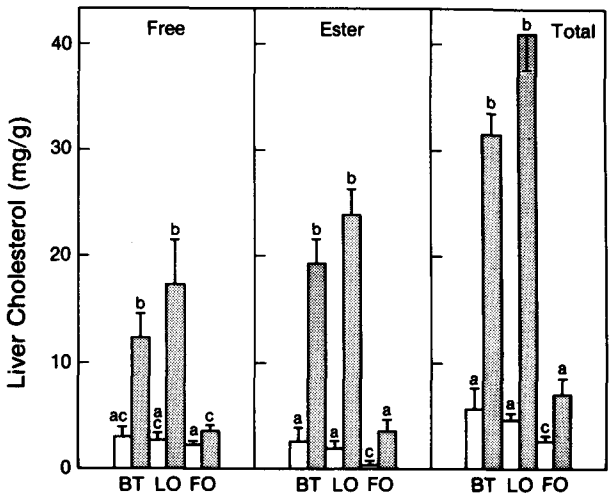

FIG. 2. Effect of dietary cholesterol and/or dietary ω3 fatty acid on cholesterol content of rat liver. Values are the mean ± standard deviation of 6 animals (n = 6). Values without a common superscript are significantly different (p < 0.05). Open bars indicate low cholesterol diets and shaded bars represent high cholesterol (2%) diets. BT, beef tallow diet; LO, linseed oil diet; FO, fish oil diet.

the proportion of 20:5ω3 and 22:6ω3 in phospholipids of plasma, liver and heart and in the triacylglycerol fraction from adipose tissue. The 18:2ω6 content of plasma, liver and heart phospholipids and that of adipose tissue triacylglycerol was significantly increased by feeding linseed oil and decreased by feeding the fish oil diet (Table 2, Fig. 3).

Addition of 2% (w/w) cholesterol to either the beef tallow or linseed oil diet reduced the 20:4ω6 content of plasma and tissue phospholipids (Fig. 3) with an accompanying increase occurring in 18:2ω6 content (Fig. 3). Cholesterol supplementation in combination with fish oil failed to alter levels of 18:2ω6 or 20:4ω6 in plasma and tissue phospholipids. The fatty acid composition of the triacylglycerol fraction in the adipose tissue remained unchanged by dietary cholesterol treatments (Table 2).

DISCUSSION

Reports from our laboratory and others have demonstrated that dietary ω3 fatty acids, particularly those of fish oils (20:5ω3 and/or 22:6ω3), and cholesterol enrichment of the diet independently alter metabolism of

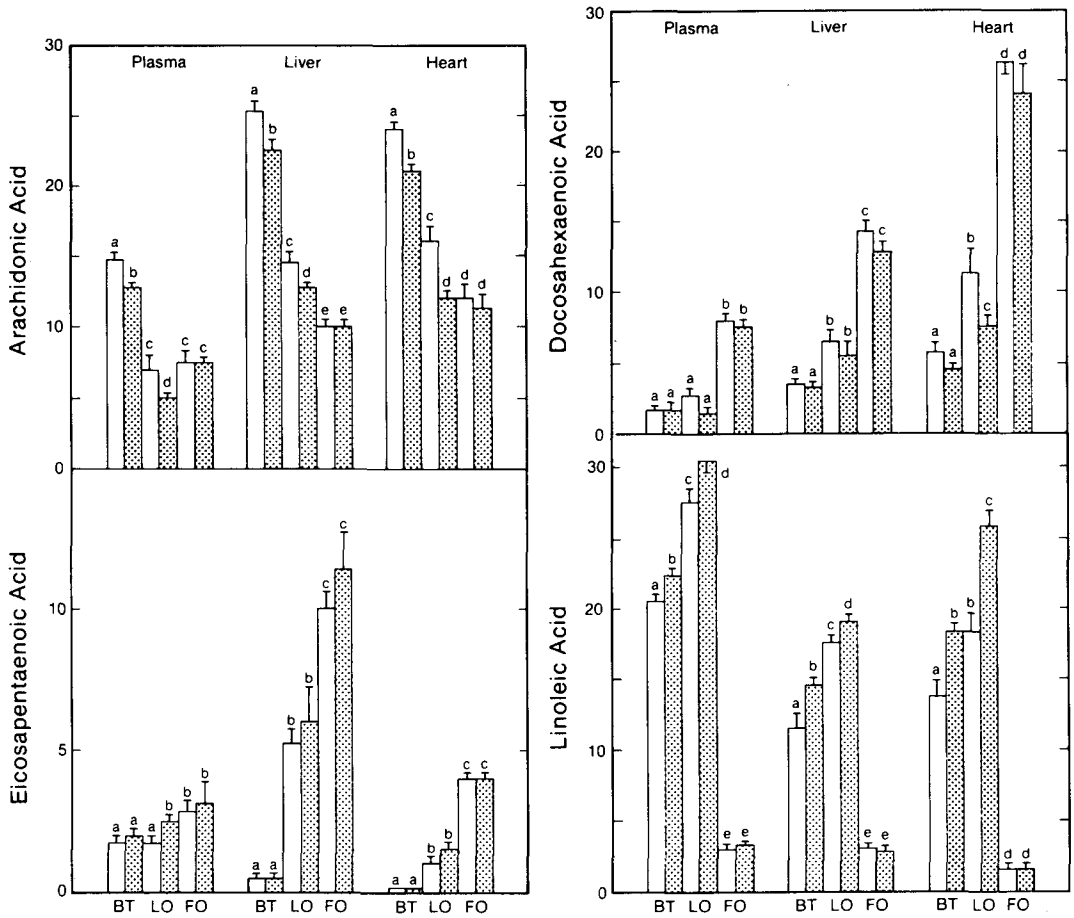

FIG. 3. Effect of dietary cholesterol and/or dietary ω3 fatty acid on polyunsaturated fatty acid 6 content (area percent) of rat plasma, liver and heart phospholipids. Values are the mean ± standard deviation of 6 animals (n = 6). Values without a common superscript are significantly different (p < 0.05). essential fatty acids (11-14,17-19). Fish oil (27-29) or cholesterol (17-19) supplementation decreases 20:4ω6 content of plasma and tissue phospholipids and in turn alters the pattern of eicosanoids synthesized from 20:4ω6 (13). The present study was designed to examine the interaction of dietary cholesterol with ω3 fatty acids of linseed oil (18:3ω3) or fish oil (20:5ω3 and 22:6ω3) to modify cholesterol content and fatty acid composition of rat plasma and tissue lipids. Feeding the diets containing linseed oil or fish oil to rats for a 4-week period lowered plasma cholesterol level by 13% and 33%, respectively, compared with animals fed the beef tallow diet (Fig. 1). These results are in agreement with several previous reports that dietary ω3 fatty acids decrease blood cholesterol levels in normal animals and human subjects (2-6). Some authors have reported that fish oil may increase serum cholesterol levels in man (1). Because the rat is a species that has a very high density lipoprotein and low levels of low density lipoprotein under normal dietary conditions, the changes in the plasma cholesterol level may be related to disturbances in lipid transport and lipoprotein metabolism (4). Feeding the fish oil diet also provided protection against cholesterol accumulation in plasma that was apparent when 2% (w/w) cholesterol was fed with diets containing beef tallow or linseed oil. These results suggest that fish oil consumption may have beneficial effects against hypercholesterolemia even under a high dietary load of cholesterol. In this regard, feeding the fish oil diet lowered cholesterol content of liver tissue, while feeding the linseed oil diet had no effect (Fig. 2). Following feeding of low-cholesterol diets, rats have been shown to accumulate more liver cholesterol when ω6 fatty acids of corn oil or sunflowerseed oil are the fat sources, than when coconut oil is the fat source (18,30,31). The present study demonstrates that when a high fat diet is fed, the ω3 fatty acid of linseed oil (18:3ω3) does not affect the concentration of liver cholesterol, whereas the ω3 fatty acids of fish oil (primarily 20:5ω3 and 22:6ω3) reduce liver cholesterol levels, chiefly in the form of cholesterol esters. This decrease in esterified cholesterol content may occur because feeding fish oil may increase the flow of cholesterol toward bile formation (28). Therefore, liver cholesterol would be expected to be utilized preferentially for bile acid synthesis instead of being stored or transported as cholesterol esters (28). In contrast to this, other research has shown that feeding fish oil increases acyl coenzyme A:cholesterol acyltransferase (ACAT) activity (32) which is expected to increase the level of cholesterol esters in liver lipids. Explanation of these conflicting observations is not apparent but may relate to the difference in levels of 20:5ω3 and 22:6ω3 fed in this study (40% w/w of fatty acids) (14) and the previous study (25% w/w of total fatty acids) (32). As well, the fish oil used in the present study contained a different amount and type of monounsaturated fatty acid (primarily 16:1 and 18:1) than utilized in the previous study (primarily 16:1, 18:1, 20:1 and 22:1). Monounsaturated fatty acids are preferred substrates for liver ACAT activity and thus may also contribute to the difference in observations between the two studies. Addition of 2% (w/w) cholesterol to the diet containing beef tallow or linseed oil increased cholesterol content of the liver tissue; however, cholesterol feeding with fish oil appears to at least partially prevent accumulation of cholesterol in the liver. Dietary cholesterol and/or ω3 fatty acids of linseed oil or fish oil did not have any appreciable effects on heart and adipose tissue cholesterol concentrations. It is conceivable that entry and exit of cholesterol is tightly regulated in heart and adipose tissue as the cholesterol content remained unaffected even after a high load of dietary cholesterol. It has been shown previously (33) that heart and adipose tissue are capable of synthesizing a small amount of cholesterol *de novo*. However, the regulation of cholesterol biosynthesis by dietary changes in these tissues remains to be examined.

Feeding ω3 fatty acids of linseed oil or fish oil and cholesterol supplementation to beef tallow or linseed oil

decreased 20:4ω6 content of rat plasma, liver and heart phospholipids (Fig. 3). This observation is in agreement with previous reports suggesting that dietary cholesterol and ω3 fatty acids individually decrease 20:4ω6 content of tissue phospholipids (17-19,27-29). The decrease in 20:4ω6 content following cholesterol feeding has been attributed to its increased utilization for cholesterol ester formation for secretion into the circulation as very low density lipoproteins (34,35). Dietary cholesterol has also been shown to inhibit Δ^6- and Δ^5-desaturase activities in liver microsomes which are key enzymes in the 20:4ω6 biosynthetic pathway (17). Reduction of 20:4ω6 levels in tissue phospholipids following fish oil consumption may occur because: (i) 20:5ω3 present in fish oil has greater affinity than 20:4ω6 for the acyltransferase responsible for the synthesis of phospholipids (10). Thus, 20:5ω3 may replace some of the 20:4ω6 in the liver phospholipids; (ii) fish oil inhibits Δ^6-desaturase activity in the liver (14), which is a rate-limiting step in the synthesis of 20:4ω6 from 18:2ω6; and (iii) we have shown recently that some 20:4ω6 may shift from phospholipid pools to cholesterol esters or triacylglycerol pools following feeding of fish oil (Garg et al., unpublished data).

Consumption of cholesterol and fish oil together failed to produce any alteration in the 20:4ω6 content of tissue phospholipids. This unique ability to resist changes in 20:4ω6 content when feeding fish oil may be attributed to the observation that feeding fish oil can prevent changes in Δ^6-desaturase activity in rat liver microsomes (14) caused by cholesterol supplementation. The possibility cannot be ruled out that feeding diets containing a high content of fish oil without any added cholesterol reduces 20:4ω6 levels to the minimal point required by the body to maintain eicosanoid balance and/or membrane phospholipid integrity.

In summary, dietary cholesterol interacts with dietary ω3 fatty acids of linseed oil (18:3ω3) to alter cholesterol and fatty acid metabolism in rat plasma and tissue pools. Feeding diets containing fish oil appears to at least partially reduce the effect of dietary cholesterol supplementation on cholesterol accumulation in and fatty acid profiles of tissue lipid. The mechanisms determining the unique effect of feeding fish oil on cholesterol levels and tissue fatty acid composition even after a high dietary load of cholesterol merit further investigation.

[Received May 24, 1988; Revision accepted November 28, 1988]

Developmental Regulation of Sterol Biosynthesis in *Cucurbita maxima* L.

Gregeory P. Fenner[a,1], **Glenn W. Patterson**[a,*] and **William R. Lusby**[b]
[a]Department of Botany, University of Maryland, College Park, Maryland 20742, and [b]Insect and Nematode Hormone Laboratory, Agricultural Research Service, USDA, Building 467, BARC-East, Beltsville, MD 20705

Twenty-two sterols were identified by capillary gas chromatography and capillary gas chromatography/mass spectroscopy in *Cucurbita maxima* grown under greenhouse conditions. Both whole plants and individual tissues (leaves, stems, roots, cotyledons, flowers) were analyzed at weekly intervals during the 12-week development of the plant. In whole plants, sterol accumulation parallels plant growth except for a period in the mid-life cycle where there is a reduction in the amount of sterol accumulated on a total sterol/plant and mg sterol/g dry wt basis. This reduction in the amount of sterol is coincident with the visual onset of flowering. During development, the percent contribution of each class of sterol (Δ^5-, Δ^7-, Δ^0-sterols) remains relatively constant. However, the percent contribution of an individual sterol species varies depending on the tissue examined and the developmental period selected for analysis. While the young plant (<2 weeks) possesses elevated levels of sterols with the $\Delta^{25(27)}$-double bond, the trend was toward a reduction in the amounts of these sterols with development. Leaves and stems accumulate large quantities of 24ζ-ethyl-5α-cholesta-7,22-dien-3β-ol (7,22-stigmastadienol) and 24ζ-ethyl-5α-cholest-7-en-3β-ol (7-stigmastenol), while roots accumulate only 7,22-stigmastadienol as their principal sterol. Male flowers and roots were found to contain elevated levels of Δ^5-sterols.
Lipids 24, 271–277 (1989).

The seeds and seedlings of some Cucurbitaceae contain primarily Δ^7-sterols possessing the $\Delta^{25(27)}$ side chain unsaturation (1,2). In higher plants this phenomenon has been reported in only a small number of other groups (4–6), and from biosynthetic considerations the $\Delta^{25(27)}$ double bond is associated with the β-configuration at C-24 (5,7–10). This is unusual because previously, sterols with the C-24 β-ethyl configuration were associated with lower organisms, especially the algae (11,12). In higher plants, sterols with the C-24 ethyl substituents and lacking the $\Delta^{25(27)}$ unsaturation were shown to have the α-configuration (7,9). However, there is some evidence that in seeds and seedlings from *Cucurbita pepo* and some species of *Cucurbita maxima*, $\Delta^{7,22}$-stigmastadienol may be an epimeric mixture at C-24 (1,13–16). The only other case in plants where a C-24 ethylsterol exists as an epimeric mixture is in the bryophytes (17,18). In the mature tissues of Cucurbitaceae analyzed, the C-24 α-isomers predominate (4,19,20) and are comprised mainly of the C-24 α-isomer of $\Delta^{7,22}$-stigmastadienol, i.e., spinasterol, and slightly lesser amounts of Δ^7-stigmastenol. Further complicating the composition of these tissues was the finding that Δ^7- and Δ^5-sterols co-exist in members of this plant group (19,21,22). The discovery that the beet (23), while having Δ^7-sterols as its major component, also contained significant quantities of Δ^5-sterols, has led researchers to examine more closely plants known to contain Δ^7-sterols. Co-existence of Δ^7- and Δ^5-sterols has been found to be rather common in the Caryophyllales (24,25). Examination of *Cucurbita maxima* (True Hubbard squash) showed that Δ^5-sterols were present but disappeared about two weeks after germination (19).

It is apparently not uncommon that different sterols predominate in different stages of plant development or in different plant parts. Previous experiments in our laboratory have shown that during the life cycle of *Cucurbita maxima* L. (var. Fordhook zucchini) and *Glycine max* L. (var. Sussex), sterol accumulation is reduced during periods of reproductive processes (16). Studies conducted by Heupel et al. showed a similar occurrence in *Sorghum bicolor* (26). Examination of the leaves, shoot apex, leaf sheath and stems, from *Lolium temulentum* during flower initiation and floral development revealed fluctuations in their sterol quality and quantity (27). Sterols or their metabolites have been suggested to be involved in reproductive processes in plants (28–31), but the exact role is not understood.

Both qualitative and quantitative sterol fluctuations during nonreproductive periods in a plant's life cycle have been witnessed also. In the 1960's Kemp et al. performed developmental studies on maize seedlings during germination and reported stage dependent changes (32). Yoshida and Kajomoto have since demonstrated developmental changes in sterol composition in cotyledons (33), and in root and axis (34) of germinating soybeans. In oats, stigmasterol represents only a few percent of the total sterol in the roots, whereas it is one of the major components in the leaves of the same plant (35). Whether these fluctuations are indicative of a metabolic or some other developmental role of endogenous sterols in plants awaits complete understanding of complex patterns of synthesis (and/or degradation).

Though developmental studies have been conducted, most have involved only seeds to seedling stages or have utilized both extremes in the life cycle (19,32-37). Other studies have focused on segregated points of development (26,27). Since there exist so many diversities between plant groups and even within a given plant, it was of interest to follow sterol changes during development of a single plant species to provide a complete account of the kinds and amounts of sterols therein. The study reported here represents the first examination of sterol profiles of a plant taken at regular intervals, beginning with the seed and continuing until mature seed of the next generation are produced. Sterol composition in the Fordhook variety of squash *Cucurbita maxima* was qualitatively and quantitatively monitored on a weekly basis from seed germination to seed production. Both whole plants and organs were analyzed. Our results indicate developmental regulation of sterol accumulation, and quantitative differences in sterol profiles from various organs.

MATERIALS AND METHODS

Cucurbita maxima L. (var. Fordhook zucchini) seeds purchased from Burpee Seed Co. (Warminster, PA) were planted under greenhouse conditions on March 9, 1984 and in a duplicate experiment on October 1, 1984. Seeds were germinated in flats 12″ × 8″ and plants of equal size were harvested weekly for 12 weeks with day 7 (after planting) taken as week 1. Plants remaining after 3 weeks were transferred from flats to pots ranging from 5-12 inches in diameter, and each pot contained one plant. This growth period produced all stages of development except senescence. At each harvest a known number of plants was washed and oven dried. Other plants from that same week's harvest were dissected into their respective roots, stems, leaves (and/or cotyledons), flowers and pericarp. In cases where the pericarp was used, care was taken to assure that seeds were completely separated from the fruits.

Plant material was ground and extracted in a Soxhlet apparatus with $CHCl_3$:MeOH 2:1 (v/v/v) following standard laboratory methods (11,18). After saponification of the total lipid, the mixture was exhaustively extracted with Et_2O and the extracts pooled and dried *in vacuo* with a rotary evaporator. Sterols were recovered after alumina chromatography. Total sterol referred to in this work actually is a combination of free sterols and sterol esters. Steryl glycosides previously have been analyzed over the squash life cycle and were found to be present in small, constant amounts (16).

Trimethyl silyl ether (TMSE) derivatives of sterols (38) were identified and quantitated by gas chromatography (GC) with cholesterol TMSE as an internal standard. The instrumentation consisted of a Varian 3700 or a Varian 3400 gas chromatograph both equipped with flame ionization detection (FID) systems, and a Varian 8000 autosampler. Data was processed on a Vista 401 data system. Sterols were analyzed on two types of capillary columns. One was a nonpolar fused silica column (SPB-1; bonded methyl silicone, Supelco Inc., Bellefonte, PA) 30 m × 0.32 mm i.d., 0.25 μ film thickness operated under the following conditions: oven temp, 230°C isothermal; injector, 290°C; detector, 300°C; split ratio, 10:1; average linear carrier gas velocity (helium), 80 cm/sec; 33 psi column head pressure. The other column was a polar fused silica column (SP-2330; cyanopropyl silane, Supelco Inc.) 30 m × 0.25 mm i.d.; 0.25 μ film thickness operated at: oven temp, 200°C isothermal; injector, 290°C; detector, 300°C, split ratio, 10:1; average linear carrier gas velocity (helium), 40 cm/sec; 26 psi column head pressure.

GC/mass spectroscopy (MS) was performed on a Finnigan Model 4510 mass spectrometer fitted with a fused silica capillary column (DB-1; bonded methyl silicone, J&W Scientific) 30 m × 0.32 mm i.d., 0.25 μm film thickness. The column was operated at 255°C with 13 psi head pressure of helium. Electron ionization (70 eV) spectra were obtained at a source temperature of 120°C, and processed with an Incos data system.

Total sterols were separated into fractions containing "methyl" sterols (here defined as sterols containing one or two methyl groups at C-4), Δ^5-sterols (also stanols) and Δ^7-sterols by alumina column chromatography on grade III alumina, eluted with increasing concentrations of Et_2O in hexane (39). Sterols were introduced to the column dissolved in hexane and eluted with 17%, 20% 23%, a second 23% (23%′), then 100% Et_2O. Following each separation, columns were thoroughly flushed with Et_2O to assure complete removal of sterols.

RESULTS AND DISCUSSION

Squash developmental stages were as follows: seeds were referred to as week 0; week 1, seedlings with cotyledons but no true leaves; weeks 2-4, seedlings with cotyledons and true leaves; week 5, cotyledons disappear; week 6, first male flowers appear; week 8, first female flowers appear; weeks 8-10, small fruits appear; weeks 10-12, plants with mature fruits and seed.

Squash plants grown in the spring were slightly larger at a comparable age than those in the fall, and development of the fall plants appeared to be delayed by one week. The trends in sterol composition were similar between the two experiments.

GC/MS performed on each fraction from the alumina column provided the identity of the components. In most cases spectra were compared to authentic sterols; otherwise, data were compared to those in the literature. Representative ions characteristic of specific sterols (40,41) are given, and the data are grouped according to the elution pattern from the alumina column.

Sterols eluting in 20% Et_2O in hexane. Cycloartenol: m/z 426$^+$ (M^+, 4%), 411 (5%), 408 (7%), 315 (1%), 286 (13%); 24-methylenecycloartanol: m/z 440$^+$ (M^+, 4%), 422 (6%), 407 (7%), 315 (2%), 300 (12%). Along with sterols in this fraction, there were compounds yielding fragmentation patterns consistent with those produced by pentacyclic triterpenoids. Characteristic of some pentacyclic triterpenoids is a prominent ion at m/z 218$^+$ upon cleavage, and these compounds are known constituents of many plant groups (37,42-44).

23% Et_2O in hexane. Obtusifoliol: m/z 426$^+$ (M^+, 15%), 411 (35%), 327 (7%), 285 (5%), 245 (45%); 4α-methyl-7-stigmastenol: m/z 426$^+$ (M^+, 60%), 411 (55%), 285 (70%), 245 (8%); citrostadienol: 426$^+$ (M^+, 40%), 411 (60%), 327 (30%), 285 (70%), 245 (5%).

23′% Et_2O in hexane. Codisterol: m/z 398$^+$ (M^+, 30%), 383 (3%), 365 (2%), 355 (1%), 314 (10%), 299 (10%), 271

(24%); 24-methylenecholesterol: m/z 398$^+$ (M$^-$, 13%), 383 (2%), 314 (20%), 271 (20%); campesterol: m/z 400$^+$ (M$^+$, 60%), 385 (10%), 382 (12%), 367 (8%), 315 (25%), 289 (30%), 273 (18%), 261 (5%); campestanol: m/z 402$^+$ (M$^+$, 60%), 315 (10%); stigmasterol: m/z 412$^+$ (M$^+$, 20%), 369 (3%), 351 (3%), 351 (5%), 300 (14%), 271 (60%), 255 (57%); 22-dehydrostigmastenol: m/z 414$^+$ (M$^+$, 54%), 371 (8%), 353 (15%), 301 (73%), 273 (40%), 257 (39%); clerosterol: m/ 412$^+$ (M$^+$, 80%), 397 (5%), 379 (10%), 314 (30%), 299 (39%); sitosterol: m/z 414$^+$ (M$^+$, 45%), 399 (10%), 396 (13%), 329 (18%), 303 (22%), 2783 (15%); stigmastanol: m/z 416$^+$ (M$^+$, 60%), 233 (85%); gramisterol: m/z 412$^+$ (M$^+$, 60%), 397 (30%), 314 (80%), 299 (21%), 285 (85%).

100% Et_2O. 7-Campestenol: m/z 400$^+$ (M$^+$, 65%), 385 (5%), 273 (6%), 255 (25%); 7,22,25-stigmastatrienol: m/z 410$^+$ (M$^+$, 40%), 395 (8%), 381 (10%), 300 (10%), 271 (35%), 255 (15%); 7,22-stigmastadienol: m/z 412$^+$ (M$^+$, 72%), 397 (20%), 369 (28%), 300 (33%), 285 (6%), 271 (56%), 255 (18%); 7,25-stigmastadienol: m/z 412$^+$ (M$^+$, 60%), 397 (59%), 299 (18%), 271 (69%), 255 (17%); 7-stigmastenol: m/z 414$^+$ (M$^+$, 98%), 399 (20%), 273 (16%), 255 (75%); 7-avenasterol m/z 412$^+$ (M$^+$, 33%), 397 (45%), 314 (40%), 271 (100%).

Akihisa reported a similar number of sterols in the Duchense variety of squash including 22-dehydrostigmastenol which was not previously reported (20). The sterol designated codisterol in the True Hubbard squash (45) was identified in this variety also. The sterols' gas chromatographic relative retention times (RRT) relative to cholesterol on SPB-1 are comparable to those reported for the packed SE-30 column (46). It is important to note that more than one column phase may be needed for identification. For example, two frequently reported cucurbit sterols; $\Delta^{7,22}$-stigmastadienol and $\Delta^{7,22,25}$-stigmastatrienol, virtually co-elute on the SPB-1, but are well separated on the polar SP-2330 column. The reverse situation exists for campesterol and stigmasterol.

Whole plant analyses. There is a gradual accumulaton in the amount of sterol per plant and mg sterol/g dry weight during the first few weeks of growth (16), after which there is a rapid increase, a decrease, and another rapid increase. One could attempt to explain the decline in sterol accumulation by a rapid increase in plant dry matter so that the level of sterol would appear to decrease proportionally. Such a phenomenon may not be the case since rapid growth is seen both before and after the period of sterol decline. No known sterol metabolic function can account for the magnitude of sterol decrease seen in this study. Nonetheless, the possibility of metabolism should not be discarded. It could be that multiple events exist related to the flowering process that are additive in terms of affecting the total quantity of sterol. As an example, accompanying flower formation in squash is the synthesis of copious amounts of carotenoids, as observed in the highly pigmented flowers. This magnitude of carotenoid synthesis may reduce the pool of sterol precursors since both pathways utilize many common intermediates (47).

In whole plants the composition of each class of sterol is relatively constant when expressed as a percent of the total sterol (Fig. 1). As expected, the Δ^7-sterols comprised the largest amount. These were followed by the Δ^5-sterols or methyl-sterols (depending on the stage). Previously in True Hubbard squash the Δ^5-sterols were shown to be higher in the seeds and to disappear soon after germination (19). In the Fordhook variety our results show that the Δ^5-sterols are higher in the seeds but their presence persisted throughout the developmental period. In order to see if there were interspecific differences, True Hubbard seeds were germinated and seedlings harvested 17 days after germination. After a qualitative analysis of sterols by our methods, it was seen that Δ^5-sterols were present during the entire period of growth (data not shown).

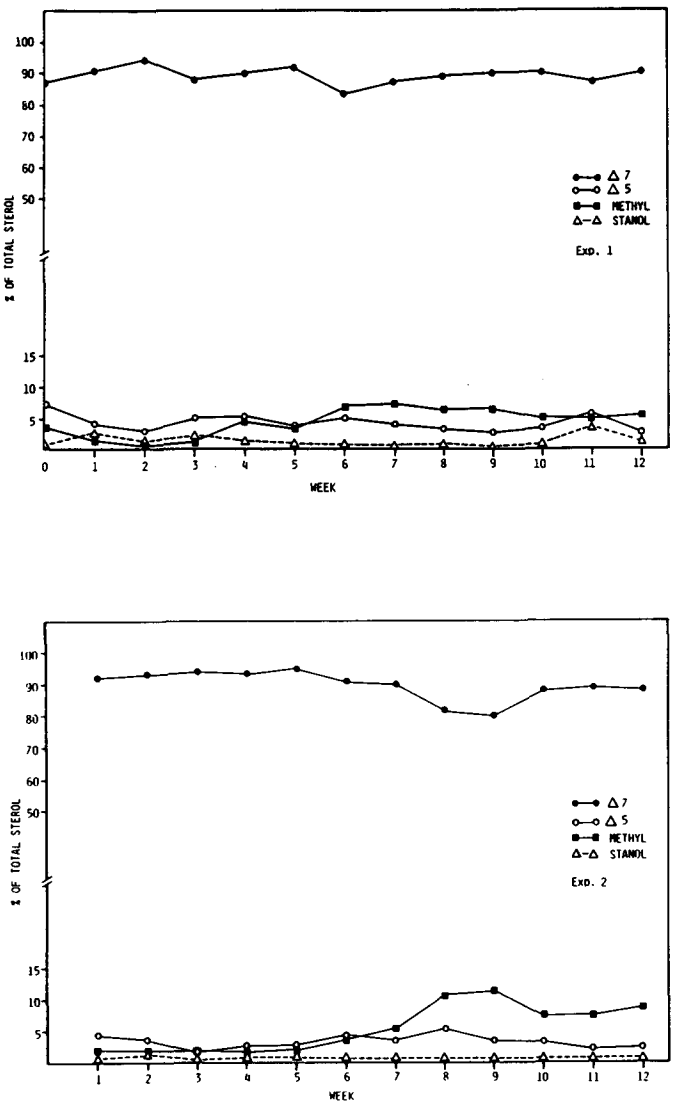

FIG. 1. Comparison of Δ^7, Δ^5, methyl-sterols and stanols as percentages of the total sterol in whole squash plants during development.

Squash plants accumulate two principal sterols during development, $\Delta^{7,22}$-stigmastadienol and Δ^7-stigmastenol (Table 1). In the seeds and in week 1, sterols with the $\Delta^{25(27)}$-unsaturated side chain make up a large proportion of the sterol fraction. The percentages of these sterols begin to decline between weeks 2 and 3 such that by the later weeks they are minor constituents. There is also a gradual increase in Δ^7-avenasterol as the plant develops. This sterol has been suggested as the precursor to the C-24 α-ethyl sterols found in the Cucurbitaceae (20). Since $\Delta^{25(27)}$-unsaturated sterols are associated with the C-24

β-ethyl configuration, a detailed study was conducted on the configurations at C-24 of $\Delta^{7,22}$-stigmastadienol and 7-stigmastenol over the course of development. The results from those experiments will be reported in a future publication. Sitosterol was the major Δ^5-sterol and comprised between 1.0% and 3.0% of the total sterol of the whole plant. None of the stanols were found above 1% of total sterols at any time. The major methyl sterol was cycloartenol and, as Table 1 shows, its percentage gradually increased with the age of the plant.

Leaves. The true leaves emerge during the second week of growth. All leaves on a plant were analyzed together. No effort was made to compare younger to older leaves. Within these organs all of the different classes of sterols were found. Upon their emergence the true leaves contained a lower percentage of sterols containing the $\Delta^{25(27)}$ double bond than was expected as compared to the seed (Tables 1 and 2). These lower levels may indicate that from the outset, leaves are synthesizing primarily C-24 α-oriented sterols. The amount of Δ^7-stigmastenol approaches that of $\Delta^{7,22}$-stigmastadienol, beginning at leaf emergence and throughout the life cycle. Sitosterol was the major Δ^5-sterol and was found to be higher in the leaves of younger plants than in those of older plants. As in the whole plant analysis, cycloartenol was the major methyl sterol and showed an increase with age of the plant.

Roots. Only one sterol, $\Delta^{7,22}$-stigmastadienol, was found to dominate the sterol profile in the roots (Table 3). This was surprising, especially since Δ^7-stigmastenol usually accompanies $\Delta^{7,22}$-stigmastadienol in significant quantities in the leaves. In the root tissue from maize seedlings, stigmasterol, the Δ^5 analog of $\Delta^{7,22}$-stigmastadienol, was also found to increase with time (32). The percentage of Δ^5-sterols was higher in the root than in the other organs throughout the squash life cycle. The Δ^5-sterols were composed mainly of sitosterol and clerosterol. Stigmastanol was also found at 1% to 3% of the total sterol. Recently, it has been suggested that a relationship exists between cholesterol and embryonic tissues (27). Embryonic regions of the root apices were not analyzed separately in the present work, but it is interesting that roots which also contain a very active primary meristem contain higher levels of Δ^5-sterols.

Stems. Unlike the whole plant, leaves and roots, stems do not show a sterol increase during the mid-life

TABLE 3

Percentages[a] of Major Sterols from Squash Roots During the Life Cycle

Sterol	Week											
	1	2	3	4	5	6	7	8	9	10	11	12

[a]Percent of the total sterol including minor components.
[b]Trace.

developmental period. There is an early accumulation of sterol, followed by a decrease to a relatively constant low level (Fig. 2). This may be a combination of pith loss during maturation and an increase in the amount of fibrous tissue. These would cause a reduction of the amount of membrane, therefore a reduction in the amount of total sterol. In the tomato a similar observation has been made (48). In terms of their sterol composition, stems were similar to the leaves in that they contain primarily 7,22-stigmastadienol and 7-stigmastenol as their major Δ^7-sterols and sitosterol as their major Δ^5-sterol (Table 4).

Cotyledons, flowers and pericarp. The cotyledons were analyzed for the first 4 weeks of growth after which they senesced and were no longer included in these analyses. In the cotyledons the percentage of sterols with the $\Delta^{25(27)}$ double bond do not show as rapid a decrease as seen in the other organs (Table 5). Although the levels of $\Delta^{7,22}$-stigmastadienol and Δ^7-stigmastenol increase, they do not dominate the sterol profile. During the first two weeks of growth the cotyledons are very similar to the seeds in their sterol composition (Tables 1 and 5), which was expected since the seeds are composed largely of two massive cotyledons. The cotyledons contain approximately 5% Δ^5-sterols comprised mainly of sitosterol.

Squash plants are monecious but imperfect (male and female reproductive organ on the same plant but not in the same flower), with male flowers produced first. In these studies the male flowers were harvested at week 6 in the first experiment (week 8 in the second), and female flowers were harvested at week 8 in the first experiment (week 10 in the second). Male flowers have relatively less $\Delta^{7,22}$-stigmastadienol and Δ^7-stigmastenol than female flowers or the pericarp. This is due to the significantly higher percentages of other sterols such as cycloartenol, 7-campestenol, 24-methylenelathosterol, stigmastanol, sitosterol and clerosterol. Sitosterol was the major Δ^5-sterol found in each of the reproductive structures and was similar in quantity in the pericarp and the flowers. These results show a slightly higher relative amount of Δ^5-sterols in the male flowers than female flowers, which had slightly more than the pericarp. Knights also analyzed squash flowers and reported the presence of Δ^5-sterols (21).

Throughout development Δ^7-sterols predominate the sterol profile in the Fordhook variety of *Cucurbita maxima* as in other Cucurbitaceae. There are significant

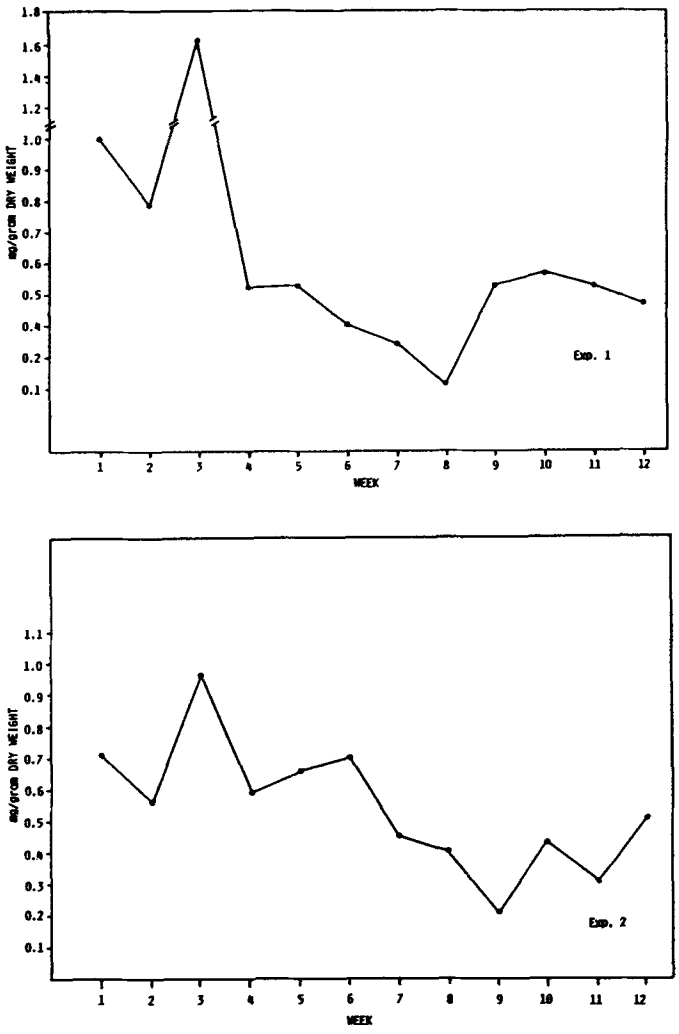

FIG. 2. Total sterol present in *Cucurbita maxima* stems on a mg/g dry wt basis over the life cycle.

quantitative changes in the kinds of sterols, and these changes appear to be organ specific. In whole squash plants or in any of the organs analyzed, $\Delta^{7,22}$-stigmastadienol was always a major component regardless of the stage of growth. The predominance of $\Delta^{7,22,25}$-stigmastatrienol and $\Delta^{7,25}$-stigmastadienol is more associated with embryonic tissues. Here we elect the term "embryonic tissues" since it was not determined if higher levels of $\Delta^{25(27)}$-sterols found during week 1 in stems and roots resulted from seed storage pools or *de novo* synthesis. However, the finding that true leaves which are not part of embryonic tissues never contained high levels of sterols possessing the $\Delta^{25(27)}$-double bond, and the early decline in the amounts of these sterols in maturing stems and roots, support the above observation. It should be pointed out that small quantities of these sterols did persist throughout development in each organ. It could likewise be suggested that Δ^{7}-stigmastenol is associated with pigmented vegetative tissue in these plants, since it was not a major constitutent of cotyledons or roots but was a major sterol in leaves, stems, flowers and pericarp.

The Δ^{7}-sterols were found in each organ. The seeds, roots and flowers were found to contain the largest quantities of these sterols. In some of the early literature there were speculations of root involvement in reproductive processes (49). Our data neither support nor disagree with such speculations, but the slightly higher levels of Δ^{5}-sterols in roots and flowers accompanied by the simultaneous increase of Δ^{5}-sterols in the stem during flower development may be significant. In this respect a selective transport mechanism would have to be assumed, but to date no confirmed mechanisms have been established. Interestingly, roots which are actively growing and seeds and flowers which undergo rapid morphologic changes both contain higher levels of Δ^{5}-sterols. These findings may suggest, as previously speculated (27,50), that meristematic cell division processes and Δ^{5}-sterols may be interconnected. Sitosterol, which is one of the more frequently reported sterols in many other plants, was also the major Δ^{5}-sterol found in this study. It appears that squash with its "atypical" sterol composition approaches "typical" higher plants with regard to its major Δ^{5}-sterol.

A project such as the one undertaken here serves to open doors to ultimately determining the roles of sterols in plants. The detailed analyses should be most useful as a means for designing future experiments. These data

indicate that each organ from this plant may be used separately to gain insight into such occurrences as site specificity of sterol synthesis, differences in regulation of sterol synthesis throughout the plant, or possible transport from one plant part to another. The low sterol accumulation during the life cycle when vigorous growth is taking place and reproductive organs are being produced can be exploited to determine if sterols are participating in developmental regulation.

ACKNOWLEDGMENT

[Received October 7, 1988; Revision accepted December 7, 1988]

Effects of Dietary n-3 Polyunsaturated Fatty Acids on Phospholipid Composition and Calcium Transport in Mouse Cardiac Sarcoplasmic Reticulum

M. Croset, J.M. Black, J.E. Swanson and **J.E. Kinsella***
Lipid Research Laboratory, Institute of Food Science, Stocking Hall, Cornell University, Ithaca, NY 14853

The effects of dietary n-3 and n-6 polyunsaturated fatty acids on the fatty acid composition of phospholipid, Ca^{++}· Mg^{++}ATPase and Ca^{++} transport activities of mouse sarcoplasmic reticulum were investigated. Mice were fed a 2 weight percent fat diet containing either 0.5 weight percent ethyl esters of 18:3n-3, 20:5n-3 or 22:6n-3 as a source of n-3 polyunsaturated fatty acid or 0.5 weight percent safflower oil as a source of n-6 polyunsaturated fatty acid for 10 days. Olive oil (2 weight percent) was used as a control diet. Although feeding n-6 polyunsaturated fatty acid induced very little modifications of the phospholipid sarcoplasmic reticulum fatty acid composition, feeding n-3 polyunsaturated fatty acid altered it markedly. Inclusion of 18:3n-3, 20:5n-3 or 22:6n-3 in the diet caused an accumulation of 22:6n-3, which replaced 20:4n-6 and 18:2n-6 in phospholipid sarcoplasmic reticulum. The saturated fatty acids were significantly increased with a concurrent reduction of 18:1n-9. These changes in the fatty acid composition resulted in a decrease in the values of the n-6/n-3 polyunsaturated fatty acid ratio and a decrease in the ratio of 20 carbon to 22 carbon fatty acids esterified in the phospholipid sarcoplasmic reticulum. This was associated with a decrease in Ca^{++} uptake by n-3 polyunsaturated fatty acid enriched sarcoplasmic reticulum vesicles as compared with n-6 fatty acid and control diet sarcoplasmic reticulum vesicles. However, neither the affinity for Ca^{++} nor the maximal velocity of ATP hydrolysis activity of Ca^{++}·MG^{++}ATPase were altered by the different diets. The data suggest that the incorporation of 22:6n-3 and/or the decrease of 20:4n-6 plus 18:2n-6 in the phospholipid sarcoplasmic reticulum may affect the membrane lipid bilayer structure and make it more permeable to Ca^{++}.
***Lipids* 24, 278-285 (1989).**

A high intake of saturated fatty acids (SAT) and cholesterol is a risk factor in coronary heart disease (1,2), whereas consumption of polyunsaturated fatty acids (PUFA) from the n-6 family (n-6 PUFA) (3) and n-3 family (n-3 PUFA) appear to have beneficial effects in reducing these diseases (4). Moreover, n-3 PUFA seem to be more effective in their antithrombotic and antiatherogenic properties than the corresponding n-6 PUFA (5,6). Dietary eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3), which are the main n-3 PUFA present in seafood and fish oil, influence several biochemical parameters described as risk factor in development of thrombosis and coronary heart diseases (4,5). Their first biological effect is related to plasma lipids and lipoproteins (6,7). The n-3 PUFA of fish oil reduce serum triglyceride, mainly through inhibition of hepatic very low density lipoproteins (VLDL) formation (8). Supplementation of human diet by fish oil also decrease plasma concentration of VLDL- and low density lipoprotein (LDL)-cholesterol (6,9). Dietary n-3 PUFA compete with arachidonic acid (20:4n-6) for acylation in the tissue phospholipids, thereby reducing the formation of vasoconstrictor, prothrombotic and proinflammatory eicosanoids derived from 20:4n-6 (10,11). They also compete directly for the enzymatic site of cyclooxygenase (12) and alter the activity of membrane-bound enzymes (13) and, possibly, receptor functions (14). Although the role of n-3 PUFA, in improving the cardiac functions, has been attributed to reduction in the development of vascular atheroma, recent evidence has indicated a direct effect of these fatty acids on myocardial performance (15,16).

Dietary modifications in cardiac lipids are associated with changes in cardiac functions (15-17). An increase in left ventricular work and coronary flow rate has been reported in isolated hearts of rats fed PUFA-enriched vs SAT fat-enriched diets (17).

Feeding n-3 PUFA as menhaden oil (16) or cod liver oil (18) causes an extensive alteration in fatty acid composition of cardiac lipids in rats, influences the basal cardiac function and the response of the heart to stress (19). Dietary menhaden oil supplementation significantly reduced infarct size in dogs, by mechanisms other than the inhibition of 20:4n-6 metabolism (20). McLennan et al. (15) have shown that the cardiac muscle contractility and the incidence of spontaneous tachyarrhytmias under isoprenaline-induced stress were reduced by feeding n-6 PUFA or n-3 PUFA-enriched diets vs SAT fats. Moreover, the extent of cardiac ischemic damage following coronary artery ligation in rats was significantly reduced by feeding menhaden oil vs corn oil (16). This was associated with an increase in the value of n-3/n-6 PUFA ratio of cardiac phospholipids. These changes may be mediated by inhibiting the formation of eicosanoids and/or by affecting different cellular processes (21).

Calcium (Ca^{++}) homeostasis plays an important role in the regulation of heart contraction and relaxation and its concentration in heart tissue is regulated by several membrane transport systems localized in the sarcolemma, the sarcoplasmic reticulum (SR), and to a lesser extent, mitochondria (22). Cardiac SR is a major site of regulation of intracellular Ca^{++} levels. The calcium-magnesium adenosine 5'-triphosphatase (Ca^{++}·MG^{++}ATPase) is a key enzyme in this regulation (22). During the contraction phases, the intracytoplasmic concentration of Ca^{++} rises, activating the Ca^{++}·Mg^{++}ATPase which pumps it back into the SR (23). This process, together with the extrusion of Ca^{++} out of the myocyte, through the

sarcolemma, reestablishes the basal cytoplasmic concentration which induces the relaxation phases (23). The activity of muscle Ca^{++}·Mg^{++}ATPase, reconstituted into synthetic membrane is dependent on surrounding phospholipids (PL), both by the nature of lipid head groups and the fatty acyl chains (24). Therefore, we have studied the ability of different n-3 PUFA to alter the SR fatty acid PL composition compared with n-6 PUFA and their subsequent effects on the specific activity of Ca^{++}·Mg^{++}ATPase and Ca^{++} uptake by SR vesicles from mouse heart.

MATERIALS AND METHODS

Animals. Male CD-1 white mice (Charles River, Wilmington, MA) weighing 18–20 g were housed at 22°C, 6 mice per cage with food and water ad libitum and a 12-hr dark/light cycle.

Diets. After 10 days on an essential fatty acid free diet, mice were randomly divided into 5 groups of 6 animals each and fed, for 10 days, a fat-free diet supplemented with 2% by wt of different combinations of olive oil and n-6 PUFA or n-3 PUFA. Olive oil 2 wt% served as a control diet (OO Diet); 1.5 wt% olive oil supplemented with 0.5 wt% safflower oil was used as a source of n-6 fatty acids (SF) and 1.5 wt% olive oil mixed with 0.5 wt% of one of the following ethyl ester fatty acids: linolenic (18:3n-3, LNA), eicosapentaenoic (20:5n-3, EPA and docosahexaenoic (22:6n-3, DHA)—were the n-3 fatty acids diets. Ethyl esters of LNA (99.5% pure), EPA (55% pure) and DHA (99% pure) were purchased from NuChek Prep (Elysian, MN). Commercial edible olive and safflower oils were obtained locally. The diets were thoroughly mixed after the addition of oils and small amounts were transferred to Whirlpak plastic bags, flushed with nitrogen and stored at 4°C in the dark. The fatty acid composition of the different diets determinated by gas chromatography (25) are shown in Table 1. The diet enriched with 20:5n-3 contained only 0.3 wt% of 20:5n-3 (Table 1) because of the presence of others fatty acids in the only available commercial source of n-3 PUFA. The mice received fresh diet every day. There was no oxidation of dietary fats as measured by thiobarbituric acid reactive materials (26).

Isolation of sarcoplasmic reticulum. The SR vesicles were prepared according to the method of MacLennan (27) as modified by Swanson et al. (28). Mice were anesthetized with diethyl ether and the heart quickly removed. Hearts from two mice were pooled, washed thoroughly in ice-cold isotonic saline, weighed and minced with a razor blade in ice-cold buffer containing 20 mM TRIS, 30 mM L-Histidine and 0.6 M KCl, pH 7.5 (Buffer 1). Minced tissues were homogenized into 25 ml of buffer 1 with a Thomas homogenizer using a glass-teflon pestle set at speed 4 with 5 slow up and down strokes. The homogenate was centrifuged at 1,600 *g* for 10 min at 4°C to remove nuclei and cell debris. The supernatant was saved and the pellet resuspended in 30 ml of buffer 1, homogenized by 2 up and down strokes and recentrifuged at 1,600 *g* 10 min. The supernatants were pooled, filtered through four layers of cheese cloth and centrifuged at 14,000 *g* for 15 min at 4°C. The resultant supernatant was filtered through 4 layers of cheese cloth and centrifuged at 45,000 *g* for 50 min at 4°C. The pellet was resuspended in 16 ml of 20 mM TRIS, 30 mM L-Histidine, 250 mM sucrose (pH 7.4) (buffer 2) using a glass-glass homogenizer and recentrifuged at 48,000 *g* for 50 min at 4°C. The SR pellet was resuspended in 2 ml of buffer 2 (pH 7.2).

Measurements of Ca^{++} transport. ATP-dependent Ca^{++} uptake by the membrane vesicles was measured isotopically on fresh material as described by Hack et al. (29). The reaction was started by adding 50–80 μg of fresh SR protein to a medium containing 50 mM TRIS·HCl, 100 mM KCl, 5 mM $MgCl_2$, 5 mM potassium oxalate, 30 μM $CaCl_2$, 50 nanocuries $[^{45}Ca]Cl_2$ (sp. act. 25 mCi/mg; Amersham, Arlington Heights, IL) and 2 mM Na-ATP (pH 7.5), in a final volume of 0.5 ml. After 15 min incubation at 30°C, samples were filtered through 0.45 μm Millipore buffer soaked filters to stop the reaction. The filters were washed 4 times with 1 ml of water prior to drying and the radioactivity remaining on the filters counted in 10 ml of scintillation liquid. The Ca^{++}-stimulated uptake was calculated by subtracting the values obtained without ATP in the medium from the total count obtained in presence of ATP.

Measurements of Ca^{++}·Mg^{++}ATPase activity. The ATPase activity was determined using the method described by Bonis et al. (30). Frozen SR was thawed and 15–25 μg of SR protein was incubated at 37°C for 10 min in a standard reaction mixture containing 50 mM TRIS·HCl, 100 mM KCl, 5 mM $MgCl_2$, 5 mM potassium oxalate, 2 mM Na-ATP (pH 7.1) to determine the ATP hydrolysis upon stimulation of the enzyme by Ca^{++}. For the determination of Ca^{++} affinity (Km) and maximum velocity (Vmax) of the enzyme, the free Ca^{++} concentrations in this medium were controlled in the range of 0.05 μM to 1.0 mM by the use of Ca^{++}-EGTA buffer according to Portzehl et al. (31). The Ca^{++}-activated ATPase activity was calculated by subtracting the values obtained without adding $CaCl_2$ and in the presence of 0.1 mM EGTA from those obtained in presence of $CaCl_2$. The enzyme affinity for ATP was measured in presence of 30 μM $CaCl_2$ and the appropriate amounts of Na-ATP. For each concentration of ATP, the "basal" ATPase activity value obtained in the presence of 0.1 mM EGTA

TABLE 1

The Fatty Acid Composition (Mol%) of the Five Diets Fed to Mice for 14 Days

Fatty acid	Dietary treatment				
	OO	SF	LNA	EPA	DHA
14:0	23.3	15.7	21.8	23.4	21.0
16:0	7.5	6.5	4.9	5.7	5.5

22:5n-3	0.0	0.0	0.0	1.1	0.0
22:6n-3	0.0	0.0	0.1	1.9	16.5

The diet contained olive oil (OO); safflower oil (SF); linolenic acid (LNA); eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) as ethyl esters, respectively.

was subtracted from those obtained in presence of $CaCl_2$. The reaction was stopped by precipitating the proteins by 0.5 ml of ice-cold 5% trichloroacetic acid (TCA), and the phosphate (Pi) released was assayed by the colorimetric method of Lebel et al. (32).

Lipid analysis. Lipids were extracted from the SR by the method of Bligh and Dyer (33). Total phospholipids were purified on high performance thin layer chromatography (HPTLC) plates using chloroform/methanol (80:20, v/v), scraped from the plate and extracted from the silica gel by chloroform/methanol (1:1). The phospholipids were saponified with 0.5 N KOH in methanol at 85°C and the free fatty acids extracted and methylated with diazomethane. The fatty acid methyl esters were quantified by gas chromatography (25) (5880 A, Hewlett Packard, PA) using a 0.75 mm by 60 m SP2330 capillary column (Supelco, Inc., Bellefonte, PA) with hydrogen as a carrier gas. The oven temperature was programmed from 140° to 240°C at 5°C/min. Fatty acids were identified by retention time comparisons with fatty acid methyl ester standards as described (25).

Protein and phospholipid estimations. Protein was estimated according to Lowry et al. (34). Total phospholipids were estimated according to Stewart (35).

Statistical analysis. Values from the different groups were compared by the student-t test (MINITAB, Inc.).

RESULTS

The amount of diet consumed and the weight gain by the animals in the different groups were identical. The heart weights, the yield of protein SR and the amounts of total phospholipids were not significantly different between the five dietary treatments (Table 2). The SR contamination by mitochondria and lysosomes was less than 10% on a protein basis and did not differ significantly between the different groups (not shown).

Fatty acid modification. Feeding a dietary supplement containing n-3 or n-6 fatty acids or olive oil for a short term period di not change the total amount of SR phospholipids (Table 2). However, the fatty acid composition of SR from different groups was drastically altered by the diets (Table 3). Substituting 0.5 wt% SF oil for

TABLE 2

Heart Weight, Protein Yield and Total Phospholipid Contents of Cardiac Sarcoplasmic Reticulum From Mice Maintained on Diets for 14 Days

Dietary treatment	Gain weight (g)	Heart weight (mg)	Sarcoplasmic reticulum protein (mg/sample)	Total phospholipids (μg/mg protein)
SF	6.0	366 ± 25	1.90 ± 0.12	101.3 ± 8.3
OO	6.3	367 ± 42	1.81 ± 0.20	113.9 ± 7.3
LNA	5.8	363 ± 58	1.96 ± 0.23	101.0 ± 7.0
EPA	6.2	348 ± 11	2.10 ± 0.24	109.3 ± 4.1
DHA	6.2	363 ± 24	1.96 ± 0.56	100.7 ± 14.4

Gain weight is a mean for 6 animals per group; heart weight, sarcoplasmic reticulum protein and total phospholipids represent the mean ±SD of n = 3 (3 pools of 2 hearts per group).

Values are reported as mol% of total fatty acids and represent the mean ±SD of 3 different experiments.

[a] $p < 0.001$.

[b] $p < 0.005$.

[c] $p < 0.02$.

[d] $p < 0.01$.

[e] $p < 0.05$.

SAT, sum (16:0 + 18:0); MONOSAT, sum (16:1 + 18:1); PUFA, sum (all fatty acids with 2 or more double bonds); C20/C22, sum (all 20-carbon fatty acids)/sum (all 22-carbon fatty acids); nd, not detected.

olive oil increased the amount of 18:2n-6 acylated in SR phospholipids by 20%, whereas 20:4n-6, its desaturation-elongation product, was not significantly increased. Long chain n-3 fatty acids were decreased by 11%, and 18:1n-9 and 20:3n-9 were significantly decreased by 19% and 41%, respectively. The inclusion of 18:3n-3, 20:5n-3 or 22:6n-3 in the diet induced a 1.20-, 1.65- and 2.20-fold increase in the 22:6n-3 levels, respectively. The accumulation of this fatty acid was associated with the displacement of n-6 fatty acids from the phospholipids. The relative decrease in 20:4n-6 and of its long chain metabolites 22:4n-6 and 22:5n-6 was more pronounced than that observed for 18:2n-6 levels. Feeding DHA, as compared with OO induced a 58% reduction in arachidonic acid content and a 36% decrease in linoleic acid, indicating that 22:6n-3 replaced 20:4n-6 more effectively than 18:2n-6. The SR from LNA-fed mice contained relatively low amounts of 18:3n-3 and of its metabolic product, 20:5n-3, which increased from trace amounts (OO) to 1.0 and 0.70%, respectively. Similarly, feeding 20:5n-3 raised its concentration in phospholipids to only 0.65%, but induced a considerable increase in long chain n-3 fatty acids. The diet supplementation by either n-6 or n-3 PUFA vs olive oil induced a significant increase of SAT fats esterified in the phospholipids, whereas the level of monounsaturated fatty acids was significantly decreased mostly because of the fall in 18:1n-9, because 16:1 increased, except after feeding DHA. Overall, although the amount of total PUFA was only slightly modified by the different dietary supplements, there was a significant alteration in the n-6/n-3 ratio which varied from 2.74 (SF) to 0.51 (DHA). The ratio of 20 carbon fatty acids to 22 carbon fatty acids (C20/C22) was also markedly modified.

Ca^{++} uptake and ATPase activity. Isolated SR vesicles actively accumulated and retained Ca^{++} from a medium containing both Ca^{++} and ATP. Previous results from our laboratory have shown that the Ca^{++} uptake by mouse cardiac SR vesicles is a quick and saturable process which reaches maximum velocity at 5 min and plateaus for up to 20 min (28). Therefore, the maximum Ca^{++} uptake by SR from the different groups were compared after a 15-min incubation time. Comparable levels of Ca^{++} accumulation were obtained for SR from animals fed SF and OO diets; however, this was significantly decreased after feeding n-3 PUFA (Fig. 1). The Ca^{++} uptake in the SR vesicles of mice fed 20:5n-3 and 22:6n-3 was significantly decreased as compared with the uptake by SR vesicles from mice fed 18:3n-3 ($p < 0.03$ and $p < 0.0002$, respectively). The alteration in Ca^{++} accumulation was associated with the change in n-3/n-6 ratio, the uptake being decreased when this ratio was increased.

The maximum specific activity (Vmax) and affinity for Ca^{++} and ATP of Ca^{++}·Mg^{++}ATPase associated with Ca^{++} uptake were compared for SR obtained from mice fed SF, EPA and DHA. The Ca^{++} activation of the enzyme was essentially the same in the three groups with a maximum Ca^{++} activation between 5 to 10 μM $-Ca^{++}$, a plateau between 10-50 μM and an inhibition of the enzyme activity at 100 μM $-Ca^{++}$ (Fig. 2). The apparent Km and Vmax values derived from double-reciprocal plots for Ca^{++} in a 0.5-50 μM $-Ca^{++}$ range did not differ significantly between the diets (Fig. 3A, Table 4). The ATP dependence of the Ca^{++}·Mg^{++}ATPase

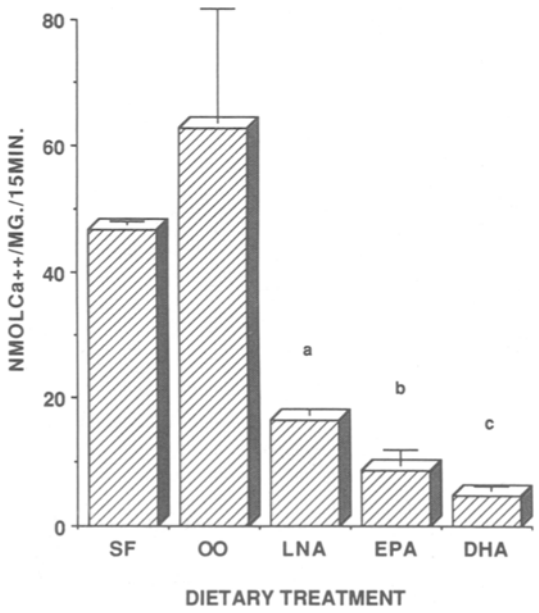

FIG. 1. The effect of different dietary unsaturated fatty acids on the maximum rate of Ca^{++} accumulation by mouse cardiac SR vesicles isolated from mice maintained on diets for 14 days. Results are mean ±SD, n = 3. The Ca^{++} accumulation in n-3 PUFA-enriched diets are significantly different than control (OO); a, $p < 0.05$, b, $p < 0.04$, c, $p < 0.03$. SF, Safflower oil; OO, olive oil; LNA, 18:3n-3; EPA, 20:5n-3; DHA, 22:6n-3.

activity was studied over a wide range of ATP concentrations (0.1-4 mM). A typical Lineweaver-Burk plot obtained over this range and using SR from mice fed SF shows a linear plot for the lower ATP concentrations (0.1-0.5 mM), whereas curvature is apparent at higher concentrations (Fig. 3B). The apparent Km values for ATP obtained at lower concentrations of ATP and in the presence of 30 μM Ca^{++} were 198, 157 and 190 μM, respectively, for the enzyme obtained from mice fed SF, EPA, DHA (average of 2 determinations).

DISCUSSION

All animals gained weight and grew normally, and there was no sign of essential fatty acid deficiency in the animals on the different dietary fatty acids throughout the period of the experiment, indicating that the 18:2n-6 level in the diet was adequate. The cardiac SR fatty acid composition was significantly modified by feeding n-6 or n-3 PUFA within a short period of time, confirming previous results from our laboratory (25,28). Feeding 18:2n-6 or one of the ethyl esters of n-3 PUFA altered the n-6/n-3 ratio in phospholipids in favor of the fatty acid family fed, although more profound modifications were obtained by feeding n-3 PUFA than by feeding n-6 PUFA. The level of n-6 PUFA was markedly lower and the level of n-3 PUFA higher in SR phospholipods of mice fed one of the three n-3 PUFA vs those fed SF or OO in accord with other studies (36-38). Previous results reported that dietary n-3 PUFA replaced 18:2n-6 more efficiently than they replaced 20:4n-6 in the rat cardiac total phospholipids (36-38). However, in the present experiment, 20:4n-6 was replaced more efficiently than 18:2n-6. It is

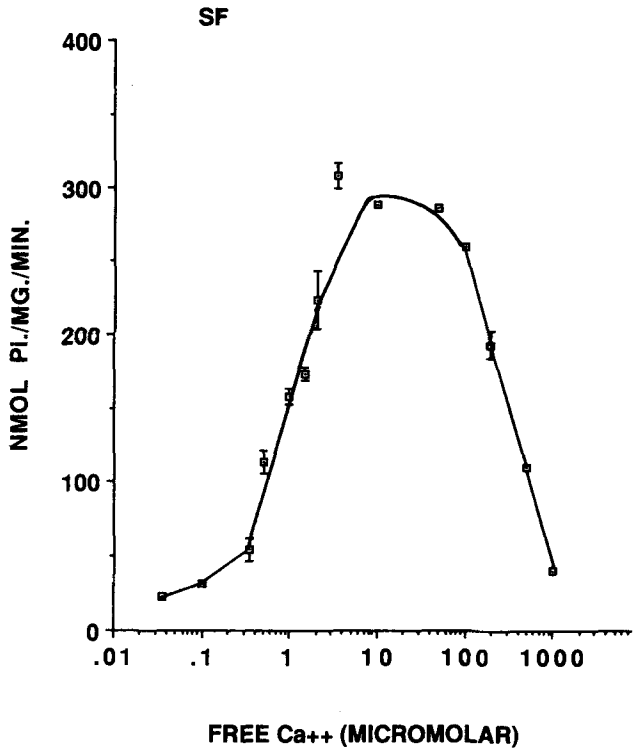

FIG. 2. (A) The dependence of mouse SR Ca^{++}·Mg^{++}ATPase activity on calcium concentration after feeding different n-6 PUFA- and n-3 PUFA-enriched diets. Reactions were carried out with 10 μg of SR protein in Ca^{++}-EGTA buffer and the reaction time adjusted to maintain initial reaction rate at low Ca^{++} concentrations. For Ca^{++} concentrations above 10 μM, only Ca^{++} was added in the medium. Mean ±SD of 3 determinations.

possible that the inhibitory effect of 22:6n-3 on Δ6-desaturase (39), together with the replacement of 20:4n-6 by 22:6n-3, contribute to the drastic decrease in phospholipid 20:4n-6 level from mice fed n-3 PUFA-enriched diets.

Feeding 18:3n-3 or 20:5n-3 resulted in a greater increase of 22:6n-3 in SR phospholipids than of these fatty acids themselves. Cardiac tissue possesses a very limited ability for desaturation (40); therefore, 22:5n-3 and 22:6n-3 acylated in SR phospholipids after feeding 18:3n-3 and/or 20:5n-3 must have been derived mainly from plasma lipids subsequent to their desaturation-elongation in the liver. This specific enrichment of 22-carbon PUFA in cardiac tissue may also reflect a stronger affinity of these fatty acids over 18- or 20-carbon chains fatty acids for the acylation enzymes of this tissues.

The mouse SR Ca^{++}·Mg^{++}ATPase showed Km values for Ca^{++} ranging from 0.8 μM to 1.46 μM. These values are slightly lower than previously reported for canine cardiac microsomes (4.7 μM) (41) and higher than obtained when determinated in absence of Ca^{++} precipitating agent (42). This might reflect a species difference. The double reciprocal plots of the Ca^{++}·Mg^{++}ATPase activity vs ATP concentrations yielded two Km values, as previously reported for ATPase from canine cardiac SR (41). None of these parameters were modified by n-3 PUFA enriched diets vs SF.

Abeywardena et al. (43) have shown that moderate modifications in the membrane fatty acid composition that occur after feeding sheep kidney fat vs sunflower oil to rats did not influence the Ca^{++}·Mg^{++}ATPase activity from cardiac microsomes. In the present experiment, although the membrane fatty acid composition was drastically altered by n-3 PUFA vs n-6 PUFA intake, the Ca^{++}·Mg^{++}ATPase was not altered by these modifications. It has been proposed that modifications in fatty composition of biological membranes result in changes in fluidity and bilayer thickness (24). The optimum activity for Ca^{++}·Mg^{++}ATPase in an enzyme-phosphatidylcholine bilayer reconstituted system is affected by fatty acid chain length (44). In the present study, we observed very little variations in 16- plus 18-carbon chain lengths in the mouse SR fed different diets; a decrease in 18-carbon chains being compensated by the increase in 16-carbon chains. However, the C20/C22 PUFA ratio varied from 1.0 (SF) to 0.19 (DHA) without affecting the enzyme activity. This is in agreement with the results reported by Lee et al. (24), showing that the enzyme is strongly stimulated when the chain length is increased from 12 to 16 carbons, with chains between 18 and 22 carbons supporting similar activities, whereas a further increase up to 24 carbons decreases it.

Membrane fluidity is also an important parameter which may modulate the membrane-bound enzyme activities (13). Electron spin resonance studies measuring the nitroxide-labeled cholestane motion in sonicated phosphatidylserine (PS) vesicles indicated that the hexaenoic

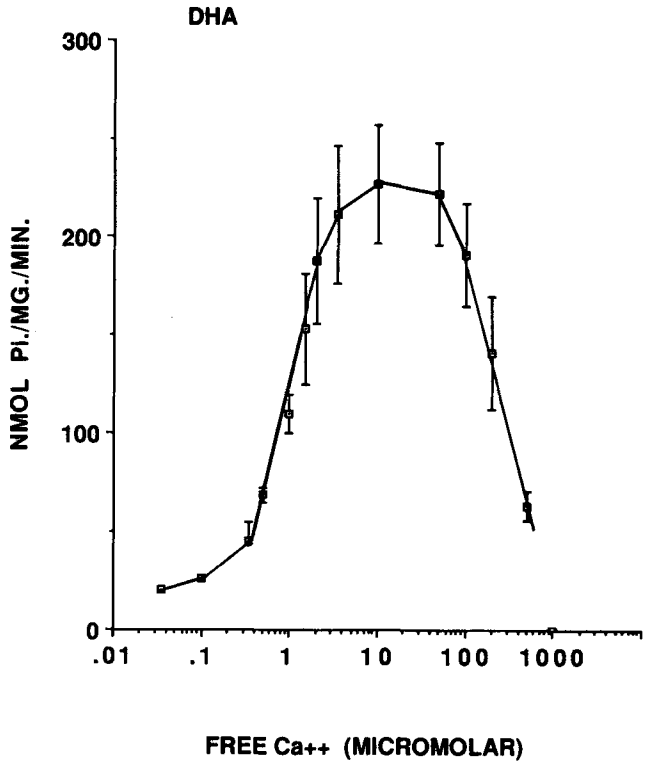

FIG. 2. (C) The dependence of mouse SR Ca^{++}·Mg^{++}ATPase activity on calcium concentration after feeding different n-6 PUFA- and n-3 PUFA-enriched diets. Reactions were carried out with 10 μg of SR protein in Ca^{++}-EGTA buffer and the reaction time adjusted to maintain initial reaction rate at low Ca^{++} concentrations. For Ca^{++} concentrations above 10 μM, only Ca^{++} was added in the medium. Mean ±SD of 3 determinations.

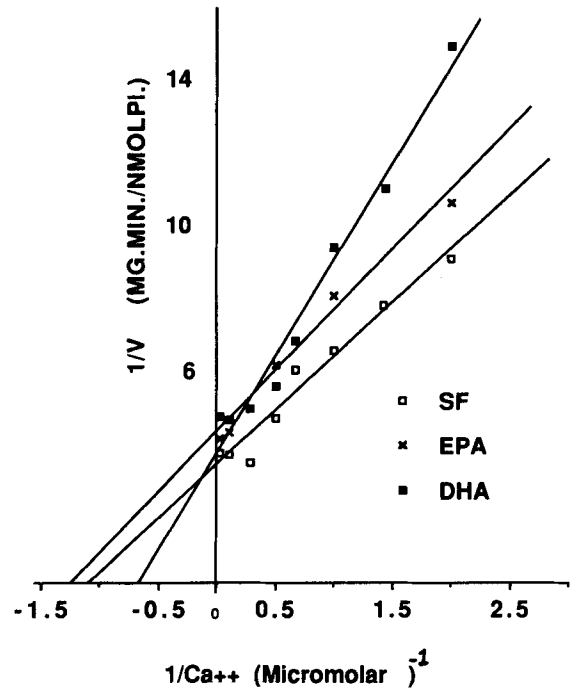
Apparent Ca^{++} Affinity (Km Ca^{++}) and Maximum Velocity (Vmax) of Cardiac Mouse SR Ca^{++}·Mg^{++}ATPase[a]

Dietary treatment	SF	EPA	DHA
Vmax (nmolPi/mg/min)	315 ± 40	246 ± 45	283 ± 50
Km Ca^{++} (μM)	0.95 ± 0.30	0.81 ± 0.37	1.40 ± 0.47

Mean ±SD, n = 3.

[a]After feeding different dietary fatty acids for 14 days.



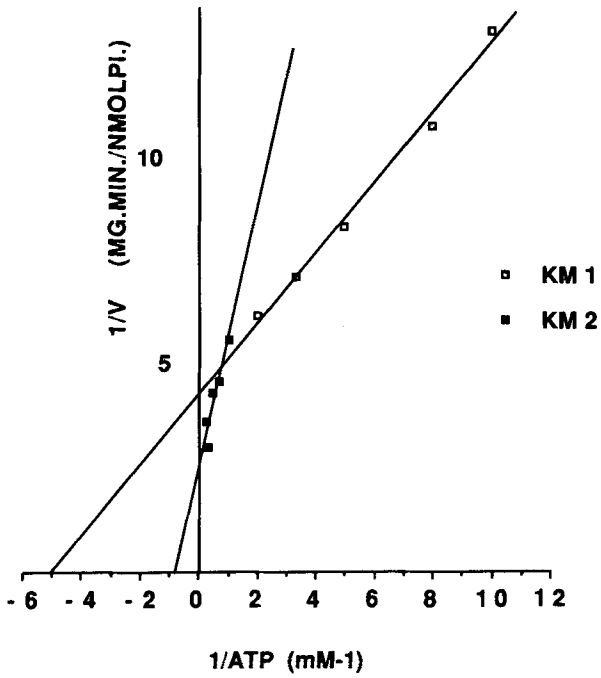


FIG. 3. (A) Lineweaver-Burk plot of the Ca^{++}·Mg^{++}ATPase of cardiac SR isolated from mice after feeding n-6 PUFA and n-3 PUFA diets for 14 days. Initial ATPase activity was measured at 37°C in presence of 2 mM ATP and 30 μg of SR protein. Each point is a mean of 3 determinations. (B) Typical Lineweaver-Burk plot of the Ca^{++}·Mg^{++}ATPase of cardiac SR isolated from mice fed safflower oil. The ATP concentration was varied between 0.1 and 4 mM. Initial ATPase activity was measured at 37°C in presence of 30 μM of Ca^{++}. Each point is an average of 2 determinations.

PS vesicles had the greater probe motion suggesting an increase in fluidity in these vesicles (45). However, in the present study, a 5-fold decrease in n-6/n-3 PUFA ratio in the SR phospholipids from mice fed SF to mice fed DHA did not alter the ATPase activity. In fact, Conroy et al. (46) recently reported that the whole intact membrane can effectively compensate for the decrease in the lipid bilayer order induced by 22:6n-3 in an in vitro model system. Moreover, when ATPase is reconstituted into phospholipids containing a variety of PUFA, the nature of PUFA is of little importance for ATPase activity as long as they maintained a liquid crystalline phase (24). We observed a high ratio of total PUFA to SAT fatty acids (P/S) in the membranes isolated from mice fed either n-6 or n-3 PUFA. These values, which varied from 1.70 (SF) to 1.33 (DHA) assure that lipids are in a liquid crystalline phase,

because the relative content of saturated fatty acids did not exceed 50% of the membrane fatty acid content (24).

Despite the similar ATPase activity, measured by ATP hydrolysis function between the different diets, we observed a significant decrease of Ca^{++} accumulation in n-3 PUFA—enriched vesicles as compared with n-9 PUFA- or n-6 PUFA—enriched vesicles. It is conceivable that a change in the membrane permeability to Ca^{++} is induced following SR enrichment with 22:6n-3 and/or 18:2n-6 plus 20:4n-6 depletion. Both saturated (47) and unsaturated fatty acids (48), when added exogenously to SR vesicles, inhibit Ca^{++} uptake and stimulate Ca^{++} release, although these effects are complex because, under some conditions they inhibited Ca^{++} release whereas they stimulated it under others (49). Fiehn and Hasselbach (50) have shown that phospholipase A_2 treatment of SR vesicles generated free fatty acids and lysophospholipids which remained trapped in the membrane, increased Ca^{++} permeability and inhibited active transport across this membrane without decreasing the ATPase activity. Subsequent removal of these molecules by binding to albumin reestablished the Ca^{++} uptake. It is possible that in the isolation procedure used herein an endogenous release of 22:6n-3 and lysophospholipids occurred which could have inhibited Ca^{++} uptake or promoted Ca^{++} release.

Furthermore, 22:6n-3 is the most oxidizable of the naturally occurring PUFA and generates oxidized products which could alter the membrane integrity of tissues highly enriched in this fatty acid (51). The decrease of Ca^{++} uptake observed after n-3 PUFA supplementation might reflect an increase in lipid oxidation in a membrane highly enriched in 22:6n-3, as it has been described for the retinal rod outer segment membrane (52). Recently, Swanson et al. (28) reported that cardiac SR from mice fed 12-wt% menhaden oil exhibit lower Ca^{++} uptake than SR from mice fed 12-wt% corn oil with a concomitant change of the ATPase activity (28). The present experiments show that decrease in Ca^{++} uptake after 22:6n-3 membrane enrichment can occur without modification in the enzymatic activity and, rather, could be the result of an alteration in the membrane integrity that contributes to decoupling of the enzyme activity and the Ca^{++} uptake by the vesicles. This hypothesis is supported by the demonstration that Ca^{++} permeability through bilayer lipid membranes is highly dependent on the amount of primary oxidation products of phospholipids in these membranes (53). It would also agree with the observation that vitamin E administration corrects the increase of catecholamine cardiotoxicity in rats fed cod liver oil (54).

In conclusion, cardiac mouse SR has a strong affinity for n-3 PUFA and extensively acylates 22:6n-3 into its phospholipids by replacing 20:4n-6 and, to a lesser extent, 18:2n-6. These alterations in fatty acid composition did not significantly modify the Ca^{++}·Mg^{++}ATPase activity, but strongly decreased the Ca^{++} transport by the SR vesicles in vitro, probably by affecting structural integrity of the membrane.

Skeletal Lipid Depletion in Spawning Salmon

C.F. Phleger[a,*], **R.J. Laub**[b] and **A.A. Benson**[c]

[a,b]Center for Marine Studies and Departments of [a]Natural Science and [b]Chemistry, San Diego State University, San Diego, CA 92182; and [c]Marine Biology Research Division, Scripps Institution of Oceanography, University of California, San Diego, La Jolla, CA 92093

Skeletal tissues in Pacific salmon are composed of significant amounts of lipid (which serves as an energy supply), that is then depleted during migration and freshwater spawning. The vertebral centra and neurocrania of ocean prespawning pink salmon *Oncorhynchus gorbuscha*, although composed respectively of 2.9–13% and 0.5–6.3% lipid (each by dry weight), amount only to 0–1.6% and 0–1.4% in river postspawning individuals. The skeletal lipids are 91–98% triacylglycerol with only small amounts of phospholipid and cholesterol. Triacylglycerols of carbon numbers 47, 49 and 51 are selectively depleted during spawning, whereas there are increases in the relative amounts of those of carbon numbers 55, 57, 59 and 61. The patterns of variation of the skeletal lipids of coho salmon, *O. kisutch*, chum salmon, *O. keta*, and sockeye salmon, *O. nerka* are similar to those of *O. gorbuscha*. *Lipids 24*, 286–289 (1989).

In an attempt to extend our understanding of the physiological changes that occur during spawning, we have explored the function of salmon skeleton as a lipid storage tissue. The work was prompted by the noval results of a number of studies in which it has been shown that, in fact, some skeletal tissues of marine fishes (the neurocranium and vertebral centra in particular) are composed of 24–90% (w/w) lipid (1–4). Moreover, the bone lipid in the majority of the 40 species examined to date is primarily triacylglycerol, which has been shown to be metabolized rapidly during starvation experiments (5).

Pacific salmon undergo starvation during the migrational spawning ritual (6–8), consuming in the process most of their body lipid (9–13). The blood calcium level, which is controlled by calcitonin secreted by the ultimobranchial gland, also drops by one half (14,15). Spawning salmon thereby lose calcium phosphate, which results, in turn, in the transformation of bone tissues into cartilage (often accompanied, as well, by grotesque deformations). It, therefore, seemed probable to us that the lipid content of the skeletal tissue also might be altered during spawning. As a result, we assayed salmon bone-lipid triacylglycerols by high-temperature capillary-column gas chromatography (GC) with the view of assessing, first, whether there might occur selective depletion of the triacylglycerols; and, second, if so, which compounds are lost during the spawning process.

MATERIALS AND METHODS

Ocean prespawning salmon were collected by purse seine near Alert Bay, British Columbia. Postspawning fish were taken by dip-net from the Ahta River, which empties into Bond Sound, BC. All were 2.0–2.2 kg, fresh weight. Seven prespawning specimens were selected for study and included three pinks, one chum, one sockeye and two coho. Four postspawning pink salmon were chosen for the work. There were both males and females in the prespawning and postspawning groups. All were dissected on the same day of collection, except for the sockeye salmon which was maintained without food for eight days in aquaria.

The neurocranial and vertebral centra skeletal tissues were dissected out of each fish, rigorously cleaned to remove flesh and brain or nerve cord, and then frozen at −20°C prior to transport. Lipids were extracted with 2:1 (v/v) chloroform/methanol. Tared bones were cut into small pieces and then macerated in a Waring Blendor. The dry weight of bone was taken following evaporation of residual solvent under N_2 or on a rotary evaporator. The lipids were isolated by silica-gel column chromatography, where the neutral species were eluted with chloroform, followed by elution of the polar lipids with methanol (4). All bone lipid examined in this work gave only phospholipid, cholesterol and triacylglycerol by thin-layer chromatography (silica adsorbent; petroleum ether/diethyl ether/glacial acetic acid eluent, 80:20:1).

The neutral lipids were assayed for cholesterol by the Liebermann-Burchard reaction (16). The amount of triacylglycerol was then determined by subtracting the amount found for cholesterol from the total weight of neutral lipids. The polar lipids were assumed to be largely phospholipid. Triacylglycerols were subsequently analyzed by GC (Carlo Erba Model 4160 GC: flame ionization detector, hydrogen carrier; 50:1 split injection). The column was a Model TAP fused-silica capillary obtained from Chrompack (Raritan, New Jersey) that contained a methylphenylsilicone stationary phase roughly equivalent to SE-52. The oven temperature was programmed from 300° to 355°C at 3° min^{-1}. Component triacylglycerols were identified by carbon number by comparison of the chromatograms with published spectra of margarine and palm-oil blends that were obtained with similar stationary phases (17–21). Quantitation was carried out manually by triangulation. The chromatograms of at least 50 samples from the eleven salmon specimens were taken; replicate analyses of those arising from the same tissue of a given fish differed by no more than 2–3%.

RESULTS

The results obtained for the assay of lipid in the neurocranial and vertebral centra tissues of several representative specimens of pre- and postspawning pink salmon, *O. gorbuscha*, are provided in Table 1. The data confirm, first, that skeletal lipid is indeed depleted during migration and spawning. For example, in prespawning specimens, 2.9–13% of the dry weight of the vertebral centra tissue was found to be lipid, as was 0.5–6.3% of the neurocranium; whereas, in postspawning salmon, the vertebral centra was composed of only 0.7–1.6% lipid and the neurocranium just 0–1.4%. (The neurocranium was found, in general, to contain less lipid as a percentage of the tissue dry weight than the vertebral centra.)

[a]Fasted in aquaria for 8 days.

Second, and perhaps somewhat surprisingly, unlike the changes in the absolute amounts noted above, the relative quantities of each class of skeletal lipid were found to be virtually unaffected by spawning. For example, triacylglycerol comprised 91-98% of bone lipid in prespawning pink salmon and 78-98% in postspawning specimens. Also, prespawning phospholipid was 0.2-2.8% and cholesterol 1.5-6.1% of the total lipid content, whereas postspawning pink salmon contained substantially the same levels, i.e., 0.5-3.6% phospholipid and 1.5-20% cholesterol, respectively.

Interestingly, the skeletal lipid of prespawners was orange, the color presumably being due to the carotenoid astaxanthin (22). In contrast, that of postspawning pink salmon was nearly colorless.

The skeletal lipids of prespawning coho salmon, *O. kisutch*, and prespawning chum salmon, *O. keta*, were also analyzed (columns 2 and 3 of Table 2) and were found to parallel those of the prespawning pink salmon previously described. For example, the coho neurocranium was composed on average of 4% lipid, and the vertebral centra 15%. Similarly, the chum neurocranium lipid content averaged 7.1% and the vertebral centra lipid 9.2%. In contrast, the neurocranium of the starved sockeye salmon, *O. nerka*, showed only 0.1% lipid, whereas the vertebral centra had only 1.7%.

Parenthetically, we note that the total skeletal lipid averaged 98-99% triacylglycerol in the coho and chum salmon, yet was composed of only 77-95% in sockeye salmon. We have, as yet, no rationale for this difference.

Gas-chromatographic analysis also revealed selective depletion of component triacylglycerols from the skeletal tissues of postspawning pink salmon, as detailed in Table 3 (note that the triacylglycerol numbers include the three carbons of glycerol). The data obtained for the skeletal triacylglycerol lipids of prespawning coho, chum and sockeye salmon, are also presented in Table 4 for comparison. Triacylglycerols of carbon numbers 47, 49 and

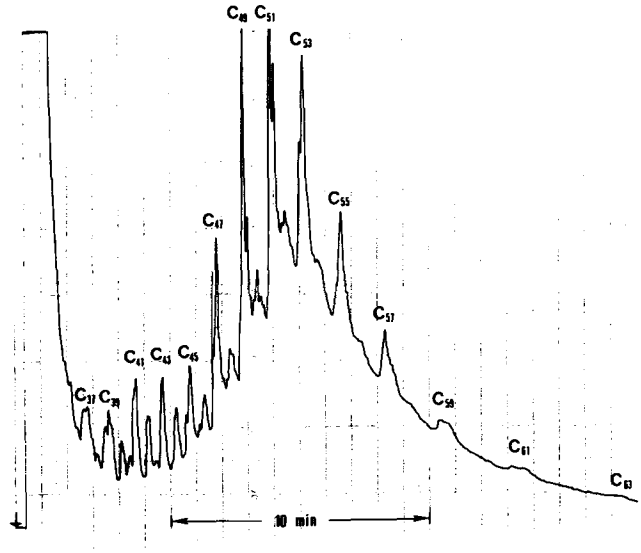

FIG. 1. Gas chromatogram of neurocranial lipid triacylglycerols of indicated carbon numbers (each including glycerol) obtained from ocean prespawning pink salmon, *O. gorbuscha*. Column: TAP fused-silica capillary (Chrompack). GC: Carlo Erba Model 4160 with FID detection and hydrogen carrier; split injections of ca. 50:1. Column temperature: programmed from 300-355°C at 3° min^{-1}.

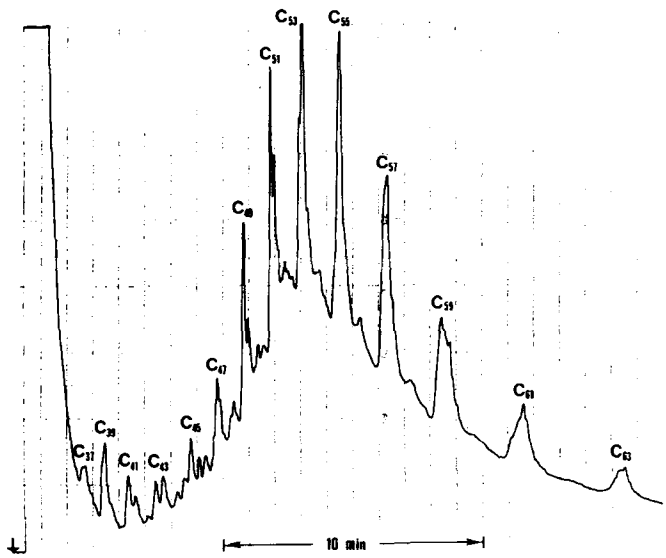

FIG. 2. Gas chromatogram of neurocranial lipid triacylglycerols of indicated carbon numbers (each including glycerol) obtained from river postspawning salmon. Column: TAP fused-silica capillary (Chrompack). GC: Carlo Erba Model 4160 with FID detection and hydrogen carrier; split injections of ca. 50:1. Column temperature: programmed from 300-355°C at 3° min^{-1}.

51 were the primary species lost, as shown in the chromatograms provided in Figures 1 and 2. Also, although those of carbon numbers 54-65 comprised, on average, only 14-16% of the total skeletal triacylglycerol content assayed in prespawners, they were enriched to 44-45% of the total in postspawning salmon. In addition, triacylglycerols of 37-46 carbons were enhanced, albeit slightly, from 2.8-5.1% in prespawners to 8.4-9.2% in postspawning specimens. (There is the possibility that minor amounts of wax esters or glyceryl ethers coeluted with the triacylglycerols; however, none of the former two classes of compounds was detected in replicate thin layer chromatography (TLC) analysis of the samples carried out prior to the GC assays.)

DISCUSSION

The demise of Pacific salmon following spawning is the result of a number of factors, including aging, starvation, atherosclerosis, arthritis and Cushing's syndrome (6), as well as cardiac infarction, liver degeneration and renal failure (23). These are, of course, important factors, as well, in human degeneration. Further, and in addition to the bone demineralization that occurs during the spawning ritual (14,15), lipid depletion in postspawning salmon can also mimic the symptoms of osteoporosis: lipid stored originally in spaces within the bone in prespawners is virtually depleted at its completion. Skeletal lipid is probably not membrane-bound, however, because the phospholipid content of bone tissue was found to be uniformly low (Table 1).

Skeletal-lipid depletion is not unique to spawning salmon. It has, for example, also been observed in controlled starvation studies recently completed on the tropical ocean surgeonfish, *Acanthurus bahianus* (24), in which neurocranium lipid was found to drop from 9-13% after 12 hr to 0.3-3.4% after 72 hr of food deprivation. Bone-lipid depletion has also been observed in the benthopelagic sablefish, *Anopoploma fimbria*, and the temperate shallow ocean sheepshead wrasse, *Semicossyphus pulchur*, following their starvation in aquaria for 96 hr (5). Further, upwards of 90% of the total body lipid of *S. pulchur* is skeletal.

The significance of bone lipid, particularly triacylglycerols, is probably identical to that of lipid in other tissues, i.e., a source of energy. For example, marrow fat cells are similar in composition to those found in adipose tissue. Moreover, in addition to supplying energy to osteocytes, bone lipid can also be used by a number of different cell types that are manufactured in bone tissue.

The evolution, as well as ecological significance, of the lipid content of the skeletal tissues of fish remains obscure, although the occurrence appears to be widespread. For example, oil-filled bones have been found in species that inhabit fresh water (25), midwaters (26), deep benthopelagic layers, (4), tropical marine regions (1,2) and various temperate aquatic climes (4). On the other hand, the representative elasmobranchs analyzed to date have been found to lack significant skeletal lipid. For example, the Chimaeran, *Hydrolagus collei*, has only 1.3% skeletal lipid (2). In mammals, lipid accounts for less than 1% of the dry weight of bone (27). (See, however, Slijper [28] for a discussion of the oil content of whale bones.) Reptiles and amphibians have yet to be assayed for skeletal lipids. Some isotope data suggest that variations encountered in the compositions of bone phosphate compounds in marine sediments might be due to differences extant in the lipid composition (as well as metabolism) of the living individuals (29,30).

Preferential utilization of the more highly unsaturated constituents of fat in starving fishes has been recognized for many years (31), which lends some credence to the selective triacylglycerol depletion from the skeletal lipid of starved postspawning salmon observed in this work. The individual fatty acids of specimen salmon triacylglycerols are, therefore, being assayed in work currently in progress, as are the number, kind, and distribution of positional isomers. The results may be of additional interest regarding heretofore-unrecognized sources of particular omega-3 and 6 fatty acids.

ACKNOWLEDGMENTS

We thank L. Sisson and the crew of the R/V J. Isaacs for help in the field; P. Jolliffe and the Seabiscuit of Alert Bay, British Columbia, for numerous salmon specimens; and the Foundation for Ocean Research for ship support. We also thank J. C. Nevenzel for help with interpreting the data, and S. Patton for his comments on the manuscript. The Department of Natural Science, San Diego State University, provided some travel funds; the analytical work was supported by grants, in part, from the Department of Energy Office of Basic Energy Sciences and from the National Science Foundation to R. J. Laub.

[Received December 14, 1987; Revision accepted December 5, 1988]

Effects of Dietary Fish Oil on Human Mammary Carcinoma and on Lipid-metabolizing Enzymes

Charlotte E. Borgeson, Lani Pardini, Ronald S. Pardini and Ronald C. Reitz*
Department of Biochemistry, Howard Medical Science Building, University of Nevada, Reno, NV 89557

The growth rate of a human mammary carcinoma, MX-1, was significantly reduced in athymic "nude" mice fed fish oil. Tumors from the fish oil-fed animals also showed a greater sensitivity to two anti-neoplastic agents, mitomycin C and doxorubicin. Mitochondria were isolated from control livers, host livers and tumors from fish oil- and corn oil-fed animals, and increased levels of 20:5n-3 and 22:6n-3 were found in mitochondrial lipids in all three tissues from the fish oil-fed animals. To investigate the effect of dietary n-3 fatty acids on lipid metabolism, the activity of the acyl-CoA:carnitine acyltransferase and three acyl-CoA desaturases were measured. Carnitine acyltransferase activity toward all four acyl-CoA substrates tested was markedly increased in mitochondria from liver by feeding fish oil. In mitochondria from tumors, feeding fish oil resulted in an increased activity toward only 18:3n-3. These data suggest that fish oil may induce an increase in the oxidation of fatty acids. The Δ^9-desaturase activity was decreased in microsomes from liver and tumor from fish oil-fed animals. However, both the Δ^6 and Δ^5 desaturases were increased in tumor and in control liver as a result of feeding fish oil. The Δ^5 desaturase was not altered in microsomes from the host animals. The effect of fish oil on the Δ^5 and Δ^6 desaturases may involve alterations to metabolism of specific polyunsaturated fatty acids especially in the tumor tissue.
***Lipids 24,* 290–295 (1989).**

Several studies have shown that dietary lipid has marked effects on the growth of mammary tumors (1). High levels of dietary fat have been shown to promote the development of mammary tumors with polyunsaturated fats (PUFA) being found to be more effective than saturated fats (2–4). Mammary tumorigenesis in rats and mice has been shown to correlate positively with the content of 18:2 in the diet (5,6). In a recent study (7), a diet containing 14% more 18:2 than found in corn oil was shown to suppress tumorigenesis. This diet also contained 9% 18:3n-6. Supplementation with 18:3n-6 has been shown to inhibit growth in three malignant tumor cell lines (8–9), but pure 18:3n-6 given in amounts below that found in primrose oil (<9%) had no effect on tumor growth (10). Of the pure PUFA tested, only linoleate, n-6, has been shown to enhance tumor growth (11). Further, diets rich in fatty acids from the n-3 family (e.g., fish oils) reduce the size and growth of transplantable (12) and induced (13) mammary tumors. Thus, the type and amount of PUFA appear to be important with respect to tumor growth.

Although the mechanism for the effect of n-6 fatty acids on tumor growth has not been elucidated, the high concentration of prostaglandin found in both human (14) and experimental tumors (15) has implicated prostaglandins as tumor growth enhancers. Indomethacin, a cyclooxygenase inhibitor, reduced the mass of a transplantable mammary adenocarcinoma in the BALB/c mice by 50% (16), further supporting the involvement of prostaglandin. Alterations to the 20:3/20:4 ratio may alter tumor growth (17); this effect may be due to a resultant change in the concentration of the monoenoic prostaglandin, PGE_1. Furthermore, PGE_2 has been shown to suppress the immune response and is present in high levels in mammary tumors (18). Thus, promotion of tumorigenesis by n-6 fatty acids may be related to their role as precursors of certain prostaglandins. Dietary n-3 fish oil fatty acids may inhibit tumorigenesis by blocking the production of prostaglandins from the n-6 fatty acids, as the n-3 fatty acids can compete effectively with the n-6 fatty acids for the cyclooxygenase (19) and be converted into different prostaglandins possessing diminished tumor-promoting properties. However, PGI_3 was not detected after incubations of radiolabeled eicosapentaenoic acid (20:5n-3) with aortic tissue (20), which brings into question the role of n-3 acids as precursors of prostaglandins in all tissues. Although conversion of 20:5n-3 to PGI_3 has been demonstrated in homogenates of rat kidney, no PGI_3 was detected in the urinary products from these animals (21). Conversely, in other studies, this prostaglandin has been detected in the urine of humans who consumed 750 g of mackerel per day (22). These data suggest that the inhibition of tumorigenesis by n-3 fatty acids may be related to an altered production of prostaglandin, but considerable research must be done before a mechanism for the effects of the n-3 fatty acids on tumor growth can be established.

The research just described was conducted on tumors of animal origin; to date, no studies have been reported in which human mammary carcinomas have been used. There also have been no reported studies measuring the effect of an n-3-enriched diet on the sensitivity of tumors to anticancer drugs. Thus, we have fed diets rich in n-3 fatty acids to athymic "nude" mice inoculated with human mammary carcinoma, MX-1, and determined the growth rate of the tumor and its sensitivity to two anticancer drugs, doxorubicin and mitomycin C. Because alterations in dietary lipid have been shown to affect lipid metabolism, we also measured the activity of three of the acyl-CoA desaturases and the acyl-CoA:carnitine acyltransferase (CPT). The first three enzymes are involved in the biosynthesis of PUFA, and the latter is a regulatory enzyme in mitochondrial oxidation of fatty acids. A preliminary account of these studies has been published (23).

MATERIALS AND METHODS

Animals and diet: Young adult athymic (nude) mice (female heterozygous BALB/c nu/+) were used. The mice were housed at 27°C in a germ-free laminar-flow animal station and fed autoclaved rodent chow prepared by

*To whom correspondence should be addressed.

Abbreviations: CPT, carnitine acyltransferase; DTNB, 5,5'-dithiobis(2-nitrobenzoic acid); PG, prostaglandin; PUFA, polyunsaturated fatty acid; AIN, American Institute of Nutrition; T/C, percentage treated/control ratio; UI, unsaturation index.

Dyets, Inc., Bethlehem, PA. The basic diet was the American Institute of Nutrition (AIN) (24) diet in which the fat had been replaced with 10% by weight of either corn oil or MaxEPA (Seven Seas Health Care, Marfleet, Hull, England). The fat was mixed with the powdered diet every 1-3 days, and the final diet was kept in the freezer at −20°C until used. The diet was autoclaved prior to use and the fatty acid composition of the diet was determined (Table 1) before and after autoclaving (25). No differences in composition were observed. The MaxEPA was obtained from the R. P. Scherer North America Corp. (Troy, MI). In one set of experiments, the amounts of diet consumed were measured; the animals fed the corn oil diet consumed an average of 4.8 g/day and the animals fed the fish oil diet consumed 4.4 g/day. The data regarding tumor growth from this experiment were representative of the data collected from the other experiments. The animals were given sterile distilled water supplemented with Avitron, a liquid vitamin supplement from Lambert Kay (Cranbury, NJ).

Tumor implantation: The animals were fed their respective test diets for 10 days prior to inoculation with the tumor. The initial source of the MX-1 tumor was from Dr. W. Wara at the University of San Francisco, School of Medicine. This tumor line has been maintained in Reno, Nevada, since 1982. A tumor fragment (1-2 mm^3) of human mammary carcinoma (MX-1) was implanted subcutaneously on the left side of each nude mouse with a 15 gauge needle, 1 cm caudal to the scapula. Tumor dimensions were determined weekly or semiweekly by measuring 3 perpendicular diameters with vernier calipers. Tumor weights were estimated by the formula (A × B × C/2) where A, B and C represent the three perpendicular dimensions in millimeters (26). The tumor growth data were subjected to a one way analysis of covariance.

Doxorubicin (Adriamycin, Adria Laboratories, Inc., Columbus, OH) and mitomycin C (Mutamycin, Bristol Laboratories, Syracuse, NY) were purchased at a local pharmacy and reconstituted or diluted with sterile water to obtain an injection solution of 0.1 ml/20 g body weight. Doxorubicin was administered at a dose of 3 mg/kg body weight, iv, once a week for 3 weeks with the dosage beginning 7-10 days after the tumor implantation. Mitomycin C was administered at a dose of 0.5 mg/kg body weight, ip, once a week for 3 weeks, again beginning 7-10 days after tumor implantation. Tumor weights were estimated every 3-5 days as described above. The percentage treated/control (T/C) ratio was calculated (in mg) as the mean tumor weight of the treated group divided by the mean tumor weight of the appropriate dietary control group multiplied by 100. The criterion for antineoplastic activity was defined as having a percentage T/C ratio <42 (27).

Lipid and enzyme measurements: The acyl-CoA derivatives used in either the desaturase reactions or the CPT reactions were prepared by the procedure of Bergstrom and Reitz (28). Radioactive [1-^{14}C] oleate, [1-^{14}C] linolenate (n-3) and [1-^{14}C] eicosatrienoate (n-6) were obtained from Du Pont NEN Research Products (Wilmington, DE) and unlabeled acid chlorides of the other fatty acids were obtained from NuChek Prep, Inc. (Elysian, MN). The final specific radioactivities of the three desaturase substrates were 3600 dpm/nmol, 2265 dpm/nmol and 5475 dpm/nmol, respectively. Mitochondria and microsomes were prepared as previously described (29,30). CPT was measured using the 5,5′-dithiobis (2-nitrobenzoic acid) (DTNB) procedure described by Parker et al. (31), and the acyl-CoA desaturases were measured as previously described (32). The lipids were extracted by the procedure of Bligh and Dyer (33). The fatty acid methyl esters were prepared from the total lipid extracts by the procedure of Metcalf et al. (34). The total mitochondrial fatty acids were analyzed by gas chromatography (25), and the products of the desaturation reactions were analyzed by radio-high performance liquid chromatography (HPLC) using a LC-8 reverse phase column 15 cm × 4.6 mm with a 3μ particle size obtained from Supelco, Inc. (Bellefonte, PA). The sample was eluted with acetonitrile/water (90:10); slight variations in this solvent ratio were necessary to maximize separation of precursor and product from the three desaturase reactions. A Spectra-Physics SP8700 delivery system was used, and the effluent from the HPLC was directed into a Flo-One Beta model IC flow through scintillation counter from RadioAnalytic, Inc. (Tampa, FL) to quantitate the labeled substrate and product. The CPT-activity data were subjected to an analysis of variance, and the fatty acid compositional data and the desaturase data were analyzed using a Student's t test.

TABLE 1

Dietary Fatty Acid Composition

Fatty acid	Corn oil (% composition)	Fish oil (% composition)
14:0	—	6.0
16:0	11.1	14.2
16:1	0.1	8.6
18:0	2.0	4.1
18:1	25.8	13.2
18:2	58.9	1.6
18:3n-6	—	0.3
18:3n-3	1.6	0.8
18:4n-3	—	3.1
20:4n-6	—	1.3
20:4n-3	—	1.0
20:5n-3	—	17.1
22:1	—	2.1
22:4n-6	—	1.3
22:5n-3	—	2.7
22:6n-3	—	11.1
n-3/n-6	0.03	8.0

The fatty acid composition was determined as previously described (34).

RESULTS

Tumor growth studies: The data in Figure 1 demonstrate that feeding fish oil to the host animals significantly depressed the growth rate of human mammary carcinoma (MX-1), when compared to the corn oil-fed control group. At the end of the experiment, the tumors were excised and measured, and the weights were calculated (Table 2), rather than being weighted directly in order to keep the data consistant with the growth data shown in Figure 1. The mean weight of the tumors from the fish oil-fed group (896 mg) was less than half the mean weight of the corn

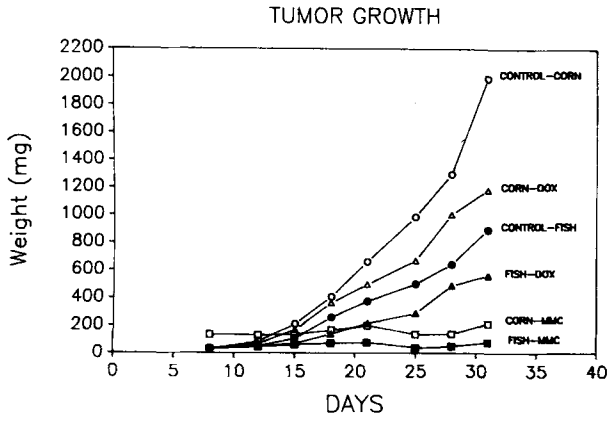

FIG. 1. Effects of corn oil, fish oil and the treatment of each of these two groups with mitomycin C and doxorubicin on the growth rate of transplantable human mammary carcinoma, MX-1, grown in athymic mice. Tumor weights were calculated using the formula (A × B × C/2) where A, B and C represent the three perpendicular dimensions of the tumor in millimeters (26). Each number represents the mean from 9–11 animals from two experiments. Using a one way analysis of covariance, the growth curves for the Control Fish Oil and the Control Corn Oil groups were statistically different with a $P < 0.001$.

TABLE 2

Anti-neoplastic Activity of Mitomycin C and Doxorubicin[a]

	Corn oil (tumor weight)		Fish oil (tumor weight)

Control	1847 ± 1104	—	896 ± 587	—
Mitomycin C	212 ± 232	12	80 ± 128[b]	9
Doxorubicin	1108 ± 484	60	565 ± 338[b]	63

[a]Towards MX-1 human mammary carcinoma grown in athymic mice fed different dietary lipids.

[b]Two of these animals were totally free of tumor at the end of the experiment. n = 11–12 for all groups.

oil-fed group (1847 mg). We also monitored the amount of diet consumed. The corn oil group ate an average of 4.8 gms/day, whereas the fish oil-fed groups ate 4.4–5.1 gms/day.

We next assessed the effect of modifying the dietary lipid on the chemotherapeutic response of the tumor to two antineoplastic agents, mitomycin C and doxorubicin (Table 2). The MX-1 human mammary carcinoma was sensitive to mitomycin C at a dose of 0.5 mg/kg body weight and demonstrated T/C ratios of 12 and 9 for the corn oil- and fish oil-fed groups, respectively. This is supported by the data in Figure 1. Conversely, when considering the T/C ratio in animals treated with doxorubicin (60 and 63 in corn oil- and fish oil-fed groups, respectively), it appeared that MX-1 was insensitive to this drug; however, the data in Figure 1 strongly suggest that feeding fish oil enhances the effect of doxorubicin. In both control and drug-treated groups, fish oil-fed animals had significantly smaller tumors than the corresponding corn oil-fed groups, suggesting that feeding fish oil enhances the chemotherapeutic effect of mitomycin C and doxorubicin. These findings are consistent with the findings of Burns and Spector (35), which showed that enrichment of L-1210 leukemic cells with PUFA increased their sensitivity towards the cytotoxic action of doxorubicin and hyperthermia. The extent to which dietary fish oil decreased the growth of MX-1 was similar to the extent to which doxorubicin decreased the growth of MX-1 in the corn oil-fed group. The mean tumor size of doxorubicin-treated corn oil-fed group was 1108 mg, whereas, the mean tumor size of the control fish oil-fed group was 896 mg. This finding implies that replacing dietary lipid with fish oil is at least as effective in treating MX-1 human mammary carcinoma in the athymic mouse as is chemotherapy with doxorubicin. It should be noted that, in our laboratory, doxorubicin has not been observed to reduce the size of the MX-1 tumor in mice fed regular pelleted rodent chow.

The data in Table 3 present the body weights from 5 separate experiments for the corn oil-fed and the fish oil-fed animals and from 2 separate experiments for the treatments of each of these two groups of animals with mitomycin C and doxorubicin. As can be seen from these studies there was no change in body weight in any of the groups of animals, indicating no toxic effect of either of the two drugs or of the fish oil.

Fatty acid composition of mitochondria: Table 4 shows that feeding fish oil results in marked increases in the content of both 20:5n-3 and 22:6n-3 in isolated mitochondria. The control animals were fed the AIN diet with the appropriate fat, and no tumors were inoculated into these animals. This increase appeared to be at the expense of the major n-6 fatty acids, 18:2 and 20:4. We also observed a significant increase in the amount of 16:0 present in the liver membranes after feeding fish oil. The mitochondria

20:3n-6	400.5 ± 72.5	168.2 ± 36.2	<0.001

Each value represents the mean ± SD from 3-5 animals. The animals were fed the same diets as noted in Table 3. The statistical data resulted from an analysis of variance.

NS, Not significant.

TABLE 6

Effect of Diet and Tumor on Desaturase Activity

	Desaturase activity (nmol/min/mg protein)		
	Control liver	Host liver	Tumor
Δ^9 Desaturase			
Corn oil	2.17 ± 0.55	1.82 ± 0.38	0.21 ± 0.04
Fish oil	1.34 ± 0.52	1.16 ± 0.34	0.16 ± 0.02
P	<0.01	<0.01	<0.01
Δ^6 Desaturase			
Corn oil	0.13 ± 0.05	0.26 ± 0.06	0.08 ± 0.03
Fish oil	0.33 ± 0.07	0.44 ± 0.06	0.14 ± 0.06
P	<0.001	<0.001	<0.01
Δ^5 Desaturase			
Corn oil	0.14 ± 0.05	0.38 ± 0.08	0.07 ± 0.03
Fish oil	0.26 ± 0.03	0.37 ± 0.09	0.10 ± 0.01
P	<0.001	NS	<0.02

Each value represents the mean ± SD from 6-12 animals. Statistical comparisons (Students-t test) were made between the corn oil and the fish oil diets and the significance (P) is shown under the comparisons. Each determination from each animal was done in duplicate. The diets were the same as described in Table 3.

NS, Not significant.

from the tumor tissue had similar changes in their content of PUFA. In addition, there was a decrease in the amount of 18:0 and an increase in 18:1. The calculated unsaturation index (UI) was increased in the liver, as well as the tumor mitochondria, and this was largely the result of the increased amounts of the n-3 PUFA. No changes were observed in the nmol/mg tissue of the total fatty acids. Thus, feeding fish oil has markedly altered only the fatty acid composition of the mitochondrial membrane lipids.

Enzyme studies: Varying the lipid composition of the diet may affect the ability of the mitochondria to oxidize fatty acids after feeding fish oil; therefore, we measured activity of the CPT, the control enzyme for fatty acid oxidation (Table 5). Several different acyl-CoA substrates were used to determine whether fish oil would affect enzyme activity with any or all substrates. In the tumor tissue, feeding fish oil increased the activity with only one substrate, 18:3n-3. However, in the liver of either the host animals or the controls (no tumors), feeding fish oil markedly increased the activity of CPT, with all substrates tested. Interestingly, in the host liver, CPT activity was about half that observed in the control liver from animals that were not inoculated with tumor.

Another group of enzymes that are associated with membranes as integral proteins and which play a role in controlling the unsaturation level of the membrane fatty acids are the acyl-CoA desaturases. We measured the activity of the Δ^9, Δ^6 and Δ^5 desaturases in liver and tumor microsomes after feeding fish oil (Table 6). Feeding

fish oil significantly decreased the activity of the Δ^9 desaturase in liver from both control and host animals and in the tumor tissue. However, in all three groups of tissues, feeding fish oil increased the Δ^6 activity. The activity of the Δ^5 desaturase was increased in control liver and in tumor, but no difference was observed in activity from host liver. The activity of all three desaturases in the tumor tissue was considerably lower than the activities found in both control and host liver, and dietary fish oil significantly decreased the Δ^9-desaturase activity in tumors, whereas both the Δ^5 and Δ^6 desaturases were increased in tumors.

DISCUSSION

All of the previously reported studies involving the effects of dietary fats on the growth characteristics of tumors have been conducted on rodent tumors. The data presented in this report clearly demonstrate that growth of the transplantable human mammary tumor, MX-1, is decreased by dietary n-3 fatty acids or fish oil fatty acids. However, because mammary tumorigenesis has been shown to correlate with the content of dietary 18:2 (4,5), we cannot rule out the possibility that there may be a dual effect of low dietary 18:2 and high n-3 fatty acids. In addition, we have demonstrated that one of the key enzymes in the control of fatty acid oxidation, the acyl-CoA:carnitine acyltransferase, is markedly altered by feeding fish oil. Studies of the oxidation of fatty acids after feeding high-fat diets (15% by wt) have suggested that the enzymes of peroxisomal β-oxidation are selectively induced (36). Furthermore, it was concluded that, in addition to a general induction by high-fat diets, the extent of induction was determined by the fatty acid composition of the diet. No data were presented concerning mitochondrial fatty acid oxidation or any of the enzymes that control fatty acid oxidation. It is generally accepted that transport of fatty acids into the mitochondria via the carnitine acyltransferase controls the oxidation of fatty acids. Although the effects of starvation (37), thyroid conditions (38), diabetes (39) and clofibrate feeding (40) on CPT activity have been examined, no other data regarding the effects of dietary conditions on the activity of CPT have been published.

The marked increase we observed in liver CPT activity from fish oil-fed animals with all of the different fatty acyl substrates may be directly related to an effect of the fish oil diet on the regulation of the enzyme. However, the increased activity may simply be related to an alteration of membrane properties of the mitochondrial membrane as a result of the incorporation of the n-3 PUFA. Brady et al. (41) demonstrated in the Zucker rat that CPT activities respond to alterations in membrane fluidity, i.e., increased fluidity is associated with increased activity. Zammit (42) has suggested that changes in the lipid structure of the inner mitochondrial membrane might alter the interaction between the malonyl-CoA binding protein and CPT. This is supported by the gradual loss in the sensitivity of CPT I to malonyl-CoA observed when the incubation temperature is increased from 0°C to 37°C (43). These data strongly suggest lipid-protein interactions may be important in the control of CPT I, and our data would be consistant with such an interaction.

Decreases in the activities of the three acyl-CoA desaturases have been reported in tumor cells from rat hepatomas with respect to control liver tissue (29). These data indicate a decrease in the de novo synthesis of PUFA and subsequently a decrease in the precursors for prostaglandin synthesis. However, PG concentration in tumor tissues has been found to be increased (14,15). Our data show that feeding fish oil resulted in an increase in the concentration of the n-3 fatty acids in the tumor membranes (Table 4). This could result in a decrease in the ability of the tumor to synthesize prostaglandin (PG) due to the competition of n-3 fatty acids with n-6 fatty acids for the cyclooxygenase (19,44). If tumor growth is correlated with increased amounts of PG, the decrease in tumor growth we noted in the fish oil-fed animals could be then the result of decreased PG synthesis. Furthermore, the slight increase in the Δ^5 and Δ^6 desaturases in tumors from fish oil-fed animals, relative to activities from tumors in corn oil-fed animals, may be an attempt by the tumor to compensate for the lack of PG precursors supplied by the n-3 fatty acids of the fish oil diet by synthesizing more n-6 fatty acids to serve as PG precursors.

Alteration of membrane lipid fatty acid content which would alter membrane fluidity could also have profound effects in the response of tumors to antineoplastic agents by directly modifying an intracellular membrane target site or by affecting the transport of drug to its active site. For example, doxorubicin has been reported to induce modifications in the surface membranes of sarcoma 180 cells (45). Indeed, Tritton and Yee (46) proposed that the antitumor activity of doxorubicin results from its interaction with the tumor cell membranes; thus, dietary alteration of the tumor cell membrane fatty acid composition could be responsible for the enhanced antineoplastic activity observed for doxorubicin when the host was fed fish oil. Alternatively, changing the membrane fluidity through dietary manipulation could alter the transport of doxorubicin and mitomycin c in and out of the tumor cell and/or its organelles. Transport modifications which increase the concentration of antitumor agent at the target site would be expected to increase antitumor activity. Finally, incorporation of the highly polyunsaturated fatty acids from dietary fish oil into the tumor membrane lipids would be expected to increase the susceptibility of the tumor lipids to lipid peroxidation and oxidative stress which could jeopardize membrane integrity, produce toxic aldehyde byproducts, inhibit thiol-containing proteins and cause DNA degradation. Because tumors from fish oil-fed animals would possess high levels of the highly unsaturated n-3 fatty acids, they may be more susceptible to pro-oxidant induced oxidative stress; thus, endogenous lipid peroxidation could be responsible for the slower tumor growth observed in the mice fed fish oil (47). Doxorubicin has been reported to undergo redox cycling with mitochondrial NADH-Coenzyme Q reductase (48) with concomitant production of toxic oxygen species capable of initiating and propagating lipid peroxidation. In fact, Doroshow (49) proposed that oxidative stress was involved in the antineoplastic activity of doxorubicin. Similarly, mitomycin C was reported to undergo bioactivation with subsequent generation of toxic oxygen radicals (50). This, in turn, was correlated to cytotoxicity of aerobically cultured EMT-6 tumor cells. Thus, it is

possible that feeding fish oil predisposes MX-1 human mammary carcinoma to lipid peroxidation and increases its susceptibility to pro-oxidant antitumor agents like doxorubicin and mitomycin C. In addition, the observed increased sensitivity of MX-1 human mammary carcinoma towards these two antitumor agents in the fish oil-fed group may be related to the pro-oxidant activity of these two chemotherapeutic agents. These possible mechanisms of antineoplastic activity require additional experimentation.

[Received June 27, 1988; Revision accepted December 5, 1988]

The Common Occurrence of Furan Fatty Acids in Plants

Kerstin Hannemann, Volker Puchta, Ernst Simon, Herta Ziegler, Gunter Ziegler and **Gerhard Spiteller***
Lehrstuhl fur Organische Chemie I der Universitat Bayreuth, D-8580 Bayreuth, Federal Republic of Germany

The observation that F-acids (1) occur in rat chow initiated a search for F-acids in human diet. We observed that the amount of F-acids with a pentyl side chain in α-position taken up with a one-day diet correlates well with the amount of excreted degradation products, the pentyl urofuran acids (2), (3) and (4). Therefore it can be concluded that F-acids with a pentyl side chain are not produced in the human body but are introduced through the diet. The origin of F-acids carrying an α-propyl side chain is less clear. The amount of propyl-urofuran acids (2) and (3) excreted in urine was found in one case out of three to be five times higher than the amount of F-acids carrying a propyl group in α-position taken up by the diet. Therefore, it can presently not be excluded that a portion of the propyl F-acids is produced by the body.

F-acids found in human food are mainly introduced into the body by vegetables and fruits. F-acids were found also in birch leaves in considerable amounts, as well as in grasses, dandelion and clover leaves. Thus, we can conclude that F-acids are common constituents of plants. ***Lipids 24,*** **296-298 (1989).**

F-acids (1), first shown by Glass and Schlenk (1,2) to occur in fish, were later found in soft corals (3) and crayfish (4). Recently, Watanabe showed that they are also present in amphibians and reptiles (5). Our research detected F-acids in mammals (6), including man (7). F-acids in plants have been reported only once: Hasma et al. (8) detected an F-acid in *Hevea brasiliensis.*

[a]Synthetically produced furan fatty acid.

FORMULA 1

Nevertheless, it was tacitly assumed that F-acids with either 3 or 5 carbons in the aliphatic side chain are produced by animals or man. Biosynthetic experiments with a linoleic acid analog as precursor, in which the side chain had been extended by one carbon atom, were carried out in our laboratory. These experiments failed, because the "labeled" compound was not incorporated into F-acids (9). In the course of these investigations we found that F-acids were introduced into the rats through the diet (9), although previous investigations had shown the absence of F-acids in the rat food (10). This could be explained by the fact that F-acids behave like fatty acids in chromatography and therefore escape detection. If a mixture of fatty acids and F-acids is hydrogenated the resulting tetrahydrofuran acids show a different behavior which allows their separation from fatty acids, even if the latter are present in large quantities (7).

The observation that F-acids are introduced into rats through the diet led us to reexamine whether these compounds may also be part of the human diet. Since it was not known which portion of the diet would contain the F-acids, the whole diet eaten in one day was collected and after extraction an aliquot of the lipids was analyzed for F-acids.

During this experiment we also measured the excretion of the degradation products of F-acids (1), the urofuran acids (2), (3) and (4) (11,12).

RESULTS

Three people each eating a different diet collected for analysis identical quantities of all foods they consumed over the period of the experiment. These food samples were analyzed for lipids as described in the Materials and Methods section of this paper. During the food collection period, urine samples from the test subjects were collected and analyzed for urofuran acids. Each lipid fraction of the dietary samples was hydrolyzed and hydrogenated to tetrahydrofuran acids (7) which, after methylation, can be more easily separated from fatty acids than the corresponding F-acids (7) by thin-layer chromatography (TLC).

[a]The values were determined by GC. Peak areas of the F-acids were compared with the area of the synthetic F-acid (**1h**) added at an amount of 100 μg as an internal standard. Each sample was lmeasured three times.

The methyl esters of the tetrahydrofuran acids were separated by gas chromatography (GC) and identified by mass spectrometry (MS). Table 1 gives the results of these measurements.

DISCUSSION

The data in Table 1 show that the amount of F-acids with a pentyl side chain in the α-position introduced into the body through the diet corresponds well with the amount of excreted urofuran acids. The results obtained with α-propyl substituted F-acids do not allow the same clear conclusion to be drawn. Considering the facts that propyl- and pentyl-urofuran acids show a different tendency for adsorption by albumin (13) and that propyl-urofuran acid is excreted in a circadian rhythm while pentyl-urofuran acid does not follow such a rhythm (14), it might be concluded that some of the propyl F-acids are produced in the body.

One source of F-acids may be meat or fish; however, the amounts of F-acids introduced into the body by normal daily fish and meat consumption are low when compared with the excreted amounts of urofuran acids (2), (3) and (4) (11). In looking for other sources of F-acids, we detected these compounds in oranges. Further, F-acids degradation products, the cyclopentenolons (5) and (6) (15), were found in soy oil, but only in low amounts.

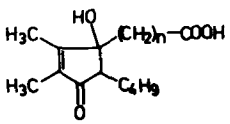
FORMULA 6



6 n = 8, 10

FORMULA 7

These findings, together with Hasma's earlier observation (8) on the occurrence of ab F-acid in the latex of *Hevea brasiliensis*, prompted us to draw the conclusion that F-acids may occur frequently in plants.

Subsequently, a thorough investigation of plant material revealed that F-acids occur in the roots and blades of grasses (*Poaceae spec.*), in clover (*Trifolium pratense*), and also in certain vegetables (e.g. in chive [*Allium sativum*] and cabbages [*Brassica oleracea spec.*]); in potato (*Solanum tuberosum*), wheat (*Triticum aestivum*) and rice (*Oryza sativa*); in some fruits (in lemon [*Citrus limon*], strawberries [*Fragaria spec.*] and orange [*Citrus sinensis osbeck*]); in algae (*Chlorophyta spec.*), in the trunk of birch (*Betula pendula*), and in dandelion (*Taraxacum officinale*). F-acids occur in comparatively high amounts in the green parts of plants (Table 2). Only small amounts (typically 1/100 to 1/1000 of that found in the green parts) occur in the trunks, roots and seeds (Table 2).

We also found the F-acid (**1d**) in mushroom (*Agaricus bisporus*), and traces of the F-acids (**1d**) and (**1g**) in yeast (*Saccharomyces cerevisiae*). In the mushroom the F-acid (**1d**) predominates, while in plants (**1g**) is the main F-acid. In comparison with the amounts found in vegetables (with the exception of potato) and fruits the amounts of (**1g**) found in the blades and leaves of grasses, in dandelion, and in birch are very high. Interestingly, among the land plants and other species so far investigated, F-acids with a propyl side chain occur only in traces. The algae *Chlorophyta spec.* were the only species treated in which high amounts of an F-acid with a propyl side chain was detected (Table 2).

MATERIALS AND METHODS

Gas chromatography (GC) and gas chromatography-mass spectrometry (GC-MS). GC was carried out with a

[a]The values were determined by comparing the GC peak areas of the identified F-acids with the area of the synthetic F-acid (1h) added to each sample as an internal standard.

Packard model 438S from United Technologies equipped with a flame ionization detector (FID), on a wall-coated open tubular (WCOT)-glass capillary (30 m × 0.3 mm) OV-101 column, temperature programmed from 100°C to 240°C at 2°C min^{-1}. The temperatures of the injector and detector were kept at 270°C and 290°C, respectively. Peak area integration was done by a Shimadzu C-R3A integrator. The carrier gas was hydrogen. The split ratio was 1:10.

GC-MS was performed on a Finnigan MAT 312 GC-MS system with a MAT SS 300 data system. Electron impact mass spectra were recorded with an ionizing energy of 70 eV. The GC column was a 25-m × 0.3-mm i.d. OV-101 WCOT glass capillary column. The carrier gas was helium (2 ml min^{-1}), and the temperature program was the same as used for GC.

Nutrition experiment. Over a period of 5 days, the urine excreted in the 24 hr between 8 a.m. of one day and 8 a.m. of the next day was collected individually from three persons (two male, one female). The urine samples were stored at −20°C.

Quantification of urofuranic acids (2), (3) and (4) in urine. One-ninety sixth (corresponding to 15 min) of a 24-hr urine sample was acidified with conc. HCl, and diluted with water to 20 ml. Ten μg 3-carboxy-4-methyl-5-pentyl-furan-2-acetic acid was added as an internal standard. The extraction of organic compounds and the quantifaication of urofuranic acids (2), (3) and (4) were done as previously described (9), using Chromabond-C_{18} and Chromabond-Si solid phase extraction columns (Macherey & Nagel; D-5160 Düren, Federal Republic of Germany). The amount of urofuranic acids (2) and (3) was calculated by peak area integration, by comparison with the internal standard.

Quantification of F-acids (1) in human food and plants. To each sample 100 μg of (1h) were added as an internal standard. The extraction of the lipids was performed according to the method of Bligh and Dyer (16), and the crude lipid extract was subjected to a "Folch wash" with 0.88% potassium chloride solution (17).

After partition, the chloroform layer was evaporated to dryness under reduced pressure and the residue was saponified with 200 ml 1-N potassium hydroxide solution (methanol/water, 9:1, v/v) under an atmosphere of nitrogen, for 14 hr, which was necessary to hydrolize amid fatty acid bonds, too (18). After cooling and acidification with conc. HCl the potassium chloride was filtered off and 100 ml chloroform and 100 ml water were added. The chloroform layer was separated, the solvent removed under reduced pressure and the residue esterified with ethereal diazomethane. Column chromatography, thin layer chromatography and hydrogenation were done as previously described (7).

The furan fatty acids (1) were quantified as to their tetrahydrofuran methyl esters by peak area integration, using the internal standard (1h) for comparison (7).

ACKNOWLEDGMENT

We thank the Deutsche Forschungsgemeinschaft, the Robert Pfleger-Stiftung in Bamberg and the Fonds der Chemischen Industrie for their financial support. We also thank Michael Glaeßner for running the mass spectra and Dietrich Laatsch for providing the glass capillary columns.

Oxidation of Vitamin E in Red Cell Membranes by Fatty Acids, Hydroperoxides and Selected Oxidants

G.T. Vatassery*

Geriatric Research, Education and Clinical Center, Neurology and Research Services, VA Medical Center, Minneapolis, MN, and the Department of Neurology, University of Minnesota Medical School, Minneapolis, MN 55455

Our laboratory previously reported that vitamin E (tocopherol) in human blood platelets was oxidized *in vitro* by various oxidants. This paper shows that diamide, superoxide, hydroperoxides and polyunsaturated fatty acids induce oxidation of tocopherols in red cell membranes. In contrast to platelets, red cell membrane tocopherol was oxidized by hydrogen peroxide and tertiary butyl hydroperoxide. Alpha tocopherolquinone was one of the products of oxidation. Among the fatty acids, the *cis* polyunsaturated acids were the most potent oxidizing agents with monounsaturated and *trans* compounds relatively ineffective. The oxidation is not a detergent effect of the fatty acids since neither the detergents Brij and Lubrol, when present in concentrations under 0.5 mM, nor sodium arachidate (1.25 mM), could oxidize the membrane tocopherol. When red cell membrane samples were incubated with 0.5 mM arachidonate, 47 ± 11% (S.D.) of the tocopherol lost was converted to tocopherolquinone. Unlike arachidonate, oxidants such as diamide, hydrogen peroxide and tertiary butylhydroperoxide are unable to oxidize all of the membrane tocopherol and produce less tocopherolquinone from oxidation (10–15%) under the experimental conditions of this study. Linoleic acid hydroperoxide is a much more potent oxidant and produces less quinone than arachidonate. The mechanisms of tocopherol oxidations induced by the various compounds seem to be different since the yields of quinone during oxidation vary with the nature of the oxidant. Tocopherol is consumed by oxidation as it protects the membrane from oxidant damage induced by compounds such as unsaturated fatty acids and hydroperoxides.
***Lipids* 24, 299–304 (1989).**

The literature contains reports of many experimental investigations demonstrating that tocopherols (T) are very potent lipid antioxidants. Most of these studies have focused on the reactions of T in chemical media and the conversion of T to tocopherolquinone (TQ) (Fig. 1) has been shown to occur under various conditions. For example, Fukuzawa and Gebicki have shown that α-T present in micelles and liposomes is oxidized to TQ by hydroxyl and superoxide free radicals (1). Alpha chromanoxyl radical is an intermediate in this reaction (2). The alpha chromanoxyl radical can be further converted to the quinone and other oxidation products or be regenerated to the original vitamin E through the action of vitamin C (2–4).

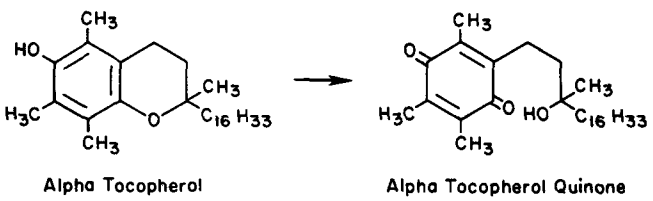

FIG. 1. Oxidation of alpha tocopherol to alpha tocopherolquinone.

The oxidation of α-T to TQ is of considerable significance in understanding the mechanism of action of the T compounds as biological antioxidants. Recently we have observed that T in human platelets can be oxidized in vitro to TQ by various oxidants (5). This report shows that a very similar (but not identical) oxidation of T takes place when human red cell membranes are challenged *in vitro* with unsaturated fatty acids such as arachidonate or other oxidants like peroxides, fatty acid hydroperoxide, diamide or superoxide.

MATERIALS AND METHODS

Human subjects. Human male subjects 25–55 years of age were selected for the study. These healthy volunteers fasted for 12 hr prior to drawing of venous blood from the arm in the morning. None of the subjects were on any weight-reducing or other dietary regimens or were taking high doses of vitamins or minerals.

Chemicals. All chemicals used were of reagent grade purity from standard sources. Solvents used for chromatography were HPLC grade from Burdick and Jackson Laboratories, Inc., Muskegon, MI 49442. Other special chemicals used were purchased from the following sources: α-T, γ-T and TQ from Kodak Laboratory Chemicals, Rochester, NY 14650; tertiarybutylhydroperoxide from Sigma Chemical Company, St. Louis, MO 63178; hydrogen peroxide from Fisher Scientific, Springfield, NJ 07081. Absolute ethanol was obtained from Midwest Solvents Company, Pekin, IL 61555 and was redistilled prior to use. Sodium salts of the fatty acids were obtained from Nuchek Prep Inc., Elsian, MN 56028. The detergents, Brij and Lubrol, were obtained as specially purified 10% aqueous solutions from Pierce Chemical Company, Rockford, IL 61105. Hydroperoxy-linoleic acid (13S Hydroperoxy) was obtained from Oxford Biomedical Research Inc., Oxford, MI 48051.

Isolation of red blood cell membranes and protocol for incubations. Blood was obtained in heparinized vacutainer tubes from human subjects who had fasted overnight. The red blood cell membranes were isolated by a procedure described by Burton et al. (6) which is a minor modification of the original procedure of Dodge et al. (7). Even though no other special precautions were taken the membranes obtained appeared white. The red cells were lyzed and the membranes isolated by centrifugation and washed three times with successively lower concentrations of phosphate buffer (6). The *in vitro* incubation of red cell membranes was done at room temperature (20–22°C) for 120 min in 50 mM potassium phosphate

*To whom correspondence should be addressed at GRECC Program, 11G, VA Medical Center, Minneapolis, MN 55417.

Abbreviations: BHT, butylated hydroxytoluene; diamide, diazine dicarboxylic acid *bis*(N,N-dimethylamide); T, tocopherols; TQ, tocopherolquinone.

buffer at pH 7.4. All incubations were performed at a final membrane protein concentration of 300 μg/ml. The total reaction volume ranged from 1 to 2 ml. The sodium salts of fatty acid or other substances were added to start the incubation. The sodium salts of unsaturated fatty acids were always kept under argon after the vial was broken and were used for only a week after opening. The salts were dissolved in water which was exhaustively deaerated wth argon. The tubes were mixed briefly on occasion during the incubations. At the end of incubation, tubes were centrifuged at 27000 g for 12 min, supernatants were removed and the pellets assayed for α-T and TQ.

Biochemical assays. All experiments were repeated on a separate day using blood samples from a different donor. Data from typical experiments are reported. Concentration of total protein was determined by the Lowry technique as modified by Markwell et al. (8).

Liquid chromatography of tocopherols. The liquid chromatographic method for determination of tocopherols was a modification of our published reports (9,10). Briefly, 2 ml ethanol containing 0.025% butylated hydroxytoluene (BHT) and 0.1 ml of 30% ascorbic acid were pipetted into the tubes containing samples for T analysis. The mixture was saponified at 60°C for 30 min after the addition of 1 ml of 10% potassium hydroxide solution. The tubes were cooled and 2 ml of water was added followed by 2 ml of hexane containing 0.025% BHT. T was extracted into the hexane phase by vortexing for one min. Hexane phase was separated out, dried with anhydrous sodium sulfate and analyzed by either normal phase (Zorbax Sil column; mobile phase—1% methanol in hexane) or reverse phase (Zorbax C18; mobile phase—methanol:water, 98:2) liquid chromatography. The tocopherols were detected by their native fluorescence (excitation 295 nm, emission 340 nm).

Liquid chromatographic conditions for analysis of TQ. The details of the procedure for determination of TQ in membrane samples have been reported (11). Briefly, the samples for TQ analysis were mixed with 0.1 ml of 30% ascorbic acid and 2 ml of distilled ethanol containing 0.05% BHT. One ml of 10% potassium hydroxide was added, and all tubes were saponified for 30 min at 55°C. The mixture was cooled and extracted with 2 ml of hexane. Known volumes of the hexane layer were pipetted into tubes and the solvent evaporated off under nitrogen using an N-evap. The residue was redissolved in 0.2 ml of the mobile phase (methanol/water, 98:2) and used for reverse phase chromatography of TQ. The TQ was detected by UV absorption of the compound at 265 nm.

Superoxide production. The xanthine-xanthine oxidase system was used for the production of superoxide as recommended by Fridovich (12). The incubation was done at room temperature (20–22°C) under the following conditions: pH 7.8, xanthine 50 μM, 100 μM EDTA, 50 mM potassium phosphate, xanthine oxidase 0.1 μM. After incubation the red cell membranes were pelleted and analyzed for T and TQ by liquid chromatography.

RESULTS

The influence of the structure of fatty acid upon oxidation of α-T in red cell membrane was studied first. The membrane samples were incubated with fatty acids of different chain lengths and unsaturation with the final concentration being 0.5 mM. The results show that only polyunsaturated fatty acids are able to cause measurable oxidation of α-T (Table 1). The data also demonstrate that linoleate with *cis* double bonds is much more potent than *trans* linoelaidate. Since it is possible that α-T could have been released into the medium when the red cell membranes were incubated with the fatty acid, samples of the incubation medium were collected after centrifugation. Analysis of these samples failed to show measurable levels of α-T in the incubation medium.

Proteins such as serum albumin which bind fatty acids are known to be present in many tissues and physiological fluids. Therefore, the effect of addition of albumin to the incubation medium prior to addition of arachidonate was studied. Oxidation of T in the red cell membrane proceeded until the final concentration of albumin reached 0.1%, at which point oxidation was inhibited. When the final concentration of albumin was 0.3% or above, the oxidation of T was completely inhibited, suggesting that the oxidation is induced by the unbound fatty acids.

Metal ions and their chelates are potent agents affecting redox equilibrium under a variety of biochemical conditions. However, addition of ethylenediaminetetraacetic acid or desferrioxamine methanesulfonate to the incubation medium before addition of arachidonate did not block oxidation of T. This suggests that metal ions or their chelates are not involved in the oxidation of T in red cell membranes by arachidonate.

Chemical changes produced in biological matrices by fatty acids (especially when they are present in high concentrations) could be ascribed to the so-called detergent properties of the fatty acids. It is difficult to rule out such detergent effects. An experiment was conducted where the red cell membranes were incubated with the detergents Brij and Lubrol. Since detergents can solubilize membranes, T concentrations in both membrane pellet and supernatant were determined. (It is interesting to note that when membrane samples were incubated with fatty acids, no T could be detected in the incubation medium.) The results given in Table 2 show that Brij does not alter T concentrations in the membrane even up to a final concentration of 5 mM. Lubrol will oxidze membrane T when the final concentration is near 1 mM. The

[a]Mean ± S.D. for three determinations.

Red cell membrane samples were isolated from the blood of one human volunteer. Each incubation tube contained 300 μg of membrane protein and was incubated under conditions given in Methods (also see legend of Table 1) after the addition of the required amount of Brij or Lubrol.

TABLE 3

Yield of Alpha Tocopherolquinone From the Oxidation of Alpha Tocopherol in Human Red Cell Membranes Upon Incubation with Arachidonate

Human donor	Total membrane protein (mg)	Alpha tocopherol originally present in membrane samples (nmol)	Alpha tocopherol oxidized (nmol)	Alpha tocopherol quinone produced (nmol)	Alpha tocoperol quinone produced as % of alpha tocopherol oxidized
A	750	0.432 ± 0.013[a]	0.275 ± 0.018	0.114 ± 0.011	42
B	600	0.423 ± 0.003	0.175 ± 0.007	0.063 ± 0.003	36
C	600	0.574 ± 0.005	0.409 ± 0.016	0.252 ± 0.015	62
D	600	0.586 ± 0.004	0.399 ± 0.009	0.188 ± 0.012	47
					47 ± 11 (S.D.)

[a]Mean ± S.D. for three incubation tubes.

Fasting blood was obtained from four separate human male volunteers, and red cell membranes were isolated. Each incubation tube contained 600–750 μg of total protein and was incubated at room temperature (20–21°C) with 0.5 mM arachidonate. Alpha tocopherol and quinone in the membrane were determined by liquid chromatography.

lack of oxidation of membrane T by 5 mM Brij, 0.5 mM Lubrol as well as saturated fatty acids (1.25 mM arachidate) suggests that T oxidation is not due to the detergent-like property of fatty acids.

The yield of quinone during oxidation of membrane T by arachidonate was then investigated by processing the membrane pellets for quantitative determination of both T and TQ. The results given in Table 3 show that the yield of TQ from T is quite variable in red cell membrane samples from different human subjects and that TQ accounts for an average of 47 ± 11% (S.D.) of the total T oxidized. It is quite likely that other oxidation products of T such as dimeric molecules are also formed during the in vitro incubations.

Many chemical compounds are known to oxidize components within the red blood cell and its membrane. Peroxides form one chemical class of such oxidants. In one set of experiments, red cell membrane samples were incubated with different concentrations of hydrogen peroxide or tertiary butyl hydroperoxide. The results in Table 4 show that substantial oxidation of T is induced by both peroxides. In contrast to arachidonate which was capable of oxidizing nearly the entire amount of tocopherols in the membrane, peroxides did not oxidize all of the membrane T even when they were present in final concentrations of 10 mM. In a separate experiment it was also found that an average of 11.3% of the T oxidized was converted to TQ during oxidations with hydrogen peroxide.

Another oxidant of the peroxide class which is of particular interest is fatty acid hydroperoxide. A comparison between the oxidations induced by arachidonate and linoleic acid hydroperoxide (13S hydroperoxy) is shown in Table 5. Linoleic acid hydroperoxide is much more potent as an oxidizing agent than arachidonate. The mechanism of oxidations of red cell membrane T by arachidonate and linoleic acid hydroperoxide appear to be different since the yield of TQ is much less with the hydroperoxide-induced oxidations (Table 5). In this respect linoleic acid hydroperoxide resembles other peroxides like hydrogen peroxide.

Diamide has been studied in great detail as an oxidant. The results of incubating red cell membranes with varying concentrations of this compound are given in Table 6. Like the other oxidants, diamide also oxidizes T in membranes. Unlike arachidonate, this compound did not completely oxidize T in the membrane sample even when present in high concentrations of up to 10 mM. Furthermore,

TABLE 4

Effect of Addition of Hydrogen Peroxide and Tertbutyl Hydroperoxide to the Incubation Medium Upon Alpha Tocopherol Concentrations in Human Red Cell Membranes

Peroxide used	Final peroxide concentrations (mM)	Alpha tocopherol in membrane after incubation (μg)	Alpha tocopherol oxidized	
			In μg	As % of original alpha tocopherol
Hydrogen peroxide	0	0.128 ± 0.002[a]		
	0.05	0.118 ± 0.008	0.010	7.8
	0.10	0.104 ± 0.004	0.014	10.9
	0.50	0.083 ± 0.004	0.045	35.2
	1.0	0.076 ± 0.006	0.052	40.6
Tertbutyl hydroperoxide	0	0.160 ± 0.005		
	0.1	0.094 ± 0.005	0.066	41.3
	1.0	0.069 ± 0.002	0.091	57.0

[a]Mean ± S.D. for separate incubation tubes.

Red cell membranes were isolated from the fasting blood of two separate human donors. Each incubation tube contained 300 μg of membrane protein. After incubation alpha tocopherol concentrations in the red cell membrane pellets (obtained after centrifugation of the incubation tube) were determined by liquid chromatography.

TABLE 5

Comparison of Oxidation of Tocopherol in Human Red Cell Membranes Induced by Arachidonate and Linoleic Acid Hydroperoxide

Oxidizing agent	Concentration	Alpha tocopherol remaining in the membrane (nmol)	Alpha tocopherol oxidized (nmol)	Tocopherolquinone produced (nmol)	Yield of tocopherol-quinone (%)[c]
None	—	0.525 ± 0.011[a]		—[b]	
Arachidonate	500 μM	0.275 ± 0.010	0.250	0.131 ± 0.007	52.4
Linoleic acid hydroperoxide	10 μM	0.171 ± 0.009	0.354	0.013 ± 0.003	3.6

[a]Mean ± S.D.

[b]The control membrane sample contained 0.008 ± 0.001 nmol of tocopherolquinone. This blank was subtracted from the experimental tocopherolquinone values for the membranes treated with arachidonate or linoleic acid hydroperoxide.

[c]The yield of tocopherolquinone is expressed as percent of alpha tocopherol oxidized.

Red cell membranes were obtained from one human volunteer. Samples containing 450 μg protein were incubated as described under Materials and Methods. Alpha tocopherol and tocopherolquinone were determined by liquid chromatography.

TABLE 6

Oxidation of Alpha Tocopherol and Production of Alpha Tocopherolquinone During Incubation of Human Red Cell Membranes With Diamide

Concentrations of diamide in the medium	Amount of alpha tocopherol in membrane after incubation (nmol)	Amount of alpha tocopherol oxidized (nmol)	Amount of alpha tocopherol quinone produced (nmol)	Alpha tocopherol quinone produced as % of alpha tocopherol oxidized
0	0.718 ± 0.018[a]	0	0	0
2 mM	0.471 ± 0.005	0.247	0.030 ± 0.003	12.2
5 mM	0.386 ± 0.008	0.332	0.034 ± 0.002	10.2
10 mM	0.349 ± 0.006	0.369	0.047 ± 0.04	12.7

[a]Mean ± S.D. for three incubation tubes.

Red blood cell membranes were isolated from the blood of one human volunteer. Enough diamide was added to each incubation tube to reach final concentrations noted in the first column. The individual tubes contained 750 μg of total protein. After incubation, concentrations of alpha tocopherol and quinone in the membrane pellets were determined by liquid chromatography.

TABLE 7

Alpha Tocopherol Oxidation in Human Red Blood Cell Membranes Induced in vitro by Superoxide

	Amount of alpha tocopherol in membrane after oxidation (μg)	Alpha tocopherol oxidized (μg)	Alpha tocopherol oxidized as % of original
Control	0.163 ± 0.003[a]	0	0
Arachidonate (1 mM)	0.034 ± 0.003	0.129	79.1
Xanthine + xanthine oxidase	0.141 ± 0.001	0.022	13.5
Xanthine + xanthine oxidase + superoxide dismutase	0.162 ± 0.001	0	0

[a]Mean ± S.D. for three separate incubation tubes.

Blood was obtained from one human volunteer after an overnight fast and red cell membranes isolated. Each tube containing 514 μg of protein was incubated after adding the different agents. Alpha tocopherol remaining in the membrane was determined by liquid chromatography. These incubations were conducted at a pH of 7.8 in 50 mM phosphate buffer.

TQ accounted for only 10–13% of the total T eliminated. The corresponding figures for the yield of TQ during oxidations induced by arachidonate, hydrogen peroxide and linoleic acid hydroperoxide wre 47% (Table 3), 11.3% (see above), and 3.6% (Table 5), respectively.

Oxidative damage produced by superoxide in biochemical systems has been studied in great detail. Using the xanthine-xanthine oxidase couple for generation of superoxide in situ, an experiment was performed to see the effect of superoxide on T in red cell membrane preparations. The incubation conditions, including a pH of 7.8, were selected to optimize the steady production of superoxide. The results in Table 7 show that superoxide generation in the medium causes oxidation of T in the membrane. TQ could be detected chromatographically as a product of oxidation even though it was difficult to quantitate the small quantity of TQ produced. The low yield of TQ was expected because the T oxidized was only 14% of the total T, and only a fraction of the T oxidized is expected to be converted to the TQ. The blocking of superoxide-induced oxidation of T in membrane by addition of superoxide dismutase to the incubation medium prior to addition of xanthine + xanthine oxidase confirms the finding that superoxide is the active agent causing oxidation of T in membrane.

DISCUSSION

Concentration of the T oxidation product TQ is quite low in normal mammalian tissue or membrane samples according to our analysis as well as the report of Bieri and Tolliver (13). One of the major reasons for this lack of detectable levels of oxidation products from T could be regeneration of T by other antioxidant substances such as ascorbic acid. In 1968, Tappel proposed that vitamin C can regenerate vitamin E from the tocopheroxyl radical (3). Investigations have also been conducted to determine whether vitamin C can have a sparing effect on the utilization of vitamin E. After reviewing several studies, many of which were done in pure chemical media, McCay (14) concluded that the data strongly suggest that vitamin C can regenerate vitamin E even though it is not possible to rule out unequivocally other alternative explanations of all the experimental data.

The experiments reported in this paper clearly demonstrate that oxidants which vary widely in chemical structure such as unsaturated fatty acids, diamide, peroxides such as hydrogen peroxide, tertiary butyl hydroperoxide and hydroperoxy linoleic acid, and superoxide oxidize T present in red cell membrane under the *in vitro* conditions used. As expected, TQ is one of the products of oxidation. Since the oxidation is expected to involve free radicals and might also result in the intermediate formation of tocopheroxyl radical, it is very likely that addition products derived from the tocopheroxyl radical are also being formed. In this study only one oxidation product, TQ, was followed. As described earlier (see Results) oxidation of T induced by arachidonate yields much more TQ than the oxidations by linoleic acid hydroperoxide, hydrogen peroxide, tertiary butyl hydroperoxide or diamide (47% vs less than 13%).

Hydrogen peroxide, tertiary butyl hydroperoxide and diamide oxidized T in red cell membranes (Tables 4 and 6). Vanderpas and Vertongen have reported that when erythrocytes from neonates and adults were incubated with 0.75 to 5.0 mM concentrations of hydrogen peroxide, T in erythrocytes was oxidized and TQ was produced (15). They also demonstrated a similar oxidation of T in red cell ghosts (15). It is important to note that oxidants like tertiary butyl hydroperoxide and diamide are also known to oxidize sulfhydryl groups (16).

In contrast to the polyunsaturated fatty acids, diamide, hydrogen peroxide and tertiary butyl hydroperoxide did not oxidize all of the membrane tocopherol (see Results). It is possible that all of the membrane tocopherol could have been oxidized by the latter three compounds (diamide, hydrogen peroxide and tertiary butyl hydroperoxide) if the incubation time and/or the concentrations of the oxidants had been greatly increased. Furthermore, a labile oxidation product produced by the three compounds may have been reduced back to α-T during saponification in the presence of ascorbic acid. Nevertheless, under the experimental conditions employed, the unsaturated fatty acids did behave differently from diamide, hydrogen peroxide and tertiary butyl hydroperoxide. This observation, as well as the differences in the yield of TQ during the oxidation (see above), suggests that the mechanism of oxidation of membrane T by

polyunsaturated fatty acids is different from that of the other three compounds.

The chemical structure of the fatty acid strongly influences its ability to induce oxidation of membrane T (Table 1). The *cis* polyunsaturates are the most potent fatty acids. Experiments with human platelets also gave very similar results (5). Several factors may contribute to the high oxidizing power of polyunsaturates. The susceptibility of unsaturated fatty acids to undergo oxidation may be an important factor. The size and shape of unsaturated fatty acid molecules could make the polyunsaturates more accessible to the membrane than the rigid, elongated saturated fatty acids. The differences in the critical micellar concentrations between the various fatty acids also may play a role. Recent studies suggest that the unbound fractions of free fatty acids are first associated with the outer layer of the red cell membrane before being translocated across the membrane (17). Therefore, the physical factors controlling the interactions of fatty acids with membranes cited earlier are crucial in understanding the oxidation of membrane tocopherol induced by unsaturated fatty acids. It is also interesting that α-T has been shown to protect the calcium ATPase of the sarcoplasmic reticulum against destabilization during thermal denaturation which was enhanced by unsaturated fatty acids (18). Since the authors did not monitor T concentrations, it is not known whether any T was oxidized during this protective action which they ascribed to stabilization of membranes by T.

Peroxides have been considered to be initiators of oxidation by a number of investigators. The data presented in Table 5 show that linoleic acid hydroperoxide is a very potent oxidizing agent causing oxidation of membrane T. Furthermore, many reports have appeared in the literature suggesting that enzyme activities (especially those involved in the biosynthesis of eicosanoids) are affected by minute traces of peroxides. The work of Lands' group (19) has established that fatty acyl hydroperoxides stimulate cyclooxygenase activity. Hydroperoxyeicosatetraenoic acid was found to stimulate 5-lipoxygenase by Rouser and Samuelsson (20). Conversely, antioxidants inhibited cyclooxygenase activity (19) and α-T inhibited 5-lipoxygenase activity (21). The redox state of membranes which could be modulated by membrane T concentration would therefore be expected to be controlled by changes in concentrations of peroxide intermediates. The converse may also be true. Therefore, as a potent antioxidant, T may be capable of playing a key role in stabilizing the redox state of membranes as well as in controlling the concentration of critical metabolic intermediates such as fatty acyl hydroperoxides.

[Received July 22, 1988; Revision accepted December 20, 1988]

Modulation of Eicosanoid Production and Cell-mediated Cytotoxicity by Dietary α-Linolenic Acid in BALB/c Mice[1]

Kevin L. Fritsche* and **Patricia V. Johnston**
Department of Food Science and Division of Nutritional Sciences, University of Illinois at Urbana-Champaign, Urbana, Illinois

The effects of dietary α-linolenic acid (18:3n-3) on fatty acid composition, eicosanoid production, and cell-mediated cytotoxic activity of immune cells before and after challenge with virus or poly I-C from BALB/c mice were studied. Weanling BALB/c mice were fed purified diets containing either 10%-by-weight corn oil or linseed oil providing a ratio of 18:3n-3 to 18:2n-6 of 1/32 or 2/1, respectively, for 6–10 weeks. Fatty acid analysis of splenocyte phospholipids showed an appreciable increase in the percentage of n-3, and a decrease in n-6, fatty acids in splenocytes from mice fed the linseed oil diet. Splenocyte prostaglandin E and peritoneal exudate cell leukotriene C production was significantly lower in the linseed oil-fed mice. In general, cell-mediated cytotoxic activity was similar for immune cells from linseed oil and corn oil-fed mice. However, 6 days after the viral challenge, splenocyte cell-mediated cytotoxic activity was significantly higher in linseed oil mice. This higher activity was associated with nonspecific cytotoxicity rather than that of viral-specific cytotoxic T-lymphocytes. Cell yields from the spleen and peritoneum were frequently significantly higher in linseed oil mice. Interactions between dietary 18:3n-3, eicosanoid production, and immune cell proliferation and/or migration are discussed. In summary, feeding mice a diet rich in 18:3n-3 elevates immune cell n-3 fatty acid content, reduces eicosanoid synthesis and, to a limited extent, enhances the cell-mediated cytotoxic response to a viral challenge.
Lipids 24, 305–311 (1989).

Lipid modulation of cell-mediated cytotoxic (CMC) activity has been demonstrated by several investigators. Gill and Clark (1) demonstrated that the incorporation of unsaturated fatty acids increased, whereas saturated fatty acids decreased, CMC activity of cytotoxic T lymphocytes (CTL). When Rice *et al.* (2) examined natural killer cell (NK) activity, they found differential effects of unsaturated fatty acid incorporation, with oleic acid (18:1n-9) increasing, and gamma-linolenic acid (18:3n-6) decreasing cytotoxic activity. The addition of exogenous, free 20:4n-6 (3) or 20:5n-3 (4) has also been shown to inhibit NK activity in a dose-dependent manner. Fewer studies have involved the effect of dietary fat. The addition of fat to low-fat diets decreases lymphocyte-mediated cytolytic activity (5,6). Polyunsaturated fats are more effective at decreasing CMC activity than saturated fats (5).

Prostaglandin (PG) E_2 has been shown to suppress the cytotoxic activity of NK (7), macrophages (8) and CTL (9). Feeding a diet rich in 18:3n-3 reduces the prostaglandin synthesizing capacity of various immunologically important tissues, including the liver, spleen, thymus (10), peripheral blood lymphocytes (11) and peritoneal macrophages (12). This occurs because of reduced levels of 20:4n-6 in the tissues, and elevated n-3 fatty acids, particularly 20:5n-3 and 22:6n-3, which directly compete for the enzymes in the eicosanoid synthesizing pathways. Magrum and Johnston (13) demonstrated that arginase activity of rat peritoneal macrophages could be altered by dietary 18:3n-3. It has been proposed that arginase activity is involved in macrophage-mediated cytolytic and cytostatic functions against tumor cells (14). Therefore, it was of interest to examine the possible influence of dietary 18:3n-3 on CMC activity of various immune cells.

MATERIALS AND METHODS

Animals and diets. Weanling BALB/c mice (Harlan Industries, Indianapolis, IN) were used in all studies. Animals were housed in polypropylene cages (4–5) per cage) with Beta-chip hardwood bedding (Northeastern Products Corp., Warrensburg, NY). A diurnal light cycle of 12 hours was maintained. Upon receipt, mice were fed one of two purified diets and provided with tap water *ad libitum.* Fresh diet was provided every other day with any remaining diet being discarded. The diets were formulated according to AIN-76 guidelines (15). Diets differed only in the source of fat, one containing 10%-by-weight corn oil (CO) and the other, 10% linseed oil (LO), providing ratios of 18:3n-3 to 18:2n-6 of 1:32 and 2:1, respectively. The composition of the diets is shown in Table 1. Autoxidation of diets was prevented by the addition of a synthetic antioxidant (0.01% butylated hydroxytoluene) to the oils upon receipt.

Collection of immune cells. Peritoneal exudate cells (PEC) were collected by flushing the peritoneum with 10 ml, followed by 7 ml of ice-cold phosphate-buffered saline (PBS), pH 7.4. Cell suspensions were pelleted (450 × g, 10 min at 4°C), then resuspended in 1 ml of complete Eagle's Minimal Essential Medium (cMEM) which contains nonessential amino acids, 25 mM HEPES (Irving Scientific, Santa Ana, CA), supplemented with 0.292 g/l L-glutamine, 2.2 g/l sodium bicharbonate, 1% antibiotic-antimycotic solution (Gibco Laboratories, Grand Island, NY) and kept on ice.

Single cell suspensions of splenocytes were made by forcing each spleen through a tissue sieve (Bellco Glass Inc., Vineland, NJ) equipped with an 80-mesh stainless steel screen. Using a 10-ml syringe without a needle, cell clumps were dispersed by several gentle washings through the sieve. RBC and dead cells were removed by centrifugation of the spleen cell suspension over

Lymphocyte Separation Medium, density 1.077–1.080 at 20°C, as described by the manufacturer (Litton Bionetics Inc., Charlestown, SC). Cells at the interface were collected, washed twice and resuspended in 2 ml cMEM.

Splenocytes and PEC were enumerated using a Coulter Counter, Model ZBI (Coulter Electronics, Inc., Hialeah, FL). Cell viability was determined, using the trypan blue exclusion test and cell viability was generally greater than 95%. Cell suspensions were diluted to a final concentration of 1×10^7 cells/ml, or pelleted and stored (−80°C) for lipid analysis.

Fatty acid analysis of splenocyte phosphoglycerides. Splenocytes previously collected were resuspended in 3 ml ice-cold 0.1 mM EDTA. Lipids were extracted with 18 ml chloroform and methanol (2:1, v/v) containing 0.005% BHT. The organic phase containing the lipid extract was collected and reduced in volume under N_2.

Splenocyte phosphoglycerides were separated by two-dimensional thin layer chromatography (16). Phospholipids were identified by comparison to chromatograms of authentic standards (Supelco, Inc., Bellefonte, PA and Applied Science Laboratories, State College, PA). Methyl esters of fatty acids were prepared by transmethylation using 4% H_2SO_4 in methanol. Fatty acid methyl esters of splenocyte choline (PC) and ethanolamine (PE) phosphoglycerides were identified using a Packard gas-liquid chromatograph, Model 428 (Packard Instrument, Co., Downers Grove, IL) with a 180 × 0.4 cm glass column packed with 10% SP 2330 on 100/120 Chromosorb W AW 1-1851 (Supelco, Inc., Bellefonte, PA) operated isothermally at 190°C. Results, expressed as percentage of total fatty acids, were determined using a Hewlett-Packard 3380A integrator (Sunnyvale, CA).

Determination of PG synthesizing capacity of immune cells. One-half ml of immune cells, isolated as previously described, was added to one-half ml of serum-free MEM containing 10 μg/ml (19 μM) calcium ionophore, A23187 (Sigma Chemical Co., St. Louis, MO). After 1 hr at 37°C, the incubation was terminated by the addition of 0.025 ml of an aspirin solution (100 mg/ml of dimethylsulfoxide). Cell-free medium was collected and stored at −80°C. Prostaglandins were determined by radioimmunoassay using rabbit antiprostaglandin E-BSA serum (Miles Laboratories, Elkhart, IN). This antiserum is reported by the manufacturer to have minimal cross-reactivity (less than 3%) with PGA_1, A_2, F_1, B_1 and B_2, 10% with F_2 and 53% cross reactivity with PGE_1. Cross reactivity with PGE_3 was undetermined. No attempt was made to correct for cross reactivity, therefore results are expressed as picograms of PGE/ml culture medium.

Determination of leukotriene (LT) production by PEC. For LT production, half of the mice on each diet treatment received intraperitoneal (i.p.) injections of brewer's thioglycollate (Difco Laboratories, Detroit, MI), three days prior to PEC collection. One ml of PEC (5×10^6 cells) was cultured in the presence of calcium ionophore at 5 μg/ml for 20 min at 37°C. Cell-free medium was collected immediately by pelleting cell suspensions for 15 sec at 12,000 × *g*. Samples were stored at −80°C, until LT determinations could be conducted. Because LTC_4 is the predominant LT synthesized by mouse peritoneal macrophages, it was determined by radioimmunoassay using a ^{3}H-LTC_4 kit from New England Nuclear (Boston, MA). The antiserum is reported by the manufacturer to have minimal cross-reactivity (<0.006%) with LTB_4, various PG, and free 18:2n-6 and 20:4n-6. Cross-reactivity with LTD_4 and LTE_4 was 55.3% and 2.3%, respectively, whereas cross-reactivity with LTC_5 was not reported. Results are expressed as nanograms of LTC/ml of culture medium.

Cell-mediated cytotoxicity studies. The effect of feeding a diet rich in 18:3n-3 on the CMC activity of cells isolated from the spleen and peritoneal cavity of BALB/c mice with or without an immunochallenge was studied.

Study 1. Spontaneous CMC was determined on 48 male mice which had been fed either the CO or LO diets for 6–7 weeks postweaning. Eight mice per diet-group were sacrificed in each of 3 experiments. Immune cells from the spleen and peritoneum were collected as previously described. Splenocytes from each mouse were tested for NK activity using the YAC-1 tumor cell line in a 4-hr Cr-51 release assay, or for natural cytotoxic cell (NC) activity by using the SV-T2 cell line in a 16-hr Cr-51 release assay. Peritoneal exudate cells (PEC) were pooled from two mice from the same diet treatment and tested for CMC activity, using YAC-1 as targets in a 16-hr Cr-51 release assay.

Study 2. Forty male mice fed CO or LO diets for 8–10 weeks postweaning were used to assess CMC 3 days postviral challenge. Mice were injected i.p. with 5×10^6 PFU of vaccinia virus in 0.5 ml of cMEM. Experiments were designed such that NK and NC activity in the spleen, and CMC against SV-T2 by PEC could be measured in each of the 4 mice per diet treatment per experiment.

Study 3. Twenty-four female mice fed a CO or LO diet for 8–10 weeks postweaning were used to determine CMC 6 days postviral challenge. Antigen-specific CMC (i.e., cytotoxic T lymphocyte activity) was demonstrated by

infecting the syngeneic fibroblast cell line (3T3) with vaccinia virus, just prior to using these cells as targets in a 16-hr Cr-51 release assay. Noninfected 3T3 and the simian virus 40-transformed cell line (SV-T2) were used as control targets in parallel assays to assess nonspecific CMC activity.

Study 4. The CMC response to a poly I-C (synthetic double-stranded RNA) immunochallenge was determined for 60 mice fed the CO and LO diets for 8–10 weeks. In each of the first two experiments, CMC activity of 8 mice per diet was tested 24 hr after mice received an i.p. injection of either 100 μg of poly I-C (P-L Biochemicals, Inc., Milwaukee, WI) in 0.5 ml of sterile saline or a sham injection (0.5 ml sterile saline). In the third experiment, mice were tested for splenic NK activity 2 and 6 days after poly I-C administration, and 2 days after sham injections.

Study 5. CMC activity 3, 6, and 9 days after an immunochallenge with two suboptimal doses of vaccinia virus in 160 female mice fed a corn oil (CO)- or linseed oil (LO)-containing diet for 6–10 weeks postweaning was determined. For each experiment 6 mice per diet received i.p. injections of vaccinia virus. Half were injected with 10^4 PFU of virus and the other half with 10^5 PFU. Immune cells were collected after either 3, 6 or 9 days postpinjection (p.i.) as previously described. Splenocytes from each mouse were tested for NK, NC and CTL activity. Cytotoxic activity of peritoneal exudate cells against SV-T2 target cells was also determined.

Cultures and virus. All cell lines were purchased from American Type Culture Collections (Rockville, MD) and maintained *in vitro* in cMEM supplemented with 10% Nu-serum, a serum substitute (Collaborative Research Inc., Lexington, MA). The virus used in this study was the WR strain of vaccinia which was originally obtained from Dr. W.A.F. Tompkins, University of Illinois (Urbana, IL). Virus was grown in VERO (African green monkey kidney) cells and titered to 1×10^7 PFU on VERO monolayers as described by Rawls *et al.* (17). Virus was dispensed in 1 ml aliquots and stored at −80°C.

Cell-mediated cytotoxicity assays. CMC activity by PEC and splenocytes was determined as described by Tompkins *et al.* (18) using a modified Cr-51 release method as originally described by Brunner *et al.* (19). In order to distinguish between NK and NC cell activity in each spleen, aliquots of splenocyte cell suspensions were tested for cytotoxic activity against two different tumor cell lines. NK activity was determined using the NK-sensitive mouse lymphoma cell line YAC-1 (TIB 160) in a 4 hr Cr-51 release assay. Assessment of NC activity in the spleen and CMC activity by peritoneal exudate cells (PEC) was conducted using the virally-transformed fibroblast cell line, SV-T2 (CCL 163.1) in a 16-hr Cr-51 release assay.

The syngeneic fibroblast cell line 3T3 (CCL 163) was used in a 16-hr Cr-51 release assay to assess vaccinia virus-specific CMC activity of splenocytes. Viral infection of target cells with vaccinia was carried out in the wells during a preincubation period, in which adherence, Cr-51 uptake and expression of viral antigens occurred (20). Viral infection of targets did not alter spontaneous release of Cr-51.

Harvesting assays. At the end of the incubation period, 75 μl of cell-free medium was removed from each well, mixed with 0.6 ml of an aqueous scintillation fluid and counted in a Beckman 2800 Liquid Scintillation Counter. Spontaneous release was determined in control wells to which 0.2 ml of cMEM with 10% Nu-serum was added to targets prior to the incubation period. Maximum release was determined by 3 freeze-thaw cycles of half of the control wells. All systems were performed in triplicate. Results of cytotoxicity assays were expressed as % specific Cr-51 released and determined as follows: [(DPMs in test wells − DPMs in spontaneous release wells)/(DPMs in maximum release wells − DPMs in spontaneous release wells)] × 100. In the text and tables, percentage specific Cr-51 released is referred to as % cytotoxicity.

Statistical analysis. Data were analyzed using Statistical Analysis System (SAS). Computer programs PROC ANOVA (for balanced data) and PROC GLM (for unbalanced data) were utilized (21). Differences between diet treatment groups and virus dosage levels were tested with single degree of freedom comparisons for statistical significance by F-test. A completely randomized design (CRD) was used for the poly I-C and the time course studies, in which the treatments were arranged as a $2 \times 2 \times 3$ factorial. In the poly I-C study diet treatment (i.e., CO vs LO), immunochallenge (i.e., sham vs poly I-C) and time post-challenge (1, 2 or 6 days) were factors A, B and C, respectively. In the time course study (Study 5) factor A was diet treatment (i.e., CO vs LO fed mice) and factor B was virus dosage (i.e., 10^4 vs 10^5 PFU) and factor C was days postchallenge mice were sacrificed (i.e., 3, 6 and 9 days). Comparisons over time and within diet treatment groups were made using Fischer's Least Significant Difference (LSD).

RESULTS

Fatty acid composition. There was a significant decrease in all n-6 fatty acids, except 18:2n-6, and an increase in all n-3 fatty acids of splenocyte phospholipids when mice were fed the α-linolenic acid-rich LO diet compared to the linoleic acid-rich CO diet. In PC, the percentage of n-3 fatty acids increased from 3.3 to 15.2% and in PE, from 7.6 to 30.0%. The n-6/n-3 ratios in these phospholipids changed from 12.1 to 1.8 in PC and 7.3 to 1.0 in PE in the CO vs LO mice, respectively.

There were marked reductions in the 20:4n-6 content of both phospholipid classes when mice were fed the LO diet compared with the CO diet. In PC, 20:4n-6 content was 64% lower (20.7% vs 7.5%), whereas in PE there was a 62% reduction (31.7 vs 11.9%) for CO vs LO mice, respectively. The content of 20:5n-3 increased significantly ($P < 0.01$) upon LO feeding and represented 5.4% of the total fatty acids in PC compared with 1.3% when CO was fed. In PE the difference in 20:5n-3 content was more marked than those seen in PC (8.3% compared with 0.9% for LO vs CO, respectively). Although 18:2n-6 content tended to be higher in mice fed LO compared with CO, these differences were not statistically significant in either PC or PE phosphoglyceride. Interestingly, the opposite trend was seen when 18:2n-6 content of splenocyte total lipids was analyzed.

Eicosanoid production. Eight weeks after the initiation of diet treatments, PGE synthesis by splenocytes was 70% lower in LO-fed compared with CO-fed mice (Fig. 1). The PG synthesizing capacity of PEC were similarly effected by dietary 18:3n-3 (data not shown). Feeding mice

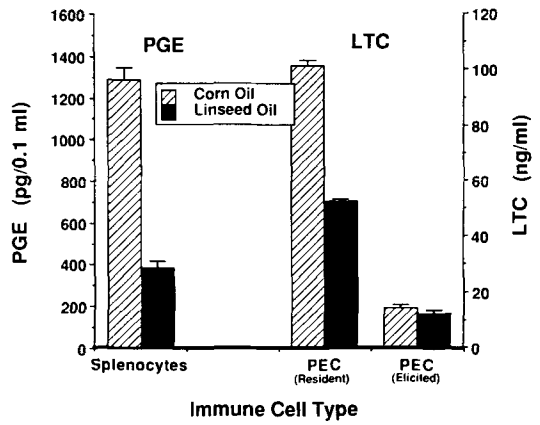

FIG. 1. Effect of high dietary 18:3n-3 intake on PGE and LTC production by immune cells from the spleen and peritoneum. Female BALB/c mice were fed diets containing 10%-by-weight corn oil (low in 18:3n-3) or linseed oil (high in 18:3n-3) for 8–10 weeks prior to the collection and testing of immune cells. Splenocytes and PEC were collected and stimulated to produce eicosanoids as described in the text. Data represents the means + S.E.M. for 4–8 samples per dietary treatment.

an 18:3n-3-rich diet for 8 weeks significantly decreased LTC_4 production by PEC. Resident PEC from CO-fed mice produced nearly twice as much LTC_4 as those from LO mice (Fig. 1). Thioglycollate-elicited PEC produced significantly less LTC compared with resident PEC and the apparent inhibition of LTC_4 production by LO feeding was only 14% in the elicited cells.

Body and spleen weight and immune cell yield. In general, there was no significant effect of dietary n-3 fatty acid intake on body weight nor spleen weight, however, spleen weights were significantly increased ($p < 0.0001$) by both viral and poly I-C challenges (data not shown).

Cell yield (i.e., the number of cells obtained) from the spleen and the peritoneum were significantly influenced by dietary 18:3n-3 intake, as well as by viral and poly I-C challenges. Splenocyte yields from virally-challenged LO-fed mice were consistently greater by 10–20% than the mice fed CO. These differences were statistically significant ($p < 0.05$) when data from Studies 2 and 3 were pooled. On average, the number of splenocytes recovered from poly I-C challenged LO-fed mice was 23% greater than that recovered from CO-fed mice. In the time course study (Study 5) splenocyte yield was significantly influenced by diet treatments ($p < 0.005$), virus dosage ($p < 0.05$) and time post-challenge ($p < 0.001$), with no significant interactions between these factors. Splenocyte yield from LO-fed mice was on the average 24% higher than that from CO-fed mice. For example, mice challenged with 10^4 PFU showed splenocyte yields of 22.6 ± 2.4 vs 24.3 ± 2.7, 24.9 ± 2.1 vs 31.0 ± 2.7, 28.8 ± 2.5 vs 35.8 ± 3.8 ($\times 10^6$ cells) at 3, 6 and 9 days postchallenge for CO vs LO-fed mice, respectively. Those mice challenged with 10^5 PFU showed a similar trend (data not shown).

The influence of diet treatment on PEC yield was variable. In unchallenged mice, LO feeding enhanced (Study 1) and had no effect (Study 4) on the PEC yield compared with CO feeding. PEC yield was significantly lower ($p < 0.05$) in LO vs CO mice at 6 days p.i. of 10^5 PFU (10.9 ± 1 vs $14.7 \pm 1.3 \times 10^6$ cells for LO vs CO mice, respectively). The reduction in PEC after poly I-C injections was significantly greater for LO-fed compared with CO-fed mice, however later recovery was not effected by the diets.

CMC activity. Summarized in Table 2 is the CMC activity in the spleen and peritoneum of unchallenged and virally challenged mice fed CO and LO diets. CMC activity by splenocytes and PEC was greatly elevated 3 days after the viral challenge compared with unchallenged mice. Both CO and LO-fed mice expressed similar levels of CMC activity at these times. CMC activity by splenocytes and PEC was also significantly stimulated by poly I-C injections (Study 3). However, again there were no significant differences between the responses of CO and LO-fed mice (data not shown).

Summarized in Figure 2 are the results of three experiments, where the CMC activity in the spleen was assessed 6 days after viral challenge in mice fed a CO or LO diet (Study 4). CMC activity against vaccinia virus-infected 3T3 cells was significantly higher ($p < 0.005$) in LO compared with CO-fed mice. Background cytotoxicity against noninfected 3T3 and SV-T2 cells was considerably lower compared with vaccina virus-infected 3T3 cells. CMC activity against these other targets was significantly higher by splenocytes from LO-fed compared with CO-fed mice.

Shown in Figures 3 and 4 are some of the results from Study 5, where CMC activity was assessed over time after two suboptimal doses of vaccinia virus challenge. NK activity (Fig. 3) was highest 3 days postchallenge, and declined significantly through days 6 and 9 p.i., whereas a similar response pattern was observed for NC activity in the spleen (data not shown). Activity in LO-fed mice appeared to decline more slowly than in CO-fed mice, with the difference in NK and NC activity being most pronounced on day 6 postchallenge. CMC activity by PEC

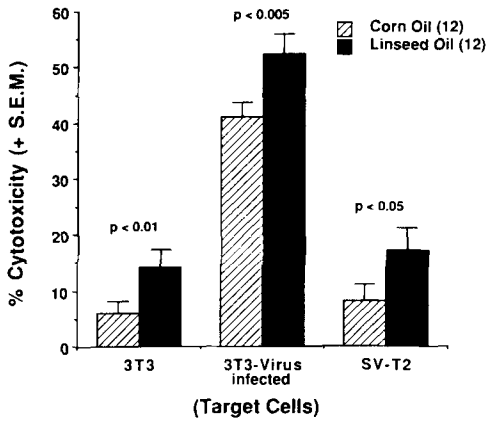

FIG. 2. Effect of high dietary 18:3n-3 intake on splenocyte anti-viral CMC activity, 6 days after a viral challenge. Female BALB/c mice were fed diets containing 10%-by-weight corn oil (low in 18:3n-3) or linseed oil (high in 18:3n-3) for 8–10 weeks prior to receiving i.p. injections of 10^6 PFU of vaccinia virus. In three separate experiments, 6 days postviral challenge, splenocytes from 4 mice per diet treatment were isolated and tested for CMC activity in a 16 hr Cr-51 release assay as described in the Methods section. A syngeneic fibroblast cell line (3T3) was infected with vaccinia virus and used as target cells in the CMC assay, whereas noninfected 3T3 and SV-T2, a virally-transformed cell line, served as controls. Effector-to-target cell ratios were 50:1 in all experiments.

TABLE 2

Cell-Mediated Cytotoxic Activity of BALB/c Mice Fed a Corn Oil (CO) or Linseed Oil (LO)-Containing Diet[a]

Dietary fat	E:T[b]	N[c]	No challenge		With challenge[d]	
			CO	LO	CO	LO
Splenocyte NK	100:1	12	5.0 ± 0.8[e]	5.4 ± 1.7	37.6 ± 5	35.7 ± 5
	50:1	20(16)	2.6 ± 0.4	3.2 ± 0.4	27.6 ± 5	23.2 ± 5
	25:1	16	nd[f]	nd	14.6 ± 3	14.2 ± 3

[f]Not determined.

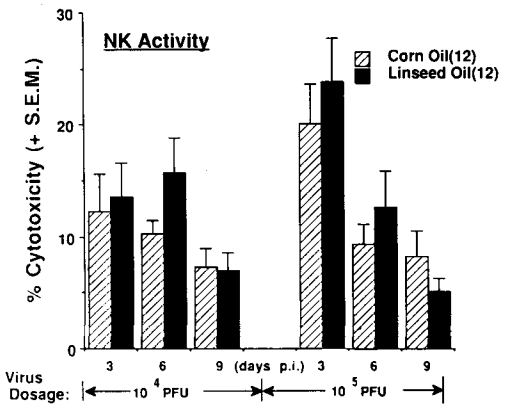

FIG. 3. Effect of high dietary 18:3n-3 intake on NK activity at various times after a viral challenge. Female BALB/c mice were fed diets containing 10%-by-weight corn oil (low in 18:3n-3) or linseed oil (high in 18:3n-3) for 8–10 weeks prior to receiving i.p. injections of 10^4 or 10^5 PFU of vaccinia virus. For each experiment, splenocytes were isolated from three mice per level of viral challenge, per diet treatment and tested for CMC activity either 3, 6 or 9 days postchallenge. NK activity was determined using YAC-1 lymphoma cells as targets in a 4 hr Cr-51 release assay as described in the Methods section. An effector-to-target cell ratio of 50:1 was used in all experiments. Results from 3–4 experiments per day are presented. Spontaneous release of the Cr-51 label averaged 8.6 ± 0.6% in the NK assays.

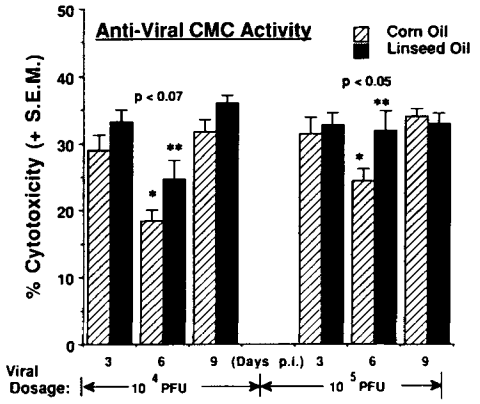

FIG. 4. Effect of high dietary 18:3n-3 intake on antiviral CMC activity at various times after a viral challenge. The same protocol outlined for Fig. 2 was followed, only target cells used to assess CMC activity differed. Antiviral CMC activity was determined using 3T3 cells, which had been infected with vaccinia virus 5–7 hours prior to use, in a 16 hr Cr-51 release assay. Spontaneous release from these cells averaged 1.6 ± 0.3%/hr. Noninfected 3T3 cells served as controls and CMC activity against these cells ranged from 1–8% (data not shown).

PEC remained elevated throughout the study period with mice fed CO and LO diets expressing similar activities (36.4 ± 4.5 vs 42.6 ± 3.9, 37.2 ± 5.1 vs 35.9 ± 4.8, 32.9 ± 5.3 vs 35.9 ± 6.5 for CO vs LO mice at 3, 6, and 9 days postchallenge with 10^5 virus, respectively). At the lower viral dose (i.e., 10^4 PFU), activity appeared to be declining by day 9 postchallenge in both the CO-fed and LO-fed mice (data not shown).

Figure 4 shows the CMC activity of splenocytes against vaccinia virus-infected 3T3 cells. Cytotoxic activity against the noninfected cells was low and ranged 2–8%. CMC activity against vaccinia virus-infected targets (3T3) was significantly greater ($p < 0.05$) on day 6 in LO vs CO-fed mice. At the lower viral dose, CMC activity was high 3 day p.i., declined on day 6, then rose to its highest level on day 9. The CMC activity was consistently higher in mice fed LO compared with CO diets. These differences between the diet groups were significant ($p < 0.005$) for days 6 and 9 together, and nearly so, individually ($p < 0.07$).

DISCUSSION

Feeding mice a diet rich in 18:3n-3 dramatically altered membrane fatty acid profiles and PG synthesizing capacity of immune cells. Similar observations have been made

and reported for various rat tissues (22-24). In the mouse, suppression of 20:4n-6 and the elevation of 20:5n-3 levels in splenocyte phospholipid fractions exceeded those achieved in rats (10), which may in part reflect the relatively greater activity of liver desaturase enzymes in mice compared with rats (25,26).

The magnitude of the reduction in LT biosynthesis by feeding an 18:3n-3 rich diet depended on the prior conditioning of the PEC. Resident PEC from LO-fed mice produce less than 50% the LTC_4 compared with CO-fed mice, whereas there was only a 14% difference in thioglycollate-elicited PEC. The observation that resident PEC produced significantly greater quantities of LT than elicited PEC, is in agreement with Humes *et al.* (27). They showed that PEC isolated after an acute bacterial infection, produced significantly less PGE_2, PGI_2 and LTC_4 compared with resident PEC. Tripp *et al.* (28) later demonstrated that the alteration in eicosanoid production was due to the migration of monocytes into the peritoneum.

Our studies demonstrate that feeding mice a diet rich in 18:3n-3 can significantly enhanced CMC activity. The effects on CMC were less dramatic than the changes in fatty acid composition, PGE and LT biosynthesis and were observed under limited circumstances. Dietary influences over CMC activity were only seen at certain times after a specific immunochallenge. Enhancement was not observed in unchallenged mice. Others have reported that alterations in endogenous PG production did not significantly alter "natural" NK activity in the spleen (29). Voth *et al.* (30) demonstrated that relatively large doses (200 μg) of the PG synthesis inhibitor, indomethacin, were required to significantly enhance CMC activity of NK or peritoneal macrophages in the absence of an immunochallange. In fact, the levels of indomethacin that were effective (200-400 μg) were very near levels that proved to be lethal (800 μg). This drug-induced enhancement in CMC activity is transient, peaking 3 days p.i., and lasts a total of 6 days. Weaker PG synthesis inhibitors were less effective, as were lower levels of indomethacin. Thus, our dietary data supports the concept that PG do not play an important role regulating basal CMC activity.

In our studies, higher NK/NC activity in the LO-fed mice accounted for some, but not all, of the higher CMC activity against vaccinia virus-infected targets at the later time points (i.e., 6 and 9 days postchallenge). This does imply that PG do act as natural feedback inhibitors of "stimulated" CMC activity, as suggested by Tracey and Adkinson (29). We believe that the reduced PGE synthesizing capacity of LO-fed mice, resulted in a slower or less complete shut-down of the nonspecific phase of the antiviral response compared with the CO-fed mice. We observed that vaccinia virus-specific CMC activity also tended to be higher in LO-fed mice. This is in agreement with the reported inhibitory action of PG on CTL generation (9,35). Lowering the concentration of the viral challenge by 10- and 100-fold, did not accentuate the diet-induced differences in the CMC response. Instead, at the lower viral concentration, stimulation of splenic NK activity was marginal. At both concentrations, the induction of antiviral CMC activity was delayed, compared with our earlier studies and the reports of others (36,37).

Two different immunochallenges were used to stimulate CMC activity above basal levels: live vaccinia virus and a synthetic double-stranded RNA (poly I-C). Although the CMC response to vaccinia virus is well defined, it is slow to develop and involves complex interactions between numerous cell types (31). Poly I-C has been shown to quickly (i.e., within hours) stimulate CMC activity by peritoneal macrophages (32) and spleen NK cells (33). We hoped that this alternate immunochallenge would avoid some of the possible confounding variables in our studies using a live virus. Both challenges share a common pathway for the stimulation of the immune system, that is, an elevation in interferon release and production. That others (34) have shown that PG do not affect interferon production may explain why we observed no differences between CO and LO-fed mice in the early stages of the CMC response to vaccinia virus or poly I-C.

Cell yields from the spleen of immunochallenged LO-fed mice were consistently greater than from CO-fed mice. This is consistent with evidence suggesting that PGE suppresses lymphocyte proliferation, and that reductions in PGE production results in enhanced T-cell proliferation (38). To the contrary, previous findings in our laboratory suggest that mitogen-induced lympho-proliferation is not regulated by PGE (39). An alternative explanation may be that dietary 18:3n-3 influenced the recruitment or migration of immune cells. Although LTB_4 production was not measured, it is probable that like LTC_4, it was also reduced in LO-fed mice. Because LTB_4 is a powerful chemotactic eicosanoid, such a reduction could have altered cell migration to or from the peritoneum and spleen. Koga *et al.* (40) showed that inhibition of PG synthesis by indomethacin resulted in an increase in T-lymphocytes in the spleen. This effect was dependent on the thymus, and appears to be the result of an elevated migration of lymphocytes from the thymus to the spleen (41).

PG also appear to modulate cell movement through the peritoneum. Voth *et al.* (30) recovered 2-fold greater numbers of PEC from indomethacin-treated mice. The 32% greater PEC recovered from the unchallenged LO-fed compared with CO-fed mice may also have been a result of the reduced PGE_2 synthesizing capacity of the LO mice. Moore *et al.* (42) demonstrated that endogenous PGE_2 inhibit macrophage proliferation and proposed that PGE_2 is the natural feedback regulator of this process.

Although the Cr-51 release assay is the most commonly used method for assessing CMC activity, it, like most other in vitro assays, has shortcomings (43). One of those is that the effector cell concentrations across treatment groups are equalized to keep E:T ratios the same. Therefore, the present results do not completely reflect the effect that dietary 18:3n-3 might have on disease resistance as it relates to *in vivo* CMC activity in the whole animal. We have shown that the number of effector cells as well as their relative activity appears to be enhanced by dietary 18:3n-3. This suggests the possibility that even greater differences in disease resistance may exist between CO-fed and LO-fed mice. Further studies using various viral, bacterial and parasitic challenges will help determine if this is the case.

Synergistic Enhancement of the Antiproliferative Activity of *cis*-Diamminedichloroplatinum(II) by the Ether Lipid Analogue BM41440, an Inhibitor of Protein Kinase C

Johann Hofmann[a], Florian Ueberall[a], Lydia Posch[a], Karl Maly[a], Dieter B.J. Herrmann[b] and Hans Grunicke[a,*]

[a]Institut für Medizinische Chemie und Biochemie, University of Innsbruck, Fritz-Pregl-Strasse 3, A-6020 Innsbruck, Austria; and [b]Boehringer Mannheim GmbH, FRG

The new phospholipid analogue 3-hexadecylmercapto-2-methoxy-methyl-propyl-1-phosphocholine inhibits the phospholipid-calcium-dependent protein kinase, partially purified from Walker carcinoma cells with a K_i value of 0.56 μM. The compound inhibits the phorbol ester stimulated phosphorylation of the ribosomal protein S6 indicating that the depression of Ca^{2+}-phospholipid-dependent protein kinase by the alkyl phospholipid also occurs in intact cells. The dose effect curve for the inhibition of cell proliferation by 3-hexadecylmercapto-2-methoxy-methyl-propyl-1-phosphocholine in Walker cells exhibits a close correlation to the dose effect curve for the depression of Ca^{2+}-phospholipid-dependent protein kinase activity. Although alternative mechanisms cannot be excluded, the data suggest that the growth inhibitory activity of 3-hexadecylmercapto-2-methoxy-methyl-propyl-1-phosphocholine correlates with the inhibition of Ca^{2+}-phospholipid-dependent protein kinase. The antiproliferative activity of 3-hexadecylmercapto-2-methoxy-methyl-propyl-1-phosphocholine is synergistically enhanced by *cis*-diamminedichloroplatinum(II).

***Lipids* 24, 312-317 (1989).**

Alkyl-lysophospholipids (ALP), a new class of antitumor drugs, represent synthetic 1-*O*-alkyl analogues of 2-lysophosphatidylcholine. ALP have been reported to inhibit the growth of a broad variety of malignant cells in culture (1-4). ALP also prevent tumor growth or inhibit metastases *in vivo* (5, 6). In contrast to the effect on malignant cells, human embryonic fibroblasts (2) and bone marrow cells (7) were found to be less affected by doses of ALP that are toxic to malignant cells.

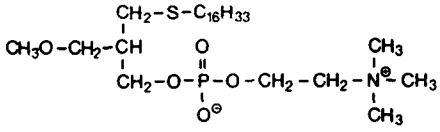
The sensitivity of malignant cells to ALP has been discussed as resulting from the inability to metabolize the drug due to the lack of 1-*O*-alkyl cleaving enzymes (8). But, despite efforts by several groups, the mechanism underlying the cytotoxic activity of ALP has not yet been elucidated (9).

Ca^{2+}-phospholipid-dependent protein kinase (protein kinase C) represents an essential element in signal transduction of a variety of growth factors and mitogens (10). It has been demonstrated, that the ALP 1-*O*-octadecyl-2-*O*-methyl-*sn*-glycero-3-phosphocholine and lysosphingolipids inhibit protein kinase C activity (11, 12) and this effect has been discussed as the possible mechanism that is responsible for the antitumor activity of these agents.

Recently the new alkyllysophospholipid analogue BM41440 has been synthesized which differs from the alkyllysophospholipids available so far (Fig. 1): The long chain alkyl group is linked by a thioether bond and the β-hydroxyl group of the glycerol has been substituted by a methoxymethyl moiety.

BM41440 is one of the most potent cytotoxic phospholipid analogues (13-15). Compared with the *O*-alkylglycerophospholipids studied so far, this molecule shows little resemblance to biological lyso-or alkylphospholipids and should, therefore, exhibit a different behavior in biological systems. Indeed, it has been demonstrated that the introduction of the thioether bond drastically reduces the platelet aggregating (PAF-like) activity, compared with corresponding *O*-alkyl derivatives (16). This is explained by the low affinity of the thioether compound to the PAF receptor, if compared with *O*-alkyl derivatives (17). The substitution of glycerol by a 2-alkyl propanol should have additional biological consequences. The enzymatic formation of alkylacyl- or dialkyl glycerols has been shown to contribute to the biological effects of alkylphospholipids (18). It is conceivable, therefore, that the lack of a glycerol moiety in BM41440 affects its biological properties. Thus, the effects of the new alkylphospholipid BM41440 on protein kinase C may differ from those of the *O*-alkylglycerophospholipids investigated so far. Furthermore, it is still unclear whether the inhibition of protein kinase C which has been observed with alkylphospholipids is related to the growth inhibitory effect of these compounds. It is shown here that BM41440 is a particularly potent inhibitor of protein kinase C and that the dose effect curves for the depression of protein kinase C and the inhibition of cellular replication are superimposable, suggesting a close correlation between these two parameters.

In a preceding publication it has been demonstrated that inhibitors of protein kinase C synergistically en-



BM41440

3-Hexadecyl-mercapto-2-methoxymethyl-propyl-1-phosphocholine

hance the antiproliferative effect of *cis*-platinum (19). It seemed interesting, therefore, to investigate whether BM41440 exhibits a similar behavior in combination with platinum complexes.

MATERIALS AND METHODS

Chemicals. BM41440, horse serum and Dulbecco's modified minimal essential medium (DMEM) were from Boehringer Mannheim (Mannheim, FRG) and *cis*-diamminedichloroplatinum(II) (*cis*-DDP) was donated by Homburg Pharma (Frankfurt, FRG). [γ^{32}P]-ATP (10 Ci/mmol) and ^{32}P-orthophosphate were from the Radiochemical Centre (Amersham, UK). GF/F-filters and DEAE-52 cellulose were from Whatman (Clifton, NJ). Leupeptin, aprotinin, 12-*O*-tetradecanoyl-phorbol-13-acetate (TPA), β-glycerophosphate, histone H1 (type III S), 3-N-morpholino propanesulfonic acid (MOPS) L-α-phosphatidyl-L-serine and 1,2-*sn*-diolein were obtained from Sigma (Munich, FRG). Tris(hydroxymethyl)-aminomethane (Tris-HCl), EGTA and Triton X-100 were purchased from Serva (Heidelberg, FRG).

Cell culture and evaluation of combined drug effects. Walker rat carcinoma cells were kindly donated by Dr. J.J. Roberts, Institute of Cancer Research, Royal Cancer Hospital, Sutton, Surrey, UK, and grown in suspension at 36.8°C in DMEM supplemented with 10% horse serum and buffered with 25 mM MOPS (pH 7.35 at 20°C). Dose-response curves were established with BM41440 by addition of the drug dissolved in 20mM Tris-HCl, pH 7.4, to Walker cells (10^5 cells/ml). After incubation for 48 hours, cells were counted by an electronic counter (Coulter-Electronics, Luton, UK). Cellular multiplication (M) was calculated by $M = T_t\text{-}T_o / C_t\text{-}C_o \times 100$, where C are untreated controls, T are drug treated cells, o and t equal the number of cells at time O and t (48 hrs), respectively. Evaluation of the effects of drug combinations were performed as described by Chou and Talalay (20, 21) employing data from at least 3 different experiments. Computation was performed employing the computer program (Apple II) by J. Chou and T.-Ch. Chou, *Dose effect analysis with microcomputers* (Elsevier Biosoftware, Cambridge, UK).

Protein kinase C. Protein kinase C was purified 31-fold from Walker cells with a yield of ca. 80% employing a DEAE-52 cellulose chromatography of cell extracts as described by Kreutter et al. (22). Protein kinase C activity was determined according to Regazzi et al. (23) by measuring [^{32}P]orthophosphate incorporation into histone H1. Briefly, the reaction mixture (125 μl) contained 0.5 μCi [γ^{32}P]-ATP, 40 mM Tris-HCl, pH 7.4, 1 mM $CaCl_2$, 700 μM EGTA, 50 μg histone and different concentrations of phosphatidylserine, diolein and BM41440, as described in the corresponding figure legend and ca. 1 μg/20 μl of enzyme protein. Assays were run for 10 minutes at 32°C. The reaction was stopped by addition of 1 ml 20% trichloroacetic acid. The precipitated proteins were collected on GF/F filters and radioactivity counted in a liquid scintillation spectrometer.

Phosphorylation of ribosomal protein S6. Cells were grown in DMEM with 0.5% horse serum for 15 hr. After 1 hr incubation in phosphate free medium [^{32}P]orthophosphate (4 μCi/ml) TPA, (0.5 μM) or BM41440 (20 μM) plus TPA (0.5 μM) was added. After 1.5 hr of incubation, cells were lysed in 50 mM Tris-HCl, pH 7.4, 25 mM KCl, 5 mM $MgCl_2$, 0.33 M saccharose, 1% Triton X-100, 1 mM phenylmethanesulfonylfluoride, 20 μg/ml leupeptin, 2 μg/ml aprotinin and 80 mM β-glycerophosphate. After 10 min at ice temperature the lysate was centrifuged for 3 hours at 100 000 × *g*. The pellet was analyzed by gel electrophoresis in a 15% polyacrylamide gel (24). Ribosomal protein S6 was identified after blotting to nitrocellulose by employing anti-S6 antiserum (kindly donated by Prof. G. Stoeffler, Innsbruck). Cell viability was checked by the trypan blue exclusion assay. Incubation with BM41440 for 1.5 hr did not reduce the number of living cells.

RESULTS

The inhibition by BM41440 of protein kinase C from Walker rat carcinoma cells is shown in Fig. 2. The inhibitory effect is inversely related to the concentration of lipid cofactors (phosphatidylserine/diacylglycerol) in the reaction mixture (Fig. 3). A Lineweaver Burk plot of the data, reveals a competitive type of inhibition in respect to lipid with a K_i of 0.56 μM. Inhibition of protein kinase C by BM41440 in cell-free extracts does not necessarily indicate that this compound reduces the enzyme activity in intact cells. Inhibition of partially purified protein kinase C depends on the concentration of phospholipids (Fig. 3). Fifteen μg/ml of the phosphatidylserine in the assay was sufficient to eliminate the inhibitory effect of BM41440. Considering the fact that a substantial fraction of protein kinase C is membrane bound (25), and that the membrane associated enzyme may represent the biologically active form (25), it may be argued that protein kinase C is hardly affected by BM41440 in intact cells. In order to analyze the inhibition by BM41440

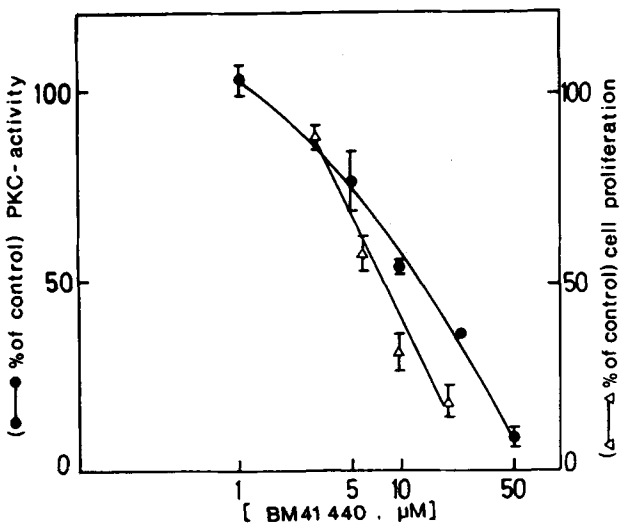

FIG. 2. Effects of BM41440 on cellular replication and protein kinase C. Protein kinase C was determined as described in the "Methods" section in presence of 2.0 μg/ml phosphatidylserine and 0.2 μg/ml diolein. 100% kinase activity represents 23 pmol phosphate/min. Data represent means ± SEM. Cellular replication, △; protein kinase C, ●.

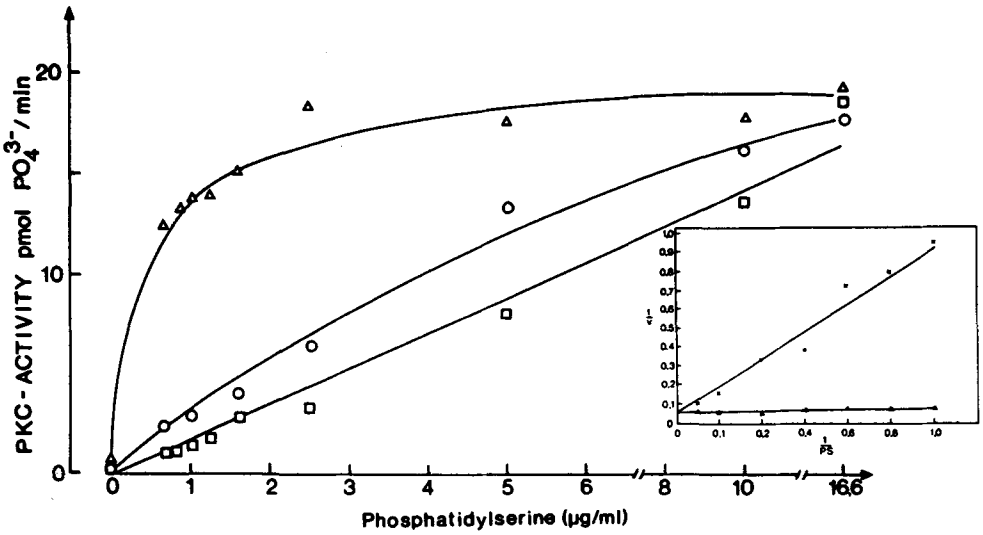

FIG. 3. Inhibition of protein kinase C by BM41440 as a function of the phosphatidylserine concentration. Protein kinase C was determined as described in the "Methods" section. The assays contained 1 µg/ml diacylglycerol and various amounts of phosphatidylserine as indicated. Each point represents the mean from three experiments. Standard deviation was < 5%. Control, △; BM41440 10 µM, ○; BM41440 20 µM, □.

of protein kinase C *in vivo*, we followed the phosphorylation of the ribosomal protein S6. Phosphorylation of S6 is catalyzed by a S6-kinase which in turn has been shown to be under control of protein kinase C (26). As protein kinase C is activated by phorbol esters, like TPA, a depression of the phorbol ester stimulated phosphorylation of S6 should be an indirect measure of intracellular protein kinase C activity. Figure 4 demonstrates the activation of the phosphorylation of the ribosomal protein S6 by TPA and an inhibition by 20 µM BM41440. The results suggest that protein kinase C is sensitive to BM41440 in intact cells.

Considering the essential role of protein kinase C in growth regulation (10) it seemed possible that the depression of protein kinase C by BM41440 is correlated to the growth inhibitory effect of this compound. In order to analyze whether an inhibition of protein kinase C is correlated to the reduction of cellular prolif-

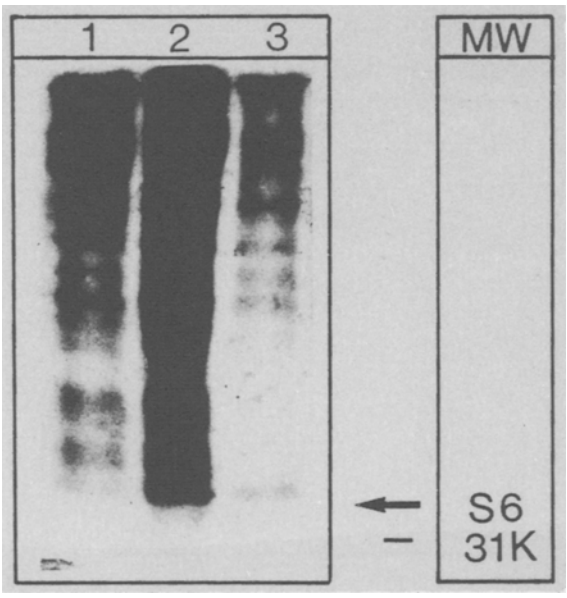

FIG. 4. Inhibition of the phosphorylation of ribosomal protein S6 by BM41440 in intact Walker cells. Ribosomal protein S6 was identified employing molecular weight markers and anti-S6 antiserum. Lane 1, control; lane 2, + TPA (0.5 µM); lane 3, TPA (0.5 µM) + BM41440 (20 µM).

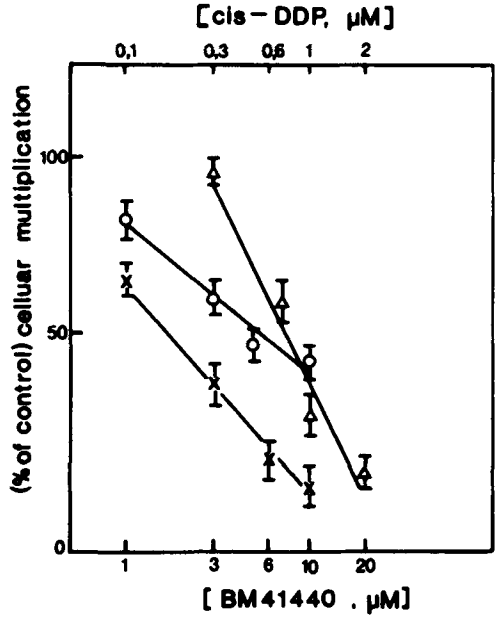

FIG. 5A. Antiproliferative effect of BM41440, *cis*-DDP and a BM41440/*cis*-DDP mixture on Walker carcinoma cells in culture. Cells were grown in presence of the drug for 48 hrs. Cell multiplication was determined as described under "Methods." BM41440, △; *cis*-DDP, ○; BM41440/*cis*-DDP (M ratio 10:1), ×; bars indicate SEM.

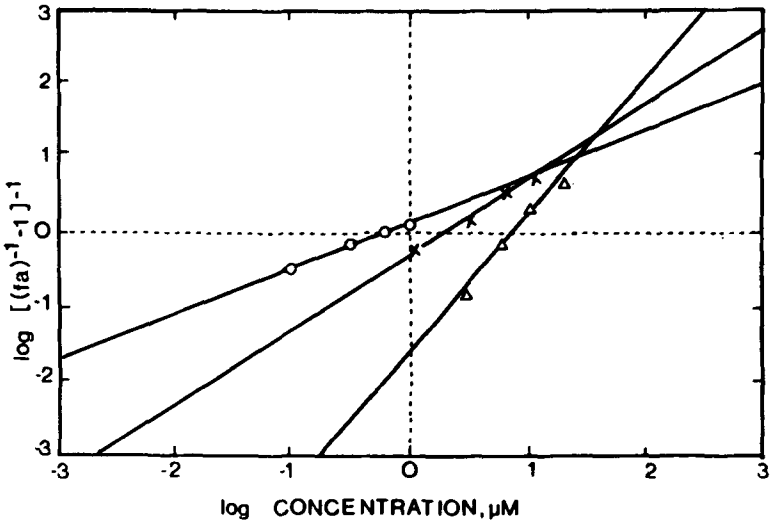

FIG. 5B. Calculated "Median Effect Plots" employing the data from Fig. 5A. Computations were performed according to Chou and Talalay (18,19). The abscissa presents: log *cis*-DDP, ○; log BM41440 + *cis*-DDP, × or log BM41440, △. Inhibition of cell multiplication is expressed as fraction affected (f_a); f_a 0.9 indicates 90% inhibition compared with controls.

eration, the dose dependent inhibition of both parameters were determined. As can be seen in Figure 2, concentrations of BM41440 which inhibit protein kinase C reduce cell proliferation to about the same extent, strongly suggesting the close correlation between these two parameters.

BM41440 enhances the antiproliferative activity of *cis*-DDP (Fig. 5A). The data from Figure 5A have been used to produce "median effect plots" (Fig. 5B) according to Chou and Talalay (20, 21). Computed regression coefficients of the linearized dose-effect curves proved to be > 0.98, indicating that the data fulfill the criteria for computation of the "combination index" (CI) according to Chou and Talalay (20, 21). This combination index has been shown to be extremely useful for quantitative evaluation of drug and inhibitory combinations. As outlined by Chou and Talalay (21), the combination index yields values of CI = 1, if summation is indicated, CI > 1, in case of antagonistic activities, and CI < 1, in case of synergism. In Figure 5C the combination indices for a mixture of BM41440 with *cis*-DDP are plotted with respect to the extent of inhibition of cell multiplication. It is evident that both drugs act synergistically (CI < 1).

DISCUSSION

O-Alkylglycerophospholipids have been shown to inhibit protein kinase C and this effect has been discussed as a possible mechanism responsible for the antitumor activity of these compounds (11, 27, 28). The new alkylphospholipid BM41440 differs from the substances studied so far. It contains a thioether instead of an *O*-ether and the glycerol is replaced by a 2-methoxymethyl-propanol.

The compound seems interesting as its exhibits strong antitumor activity against various *in vitro* and *in vivo* tumor systems (13-15). In view of the major differences between BM41440, biological phospholipids and phospholipid analogues investigated so far, it seemed interesting to determine whether BM41440 affects protein kinase C and, if this is the fact, whether a depression of the enzyme could account for the growth inhibitory effect of the molecule. The data presented here demonstrate that BM41440 inhibits protein kinase C in cell free extracts. The mechanism of inhibition appears similar to that suggested for the effect of the *O*-alkylglycerophospholipids, which are thought to compete with the phospholipid binding site of the enzyme (11). The K_i-value for BM41440 corresponds to K_i values reported for other alkylphospholipids. Helfman et al. (11) report an inhibition of protein kinase C from

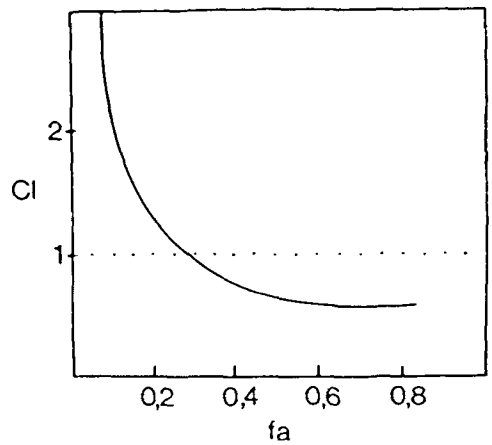

FIG. 5C. Computed plot of the combination index (CI) with respect of inhibition of cell multiplication by *cis*-DDP and BM41440 (molar ratio 1:10). Inhibition of cell multiplication is expressed as fraction affected (f_a); f_a 0.9 indicates 90% inhibition compared with controls. Computation was performed as described by Chou and Talalay (19) employing data from chart 5b. For definition of combination index see text.

human myelocytic leukemia cells by 1-octadecyl-2-methyl-*sn*-glycero-3-phosphocholine with a K_i of 6.3 μM.

The phosphorylation of the ribosomal protein S6 was used as an indirect marker for the intracellular protein kinase C activity. Our data demonstrate that submaximal inhibitory concentrations of BM41440 reduce the phosphorylation of S6 in intact cells. These results suggest that BM41440 at therapeutic concentrations affects protein kinase C in intact cells.

The dose effect plot for a protein kinase inhibition by BM41440 closely resembles the dose effect curve of the growth inhibitory action of this phospholipid analogue. Although it can be questioned whether the conditions in the cell-free extract permits conclusions concerning the behavior of the enzyme in intact cells, the data are in agreement with the assumption that protein kinase C is the major target of a alkylphospholipid—although additional mechanisms cannot be excluded.

Various inhibitors of protein kinase C have been shown to enhance the antiproliferative activity of *cis*-DDP (19). The data demonstrate that BM41440 shares this property. The protein kinase C inhibitors which have been studied with respect to their behavior in combination with *cis*-DDP comprise a variety of chemically distinct compounds with very different mechanisms of action and include quercetin, tamoxifen, phorbol esters, staurosporine and alkylphospholipids. None of these drugs is specific for protein kinase C. But, the common denominator of these chemically very-different compounds is their inhibitory effect on protein kinase C. It is likely, therefore, that it is indeed the ability of these agents to depress protein kinase C which is responsible for their enhancement of *cis*-DDP activity. By which mechanism inhibitors of protein kinase C potentiate the antiproliferative activity of cis-DDP is still obscure. It should be noticed, however, that *cis*-platinum complexes exert a series of membrane effects which seem to be correlated to the sensitivity against *cis*-platinum and which may contribute to the cytotoxic activity of these drugs (29—31). There is no direct inhibition by *cis*-DDP of protein kinase C (data not shown).

An enhancement of the antiproliferative activity of *cis*-DDP by ether lipid analogues has recently also been described by Noseda et al. (32). In contrast to our findings demonstrating a synergistic potentation of *cis*-DDP activity by BM41440, the compounds investigated by Noseda et al. (32) increase the growth inhibitory effect of *cis*-DDP via an additivity phenomenon. Whether this discrepancy is explained by the chemical differences of the compounds used or whether it is due to biological differences between the cell types studied remains to be investigated.

It seems unlikely that the synergistic enhancement of the antiproliferative activity of BM41440 by *cis*-DDP is specific for platinum complexes because similar effects have been obtained employing combinations of various protein kinase C-inhibitors with nitrogen mustard (19). It should be emphasized, however, that nitrogen mustard, as well as other alkylating agents, cause a variety of membrane lesions at therapeutic concentrations (33–36) which may be related to the potentiation of the antitumor activity by protein kinase C-inhibitors.

[Received August 29, 1988; Revision accepted December 5, 1988]

Environmental Temperature and Metabolism of the Molecular Species of Phosphatidylcholine in the Tissues of the Rainbow Trout

Nabil Abdul Malak[a], Gerard Brichon[b], Roger Meister[c] and Georges Zwingelstein*[,c]
[a]Laboratory of Physiology, Lebanese University of Beirut, Beirut, Lebanon; [b]Institut Michel Pacha, 83500, La Seyne-sur-Mer, France; and [c]Laboratoire de Physiologie generale et comparee, UA CNRS 613, Universite Claude Bernard, F. 69622 Villeurbanne cedex, France.

The phospholipid composition and the fatty acid pattern of phosphatidylcholine from major tissues of the rainbow trout acclimated to 11° and 21°C were analyzed. A significant difference in the level of 20:5ω3 fatty acid between gill, kidney, intestine and liver phosphatidylcholine is observed in both groups of animals. These differences correlate with a modification of the molecular species distribution in the phosphatidylcholine in these organs. In vivo incorporation of ^{32}P into phospholipids of gills, kidney, intestine, liver and muscle was determined in trout acclimated to 11° and 21°C. Temperature acclimation specifically modify the relative specific radioactivity of the monoene and hexaene molecular species of phosphatidylcholine in gills, intestine, kidney and liver. It can be concluded from these results, that the metabolism of the diacylglycerol moiety and the coupled fatty acids of phosphatidylcholine differs with the tissue and the temperature. It is suggested that different associated mechanisms specific for each organ determine the fatty acid composition of phosphatidylcholine required for its physiological functions at each temperature.
Lipids 24, 318-324 (1989).

In fish, phospholipids have a characteristic and complex fatty acid pattern with large amounts of highly unsaturated fatty acids (1). It is often assumed that this unsaturation of the diacylglycerol moiety of phospholipids in these animals is related in a direct manner to the cell membrane fluidity (2,3). In fact, a wide variety of poikilotherms possess the ability to alter the fatty acid composition of their phospholipids in response to a change in environmental temperature (2,4,5). The adjustment of the types of fatty acid esterified in phospholipids of the membranes probably involves various regulatory mechanisms and may occur at several points in the lipid metabolic pathway (3). However, these adaptation mechanisms can differ among tissues of a single species, and additional studies are needed to understand the metabolic alterations that occur during homeoviscous adaptation (6).

The metabolic reactions involved in the changes in fatty acid composition of phospholipids in poikilothermic organisms acclimated to extreme temperature have not been completely elucidated. Recently, a temperature-controlled metabolic heterogeneity in the molecular species of different phospholipids has been observed in crabs (7), trout (8,9) and goldfish (10), suggesting that a possible adaptative mechanism may occur at this level.

Phospholipids could be synthesized by several different routes: de novo synthesis from the 1,2-diacylglycerols (11); reacylation of lysophospholipids (12); stepwise methylation of phosphatidylethanolamine to form phosphatidylcholine (13); decarboxylation of phosphatidylserine to give phosphatidylethanolamine (14); and base exchange reactions (14). However, these different pathways have not the same activity in the major organs of fish and evaluating their respective roles requires additional studies in these species.

The present work was undertaken to determine, in the different tissues of the rainbow trout (*Salmo gaidnerii*), the influences of the environmental temperature on the biosynthesis of the major molecular species of phosphatidylcholine. We have investigated by ^{32}P labeling, whether phospholipid biosynthesis is temperature-dependent in all tissues and whether the temperature of the adaptation medium alters, similarly in all organs, the concentration and renewal of the molecular species of phosphatidylcholine.

MATERIALS AND METHODS

Rainbow trout (weighing 150-180 g) were purchased from a local supplier and kept in highly aerated running water at 11° and 21°C for at least six weeks. The animals were fed daily with SARB (Decines, France) commercial trout food. Before use, the animals were starved 24 hr. Each trout received 300 μCi of $^{32}PO_4Na_2H$ (10 mCi/ml, Amersham, Buckinghamshire, UK) in isotonic solution by intraperitoneal injection. Water radioactivity was measured for each trout 3 hr after ^{32}P injection to estimate the leakage of radioactive material from the point of injection, and animals with a loss of less than 10% of the injected dose were used. Injected trout were killed 12, 24 and 48 hr after the initial injection and tissue lipids were extracted by a modification of Folch's method (15) as previously described (9,16). The washed organic phase was evaporated to dryness in a rotary evaporator, and the lipid extract stored in a minimum volume of 2:1 (v/v) benzene/methanol at −70°C.

Phospholipids were separated by two dimensional thin-layer chromatography on 10 × 10 cm silica gel 60 precoated plates (Merck, Darmstadt, Germany) using solvents previously described (17). The spots on the chromatogram were visualized with the phosphorus-specific spray reagent of Dittmer and Lester (18). Spots were scraped off into counting vials and 4 ml of water/ethanol (1:1, v/v) and 10 ml of Picofluor (Packard, Downers Grove, IL) were successively added (19). After mixing, each vial was counted. Counting efficiency was

determined by the external standard channels ratio method. Under these conditions, 95–98% of the radioactivity in each spot was recovered (20).

The phosphatidylcholines were purified by one-dimensional thin-layer chromatography on 0.5-mm thin layers silica gel H (Macherey-Nagel, Düren, Germany) plates with chloroform/methanol/acetic acid/water (60:30:7:3, v/v) as developing solvent (21). After localization with primuline spray reagent under UV light (22), the phospholipids were eluted with a mixture of chloroform-methanol-acetic acid-water (50:39:1:10, v/v) and washed as described by Arvidson (23). The purity of the isolated phosphatidylcholine was controlled by analytical two-dimensional thin layer chromatography on silica gel 60 precoated chromatoplates (Merck, Darmstadt, Germany) according to Portoukalian et al. (17).

Molecular species of the purified phosphatidylcholines were fractionated on precoated silica gel 60 plates impregnated with $AgNO_3$ by dipping for 30 min in 100 ml of 50% (w/v) Ag NO_3 in water. The plates were dried for 10 min at 115°C, stored in the dark and activated for 8 min at 170°C immediately before use. A maximal amount of 2 mg of phosphatidylcholine was applied to each plate, which was developed in chloroform/methanol/water (60:40:7.5, v/v) (24). The 4 major separated fractions stained with phosphorus-specific spray were either scraped off into scintillation vials for liquid scintillation counting or eluted and washed as described by Arvidson (23). Determination of lipid phosphorus was made on each eluate by Bartlett's method (25) as modified by Portoukalian et al. (17). The fatty acid composition was analyzed by gas chromatography after methanolysis of each eluate by the procedure previously described (26). All analyses were carried out isothermally at 190°C using a gas liquid chromatograph (Packard, Downers Grove, IL) with a 10% SP 2330 on 100/120 chromosorb W AW column of 9 ft 1/16 in. S.S.

RESULTS

Phospholipid composition of the tissues of rainbow trout acclimated at 11° and 21°C. The phospholipid content of the different tissues differ widely from 2.2% of wet tissue in liver to 0.6% in muscle (Table 1). Increased acclimation temperature induced a significant decrease of phospholipid content in gills and kidney.

The phospholipids present the same general pattern in the liver, gills, kidney, muscle and intestine, but differences exist in the composition, which is mostly quantitative. As shown in Table 1, there is a significantly higher percentage of phosphatidylcholine (PC) in liver and muscle as compared with intestine, kidney and gills. This observation is in agreement with the data obtained by one-dimensional TLC of lipids extracted from liver and gills of trout by Hazel (27,28). The highest ratio of PC/sphingomyelin (SPH), resulting from a lower percentage of SPH is observed in the muscle (PC/SPH = 21.6 at 11°C and 27.5 at 21°C) and the lowest in intestine where the ratio decreases to 5.9 at 11°C and 6.8 at 21°C. The ratios phosphatidylethanolamine (PE)/PC and PS/phosphatidylinositol (PI) were higher in the three organs implicated with osmoregulatory processes. The highest proportion of diphosphatidylglycerol (DPG) exists in the lipids from liver. The greatest amount of lysophosphatidylcholine (LPC) appears to be in intestine and gills, two organs in contact with the environmental medium. 11° or 21°C-Acclimation temperature have no particular effect on this composition.

Fatty acid composition of phosphatidylcholines from the tissues of rainbow trout acclimated at 11°C and 21°C (Table 2). The fatty acid pattern of phosphatidylcholines extracted from the tissues of 11° and 21°C-acclimated trouts is summarized in Table 2. Examination of their fatty acid compositions revealed that palmitic (16:0), oleic (18:1) and docosahexaenoic (22:6ω3) acids are the major fatty acids in all tissues and represent 70–75% of the total fatty acids esterified in PC. A similar pattern for PC fatty acids has been observed in the liver by Hazel (27) and in the gills by Sellner and Hazel (29). Muscle PC appears as the most unsaturated as shown by its unsaturation index (UI). The higher proportion of 20:4ω6 was observed in gills, kidney and intestine, but the sum of ω6 fatty acids remains approximately the same in all tissues. In contrast, the sum of ω3 varies largely between the different organs, the highest being in liver and muscle. An important point is that the temperature of acclimata-

tr, Traces, ND not detected.
UI, the unsaturation index, is the sum of the percentage multiplied by the number of double bonds for each fatty acid in the mixture.

tion does not seem to affect greatly the major fatty acid pattern of PC in all tissues. Only a significant decrease of eicosapentaenoic acid (20:5ω3) is seen in gills, kidney, liver and intestine of 21°C-acclimated trout. In contrast, in muscle, there is an increase in the percentage of this fatty acid. On the basis of these analyses, it is only possible to differentiate the two kinds of tissues by considering the ratio, 20:5ω3/20:4ω6, which decreases significantly in liver from 2.3±0.2 at 11°C to 1.3±0.1 at 21°C. A similar variation is observed in gills (from 1.5±0.1 to 1.2±0.1), kidney (from 2.4±0.2 to 2.1±0.1) and intestine (from 1.8±0.2 to 1.3±0.1). In muscle, the ratio increases from 3.0±0.1 to 3.3±0.2 at 21°C.

In vivo incorporation of $^{32}PO_4HNa_2$ into phospholipids of rainbow trout acclimated at 11° and 21°C. To determine whether the differences in the composition of tissue phospholipids in 11°- and 21°C-acclimated trout result from variations in their synthesis, the kinetics of in vivo incorporation of radioactive phosphate was investigated. Figure 1 shows the total amount of radioactivity accumulated in the tissue lipids of *Salmo gaidnerii* 12, 24 and 48 hr after injection of the radiolabel. During the 48-hr period after the ^{32}P injection, the level of radioactivity in total lipids increases continuously (see Fig. 1). The slowest uptake appears in the muscle and the fastest in liver. Increasing acclimation temperature results in an increased rate of ^{32}P incorporation in gills, kidney and liver lipids. In muscle, no significant difference between 11° and 21°C is observed.

In all tissues, the major part of the radioactivity is concentrated in three lipid species, 60-80% in the PC, 15-30% in the PE and 5-30% in the PI (Table 3). The remainder is distributed between the other constituents, chiefly in PS (1-4%), SPH (1-3%), DPG (0.5-1.5%) and LPC (0.5-1.5%). The distribution of the radioactivity into the different constituents of the phospholipid pool remains approximately the same during the 48-hr period of incubation in the liver (see Table 3). In contrast, in gills, kidney, muscle and intestine, the percentage of radioactivity incorporated into PC, PE and PI varies largely with time and adaptation temperature. The percentage of radioactivity declined for PI in these tissues at both temperatures; whereas, the radioactivity of PC increased at 11° and remained stable at 21°C. For PE, the percentage decreased in the kidney and intestine at 11° and in muscle at 21°C, and remained stable in gills and muscle at 11°C. At 21°C, the percentage of radioactivity in PE increases in gills, kidney and muscle.

[b]$p<0.05$, value statistically different between 11 and 21°C.
[c]$p<0.01$; value statistically different between 1 and 21°C.

As can be seen in Table 4, the highest specific radioactivities of PC and PE are observed in liver and are 2- to 3-fold more than those in the gills, kidney and intestine at both temperatures. Increasing the temperature multiplies by 1.5-2 the specific radioactivity of these two phospholipids in these last tissues. PC and PE have the lower specific activity in muscle in which phospholipids have a slow labeling. However, in intestine, in contrast with the other tissues, PE has a higher specific radioactivity than PC.

The results presented above give only an imperfect picture of the extent of the changes due to temperature influence, as PC consists of molecular species with different degrees of unsaturation. For this reason, we have examined the molecular species of PC synthetized in the both groups of trout.

Distribution of radiolabel among the different molecular species of PC of trout acclimated at 11° and 21°C. After ^{32}P injection, PC from tissues from 11° and 21°C-acclimated trout have been resolved into fractions of different degrees of unsaturation by chromatography on silica gel plates impregnated with $AgNO_3$. Trout PC were routinely separated into four fractions stained by phosphorus reagent on the chromatogram, but in some cases, the fourth fraction was separated into two bands. As their fatty acid compositions were relatively close, we used these as a single fraction. Each fraction separated on the chromatogram was arbitrarily named according to its unsaturated fatty acid content.

Figure 2 shows the fatty acid compositions of the molecular species isolated by $AgNO_3$ thin-layer chromatography from PC. The percentage of C_{18}, C_{20} and C_{22} fatty acid in the major molecular species of PC extracted from the different tissues showed striking variations corresponding to the differences in fatty acid composition of the initial phospholipid (see Table 2). However, no statistically significant differences were observed in relative proportions of fatty acids in the similar molecular species of PC isolated from the same tissues from either 11°- or 21°C-acclimated trout. In fraction 4, separated in some cases as two bands on the chromatogram, differences were observed in the two separated bands, but were not statistically significant.

From the data on the percentage distribution of P between the subfractions of PC in Table 5, it is seen that the monoenoic and hexaenoic fractions together account for 70-80% of total PC phosphorus. In liver PC, there is 2-fold more hexaenoic fraction than in gills, and this difference corresponds to the higher

TABLE 4

Average of Specific Activities of Phosphatidylcholine and Phosphatidylethanolamine During the 48-hr Experimental Period

[a]Specific radioactivity was expressed as dpm/μg of Plip. Values are means of 12-, 24- and 48-hr specific activities of PC or PE.

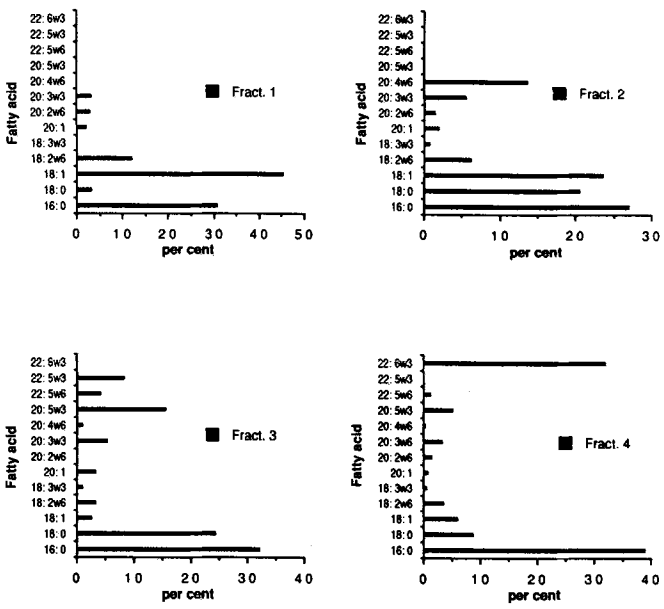

FIG. 2. Fatty acid compositions of the molecular species isolated by $AgNO_3$ thin-layer chromatography from phosphatidylcholine of gills.

content of 22:6ω3. By increasing acclimation temperature, a higher percentage of the more saturated fraction is observed in liver (+92%), gills (+16%) and kidney (+17%). These increases were concomitant with decreases of hexaenoic fraction.

To compare the labeling of each constituent of the PC between animals living at 11° and 21°C, we have calculated their relative specific radioactivities (sp. act. of the component/sp. act. of total lipids) which are given in Table 6. These ratio values which are independent of the rate of ^{32}P incorporation into the PC facilitate the comparison of the renewal of the species studied. Significant differences in renewal of the most saturated (monoene) and the unsaturated (tetraene and hexaene) fractions between 11° and 21°C trout were observed in gills, kidney, intestine and liver (Table 6). At 21°C, the monoene and tetraene fractions have a higher renewal compared with 11°C in gills, kidney and intestine. In contrast, these fractions have a lower renewal in liver at 21°C. The most unsaturated fraction (hexaene), has a lower renewal at 21°C in gills and intestine, but a higher one in liver. A higher ratio (sp. act. of monoene fraction/sp. act. of hexaene fraction) of 12.6±1.6 in the liver as compared, respectively, with 2.7±0.3, 2.6±0.6 and 3.9±0.9 in the gills, kidney and intestine was observed in 21°C-acclimated trout. However, at 11°C, this ratio has the higher value (13.4±0.9) in intestine as compared with 4.8±0.5, 3.9±0.7 and 4.5±0.8, respectively, in gills, kidney and liver.

DISCUSSION

Phosphatidylcholine, one of the most abundant of commonly occurring phospholipids in trout tissues (see Table 1), has been studied during acclimatation of the trout at two different temperatures.

At 11°C, our results show that the organs involved in osmoregulation (gills, kidney and intestine) differ greatly from the liver and muscle. The PC of these organs presents the lowest percentage of saturated fatty acids and ω3 fatty acids, the highest percentage of arachidonic acid (20:4ω6) and the lowest ratio, Σ ω3/Σ ω6. Also, the most abundant molecular species of these PC is monoene, whereas in the liver it is hexaene.

Increasing the acclimation temperature from 11° to 21°C results in the following changes in the PC: increase in saturated fatty acids, except the intestine; decrease in 22:5ω3 and 22:6ω3 acids, and in ratio 20:5ω3/20:4ω6; and decrease in ratio, Σω3/Σω6, except in the kidney.

This results in an increase in the monoenoic molecular species and a decrease in the hexaene. The tetraene molecular species remains stable; whereas, there is a significant decrease in the pentaenes in the gills and the liver.

The increase in the temperature, also accelerates the incorporation of ^{32}P into the tissue lipids, with the exception of the muscle. There is an increase of radiolabel incorporated into the most saturated (monoene) species of PC at 21°C in the osmoregulatory organs and a decrease in the liver. It is similar for the tetraene,

TABLE 5

Effect of the Temperature on the Distribution of the Molecular Species in PC of the Trout Tissues

		Molecular species			
	Temp (°C)	Monoenes	Tetraenes	Pentaenes	Hexaenes
Gills	11°	49,5±1.8[a]	11,6±1,2	12,2±0,3	26,9±0,3
	21°	57,2±0,7[b]	10,6±0,7	10,9±0,2[b]	21,4±1,7[c]
Kidney	11°	45,1±1,2	10,0±2,1	10,1±0,1	34,9±3,3
	21°	52,7±1,9[c]	9,2±0,7	10,8±1,2	27,3±0,6
Liver	11°	22,4±1,2	7,6±0,4	12,8±0,1	57,3±1,3
	21°	43,1±3,9[d]	7,7±0,7	8,1±1,0[d]	41,1±3,7[d]
Intestine	11°	45,2±0,1	13,6±1,0	11,4±1,3	29,9±0,3
	21°	45,5±0,2	13,2±1,7	10,2±0,3	31,2±1,3

[a]Results are expressed as the percentage of total phosphorus recovered on the TLC plate. Values [mean ± SEM (n = 6)] with a superscript are significantly different by Student t test between the 11°C and 21°C trout.
[b]$p>0.02$, [c]$p<0.05$, [d]$p<0.01$.

TABLE 6

Relative Specific Activities[a] of Molecular Species of Phosphatidylcholines

		Monoenes	Tetraenes	Pentaenes	Hexaenes
Gills	11°C	0.45±0.4	0.80±0.07	0.90±0.02	2.14±0.08
	21°C	0.68±0.06[b]	1.04±0.05[c]	0.87±0.05	1.84±0.07[c]

		Distribution in dpm %			
			Fract. 1+2	Fract. 3	Fract. 4
Muscle	11°C		20.1±2.7	6.1±0.9	73.8±2.1
	21°C		28.5±8.0	6.1±1.0	66.3±7.3

[a]Relative specific activity was the ratio of the specific radioactivity of a molecular species to the specific radioactivity of total PC. Muscle results are expressed only as the distribution of ^{22}P among PC of different degrees of unsaturation.
[b]$p<0.01$; [c]$p<0.05$.

but the hexaene is renewed more slowly in the gills and in the intestine and quicker in the liver.

From these results, it can be concluded that the metabolism of the diacylglycerol moiety and the coupled fatty acids of PC differs with the tissue and the temperature. They can be modified selectively. This determines for each organ a fatty acid composition of PC required for physiological functions at different temperatures.

This restructuration of the PC in function of the temperature is probably the result of an overall rearrangement, conjunction of : direct influence of the temperature on the speed of synthesis or degradation of these molecules within each organ (10,30-34); influence of the concentration of different substrates and in particular the relative ratio of the different constituents of the fatty acyl-CoA pool in each organ (35-37); activation or inactivation in certain organs of accessory pathways of PC synthesis, such as acylation of LPC (38-41), decarboxylation of PS to PE (42, 43), methylation of PE (44-46) or base exchange (41); vesiculation processes of cell membranes more or less important depending on the organ (47) and provoking the exportation of certain molecular species of PC present in the lipid layer of the membrane (46).

These modifications, in the composition and distribution of the molecular species of each phospholipid or their turnover, will have an effect on the physical properties of each membrane bilayer (48).

However, this compensation against the temperature requires an external source of certain essential elements, such as the ω3 and ω6 polyunsaturated fatty acid (49-53). This varies with the animal studied and these diverse requirements can be explained by differences in the activity of Δ9, Δ6 and Δ5 desaturases (54-56). The activities of these desaturases vary differently with the temperature (57, 58) and so the metabolism of certain molecular species of PC will be dependent with the evolution of the latter. However, the process is probably more complex, certain fatty acids (20:4 ω6 and 20:5 ω3) are transformed into prostaglandins in osmoregulatory organs (59-60). Thus, the increase of specific radioactivity of the tetraene fraction in these organs and decrease in the liver could be due to the exchange of constitutive fatty acids between these different organs. An inverse phenomenon is observed with the hexaene fraction. Acting as a salvage pathway, this process could deliver to the organs which need them the essential fatty acids to function. Such an exchange process has been described in the crab, *Carcinus maenas* (46), and in the eel, *Anguilla anguilla* (unpublished observations).

ACKNOWLEDGMENTS

The authors wish to express their appreciation to T.F. Wild (U.M. CNRS 380030) for his help in preparing the paper and gratefully acknowledge the care given to the animals by D. Corigliano.

[Received May 16, 1988; Revision accepted November 29, 1988]

Sterol Metabolism in the Nematode *Panagrellus redivivus*

Thomas A. Salt[a], David J. Chitwood[b] and William R. Lusby[b]
[a]Department of Botany, University of Maryland, College Park, MD 20742, and [b]Insect and Nematode Hormone Laboratory, Agricultural Research Service, USDA, Building 467, BARC-East, Beltsville, MD 20705

Panagrellus redivivus **was propagated in media containing three structurally different sterols: 7-dehydrocholesterol, campesterol or stigmastanol. Nematodes propagated with 7-dehydrocholesterol contained mostly lathosterol and 7-dehydrocholesterol. Nematodes propagated with campesterol contained mostly cholesterol and cholestanol. Nematodes propagated with stigmastanol contained mostly cholestanol. The sterol ester fraction was enriched with 4α-methylsterols and contained the same sterols as the free sterol fraction except for nematodes propagated with 7-dehydrocholesterol, where no dietary sterol was found in the ester fraction.** ***P. redivivus*** **is capable of reducing the Δ^5-bond, C-24 dealkylation and methylating the sterol nucleus at C-4.**
Lipids 24, **325-328 (1989).**

Nematodes lack the ability to synthesize sterols *de novo* and therefore possess a nutritional requirement for exogenous sterols (1—4). Nematodes, however, do possess the ability to metabolize dietary sterols (5—14). Although the sterol content and composition of many nematodes is known, the difficulty in propagating plant-parasitic nematodes axenically has limited studies to comparisons of sterol composition of the host and the parasite (15—21). Extensive studies on sterol metabolism in nematodes, therefore, have utilized the free-living nematode *Caenorhabditis elegans* as an axenically grown model organism (6—10, 12). *C. elegans* is capable of C—24 dealkylation but generally produces 7-dehydrocholesterol (cholesta-5,7-dien-3β-ol), a sterol not yet detected in parasitic nematodes (6—10, 12).

When fed Δ^5-sterols, the free-living nematode *Panagrellus redivivus* produces cholesterol (cholest-5-en-3β-ol) and cholestanol (5α-cholestan-3β-ol) as its principal sterols (13). As sterols with a Δ^5-bond or a saturated nucleus are more characteristic of plant-parasitic nematodes (18, 20, 22), we suggested that *P. redivivus* may be a more suitable model organism for investigating sterol metabolism representative of these nematodes (13). Therefore, it was of interest to extend our previous study on sterol metabolism in *P. redivivus* to include sterols with differing side chains and nuclear modifications.

EXPERIMENTAL

Nematode cultures. Panagrellus redivivus was propagated axenically at 22°C in a semi-defined aqueous medium containing 30 mg/ml yeast extract, 30 mg/ml soy peptone, 10 mg/ml casein hydrolyzate and 10 mg/ml dextrose (23). All ingredients except the soy peptone were extracted (3×) with chloroform/methanol (2:1, v/v) to remove any exogenous sterols. A filter-sterilized stock solution of dichloromethane-extracted hemoglobin (0.5 mg/ml in the final medium) was added after autoclaving of the basal medium. The dietary sterols were solubilized in aqueous Tween 80, filter-sterilized and similarly added at a final concentration of 10 μg/ml. The nematodes were acclimated through two subcultures in the appropriate medium prior to introduction into mass culture.

Dietary sterols. The dietary sterols contained no impurities by thin layer chromatography (TLC). The stigmastanol (24α-ethyl-5α-cholestan-3β-ol) and 7-dehydrocholesterol (cholesta-5,7-dien-3β-ol) contained no detectable impurities (<0.05%) by capillary gas liquid chromatography (GC). The campesterol (24α-methylcholest-5-en-3β-ol) contained approximately 4% sitosterol (24α-ethylcholest-5-en-3β-ol) by capillary GC.

Sterol isolation. Replicate cultures of living nematodes were isolated from late logarithmic phase cultures by centrifugation and sucrose flotation (24). Total lipids were isolated from lyophilized nematodes by homogenization (4×) with chloroform/methanol (2:1, v/v) in a Ten Broeck tissue grinder. The neutral lipids were separated by column chromatography through silica gel 60 (E. Merck, Darmstadt, FRG) by eluting with chloroform. The neutral lipids were then fractionated on a 15-g silica gel 60 column (22 mm i.d.) by eluting with: 1) 100 ml hexane; 2) 50 ml hexane/benzene (1:1, v/v); 3) 50 ml hexane/benzene (2:8, v/v); 4) 50 ml benzene; 5) 50 ml chloroform; 6) 50 ml chloroform; 7) 50 ml ether, and 8) 100 ml methanol. Fractions 1—3 (steryl esters) and 6—7 (free sterols) were saponified for 4 hr in 4% KOH in methanol at 65°C.

The sterols were isolated from the saponification products on a 7-g silica gel 60 column (1.0 cm i.d.) by eluting with 20 ml each of 0, 10, 12, 14, 16, 17, 20, 30 and 100% ether graded into hexane. The 4-methylsterols eluted in the 16 and 17% ether fractions and the 4-desmethylsterols eluted in the 20 and 30% ether fractions. The sterols were acetylated with pyridine/acetic anhydride (2:1, v/v) for 16 hr at ambient temperature. The steryl acetates were fractionated on a 5-g 20% $AgNO_3$-Unisil column (1.0 cm i.d) by eluting with 20 ml each of 0, 2, 3, 4, 5, 6, 7 and 100% ether graded into hexane. All chromatographic columns except the 20% $AgNO_3$-Unisil columns were monitored by thin-layer chromatography (TLC) on Anasil H TLC plates (Analabs, North Haven, CT) developed in hexane/ether/acetic acid (8:2:0.1, v/v/v) and visualized by acid charring.

Instrumentation. GC of the sterols and steryl acetates was performed isothermally on a glass column (2mm i.d. × 2 m) packed with 2% OV-17 and a J&W DB-1 fused silica capillary column (0.25 mm i.d. × 15 m, 0.25 μm film) in a Varian model 3700 gas chromatograph equipped with a flame ionization detector (FID). Retention times and areas were recorded on a Shimadzu C-R1B Chromatopac data processor. GC/mass spec-

Abbreviations: FID, flame ionization detector; GC, gas chromatography; MS, mass spectroscopy; RRT, relative retention times; TLC, thin-layer chromatography.

TABLE 1

Lipid and Sterol Content of *Panagrellus redivivus*

Dietary sterol	Total lipid[a] % dry wt	Total sterol[b] % dry wt	Esterified sterol[b] % total sterol
Campesterol	18.5	0.04	2.4
Stigmastanol	17.2	0.03	12.1
7-Dehydrocholesterol	17.7	0.05	2.5

[a]Determined gravimetrically.
[b]Determined by OV-17 GC quantitation.

troscopy of the steryl acetates was performed at 70 eV on a Finnigan model 4510 equipped with a J&W DB-1 fused silica capillary column (0.32 mm i.d. × 30 m, 0.25 μm film) and interfaced with an Incos Data System. Ultraviolet spectroscopy of the steryl acetates (when applicable) was performed with a Perkin-Elmer 559 spectrophotometer scanning between 190 and 400 nm.

RESULTS

The total lipid content on a dry weight basis was similar when *Panagrellus redivivus* was propagated with any of the three dietary sterols (Table 1). The total sterol content ranged from 0.03 to 0.05% of the nematode dry weight. The steryl esters comprised 2.4 and 2.5% of the total sterol when propagated with campesterol and 7-dehydrocholesterol (respectively); however, elevated levels of esterified sterols (12.1%) were present when *P. redivivus* was propagated with stigmastanol.

The isolated sterols and steryl acetates possessed GC relative retention times (RRT) to cholesterol and cholesteryl acetate (Table 2), respectively, identical to authentic standards and were in agreement with previously published values (6—10, 13, 14, 25). The 4α-methylsteryl acetates exhibited the characteristic shift in RRTs previously reported (6). The mass spectra and UV spectra of the steryl acetates were identical to authentic standards and were in agreement with previously published values (6—10, 13, 14, 25). The cholesta-7,9(11)-dien-3β-ol was identified by the mass spectrum and UV spectrum of the acetate. This sterol possessed a mass spectrum for the acetate with ions at m/z (relative intensity): 426 (M^+, 100), 411 (22), 366 (19), 351 (37), 313 (30), 286 (19), 271 (11), 259 (31), 253 (38), with other prominent ions at 211 (62), 199 (33), 183 (21), 171 (22), 157 (31), 145 (50), 131 (42), 118 (30), 105 (43), 81 (40), 69 (40), 55 (50). The molecular ion at m/z 426 indicated a diunsaturated sterol. The fragments for loss of side chain (m/z 313) and loss of side chain and acetic acid (m/z 253) indicated that both double bonds were in the nucleus. The prominent molecular ion (m/z 426) for the acetate indicated the absence of a C-5 double bond. The UV spectrum exhibited λ_{MAX}^{EtOH} nm: 233, 243, 253 characteristic of a 7,9(11)-ring system (25). This sterol was therefore identified as cholesta-7,9(11)-dien-3β-ol.

Exclusive of dietary sterol, the steryl ester fractions contained the same sterols as the free sterol fractions and were enriched with 4α-methylsterols (Table 3). When *P. redivivus* was propagated with 7-dehydrocholesterol as the dietary sterol, the major recovered free sterol was lathosterol (46.8%) with lesser amounts of dietary sterol (31.0%). Cholesta-5,7,9(11)-trien-3β-ol comprised only 5.3% of the free sterol fraction but was the major sterol in the sterol ester fraction (51.8%).

P. redivivus metabolized greater than 70% of the campesterol taken up from the medium; however, less than 57% of the isolated free sterols were dealkylated at C-24 (Table 3). Exclusive of dietary sterol, the major isolated free sterols were cholesterol (36.1%) and cholestanol (15.1%) with lesser amounts of campestanol (9.0%). Substantial quantities of the unusual 24-methyl-23-dehydrocholesterol were also present as previously reported (14).

When *P. redivivus* was propagated with stigmastanol, 93.1% of the isolated free sterol was dealkylated at C-24 (Table 3). The major isolated free sterols were cholestanol (79.9%) and 4α-methylcholestanol (7.4%). Only 1.8% of the free sterol possessed nuclear unsaturation, whereas higher levels (8.9%) of unsaturated sterols were detected in the steryl ester fraction.

TABLE 2

Gas Chromatographic Relative Retention Times of Sterols and Steryl Acetates Isolated From *Panagrellus redivivus*

Sterol	RRT[a] DB-1	RRT[a] OV-17
Cholesterol	1.00	1.00
Cholestanol	1.02	1.02
Lathosterol	1.12	1.17
Campesterol	1.30	1.32
Campestanol	1.32	1.34
24-Methyl-23-dehydrocholesterol	1.26	1.36
Sitosterol	1.60	1.64
Stigmastanol	1.63	1.66
Desmosterol	1.08	1.20
Cholest-24-enol	1.11	1.26
7-Dehydrocholesterol	1.11	1.17
Cholesta-5,7,9(11)-trienol	0.98	1.06
Cholesta-7,9(11)-dienol	1.05	1.16
4α-Methylcholestanol	1.20 (1.17)	1.15 (1.13)
4α-Methylcholest-7-enol	1.31 (1.27)	1.35 (1.32)
4α-Methylcholest-8(14)-enol	1.17 (1.14)	1.16 (1.13)
4α,24α-Dimethylcholestanol	1.53 (1.50)	1.52 (1.48)

[a]Relative retention times of sterols to cholesterol. If not indicated, relative retention times of the steryl acetates to cholesteryl acetate are the same as those for the sterol to cholesterol.
[b]Numbers in parentheses are relative retention times of steryl acetates relative to cholesteryl acetate.

TABLE 3

Relative Percentages of Free Sterol (FS) and Esterified Sterol (ES) Recovered From *Panagrellus redivivus* Grown on Various Dietary Sterols

	Dietary sterol

[a]Previously reported (9).

DISCUSSION

The total lipid and sterol content are consistent with previous reports for *P. redivivus* and other species of free-living nematodes (6—9, 12). However, elevated levels of esterified sterols (12.1%) occurred when the nematodes were propagated with stigmastanol. The reason for the elevated levels of steryl esters when propagated with a sterol with a saturated nucleus is currently unknown. Previous reports with *Caenorhabditis elegans* indicate that the levels of steryl esters are depressed from the usual 13% to 21% level to 7.3% when propagated with stigmastanol (9). However, when *C. elegans* was propagated with cholestanol, 19.1% of the sterols were found in the steryl ester fraction (12). This might be indicative of the variability of the steryl ester fraction with respect to a storage function or might be peculiar to the metabolism of sterols with a saturated nucleus in these nematodes.

P. redivivus has the ability to dealkylate the 24-alkyl group of phytosterols, reduce a Δ^5-bond and introduce a methyl at C-4 of the sterol nucleus (Table 3). Dealkylation of the 24-alkyl group appears to be independent of nuclear unsaturation as both sitosterol and stigmastanol are dealkylated to greater than 80%. The presence of sterol metabolites possessing the Δ^{24}-bond when *P. redivivus* was propagated with 24-alkylsterols suggests that dealkylation proceeds via 24-alkylsterol → 24-alkenesterol → 24-desalkyl-24-dehydrosterol as demonstrated in *C. elegans* and *Turbatrix aceti* (7–11, 13, 14). As in *C. elegans, P. redivivus* is less efficient in removing a 24-methyl group than a 24-ethyl group, as 43.2% of the free sterols still possessed a methyl group at C-24 when the nematodes were propagated with campesterol as the dietary sterol. *C. elegans* was demonstrated to exhibit a preference for demethylating 24β-methylsterols as only 43% of the dietary campesterol (24 α-epimer) was dealkylated but 67% of the dietary 22-dihydrobrassicasterol (24 β-epimer) was dealkylated (9). Whether this preference is shared by *P. redivivus* is unknown. The presence of the unusual 24-methyl-23-dehydrocholesterol in *P. redivivus* and *C. elegans* suggests that an alternative minor demethylation pathway may also exist in these nematodes as previously reported (14).

P. redivivus reduces the Δ^5-bond in the sterol nucleus, as evidenced by the production of substantial quantities of cholestanol when the nematodes were propagated with campesterol, sitosterol or cholesterol and by the production of lathosterol when propagated with 7-dehydrocholesterol (Table 3). The production of 4α-methylcholest-8(14)-enol in 7-dehydrocholesterol-fed *P. redivivus* suggests that isomerization from the Δ^7- to the $\Delta^{8(14)}$-bond also occurs as in other nematodes (6—13). An isomerization mechanism is supported by the lack of $\Delta^{8(14)}$-sterols when *P. redivivus* is propagated with any of the Δ^5-sterols. *P. redivivus* might reduce the Δ^7-bond to some extent, as small quantities of cholesterol and cholestanol are detected when the nematodes are propagated with 7-dehydrocholesterol. However, the lack of 4α-methylcholestanol, the preferred 4-methylsterol in *P. redivivus*, suggests that this does not occur. It appears more likely that the cholesterol is a contaminant concentrated from the medium and the cholestanol is a metabolite of this contaminant.

Whether *P. redivivus* is capable of introducing a double bond into the sterol nucleus is unclear. The small quantities of lathosterol detected when the nematodes were propagated with the Δ^5-sterols and with the Δ^0-sterol would indicate that Δ^7-unsaturation might occur to some extent. The introduction of a Δ^7-double bond has been demonstrated in the free-living nema-

todes *Caenorhabditis elegans* (6—10, 12) and *Turbatrix aceti* (8, 13). This is not limited to nematodes, as some marine invertebrates (26—28) and certain insects (29—31) share this ability. However, the isolation of consistently low levels of Δ^7-sterols when *P. redivivus* was propagated with any of the Δ^5-sterols or the Δ^0-sterol indicates that the lathosterol might also be concentrated from the medium. Trace quantities (<15 μg/l) of ergosterol (24β-methylcholesta-5,7,22-trien-3β-ol) from the yeast extract have been detected when some media preparations have been extracted (unpublished data). The low levels of lathosterol might represent the concentration and metabolism of this trace media contaminant. Investigations with radiolabeled dietary sterols should resolve this question.

Of particular interest is the 4α-methylation pathway, which is unique to nematodes. The 4α-methylsterols of *P. redivivus* consist entirely of 4α-methylstanols except when propagated with 7-dehydrocholesterol. In the latter case, the Δ^5-double bond is still reduced indicating that lathosterol may be a better substrate for the 4α-methylation enzymes than 7-dehydrocholesterol. In campesterol-fed nematodes, the 4α-methylation enzymes were not hindered by the presence of the 24-methyl group as the majority of the 4α-methylsterols in the steryl ester fraction were still alkylated in the side chain. In contrast, a 24-ethyl substituent apparently abolishes any affinity for binding between the sterol substrate and the nuclear methylating enzymes.

P. redivivus is similar to several economically important genera of plant-parasitic nematodes in producing substantial quantities of saturated sterols from unsaturated dietary sterols (32). The Δ^5 and Δ^0-sterols may be better suited for reproduction and development in these nematodes. Whether all plant-parasitic nematodes are also capable of C-24 dealkylation and 4α-methylation is unknown and warrants further investigation. The nutritional requirement of *P. redivivus* for exogenous sterol, the production of substantial quantities of saturated sterols and the ability to disrupt nematode growth and reproduction by inhibitors of nematode sterol metabolism make *P. redivivus* a good model organism for development of compounds that may disrupt the nematode life cycle.

ACKNOWLEDGMENTS

We thank Malcolm J. Thompson of the Insect and Nematode Hormone Laboratory for supplying dietary and reference sterols and Dawn Harrison for performing the mass spectra.

[Received September 2, 1988; Revision accepted December 12, 1988]

Quantification, Characterization and Fatty Acid Composition of Lysophosphatidic Acid in Different Rat Tissues

Arun K. Das and Amiya K. Hajra*
Neuroscience Laboratory, Mental Health Research Institute and Department of Biological Chemistry, University of Michigan, 1103 E. Huron, Ann Arbor, MI 48109

The amount and composition of lysophosphatidate present in different rat tissues have been estimated by an internal standard method in which a synthetic unnatural isomer (1-heptadecanoyl-*rac*-glycerol-3-phosphate) was added to the total lipid extracts, and the fatty acid composition of purified lysophosphatidate was determined. Lipids from tissues were extracted under acidic conditions, and the lysophosphatidate was purified by solvent partitions followed by thin-layer chromatography in multiple solvent systems. The purified lipid was shown to be 1-acyl-*sn*-glycerol-3-phosphate by chromatographic and chemical analysis, by its resistance to hydrolysis when treated with phospholipase A_2 and also by its complete conversion to 1-acyl-*sn*-glycerol when treated with alkaline phosphatase. The fatty acid consituents of this lipid were determined by gas-liquid chromatography of the derived methyl esters. The concentrations (nmol/g of tissue) of lysophosphatidate in various tissues were: 86.2 ± 4.2 in brain, 60.3 ± 6.3 in liver, 46.4 ± 6.5 in kidney, 30.6 ± 5.0 in testis, 22.3 in heart and 19.3 in lung. Mostly (80%) saturated fatty acids were found to be present in this lyso lipid. A significantly high level of stearic acid was present in this lipid from all the tissues (50–60% in liver, kidney, brain and testis, and about 40% in heart and lung) compared to palmitic acid (10–15% in liver, kidney and brain and 25–30% in testis, heart and lung). The fatty acid compositions of phosphatidic acid, the putative product of lysophosphatidate acylation, from different tissues were also determined and palmitate was found to be the major saturated fatty acid. These results suggest that tissue lysophosphatidic acid is not only formed by *de novo* biosynthesis but is also generated via the breakdown of phospholipids such as phosphoinositides.
***Lipids 24,* 329–333 (1989).**

Lysophosphatidic acid (lysoPA) is a key intermediate for the biosynthesis of glycerolipids (1–3). This lipid is formed in three different subcellular compartments, either via direct acylation of glycerol-3-phosphate (G-3-P) in mitochondria and microsomes or via acylation of dihydroxyacetone phosphate (DHAP) in peroxisomes followed by reduction (2–4). This lyso lipid may also originate from the degradation of other lipids (5). The steady state concentrations of this important phospholipid in different animal tissues and its fatty acid compositions have not yet been reported in the literature. This is probably because during standard lipid extraction method (6), at neutral pH, this acidic lyso lipid is lost with the aqueous wash and therefore escapes detection (7). We recently developed a combined acid extraction and solvent partition method to isolate acyl DHAP from guinea pig liver and found that lysophosphatidate is extracted and partitioned in the same manner (8). After purification by TLC and analysis it was found that guinea pig liver contained fairly high level of lysoPA (140 nmol/g) and stearic acid was the major fatty acid component (66%) of this lipid. We also estimated lysoPA in three different rat tissues by enzymatically measuring the *sn*-glycerol-3-phosphate released after alkaline methanolysis of partially purified lipid extracts and found it to be relatively high (50–90 nmol/g) (8). However, in that work the loss incurred during purification of lysoPA was not considered and whether the lysoPA in rat tissues was also enriched in stearic acid had not been determined. Therefore, the present method of analysis of lysoPA in different tissues was developed where an internal standard was used to account for the loss of lysoPA during its extensive purification and for the quantitative determination and the fatty acid composition of this polar lipid. These results are reported here.

MATERIALS

Gas-liquid chromatographic (GLC) reference mixture of saturated fatty acid methyl esters of different carbon chains was purchased from Nu Chek Prep, Inc. (Elysian, Minnesota) and that of polyunsaturated fatty acids (PUFA, No. 2, animal source) was from Supelco, Inc. (Bellefonte, Pennsylvania) and used for the identification of unknown saturated and unsaturated fatty acids. n-Heptadecanoic acid was from Aldrich Chemical Co. (Milwaukee, Wisconsin); the methyl ester of this compound showed a single peak on GLC chromatogram. Authentic lipids including lysoPA, phosphatidic acid (PA), 1- and 2-palmitoyl-*sn*-glycerol, phospholipase A_2 from *Naja naja* venom and alkaline phosphatase from *E. coli* were obtained from Sigma Chemical Co. (St. Louis, Missouri). 1-Heptadecanoyl DHAP was prepared from n-heptadecanoic acid and glycolic acid as described before (9). 1-Heptadecanoyl-*rac*-G-3-P, which was used as an internal standard during the present studies for estimation of lysoPA, was made by reducing 1-heptadecanoyl DHAP by $NaBH_4$ in ethanol at pH 7.5 for 2 hr at 37°C as described before (8). This synthesized material gave one spot on TLC in different solvent systems and was found to contain only heptadecanoic acid as checked by GLC of the derived methyl ester. The fatty acid to phosphate ratio was 1:1. The phosphorus concentration of this material and other lipids was determined by the method of Ames and Dubin (10). Adult Sprague-Dawley male rats (200–250 g) were purchased from Harlan Sprague-Dawley, Inc. (Indianapolis, Indiana) and fed standard diet (Purina Chow) and water ad libitum. Other materials were the same as described previously (8,9).

METHODS

Extraction of lysoPA from tissues. Total lipids from liver, kidney, brain, testis, heart and lung of adult rats (150–200 g) were extracted by an acidic solvent extraction method (8). The rats were anesthetized with diethyl ether, the tissues were removed and immediately (within 15 sec) frozen in an isopentane/dry ice bath and, if necessary, stored at −70°C. The frozen tissues were weighed and quickly ground into small pieces with a pre-chilled (−20°C) mortar and pestle and immediately homogenized in chloroform/methanol/2M H_3PO_4 (1:1:0.05). During homogenization of the tissues, 25 nmol of synthetic 1-heptadecanoyl-*rac*-G-3-P per g of tissue was added to the homogenates. The lysoPA was separated from most other tissue lipids by partitioning the lipids between two phases, first at pH 4.4 where lysoPA was partitioned into the upper aqueous layer and then at pH 1.5 when lysoPA is extracted back into the lower chloroform layer by the methods previously described (8).

Purification of lysoPA. This partially purified lysoPA was further purified to homogeneity by using three consecutive thin layer chromatographic systems. The lipid extract was put as a band on a preparative TLC plate (E. Merck, Silica Gel-60, 0.5 mm thick) along with an authentic standard lysoPA spot side-by-side and the plate was developed in the first solvent system, chloroform/methanol/acetic acid/5% sodium bisulfite (100:40:12:4). The lipid bands were visualized under UV light after spraying the plate with Primuline (11). The lysoPA band was located by comparing its mobility to that of standard lysoPA (Rf = 0.33) and the content of this band was recovered by scraping it out and extracting the scrapings three times with chloroform/methanol (1:1) containing HCl (0.1M). The combined extract was washed with half volume of water to remove the acid. The lower layer containing the lysoPA was dried by blowing nitrogen, and the dried lipid was subjected to a second TLC using a basic solvent system i.e. chloroform/methanol/8 M NH_4OH (60:40:5). The lysoPA (Rf = 0.07) was recovered from the TLC plate as described above and then finally purified by TLC by using another solvent system of chloroform/methanol/acetic acid/acetone/water (100:30:20:40:10) (12). The lysoPA (Rf = 0.46) was extracted out from the TLC spot as described above and used for analysis.

Hydrolysis by alkaline phosphatase. About 50 μg of standard lysoPA or rat liver lysoPA (purified without the addition of the internal standard) dispersed in Tris buffer (0.15M, pH 8.5) by sonication was incubated with *E. coli* alkaline phosphatase (35 μg, 1.5 U) in a final volume of 0.5 ml. The mixture was incubated at 37°C for 2 hr. The product was extracted using an acidic Bligh and Dyer extraction method (13). When necessary, the progress of the reaction was studied by taking out an aliquot of the reaction mixture, extracting the lipids under acidic conditions (8) and separating them on TLC using chloroform/methanol/acetic acid/water (100:40:12:4). In this system the product monoacyl glycerol has an Rf of 0.88 and the Rf of lysoPA is 0.42.

Separation of monoacylglycerols. The positional isomers of monoacyl glycerol(1-*sn* and 2-*sn*) were separated from each other by TLC on silica gel containing boric acid (14). The boric acid impregnation was done by immersing the plates (5 × 20 cm Merck Silica gel-60) in methanolic boric acid (12% w/v) for 30 min. The plates were air dried for 15 min, activated at 110°C for 30 min and used immediately. By this procedure, the TLC plate was found to contain boric acid about 10% of the weight of the adsorbent. The monoacylglycerols were separated from each other by using a solvent system of chloroform/acetone (90:10). The respective Rf values for 1-palmitoyl and 2-palmitoyl-*sn*-glycerol were 0.12 and 0.20.

Extraction and purification of PA. The lower, washed chloroform layer which was saved during the lipid partitioning process (8) was concentrated under a stream of N_2. From this total lipid extract PA was isolated by two-dimensional TLC on a preparative plate (0.5 mm thick E. Merck Silica gel 60) using the solvent mixture of chloroform/methanol/8 M HN_4OH (17:7:1) in the first dimension followed by chloroform/methanol/acetic acid/water (80:40:7.4:1.2) in the second dimension essentially as described by Pumphrey (15). Purified PA migrated as a single spot having Rf of 0.04 in the first and 0.55 in the second solvent.

Treatment with phospholipase A_2. To 100 μg of PA or lysoPA dissolved in 0.5 ml of diethyl ether/methanol (98:2), 50 μl of a solution of lyophilized *Naja naja* venom (1 mg/0.5 ml of 0.3 M Tris-HCl, pH 7.5 containing 20 mM $CaCl_2$) was added. The mixture was vortexed vigorously for 30 sec and then incubated at room temperature for 3–4 hr with gentle magnetic stirring under N_2 essentially as described by Wells and Hanahan (16). After the reaction, most of the ether and methanol were evaporated off under N_2 and the product was dissolved in 2 ml of chloroform/methanol (1:1), followed by the addition of 0.8 ml of water containing 0.1M HCl. The lower chloroform layer was washed with chloroform/methanol/water (1:12:12). An aliquot of the lipid extract was put on TLC plate and developed with chloroform/methanol/acetic acid/water (100:40:12:4) for identification of the products by comparing the Rf values of standard compounds applied side by side. The Rf values of PA, lysoPA and free fatty acid in this solvent system were 0.77, 0.42 and 0.98, respectively.

Preparation and analysis of fatty acid methyl esters from lysoPA and PA. Fatty acid methyl esters were prepared from these lipids by alkaline methanolysis (17) with modification. In a screw-capped tube, a portion of lipid solution (~ 15 μg of lipid phosphorus) was dried down under N_2. One ml of 0.2 M NaOH in methanol and 2.0 ml of chloroform were added. The reaction mixture was mixed well and left at room temperature. After one hr of incubation, 0.75 ml of 0.35 N acetic acid was added, mixed well, and the phases were separated by centrifugation. Upper layer was removed and the lower layer was washed with 2 ml of 0.9% NaCl/methanol mixture (1:1). The methyl esters present in the final chloroform layer were purified by TLC using a solvent system of n-hexane/ether/acetic acid (50:50:2). The purified ester (Rf = 0.67) was extracted from TLC powder by three extractions with diethyl ether. After removing the ether by blowing N_2, the sample was dissolved in a small volume of n-hexane

and analyzed in a Hewlett-Packard gas chromatograph, Model No. 5710A, equipped with flame ionization detector and an electronic integrator (Spectra Physics). The stationary phase was 15% Silar 10C supported on Gas Chrom R in a glass-lined stainless steel analytical column (183 cm × 0.32 cm) and the temperature programming of 150-220°C was used for the GLC run. The components of methyl esters were identified by comparing the retention times with those of standards.

Estimation of lysoPA in tissues. The amount of lysoPA present in different tissues was evaluated from the relative amount of 17:0 in the fatty acid mixtures derived from the lipid. Because the endogenous 17:0 content of lysoPA isolated from different tissues was found to be very low (<1% of total fatty acids), it was assumed that all the 17:0 present in the final GLC analysis of the fatty acid composition of lysoPA was from the heptadecanoyl GP added (25 nmol/g tissue) during the lipid extraction process. This and the assumption that the proportional loss of this internal standard during purification is the same as the other molecular species of lysoPA were used to calculate the lysoPA content of different tissues. For example, nmol lysoPA/g tissue = [(100 − wt % 17:0)/wt % 17:0] × 25. The amount of each individual fatty acid present in lysoPA can also be calculated this way.

All other methods were the same as described previously (8,9). Lipids were stored, when necessary, at −70°C under N_2.

RESULTS

Isolation and characterization of lysoPA. The lysoPA purified by the above method migrated as a single spot with the mobility same as standard lysoPA in two other TLC systems: (a) chloroform/methanol/2-propanol/0.25% aqueous potassium chloride/ethyl acetate (30:9:25:6:18) (18) (Rf = 0.15) and (b) chloroform/methanol/acetic acid/water (100:40:12:4) (Rf = 0.42). When analyzed (8), the phosphorus/*sn*-glycerol-3-P/fatty acid molar ratio in different lysoPA tissue samples was found to be 1.0:1.0:1.0. From these criteria the isolated lysoPA was judged to be pure. The recovery of lysoPA from each TLC purification was 80-90% as measured by using radioactive lysoPA (8). The overall recovery of lysoPA from the crude lipid extract varies from 50-60% as indicated by the recovery of the internal standard (17:0) by GLC.

The lysoPA isolated from liver and kidney seemed to be 1-acyl isomer since it was not hydrolyzed by phospholipase A_2 as indicated by the absence of free fatty acid as a product when analyzed on the TLC plate and the total phosphorus content of lysoPA before and after the enzymatic treatment was the same. This is confirmed by hydrolyzing the lysoPA by alkaline phosphatase and analyzing the product. The lysoPA from liver, like the standard lysoPA, was completely hydrolyzed in 2 hr when treated with alkaline phosphatase as described in Methods. The resulting product, i.e., monoacyl glycerol, when chromatographed on 10% boric acid impregnated silica gel plate migrated as a single spot with authentic 1-palmitoyl-*sn*-glycerol. There was no spot corresponding to 2-palmitoyl-*sn*-glycerol.

TABLE 1

Lysophosphatidate Content of Different Rat Tissues[a]

Tissue	LPA (nmol/g of tissue) ± S.D.
Liver	60.3±6.3 (n=4)
Kidney	46.4±6.5 (n=4)
Brain	86.2±4.2 (n=3)
Testis	30.6±5.0 (n=3)
Heart	19.5, 25.1[a]
Lung	17.0, 21.6[a]

[a]The contents of LPA in different tissues of rat were estimated by GLC analysis of the fatty acid methyl esters including the internal standard methyl heptadecanoate (17:0) as described in the text.

n, Number of experiment; a, results of two experiments.

Tissue distribution of lysoPA. As shown in Table 1, the contents of lysoPA in different tissues of rat ranged from 20-90 nmol/g of tissue. Brain contained the highest level of this lipid (78-92 nmol/g of tissue) compared to other organs (20-60 nmol/g of tissue). Very little variation was observed in the lysoPA content of corresponding tissues from different animals. This is probably because of the use of adult animals of the same age group and using identical conditions to harvest the tissues. The amount of lysoPA present, however, is sufficient to isolate it from a small amount (0.5 g) of tissues and accurately analyze its fatty acid composition.

The presence of alkali stable lysoPA, i.e., lysoPA which may contain ether bond (instead of ester bond) was investigated by using rat kidney lysoPA. The phosphorus concentration before and after alkaline methanolysis of lysoPA was determined. The results indicated that about 10% of kidney lysoPA was alkali stable. The nature of this alkali stable lipid, however, was not investigated further. This is most probably alkyl G-3-P as any alkenyl G-3-P will be degraded by the repeated acidic extractions used to purify the lysoPA.

Fatty acid compositions of lysoPA from different tissues. Table 2 presents the fatty acid compositions of lysoPA from six different tissues of rat. Basically,

TABLE 2

Fatty Acid Compositions of LPA in Different Tissues of Rat[a]

Fatty acid	Composition in wt %					
	Liver	Kidney	Brain	Testis	Heart	Lung
14:0	9.5	5.2	0.5	tr	0.6	tr
16:0	16.0	13.6	9.9	31.5	26.1	28.4
18:0	50.6	59.9	51.3	56.6	35.6	42.6
18:1(n-9)	17.3	10.3	31.6	9.2	25.4	20.8
18:2(n-6)	5.2	6.9	tr	1.6	6.2	7.1

20:4(n-6)	1.4	2.1	1.5	0.9	tr	tr

[a]The methyl esters were prepared from the purified LPA of different tissues containing 1-O-heptadecanoyl-rac-G-3-P as internal standard and analyzed by GLC as described in the text. The wt % of each fatty acid was calculated from the known amount of the internal standard (17:0). The data are the averages (ranges ± 3%) of three experiments.

tr, Trace, less than 0.1 %.

16:0, 18:0 and 18:1 were the three major components of lysoPA from all tissues. As can be seen (Table 2), 18:0 was the major fatty acid present in the lysoPA, e.g., more than half (50–60%) of total fatty acids were composed of 18:0 in the lysoPA isolated from liver, kidney, brain and testis. The ratio of 18:0/16:0 is also very high (3 to 5) in most of the tissues (Table 2). The fatty acid compositions of lysoPA from all these tissues were found to be very similar to guinea pig liver lysoPA which also contained very high amounts of stearic acid (65.9%) (8).

Purification and fatty acid composition of PA from different tissues. We also analyzed the fatty acid compositions of PA, the putative biosynthetic product from lysoPA, isolated from different tissues. Although the fatty acid compositions of rat liver and brain PA have been reported previously (19, 20), no information is available regarding the composition of PA of other organs. PA was isolated by two dimensional TLC using the same solvent systems as described by Pumphrey (15). An excellent and reproducible separation of this lipid from all other lipids was achieved; however, instead of the double spots for PA reported by Pumphrey (15), a single spot was found. This difference is probably because under the acidic lipid extraction used here, all the tissue phosphatidates were converted to the free acid form which migrated as a single spot on the TLC plate.

The amounts of PA present in various organs of rat, human and other animals have been reported by other workers (21—23). The fatty acid compositions of PA of different tissues of rat are presented in Table 3. It should be noted that, except in the case of brain and heart, the levels of 16:0 in the PA of different tissues were much higher than that of 18:0. For example, the ratio of 16:0/18:0 in brain was 0.53, which is lower than that in liver (1.48), kidney (1.25), testis (2.62) lung (1.31) and heart (0.91) (Table 3). The values of this ratio as calculated from literature reports are 2.2 (19) and 0.87 (20) for rat liver and brain, respectively. Among the mono- and polyunsaturated fatty acids, 18:1, 18:2 and 20:4 were the major components; however, in brain, a significant amount of 18:3 (6.0%) was also present.

Possmayer et al. have shown that rat liver PA contained 51% of 16:0 and 33% of 18:0 at the *sn*-1 position of glycerol (19). We determined the positional distribution of fatty acids in rat kidney PA by stereospecific hydrolysis with phospholipase A_2 and then analyzing the fatty acid composition of the resulting lysoPA. The results showed that 16:0 is present at a relatively higher amount (53%) than 18:0 (24%) at the *sn*-1 position of rat kidney PA.

TABLE 3

Fatty Acid Compositions of PA in Different Tissues of Rat[a]

[a]PA from different tissues were isolated by two dimensional TLC and the total fatty acid contents were analyzed by GLC (see text). The data are the averages (ranges ± 5%) of two experiments.

tr, Trace, less than 0.1 %.

DISCUSSION

The use of the internal standard, 1-heptadecanoyl glycerol-3-P, was advantageous for the simultaneous quantification of the amount and fatty acid composition of the lipid. Since, like any other internal standard method a quantitative recovery of lysoPA was not necessary, the estimation was more easily done than any other method. This method should have a general applicability for the accurate analysis of any tissue lipid as the standards containing unnatural fatty acids can be easily synthesized by chemical or enzymatic methods.

As described above, lysoPA isolated from different tissues was found to be pure by chromatographic and chemical analysis. The lysoPA of rat liver was characterized as 1-acyl-*sn*-glycerol-3-P by the following criteria: (a) After alkaline methanolysis of the lipid, the products, i.e., fatty acid methyl esters and *sn*-glycerol-3-P formed were in 1:1 molar proportion. (b) Hydrolysis by alkaline phosphatase yielded 1-acyl-*sn*-glycerol as the sole lipid product. (c) The lipid is not hydrolyzed by phospholipase A_2. Van Deenen and de Haas (24) have shown that lysophosphatides (2-acyl) are hydrolyzed by snake venom phospholipase A_2.

Though the exact structure of lysoPA of organs other than liver was not determined, the similarity in the chromatographic migration rate with rat liver lysoPA, formation of 1:1 molar proportion of fatty acid and *sn*-glycerol-3-P after alkaline hydrolysis and the presence of mainly saturated fatty acids in the purified lysoPA (Table 2) indicate that this lipid in all tissues is predominantly 1-acyl-*sn*-glycerol-3-P.

The tissue concentrations of lysoPA, as reported here, are relatively high (20–90 nmol/g of tissue) compared to similar lipid biosynthetic intermediates such as acyl DHAP (2–10 nmol/g of tissue) (8) or CDP diacylglycerol (9–15 nmol/g of tissue) (25) but are lower than the corresponding amounts of phosphatidic acid present in these tissues (150–200 nmol/g of tissue) (21, 22). LysoPA is biosynthesized in three different subcellular compartments, i.e., mitochondria, peroxisomes and endoplasmic reticulum, but only in endoplasmic reticulum it is enzymatically acylated to PA (2, 3). This may account for the relatively high steady-state concentration of lysoPA in different tissues because the mitochondrial and peroxisomal-derived lysoPA must be transported to the endoplasmic reticulum for lipid biosynthesis. Also, from the high stearate content of

lysoPA (Table 2), it seems that a large fraction of tissue lysoPA originates from sources other than via the biosynthetic routes. This is because biosynthetically-derived lysoPA should have mostly 16:0, as both glycerophosphate acyltransferase and dihydroxyacetone phosphate acyltransferase have been shown to preferentially utilize 16:0 rather than 18:0 for the acylation of GP and DHAP, respectively (26-28). The predominance of 16:0 at the *sn*-1 position of PA as shown here and by other workers (19) also indicates that biosynthetic lysoPA should contain a relatively higher amount of 16:0 than 18:0. Therefore, our results suggest that a major fraction of lysoPA is probably formed via catabolic breakdown of lipids. One such possibility is the formation of this lipid from phosphoinositides which have mostly 18:0 at the *sn*-1 position (20, 29, 30). Lapetina and co-workers have shown that by the consecutive actions of phospholipase C, diacylglycerol kinase and PA-specific phospholipase A_2, the phosphoinositides are converted to lysoPA (5, 31). Therefore, it is possible that a portion of the tissue lysoPA originates from such receptor mediated breakdown of membrane lipids (32, 33). Further experiments such as the effects of chronic stimulation of phosphoinositide-linked receptor on the concentration and composition of lysoPA in cells would be useful to establish the source and function of this polar lipid in cellular metabolism.

[Received September 30, 1988; Revision accepted December 7, 1988]

Dietary Saturated Fat Level Alters the Competition Between α-Linolenic and Linoleic Acid

M.L. Garg, A.A. Wierzbicki, A.B.R. Thomson and M.T. Clandinin*
Nutrition and Metabolism Research Group, Departments of Foods and Nutrition and Medicine, 533 Newton Research Building, University of Alberta, Edmonton, Alberta, Canada T6G 2C2

Male weanling rats were fed semi-synthetic diets high in saturated fat (beef tallow) vs high in linoleic acid (safflower oil) with or without high levels of α-linolenic acid (linseed oil) for a period of 28 days. The effect of feeding these diets on cholesterol content and fatty acid composition of serum and liver lipids was examined. Feeding linseed oil with beef tallow or safflower oil had no significant effect on serum levels of cholesterol. Serum cholesterol concentration was higher in animals fed the safflower oil diet than in animals fed the beef tallow diet without linseed oil. Feeding linseed oil lowered the cholesterol content in liver tissue for all dietary treatments tested. Consumption of linseed oil reduced the arachidonic acid content with concomitant increase in linoleic acid in serum and liver lipid fractions only when fed in combination with beef tallow, but not when fed with safflower oil. Similarly, ω3 fatty acids (18:3ω3, 20:5ω3, 22:5ω3, 22:6ω3) replaced ω6 fatty acids (20:4ω6, 22:4ω6, 22:5ω6) in serum and liver lipid fractions to a greater extent when linseed oil was fed with beef tallow than with safflower oil. The results suggest that the dietary ratio of linoleic acid to saturated fatty acids or of 18:3ω3 to 18:2ω6 may be important to determine the cholesterol and arachidonic acid lowering effect of dietary α-linolenic acid.
***Lipids 24*, 334-339 (1989).**

Hypocholesterolemic effects of polyunsaturated fatty acids have been thought to be mediated via a redistribution of cholesterol from blood to the tissue pools (1-8). In a recent study, we demonstrated that this redistribution may not be true for all types of polyunsaturated fatty acids but may be restricted to ω6 fatty acids (9). Omega-3 fatty acid from linseed oil (i.e., 18:3ω3) decreases cholesterol content of plasma without affecting the liver cholesterol concentration (9). Omega-3 fatty acids of marine origin such as eicosapentaenoic acid (20:5ω3) and docosahexaenoic acid (22:6ω3) are more effective than ω6 fatty acids in reducing serum or plasma levels of cholesterol (10-13). In terms of platelet aggregation, polyunsaturated fatty acids of the ω6 family present in vegetable oils have pro-aggregatory thrombotic effects (14-16) while the ω3 polyunsaturated fatty acids of seafoods increase bleeding time. On this basis, we postulated that 18:3ω3 may have an intermediate place for prevention of atherosclerosis and thrombosis between ω6 fatty acids and C20 and C22 ω3 fatty acids (20:5ω3 and 22:6ω3) of marine oils (9).

The present study examined the effects of feeding 18:3ω3 to rats in the presence of either saturated fatty acids or linoleic acid on the cholesterol content and fatty acid composition of serum and liver lipids. The results suggest that the dietary ratio of 18:3ω3/18:2ω6 or of linoleic acid to saturated fatty acids may be important in determining the cholesterol and 20:4ω6 lowering effect of dietary 18:3ω3.

MATERIALS AND METHODS

Animals and diets. Male Sprague-Dawley rats weighing 30-40 g were maintained on Wayne rat chow (Allied Mills Inc., Chicago, IL) for three days before feeding the experimental diets. The semipurified diets fed (20) contained 200 g fat/kg diet from one of the following sources: 90% w/w hydrogenated beef tallow plus 10% w/w safflower oil (beef tallow diet); 100% w/w safflower oil (safflower oil diet); 70% w/w hydrogenated beef tallow plus 25% w/w linseed oil plus 5% safflower oil (beef tallow and linseed oil diet); 75% w/w safflower oil plus 25% w/w linseed oil (safflower oil and linseed oil diet). The fatty acid composition of the diets is indicated (Table 1). The beef tallow diet contained mainly saturated fatty acids (86.3% w/w of total fatty acids) and enough linoleic acid (9.5% w/w) to prevent essential fatty acid deficiency. The safflower oil diet was enriched with linoleic acid (70.5% w/w). Both the beef tallow and safflower oil diets with linseed oil provided similar amounts of α-linolenic acid (ca. 18% w/w) but differed in linoleic acid to saturated fatty acid ratios (0.16 and 5.85, respectively). Animals were housed individually in hanging stainless steel cages in a well ventilated room maintained at 22°C on a 12/12 hr light/dark cycle. All diets were prepared weekly and stored at −20°C. Food and water were provided ad libitum. Body weights were monitored once a week throughout the feeding trial.

Lipid analysis. After four weeks of feeding experimental diets, the rats were killed by decapitation, between 8 and 10 a.m. Livers were quickly excised and rinsed in ice-cold saline. Blood samples were also collected for separation of serum by centrifugation. Total lipids from serum and liver samples were extracted with chloroform/methanol (2:1, v/v) (21) containing 0.005% (w/v) butylated hydroxytoluene. Total, free and esterified cholesterol contents in aliquots of serum and liver lipid extracts were determined enzymatically (22,23). Total phospholipids, triacylglycerol and cholesterol esters were separated by thin layer chromatography on Silica Gel G plates (Analtech, 250 μm, 20 × 20 cm) using a solvent system comprised of petroleum ether/diethyl ether/acetic acid (80:20:1, v/v/v) (24). Phospholipids were methylated with 14% (w/w) BF_3-methanol reagent at 100°C for one hr (25). Triacylglycerol and cholesterol ester fractions were saponified with 0.5 M methanolic potassium hydroxide by heating at 85°C for 90 min, followed by methylation with 14% (w/w) BF_3-methanol reagent (25). Fatty acid methyl

[a]Fats were added to the basal diet in the proportions explained in Materials and Methods. The basal diet contained the following components (g/kg diet): casein, 270; starch, 200; glucose, 207; nonnutritive cellulose, 50; vitamin mix, 10; mineral mix, 50; choline, 2.75; L-methionine, 2.5, and inositol, 6.25, as described elsewhere (20).

[b]U.I., Unsaturation Index; Σ [(a)(b)], where a is the percentage of each unsaturated fatty acid and b is the number of double bonds for that particular fatty acid.

esters were extracted and analyzed by automated capillary gas chromatography (Varian Model 6000 equipped with a flame ionization detector) (26). Authentic standard mixtures of fatty acid methyl esters were injected to identify fatty acid methyl esters. Peak areas and weight percent fatty acid composition were computed by a chromatography data system (Varian Model DS 604).

Statistical analyses. The data are expressed as mean ± standard deviation. The effect of diet fat treatment was determined by analysis of variance procedures. The comparison between treatments was made using Newman-Keuls multiple range test (27).

RESULTS

Body weights, liver weights and food consumption. All animals appeared healthy after four weeks of feeding. The dietary fat treatment had no significant effect on body weight, liver weight or liver weight to body weight ratio in these animals. Rats fed the different dietary regimens consumed a similar amount of food (data not shown).

Cholesterol content of rat serum and liver lipids. The total cholesterol content of serum in rats fed the safflower oil diet was significantly higher than those fed the beef tallow diet, while addition of linseed oil to these diets had no significant effect on serum cholesterol levels (Fig. 1). Neither free nor esterified cholesterol content of serum was affected by the dietary fat composition.

In liver tissue, the level of cholesterol was significantly higher in animals fed safflower oil than in those fed the beef tallow diet (Fig. 1). Addition of linseed oil either to the beef tallow or safflower oil diet lowered the cholesterol content of liver. The increase in liver cholesterol concentration following feeding of the safflower oil diet was detected in both free and esterified cholesterol content. The decrease in cholesterol level after consumption of diets containing linseed oil was associated with the esterified cholesterol content and not with the nonesterified cholesterol content (Fig. 1).

Fatty acid composition of rat serum and liver phospholipids. Feeding rats the safflower oil diet increased the 18:2ω6 and 20:4ω6 content of serum and

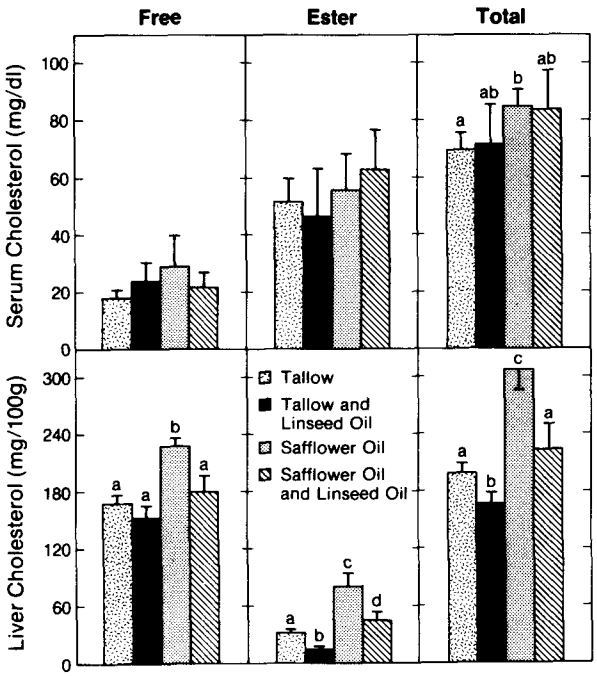

FIG. 1. Effect of dietary α-linolenic acid on cholesterol content of rat serum and liver. Values are the mean ± standard deviation of 5 rats (n = 5) in each dietary group. Values without a common superscript are significantly different ($p < 0.05$).

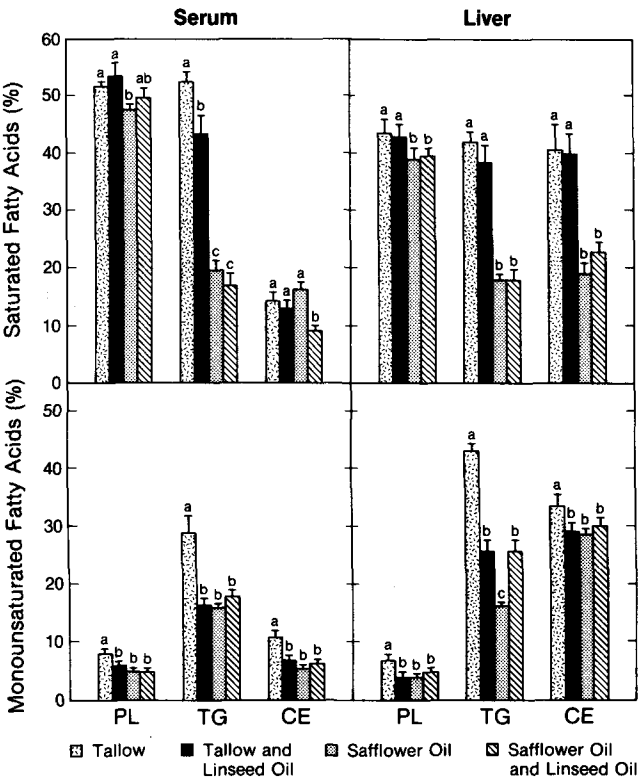

FIG. 2. Effect of dietary α-linolenic acid on saturated and monounsaturated fatty acid content of rat serum and liver lipid fractions. PL, phospholipid; TG, triacylglycerol; CE, cholesteryl ester. Values are the mean ± standard deviation of 5 rats (n = 5) in each dietary group. Values without a common superscript are significantly different ($p < 0.05$).

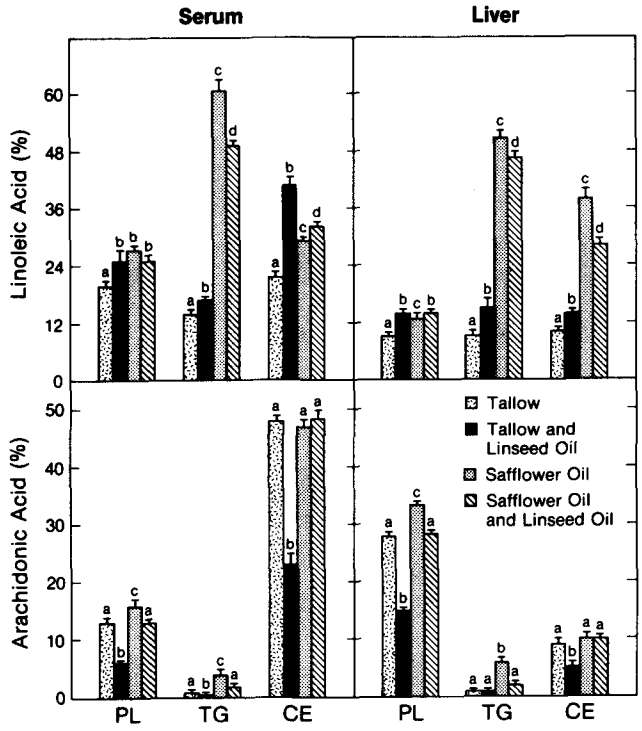

FIG. 3. Effect of dietary α-linolenic acid on linoleic and arachidonic acid content of rat serum and liver lipid fractions. PL, phospholipid; TG, triacylglycerol; CE, cholesteryl ester. Values are the mean ± standard deviation of 5 rats (n = 5) in each dietary group. Values without a common superscript are significantly different ($p < 0.5$).

liver phospholipids with an accompanied decrease in saturated (16:0), monounsaturated (18:1ω9) and 22:6ω3 content (Fig. 4). Consumption of 18:3ω3 with saturated fatty acids reduced the 20:4ω6 content of both serum (55%) and liver (45%) phospholipids followed by a concomitant increase of 18:2ω6 content compared with that observed for animals fed the diet high in saturated fatty acids without 18:3ω3. These changes in 18:2ω6 and 20:4ω6 with the beef tallow and linseed oil diet were also followed by decreases in 22:4ω6 and 22:5ω6 and increases in 20:5ω3 and 22:5ω3 contents of serum and liver phospholipids. Liver phospholipid 22:6ω3 content increased but serum phospholipid 22:6ω3 levels were not affected (Figs. 2-4). Animals fed the linseed oil with safflower oil diet exhibited amounts of 20:4ω6 in serum and liver phospholipids similar to those in animals fed the beef tallow diet. The safflower oil and linseed oil diet also failed to elevate phospholipid 20:5ω3 and 22:6ω3 levels (Figs. 2-4).

Fatty acid composition of serum and liver triacylglycerols. The fatty acid composition found in the serum triacylglycerol fraction resembled that of the dietary fats fed. Animals fed the beef tallow diet exhibited high levels of saturated (52.8%) and monounsaturated (28.7%) fatty acids; those fed the safflower oil diet had elevated levels of 18:2ω6 (60.7%); and linseed oil fed animals had higher levels of 18:3ω3 (17.1 and 10.6%) in serum triacylglycerols (Figs. 2-4). Feeding 18:3ω3 in combination with saturated fatty acids (beef tallow and linseed oil diet) increased the level of 18:3ω3, 20:5ω3, 22:5ω3 and 22:6ω3 at the expense of ω6 fatty acids (20:4, 22:4 and 22:5) in both serum and liver triglycerides (Figs. 2-4). Changes in fatty acid composition observed after feeding the safflower oil and linseed oil diet were similar but of smaller magnitude than those changes observed after feeding the beef tallow and linseed oil diet (Figs. 2-4).

Fatty acid composition of serum and liver cholesteryl esters. The cholesterol ester fraction of serum lipids exhibited the largest change in 18:2ω6, 20:4ω6 and 20:5ω3 content following consumption of the beef tallow and linseed oil diet. Serum levels of 18:2ω6 in the cholesteryl ester fraction almost doubled, and 20:4ω6 content decreased to less than half in rats fed the beef tallow and linseed oil diet compared to animals fed the beef tallow diet (Fig. 3). There was a 10-fold increase in 20:5ω3 content and a small increase in 22:5ω3 and 22:6ω3 following the feeding of linseed oil in the saturated fat diet. Feeding 18:3ω3 in combination with 18:2ω6 failed to produce change in 20:4ω6, 20:5ω3,

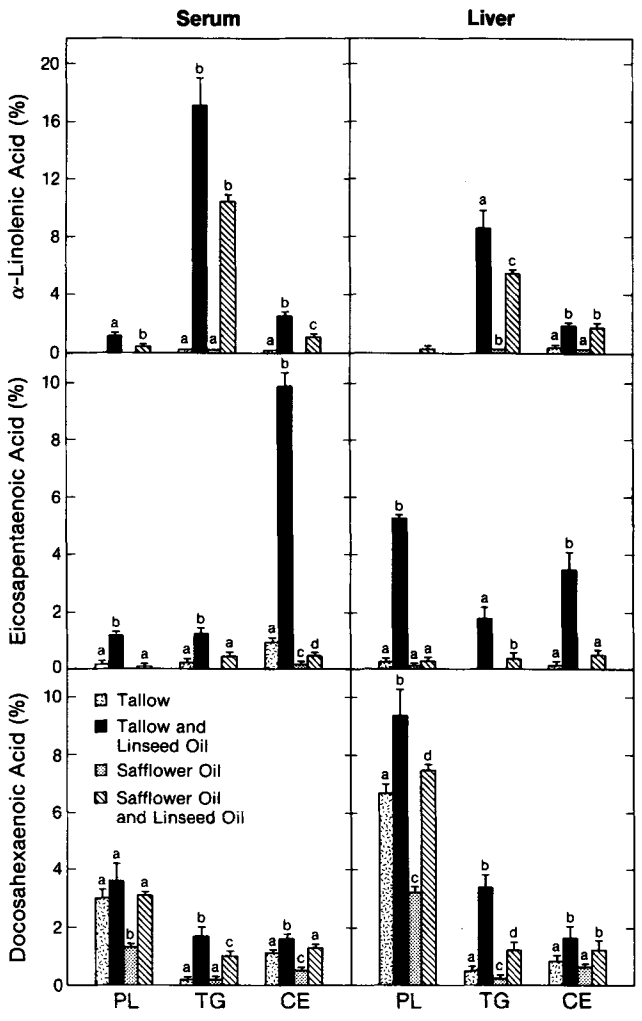

FIG. 4. Effect of dietary α-linolenic acid on α-linolenic, eicosapentaenoic and docosahexaenoic acid content of rat serum and liver lipid fractions. PL, phospholipid; TG, triacylglycerol; CE, cholesteryl ester. Values are the mean ± standard deviation of 5 rats (n = 5) in each dietary group. Values without a common superscript are significantly different ($p < 0.05$).

22:5ω3 and 22:6ω3 levels in the cholesteryl ester fraction of rat serum (Figs. 3 and 4). The pattern of changes in fatty acid composition of liver cholesteryl esters was similar to but of smaller magnitude than that found in the serum (Figs. 2–4).

DISCUSSION

Increased attention has been given in the past few years to the question of the potential health benefits of ω3 of polyunsaturated fatty acids (28–30). While ω3 fatty acids (20:5ω3 and/or 22:6ω3) of marine origin decrease cholesterol and triacylglycerol levels in normal (10–13) and hyperlipidemic subjects (31–32) and have beneficial effects against cardiovascular diseases (28–30), controversy exists concerning the usefulness of 18:3ω3 as a potential therapeutic agent (33–37). The effects of dietary 18:3ω3 on lipid metabolism in animals (16, 38–40) and humans (34,36,37) have been examined by various workers, but the importance of the dietary ratio of linoleic acid to saturated fatty acids has not been considered. In the present study, we compared the effect of feeding 18:3ω3 in combination with saturated fatty acids or 18:2ω6 on the cholesterol content and fatty acid composition of serum and liver lipids. It is important to stress that the effects observed in this study are specific to the dietary 18:3ω3 level and not due to increase in the overall unsaturation of the diet, as the beef tallow and linseed oil diet was found to be most effective in modifying cholesterol and fatty acid profiles despite having a lower unsaturated (U.I. 84.9) fatty acid composition than the safflower oil diet with (U.I. 182.5) or without (U.I. 157.7) addition of linseed oil (Table 1).

Feeding the safflower oil diet for 28 days elevated serum cholesterol levels (Fig. 1). Previously, other workers have reported either no change (8,41) or a decrease (42,43) in cholesterol concentration in serum after feeding diets enriched with 18:2ω6. The reason for this discrepancy is not clear but may be due to differences in the length of the feeding period, level of 18:2ω6 and species of animals used. In liver tissue, the cholesterol content was elevated by feeding the safflower oil diet and suppressed by feeding the beef tallow and linseed oil diet. Both free and esterified cholesterol content were increased by feeding the safflower oil diet. The increase in cholesteryl ester content is most likely due to increased acylcoenzyme A:cholesterol acyltransferase activity in liver microsomes after consumption of the 18:2ω6 enriched diet (44,45). The increase in free cholesterol may be due to increased capacity of hepatic membranes to accommodate more cholesterol following feeding of 18:2ω6 enriched diets (46).

The fact that high dietary 18:3ω3 levels suppressed the cholesterol level in liver merits further investigation. 18:3ω3 is a precursor for the formation of 20:5ω3 and 22:6ω3. Recently, it has been demonstrated that consumption of 20:5ω3 and 22:6ω3 accelerates the flow of cholesterol toward bile formation and secretion (10). Therefore, decrease in free cholesterol content following the feeding of the diets containing linseed oil may be due to increased utilization of cholesterol for bile synthesis in the liver. These observations are supported by the fatty acid compositional data of liver lipid fractions which indicate accumulation of metabolites of 18:3ω3 (20:5ω3, 22:5ω3 and 22:6ω3) after feeding diets high in 18:3ω3 in the presence of saturated fatty acids. Thus, the importance of feeding 18:3ω3 in increasing cholesterol content in the bile needs to be explored.

Dietary linseed oil suppresses the 20:4ω6 content of serum and liver lipid fractions only when fed with saturated fatty acids and not with 18:2ω6. Previous reports have shown that 18:3ω3 competes with 18:2ω6 for Δ^6-desaturation and chain elongation (47,48). The present study demonstrates that this competition is apparent only when the dietary 18:2ω6 content is low. The optimum ratio of 18:2ω6 to saturated fatty acids required for competition of 18:3ω3 with 18:2ω6 for Δ^6-desaturation at enzyme or molecular level remains to be determined. Some work suggests that dietary 18:3ω3 does not inhibit conversion of 18:2ω6 to 20:4ω6 when the 18:3ω3 content of the diet is < 15% (38). In

the present study both diets containing linseed oil provide ca. 18% of the diet fat as 18:3ω3. Feeding diets containing safflower oil and linseed oil did not affect the 20:4ω6 content of serum and liver lipid fractions even though the 18:3ω3 content of this diet is more than that reported to be required to reduce 20:4ω6 levels (38). On the other hand, when a similar amount of 18:3ω3 was fed in combination with saturated fatty acids (beef tallow and linseed oil diet), 20:4ω6 levels were reduced with a concomitant increase in 18:2ω6 concentration indicating impairment of desaturation and chain elongation of 18:2ω6. Thus, 18:3ω3 competes with 18:2ω6 for desaturation at Δ^6-desaturase or molecular level, but this process appears to be dependent on the 18:2ω6 to saturated fatty acid or 18:3ω3 to 18:2ω6 ratios of the diet. These observations are supported further by a recent study which, using cultured glioma cells, demonstrates that a balance of saturated and unsaturated fatty acids is important to enzymes responsible for synthesis of crucial membrane components and substrates for eicosanoid formation (20:4ω6, 20:5ω3 and 22:6ω3) (49). The identification of this ideal balance for the activity of the Δ^6-desaturase in hepatic and intestinal tissue remains to be established.

Another critical question is to what extent 18:3ω3 can be converted to 20:5ω3 and 22:6ω3 in humans and animals. Existing evidence suggests that both animals and humans possess limited ability to convert 18:3ω3 to 20:5ω3 and 22:6ω3, whereas 18:2ω6 is rapidly desaturated and elongated to 20:4ω6 (33,34,50). Therefore, in the studies of Dyerberg (33) and Sanders and Rasahanai (34), 18:3ω3 supplementation failed to produce substantial increases in 20:5ω3 and 22:6ω3 content of plasma lipid fractions. The present study suggests that conversion of 18:3ω3 to 20:5ω3 and 22:6ω3 can be accelerated if the rest of the fat in the diet is saturated fat. Dietary α-linolenic acid was associated with the accumulation of 20:5ω3 to a greater extent in serum and liver lipid fractions when fed in combination with beef tallow than with safflower oil. The possibility that 18:3ω3 is poorly absorbed when 18:2ω6 content of the diet is high (51), e.g., after consumption of the safflower oil and linseed oil diet, cannot be ruled out. However, this seems unlikely as dietary 18:3ω3 has been shown to be absorbed to the same extent regardless of the quality of the rest of the dietary fat (Thomson et al., unpublished data).

Controversy exists about the usefulness of 18:3ω3 in platelet aggregation and atherosclerosis (50) and revolves around the rate of desaturation and elongation of 18:3ω3 in man. Although it may be inappropriate to interpret the animal data in humans, the present study suggests that conversion of 18:3ω3 to 20:5ω3 and inhibition of the conversion of 18:2ω6 to 20:4ω6, both steps considered as inhibitory for platelet aggregation and atherosclerosis, can be maximized by partial replacement of dietary 18:2ω6 by saturated fat. In this regard, high dietary levels of 18:3ω3 also appear to be hypocholesterolemic, decreasing liver cholesterol levels regardless of the dietary fat fed. These observations could provide a useful basis for formulating human clinical trials to examine the efficacy of 18:3ω3 on platelet aggregation and cholesterol metabolism.

[Received May 24, 1988; Revision accepted November 28, 1988]

The Essential Fatty Acid Requirement for Azoxymethane-Induced Intestinal Carcinogenesis in Rats

Arthur W. Bull[*,a], **Joel C. Bronstein**[b] and **Norman D. Nigro**[b]
[a]Department of Internal Medicine and [b]Department of Surgery, Wayne State University, School of Medicine, 645 Mullett, Detroit, MI 48226

The essential fatty acid requirement for the development of intestinal carcinogenesis was determined and compared to the overall essential fatty acid status of the animals as measured by the triene/tetraene ratio in the plasma, liver and colon. To induce tumors, male Sprague-Dawley rats were given two weekly injections (20 mg/kg body wt) of azoxymethane. Two weeks after the last injection, the rats were divided into groups of 25 and given one of six diets containing various levels of essential fatty acids (as linoleate). The diets contained 5% total fat and were prepared by mixing safflower oil (high essential fatty acids, beef fat (low essential fatty acids), and medium chain triglyceride oil (no essential fatty acids). One group of rats was fed a 20% beef fat diet. The range of essential fatty acids was from <0.03% to 1.28% (w/w). Twenty-six weeks after the first azoxymethane injection, the animals were killed and intestinal tumor incidence and multiplicty were determined. Samples of plasma, liver and colon were also taken for measurement of the triene/tetraene ratio by gas chromatography.

Large bowel tumor incidence showed a dependence on the essential fatty acid content of the diet. The results were as follows: (percent essential fatty acids: percent tumor incidence) Group A (1.28: 72.4), Group B (0.60: 73.3), Group C (0.11: 55.2), Group D (0.08: 39.3), Group E (<0.03: 37.9) and Group F, which was fed 20% beef fat, (0.34: 88.5). These data suggest the essential fatty acid requirement for colon tumorigenesis is much lower than values previously reported for tumorigenesis in the breast and pancreas. The plasma and liver triene/tetraene ratios showed clear-cut essential fatty acid deficiency (ratio >0.4) in Groups D and E, although no clinical symptoms were evident. In all dietary groups, the triene/tetraene ratio in the colon was lower than 0.3. In addition, in the colon, the percentage of fatty acids present as 20 carbon polyunsaturated fatty acids was lower than in the plasma and liver. These data suggest the colon possesses low levels of the fatty acid desaturase and elongase needed for conversion of linoleate to 20 carbon fatty acids, and therefore, that the colonic requirement for essential fatty acids may be low. Furthermore, in the absence of other clinical symptoms, the reduced tumorigenesis observed in the groups fed low essential fatty acids suggests the essential fatty acid requirement of tumor tissue may be higher than that of normal colon mucosa.
***Lipids 24,* 340-346 (1989).**

Intestinal carcinogenesis has been shown to be strongly influenced by environmental factors. The environmental factor with the greatest impact appears to be the diet, and in particular the fat content of the diet. A majority, but not all, studies of intestinal carcinogenesis have shown that a high-fat diet enhances tumorigenesis (1, 2). For most fats, the enhancement of tumorigenesis has been shown to occur during the post-initiation phase (3,4). Recent investigations of the relationship between dietary fat and tumorigenesis have concentrated on the fatty acid composition of different fats. Reddy and Maeura have shown that high-fat diets containing predominantly unsaturated sources of fat enhance tumorigenesis more than diets containing fairly highly saturated fats (5). Another group of investigators demonstrated greater tumorigenesis in rats fed 5% linoleate as a fat source than in rats fed 0.5% linoleate and 4.5% stearate (6). Thus, at both high- and low-fat levels, it appears that unsaturated fats promote tumorigenesis more than saturated fats.

The effect of polyunsaturated fatty acids (PUFA) on intestinal tumorigenesis is similar to that reported in several other organs in which dietary fat acts as a promoter of carcinogenesis. There is evidence from these studies that linoleate is required for the development of cancer (7). In particular, studies in the breast and pancreas have demonstrated the influence of PUFA in tumor promotion (8, 9). Furthermore, in these organs, the specific level of essential fatty acid (EFA) necessary for maximal tumorigenesis has been defined (10, 11). To our knowledge, a similar titration of the PUFA requirement for colon tumorigenesis has not been reported.

Essential polyunsaturated fatty acids play numerous roles in cellular physiology. One major metabolic fate is to serve as precursors for the biosynthesis of arachidonic acid with subsequent conversion to prostaglandins and lipoxygenase products (12). These fatty acid oxygenation products have been shown to play important roles in many cellular processes. The involvement of these compounds in tumorigenesis is supported by the fact that inhibitors of prostaglandin biosynthesis as well as lipoxygenase inhibitors reduce the development of tumors in animal models (13-16).

The present investigation was undertaken to determine the influence of EFA status on intestinal tumorigenesis. The overall EFA status of the animals was determined by evaluating the plasma and liver triene to tetraene ratios. The intestinal EFA requirement was also assessed and compared to that necessary for maintaining the general health of the animal.

Abbreviations: ANOVA, analysis of variance; AOM, azoxymethane; BF, beef fat; EFA, essential fatty acids; FID, flame ionization detection; GC, gas chromatography; MCT, medium chain triglyceride; NRC, National Research Council; PUFA, polyunsaturated fatty acids; SO, safflower oil; 20:4, 5,8,11,14-eicosatetraenoate; 20:3ω-9, 5,8,11-eicosatrienoate.

The relationship of these criteria to the development of azoxymethane-induced intestinal tumors was examined. The results of this study provide information with respect to the enhancement of intestinal tumorigenesis by dietary fat.

EXPERIMENTAL

Azoxymethane (AOM, CAS: 25843-45-2) was purchased from Ash-Stevens, Inc. (Detroit, MI) and was prepared as an aqueous solution for injection. Dextrose was obtained from a local bakery supply house. Beef fat was donated by Belmont Packing Co. (Detroit, MI) and was rendered in the laboratory prior to use in preparation of the diets. Medium chain triglyceride oil (MCT) was donated by Capital City Products Corp. (Columbus, OH). All other dietary components were obtained from Dyets, Inc. (Bethlehem, PA). Solvents for lipid extraction were purchased from a local laboratory supply company and were of the highest purity obtainable.

Animals and diets. Male Sprague-Dawley rats (240) weighing 100–125 g were obtained from Charles-River breeding Laboratories Inc., Portage, MI. Animals were housed individually in hanging wire cages and maintained under conditions of controlled lighting (12 hr/day), temperature and humidity. Diets and water were provided *ad lib.* Diets were prepared fresh weekly and stored at 4°C prior to dispensing to the animals. Body weights were recorded weekly, and food consumption was determined monthly.

Upon arrival, rats were fed a diet containing 5% corn oil. After one week acclimation, 180 rats received sc injections of AOM (20 mg/kg body wt) once a week for two weeks. Noncarcinogen controls (60 rats) received injections of sterile water. One week after the last injection the rats were placed into one of six dietary groups. Each group contained 30 carcinogen-treated and 10 control rats. Five of the groups were fed diets containing 5% total fat, and one group was fed a diet containing 20% beef fat. The 5% fat diets were designed to provide different levels of essential fatty acids and were prepared by mixing either safflower oil (SO), beef fat (BF), or MCT oil. These three fats were chosen because they contain high (SO), low (BF), or no (MCT) essential fatty acids. From previous studies using 5% beef fat (0.1% EFA) it was suspected the EFA requirement for colon tumorigenesis may be low. Therefore, two groups of rats were fed diets containing high proportions of MCT oil to make the diets significantly EFA deficient. Samples of each diet were analyzed to determine precisely the level of dietary linoleic acid given to each group of animals. The individual dietary groups are presented in Table 1. The composition of the diets (wt %) was as follows: mineral mix 3.6, vitamin mix 2.0, D,L-methionine 0.2, cellulose 5.0, casein 20.0 (16). In addition, the 5% fat diets contained 5% fat, 45.2% dextrose and 19.0% cornstarch and had a caloric density of 3.818 kcal/g, while the 20% fat diet contained 20% fat, 40.2% dextrose and 9.0% cornstarch, and had a caloric density of 4.568 kcal/g.

Twenty six weeks after the first carcinogen injection, all rats were killed and necropsies performed. Tissues were examined grossly for tumors; the intestine was slit lengthwise from stomach to anus and rinsed free of debris; the number, size and location of all intestinal tumors was recorded. Only those tumors grossly observable (>1.0 mm) were included for analysis. Extensive experience with this animal model has shown that at 26 weeks after the initiation of carcinogen treatment, the vast majority of induced tumors are detectable upon gross examination. Ten representative large intestinal tumors from each dietary group were taken for histological analysis. The tumors were removed, fixed in phosphate buffered formalin, embedded in paraffin and stained with hematoxylin and eosin then examined microscopically. The data were analyzed statistically by Chi-square (tumor incidence) and analysis of variance (ANOVA) (tumor frequency).

Lipid analysis. At the time of sacrifice, samples of plasma, liver and colon were collected for analysis of lipid composition to determine EFA status. The tissue samples were extracted with $CHCl_3$/methanol (2:1), transesterified, methylated and subjected to analysis by gas chromatography (GC) utilizing flame ionization detection (FID) and electronic integration to quantitate individual fatty acids. The fatty acids were identified by co-elution with authentic standards. The ratio of 5,8,11-eicosatrienoate (20:3ω-9) to 5,8,11,14-eicosatetraenoate (20:4) was determined to obtain a quantitative assessment of the EFA status of animals consuming a particular diet. The results of the lipid analyses were evaluated statistically by ANOVA.

RESULTS

Body weights and food consumption. In the carcinogen-treated animals, there were no significant differences in mean body weight between any of the dietary groups at any point in the experiment. In general, the carcinogen-treated animals weighed less than animals in the re-

TABLE 1

Dietary Groups to Determine Effect of Linoleic Acid on Intestinal Tumorigenesis

Group	Dietary fat source (wt %)	Actual 18:2 (wt %)[a]
A	1% Beef fat + 4% safflower oil	1.28
B	3.75% Beef fat + 1.25% safflower oil	0.6
C	5% Beef fat	0.11
D	2.5% Beef fat + 2.5% MCT oil[b]	0.08
E	0.5% Beef fat + 4.5% MCT oil	<0.03
	20% Be	0.34

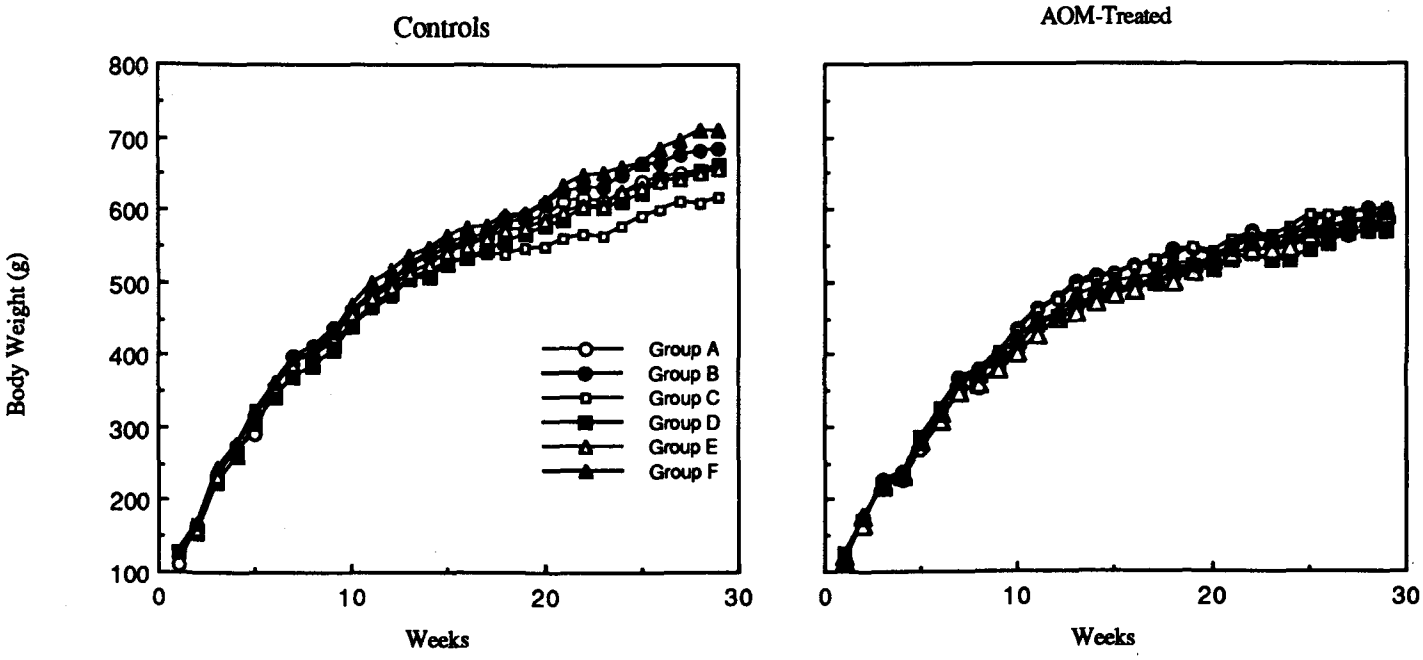

FIG. 1. Mean body weights of animals in the tumorigenesis study. There were no statistically significant differences in the mean body weights between any of the dietary groups.

spective control group. The mean body weights of control animals were also similar, although toward the end of the experiment, the rats fed 20% beef fat tended to weigh more than those fed 5% beef fat, which is consistent with previous observations (3). These data are presented in Figure 1.

The food consumption of rats consuming the 5% fat diets was similar for all the various diets. Rats fed 20% fat ate less food than those fed 5% fat and, therefore, maintained similar body weights. The greatest difference was observed between rats fed 20% beef fat and those fed 5% beef fat where the rats fed high fat ate an average of 20.9% less food over the course of the experiment. While reduced food consumption in animals fed high-fat diets has been reported by others, in our previous experience, the divergence in food consumption did not occur until the fat content of the diet was 30% or more. The vitamin and mineral mixes used in preparation of the diets in this experiment contained two times the National Research Council (NRC) requirement for maintenance of laboratory rats (17). Therefore, the slightly reduced food consumption in the animals fed high fat was not great enough to lead to nutrient deficiency. The caloric intake of rats fed the different diets is shown in Figure 2. For the first two months of the experiment, rats fed the 20% fat diet had a slightly higher caloric consumption than the rats fed the 5% fat diets. However, in the third through sixth months the caloric intake was similar in all dietary groups.

Tumor incidence and multiplicty. The incidence (percent of animals with tumors), number of tumors per tumor-bearing animal, and tumor frequency (number of tumors per rat) of intestinal tumors in the AOM treated animals are shown in Table 2. There were no tumors in the animals that did not receive AOM injections. For the initial recording of tumor data, the small and large intestines were divided into proximal and distal halves. However, for presentation, the numbers were combined since there were no differences in the proximal and distal halves that were not evident in the combined data. Ten representative large intestinal tumors from each group, five larger than 0.5 cm and five smaller, were examined histologically. All lesions, regardless of size, were adenocarcinomas with varying degrees of differentiation and invasion of the intestinal wall. These characteristics were not significantly different between the various groups. The production of 100% adenocarcinoma with carcinogen treatment pro-

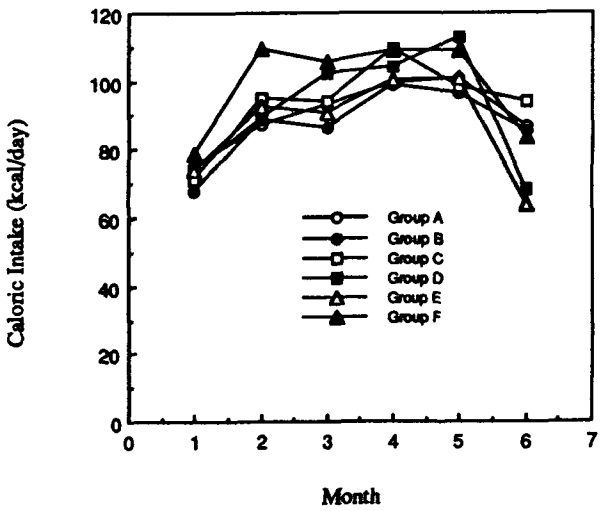

FIG. 2. Daily caloric intake of rats in the tumorigenesis study. The data presented represent the mean daily intake per rat. For data collection, the food consumption of five animals in each group was measured over a three-day period.

[f]P<0.05 to P<0.005 compared to Group E.

tocol used in the present study is consistent with previous studies utilizing this animal model (3, 16).

Small intestinal tumors developed almost exclusively in the proximal half. In fact, out of a total of 333 small bowel tumors in all the groups, only 4 (1.2%) were found in the distal segment. In the large bowel, the distribution of tumors, both incidence and multiplicity, was nearly the same between the proximal and distal halves. The only notable difference was found in the rats consuming 20% beef fat where the incidence in the distal half (73.3%) was slightly higher than in the proximal segment (53.8%).

Tumor metastasis occurred in only two of the carcinogen-treated rats, one in group A and one in D. The frequency of ear tumors was also low with a total of only eight tumors observed in all the carcinogen-treated rats. There was no clear correlation between metastasis or ear tumor formation and either the linoleate or total fat content of the diet.

The incidence of large bowel tumors showed a dependence on the linoleate content of the diet. The NRC recommendation for EFA content in the diet of rats is 0.6% (17). The diet fed to Groups A and B met or exceeded this recommendation. The diet fed to Groups C (0.11%), D (0.08%) and E (<0.03%) were below this level, and animals in these groups showed a reduced tumor incidence. The lowest tumor incidence was observed in groups of rats fed less than 0.1% linoleic acid. It is noteworthy that rats consuming the 20% beef fat diet (0.34% linoleate) had less than the recommended EFA level (0.6%) but had the highest incidence of tumors of any group in the study. It is also interesting that the tumor incidence did not increase as the EFA content of the diet was doubled from 0.6% (Group B) to 1.28% (Group A).

On the other hand, in the large intestine, the number of tumors per tumor-bearing animal did not reflect the dietary EFA content, although it did reflect the total fat content of the diet. Thus, a statistically significant increase in tumors per tumor-bearing animal was noted in the 20% beef fat group (Group F) compared to those groups fed 5% fat (Groups A, B, D and E) with the exception of Group C (5% BF, 0.11% linoleate). Since the incidence of tumors varied, the tumor frequency (average number of tumors per rat) of the individual dietary groups showed the same trend as the tumor incidence. Moreover, the frequency of large intestinal tumors in the group fed 20% beef fat (Group F) was greater than that in the groups fed the 5% fat diets, regardless of the linoleate content. The difference was statistically significant in all cases.

Tumor yield in the small intestine was distinctly different than that in the large intestine. The incidence of small intestinal tumors was generally equal to or greater than that in the large intestine and independent of the EFA content of the diet. Thus, rats consuming the lowest level of EFA (<0.03%) had essentially the same tumor incidence as those consuming the highest level of EFA (1.28%). The number of tumors per tumor-bearing animal was highest in groups B, C and F compared to the other three groups. However, this did not correlate with the linoleate content of the diet since Group A, which was fed the highest linoleate level, had a relatively low number of tumors per tumor-bearing animal.

Quantitative EFA status of animals. In an attempt to provide a quantitative assessment of the EFA status of the animals in this study, samples of plasma, liver and colon were taken at the termination of the study. The lipids in these samples were extracted, methylated and subjected to analysis by gas chromatography. The relative amounts of the major fatty acids were determined, and particular attention was paid to the amounts of 20:3ω-9 (triene) and 20:4 (tetraene). The ratio of these two fatty acids (triene/tetraene) is frequently used as a measure of the EFA status of an animal with a ratio, in the plasma, of greater than 0.4 usually taken as an indication of EFA deficiency (18).

The results of analysis of the different diets are shown in Figure 3. The various diets provided a good spectrum of EFA levels (as linoleate) with the highest level of 1.28% linoleate in Group A and the lowest linoleate content of <0.03% in Group E. The difference in measured linoleate content was statistically significant between all dietary groups. The level of linolenate provided by the diets was negligible in all groups. In addition to the fatty acids shown in Figure 3, the diets in Groups D and E also contained significant quantities of octanoate (8:0) and decanoate (10:0) which were supplied by the MCT oil. These two

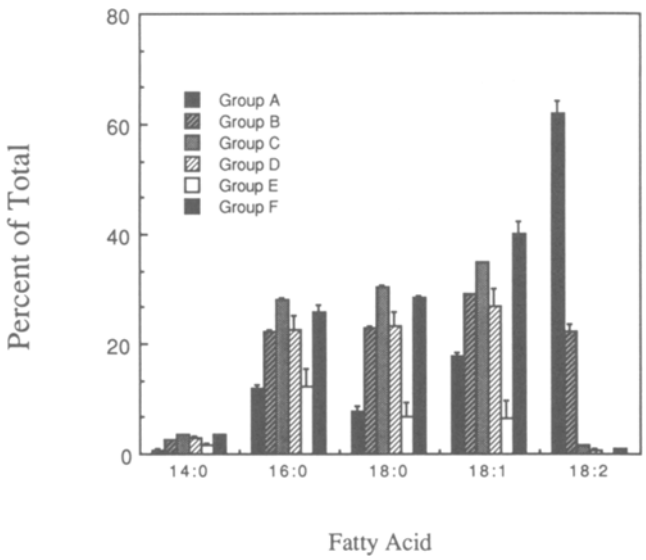

FIG. 3. Major fatty acid composition of the diets in the tumorigenesis study. Fatty acids are presented as percent of total fatty acids. The diets fed to Groups D and E also contain significant quantities of 10:0 and 12:0 derived from the MCT oil. Data presented are the mean ± SD.

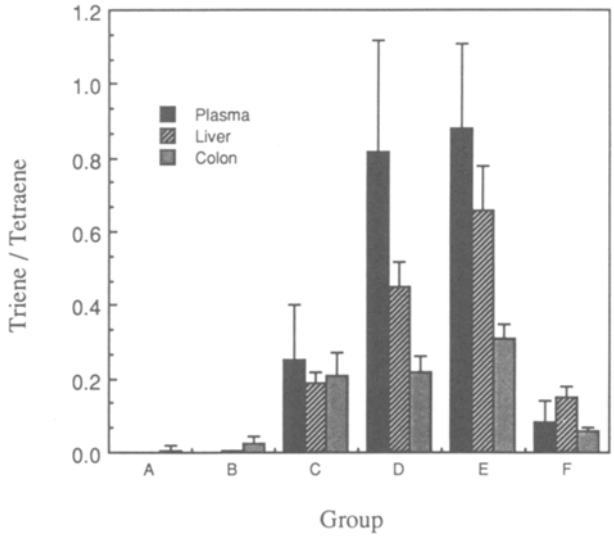

FIG. 4. Triene/tetraene ratios of rats in the various dietary groups. Where no column is shown, the level of triene detected was too low to allow calculation of a ratio. Due to technical problems, the lipid content in Group B was not determined. Data presented are the mean ± SD for 5 animals in each group.

fatty acids were present in only trace amounts in the other dietary groups.

The triene/tetraene ratios of the plasma, liver and colon from animals in the various groups is shown in Figure 4. There was little 20:3ω-9 in the plasma of animals fed 1.28 or 0.6% linoleate in the diet, thus the triene/tetraene ratio in these animals is very low. In contrast, animals in groups D and E were clearly EFA deficient as evidenced by plasma ratio of 0.82 and 0.88, respectively. On the other hand, Groups C and F had detectable plasma levels of 20:3ω-9 although the triene/tetraene ratios obtained were well below those indicative of deficiency. In the plasma, the difference between the triene/tetraene ratio in the different groups is statistically significant with the exception of Groups C versus F and Groups D versus E.

The liver triene/tetraene ratios showed a trend similar to those in the plasma although they were generally lower. As before, only Groups D and E had ratios high enough to indicate EFA deficiency. For all dietary groups, the difference in the liver triene/tetraene ratio is statistically significant with the exception of Group D versus F. None of the animals, in any dietary group, showed visible clinical symptoms of EFA deficiency.

The fatty acid content of the colon was significantly different than that of the plasma and liver as shown in Figure 5. In the colon, the total amount of the 20 carbon fatty acids, 20:4 and 20:3ω-9, was small in all dietary groups. For example, in group A, arachidonic acid represented 19.5% of the fatty acids in the plasma and 13.7% in the liver. In contrast, the percentage of 20:4 in the colon was only 3.1% of the total fatty acids. Similarly, low levels of 20:3ω-9 were also found. This observation of a low level of 20 carbon fatty acids in the colon was seen in all the dietary groups. Within any given dietary group, the difference between the 20:4 content in the colon compared to the plasma and liver was statistically significant.

In addition to a low level of 20 carbon fatty acids in the colon, the triene/tetraene ratio was also low. Group E, which received the lowest level of dietary linoleate (<0.03%), had the highest ratio of 0.31. Thus, while data from the plasma and liver suggested a general state of EFA deficiency, the colon did not give a similar indication.

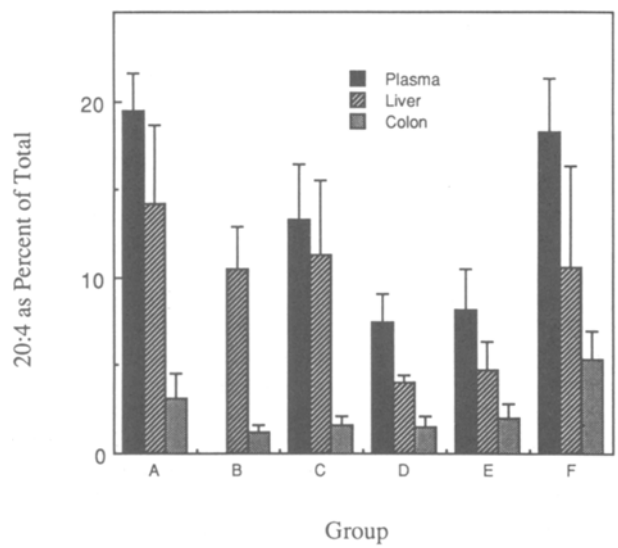

FIG. 5. Content of arachidonic acid (20:4) in the plasma, liver and colon of rats in the various dietary groups. Data are the amount of 20:4 as a percent of total major fatty acids. Due to technical problems, the plasma content of 20:4 in Group B was not determined. Mean ± SD for 5 animals in each group.

DISCUSSION

In the present experiment the effect, on intestinal tumorigenesis, of the EFA content of 5% fat diets and the overall EFA status of rats fed the diets was studied. The EFA status of the animals was assessed by measurement of the triene/tetraene ratios in plasma, liver and colon. Large bowel tumorigenesis was shown to be dependent upon the EFA content of the diet; however, this dependence did not become apparent until the dietary EFA content was much lower than the amount considered optimal for overall animal health. The EFA requirement for general health of laboratory rats is 0.6% of the diet (17). In the present experiment, large bowel tumor incidence was only slightly depressed in animals fed 0.1% EFA compared to those fed 0.6% (55.6% incidence vs 73.3% incidence). On the other hand, an increase in EFA content from 0.6% to 1.28% was not associated with enhanced tumorigenesis. Furthermore, in rats fed 20% beef fat which provided 0.34% EFA, the yield of tumors was greater than that in animals fed 0.6% EFA. These results suggest the EFA requirement for tumorigenesis in the large bowel is much lower than that for overall health and that the upper limit of the EFA requirement is between 0.1% to 0.34%.

It has been shown previously that the response of various organs to EFA deficiency is different (19). This suggests the EFA requirement for maintenance of normal function also differs. For example, under conditions of EFA deprivation, the polyunsaturated fatty acid content of certain liver phospholipids has been shown to decrease rapidly while those in the heart and kidney are maintained at near normal levels for longer periods of time. Based on these observations, plus the results of the current study, it is reasonable to suggest that the EFA requirement for the promotion of tumorigenesis may also differ between organs. In fact, the finding that tumorigenesis in the small bowel appeared to be independent of EFA status, whereas colon tumorigenesis showed the opposite response, may be relevant to this point.

The finding that large bowel carcinogenesis is reduced when EFA levels fall below 0.6%, but does not increase with levels of EFA greater than 0.5%, is in direct contrast to results obtained in other organ systems responsive to dietary fat. For example, the EFA requirement for optimal development of breast tumors has been estimated to be 4.4% (10). Similarly, high values of the EFA requirement have also been reported in studies of the enhancement of pancreatic carcinogenesis by dietary fat (11). Thus, an important distinction can be made between tumorigenesis in the colon compared to these other organs. Specifically, the EFA requirement for optimal tumorigenesis in the breast and pancreas is in excess of that required for good nutrition, whereas in the colon the optimal EFA requirement is less than the required amount.

It appears that the enhancement of cancer by high-fat diets is composed of two factors; the first is dependent on EFA and their metabolism, while the second is the result of other effects of fat. Thus, once the EFA requirement is met, the non-EFA dependent factors could make an additional contribution to carcinogenesis. There is evidence from studies of mammary carcinogenesis that this situation exists (20). A major difference between studies of EFA and carcinogenesis in the other organs and the present experiment is that the other studies utilized a high-fat diet whereas this experiment was conducted primarily with 5% fat diets. Thus, in the current study, the contribution of non-EFA dependent fat effects would be small.

Along these same lines, the observation of a higher tumor yield in rats fed 20% beef fat compared to those fed 5% fat is important. This observation suggests the enhancement of colon tumorigenesis by beef fat is not due solely to a difference in EFA content. While some of the enhancement may be due to this factor, it is clear that an increase in EFA from 0.34% (20% beef fat) to 1.28% (1% BF + 4% SO) did not enhance tumorigenesis. In fact, the rats fed the lower level of EFA, but higher total fat content, actually had the highest tumor yield. Thus, the enhancement of colon tumorigenesis by high beef fat diets must include non-EFA dependent components. These non-EFA components may include biliary steroids, although it has been suggested recently that oxidation products of unsaturated fatty acids, including those of oleic acid, may be a contributing factor (21, 22).

It has been suggested the enhancement of tumorigenesis by high dietary fat is due to a difference in caloric consumption and not to any direct effect of fat itself. In the present experiment this does not appear to be the case as there are clear differences in the tumor yield among rats fed only 5% fat diets, for example, Group A as opposed to Group E. Thus the alteration in tumorigenesis observed must be due to the composition of the dietary fat and not the caloric content of the diet. Furthermore, with respect to the high-fat versus low-fat diets, the rats fed the high-fat diets had a similar caloric intake, throughout most of the experiment, to rats fed 5% fat diets, again suggesting a fat-specific as opposed to a caloric effect. In support of this, the data of Reddy and Maeura demonstrate a difference in tumorigenesis due to fat composition, not caloric content (5).

The determination of the triene/tetraene ratios in the animals in this study provided some interesting results. A plasma triene/tetraene ratio of greater than 0.4 is usually considered indicative of EFA deficiency (18). The ratio in the plasma in the two groups of rats fed the lowest level of EFA (Groups D, 0.08%, and E, <0.03%) clearly indicates EFA deficiency. There were no overt clinical signs of deficiency such as scaly tails, weight loss, poor coat development or hematuria, although it is known that elevated triene/tetraene ratios will precede the clinical manifestation of deficiency. From the data in this experiment, it is apparent that tumorigenesis is affected even though other symptoms of deficiency do not develop. Since the disease process is affected while the target tissue does not indicate EFA deficiency, the possibility exists that the biochemical definition of EFA deficiency is different for different organs. For example, an organ such as the colon may be functionally EFA deficient at a triene/tetraene ratio much lower than the accepted plasma value of 0.4. Alternatively, as discussed below, it is possible the EFA requirement of normal colon mucosa

is different than that of colon tumors. Thus, while the normal colon was unaffected, the tumor tissue may have been EFA deficient and its growth depressed.

In the present experiment, the colonic content of 20:4 was found to be a much lower percentage of total fatty acids than in either the plasma or liver. Similarly, the level of 20:3ω-9 in the colon was also low. These two fatty acids are biosynthesized from precurosr fatty acids by the action of delta-5 and delta-6 desaturases and a fatty acid elongase (12). While we did not measure the amount of elongase and desaturase activity, the data from this experiment suggest that, in the colon, the activity of these enzymes is low. Low levels of these enzyme activities have been reported previously in rat and guinea pig skin, which is similar to the colon in the need for constant cell turnover during epithelial renewal (23). There are two interpretations to this observation. One possibility is that, since the colon cannot efficiently elongate EFA to eicosanoid precursors, there is a stringent requirement for dietary EFA. The other possibility is that low levels of biosynthesis reflect a decreased requirement of the tissue for 20 carbon PUFAs. Data from the present experiment suggest the latter possibility is operative since colon tumorigenesis was not affected until the EFA level was much lower than the required daily amount.

It is generally believed that the major role of EFA is to provide precursors for the biosynthesis of prostaglandins and other eicosanoids (12). How, then, is it possible to reconcile the finding of a low colon requirement for EFA with the observations of inhibition of colon tumor growth by inhibitors of prostaglandin biosynthesis such as piroxicam and indomethacin (14-16)? One possible explanation is that as colonic tissue undergoes the transformation from normal mucosa to maligant tissue, the essential fatty acid requirement also changes. This suggestion is consistent with the observation that indomethacin is an effective inhibitor when administered late in the carcinogenic process and actually exerts a chemotherapeutic action on colon tumor growth (24-26). The suggestion that a change in the EFA requirement occurs during cell transformation, if confirmed, may prove useful in the chemoprevention and treatment of colon cancer.

METHODS

On-Line Hydrogenation in GC-MS Analysis of Cyclic Fatty Acid Monomers Isolated from Heated Linseed Oil[1]

J.L. Le Quéré[a,*], E. Sémon[a], B. Lanher[a] and J.L. Sébédio[b]

[a]INRA - Laboratoire de Recherches sur les Aromes, 17 Rue Sully - 21034 DIJON Cedex - France, and [b]INRA - Station de Recherches sur la Qualite des Aliments de l'Homme

A simple on-line hydrogenation method in GC-MS analysis of unsaturated fatty acid esters is described. Using hydrogen as carrier gas, hydrogenation takes place in a capillary reactor connected to the outlet of the analytical column in the oven of the gas chromatograph. The reactor is a fused silica tube (60 cm × 0.32 mm i.d.) coated with palladium acetylacetonate. Selective hydrogenation of olefinic bonds is achieved after a normal chromatographic run. Structural information (carbon-skeleton, double bond equivalents) can thus be deduced, and structural correlations between the saturated and unsaturated components can be obtained. Structures of cyclic fatty acid esters isolated from heated linseed oil were elucidated using this simple method which was found very useful for structural investigations on unsaturated compounds by GC-MS.

Lipids 24, 347-350 (1989).

Separation and spectral characterization of the methyl esters of unsaturated cyclic fatty acid monomers (CFAM) isolated from heated vegetable oils were described recently (1,2). However, many structural problems remained unsolved because the mass spectra of the unsaturated compounds of the mixtures were ambiguous. Generally, the mass spectra of saturated species are interpreted more readily than those of related unsaturated compounds. For example, distinction of the carbon-skeleton types is much easier (ring size, nature of the substituents).

The easiest and most commonly used method to obtain saturated components is by catalytic hydrogenation of the unsaturated mixture before analysis. This was done very recently on CFAM mixtures isolated from sunflower and linseed oils. The carbon-skeletons of the major constituents were elucidated, and the double bond equivalents were determined (1,3).

However, this kind of data is useful only if the correlations between the saturated and their corresponding unsaturated analogues can be carried out easily. Correlations become difficult if various unsaturated species are converted into the same saturated products. Positional and geometrical isomers, for example, apparently rather abundant in the CFAM mixtures (2), will give the same hydrogenated product; therefore, only one peak will be detected by gas chromatography. Consequently, it was impossible to determine correlations between the unsaturated and saturated CFAM mixture obtained after total hydrogenation.

Another method of hydrogenation would be to obtain selective hydrogenation of all the unsaturated species after chromatographic separation. An on-line technique (4,5), just before mass spectrometry, may be used. We now describe an on-line hydrogenation method for use in GC-MS analyses of methyl esters of CFAM isolated from a heated linseed oil. This method proved easy and useful in structural studies.

EXPERIMENTAL

Cyclic fatty acid monomers were isolated from linseed oil heated at 275°C under nitrogen and esterified according to published procedure (1).

Gas chromatography-mass spectrometry (GC-MS). All GC-MS analyses were performed with a Nermag R 10-10 C mass spectrometer directly coupled to a Girdel 31 gas chromatograph. The analytical column used throughout the study was a fused silica capillary column (30 m × 0.25 mm i.d.) coated with DB Wax (J and W Scientific, 0.5 μm film thickness).

Splitless injections were used and oven temperatures were programmed from 60 to 180°C/min at 10°C/min, then to 220°C at 3°C/min and held at 220°C until completion of the analyses. Hydrogen was used as the carrier gas with a linear velocity of 53 cm/s at room temperature. Electron impact mass spectra were generated at 70 eV with a source temperature of 150°C, the instrument scanning from 42 to 310 amu on an 0.8 s cycle.

Hydrogenation capillary reactor. A deactivated fused silica capillary column (5 m × 0.32 mm i.d.) was statically coated with a 0.5% methylene chloride solution of palladium acetylacetonate (Fluka). After drying under a stream of nitrogen, 50 cm of both ends of the column were discarded. A 60-cm piece of the capillary was inserted with zero-dead volume butt connectors (Supelco Inc., Bellefonte, PA) between the analytical column and a deactivated fused silica capillary column (3 m × 0.25 mm i.d.) directly connected, through the heated interface, to the ion source of the mass spectrometer.

Palladium metal was precipitated in a stream of hydrogen carrier gas by heating to the normally-applied column temperature (220°C).

RESULTS AND DISCUSSION

A recent structural study on unsaturated CFAM methyl esters isolated from heated linseed oil revealed that the CFAM fraction was a mixture of cyclohexenyl and cyclopentyl and/or cyclopentenyl derivatives (2). After total hydrogenation of the CFAM fraction, another study (3) partially confirmed an earlier one (6) while extending our knowledge of the MS fragmentation of alkylcyclopentyl esters. The structures of some of them were definitely established by organic synthesis (7).

[1]Presented in part at the AOCS meeting in May 1988 in Phoenix, AZ.

Abbreviations: CFAM, cyclic fatty acid monomers; GC, gas chromatography; MS, mass spectroscopy; TIC, total ion currents.

However, in the GC-MS analyses of the hydrogenated CFAM mixture isolated from linseed oil, the chromatograms obtained before and after total hydrogenation were, as expected, completely different (2,3). It was then rather difficult to assign structures to positional isomers of unsaturated CFAM which gave only one product after hydrogenation.

In order to obtain better GC correlations between saturated and unsaturated species, we investigated an on-line hydrogenation method first described by Schomburg et al. (4,5). Schomburg and his coworkers determined important parameters (activity of catalysts, hydrogen flow in the capillary reactor and temperature of hydrogenation) using a double oven chromatograph equipped with a switching device (5). However, a simpler way to operate, compared to the method described by Schomburg et al., would be to connect a capillary catalytic reactor either before or after the analytical column, directly in the oven of the gas chromatograph. Hydrogen would be provided as the carrier gas and reaction temperature would be the oven temperature. The availability of deactivated fused silica capillaries and of various zero-dead volume connectors permitted us to investigate this direct simple arrangement.

For the selective hydrogenation of olefinic double bond, a palladium catalyst was chosen, because platinum catalysts may also hydrogenate other functions, such as ester groups (5).

The capillary reactor was placed in the oven of the GC behind the analytical column and ahead of the mass spectrometer. Connecting the reactor to the inlet of the analytical column would not afford an advantage as compared to classical hydrogenation before GC-MS analysis.

The activity of the catalyst, its selectivity for carbon-carbon double bonds, and adsorption on its surface were tested with mixtures of unsaturated esters. For instance, a mixture of methyl oleate and methyl linoleate (Fig. 1A) gave two peaks of methyl stearate when injected with the Pd reactor connected to the outlet of the column (Fig. 1B). Only slight variations of a few seconds were noted between independent runs. Peak tailing, due to adsorption of the eluates on the surface of the catalyst, was considered acceptable. Complete hydrogenation was obtained when the sample load did not exceed 1 μg/peak.

The unsaturated CFAM mixture described above was therefore submitted to post-column hydrogenation. The total ion currents obtained without and with the Pd

reactor could be superimposed (Fig. 2). Under the same chromatographic conditions, retention times were not altered by inserting the capillary reactor into the system. Only slight tailing of peaks was observed due to adsorption. Mass spectra of the pure hydrogenated species were obtained for each of the major 10 peaks. The carbon skeleton of each of the compounds (peaks 1 to 10) could clearly be established by the information gained through the mass spectra of their hydrogenated counterparts 1H to 10H (Fig. 2). For instance, peak number 1 was identified as a propylcyclopentenyl decenoate, because the mass spectrum of its hydrogenated product 1H (Fig. 3B) was identified as that of methyl (2-propylcyclopentyl) decanoate. The molecular ion was increased by four mass units from 292 to 296 (Fig. 3). Extensive changes in the spectrum occurred in the mass range of 50–150 as a result of hydrogenation. Diagnostic ions (Fig. 3B) B (*m/z*: 185), C (*m/z*: 111), D (*m/z*: 253), D-32 (*m/z*: 221) and D-32-18 (*m/z*: 203) were unambiguously assigned. We also noted ions of low intensity (*m/z*: 267 and 235) and attributed them to fragment ions D_β and D_β-32 resulting from a second cleavage of the alkyl moiety in the β-position. This hypothesis was confirmed by mass spectrometry of some synthesized alkyl-cyclopentyl derivatives (7), and the β-fragmentation of the alkyl chain seems to be characteristic of these alkyl-cyclopentyl esters.

Peak 2 was identified as the *cis*-isomer of 1, peaks 3 to 6 were identified as butylcyclopentenyl nonenoates, differing only by the position of the double bond in the side-chain, and peaks 7 to 10 were confirmed (2) to be isomers of propylcyclohexenyl nonenoates.

Activity and selectivity of the catalyst were tested periodically. Good results were obtained through several days of operation using one 60-cm piece of capillary reactor. The technique was found useful for structural investigations on mono- and polyunsaturated compounds of various origins as they occur in complex mixtures.

The Effect of Dietary Fish Oil on Muscle and Adipose Tissue Lipoprotein Lipase

Gene R. Herzberg* and **Maria Rogerson**
Department of Biochemistry, Memorial University of Newfoundland, St. John's, Newfoundland A1B 3X9, Canada

The activity of lipoprotein lipase (LPL) in the adipose tissue and skeletal muscle of rats fed glucose- or fructose-based diets containing fish oil, corn oil or tallow was examined. In addition, heart LPL activity was measured in rats fed a glucose-based diet containing either corn oil or fish oil. Adipose tissue LPL activity was unaffected by dietary fat. In both heart and skeletal muscle, LPL activity was higher in rats fed the fish oil diet. These results suggest that increased removal of triglyceride by muscle may contribute to the blood triglyceride lowering effect of dietary fish oil.
Lipids 24, 351-353 (1989).

Dietary omega-3 fatty acids have been shown to lower blood triglyceride levels. This effect has been shown to be due at least in part to decreased hepatic synthesis of triglycerides coupled with decreased VLDL secretion (1-5). However, increased clearance of triglyceride-rich lipoproteins could also contribute to the triglyceride-lowering effect of dietary fish oils. Harris and Connor (6) reported that in subjects who had consumed diets enriched in salmon or corn oil for two weeks, the increase in plasma triglyceride after a single dose of salmon oil was lower than after corn oil. They suggested this could be due to more rapid clearance of the omega-3 containing chylomicrons. However, they subsequently reported that postheparin lipolytic activity was unaffected by fish oil consumption (7). Brockerhoff et al. (8) and Bottino et al. (9) suggested that fish oils were poorly digested and absorbed, which could explain the lower plasma triglyceride responses reported by Harris and Connor (6). Chen et al. (10,11) have shown that the hydrolysis of chylomicron triglyceride enriched with EPA is similar to that of those enriched with oleate using recirculating heart perfusion, and this was confirmed in vivo. In the studies of Chen et al., the rats had been fed rat chow (Purina Rat Chow, Ralston Purina Co., St. Louis, MO). If lipoprotein lipase (LPL) activity and consequently, chylomicron clearance, changes with different dietary fats, it would not have been observed in these studies. Because of the inconclusive nature of these studies with regard to the effect of dietary fish oils on lipoprotein lipase activity, we have studied the activity of lipoprotein lipase in cardiac and skeletal muscle and adipose tissue in animals fed diets rich in saturated or omega-6 or omega-3 fatty acids. In addition, because of the known hypertriglyceridemic effects of dietary fructose, we have also examined the effects of these fats in animals consuming fructose- or glucose-based diets.

MATERIALS AND METHODS

Male Sprague-Dawley rats were obtained from Canadian Biobreeding Labs (Montreal). Animals were housed individually in plastic metabolic cages. The animals were maintained at a temperature of 25°C in a light controlled room (lights on 0800-2000). The rats were given 20 g of food per day at 0800. Uneaten food was removed at 1100. Thus, the animals had access to food for only 3 hr per day. Water was available *ad libitum.* Food consumption was measured daily. Six diets were used: fructose + tallow (FT); fructose + corn oil (FCO); fructose + fish oil (FMaxEPA); glucose + tallow (GT); glucose + corn oil (GCO); and glucose + fish oil (GMaxEPA). The diets had the compositions shown in Table 1. No antioxidant other than the vitamin E contained in the vitamin mix was added to the diets, and no attempt was made to equalize the cholesterol content. The diets were made fresh every other day and stored in sealed containers at −70° to minimize oxidation. In each experiment, four rats received each diet. The average initial weight of the animals was 220 ± 8 g (mean ± S.D.) in the fed experiment, 211 ± 12 in the fasted experiment. In a separate experiment, rats were meal fed a glucose based diet containing either corn oil or fish oil as described above. The average weight of all the rats in this experiment was 224 ± 13 g (mean ± S.D.). The average final weight of the fasted rats for each group was GCO, 248 g; GT, 250; GMaxEPA, 252; FCO, 259; FT, 258; FMaxEPA, 242. The average final weight of the fed rats in each group was GCO, 286 g; GT, 287; GMaxEPA, 283; FCO, 277; FT, 273; FMaxEPA, 263. There was no significant difference in initial or final weight among the dietary treatments in any experiment.

Dietary fats were transmethylated according to the procedure of Parkes and Thompson (12). Fatty acid methyl

esters were quantitated by gas chromatography using a Supelco SP2330 capillary column (0.25 mm × 30 m) in a Perkin Elmer 8310 gas chromatograph. The oven temperature was 180°C. The carrier gas was Helium at a flow rate of 2 ml/min. Fatty acids were identified by retention time in comparison with known standards. The fatty acid composition of the dietary fats is presented in Table 2. Fatty acids which make up less than 1% of the total are not included.

LPL activity was determined in the epididymal fat pads and skeletal muscle of rats which had been fed on the day of the experiment and in rats which had not been fed on the day of the experiment. Tissue samples from fed rats were taken at 10:00, 2 hr after the start of the meal. Fasted samples were also taken at 10:00, that is 23 hr after the end of the previous days meal. In addition, LPL was determined in the hearts of fasted, glucose-fed rats. Fed rats had full stomachs at the time of the experiment. Rats which were not fed had empty stomachs. LPL activity was determined from the rate of release of [^{14}C]-oleate from ^{14}C-labelled triolein emulsion (specific activity = 7.5×10^5 dpm/μmol) according to the method of Nilsson-Ehle et al. (13). Extracts of acetone powders were used for the determination of epididymal fat pad LPL activity. Heart and skeletal muscle LPL were assayed on extracts of acetone powders of heart and the muscles from an entire hindlimb. Heart or muscle was rapidly frozen in liquid nitrogen and ground to a fine powder. A portion of the powder was homogenized in acetone. The acetone powder was extracted with 0.05 M NH_4OH/NH_4Cl buffer pH 8.1, and this extract was used for the assay of LPL activity. Activity was shown to be linear with time and enzyme concentration. LPL activity was calculated as the serum dependent, NaCl inhibitable activity.

Results for adipose tissue and hindquarter were analyzed by two way analysis of variance (ANOVA); heart LPL was analyzed by Student's t test. Where the ANOVA showed significant treatment effects, individual mean differences were determined by Duncan's new multiple range test (14). Effects were considered significant if $p < 0.05$.

Chemicals and biochemicals were obtained from Fisher Scientific Co., Sigma Chemical Co. or Boehringer Mannheim. Diet components were obtained from ICN Nutritional Biochemicals except for maize oil, which was obtained locally (Mazola, Canada Starch Co., Montreal) and MaxEPA, a marine oil which was a gift of D. B. Hutchinson, R.P. Scherer (Canada), Windsor, Ontario. Isotopes were obtained from New England Nuclear (LaChine, Quebec).

RESULTS AND DISCUSSION

Adipose tissue LPL activity was unaffected by either dietary fat or carbohydrate (Table 3), although activity was reduced by fasting as previously reported (15). There was no effect of diet composition on the weight of the epididymal fat pads in either the fed or fasted rats ($p > 0.05$ for main effects and interaction by ANOVA). The fatty acid composition of the diet has been shown to alter adipose tissue LPL activity although with varying results. In male Wistar rats fed a 30% fat diet of which 11 vs 2.5% were n-3 polyunsaturated fatty acids, LPL activity was lower in those fed 11% PUFA (16). In contrast, rats fed 20% corn oil vs lard had higher LPL (17). Similarly, male guinea pigs fed diets rich in CO had higher LPL activity than those fed tallow (18). Haug and Høstmark (19) reported that rats fed fish oil or a 50:50 mixture of fish oil and coconut oil had lower activity of epididymal fat pad LPL and hepatic lipase compared to those fed coconut oil. Nadeau et al. (20) reported that LPL was lower in rats fed corn oil than lard.

The activities of both heart and skeletal muscle LPL were greater in rats fed fish oil compared to corn oil (Tables 4 and 5). Skeletal muscle LPL activity was increased by starvation as previously reported for both heart and skeletal muscle LPL (21,22). Our finding of a modest increase in heart LPL is inconsistent with the findings of Chen et al. (10) that the clearance of oleate and EPA enriched chylomicrons by nonworking perfused rat hearts was the same. However, the hearts were from rats which had been consuming Purina Rat Chow, and it is probable that the differences we observed in LPL activity require adaptation to the dietary fats. Further, the

[a]Significantly different ($p < 0.05$).

chylomicrons prepared by Chen et al. were collected by lymph cannulation, washed and then used in the perfusions. It is possible that the modest difference in LPL activity we report is insufficient to alter the rate of clearance by perfused heart. Subsequent work by Chen et al. (11) showed no differences in the rate of clearance *in vivo*, but again in rats fed Purina Rat Chow so there was no opportunity for adaptation of LPL to the different dietary fats.

Huff et al. have reported increased conversion of VLDL apo B to LDL in miniature pigs fed fish oil compared to corn oil (23). However, the fish oil reduced both post-heparin lipoprotein and hepatic triglyceride lipase. In humans consuming fish oil, there was no difference in post-heparin lipolytic activity compared to subjects consuming vegetable oils (7). We don't feel that these results are inconsistent with our finding of increased muscle LPL in fish oil fed rats. Post-heparin plasma LPL activity represents both muscle and adipose tissue activity. We found no differences in adipose tissue LPL due to dietary fat. In post heparin plasma, the difference in heart and skeletal muscle activities could be masked by the contribution of adipose tissue activity to the total measured.

In addition to the differences in the omega-3 fatty acid content, the dietary fats used in this study also differed in their content of oleic and linoleic acids. The tallow and corn oil have very different content of linoleic acid but rats consuming these fats had similar activity of muscle LPL, so it does not seem that differences in this fatty acid contribute to the observed effects of diet on muscle LPL activity. The case of oleic acid is not as clear, but if the increased activity of LPL were due to the reduction in the oleic acid content of the diet one might expect there to be a concentration dependence of the effect. That is, the activity of muscle LPL should be intermediate for the corn oil diet. In fact, the activity of muscle LPL in rats fed the tallow diet is generally between the other two. If the classes of fatty acids as given at the bottom of Table 2 are examined, the predominant difference between the MaxEPA diet which resulted in the highest muscle LPL activity and the other two diets is the omega-3 fatty acid content. We believe that it is the omega-3 fatty acid content of the fish oil diet which is responsible for the higher activity of muscle LPL activity.

We believe that increased heart and skeletal muscle LPL activity could contribute to the lower plasma triglyceride in fish oil fed animals and humans. It might also direct more of the omega-3 enriched chylomicrons toward muscle for oxidation of the n-3 fatty acids. Increased oxidation of omega-3 fatty acids by muscle could at least partially explain the low quantities of n-3 fatty acids in the adipose tissue of rats fed omega-3 enriched diets (24).

Association of the Intestinal Brush-Border Membrane Phospholipase A_2 and Lysophospholipase Activities (Phospholipase B) with a Stalked Membrane Protein

Steven Pind and **Arnis Kuksis***
Department of Biochemistry and Banting and Best Department of Medical Research, University of Toronto, C.H. Best Institute, 112 College St., Toronto, Ont., Canada M5G 1L6

We have attempted to determine the size and membrane orientation of a recently described rat jejunal brush-border protein possessing phospholipase A_2 and lysophospholipase activities (phospholipase B) (Pind, S. and Kuksis, A. [1988] *Biochim. Biophys. Acta 938,* 211-221). The phospholipase A_2 and lysophospholipase activities were renatured following nonreducing sodium dodecyl sulphate polyacrylamide gel electrophoresis of the total membrane proteins and were shown to migrate as a component of a protein band having a relative molecular mass of 170 kDa. This band accounted for approximately 1% of the total Coomassie Blue staining proteins. Phospholipase B was also shown to be solubilized from the membranes, in an active form, by a proteolytic digestion with papain. Papain solubilization resulted in a loss of the hydrophobic properties observed for the intact phospholipase. These results suggest that the active site of the phospholipase projects from the luminal surface of the membrane vesicles. In support of this, phospholipase activity towards exogenous, detergent-solubilized phosphatidylcholine was demonstrated under conditions in which the membranes remained intact. We conclude that the phospholipase B has the characteristics of a stalked, brush-border membrane protein and may be considered as another digestive enzyme anchored in this membrane. *Lipids 24,* 357-362 (1989).

The intestinal brush-border membrane is characterized by the presence of several stalked membrane proteins that project from the membrane surface into the intestinal lumen (1-4). These proteins, often dimeric in structure, are hydrolytic enzymes capable of splitting peptide, glycoside or ester bonds, thereby converting complex macromolecules into lower-molecular-weight components prior to their absorption from the gut. They are stalked proteins in that most of their mass, including their active sites, is not in direct contact with the membrane; anchorage to the membrane is accomplished via small hydrophobic segments, generally comprising only 3-6% of the total protein, and which are connected to the main protein mass by polypeptide stalks. These enzymes are intrinsic membrane proteins in that detergents are necessary for their solubilization. However, many can also be released from the membrane by protease digestion (usually with papain or elastase) of the stalk region. Perhaps the best characterized of these proteins is the sucrase-isomaltase complex (4) which comprises approximately 10% of the total brush-border membrane protein and has been recently cloned (5).

We have previously shown that purified brush-border membrane vesicles from rat jejuna contain membrane-bound phospholipase A_2 and lysophospholipase activities (6,7). The A_2 activity is Ca^{2+}-independent, maximally active at pH 8-11, and specifically stimulated by bile-salt detergents. The lysophospholipase activity is also Ca^{2+}-independent, but is only minimally activated by bile salts. Based on competition experiments, we proposed that a single active site was responsible for both activities (i.e., phospholipase B) (7). It has been suggested (8,9) that a phospholipase in the brush-border membrane may play a role in digestion of dietary phospholipids. In order to further characterize this protein, we have attempted to identify the size and location of the enzyme within the brush border. This study shows that both enzymatic activities are associated with a protein having a relative molecular mass of ca. 170 kDa which is located on the luminal surface of the membrane. This phospholipase B conforms with the general model of a stalked membrane protein and may, therefore, be considered as another digestive enzyme associated with this membrane. An abstract has appeared (10).

MATERIALS AND METHODS

Materials. Papain (from *Papaya carica*) and Triton X-114 (purified for membrane research) were obtained from Boehringer Mannheim Canada Ltd. (Dorval, Que.). Phenyl-Sepharose CL-4B and Sephacryl S-300 were purchased from Pharmacia (Canada) Ltd. (Dorval). Aquacide II was from Calbiochem-Behring Corp. (San Diego, CA). Lysopalmitoylphosphatidylcholine, L-1-[palmitoyl-1-^{14}C] (55 mCi/mmol), was obtained from New England Nuclear/Dupont Canada Inc. (Lachine, Que.). All other materials were as previously described (6,7) or were of reagent grade or better quality.

Brush-border membrane preparation. Brush-border membrane vesicles were purified 25-30-fold from rat jejunal scrapings as described (6). Membranes were suspended, at a concentration of 1-2 mg protein/ml, in 50 mM mannitol/2 mM Hepes (pH 7.1) and stored at −30°C. All experiments were done with samples stored for less than one week.

Phospholipase assays. Phospholipase A_2 and lysophospholipase activities were assayed as previously described (7) using egg yolk phosphatidylcholine mixed with tracer amounts of 1-palmitoyl-2-[1-^{14}C]oleoyl-*sn*-glycerol-3-phosphorylcholine, and using *sn*-1-acyl-lysophosphatidylcholine mixed with tracer quantities of 1-[1-^{14}C]-palmitoyl-*sn*-glycerol-3-phosphorylcholine, respectively. The labeled phosphatidylcholine was diluted to ca. 130 cpm/nmol. Unlabeled *sn*-1-acyl-lysophosphatidylcholine

Abbreviations: BCA, bicinchoninic acid; CHAPS, 3-[(cholamidopropyl)-dimethylammonio]-1-propanesulphonate; DTT, dithiothreitol; EDTA, ethylenediaminetetraacetate (disodium); Hepes, 4-(2-hydroxyethyl)-1-piperazineethanesulphonic acid; PBS, phosphate buffered saline; SDS, sodium dodecyl sulphate; Tris, 2-amino-2-hydroxymethylpropane-1,3-diol.

was prepared from egg yolk phosphatidylcholine (7) and mixed with the palmitate-labeled material to yield ca. 130 cpm/nmol. All assays were done in the presence of 1% CHAPS detergent. The phospholipase activity of intact brush-border membrane vesicles was also measured. For this purpose membranes (300 μg protein) were incubated in 7 mM taurocholate/1 mM labeled phosphatidylcholine mixed micelles (1 ml final volume in 20 mM Hepes, pH 7.2), prepared as described by Child and Kuksis (11). Following 15 min at 37°C the membranes were separated from the aqueous solution by centrifugation at 15,000 × *g* for 30 min in an Eppendorf microcentrifuge (Brinkman Instruments Ltd., Toronto). The resulting supernatant was removed and free fatty acids were extracted and quantitated (7), whereas the pellet was resuspended and assayed for protein content.

Renaturation of phospholipase activities. Renaturation of proteins separated by SDS-polyacrylamide gel electrophoresis was accomplished essentially as described by Hager and Burgess (12), with the exception that reducing agents were not used in any of the steps and the dilution buffer was modified to contain 0.5% CHAPS. Briefly, aliquots of the membrane vesicles, corresponding to 200 μg total protein, were centrifuged at 15,000 × *g* for 30 min. The resulting pellets were resuspended in 100 μl of nonreducing Laemmli sample buffer (13) containing 10 μg soybean trypsin inhibitor as a low-molecular-weight protective agent, and heated at 95°C for 5 min. Samples were loaded into 8-mm wide lanes and electrophoresed down a 7.5% polyacrylamide slab gel at 8 mA constant current (13). When the dye front reached the bottom of the gel (16–18 hr) the gel was removed and cut lengthwise into two. One-half was stained with Coomassie Blue R-250 (6), whereas the other half was visualized with ice-cold 0.25 M KCl. Individual gel lanes were isolated and cut into 3- to 10-mm pieces which were placed into 13 × 100 mm borosilicate glass tubes, rinsed with H_2O and crushed in 1.5 ml of the SDS-containing elution buffer (−DTT). After 6 hr of elution at room temperature the buffer was removed, a further 1.0 ml was added to the gel pieces, and elution was allowed to continue overnight. The next morning the second gel eluate was combined with the first and the eluted proteins were recovered by acetone precipitation and centrifugation. The acetone precipitate was allowed to dry for 10 min and then dissolved in 40 μl of 6 M guanidine-HCl in the modified dilution buffer (+0.5% CHAPS, −DDT) and allowed to stand at room temperature for 20 min. Following this, 2.0 ml of the modified dilution buffer was added and the samples were left to renature for 2 hr at room temperature. Aliquots (0.2 ml) of each sample were then assayed for phospholipase A_2 and lysophospholipase activities.

Papain digestion. Papain solubilization of brush-border membrane proteins was accomplished using the methods described by Sigrist *et al.* (14). Commercial papain was activated by diluting 100 μl (1 mg protein) of the crystalline suspension with 2.9 ml of 50 mM KH_2PO_4/1 mM EDTA (pH 6.5) containing 5 mM freshly added cysteine hydrochloride, Buffer I, and allowing the mixture to stand for 30 min at room temperature. Prior to digestion, membrane vesicles were pelleted by centrifugation at 15,000 × *g* for 30 min in the microcentrifuge and were resuspended at a concentration of ca. 1 mg protein/ml in Buffer I. Seven volumes of the membranes were mixed with 2 volumes of the activated papain and incubated at 37°C for various time periods. Following incubation, 1 volume of 0.1 M iodoacetamide was added to stop the digestion and the solubilized proteins were separated from the remaining membranes by centrifugation, as previously described.

Gel-filtration chromatography. The solubilized fraction arising from papain digestion of the brush-border membranes from 6 rats was separated from the residual membranes by centrifugation at 27,000 × *g* for 30 min (Sorvall, SS34). The volume of this fraction (20 ml) was reduced to 3–4 ml by placing it in a dialysis bag and surrounding the bag with dry Aquacide II. The concentrated fraction was dialyzed overnight against 500 volumes of PBS (2.7 mM KCl, 1.5 mM KH_2PO_4, 137 mM NaCl, 8 mM Na_2HPO_4, pH 7.4) and then loaded onto a column of Sephacryl S-300 (1.5 × 102 cm) which had been packed and equilibrated in the PBS. The column was eluted with PBS, under gravity flow, at a rate of ca. 10 ml/hr.

Hydrophobic-interaction chromatography. Proteins were solubilized from brush-border membranes by papain digestion, as indicated, or with 2% CHAPS as previously described (7). Aliquots (2 ml, 1.1–1.5 mg protein) of the supernatants obtained following centrifugation were placed into dialysis bags and dialyzed against 500 volumes of 25 mM Tris-HCl (pH 7.8). As a control, one aliquot of the papain solubilized proteins was mixed with CHAPS (final concentration 2%) prior to dialysis. Following dialysis for 1.5 days, the samples were passed over 1-ml columns of phenyl-Sepharose (packed in Pasteur pipets) which had been previously equilibrated in the 25 mM Tris-HCl buffer. Unbound proteins were eluted by washing with a further 5 ml of 25 mM Tris-HCl and then bound proteins were eluted with 10 ml of 1% CHAPS in the same buffer.

Other methods. Brush-border membrane proteins solubilized following extraction with 1% (w/v) Triton X-114 and centrifugaton were subjected to phase separation as described by Bordier (15). Proteins were assayed using the BCA protein assay reagent as previously described (7). Gels to be silver stained were fixed in 40% ethanol–10% acetic acid and rinsed in 10% ethanol (16), before equilibrating overnight in distilled water and staining as described by Morrissey (17), beginning at his step four. The staining reaction was stopped using acetic acid (16). Sucrase was assyed as previously described (6).

RESULTS

Preliminary trials of the protein renaturation procedures described by Hager and Burgess (12) revealed that the brush-border phospholipase activity could be recovered if reducing agents were omitted. Exposing SDS or guanidine-HCl denatured brush-border membrane proteins to 1 mM DTT resulted in a complete absence of activity following renaturation. This effect was specific for the denatured protein as 1 mM DTT caused only a slight (10%) inhibition of phospholipase activity when the native enzyme was assayed in the presence of this reducing agent. Figure 1 shows the region of the gel from which phospholipase A_2 and lysophospholipase activities were recovered following electrophoresis. The two activities comigrated exactly on the gel and also appeared to comigrate with a protein band having a relative molecular

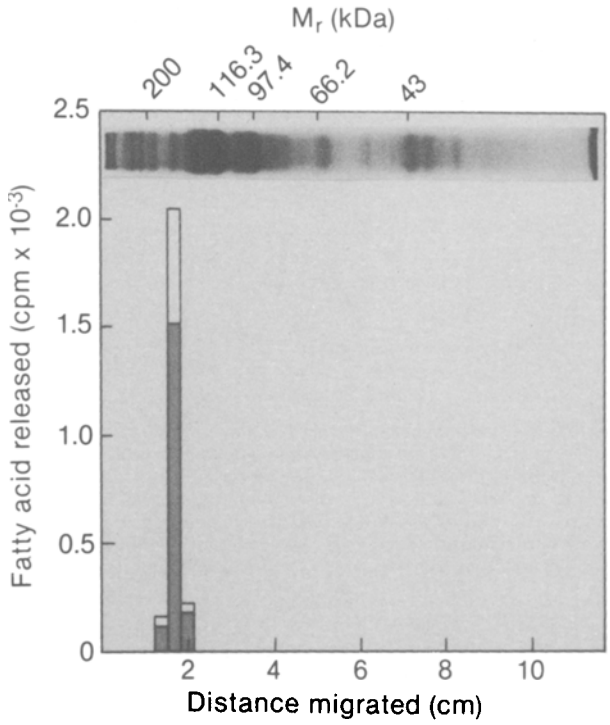

FIG. 1. Location of brush-border membrane phospholipase activity following SDS-polyacrylamide gel electrophoresis. 7.5% gels were run under nonreducing conditions and the separated proteins were eluted, renatured and assayed as described in Materials and Methods. The graph shows the distance migrated by phospholipase A_2 (open bars) and lysophospholipase (shaded bars) activities. Shown at the top of the figure is a corresponding Coomassie Blue-stained lane, aligned with the distance markers on the bottom. The mobilities of molecular weight standards are shown along the top edge of the figure. In this experiment 38% of the total phospholipase activity loaded onto the gel was recovered in the active fractions.

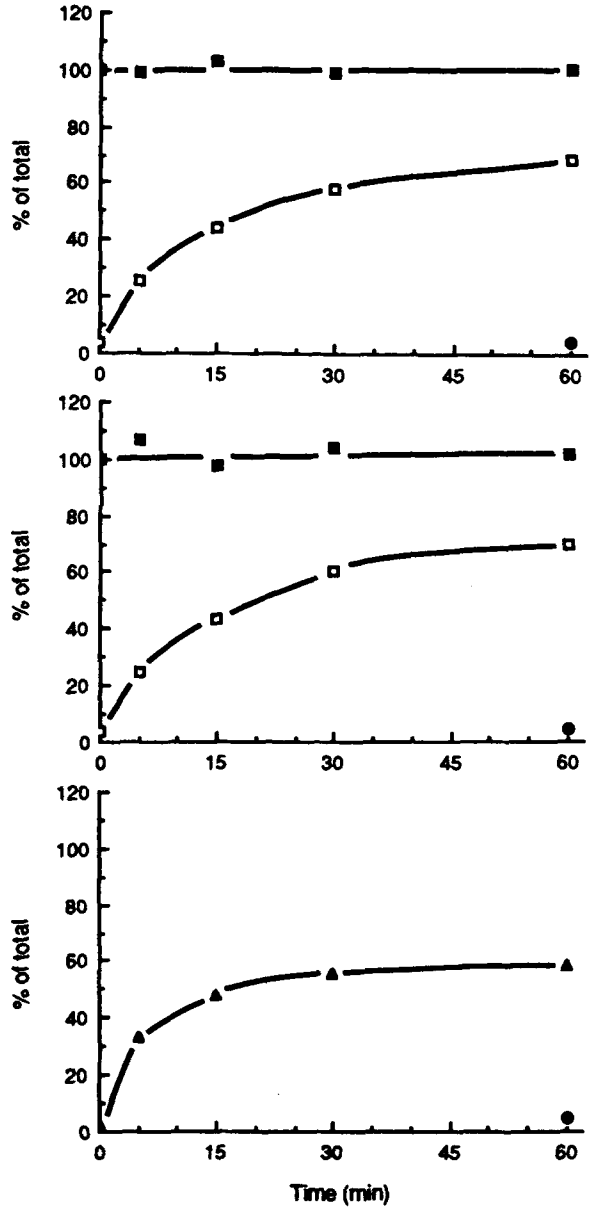

FIG. 2. Solubilization of phospholipase activity and protein by papain digestion of brush-border membrane vesicles. Papain incubation and centrifugal separation of the solubilized and residual membrane components were done as described in Materials and Methods. Phospholipase activities in the soluble and membrane bound fractions and the protein content of the membranes were measured as described in Materials and Methods. The % of total activity remaining (soluble + membrane bound, closed squares) and the % of activity solubilized (open squares) is shown for phospholipase A_2 (top) and lysophospholipase (middle), following papain digestion for 0–60 min. The bottom graph shows the % of total protein solubilized during the same incubations. The closed circle in each graph shows the % of activity (protein) that was solubilized during an incubation in the absence of papain.

mass of 170 kDa. Based on Coomassie Blue staining intensities, this band accounts for ca. 1% of the total brush-border membrane proteins. Although this band appears well separated from most of the others, this analysis does not reveal how many protein components overlap at this position. Our recent results indicate that three distinct proteins migrate with this 170 kDa band (Pind, S. and Kuksis, A., unpublished results). The total enzymatic activities recovered following elution and renaturation consistently corresponded to 25–50% of those loaded onto the gel.

Figure 2 shows that phospholipase A_2 and lysophospholipase activities were solubilized in an identical manner from the brush-border membrane by digestion with papain. Papain was essential for this solubilization as less than 5% of the activities or total protein were released during a 60-min incubation in the absence of this protease. Release of total protein and phospholipase activities was initially rapid but leveled off to a plateau value by 20 (protein) or 30 min (activities). Recovery of the total phospholipase activities (soluble + membrane bound) remained constant throughout the incubations, indicating that the protease was not affecting the enzyme's active site. A papain digestion of 60 min resulted in the solubilization of ca. 70% of both enzyme activities and ca. 60% of the total membrane protein. A 60-min digestion also solubilized 97% of the total sucrase activity. Several previous studies have shown that virtually all of the brush border sucrase activity and from 30–60% of the total membrane proteins are solubilized during papain digestion (18–20), in agreement with our results.

Figure 3 shows that the papain digestion did effect a specific solubilization of the membrane proteins, with

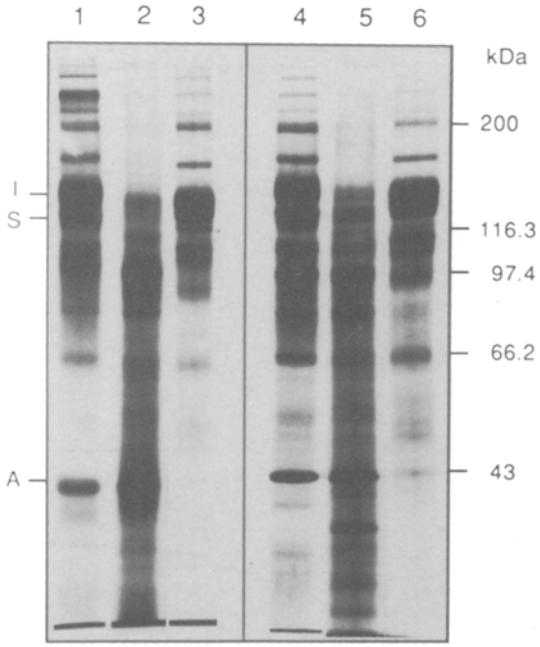

FIG. 3. SDS-polyacrylamide gel analysis of the various fractions resulting from papain digestion. Protein from the intact brush-border membranes (lanes 1 and 4) and the residual membrane (lanes 2 and 5) or the soluble fraction (lanes 3 and 6) obtained following a 60-min papain digestion were electrophoresed under nonreducing (lanes 1-3) or reducing (lanes 4-6) conditions on 7.5% polyacrylamide gels. Bands were visualized by silver staining. The mobilities of molecular weight standards are shown along the righthand margin. I, isomaltase-rich band; S, sucrase-rich band; A, actin-rich band.

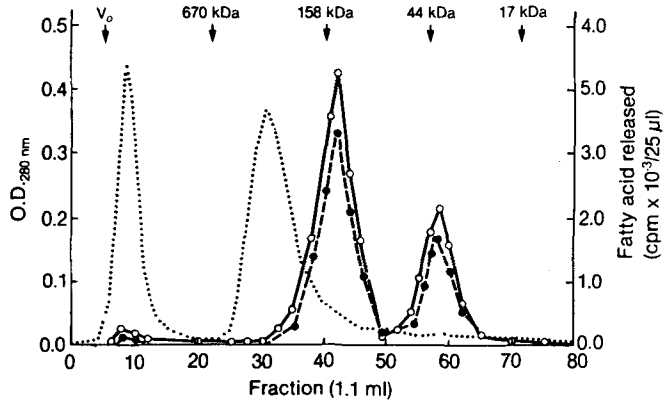

FIG. 4. Gel-filtration profile of the proteins solubilized by a 60-min papain digestion. The solubilized sample was prepared and applied to the Sephacryl S-300 column as described in Materials and Methods. A 55-ml fraction was collected before beginning the 1.1 ml fractions. The elution position of gel-filtration standard proteins (Bio-Rad) are shown along the top edge of the figure. ·····, O.D. 280 nm; O—O, phospholipase A_2 activity; ●—●, lysophospholipase activity.

some bands being retained by the residual membrane (lanes 2 and 5) and others appearing in the soluble fraction (lanes 3 and 6). For example, the band composed primarily of actin, which originates from the interior of the vesicles (3), was not digested with papain and was recovered almost exclusively in the membrane pellet, whereas the isomaltase- and sucrase-rich bands were largely transferred to the supernatant fraction. These bands were identified by their size, the prominence of the respective proteins in the brush-border membrane (1-4), by comparison with published figures (21,22), and with the knowledge that sucrase activity was solubilized by papain. That an intact actin band was observed following papain digestion suggests that the vesicles remained sealed during digestion, in agreement with previous results (20,21). Although the bands were sharper under reducing conditions (lanes 4-6), the protein profiles appeared similar under reducing and nonreducing conditions. The protein profile of the residual membrane fraction is similar to that published by Klip *et al.* (21,22), following papain digestion of rabbit brush-border membranes. These results indicate that the active site of the phospholipase is present on the luminal surface of the vesicles and that a portion of the enzyme containing the active site can be released from the membrane by papain digestion.

Figure 3 also shows that papain digestion solubilized a protein band having an apparent molecular mass of 160-165 kDa, which was similar in abundance to the 170 kDa band in the total membrane fraction. It is not possible, as yet, to definitely assign the solubilized phospholipase as a component of this band. Renaturation experiments were inconclusive as very little total activity was recovered. Gel-filtration chromatography of the proteins released by a 60-min papain digestion showed that the active site of the solubilized phospholipase was associated with two major fragments, having approximate molecular weights of 120 and 35 kDa (Fig. 4). Phospholipase and lysophospholipase activities were found in similar proportions in both of these fragments, again indicating that one active site is responsible for both activities. Following a 2-hr papain digestion, the relative proportion of the 35 kDa fragment increased, suggesting that it was produced from the larger fragment by a further proteolytic step. This result shows that the phospholipase has more than one susceptible site for protease attack during the papain digestion. SDS-polyacrylamide gel analysis of the 120 kDa region of the elution profile in Figure 4 showed that a 160-165 kDa band, among others, was found in this region (not shown).

Papain digestion was shown to reduce the hydrophobicity of the phospholipase by two different criteria. First, more than 75% of the activity in a sample of CHAPS-solubilized and dialyzed brush-border membrane proteins became bound to a hydrophobic column of phenyl-Sepharose during a buffer wash and was eluted only after 1% CHAPS was added to the eluant. In contrast, more than 95% of the phospholipase activity passed through the column during the buffer wash following papain solubilization of the proteins (+/− added CHAPS). Second, during Triton X-114 phase partitioning of the intact membrane proteins, the phospholipase partioned exclusively (>98%) with the detergent phase, whereas following papain digestion, the phospholipase remained (>98%) in the aqueous phase. In both of the above procedures, phospholipase A_2 and lysophospholipase activities were distributed identically. These results indicate that the intact phospholipase possesses a significant hydrophobic character that is lost upon papain solubilization.

To investigate the ability of intact brush-border membranes to hydrolyze exogenous phospholipids, the vesicles were incubated with mixed taurocholate-phosphatidylcholine micelles. These conditions have previously been shown to be nondestructive towards brush border (11) and red blood cell (23) membranes. Furthermore, taurocholate displayed the mildest membrane-solubilizing effect towards the brush border of a number of different surfactants analyzed (7,24). Under the test conditions, the membranes were recovered intact and the incubation resulted in significant hydrolysis of phosphatidylcholine. The specific activity of the phospholipase A_2 hydrolysis was calculated to be ca. 50 nmol/mg protein per min, which is about 40% of that observed under maximal conditions (7). More than 80% of the total protein was recovered in the membrane pellet following incubation.

DISCUSSION

The results presented in this report substantiate and extend our earlier claim (7) that a single brush-border membrane protein possesses both phospholipase A_2 and lysophospholipase activities. The activities were found at the same position and renatured to the same extent following SDS-polyacrylamide gel electrophoresis, were solubilized in an identical fashion by papain digestion, possessed similar amphipathic properties either before or after papain digestion, and coeluted during gel-filtration chromatography. In other studies, we have shown that the phospholipase is retained by a column of Concanavalin A-Sepharose, suggesting that it is a glycoprotein (Pind, S. and Kuksis, A., unpublished data). Our present results further indicate that this protein migrates on nonreducing SDS-polyacylamide gels with an apparent molecular mass of 170 kDa. This size is significantly larger than that of most other intra- or extracellular phospholipases studied to date (25–28), but should be taken as an estimate as many glycoproteins behave anomalously during electrophoresis (29). However, it is also noted that a size of 170 kDa is similar to that determined for several of the other brush-border membrane hydrolases (1,2).

Papain solubilization of phospholipase B activity, combined with the knowledge that papain attacks only the outer, luminal surface of brush-border membrane vesicles (18–20), indicates that the active site projects into the intestinal lumen. It also shows that this phospholipase shares structural similarities with the other brush-border hydrolases and is likely to be a stalked membrane protein. Papain digestion removed the hydrophobic character of the phospholipase, presumably by releasing the nonpolar part which interacts with the membrane bilayer. This hydrophobic part also caused the intact protein to associate with the detergent phase in the Triton X-114 partitioning assay. Tiruppathi *et al.* (30) have shown that many of the brush-border membrane enzymes (alkaline phosphatase, leucine aminopeptidase, γ-glutamyl transpeptidase and Ca^{2+}-Mg^{2+} ATPase) partition into the detergent phase, while several others (glucoamylase, sucrase-isomaltase, trehalase and lactase) remain in the aqueous phase. The phospholipase appears to be most similar to leucine aminopeptidase (aminopeptidase N) and γ-glutamyl transpeptidase in that these enzymes have sufficient hydrophobic character to partition into the Triton detergent phase and are also solubilized from the membrane by papain digestion (1,2).

Although most of the membrane hydrolases are normally resistant to proteolytic digestion following papain solubilization (1,2), it is expected that prolonged digestion would lead to multiple cleavages of a brush-border enzyme, provided that the appropriate susceptible sites were accessible. For example, porcine enterokinase is solubilized from duodenal brush-border membranes with papain, but rapidly loses activity due to further degradation of the solubilized fragment by this protease (31). In addition, aminopeptidase N from porcine intestine (32,33) or kidney (32,34) is converted by a trypsin treatment from a single subunit into two smaller subunits. It appears that the phospholipase has at least two papain susceptible regions; cleavage at one site (the stalk region) releases a large active fragment from the membrane, whereas cleavage at a second site produces a much smaller active fragment. Identifying the location of these cleavages and their resulting products will require more sensitive methods than those presently applied, including an analysis of the action of papain on the purified phospholipase.

Only one other intestinal phospholipase has been studied in detail. A low molecular weight, Ca^{2+}-dependent phospholipase A_2 with a substrate preference for phosphatidylglycerol has been described (35) and purified (36) from pig ileum. This enzyme has subsequently been localized in the Paneth cells and was postulated to be of importance in the digestion of plant and bacterial phospholipids (37). This enzyme is, thus, quite different from the phospholipase B described in the present report.

Although the physiological importance of a brush-border phospholipase B has yet to be determined, this enzyme may assist pancreatic phospholipase A_2 in the digestion of dietary or biliary phospholipids. We have previously shown that the phospholipase can attack endogenous, membrane phosphatidylethanolamine *in vitro* (6) and that the detergent-solubilized enzyme can attack exogenous, detergent-solubilized phospholipids (7). We have now shown that brush-border vesicles can hydroyze exogenous phospholipids in mixed bile-salt micelles, under conditions in which the membrane remains intact. This is consistent with the papain digestion results, predicting a localization of the active site on the luminal surface of the membrane. Numerous studies in animals and humans have shown that luminal phospholipids are hydrolyzed to *sn*-1-acyl-lysophospholipids and free fatty acids prior to their absorption into the enterocyte (38–43). Several of these experiments demonstrated that significant amounts of the resulting lysophospholipids were further hydrolyzed (38–42). Le Kim and Betzing (42) have estimated, on the basis of a test meal in rats, that up to 50% of the phosphatidylcholine was completely hydrolyzed to free fatty acids and glycerophosphocholine or its hydrolysis products. The brush-border phospholipase B has the ability to remove both acyl groups from luminal phospholipids. We have shown that the lysophospholipase activity predominates in the absence of detergent, whereas in the presence of bile salts, the normal luminal detergents, diacyl- and lysophospholipids compete for hydrolysis (7). At any given instant, phospholipase activity would then be determined by the bile-salt concentration and the relative proportions of diacyl- and lysophospholipids which reach the luminal surface of the

brush-border membrane. This membrane is, thus, well equipped to digest luminal lipids, as it also contains enzymes that hydrolyze glycosylceramides (44), sphingomyelin (45) and ceramides (45). The recognition that two enzyme activities are associated with a single, 170 kDa protein ought to facilitate purification of this phospholipase to homogeneity.

[Received September 14, 1988; Revision accepted January 9, 1989]

1-*O*-Alk-1′-enyl-2-acyl and 1-*O*-Alkyl-2-acyl Glycerophospholipids in White Muscle of Bonito *Euthynnus pelamis* (Linnaeus)

Toshiaki Ohshima*, Shun Wada and **Chiaki Koizumi**
Department of Food Science and Technology, The Tokyo University of Fisheries, Konan 4, Minato-ku, Tokyo 108, Japan

The existence of ether-linked phospholipids, including 1-*O*-alk-1′-enyl-2-acyl and 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholines and ethanolamines, in bonito *Euthynnus pelamis* (Linnaeus) white muscle, was investigated by gas chromatography and gas chromatography–mass spectrometry. Chemical ionization (*iso*-butane) mass spectrometry of trimethylsilyl ethers derived from the corresponding ether-linked glycerophospholipids proved effective not only for determining molecular weights but also for structural identification based on the ions $[M - R]^+$, $[M - RO]^+$ and $[M + 1]^+$. 1-*O*-Alk-1′-enyl-2-acyl-*sn*-glycero-3-phosphocholine and ethanolamine accounted for 3.0–6.0% and 3.6–7.6% of the total glycerophospholipids, respectively. 1-*O*-Alkyl-2-acyl-*sn*-glycero-3-phosphocholine and ethanolamine were also determined for one fish and accounted for 1.4% and 0.6% of the total glycerophospholipids, respectively. The predominant long chains in the *sn*-1 position of the glycerol moieties were 16:0, 18:0 and 18:1 in the case of the alkenylacyl and alkylacyl components. Fatty acid distribution of individual glycerophospholipids was also determined.
Lipids 24, 363–370 (1989).

Ether linked phospholipids, including 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholine and ethanolamine and 1-*O*-alk-1′-enyl-2-acyl-*sn*-glycero-3-phosphocholine and ethanolamine (plasmalogens), occur in various species of marine organisms (1–3). Lewis reported on the alkyl chain composition of total phospholipids of anchovy, shrimp and squid (4). Marine worms (5), abalone (6), sponges (7) and starfish (8) also contain a significant amount of plasmalogen. The gills of crustaceans such as crayfish and lobster, and the body lipids of certain species of crab, mussel, oyster and scallop are rich sources of plasmalogen (9–12). Goldfish brain (13) and garfish olfactory nervous systems (14) are well known to contain alk-1′-enylacyl glycerophospholipids as choline and ethanolamine analogues of the better-known diacyl glycerophospholipids, although their biological significance is not well understood (15). There is little information on ether-linked phospholipids in fish muscle; the presence of plasmalogen was confirmed in South African pilchard flesh by a positive Schiff reaction (16). The occurrence of plasmalogen has also been reported in carp muscle mitochondria (17), rock trout, saury, sardine, codfish (18) and dogfish (19).

In the present study, ether-linked phospholipids of fish muscle were investigated and found to be present in bonito white muscle at a relatively high level. Identification of 1-*O*-alkylacyl and 1-*O*-alk-1′-enylacyl glycerophospholipids of bonito were carried out by gas liquid chromatography (GLC) combined with chemical ionization (CI) mass spectrometry (MS) of the corresponding trimethylsilyl (TMS) ether derivatives.

MATERIALS AND METHODS

Standard materials. Bovine heart ethanolamine plasmalogen and 1-palmityl glyceryl ether were purchased from Serdary Research Laboratories (London, Ontario, Canada).

Lipid extraction and fractionation. White muscle lipid of bonito, *Euthynnus pelamis* (Linnaeus), was extracted with chloroform/methanol according to the Bligh and Dyer procedure (20). The phospholipid fraction was separated from other lipids by column chromatography on Bio-Beads S-X2, using benzene as eluent (21).

Quantitation of phospholipid species. Phospholipid classes were separated from each other by two-dimensional thin-layer chromatography (TLC) on precoated Silica Gel G plates (0.25 mm thickness, Merck Japan Ltd., Tokyo) using the solvent system chloroform/methanol/water/acetic acid (65:35:2:1, v/v/v/v) in the first direction and chloroform/methanol/water (60:30:8, v/v/v) in the second direction. The spots corresponding to phospholipids were visualized by exposing the plates to iodine vapor and were each scraped off. The phospholipids were extracted from the silica gel with chloroform/methanol (2:1, v/v). Phosphorus content was determined spectrophotometrically according to the method of Bartlett (22). The ratios of 1-*O*-alkyl-2-acyl vs 1,2-diacyl compounds were estimated by measuring total fatty acids, using 13:0 methyl ester as internal standard (23).

Mild acid hydrolysis and Iatroscan thin-layer chromatography. An aliquot of a chloroform solution of the phospholipid class was evaporated to dryness in a round-bottomed flask, which was then placed in a glass tank saturated with hydrochloric acid fumes for 5 min at room temperature (24). After removal of hydrochloric acid by flushing with a nitrogen stream, the acid-hydrolyzed phospholipid in the flask was subjected to Iatroscan TLC on Chromarods S-II (Dia-Iatron Co., Tokyo, Japan) using a double development technique in the same direction with acetone first to move neutral lipids and then a mixture of chloroform/methanol/acetic acid/water to resolve polar lipids (25).

Lipid derivatization. Phospholipids were reduced with Vitride reagent (Tokyo Kasei Co., Ltd., Tokyo, Japan) to the corresponding 1-alk-1′-enyl or 1-alkyl *sn*-glycerols (26). 1-*O*-Alkyl and 1-*O*-alk-1′-enyl glycerols were separated from each other by TLC on Silica Gel G (diethyl ether/ammonia, 100:0.25, v/v) and extracted from the silica gel with chloroform/methanol (1:2, v/v). Treatment with a mixture of hexamethyldisilazane and trimethylchlorosilane in dry pyridine produced the TMS ether derivatives (27).

Dimethylacetal (DMA) derivatives of long chain aldehydes, which were liberated from the corresponding

alkenylacyl phospholipids by the mild acid hydrolysis mentioned above, were prepared by heating the aldehydes under reflux with 5% methanolic hydrogen chloride (28).

Determination of 1-O-alkyl-2-acyl, 1-O-alkenyl-2-acyl, and 1,2-diacyl chain distribution. The individual phospholipid classes were analyzed according to Mueller *et al.* (29). Our preliminary examination showed that iodine vapor used for visualizing the spots on the TLC plate could cause decomposition of the alkenylacyl phospholipids. Therefore, 2′,7′-dichlorofluorescein in ethanol was used for detection of the samples prepared for the analysis of fatty chain distribution. The purified choline and ethanolamine glycerophospholipid fractions were treated with phospholipase C (Boehringer Mannheim GmbH-Yamanouchi, Tokyo, Japan) to yield diradyl glycerols (30). The products were then acetylated (31) to the corresponding 1-*O*-alkyl-2-acyl-3-acetylglycerol, 1-*O*-alk-1′-enyl-2-acyl-3-acetylglycerol and 1,2-diacyl-3-acetylglycerol. These three acetylglycerols thus obtained were separated from each other by preparative TLC on Silica Gel G using the solvent system of petroleum ether/diethyl ether/acetic acid (90:10:1, v/v/v). The purified acetyl glycerols were saponified individually with 1 N KOH in ethanol at 85°C for one hr. Unsaponifiable matter (1-*O*-alkylglycerol or 1-*O*-alk-1′-enylglycerol) was extracted by *n*-hexane and converted to the corresponding TMS ether derivatives as mentioned above to analyze the aliphatic chain distribution in the *sn*-1 position of the glycerol moiety. The fatty acid compositions in the *sn*-1 and *sn*-2 positions of 1,2-diacyl glycerophospholipid and in the *sn*-2 position of ether-linked glycerophospholipids were analyzed as their methyl esters by GLC as mentioned below.

Gas liquid chromatography and gas chromatography-mass spectrometry (GC-MS). TMS ether derivatives of 1-*O*-alkylglycerol and 1-*O*-alk-1′-enylglycerol were analyzed by GC using a Shimadzu GC 12A instrument (Kyoto, Japan) equipped with a Supelcowax-10 fused silica open tubular capillary column (30 m × 0.25 mm i.d., Supelco Japan Ltd., Tokyo) and a Shimadzu CLH 702 split injector. The injector and the column were held at 250 and 210°C, respectively, the split ratio was 1:60, and helium was used as carrier gas at a constant inlet pressure of 1.2 Kg/cm^2.

Analysis of fatty acid methyl esters was performed on a Shimadzu GC 8APF gas chromatograph with a Chromatopack CR6A data processor. The conditions were similar to those of the TMS ether derivatives analysis, except that the column temperature was at 195°C.

Mass spectrometric analysis of the TMS ether derivatives was carried out on a Shimadzu GC-MS 9020 DF mass spectrometer fitted with a CI source to which an outlet of Supelcowax-10 column (30 m × 0.25 mm i.d.) was connected directly. The column and a Shimadzu movable on-column injector were kept isothermally at 220 and 300°C, respectively. Data acquisitional processing was carried out by an on-line Shimadzu GC-MS PAC 1100 data system. The sample, which was separated by GLC, was ionized in the CI mode by adding *iso*-butane as a reagent gas into the ion source at a pressure of about 1 Torr, using 200 eV electron beam energy, 200 μA emission current, 3 KV acceleration voltage and a source temperature of 250°C.

Electron impact (EI) mass spectra of DMA derivatives of long chain aldehydes were obtained by a Shimadzu QP 1000 quadrupole mass spectrometer with a Supelcowax-10 column (30 m × 0.25 mm i.d.), under the conditions of 70 eV electron beam energy, 3 KV acceleration energy and a source temperature of 250°C.

RESULTS AND DISCUSSION

Iatroscan TLC-flame ionization detection analyses of acid-labile phospholipid. Separations of bonito white muscle phospholipids before and after mild acid hydrolysis are compared in Figure 1. The phospholipid before acid hydrolysis showed four well-resolved peaks corresponding to choline and ethanolamine glycerophospholipids (abbreviated as CPG and EPG respectively, in Fig. 1) and lysoglycerophospholipids (LPC and LPE in the figure); the peak ascribed to LPC was larger than that of CPG and the peak ascribed to LPE was smaller than that of EPG, as had been reported previously (32,33). After mild acid hydrolysis, the peaks of LPC and LPE were large, compared with those of CPG and EPG, respectively, and a moderate peak was found in the highest moving band on the Chromarod S-II. The highest peak in Rf was consistent with that of long chain aldehydes. These changes clearly indicate that the EPG and CPG in the phospholipids were hydrolyzed with hydrochloric acid into LPE, LPC and LCA, respectively. It is well accepted that an ether bond in the alk-1′-enyl group is acid-labile, and that phospholipids having such chemical bonds are readily hydrolyzed into lysophospholipids and LCA under mild acidic condition such as saturated hydrochloric acid fumes (8). Therefore, the LPE and LPC that were produced on mild acid hydrolysis seemed to indicate the existence of alk-1-enyl ether bonds in the precursor lipid classes, EPG and CPG, of bonito white muscle phospholipids. These observations correspond well with the results of Foot and Clandinin, in which they separated those hydrolysis products of acid-labile phospholipids by Iatroscan TLC-flame ionization detection (FID) on Chromarod S-II (34).

Identification of ether-linked glycerophospholipids. Gas chromatograms of 1-*O*-alk-1′-enyl-2,3-TMS ether glycerols

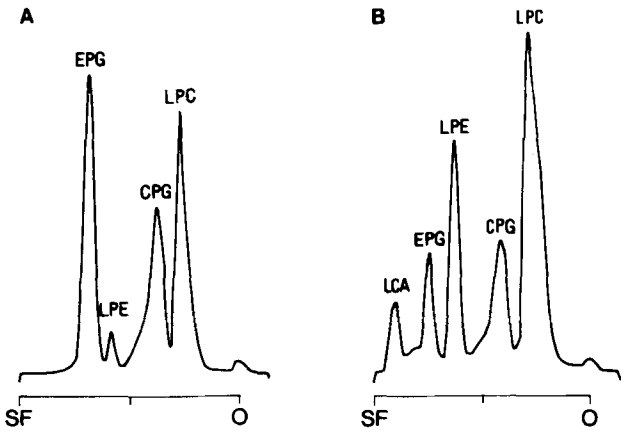

FIG. 1. Iatroscan TLC-FID chromatograms of the phospholipids of bonito white muscle before (A) and after (B) mild acidic hydrolysis. EPG, ethanolamine glycerophospholipid; LPE, lysoethanolamine glycerophospholipid; CPG, choline glycerophospholipid; LPC, lyso choline glycerophospholipid; LCA, long chain aldehyde; O, origin; SF, solvent front.

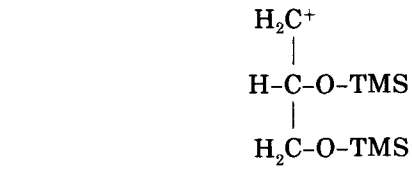
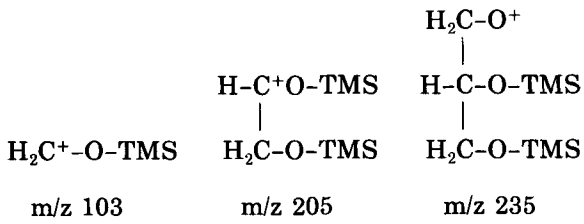
derived from a commercially available bovine heart ethanolamine plasmalogen (authentic), a laboratory-prepared bovine heart phospholipid, and a bonito white muscle phospholipid are shown in Figure 2 (A, B and C, respectively). Wood and Snyder reported that TMS ether derivatives of alkyl glycerol were successfully separated by GLC on a polar liquid phase column such as diethyleneglycol succinate polyester (35). Therefore, a Supelcowax-10 column, similar to a DEGS column in polarity of liquid phase, was used in the present study. In all samples, well resolved peaks were obtained on chromatograms: 6, 13 and 13 peaks in the authentic plasmalogen standard, bovine heart and bonito white muscle phospholipids, respectively. The CI spectrum of the most prominent peak of the authentic plasmalogen standard (No. 8 in Fig. 2A) was determined and is illustrated in Figure 3A. The spectrum showed a base peak at m/z 219 which indicates formation of the following ion by cleavage of alk-1′-enyl group from the glycerol moiety:



The relatively intense fragment peaks at m/z 103, m/z 205 and m/z 235 in Figure 3A strongly suggest that the following fragments, from the glycerol backbones in the TMS ether derivatives, are produced:



The peak at m/z 459 was considered attributable to $[M + 1]^+$, indicating the TMS ether derivative to have

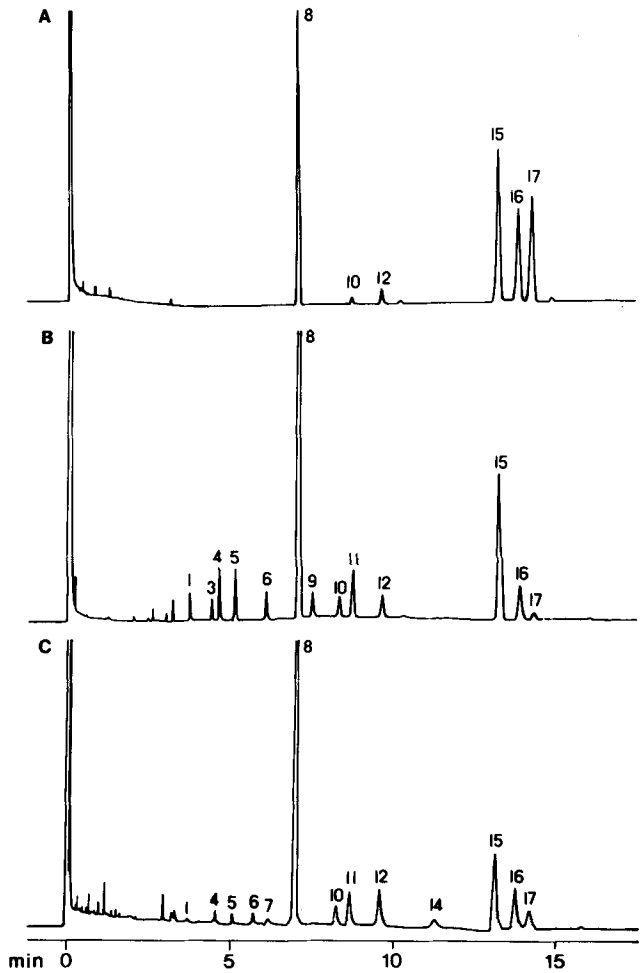


FIG. 2. GC analyses of the 2,3-TMS ether of 1-*O*-alk-1′-enyl-glycerols from (A) bovine heart muscle ethanolamine plasmalogen (authentic), (B) bovine heart muscle phospholipids (prepared in this laboratory) and (C) bonito white muscle phospholipids. See the text for peak components. Supelcowax-10 FQ column, 25 m × 0.25 mm i.d. and operated at 210°C, with helium as carrier gas.

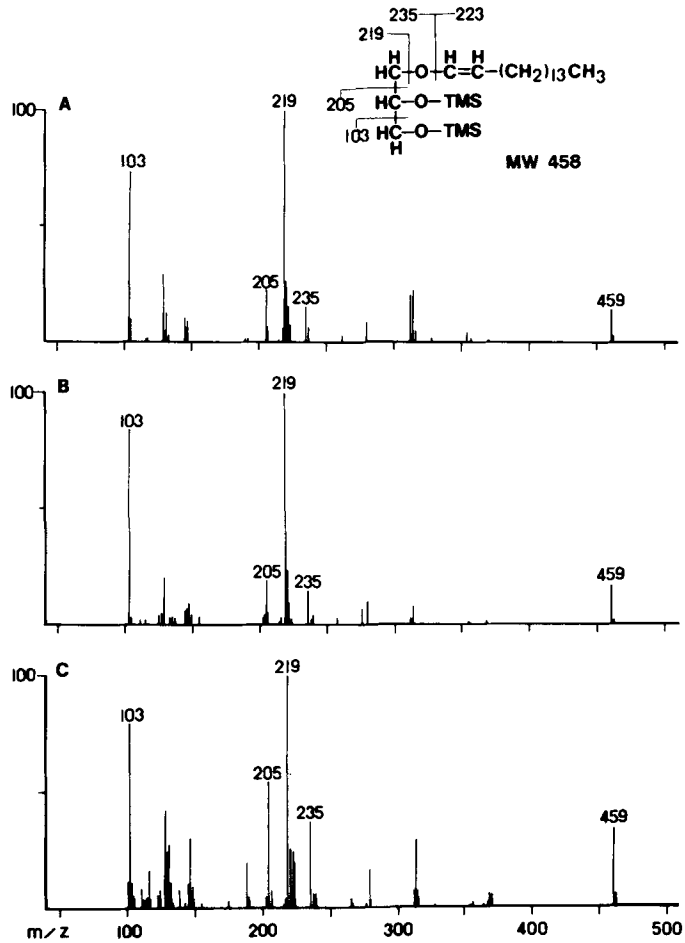

FIG. 3. CI (*iso*-butane) mass spectra of the predominant 2,3-TMS ethers of 1-*O*-alk-1′-enyl-glycerols derived from (A) bovine heart muscle ethanolamine plasmalogen (authentic), (B) bovine heart muscle phospholipids (prepared in this laboratory) and (C) bonito white muscle phospholipids. 200 eV electron beam energy, 200 μA emission current, 3 KV accelerating voltage, and source temperature of 250°C.

a molecular weight of 458. The characteristic fragmentation shown in Figure 3A definitely suggests that, in the TMS ether derivative, a hexadecenyl ether group is linked to the glycerol moiety.

Each TMS ether derivative prepared from the bovine heart phospholipid (Fig. 2B) and the bonito white muscle phospholipid (Fig. 2C) presented similar chromatographic patterns, although the former lacked peaks No. 7 and No. 14, while the latter lacked peaks No. 3 and No. 9. Of those peaks on the chromatograms, retention times (Rt) of the peaks of No. 8, 10, 12, 15, 16 and 17 were consistent with those on the chromatogram of the authentic plasmalogen standard (Fig. 2A). The CI mass spectra of three peaks numbered 8 closely corresponded to one another, as shown in Figure 3 (A, B and C).

The mass spectra in Figure 3 (A, B and C), however, did not show any specific fragment ions which offered information concerning a location of the double bond on the hexadecenyl ether group. In order to clarify this point, the alkenyl group on the glycerophospholipid was completely hydrolyzed to the corresponding LCA under mild acid conditions (8), and the chain structure of the DMA derivatives of the LCA thus obtained was explored by EI-MS.

Figures 4A and 4B show the gas chromatogram of the DMA derivatives of the LCA prepared from the bonito phospholipid by mild acid hydrolysis and the EI mass spectrum of peak No. 8 of Figure 4A, respectively. The spectrum yielded characteristic ions of $[M - 31]^+$ (due to the loss of methoxy group from the parent ion) and of m/z 75 (due to $[CH(OCH_3)_2]^+$) which usually appear in EI spectra of DMA derivatives (36). From these results, it is obvious that the predominant LCA has a structure of $CH_3(CH_2)_{14}CHO$, which is liberated with acid hydrolysis from the 1-*O*-alk-1′enyl group of plasmalogen prepared from the bonito phospholipid. In addition to this, the difference in mass number units between molecular ion and m/z 235 ion, i.e. $(M^+ - 235)$, is proposed to reflect the molecular weight of the alk-1′-enyl group; in the case of 1-*O*-alk-1′-enyl-2,3-TMS ether glycerol (Fig. 3A), mass number unit $(M^+ - 235)$, i.e. 223 in mass number unit, corresponds to the molecular weight of the ion $[CH{=}CH(CH_2)_{13}CH_3]^+$ (refer to Fig. 3A). On the basis of these results, it is concluded that 1-*O*-alk-1′-enyl glycerophospholipids certainly exist in bonito white muscle. The other components corresponding to the peaks shown in Figures 2A, 2B and 2C were identified in the same manner as follows: 1, 14:0; 3, *iso*-15:0; 4, *anteiso*-15:0; 5, 15:0, 6, *iso*-16:0; 7, *anteiso*-16:0; 9, 16:1; 10, *iso*-17:0; 11, *anteiso*-17:0; 12, 17:0; 14, *iso*-18:0; 15, 18:0; 16, 18:1; 17, 18:1 (abbreviated as carbon number:number of double bonds in the alkenyl group). The peaks numbered 2 and 13 are omitted on the chromatogram, because the alkyl components having the corresponding carbon number and number of double bonds were detected as a result of GLC analysis, as will be mentioned below (Fig. 5B).

Figure 5 compares gas chromatograms of 1-*O*-alkyl-2,3-TMS ether derivatives prepared from an authentic hexadecyl ether glycerol (A) and of bonito white muscle (B). The retention time of the most prominent peak in the chromatogram of the bonito phospholipid was consistent with that of the authentic hexadecyl ether glycerol (Figs. 5A and 5B). The CI mass spectra of these peaks are illustrated in Figure 6. The TMS ether derivatives from the bonito sample yielded m/z 461 ion (base peak) as $[M + 1]^+$, and m/z 205, m/z 219 and m/z 103 ions occurred from their glycerol backbone similarly in the case

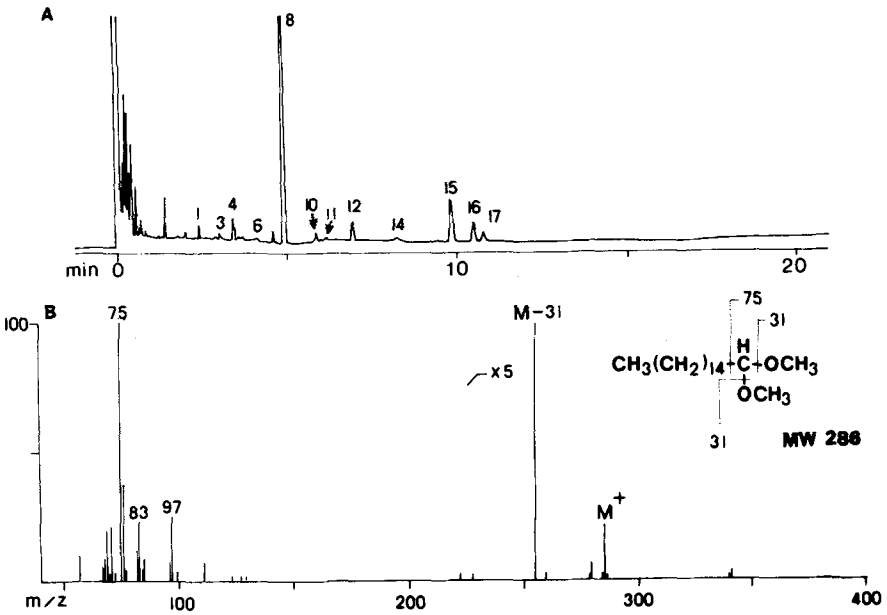

FIG. 4. GC analysis of dimethylacetal derivatives of long chain aldehydes liberated from 1-*O*-alk-1′-enyl-2-acyl glycerophospholipid of bonito white muscle by mild acid hydrolysis (A) and a typical EI mass spectrum of peak No. 8 (B). 1, 14:0; 3, *iso*-15:0; 4, *anteiso*-15:0; 6, *iso*-16:0; 10, *iso*-17:0; 11, *anteiso*-17:0; 12, 17:0; 14, *iso*-18:0; 15, 18:0; 16, 18:1; 17, 18:1. The components of No. 16 and No. 17 are positional isomers. GLC conditions are similar to those of Fig. 2, but column temperature was 195°C.

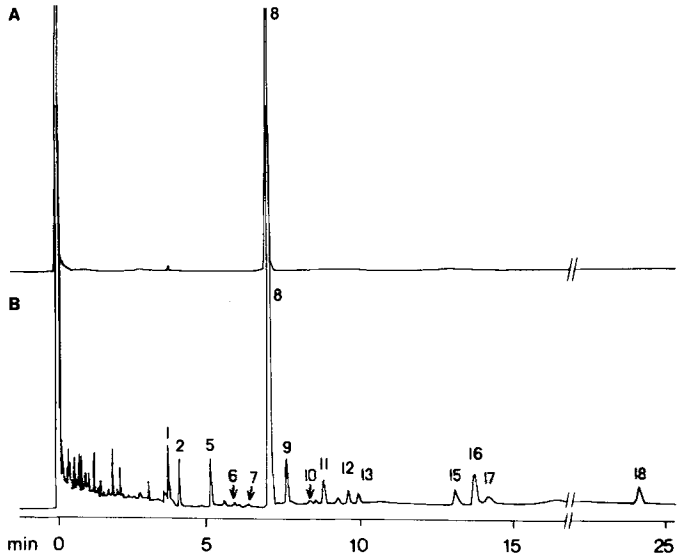

FIG. 5. GLC analyses of the 2,3-TMS ethers of 1-*O*-alkyl-glycerols derived from (A) authentic 1-*O*-hexadecyl glycerol and (B) bonito white muscle phospholipids. The analysis was performed under the conditions given in Fig. 2.

of 1-*O*-alk-1′-enyl-2,3-TMS ether derivatives, which have already been mentioned, although the 1-*O*-alkyl-2,3-TMS ether glycerol derivative did not yield a fragment ion of m/z 235. This fragmentation pattern in CI-MS of the sample prepared from bonito white muscle accorded well with that of authentic hexadecyl ether glycerol which is the component of peak No. 8 in Figure 5A. Similarly, the following results were obtained from the peak components shown in Figure 5B: 1, 14:0; 2, 14:1; 5, 15:0; 6, *iso*-16:0; 7, *anteiso*-16:0; 9, 16:1; 10, *iso*-17:0; 11, *anteiso*-17:0; 12, 17:0; 13, 17:1; 15, 18:0; 16, 18:1; 17, 18:1; 18, 20:0. The peaks numbered 16 and 17 were separated from each other as positional isomers.

Content of ether-linked glycerophospholipids. Table 1 lists the phospholipid composition of bonito white muscle. The total amount of alkylacyl glycerophospholipid and diacyl glycerophospholipid was determined in the fish samples numbered 1 to 5. Only in fish sample No. 6 were the choline and ethanolamine glycerophospholipids isolated separately from other phospholipids by column chromatography on silicic acid (37), and the proportional ratio of 1-*O*-alkyl-2-acyl glycerophospholipid and 1,2-diacyl glycerophospholipid was determined.

In the case of the choline glycerophospholipid, the alk-1′-enylacyl analogue accounted for 3.0–6.0% of the total phospholipid (5.7–11.2% of choline glycerophospholipids). The level of alkylacyl analogue was very low, only 2.4% of choline glycerophospholipids in fish sample No. 6. The most prominent component of the phospholipids seemed to be diacyl, accounting for 91.4% of choline glycerophospholipids of fish sample No. 6. In the case of ethanolamine glycerophospholipids of bonito white muscle, the amount of alk-1′-enylacyl analogue showed considerable variation, accounting for 3.6–7.6% of the

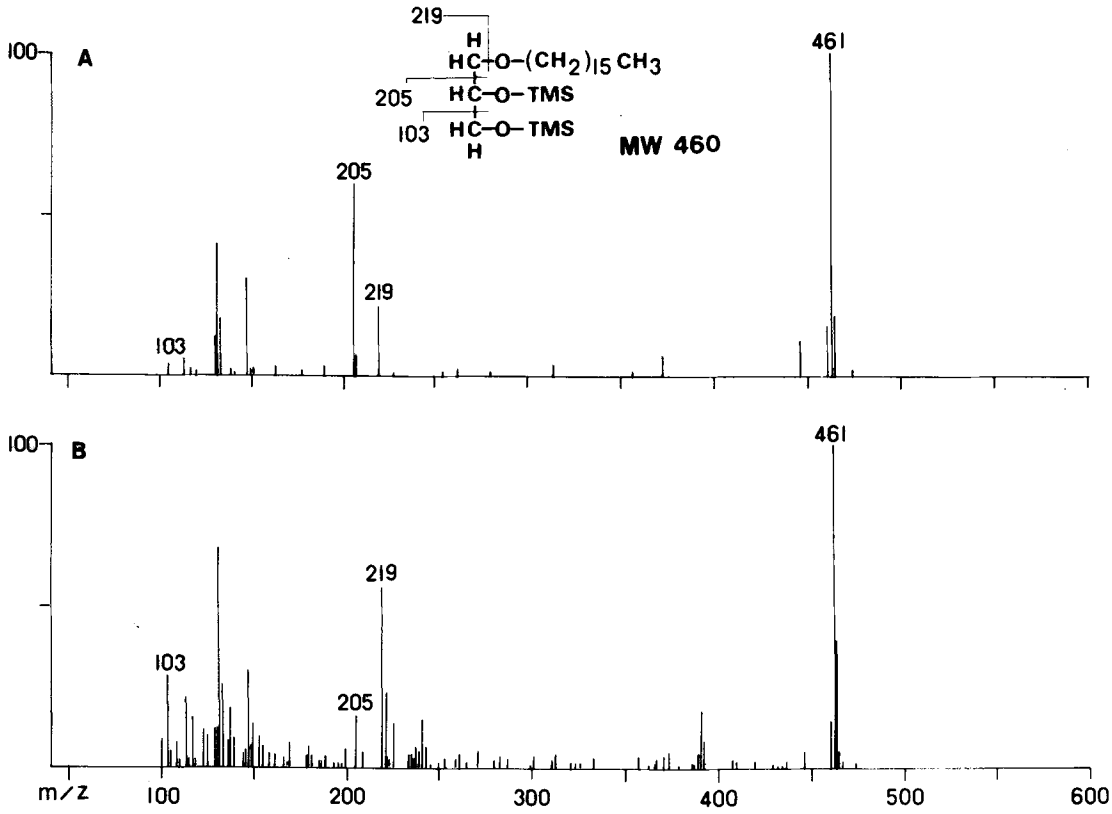

FIG. 6. CI (*iso*-butane) mass spectra of the 2,3-TMS ethers of 1-*O*-alkyl-glycerols derived from (A) authentic 1-*O*-hexadecyl glycerol and (B) bonito white muscle phospholipids. GC–MS conditions are as given in Fig. 3.

TABLE 1

Glycerophospholipid Compositions of Bonito White Muscle (as % of Recovered Phosphorus)

Lipid class	Fish sample 1	2	3	4	5	6
Choline glycerophospholipids	53.2	52.2	46.7	52.1	53.4	57.3

[a]The data are presented as the mean ± standard deviation of three separate determinations done on the purified choline glycerophospholipid of fish No. 6.

[b]The position of double bond applies to fatty acyl chains.

[c]Other fatty acid less than 1% each of the total included 16:4n-3, 16:4n-1, 18:2n-9, 18:2n-7, 18:3n-6, 18:4n-1 and 22:5n-3.

total phospholipid (17.5–32.2% of the ethanolamine glycerophospholipids). The alkylacyl analogue was 0.6% of the total phospholipid (2.5% of the ethanolamine glycerophospholipids) as shown in fish sample No. 6 (Table 1). Of other lipid classes, lysocholineglycerophospholipid accumulated at a relatively high level (6.8 to 14.2% of the total phospholipid). These results obtained by phosphorus analysis were also supported by Iatroscan TLC-FID analysis (Fig. 1). In general, the plasmalogen content in ethanolamine glycerophospholipid is higher than that of the choline analogue. This may be a typical example, since plasmalogens in the gill lipid of two species of Pacific crab, *Cancer antennarius* and *Portanus xantusi*, were found to occur at higher levels in the ethanolamine

[a]The data are presented as the mean ± standard deviation of three separate determinations done on the purified ethanolamine glycerophospholipid of fish No. 6.

[b]The position of double bond applies to fatty acyl chains.

[c]Other fatty acids less than 1% each of the total included 16:4n-3, 16:4n-1, 18:2n-9, 18:2n-7, 18:3n-6, 18:4n-1 and 22:5n-3.

components (38). Also, bonito white muscle was rich in ethanolamine glycerophospholipid compared with choline analogue.

Fatty chain distributions of choline (CPG) and ethanolamine glycerophospholipids (EPG). The fatty chain distribution of CPG in bonito (fish No. 6 in Table 1) white muscle is shown in Table 2. The prominent fatty acids in the *sn*-1 and *sn*-2 positions of 1,2-diacyl CPG were 16:0, 22:6n-3, 18:1n-9 and 20:5n-3, and the percentages of polyunsaturated fatty acids (PUFA) were quite high. For 1-*O*-alkyl-2-acyl GPC, the percentages of saturated alkyl chains such as 16:0 and 14:0 were higher in the *sn*-1 position; in the *sn*-2 position PUFA were predominant. In 1-*O*-alk-1′-enyl-2-acyl CPG, the sum of monounsaturated and saturated aliphatic chains in the *sn*-1 position amounted to over 80%, while PUFA in the *sn*-2 position accounted for more than 48%.

Table 3 shows the chain distributions of EPG in the white muscle of bonito (fish No. 6 in Table 1). The prominent fatty acids of 1,2-diacyl EPG were similar to those of CPG, except that 18:0 in the former was higher, accounting for 34%. The degrees of unsaturation of the alkyl chain in the *sn*-1 position and of the fatty acyl chain in the *sn*-2 position of 1-*O*-alkyl-2-acyl EPG were lower than those of CPG; more than 66% of the alkyl chains were saturated and 22:6n-3 fatty acid amounted to only 9%. For 1-*O*-alk-1′-enyl-2-acyl EPG, the composition of the alkenyl chain in the *sn*-1 position showed a lower degree of unsaturation, although 22:6n-3 accounted for 63% of the fatty acyl chains in the *sn*-2 position. These observations made for the ether-linked glycerophospholipids of bonito white muscle agreed well with previous data on the ether-linked glycerophospholipids of rabbit alveolar macrophages (39), human platelets (23) and murine mastocytoma (40), except that PUFAs such as 22:6n-3 and 20:5n-3 were prominent in the phospholipid classes of bonito white muscle examined here.

In order to identify ether-linked glycerophospholipids, various analytical techniques, such as two-dimensional TLC (8,41), and GLC of DMA (36) and TMS ether derivatives (35), have so far been applied as conventional methods. More recently, Iatroscan TLC-FID combined with a mild acid hydrolysis procedure (34), GLC (42) and high-performance liquid chromatography (43) of *tert*-BDMS ether derivatives and fast atom bombardment mass spectrometry without any derivatization of the phospholipid (44) have been used successfully. Of these techniques, EI mass spectra of *tert*-BDMS ether derivatives, which are prepared from ether-linked glycerophospholipids, provide information concerning their molecular weights by yielding a $[M - 57]^+$ ion, differing from those of the corresponding TMS ether derivatives (42). On the other hand, the proposed CI-MS technique of TMS ether derivatives, which are prepared from ether-linked glycerophospholipids, seems to be effective not only for determining molecular weights but also for obtaining structural information on ether-linked glycerophospholipids.

In conclusion, the occurrence of novel ether-linked glycerophospholipids has been confirmed in bonito white muscle. Recent interest in the unique physiological and biological properties of 1-*O*-alkyl-2-acetyl glycerophospho-

cholines as the platelet-activating factor (23,40,45-48) also suggests a need for further studies on the molecular species of marine lipids.

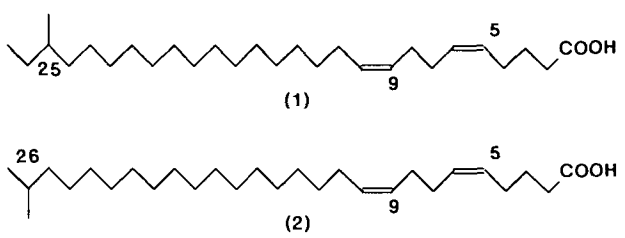
[Received February 8, 1988; Revision accepted December 12, 1988]

New Phospholipid Fatty Acids from the Caribbean Sponge *Ectyoplasia ferox*

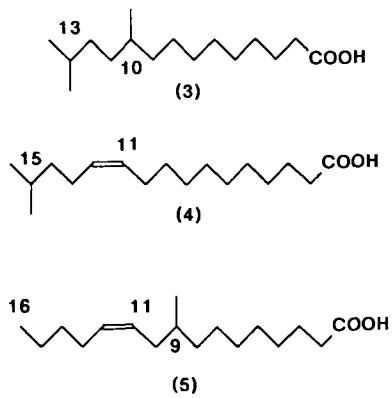
Néstor M. Carballeira* and **Maria E. Maldonado**
Department of Chemistry, University of Puerto Rico, Rio Piedras, Puerto Rico 00931

The phospholipid fatty acids from the Caribbean sponge *Ectyoplasia ferox* were studied. The novel fatty acids 25-methyl-5,9-heptacosadienoic (1) and 26-methyl-5,9-heptacosadienoic (2) were identified in 3.4 and 2.0% abundance, respectively, representing the longest set of Δ5,9 *iso* and *anteiso* acids yet isolated from a marine sponge. The new acid 10,13-dimethyltetradecanoic (3), the unusual acid 15-methyl-11-hexadecenoic (4) and the also novel acid 9-methyl-11-hexadecenoic (5) were also identified in *E. ferox*. The principal sterols isolated from *E. ferox* were 24-ethylcholest-5-en-3β-ol (46%) and 24(R)-methylcholesta-5,22-dien-3β-ol (14%).
***Lipids 24,* 371-374 (1989).**

It is now well established that the phospholipids of marine sponges are a rich source of structurally unusual and interesting fatty acids. Common phospholipid fatty acids from marine sponges include 5,9-hexacosadienoic (26:2), which occurs in most known sponges as described originally by Litchfield and coworkers (1), 5,9-heptacosadienoic (27:2) and 5,9-octacosadienoic (28:2). However, there are other very long chain phospholipid fatty acids that have been encountered recently in several species. For example, work by Ayanoglu et al. (2) with the sponge *Petrosia ficiformis* revealed the presence of the unusual phospholipid fatty acids 25-methyl-5,9-hexacosadienoic and 24-methyl-5,9-hexacosadienoic, interesting cases of *iso* and *anteiso* terminal methyl branching in these so called "demospongic" acids. The Australian sponge *Jaspis stellifera* has also been shown to contain the same 27:2 *iso* and *anteiso* acids (3). However, in the sponges analyzed to date, the only reported cases of terminal *iso* and *anteiso* branching are those of the 26:2 and 27:2 series. In our search for similar acids in Caribbean sponges around Puerto Rico we have found that the sponge *Ectyoplasia ferox* contains the 28:2 series of the hitherto undescribed very long chain phospholipid fatty acids 25-methyl-5,9-heptacosadienoic (1) and 26-methyl-5,9-heptacosadienoic (2), which now represents the longest set of Δ5,9 *iso* and *anteiso* phospholipid fatty acids from any marine sponge. We also wish to report in this work the isolation of the new acid 10,13-dimethyltetradecanoic (3), the acid 15-methyl-11-hexadecenoic (4) and the also novel acid 9-methyl-11-hexadecenoic (5). Herein we report the results of our investigation.



SCHEME 1



SCHEME 2

EXPERIMENTAL PROCEDURES

Ectyoplasia ferox was collected May 3, 1988 near La Parguera, Puerto Rico. The sponge was washed in sea water, carefully cleaned of all nonsponge debris and cut into small pieces. Immediate extraction with chloroform/methanol (1:1, v/v) yielded the total lipids. The neutral lipids, glycolipids and phospholipids were separated by column chromatography on ammonium hydroxide-treated silicic acid (100-200 mesh) using the procedure of Privett et al. (4). The phospholipid classes were investigated by preparative thin-layer chromatography (TLC) using silica gel and chloroform-methanol-water (65:25:4, v/v/v) as solvent. The fatty acyl components of the phospholipids were obtained as their methyl esters by reaction of the phospholipids with methanolic hydrogen chloride (5) followed by purification on column chromatography eluting with hexane/ether (9:1, v/v). The resulting methyl esters were analyzed by gas chromatography-mass spectrometry (GC-MS) using a Hewlett Packard 5995 A gas chromatograph-mass spectrometer equipped with a 30-m × 0.32-mm fused silica column coated with SE-54. For the location of double bonds, N-acylpyrrolidide derivatives were prepared by direct treatment of the methyl esters with pyrrolidine/acetic acid (10:1, v/v) in a capped vial (1 hr at 100°C) followed by ethereal extraction from the acidified solution and purification by preparative layer chromatography (PLC). Hydrogenations were carried out in 10 ml of absolute methanol and catalytic amounts of platinum oxide (PtO_2). Mass spectral data of key fatty acids for this discussion are presented below.

10,13-Dimethyltetradecanoic acid methyl ester. MS m/z (rel intensity) 270 (M^+, 7), 256 (4), 227 (6), 213 (2), 199 (7),

RESULTS

The phospholipid fatty acids isolated from *Ectyoplasia ferox* are shown in Table 1. The fatty acid mixture presented a rather unusual series of highly branched-unsaturated acids. One acid that occurred in big amounts (10.6%) was 4,8,12-trimethyltridecanoic (16:0), an acid that has been encountered before in several sponges and was easily characterized by its typical mass spectrum (6). Much to our surprise, we also encountered a second highly branched acid that has not been identified before in any marine sponge, namely the new acid 10,13-dimethyltetradecanoic (3). The multiple methyl substitution in the latter acid was evidenced by a low ECL value of 15.05 for its fatty acid methyl ester but the methyl group positions were determined by synthesizing the corresponding pyrrolidide and measuring its electron impact mass spectrum (Fig. 1). The pyrrolidide spectrum displayed the expected molecular ion peak at m/z 309 with diminished fragments at m/z 280 (carbon 13) and at m/z 224 (carbon 10). Therefore, we have to conclude that the compound in question is the new acid 10,13-dimethyltetradecanoic (3) which occurred in 1.8% abundance in this sponge.

TABLE 1

The Phospholipid Fatty Acids from *Ectyoplasia ferox*

Fatty acid	Abundance (%)
Tetradecanoic (14:0)	1.6
4,8,12-Trimethyltridecanoic (16:0)	10.6
13-Methyltetradecanoic (15:0)	5.0
10,13-Dimethyltetradecanoic (16:0)[a]	1.8
14-Methylpentadecanoic (16:0)	0.6
13-Methylpentadecanoic (16:0)	2.5
Hexadecenoic (16:1)	7.4
Hexadecanoic (16:0)	2.1
9-Methyl-11-hexadecenoic (17:1)[a]	8.0
15-Methyl-11-hexadecenoic (17:1)	1.0
Octadecenoic (18:1)	4.4
Octadecanoic (18:0)	5.1
11-Methyloctadecanoic (19:0)	5.6
17-Methyloctadecanoic (19:0)	0.6
5,8,11,14-Eicosatetraenoic (20:4)	7.7
6,9,12,15-Eicosatetraenoic (20:4)	6.4
Pentacosanoic (25:0)	3.0
24-Methyl-5,9-pentacosadienoic (26:2)	2.7
5,9-Hexacosadienoic (26:2)	5.3
25-Methyl-5,9-hexacosadienoic (27:2)	6.9
5,9-Heptacosadienoic (27:2)	2.4
26-Methyl-5,9-heptacosadienoic (28:2)[a]	2.0
25-Methyl-5,9-heptacosadienoic (28:2)[a]	3.4
5,9-Octacosadienoic (28:2)	2.5

[a]These compounds are unprecedented in nature.

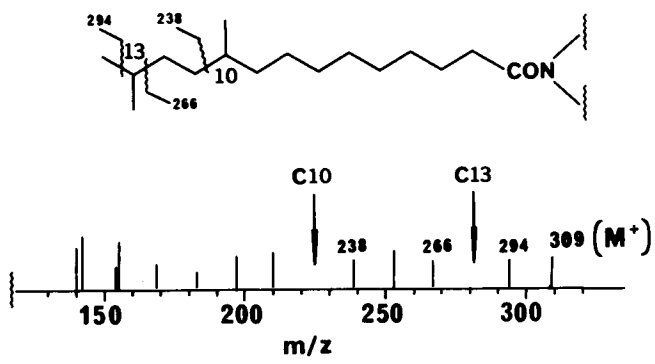

FIG. 1. Partial mass spectrum of 10,13-dimethyltetradecanoic acid pyrrolidide. Spectrum is expanded four times.

Two very similar but rather unusual C17:1 fatty acids were also isolated from *Ectyoplasia ferox*. Critical for the characterization of these acids were their corresponding pyrrolidides. The first acid, which occurred in ca. 8.0% abundance, presented a molecular ion peak at m/z 321 indicating 17 carbons with one unsaturation. The unsaturation was readily determined when it was observed that a difference of 12 amu occurred between fragments at m/z 224 (C_{10}) and m/z 236 (C_{11}) indicating Δ11 desaturation. Methyl branching was also evident since a diminished peak occurred at exactly m/z 210 corresponding to carbon 9 (Fig. 2). Methyl branching at position 9 was also corroborated by the MS spectrum of the corresponding hydrogenated fatty acid methyl ester (ECL 16.42) which essentially displayed a diminished peak at m/z 171 (C_9) concurrent with enhanced C_8 (m/z 157) and C_{10} (m/z 185) peaks. All of our experimental data supports the acid 9-methyl-11-hexadecenoic (5) which, to the best of our knowledge, is unprecedented in nature. The other C17:1 fatty acid (1.0%) turned out to be 15-methyl-11-hexadecenoic (4), a new fatty acid for marine sponges but known in several bacteria (7). The latter acid was again readily characterized by means of mass spectrometry of the corresponding pyrrolidide since it also presented a 12-amu difference between fragments at m/z 224 and m/z 236 supporting Δ11 unsaturation. Hydrogenation of the parent fatty acid methyl ester afforded the known 15-methylhexadecanoic acid (ECL 16.62) which was compared with an authentic sample isolated by us from other sponges.

Two 19:0 branched acids were detected in *E. ferox* in a combined 6% abundance. The first of these acids (ECL 18.39) presented a molecular ion peak, as the methyl ester derivative, of m/z 312. The most important feature of the spectrum was that peaks at m/z 185 and m/z 213 were bigger than normal (as compared with a straight chain acid) and the peak at m/z 199 was diminished. A further study of the pyrrolidide spectrum revealed a diminished peak at exactly m/z 238, thus indicating methyl substitution at position 11. This acid was characterized as the rare 11-methyloctadecanoic, which has been reported before in the demosponge *Aplysina fistularis* (8). The other 19:0 acid (ECL 18.61) was readily characterized as 17-methyloctadecanoic acid by comparison with an authentic sample and GC-MS data.

The most interesting feature in *E. ferox* was the presence of seven very long chain phospholipid fatty acids possessing the typical Δ5,9 unsaturation of "demospongic" acids. The Δ5,9 unsaturation was readily identified since all of these acids afforded the characteristic peak at m/z 180 when the corresponding pyrrolidides were analyzed by GC-MS, a typical peak resulting from allylic cleavage between carbons 7 and 8 of the fatty acid (8). Three of these straight-chain acids were characterized as 5,9-hexacosadienoic (26:2), 5,9-heptacosadienoic (27:2) and 5,9-octacosadienoic (28:2), on the basis of their mass spectra, ECL values of the corresponding hydrogenated acids, and comparison with authentic samples isolated before by us from other sponges. Again, critical for the double bond assignments were the peaks at m/z 81 (base peak) for the methyl esters and m/z 180 for the pyrrolidides. The corresponding *iso* acids of the latter phospholipid acids were also present in the mixture, namely 24-methyl-5,9-pentacosadienoic (*iso*-26:2), 25-methyl-5,9-hexacosadienoic (*iso*-27:2), and 26-methyl-5,9-heptacosadienoic (*iso*-28:2). The first two phospholipid fatty acids (*iso*-26:2 and *iso*-27:2) have been reported before in other sponges (2) but the *iso*-28:2 (2.0% abundance) is, to the best of our knowledge, new in nature. The corresponding saturated *iso*-28:0 (after hydrogenation) presented an ECL value of 27.61. In addition to the *iso*-28:2 acid we also identified, in the mixture, the corresponding *anteiso*-28:2 acid (3.4% abundance), namely 25-methyl-5,9-heptacosadienoic (1), which also has not been reported to occur in nature (Fig. 3). The latter acid, after hydrogenation, presented an ECL value of 27.72, typical of *anteiso* acids (Fig. 4).

The phospholipids from *E. ferox* were analyzed by TLC and they mainly consisted of phosphatidylethanolamine (PE), phosphatidylserine (PS), phosphatidylcholine (PC), phosphatidylinositol (PI) and small amounts of phosphatidylglycerol (PG). Phosphatidylethanolamine and phosphatidylserine were observed in ca. 60% and 18%, respectively, while phosphatidylinositol and phosphatidylcholine were present in ca. 13% and 8%, respectively. The new acids isolated in this work, especially the 26:2-28:2 series, were concentrated in PE, PS, and PI with lesser amounts in PC and PG.

Because sterols are known to coexist with phospholipids in cell membranes, we decided to take a look at the sterols from *E. ferox* in detail to see if unusual branching was present in the sterol mixture. By means of standard isolation procedures and final separation by high pressure liquid chromatography (HPLC) and characterization aided by 300 MHz ^{1}H NMR, MS, and comparison with authentic samples, the following sterols were isolated from *E. ferox:* cholesta-5,22-dien-3β-ol (3% abundance of

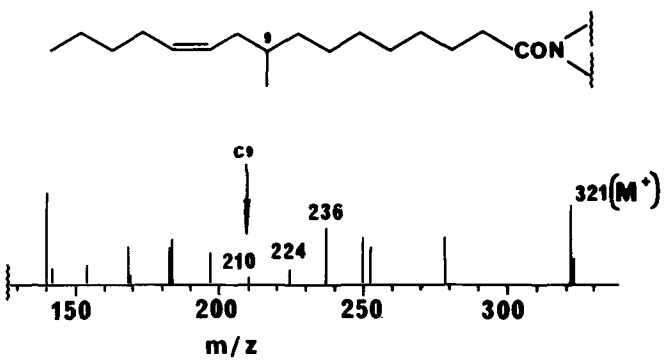

FIG. 2. Partial mass spectrum of 9-methyl-11-hexadecenoic acid pyrrolidide. The spectrum is expanded four times.

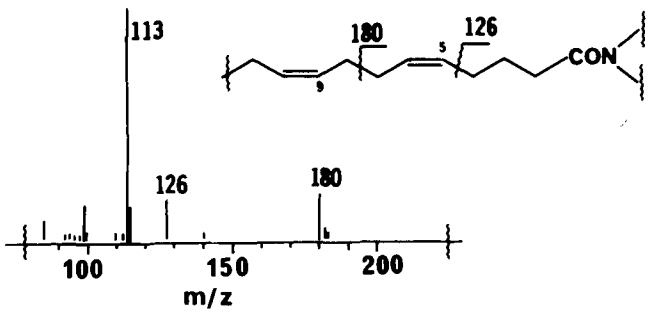

FIG. 3. Partial mass spectrum of 25-methyl-5,9-heptacosadienoic acid pyrrolidide showing the typical fragmentation peak at m/z 180.

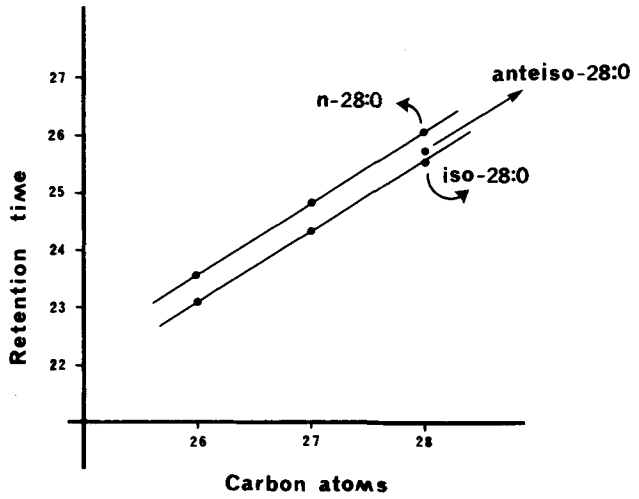

FIG. 4. Plot of retention time (min) vs carbon atoms for the hydrogenated mixture of the very long chain acids from *E. ferox*. Notice the 26:0–28:0 *iso* series as well as the *anteiso*-28:0 compound.

the total sterol mixture), 24(S)-methylcholesta-5,22-dien-3β-ol (8%), 24(R)-methylcholesta-5,22-dien-3β-ol (14%), cholesterol and fucosterol (7%), 24-ethylcholesta-5,22-dien-3β-ol (12%), 24-methylcholest-5-en-3β-ol (10%), and 24-ethylcholest-5-en-3β-ol (46%). Therefore, *E. ferox* presented a common sponge sterol composition.

DISCUSSION

The main thrust of this report, namely the isolation of the very long chain fatty acids 25-methyl-5,9-heptacosadienoic (1) and 26-methyl-5,9-heptacosadienoic (2), adds a new dimension to the series of possible Δ5,9 branched very long chain "demospongic" acids. One previously encountered pair of *iso* and *anteiso* 27:2 acids from the sponge *Jaspis stellifera* have been the subject of various biosynthetic experiments (3) revealing that the branched 27:2 acids are true sponge metabolites originating from their corresponding *iso-anteiso* short-chain analogues by a mechanism of chain elongation and subsequent desaturation. Possibly in *E. ferox* a similar biosynthetic pathway might be operative, but until the necessary biosynthetic experiments are performed we can only speculate at this point.

Of the two branched 17:1 acids isolated in this work, 9-methyl-11-hexadecenoic acid (5) is certainly the most interesting since, to the best of our knowledge, it has not been reported to occur in nature before. The saturated analogue, namely 9-methylhexadecanoic acid, has been reported to occur before in *Staphylococcus aureus* (9). We think that the acid reported here is probably of bacterial origin. The *iso* acid 15-methyl-11-hexadecenoic (4) has been isolated before from several sources including the marine bacterium *Flexibacter polymorphus* (10).

A very interesting finding in *E. ferox* is the presence of the new branched acid 10,13-dimethyltetradecanoic (3). It origin in sponges is certainly worthy of investigation. The final unusual acid isolated in this sponge, namely 11-methyloctadecanoic (19:0), seems to be a two-carbon extension of 9-methylhexadecanoic acid (17:0).

ACKNOWLEDGMENTS

Vance Vicente of La Parguera, Puerto Rico, did the collection and classification of the sponge. O. Rosario and Isaura Diaz assisted in the mass spectrometry. This material is based upon work supported by the National Science Foundation under Grant No. CHE-8715649 and NIH (Grant No. S06 RR08102-17) and the NIH-RCMI program (Grant No. G12 RR03641). [Received September 26, 1988; Revision accepted December 9, 1988]

Effect of pH on the Affinity of Phospholipids for Cholesterol

Myra K. Jacobsohn*, Linda S. Bazilian, Janice Hardiman and **Gert M. Jacobsohn**
Department of Biological Chemistry, Hahnemann University, Philadelphia, PA 19102

The ability of multilamellar vesicles of phosphatidylcholine and phosphatidylethanolamine in aqueous phase to prevent access to cholesterol by a nonpolar solvent was examined. Phosphatidylethanolamine vesicles retained less sterol than phosphatidylcholine vesicles. In mixed vesicles, cholesterol was retained in proportion to the amount of phosphatidylcholine. To alter the charge and hydration of head groups, pH was adjusted from 1.2 to 12.5. Above pH 8, both phosphatidylethanolamine and phosphatidylcholine retained sterol in a 1:1 molar ratio of phospholipid to cholesterol, regardless of acyl side chain composition. Between pH 2.0 and pH 8.0, sterol retention varied with type of head group and side chain. Lipids with 16-carbon saturated side chains retained more sterol than 18-carbon unsaturated or 12-carbon saturated side chains. Between pH 1.1 and 2.0, none of the phosphatidylethanolamines retained sterol, but long chain phosphatidylcholines, saturated or unsaturated, retained sterol in a 1:1 molar ratio of phospholipid to sterol. Short chain phosphatidylethanolamines and phosphatidylcholines retained 0 to 20% at the low- to mid-pH range. Size of multilamellar vesicles, measured by Doppler effect light scattering analysis, had no bearing on sterol retention. Sonication of vesicles, which increases surface curvature, increases the retention of sterol. Fluorescence polarization indicated that cholesterol does not interact with DPPC or DLPC side chains. The observations can be interpreted in terms of space requirements of head groups, including charge repulsion and hydration. Other factors, such as monovalent cation replacement by protons, juxtaposition of charged groups on vesicle surfaces and length and unsaturation of acyl side chains affect the affinity of phospholipids for cholesterol.
Lipids 24, 375–382 (1989).

We have described previously a procedure for quantifying lipid retention by multilamellar vesicles (MLV) of phosphatidylcholine (PC) by extraction with a nonpolar solvent (1). The study showed that MLV of PC without cholesterol retained most of their phospholipid upon extraction with petroleum ether, but if the sterol was present, MLV varied in their retention of sterol or phospholipid. The ability of sterol-containing vesicles to retain lipid upon extraction was related to mobility of acyl side chains. MLV of PC above their transition temperatures (T_c) retained less sterol or phospholipid than PC below their T_c. In the present study, observations on lipid retention were extended to MLV of phosphatidylethanolamine (PE) and mixtures of PC and PE. We found that PE, like PC, retains cholesterol as a function of side chain mobility, but PE vesicles retained less sterol than equivalent PC vesicles. These findings led us to explore some of the reasons why PE vesicles retain less cholesterol than PC vesicles on extraction with a nonpolar solvent.

We based this study on the premise that cholesterol is best protected from extraction when it is sequestered beneath the polar surfaces of phospholipids, i.e., when the phospholipids are in a lamellar phase. Extraction of cholesterol from a phospholipid-sterol complex will occur when the phospholipid assumes a reverse hexagonal phase or when the lamellar phase becomes unstable. Several authors have discussed parameters which control lamellar phase formation. Israelachvili *et al.* (2) proposed that molecular shape is a critical factor. Cylindrical phospholipids, with cross-sectional areas of head groups and of acyl side chains nearly equal, would be most likely to form bilayers, whereas conical lipids, with cross-sectional areas of polar head groups smaller than acyl side chains, would form reverse hexagonal (H_{II}) phases. DeKruijff *et al.* (3) modified the concept of molecular shape and included other factors which may influence the shape occupied by lipid molecules. Hydration of head groups (4,5), intermolecular hydrogen bonding (6–8) and rotation about the long axis of the molecule (9) have been shown to affect molecular shape. We found it useful to consider the space occupied by the molecules, taking into account the influence of like charge repulsion and surface curvature of vesicles. Repulsion of like charge will cause adjacent head groups to occupy more space than predicted by considerations of the shape of single molecules. Organization of phospholipids into vesicles with highly curved surface will have the same effect.

The space requirements of anionic and zwitterionic lipids can be manipulated by varying the pH of the bulk phase surrounding the lipid or by controlling the size, and therefore, the surface curvature, of lamellar vesicles. By these methods, a conical lipid can be made to occupy a cylindrical space without altering its physico-chemical properties, as occurs with the addition of bulky substituent groups (10). Unsaturated phosphatidylethanolamines, which tend to form H_{II} phase structures at ambient temperature and neutral pH (11–13), can be induced to assume a lamellar phase by increasing the pH above the pK_a of the amine group (14,15).

To test the hypothesis that cholesterol is sheltered when entrapped beneath the polar head groups of phospholipids, we varied the pH of the aqueous phase to influence the charge on head groups. At pH 2 or less, both PC and PE are fully protonated and have a net positive charge (16). We expected the effect of a net positive charge to be counterbalanced by the loss of hydration around the phosphate group. PC, because of its large choline group, would be more likely to form a lamellar phase at low pH than PE. At pH 10 and above, PE is deprotonated and has a net negative charge, whereas PC at the same pH is neutral (16). Both PC and PE should form lamellar phases at high pH because the phosphate groups will be hydrated and the bulk provided by hydration will be additive to the space occupied by the choline groups in the former and by the space required by charge

repulsion in the latter. At extremes of pH, we expected the cholesterol retaining ability of PE to almost equal the ability of PC vesicles to retain the sterol. Between pH 3 and pH 8, intermolecular hydrogen bonding would discourage lamellar formation in PE but not in PC. We also expected that unsaturated PC would approach the capacity of saturated PC's of equivalent side chain length to retain cholesterol at both high and low pH because the space requirements for the head groups would be large in either case. PC or PE with short acyl side chains were not expected to retain cholesterol at any pH because the side chains are too short to accommodate the sterol. All expectations were met, except the last. Short chain phospholipids of both types retained cholesterol at high pH. Suggested reasons for this observation are discussed below.

METHODS

Materials. 1,2-Dipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC), 1,2-dilauroyl-*sn*-glycero-3-phosphocholine (DLPC) and 1,2-dilauroyl-*sn*-glycero-3-phosphoethanolamine (DLPE) were purchased from Sigma Chemical Co. (St. Louis, MO); 1,2-dioleoyl-*sn*-glycero-3-phosphocholine (DOPC) and 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE), from Avanti Polar Lipids (Birmingham, AL); and 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine (DPPE(from Calbiochem (La Jolla, CA). Purities of phospholipids were checked by thin layer chromatography on silica gel G plates, purchased from Applied Science (State College, PA) and developed with chloroform/methanol/water (65:25:4, v/v/v). Phospholipids were visualized with iodine vapors. Cholesterol was recrystallized twice from methanol; 4-[^{14}C]cholesterol was obtained from Amersham (Arlington Heights, IL). All other substances and solvents were reagent grade and were used without further purification.

Preparation of MLV. The procedures for preparing MLV, quantitating cholesterol and phospholipid extracted from vesicles, and measurement of fluorescence polarization have been described (1). At pH 1.2, MLV were prepared in 0.1 N phosphoric acid; at pH 2.0, they were made in 0.1 M potassium dihydrogen phosphate and phosphoric acid; and at pH 4.0, they were prepared in unbuffered 0.9% sodium chloride. For pH ranges between 5.8 and 7.8, 0.1 M potassium phosphate buffers were used. MLV at pH 10.0 were prepared in 0.1 M CAPS (cyclohexylaminopropane sulfonic acid) and sodium hydroxide and for pH 12.5 they were prepared in 0.15 M potassium chloride and sodium hydroxide. The extraction with petroleum ether and with chloroform/methanol (2:1, v/v) was carried out at 22°C and has been described (1). Sonicated vesicles were prepared from dried lipid films in unbuffered 0.9% sodium chloride in an Artek Dismembrator Model 300 (Farmingdale, NY) at 105 W for 10 min in an ice bath. Fluorescence polarization (p), corrected for light scattering, was determined with 1,6-diphenyl-1,3,5-hexatriene as a lipid probe and measured in a Perkin-Elmer Model MFP 44 spectrophotometer (1). The sizes of vesicles of DOPC and DPPE with cholesterol at various pH values were determined by Doppler Effect Laser Light Scattering Analysis (9) on a Coulter DELSA instrument generously made available by Langley-Ford Instruments in Amherst, MA. Light scattering measurements were made with a frequency range of 500 Hz and a frequency shift of 250 Hz. Current was at 6 mA, on time was 2 sec and off time was 0.5 sec.

RESULTS

Cholesterol retention by PE and mixed PC/PE MLV. MLV were prepared in unbuffered 0.15 M NaCl from phospholipid mixtures, with and without equimolar amounts of cholesterol, and extracted three times with petroleum ether. Fluorescence polarization for each sample was determined with diphenylhexatriene as a lipid probe. Figure 1 (A) shows cholesterol retention by vesicles

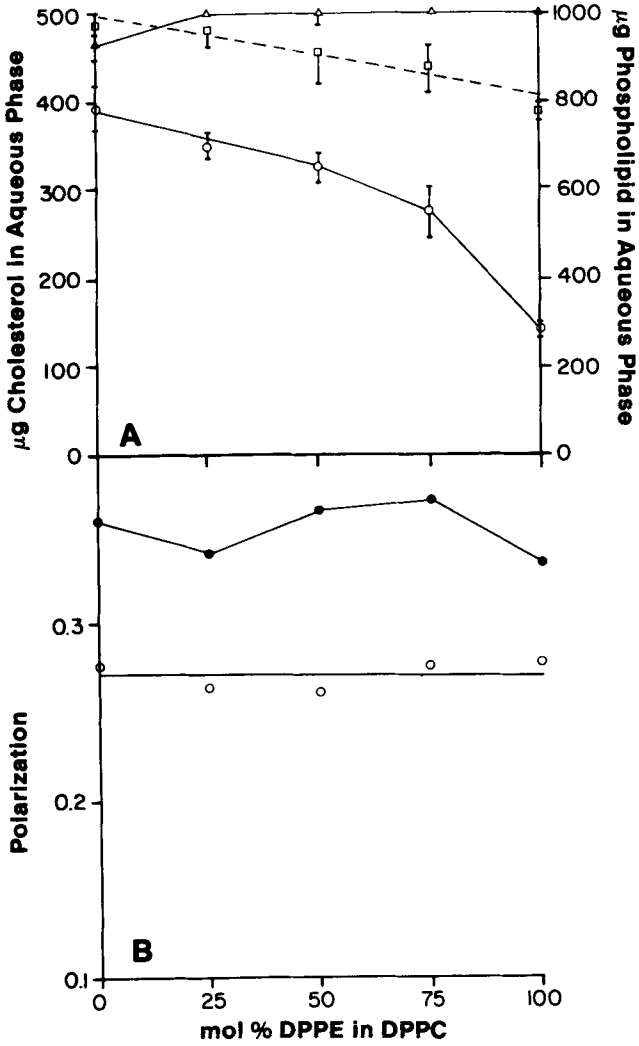

FIG. 1. (A) Cholesterol and phospholipid retention by MLV of DPPC and DPPE, with or without cholesterol, in molar ratio of 1:1 of sterol to phospholipid. Vesicles were prepared as described in Materials and Methods. Sterol was determined by [4-^{14}C]cholesterol remaining in the aqueous phase after petroleum ether extraction. Phospholipid was determined by phosphate assay of dry petroleum ether extracts. Points are the means of 4 to 7 samples; S.D.s are shown by bars. ○, Cholesterol in aqueous phase; □, phospholipid in aqueous phase from vesicles prepared with cholesterol; △, phospholipid in aqueous phase from vesicles without cholesterol. (B) Fluorescence polarization of vesicles prepared as in (A). Each point is the mean of 3 samples; S.D.s are included in the points. ○, DPPC and DPPE prepared with cholesterol; ●, DPPC and DPPE without cholesterol.

of DPPC, DPPE and mixtures of the two at pH 5.8. Extractability of phospholipid in presence and absence of cholesterol was determined. In absence of cholesterol, phospholipid was not extractable from the vesicles but with sterol present, 20% of the lipid was extractable. Cholesterol was selectively removed from vesicles of DPPE and DPPC and their mixtures. The amount of cholesterol retained decreased with increasing DPPE content from 80% with DPPC alone to 30% with DPPE alone. Fluorescence polarization, Figure 1B, was somewhat lower for vesicles with cholesterol than for vesicles without sterol. The failure of DPPE to retain substantial amounts of sterol is not due to mobility of the acyl side chains of the phospholipids because cholesterol retention decreases even though the p value remains fairly constant.

Cholesterol retention and fluorescence polarization for MLV prepared from DLPE and DPPE were measured (Fig. 2). Vesicles containing DLPE or mixtures of DLPE and DPPE retain almost no sterol, whereas DPPE vesicles retain about 30%. The measured pH of the unbuffered medium of these preparations was 3.5-4.0. No phospholipid was extracted from DPPE vesicles, whereas mixed vesicles of DLPE and DPPE lost from 60 to 80% of their lipid. Vesicles of DLPE lost somewhat less phospholipid than vesicles made from DLPE mixed with DPPE. In these preparations, the presence of cholesterol had little influence on the amount of phospholipid extracted. Fluorescence polarization for vesicles with mixed DLPE and DPPE was lower than that of either lipid alone. The presence of cholesterol decreased polarization for all vesicles except those made entirely from DLPE. The fact that fluorescence polarization did not change when cholesterol was present in DLPE vesicles and that no sterol was retained indicates that cholesterol is not incorporated into the vesicles. In this case, as in the case of DPPC and DPPE mixtures described above, cholesterol retention was not related to side chain mobility.

The pattern of cholesterol retention by DOPE/DPPC vesicles is shown in Fig. 3A. In absence of cholesterol, no phospholipid could be extracted from DPPC vesicles

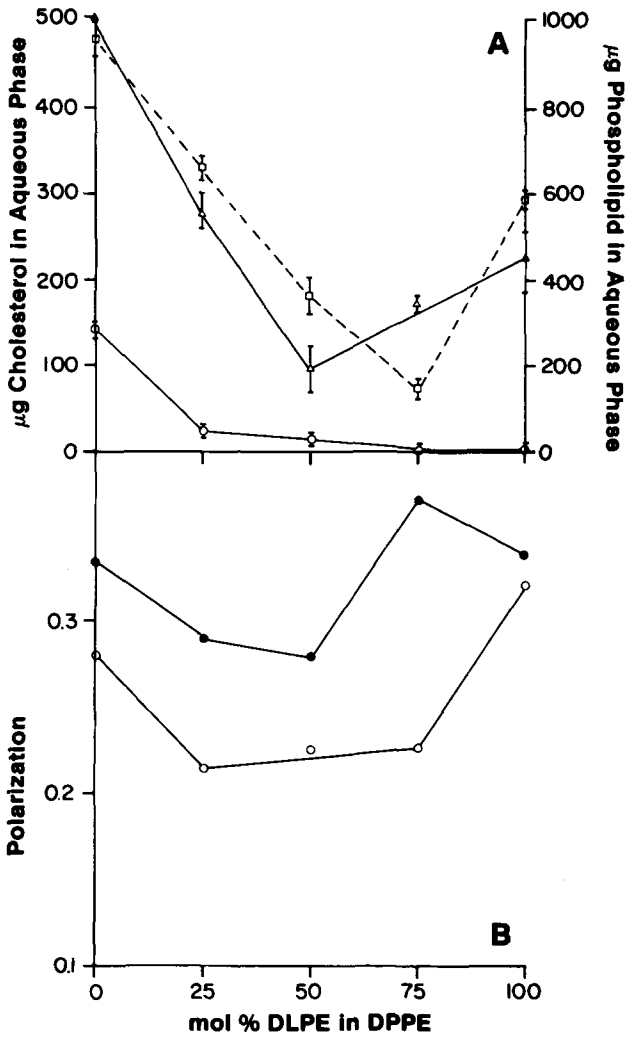

FIG. 2. (A) Cholesterol and phospholipid retention by MLV of DLPE and DPPE with or without cholesterol, in ratio of 1:1 of sterol to phospholipid. Other details are shown in Fig. 1A. (B) Fluorescence polarization of vesicles prepared as in (A). Details are shown in Fig. 1B. O, vesicles with cholesterol; ●, vesicles without cholesterol.

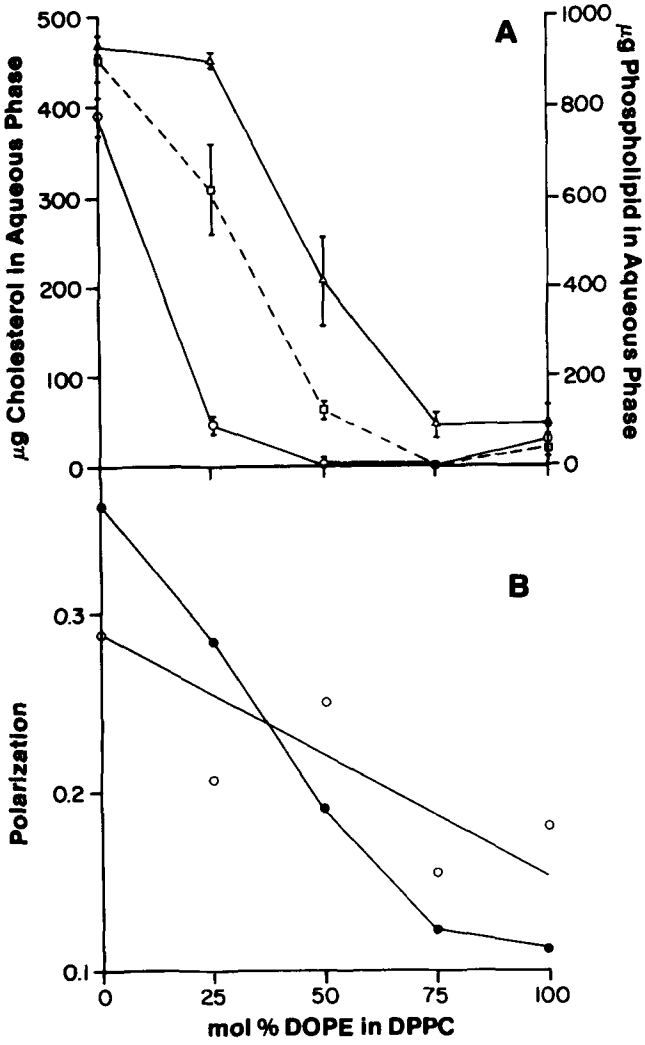

FIG. 3. (A) Cholesterol and phospholipid retention by MLV of DOPE and DPPC with or without cholesterol, in ratio of 1:1 of sterol to phospholipid. Other details are shown in Fig. 1A. (B) Fluorescence polarization of vesicles prepared as in (A). Details are shown in Fig. 1B. O, vesicles with cholesterol; ●, vesicles without cholesterol.

by petroleum ether, but substitution of 25% of DPPC by DOPE caused a substantial increase in phospholipid extraction: 90% could be extracted from vesicles with 75–100% DOPE. When cholesterol was included, extraction of phospholipid from DOPE-containing vesicles was increased and 10% or less of the sterol was retained. Cholesterol modified the fluorescence polarization of all vesicles (Fig. 3B) indicating that acyl side chains of saturated phospholipids became more mobile, whereas unsaturated side chains became less mobile. Cholesterol retention was not proportional to side chain mobility. It appears that DOPE interacts with cholesterol, but the sterol is not protected from the extracting solvent. This observation suggests the presence of an H_{II} phase, because in this configuration, the acyl side chains are exposed to the aqueous phase and would interact with the solvent.

The combination of DOPC and DPPE was difficult to study. The 50 mol% mixture formed waxy particles which stuck to the walls of the tube and dispersed poorly, no matter how long they were agitated. Cholesterol retention by these vesicles did not vary with phospholipid composition (Fig. 4A). Cholesterol moderated the fluorescence polarization of the vesicles, but the p value for all vesicles containing DOPC was the same (Fig. 4B). Cholesterol retention for vesicles containing a large proportion of DPPE was unrelated to side chain mobility.

Effect of pH on cholesterol retention by PC and PE MLV. Cholesterol retention by vesicles of single species of phospholipid was studied as a function of pH. Figure 5A shows cholesterol retention by DPPE vesicles. There was a marked transition between pH 6.0 and 6.8, where cholesterol retention was doubled from 45% to 90%. An increase in the pH to 10.0 or 12.5 caused a slight decrease of sterol retention. Cholesterol retention at pH 1.1 and 2.0 was less than the amount retained at pH 3.5 to 6.0. Cholesterol retentions by DOPE and DLPE were similar, Figure 5B and 5C, and showed a marked increase above pH 8.0: cholesterol retention was 90% for both types of vesicles. Below pH 8.0, the vesicles retained almost no sterol. Studies with DPPC, Figure 5D, yielded a different pattern. Retention of cholesterol by MLV of DPPC above pH 8.0 was over 90%. Between pH 4.0 to 5.5, cholesterol retention varied from 75 to 80%, but at pH 2.0, 95% of the sterol was retained. The effect of pH on DOPC vesicles was similar but more striking. Cholesterol retention rose from 45% at pH 5.0 to 90% at pH 10, Figure 5E. At pH 2.0, the amounts of sterol retained was 85%. DLPC was unlike its long chain analogs at low pH. At pH 1.0 to 2.0, it retained less than 20% of cholesterol. Between pH 2.0 and 7.0, the amount of sterol retained rose from 0 to 30%, but above pH 7.0, cholesterol retention increased to 90%, Figure 5F. Phospholipid remaining in the aqueous phase above pH 8.0 was nearly 100% for all lipids. Phospholipid retention in the mid-pH range varied with each lipid. Values can be read from Figures 1 to 4 and from Figures 1 and 5 (A) in (1). At pH 2 and below, phospholipid retention was between 80 and 100% for DPPC, DOPC, DPPE and DLPE. DOPE retained no phospholipid and DLPC retained about 50%.

We considered the possibility that differences in size of vesicles at various pHs might influence cholesterol extraction. The average size of DOPC and DPPE vesicles with cholesterol at pH 2.0, 6.0 and 10.0 was determined by Doppler effect light scattering analysis. The results are shown in Table 1. The sizes of vesicles differed considerably with pH, ranging from 620 nm to over 6000 nm.

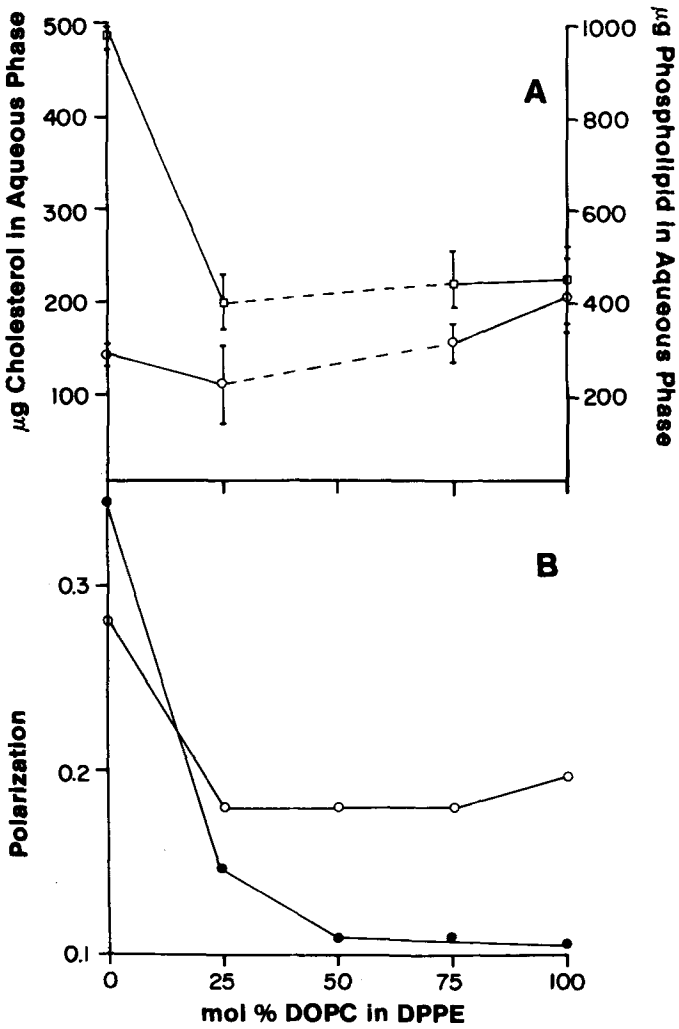

FIG. 4. (A) Cholesterol and phospholipid retention by MLV of DOPC and DPPE with or without cholesterol, in ratio of 1:1 of sterol to phospholipid. Other details are shown in Fig. 1A. Data for 50 mol% DOPC in DPPE were not obtained. (B) Fluorescence polarization of vesicles prepared as in (A). Details are shown in Fig. 1B. ○, vesicles with cholesterol; ●, vesicles without cholesterol.

TABLE 1

Diameters of Vesicles

	pH		
Vesicle composition	2.0	5.8	10.0
DPPE + cholesterol	2598 nm	6432 nm	1230 nm
DOPC + cholesterol	620	1414	2800

Diameters of DOPC and DPPE vesicles with cholesterol in a 1:1 molar ratio measured at pH 2.0, 5.8 and 10.0. Vesicles were prepared as described under Materials and Methods with unlabeled sterol. Vesicle size was determined by Doppler Effect Light Scattering Analysis (9).

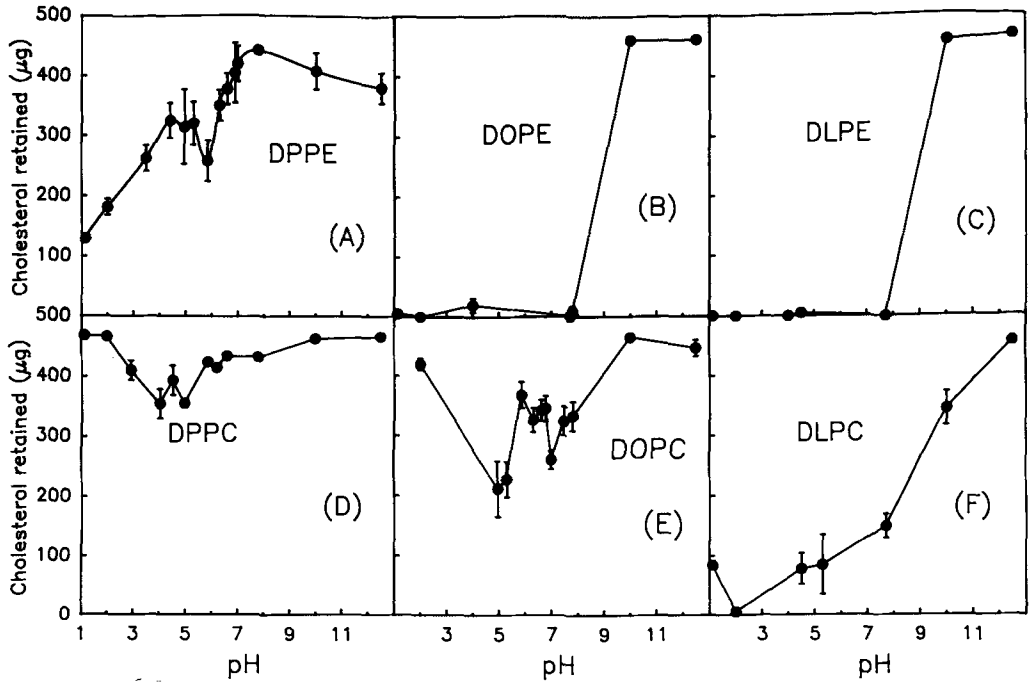

FIG. 5. Cholesterol retention by phospholipid vesicles as function of pH. Vesicles were prepared with cholesterol in molar ratio of 1:1 of sterol to phospholipid in solutions of pH 1.1 to pH 12.5, as described under Materials and Methods. Other details are shown in Fig. 1A. Each point is the mean of 3 to 6 samples, with S.D. shown by bars or included within symbols. (A) DPPE; (B) DOPE; (C) DLPE; (D) DPPC; (E) DOPC; (F) DLPC.

DOPC vesicles prepared with equimolar cholesterol retained 90% of the sterol at both pH 2 and pH 10, but the average size of the vesicles at pH 10 is more than 4 times greater than at pH 2. For DPPE vesicles, cholesterol retention at pH 2 and 6 was about the same, but the vesicles at pH 6 are 2.5 times larger than at pH 2. It does not appear that vesicle size affects cholesterol retention.

Sonicated vesicles. Vesicles of DPPE, DPPC and DOPC with equimolar amounts of cholesterol and trace amounts of 4-[^{14}C]cholesterol were prepared by sonication as previously described. The resultant vesicles were extracted three times with petroleum ether. The amounts of cholesterol retained in the aqueous phase by each type of vesicle are shown in Table 2 and compared with the amounts of sterol retained by unsonicated vesicles at acid and basic pH and in unbuffered sodium chloride solution. Sterol retention by sonicated vesicles of DPPC and DPPE was in a 1:1 molar ratio, but DOPC vesicles retained sterol in a 0.75:1 cholesterol to phospholipid ratio.

TABLE 2

Cholesterol Retention by Vesicles

	0.9% NaCl		KH_2PO_4-K_2HPO_4 buffer	
	Unsonicated	Sonicated	pH 5.8	pH 7.8
DOPC	211 ± 47	368 ± 28	358 ± 25	333 ± 25
DPPC	390 ± 28	465 ± 3	415 ± 6	432 ± 4
DPPE	142 ± 6	455 ± 4	218 ± 32	442 ± 7

Vesicles were prepared from DPPE, DPPC or DOPC with cholesterol in a 1:1 molar ratio and trace amounts of [4-^{14}C]cholesterol, as described in Materials and Methods. Values for cholesterol retention by similar vesicles in unbuffered NaCl and in phosphate buffer at pH 5.8 and 7.8 are given for comparison. Values in μg.

DISCUSSION

Between pH 3.5 and 6.0, MLV of PE retain less cholesterol after extraction with a nonpolar solvent than MLV of PC. These differences are eliminated at pH values between 6.5 to 8.0, depending on the acyl side chain composition of the phospholipid. The difference also disappears for vesicles prepared by sonication. Mixed phospholipid vesicles retain cholesterol in proportion to the amount of PC incorporated into the bilayers. PC with saturated 16-C side chains were more susceptible to ordering than the unsaturated compounds. The influence of saturated 16-C side chains extends to PE lipids also. DPPE exhibited the greatest capacity of all PE lipids examined to retain cholesterol in the aqueous phase (Fig. 1). The ability of saturated acyl side chains to enhance cholesterol retention does not apply to short chain phospholipids. Neither DLPE (Fig. 2) nor DLPC (1) retained significant amounts of cholesterol in the aqueous phase. Fluorescence polarization studies indicate that mobility of DLPC side chains was modified by cholesterol whereas the mobility of DLPE side chains was not (Fig. 2 and [1]); however, the configuration assumed by the DLPC-cholesterol complex did not protect the sterol from extraction. Low pH had different effects on PC and PE lipids. Long chain PC, saturated or unsaturated, retained cholesterol in a nearly 1:1 molar ratio at pH 2, whereas DLPC, DLPE, DPPE and DOPE retained little or no sterol.

Two factors must be considered in explaining the behavior of cholesterol in aqueous phospholipid-containing

media. One, cholesterol can intercalate itself into the hydrocarbon domain of structures assumed by phospholipids (17) and two, once intercalated, cholesterol maintains its relationship to the phospholipid because of thermodynamic constraints placed upon amphipathic molecules in an aqueous phase. The hydrophobic interactions and van der Waals forces that characterize the association between the sterol and paraffin side chains of phospholipids are applicable only to the extent that phospholipids maintain a relationship to one another. This relationship is dependent on the polarity of the bulk phase (5,18), the hydrogen ion concentration (15), intermolecular hydrogen bonding (6–8) and the presence of inorganic cations (19,20).

The effect of pH on the phase structure of phospholipids has been examined previously. Saturated PE, below their transition temperatures, pack more closely in bilayer structures at low pH than at high pH (15,21). At pH less than 3, the phosphate groups are fully protonated (16). This results in a loss of hydration around the head groups and a reduction of their space requirements (13,21). At room temperature, which is below the T_c for saturated PE (22), the acyl side chains are in the gel state and can be pushed closer together. The space occupied by the molecule becomes cylindrical and the bilayer conformation would be maintained. At high pH, the phosphate groups are ionized and hydrated, occupying a larger space than at low pH. The head groups are spread apart, allowing more mobility among acyl side chains. Introduction of cholesterol into the bilayers reduces the mobility of the side chains (15) and the bilayer structure remains stable. Unsaturated PE, such as DOPE, form an H_{II} phase at low pH (11–13,21,23) because the space requirements for the acyl side chains exceed those of the head groups and the molecules occupy conical spaces. Haines (6) has proposed that acid-anion pairs may form among head groups in the mid-pH range. Chaotropic agents, which disrupt hydrogen bonding, stabilize lamellar phases of PE, and this finding led to the conclusion that hydration of the bilayer surface determines phase state (5). At high pH, the space requirements of head groups and side chains are more nearly equal and the molecules occupy a cylindrical space, assuming a bilayer conformation (14).

Above pH 3, PC occurs as zwitterion but it is not clear why pH of 8 and higher caused an increased cholesterol retention, indicative of a spreading of head groups. PC form bilayers throughout the pH range (15). Cevc (21) reported that the T_c of DPPC decreases by 8°C between pH 0 and pH 13 and suggested a decrease in the ordering of acyl side chains at the higher pH. Hsia and Boggs (15), using ESR studies, found similar evidence of disorder at high pH but ascribed it to the effect of pH on the spin label. Introduction of cholesterol into PC bilayers moderates the mobility of acyl side chains (17), but does not alter the phase structure, except when unsaturated PC and PE lipids are mixed (24).

At the temperature of these experiments and at low to neutral pH, all of the PC and PE phospholipids, except DOPE, were below their transition temperatures (22) and were expected to be in the bilayer state (15,21). Mixed vesicles containing unsaturated PC and PE are unstable and may form H_{II} phases (24). The bilayer conformation should protect phospholipid from extraction by a nonpolar solvent and the data show this to be the case. The exception was DLPE, for which half the phospholipid was extractable. Incorporation of cholesterol into bilayers, particularly if two species of phospholipid were present, increased extractability of phospholipids. Fluorescence polarization and extraction data for the pH range of 3.5 to 5.8 show that DLPE does not retain or interact with cholesterol. The p value was the same for DLPE with or without sterol (Fig. 2B). DLPC interacts with the sterol but does not prevent its extraction (1). DPPE interacts with the sterol, but only retains it in a 0.33:1 cholesterol to phospholipid molar ratio (Fig. 1). DOPC and DOPE both interact with the sterol, but the association is unstable, as evidenced by the fact that sterol and phospholipid are both extracted by the solvent in the same molar proportions. DPPC interacts with cholesterol and sequesters it from the extracting solvent.

Above pH 8.0, all of the phospholipids retained cholesterol in a 1:1 molar ratio, but below pH 3.0, only DPPC and DOPC protected the sterol from extraction. The latter is in agreement with the findings of van Blitterswijk *et al.* (25), who showed that the affinity of phospholipids for cholesterol increases with the fraction of sphingomyelin or PC in the vesicles and that PC with saturated 16-C side chains were more susceptible to ordering than unsaturated side chains.

Charge repulsion and hydration do not suffice to explain all of the effects of high pH. Monovalent cations from the bulk phase may be shared among negatively charged groups as pH is increased. McLaughlin (26) has calculated that if 20% of the lipid in a membrane is anionic, then the molar concentration of cation at the membrane surface will be 1.0 M. If monovalent cations were to replace hydrogen ions, which were shared among PE or anionic head groups at low pH, they would spread the head groups further apart. Li and Haines (20) observed that unilamellar vesicles made from dioleoylphosphatidic acid by titration to pH 9.0 or 10.0 in sucrose-TRIS buffer were approximately half the size of vesicles made in buffered potassium chloride solution. Vesicles diluted in sucrose-buffer solutions swell more than vesicles diluted in KCl-buffer solutions (19), indicating that monovalent cations prevent vesicle expansion. In our experiments, vesicles were made up in media which contained either Na^+ or K^+ ions. The sharing of monovalent cations among the anionic forms of PE affects the space requirements of head groups and the ability of the entire molecule to interact with cholesterol.

The role of acyl chain length in determining cholesterol intercalation into a bilayer at high pH is illustrated by DLPC and DLPE. DLPC retains 20 mol% or less of cholesterol on extraction by a nonpolar solvent at pH less than 8.0, whereas DLPE retains none (Fig. 5B). It has been suggested that the 12 carbon acyl chain of dilauroyl lipids is too short to fit the sterol (27); however, we found that both lipids retain 90 mol% of cholesterol above pH 8.0. The space between head groups afforded by charge repulsion and hydration or by monovalent cation sharing does not afford more space to fit the sterol into the hydrocarbon domain of the bilayer. The negative charge within head groups or increased hydration may draw the hydroxyl group of cholesterol closer to the surface of the bilayer. The sterol ring structure would then be pulled into the hydrocarbon domain and intercalate with paraffin side chains. This consideration can also explain why

DLPC, unlike its long chain analogs, does not retain cholesterol at low pH. Loss of the negative charge on the head group decreases the attraction for the 3-hydroxy group of the sterol.

The behavior of DOPC in the mid-pH range raises an interesting question. Between pH 4.5 and pH 8.0, DOPC retains less than 50 mol% of cholesterol, losing both sterol and phospholipid to the extracting solvent (Fig. 5F and [1]). The acyl chain is long enough to accommodate cholesterol, and the *cis* double bond at C-9 does not interfere with cholesterol interaction (28). Both phosphate and choline groups are charged so that the head group is fully hydrated. However, removal of cholesterol from these vesicles increased with each successive petroleum ether extraction (unpublished observations), indicating that the vesicles were initially in the lamellar state. Solvent may enter the hydrocarbon domain and disrupt the ordered arrangement of cholesterol and acyl side chains. The disorder created by presence of the solvent would increase the space requirement of the hydrocarbons beyond the umbrella provided by the polar head groups.

Why would solvent enter the hydrocarbon domain? Although it is generally assumed that a net charge is necessary for head group repulsion, this may not always be the case. PC head groups are oriented with phosphate groups at an angle of 50° to the plane of the bilayer and choline groups nearly parallel to the plane (29). In this configuration, positively charged groups will lie adjacent to each other and will occupy maximal space due to repulsion, and negatively charged groups will behave correspondingly. Solvent may penetrate between head groups and enter the hydrocarbon domain.

Sonication of vesicles at pH 3.5–5.0 has the same effect as raising pH (Table 2). Sonication for long periods produces small vesicles with highly curved surfaces (30). The space occupied by choline head groups on the outer surfaces of such vesicles has been calculated to be 0.74 nm^2, which is greater than the area occupied by the same head group on the inner surface, 0.61 nm^2 (31). The increase in effective diameter of head groups in the outer layer of the vesicle allows for greater spreading of all acyl side chains and would permit cholesterol to fit into both leaflets of the bilayer.

The present studies, some of which were performed at extremes of pH, are applicable to physiological states. Subcellular organelles such as inner mitochondrial membranes, chloroplasts and bacterial cell membranes are the site of proton pumps and have been shown to contain high proportions of anionic and PE lipids (32–34). Neither of these membranes incorporate significant amounts of sterol. Natural and artificial membranes rich in PE give up cholesterol to membranes with high proportions of PC and/or sphingomyelin (35–37). Low pH has been reported to facilitate the fusion of lipid vesicles (38) and Ca ion displacement from phosphatidyl serine monolayers *in vitro* (39).

In the present work, the effect of pH on the cholesterol retaining characteristics of PE and PC vesicles can be explained partly by the influence of repulsion of like charges and differences in degree of hydration of head groups. These two factors influence the space requirements of head groups but other factors need to be taken into account. Data suggest that acyl chain length, interaction of negatively charged groups with cationic species, juxtaposition of charged groups and charge state of the head group anion are pertinent to the affinity of phospholipids for cholesterol.

ACKNOWLEDGMENT

We thank Karin S. Evans and the staff at Langley-Ford Instruments, Coulter Laboratories, Amherst, MA for their assistance in determining the size of vesicles. This work was supported in part by Grant DK 36122 of the NIH, U.S. Public Health Service.

Changes in Lipid Composition of Liver Microsomes and Fatty Acyl-CoA Desaturase Activities Induced by Medium Chain Triglyceride Feeding

José L. Periago, María L. Pita, María A. Sanchez del Castillo, Guillermo Caamaño and María D. Suárez*
Department of Biochemistry and Molecular Biology, University of Granada, Granada, Spain

Changes in fatty acid composition, microsomal Δ^9- and Δ^6-desaturase activities and liver contents of cholesterol and phospholipids were studied in rats fed medium chain triglyceride-supplemented diets. Weanling rats were divided into four groups and fed for three weeks a basal diet with different 10%-fat supplements: corn oil, medium chain triglyceride–corn oil, olive oil and medium chain triglyceride–olive oil. The highest relative content of saturated fatty acids corresponded to corn oil-fed animals. Both monounsaturated fatty acid content and Δ^9-desaturase activity were higher in the animals fed olive oil diets than in corn oil-fed rats. The long chain polyunsaturated fatty acids of the n-3 series were increased in the olive oil and medium chain triglyceride–olive oil-fed groups probably due to the lower linoleic/α-linolenic ratios found in these two diets. The cholesterol/phospholipid molar ratio was unaffected by diet and the unsaturation index was only slightly changed in the four groups. Thus, some mechanism may be operative under these conditions to maintain the homeostasis of the membrane.
***Lipids 24,* 383-388 (1989).**

Changes in lipid composition have been observed in mitochondrial and other membranes when feeding animals diets supplemented with higher levels of saturated or unsaturated fatty acids (1-6). Changes in membrane lipid composition are convenient means of changing membrane physical properties, and these physical changes modulate many membrane-associated enzymes (7).

Medium chain triglycerides (MCT) are a type of fat not common in human nutrition. MCT are absorbed via the portal system, do not require chylomicron formation and are not carnitine-dependent for oxidation. MCT are absorbed and metabolized as rapidly as glucose and have better than twice the caloric density of protein and carbohydrate. They are easily oxidized and utilized as fuel and energy with little tendency to deposit as body fat (8). MCT appear to be less lipogenic in adipose tissue than long chain triglycerides (LCT) in rats, and the mechanism for the diminished adiposity of MCT-fed rats is related to the extensive oxidation of MCT and the enhancement of thermogenesis leading to lessened energy efficiency (9).

As MCT are important components of diets used in many clinical conditions, in the present work, we have investigated whether the addition of MCT to olive or corn oil can modify the fatty acid composition of liver microsomes in rats. At the same time, we have determined the activities of Δ^9- and Δ^6-desaturases, as tightly bound membrane enzymes involved in fatty acid unsaturation, to determine possible modifications in their activity induced by dietary fat.

Abbreviations: C, corn oil; LCT, long chain triglyceride; MCT, medium chain triglyceride; O, olive oil; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PL, phospholipid; PUFA, polyunsaturated fatty acid; GLC, gas liquid chromatography; P/S, polyunsaturated/saturated fatty acid ratio; TLC, thin layer chromatography; UNID, unsaturation index.

MATERIAL AND METHODS

Animals and diets. Male weanling Wistar rats weighing 50-55 g were housed in wire-bottom cages with a 12-hr light/dark cycle. Rats were randomly assigned to 4 groups each containing 10 animals. Each group was fed the same basal diet but with different 10%-fat supplements: 10% corn oil (C), 5% MCT and 5% corn oil (MCT-C), 10% olive oil (O), and 5% MCT and 5% olive oil (MCT-O). In addition to fat, the diets contained 65.6% starch, 10% vitamin-free casein, 8% cellulose, 4.5% mineral mix, 1.5% vitamin mix, 0.55% D,L-methionine and 0.33% choline chloride. The fatty acid composition of the four diets is shown in Table 1.

The diets were stored at 4°C and the rats were fed fresh food daily. Food and water were provided ad libitum. The amount of food consumed by animals was comparable for all groups, and all animals had similar weights at the end of the experiments. After consuming the experimental diets for 3 weeks, the rats were anesthetized with 0.5 ml/100 g rat weight of 20% urethane, and the livers were excised.

Reagents and substrates. [1-^{14}C] Palmitic acid (16:0) (sp. act. 54 mCi/mmol, 97.1% radiochemical purity) and [1-^{14}C] linoleic acid (18:2n6) (sp. act. 58.7 mCi/mmol, 98.8% radiochemical purity) were purchased from Amersham International (Amersham, U.K.). Unlabeled fatty acids, ATP, NADH, and Coenzyme A were purchased from Sigma Chemicals Co. (St. Louis, MO). All other reagents and chemicals were of analytical grade.

Preparation of liver microsomes. Immediately upon removal, the livers were rinsed in cold saline solution and microsomes were prepared as described by Philipp and Shapiro (10).

TABLE 1

Fatty Acid Composition of Diets

Fatty acid	Olive oil	MCT-Olive oil	Corn oil	MCT-Corn oil
8:0	—	14.4	—	14.4
10:0	0.2	33.6	—	34.3
12:0	0.5	1.9	0.1	0.9
14:0	0.5	0.4	0.4	0.5

Results are expressed as the percentages of total fatty acid methyl esters.

Analytical methods. Lipids of liver microsomes were extracted with chloroform/methanol (2:1, v/v) (11). The phospholipids were separated by thin layer chromatography (TLC) on Silica Gel G 60 using two different solvent systems, hexane/ethyl ether/acetic acid (80:20:1, v/v/v) (12) to isolate total phospholipids and ethyl acetate/chloroform/n-propanol/methanol/0.25% KCl (25:25:25:10:9, v/v/v/v/v) (13) to separate individual phospholipid fractions. Total phospholipids (PL), phosphatidylethanolamine (PE), phosphatidylcholine (PC) and phosphatidylinositol (PI) were immediately scraped and analyzed for fatty acid composition.

Methylation of fatty acids from each phospholipid class was done according to Morrison and Smith (14). Fatty acid methyl esters were stored at −30°C under nitrogen until analyzed.

Fatty acid analysis was performed by gas liquid chromatography (GLC) using a Hewlett-Packard 5880 A gas chromatograph equipped with a 4 m length × 2 mm i.d. glass column packed with 10% SP 2330 on 100–120 mesh Chromosorb WAW. Peaks were identified by comparison with known standards (Supelco, Barcelona), and the results were reported as area percentages.

Cholesterol in the liver microsomal extracts was determined by the enzymatic method of Röschlau et al. (15).

Phospholipid phosphorus was measured by spectrometry according to the Fiske and Subarrow method as modified by Bartlett (16).

Microsomal proteins were determined by the Lowry method (17) on the aqueous liver microsomal suspensions.

Enzymic assay. Δ^9- and Δ^6-Desaturase activities were assayed according to methods previously described (18–22). The assay was initiated by adding 0.5–1.0 mg of microsomal protein to the incubation mixture which contained 250 μM NADH, 100 μM reduced glutathione, 130 μM ATP, 1 mM $MgCl_2$, 20 μM coenzyme A and 75 μM ^{14}C-palmitic (sp. act. 0.49–2.45 μCi/μmol) or 75 μM ^{14}C-linoleic acid (sp. act. 0.49–2.45 μCi/μmol) in a final volume of 1 ml. Fatty acids were used as sodium salt-albumin-complex (1 μg free fatty acid/11.5 μg bovine serum albumin). Incubations were carried out at 37°C for 20 min in a metabolic shaker. Enzyme assays were terminated by addition of 1 ml of 10% (w/v) KOH followed by saponification at 100°C for 30 min and addition of 1 ml of 4N H_2SO_4. Lipids were extracted twice with 5 ml chloroform/methanol (2:1, v/v). Both organic phases were combined and evaporated under nitrogen. Before methylation 2 μmol of both 16:0 and palmitoleic (16:1n7) acids were added to the substrate and products of fatty acid mixtures in case of Δ^9-desaturase, and 2 μmol of both 18:2n6 and γ-linolenic (18:3n6) acids were added in case of Δ^6-desaturase to serve as unlabeled carriers for TLC separation of substrate and products. Methylation of fatty acids was carried out with 14% boron trifluoride in methanol (14). Fatty acid methyl esters were separated on Silica Gel G-60 TLC plates containing 5% (w/w) $AgNO_3$, using chloroform for Δ^9-desaturase and ethyl ether/hexane/formic acid (25:75:2, v/v/v) for Δ^6-desaturase as solvents. Plates were sprayed with a 0.1% Rhodamine G solution in acetone and visualized under ultraviolet light. Bands of product, unreacted substrate and origin were collected and eluted with ethyl ether. The ether was evaporated under nitrogen and the radioactivity in the residues was counted in a Beckman LS 7500 liquid scintillation spectrometer (Beckman Instruments, Palo Alto, CA) using as fluor toluene/ethyl acetate/PPO/POPOP (934/665/0.3, v/v/w/w). The percentage of conversion of substrate to product was calculated.

Statistical assay. Comparisons between mean values for fatty acids and related indices were made by a two-way analysis of variance and an a posteriori Scheffe test (23).

RESULTS

The relative fatty acid composition of diets is shown in Table 1. The saturated fatty acid percentages were higher in the two MCT diets. Differences in the percentages of major unsaturated fatty acids among diets were apparent for oleic acid (18:1n9) at a higher level in the olive oil diets and linoleic acid (18:2n6) at a high level in the corn oil diets. It should be noted that the linoleic/α-linolenic acid ratio was different among the diets: 59.1 in the corn oil diets and 11.3 in the olive oil diets.

The relative fatty acid composition of liver microsomal total PL, PC, PE, and PI of rats maintained on the diets for 3 weeks is shown in Tables 2–5. Palmitic (16:0) and stearic (18:0) were the major saturated fatty acids in lipid microsomes. In PL, PC and PE, these fatty acids represented 25%, whereas the others such as lauric (12:0), myristic (14:0) and lignoceric (24:0) acids only represented 1% of the total fatty acids. In PI, myristic acid represented 2–4% of total fatty acids. This fraction also showed an elevated proportion of stearic acid. The level of total saturated fatty acids in liver microsomes was slightly increased in rats fed the C and MCT-C diets. The addition of MCT to olive or corn oil did not significantly modify the saturated fatty acid level.

The proportion of monounsaturated fatty acid was different in each type of phospholipid and was influenced by the type of dietary lipid treatment. Microsomes from animals fed O and MCT-O diets had a higher relative content of oleic and palmitoleic acids in PL, PC and PE. For PI, the relative content of these two fatty acids was similar in microsomes from animals of all groups.

The relative content of linoleic acid was higher in the different phospholipid fractions of microsomes from animals fed C and MCT-C diets. Eicosatrienoic acid (20:3n6) was present in greater proportions in the MCT-O and O groups than in the corn oil groups. PL, PC and PI had higher contents of arachidonic acid (20:4n6) in the MCT-C and C groups. In PE, the highest level of arachidonic acid was in the MCT-O and O groups. Docosatetraenoic acid (22:4n6) and docosapentaenoic acid (22:5n6) were higher in the corn oil groups than in the olive oil groups. The highest values of the n6 > 18 index were obtained for the MCT-C and C groups.

The polyunsaturated fatty acids from the n3 series include α-linolenic (18:3n3), eicosapentaenoic (20:5n3), docosapentaenoic (22:5n3) and docosahexaenoic (22:6n3) acids. The highest values were generally for 22:5n3 and 22:6n3. In general these four fatty acids were at higher levels in the olive oil groups than in the corn oil groups. The n3 > 18 index was highest in the olive oil groups.

The unsaturation index (UNID) was decreased in PL of O-fed rats, but was mostly unaffected by diet in PC, PE and PI.

Table 6 shows the results for the Δ^9- and Δ^6-desaturase activities. Δ^6-Desaturase activity was higher in MCT-C

[b] $p < 0.01$ significance with respect to corn oil-fed rats.

and C groups than in MCT-O and O groups. Δ^9-Desaturase activity changed in a direction opposite to that of the Δ^6-desaturase; it was highest in the MCT-O and O groups.

Table 7 shows the results obtained for microsomal content of cholesterol and phospholipid. Cholesterol was significantly lower in the MCT-C group than in the C and MCT-O groups. There were no differences in the cholesterol/phospholipid molar ratio related to the diet.

DISCUSSION

Many studies have been performed related to the changes occurring in tissue and membrane lipids as a result of feeding a variety of lipid supplements (2,3,21,22). For mammalian membrane lipids, it has been observed that large changes in the level of dietary lipid saturation have little or no effect on the level of saturation present in membrane lipids (2,7,22,25,26). This may reflect on the existence of some homeostatic mechanism that preserves a constant ratio of saturated to unsaturated fatty acids and the fluidity of membranes (6,27).

In the present study, we tried to ascertain if MCT feeding can introduce apparent changes in individual fatty acids or desaturase activities in hepatic microsomes of rats when fed with O or C.

Liver microsomal phospholipids obtained from the C group had a higher relative content of saturated fatty acids than those obtained from the O group, despite the fact that the polyunsaturated/saturated fatty acid ratio (P/S) was higher in the C than in the O diet. This difference cannot be attributed to the saturated fatty acid content of the C and O diets, which is similar for the two major saturated fatty acids, palmitic and stearic. Similar results have been obtained by others (2), who suggested that the increase observed in the level of saturated fatty acids in animals fed a linoleic acid-rich diet compensated for the high deposition of longer metabolites of the n6 series in membrane lipids which occurs with these diets. However, different authors have described that dietary PUFA produce an inhibition of hepatic lipogenesis (28–31).

In liver microsomal phospholipids from the MCT-C and MCT-O groups, the long chain saturated fatty acid level was not significantly modified with respect to their control groups. It is probable that medium chain fatty acids are not present because of their high oxidation rate in liver (8).

Oleic acid and palmitoleic acid contents were higher in the liver microsomes of rats fed O and MCT-O, both diets having a high content of these two acids. Moreover, Δ^9-desaturase activity was lower in the C- and MCT-C-fed groups. This was probably due to the high dietary content of linoleic acid which inhibited this activity (20,22). The increase observed in palmitoleic acid in the two groups fed MCT, when compared with their respective controls could be due to the hepatic lipogenic effect of MCT (32–34).

The relative content of linoleic acid in microsomes was elevated in the two groups fed MCT-C and C because of diet composition. The higher proportion of 20:3n6 fatty

acid in the two groups fed MCT, when compared with their respective control groups C and O, suggests an enhanced Δ^6-desaturase activity as a result of the hyperinsulinemic effect of MCT (35,36). However, our results for in vitro Δ^6-desaturase activity show a decrease or no change in MCT-C and MCT-O, when compared to their respective control C and O. The influence in vivo of MCT could be through a decrease in Δ^5-desaturase activity although levels of arachidonic acid found in microsomes were not significantly modified in MCT-fed animals. The accumulation of 20:3n6 fatty acid is noteworthy because it is precursor of PGE_1, an antiaggregatory factor, and also because 12 and 15 hydroxyeicosaenoic acids formed from 20:3n6 are inhibitors of platelet aggregation (37,38).

The precursor of the n3 series of PUFA (α-linolenic acid), was present in relatively small amounts in the different phospholipid fractions. The higher level of PUFA from the n3 series found in the 2 O-fed animals is interesting to note because of the its important antiaggregatory properties of these fatty acids (39).

The n3/n6 PUFA ratio in tissues depends more on the linoleic/α-linolenic ratio in the diet than on the absolute content of the individual fatty acid. Studies both in vivo and in vitro (40,41) have demonstrated that the competition of 18-carbon unsaturated fatty acids for further desaturation is in the order of n3 > n6 > n9 (42). This would account for the increased synthesis of n3 PUFA series in our groups fed O and MCT-O, diets in which the linoleic/α-linolenic ratio was lowest (11.3) although Δ^6-desaturase determined in vitro was also lower. PUFA n6 > 18 were higher in the C and MCT-C groups in agreement with the Δ^6-desaturase activity shown in vitro. Moreover, these C and MCT-C diets were rich in the precursor, linoleic acid, and had a higher linoleic/α-linolenic ratio (59.1).

Despite the dietary induced changes in PUFA, the value of UNID (which is a general way of expressing membrane unsaturation (7)) was only slightly affected by the nature of the dietary lipid intake.

The microsomal cholesterol content was lower in the MCT-C group. Phospholipid phosphorus and the cholesterol/phospholipid molar ratio showed similar values in the 4 groups. Because the UNID was mostly unaffected by the diet and the cholesterol/phospholipid ratio did not significantly change, we can conclude that these different diets do not produce any profound modifications in factors altering membrane fluidity. Changes observed in the Δ^9- and Δ^6-desaturase activities could be due to the different microsomal fatty acid patterns induced by the diets. This presumed that the response of these desaturase activities to the different diets takes place in order to maintain the homeostasis of membranes.

[Received March 28, 1988; Revision accepted November 29, 1988]

Δ6 and Δ5 Desaturase Activities in Liver from Obese Zucker Rats at Different Ages

Jean-Paul Blond*, Cherifa Henchiri and Jean Bézard
Laboratoire de Physiologie Animale et de la Nutrition, U.A. C.N.R.S. 273, Faculté des Sciences Mirande, B.P. 138, 21004 Dijon Cedex, France

Δ6 Desaturation of linoleic acid (18:2 n-6) and Δ5 desaturation of dihomo-γ-linolenic acid (20:3 n-6) were measured in liver microsomes from genetically obese Zucker rats (fa/fa) and from their lean littermates (Fa/—). Both groups were fed a balanced commercial diet. The rats were 6, 9 and 12 weeks old, which corresponded to stages in their active growth period. The content of total fatty acids and n-6 polyunsaturated fatty acids in whole liver and liver microsomes was also determined in order to ascertain how the desaturase activities measured *in vitro* reflected regulation of essential fatty acid metabolism *in vivo*. Contrary to values obtained for Δ6 desaturation, Δ5 desaturation at nonsaturating substrate levels were lower in obese rats than in lean controls. In contrast, at saturating substrate level, the maximal Δ5 desaturase activities were the same in both phenotypes and they increased with age. Study of Δ5 desaturation kinetics (1/V vs 1/S) showed that V_m did not differ between 12-week-old obese and lean rats, whereas K_M in obese rats was much lower than in controls, expressing the very low affinity of the enzyme for the substrate in obese animals. The fatty acid composition of liver lipids reflected the results of desaturase activities *in vitro*. In particular, the ratios 20:4 n-6/20:3 n-6 were lower in obese rats than in lean rats, which can be explained by the lower conversion of 20:3 n-6 into 20:4 n-6 by Δ5 desaturation. However, the total amount of 20:4 n-6 in the whole liver did not differ between phenotypes, whatever their age. This work presents evidence for a relationship between the changes in fatty acid compositional data in hepatic total lipids, total lipids of liver microsomes and modifications of fatty acid desaturase activities in the genetically obese Zucker rat.
***Lipids 24,* 389–395 (1989).**

Obesity in the genetically obese Zucker rats is associated with hyperinsulinemia and hyperlipidemia (1–4). Rates of lipogenesis and Δ9 desaturase activity in the liver of obese rats are generally elevated when compared with their lean littermates. Oleic acid (18:1 n-9) and particularly palmitoleic acid (16:1 n-7) contents are thus increased both in liver and in adipose tissue. This increase, however, depends on the dietary lipids (8,9). Modifications in the composition of n-6 polyunsaturated fatty acids, especially linoleic acid (18:2 n-6) and arachidonic acid (20:4 n-6), are also observed in liver and blood lipids of obese compared with lean rats (8,11), with a decreased ratio of 20:4 n-6/18:2 n-6. This altered essential fatty acid composition may be related to differences in desaturation activity in livers of obese rats when compared with their lean littermates.

In rats, Δ6 desaturase, which converts 18:2 n-6 into 18:3 n-6 (γ-linolenic acid), and Δ5 desaturase, responsible for the transformation of 20:3 n-6 (dihomo-γ-linolenic acid) into 20:4 n-6, are present in the liver cell endoplasmic reticulum (12,13). Desaturation reactions are slower than the intermediary step of elongation (14–16) and are influenced by hormonal and nutritional factors (17–22). Insulin seems more specifically involved in the regulation of Δ6- and Δ5 desaturase activities since injection of the hormone into diabetic rats increases these activities (23–25). The enzyme activities can also depend on the amount of ingested 18:2 n-6, as we have previously observed (22,26).

In the present work, we studied the biosynthetic rate of 20:4 n-6 from 18:2 n-6 *in vitro* and its consequence on liver fatty acid composition *in vivo* in both obese and lean Zucker rats at different ages. The aim of this work was to obtain a better insight into the control of this biosynthetic pathway by factors such as hyperphagia and hyperinsulinemia. To ascertain how the enzyme activities measured *in vitro* were regulated *in vivo*, the fatty acid composition of total liver and liver microsome lipids was determined. Six-, nine- and twelve week-old rats were chosen because this corresponds to their active growth period during which morphological and biochemical parameters rapidly change (2) as do the enzymatic activities of hepatic lipogenesis (27).

MATERIALS AND METHODS

Chemicals. [1-^{14}C] linoleic acid and [2-^{14}C] dihomo-γ-linolenic acid (55 mCi mmol^{-1}, 97% radiochemically pure) were purchased from the Radiochemical Center (Amersham, U.K.). Coenzymes and unlabelled fatty acids were provided by Sigma Co. Inc. (St. Louis, MO). All other chemicals used, issued from Sigma and Merck (Darmstadt, Germany), were of analytical grade.

Animals and diet. Three experiments were carried out with Zucker rats from the Centre de Sélection et d'Elevage d'Animaux de Laboratoire (Centre National de la Recherche Scientifique, Orléans la Source, France). In each experiment, 4 obese rats (fa/fa) and the same number of their lean littermates (Fa/—) were used. In the first two experiments, the 4-week-old obese and lean rats weighed 112 ± 8 g and 91 ± 7 g, respectively, at their arrival. They were allowed free access to tap-water and were fed ad libitum on the standard diet (AO4 from UAR, Villemoisson sur Orge, France) for 2 weeks or for 5 weeks and were thus sacrificed at 6 and 9 weeks of age, respectively. In the third experiment, the obese and lean rats were 11 weeks old at their arrival and weighed 317 ± 18 g and 226 ± 14 g, respectively. They were given the commercial diet for one week before being sacrificed (12 weeks old). The weight composition of the commercial diet received before and after arrival at the laboratory was as follows: proteins 17%, carbohydrates 58.7%, lipids 3%, cellulose 4.3%, mineral salts 4%, vitamins 1% and water 12%. Linoleic acid which represented 52.7% of the total fatty acid of the diet was in sufficient amount to avoid fatty acid deficiency likely to modify the conversion rate of 18:2 n-6 into 20:4 n-6.

Isolation of microsomes. At the end of the experiment, obese and lean rats were killed by decapitation between

*To whom correspondence should be addressed.

8 and 9 a.m. Livers were removed, weighed and washed. About 3 g of each liver were cut into thin slices and homogenized in 6 volumes of 0.25 M sucrose and 0.05 M phosphate (pH 7.4) solution. The homogenate was centrifuged at 13,000 × g for 20 min to precipitate cell fragments, nuclei and mitochondria. After the floating lipids were removed with filter paper, the supernatant was centrifuged at 100,000 × g for 60 min. The pellet, principally composed of microsomes, was resuspended in 0.4 ml supernatant and 0.8 ml homogenizing solution. The microsomal protein content was estimated, according to Layne (28), to be about 30 mg ml^{-1}. All the operations wre conducted at 4°C. Four separate assays were performed for each type of rat.

Enzyme assays in vitro. In each assay, 5 mg microsomal protein were incubated at 37°C and with continuous shaking with 60 nmol [1-^{14}C] 18:2 n-6 or 20 nmol [2-^{14}C] 20:3 n-6. Each radioactive substrate was diluted with the corresponding unlabelled fatty acid to obtain an ethanol solution with a specific activity of 5 mCi $mmol^{-1}$ (20 nmol 10 μl^{-1} of solution). The incubation medium contained 72 mM phosphate buffer, pH 7.4, 4.8 mM $MgCl_2$, 0.5 mM coenzyme A, 3.6 mM ATP and 1.2 mM NADPH, in 2.1 ml of total volume, as reported elsewhere (26). The duration of incubation was 10 min for Δ6 desaturation and 5 min for Δ5 desaturation, corresponding to linearity between the transformed amount of substrate and the amount of microsomal protein. The substrate levels were nonsaturating in order to gain a better appreciation of the influence of microsomal lipids on the desaturation rate (29,30). For Δ5 desaturation, a saturating substrate level (40 nmol) was also used in order to determine the maximum Δ5 desaturation capacity of liver microsomes.

The reactions were stopped with KOH in ethanol and the fatty acid methyl esters were prepared as previously reported (26). The conversion of the substrates was determined by measuring the radioactivity of the newly formed fatty acids after fractionation by gas-liquid chromatography and collection according to Bézard et al. (31). A Packard model 470 gas chromatograph (Packard Instr., Downers Grove, IL) was equipped with a 180-cm × 4-mm i.d. coiled glass column filled with 24% DEGS (Applied Science Lab., State College, PA) on 80–100 mesh Chromosorb (Johns-Manville, Denver, CO). The fraction collector was from Packard and the radioactivity was measured by liquid scintillation spectrometry in a 300 C Tricarb Packard Spectrometer.

The percentage of conversion of substrate was deduced from the ratio of the radioactivity recovered in the newly formed fatty acids to the total radioactivity recovered in the analysis. Desaturation activity was calculated from the conversion percentage and expressed as nmol of transformed substrate under the conditions used. With the saturating level of 20:3 n-6, the maximal capacity of Δ5 desaturation was expressed as nmol of desaturated substrate per min and per whole liver.

Fatty acid analysis. Lipids from total liver and from liver microsomes were extracted according to Delsal (32). The amount of total lipids per g of liver was determined gravimetrically from an aliquot. Another aliquot was transmethylated, and the fatty acid methyl esters were analyzed by capillary gas-liquid chromatography on a model 419 Becker-Packard apparatus equipped with a 30-m × 0.3-mm i.d. glass capillary column coated with Carbowax 20 M. Before methylation, a known amount of heptadecanoic acid was added to the lipid extract as an internal standard to calculate the amount of total and individual fatty acids. The separation of lipid classes was achieved by liquid column chromatography following the procedure of Hirsch et al. (33).

Statistics. Statistical evaluation of the means was performed by analysis of variance and by classification of the means using the Duncan's multiple range test (34).

RESULTS

Data reported in Table 1 show that the body weight of obese rats was higher than that of lean controls whatever the age studied. It increased in both phenotypes with age. Liver weight was also greater in obese rats compared with lean at the 3 ages and it also increased with age in both phenotypes. When expressed as a proportion of body weight, liver weight was still generally higher in obese rats and it decreased with age in both phenotypes. The higher liver weight in obese rats was partly due to higher lipid content and this content increased with age, contrary to the liver lipid content of lean rats.

As shown in Table 2, at nonsaturating level of substrate, the Δ6 desaturation activity was found to be different in obese and lean rats only at 9 weeks. Δ5 Desaturation, on the contrary, was lower in obese rats whatever the age but it was more evident at 12 weeks. However, when measured at saturating level of 20:3 n-6 (Table 3), the maximal Δ5 desaturation activity in obese rats was not significantly different from that in lean controls except at 6 weeks. Because of enlargement of the liver, the capacity of the whole organ to convert 20:3 n-6 into 20:4 n-6 was nonetheless higher in obese rats.

When comparing the data reported in Table 2 and Table 3 for Δ5 desaturation, it appears that the amount of 20:4 n-6 formed from 20:3 n-6 only clearly increased in 12-week-old rats when the amount of substrate increased from 20 to 40 nmol. At this age, the determination of V_m and K_M for Δ5 desaturation (Fig. 1) shows that V_m was

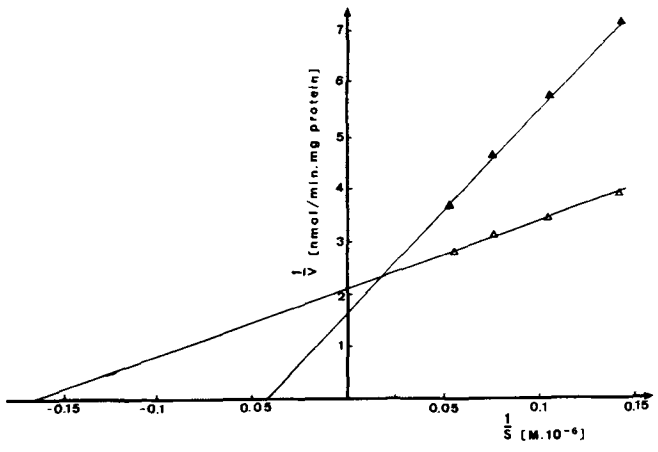

FIG. 1. Lineweaver-Burk plot of dihomo-γ-linolenic acid (20:3 n-6) desaturation to arachidonic acid (20:4 n-6) in liver microsomes of 12-week-old obese (▲—▲) and lean (△—△) rats. The details of animal groups and analytical procedure are given in Materials and Methods and in the legend to Table 1. Approximate kinetic parameters: K_m = 2.5 10^{-5}M; V_{max} = 0.58 nmol/min/mg protein (obese rats); K_m = 0.6 10^{-5}M; V_{max} = 0.48 nmol/min/mg protein (lean rats).

TABLE 1

Body Weight, Liver Weight and Liver Lipid Content of Obese and Lean Zucker Rats at Different Ages

	Phenotype	Age (weeks) 6	9	12
Body weight (g)	Obese	202 ± 6^{c}	251 ± 5^{b}	373 ± 32^{a}
	Lean	136 ± 7^{z}	219 ± 3^{y}	290 ± 9^{x}
	Significance	$p < 0.001$	$p < 0.001$	$p < 0.01$
Liver weight (g)	Obese	9.7 ± 0.5^{c}	11.9 ± 0.3^{b}	16.1 ± 2.4^{a}
	Lean	6.1 ± 0.3^{y}	9.0 ± 1.0^{x}	11.0 ± 1.4^{x}
	Significance	$p < 0.001$	$p < 0.01$	$p < 0.05$
Liver weight (g/100 g of body weight)	Obese	4.82 ± 0.08^{a}	$4.74 \pm 0.20^{a,b}$	4.30 ± 0.30^{b}
	Lean	4.48 ± 0.28^{x}	$4.11 \pm 0.15^{x,y}$	3.80 ± 0.17^{y}
	Significance	NS	$p < 0.01$	$p < 0.05$
Lipid content (mg/g of liver)	Obese	52.5 ± 2.1^{c}	60.3 ± 3.9^{b}	68.5 ± 1.6^{a}
	Lean	48.9 ± 0.6^{y}	45.8 ± 1.5^{x}	$50.0 \pm 3.5^{x,y}$
	Significance	$p < 0.02$	$p < 0.001$	$p < 0.001$

Results are expressed as means ± S.D. for 4 rats of each phenotype. Statistical evaluation of the means was performed by analysis of variance and by classification of the means using the Duncan's multiple range test. For each age means were compared between phenotypes and the differences estimated at different threshholds (NS = nonsignificant; $p < 0.05$.) Means were also compared between ages for each phenotype. Values not followed by the same superscript were significantly different ($p < 0.05$): a, b, c in order of decreasing magnitude for obese rats; x, y, z for lean rats.

TABLE 2

Δ6- and Δ5-Desaturase Activities of Hepatic Microsomes of Obese and Lean Zucker Rats at Different Ages (at nonsaturating substrate levels)

	Phenotype	Age (weeks) 6	9	12
Δ6 desaturation[a] (60 nmol)	Obese	4.70 ± 0.65^{a}	4.90 ± 0.25^{a}	5.40 ± 0.40^{a}
	Lean	4.50 ± 0.10^{z}	7.40 ± 0.70^{x}	6.00 ± 0.30^{y}
	Significance	NS	$p < 0.01$	NS
Δ5 desaturation[b] (20 nmol)	Obese	$3.93 \pm 0.42^{a,b}$	3.68 ± 0.15^{b}	4.35 ± 0.50^{a}
	Lean	5.12 ± 0.45^{y}	5.05 ± 0.52^{y}	7.55 ± 0.32^{x}
	Significance	$p < 0.01$	$p < 0.01$	$p < 0.001$

Means values ± S.D. given for three rats (Δ6 desaturation) or four rats (Δ5 desaturation) of each phenotype and of each age.

[a]nmol 18:2 n-6 fatty acid converted to 18:3 n-6/10 min/5 mg of microsomal protein.

[b]nmol 20:3 n-6 fatty acid converted to 20:4 n-6/5 min/5 mg of microsomal protein.

For statistical evaluation, see footnote in Table 1.

only slightly higher in obese rats (0.58 nmol of substrate transformed per min per mg of microsomal protein compared with 0.48 nmol in lean rats). On the contrary, K_M was distinctly higher in obese rats (2.5 10^{-5}M) than in lean controls (0.6 10^{-5}M). The determination of K_M for Δ6 desaturation was not made in this work for 12-week-old rats. However, determinations of Δ6 desaturase activity, at saturating substrate level (120 nmol), gave the following figures: 8.1 ± 0.3 and 8.3 ± 0.4 nmol 18:2 n-6 converted to 18:3 n-6/10 min/5 mg of microsomal protein, for obese and lean rats, respectively. Since the activities were not significantly different at nonsaturating (Table 2) and saturating substrate levels, K_M could not be distinctly different in obese and lean rats.

The quantities per g of liver of total and n-6 fatty acids are reported in Table 4. The concentration of total fatty acids was higher in liver from obese rats than from their lean littermates and increased with age in both phenotypes. Since the obese rat livers were larger than the controls, the differences, expressed as mg per whole liver, are still more important between the two types of rats. The amount of 18:2 n-6 and 20:4 n-6 per g of liver was generally lower in obese rats, but the amount per whole liver was not significantly different between the

two phenotypes because of the larger liver of obese rats. However, the amount of 20:3 n-6 per g of liver was clearly higher in obese rats compared with lean. The difference was even greater in the whole organ. The lower ratio of 20:4 n-6/18:2 n-6 in obese rats reflects a lower rate of the overall conversion of 18:2 n-6 into 20:4 n-6 (Δ6 desaturation, elongation and Δ5 desaturation). This seems primarily due to a decrease in the rate of Δ5 desaturation of 20:3 n-6 since the ratio of 20:4 n-6/20:3 n-6 was found to be even lower. This ratio was not modified with age in obse rats.

Table 5 shows the quantities per g of liver of total and n-6 fatty acids in liver phospholipids from obese and lean rats. Comparison with data reported in Table 4 allows

appreciation of the proportion of phospholipid-bound fatty acids in total lipids. This proportion was high and of the same magnitude in obese and lean rats (more than 80% at 6 weeks of age). It decreased with age in both phenotypes but to a greater extent in obese rats, reflecting enrichment of the liver with triacylglycerols. Contrary to 18:2 n-6, the quasi totality of 20:3 n-6 and 20:4 n-6 was present in phospholipids at 6 weeks of age in obese and lean rats. The contribution of phospholipids to the total n-6 fatty acids then decreased with age, except for 20:3 n-6 in lean rats. Thus, the higher proportion of 20:3 n-6 in the total lipids of the obese rat liver became less and less a reflection of its proportion in phospholipids which was contrary to that found in lean rat liver. The proportion of 20:4 n-6 in phospholipids also decreased with age, but this was similar in both phenotypes. As above, the higher ratio of 20:4 n-6/20:3 n-6 in obese compared with lean rats reflects a lower rate of Δ5 desaturation in these animals.

Concentrations of total fatty acids and n-6 fatty acids of liver microsomes (mg per g of liver) are reported in Table 6. Differences which were observed between obese and lean rats in total liver lipids (Table 4) were not generally observed in microsomal lipids. Only the ratios 20:4 n-6/20:3 n-6 were found to be significantly lower in obese rats. However, the amount of 20:3 n-6 and 20:4 n-6 in microsomes per g of liver in obese rats was higher than in lean rats at 12 weeks of age. In these 12-week-old rats, the neutral lipid fatty acids represented 32% of total microsomal fatty acids in obese rats and 17% in lean rats. The saturated and monounsaturated fatty acids were predominant in this fraction amounting to 0.47 and 0.12 mg/g of liver in obese and lean rats, respectively.

DISCUSSION

This work shows that results obtained on desaturation rates *in vitro* (Tables 2 and 3) correlate with the fatty acid composition of total liver and liver microsomes (Tables 4 and 6) in obese rats. *In vivo,* the lower ratios of 20:4 n-6/18:2 n-6 and especially of 20:4 n-6/20:3 n-6 observed in obese rats suggest a lower rate of overall desaturation of 18:2 n-6 into 20:4 n-6, mainly due to a lower rate of Δ5 desaturation. The amount of 20:4 n-6 increased in liver with age, also suggesting that desaturation rates increase. However, persistence of a low 20:4 n-6/20:3 n-6 ratio in obese rats suggests that the Δ5 desaturation step remained the most affected in these animals.

These results were corroborated by results obtained by direct enzyme assays *in vitro* on the Δ6 desaturation of 18:2 n-6 and the Δ5 desaturation of 20:3 n-6 by liver microsomes. At nonsaturating substrate levels, which better reflect physiological conditions (29), the Δ6 desaturation rate was not different between obese and lean rats. Such a result agrees with recent observations by Wahle (35). In contrast, the Δ5 desaturation rate of

20:3 n-6 at nonsaturating substrate level was found to be lower in obese rats, whatever the age tested. The same tendency existed with saturating level of 20:3 n-6 but the difference between obese and lean rats was not statistically significant. Values of K_M and V_m for Δ5 desaturation found in 12-week-old obese rats (Fig. 1) suggested that the affinity of the enzyme for its substrate was lower in obese than in lean rats. Obviously, the measured Δ5 desaturation assay incorporates several reactions, i.e., activation of the substrate to acyl-CoA, desaturation itself and incorporation of both the substrate and of reaction product into microsomal lipids. The measured K_M and V_m values are approximate but they nonetheless indicate that the overall Δ5 desaturation rate was lower in obese rats. The desaturation activity also depends on the lipid environment (30). The activity can be modified by the fatty acid composition of the membrane phospholipids of microsomes. It can also be partially inhibited by certain free fatty acids present in neutral lipids acting as substrates for the enzyme. Pugh and Kates (36) provided evidence that arachidonic acid can be synthesized either from the CoA derivative or from the phospholipid-bound form of eicosatrienoic acid. The decrease in Δ5 desaturase activity in obese rats can thus reflect a lower affinity for the phospholipid substrate or a reduced capability to form the CoA derivative. Our data do not resolve these options.

Our results also show that hepatic desaturase activity and the amount of 20:4 n-6 in liver lipids increased with age in obese rats. Since hyperphagia takes place after weaning in these rats, an increase in 18:2 n-6 intake could in part explain the desaturase stimulation during the 6 to 12 weeks growth period. However, the same variations were also observed in lean rats which do not exhibit hyperphagia. The explanation could be that the amount of 18:2 n-6 ingested also increases with increased dietary consumption in both types of rats during growth. Moreover, growth activity is accompanied by modifications of hormonal status which can in turn influence desaturase activities. In particular, the hormonal status in obese rats, which are characterized by hyperinsulinemia and hypothyroidism (1-4), could afford an explanation for the differences observed in desaturase activities between obese and lean phenotypes. Thyroid hormones are known to inhibit microsomal Δ6 desaturation in rats (37,38) but nothing is known about Δ5 desaturation. In diabetes, Δ9, Δ6 and Δ5 desaturations are reduced but are restored by insulin injection (23-25). Our results could, in this view, be explained by a lower sensitivity of Δ5 desaturation to the stimulatory effect of insulin in obese rats. However, Weekes et al. (9) demonstrated that changes in the plasma insulin level illicited by changes in the diet in obese and lean rats were not correlated with changes in Δ9 desaturation. Is it the same with Δ6 and Δ5 desaturations? Moreover, despite a low level of plasma insulin in lean rats, the Δ6 desaturation rate in these animals at nonsaturating levels of substrate was identical to that observed in obese

rats. Lastly, the maximal Δ5 desaturation rate measured at saturating substrate level was the same in both phenotypes. It can be concluded from these observations that insulin level does not constitute a major factor in the regulation of Δ6 and Δ5 desaturation activities in obese Zucker rats.

In these animals the total amount of liver arachidonic acid was generally close to that found in lean rats, suggesting that liver Δ6 and Δ5 desaturation rates were high enough in obese rats to satisfy the requirement of the liver for 20:4 n-6. This does not prove, however, that the requirement for 20:4 n-6 for secretion of VLDL phospholipids by the liver is also satisfied.

Results reported in this work which complement others previously reported (11,39,40) enforce the idea that liver Δ6 and Δ5 desaturases are two distinct enzymes, since genetic obesity does not similarly affect their activity.

A lower ratio 20:4 n-6/20:3 n-6 was also found in platelet phospholipids from 12-week-old obese rats compared with lean rats (11). This can be correlated to what was observed in this work on total liver and microsome lipids since plasma phospholipids principally originate from liver and since they exchange with platelet phospholipids. In obese rats, this ratio in microsomal lipids was the same at 6 and 9 weeks whereas it is increased at 12 weeks but much less than in lean rats (Table 6). However, the amount of 20:4 n-6 in total liver microsomes increased in obese rats at a higher level than in lean rats. The same was true for platelets in which the amount of 20:4 n-6 was higher than in their lean littermates, despite a lower 20:4/20:3 ratio (11). In platelets, 20:4 n-6 is the precursor of thromboxane A_2 which induces aggregation. This would then agree with the influence of aging, associated with obesity, in increasing platelet aggregability and in decreasing vessel prostacyclin production in genetically obese rats (41).

To our knowledge, this work constitutes the first insight in the relations between Δ6 and Δ5 desaturation activities in liver microsomes and n-6 fatty acid content of liver lipids in obese Zucker rats. In contrast, in the genetically obese mouse (ob/ob), it was demonstrated that liver phospholipids contained a higher amount of 20:4 n-6 than in lean controls (42). The Δ6 and Δ5 desaturation activities were also higher (43). These observations seem to prove that essential fatty acid metabolism and its regulation by hormones are different in the obese mouse (ob/ob) and in the obese rat (fa/fa).

Molecular Species of Glycerophospholipids and Sphingomyelins of Human Erythrocytes: Improved Method of Analysis

J.J. Myher, A. Kuksis* and **S. Pind**
Banting and Best Department of Medical Research and Department of Biochemistry, University of Toronto, 112 College St., Toronto, Ontario, Canada M5G 1L6

This study reports the application of modern methods of molecular species analysis in determination of the structure of both major and minor glycerophospholipids and sphingomyelins of human erythrocytes. Individual phospholipid classes were resolved from total lipid extracts by thin-layer chromatography. Diradylglycerols were released by phospholipase C and converted into trimethylsilyl ethers, which were resolved into the alkenylacyl, alkylacyl and diacylglycerol subclasses by normal phase high performance liquid chromatography. Molecular species of diradylglycerols and ceramides were quantitated according to carbon and double bond number by gas liquid chromatography using a fused silica capillary column wall-coated with bonded RTx-2330. The molecular species of ceramides were determined by GC/MS. The diradyl glycerophosphocholines contained 93.0% diacyl, 4.6% alkylacyl and 2.5% alkenylacyl, while the diradyl glycerophosphoethanolamines were made up of 48.8% diacyl, 47.8% alkenylacyl and 3.4% alkylacyl subclasses. Analysis of the molecular species showed that the long chain polyunsaturated acids were mainly combined with C_{16} in all diradyl GPC subclasses and in diacyl GPE, while in the alkylacyl and alkenylacyl GPE and in diacyl glycerophosphoinositol and diacyl glycerophosphoserine they were combined mainly with C_{18} saturated fatty chains. In addition to the C_{16} and C_{18} alkyl and alkenyl, the ether fractions also contained significant proportions of C_{20}, C_{22} and C_{24} chains. The molecular species of the ceramide moieties of the SPH were made up largely of mono- and diunsaturated species. Over 200 molecular species were identified and quantitated in a representative sample of human red blood cells.
***Lipids 24,* 396-407 (1989).**

During the past several years specific physiological functions have been recognized for minor molecular species of glycerophospholipids (GPL) of plasma and subcellular membranes of cells. Thus, specific diacyl GPL classes have been shown to provide characteristic diacylglycerol species as second messengers for the activation of protein kinase C (1), while other diacyl GPL species donate their arachidonic acid residues for prostanoid formation (2). In the retinal rods minor amounts of very long chain polyunsaturated species of glycerophosphocholines (GPC) have been discovered to provide highly organized membrane structures for light perception (3). The ether-linked GPL have long been known to be present in increased amounts in neoplastic tissues (4), where they may serve both as promoters and inhibitors of invasiveness (5). The identification of *sn*-glycero-1-palmityl-2-acetyl-3-phosphocholine as the platelet activating (6) and antihypertensive (7) factor has served to focus further attention on the physiological function of specific molecular species of GPL. In addition, the recent identification of specific molecular species of glycerophosphoinositol (GPI) as structural components of the lipid anchor of specific cell membrane proteins (8) has stimulated interest in the identification of the minor molecular species of GPL of all cell membranes and lipoproteins.

In the present study we have combined several chromatographic and mass spectrometric techniques to identify and quantitate over 200 molecular species of GPL and over 50 molecular species of sphingomyelins (SPH) in a representative sample of human red blood cells. A preliminary report has appeared (9).

MATERIALS AND METHODS

Erythrocytes. The erythrocytes for all analyses of the GPL classes and molecular species were obtained from the same healthy adult male (26 years) in the fasting state. The subject also provided the red cell SPH which, however, were examined only for the fatty acid composition and carbon number distribution of the ceramide moieties. The molecular species of erythrocyte SPH had been obtained previously (J. J. Myher and A. Kuksis, unpublished results) on another healthy adult male, who had a closely similar fatty acid and ceramide composition for its erythrocyte SPH. Comparable carbon number distributions of the ceramide moieties of erythrocyte SPH were obtained on three other healthy adult males (26–50 years). Plasma and cells were separated by centrifugation, and cells were washed to remove the buffy coat (10).

Lipid isolation and derivatization. Total lipid extracts were obtained with chloroform-methanol (2:1, v/v) (11). Individual GPL classes and SPH were isolated from the total lipid extracts by thin-layer chromatography (TLC) using chloroform-methanol-acetic acid-water 75:45:12:6 as solvent. The phosphatidylserine/phosphatidylinositol (PS/PI) fraction was resolved using chloroform-methanol-3 M ammonia 65:35:6.5 (12). Diradylglycerols and ceramides, released from the GPL and SPH, respectively, by phospholipiase C *(B. cereus)* were converted into the trimethylsilyl (TMS) and tBDMS ethers (13). Aliquots of the TMS ethers of the diradylglycerols were converted to the fatty acid methyl esters and dimethylacetals by a 2-hr reaction at 80°C with fresh methanol-H_2SO_4 (94:6, v/v). Alkylglycerol diacetates were prepared with acetic anhydride/pyridine (1:1, v/v) after transmethylation of the alkylacylglycerol TMS ether with 1N sodium methoxide in methanol-toluene (3:2, v/v) for 15 min at 20°C. Following methanolysis, the mixture was neutralized with 1% acetic acid in hexane and extracted by adding 200 μl

chloroform, 0.5 ml water and 50 μl 3 M aqueous ammonia. The organic phase was washed with 250 μl water and then dried by passing it through a small column of anhydrous sodium sulfate. After drying under nitrogen, the sample was acetylated for 0.5 hr at 80°C with 75 μl acetic anhydride-pyridine (1:1, v/v). The reagents were removed by evaporation under nitrogen and the products purified by high performance liquid chromatography (HPLC).

Chromatographic analyses. The TMS ethers of the diradylglycerols were separated within 10 to 15 min into alkylacyl, alkenylacyl and diacylglycerol fractions by HPLC on a Supelcosil LC-Si (5 μ) column (250 cm × 4.6 mm i.d.) using 0.3% isopropanol in hexane (1 ml/min) (14). The analyses were done at 30°C and the lipid solutes were monitored at 214 nm. After evaporation of the solvent under nitrogen the samples were redissolved in a small volume of hexane and quantitated by gas liquid chromatography (GLC). Fatty acid methyl esters (FAME) (5.2–7.2 min) and dimethylacetals (7.7–10.7 min) were resolved by normal phase HPLC, using 0.25% isopropanol in hexane, while FAMEs (3.5–4.3 min) and alkylglycerol acetates (7.3–9.9 min) were separated with 0.8% isopropanol in hexane. SPH was converted to FAMEs by acidic transmethylation as described for the diacylglycerols. The molecular species of the di-tBDMS ethers of ceramides were analyzed by gas chromatography/mass spectroscopy (GC/MS) as previously described (15). The species were first quantitated by carbon number by gas chromatography (GC) using flame ionization detection (FID), and the individual species within each carbon number were determined by GC/MS. The composition by molecular weight was determined from the $[M - 57]^+$ ions. The composition of the long chain bases was derived from the $[CH_3(CH_2)_n(CHCH)_mCHO\text{-}tBDMS]^+$ and the $[CH_3(CH_2)_n(CHCH)_mCHO(tBDMS)CHCHOSi(CH_3)_2]^+$ ions, whereas the composition of the fatty acids was determined from the $[CH_3(CH_2)_nCONHCHCH_2O\text{-}tBDMS]^+$ ion. By solving a set of simultaneous equations it was possible to quantitate as many as 9 molecular species within a single GC peak. Separation of the di-TMS ethers of ceramides according to carbon number and degree of unsaturation in the long chain base or fatty acyl chain could also be obtained by GLC using the RTx 2330 (Restek Corp., Port Matilda, PA) capillary column. Diradylglycerol TMS ethers and alkylglycerol diacetates were resolved on the basis of carbon number by means of a fused silica capillary column (8 m × 0.32 mm i.d.) coated with permanently bonded SE-54 liquid phase. Samples were injected on-column and temperature was programmed in 4 ramps from 40 to 350A°C as previously described (16). The molecular species were separated according to carbon number and degree of unsaturation on a polar capillary column as previously reported (14,17), except that a fused silica column (15 m × 0.32 mm i.d.) coated with cross-bonded RTx 2330 (Restek Corp., Port Matilda, PA) was substituted for the glass column. Diradylglycerol TMS ethers were separated isothermally at 250°C using a split injection (split ration 7:1) and H_2 carrier gas at 3 psi head pressure. Fatty acid methyl esters and alkylglycerol diacetates were resolved on the same column using two temperature programs. Injections were made at 100°C and after 0.5 min the oven temperature was programmed at 20°C/min to either 130°C or 180°C and then to 240°C at 5°C/min. Determinations of major components (greater than 10%) had coefficients of variation (CV) of 2% or less, whereas minor components (less than 1%) had CV of approximately 10%. The overall analytical scheme is outlined in Figure 1.

RESULTS

Total lipid composition. The phospholipid class composition was similar to that determined previously by TLC separation and phosphorus analysis (18) or GLC analysis of the component fatty acids (19,20). As shown below the diradyl glycerophosphoethanolamines (GPE) contained 51% and the diradyl GPC about 7% of total as ether lipids. Figure 2 shows the HPLC separation of alkenylacyl, alkylacyl and diacylglycerol subclasses of the diradyl GPE. The erythrocyte diradyl GPE was made up of 48.8% diacyl, 47.8% alkenylacyl and 3.4% alkylacylglycerols, which were similar to values reported previously (21,22), except that alkylacyl GPC was not detected in the earlier work. The normal phase HPLC yielded

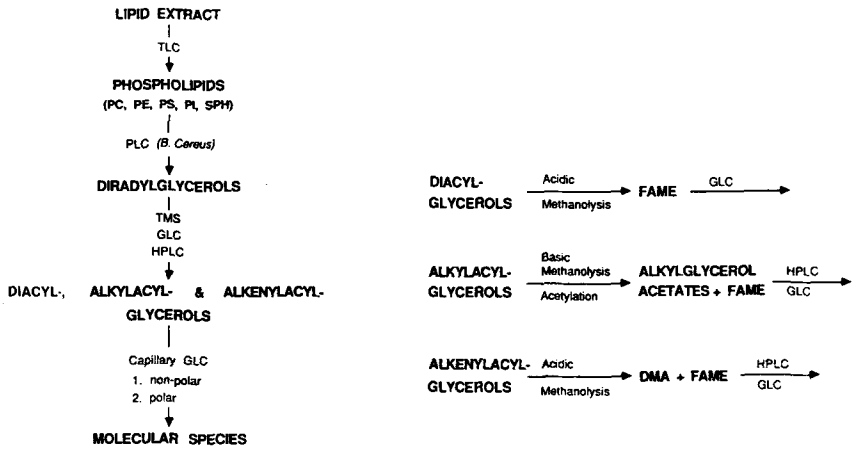

FIG. 1. Overall scheme of separation and identification of molecular species of diradylglycerophospholipids. DMA, dimethylacetals; FAME, fatty acid methyl esters; other abbreviations as given in text.

essentially a complete separation and purification of the diradylglycerol subclasses when run as the TMS ethers, which were slightly better resolved than the t-BDMS ethers. The HPLC procedure is clearly superior to the TLC method used previously (13), especially with respect to the resolution of the alkylacyl and diacylglycerol fractions. There was also a partial resolution of the molecular species within each diradylglycerol class. The broadening of the diacylglycerol peak observed at higher sample loads did not affect the resolution of the ether fractions. Derivatization of the diradylglycerols immediately after phospholipase C digestion is needed to prevent isomerization during the subsequent chromatographic analyses. The separation of the TMS ethers by normal phase HPLC is unique. Attempts to resolve these derivatives by TLC led to significant breakdown of the TMS ethers. The overall fatty acid compositions of the various phospholipid classes of the erythrocytes were similar to those reported in the literature (18-21,23). The detailed fatty acid composition of the various diradylglycerol fractions derived from them is discussed below under molecular species.

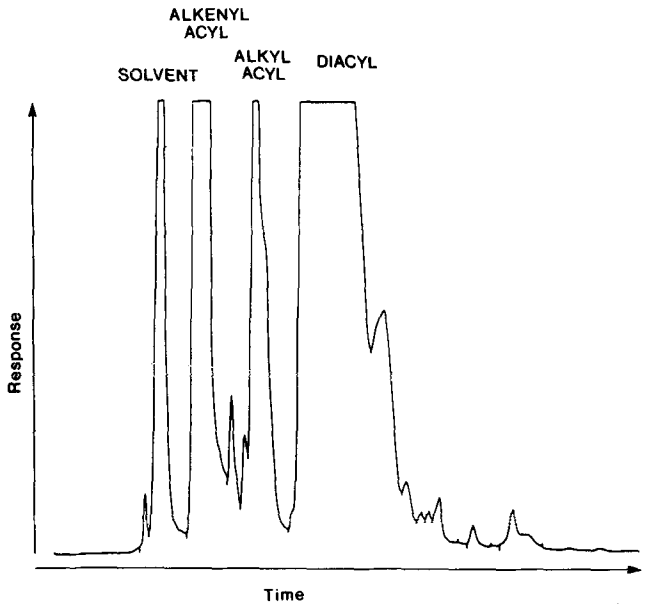

FIG. 2. Normal-phase HPLC separation of alkenylacyl, alkylacylacyl and diacylglycerol moieties of human red cell diradyl GPE. Peak identification as given in figure. HPLC conditions: column, Supelcosil LC-Si (5 μ), 250 cm × 4.6 mm i.d.; solvent, hexane/isopropanol (99.7:0.3, v/v), 1 ml/min; temperature, 30°C, isothermal. Sample: diradylglycerol TMS ethers.

Analysis of molecular species. The detailed analyses of molecular species using the improved methodology are presented from one sample of red cells only. The new fused silica capillary columns are easier to install, provide higher column efficiency and stability at elevated temperatures (250-260°C) and permit higher sample loads than the glass capillaries used previously (13,17). Less complete analyses on other samples were obtained using the older procedures (13), but these results are not shown. Figure 3 illustrates the carbon number resolution of the diacyl, alkylacyl and alkenylacylglycerol subclasses of the diradyl GPC. It is seen that the subclasses differ significantly in the relative proportions of the chain lengths, with the alkylacylglycerol species possessing a much higher proportion of the longer chain lengths. Of particular interest here is the presence of appreciable amounts of C_{20}, C_{22} and C_{24} alkyl chains (total carbon numbers 40-44). There is even a small amount of C_{26} species. A comparable increase in the chain length was not seen for the alkylacyl GPE. There were also chain

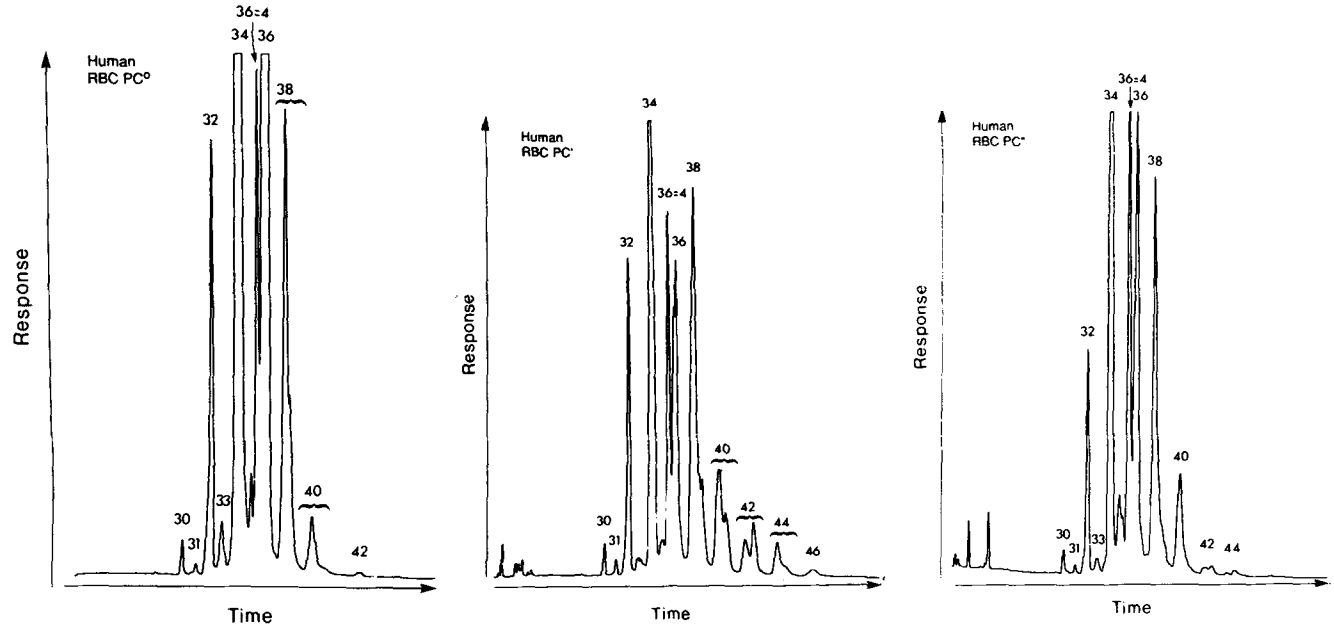

FIG. 3. Carbon number resolution of diacyl, alkylacyl and alkenylacylglycerol moieties of human red cell diradyl GPC. Peak identification as given in figure. GLC conditions: column, 8 m × 0.32 mm fused silica capillary coated with cross-linked 5% phenylmethyl silicone (HP-5), 0.17 μ film thickness; carrier gas, H_2, 6 psi; instrument and other operating conditions as given in text. Sample: diradylglycerol TMS ethers.

length differences among the various diradyl GPE, as well as among the diacyl GPC, GPE, glycerophosphoserine (GPS) and GPI, as shown in Table 1. These data, when combined with the data derived from polar capillary GLC (see below), yielded the quantitative composition of the molecular species of the diradylglycerols.

Figures 4 and 5 show the polar capillary GLC profiles of the inositol and serine phosphatides of the red blood cells, which contain only the diacylglycerol subclass. The quantitative composition of the molecular species of red cell diacyl GPI and GPS is given in Table 2 along with that of the diacyl GPC and GPE. The molecular species seen are consistent with the fatty acid composition shown in Table 3. There are marked differences between the major and minor molecular species among the different GPL classes. Thus, while the diacyl GPC and GPE contain closely similar amounts of 16:0-18:1ω9 (18.0 vs 15.1%), 18:0-18:1ω9 (5.8 vs 4.3%) and 16:0-20:3ω6 (5.2 vs 3.5%), they dffer greatly in the content of 16:0-18:2ω6 (26.9 vs 6.2%), 18:0-18:2ω6 (11.2 vs 2.1%), 16:0-20:4ω6 (5.1 vs 13.5%), 18:0-20:4ω6 (3.9 vs 12.6%) and 18:1ω9-20:4ω6 (0.6 vs 8.4%). In contrast, the diacyl GPI and GPS contained closely similar amounts of 18:0-20:4ω6 (18:0-20:3ω6) (45.3 vs 47.4%), 18:0-18:1ω9 (3.6 vs 5.9%) and 18:1-20:3 + 18:1t-20:4 (4.5 vs 4.9%), but differed in the content of 18:0-22:4ω6 (2.3 vs 11.3) and 18:0-22:5 plus 18:0-22:6ω3 (2.8 vs 21.0).

Figures 6 and 7 compare the elution patterns obtained on polar capillary GLC for the TMS ethers of the alkylacylglycerols derived from the erythrocyte diradyl GPC and GPE. The corresponding quantitative values are given in Table 4. There are marked differences in both qualitative and quantitative composition, which indicate that the alkylacylglycerols represent different pools of molecular species. While the alkylacyl GPC and GPE contain nearly identical proportions of 16:0′-20:4 and

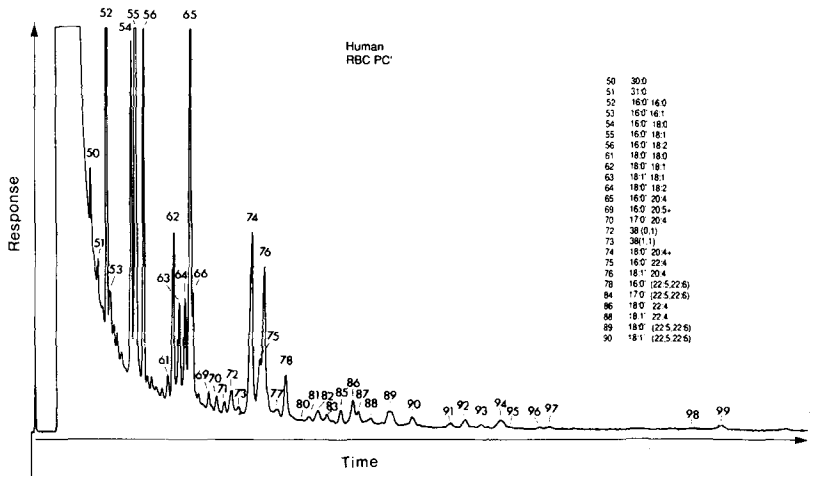

FIG. 6. Polar capillary GLC profiles of the alkylacylglycerol moieties of human red cell alkylacyl GPC. Peak identification as given in figure. GLC conditions as given in Fig. 4. Sample: 1 μl of 0.1% diradylglycerol TMS ethers in hexane.

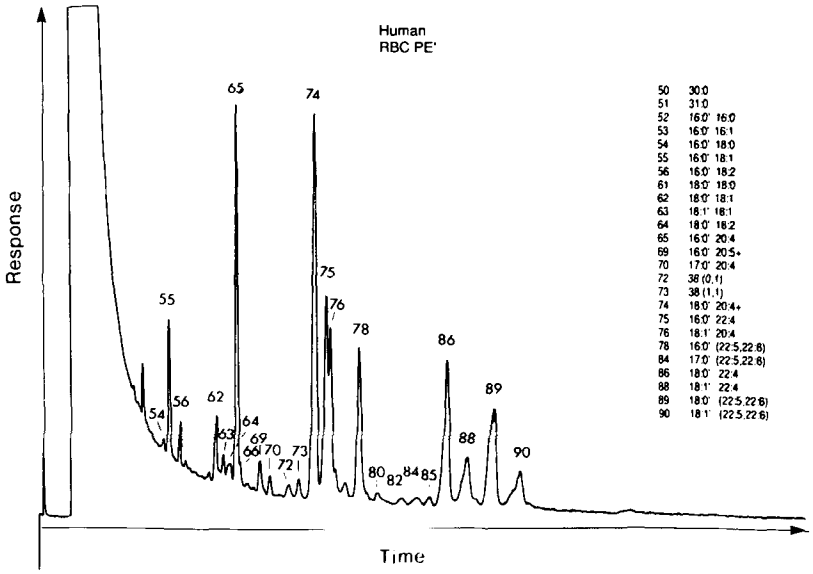

FIG. 7. Polar capillary GLC profiles of the alkylacylglycerol moieties of human red cell alkylacyl GPE. Peak identification as given in figure. GLC conditions as in FIG. 4. Sample: 1 μl of 0.1% diradylglycerol TMS ethers in hexane.

18:1′-20:4 species, the alkylacyl GPC contains much more of the saturated and monoenoic and less of the 18:0′-20:4, 16:0′-22:4, 18:0′-22:4 and other polyunsaturated species than alkylacyl GPE. This identification of the molecular species is supported by independent analysis of the alkylglycerol and fatty acid composition of the alkylacyl GPC and GPE (see below).

Figures 8 and 9 illustrate the separations obtained for the diacetates of the alkylglycerol moieties of the red blood cell alkylacyl GPC on nonpolar and polar capillary columns, respectively. From Figure 8, it is seen that the major carbon numbers range from 16 to 24 and that all, except 16, show partial splitting due to a slightly earlier elution of the corresponding mono- and diunsaturated species. From Figure 9, it can be seen that the saturated, monoenoic and dienoic alkylglycerol chains are resolved. It can now be appreciated that the 18:1′ peak contains a significant quantity of the *trans*-isomer, which is eluted earlier, and the ω7 isomer, which is eluted later, than the 18:1′ ω9 isomer. The corresponding quantitative compositions of the alkylglycerols and the FAMEs are given in Table 5.

Figures 10 and 11 give the polar capillary GLC elution patterns recorded for the alkenylacylglycerol moieties of the diradyl GPC and GPE. The corresponding quantitative values are given in Table 6. There are significant differences between two GPL classes in the composition of the alkenylacyl species, indicating the existence of either separate pools of precursors or independent transformation mechanisms. For each phospholipid type there

appears to be a much greater similarity between the alkylacyl and alkenylacyl subclasses. The alkenylacyl GPC species are much richer in the saturated, monoenoic, dienoic and trienoic and poorer in tetraenoic and other polyunsaturated components than the alkenylacyl GPE. The above identities of the molecular species of the alkenylacylglycerol moieties of the erythrocyte diradyl GPC and GPE are supported by independent determination of the composition of the alkenyl and fatty acid chains by polar capillary GLC of the dimethylacetals and the FAMEs, respectively, as shown in Table 7. The present data indicate much less oligoenoic fatty acids (16:0, 18:0, 18:1, 18:2) in the alkenylacyl GPE than previously reported (24).

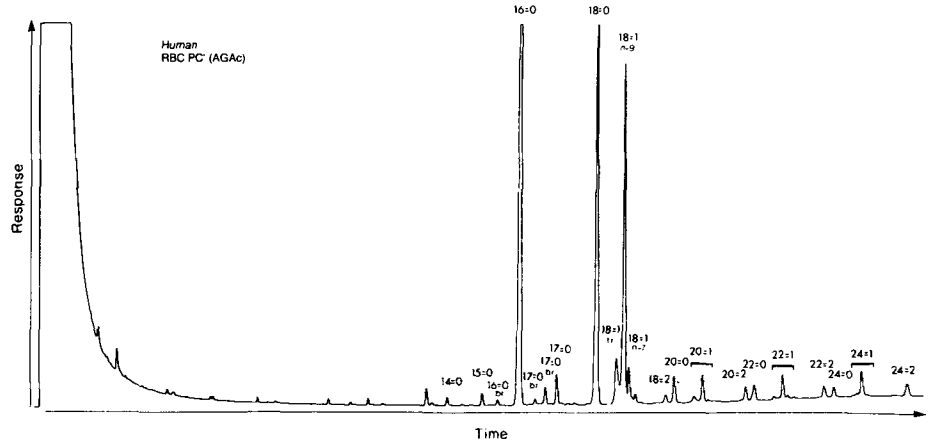

FIG. 9. Polar capillary GLC resolution of alkylglycerol moieties of alkylacyl GPC. Peak identification as given in figure. Column and carrier gas as in Fig. 4. Temperature programmed from 100°C (0.5 min) to 180°C at 20°C/min, then to 240°C at 5°C/min. Instrument and other GLC conditions as given in text. 24:2 eluted in 17.5 min. Sample: alkylglycerol diacetates.

Table 8 gives the carbon number distribution of the ceramide moieties of red blood cell SPH from three subjects. They all possess a closely similar range and proportions of carbon numbers. The major components are the C_{34} and C_{42} even carbon number species, but odd carbon number components are also present in readily

detectable amounts. The molecular species determined by GC/MS are given in Table 9. There has been no comparable previous analysis of the molecular species of red cell SPH.

DISCUSSION

The present study provides the first detailed description of the molecular species of the GPL and SPH from the red blood cells isolated from the same subject. Previously

only a few of the phospholipid classes have been analyzed for molecular species, and most of the analyses had been based solely on the fatty acid composition. The relative proportions of the various lipid classes found in the present study were similar to those recorded by earlier workers (18,20). Furthermore, the major molecular species of the diacyl GPC compare favorably with selected earlier analyses (19,20,25), but the species of the other classes have not been assessed previously, either qualitatively or quantitatively. There have been no previous analyses of the molecular species of the alkylacyl and alkenylacyl GPC and GPE, although the presence of both alkylacyl and alkenylacyl subclasses in red blood cell GPE had been recognized (22,24).

[a]Molecular species from a single subject but other than the one who supplied the diradylglycerophospholipids of the erythrocytes.

As a result of the sampling and analytical strategy it was possible to compare the molecular species composition of the different diradylglycerol subclasses among the different GPL, without the need to correct for dietary and metabolic differences in different individuals or pooled samples. The extensive differences noted among the different GPL classes emphasize the metabolic heterogeneity of the red blood cell phospholipids, which must reflect some as yet unrecognized physiological requirement. The analyses reveal that the differences among the diradylglycerol moieties of the GPL are present in both major and minor molecular species and between species, which are known to arise from common metabolic pathways. While previous analyses (19,20) of molecular species retained some uncertainty because of a possible error associated with the extensive reconstitution of data from complementary analytical methods, the present study eliminates this doubt because intact molecular species are being analyzed. The positional distribution of the fatty chains in the individual diacyl GPL molecules was not independently determined; thus, the relative proportions of the reverse isomers have not been estimated. The phospholipase A_2 data is available in the literature (18–20) and we have taken advantage of it in compiling the tabulated material. There should be no doubt about the location of the alkyl and alkenyl groups in the *sn*-1 position of the GPL, although 2-alkenyl GPL has recently been reported in rabbit sperm (26).

Unlike other cell types, the red blood cells do not possess enzymes for *de novo* formation of GPL. They must be derived from the original membrane synthesized in the bone marrow (27) or from a limited exchange of intact GPL with plasma lipoproteins, which is believed to be catalyzed by specific phospholipid exchange proteins (28), as well as limited exchange of acyl groups within the red blood cell membrane (29). In a separate paper (30), we have compared the molecular species composition of the red blood cell phospholipids and the plasma lipoproteins derived from the same subject and have discussed any possible precursor-product relationships. Little evidence was found to suggest that the GPL undergo separate and independent metabolism in the red cell membrane. In this connection, it is pertinent to note the recent identification of specific alkylacyl GPI species as lipid anchors of acetylcholine esterase in bovine (31) and human (32) red blood cell membranes. The bulk of the red cell diradyl GPI did not contain any such species, although they could have been present in the form of GPL glycans as now demonstrated for other cell membranes and other lipid anchors (33). In fact, no significant alkylacyl or alkenylacylglycerol species were found in red cell diradyl GPS or GPI, although both types of ether linkages were present in diradyl GPE and GPC. The physiological significance of the ether-linked GPL is not known, but it has been shown that they affect membrane fluidity (34).

The SPH of human red blood cells has been characterized in the past on the basis of fatty acid and nitrogenous base composition and distribution of the carbon numbers. The present analyses provide the first account of the detailed molecular association of the fatty chains as revealed by GC/MS. As shown elsewhere (15), the composition of the ceramide moieties of plasma SPH is clearly different from that of red blood cell SPH, which apparently do not equilibrate with them. The red cell SPH originate in the bone marrow and do not undergo further metabolism in the red blood cell membrane (27).

Finally, it is known that the diradyl GPC and SPH reside mainly in the outer half of the lipid bilayer of the red blood cell, whereas the diradyl GPE, GPS and GPI are found mainly in the inner half (35). Although the flip-flop rate is slow, it has been reported that for GPC and GPE the fatty acid compositions are the same on both sides of the membrane (36). The fatty acids of the SPH pools of the outer and inner layers of the membrane are known to differ in composition (37). However, fatty acid composition alone is not a good indicator of the type of molecular species to be found in any membrane. Fatty acid composition also does not provide any evidence about the distribution of the alkylacyl and the alkenylacylglycerol subclasses, although the dimethylacetals may indicate the presence or absence of plasmalogens. It would therefore be of interest to employ in future work the improved methods of molecular species analysis to determine the sidedness of the distribution of all GPL of the red blood cell membrane.

Molecular Species of Glycerophospholipids and Sphingomyelins of Human Plasma: Comparison to Red Blood Cells

J.J. Myher, A. Kuksis* and S. Pind
Banting and Best Department of Medical Research and Department of Biochemistry, University of Toronto, Toronto, Canada M5G 1L6

In addition to diacyl glycerophosphocholine and sphingomyelin, human plasma also contains small amounts of other glycerophospholipids, which may have special metabolic function. The structure and origin of these minor plasma lipids has not been determined. Knowledge of the detailed composition of the phospholipids of red blood cells (Myher *et al., Lipids 24,* 1989) permits evaluation of one of the possible sources. This study reports the detailed analyses of plasma glycerophospholipids made in parallel to those of the erythrocyte lipids obtained from the same blood using HPLC and GLC methods. The proportions of the major phospholipid classes in the plasma and erythrocytes were similar to published values, including the essential absence of diradyl glycerophosphoserine from plasma. Plasma diradyl glycerophosphocholine contained 93.0% diacyl, 3.4% alkylkacyl and 3.6% alkenylacyl, whereas the diradyl glycerophosphoethanolamine consisted of 71.8% alkenylacyl, 19.9% diacyl and 8.3% alkylacyl subclasses. The diradyl glycerophosphoinositol was 100% diacyl. The content of the minor subclasses of plasma diradyl glycerophosphocholine is similar to that of the red cells, but the ether content of the diradyl glycerophosphoethanolamine is higher in plasma than in cells. The lipid ether subclasses of plasma glycerophospholipids also contained a higher proportion of the C_{20}, C_{22} and C_{24} alkyl and alkenyl chains than those of the cells. Furthermore, the C_{16} and C_{18}-containing species in diradyl glycerophosphoethanolamine subclasses varied with the nature of the polyunsaturated acid, whereas in diradyl glycerophosphocholine subclasses the polyunsaturated acids were combined with the C_{16} and C_{18} acids in equal proportions. The significant differences in the molecular species of glycerophospholipids and sphingomyelin between plasma and red cells would appear to limit any direct transfer or equilibration of their lipid components.
***Lipids 24,* 408-418 (1989).**

The phospholipid class composition of plasma lipoproteins is unusual. It differs from that of the red blood cell membranes and from the plasma membranes of the cells lining the vascular bed. Thus, although diradyl glycerophosphocholine (GPC) and sphingomyelin (SPH) comprise the bulk and the diradyl glycerophosphoethanolamine (GPE) and glycerophosphoinositol (GPI) constitute minor components, the red cell membrane contains the diradyl GPC, GPE, glycerophosphoserine (GPS) and SPH as major and GPI as minor components (1). The glycerophospholipids (GPL) from both sources contain a wide variety of fatty chains, attached by ester or ether linkages, with chain lengths of 16-22 carbons and up to 6 double bonds, whereas SPH is made up of a separate pool of fatty acids and nitrogenous bases joined by amide linkages. This results in several hundreds of chemically distinct species of phospholipids. We have recently determined the detailed molecular species composition of the red blood cells of man (2). The present study extends this work to the plasma GPL and SPH and, along with the accompanying study (2), constitutes the first comprehensive assessment of the composition of GPL species of plasma and erythrocytes from the same blood. A preliminary account on the comparative composition of plasma and red cell GPL has appeared (3). A summary of the SPH data has been published previously (4).

MATERIALS AND METHODS

Blood plasma. The plasma for the diradyl GPL analyses was obtained from the same sample of blood as the erythrocytes analyzed in the accompanying paper (2). This subject also provided plasma SPH, which, however, was analyzed only for fatty acid composition and the carbon number distribution of the ceramide moieties. The molecular species analyses of the sphingomyelins had been performed on 4 other samples of plasma from 3 normolipemic subjects in the fasting state (VLDL, LDL and HDL_3) and one normolipemic subject in the postprandial state (chylomicrons and VLDL), who had shown fatty acid and ceramide compositions of VLDL and LDL similar to those obtained for plasma total SPH from the subject supplying the diradyl GPL. Plasma and cells were separated by centrifugation and cells were washed to remove the buffy coat. Some of the plasma samples were resolved into the major lipoprotein classes by ultracentrifugation as described elsewhere (5).

Lipid analyses. The methods of lipid extraction and chromatographic analyses of molecular species were as previously described in detail (2). Plasma and lipoprotein total lipid profiles were determined by capillary GLC as reported (6).

RESULTS

Total lipid composition. The phospholipid class composition of whole plasma was of the order reported previously on basis of TLC separation and phosphorus analyses (7) or GLC analyses of the component fatty acids (8), with 67.0% diradyl GPC, 17.7% SPH, 2.5% diradyl GPE and 2.1% diradyl GPI. Figure 1 shows the separation of alkenylacyl, alkylacyl and diacyl subclasses of the diradylglycerol moieties of the plasma ethanolamine GPL. A similar separation of the diradylglycerol moieties of plasma choline GPL gave much smaller but readily detectable fractions for the ether-linked species. These separations were performed with the TMS ethers of the diradylglycerols. Based on GLC quantitation the diradyl GPC contained 93.0% diacyl, 3.4% alkylacyl and 3.6% alkenylacyl, whereas the diradyl GPE contained 71.8%

Abbreviations: GPC, glycerophosphocholine; GPE, glycerophosphoethanolamine; GPI, glycerophosphoinositol; GPL, glycerophospholipids; GPS, glycerophosphoserine; SPH, sphingomyelin; PC° and PE°, diacyl GPC and GPE; PC′ and PE′, alkylacyl GPC and GPE; PC″ and PE″, alkenylacyl GPC and GPE.

alkenylacyl, 19.9% diacyl and 8.3% alkylacylglycerol subclasses. The diradyl GPI was 100% diacyl. Although the ether-linked GPL content was not measured in the individual lipoprotein classes, it has been observed that each lipoprotein contained at least some of this lipid class (9). The overall fatty acid composition of the various plasma phospholipid classes was similar to those reported in the literature (7,8,10). The detailed fatty acid composition of the various diradylglycerol fractions derived from them is discussed below under molecular species.

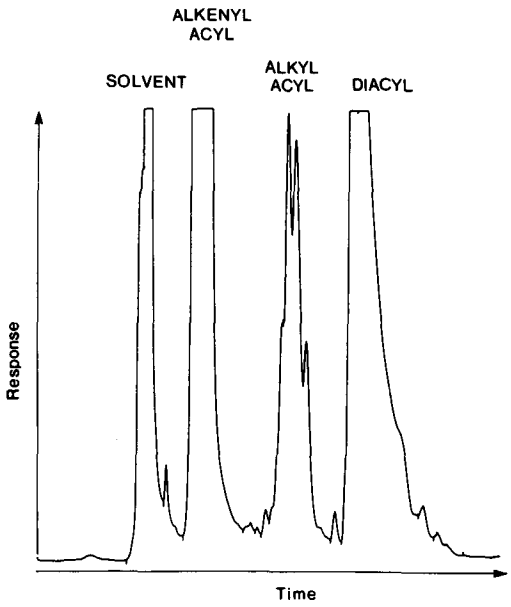

FIG. 1. Normal-phase HPLC separation of alkenylacyl, alkylacyl and diacylglycerol moieties of human plasma diradyl GPE. Peak identification as given in figure. HPLC conditions: column, Supelcosil LC-Si (5 μ), 250 cm × 4.6 mm i.d.; solvent, hexane-isopropanol 99.7:0.3 (v/v), 1 ml/min; temperature, 30°C, isothermal. Sample: diradylglycerol TMS ethers.

Analyses of molecular species. Figure 2 shows the carbon number resolution of the diacyl, alkylacyl and alkenylacyl subclasses of the diradyl GPC. The corresponding quantitative values are given in Table 1. It is seen that the subclasses differ significantly in the relative proportions of the chain lengths, with the alkylacylglycerol species possessing a much greater proportion of the longer chain lengths. Of particular interest here is the presence of appreciable amounts of C_{20}, C_{22} and C_{24} alkyl chains. A comparable increase in chain length was not seen for the alkenylacyl GPC. There were also chain length differences among the diradyl GPE, as well as among the diacyl GPC, GPE and GPI, as shown in Table 1. These data were used for reconstitution of the quantitative composition of the molecular species of the diradylglycerols derived from polar capillary GLC (see following discussion).

Figure 3 shows the polar capillary GLC profile of the diacylglycerol moieties of ethanolamine GPL, whereas Figure 4 shows the polar capillary GLC profile of the diacylglycerol moieties of diacyl GPI. The quantitative composition of the molecular species of the diacyl GPC, GPE and GPI is given in Table 2. The corresponding fatty acid compositions are given in Table 3. It is seen that the diacylglycerol moieties of the three GPL classes differ greatly from each other and from the alkylacyl and alkenylacylglycerol moieties of diradyl GPC and GPE. Thus, combinations of 16:0 with 18:1 and 18:2 form the most abundant species of diacyl GPC, whereas

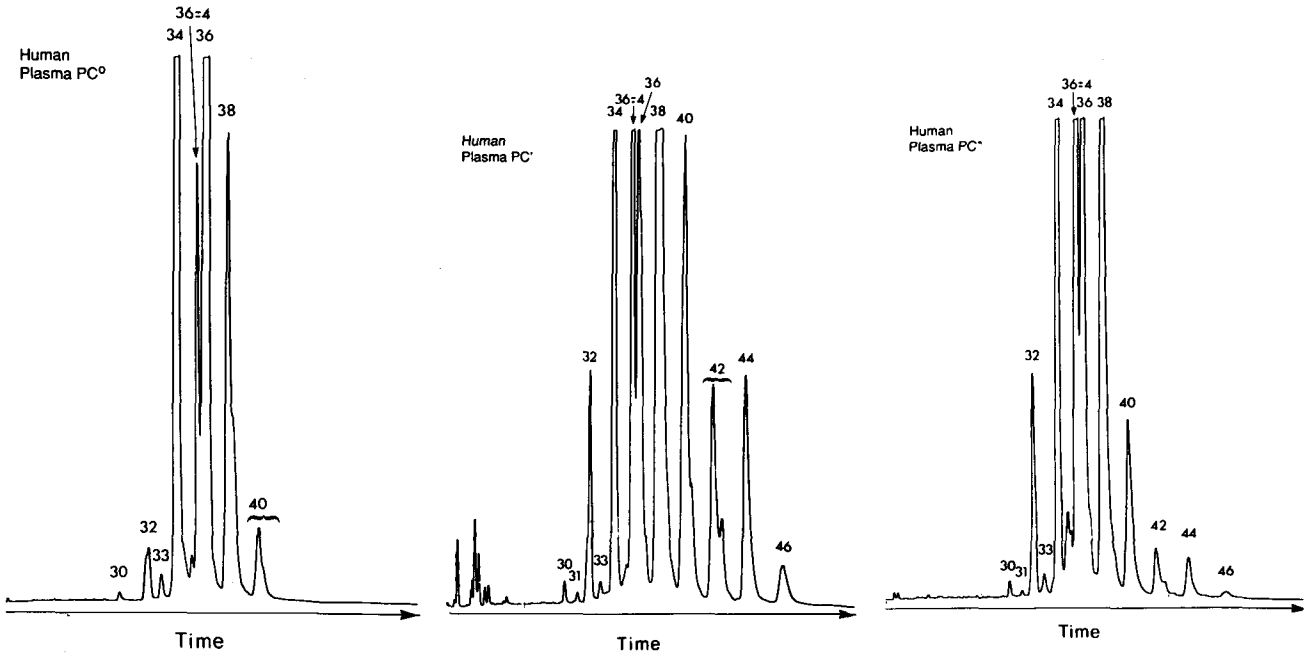

FIG. 2. Carbon number resolution of diacyl (PC°), alkylacyl (PC') and alkenylacylglycerol (PC") moieties of human plasma diradyl GPC. Peak identification as given in figure. GLC conditions: column 8 m × 0.32 mm fused silica capillary coated with cross-linked 5% phenylmethyl silicone (HP-5), 0.17 μ film thickness; carrier gas H_2, 6 psi; instrument and other operating conditions as previously described (2). Sample: 1 μl of 0.1% diradylglycerol TMS ethers in hexane.

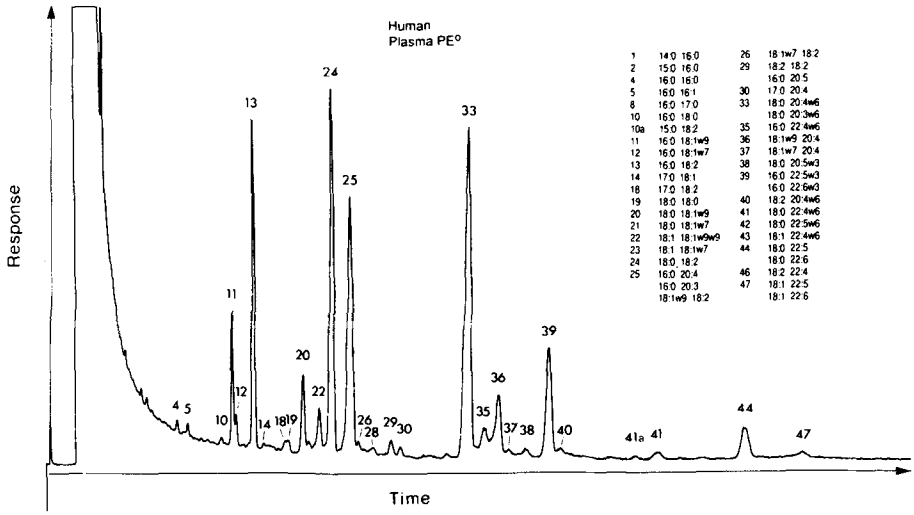

FIG. 3. Polar capillary GLC profile of the diacylglycerol moieties of human plasma diacyl GPE. Peak identification as given in figure. GLC conditions: column, 15 m × 0.32 mm fused silica capillary coated with cross-bonded RTx 2330; carrier gas, H_2, 3 psi; temperature, 250°C, isothermal; instrument and other operating conditions as given (2). Split ratio 7:1. Sample: 1 μl of 0.1% diacylglycerol TMS ethers in hexane.

combinations of 18:0 with 18:2 and/or 20:4 are favored in diacyl GPE and GPI.

Figures 5 and 6 show the elution patterns obtained on polar capillary GLC for the TMS ethers of the alkylacylglycerols derived from plasma choline and ethanolamine GPL, respectively. The corresponding quantitative values are given in Table 4. There are marked differences in both qualitative and quantitative composition, which indicates that the alkylacylglycerols represent different subcellular pools of biosynthetic precursors. Although both choline and ethanolamine GPL contain nearly identical proportions of 16:0′ 20:4 and 18:0′ 20:4 species, the alkylacyl GPC contain much more of the saturated, monoenoic and 18:1′ 20:4 and 16:0′ 22:4, and less of other polyunsaturated species than alkylacyl GPE. Figures 7 and 8 show the separation obtained for the alkylglycerol moieties of the alkylacyl GPC on the nonpolar and polar capillary columns, respectively. From Figure 7, it is seen that the major carbon numbers range from 16 to 24 and that all, except 16, show partial splitting due to a slightly earlier elution of the corresponding mono- and diunsaturated species. From Figure 8, it is seen that the saturated, monounsaturated and diunsaturated alkylglycerol chains are resolved. It can now be appreciated that the 18:1′ peak contains a significant proportion of the *trans* isomer, which is eluted earlier, and the ω7 *cis* isomer, which is eluted later, than the 18:1 ω9 *cis* isomer. The identity of the plasma alkylglycerol diacetates on the polar column was confirmed by GLC analysis of the alkylglycerol fractions resolved by argentation TLC. The

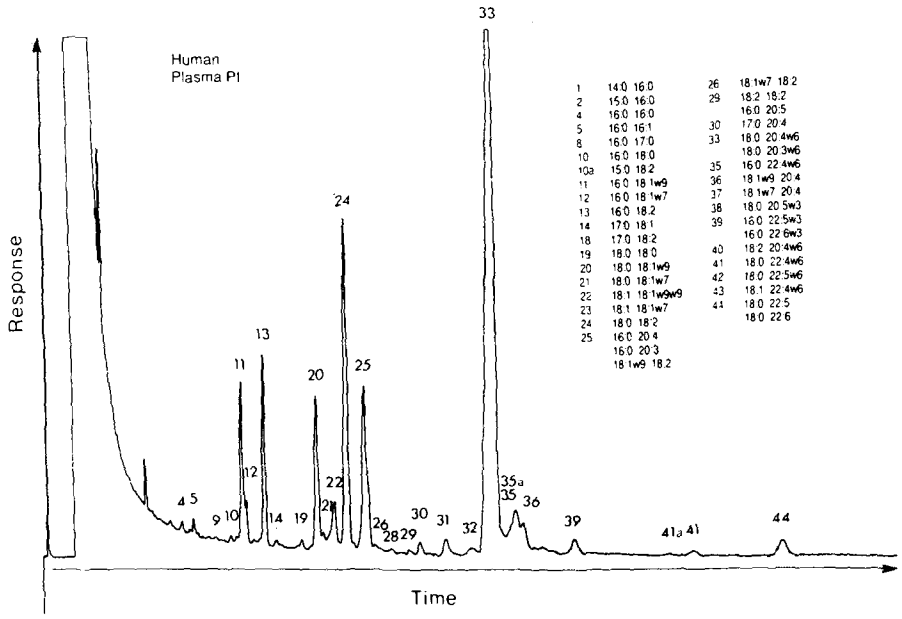

FIG. 4. Polar capillary GLC profile of the diacylglycerol moieties of human plasma diacyl GPI. Peak identification as given in figure. GLC conditions as given in Figure 3. Sample: 1 μl of 0.1% diacylglycerol TMS ethers in hexane.

peaks identified as *trans* isomers migrated well above the long and short chain *cis*-monoenes on the silver nitrate plates. Thus, the GLC and argentation TLC behavior of these compounds is consistent with the known chromatographic properties of the corresponding *trans* acids (11). The GLC retention of alkylglycerol esters was consistent with their known chromatographic properties (12) and the elution of reference standards. The corresponding quantitative composition of the alkylglycerol and the fatty acid methyl esters is given in Table 5.

Figures 9 and 10 give the polar capillary GLC elution patterns recorded for the alkenylacylglycerol moieties of

plasma diradyl GPC and GPE. The corresponding quantitative values are given in Table 6. There are significant differences between the two lipids in the composition of the alkenylacyl species indicating the existence of separate pools of precursors or independent transformation mechanisms. The alkenylacyl GPC is much richer in species in which a 16:0″ alkenylglycerol is combined with saturated, monoeneoic, dienoic and tetraenoic fatty acids, whereas alkenylacyl GPE is much richer in 18:0″ alkenylglycerol combined with dienoic, tetraenoic and hexaenoic fatty acids. The above identities of the molecular species of the alkenylacylglycerol moieties of the diradyl GPC and

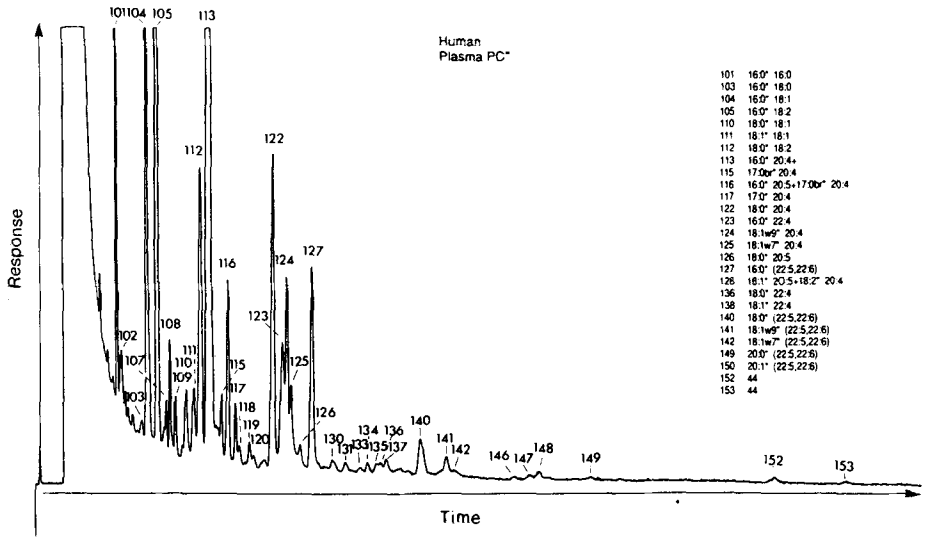

FIG. 9. Polar capillary GLC profile of the alkenylacylglycerol moieties of human plasma diradyl GPC. Peak identification as given in figure. GLC conditions as given in Figure 3. Sample: 1 μl of 0.1% diradylglycerol TMS ethers in hexane.

GPE are supported by the composition of the alkenyl chains, determined independently by polar capillary GLC of the dimethylacetals, and the fatty acid methyl esters derived from the corresponding alkenylacylglycerol fractions, shown in Table 7.

Table 8 gives the molecular species composition of the ceramide moieties of the SPH of VLDL, LDL, HDL_3 and chylomicrons. The SPH from the fasting plasma samples had been obtained from 3 normolipemic subjects other than the one who supplied the plasma diradyl GPL. The SPH from the postprandial plasma was obtained from another normolipemic subject 2 hr after ingesting a fatty meal. Because the plasma total SPH of the present subject had fatty acid and ceramide composition closely similar to that of the VLDL and LDL of the previously analyzed subjects (data not shown), it was assumed that the molecular species would be similar to those already determined, but not previously reported. As a result the data in Table 8 show minor interlipoprotein and intersubject variation, except for HDL_3. They possess closely similar ranges of carbon numbers, but differ significantly in the relative proportions of the short and long chain lengths. The major components are the even carbon number species, especially C_{34} and C_{42}, but odd carbon number components are also present in readily detectable amounts. We have previously pointed out the differences between HDL and LDL in the chain length distribution of the plasma SPH (4,9), but the present report gives the first full documentation of the composition of the major and minor species including VLDL and chylomicrons.

DISCUSSION

The present study provides the first detailed description of the molecular species of the different classes of GPL

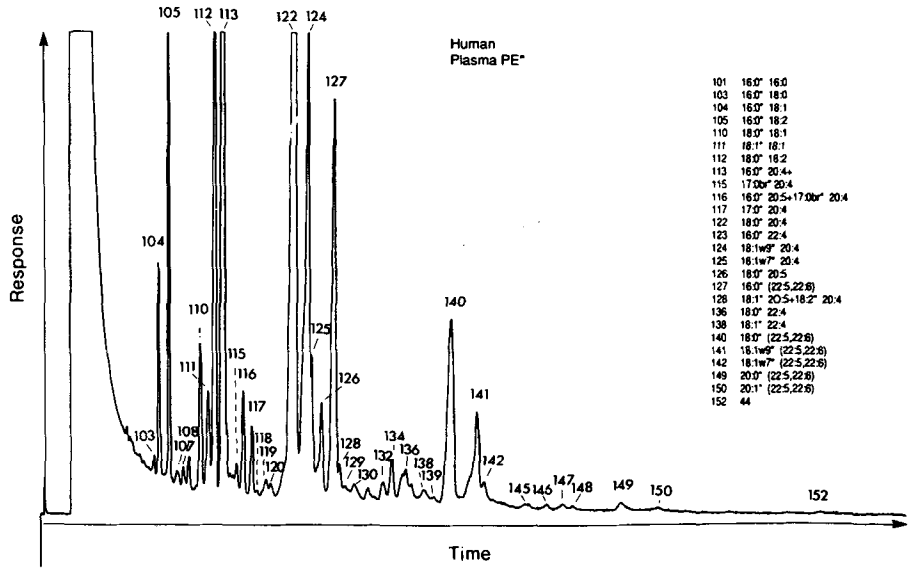

FIG. 10. Polar capillary GLC profile of the alkenylacylglycerol moieties of human plasma diradyl GPE. Peak identification as given figure. GLC conditions as given in Figure 3. Sample: 1 μl of 0.1% diradylglycerol TMS ethers in hexane.

from human plasma isolated from the same subject and of the molecular species of SPH isolated from different lipoprotein classes. Previously only the major diacyl GPC species had been identified (13,14) in pooled or mismatched samples, whereas the analyses of plasma diradyl GPE (15) and GPI (10) had been confined to the estimation of the total lipid amount and fatty acid composition. The presence of ether-linked phospholipids, especially the high proportion of the alkenylacyl GPE, has not been appreciated. The characteristic composition of the molecular species of the diacyl GPI, however, could have been approximately predicted from the fatty acid composition (10). The presence of phospholipids having *trans*-monoenoic alkyl and alkenyl chain in both plasma and erythrocytes presumably arises from dietary *trans*-fatty acid precursors. The metabolic consequences of such substitution, if any, are unknown. We had previously reported (9) the ceramide carbon numbers of the VLDL, LDL and HDL fractions, but molecular species had been given for only 4 of the total of 12 carbon numbers. In another study (4) the ceramide carbon numbers of VLDL, LDL and HDL were determined for subjects on saturated

and unsaturated fat diets, but molecular species were reported only for LDL. Neither of the previous publications gave the composition of the chylomicron SPH. The present study shows that the chylomicrons and VLDL possess SPH species, which are closely similar to those of LDL and differ from those of HDL by a lower proportion of the longer chain lengths.

The present study also permits the first systematic comparison of the molecular species of GPL and SPH of erythrocytes and plasma isolated from the same blood. The identification and quantitation of the species is based on polar capillary GLC resolution performed in parallel on purified subclasses and total diradylglycerol moieties of the GPL. The method allowed a resolution of most species on the basis of carbon number and degree of unsaturation, as well as of certain positional and geometric double bond isomers. The determined composition of the molecular species was found to be consistent with the independently measured fatty acid methyl ester, dimethylacetal and alkylglycerol composition.

Although the qualitative compositions are similar, marked differences are seen among the quantitative proportions of both major and minor molecular species between the corresponding plasma and red cell GPL, excluding extensive equilibration. The quantitative differences are as great between the choline and ethanolamine GPL within plasma or cells, as between the corresponding GPL of plasma and cells. However, the similarity in the composition of long chain saturated and unsaturated alkyl groups in the alkylacyl GPC from plasma and red cells suggests a common origin. In contrast to the other GPL, the diacyl GPI of plasma and cells possess closely similar qualitative and quantitative composition of molecular species. The serine phosphatide, which was detected in measurable amounts only in the red cells, possessed molecular species that differed greatly from those of all other GPL, and were characterized by a high proportion of the polyunsaturated long chain length species. The use of whole plasma GPL for the comparison is justified on the basis of the known similarity of the major molecular species of choline GPL in the different lipoprotein classes (16). The use of GPL pooled from the inner and outer halves of the red cell membrane is justified on the basis of the known equilibration of the major diacyl GPC and GPE species between the inner and outer halves of the erythrocyte membranes (17). Such an equilibration, however, does not appear to exist for the SPH either between the inner and outer half of the red cell membrane (18) or among the different lipoprotein classes (4,19).

Red cells could be a potential source of longer chain SPH species in HDL, but a comparison of species indicates that it is unlikely. For C_{42} the ratio of d18:1 to d18:2 containing species is slightly lower in HDL (2.3) than in LDL (3.7). If red cells were the source of elevated C_{42} (d18:1/d18:2 = 8.4) an increase of this ratio rather than the observed decrease would be anticipated. The same argument applies to the ratio of d18:1 24:0 to d18:1 24:1. The chain length differences in SPH between HDL and LDL, therefore, must be attributed to the origin of these lipoproteins in liver and intestine, respectively (20).

The major differences in the quantitative and to a lesser extent in the qualitative composition of the GPL species between plasma and red cells can be explained on the basis of differences in the metabolic origin of the species and the absence of significant mass equilibration among the GPL of plasma and red cells. The present results do not exclude, however, selective exchanges of major (21) or nonselective exchange of minor species. The study would appear to eliminate red cell PE as the only source of plasma PE, including the alkylacyl and alkenylacyl subclasses. Dietary fatty acids affect plasma lipids much more rapidly and extensively than the red cell lipids (22), which are subject to much slower turnover (23). Some of the molecular species of GPL and SPH are clearly derived from the clearance of intestinal VLDL and chylomicrons (24), whereas other GPL species are derived from the nascent HDL secreted by liver (25). The GPL transformations resulting from the activity of plasma lipoprotein (26) and hepatic (27) lipases, and lecithin-cholesterol acyltransferase (28) must also be considered. Although the intestinal GPL is relatively rich in the alkylacyl and the alkenylacyl species (29), the liver GPL is essentially free of them (30).

Although the detailed comparisons were performed on blood from one subject only, these results were representative of the GPL analyses from other subjects. The present analyses are of interest in view of the increasing importance of the minor species of GPL in lipoprotein and cell membrane structure and function. A more complete assessment of the origin of the GPL and SPH of plasma must await studies of the kinetics of appropriately labeled molecular species of GPL and SPH.

[Received September 6, 1988; Revision accepted January 13, 1989]

Modulating Influence of Dietary Lipid Intake on the Prostaglandin System in Adult Men

Aldo Ferretti[a,*], Joseph T. Judd[a], Philip R. Taylor[b], Arthur Schatzkin[b] and C. Brown[b]
[a]Lipid Nutrition Laboratory, Beltsville Human Nutrition Research Center, ARS-USDA, Beltsville, MD 20705; and [b]Division of Cancer Prevention and Control, National Cancer Institute, NIH, DHHS, Bethesda, MD 20892

We evaluated the effect of moderate dietary changes on the prostaglandin system by measuring the urinary excretion of 7α-hydroxy-5,11-dioxo-tetranorprostane-1,16-dioic acid (PGE-M). In a crossover design, twenty-four free-living male subjects in good health (24 to 54 years of age) were fed two diets: (i) Regular (R) diet, 41% energy (en%) from fat, P/S 0.59, M/S 0.96; (ii) Experimental (E) diet, 19 en% from fat, P/S 1.31, M/S 1.48. Diet R contained 13.9 g/day of neutral detergent fiber (NDF) and about 600 mg/day of cholesterol per 3200 kcal; Diet E contained 35.5 g/day NDF and about 280 mg/day cholesterol. Each controlled-diet period lasted ten weeks. The menu cycle was 7 days, and all diets were calculated to provide adequate amounts of essential nutrients. The PGE-M excretion rates were determined in 24-hr urine by stable-isotope dilution gas chromatography-mass spectrometry in the selected ion-monitoring mode. Low-fat Diet E, with an intake of 6.6 en% from polyunsaturates, was associated with an average 14.2% reduction in PGE-M daily output, compared to high-fat Diet R with a 9.3 en% from polyunsaturates ($P = 0.046$). These results support the view that dietary lipid changes can significantly alter the *in vivo* production of E-series prostaglandins. We cannot conclude, however, if this apparent diet effect was brought about by the change in linoleate intake alone or was the result of complex biochemical interactions among individual fatty acids, both saturated and unsaturated.
***Lipids 24,* 419–422 (1989).**

The molecular basis of nutritionally-induced changes in cardiovascular parameters is a subject of considerable interest. According to the "eicosanoid hypothesis," the putative vascular effects of dietary polyunsaturates result from associated alteration of the endogenous production of prostaglandins. Thus, a quantifiable diet/prostaglandin link is of interest to clinicians, nutritional biochemists and epidemiologists. Progress in this area has been hindered by the limited availability of highly sensitive and specific analytical methods for the quantification of appropriate markers in complex biological matrices.

Biosynthesis of eicosanoids ultimately depends on the availability of their immediate precursors: arachidonate (AA, 20:4ω6), dihomo-gamma-linolenate (DGLA, 20:3ω6), and eicosapentaenoate (EPA, 20:5ω3). Only EPA can be introduced in significant amounts through the diet or through fish oil supplementation. AA and DGLA, the precursors of diene and monoene prostaglandins (PG), respectively, are derived from elongation and desaturation of linoleate (LA, 18:2ω6) which is plentiful in a conventional "Western" diet. That lipid intake should influence PG biosynthesis *in vivo* seems, in general, a reasonable expectation. Direct dietary effects have indeed been demonstrated with arachidonate (1) and eicosapentaenoate (2–5). In contrast, the consequences of dietary LA manipulations on the PG system are much less predictable (6,7). It is probably so because many enzymes are involved in the conversion of linoleate to DGLA and AA. Such enzymes are influenced by several factors, nutritional as well as hormonal (8,9). It has been shown recently in a rat study that *ex vivo* PG biosynthesis can be modulated by dietary alterations involving fatty acids which are non-PG precursors, e.g., saturated fatty acids (10). These observations have enhanced interest in unraveling the complex relationships among dietary fat, eicosanoid production and physiologic effects.

Because present dietary modifications recommended to the general public for the prevention of atherothrombotic disorders and cancer include reduction of total fat and replacement of saturated fats with polyunsaturates, we deemed it relevant to evaluate the comparative effects of two types of diets on the activity of the prostaglandin system in a group of twenty-four healthy male volunteers. As a chemical marker of such activity we selected the whole-body turnover of E-series prostaglandins ($E_1 + E_2$) which was measured by the urinary excretion rate (μg/24 hr) of 7α-hydroxy-5,11-dioxo-tetranorprostane-1,16-dioic acid (PGE-M). Prominent among the physiological properties of PGE_2 is its powerful influence on myocardial and coronary circulation and on peripheral microvessels (11). Thus, any agent that can modify the PGE_2 biosynthetic level is expected to produce an effect on important cardiovascular variables. The two diets considered in this study differ in their percent of energy (en%) from fat, P/S and M/S ratios. Could such dietary manipulation have a quantifiable effect on the prostaglandin system? Based on present knowledge, and given the acute scarcity of similar studies with human subjects, the answer to this question is not obvious. Cholesterol and fiber intakes also differ in the two diets but, for the purpose of this study, they are not regarded as significant variables. This is part of a larger study in which the two diets must approximate, in all their variables, a typical American diet and a diet recommended for prevention of heart attack and cancer.

MATERIALS AND METHODS

Subjects. Twenty-four male volunteers between 24 and 54 years of age (mean 36.1 ± 8.6, SD) were recruited in the area immediately surrounding the Beltsville Agricultural Research Center. The subjects ultimately selected were free from known metabolic abnormalities as determined by a complete physical examination and laboratory tests. None of them had been on a special dietary regimen, e.g. vegetarian, over the previous year, nor had they taken prescription medications, vitamins, aspirin, aspirin-

Abbreviations: AA, arachidonate; DGLA, dihomo-gamma-linolenate; en%, energy %; EPA, eicosapentaenoate; E, experimental; LA, linoleate; NDF, neutral detergent fiber; PGE-M, 7α-hydroxy-5,11-dioxo-tetranorprostane-1,16-dioic acid; PG, prostaglandin; R, regular.

containing drugs or nonsteroidal anti-inflammatory drugs ten days before the beginning of the study and during the study. Nutrient supplements were also forbidden for the duration of the study. The subjects continued their normal life and normal activities throughout the experiment and were informed of the purpose of the study, procedures to be followed, and samples to be collected. All the procedures were approved by the Human Studies Committees of the U.S. Department of Agriculture, the National Institutes of Health and the Georgetown University Medical School.

Controlled diets. Two diets designated as E (experimental) and R (regular) were formulated from commonly available foods. Diet E contained about 19% of energy (en%) as fat, 35.5 g/day of neutral detergent fiber per 3200 kcal, and a P/S ratio of 1.31. This ratio is more than twice that found in typical Western Diets, and is characteristic of low-risk populations. It has been recommended for prevention of coronary artery disease. Diet R contained about 41 en% as fat, 13.9 g/day of neutral detergent fiber per 3200 kcal, and a P/S ratio of 0.59. This ratio approximates that observed in earlier studies (12) among free-living subjects in the Beltsville area. Tables 1 and 2 show the nutrient contents of two typical diets. The relative distribution of polyunsaturates to saturates and monounsaturates (P:S:M) was approximately 1.31:1:1.48 in the experimental diet and 0.59:1:0.96 in the regular diet. The mean daily cholesterol intake was 280 mg/day on Diet E (3200 kcal) and 600 mg/day on Diet R, with proportional adjustments for different caloric intakes. Total energy input was adjusted to maintain a constant body weight for the duration of the study.

TABLE 1

Composition of a Typical 3200-Kcal Diet: Mean Daily Intake of Nutrients[a]

[a]Minor fatty acid constituents: arachidonic (20:4ω6), 0.12 g/day; eicosapentaenoic (20:5ω3), 0.02–0.1 g/day.

We used a seven-day menu cycle to provide variety and maintain acceptability of the diets. All nutrients for which food data are available were provided by the diets in amounts to meet the Recommended Dietary Allowances (13). Nutrient compositions of the diets were calculated by using the Lipid Nutrition Laboratory food database, which provided the latest data on food composition from the USDA, together with data provided by the food industry, the Nutrient Coding Center in Minneapolis, and analysis. The controlled-diet meals were prepared in the Human Studies Facility of the Beltsville Human Nutrition Research Center (BHNRC). On weekdays, all meals were eaten in the Center's dining facility. Meals for Saturdays, Sundays and holidays were prepacked and distributed for home consumption. No food other than what was provided by the study was permitted, and alcohol consumption was not allowed during the controlled-diet periods. Consumption of coffee, tea, and water was unrestricted.

Experimental design. The study employed a crossover design with two phases involving controlled diets: after a pre-diet free-choice period (baseline) lasting two weeks, twelve subjects were placed on the E Diet and the other twelve on the R Diet for ten weeks (phase 1); phase 2 was another ten-week controlled-diet period (switchover from the diet in phase 1). After phase 1 there was a ten-day holiday break during which the volunteers consumed self-selected diets. Subjects in the two groups were balanced on the basis of their body mass index.

Urine collection. Twenty-four-hour urine was collected in silanized glass bottles and kept on ice during the collection period, three times during week 2 of the pre-diet free-choice period and three times during week 10 of phases 1 and 2. After the 24-hr collection was completed, the volumes were measured, portions were taken (*vide infra*), and either analyzed immediately or stored at −22°C for a few days.

Measurement of PGE-M. Two-percent portions of each 24-hr collection, in a given week, were pooled. A 20-ml aliquot of the resulting mixture was analyzed for 7α-hydroxy-5,11-dioxo-tetranorprostane-1,16-dioic acid (PGE-M) to assess the mean daily turnover of prostaglandins $E_1 + E_2$ *in vivo* during the 72-hr period. We used stable isotope dilution mass spectrometry in the selected ion-monitoring mode. Procedures and instrumentation have been described (14). When storage of urine specimens lasted more than one day, PGE-M values were adjusted to compensate for decay according to a first-order rate constant determined in our laboratory (15). PGE-M excretion rates are all expressed as μg/24 hr.

Statistical methods. Twenty-four-hour PGE-M excretion rates and lipid intakes were evaluated by linear regression and by paired t tests with the computer methodology of the Statistical Analysis System (SAS Institute, Inc., Cary, NC). Multiple linear regression with backwards elimination was used to evaluate the potential influence of height, weight, and baseline PGE-M

levels on the differences observed between individual PGE-M levels on Diet E and Diet R.

RESULTS

One subject withdrew for personal reasons at the end of phase 1 and another withdrew later for health reasons leaving 22 subjects for analysis. Before conducting further statistical analyses, we first determined that the order in which the subjects went on the controlled diets (R or E first) did not have an effect on the results. The mean of PGE-M urinary excretion was 13.44 ± 1.63 (SEM) μg/24 hr after ten weeks on controlled Diet R and 11.53 ± 1.24 (SEM) μg/24 hr after ten weeks on Diet E. Paired t testing indicated a significant reduction in the urinary marker after ten weeks on the experimental diet (difference = 1.91 ± 0.90 (SEM) μg/24 hr, $P = 0.046$). Values for individuals are shown graphically in Figure 1 for each of the 22 individuals who completed both study diets. The mean PGE-M excretion rates of subjects who switched from Diet E to Diet R were 11.61 and 13.57 μg/24 hr, respectively; those of subjects who switched from Diet R to Diet E were 13.28 and 11.44 μg/24 hr, respectively. In multiple regression models, weight was shown to have a significant effect on the difference in PGE-M levels between diets: lighter weight individuals (weight range 56.3–75.8 kg) showed greater reduction (16% vs 1%) in PGE-M levels on Diet E compared to Diet R than heavier individuals (weight range 77.4–108.2 kg).

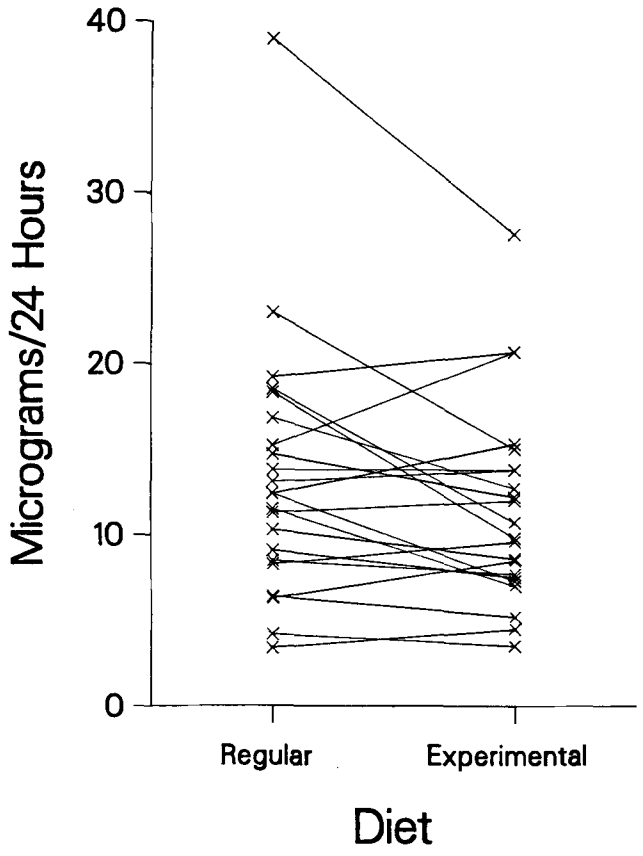

FIG. 1. PGE-M urinary excretion rates of the 22 individuals who completed both study diets.

DISCUSSION

This study was conducted to determine if relatively minor dietary modifications can significantly influence the systemic production of E-series prostaglandins as measured by the urinary excretion rate of 7α-hydroxy-5,11-dioxotetranorprostane-1,16-dioic acid (PGE-M). Because plasma fatty acids do not represent the PG precursor pool (6,7,17–19), we omitted their determination. The most direct and meaningful means of assessing *in vivo* prostaglandin production is by measurement of their urinary catabolites (20). The PGE-M excretion rate provides a measure of the aggregate endogenous synthesis of prostaglandins E_2 and E_1 (21). This methodology neglects the contribution from kidney and seminal vesicles to whole-body turnover of PGE. The rationale for disregarding such contribution has been discussed (22).

Pioneering studies by Zöllner *et al.* (23), Nugteren *et al.* (24) and Adam *et al.* (25,26) demonstrated the possibility of nutritionally altering the endogenous biosynthesis of primary prostaglandins in humans. Those studies, however, involved very substantial variations of the levels of linoleate intake. Similarly, a more recent study by Adam and Wolfram (27) compared the effects of linoleate intake of 0 and 20% energy on the excretion of tetranorprostanedioic acid, an analytical artifact which has been proposed as an index of systemic turnover of primary PG of both the E and F series (28). In contrast, the objective of our study was to compare the effect of a typical American diet (R) with that of a diet which has been recommended for the prevention of coronary artery disease. The main finding here is that—while all the subjects were presumably in a PUFA nondeficient status—variations in lipid intake profile (see Table 3) brought about a measurable and statistically significant change in the biosynthetic level of E prostaglandins. In a recent human diet study from this laboratory (22) we could not detect an effect on the PGE-M excretion rate when two levels of linoleate intake (10 and 30 g/day) were considered in a crossover design in which the energy from fat was maintained constant at 35%. That preliminary study, however, was conducted with only four volunteers. Moreover, the analytical method we used then to measure PGE-M (29) did not afford the same level of accuracy as the method used in this study (14).

We must consider the possibility that the apparent diet effect on the prostaglandin system observed in this study may have not been brought about solely by the different linoleate intakes in the two diets. As shown in Table 3, the intake of monounsaturates in Diet R is twice that in Diet E, while the level of saturates in Diet R is three times that in Diet E. The intake of polyunsaturates (93% of which is linoleate) in the "regular" diet is only 1.4 times

TABLE 3

Energy Percent Contributed by Various Lipid Classes[a]

Lipid class	Diet E	Diet R
Polyunsaturates (P)	6.6	9.3
Saturates (S)	5.0	16.0
Monounsaturates (M)	7.4	15.4

[a]Calculated from data of Table 2.

the level in the "experimental" diet, namely 9.3 en% versus 6.6 en%. It would indeed be extraordinary if the only driving force behind the modulation of the endogenous PGE production were such a modest change in 18:2ω6 intake. Results of whole animal nutritional studies and of biochemical studies performed at the enzyme or subcellular levels have led to the hypothesis, now widely accepted, that competitive inhibition may occur among all dietary unsaturated fatty acids, i.e., those of the ω3, ω6 and ω9 groups, at each step of their metabolic transformation (6,9). Specifically, each of the most important members of dietary unsaturates—linoleic, oleic and α-linolenic—inhibits the elongation and desaturation of the other (30,31). Interactions among saturated and unsaturated fatty acids present in the diet and in the metabolic pool have also been demonstrated (32). The nature of our study does not permit us to conclude whether we are observing the direct and simple effect of linoleate intake or the cumulative effect of complex interactions. Perhaps the more important point to keep in mind is that a diet very similar to the typical American diet is associated with a higher biosynthetic rate of E-series prostaglandins compared to a diet with fewer fatty calories and a higher P/S ratio. The lowering of systolic blood pressure in conjunction with enhanced intakes of polyunsaturates observed in several studies (33,34) may have been brought about at least in part by alteration of the eicosanoid system, possibly involving the E prostaglandins. The effect of a nutritionally-induced alteration of the thromboxane to prostacyclin ratio in those studies cannot be ruled out.

Dietary fiber has been shown to affect cholesterol absorption and metabolism (35). But, to our knowledge, there is no report suggesting a fiber-modulating influence on the prostaglandin system. The effect of dietary fiber in this study was probably insignificant. Similarly, a direct correlation between dietary cholesterol and eicosanoid synthesis *in vivo* has not been demonstrated.

ACKNOWLEDGMENTS

Synthetic PGE-M, used to prepare the internal standard for the quantitative analyses, was supplied by Dr. J. Pike, The Upjohn Co. We are indebted to W. Campbell, BS, RN, for keeping medical records and for supervising the subjects. V. P. Flanagan and V. B. Reeves provided excellent technical assistance.

[Received October 20, 1988; Revision accepted January 30, 1989]

Eicosapentaenoic and Arachidonic Acid: Comparison of Metabolism and Activity in Murine Epidermal Cells

Martha A. Belury[b], Kelly E. Patrick[a], Mary Locniskar[b] and Susan M. Fischer[a,*]

[a]University of Texas M.D. Anderson Cancer Center, Science Park - Research Division, Smithville, TX 78957 and [b]University of Texas at Austin, Dvision of Graduate Nutrition, Austin, TX 78712

The biological activity, including metabolism and modulation of ornithine decarboxylase activity and DNA synthesis, of arachidonic acid (AA) and eicosapentaenoic acid (EPA) were compared in epidermal cells from SENCAR mice. Radiolabelled AA and EPA were found to be similarly incorporated into and released from membrane phospholipids of unstimulated cultures. However, when cells were stimulated with the tumor promoter 12-0-tetradecanoylphorbol-13-acetate (TPA), the release of AA was significantly higher than the release of EPA. The extent of metabolism of AA and EPA to prostaglandins was determined in both freeze-thawed cell preparations and in viable cultured cells. In the freeze-thawed preparations, use of AA as a substrate resulted in significantly more PGF than when EPA was used as the substrate. However, more PGE_3 was formed than PGE_2. PGD levels were the same for either fatty acid precursor. Prostaglandin production was also determined in viable cultured cells since other influences such as phospholipase A_2 activity can modify prostaglandin production. Control cultures prelabelled with either AA or EPA produced similar amounts of the respective PGF, PGE, and PGD. However, TPA-stimulated cultures produced significantly higher amounts of each prostaglandin in cultures prelabelled with AA compared to cells prelabelled with EPA. HETE or HEPE production was the same both for cultured cells prelabelled with AA or EPA and for homogenates from uncultured cells incubated directly with the radiolabelled fatty acids. TPA-induced ornithine decarboxylase (ODC) was significantly higher in AA-treated cultures compared to EPA-treated cultures. AA supports DNA synthesis to a greater extent than EPA, either alone or in the presence of TPA. These findings suggest that AA and EPA do not have equivalent biological activity in mouse epidermal cells.

Lipids 24, 423–429 (1989).

The type of fat in the diet has been shown to modulate tumor development in several organs (1,2). In particular, increasing the amount of dietary linoleic acid (18:2, n-6) is correlated with increased incidence and yield of rat mammary tumors (3,4). In contrast to the tumor enhancement associated with this n-6 fatty acid, animals fed diets high in linolenic acid (18:3, n-3) and other n-3 fatty acids demonstrate reduced tumorigenesis in several animal models (5–8).

Increases in prostaglandin E_2 (PGE_2), a product of arachidonic acid (AA), which is derived from elongated and desaturated linoleic acid, have been associated with increased tumor incidence (9), suggesting that n-6 eicosanoids are potential modulators of tumorigenesis. It has also been reported that the promotion stage of carcinogenesis is particularly sensitive to prostaglandin levels (10,11 and reviewed in 12). The multistage skin carcinogenesis model has been used extensively to study the regulation of tumor development since the initiation and promotion stages can be operationally separated. The promotion stage is achieved by repetitive treatments with tumor promoters, such as the phorbol ester 12-0-tetradecanoylphorbol-13-acetate (TPA), following the application of a subthreshold dose of carcinogen. Hyperproliferation, inflammation and induction of ornithine decarboxylase (ODC) are hallmarks of TPA promotion (13), and are, in part, mediated by the cyclooxygenase and/or lipoxygenase products derived from AA (14, reviewed in 12). This is supported by the evidence that indomethacin and other anti-inflammatory inhibitors of AA metabolism inhibit both TPA promotion and TPA-induced ODC (10,11, 15,16). Verma and Boutwell (16) further demonstrated that exogenous application of PGE_1 or PGE_2 could overcome the indomethacin inhibition of TPA induced ODC. These observations support the hypothesis that AA metabolites are important mediators of the TPA-induced inflammatory and proliferative responses (17).

Eicosapentaenoate (20:5) (EPA), an n-3 fatty acid found in fish oil, competes with AA for incorporation into cell membrane phospholipids *in vivo* (18,19) and *in vitro* (20, 21). Partial substitution of AA by EPA in membrane phospholipids should therefore lead to the replacement of AA-derived cyclooxygenase and lipoxygenase products (2-series eicosanoids) with EPA-derived metabolites (3-series eicosanoids). Competitive inhibition of AA metabolism by EPA has also been indicated in platelets (22). Not only would less AA-derived products be available but the EPA-derived eicosanoids may be less biologically active (23).

Based on the above considerations, we hypothesized that murine epidermal cells would differ in their response to EPA and AA with regard to incorporation and metabolism. In addition, we postulated that the cyclooxygenase metabolites formed from EPA would not be as biologically active as AA-derived prostaglandins in influencing specific responses associated with tumor promoter treatment of epidermal cells. This paper compares several parameters of the biological activity of AA and EPA in murine epidermal cells including: 1) the rate of incorporation into and release of these fatty acids from membrane phospholipids; 2) the amount of PGE, PGD, and PGF produced by cells pre-labelled with each fatty acid; 3) the extent of production of the lipoxygenase products; and 4) the effect of the two fatty acids on TPA-induced ODC activity and DNA synthesis.

MATERIALS AND METHODS

Chemicals. TPA was obtained from Life Systems (Newton, MA) and diluted in acetone. Purchased from

*To whom correspondence should be addressed.

Abbreviations: AA, arachidonic acid; EPA, eicosapentaenoic acid; TPA, 12-0-tetradecanoylphorbol-13-acetate; ODC, ornithine decarboxylase; HETE, hydroxyeicosatetraenoic acid; HEPE, hydroxyeicosapentaenoic acid; PG, prostaglandin; TLC, thin layer chromatography.

Amersham Corp. (Arlington Heights, IL) were [1-^{14}C]-arachidonic acid, [1-^{14}C]-eicosapentaenoic acid (specific activity of both is 59.6 mCi/mmol), [^{3}H]-AA, [^{3}H]-EPA (specific activities, 94.5 Ci/mmol and 79.0 Ci/mmol respectively), [1-^{14}C]-ornithine hydrochloride (specific activity, 55 mCi/mmol) and [methyl-^{3}H]-thymidine (specific activity, 6 Ci/mmol). Authentic prostaglandin and phospholipid standards were purchased from Sigma Chemical Co. (St. Louis, MO) and the 5-, 8-, 12- and 15-HETE standards from Caymen Chemical (Ann Arbor, MI). Silica Gel 60-254 (0.25 mm; Merck, Darmstadt, West Germany) was used for thin layer chromatograph (TLC). Solvents and other chemicals were of the highest quality commercially available.

Cell isolation. Inbred newborn SENCAR mice (24) were obtained from the Science Park - Veterinary Division breeding colony. Intact epidermal cells were isolated from either 1- or 2-day-old newborn mice by the trypsinization procedure of Yuspa and Harris (25). For culture experiments, the cells (basal-like) were plated at a density of 2×10^6 per 35 mm tissue culture dish for arachidonate or eicosapentaenoate metabolite analysis or at a density of 5×10^6 per 60 mm tissue culture dish for ODC assays. The plating medium was an enriched Waymouth's, containing 10% fetal bovine serum; the growth medium was an enriched MCDB 151 (referred to as SPRD 110), containing 0.1% bovine serum albumin but no serum, as described by Morris *et al.* (26). Following plating, the cultures were incubated at 37°C in 5% CO_2 for 24 hr prior to use in the assays described below.

Freeze-thawed cells. For experiments using non-viable cells, isolated epidermal cells were frozen at −70°C prior to incubation with radiolabelled fatty acids.

Phospholipid extraction and analysis. Incorporation of labelled fatty acids into phospholipids was determined by replacing the plating medium with SPRD-110 medium containing radiolabelled AA or EPA (0.10 μCi/ml media) for 12 hr. At designated times the medium was aspirated from the cells, the cell layer immediately washed once with cold saline, and frozen at −70°C. The thawed cells were scraped into 1.0 ml methanol and the phospholipids extracted by adding 3 ml of chloroform (chloroform:methanol, 3:1, v/v) and 1 ml 2M KCl; the chloroform:methanol extracts were dried under vacuum. Reconstituted extracts were separated by TLC together with authentic standards using a solvent system of chloroform:methanol:acetic acid (65:25:4; v/v/v) (27). Standards were identified with iodine vapors and the corresponding sample phospholipid bands were then scraped and counted by liquid scintillation.

Competition of AA and EPA for incorporation into phospholipids was determined by incubating cultured epidermal cells with SPRD 110 medium containing 0.25 μg/ml AA and EPA and tracer amounts (2.5 μCi or 9 ng/ml) of either ^{3}H-AA or ^{3}H-EPA for designated incubation times. The phospholipids were extracted and quantitated as described above.

Release of the fatty acids from the phospholipids was analyzed by labelling cultures with either ^{3}H-AA or ^{3}H-EPA in SPRD 110 (0.1 μCi/ml medium) after which the labelled media was replaced with fresh SPRD 110 containing either acetone or TPA (1.0 μg/ml). At designated times, the cells were harvested from the plates and phospholipid extraction and quantitation were performed as described above.

Prostaglandin synthesis. To determine whether AA and EPA were metabolized to the same extent by epidermal prostaglandin synthetase, freshly isolated cells (28×10^6) were freeze-thawed several times. The broken cell preparations were incubated with either ^{14}C-AA or ^{14}C-EPA for 1 hr in SPRD 110 and the prostaglandins extracted twice with 3 ml of ethyl acetate. The extraction efficiencies were usually greater than 90%. The pooled extracts were dried under vacuum, redissolved in ethyl acetate, and applied with standards to thin-layer silica gel plates. The plates were developed with the organic phase of ethyl acetate: iso-octane:acetic acid:water (28:13:5:25, v/v/v/v) (28). The metabolites were detected by staining with iodine vapors, and then scraped and counted. Autoradiograms were made to ascertain that the AA and EPA metabolites co-chromatographed.

To determine prostaglandin production from viable cells, cultures were labeled for 12 hr, previously determined to be the time of maximum incorporation into epidermal phospholipids by Fischer *et al.* (29), in SPRD 110 containing ^{3}H-AA or ^{3}H-EPA (0.1 μCi/ml). Following replacement with fresh medium containing either acetone or TPA (1 μg/ml), the medium was collected at the appropriate time points and acidified to approximately pH 3 with 1 N HCl and extracted as described above.

Lipoxygenase activity. Freshly-isolated epidermal cells were homogenized as previously described (30) and centrifuged at $12,500 \times g$ for 10 min, followed by centrifugation of the supernatant for 60 min at $105,000 \times g$. This supernatant was used for lipoxygenase assays. ^{14}C-AA or ^{14}C-EPA (0.5 μCi) was added to the reaction assay containing 1 mg protein/ml Tris buffer (29). After 30 min incubation time at 37°C the reaction was stopped by acidification, and ethyl acetate extraction was performed as above. The HETEs were separated by TLC using a solvent system of diethyl ether:hexane:acetic acid (60:40:1; v/v/v).

Ornithine decarboxylase induction. These assays were performed on viable epidermal cultures treated for 7 hr with solvent (acetone) or TPA. A $12,000 \times g$ centrifugation was performed on homogenized scraped cells, using a Na/K-phosphate buffer containing pyridoxal phosphate. The supernatant was used to determine enzyme activity, as described by Weeks and Slaga (31), and the total protein was measured by the Coomassie blue reaction (Bio-Rad, Richmond, CA).

DNA synthesis. Twenty-four hours after plating epidermal cells at 1.5×10^6/35-mm tissue culture dish, the cultures were treated with 0.1 μg/ml either AA or EPA in the presence or absence of 0.1 μg/ml TPA in SPRD-110 medium. The specific activity of DNA synthesis was measured at the given times after treatment by determining the amount of ^{3}H-thymidine incorporated per μg DNA after a 1 hr pulse label with 2 μCi/ml, using the Schmidt-Thannhauser isolation procedure (32) and Burton assay (33).

Statistical analysis. The data were analyzed using the Student's t-test.

RESULTS

Phospholipid analysis. Since incorporation of fatty acids into cell membrane phospholipids is the first step in fatty acid metabolism, it was important to compare rates of

incorporation of both fatty acids into epidermal cell phospholipids and to determine whether incorporation occurred equally within the same phospholipid classes. Uptake of both ^{3}H-AA or ^{3}H-EPA into total phospholipids increased over time at similar rates and to the same extent, as indicated in Figure 1. Uptake was nearly maximal by 4 hr. As shown in Table 1, incorporation into specific phospholipid classes was similar for both fatty acids.

In order to determine whether EPA could compete equally with AA for incorporation into phospholipids, epidermal cells were incubated with both AA and EPA. Measurement of incorporation of tracer amounts of either ^{3}H-AA or ^{3}H-EPA in the presence of unlabelled fatty acids showed that EPA was incorporated into phospholipids at a slightly higher, although not significant ($p > 0.05$), level at 1, 3, or 6 hr as shown in Figure 2. Overall, AA and EPA appear to be equally competitive for incorporation into epidermal phospholipids.

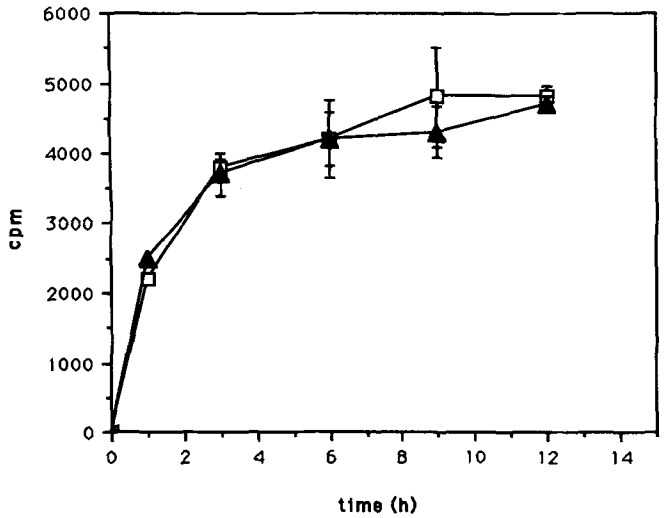

FIG. 1. Rate of incorporation of ^{3}H-AA or ^{3}H-EPA into total phospholipids of cultured mouse epidermal cells. Each point represents cultures (n = 2 to 4) of 2 × 10^6 cells grown for up to 12 hr in serum-free medium containing 0.15 μCi of AA or EPA. Total phospholipids were extracted at the designated times and counted. Results are expressed as mean cpm ± std. dev. of ^{3}H-fatty acid incorporated into 2 × 10^6 cells from two experiments. □, ^{3}H-AA; ▲, ^{3}H-EPA.

TABLE 1

Incorporation of Arachidonate and Eicosapentaenoate into Epidermal Cell Phospholipids

	% total incorporation	
	AA	EPA
PC	19.8 (15.4-24.2)	19.4 (16.4-22.4)
PE	48.3 (46.2-50.3)	50.1 (46.1-54.1)
PI/PS	30.4 (28.1-32.6)	28.5 (22.7-35.9)
Other	1.6 (1.5- 1.7)	2.1 (1.6- 2.5)

Epidermal cells were labelled with either ^{14}C-AA or ^{14}C-EPA (0.1 μCi/ml) for 15 hr. Phospholipids were extracted, separated by TLC and counted. Values represent the means of two experiments (the ranges are shown in parentheses). PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI/PS, phosphatidylinositol and phosphatidylethanolamine (comigration); Other, tentatively identitied as sphingomyelin.

Release of either ^{3}H-AA or ^{3}H-EPA from phospholipids was also found to be similar for both fatty acids (Fig. 3) in unstimulated cultures. However, when the cultures were treated with TPA, ^{3}H-AA prelabelled cells released this fatty acid at a faster rate and to a higher extent than the cells prelabelled with ^{3}H-EPA (Fig. 3).

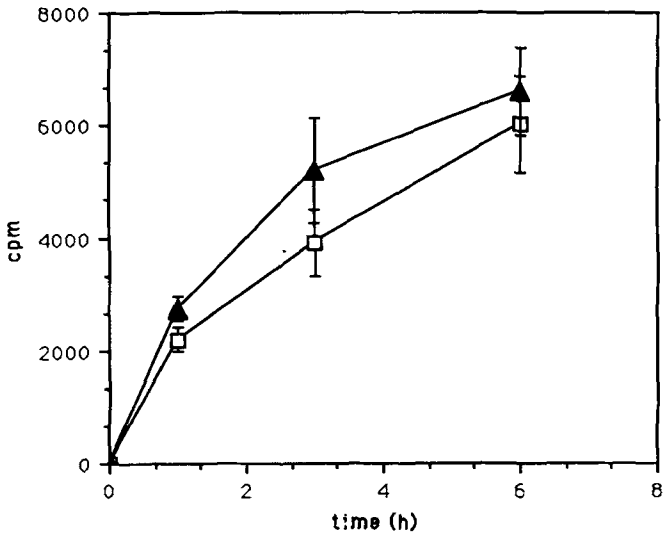

FIG. 2. Competition of ^{3}H-AA and ^{3}H-EPA for incorporation into total phospholipids of mouse epidermal cells as a function of time. Cultures of 2 × 10^6 cells were incubated with tracer amounts of radiolabelled AA or EPA and 0.5 μg/ml of unlabelled EPA and AA respectively. Each point represents the mean cpm ± std. dev. in the extracted phospholipids from four cultures in a representative experiment. □, ^{3}H-AA; ▲, ^{3}H-EPA.

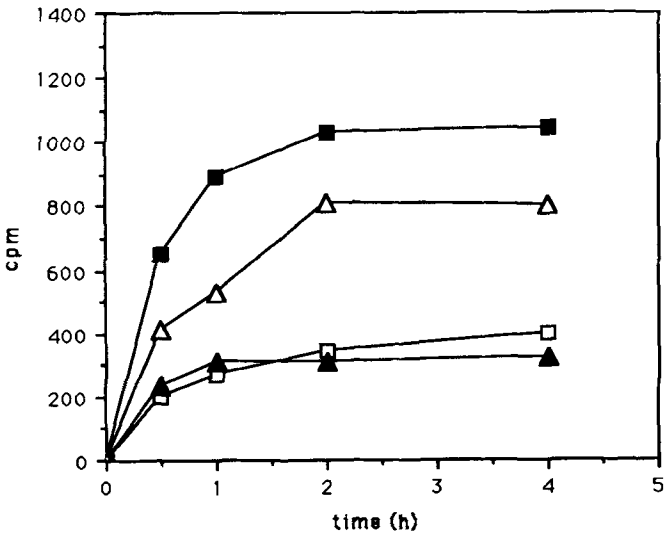

FIG. 3. Rate of release of incorporated ^{14}C-AA and ^{14}C-EPA from phospholipids of solvent control or TPA-stimulated murine epidermal cell cultures. Each point represents the mean of cultures of 2 × 10^6 cells labelled as in Figure 1. Following treatment for the designated times with either solvent (acetone) or TPA (1 μg/ml), the medium was removed and counted. The points are from a representative experiment. The average fold increase in release of radiolabel from acetone-treated cultures at 4 hr was statistically significant from TPA-treated cultures for both fatty acids ($p = 0.002$, n = 10 from 6 independent experiments). □, AA; ▲, EPA; ■, AA-TPA; △, EPA-TPA.

By 4 hr, TPA induced an average increase over control of 3.6 fold for AA and 2.4 fold for EPA prelabelled cultures. This difference in release between AA and EPA was statistically significant ($p < 0.002$).

Prostaglandin synthesis. In order to determine if epidermal prostaglandin-synthesizing enzymes use AA and EPA as substrates equally well, epidermal cells were freeze-thawed (to eliminate competing incorporation processes), and incubated with the appropriate fatty acid, and prostaglandins F, E and D quantitated by liquid scintillation. Autoradiography revealed that PGF was not formed as efficiently from EPA as from AA: the percent PGF production of the total prostaglandin synthesized from EPA was 15.8% compared to 32.9% for AA-derived prostaglandins (Fig. 4). However, EPA appears to be a slightly better substrate for PGE production: synthesis of PGE from EPA was 66.3% while PGE derived from AA was 51.0%. PGD production was found to be equally efficient with either EPA or AA (17.9% and 16.1% respectively).

The products of the cyclooxygenase pathway were also compared between viable cultures prelabelled with ^{3}H-AA or ^{3}H-EPA (Fig. 5). At 4 hr, the major cyclooxygenase metabolite in either solvent- or TPA-treated cultures was PGE followed by PGD and PGF. TPA-treated AA prelabelled cultures produced 8.2 times more PGE than control AA cultures. This is a statistically significant increase ($p < 0.001$; $n = 10$ from five independent experiments). Similarly, cultures prelabelled with EPA and stimulated with TPA produced more prostaglandins than control EPA cultures but the difference was not significant. Both AA-control and AA-TPA cultures produced more PGE than the respective EPA-control cultures or EPA-TPA cultures; the difference between AA and EPA cultures which were stimulated with TPA was significant ($p < 0.001$).

Lipoxygenase activity. HETE and HEPE production were similar in homogenates using either labelled AA or EPA as substrate (Fig. 6): 65% of the HETE products consisted of 12- and 15-HETE for AA, while 67% of the HEPE products were the 12- and 15-HEPE. Both fatty

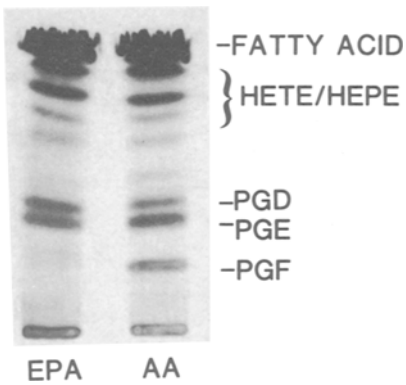

FIG. 4. Autoradiogram of prostaglandin metabolites from either ^{14}C-AA or ^{14}C-EPA incubated with freeze-thawed epidermal cells. The major sample metabolites were identified by co-chromatography with authentic standards and the position of the sample metabolites verified by autoradiography. The experiment was performed twice.

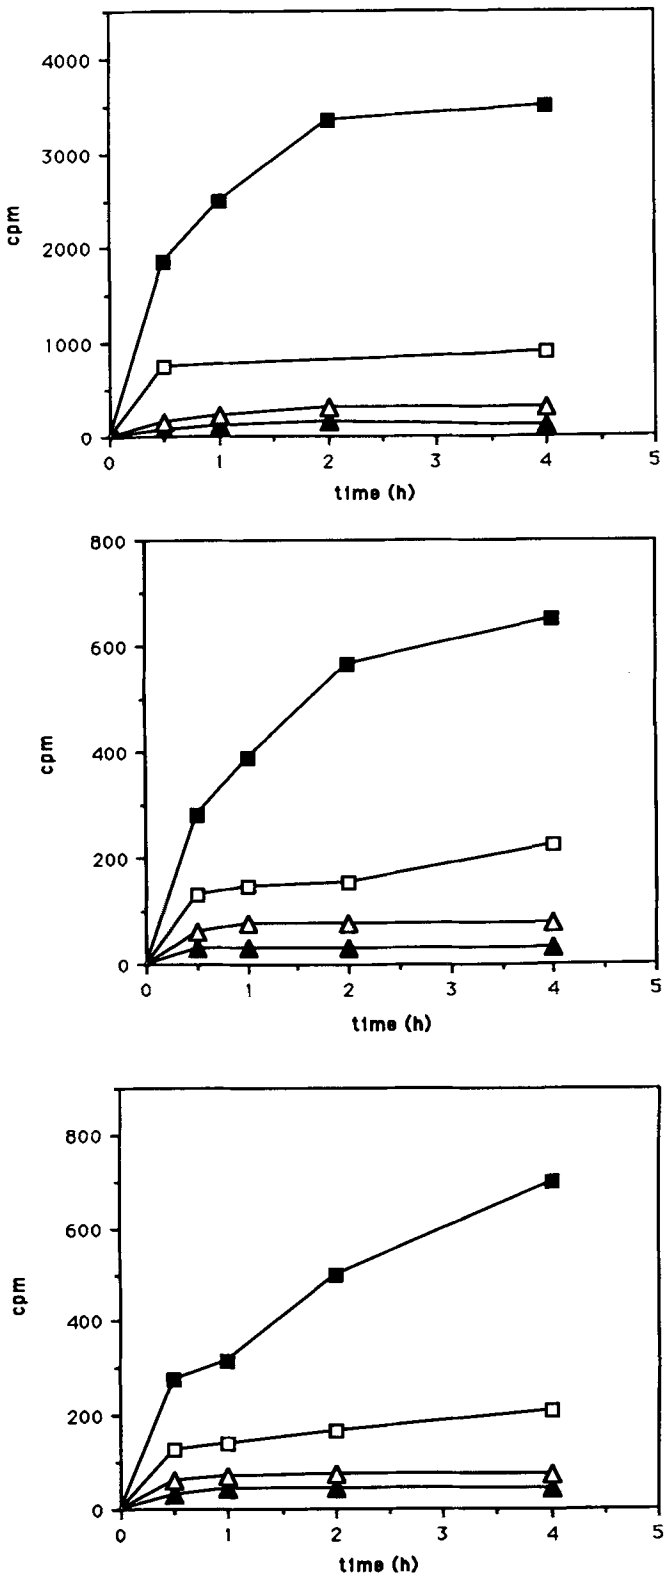

FIG. 5. Prostaglandin synthesis in solvent control and TPA-stimulated cultured epidermal cells. Primary cultures were prelabelled as described with either ^{3}H-AA or ^{3}H-EPA and were treated with either acetone or 1 μg/ml TPA. Cultures were terminated at times specified and the metabolites, PGE (top panel), PGF (middle panel) and PGD (bottom panel) separated by thin-layer chromatography and counted. Five separate experiments were performed. Values represent mean cpm from a typical experiment, performed in duplicate. □, AA; ■, AA-TPA; ▲, EPA; △, EPA-TPA.

acids produced 2% or less of the 5- and 8-hydroxy fatty acids. HETE production in prelabelled cultured cells was also the same as HEPE production (data not shown).

Ornithine decarboxylase activity. The induction of ODC activity by TPA is at least partially dependent on the production of PGE_2 (21). It was therefore of interest to determine whether EPA-mediated PGE_3 production would support TPA-stimulated ODC activity to the same extent as arachidonate-derived PGE_2 (Table 2). ODC activity was not found to differ significantly between cells cultured with either fatty acid in the acetone-control group. A comparison of the (AA + TPA) vs (AA) groups shows a seventeen-fold increase in experiment 1 and a sixteen-fold increase in experiment 2. A similar comparison of the (EPA + TPA) and (EPA) groups shows eight- and twelve-fold increases, respectively. The difference in TPA-induced ODC activity between the two fatty acid groups was statistically significant ($p < 0.01$).

DNA synthesis. Comparisons were made between the specific activity of DNA synthesis in epidermal cells grown in the presence of either AA or EPA, with or without TPA. Employing standard medium formulations, an initial experiment (data not shown) indicated that at 1 μg/ml EPA was toxic since it caused a large number of cells to slough from the culture dishes; AA did not have this effect. For this reason, subsequent DNA synthesis experiments used 0.1 μg/ml for both fatty acids. A three-day incubation time was chosen since it was previously determined that this was optimum for TPA. As shown in Figure 7, AA supported DNA synthesis to nearly twice the level observed with EPA ($p = 0.01$). The DNA content of all dishes was the same and no toxicity was observed. The level of DNA synthesis in the presence of TPA was also significantly higher ($p = 0.01$) for AA than EPA. The effect of TPA on AA was also significantly different ($p = 0.01$); however, TPA did not significantly enhance DNA synthesis in EPA cultures.

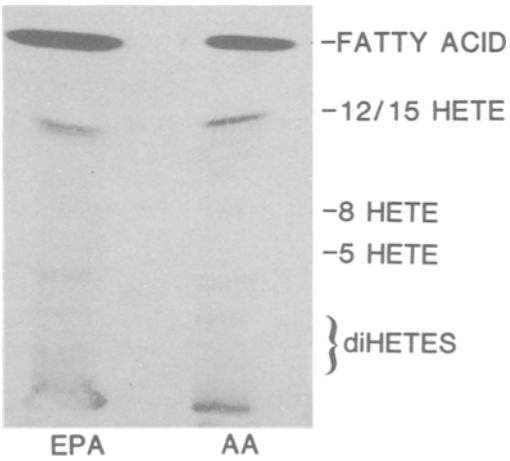

FIG. 6. Autoradiogram of HETE/HEPE synthesis from cytosolic preparations of murine epidermal cells incubated with ^{14}C-AA or ^{14}C-EPA. The major products were identified by co-chromatography, with authentic standards and the position of the sample metabolites verified by autoradiography. The experiment was performed twice.

TABLE 2

Effect of AA versus EPA on TPA-induced ODC Activity in Murine Epidermal Cells *in vitro*

Treatment	nmol CO_2/mg protein/hr[a]	
	Experiment 1	Experiment 2
Control	0.079 ± 0.039	0.070 ± 0.032
TPA (1 μg/ml)	0.424 ± 0.089	0.827 ± 0.195
AA[b]	0.107 ± 0.031	0.054 ± 0.023
AA + TPA	1.309 ± 0.238[c]	1.118 ± 0.243[c]
EPA	0.095 ± 0.042	0.059 ± 0.022
EPA + TPA	0.777 ± 0.215[c]	0.688 ± 0.125[c]

[a]ODC activity.

[b]Fatty acids were used at 1 μg/ml media, complexed to fatty acid free BSA prior to addition to serum free medium. Values represent the mean ± std. dev. of 2 experiments with 4 to 6 dishes each per treatment group.

[c]The difference in ODC activity between AA + TPA and EPA + TPA was statistically significant ($p < 0.01$; student's t-test) for both experiments.

DISCUSSION

Incorporation of AA and EPA into phospholipids appears to be equivalent in non-stimulated murine epidermal cultures with respect to rate and class of phospholipid. Our findings are similar to those found by Morita *et al.* (20) where incorporation of either fatty acid was equal in

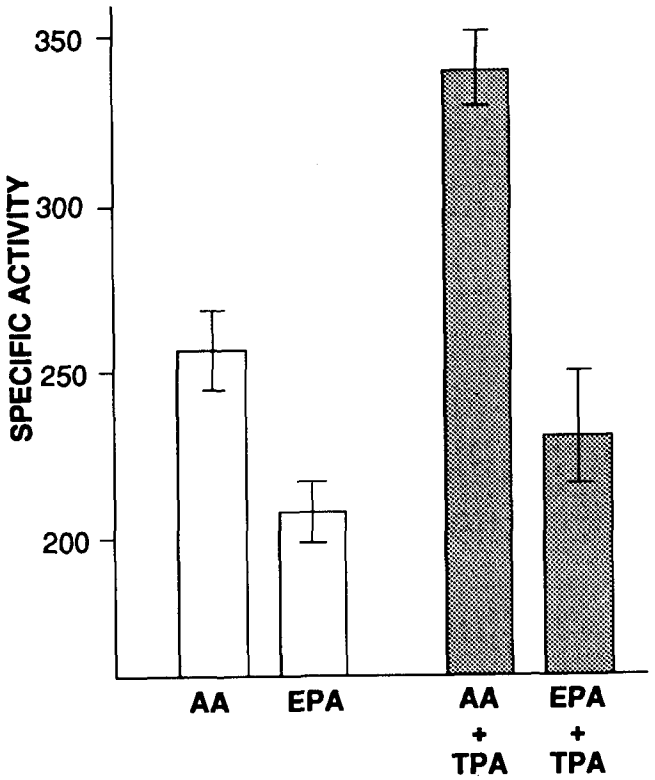

FIG. 7. DNA synthesis in epidermal cells cultured with either AA or EPA. The specific activity of ^{3}H-thymidine incorporation was determined 3 days after continuous treatment of cultures with either 0.1 μg/ml AA or EPA alone or in the presence of 0.1 μg/ml TPA. Values represent the mean ± SEM (n = 3 to 4).

aortic smooth muscle cell cultures. However, Morita *et al.* (20) and Weaver and Holub (21) found that platelets preferentially incorporate AA, suggesting that the extent of incorporation is cell-type specific.

Release of either AA or EPA from phospholipids of non-stimulated epidermal cells was also similar. However, when the cultures were stimulated with TPA, a phorbol ester which activates phospholipase A_2 (34), AA was released from the phospholipids to a greater extent than EPA, suggesting that phospholipase A_2 has a preference for phospholipids containing AA.

To determine if the prostaglandin-synthesizing enzymes can use AA or EPA equally as a substrate, in the absence of the competing reaction of incorporation into phospholipids, freeze-thawed cells were used to study metabolism *in vitro*. We found that PGF was produced to a greater extent when labelled-AA was the substrate. In contrast, PGE production was slightly more efficient with EPA as the substrate. Lands and Byrnes (35) also found less prostaglandin production from EPA when compared to AA. Their data support our findings that in general EPA is not as easily enzymatically oxygenated under the same conditions in which AA is rapidly oxidized.

Viable cell cultures were then used to determine if metabolism was different in living cells in which incorporation and other regulatory processes (i.e. phospholipase A_2 activity) are ongoing. Flower and Blackwell (28) suggest that substrate availability for prostaglandin synthetase is controlled by activated phospholipase A_2. We found that TPA-treated AA-cultures produced more PGE compared to the EPA-TPA cultures. The higher amount of this oxygenated product in the AA-TPA cultures is probably due to more AA liberated and available for cyclooxygenase activity, an effect of TPA treatment. We found similar results with PGD and PGF indicating that even with TPA stimulation, EPA is not as readily converted to cyclooxygenase products as is AA. Similar findings were reported by Magrum and Johnson (36) in studies on zymosan-activated macrophages cultured in the presence of either AA or EPA.

In vivo studies have also demonstrated that diets high in n-3 fatty acids are associated with a reduction in PGE production (37). In the present study, the possible inhibitory effect of EPA on total PGE production was not measured. However, other investigators have found that n-3 fatty acids, including linolenate and eicosatrienoate, can inhibit prostaglandin production (38–40). Mohrhauer and Holman (41) suggest that the inhibition of PGE production by linolenic acid is due to an inhibitory effect of linolenic acid on the conversion of linoleic acid to AA.

When prostaglandin synthesis is inhibited with agents such as indomethacin, the lipoxygenase products can become the predominant oxygenated metabolites (42). Our data indicate that lipoxygenase activity was similar in cytosol preparations to which AA or EPA were added directly, as well as in prelabelled, viable cultured cells. It has been previously reported (43) that 5-HETE synthesis in rat leukocytes was greater in rats fed EPA compared to animals fed AA. Analysis of HETE production is important since high amounts of these lipoxygenase products are associated with the hyperproliferative disease, psoriasis (44). In the mouse skin carcinogenesis model, the lipoxygenase products have been shown to be required in several TPA responses. Specifically, lipoxygenase inhibitors have been reported to reduce TPA tumor promotion in several strains of mice (45–48). These same inhibitors will also depress TPA-induced ODC activity (45–47). In addition, when indomethacin, a cyclooxygenase inhibitor, was applied to TPA-treated skin of SENCAR mice, an enhancement of tumor promotion was observed (15). It was suggested that this was due to inhibition of cyclooxygenase activity which resulted in a shunting of the liberated AA to the lipoxygenase pathway, thereby increasing HETE production.

Verma and Boutwell (16) have shown that indomethacin also inhibited the induction of ODC by TPA in mouse epidermis in a dose-response manner. When exogenous PGE_2 was added back, the inhibitory effect of indomethacin on ODC activity was overcome, suggesting that ODC activity is at least partially mediated by the eicosanoids derived from AA. We found that epidermal cells grown in EPA did not support as large an induction of ODC as cells cultured with AA, further supporting the hypothesis that cyclooxygenase metabolites of AA are involved in ODC induction. This function of AA metabolites on ODC induction is significant to the tumor promotion process since inhibitors of ODC induction have also been shown to inhibit tumor promotion (reviewed in 17).

The induction of ODC is usually followed by elevated polyamine production, which is thought to be a factor in the stimulation of DNA synthesis. On this basis it is reasonable to expect that agents that support higher levels of ODC induction would also support higher levels of DNA synthesis. Our results indicate that this correlation holds for AA and EPA.

Our *in vitro* results indicate that incorporation of either AA or EPA into phospholipids is equal. Since numerous dietary studies have shown that the fatty acid composition of membrane phospholipids of various organ systems can be altered by changing the types of fatty acids in the diet (18,19,37), it should also be possible to alter epidermal membrane composition. Because our results indicate that TPA-induced ODC activity and DNA synthesis are significantly lower in EPA-stimulated cultures, it can be predicted that tumor incidence should be lower in animals fed n-3 enriched diets compared to animals fed diets high in n-6 fatty acids. Studies are currently underway in our laboratory to determine whether such diets do alter the fatty acid composition of epidermal cells, as well as altering the level of cyclooxygenase metabolites and affecting tumor incidence in a multistage carcinogenesis model. A combination of *in vitro* and *in vivo* studies will be useful in elucidating the relationship of specific dietary fatty acids to the modulation of cancer development.

Dipyridamole Inhibits Lipid Peroxidation and Scavenges Oxygen Radicals

L. Iuliano, F. Violi*, A. Ghiselli, C. Alessandri and F. Balsano
Institute of Clinica Medica I, University of Rome "La Sapienza," Policlinico Umberto I, 00161 Rome, Italy

Dipyridamole incubated *in vitro* in systems which peroxidize fatty acids inhibited arachidonic acid, gamma-linolenic acid and linoleic acid peroxidation. In the xanthine-xanthine-oxidase system, which produces superoxide anion, dipyridamole inhibited the reduction of cytochrome-C in a dose-dependent fashion. In systems generating hydroxyl radicals, dipyridamole reduced deoxyribose degradation in a dose-dependent manner. The study suggests that dipyridamole inhibits lipid peroxidation, probably by scavening oxygen free radicals.
***Lipids* 24, 430-433 (1989).**

Dipyridamole is an antiplatelet drug, shown to interrupt platelet consumption in experimental thrombotic models and to prolong platelet survival time in patients with cardiovascular diseases (1-3). The mechanism of action of dipyridamole is yet to be understood. However, elevation of platelet cyclic-AMP and blood adenosine have been proposed to explain its antithrombotic effect (1, 4, 5). Dipyridamole has been shown to possess an antioxidant property as it inhibits *in vitro* lipid peroxidation (6, 7), but the mechanism of its antioxidant action has not been investigated. Biological molecules such as unsaturated fatty acids, sugars, proteins, aminoacids and catecholamines undergo degradative changes mediated by oxygen free radicals, via superoxide (O_2^-) and hydroxyl radicals (OH•) (8—10). Therefore, the present study is aimed at understanding the antioxidant action of the dipyridamole on peroxidation of unsaturated fatty acids, degradation of deoxyribose, and reduction of cytochrome-C, induced by different free radical-generating agents in model *in vitro* systems.

MATERIALS AND METHODS

Methyl esters of arachidonic acid, linoleic acid and gamma-linolenic acid, arachidonic acid sodium salt, cytochrome-C (horse heart, type VI), and butylated hydroxytoluene (BHT) were obtained from Sigma Chemical Co. (St. Louis, MO). Bovine liver superoxide-dismutase and bovine milk xanthine-oxidase were obtained from Boehringer Mannheim GmbH (Mannheim, West Germany) and Calbiochem-Behring (San Diego, CA), respectively. Desferrioxamine and all other reagents of highest quality were available from Ciba-Geigy (Basel, Switzerland) and Merck (Darmstadt, West Germany), respectively. Dipyridamole was a gift from Boehringer Ingelheim (Reggello, Italy). Deionized, double-distilled water was used throughout this investigation.

UV-Visible radiation studies were performed on a Hewlett Packard 8452A Diode Array Spectrophotometer.

Methyl esters of arachidonic acid (40 μM), linoleic acid (50 mM) and gamma-linolenic acid (1 mM) were dispersed in 1 ml 0.5 M phosphate buffer (pH 6.0) by vortexing for 30 seconds. Peroxidation was induced by subjecting these dispersion systems to continuous UV light (Philips TL 40W tube, placed 40 cm above) for 60 min at 37°C in open air.

Sodium arachidonate (100 μM) was dissolved in 10 mM NaH_2PO_4 medium (pH 4.5) containing 10 μM Na_2CO_3. Lipid peroxidation in this system was induced by 38 μM ascorbic acid and 8 μM Fe(II), as ferrous ammonium sulphate, upon incubation for 2 hr at 37°C. While studying the effects of dipyridamole and/or BHT separately, the incubation medium contained 5 μM dipyridamole or 10 mM BHT. Simultaneous controls were established which contained equal amounts of ethanol that served as the solvent of dipyridamole and BHT. At the end of the incubation period, lipid peroxidation in the fatty acid systems was assayed by the thiobarbituric acid (TBA) reaction method according to Cordova et al. (11) as follows: the reaction mixture was mixed with 0.5 ml trichloroacetic acid (TCA) (20% w/v) and 1.0 ml TBA (1% w/v). The solution was mixed thoroughly, boiled for 10 min, cooled to room temperature and the absorbance of the chromophore was measured at 532 nm against an appropriate blank. The extent of peroxidation in the fatty acid system was expressed as moles malondialdehyde (MDA)/mole fatty acid (12).

Effect of dipyridamole on O_2^--mediated reduction of cytochrome-C was studied according to Fridovich (13). The reaction mixture contained 50 mM KH_2PO_4 (pH 5.4), 50 μM xanthine, 30 nM xanthine-oxidase 0.1 mM EDTA, and various concentrations of dipyridamole (30-300 μM) in a final volume of 3.0 ml. Reduction of cytochrome-C was followed by the change in absorbance at 550 nm at 37°C.

Effect of dipyridamole on Fe(II)- and Fe(III) + H_2O_2 + ascorbate-induced deoxyribose degradation was studied according to Halliwell and Gutteridge (14), Gutteridge (15), and Winterbourn (16). The system in which Fe(II) was used as a radical-generating agent contained 1.5 mM 2-deoxy-D-ribose in 1.0 ml of 63 mM NaCl and 44 mM NaH_2PO_4 (pH 4.5). Reaction was initiated by the addition of ferrous ammonium sulphate (244 μM, final concentration).

The system in which Fe(III) + ascorbate + H_2O_2 was used as a radical-generating agent contained 2.8 mM 2-deoxy-D-ribose in 1.0 ml of 10 mM NaH_2PO_4 buffer (pH 4.5). The reaction was initiated by 15 μM Fe(III) as ferric chloride, 100 μM ascorbate, and 1.44 mM H_2O_2. The reaction medium contained various concentrations of dipyridamole. The reaction was carried

*To whom corespondence should be addressed.

Abbreviations: BHT, butylated hydroxytoluene; EDRT, endothelium-derived relaxing factor; EDTA, ethylene diamine tetraacetic acid; LOOH, lipid hydroperoxide; MDA, malondialdehyde; TBA, thiobarbituric acid; TCA, trichloroacetic acid.

out for 15 min at 37°C. The degradation of deoxyribose was assayed according to Halliwell and Gutteridge (14) as follows: at the end of the incubation period, 1.0 ml of TCA (2.8% w/v) and 1.0 ml of TBA (1% w/v in 50 mM NaOH) were added to the incubation mixture, mixed thoroughly, and boiled for 10 min in a water bath. The pink chromophore formed was measured at 532 nm against a suitable blank. The extent of deoxyribose degradation was expressed as absorbance unit/time.

All the data were subjected to statistical analysis. Significance between two means was calculated employing the Student's t-test.

RESULTS

Lipid peroxidation. UV-induced lipid peroxidation in the fatty acid systems was significantly inhibited by dipyridamole (5 μM) and BHT (10 mM) (Fig. 1) and no further inhibition was observed at higher concentrations of dipyridamole. A similar trend was observed in the Fe(II)/ascorbate system where 5 μM dipyridamole significantly inhibited arachidonate peroxidation (52% inhibition) and did not appear to change upon increasing the concentration of dipyridamole (Fig. 2).

Superoxide anion-mediated reduction of cytochrom-C. The O_2^- flux generated by the xanthine-xanthine-oxidase system was monitored by following the rise in absorbance at 550 nm due to the reduction of cytochrome-C. The effect of added dipyridamole on the absorbance changes was analyzed in terms of a simple competition between dipyridamole (inhibitor) and cytochrome-C (substrate for the O_2^- generated). Data were arranged graphically according to Dixon (17) where the reverse of velocity is plotted against the concentration of inhibitor, keeping the substrate constant (Fig. 3). The plot, where each line represents an experiment made at a fixed substrate concentration, clearly demonstrates a competitive inhibition. Interferences of dipyridamole with the xanthine-xanthine-oxidase system were excluded by measuring urate production at 290 nm in the absence of cytochrome-C. In the system the rate of cytochrome-C reduction was not influenced by catalase (25 μg/ml), but was fully prevented by superoxide-dismutase (5 μg/ml).

Hydroxyl radical-dependent deoxyribose degradation. The influence of dipyridamole on OH•-generating systems is shown in Figure 4. Dipyridamole inhibited the deoxyribose degradation in a dose-dependent manner; when OH• was generated by the direct addition of Fe(II) salts to the reaction mixture containing phosphate buffer, according to the following equations:

$$\begin{array}{lllll} Fe(II) & + O_2 & \rightarrow Fe(III) & + O_2 \\ 2O_2 & + 2H^+ & \rightarrow H_2O_2 & + O_2 \\ Fe(II) & + H_2O_2 & \rightarrow Fe(III) & + OH^- + OH^{\bullet}, \end{array}$$

the inhibition was 21.8%, 49.5% and 64.7% at dipyridamole concentrations of 19.8 μM, 79.2 μM, 158 μM, respectively. Similarly, dipyridamole inhibited deoxyribose degradation in a dose dependent manner in a system where OH• was generated at a higher rate through a modified metal-catalyzed Haber-Weiss cycle according to the following scheme:

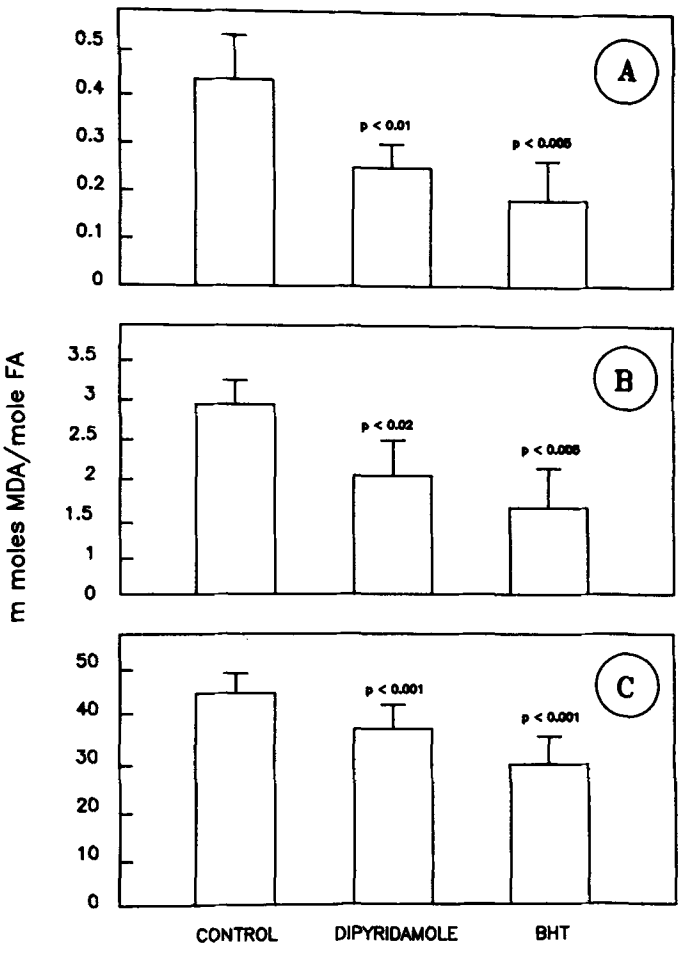

FIG. 1. Effect of dipyridamole and BHT (butylated hydroxytoluene) on UV-induced peroxidation of methyl esters of linoleic acid (A), gamma-linolenic acid (B) and arachidonic acid (C). Control: treated with ethanol (10 μl/ml). Dipyridamole: 5 μM in ethanol. BHT: 10 mM in ethanol. Each value is the average of 5 experiments.

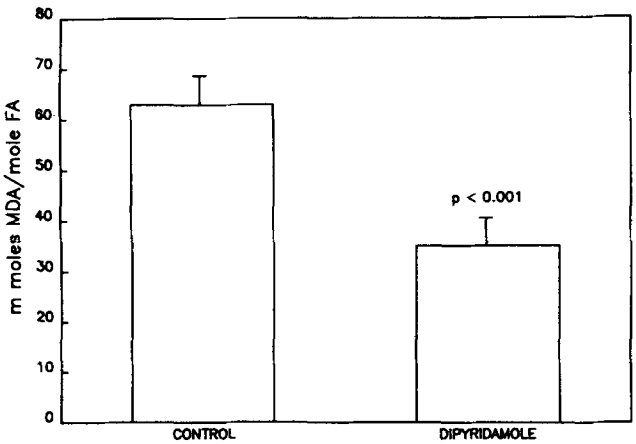

FIG. 2. Effect of dipyridamole on Fe(II) + ascorbate-induced peroxidation of arachidonic acid. Control: treated with ethanol (10 μl/ml). Dipyridamole: 5 μM in ethanol. Each value is the average of 4 experiments.

$$\text{ascorbate} + 2\text{Fe(III)} \rightarrow 2\text{Fe(II)} + \text{dehydroascorbate} + 2\text{H}^+ \quad [1]$$

$$\text{ascorbate} + \text{O}_2 \rightarrow \text{dehydroascorbate} + \text{H}_2\text{O}_2 \quad [2]$$

$$\text{Fe(II)} + \text{H}_2\text{O}_2 \rightarrow \text{Fe(III)} + \text{OH}^- + \text{OH}^\bullet \quad [3]$$

In this pathway ascorbate plays a dual role: it reduces metal ions [1] and generates H_2O_2 [2]. The reduced metal ions react in turn with H_2O_2, giving OH• by a Fenton mechanism [3]. Addition of EDTA to the reaction system removes iron from binding sites in order to produce OH• in "free" solution (15). In this system the inhibition was 15.9%, 31.9% and 43.2% at dipyradamole concentrations of 49.4 μM, respectively.

DISCUSSION

Previous investigations have shown that dipyridamole is an antioxidant that diminishes fatty acid peroxidation in model systems and in tissue culture (6, 7). Our research supports these findings and gives insight into the mechanism leading to inhibition of lipid peroxidation by dipyridamole. Indeed, we have demonstrated that dipyridamole reduces the formation of lipid peroxides in two different in vitro model systems, where fatty acid peroxidation was induced by UV light or by iron/ascorbate.

Lipid peroxidation is a complex chemical process which is started by a highly reactive species (R•), such as O_2^- and OH•. This oxidant (R•) interacts with fatty acids (LH) and, by abstracting hydrogen atoms from their alpha-methylene carbons, gives rise to the formation of a carbon-centered radical; this intermediate compound undergoes a molecular rearrangement to form a conjugated diene (L•) which reacts rapidly with oxygen to give a peroxy radical (LO_2•). The peroxy radical has sufficient energy to abstract a hydrogen atom from another lipid molecule to continue the chain reaction and to convert itself into a lipid hydroperoxide (LOOH):

$$\text{LH} + \text{R}^\bullet \rightarrow \text{L}^\bullet + \text{RH} \quad [4]$$

$$\text{L}^\bullet + \text{O}_2 \rightarrow \text{LOO}^\bullet \quad [5]$$

$$\text{LOO}^\bullet + \text{LH} \rightarrow \text{LOOH} + \text{L}^\bullet \quad [6]$$

In the present investigation we have shown that in three different model systems that produce free oxygen radicals, dipyridamole decreased the detection of both O_2^- and OH• in a dose-dependent fashion.

This effect could be attributed to a scavenging property of dipyridamole, which should inhibit lipid peroxidation by limiting the interaction between fatty acids and oxygen free radicals (reaction [4]).

However, it cannot be excluded that the decrease of lipid peroxides is related to the direct interaction of dipyridamole with intermediate compounds of the lipid peroxidation process such as conjugated diene, peroxy radical or hydroperoxides [5, 6] thus interrupting the autocatalytic chain reaction.

Also, interaction of dipyridamole with metal ions, contained in the model systems, cannot be excluded since lipid hydroperoxides can be decomposed by transition metal ions (M) to give alkoxy (LO•) and peroxy radicals:

$$\text{M}^{(n)+} + \text{LOOH} \rightarrow \text{LO}^\bullet + \text{OH}^- + \text{M}^{(n+1)+} \quad [7]$$

$$\text{M}^{(n+1)+} + \text{LOOH} \rightarrow \text{LOO}^\bullet + \text{H}^+ + \text{M}^{(n)+} \quad [8]$$

The antioxidant activity of dipyridamole could contribute to further explain some of its biological effects. There is increasing evidence that polyunsaturated fatty acids are involved in the control of cell proliferation.

Unsaturated fatty acid intermediates and their derivatives, either of the lipid peroxide pathway or the prostanoid pathway, generate both positive and negative signals for cell proliferation (7). Lipid peroxides

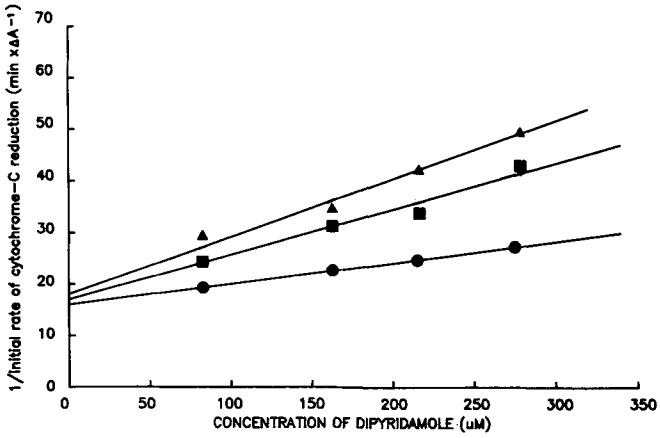

FIG. 3. Effect of dipyridamole on superoxide (O_2^-)-mediated reduction of cytochrome-C. Experiments were carried out at pH 5.40, 37°C, as described in Materials and Methods using horse heart cytochrome-C at a final concentration of ●, 2 μM; ■, 4 μM, and ▲, 6 μM.

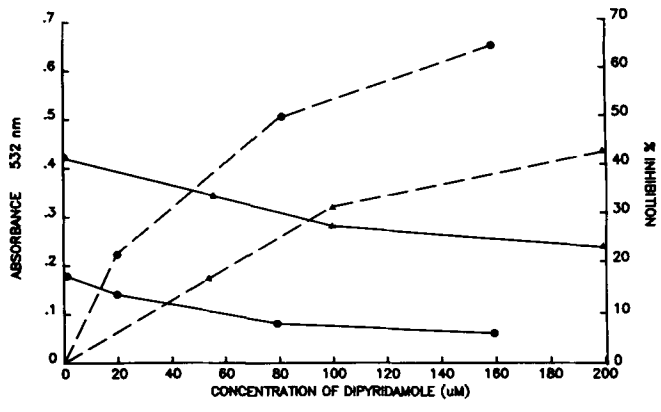

FIG. 4. Effect of dipyridamole on deoxyribose degradation induced by Fe(II) and Fe(III) + ascorbate + H_2O_2. Solid lines: absorbance values. Dashed lines: % inhibition. Circles: Fe(II). Triangles: Fe(III) + ascorbate + H_2O_2. See Materials and Methods for details of incubation conditions and assay procedures.

give inhibitory signals on cell proliferation that can be overcome by antioxidants such as dipyridamole. Thus, dipyridamole was reported to enhance guinea pig SMC proliferation in tissue culture (6), to enhance the proliferative activity of myocardial capillary wall cells (18), and to prolong the survival of experimental skin flaps (19).

The antioxidant properties of dipyridamole may help to explain why this agent enhances (7, 20) prostacyclin synthesis; this was supposed to be due to the protection of prostacyclin synthetase from self destruction by oxygen free radicals (7) or by lipid peroxides (20). This effect could be important in atherosclerotic disease where lipid peroxides accumulate in the vessel plaque and inhibit prostacyclin synthesis (21). The prevention and/or decrease of lipid peroxide accumulation in the endothelium could be the mechanism by which dipyridamole retards the progression of atherosclerotic plaque in patients with peripheral vascular disease (22).

The vasodilating activity of dipyridamole could also be mediated by its antioxidant property. The scavenging of oxygen free radicals by dipyridamole could indeed stabilize endothelium-derived relaxing factor (EDRF), a vasodilating substance which is inactivated by O_2^- (23).

In conclusion, this study provides further evidence of the antioxidant properties of dipyridamole which in turn could contribute to its antithrombotic property.

Synthesis and Lipase Catalyzed Hydrolysis of Thiolesters of 2-, 3- and 4-Methyl Octanoic Acids

Philip E. Sonnet* and **Mary Welch Baillargeon**
Eastern Regional Research Center, ARS/USDA, 600 E. Mermaid Lane, Philadelphia, PA 19118

Racemic 2-, 3- and 4-methyloctanoic acids were synthesized. The 2-mercaptoethanol S-esters of these branched acids, and of octanoic acid, were exposed to lipases of the fungi *Candida rugosa* and *Aspergillus niger*. Reactions were followed spectrophotometrically using Ellman's Reagent. Branching at the 3-position retards lipolysis more severely than at either the 2- or 4-positions. Features of the assay method are discussed with reference to titrimetry.
***Lipids 24,* 434-437 (1989).**

There is considerable interest in enhancing, and understanding the basis for, the several kinds of selectivity (positional, fatty acid and stereo) exhibited by lipases. Recently we synthesized 1,2- and 1,3-dialkylglycerol ethers and developed methods for analyzing their configurations. These compounds and their esters were viewed as complementary to the triglycerides and would avoid some of the ambiguities inherent in the use of the trifunctional substrates (1). As was the case for the major portion of the literature dealing with lipase stereoselection (2), asymmetry resided only in the alcohol portion of the compounds. At this time far less is known of the effects of chirality in the acid residue, despite the inference that one might develop from the literature that lipases primarily bind the acid.

A survey of the effects of methyl branching on the maximum velocity (V_{max}) of ester hydrolysis catalyzed by porcine pancreatic lipase was limited to commercially available, and racemic, fatty acids (3). Little could be learned from these other than that branching close to the acid carbonyl severely retarded reaction. Nevertheless, α-substitution by halogen or ether oxygen does not preclude reaction; and hydrolysis, esterification, and transesterification methods served as the basis for resolving the enantiomers of such acids (2, 4—8). A recent examination of fungal lipases that had been solubilized in organic solvents by derivatization with polyethylene glycol indicated that 4-methylvaleric acid was as reactive as valeric acid itself in esterification of 1-pentanol in benzene, although 2- and 3-methylvaleric acids were not (9). A selection of configurationally pure methyl branched fatty acids could prove useful for learning more of the details of lipase binding, as well as serving to monitor and guide efforts at protein engineering of these enzymes. However, since such compounds are not available they would have to be synthesized.

Abbreviations: DTNB, 5,5′-dithio-bis-(2-nitrobenzoic) acid; GLC, gas-liquid chromatography; HMPT, hexamethyl phosphoric triamide; IR, infrared; LDA, lithium diisopropylamide; MS, mass spectra; NMR, nuclear magnetic resonance; V_i, initial velocity; V_{max}, maximum velocity.

Before undertaking the preparation of a series of configurationally pure methyl branched fatty acids, we prepared the more readily obtainable racemic 2-,3- and 4-methyloctanoic acids as model compounds. In addition, it was necessary to select 1) a suitable acid derivative to submit to lipolysis, and 2) a lipase assay. The initial velocities (V_i) of several octanoic acid esters were obtained by titrimetry, and those of several thiolesters were measured both titrimetrically and spectrophotometrically (10, 11) using commercial lipase preparations of the fungi *Candida rugosa* and *Aspergillus niger*. The reactivities of the 2-mercaptoethanol S-esters of the racemic acids were then determined spectrophotometrically.

MATERIALS AND METHODS

Infrared spectra (IR) were obtained on a Perkin-Elmer 1310 Spectrophotometer (Norwalk, CT) using 3% solutions in CCl_4. ^1H Nuclear magnetic resonance spectra (NMR) were obtained with a Varian A-60 spectrometer (Florham Park, NJ) using CCl_4 solutions. Gas liquid chromatography (GLC) was accomplished using a Shimadzu GC-Mini 2 instrument (Columbia, MD) using an SBP-1 column (0.25 mm i.d. × 30 m) fitted with flame ionization detection and employing He as carrier gas with a 50:1 split ratio. Mass spectra (MS) were obtained with a Hewlett-Packard 5995 GC-MS system (Avondale, PA) interfaced with an OV-1 column (0.25 mm i.d. × 12 m). Free fatty acid titrations were performed with a Radiometer titrilab II unit (Westlake, OH), and the spectrophotometric assays were conducted with a Perkin Elmer Model 559 UV-Vis spectrophotometer.

All organic solvents were reagent grade; hexamethyl phosphoric triamide (HMPT), 99%, was purchased from Aldrich Chemical Co. (Milwaukee, WI) and was stored over 13A molecular sieves to remove dimethylamine. Ellman's Reagent, 5,5′-dithio-bis-(2-nitrobenzoic) acid (DTNB) was obtained from Aldrich Chemical Co. All other chemicals were reagent grade and were obtained from commercial sources.

2-Methyloctanoic acid (2). The general procedure of Pfeffer and Silbert was followed (13) to alkylate the dianion of octanoic acid 1 with methyl iodide producing 2 (92%): b.p. 131-135°C (20 mm) IR,NMR data consistent with assignment (13).

Methyl E-2-octenoate (5). Hexanal (freshly distilled) (104 ml, 0.87 mol), malonic acid (100 g, 0.96 mol), pyridine (dried over KOH) (100 ml) and diisopropylamine (3 ml) were brought together and allowed to stand for 24 hr. The mixture was then heated to 60°C for about 24 hr. The reaction mixture was acidified with cold 6N H_2SO_4 and extracted with ether. The organic phase was washed with water, dried ($MgSO_4$), and concentrated, stripping with benzene to remove residual water azeotropically. The crude acid was esterified with methanol (500 ml) containing H_2SO_4 (1 ml) by heating under

reflux for 16 hr. The mixture was concentrated and worked up in a standard manner, then distilled to give 5 (72% from hexanal): b.p. 88—93°C (20 mm); IR and NMR were consistent with assignment (14).

3-Methyloctanoic acid (3). Cuprous iodide (23.9 g, 0.125 mol) was stirred in dry ether under an inert atmosphere and cooled in an ice bath as methyllithium (180 ml of 1.4 M in ether) was injected. The mixture was stirred for 0.3 hr at 0-5°C, and then was cooled in dry ice-acetone. Compound 5 (19.5 ml, 0.11 mol) was injected, and the resulting mixture was stirred overnight attaining room temperature. The reaction was worked up by adding a solution of 90 ml of sat. NH_4Cl and 10 ml of conc. NH_4OH (slowly). The resulting mixture was filtered by suction through Celite, and the organic phase was isolated and washed several times with water. After drying ($MgSO_4$) and removal of solvent, the product was distilled to give methyl 3-methyloctanoate (56%): b.p. 84-86°C (20 mm); IR, 1740 cm^{-1}. The ester was saponified with 6N KOH:methanol (1:1) by heating under reflux for 2 hr. Product workup was standard and produced the acid 3 (15) (quantitatively): b.p. 93-96°C (0.5 mm) (16); IR 1700 cm^{-1}; NMR, 0.90 (bt, CH_3), 0.95 (unresolved d, CH_3), 1.28 (CH_2 envelope), 2.2 (2H, m, CH_2 C=0), 11.97 (1H, s, CO_2H).

4-Methyl-E-2-octenoic acid (8). Hexanal (freshly distilled) and *t*-butylamine were converted to N-*t*-butylhexanimine, 6, in 78% yield by the general method of Stork and Dowd (16): b.p. 56—62°C (20 mm); IR, 1670 cm^{-1}. Imine 6 was treated with 1.1 equiv of lithium diisopropylamide (LDA) in dry tetrahydrofuran in a manner completely analogous to the alkylation of octanoic acid. Reaction with excess CH_3I followed by the usual workup procedure gave N-*t*-butyl-2-methylhexanimine, 7, in 84% yield: b.p. 60-70°C (20 mm); IR, 1670 cm^{-1}; NMR, 0.94 (m, $2CH_3$), 1.10 (s, *t*-butyl CH_3), 1.3 (CH_2 envelope), 2.2 (m, CH), 7.35 (d, J=5, N=CH). Imine 7 (30 g, 0.178 mol), malonic acid (27.7 g, 0.178 mol) and pyridine (25 mol) were allowed to react as above for the preparation of 5. Acid 8 was obtained in 81% yield: b.p. 140-144°C (20 mm); IR, 1690, 1650 cm^{-1}; NMR, 0.92 (bt, CH_3), 1.08 (d, J=7, CH_3), 1.3 (CH_2 envelope), 5.72 (d, J=16, C=CHC=0), 6.94 (d of d, J=8, 16, HC=CC=0), 11.95 (s, CO_2H). Anal. calcd for: C,69.19; H,10.33; found: C,68.99; H,10.31.

4-Methyloctanoic acid (4). Acid 8 (5.7 g, 36.5 mmol) was hydrogenated in absolute ethanol (30 ml) over 20% Pd/C at 3 atm in a Paar shaking apparatus. The reaction mixure was filtered, diluted with water, and extracted with ether. Continuing a standard workup procedure, the product was distilled giving the acid 4 (quantitatively): b.p. 94-98°C (0.5 mm) (17), IR and NMR were consistent with assignment.

Thiolesters. Compounds 1a, 1b, 1c (Table 1) were prepared by a general procedure of Renard et al. (11) whereby the requisite thiol was treated with one equiv of octanoyl chloride and 2.4 equiv of pyridine in anhydrous ether (ice bath). The reaction product was obtained by a conventional workup procedure, and the hydric thiolesters (containing O-ester) were chromatographed over silica gel (12). Obtained in this manner were: 1a (33%); IR, 1690 cm^{-1}; NMR 0.90 (bt, CH_3), 1.3 (CH_2 envelope), 2.56 (t, J=7, CH_2C=0), 3.02 (t, J=5, CH_2S), 3.68 (t, J=5, CH_2O); MS, m/e 127 ($C_7H_{15}C$=0)$^+$; b.p. 86-89°C (0.6 mm)-rearranges!

1b (24%); m.p. 59-60°C (hexane); IR, 1690 cm^{-1}; NMR, 0.92 (bt, CH_3), 1.3 (CH_2 envelope), 2.62 (bt, CH_2C=0), 3.04 (d, J=5, CH_2S), 3.6 (m, CHOH, CH_2OH).

1c (98%); b.p. 120-123°C (0.45 mm); IR, 1690 cm^{-1}; NMR, 0.90 (m, CH_3), 1.25 (CH_2 envelope + CH_3), 1.30 (s, CH_3), 2.5 (m, CH_2 C=0), 2.96 (d, J=6, CH_2S), 3.4-4.2 (CHOH, CH_2OH); MS, m/3 259 (M-15)$^+$, 127 ($C7H_{15}C$=0)$^+$. The required thiol for 1c was obtained by converting 3-mercapto-1,2-propanediol to a mixture of the two acetonides and separating these by silica gel column chromatography (19).

Compounds 2a, 3a and 4a, the 2-mercaptoethanol S-esters of the branched octanoic acids, were prepared directly from the acids (1 equiv) and dicyclohexylcarbodiimide (1.1 equiv) in methylene chloride. The product was principally S-esterified and was isolated by precipitating dicyclohexylurea with hexane followed by suction filtration. The solvent was removed from the filtrate, and the crude product was chromatographed as before. Each adduct was obtained in 60-70% yield: IR, 1690 cm^{-1}; MS m/e 141 ($C_8H_{17}C$ = 0)$^+$; NMR consistent with structure. All S-esters containing vic-hydroxyl underwent rearrangement to a mixture of O- and S-esters in the injection port (glass liner) of our GLC.

Lipase assays: Titrimetry. Weighed amounts of commercial lipase were allowed to react in an emulsion created by brief sonication of mixtures containing several concentrations of substrate esters in 5 ml of 10% gum arabic. Free fatty acid release was measured by titration with 0.10 N NaOH using "pH stat" mode at pH 7.3. enzyme solutions were prepared in distilled water; substrate concentrations were varied to maximize the initial reaction rate.

Lipase assays: Spectrophotometry. The general procedure of Renard et al. (11) was followed in which solutions of substrate in HMPT (100 μl of 0.0105 M stock), 100 μl of DTNB (Ellman's reagent) in HMPT (20 mg/ml), HMPT (300 μl) and 2.4 ml of 0.05 M Tris buffered at pH 8.0 were brought together in a cuvette. The absorption at 412 mm was immediately monitored

for background hydrolysis. A solution of the enzyme in buffer (100 μl) was added and the new slope calculated. The Ellman's reagent did not react with the enzyme itself.

RESULTS AND DISCUSSION

Synthesis of methyl branched octanoic acids. Octanoic acid, 1, (Fig. 1) was deprotonated with lithium diisopropylamide (LDA), and the resulting dianion was alkylated with methyl iodide to give 2-methyloctanoic acid, 2. Hexanal was condensed with malonic acid in pyridine and then heated to decarboxylate the adduct producing E-2-octenoic acid. The methyl ester of this acid, 5, was alkylated with lithium dimethylcuprate in ether, and the resulting methyl 3-methyloctanoate was saponified to 3-methyloctanoic acid, 3. The N-*t*-butylimine of hexanal, 6, was deprotonated with LDA and methylated to give 7, and this intermediate was condensed directly with malonic acid to give 4-methyl-E-2-octenoic acid, 8. Hydrogenation of 8 over palladium/carbon in ethanol led to 4-methyloctanoic acid, 4.

Synthesis of thiolesters. Thiolesters 1a, b, c were synthesized from the corresponding thiols using octanoyl chloride and pyridine in ether and purifying the product by column chromatography in the case of 1a, b (11) or by distillation for 1c. The thiolesters of 2-mercaptoethanol and the branched acids, namely 2a, 3a and 4a, were prepared using dicyclohexylcarbodiimide in methylene chloride.

Lipase assays. Earlier we had noted that esters of the 1,2-acetonide of glycerol, 2,2-dimethyl-4-hydroxymethyl-1,3-dioxolane, often were hydrolyzed by lipases with rates comparable to those of the corresponding triglycerides (19). The data of Table 1 indicate again that the octanoate ester of the acetonide of glycerol, 13, does react more rapidly than methyl octanoate and comparably to (trifunctional) trioctanoin. The corresponding thiolester 1c similarly reacted more readily than did the other thiolesters examined (except that 1a was slightly more reactive than 1c), though more slowly than 13. An assay of thiolesters has been devised that makes use of Ellman's Reagent at pH 8 to monitor formation of thiolate ion (10); some examples of its utility have been reported (20)(21). The suggested use of HMPT as a cosolvent (11) can provide a homogenous medium that avoids the preparation of emulsions normally required for studies of lipase catalyzed hydrolysis. The reproducibility of such data and the ability to refer with greater certainty to "substrate concentrations" improves the value of kinetic data obtained. Additionally, this methodology would be more sensitive so that precious substrates might be employed sparingly. Implicit are assumptions that 1) candidate substrates do not hydrolyze under these conditions; 2) S to O migration in compounds such as 1a and 1b does not occur during lipolysis—the assay monitors for thiolate ion generated, hence indirectly for free fatty acid, and 3) the same HMPT concentration will maintain a clear solution for a broad range of substrates.

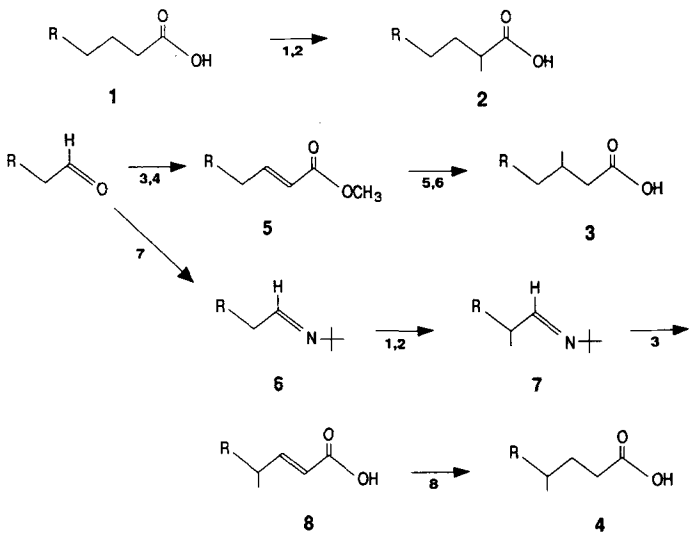

FIG. 1. Synthesis of racemic methyl branched octanoic acids. 1) LDA; 2) CH_3I; 3) malonic acid, pyridine; 4) CH_3OH, H^+; 5) lithium dimethyl cuprate; 6) OH^-; 7) *t*-butylamine; 8) H_2, Pd/C.

The data of Table 2 indicate slower rates of lipolysis in the HMPT containing solutions, with compound 1c faster reacting than 1a and 1b with both lipases. The solution of 1c was cloudy, however, and underwent spontaneous hydrolysis as determined by titrimetry at (the required) pH 8.0. Although solutions of 1a and 1b were homogeneous, a low background hydrolysis was observed as well (about 10%). The values in Table 2 have been corrected for the backgrounds. Although the point was not thoroughly evaluated, synthetic work in our laboratory indicates that S to O migration can occur at high pH, and titrimetry using the HMPT mixtures does not indicate non-enzymatic hydrolysis of compounds 1a and 1b.

The spectrophotometric assay was then performed with the S-mercaptoethanol esters of the branched acids, 2a-4a, (Table 2). The reaction velocities relative to 1a (unbranched analog) showed slower reaction for 2a and 4a, and no reaction at all for 3a. The activity changes are roughly parallel for both commercial lipases.

In summary, we prepared several methyl branched octanoic acids. Several esters and thiolesters of oc-

tanoic acid itself were hydrolyzed by two commercial lipase preparations, and the 2-mercaptoethanol S-ester was selected as the most conveniently prepared derivative. We then made and assayed the esters of the racemic methyl branched acids. Although faster reacting thiolesters than those originally described (11) are evidently possible, reaction homogeneity may have to be sacrificed. The parallel changes in reactivity of the branched octanoic acid esters observed using two randomly selected (impure) lipases is intriguing, and studies are projected for the corresponding configurationally pure compounds, as well as the remaining methyl branched octanoic acids of the series.

The Hepatocellular Transport of Sulfobromophthalein-Glutathione by Clofibrate Treated, Perfused Rat Liver

Dario Sorrentino*, Richard A. Weisiger, Nathan M. Bass and Vojtech Licko
Department of Medicine and the Liver Center, University of California, San Francisco, CA 94143

The hypolipidemic drug clofibrate is known to affect the hepatic transport of various organic anions including bilirubin, fatty acids and sulfobromophthalein. Changes in the rate of metabolism and/or intracellular transport have been claimed responsible for the effect. To evaluate these possibilities, the transport of sulfobromophthalein-glutathione, a model compound that does not require metabolism for biliary excretion, was studied in perfused livers isolated from clofibrate-treated and control rats. Cytosolic fatty acid binding protein and glutathione S-transferase activity were also measured. Clofibrate treatment significantly increased liver weight; as a result glutathione S-transferase activity (toward 1-chloro-2,4-dinitrobenzene) fell if expressed per gram of liver (4560 ± 420 (SE) vs 7010 ± 260 nmoles/min for clofibrate treated and controls respectively, $p<0.002$), but was unchanged when expressed per total liver (60.8 ± 6.5 vs 64.6 ± 3.5 μmoles/min for clofibrate and controls $p>0.5$). Irrespective of how it was expressed fatty acid binding protein was significantly increased by the drug treatment. Steady state sulfobromophthalein-glutathione removal velocity was saturable with increasing concentrations of sulfobromophthalein-glutathione in both control and clofibrate-treated livers. Steady state extraction ratio, as well as Vmax and Km for removal, did not differ between the two groups. In keeping with other observations, these data collectively indicate that the hepatic steady state removal of nonmetabolized compounds is not affected by clofibrate. Because the concomitant decrease in glutathione S-transferase activity only reflects an opposite change in liver weight, it remains to be determined whether clofibrate alters the hepatic transport of sulfobromophthalein and other compounds that are conjugated with glutathione solely by changing their rate of metabolism.
***Lipids 24,* 438–442 (1989).**

Clofibrate and structural analogs such as nafenopin and ciprofibrate are drugs currently used for the treatment of hyperlipidemic disorders. In addition to their lipid-lowering properties, these compounds have been shown to affect various aspects of hepatic structure and function such as bile flow, liver weight, peroxisomal membrane composition and enzymatic activities (1–3). They are also known to affect the hepatic content of cytosolic fatty acid binding protein ($FABP_c$) (4–6) and of various transferases (7–8). Although their mechanisms of action are still poorly understood, it has been recently proposed that the active form of clofibrate and analogs may be their acyl coA thioester (9) and that the drug-induced pleiotropic response may be regulated by a peroxisome proliferator binding protein which binds these agents with high affinity [10].

An interesting phenomenon which follows the administration of many hypolipidemic drugs is a change in the hepatic transport of various compounds including bilirubin, sulfobromophthalein (BSP) and fatty acids (11–15). Several (11, 13, 16, 17), although not all (18), reports suggest that BSP transport is decreased by clofibrate, whereas fatty acids and bilirubin are taken up at a greater rate. It has been proposed that the increased fatty acid uptake in clofibrate-treated livers could be the result of a greater cytoplasmic transport rate which in turn could be mediated by the increased content of $FABP_c$ [14]. Although it is entirely possible that $FABP_c$ plays a role in the hepatic transport of fatty acids (19), it remains to be established whether a change in $FABP_c$ content may affect steady state fatty acid removal rates. Other explanations such as a change in membrane transport, in metabolism and/or in the electrochemical driving forces need to be carefully explored.

On the other hand, the hepatocellular transport of bilirubin and BSP in clofibrate-treated livers seems to parallel their metabolic rates because the drug has been reported to increase the conjugating enzyme activity of bilirubin (UDP-glucuronosyl transferase) and decrease that of BSP (GSH-transferase) (11, 15, 20). Consistent with the hypothesis of metabolism-dependent changes in the hepatic transport of these organic anions are the findings of an increased conjugated bilirubin/unconjugated bilirubin and unconjugated BSP/conjugated BSP ratios in bile following clofibrate treatment (11, 13, 16). Because bilirubin and BSP share the same sinusoidal membrane transport system (21, 22), it is unlikely that clofibrate affects their removal by acting at the membrane level. Nevertheless, this and other explanations (cytoplasmic diffusion and excretion rates) have not been ruled out. To evaluate these possibilities, we studied the effect of clofibrate on the hepatic transport of BSP-glutathione (BSP-GSH), a substance which shares the same transport system with BSP (23), but does not require metabolism for biliary excretion (24, 25). Although preliminary data suggested that BSP-GSH transport may be decreased in clofibrate treated livers (26), a larger number of experiments revealed that this drug does not affect steady state BSP-GSH hepatic removal.

MATERIALS AND METHODS

Materials. Sulfobromophthalein (BSP) bovine serum albumin (BSA, fraction V essentially fatty acid free) reduced glutathione (GSH) and clofibrate (Ethyl 2-[p-chlorophenoxy] isobutyrate) were purchased from Sigma

*To whom correspondence should be addressed at: Department of Medicine, Box 1079, Mount Sinai School of Medicine, New York, NY 10029.

Abbreviations: BSA, bovine serum albumin; BSP, sulfobromophthalein; BSP-GSH, glutathione conjugate of sulfobromophthalein; $FABP_c$, cytosolic fatty acid binding protein; GSH, reduced glutathione; GSH-transferase, glutathione S-transferase.

Chemical Co. (St. Louis, MO). Oxypherol FC-43 was obtained from Alpha Therapeutics (Los Angeles, CA). BSP-GSH was prepared by the *in vitro* method of Whelan *et al.* [27]: after collection and purification, thin layer chromatography (28) indicated the resulting material being at least 95% monoconjugate.

Clofibrate Treatment. Sprague-Dawley male rats (55-65 days old, Bantin and Kingman, San Leandro, CA) were fed *ad libitum* powdered standard rat chow with or without 0.5% (w/w) clofibrate for ten days.

Liver Perfusion. Livers were removed under light ether anesthesia, placed in a thermoregulated (37°C) and humidified cabinet and perfused via portal vein with Oxypherol FC-43 as previously described [29]. Perfusate flow rate was adjusted to 2.5-3 ml/min/g liver with a peristaltic pump (LKB, Bromma, Sweden); the pH was controlled and kept constant (7.35-7.45) by modifying pO_2 and pCO_2 of Oxypherol as necessary. Viability was assessed by bile flow, gross appearance, oxygen consumption, perfusion pressure and by remeasuring, at the end of the experiments, the extraction ratio of the initial BSP-GSH solution; experiments in which the extraction was decreased by more than 10% were discarded. After a 30-min equilibration period the circuit was switched from recirculating to single-pass mode and the liver perfused for four min with Krebs Henseleit buffer (containing 1% BSA and previously equilibrated with 95% O_2 and 5% CO_2) to remove Oxypherol from the liver. Thereafter, various BSP-GSH solutions in Krebs Henseleit buffer (concentrations from 5.6 to 100 μM) were infused for 2 min each and effluent samples collected every 30 sec. Each infusion was followed by a 4-min washout with the same buffer containing no BSP-GSH. The concentrations of BSP-GSH in the effluent samples were measured (after alkalinization with 2 M NaOH) by absorption at 580 nm. From the measured concentrations, BSP-GSH extraction ratio was calculated as E = (Ci-Co)/Ci where Ci and Co are the concentrations entering and exiting the liver respectively, and the velocity of removal as V = E•F•Ci, where F is the perfusate flow rate per gram of liver. These calculations assume that no BSP-GSH concentration gradients develop along the sinusoid during the infusion and that all the hepatocytes are exposed to the same BSP-GSH concentration. This potential source of error does not make the adoption of a distributed model strictly necessary in this study because BSP-GSH is a substance with low first pass extraction (~30%; see Results) and, thus, the bias introduced by a lumped model is negligible (30). The relationship between BSP-GSH removal velocities and BSP-GSH concentrations was analyzed by nonlinear least square computer curve fitting as reported (31). Single experiments were individually fitted and the resulting values averaged to give the data presented in the Results section. The quality of the fit was judged on the basis of the sum of squares, correlation coefficient, standard error and uncertainty of the resulting parameters. The statistical significance of differences between the two groups was assessed by the unpaired Student's t test.

Determination of $FABP_c$ concentration and GSH-transferase activity. After perfusion, livers were blotted dry, weighed and homogenized. After centrifugation (20,000 *g* × 20 min and 100,000 *g* × 60 min) the resulting supernatant was stored at −70°C until assayed (24). The $FABP_c$ was measured by radial immunodiffusion using purified $FABP_c$ as standard (32). GSH transferase activity was assessed spectrophometrically toward 1-chloro-2,4-dinitrobenzene (33). The activity, measured with excess of substrate, was linearly related to the protein concentration. Protein concentration was measured according to Lowry (34) using BSA as standard.

RESULTS

Time dependence and kinetic features of BSP-GSH removal. Figure 1 illustrates the time course of BSP-GSH extraction by the single pass perfused rat liver. In control livers, steady state extraction was achieved within 30 sec and maintained throughout the experiment irrespective of the BSP-GSH concentration used. In clofibrate-treated livers, steady state extraction was achieved within 30 sec of infusion only at low BSP-GSH concentrations; at higher concentrations steady state was achieved later in time. This phenomenon may indicate a change in both components of a bidirectional transport step in clofibrate-treated livers (see Discussion). In all cases, extractions at 90 and 120 sec were taken as steady state values, averaged and further analyzed. When velocities of removal were calcu-

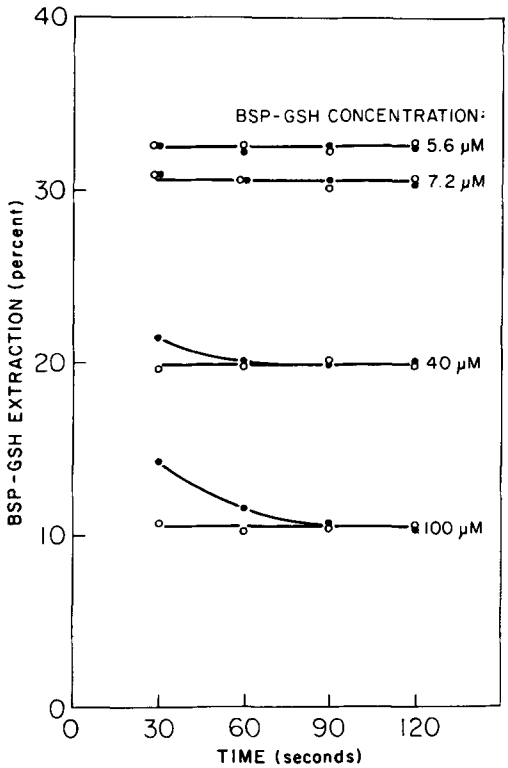

FIG. 1. Representative data illustrating the time course of BSP-GSH extraction by clofibrate-treated livers (closed circles) and controls (open circles). Steady state extraction is rapidly achieved in the control group, whereas clofibrate treated livers require a longer time to reach steady state at high BSP-GSH concentrations.

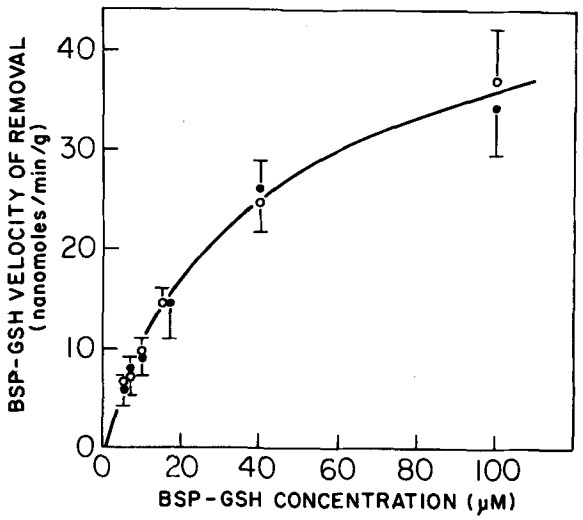

FIG. 2. BSP-GSH removal velocity vs BSP-GSH concentration curve in controls (open circles) and clofibrate-treated livers (closed circles). Single experiments were individually analyzed and averaged as described in Methods. Because the fits are virtually identical for the two groups, for the sake of clarity, only one fit is shown (x ± SE; n = 5).

lated as described in Methods and plotted against BSP-GSH concentrations, the uptake was saturable and conformed to Michaelis-Menten kinetics for both groups (Fig 2). The model best describing the removal process consisted of a single saturable component; other models including additional saturable or nonsaturable components did not improve the quality of the fit and were associated with a large uncertainty of the calculated parameters. The steady state Vmax, Km and intrinsic clearance (Vmax/Km) values did not differ between the two groups (Table 1) since clofibrate treatment significantly increased the liver weight, the perfusate flow was adjusted accordingly so that the two groups were perfused at the same rate (Table 1).

$FABP_c$ levels and GSH-transferase activity. In keeping with prior observations (5), clofibrate treatment increased hepatic $FABP_c$ by 2-3-fold (Table 2). The specific activity of GSH-transferase was determined using 1-chloro-2,4-dinitrobenzene, a substrate conjugated with glutathione by all forms of the enzyme including the BSP-conjugating enzyme [33]. This assay is also a measure of ligandin concentrations [35]. Clofibrate decreased GSH-transferase activity when the latter was expressed per mg of protein or per gram of liver weight (Table 2). Due to the concomitant increase in liver weight, GSH-transferase activity per total liver was not affected by the drug treatment.

DISCUSSION

Like other peroxisomal and microsomal inducers, clofibrate and analogs are known to affect a variety of hepatobiliary functions including bile flow, enzymatic activities and hepatocellular uptake of various compounds. (1-3, 36, 37). Recently, the possibility has been raised that, on the long term, these drugs may act as chemical carcinogens in rats and mice (38, 39). Although the hypolipidemic action of these compounds does not appear to be linked to peroxisomal proliferation (40, 41), it is not known whether other effects represent the end results of a common pathophysiologic mechanism or are diverse in their nature. This uncertainty derives in part from the complexity of many aspects of liver physiology and from the difficulty to dissect and study the events which define them. Thus, hepatic transport function could be affected by these drugs at several levels including membrane transport, intracellular binding and diffusion, metabolism and/or (for cholephilic compounds) biliary excretion. In this respect, previous reports have suggested that changes in BSP and bilirubin transport could be mediated by parallel, concomitant changes in their rate of metabolism (11, 13, 15-17). Other possible explanations, however, were not thoroughly investigated. Furthermore, most previous studies (11, 13, 15-17) were conducted *in vivo*, where additional factors such as blood flow, binding to plasma proteins and extrahepatic elimination may contribute to the overall removal process.

In the present investigation, we studied whether clofibrate treatment affects the transport of BSP-GSH by the single pass perfused rat liver, a system which allows monitoring extraction ratios during steady state and nonsteady state conditions under both first and zero order kinetics. Even though BSP-GSH shares the same membrane transport system with bilirubin and BSP (21-23), and like these organic anions binds (although with less affinity: refs. 24, 42) to cytosolic binding proteins, it is nevertheless rapidly excreted in bile without requiring further metabolism (24, 25). To define their role in any observed difference, we also measured $FABP_c$ levels and GSH-transferase activity (the latter by an enzymatic assay which provided, as well, an indirect estimate of ligandin content).

Steady state BSP-GSH extraction was not affected by clofibrate treatment: for both groups uptake was saturable with increasing BSP-GSH concentrations and

$FABP_c$ was measured by immunodiffusion. GSH-transferase activity was assessed toward 1-chloro-2,4-dinitrobenzene (x ± SE of 5-6 experiments for each group).

the calculated Vmax, Km and intrinsic clearances were the same in drug-treated and control livers. However, although steady state extraction was rapidly achieved in both groups at low BSP-GSH concentrations, under saturating conditions steady state was reached later in clofibrate-treated livers compared to controls. This interesting observation deserves further comment. This phenomenon cannot be accounted for by a change in a single unidirectional BSP-GSH transport rate because, were this the case, the steady state extraction would also be affected. Also, a change in hepatic distribution spaces, due to the greater weight of clofibrate-treated livers, is not a likely explanation because steady state would have been reached later even at low BSP-GSH concentrations. These data rather suggest that clofibrate may decrease to the same extent both components of a bidirectional exchange process located between the extracellular space and the biliary pole of the hepatocyte (e.g., sinusoidal influx-efflux). Such an effect, which becomes pronounced under saturating conditions, would prolong the time required to reach steady state BSP-GSH extraction without affecting the actual steady state extraction value.

As expected, clofibrate significantly induced $FABP_c$, whereas GSH-transferase was reduced only when expressed per unit of liver weight, the total activity being unchanged. The latter finding confirms other reports which indicate that clofibrate and related compounds have only a "dilutional" effect on this enzymatic activity (and on ligandin content) due to the concomitant increase in liver weight (4, 43). Therefore, a decreased transport of BSP (and other compounds conjugated with GSH) in clofibrate-treated animals may not be entirely dependent on a depressed GSH-transferase activity. Indeed, Foliot *et al.* (43) have recently reported that other hypolipidemic agents, related or unrelated to clofibrate, reduce the maximal BSP excretory capacity in rats without affecting total GSH-transferase activity. Nevertheless, a specific (molecule to molecule) interaction between GSH-transferase and the drug could inhibit the enzyme and consequently reduce conjugation rates and the overall transport. This hypothesis is consistent with the finding that ciprofibrate (a clofibrate analog) irreversibly inhibits GSH-transferase both *in vivo* and *in vitro* (44) and with the observation that the hepatic transport of non-metabolized compounds is not affected by hypolipidemic drugs (11, 17, 43). With regard to the effects of clofibrate on bilirubin hepatic transport, our study does not allow speculation. In any event, the association between bilirubin transport and UDP-glucuronosyl transferase activity appears strong (7, 13, 15-17, 45).

Finally, the lack of parallelism between $FABP_c$ content and BSP-GSH transport confirms that $FABP_c$ may not play a major role in hepatic transport processes (18). In fact, $FABP_c$ may not greatly affect the uptake of substances, like fatty acids, which are bound with a much greater affinity than BSP or BSP-GSH. Due to its intracellular location, $FABP_c$ may be expected to affect initial net uptake by decreasing efflux rates as suggested for ligandin (46). However, in female hepatocytes, a 50% greater $FABP_c$ content is associated with a greater oleate efflux rate constant compared with males (D. Sorrentino, unpublished). By contrast, in starvation, a condition of decreased $FABP_c$ content (47) initial net oleate uptake is unchanged suggesting that the primary determinant of hepatic fatty acid flux is transport across the membrane (48).

In conclusion, our study shows that clofibrate treatment does not affect the steady state removal of BSP-GSH by the single pass perfused rat liver. The clofibrate-induced decrease in GSH-transferase does not involve the total enzymatic activity; the latter in turn may not be causally related to the reduced hepatic removal of BSP and other GSH-conjugated compounds.

ACKNOWLEDGMENTS

The authors wish to thank Linda Kendrick and Joan Manning for technical assistance and Mary Barrett for preparation of the manuscript. This research was supported in part by a grant from Regione Sardegna, Assessorato P.I. Italy; by individual research grants DK 32898 (R.A.W.) and DK 32926 (N.M.B.); and Liver Core Center Grant DK 26743.

Total lipids from hepatopancreas of the horseshoe crabs, *Tachypleus gigas* and *Carcinoscorpius rotundicauda*, obtained in 7.6 and 3.3% wet weight respective yields, were fractionated by various chromatographic techniques and identified by gas-liquid chromatography and spectroscopic methods. Fatty acid-containing lipids were rich in 16:0 (8.0–25%), 18:1ω9 (6.9–22%) and 18:2ω6 (6.8–18.5%); appreciable amounts of 16:1ω7, 18:3ω3, 20:5ω3 and 22:6ω3 were also present. The level of 26:0 in the hydrocarbon fractions was unusually high (64 and 68%). Carbon chain lengths of major wax esters were 44, 46 and 48 for *T. gigas* and 38, 40 and 42 for *C. rotundicauda*. 1-*O*-Alkyl diglycerides were 7.2 and 9.1% of the total lipids in the two species and contained 14:0(20%), 16:0(60%) and 18:0(20%) alkyl chains along with a relatively higher percentage (32–35%) of saturated fatty acids. High levels of cholesterol (>50% of total sterol) in the free and combined state were encountered in both samples, phospholipid contents being 40 and 35%, respectively, and contained highest levels of unsaturated fatty acids.

***Lipids 24,* 443–447 (1989).**

Horseshoe crabs or king crabs, popularly known as "living fossils," belong to the phylum Arthropoda, subphylum Chelicerata, class Meristomata, and subclass Xiphosura. *Carcinoscorpius, Limulus* and *Tachypleus,* the three genera of the subclass, are currently represented only by four species, *C. rotundicauda, L. polyphemus, T. gigas* and *T. tridentatus.* Of them, the first two are important sources for the lectins carcinoscorpin (1) and limulin (2). Because of our interest in the flora and fauna of the Sundarbans mangrove ecosystem from the standpoint of biochemical ecology, we undertook investigation of the various lipid components and fatty acids of the hepatopancreas of two species of horseshoe crabs, namely *C. rotundicauda* and *T. gigas*, which are abundantly available in the coastal region of the Bay of Bengal. Hepatopancreas appears to be the major lipid storage organ in crabs (3–5) and other marine invertebrates, e.g., *Mesodesma mactroides.* However, during reproduction lipids are also distributed to the gonad, and high levels of polyunsaturated fatty acids are found in both organs (6–8). Though preliminary investigation on the lipids of *L. polyphemus* has been reported (9), no data is available on those of *C. rotundicauda* and *T. gigas*.

Abbreviations: ECL, equivalent chain length; GLS, gas-liquid chromatography; NMID, nonmethylene interrupted dienoic; PL, phospholipids; RRT, relative retention times; TAG, triacylglycerol; TLC, thin-layer chromatography; TMS, tetramethylsilane.

MATERIALS AND METHODS

The two species of horseshoe crabs, *C. rotundicauda* and *T. gigas*, were collected from Prentice Island, between latitudes 21.43° and 21.46°N and longitudes 88.18° and 88.19°E of the Sundarbans mangrove forest, West Bengal, India. Mature animals which do not moult were captured at different times during breeding season (March–June in India) when they came ashore at high tides in pairs, male clinging to the carapace of the female. Five pairs of each species were collected. Sizes of the animals varied between 25—40 cm including caudal spine. Living animals were killed after 24—30 hr following each collection and hepatopancreases were stored in a deep freezer at −25°C. These organs from different collections, regardless of sex, were pooled and extracted for lipids according to Bligh and Dyer (10). Lipids were stored under nitrogen in redistilled hexane at −18°C.

The total lipid was resolved into neutral and phospholipids (PL) by column chromatography on silicic acid (11). The neutral lipid was fractionated by preparative TLC (12) using petroleum ether/diethyl ether/acetic acid (90:10:1, v/v/v). While steryl esters, 1-*O*-alkyl diacyl glycerol, triacylglycerol (TAG) and sterols were separated, the overlapping hydrocarbon and wax ester bands could only be resolved by rechromatography using n-hexane as developing solvent (13). The alkyl diglyceride was further purified by preparative TLC (14) in petroleum ether/benzene (95:5, v/v).

Hydrocarbons were analyzed directly by GLC on a 3% OV-17 packed column (2.1 m × 0.4 cm). Column oven temperature was at 200°C for 4 min and then programmed at 4°/min to 300°C. Identification and quantification were done as described previously (15).

GLC of intact wax esters was carried out on a 3% SE-30 column (1.8 m × 3 mm) (16). Oven temperature was initially at 230°C for 16 min and then programmed (4°/min) to 350°C. Peaks were identified by addition of authentic synthetic compounds (17). Wax esters were hydrolyzed using lipid-free (18) porcine pancreatic lipase on a TLC plate and resulting fatty acids and alcohols were analyzed by GLC as methyl esters and acetates, respectively (17). Steryl esters were similarly lipolysed on a TLC plate (19). Sterols and fatty acids were separated on the same plate, recovered, derivatized (19, 20) and analyzed by GLC (19).

The 1-*O*-alkyl-diglyceride was initially characterized by strong ester bands at 1735 and 1180 cm^{-1} and a *O*-alkyl ether band at 1110 cm^{-1} in its IR spectrum as well as by ^{1}H-NMR spectroscopy. Alkyl glycerol ethers and methyl esters of fatty acids were obtained by refluxing alkyl-diglycerides in methanolic HCl for 2 hr (14). Usual workup followed by preparative TLC (12) separated the components. An aliquot of alkyl glycerol ether was silylated using Trisil-Z (Pierce Chemi-

cal Company, Rockford, IL), and analyzed by GLC on a 3% OV-17 column (14).

For determination of hydrocarbon side chains, a portion of alkyl glycerol ether was converted to alkyl iodide by refluxing with hydriodic acid for 3 hr (21). The iodide was heated with NaCN in DMSO at 90°C for 30 min (22), and the nitrile formed was refluxed with 6% KOH in ethanol for 16 hr (23). The resulting fatty acids were converted to the corresponding methyl esters (20) and analyzed by GLC.

Fatty acids liberated through saponification of triacylglycerols and phospholipids according to Kates (24) were extracted with ether and methylated (20). GLC of the methyl esters, obtained also from various other lipid fractions, was carried out on a 10% DEGS column using a Pye Unicam Model 104 instrument equipped with dual column and dual FID. Peaks were identified and estimated using relative retention times (RRT), equivalent chain lengths (ECL) and cod liver oil fatty acid methyl esters as secondary standard according to Ackman and Burgher (25), confirmed by GLC of the hydrogenated samples. Incidentally, the isomeric monoenoic fatty acids generally present in marine lipids (26,27) and detectable only by open tubular GLC could not be separated and consequently have been represented by the most common isomeric forms known to occur in marine lipids.

Sterols, free or obtained by lipolysis of steryl esters, were analyzed as acetates (28) and trimethylsilyl ether derivatives (29) by GLC on a 3% SE-30 and a 3% OV-17 column, respectively. Aliquots of hydrocarbons, fatty acid methyl esters and wax esters were hydrogenated over Adams' catalyst (30) and were analyzed by GLC.

NMR spectra of 1-*O*-alkyl-diglyceride were recorded on a JEOL FX-100 FT-NMR using $CDCl_3$ as solvent with tetramethylsilane (TMS) as internal standard and IR spectra on a Shimadzu IR-408 spectrophotometer.

RESULTS AND DISCUSSION

The total lipid content of hepatopancreas in *T. gigas* was more than twice that of *C. rotundicauda* with a preponderance of neutral lipids in both the samples (Table 1). The lipid class composition of both species was similar (Table 1), triacylglycerols being the major neutral lipid with hydrocarbons and 1-*O*-alkyl diglycerides also present in appreciable amounts.

Fatty acid methyl esters derived from sterol esters, 1-*O*-alkyl-diglycerides, TAG and PL did not show the presence of conjugation, *trans*-unsaturation or functional groups other than ester carbonyl (Table 2). Alkyl diglycerides contained the highest proportion of saturated fatty acids (32—35%). Palmitic acid (16:0) was the major saturated acid in all the samples, other components being myristic (14:0), stearic (18:0), arachidic (20:0) and behenic (22:0) acids. Oleic acid was present at levels of 20 and 22% in alkyl diglycerides of the two species, almost double the proportion in steryl esters, TAG and PL. Steryl ester of *T. gigas* contained a particularly high proportion of palmitoleic acid (16:1ω7). Alkyldiglyceride contained about 41% and 48% of total fatty acids as polyenoics in *C. rotundicauda* and *T. gigas*, respectively, as against 55–60% in steryl esters and TAG and about 86% in PL. Among polyunsaturated, 18:2ω6, 18:3ω6, 20:5ω3 and 22:6ω3 fatty acids were present in appreciably high proportions in almost all the samples of two animals. Phospholipids of two animals were particularly rich in 18:3ω3 (12–14.5%) and 20:5ω3 (15.5–16.0%) fatty acids. The two dienoic acids with 20- and 22-carbon chains found in the present study might be associated with the nonmethylene interrupted dienoic (NMID) fatty acids, viz., 20:2Δ5, Δ13 and 20:2Δ5, Δ11; 22:2Δ7, Δ15 and 22:2Δ7, Δ13 which were found to occur in the American oyster *Crassostrea virginica* and also in several other marine invertebrates as reported by Paradis and Ackman (31,32). Recently, some unusual *cis*-5-olefinic acids have been found to occur as distinctive lipid components in sea urchins (30), including 18:1, 20:1, 20:2, 20:3 and 20:4 acids.
