Platelet-activating factor (PAF) is a lipid mediator formed in the early response of the central nervous system to ischemia or convulsions. Free polyunsaturated fatty acids and arachidonic and docosahexaenoic acids are accumulated along with PAF. Antagonists of PAF have been found to improve cerebral blood flow and partially block the rise in free fatty acids, an effect that may arise by way of inhibition of PAF receptors or stimulation of the reacylation of free fatty acids released upon insult. Three intracellular PAF-binding sites have been identified in rat cerebral cortex. These very high-affinity binding sites are inhibited by PAF antagonists, with certain antagonists exhibiting specificity for a particular binding site. This specificity indicates heterogeneity in these binding sites. Ischemia or stimulation also leads to protooncogene transcriptional activation. Here, we discuss studies with cells in culture showing that PAF promotes transcriptional activation of immediate-early genes. PAF activates the transcription of the immediate-early genes *fos* and *jun*, whose gene products are regulators of the transcription of other genes. Transcription of *fos* is also activated by convulsion or ischemia in the central nervous system. The activation of these genes by PAF can be inhibited by PAF antagonists, and is apparently accomplished by way of an AP-1 transcription regulatory sequence in the promoter region of the target genes. Studies with deletion mutants show that PAF can also exert its activating properties by way of cyclic adenosine-3′,5′-monophosphate-(cAMP) and Ca^{2+}-responsive elements, and suggest that PAF is involved in an interconnected network of cell signaling that may coordinate short-term and long-term responses of cells to stimulus and injury.

Lipids 26, 1236–1242 (1991).

Several neural cell signal transduction systems involve the degradation of membrane phospholipids by phospholipases C and A_2 through various and selective receptor-mediated events. Many products of these enzymes are second messengers. Under pathological conditions (*e.g.* ischemia or convulsions), an overactivation of these events leads to the synthesis and accumulation of biologically active mediators in brain.

Certain phospholipids of synaptic membranes are rapidly deacylated by phospholipase A_2 during convulsions, leading to the accumulation of free arachidonic and docosahexaenoic acids (1–3). Ischemia and other forms of brain injury, such as cryogenic brain edema, also lead to the accumulation of free polyunsaturated fatty acids (PUFA) (1,4–12). Moreover, the ischemia-induced accumulation of free fatty acids preferentially takes place in gray matter as compared with white matter (13). In the retina, an integral part of the central nervous system, similar responses occur during relative anoxia (14), or when exposed to depolarizing K^+ concentrations (15). An enhanced production of lipoxygenase products takes place under these conditions in the retina as well as in synaptosomes. Synaptosomal fractions from rats undergoing bicuculline-induced status epilepticus show that this fraction, and not endoplasmic reticulum, is the prevalent site of phospholipase A_2 activation and accumulation of lipoxygenase reaction products (16).

During reperfusion after ischemia, the renewed availability of oxygen leads to enzyme-mediated oxygenation of arachidonic acid (and perhaps also of docosahexaenoic acid) and to the triggering of lipid peroxidation. In the pathogenesis of brain damage, degradation of certain phospholipids of excitable membranes, effects triggered by the accumulated free polyunsaturated fatty acids, and/or subsequent synthesis of oxygenated metabolites of those fatty acids, may contribute to functional impairment (9,17,18). These early responses of the nervous system may result from overstimulation of receptors and increased intracellular calcium (2,17,19). The membrane phospholipids that are degraded by phospholipases are thought to be ethanolamine plasmalogen (20), inositol lipids (21), or phosphatidylcholine (2,22). The involvement of inositol lipids is further documented since these lipids decrease in ischemia (11) and convulsions while stearoyl-arachidonoyl-*sn*-glycerol increases (1,4,23). The molecular species of choline phospholipids (alkyl-acyl-glycerophosphocholine) that lead to platelet-activating factor (PAF) synthesis may also serve as the source of the free polyunsaturated fatty acids that accumulate in the nervous system under these conditions.

The synthesis of platelet-activating factor (PAF, PAF-

---

Abbreviations: AGEPC, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; B_{max}, binding sites density; cAMP, cyclic adenosine-3′,5′-monophosphate; CNS, central nervous system; DSE, dyad symmetry element; FFA, free fatty acids; GPC, glycerophosphocholine; HIV-1, human immunodeficiency virus-1; IC_{50}, 50% inhibitory concentration; K_D, rate of dissociation; K_i, inhibitor constant; LTR, long terminal repeat; mRNA, messenger ribonucleic acid; PAF, platelet-activating factor; PLA_2, phospholipase A_2; PMA, phorbol myristate acetate; PUFA, polyunsaturated fatty acids; SRE, serum response element.

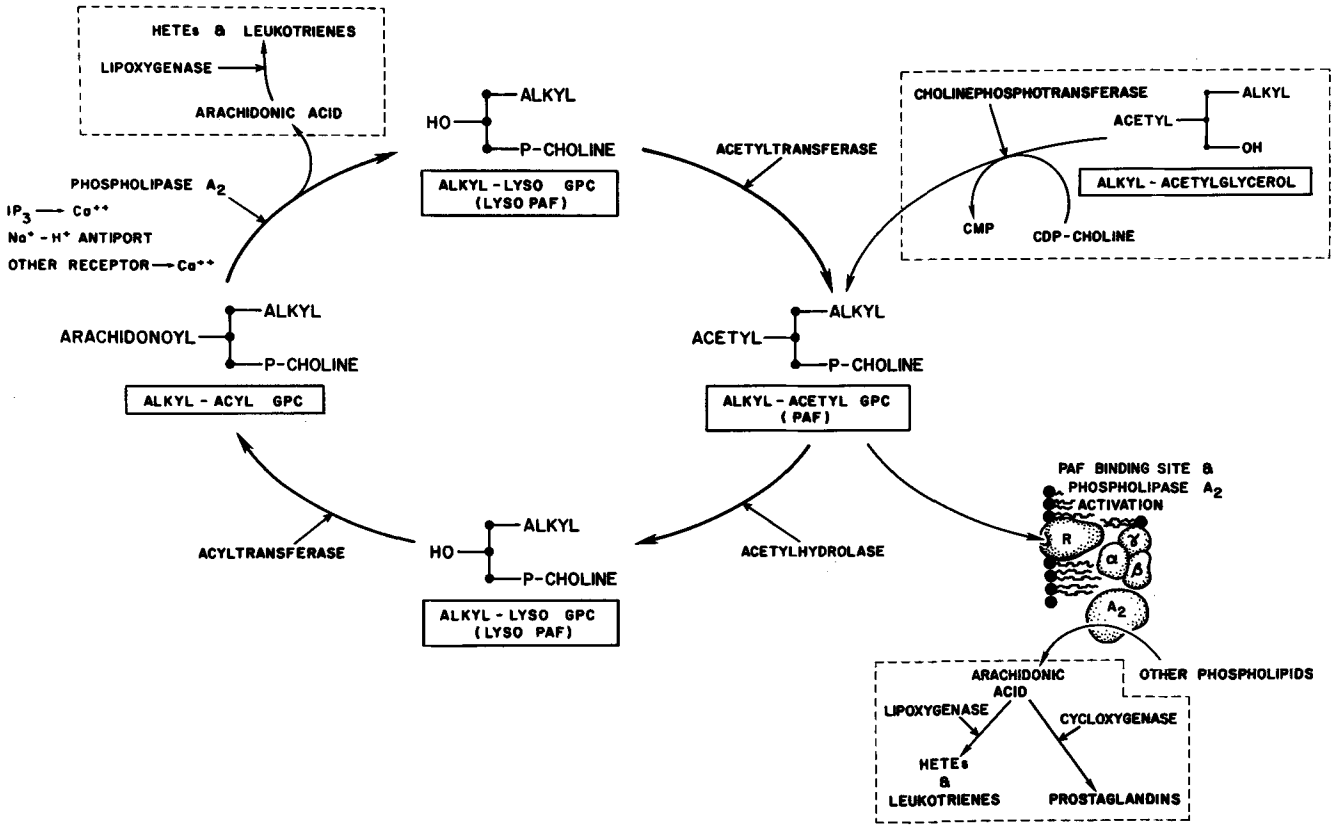

FIG. 1. The PAF (platelet-activating factor) cycle. Synthesis of PAF can involve two different routes. One pathway stems from alkyl-acyl-glycerophosphocholine (alkyl-acyl-GPC) which is enriched in arachidonoyl chains. The first step toward PAF synthesis is the deacylation of alkyl-acyl-GPC by phospholipase A_2 to form lysoPAF, which releases mostly arachidonic acid. Then an acetyltransferase introduces an acetyl group at C-2 of lysoPAF. Effector systems that can modulate the activity of phospholipase A_2 include IP_3-induced calcium mobilization, the Na^+,H^+ antiport (34), and other receptor-mediated events that may enhance intracellular calcium concentration. The second route of PAF synthesis involves the transfer of phosphocholine from CDPcholine to alkyl-acetyl-glycerol. PAF interaction with specific membrane binding sites results in activation of phospholipases and other second-messenger systems. PAF can be metabolized by acetyl hydrolase followed by acylation *via* an acyltransferase or transacylase.

acether, AGEPC, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) is triggered in several tissues in response to injury, inflammation, or during immune reactions. Since this synthetic route involves as the initial step a phospholipase A_2 cleavage (Fig. 1), it was suggested that PAF synthesis may be engaged, at least in part, in the generation of free polyunsaturated fatty acids following ischemia or convulsions in the nervous system (24–26). Furthermore, alkyl-acyl-glycerophosphocholine (GPC), upon which phospholipase A_2 acts, is known to be enriched in arachidonoyl groups at *sn*-2 in several cells and tissues although information about neural tissue is not yet available. PAF may also elicit its effects as an agonist activating phospholipases after it has been synthesized during early events after ischemia or convulsions. The other phospholipase A_2 cleavage product, lysoPAF, is subsequently acetylated to form PAF.

Here we summarize studies showing that PAF antagonists restore blood flow during ischemia-reperfusion and that in ischemia or convulsions, the accumulation of free polyunsaturated fatty acids is ameliorated. Because of these observations, the subcellular distribution of PAF-binding sites was studied, and, in addition to sites on synaptic plasma membranes, high-affinity intracellular PAF-binding sites were found in cerebral cortex. Moreover, in human neuroblastoma cells, PAF-induced transcriptional activation of proto-oncogenes was observed. How all of these events and effects may interrelate is discussed here in terms of a working model linking signaling modulators to gene expression.

EFFECTS OF PAF ANTAGONISTS ON CEREBRAL BLOOD FLOW AND ON ENDOGENOUS FREE PUFA DURING ISCHEMIA OR CONVULSIONS

Alkyl-acyl-GPC contains a large proportion of arachidonoyl chains, and its deacylation by phospholipase A_2 may underlie, at least in part, the free polyunsaturated fatty acid (PUFA) changes that occur at the onset of ischemia or convulsions. In Figure 2, possible factors involved in phospholipase A_2 activation and PAF synthesis are indicated. Both free polyunsaturated fatty acids and PAF can have potent biological consequences. One of the effects of the fatty acids released by phospholipase A_2 (PLA_2) is the uncoupling of oxidative phosphorylation. Therefore, the effects of a PAF antagonist systemically administered at the onset of reperfusion after 10 min of bilateral carotid artery ligation in gerbils were studied. It was found that the PAF antagonist BN 52021 improves cerebral blood flow and decreases the

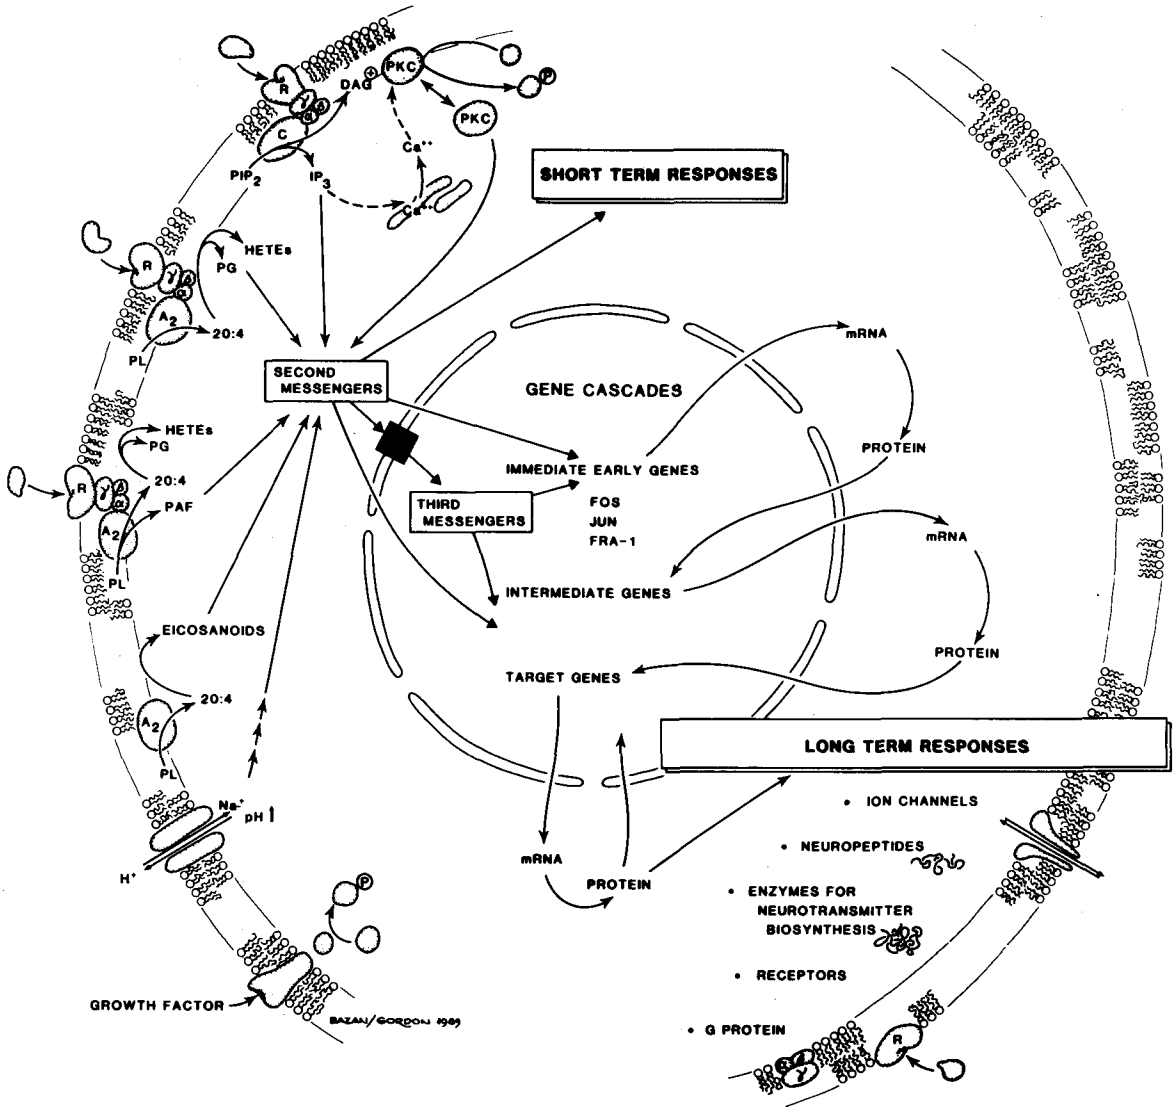

FIG. 2. Outline of the possible events coupling second messengers with long-term responses to cell activation. The events depicted here are a composite of those taking place in several different cells. The cell-signal transduction molecules depicted, on the left of the diagram, on the plasma membrane, lead to the formation of second messengers that in turn bring about short-term responses. These second messengers or mediators are synthesized by receptor-mediated hydrolysis upon interaction of an agonist (*e.g.* hormone, growth factor, neurotransmitter) with a receptor. As a response to injury, ischemia, convulsions, or inflammation, several of these messengers or mediators are accumulated and actively participate in the pathophysiological responses. In the center of the figure, gene cascades are outlined, starting from immediate-early genes, and possible effects of the second messengers are indicated. Target genes may then be engaged in the long-term responses by synthesizing mRNA. Most of the events depicted in the figure occur in neural cells, although how the events are interlinked is not understood. Reprinted with permission from Bazan, N.G., and Bazan, H.E.P. (1990) Ocular Responses to Inflammation and the Triggering of Wound Healing: Lipid Mediators, Proto-Oncogenes, Gene Expression, and Neuromodulation in *New Trends in Lipid Mediators Research,* Bazan, N.G., ed., S. Karger AG, Basel Switzerland, pp. 1-10.

accumulation of free fatty acids (FFA) in brain (24). Moreover, this antagonist also partially blocks the electroconvulsive shock- or ischemia-induced rapid rise in brain free fatty acids (25). The rise in FFA reflects activation of phospholipase A_2, as evidenced by the fact that arachidonic and docosahexaenoic acids are the prevalent fatty acids liberated (1).

Whether the PAF antagonist BN 52021 elicited these effects by "antagonizing" a PAF-binding site remains to be ascertained. However, additional and/or alternative effects are also possible.

The free fatty acids released during central nervous system (CNS) stimulation can also be reacylated and incorporated into membrane lipids. This reuptake may be stimulated by the PAF antagonist BN 52021, which may also facilitate the washout of fatty acids into the bloodstream or the cerebrospinal fluid.

Other events taking place under these conditions are not well-understood. For example, the generation of free radicals is stimulated by PAF and appears to be sensitive to PAF antagonists, and the arachidonic acid cascade, which gives rise to several metabolites through the actions of cyclooxygenase and lipoxygenases, may also be affected.

From this incompletely understood network of events in cerebral injury, steps sensitive to PAF antagonists are

involved thereby implicating PAF as an effector in these reactions. PAF also has been identified as one of the most potent chemotactic agents for eosinophils, which are recruited to sites of injury and produce rapid and profound effects on the vascular system (27).

INTRACELLULAR PAF-BINDING SITES IN CEREBRAL CORTEX

Since PAF accumulates during ischemia or convulsions in brain (28) and because PAF antagonists exert a protective neurological effect under these conditions and reverse some of the neurochemical changes, it was important to define the subcellular distribution of specific PAF-binding sites in brain.

Two distinct PAF-binding sites occur in the microsomal fraction, and a third binding site is present on the synaptic plasma membranes of rat cerebral cortex (29–31). These binding sites are sensitive to the ionic environment, since concentrations of free Ca^{2+} over 10 μM induce a 50% inhibition of PAF binding to microsomal membranes. These membranes also have the highest binding affinity measured for PAF, with a rate of dissociation (K_D) of 22.5 pM (Table 1). This K_D value is in the range of that for accumulated endogenous PAF induced by picrotoxin or bicuculline-induced convulsions (28). Tables 2 and 3 show the 50% inhibitory concentration (IC_{50}) and inhibitor constant (K_i) for different PAF antagonists in microsomal and synaptosomal membranes, indicating different pharmacological responses between those binding sites. In the microsomal fraction, some of the antagonists tested show activity on both binding sites (CV-3988, BN-52115). Meanwhile, the antagonists L-652731 and CV-6209 are specific for only one binding site, indicating heterogeneity in the binding sites (31).

TABLE 1

Rate of Dissociation (K_D) and Binding Sites Density (B_{max}) for PAF Receptors in Microsomes and Synaptic Membranes from Rat Cerebral Cortex[a]

Membranes	K_D	B_{max}
Microsomes	22.5 ± 1.7 pM (4)	82.5 fmole/mg protein
	25.0 ± 0.8 nM (4)	60.0 pmole/mg protein
Synaptic membranes	1.2 ± 0.6 nM (3)	0.06 pmole/mg protein

[a]Values are averages ± SD for (n) independent experiments, using cerebral cortex from 25 rats in each experiment. Curves were fitted by means of an EBDA-LIGAND program (62) up to reach the best-fit model ($p < 0.05$). Subcellular fractionation procedure was presented in detail elsewhere (31). The binding assay was carried out at 25°C for 30 min, 175 μg membrane protein were used in 1 μL assay volume. The buffer was 10 mM tris(hydroxymethyl)-aminomethane (Tris), 5 mM $MgCl_2$, 2 mM ethyleneglycol *bis*(β-aminoethyl ether)*N,N'*-tetraacetic acid (EGTA), 0.025% bovine serum albumin (BSA), 0.1 mM phenyl methyl sulfonyl fluoride (PMSF), 56 title international units (TIU)/L aprotinin, pH 7.6. The labeled ligand was [^{3}H]hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine (PAF) in a 50 pmole-12 nmole concentration range. A 3-nM concentration was selected as standard. Nonspecific binding was assessed with 1 μM unlabeled PAF. The bond-labeled ligand was recovered by filtration on glass microfiber filter glass/fiber, grade "b" (gf/b) from Whatman Int., Ltd. (Maidstone, England).

CV-3988	2.54×10^{-7}	2.37×10^{-6}
WEB-2086BS	7.93×10^{-7}	1.90×10^{-7}
CV-6209	2.13×10^{-6}	1.64×10^{-6}

[a]Data expressed as molar concentration. Calculations and conditions were the same as Table 1.

The presence of high-affinity PAF-binding sites in the cerebral cortex agrees with the active cellular uptake of PAF (32) and retention in the cell (33). Moreover, in retina, neurotransmitter-mediated PAF synthesis leads to tissue retention rather than release of the lipid mediator (34). An intracellular mediator role has been suggested for PAF (33,35,36), and the discovery of intracellular binding sites supports this contention.

IMMEDIATE-EARLY GENES

Several hormones, growth factors and experimental conditions that elicit activation of many membrane receptors lead to transcriptional activation of immediate-early genes. The messenger system(s) linking the plasma membrane with genomic response are not well-understood (37,38). The rapid activation of immediate-early genes gives rise to proteins that are regulators of transcription of other genes. Two of these genes are c-*fos* and c-*jun*, whose gene products, Fos and Jun, interact with a regulatory sequence, AP-1, found in the promoter region of many genes (39–41).

C-*fos* transcription is activated in response to such conditions as convulsions (42–47) and ischemia (48) in the

central nervous system. C-*fos* messenger ribonucleic acid (mRNA) has also been observed after stimulation of neurotransmitter receptors and membrane depolarization (42). Also during convulsions or ischemia, membrane phospholipids, particularly those linked through phospholipase A_2 and phospholipase C to cell signal transduction events, are targets that generate the potentially active lipid mediators arachidonic acid, docosahexaenoic acid, oxygenated metabolites of arachidonic acid (*e.g.* prostaglandins, hydroxyeicosatetraenoic acids, leukotrienes) and platelet-activating factor. It was postulated, therefore, that a lipid mediator may play a role as a messenger in the transcriptional activation of immediate-early genes (49). PAF was studied as a lipid mediator because i) it accumulates in brain during ischemia or convulsions (28), ii) its synthesis involves a phospholipase A_2 that generates arachidonic acid, iii) PAF antagonists inhibit the accumulation of free polyunsaturated fatty acids in brain triggered by ischemia or convulsions (24,25), and iv) because in addition to cell-surface PAF-binding sites there are very high-affinity intracellular binding sites in brain (29,31).

PAF ACTIVATES TRANSCRIPTION OF C-*FOS* AND C-*JUN*

The effect of PAF on the transcription of the genes c-*fos* and c-*jun* was studied in cultured human neuroblastoma SH-SY5Y cells (49). PAF results in a 7-fold increase of c-*fos* mRNA in 15 min to a maximum of 12-fold, after 30 min. This stimulation is inhibited by pretreatment of the cells by the PAF antagonist BN 52021.

The activation of c-*fos* transcription in neural cells was compared to the effect of PAF on c-*fos* activity in MOLT-4 T-cells. PAF treatment elicits a 2–3-fold increase in c-*fos* transcription, which is also inhibited by BN 52021 pretreatment of the cells. These effects on MOLT-4 T-cells are much smaller, as compared with neuroblastoma cells.

The stimulatory effect of PAF on the transcription of c-*jun* is similar to its effect on the c-*fos* gene in SH-SY5Y cells, and is inhibited by pretreatment with PAF antagonist. Similar to c-*fos*, c-*jun* activation elicited by PAF in T-cells is lower than in the neuroblastoma cells. The c-*jun* response is also much slower than the c-*fos* response, reaching maximum level, an 8-fold increase in transcription, in 60 min, as compared to 30 min for c-*fos*. Moreover, nuclear run-off experiments demonstrate that the PAF effect is a result of transcriptional activation (49).

An 11.5-fold increase in transcription is seen after addition of the phorbol ester phorbol myristate acetate (PMA) to SH-SY5Y cells. When PMA and PAF are added at the same time to these cells, a massive, 27-fold increase in transcription is observed. This synergistic interaction needs to be studied further, since it suggests that PAF may elicit its effect by a protein kinase C-independent pathway.

Cloned deletion mutants were transfected into the SH-SY5Y cells to determine which parts of the promoter gene sequences are necessary to produce the PAF-induced activation of transcription. In cells containing the sequence PF4CAT, transcription is elevated 10-fold by addition of PAF, a response that is inhibited by the PAF antagonist BN 52021. Removal of the sequence DSE, dyad symmetry element, which is an AP-1-like sequence, reduces this effect of PAF. Replacement of the DSE sequence results in a PAF-induced activation of transcription comparable to the PF4CAT control. However, replacement of an AP-1-like sequence does not restore the PAF-induced effect. Replacement of two tandem copies of the DSE from a different mutant results in PAF stimulation comparable to the PF4CAT control. Deletion mutants lacking the Ca^{2+}- and cAMP-responsive elements show no PAF-induced transcription (49).

One question addressed by these studies was whether PAF elicits mRNA production from genes containing AP-1 sequences, because AP-1 regulatory elements are responsive to stimulation by Fos/Jun heterodimers, and PAF activates both *fos* and *jun* transcription (49).

Transcription in SH-SY5Y cells transfected with a plasmid containing four copies of the AP-1 sequence is activated by PAF, but this effect is not observed when the transfecting plasmids do not contain the AP-1 sequence. The specificity of this effect was shown by its inhibition by BN 52021 (49).

Another gene with an AP-1 sequence, human immunodeficiency virus-1 (HIV-1), was assayed for PAF activation. One part of the promoter region of this gene, the LTR (long terminal repeat sequence), contains two AP-1-like regions. When this gene is transfected into SH-SY5Y cells, PAF produces a 6-fold stimulation of transcription, which is blocked by pretreatment with BN 52021 (50).

PAF produces a rapid, transient activation of c-*jun* and c-*fos* proto-oncogenes in SH-SY5Y cells, and a lesser activation in MOLT-4 T-cells. The possibility that this effect represents a receptor-mediated activation is suggested by its inhibition by the PAF antagonist BN 52021. This suggests that PAF may act as a messenger in neural cells, activating transcription in target genes containing an AP-1 sequence within their promoters.

The immediate-early gene c-*fos* is activated by several extracellular signals, including growth factors and serum, by way of the sequence SRE (serum response element). Within the SRE is a sequence, DSE (dyad symmetry element), which binds a serum-response factor. These elements interact in the activation of c-*fos* transcription.

C-*jun* transcription is elicited by both serum factors and growth factors, but the promoter of c-*jun* does not have the SRE (51). Therefore, it is possible that the two genes, c-*fos* and c-*jun*, are activated by way of different promoter regulatory sequences in response to extracellular signals.

PAF seems to exert actions on both the SRE and a cAMP- and Ca^{2+}-responsive sequence in the c-*fos* promoter (52). The latter sequence is necessary, as shown in deletion mutant studies. Therefore the SRE sequence is not needed for the PAF-induced activation of transcription, but nevertheless contributes to the effect of PAF on the gene.

Perhaps the requirement for the Ca^{2+}- and cAMP-sensitive sequences suggests that the effects of PAF involve the release of these messengers in order to activate transcription. The fact that phorbol esters use the SRE sequence for activation of c-*fos* indicates that PMA activates protein kinase C (53). Furthermore, various control mechanisms, including Ca^{2+}, cAMP, and protein kinase C, may be interrelated in the nuclear response to PAF.

The gene products Fos and Jun produce heterodimers that interact with the transcription regulatory sequence

AP-1, present in many genes (41,54,55). As to whether PAF interacts directly with the AP-1 sequence, the transfection assays suggest, in fact, that PAF does interact with the AP-1 sequence. Therefore, PAF may act by way of a specific receptor or receptors to elicit the transcription of a set of immediate-early genes whose protein products may further activate regulatory sequences in AP-1-containing target genes.

MODULATORS OF CELL SIGNALING AND GENE EXPRESSION IN NEURAL CELLS

Some of the lipid mediators that accumulate during the early phases of ischemia or during convulsions may also play a role in linking early responses with long-term changes (56). Figure 2 outlines the possible role of lipid mediators coupling membrane-derived messengers with genomic changes. PAF is one candidate for such a role, since Kornecki and Ehrlich (57) found that PAF modulates neuronal differentiation as well as calcium fluxes. PAF accumulates in the brain during convulsions (28), and PAF antagonists decrease damage and the accumulation of free fatty acids in the brain during ischemia or convulsions (24,25,58).

There is only preliminary evidence that other genes may be activated subsequent to proto-oncogene induction by PAF (59,60). The studies discussed here were conducted using PAF in the micromolar range in cultures maintained in fetal calf serum-containing medium. Therefore it is likely that the concentration of PAF that reaches the cells is even lower, due to binding by lipoproteins and hydrolysis by serum acetylhydrolase. To overcome these effects, nonhydrolyzable forms of PAF were studied and found to be effective in eliciting proto-oncogene expression in the nanomolar range (60,61).

The link between platelet-activating factor—already recognized as intimately involved in the short-term neural responses to trauma and inflammation—and gene expression may contribute to the understanding of neural plasticity and other cellular long-term responses to stimulation or injury.

[Received March 20, 1990; Revision accepted October 9, 1990]

Calcium Ion Mobilization in Neuronal Cells Induced by PAF[1]

Elizabeth Kornecki[a,*] and **Yigal H. Ehrlich**[b,2]

[a]Department of Anatomy and Cell Biology, State University of New York Health Science Center, Brooklyn, New York 11203 and the [b]CSI/IBR Center for Developmental Neurosciences, College of Staten Island, City University of New York, Staten Island, New York 10301

We have reported previously that platelet-activating factor (PAF) interacts with the neuronal cell line NG108-15 (neuroblastoma X glioma hybrid) and the pheochromocytoma cell line, PC12. PAF acts on these cells by raising levels of intracellular free calcium ions. In the present report, we extend these studies. PAF induced the vesicular release of adenosine 5′-triphosphate (ATP) from PC12 cells in a dose-dependent manner. The PAF-induced ATP release was inhibited by the PAF antagonists, CV-3988 and CV-6209, and the calcium antagonist prenylamine. The relevance of the interaction of PAF with neuronal cells was investigated further by using brain synaptosomal preparations and primary cortical and neostriatal cells. Nanomolar concentrations of PAF induced calcium transients in aequorin-loaded synaptosomal preparations, and cortical and neostriatal cells were sensitive to the action of PAF. The possible physiological and pathophysiological roles of PAF in brain function are discussed.
Lipids 26, 1243–1246 (1991).

Studies on the effectiveness of certain neuroactive drugs, the triazolobenzodiazepines, as specific platelet-activating factor (PAF) antagonists, have lead to the suggestion that PAF may play a role in the regulation of neuronal function (1). Subsequent studies in our laboratories as well as those of others have provided experimental findings in support of this suggestion. Biosynthesis of PAF in neural tissue was reported by Bussolino *et al.* (2) using preparations of chick retina. The neurotransmitters, acetylcholine and dopamine, stimulated PAF biosynthesis *via* the *de novo* pathway in these preparations (3). More recently, Kumar *et al.* (4) demonstrated PAF biosynthesis in perfused rat brain, and its stimulation by administration of the convulsant drugs bicuculline and picrotoxin. The presence of specific binding sites for PAF was detected in membranes prepared from gerbil brain (5). Several studies utilizing PAF antagonists have implicated PAF in neuropathological processes (6). The mechanism mediating these effects appears to involve activation of phospholipase A_2 (7), possibly as a secondary event to a pathophysiological increase in the level of intracellular free calcium (8).

We have reported previously that in cultured neural cells, PAF can induce an increase in the levels of intracellular free calcium, and stimulate calcium-dependent vesicular secretion of adenosine 5′-triphosphate (ATP) (8). Using PC12 cells, Bussolino *et al.* (9) demonstrated that the PAF-induced increase of intracellular calcium levels is associated with dopamine release. In the present report, we extend our previous findings and demonstrate the effectiveness of the PAF antagonist CV-6209 in blocking these effects. In addition, we report here the effects of PAF on calcium ion mobilization in cells and synaptosomes derived from the central nervous system.

MATERIALS AND METHODS

Reagents. CV-3988, namely 2-methoxy-3-(octadecylcarbamoyloxy)propyl 2-(3-thiazolio)ethyl phosphate, and CV-6209 which is 2-[*N*-acetyl-*N*-(2-methoxy-3-octadecylcarbamoyloxypropoxycarbonyl)aminomethyl]-1-ethylpyridimium chloride were obtained from Takeda Chemical Industries, Ltd. (Osaka, Japan). The CV-3988 solution was heated to 50°C, cooled to room temperature, and the pH adjusted to 7.4. CV-6209 was dissolved in *N*-2-hydroxyethyl piperazine-*N*′-2-ethane sulfonic acid (HEPES) (5 mM) buffer, pH 7.4, containing sodium phosphate (10 mM), NaCl (150 mM), 1mM $MgCl_2$, and 1% glucose. Aequorin was obtained from Dr. John R. Blinks, Department of Pharmacology, Mayo Foundation, (Rochester, MN). The luciferin and luciferase reagent mixture was obtained from ChronoLog (Havertown, PA) and dissolved in water. Prenylamine was obtained from Sigma Chemical Co. (St. Louis, MO). PAF was obtained from Calbiochem Corp. (San Diego, CA) as a pure lyophilized preparation, with chains consisting mainly of C_{16} and C_{18}. A 10 mM stock solution of PAF, dissolved in a solution of 0.35% bovine serum albumin and 0.15M NaCl, was stored frozen at −20°C.

Preparation of PC12 cells for measurement of intracellular calcium and ATP release. Cells of the pheochromocytoma clone PC12 were cultured as monolayers in RPMI 1640 medium containing 10% heat-inactivated horse serum and 5% fetal calf serum as described (10). For the aequorin studies, cells at 80 to 95% confluency were harvested, washed, and resuspended in a HEPES (5 mM) buffer (pH 7.4) containing ethyleneglycol-*bis*(β-aminoethyl ether)*N,N*′-tetraacetic acid (EGTA((5mM), sodium phosphate (10 mM) , NaCl (150 mM), and 1% glucose. The cells were washed and resuspended in the same buffer, then loaded with aequorin according to the dimethyl sulfoxide (DMSO) method of Yamaguchi *et al.* (11). For measuring aequorin signals, aequorin-treated cells were resuspended at a final count of 10^6 cells per milliliter in a buffer containing 1 mM $MgCl_2$ and 1 mM $CaCl_2$. Aliquots (1.1 mL) were placed in cuvettes and examined in a Platelet Ionized Calcium Aggregometer (PICA; ChronoLog) set at 400 rpm and 37°C. Agents tested for inducing changes in intracellular free Ca^{++} were added by injection through a rubber septum, and aequorin luminescence was plotted by a chart recorder.

[1]Based in part on a paper presented at the Third International Conference on Platelet-Activating Factor and Structurally Related Alkyl Ether Lipids, Tokyo, Japan, May 1989.

Abbreviations: ATP, adenosine 5′-triphosphate; CNS, central nervous system; DMSO, dimethyl sulfoxide; EGTA, ethyleneglycol-*bis*(β-aminoethyl ether)*N,N*′-tetraacetic acid; HEPES, *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid; PAF, platelet-activating factor; PAF-acether, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine.

For measuring ATP release from PC12 cells, cells were harvested and washed in phosphate-buffered saline supplemented with 1 mM $MgCl_2$, 1 mM $CaCl_2$, and 1% glucose. The cells were aliquoted (0.45 mL) into a cuvette and placed into a ChronoLog Lumi Aggregometer set at 37°C and 400 rpm. Agents (10 μL) tested for inducing ATP release were added to cell suspensions containing luciferin/luciferase reagent. ATP release was measured in luminescence units.

Preparation of rat brain synaptosomes. Adult rat brain synaptosomes were prepared using Ficoll-sucrose gradients, essentially as described by Sapirstein *et al.* (12) with the following modification: 8.5% Ficoll layer was used instead of a 7.5% Ficoll layer, and two successive gradients were employed for the isolation of the synaptosomal fraction (P_2B). Synaptosomal preparations at a protein concentration of 7.0 mg/mL were loaded with aequorin according to the DMSO procedure of Yamaguchi *et al.* (11). Aliquots (1.1 mL) of the synaptosomal preparations at a protein concentration of 56.1 μg/mL were placed into cuvettes in a ChronoLog PICA instrument at 37°C under stirring. Reactions were initiated by the injection of PAF (10 μL) into the 1.1 mL synaptosomal preparation through a rubber septum.

Preparation of mouse brain cortical and striatal cells from mouse embryos. CD1 mice were obtained from Charles River Laboratories (Wilmington, MA). Neostriata and cortex were dissected from the brain of 14-day-old mouse embyros and mechanically dissociated, basically as described by Zhang *et al.* (13), and suspended in HEPES-phosphate buffered saline (pH 7.4) containing 1% glucose, 1 mM $MgCl_2$ and 1 mM $CaCl_2$ at a cell count of approximately 10^5 cells/mL. The cells were loaded with aequorin by the DMSO method (11). Cell suspensions (1.1 mL) were aliquoted into cuvettes and placed into a ChronoLog PICA instrument set at 37°C and 400 rpm. Aliquots of PAF (10 μL) were injected into the cell suspension to initiate an aequorin response.

RESULTS AND DISCUSSION

The influx and efflux of calcium through the plasma membrane and the delicately balanced control of the intracellular level of free calcium ions play a crucial role in the maintenance of neuronal physiological activity. In addition, Ca^{++} fluxes control the communication between neurons by regulating the critical process of neurotransmitter release (14). We have shown previously that PAF can induce an increase in intracellular levels of free calcium in cultured cloned neural cells (8). The results suggested that these effects appear to be mediated by the activation of low affinity PAF receptors which are coupled to calcium channels (8). This conclusion is further supported by the results obtained with additional drugs tested in the present study. As shown in Table 1, the PAF antagonist CV-6209 was found to be a potent inhibitor of PAF-induced aequorin signals in PC12 cells, exerting this effect with an IC_{50} value of 1.3 μM. This IC_{50} value was an order of magnitude lower than that obtained for CV-3988 (IC_{50}=20 μM). As can be seen in Table 1, CV-6209 also inhibited the PAF-induced vesicular release of ATP from PC12 cells. As reported previously, the calcium antagonistic drug prenylamine inhibited the PAF-induced increase in intracellular free calcium in PC12 cells (8). We have now found that, in addition, prenylamine also inhibited the PAF-induced ATP release from PC12 cells (Table 1). Based on the observation that the PAF-induced ATP release required the presence of extracellular calcium, we proposed that PAF induces in neural cells a calcium-dependent vesicular secretion (8). The present finding that prenylamine potently inhibits this process further supports this conclusion.

TABLE 1

Comparison of the Effects of Various Drugs on the PAF-Induced Aequorin Response and ATP Release in PC12 Cells[a]

Drugs tested	Aequorin response IC_{50}	ATP release IC_{50}
Prenylamine	5 μM	2 μM
CV-3988	20 μM	30 μM
CV-6209	1.3 μM	6 μM

[a]PC12 cells were prepared in suspension as described in the Methods section. Incorporation of aequorin into PC12 cells was performed in the presence of DMSO as described in the Methods section. Aliquots (1.1 mL) of the cell suspension were tested for their response to PAF in the presence of various concentrations of the drugs indicated above. Cell suspensions were incubated with drugs for 5 min at 37°C prior to addition of PAF (4μM, final concentration). For ATP release measurements, aliquots (0.45 mL) of the cell suspension containing the luciferin/luciferase reagent were incubated for 5 min at 37°C with various concentrations of drugs. PAF was added to initiate the release of ATP.

The effects of PAF on calcium mobilization in neural cells were reported to date using cloned neuronal cell lines originating from neuroblastomas of the peripheral nervous system, or from pheochromocytoma of the adrenal medulla. To determine whether PAF affects calcium mobilization of cells from the central nervous system (CNS), we have used dissociated cells obtained from embryonic mouse brain, and loaded with aequorin using the DMSO method (11). Dissociated cells from two brain regions were tested separately for their responses to PAF: neostriatum and cerebral cortex. Figure 1 shows the effect of various concentrations of PAF on neostriatal cells. Concentrations of PAF below one micromolar induced an aequorin response indicative of calcium mobilization in these cells. Higher concentrations of PAF induced larger aequorin signals with maximal responses to PAF occurring at approximately 9 μM PAF. Dissociated cortical cells also exhibited responses to PAF as shown in Figure 2. The aequorin response of cortical cells to PAF was much higher than that observed with neostriatal cells, and a ten-fold greater sensitivity of cortical cells to PAF was observed. The maximal aequorin response in striatal cells was approximately 80 units (as measured from a chart recorder) as compared to the maximal aequorin response in cortical cells of 550 units measured under identical assay conditions. Maximal aequorin responses to PAF in cortical cells occurred with approximately 12 μM PAF.

The dissociated cell preparations used in the experiments described above contained mixed populations of neuronal and glial cells, and either or both of these cell types may be responding to PAF. To test the responsiveness of neuronal elements to PAF, we have used

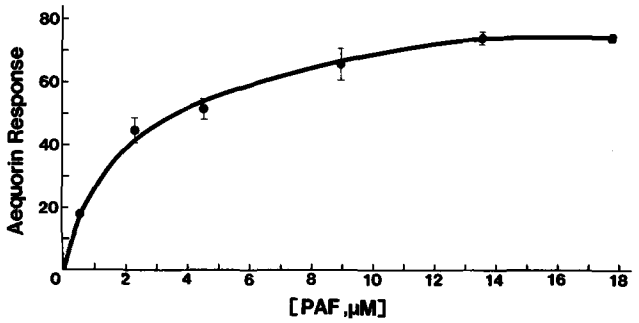

FIG. 1. Effect of PAF on aequorin-loaded neostriatal cells. Mouse embryo neostriata were dissociated and loaded with aequorin as described in the Methods section. Cell suspensions (10^5/mL) were aliquoted into cuvettes and placed in a ChronoLog PICA instrument for measurement of calcium transients. PAF (10 μL) was injected through a rubber septum directly into the cell suspensions. The concentrations of PAF shown above are final. The aequorin response was measured in units of luminescence. Data shown are the means ± S.E.M. for three experiments.

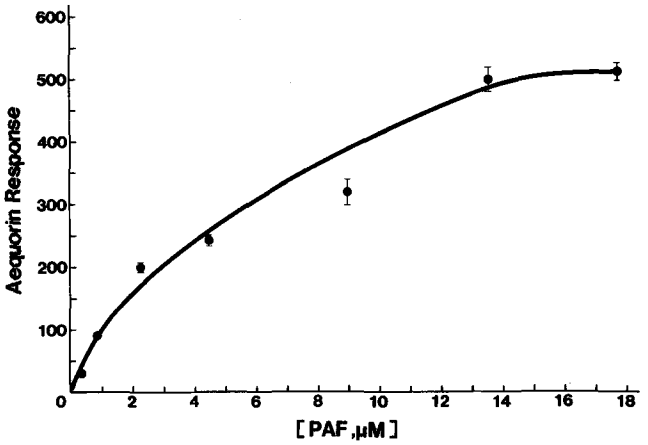

FIG. 2. Effect of PAF on aequorin-loaded cortical cells. Mouse embryo cortices were dissociated and loaded with aequorin as described in the Methods section. Calcium transients resulting from the addition of various concentrations of PAF to aliquots of cortical cell suspensions were measured as described in Figure 1. Data shown are the means ± S.E.M. for three experiments.

preparations of pinched-off nerve endings (synaptosomes) prepared from adult rat brain using density gradient centrifugation. We now report that rat brain synaptosomes preloaded with aequorin also respond to PAF. Table 2 shows the response of adult rat brain synaptosomal preparations to various concentrations of PAF. The synaptosomes responded to PAF with an aequorin signal that could be achieved with PAF concentrations as low as 9.9 nM. Maximal responses to PAF were obtained with approximately 497 nM PAF.

The results presented here confirm the notion based on studies using neuroblastoma and pheochromacytoma cells that PAF can exert regulatory effects on neuronal calcium mobilization and that these effects may be mediated by receptor-operated calcium channels. In addition we demonstrate here for the first time direct effects of PAF on cells derived from the central nervous system of embryonic brain.

Recent studies by Kumar *et al.* (4) provided data

TABLE 2

PAF Induces an Increase in Free Ca^{++} in Rat Brain Synaptosomes[a]

[PAF]	Aequorin response (% maximal)
0	0
9.9 nM	42
249 nM	64
497 nM	100
990 nM	100

[a]Rat brain synaptosomes were prepared and loaded with aequorin using the DMSO method as described in the Methods section. Synaptosomes, 1.1 mL aliquots, were incubated in a cuvette at 37°C under stirring conditions using a ChronoLog PICA instrument. PAF was added to initiate an aequorin response. Final concentrations of PAF are shown above.

indicating that the blood-brain barrier is impermeable to circulating PAF. Thus, physiological effects of PAF on neuronal function would require biosynthesis of PAF within brain tissue. Indeed, such biosynthesis was demonstrated by Kumar *et al.* (4) in adult perfused brain, and by Bussolino *et al.* (2) in retinal preparations. More recently, Bussolino *et al.* (3) demonstrated PAF synthesis in immature retina suggesting a role for PAF in neuronal development and maturation. This suggestion is consistent with our finding that low concentrations of PAF, such as can be synthesized by brain tissue, can induce neuronal differentiation in cultured NG108-15 cells (8). A physiological increase in intracellular levels of free calcium ions may be one of the molecular mechanisms through which PAF influences neuronal development.

Under certain conditions of trauma and injury, or pathophysiological processes which compromise the blood-brain barrier, cells in the central nervous system may become exposed to relatively high levels of PAF which would induce an exaggerated increase in intracellular free calcium levels resulting in neurodegeneration (8). A body of evidence, based primarily on documenting the protecting effects of PAF antagonists, demonstrates the involvement of PAF in cerebral ischemia (15–17). The results reported here, demonstrating that the calcium system of cells derived from the central nervous system are responding to PAF, indicate that also the pathophysiological effects of PAF in the CNS may be mediated by calcium mobilizing systems.

Role of Platelet-Activating Factor in Aggregation of Leukocytes and Platelets in Cerebral Ischemia[1]

S. Uchiyama*, M. Yamazaki and S. Maruyama
Department of Neurology, Neurological Institute, Tokyo Women's Medical College, Tokyo 162, Japan

Leukocyte and platelet aggregation stimulated with formyl-methionyl-leucyl-phenylalanine (FMLP) was measured in 32 patients with cerebral ischemia and in 15 controls, using a whole blood aggregometer. The increases in impedance and the reductions in leukocyte and platelet counts were significantly greater in stroke patients than in controls. Aggregation was inhibited by oral ticlopidine, but not by oral aspirin. The effects were clearly counteracted by platelet-activating factor (PAF) antagonists, and counteracted in part by a 5-lipoxygenase inhibitor. The results suggest that platelets tend to be activated by PAF and leukotrienes liberated from hyperaggregable leukocytes in patients with ischemic stroke.
***Lipids* 26, 1247-1249 (1991).**

Recent evidence suggests that not only platelets but also leukocytes play an important role in thrombogenesis and other related pathological processes of cerebral ischemia by releasing various chemical mediators such as platelet-activating factor (PAF), leukotrienes, free radicals and cytokines (1-4). We measured leukocyte and platelet aggregation stimulated by the chemotactic peptide formyl-methionyl-leucyl-phenylalanine (FMLP) in patients with cerebral ischemia. We also investigated the effects of various pharmacological agents on the aggregation of leukocytes and platelets in order to determine what mediates leukocyte-platelet interaction.

MATERIALS AND METHODS

The subjects were 26 patients with cerebral infarction (18 males and 8 females, mean age 64 years, range from 40 to 82 years), 6 patients with transient ischemic attacks (4 males and 2 females, mean age 59 years, range from 43 to 78 years), and 15 controls including patients with various neurological disorders other than stroke (9 males and 6 females, mean age 58 years, range from 40 to 79 years). Patients with hypertension, diabetes mellitus, ischemic heart disease, peripheral vascular disease, collagen vascular diseases, infections or other conditions that could possibly affect platelet or leukocyte function were excluded from the control group. The patients had not been treated with any antiplatelet agents, anticoagulants, or fibrinolytic agents for at least 14 days prior to blood collection. Aggregation studies were performed as follows (5-7). Nine mL of venous blood was collected in a disposable plastic syringe containing 1 mL heparin sodium solution at a final concentration of 10 units/mL. The blood was stored for 30 min at room temperature. Then, 5 μL of 1 mg/mL cytochalasin B (Sigma Chemical Co., St. Louis, MO) was added to 975-μL aliquots of heparinized blood placed in plastic cuvettes (Chrono-Log, Havertown, PA). Stirring was continued for 1 min at 900 rpm at 37°C. Changes in electrical impedance (ohms) were measured using a whole blood aggregometer (Chrono-Log C540) 10 min after adding FMLP (Sigma) at a final concentration of 2 μM. Aliquots were collected into an equivalent volume of 1.5% formalin containing 5 mM EDTA both before and 10 min after adding FMLP and were used for measuring leukocyte and platelet counts.

In order to pinpoint the mediator of the interaction between leukocytes and platelets, the effects of various pharmacological agents were studied *ex vivo* and *in vitro*. Aggregation studies were performed before and on the 7th day after starting daily oral administration of either of the following drugs: one Baby's Bufferin® tablet (Banyu Pharmaceutical Co., Tokyo, Japan) containing 81 mg aspirin; 200 mg of ticlopidine hydrochloride (2 tablets of Panaldine®, Daiichi Pharmaceutical Co., Tokyo, Japan), or 100 mg of CV-4151 (Takeda Chemical Industries, Osaka, Japan) (8), a thromboxane A_2 (TXA_2) synthetase and receptor inhibitor. The *in vitro* effects on leukocyte and platelet aggregation stimulated with FMLP of the following compounds were also measured: dazoxiben (Pfizer, London, U.K.), a TXA_2 synthetase inhibitor; ONO-3708 (Ono Pharmaceutical Co., Osaka, Japan) (9), a TXA_2 receptor inhibitor; the PAF antagonists CV-3988 (Takeda) (10) and CV-6209 (Takeda) (11); and AA-861 (Takeda) (12), a 12-lipoxygenase inhibitor.

Student's independent t-test was used to verify the difference between the group of stroke patients and the group of patient controls. Student's dependent t-test was used to verify the difference between before and after medication or upon adding an inhibitor; $p<0.05$ was taken to indicate a significant difference.

RESULTS AND DISCUSSION

The addition of FMLP did not alter the impedance of platelet suspensions, although it slightly increased impedance of leukocyte suspensions. However, FMLP caused a marked increase in the impedance of combined leukocyte-platelet suspensions (Fig. 1). Oda *et al.* (13) and Cöeffier *et al.* (6) had previously shown, using turbidimetric aggregometry, that FMLP induces biphasic aggregation (an immediate weak phase and a delayed strong phase) in a mixture of rabbit polymorphonuclear leukocytes (PMN) and platelets. They found only immediate aggregation when they used PMN alone; no aggregation occurred with platelets alone. These results imply that the aggregation response to FMLP is initiated by leukocytes and is later amplified by platelets (6,13). The electron microscopic study by Cöeffier *et al.* (6) provides some confirmation of this. These authors found that washed rabbit platelet suspensions never showed aggregation while

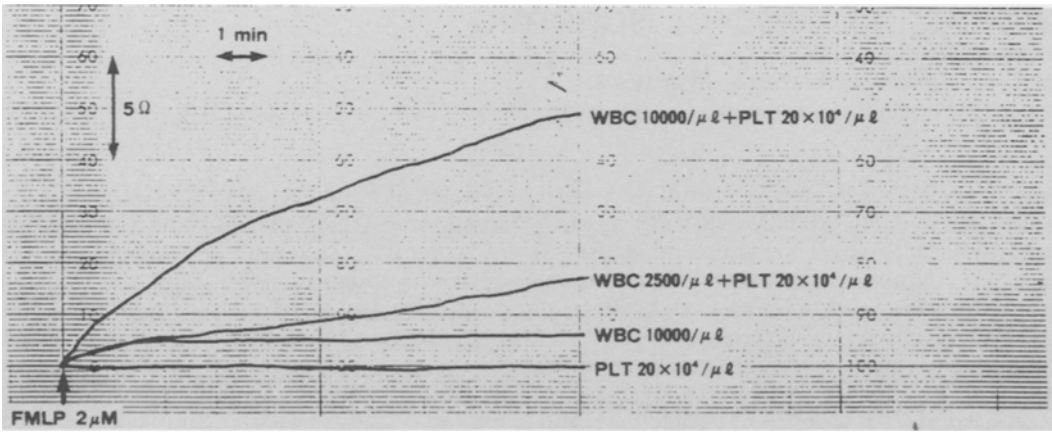

FIG. 1. Impedance changes produced by FMLP in purified platelet and/or leukocyte suspensions.

PMN suspensions showed small aggregates, and large, dense platelet aggregates were formed around the PMN aggregates in mixed suspensions.

We noted that the increase in impedance was significantly greater in patients with ischemic stroke than in controls (8.25 ± 2.03 Ω *vs* 6.77 ± 1.85 Ω, mean ± SD, $p < 0.02$). The percent reductions of leukocytes and platelets were also significantly greater in patients with ischemic stroke than in controls (48 ± 21% *vs* 33 ± 18%, 54 ± 23% *vs* 39 ± 21%, respectively; both $p<0.05$). The results for 1 μM FMLP were similar to those obtained with 2 μM FMLP. The variability of the percent reductions in leukocytes and platelets was large among the subjects with low cell counts, since these data were calculated from the ratio of the cell counts before and after adding FMLP. However, the differences between the two groups were still significant despite this variability. The results imply that leukocyte-platelet aggregation coupling is increased in patients with cerebral ischemia, since there was a significant correlation between the reduction in the leukocyte count and the platelet count in our subjects ($r = 0.64$, $p<0.05$). Arterial thrombi are composed primarily of aggregated platelets, but are also rich in granulocytes (2). Thus, platelets and leukocytes are associated in thrombosis, and their interaction may amplify the course of thrombosis.

Oral aspirin did not clearly affect the aggregation response, which suggests that the arachidonic cyclooxygenase system is not important in leukocyte-platelet interaction (Table 1). In addition, the oral intake of CV-4151, which inhibits TXA_2 synthetase and antagonizes TXA_2 receptors, did not affect the aggregation response (Table 1). Moreover, neither dazoxiben, a TXA_2 synthetase inhibitor, nor ONO-3708, a TXA_2 receptor antagonist, altered the aggregation response *in vitro*. Thus, we concluded that TXA_2 does not participate in leukocyte-platelet interaction.

By comparison, ticlopidine clearly inhibited the aggregation response stimulated with FMLP. We have previously investigated in patients with ischemic stroke the effects of aspirin and ticlopidine on platelet aggregation stimulated with adenosine diphosphate (ADP), arachidonic acid (AA) and platelet-activating factor (PAF) (14). We found that aspirin inhibited platelet aggregation by ADP and AA, but not by PAF, while ticlopidine inhibited platelet aggregation by ADP and PAF but not by AA. These results suggested that the chemical mediator of leukocyte and platelet aggregation was possibly PAF.

In order to confirm this, we studied the effects of the specific PAF antagonists, CV-3988 and CV-6209, on the aggregation response stimulated with FMLP. Preincubation of whole blood samples with 10 μM CV-3988 clearly

inhibited the delayed aggregation response (Table 1). This has already been reported by Oda *et al.* (13) for a rabbit PMN-platelet mixture. In addition, preincubation with CV-6209, which has 100 times the potency of CV-3988, produced a more pronounced inhibition of the aggregation response (Table 1). These results strongly suggest the importance of PAF as a chemical mediator of leukocyte-platelet interaction.

Other candidates for mediating leukocyte-platelet interaction are lipoxygenase-dependent metabolites including leukotrienes (15,16). Cöeffier *et al.* (6) reported that nazafatrom, a lipoxygenase inhibitor, suppressed the aggregation response stimulated with FMLP in rabbit whole blood. We found in the present study that AA-861, a lipoxygenase inhibitor, partially inhibited FMLP-induced aggregation in human whole blood (Table 1). These *in vitro* experiments were carried out with samples from patients or controls. There was no difference in test results between the patients and the controls.

The above results suggest that platelets tend to be activated by PAF and leukotrienes liberated from hyperaggregable leukocytes in patients with ischemic stroke. Inhibition of leukocyte-platelet interactions by drugs may be potentially valuable for treating thrombotic stroke, a disease in which leukocytes may play a pivotal role.

Cardiovascular Effects of Platelet-Activating Factor[1]

Sudden release of platelet-activating factor (PAF) into the circulation can cause hypotension, tachycardia, and circulatory collapse. To further examine this response, we performed detailed studies of cardiovascular function after PAF administration to young domestic pigs and newborn piglets. Our results indicate that circulatory dysfunction after PAF reflects severe constriction of pulmonary resistance vessels and consequent acute right ventricular failure. Although PAF-induced coronary artery constriction and contractile depression may be complicating problems, left ventricular underperfusion and dysfunction after PAF are mainly the result of systemic arterial hypotension and diminished left ventricular filling. The adverse hemodynamic effects of PAF are accompanied by substantial release of thromboxane A_2 (TxA_2). These effects are mimicked by the TxA_2 agonist U-46619 and partially blocked by specific and nonspecific inhibitors of TxA_2 synthesis (OKY-046 and indomethacin). Even more potent blockade of PAF action is exerted by the TxA_2 receptor blocker, SQ 29,548. Taken together, these findings indicate that severe pulmonary vascular constriction and hemodynamic collapse soon after intravenous PAF are at least partially mediated by PAF-induced TxA_2 release.

Tachyphylaxis to PAF influence has been observed in studies of leukocyte and platelet function. We hypothesized that tachyphylaxis to PAF might also occur in our studies of constrictor responses in pulmonary vessels. Recently, we have examined the capacity of PAF to produce sustained pulmonary vasoconstriction in open-chested, anesthetized newborn piglets. Infusions sufficient to produce 100% increase in mean pulmonary artery pressure after 3 min showed no loss of efficacy when sustained for 30 min. The same was true for infusions of U-46619. Thus, the pulmonary vasoconstrictor influence of PAF or U-46619 is not readily diminished by tachyphylaxis. These findings favor the viewpoint that PAF or TxA_2 release during inflammatory processes could have prolonged adverse actions on pulmonary and systemic circulations.

***Lipids 26,* 1250–1256 (1991).**

Platelet-activating factor (PAF) can exert major effects on cardiovascular function. During inflammatory and hypersensitivity reactions, PAF is likely released by activated granulocytes, macrophages, and platelets (1,2). Certain stimuli, *e.g.*, thrombin exposure, also promote PAF synthesis (3) and possibly PAF release from endothelial cells. Stimulated release of PAF may be an important factor altering circulatory performance during inflammatory states.

PAF affects many cells and tissues concerned with cardiovascular function. *In vitro* studies show that PAF depresses contractility of superfused papillary muscles (4). When given to isolated hearts, PAF causes marked decrease in myocardial contractility and perfusion (5–7). Isolated, precontracted blood vessel segments respond to PAF with endothelium-dependent relaxation (2,8,9). Despite this, PAF often acts to inhibit blood flow. PAF-induced aggregation of circulating granulocytes and platelets can lead to mechanical plugging of microvessels. Moreover, PAF-initiated stimulation of granulocytes and platelets can cause release of a variety of substances with vasoconstrictor influence, *e.g.*, thromboxane A_2 (TxA_2), peptide leukotrienes, and superoxide anion (10–12).

In vivo, PAF administration can induce significant arterial hypotension and even sudden death in several species (13–18). Such exposure to PAF might occur during septic or anaphylactic shock and figure in the pathogenesis of cardiovascular collapse. The primary hemodynamic events underlying PAF-induced hypotension are uncertain. Understanding of these events might elucidate the pathophysiology of PAF-related circulatory disorders. This article will examine the influence of intravenously administered exogenous PAF (1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine or 16:0-AGEPC) on hemodynamic performance and on changes in a correlated metabolic parameter, the plasma level of thromboxane B_2 (TxB_2), the stable metabolite of TxA_2. The chromatographically pure 16:0-AGEPC administered in our laboratory was kindly provided by Dr. Fred Snyder, Oak Ridge Associated Universities, Oak Ridge, TN.

HEMODYNAMIC CHANGES DURING PAF-INDUCED CIRCULATORY COLLAPSE

Earlier observations showed that prolonged PAF-induced hypotension was associated with decreased cardiac output and left ventricular contractility and increased systemic and pulmonary vascular resistances (13,15). In addition, effective arterial blood volume progressively fell and hematocrit rose, suggesting plasma sequestration (13). These observations did not indicate whether such alterations were primary responses to PAF or secondary responses to a PAF-induced, protracted low output state. Less attention has been directed toward the hemodynamic changes at the beginning of PAF-induced circulatory collapse. In particular, pulmonary vascular resistance early after PAF exhibited a severe and sustained rise, along with an early but unsustained peak in pulmonary arterial pressure (15). In several models, pulmonary artery hypertension was at least partially mediated by release of TxA_2 (13–17). The impact of pulmonary vascular alterations on the pathogenesis of PAF-induced circulatory collapse remained uncertain.

We examined the possibility that PAF-induced reduction in cardiac output was primarily the result of acute right ventricular failure (*i.e.*, an acute decrease in forward stroke volume despite elevated right ventricular filling pressures and volumes) and consequent left ventricular underfilling in the setting of severe, sustained increase in pulmonary vascular resistance (PVR). The increase, in turn, would be caused by PAF-induced release of TxA_2. These possibilities were tested in several ways. Initially, we evaluated synchronous pulmonary and systemic vascular changes during PAF administration to open-chested young (10-week-old) pigs (18) or neonatal piglets (19). Then we examined the hemodynamic effects of infused U-46619, a stable TxA_2 analogue. We also compared the actions of PAF and U-46619 with those of mechanical occlusion of the main pulmonary artery. In further experiments we gave PAF to closed-chested pigs before and after blockade of TxA_2 synthesis with the nonspecific cyclooxygenase blocker, indomethacin, or the specific thromboxane synthetase inhibitor, OKY-046, while monitoring plasma levels of TxB_2.

In our first studies, anesthetized, open-chested 25-kg pigs were instrumented for simultaneous recording of contractile function (shortening of distance between implanted ultrasound crystals) in right and left ventricles as well as intracardiac pressures and cardiac output (18). Ten pigs were infused with PAF, 0.04–0.28 nmol/kg/min. Doses were begun at the low end of this range and escalated every 2 min until the appearance of systemic hypotension (mean arterial pressure decrease >50%). PAF infusion resulted in a progressive rise in PVR (Fig. 1). Initially, this was manifested as a rise in mean pulmonary artery pressure (MPAP) with little associated change in cardiac output. As PVR rose further, cardiac output began to fall along with rising systemic vascular resistance (SVR) and declining systemic arterial presssure.

Right ventricular overload during PAF infusion was manifested by increased right atrial pressure, rise in right ventricular segment length (intercrystal distance) at end-systole and end-diastole, and decrease in right ventricular segmental shortening. At this time, left ventricular segmental shortening also decreased. In contrast to right ventricular performance, however, the left ventricular segment length was smaller at end-systole and end-diastole, indicating a diminution in left ventricular dimensions. This was accompanied by a decrease in left ventricular end-diastolic pressure.

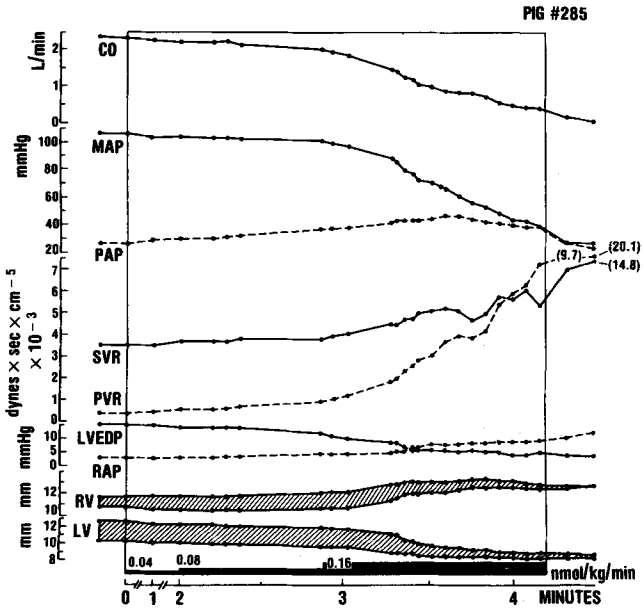

FIG. 1. Representative plot showing sequence of hemodynamic alterations induced by PAF infusion in an open-chested pig. Initial dose of 0.04 nmol/kg/min was increased stepwise to 0.16 (bottom bar). Pulmonary vascular resistance (PVR) rose initially along with an increase in mean pulmonary artery pressure (PAP). Further PVR rise was associated with a decrease in both cardiac output (CO) and PAP. Heart rate was 112–120 beats/min. At peak PAF effect, PVR surpassed systemic vascular resistance (SVR) while CO and mean systemic arterial pressure (MAP) fell markedly. Left ventricular (LV) and right ventricular (RV) segment lengths are each shown by paired lines (upper, end-diastolic length; lower, end-systolic length) separated by shading. RV segment shortening (vertical distance between line pairs) decreased despite elevated preload, as assessed by increase in RV diastolic segment length and mean right atrial pressure (RAP). LV segment shortening also fell during PAF. In contrast to RV performance, LV end-diastolic pressure (LVEDP) and end-diastolic segment length dropped significantly, indicating a marked decrease in LV preload. Reproduced with permission of the American Physiologic Society (18).

Further PAF-induced increase in PVR resulted in peaking and then actual decline of MPAP. Eventually, cardiac output fell rapidly. Despite progressively rising SVR, severe systemic hypotension supervened, often accompanied by transient bradycardia. As segmental shortening continued to fall in each ventricle, the differences between right and left ventricular performance became even more pronounced: right ventricular dimensions and filling pressures (right atrial pressures) continued to rise and left ventricular dimensions and filling pressures continued to fall. Although one animal died with prolonged right ventricular failure, the remaining nine had recovery of systemic arterial pressures to >90% of baseline within 3 min of PAF discontinuation. In the initial recovery phase, MPAP actually rose even as PVR fell from 10,800 ± 2,700 (SE) to 2,100 ± 200 dyne sec cm^{-5}. By 10 min after PAF discontinuation MPAP declined from a peak of 47 ± 2 to 29 ± 5 mm Hg; by 30 min after discontinuation, all parameters had returned to within 10% of baseline values.

The sequence of hemodynamic changes observed with PAF infusion suggested that early-appearing pulmonary vasoconstriction and right ventricular failure were important contributors to PAF-induced shock. Later-appearing decline in cardiac output, underfilling of the left ventricle, and eventual systemic hypotension primarily reflected the consequences of right-sided events.

In four pigs we attempted to reverse PAF-induced left ventricular underfilling and possible peripheral venous pooling by the rapid infusion of large volumes of 0.9% NaCl. This infusion did not mitigate any of the hemodynamic deterioration caused by PAF. On the contrary, it only elevated right ventricular filling pressures without any improvement in right ventricular output. This experience confirmed the concept that PAF-induced circulatory collapse was the result of severe pulmonary vasoconstriction and consequent right ventricular dysfunction, conditions that would not be expected to improve with further increase in already-elevated right ventricular filling pressures. It apparently excluded an important PAF-induced removal of plasma volume from the circulating pool by venodilation or extravasation.

Results similar to data from open-chested animals given PAF infusion were obtained with bolus intravenous administration of PAF to closed-chested animals (18). In 12 young (10-week-old) pigs, a low PAF dose (0.3 nmol) produced only modest rises in PVR (Fig. 2). Larger doses (>0.6 nmol) caused the marked increase in PVR and right atrial pressure and the fall in cardiac output, systemic arterial pressure, and left ventricular end-diastolic pressure seen in open-chested pigs of the same age.

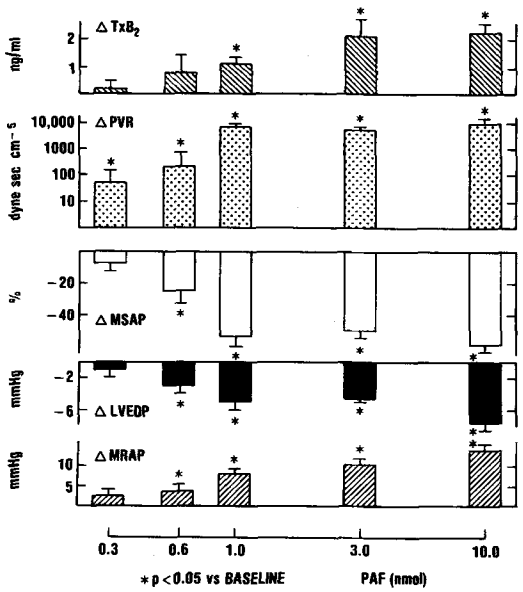

FIG. 2. Effects of PAF boluses in 12 closed-chested pigs. PAF doses were given in random order; each mean (± SE) represents 5–7 replications. Results are expressed as absolute deviation from respective baseline values, except for mean systemic arterial pressure (MSAP), which is given as percent change. Baseline values were not different for each dose (analysis of variance). Variations in PVR are depicted on a logarithmic scale. Peak PAF effects on PVR and MSAP were evident at 1 nmol, although changes in ventricular filling pressures and thromboxane B_2 (TxB_2) levels tended to be successively larger up to the 10 nmol dose. Reproduced with permission of the American Physiologic Society (18).

Thromboxane levels were also measured in animals receiving PAF. Plasma TxB_2 levels rose after PAF in a dose-related manner (Fig. 2). The magnitude of increase in TxB_2 was not consistently correlated with the corresponding change in PVR. However, animals with particularly large increases in PVR had much greater elevations of plasma TxB_2.

Because of the reactivity of neonatal pulmonary vessels and the likelihood of inflammatory pulmonary problems in neonates, additional studies of PAF-induced hemodynamic responses were conducted in 34 open-chested newborn piglets (19). In these animals as little as 0.01 nmol *i.v.* PAF produced increments in pulmonary vascular resistance and pulmonary pressure. At doses of 0.3–1.0 nmol, PVR index increased 15-fold. However, cardiac index fell, left ventricular shortening fraction declined, and systemic vascular resistance index rose only at the highest (1 nmol) dose level. These latter findings may reflect a greater ability of the neonatal right ventricle to maintain pump function despite an augmented pressure load. Our results demonstrated the capacity of PAF to induce pulmonary vasoconstriction in neonates and suggested that this inflammatory mediator may play a role in neonatal shock states that accompany infection and other disorders. Experiments with blocking agents, described subsequently, indicated that PAF-induced pulmonary vasoconstriction in newborns was at least partially mediated by release of TxA_2. In contrast, effective receptor blockade of peptide leukotrienes with LY171883 (an inhibitor of leukotriene C_4) had no influence on PAF action (19). We considered that PAF-induced release of serotonin might figure in the pulmonary vasoconstrictor responses. However, our piglet preparation exhibited no vasoreactivity in response to large intravenous doses of serotonin.

HEMODYNAMIC EFFECTS OF PAF-RELATED INTERVENTIONS

The studies just described suggested that hemodynamic collapse after PAF administration was related to PAF-induced release of TxA_2 and the consequent, marked rise in PVR. These hypotheses were further explored by assessing hemodynamic changes during infused U-46619, a potent and specific TxA_2 receptor agonist, or during mechanical constriction of the main pulmonary artery (18).

U-46619 was administered to six open-chested pigs according to the same protocol used for PAF—initial dosage of 0.3–3.0 nmol/kg/min was increased every 2 min until hypotension supervened. Hemodynamic effects were very similar to those seen with PAF infusion. A progressive, marked rise in PVR (eventually increasing 33-fold) was associated with an initial rise in mean pulmonary artery pressure and then a decline. Falling cardiac output, systemic vascular resistance, and ultimate, severe drop in systemic arterial pressure all appeared with U-46619 infusion, replicating the results seen with PAF infusion. Similarly, both right and left ventricles exhibited decreased segmental shortening in this later phase of infusion with the right ventricle manifesting signs of pressure and volume overloading (rising right atrial pressures and right ventricular segmental dimensions) and the left ventricle showing indications of underloading (falling left

ventricular end-diastolic pressure and left ventricular segmental dimensions). Thus, U-46619 administration caused systemic hemodynamic actions that were essentially the same as the actions of PAF infusions with similar pulmonary vasoconstrictor efficacy.

Because dose equivalence of TxA_2 and U-46619 has not been established, the interpretation of these infusion data is open to question. Nonetheless, the results emphasize the capacity of TxA_2 receptor activation to reproduce the sequence of PAF-induced hemodynamic changes leading to circulatory collapse. TxA_2 release is very likely a contributor to PAF-induced hypotension. If present in sufficient quantity, TxA_2 might well mediate the entire phenomenon.

Stepwise mechanical occlusion of the main pulmonary artery in five open-chested pigs caused a sequence of hemodynamic responses very similar to those observed during infusion of PAF or U-46619. Early changes included a rise in right ventricular systolic pressures with later decline accompanied by a steep fall in cardiac output and systemic arterial pressures. Segmental shortening was markedly reduced in both the left ventricle (12 ± 2% to −0.9 ± 1.6%) and right ventricle (6 ± 1 to 1.5 ± 2.1%). As in the case of infused PAF or U-46619, decrease in myocardial shortening was accompanied by a fall in indices of left ventricular filling (left ventricular end-diastolic pressures and end-diastolic length) and a rise in indices of right ventricular filling (mean right atrial pressure and right ventricular end-diastolic segment length).

The similarity of hemodynamic events after administration of PAF or U-46619 and after mechanical pulmonary occlusion suggests that the observed circulatory actions of these drugs are mainly due to pharmacologically-induced pulmonary vasoconstriction. Additional hemodynamic consequences, including ultimate circulatory collapse during PAF or U-46619 infusion, may reflect relatively non-specific responses to acute, severe rises in right ventricular afterload. The acutely overloaded right ventricle fails to propel blood forward against massive resistance. Backward leakage occurs due to dilation of the tricuspid valve ring. The failing right ventricle cannot sustain flow delivery to the left side of the heart. Although systemic arterial pressure is supported transiently by baroreceptor-mediated compensatory increases in systemic vasoconstriction, severe hypotension ultimately supervenes. Hypotension of any cause is likely to exaggerate this situation by inducing myocardial ischemia and diminished contractility, particularly in the overloaded right ventricle.

In vitro studies have shown that PAF exerts primary depressant effects on cardiac muscle (5–7). The rather close resemblance of PAF infusion and mechanical pulmonary artery constriction suggests that this depressant action plays a relatively modest role in the context of our *in vivo* experiments.

EFFECTS OF MORE PROLONGED EXPOSURE TO PAF

To date, studies of exogenous PAF have only administered the substance as a bolus or brief infusion. During inflammatory disorders, however, PAF release would presumably occur over a more prolonged period. The circulatory effects of sustained PAF administration may be important in assessing the potential role of PAF in shock states. PAF influence might actually disappear with prolonged exposure. Studies of isolated platelets or leukocytes have suggested that PAF exposure rapidly induces tachyphylaxis—PAF unresponsiveness—due to unavailability of PAF receptors (20). Should this phenomenon occur *in vivo,* it would question the relevance of PAF to circulatory disorders that accompany inflammation.

Recently, we have evaluated the capacity of PAF to produce sustained pulmonary vasoconstriction in nine open-chested newborn piglets. After baseline parameters were measured, PAF was administered in rapidly escalating intravenous doses to achieve a 100% increase in mean pulmonary artery pressure within 3 min. The dose that achieved this effect, averaging 0.15 nmol/kg/min, was then maintained for another 30 min. Throughout this period of constant infusion, pulmonary vascular resistance and mean pulmonary artery pressure remain steadily elevated (Fig. 3). Thus, there was no evidence of tachyphylaxis to infused PAF in the intact circulations of newborn piglets. Systemic vascular resistance and other parameters of systemic circulatory function remained undisturbed by the PAF infusion. These data indicated that there was no cumulative circulatory dysfunction during relatively prolonged exposure to PAF. Hemodynamic changes might persist after discontinuation of PAF infusion if these were due to PAF-induced microvessel plugging or other self-perpetuating inflammatory phenomenon. In our newborn piglets all hemodynamic parameters reverted to baseline values within 3 min of stopping PAF infusion. When PAF infusion was repeated at the same dose rate after administration of the selective PAF receptor blocker, SRI 63-441, 5 mg/kg i.v., its effects were entirely eliminated. Moreover, giving SRI 63-441 20 min after initiating a 30

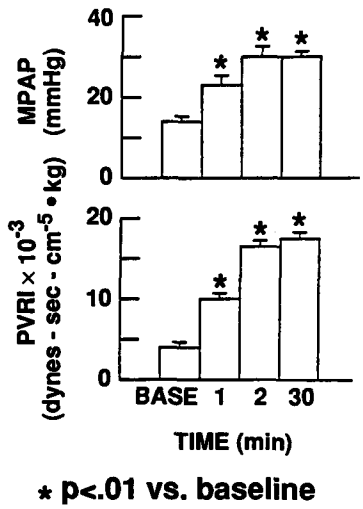

FIG. 3. Time course of MPAP and pulmonary vascular resistance index (PVRI) in nine newborn piglets receiving an intravenous infusion of PAF. Infusion rates were initially adjusted upward to achieve stable doubling of MPAP after 2 min and then maintained constant for the ensuing 30 min. Mean values are shown ± SE. Between 2 and 30 min, both MPAP and PVRI remained constant, indicating that PAF-induced pulmonary vasoconstriction did not exhibit tachyphylaxis. Moreover, the potent PAF infusion did not cause cumulative toxic effects on the neonatal circulation. Measured parameters reverted to baseline as soon as the infusion was halted.

min steady PAF infusion interrupted the pulmonary vasoconstriction induced by PAF. These findings indicated that sustained PAF receptor stimulation was responsible for continuing PAF efficacy and further documented the rapidly reversible nature of PAF action on the pulmonary vasculature.

PAF INHIBITION RESULTING FROM BLOCKADE OF TxA_2

Mechanisms of PAF action may vary depending upon the way in which PAF is tested. When the heart is perfused with cell-free, PAF-containing fluids (5–7), actions mediated by PAF influence on circulating elements are excluded. When distributed *via* the intact circulation, however, PAF is likely to induce release of inflammatory mediators from granulocytes, platelets, endothelium, and other cells in intimate contact with circulating blood. Such mediators may be responsible for important components of PAF action on the intact circulation.

In studies of intravenous PAF administration to intact pigs we found that PAF-related changes in hemodynamic performance were regularly accompanied by increases in plasma TxB_2 (14,18,19). This suggested—but clearly did not prove—that TxA_2 production was involved in PAF-induced pulmonary vasoconstriction and other PAF-induced changes. To further explore the potential mediating role of TxA_2, we evaluated the capacity of blockers of TxA_2 synthesis and TxA_2 receptor activation to alter responses to intravenous PAF (18,19,21).

Cyclooxygenase blockade. Eleven closed-chested pigs were tested with three bolus doses of PAF, 0.1–10 nmol *i.v.* (18). These animals were then given indomethacin, 6 mg/kg, and the dosing sequence repeated. A submaximal PAF dose, 3 nmol, produced severe hemodynamic changes: PVR rose 16-fold and systemic arterial pressure fell by 51%. These changes and an associated rise in plasma TxB_2 were eliminated after indomethacin. The maximal 10 nmol PAF dose caused even greater changes: in the absence of indomethacin, PVR rose 28-fold and systemic arterial pressure fell by 59%. Plasma TxB_2 rose from 0.71 ± 0.18 to 3.03 ± 0.32 ng/mL. After indomethacin, PVR still increased 13-fold and arterial pressure decreased 30% ($p<0.05$ for either change), although these were diminished from pre-indomethacin values. The PAF-induced rise in plasma TxB_2 was eliminated by indomethacin: after this cyclooxygenase blocker, TxB_2 was 0.74 ± 0.18 before PAF and 0.76 ± 0.06 after PAF. Cyclooxygenase blockade with indomethacin proved sufficient to eliminate effects after all but the highest dose of PAF. These data suggest that TxA_2 is an important mediator of the circulatory actions of PAF even when PAF is introduced in amounts sufficient to produce marked hypotension. They also suggest that very-high-dose PAF has an ability to induce pulmonary vasoconstriction independent of cyclooxygenase metabolites, *e.g.*, by direct agonist action on vascular smooth muscle or by induced release of alternative mediators. Lipoxygenase products, such as the peptide leukotrienes might be elaborated when PAF-released arachidonate is shunted to alternative pathways due to cyclooxygenase blockade. Any vasoconstrictor release would be amplified by the absence of vasodilator cyclooxygenase products.

Indomethacin produced similar blockade of PAF action in nine newborn piglets (19). The marked rise in pulmonary artery pressure and PVR induced by PAF, 0.01–0.03 nmol *i.v.*, was eliminated after indomethacin, 6 mg/kg. PAF, 1 nmol, was only partially blocked after indomethacin; systemic effects were not apparent but pulmonary artery pressure and PVR rose significantly. Plasma levels of TxB_2 and 6-keto-$PGF_{1\alpha}$ (the stable metabolite of prostacyclin) showed complete inhibition of synthesis *via* cyclooxygenase pathways after indomethacin, even with the 1 nmol PAF dose.

TxA_2 synthetase blockade. To further evaluate the role of TxA_2 as mediator of PAF effects, we examined the capacity of a selective inhibitor of TxA_2 synthetase, OKY-046, to modulate PAF action in six closed-chested pigs (18). OKY-046 significantly reduced the elevated PVR (by 71%) and attenuated the augmented systemic vascular resistance (by 63%) that were seen when PAF, 1 nmol, was given without OKY-046. Similarly, OKY-046 lowered the increased pulmonary artery pressure (by 22%) and tended to diminish other effects produced by PAF, 0.3 nmol. OKY-046 was not consistently effective against PAF, 3 nmol. OKY-046 did reduce plasma TxB_2, even after PAF, 3 nmol: levels were 0.87 ng/mL with PAF alone and 0.40 with PAF plus OKY-046. Similar reductions in plasma TxB_2 were evident after lower doses of PAF plus OKY-046. In agreement with previous studies, 6-keto-$PGF_{1\alpha}$ increased from 0.06 ± 0.02 to 0.24 ± 0.04 ng/mL after PAF, 1 nmol, indicating PAF enhancement of prostacyclin production. The same PAF dose during thromboxane synthetase inhibition with OKY-046 increased 6-keto-$PGF_{1\alpha}$ to 0.50 ± 0.08 ng/mL, significantly ($p<0.05$) greater than levels after PAF alone (22).

In our studies OKY-046 was effective in blocking the hemodynamic actions and rise in plasma TxB_2 after PAF. These results provide further support for the hypothesis that circulatory actions of PAF are mediated to a substantial degree through PAF-induced release of TxA_2. OKY-046 did not appear to block PAF as effectively as indomethacin. This may reflect a lesser ability of OKY-046 to prevent TxA_2 synthesis, although our values for plasma TxB_2 do not consistently favor this viewpoint. It should be noted that thromboxane synthetase inhibitors may increase levels of TxA_2 precursor metabolites, PGG_2 and PGH_2, substances that can exert significant TxA_2 agonist properties. Increased production of PGG_2 and PGH_2 may explain dose-related increases in pulmonary vasoconstriction after PAF and OKY-046 despite attenuation of TxB_2 levels.

Evidence of an augmented rise in prostacyclin production was seen when PAF was accompanied by OKY-046. This may represent a redirection of arachidonate from synthesis of TxA_2 to synthesis of prostacyclin, a novel occurrence *in vivo*. It is possible that OKY-046 could convert local production of vasoconstrictor and platelet-aggregator substances such as TxA_2 to local production of the vasodilator and platelet-disaggregator, prostacyclin. Although such redirection may have value in other contexts, it is noteworthy that PAF accompanied by OKY-046 caused more (rather than less) pulmonary vasoconstriction than PAF accompanied by indomethacin and the presumed elimination of both prostacyclin and TxA_2 synthesis.

TxA_2 receptor blockade. Simultaneous administration of the thromboxane receptor antagonist SQ 29,548

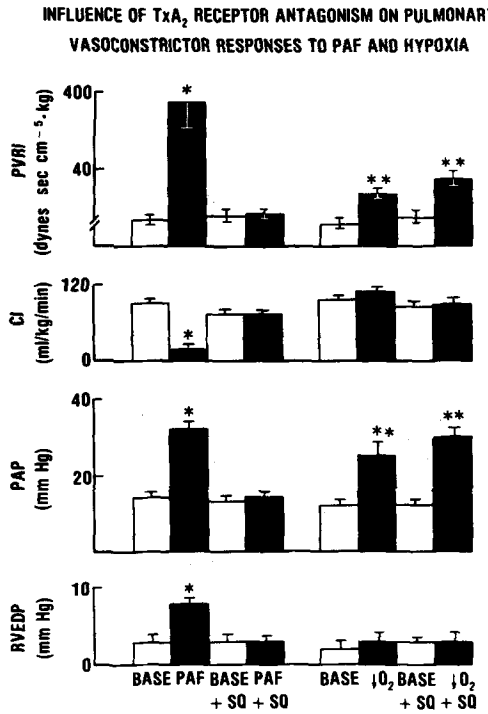

FIG. 4. Influence of thromboxane A_2 (TxA_2) receptor antagonism on pulmonary vasoconstriction due to PAF or hypoxia ($\downarrow O_2$). Both PAF, 0.1 nmol/kg, and hypoxia caused significant rises in pulmonary artery pressure (PAP) and PVRI when compared to baseline. PAF administration also caused right ventricular end-diastolic pressure (RVEDP) to increase and cardiac index (CI) to decrease. Baseline values were not different before and during infusion of the TxA_2 blocker, SQ 29,548. TxA_2 receptor antagonism completely blocked PAF-induced pulmonary vasoconstriction and the related fall in CI; hypoxic pulmonary vasoconstrictor responses remained intact. Results are expressed as absolute means ±SE. PVRI data are multiplied by 10^{-3} and displayed on a logarithmic scale. BASE, baseline; BASE+SQ, baseline during SQ 29,548 infusion; PAF+SQ, PAF during SQ 29,548; $\downarrow O_2$+SQ, hypoxia during SQ 29,548. *p<0.05 *vs.* BASE; **p<0.01 *vs.* BASE. Reproduced with permission of the International Pediatric Research Foundation (21).

appeared to block the circulatory effects of PAF at least as effectively as any of the agents tested to date (21). Thirteen open-chested newborn piglets were given PAF doses (0.1 nmol/kg *i.v.* bolus) causing near-maximal hemodynamic response. The same PAF dose was repeated during administration of SQ 29,548 (0.05 mg/kg/min *i.v.*) or its vehicle. The first PAF dose markedly raised PVR from 9.4 ± 1.4 to 340 ± 66 dynes sec cm^{-5}·kg with concomitant reductions in cardiac index (91 ± 5 to 15 ± 5 mL/kg/min) and systemic arterial pressure (62 ± 4 to 37 ± 4 mm Hg). Repeat dosing with PAF plus vehicle produced the same hemodynamic response. Repeat dosing with PAF plus SQ 29,548, however, completely eliminated these hemodynamic changes (Fig. 4). PAF-induced rises in TxB_2 and 6-keto-$PGF_{1\alpha}$ were unaffected by the TxA_2 receptor blocker. In the absence of PAF, SQ 29,548 had no effect on our preparation. Additional studies of blocker specificity showed that SQ 29,548 was a highly effective inhibitor of the TxA_2 mimetic agent, U-46619, but did not alter pulmonary vasoconstrictive actions of hypoxia or leukotriene D_4.

The PAF-inhibitory efficacy of SQ 29,548 provides further support for the concept that TxA_2 is an important mediator of the circulatory actions of PAF *in vivo*. TxA_2 receptor blockade may be a particularly potent intervention because there is no concomitant interference with synthesis of prostanoid vasodilators, as seen with cyclooxygenase inhibition and no enhancement in levels of precursors with TxA_2 agonist activity, as is likely the case with thromboxane synthetase inhibition.

CONCLUSIONS

During inflammatory states, activated leukocytes, platelets, or other cells may release PAF in amounts sufficient to alter cardiovascular function. This possibility is suggested by the capacity of PAF inhibitors to attenuate endotoxic shock (23–26) as well as the ability of exogenous PAF to produce shock when administered by vein to intact animals (13–18).

Assuming that PAF delivery by vein has pathophysiologic importance, we examined mechanisms by which PAF might induce hypotension. Our results in intact animals indicate that pulmonary vasoconstriction is a major mediator of PAF-induced hypotension. This pulmonary vasoconstriction leads to right heart failure, manifested as declining cardiac output accompanied by increased right ventricular filling pressures and overstretched right ventricular myocardium as well as reduced right ventricular shortening fraction. Inadequate flow delivery to the left side of the circulation causes left ventricular underfilling, seen as reduced filling pressures and volumes as well as declining contractility. Although rising systemic vascular resistance can transiently counter the effects of reduced cardiac output, eventually hypotension supervenes.

The sequence just described was seen in neonatal as well as older animals. The prominent pulmonary vascular response to PAF was evident in sustained infusions as well as brief bolus presentations. These findings suggest that PAF may figure in disorders of the very young and that tachyphylaxis to PAF, a common observation in isolated cells and tissues, is not seen in circulatory responses.

It should be noted that experiments in our laboratory used only a single molecular species, 16:0-AGEPC, in evaluating the actions of PAF. Other closely related molecular species, such as 18:0-AGEPC, may have somewhat different effects on the cardiovascular system.

The circulatory effects of PAF appear to involve the release of TxA_2. Pulmonary vasoconstriction and other manifestations of circulatory distress after PAF are regularly accompanied by rises in the TxB_2, the stable metabolite of TxA_2, in rough proportion to the extent of hemodynamic change. Administration of a TxA_2 mimic, U-46619, produces hemodynamic changes very similar to those of PAF. Most importantly, specific and non-specific blockers of TxA_2 synthesis and a blocker of TxA_2 receptors each had the capacity to abridge or totally interrupt the circulatory actions of PAF. The cardiovascular effects of PAF may ultimately involve release of other inflammatory mediators, *e.g.*, lipoxygenase products. However, our findings identify a preponderant role for TxA_2. They suggest that pharmacologic strategies for interrupting the synthesis or receptor agonist actions of TxA_2 may well prove as effective as PAF blockers in attenuating the cardiovascular consequences of PAF exposure.

Platelet-Activating Factor in Cardiovascular Stress Situations[1]

Reuven Rabinovici, Tian-Li Yue and Giora Feuerstein*
Cardiovascular Pharmacology, SmithKline Beecham Laboratories, King of Prussia, Pennsylvania 19406-0939

Since the elucidation of its chemical structure two decades ago, platelet-activating factor (PAF) has emerged as an important mediator of various cardiovascular stress situations. Most notably, PAF was implicated as a key factor in the septic shock syndrome, based on the similarities between endotoxin and PAF biological effects, the elevation of circulating and tissue levels of PAF during endotoxemia, and the protective effect of PAF antagonists in the septic state. In addition, accumulating data suggest the involvement of PAF in the pathophysiological processes associated with ischemia, hemorrhage and trauma, where PAF exerts its effects directly on cells and blood elements or indirectly through interactions with other mediators such as cytokines and prostaglandins. Nevertheless, the relative contribution of PAF to the pathophysiological processes in endotoxemia is still unknown and should await further investigations. The primary aims of this chapter are: to delineate the effects of PAF on the cardiovascular system, to summarize the data which suggest the involvement of PAF in stress situations of the cardiovascular system, and to identify areas where future experimental efforts should be focused.
***Lipids 26,* 1257–1263 (1991).**

Platelet-activating factor (PAF, PAF-acether, AGEPC, APRL) was first found to be released from rabbit basophils through an IgE-dependent mechanism (1), and its chemical structure was later identified as 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (2,3). The synthetic preparation of PAF and the introduction of specific PAF antagonists contributed profoundly to the accelerated research on PAF biology and pathophysiology. Consequently, within a short period of time PAF has become recognized as one of the major mediators of inflammatory and tissue injury reactions, including various shock states.

The purpose of this chapter is to give an overview on the state of the art of PAF in the cardiovascular system with special emphasis on the role of PAF in the pathophysiology of septic, traumatic and hemorrhagic shock.

PAF METABOLISM

PAF is generated by various organs and cells. The predominant cells shown to produce PAF are macrophages, neutrophils, natural killer lymphocytes, platelets, and endothelial cells (4–6). Kidney (7), heart (8,9), brain (10,11), lung (12), and intestine (13) are the predominant sites for PAF synthesis. However, in every cell where PAF production has been shown, it follows the basic scheme illustrated in Figure 1. PAF synthesis occurs in the intracellular compartment (14–16), whereas its inactivation occurs in both the cell (17,18) and the plasma (19–21). PAF is stored within cellular membranes in the form of its precursor, alkylacyl-glycerophosphocholine (alkylacyl-GPC). The stimulation-dependent action of phospholipase A_2 on this precursor results in the production of lyso-PAF, an inactive intermediate substance. The lysoPAF is then metabolized to PAF by the acetyl transferase system. Some of the newly produced PAF is inactivated within the cell and converted back to alkylacyl-GPC via an opposing pathway which includes the sequential catalytic activity of acetylhydrolase and acyltransferase. Part of those PAF molecules that reach the circulation are inactivated rapidly in the plasma through the conversion to lysoPAF, a process catalyzed by plasma acetylhydrolase. This reaction was suggested to determine the short half-life of PAF, <30 min (20), and to explain the short duration of its low-dose hypotensive effect (22). The remaining circulating PAF interacts with its cellular receptor to induce biological response, and then after leaving the receptor and crossing the membrane, is inactivated by the intracellular pathway.

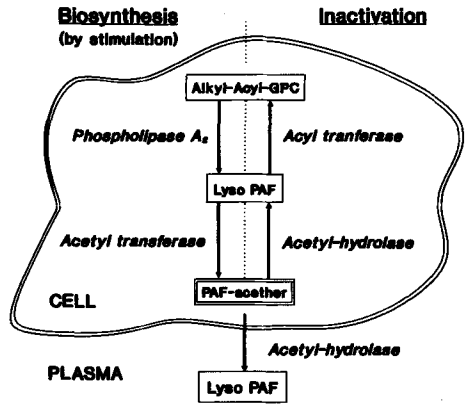

FIG. 1. The metabolic cycle of PAF.

CARDIOVASCULAR EFFECTS OF PAF

Systemic hemodynamic. PAF, when administered systemically, induces a prominent hypotensive effect in all species studied (23–27). Nevertheless, this effect was most thoroughly investigated in the rat (Table 1). The PAF-induced hypotension has several characteristics: i) it is dose-dependent (20), ii) its action is very rapid and reaches maximal effect within 30–60 sec (28,29), iii) recovery time is dose-dependent, and basal mean arterial pressure is

obtained within 5-10 min (28,29), and iv) it does not show tachyphylaxis (29,30). Although the mechanisms involved in PAF-induced hypotension are not yet fully understood, accumulating data suggest that its actions on the heart, peripheral vasculature and microcirculation play a key role in the pathogenesis of this biological response. These specific actions will be discussed below. Both PAF-induced increase in pulmonary vascular resistance (31,32) and PAF-induced bronchoconstriction (33) contribute to hypoxemia and hence reduction in oxygen delivery to essential organs such as the heart. Ultimately, this process may result in reduced cardiac output and shock. The platelet's sensitivity to PAF was suggested to mediate the PAF-induced bronchoconstriction (33). However, the species-specificity of the PAF-induced thrombocytopenia in guinea pigs (34) but not in the rat (35), might indicate that the vasodepressor response is independent of the respiratory or hematologic effects of PAF. In addition, studies on PAF-induced hypotension ruled out renin, vasopressin, and angiotensin II inhibition, central mechanism, and α-adrenergic blockade as important contributing factors (36).

The PAF-induced hypotension is usually associated with tachycardia. Several observations support the possibility that this response reflects a hypotension-triggered sympathetic reflex: i) hypotension induced by PAF was accompanied with elevated levels of plasma catecholamines (26,27), ii) β-adrenergic receptor blockers completely prevented the tachycardic response (26,27), and iii) pithed rats in which the spinal cord and central nervous system were completely disrupted did not elevate their heart rate in response to PAF administration (26).

Cardiac. There is still considerable debate in regard to the effect of PAF on the coronary circulation, and its systemic hemodynamic significance. While some *in vitro* studies using guinea pig, dog or rat isolated perfused hearts demonstrated PAF-induced coronary vasoconstriction (9,37-40), other studies failed to report such response (41). *In vivo* studies, conducted in the domestic pig and dog, showed an initial increase in coronary flow (due to vasodilatation) followed by a decrease in flow (due to coronary constriction) (42-44). The coronary vasoconstrictive response to PAF seem to be mediated, at least in part, by thromboxane A_2 since it was associated with selective thromboxane B_2 production, and was blocked by the cyclooxygenase inhibitor indomethacin. The relative contribution of the coronary flow changes produced by PAF to the overall reduction in myocardial performance is difficult to assess in view of the overall cardiac pathophysiology induced by PAF via several different types of cardiovascular dysfunction.

In respect to myocardial function, some controversy exists as to whether PAF exerts a direct negative inotropic effect on the cardiac muscle. Several *in vivo* and *in vitro* studies which supported this possibility were not conclusive since they did not completely separate the direct effect of PAF on the myocardium from its effects on the coronary and intra-mural hemodynamics: i) Low-dose PAF infused intra-coronary in the domestic pig caused substantial reduction in the myocardial contractility at times where no changes in mean arterial and left ventricular pressures were recorded (45,46). In the rat, however, PAF reduced cardiac index only at doses which produced hypotension (28). ii) PAF reduced the contractile force of several isolated perfused heart preparations (9,40,47,48). However, other investigators, using models which could reasonably exclude neural, humoral and hemodynamic mechanisms, also suggested a direct effect on the myocardium—PAF compromised the myocardial function of human cardiac muscle strips (49), and of paced non-coronary perfused left atrium and ventricular papillary muscle (9,50).

The possibility that PAF might be involved in direct myocardial dysfunction was also obtained in ischemia-reperfusion models; in rabbits, PAF administration during the post-ischemic reperfusion period augmented the decrease in cardiac performance (51), and PAF was found to be released in significant amounts during the initial reperfusion period (52). PAF was also elevated in lipid extracts from ischemic baboon heart 24 hr after ligation of

the left anterior descending artery (53). Recently, PAF was suggested to play a role in the "stunned myocardium" syndrome following ischemia and reperfusion (54). Pharmacological studies with several PAF antagonists also support the possible direct effect of PAF on cardiac functions. For example, BN 52021, BN 52020, kadsurenone and L-652,731 attenuated the PAF-induced decrease in myocardial contractility and coronary flow in the perfused guinea pig heart (55–59).

The pathogenic mechanisms of PAF-induced myocardial dysfunction are poorly understood. However, interference by PAF with Na^+ conductance (46) or with Ca^{2+} flux through the slow Ca channels (47,60) was suggested.

PAF was found to interfere with the cardiac conducting system, and to produce lethal arrhythmias (24). Moreover, purkinje fibers of guinea pigs demonstrated PAF-induced electrophysiological changes such as abnormal automaticity and decreased action potential amplitude (61). Interestingly, similar effects were found in the papillary muscle as well.

Peripheral vasculature. The effect of PAF on blood vessels has not yet been established, mainly due to the following factors: i) the direct *in vivo* effect of PAF on blood vessels is masked by the profound sympathetic vasoconstrictor reflex triggered by the PAF-induced hypotension; ii) PAF effects on blood vessels seem to be dose- and species-dependent. However, if selected organs are perfused under constant pressure with low-dose PAF, the common response is vasodilatation. This response was demonstrated in the coronary circulation of the domestic pig (42) and the dog (43). Moreover, vasodilatory response of the kidney, mesenteric and hindquarters vessels (measured by chronically implanted miniaturized doppler probes) was produced by intravenous doses of PAF which had no or minimal systemic effects (25). In addition, mesenteric vasodilatation was also produced following topical application of PAF (62). The vasodilatory effect of PAF was also confirmed in an *in vitro* study of isolated rat kidneys (63). Nevertheless, other studies reported PAF-induced vasoconstriction in both *in vivo* and *in vitro* preparations such as the pig pulmonary vessels (64–66) and dog renal vessels (67,68). This response was shown in some models to be thromboxane A_2 and peptidoleukotriene dependent (31,42,69).

Microcirculation. PAF was shown to increase the permeability of the microcirculation in all species studied (35,70,71) including humans (72). This phenomenon was shown in several models including intra-dermal PAF injection (71), and ^{125}I (30) and dye concentration measurement (73) following i.v. PAF injection. The change in capillary permeability leads to hemoconcentration and decrease in intravascular volume. Although some studies suggested that the contracted intravascular volume contributes to the PAF-induced hypotension and decrease in cardiac output (70), it is possible that the hypotension and the permeability defect are two independent events. The latter hypothesis is supported by the fact that hypotension occurs at lower doses and is immediate and reversible (74), whereas the extravasation response requires 4–10 min to peak and several hours to reverse (75–78).

The mechanism by which PAF increases the permeability of the microcirculation is unknown. However, PAF was shown to disrupt endothelial cell junctions and to cause vacuolization (71). Generally, PAF exerts its effects directly on the microcirculation through interaction with endothelial wall receptors (78,79). The permeability defect is augmented by histamine, associated with prostaglandin I_2 production (80) and increased Ca^{2+} fluxes (81), and might involve polymorphonuclear leukocyte adhesion and activation (82). Since PAF and several other phospholipid mediators can induce the release of each other, it is possible that positive self-generated feedback cycles contribute to the pathogenic mechanism by which PAF damages the microcirculation. For example, PAF induces peripheral blood-derived monocytes to produce tissue necrosis factor (TNF), and enhances the endotoxin-induced TNF synthesis.

These effects are prevented by various PAF antagonists (83). Furthermore, PAF was shown to modulate the production of interleukin 1 (IL-1) and IL-2 from rat monocytes (84) and lymphocytes (85). On the other hand, TNF and IL-1 (but not IL-2, IL-3, IL-6 and colony-stimulating factor) induce PAF synthesis by cultured endothelial cells (86). In addition, TNF can prime PAF-induced superoxide generation by human neutrophils (87), and granulocyte-monocyte colony-stimulating factor (GM-CSF) facilitates PAF synthesis by human polymorphonuclear leukocytes (88). Interestingly, GM-CSF, in combination with IL-3, also induced monocytes to produce TNF (89). Although the regulatory mechanisms of this feedback network under physiological conditions and in shock states are unknown, several endogenous inhibitors of PAF, TNF, IL-1 and IL-2 have been reported (87). The fact, that endothelial cells were shown to produce and metabolize PAF (90) in a PGI_2-regulated process, may suggest another positive feedback cycle in the pathogenicity of PAF.

Blood cells. The PAF-platelet interactions, which probably play a key role in the pathogenicity of PAF, are not clearly understood. Controversy exists as to: i) the effect of PAF on platelet count—PAF consistently induced thrombocytopenia in the rabbit (55,91) or guinea pig (24) but not in the rat (35). The thrombocytopenic response to PAF may reflect PAF-induced platelet aggregation (92), PAF-induced platelet redistribution due to pulmonary platelet recruitment (93), or a combination of these two mechanisms. ii) the mechanism of PAF effect on platelets—PAF was hypothesized to mediate a "third pathway of platelet aggregation" since neither its production by stimulated platelets nor its effects were ADP or arachidonic acid-dependent (92). However, several recent studies cast doubt on this possibility. For example, several PAF antagonists failed to prevent thrombin-induced aggregation of aspirin-treated ADP-depleted platelets (94). Despite the possible role of arachidonic acid metabolites and ADP in the activation of platelets by PAF, it seems that PAF acts through a specific mechanism since it activates aspirin-treated or ADP-depleted platelets (95). Platelets activated *in vitro* by PAF secrete a variety of secondary mediators such as serotonin, leukotrienes, prostaglandins and oxygen radicals. Moreover, the PAF-stimulated platelets form a propagating thrombus (96) which is surrounded by leukocytic infiltration over the adjoining vacuolized epithelium. Thus, it seems that PAF-activated platelets interact with other blood elements which produce and secrete inflammatory mediators. The end point of these processes is tissue injury or thrombus formation.

Systemic administration of PAF leads to leukopenia in most species studied (24,55,91). However, PAF-induced leukocytosis following high *in vivo* doses was reported as well (97). These effects are associated with leukocyte activation and cell margination. On the other hand, stimulated neutrophils (98), monocytes (99), macrophages (100), mast cells (101), and eosinophils (98) produce PAF. Of great importance is the fact that PAF-induced permeability capillary defect (88), pulmonary injury (102) and anaphylactic reactions (103) were all associated with leukocytic activation and aggregation. Therefore, it is possible that leukocytes are activated directly by PAF or indirectly by platelets (see above), and so facilitate ultimate tissue injury.

PAF IN SHOCK STATES

Septic and endotoxic shock. PAF was recently implicated as one of the major mediators of septic and endotoxic shock. However, there is only little biochemical evidence that PAF is produced during specific organ or systemic pathophysiological processes. This is the result of the short half-life of PAF (hydrolyzed rapidly in the plasma) combined with the limitations of the techniques employed for PAF extraction and assay. However, elevated levels of PAF (measured by a rabbit platelet aggregation bioassay after partial purification) were found during *E. coli* endotoxemia in rats (29). The delayed appearance of PAF following the endotoxin administration (at 10 min following the injection of endotoxin but not at 1.5 min) correlated with the LPS-induced hypotension, which only began 3 min following injection. Since PAF decreases systemic arterial pressure immediately, it is conceivable that the delayed elevation of circulating PAF level reflects the time required for PAF synthesis and secretion. Furthermore, enhanced release of PAF (measured by the [^{3}H]serotonin release from washed rabbit platelets) from spleen lymphocytes and peritoneal cells taken from rats exposed to *E. coli* peritonitis was also reported (104). Significant amounts of PAF in the peritoneal protein-rich exudate could be obtained already at 30 min after the inoculation of *E. coli,* while PAF in peritoneal and splenic leukocytes was elevated only at 2 hr following the injection of endotoxin. The endotoxin-induced elevation of PAF levels in the peritoneal and splenic cells occurred before the PAF-induced blood volume depletion, suggesting that hemoconcentration and volume contraction are secondary to PAF production. Additional biochemical evidence for the production of PAF during endotoxemia was presented by Chang *et al.* (30) who reported a three-fold elevation in plasma PAF, and a ten-fold elevation in whole lung homogenate PAF, 20 min following intraperitoneal injection of Salmonella enteritidis. It is important to note that these levels persisted for at least 2 hr. In the kidney, PAF values 90 min after endotoxin administration were significantly increased over the controls (30). Both the baseline and post-endotoxin renal PAF levels were markedly lower than those found in the lung. The persistent elevation of plasma PAF levels might cause other organs to experience prolonged PAF exposure, although no direct PAF production took place in the specific organ. Interestingly, vinblastine-induced leukocyte depletion did not reduce the endotoxin-induced PAF production in the lung. These data, taken together with the *in vivo* and *in vitro* reports of PAF release from injured pulmonary endothelial cells (105,106), suggest that these cells play a major role in PAF production during septic shock, and negate a neutrophil source for the accumulation of PAF in the lungs.

While only few studies actually measured circulating PAF levels in septic shock, most of the data concerning the role of PAF in endotoxemia were obtained by *in vivo* experiments with PAF antagonists. The majority of the studies investigated the effect of various PAF antagonists on LPS-induced hypotension (Table 2). Other studies, using a large variety of PAF antagonists, have shown protection or reversal of endotoxin-induced leukopenia, thrombocytopenia and hemoconcentration. For example, FR-900452, tested in anesthetized rabbits (107), and the specific PAF antagonist BN 52021, injected to anesthetized guinea pigs (108), were shown to attenuate the endotoxin-induced thrombocytopenia. Moreover, ONO 6240 partially prevented the leukopenia induced by endotoxin in conscious sheep (109). The same antagonist was also shown to abolish the *E. coli*-induced decrease in cardiac output observed in conscious sheep (109). A recent preliminary study demonstrated a protective effect of CV-3988 against endotoxin-induced low cardiac output and increased peripheral resistance. Blood flow to essential organs such as heart, kidney and splanchnic bed was also substantially improved over the non-treated septic group (110). Only few reports extended their study to end points which included survival rate (Table 3). These studies, which utilized several PAF antagonists, demonstrated improved survival rates in the PAF antagonist-treated groups. However, it should be noted that all these studies evaluated the effect of pretreatment rather than treatment with PAF antagonists.

Hemorrhagic and traumatic shock. The role of PAF in mediating traumatic shock is supported by several recent studies conducted in rats subjected to the Noble-Collip trauma; the most direct evidence for PAF production during traumatic shock was provided by Stahl *et al.* (111) who reported that peritoneal fluid from traumatized or PAF-infused rats, analyzed by high performance liquid chromatography (HPLC), contained a phospholipid which had a similar retention time to authentic PAF, and aggregated washed rabbit platelets. This aggregation was blocked by a specific PAF antagonist, CV-6209. Other studies utilizing the same traumatic shock model reported beneficial effects of various PAF antagonists. For example, combined treatment with CV-6209 and PGE_1 improved survival and decreased the accumulation of myocardial depressant factor (MDF, 112). Moreover, three structurally different PAF antagonists—WEB 2086, L-652,731 and CV-6209—increased the post-trauma mean arterial pressure and survival rate (113). In addition, PAF antagonists had salutary effects in a hemorrhagic shock model (114), although no direct biochemical evidence is available at the present time on the release of PAF in this model.

SUMMARY

PAF has been recognized as an important mediator of septic, traumatic and hemorrhagic shock. However, while there is a wide spectrum of pharmacological evidence (i.e., studies with PAF antagonists) to support the central role

TABLE 2

Summary of PAF Antagonists Which Protect Against Endotoxin-induced Hypotension

Antagonist	Reference	Dose, mode and time of administration	Species	Anesthesia	Endotoxin	Degree of prevention/reversal
ONO-6240	(109)	i.v.[a] 3 mg/kg 15 min before LPS,[b] and 0.1 mg/kg/min maintenance	sheep	conscious	*E. coli* i.v. 1 μg/kg	complete
SRI 63-441	(117)	i.v. 0.18 mg/kg (ED_{50}) 1 min after LPS	rat	pentobarbital	*E. coli* i.v. 5 mg/kg	complete
SRI 63-072	(118)	i.v. 1 mg/kg 6–8 min after LPS	rat	pentobarbital	*E. coli* i.v. 15 mg/kg	complete
kadsurenone	(29)	i.v. 2.2 μmole/kg 6 min after LPS, and 0.9 μmole/kg maintenance	rat	nembutal	*E. coli* i.v. 50 mg/kg	partial
WEB 2086	(119)	PO[c] 1–10 mg/kg 60 min before, and i.v. 0.1–5 mg/kg 5 min before LPS	rat	pentobarbital	*E. coli* i.v. 15 mg/kg	complete
CV 3988	(116)	i.v. 5 mg/kg 5 min before, i.v. 0.05–1 mg/kg 7–10 min after LPS	rat	pentobarbital	*E. coli* i.v. 15 mg/kg	complete
CV 3988	(30)	i.v. 10 mg/kg 5 min before, and i.v. 5 mg/kg 50 min after LPS	rat	conscious	Salmonella enteritidis IP[d] 20 mg/kg	partial

of PAF in these pathophysiological processes, there is only a handful of reports that provided direct chemical evidence (i.e., measurement of PAF in biological material). Therefore, future experimental efforts should focus on the facilitation of the available methods that directly measure PAF, and on their utilization in shock states.

In addition, therapeutic efficacy has only been established in prophylactic endotoxemic studies, where PAF antagonists were given prior to the bolus administration of a single endotoxin. Therefore, at the present time there is no data on the capacity of PAF antagonists to reverse hemodynamic, metabolic and biochemical derangements produced by endotoxins in addition to improved survival. Furthermore, one should notice that the endotoxemic models may not fully represent septic shock where multiple toxins in addition to bacterial growth confound the disease process.

Finally, it is important to keep in mind that multiple mediators (e.g. leukotrienes, catecholamines, prostaglandins, MDF, etc.) are produced during these complex pathological conditions. It is therefore conceivable that the pathogenic process of the different shock states reflects the actions and interactions of these multiple mediators. Consequently, future studies should be conducted to establish the relationships between the various vasoactive mediators. Moreover, the therapeutic strategy should be based on multiple sites of actions.

Circulating levels of 1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine (C_{16}PAF) in human subjects were measured by gas chromatography/mass spectrometry using negative ion chemical ionization. The mean (± S.D.) circulating C_{16}PAF levels in patients with essential hypertension (18.1 ± 5.3 pg/mL, n=16) were not significantly different from those in normotensive subjects (17.2 ± 7.2 pg/mL, n=14). During a salt balance study, high salt intake (20 g/day) significantly increased the circulating level of C_{16}PAF, and changes in circulating C_{16}PAF significantly and positively correlated with changes in mean arterial blood pressure ($r=0.47$, $p<0.05$). Changes in C_{16}PAF also correlated with changes in creatinine clearance ($r=0.55$, $p<0.05$), but did not correlate with changes in plasma sodium concentration, plasma chloride concentration and plasma volume. An intravenous injection of 50 μg of human atrial natriuretic peptide (hANP) decreased circulating C_{16}PAF levels from 20.0 ± 2.7 to 13.9 ± 2.4 pg/mL of blood (n=10, $p<0.01$) in healthy subjects. The data appear to indicate that C_{16}PAF levels are changed by salt intake-induced mild increase in blood pressure, and that hANP may be an endogenous factor which lowers circulating C_{16}PAF.

***Lipids 26,* 1264–1268 (1991).**

Platelet-activating factor (PAF) is an alkyl ether lipid with diverse biological activities. The composition of the alkyl group of PAF in human neutrophils has been reported to be 59% C_{16}PAF (1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine), 18% C_{18}PAF (1-*O*-octadecyl-2-acetyl-*sn*-glycero-3-phosphocholine) and 23% $C_{18:1}$PAF (1-*O*-octadecenyl-2-acetyl-*sn*-glycero-3-phosphocholine) (1). The pathophysiological role of PAF is not yet clearly understood, which has been due partly to a lack of sensitive methods to measure changes in endogenous PAF levels. Recently, a highly sensitive method to measure C_{16}PAF in circulating blood has been developed utilizing gas chromatography/mass spectrometry (GC/MS) with negative ion chemical ionization (NICI) after conversion of PAF to its pentafluorobenzoyl derivative (2).

PAF has potent hypotensive activity (3). We previously reported that a PAF-like substance, as well as an unknown factor which inhibited the aggregation of platelets, were found in renal venous blood of patients with renovascular hypertension after percutaneous transluminal renal angioplasty (PTRA) (4). We also suggested that PAF may participate in blood pressure regulation following PTRA in these patients (4). It is known that PAF decreases the glomerular filtration rate (GFR), urine volume (UV) and urinary sodium (UNa) excretion in animals *in vivo* (5,6). A decrease in GFR by PAF was also confirmed in perfused kidney (7). By contrast, human atrial natriuretic peptide (hANP) increases GFR, UV and UNa excretion and inhibits glomerular contraction induced by PAF (8). Although stimuli such as antigen-induced immunoglobulin E, calcium ionophore A23187 and thrombin activate PAF biosynthesis, no endogenous factor such as hANP has been reported to inhibit PAF synthesis.

In the present paper, we describe the effects of dietary salt on circulating C_{16}PAF levels, on the role of PAF on systemic blood pressure regulation, and on the suppressive effect of hANP on circulating C_{16}PAF in humans.

MATERIALS AND METHODS

Subjects and study protocol. Thirty-seven healthy human subjects (20 males, 17 females, mean ± S.D. age of 47 ± 9 years) and 16 untreated patients with essential hypertension (10 males, 6 females, WHO classifications I and II, 46 ± 9 years) with a mean blood pressure of 163 ± 13/97 ± 12 mm Hg were used for the basal study in which we measured circulating C_{16}PAF levels. Blood samples were collected at 8:00 a.m. after overnight fasting. Blood was also obtained at 4:00 p.m. from eight healthy subjects to study circadian rhythm.

The sodium balance study was performed in 12 patients (8 males and 4 females, 44 ± 8 years, 167 ± 12/98 ± 9 mm Hg) out of the 16 hypertensive patients with essential hypertension. These patients had a normal salt diet, a low salt diet, or a high salt diet, with a sodium chloride intake of 10, 2 and 20 g/day, respectively, for 14 days. Blood samples were obtained early in the morning of the last day of each period, and urine samples were collected over a 24-hr period on the last day.

Ten healthy male volunteers (mean age ± S.D., 27 ± 3 years) were used for the hANP injection study. Subjects started the study with a void urine bladder and were placed at rest for 1 hr before hANP injection. hANP (Peptide Institute, Osaka, Japan; in 50 μg/mL of saline) was injected intravenously, and the C_{16}PAF levels in blood were monitored. Blood was collected before and 1 hr after hANP injection.

Measurement of C_{16}PAF. Fresh blood (5 mL) was immediately mixed with 30 mL of ice-cold methanol for the assay of C_{16}PAF. The resulting slurry was centrifuged at 10,000 × *g* for 10 min at 4°C. The supernatant was used

[1]Based on a paper presented at the Third International Conference on Platelet-Activating Factor and Structurally Related Alkyl Ether Lipids, Tokyo, Japan, May 1989.

Abbreviations: ANP, atrial natriuretic peptide; C_{16}PAF, 1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine; C_{18}PAF, 1-*O*-octadecyl-2-acetyl-*sn*-glycero-3-phosphocholine; $C_{18:1}$PAF, 1-*O*-octadecenyl-2-acetyl-*sn*-glycero-3-phosphocholine; GC/MS, gas chromatography/mass spectrometry; GFR, glomerular filtration rate; hANP, human atrial natriuretic peptide; PAF, platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; PTRA, percutaneous transluminal renal angioplasty; UNa, urinary sodium excretion; UV, urine volume.

for the C_{16}PAF assay (2). Briefly, 2 mL of fresh blood was immediately mixed with 30 mL of ice-cold methanol and centrifuged at 3,000 × *g* for 20 min. Three mL of the methanol layer were mixed with 1 mL of distilled water and 4 mL of chloroform. The lower phase was collected and evaporated, the residue dissolved in chloroform and then applied to a Bond Elute SI column (Analytichem International, Harbor City, CA) for collection of the C_{16}PAf fraction. The PAF fraction was then incubated with 0.8 U of phospholipase C, 72 mM $CaCl_2$ and 50 mM Tris-HCl (pH 7.5) at 37°C for 60 min. The hydrolyzed mixture was extracted by the method of Folch and was evaporated, the residue was treated with 3 mM pentafluorobenzoyl chloride in distilled acetonitrile, and incubated at 35°C for 60 min, after which time the derivatization was complete. After evaporation, the residue was dissolved in ethyl acetate and injected into the gas chromatograph/mass spectrometer. The detection limit of PAF in the system was 5 pg, and the intraexperimental coefficient of variation was 3.8% (2).

Other measurements. Serum levels of Na^+, Cl^-, creatinine, and total protein, and the urinary level of creatinine were measured using a Technicon autoanalyzer (Technicon Co., Tarrytown, NY).

Statistical analysis. All data are expressed as mean ± S.D. The data were analyzed by paired Student's *t*-test.

RESULTS

Stability of C_{16}PAF in blood samples. Figure 1 shows the time-dependent decrease in measured C_{16}PAF levels of blood samples before mixing with ice-cold methanol. Thirty percent of C_{16}PAF was rapidly degraded within 30 seconds. Subsequent data were therefore obtained on blood samples which had been immediately mixed with ice-cold methanol.

Circulating levels of C_{16}PAF in healthy subjects. The circulating level of C_{16}PAF in 37 healthy subjects ranged from 5 pg/mL of blood to 25 pg/mL of blood, with a mean value of 18.4 ± 6.2 pg/mL (Table 1). The mean circulating

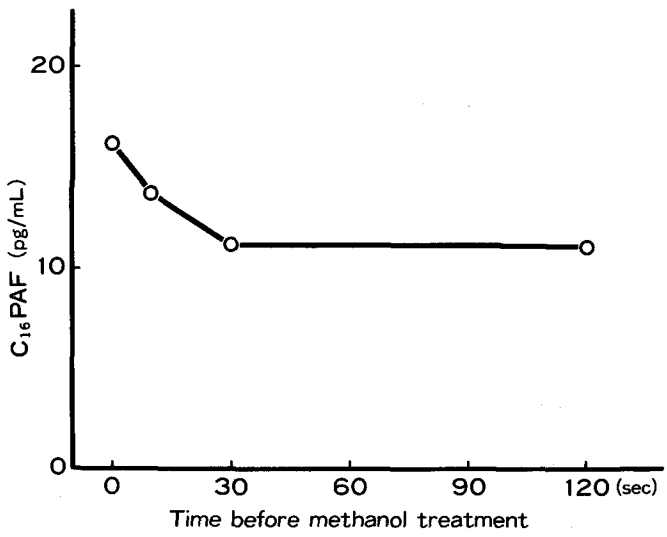

FIG. 1. Time-dependent decrease of C_{16}PAF levels in blood samples before mixing with ice-cold methanol. The C_{16}PAF levels were determined for samples of the same origin differing in pretreatment time before addition of ice-cold methanol.

TABLE 1

Circulating Levels of C_{16}PAF in Healthy Human Subjects and Hypertensive Patients

	N	C_{16}PAF (pg/mL blood)
Total subjects	37	18.4 ± 6.2
Younger subjects (<60)	22	18.5 ± 4.6
Elderly subjects (≥60)	15	18.3 ± 6.3[a]
Male subjects	20	18.5 ± 5.4
Female subjects	17	18.4 ± 5.4[b]
Male subjects	8 (a.m. 8:00)	18.4 ± 5.1
	(p.m. 4:00)	18.4 ± 5.0
Blood pressure difference		
Normotensives	14	17.2 ± 7.2
Hypertensives	16	18.2 ± 5.0

[a]Values are not significantly different from values in younger subjects.

[b]Values are not significantly different from values in male subjects.

C_{16}PAF levels in younger subjects (<60 years old) at 18.5 ± 4.6 pg/mL of blood did not differ from those in elderly subjects (≥ 60 years old) at 18.3 ± 6.3 pg/mL. The mean circulating levels of C_{16}PAF in male subjects at 18.5 ± 7.1 pg/mL of blood also did not differ from those in female subjects at 18.4 ± 6.4 pg/mL (Table 1). A comparison of the circulating values at 8:00 a.m. with those at 4:00 p.m. in eight healthy subjects showed no circadian rhythm of C_{16}PAF levels (Table 1).

Circulating levels of C_{16}PAF in hypertensive patients. The mean values of circulating C_{16}PAF in hypertensive patients were 18.1 ± 5.0 pg/mL of blood; in age- and sex-matched normotensive subjects (9 males and 5 females, 46 ± 9 years) the corresponding values were 17.2 ± 7.2 pg/mL of blood. The difference was not statistically significant (Table 1).

Dietary salt intake and C_{16}PAF levels. The effects of dietary salt intake on haematocrit, plasma total protein, plasma creatinine, UV, urinary excretion of creatinine and on mean blood pressure in the 12 patients with essential hypertension are shown in Table 2. The high salt diet significantly decreased the values of haematocrit, plasma total protein, and plasma creatinine, and significantly increased the values of UV and mean blood pressure in the patients compared to those on a normal and/or low salt diet (Table 2). The mean circulating level of C_{16}PAF slightly, but not significantly, decreased with dietary salt depletion, and significantly ($p<0.01$) increased with the high salt diet (Fig. 2). During the salt balance study, changes in circulating C_{16}PAF levels in individual patients correlated significantly with both changes in mean blood pressure ($r=0.47$, $p<0.05$; Fig. 3) and with changes in creatinine clearance (($r=0.55$, $p<0.05$; Fig. 4), as the latter were effected by changes in dietary sodium. However, there was no significant correlation with changes in plasma sodium concentration ($r=0.32$, NS), chloride concentration ($r=0.39$, NS), or plasma volume ($r=0.34$, NS) (Fig. 5).

Effect of hANP injection on circulating C_{16}PAF levels. The effect of hANP on circulating C_{16}PAF levels was determined in 10 normotensive subjects. Circulating C_{16}PAF levels significantly decreased from 20.0 ± 9.0 to

TABLE 2

Plasma Parameters During Sodium Balances[a]

	Dietary salt		
	Normal	Low	High
Haematocrit (%)	33.4 ± 5.7	36.4 ± 4.8[b]	32.1 ± 6.7[c]
Plasma total protein (g/dL)	6.7 ± 0.4	7.2 ± 0.6[b]	6.7 ± 0.6[c]
Plasma creatinine (mg/dL)	0.94 ± 0.30	1.20 ± 0.41[d]	0.81 ± 0.26[e]
Urinary volume (mL/day)	1033 ± 38	1108 ± 33	1247 ± 32[d]
Urinary creatinine (mg/day)	848 ± 211	886 ± 173	1080 ± 199
Mean blood pressure (mm Hg)	108.7 ± 6.5	103.3 ± 6.5[b]	112.8 ± 7.8[b,c]
Creatinine clearance (mL/min)	62.8 ± 15.6	51.2 ± 12.3	92.6 ± 11.5

[a]Significant difference: normal *vs.* low or high; [d]p<0.05; [b]p<0.01; significant difference: low *vs.* high; [e]p<0.05, [c]p<0.01.

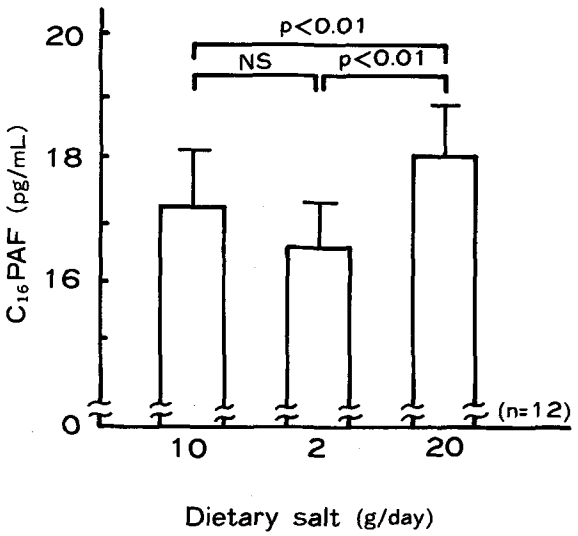

FIG. 2. Changes in circulating C_{16}PAF levels caused by dietary salt intake in twelve patients with essential hypertension (8 males and 4 females, 44 ± 8 years). The patients had normal salt diet, low salt diet, or high salt diet with sodium chloride levels of 10, 2 or 20 g/day, respectively, for each 14 days.

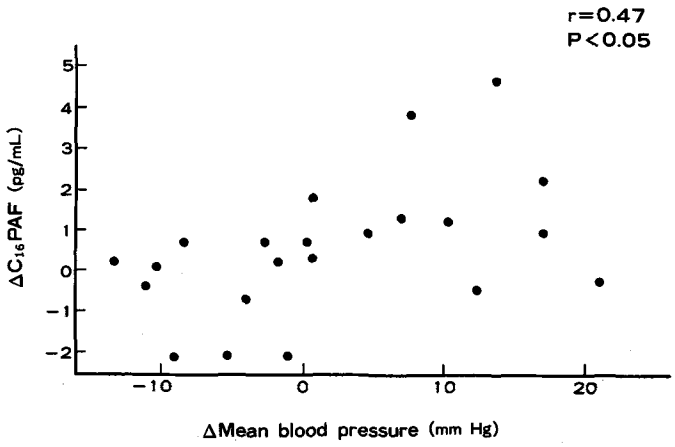

FIG. 3. Relation between changes in circulating C_{16}PAF levels and changes in mean arterial blood pessure in twelve patients with essential hypertension during the salt balance study.

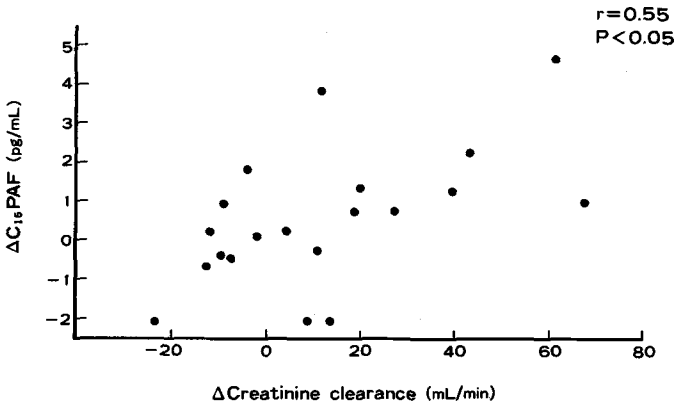

FIG. 4. Relation between changes in creatinine clearance and changes in circulating C_{16}PAF in twelve patients with essential hypertension during the salt balance study.

13.9 ± 5.9 pg/mL of blood (p<0.01) upon hANP injection (Fig. 6).

DISCUSSION

Circulating levels of C_{16}PAF in normal subjects were found to be 18.4 ± 6.2 pg/mL of blood, or 3.7×10^{-11} M, based on plasma volume. *In vitro*, 10^{-7} M PAF activates human platelets (9). Therefore, the concentration of circulating C_{16}PAF is less than one thousandth of the concentration that would activate platelets. Moreover, circulating C_{16}PAF levels were similar for different age- and sex-groups. The data indicate that a small but steady level of C_{16}PAF is present in circulating blood and that this PAF concentration is too low to activate circulating platelets in healthy human subjects. A circadian rhythm in circulating PAF levels was not observed, although the levels were measured only for two time points per day. This may indicate that plasma cortisol levels, which affect phospholipase A_2 activity, do not influence circulating C_{16}PAF levels. Plasma-free PAF is thought to be rapidly hydrolyzed to lysoPAF by acetylhydrolase (10). As shown in Figure 1, a portion of measurable PAF was rapidly degraded within 30 seconds, but the remaining portion of PAF was quite stable beyond that time. This may suggest that more than half of the total PAF present in blood

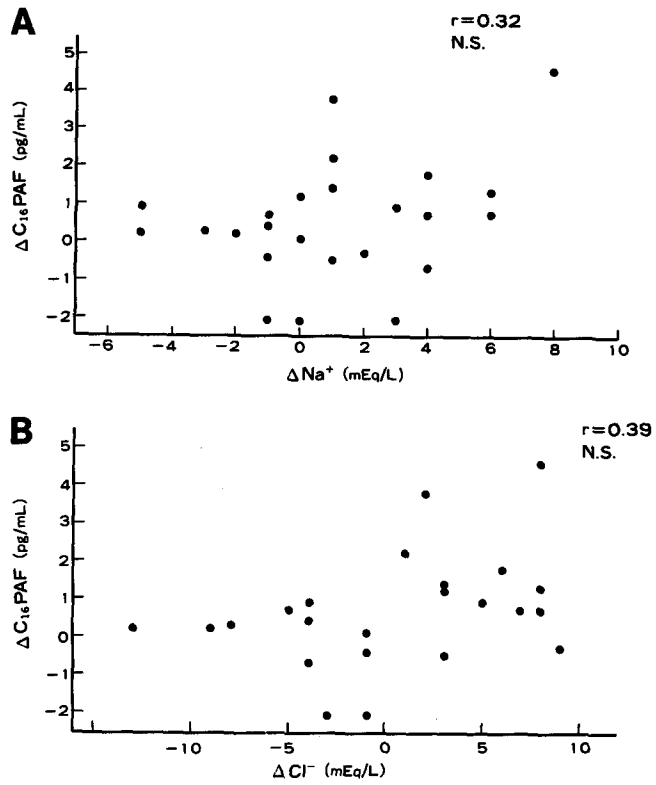

FIG. 5. Relation between changes in C_{16}PAF levels and changes in plasma sodium concentration (A), plasma chloride concentrations (B) and plasma volume (C) in twelve patients with essential hypertension during the salt balance study.

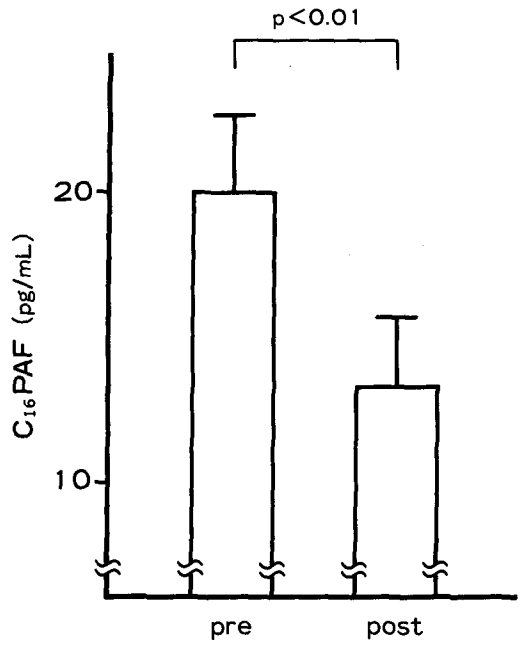

FIG. 6. Effect of hANP on C_{16}PAF levels in 10 normal subjects. A saline solution of hANP (50 μg) was injected into 10 normal volunteers and C_{16}PAF levels in circulating blood were determined before and 60 min after hANP injection.

would exist in a bound or cell-associated form. It is known that newly synthesized PAF is not readily released from cells (11,12). Another explanation for the persistent levels of PAF beyond 30 seconds might be the limited concentration or activity of acetylhydrolase *ex vivo*. Although the effect of dietary salt on circulating PAF levels was rather small, the changes in circulating C_{16}PAF levels effected by the salt balance significantly correlated with the changes in mean arterial blood pressure. This may indicate that free PAF in the circulation directly affects systemic blood pressure.

PAF has been shown to affect intrarenal hemodynamics (5,6). Infusion of PAF into a renal artery resulted in the reduction of GFR and renal plasma flow (5,6). On the other hand, atrial natriuretic peptide (ANP) has been reported to inhibit glomerular contraction induced by PAF (8). Moreover, we have shown for the first time that injection of a natriuretic dose (50 μg) of hANP decreases circulating PAF levels. These results suggest that hANP-induced modulation of GFR or UNa excretion may be mediated through its effects on PAF synthesis. ANP increases prostaglandin production in the kidney *in vivo* (13), but has no effect on renal prostaglandins *in vitro* (14). This would indicate that hANP does not decrease phospholipase A_2 activity, and therefore, that this is not a mechanism by which PAF is decreased. Cholinephosphotransferase activity may contribute to the control of basal PAF levels, but we do not have data in support of this hypothesis. Further work is needed to elucidate the precise mechanism(s) for the ANP-induced decrease in the circulating PAF and to pinpoint the relationship between the hANP-induced decrease in circulating C_{16}PAF levels and other circulatory blood-pressure related factors such as renin, angiotensin II, aldosterone, and calcitonin gene-related peptide.

In conclusion, PAF levels in circulating blood are increased by high dietary salt intake and are decreased by exogenous hANP injection, suggesting that dietary salt and hANP may be regulators of circulating PAF levels.

ACKNOWLEDGMENT

This study was supported in part by Grants-in-Aid from the Kidney Bank of Osaka and from the Ministry of Education of Japan.

Intravascular Release of a Platelet-Activating Factor-Like Lipid (PAF-LL) Induced by Cigarette Smoking[1]

Tada-atsu Imaizumi*
Department of Pathologic Physiology, Institute of Neurological Diseases, Hirosaki University School of Medicine, Hirosaki, 036, Japan

To assess the role of platelet-activating factor (PAF) in smoking-induced vascular injury, the effect of cigarette smoking on PAF-like lipid (PAF-LL) in plasma was studied. The subjects were 12 young smokers (22 ± 1.3 years old), 13 young non-smokers (22 ± 2.1 years old), 14 older smokers (59 ± 9.6 years old), and 11 older non-smokers (60 ± 8.7 years old). Lipids were extracted from 5 mL of plasma and then were separated by thin-layer chromatography. The fraction with the same migration as authentic PAF was recovered and tested for the ability to aggregate human polymorphonuclear neutrophils (PMN). The activity was identified as PAF-LL because it was inactivated by phospholipase A_2, and because the effects on PMN were blocked by CV-3988, a competitive antagonist of the PAF receptor. PAF-LL was detected in plasma from 3 young non-smokers (23%), 5 young smokers (42%), 3 older non-smokers (27%) and 11 older smokers (79%). The incidence of the detection of plasma PAF-LL in older smokers was significantly higher than those in young non-smokers ($p<0.01$) or in older non-smokers ($p<0.05$). In young smokers, the acute effect of smoking was also studied. Plasma PAF-LL was detected in all of the 12 subjects immediately after smoking a cigarette, in sharp contrast to the incidence of 42% before smoking. Plasma β-thromboglobulin was highest in older smokers, and it increased significantly after smoking a cigarette in young smokers. Smoking is associated with increased production of PAF or a similar lipid, which may play an important role in the pathogenesis of smoking-induced vascular diseases.
Lipids 26, 1269–1273 (1991).

Cigarette smoking is an important risk factor of atherosclerotic disease (1), and platelet activation is thought to be one of the mechanisms by which smoking induces vascular injury (2,3). However, the precise mechanisms by which cigarette smoking exerts its adverse effect have not been elucidated.

Platelet-activating factor (PAF) is a phospholipid autacoid with a variety of activities. PAF induces aggregation of human platelets in the concentration range of 10^{-9}–10^{-8}M (4) by interaction with a specific receptor (5), and has been implicated in the basic mechanism of platelet aggregation. PAF is produced by and active on platelets (4), leukocytes (6) and vascular endothelial cells (7,8), and it may be one of the crucial mediators in the interactions of these cells. Therefore, PAF may play a role in the pathogenesis of thrombosis and vascular disorders.

The rationale for this study was that PAF may be involved in the pathogenesis of smoking-induced vascular disease. This hypothesis was addressed by examining plasma for a PAF-like lipid (PAF-LL) following both chronic and acute cigarette smoking. Plasma β-thromboglobulin (β-TG), an indicator of *in vivo* platelet activation (9), and platelet aggregability were also measured in order to observe the relation between PAF-LL and platelet function.

MATERIALS AND METHODS

Study design. First, the chronic effect of cigarette smoking was examined. For this purpose, four groups of healthy male volunteers were chosen, *i.e.*, 13 young non-smokers with an average age of 22 ± 2.1 years (mean ± SD), 12 young smokers (22 ± 1.3 years old), 11 older non-smokers (60 ± 8.7 years old) and 14 older smokers (59 ± 9.6 years old). Young smokers had smoked an average of 15 ± 5.6 cigarettes a day for 3.5 ± 1.7 years, and older smokers had smoked 18 ± 4.7 cigarettes a day for 37 ± 12.9 years. The young volunteers were recruited from university students, and the older ones were selected from participants in an annual screening for circulatory diseases. The dietary habit and constitution of these subjects were about average for Japan. They had no abnormalities by detailed history and physical examination including blood pressure, electrocardiogram and blood chemistry. All had abstained from medications for at least 4 wk prior to this study. Venous blood was obtained early in the morning, after the subjects had fasted and refrained from smoking for at least 9 hr.

The study on the acute effect of cigarette smoking was conducted in the same group of young smokers. After the first blood drawing, they had a 15-min rest and then smoked one filtered cigarette containing 1.1 mg nicotine and 1.6 mg tar (Nihon Tobacco, Tokyo, Japan) within 3 min. They were instructed to inhale deeply. Immediately after smoking the cigarette, another venous blood sample was obtained.

Extraction of plasma PAF-LL. Blood was taken into a plastic tube containing 15% (v/v) acid-citrate dextrose solution. The lipids were extracted from 5 mL plasma by the method of Folch *et al.* (10) and separated by thin-layer chromatography (TLC) on a silica gel plate (Silica gel 60, Merck, Darmstadt, Germany) using chloroform/methanol/acetate/water (50:25:8:4, by vol) as a solvent system. The area of silica gel with the same migration as authentic PAF (1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine, Sigma, St. Louis, MO) was scraped off, and the lipids were re-extracted and dissolved in 250 μL of 20 mM phosphate-buffered saline (PBS), pH 7.4, containing 2.5 mg/mL human serum albumin (HSA; Sigma). This solution was tested for the activity to aggregate human polymorphonuclear neutrophils (PMNs) according to the method described by Prescott *et al.* (8).

Abbreviations: β-TG, β-thromboglobulin; HSA, human serum albumin; PAF, platelet-activating factor; PAF-LL, platelet-activating factor-like lipid; PBS, phosphate-buffered saline; PLA_2, phospholipase A_2; PMN, polymorphonuclear neutrophil(s); PPP, platelet-poor plasma; PRP, platelet-rich plasma; TLC, thin-layer chromatography.

PMN aggregation. PMN were separated from heparinized venous blood of healthy non-smoking subjects using Ficoll-Paque according to the method of Böyum (11). PMN were finally suspended in Hanks' balanced salt solution containing 2.5 mg/mL HSA. The number of white cells was adjusted to 0.5–1 × 10^7/mL. The PMN aggregation studies were performed by the light transmission method (12). To 200 μL of PMN suspension in a siliconized cuvette, 50 μL of 25 μg/mL cytochalasin B (Sigma) was added and the mixture was stirred at 37°C for 10 min. Then, 50 μL of the TLC fraction of the plasma lipid or authentic PAF was added, and the changes in light transmission were recorded. Aggregation of PMN was observed, in a concentration-dependent manner, with 10^{-9}–10^{-7} M authentic PAF.

Characterization of PAF-LL. For the characterization of the PMN aggregating activity in plasma, the effects of phospholipase A_2 (PLA_2) and a PAF receptor antagonist were examined. PLA_2 treatment was according to the method of Blackwell *et al.* (13). The TLC fraction with PMN aggregating activity was incubated with 77 U/mL PLA_2 from porcine pancreas (Sigma) at 37°C for 1 hr. After the incubation, lipids were extracted and tested for the ability to aggregate PMN as described above.

The effect of CV-3988, a specific antagonist of the PAF receptor (14), was tested by treating the PMN with 10 μM CV-3988 for 10 min prior to the addition of the TLC-purified plasma lipid fraction.

Measurement of plasma β-thromboglobulin. Venous blood was obtained without stasis by the two syringe technique. Blood was taken into a glass tube containing sodium citrate, citric acid, theophylline, adenosine and dipyridamole (Diatube H®, Diagnostica Stago, Asnières, France), and mixed immediately. The samples were kept on ice for at least 15 min and then were centrifuged for 30 min at 2,500 × *g* at 4°C. Plasma β-TG was estimated by enzyme-linked immunosorbent assay (15) using a commercially available kit, Asserachrom β-TG (Diagnostica Stago).

Platelet aggregation. Platelet aggregation was performed by the method of Born (16). Blood samples for platelet aggregation were collected with 1/10 vol of 3.8% trisodium citrate. The blood was centrifuged at 100 × *g* for 15 min and platelet-rich plasma (PRP) was obtained. The remaining blood was then centrifuged at 900 × *g* for 10 min to yield platelet-poor plasma (PPP). The platelet count of PRP was adjusted to 300–400 × 10^3/mm^3 with PPP. The aggregating agents used were 2 μM ADP (Sigma) and 40 ng/mL PAF (Sigma). Aggregation was expressed as a percentage of maximal light transmission.

Statistical analyses. Statistical analyses were performed using Fisher's exact probability test, Student's t-test and paired t-test.

RESULTS

Detection and characterization of PAF-LL in plasma. The separation of PAF-LL from total plasma lipids by TLC is shown in Figure 1. The PMN aggregating activity in plasma was always detected in a single fraction which showed the same migration as authentic PAF. This PAF-LL was almost completely inactivated by treatment with 77 U/mL PLA_2 for 1 hr (Fig. 2). Aggregation of PMN by the plasma PAF-LL was inhibited by pretreating the PMN with 10 μM CV-3988 (Fig. 3).

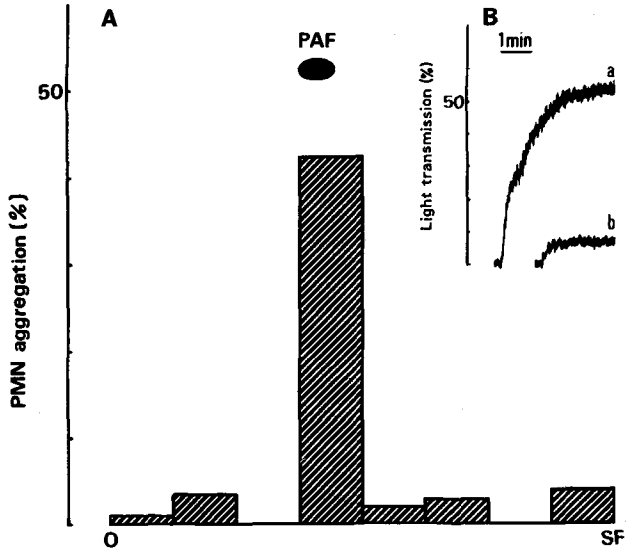

FIG. 1. Plasma PMN aggregating activity separated by TLC. (A) PMN aggregating activity of plasma lipid fractions separated by thin-layer chromatography. Areas of silica gel 1 cm in length were scraped off and the lipids were extracted and tested for the PMN aggregation activity. The migration of authentic PAF is marked as a black eclipse. O: origin, SF: solvent front. (B) Typical patterns of PMN aggregation induced by active (a) and inactive (b) fractions.

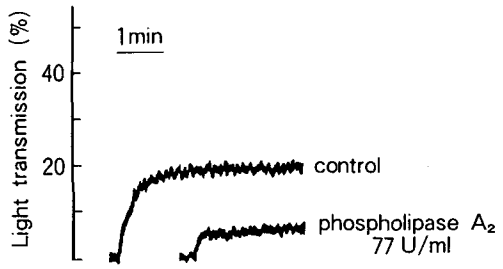

FIG. 2. Effect of phospholipase A_2 (PLA_2) on PMN aggregating activity. The fraction with PMN aggregating activity was incubated with 77 U/mL PLA_2 or buffer at 37°C for 1 hr. After the incubation, lipids were extracted and tested for the PMN aggregation.

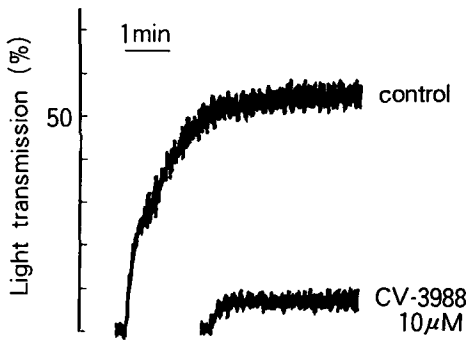

FIG. 3. Effect of CV-3988 on PMN aggregation. PMN were treated with 10 μM CV-3988 of buffer for 10 min prior to the addition of the TLC-purified plasma lipid fraction.

Chronic effect of cigarette smoking. The incidence of the PMN aggregating activity in each of four groups is shown in Table 1. The activity was detected in plasma from 3 young non-smokers (23%), 5 young smokers (42%), 3 older non-smokers (27%) and 11 older smokers (79%). The incidence of PMN aggregating activity in older smokers was significantly higher than that in young non-smokers ($p<0.01$), or older non-smokers ($p<0.05$). However, there was no significant difference between young smokers and young non-smokers.

The levels of plasma β-TG and platelet aggregability in four groups are shown in Table 2. Plasma β-TG was highest in older smokers, and lowest in young non-smokers. There was a statistically significant difference between plasma β-TG levels in young non-smokers and those in older non-smokers ($p<0.01$) or older smokers ($p<0.05$). The platelet aggregability induced by ADP in young smokers was significantly higher than that in young non-smokers ($p<0.05$) or older smokers ($p<0.01$). On the other hand, there was no such difference in the platelet aggregability in response to PAF. Platelet aggregability with both agonists in older smokers was the lowest in four groups.

Acute effect of cigarette smoking. The incidence of PMN aggregating activity in plasma samples from young smokers before and after smoking is shown in Table 3. The activity was detected in plasma from 5 to 12 subjects before smoking, and in all of 12 plasma samples obtained after smoking. The occurrence of the PMN aggregating activity in plasma after smoking was significantly more frequent than that before smoking ($p<0.01$).

Acute effects of cigarette smoking on platelet function are shown in Table 4. Plasma β-TG increased significantly after smoking ($p<0.05$); however, platelet aggregability was not affected.

DISCUSSION

The most widely used method for measuring PAF is the bioassay utilizing the aggregation or secretion response of rabbit platelets (17). However, at present there is no absolutely quantitative technique for the assay of PAF in biological materials. The assay also has to be sensitive enough to permit the quantitation of trace amounts of PAF. In the present study, the author employed a bioassay based on the aggregation of human PMN as described previously (8,12). Although this bioassay is a little less sensitive than the method based on rabbit platelets, authentic PAF did induce PMN aggregation in the concentration range of 10^{-9}–10^{-7} M, which covered the changes in plasma PAF-LL levels induced by cigarette smoking in most cases.

The occurrence of the PMN aggregating activity in plasma was more frequent in habitual smokers than in non-smoking controls. In the experiment on the acute effect, the PMN aggregating activity was detected in the plasma of each of 12 volunteers after smoking a cigarette. This PMN aggregating activity in plasma had the same migration in TLC as synthetic PAF, and it was inactivated by pretreatment with PLA_2 and antagonized by CV-3988. These results suggest that cigarette smoking induces intravascular release of PAF, or of a closely related phospholipid, as an acute effect. The accumulative acute effect may bring about the increased plasma PAF-LL levels observed in chronic smokers.

PAF is inactivated by PAF acetylhydrolase, an enzyme which metabolizes PAF (18). In consideration of the relatively high activity of PAF acetylhydrolase in plasma (19,20), the presence of PAF-LL in plasma is somewhat surprising. However, it has been reported that PAF in plasma is carried complexed with lipoproteins (21) or a binding protein (22), which may prevent the conversion of PAF to lysoPAF.

PAF is produced by various cell types including cultured type II alveolar epithelial cells (23). Although the source of plasma PAF-LL is unknown, the possibility exists that it may be derived from leukocytes, platelets, lung, and vascular endothelial cells. However, considering the direct effect of cigarette smoke inhaled into the lung, it is likely that alveolar epithelial cells are one of the major sources of PAF-LL observed after smoking.

Caramelo *et al.* (24) have detected a small amount of PAF in the plasma of healthy humans and rats, and suggested the kidneys as the source since plasma PAF was undetectable in anephric patients and nephrectomized animals. Increased levels of PAF in blood have been reported in patients with cold urticaria (25), sepsis (26), drug-induced allergic reactions (27) and liver cirrhosis (28). It also has been shown that blood PAF is higher in experimental animals with renal allograft rejection (29), endotoxin-induced hypotension (30) and intestinal ischemia (31). These facts suggest that leukocytes and platelets serve as the sources of PAF in blood; these cells may also account for the increase in plasma PAF-LL induced by smoking. The activation of platelets by smoking is also consistent with the observation of increased plasma β-TG levels found after smoking a cigarette. This increase was closely associated with the occurrence of PAF-LL in plasma.

Numerous investigations have dealt with *in vitro* platelet aggregation to assess the effects of cigarette smoking on platelet function. However, they have produced inconsistent results. Fitzgerald *et al.* (32) pointed out that *in vitro* studies of platelet aggregation are inherently limited in the information that they can provide concerning the effects of cigarette smoking on platelet function. Nowak *et al.* (3) observed elevated levels of urinary metabolites of thromboxane in habitual smokers and concluded that platelet activation *in vivo* was induced by chronic smoking. In the present study, although the effects of cigarette smoking on platelet aggregability were not clear, the aggregability in older smokers was lowest. This suggests that platelets obtained from older smokers have decreased sensitivity to agonists, perhaps due to the repeated stimulation by cigarette smoking.

A recent study by Stremler *et al.* (33) showed that an oxidized phospholipid was a substrate for the PAF acetylhydrolase in plasma. It will be of interest to determine whether these oxidized lipids have bioactivities and chemical properties similar to PAF, since cigarette smoking has been suggested to induce oxidation of lipoproteins (34).

In the present study, the author has used TLC only for the isolation and characterization of PAF. Therefore, the phospholipid with PMN-aggregating activity was considered a PAF-like lipid (PAF-LL). This PAF-LL will be characterized further by high-performance liquid chromatography (HPLC) or gas chromatography/mass spectrometry (GC/MS).

In conclusion, cigarette smoking induces enhanced production of PAF, or of a PAF-like lipid, which may play an important role in the pathogenesis of smoking-induced vascular disease.

Platelet-Activating Factor (PAF) Induces Contraction of Saponin-Skinned Smooth Muscle of Coronary Artery[1]

A.I. Soloviev[a,*] and **P. Braquet**[b]

[a]A.A. Bogomoletz Institute of Physiology, Kiev-24, 252024, Ukraine, U.S.S.R. and [b]H. Beaufour Institute, F-92350, Le Plessis Robinson, France

The effect of platelet-activating factor (PAF) on the development of isometric tension by saponin-skinned coronary artery was studied. PAF caused two types of contractions of coronary smooth muscle cells (SMC): (i) rapid, transient (phasic) contractions of SMC were induced by inositol 1,4,5-trisphosphate dependent Ca^{2+} release from sarcoplasmic reticulum (SR); (ii) slow sustained (tonic) contractions were induced by increase in Ca^{2+}-sensitivity of the contractile apparatus of SMC by protein kinase C activation. The present results support the hypothesis that, in SMC of coronary artery, PAF receptors are located not only on the plasma membrane, but also on the SR membranes.

Lipids 26, 1274–1276 (1991).

Spasm of the large epicardial coronary arteries is one of the main causes of cardiac pathology, *i.e.* angina pectoris, myocardial infarction, disturbances in heartbeat, and sudden death. Angiographic tests on patients during anginal attacks have shown that coronary spasm is the reason for onset of heart pain and the development of myocardial infarction (1). The cellular mechanisms of coronary spasm have not yet been established. But it is well documented that the main determinants of vasospasm are intrinsic to the vascular wall. Among the potential endogenous mediators of coronary vasospasm, special attention has recently been given to platelet-activating factor (PAF), a phospholipase A_2-sensitive phospholipid identified as 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine.

PAF can cause dose-dependent contraction of coronary arteries and a significant decrease in coronary blood flow (2,3) and may be one of the mediators of coronary spasm under hypoxic conditions (4). In addition, PAF binds to specific receptors on the plasma membrane, which induces the activation of phospholipase C, the degradation of phosphatidylinositol 4,5-bisphosphate, and the formation of inositol 1,4,5-trisphosphate (Ins P_3) and diacylglycerol (DG) (5).

We have shown that PAF can contract not only intact vascular smooth muscle strips but also skinned smooth muscle cells (SMC) which have been made hyperpermeable by the cholesterol-precipitating agent saponin.

The purpose of the present investigation was to study the mechanisms by which PAF affects skinned SMC of coronary arteries.

MATERIALS AND METHODS

Materials. Na_2ATP and EGTA were obtained from Calbiochem Behring Corporation (La Jolla, CA). Saponin was from Merck (Darmstadt, Germany). Tris-HCl, procaine, caffeine, and rotenone were purchased from Serva (Heidelberg, Germany). Triton X-100 (alkylphenylpolyethyleneglycol) was from Ferak (Berlin, Germany). Ruthenium red was from Fluka (Buchs, Switzerland), PAF was from Novabiochem (Läufelfingen, Switzerland), BN 52021 was from H. Beaufour Institute (Le Plessis Robinson, France), and polymyxin B was obtained from MinMed-Bioprom (Kiev, Ukraine, U.S.S.R.). Sodium vanadate was from Reachem (Sverdlovsk, Russia, U.S.S.R.), and 1-(5-isoquinolinylsulfonyl)-2-methylpiperazine (H-7) was obtained from Sigma (St. Louis, MO).

Skinned artery strip preparation and tension measurements. Circular strips of isolated porcine coronary artery, 3 mm long and 150 to 200 μm wide, were used in the experiments. Each artery strip was suspended, in a tissue bath, between a stationary hook and a force displacement transducer coupled to a physiograph. The artery strips were lengthened sufficiently to produce a passive force of approximately 4 mN and allowed to stress-relax for 60–90 min. The bathing medium (modified Krebs bicarbonate buffer) contained (in mM): NaCl, 133; KCl, 4.7; $NaHCO_3$, 16.3; NaH_2PO_4, 1.38; $CaCl_2$, 2.5; $MgCl_2$, 1.2; glucose, 7.8; pH 7.4. Following equilibration and relaxation in Krebs bicarbonate buffer, the strips were exposed to the so-called relaxing solution, pH 6.8, containing (in mM): KCl, 130; $MgCl_2$, 5; Tris-HCl, 20; ethyleneglycol-*bis*(β-aminoethylether)tetraacetic acid (EGTA), 4; Na_2ATP, 3.3; and dithiothreitol, 0.5, at a temperature of 20°C for 20 to 30 min. To obtain the skinned fibers, strips were treated with the same relaxing solution, containing 0.05–0.1 mg/mL of saponin for 20–30 min. The concentration chosen and the duration of the saponin action on the artery strips depended on whether the sarcoplasmic reticulum (SR) needed to be preserved or could be destroyed. The presence of intact SR in skinned SMC was evaluated by its ability to contract in response to caffeine.

The contractions of skinned SMC were produced by the activating solution. This solution had the same composition as the relaxing solution, except that EGTA was substituted for by Ca^{2+}/EGTA. The free Ca^{2+} concentration in the activating solution was determined using a computer program that solved the equations for multiple binding constants. Contractions were elicited by increasing the Ca^{2+}/EGTA ratio to obtain the desired free Ca^{2+} concentration in the range of 1 nM to 10 μM while keeping the total EGTA concentration at 5 mM. The apparent binding constant for the Ca^{2+}/EGTA complex was assumed to be 10^6 M^{-1}. The binding constant of Na_2ATP

Abbreviations: DG, diacylglycerol; EGTA, ethyleneglycol-*bis*(β-aminoethylether)tetraacetic acid; Ins P_3, inositol 1,4,5-trisphosphate; PAF, platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; SMC, smooth muscle cells; SR, sarcoplasmic reticulum.

for Mg^{2+} was found to be 4×10^3 M^{-1}. The ionic strength of the solution was kept constant by changing the concentration of KCl. Finally, the Ca^{2+} concentration in the activating solution was expressed as pCa (negative logarithm of Ca^{2+} concentration).

The maximum isometric tension developed by skinned preparations at a free Ca^{2+} concentration of 10^{-5}M averaged 80% of the tension elicited by 130 mM K^+ for the preskinned (intact) preparations.

RESULTS

The minimal free Ca^{2+} concentration in the activating solution, leading to a marked increase in the level of isometric tension of the skinned artery strips, is 2×10^{-7} M. The maximal tension of SMC is attained at 7×10^{-6} M Ca^{2+}. In this case, the curve of "pCa-tension" shows a typical S-shaped pattern, and the Michaelis-Menten constant (Km) is 8.2×10^{-7} M (Fig. 1).

Figure 2 shows that PAF induces dose-dependent contraction of skinned SMC with intact SR in Ca^{2+}-free solution (SR was prior loaded with Ca^{2+} in buffer solution containing 3×10^{-7} M Ca^{2+}). When the SMC are preconstricted with Ca^{2+}, PAF is capable of causing additional contraction with an amplitude that can reach 25–100% of the Ca^{2+}-induced contraction. These contractions are rapid and transient (phasic) at the low Ca^{2+} concentration (Fig. 3 B) and slow and sustained (tonic) at the maximal Ca^{2+} concentration in the activating solution (Fig. 3 A).

The PAF-induced phasic contraction of the skinned artery strips significantly decreases, or even disappears, after treatment of SMC with ruthenium red (3×10^{-6} M) or procaine (5×10^{-3} M), which block Ca^{2+}-release from the SR. Upon destruction of SR by saponin or Triton X-100, and also after depletion of the SR Ca^{2+}-stores by caffeine, PAF induces only slow tonic contraction. The maximal amplitude of this contraction is about one-quarter of that of the PAF-induced contraction of SMC with intact or non-depleted SR (Fig. 4).

In our experiments, preliminary incubation for 10–50 min with lithium ions (10^{-3} M), which inhibit both inositol 1-monophosphatase and G protein, led to a significant decrease (by 75%) in the amplitude of PAF-induced phasic contraction.

Sodium vanadate, an inhibitor of Ca^{2+}-ATPase in SR, reduced at 5×10^{-4} M the amplitude of PAF-induced

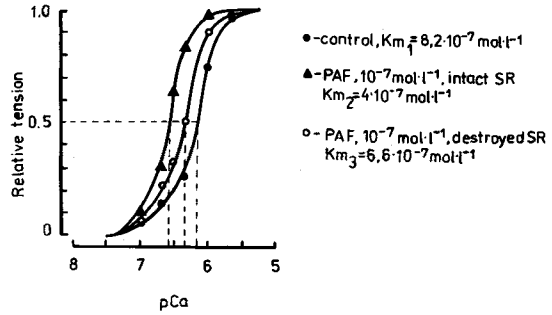

FIG. 1. The effect of PAF on the contractions of saponin-skinned coronary artery strips with intact or damaged sarcoplasmic reticulum ("pCa-tension" relationships). Vascular preparations initially resting in relaxing solution ($Ca^{2+} < 5 \times 10^{-8}$ M) were contracted by replacing the original solution with solutions of progressively higher free Ca^{2+} concentration to which PAF (10^{-7} M) was added. Closed circles, control, Km_1, 8.2×10^{-7} M; control strip (no PAF) had intact SR. Open circles, PAF, damaged SR, Km_2, 6.6×10^{-7} M. Triangles, PAF, intact SR, Km_3, 4×10^{-7} M. Symbols represent means ± SEM (n = 11).

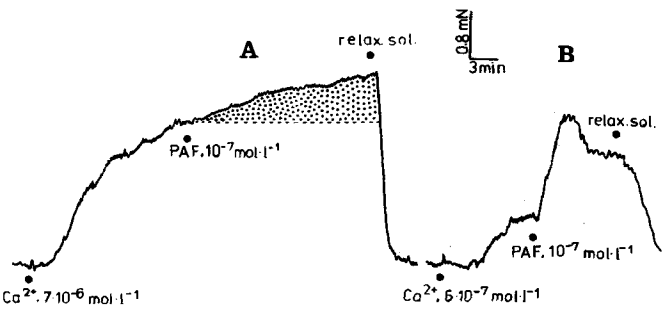

FIG. 3. Effects of PAF on isometric tension in skinned coronary artery strips preconstricted by low (B) and high (A) Ca^{2+} concentration in the activating solution.

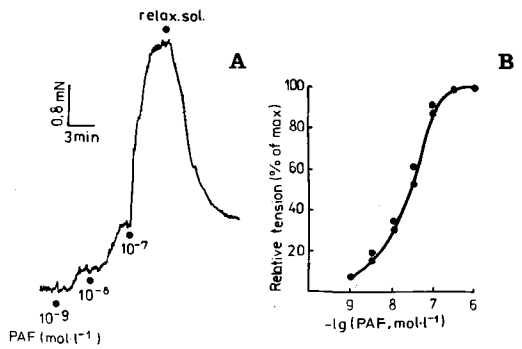

FIG. 2. Contractile responses to PAF of saponin-skinned coronary artery strips with intact sarcoplasmic reticulum after Ca^{2+} loading of SR. (A) the force recording of an artery strip illustrating the PAF concentration dependence of force development; (B) the "dose-response" curve for artery strips treated with different concentrations of PAF. Symbols on panel B represent means ± SEM (n = 9).

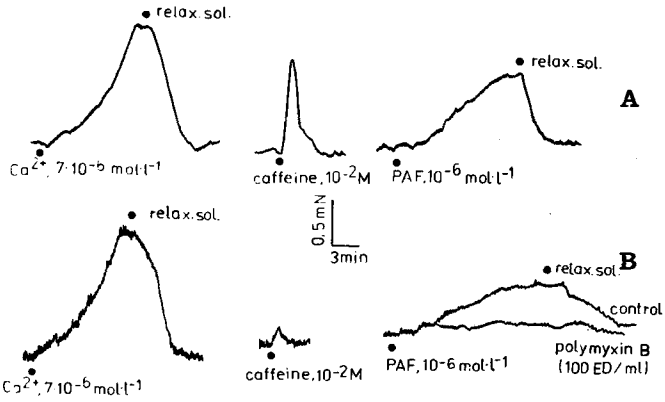

FIG. 4. Contractile responses to PAF of saponin-skinned coronary artery strips before (A) and after (B) the destruction of sarcoplasmic reticulum by Triton X-100. The presence of intact SR in SMC was evaluated by its ability to contract in response to caffeine (10^{-2} M).

contraction by not more than 10–15%. Inhibitors of mitochondrial oxidative phosphorylation, such as KCN (0.5–1.0 mM) or rotenone (0.5–1.0 mM), did not affect the amplitude of PAF-induced contraction.

Figure 1 shows the effect of PAF on typical "pCa-tension" curves for a skinned coronary artery with intact and destroyed SR. As can be seen from Figure 1, a sigmoidal relationship exists between the calcium ion concentration in the medium and force development in skinned fibers. When 10^{-7} M PAF is added to the medium, the force/calcium relationship shifts to the left, *i.e.* to higher pCa values, indicating that calcium sensitivity of the myofilaments had increased.

We have also shown that polymyxin B and H-7 (2×10^{-5} M), putative inhibitors of protein kinase C, completely suppressed the sustained tonic contraction of skinned coronary artery strips induced by PAF (Fig. 4 B). PAF-induced contraction of the SMC was inhibited by BN 52021, a specific blocker of PAF receptors. But even at a very high concentration of BN 52021 (2×10^{-4} M), the amplitude of the PAF-induced contraction decreased not more than 2-fold.

DISCUSSION

It is well known (5) that after binding to its receptor, PAF activates a yet undefined receptor protein, which in turn activates the guanine nucleotide binding protein (G protein) causing GTP hydrolysis. The activation of G protein could lead to two concomitant events: (i) Induction of phospholipase C which can trigger phosphoinositide breakdown and produce Ins P_3 and DG, both of which are classical second messengers. Ins P_3 would induce release of Ca^{2+} from SR and cause tension development (6). On the other hand, DG is involved in protein kinase C activation resulting in the phosphorylation of cellular proteins that could, in turn, contribute to the modulation of various physiological processes, including changes in Ca^{2+}-sensitivity of the SMC contractile machinery; (ii) Internalization of the PAF/receptor complex and transmembrane movement of PAF.

Thus, PAF induced dose-dependent contractions of the skinned coronary SMC. The contractions were rapid and transient at low Ca^{2+} concentration and slow (tonic) at maximal Ca^{2+} concentrations. Ruthenium red or procaine, drugs which block Ca^{2+} release from SR, and destruction of the SR by Triton X-100 led to a significant decrease in the amplitude of PAF-induced rapid (phasic) contraction of SMC. Pretreatment of SMC with lithium ions caused the same effect on expression of PAF-induced phasic contraction. The data suggest that this type of PAF-induced contraction is mediated *via* Ins P_3-induced Ca^{2+} release from intracellular stores and that its main source is the SR.

Sodium vanadate, an inhibitor of Ca^{2+}-ATPase in SR, reduced the amplitude of PAF-induced phasic contraction by not more than 15%. Hence, the release of Ca^{2+} from SR after PAF treatment is caused by the increase in calcium permeability of the SR membrane under influence of Ins P_3 rather than by the inhibition of Ca^{2+}-ATPase. PAF-induced phasic contraction of SMC is not related to Ca^{2+} release from mitochondria since KCN or rotenone had no effect on this contraction.

PAF shifts the "pCa-tension" relationship to the left, *i.e.* to higher pCa values, which indicates that the Ca^{2+}-sensitivity of contractile proteins in SMC had increased. The increased sensitivity of the contractile proteins of SMC to Ca^{2+} may be linked to protein kinase C activation (7,8). It is known that protein kinase C maintains its activity in skinned SMC, because it usually binds to the plasma membrane in the presence of increased cytosolic Ca^{2+}. Since the skinning process takes place in a Ca^{2+}-free solution in the presence of EGTA, it is unlikely that this membrane-associated enzyme loses its activity during treatment of SMC plasma membrane with detergent.

It has been established (8) that the activation of protein kinase C may lead to contraction in coronary artery SMC, which is linked to an increase in Ca^{2+} sensitivity of the contractile proteins. Actually, polymyxin B or H-7, which are protein kinase C inhibitors, completely supressed the PAF-induced sustained tonic contraction.

Thus, our results are consistent with the hypothesis that the contraction of skinned epicardial coronary artery strips induced by PAF occurs through at least two mechanisms: (i) Ins P_3-induced release of Ca^{2+}, stored in the SR, and (ii) activation of protein kinase C and increase in the Ca^{2+}-sensitivity of the contractile machinery. These two mechanisms are closely interrelated; the formation of Ins P_3 upon binding of PAF with specific receptors and the synthesis of DG, which is capable of activating protein kinase C, occur simultaneously. The data also suggest that PAF receptors are not only located on the plasma membrane of the SMC, but also on the membrane structures of the SR.

ACKNOWLEDGMENT

We wish to thank Dr. A. Bobik for the gift of H-7.

REVIEW

Role for Platelet-Activating Factor in Asthma[1]

K.F. Chung* and **P.J. Barnes**

Department of Thoracic Medicine, National Heart & Lung Institute and Royal Brompton National Heart & Lung Hospital, London SW3 6LY, United Kingdom

Recent studies of the effects of platelet-activating factor (PAF) on human and animal airways would support a putative role for this lipid mediator in asthma. PAF can induce many aspects of the clinical and pathological features seen in asthmatic airways such as airway oedema, eosinophil accumulation in the airway wall, and bronchial hyperresponsiveness. PAF has potent activity as a chemotactic agent and as an activator of eosinophils, which are prominent cells in asthmatic airways, through the activation of specific surface receptors. The interaction between PAF and eosinophils may be crucial in the pathogenesis of bronchial hyperresponsiveness in asthma. A role for PAF in asthma can now be studied using the recently developed antagonists of the PAF receptor. ***Lipids 26*, 1277-1279 (1991).**

Over the past five to six years, there has been considerable interest in the possibility that platelet-activating factor (PAF) may contribute to the pathophysiology of asthma. This increasing interest is partly due to the observations that PAF can induce many of the clinical and pathological features of asthmatic airways, such as airway oedema, eosinophil accumulation into the airway wall and bronchial hyperresponsiveness. In this review, we will examine some of the effects of exogenously administered PAF on the airways. One unique property of PAF is its potent activity as a chemotactic agent and as an activator of eosinophils, which are prominent cells in asthmatic airways. We hypothesize that this interaction between PAF and eosinophils may be crucial in the pathogenesis of bronchial hyperresponsiveness in asthma. Finally, we will review some recent data concerning the effect of specific PAF antagonists in disease models related to asthma.

EFFECT OF PAF ON AIRWAYS

Airway narrowing. PAF is a potent bronchoconstrictor *in vivo* but exerts negligible direct contractile effects on airway smooth muscle preparations *in vitro* (1-4). This suggests that PAF induces airway narrowing by indirect mechanisms *in vivo*, such as the release of smooth muscle constricting mediators. Another potential mechanism underlying the airway narrowing may be the induction of airway oedema secondary to airway microvascular leakage. Human airway smooth muscle contracts in response to PAF in the presence of platelets *in vitro* (5); whether similar responses can be obtained in the presence of other cells, such as neutrophils or eosinophils, is not known. In man, PAF aerosol induces bronchoconstriction within 2-3 min of inhalation (1); facial flushing occurs transiently and is maximal at 5 min. Rapid tachyphylaxis develops in response to the bronchoconstrictor effect of PAF. Airway responsiveness to PAF aerosol is approximately 100-fold lower than that to methacholine (1). Mild asthmatic subjects, who are hyperresponsive to methacholine, do not appear to be more sensitive to PAF as compared to normal subjects (6).

The role of cells and mediators in PAF-induced bronchoconstriction in man remains unclear. Prostacyclin infused at a concentration required to inhibit PAF-induced platelet aggregation *ex vivo* does not inhibit PAF-induced bronchoconstriction, suggesting that platelets do not contribute to this response (7). Although histamine may mediate PAF-induced wheal formation in the skin, it is unlikely to do so in the airway (8).

Airway microvascular leakage and oedema. PAF is one of the most potent inducers of microvascular leakage throughout the respiratory tract of the guinea pig (9,10). This effect is independent of circulating platelets or of eicosanoid generation (9). An immediate and a delayed increase in airway microvascular leakage of radiolabeled albumin has been observed upon intratracheal administration of PAF, associated with a concomitant exudation of plasma proteins across the airway epithelium (11). Whether PAF-induced airway microvascular leakage and oedema results in airway narrowing *in vivo* is difficult to establish directly. In man, PAF-induced bronchoconstriction is only partially inhibited by a dose of a β-agonist that completely blocks a similar degree of bronchoconstriction induced by the smooth muscle constrictor, methacholine (12). It is possible that the response which is resistant to the β-agonist represents the effect of oedema.

Effect on circulation and bronchoalveolar cells. When inhaled by normal and asthmatic subjects, PAF induces a profound transient neutropenia, with a rebound neutrophilia after 15 min (6,12). No significant decrease in platelet count was observed. The decrease in circulating neutrophils may result from haemodynamic factors such as slowing of pulmonary blood flow induced by PAF; in addition, PAF has been shown to cause an increase in the rigidity of cell membrane structures leading to the trapping of cells within the pulmonary capillary bed. In man, circulating neutrophils become hypodense within 15 min of inhalation, as a result of an increase in cell volume, probably indicating neutrophil activation which would predispose toward an increased adherence to the endothelium (13). Following PAF inhalation, circulating platelets do not show desensitization of PAF-induced aggregation *ex vivo*; by comparison the release of chemiluminescence from circulating neutrophils by PAF is reduced at 90 min (14). Thus, *ex vivo* platelet desensitization to PAF cannot be used as evidence against endogenous PAF release.

Four hours after PAF inhalation, there is an approximate 2-fold increase in neutrophil recovery in bron-

Abbreviations: LysoPAF, lyso platelet-activating factor, 1-*O*-alkyl-*sn*-glycero-3-phosphocholine; PAF, platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine.

choalveolar lavage fluid without any significant increase in eosinophil counts in normal volunteers (13). In allergic subjects, intradermal injections of PAF causes a selective cutaneous accumulation of eosinophils (15), raising the possibility of a selective response of eosinophils of allergic subjects to PAF.

Bronchial hyperresponsiveness. PAF induces an increase, sometimes, prolonged, in bronchial responsiveness to methacholine and histamine in several species including man (1,4,16–18). Normal subjects demonstrate a mean 3-fold increase in bronchial responsiveness at 3 days, with a continuing effect for 1–3 wk (1). By comparison, asthmatic subjects do not show an overall increase in airway responsiveness (6). The lack of response observed in asthmatic subjects may reflect the difficulty in further enhancing inflammatory mechanisms that are maintaining bronchial hyperresponsiveness in the asthmatic and that would not be present in the normal subject. The mechanisms underlying PAF-induced bronchial hyperresponsiveness are of interest and may involve eosinophil accumulation and interaction with airway epithelial cells (see below).

INTERACTION OF PAF AND EOSINOPHILS

Human eosinophils, of all types of circulating cells, possess the PAF precursor, alkylacylglycerophosphocholine, in highest abundance (19). Purified human hypodense eosinophils, which are found in increasing amounts in the circulation of asthmatic patients (20), release PAF after IgE- (but not IgG-) mediated activation (21). PAF is a potent activator of human eosinophils. Specific binding of the labeled PAF antagonist [^{3}H]WEB 2086 has been described on isolated human eosinophils, with similar affinity and number of binding sites as on human neutrophils (22). Activation of eosinophils by PAF results in an early rapid rise in intracellular calcium followed by the release of granule-associate enzymes such as eosinophil peroxidase (23,24). Incubation of guinea pig eosinophils with PAF for 2 hr resulted in a significant reduction in the density of these cells (25), thus reproducing the hypodensity of circulating eosinophils found in asthma. Electron microscopy of eosinophils, after incubation with PAF, revealed degranulation of dense-core vesicles, with some increase in cell volume (25). PAF also induces a dose-dependent enhancement of eosinophil cytotoxicity (26) and is one of the most potent chemotactic and chemokinetic mediators for eosinophils *in vitro* (27); it also promotes the adhesion of neutrophils and eosinophils to vascular endothelial cells (28).

This interaction between PAF and eosinophils may be crucial in the pathogenesis of the bronchial hyperresponsiveness of asthma and may be self-perpetuating and self-enhancing. Our hypothesis is that release of granule-associated enzymes such as eosinophil peroxidase, eosinophil cationic protein and major basic protein from the eosinophil induced by PAF may result in damage to airway epithelium, which is another pathological hallmark of asthma (29). Epithelial damage may in turn contribute to bronchial hyperresponsiveness by several mechanisms. These include loss of a putative epithelial-derived relaxant factor, or activation of exposed airway afferent nerves by mediators, or the production of inflammatory mediators (30). We recently incubated guinea pig tracheal segments with eosinophils *in vitro* and found extensive epithelial damage and reduction in ciliary beat frequency when PAF was added to the preparation (31). This effect was not seen with lyso platelet activating factor (lysoPAF). PAF on its own had no cytotoxic effect on the epithelium. These results suggest that epithelial damage may occur through the interaction of PAF with eosinophils.

PAF ANTAGONISTS

Specific and potent PAF antagonists are now available for studying the role of PAF in asthma (32). Several studies have been reported on the effect of PAF antagonists in animal models concerned with induced bronchial hyperresponsiveness and late phase responses. For example, WEB 2086, a triazolobenzodiazepine PAF antagonist, inhibits the late response after challenge with Ascaris antigen in allergic sheep, without affecting the early response (33). BN 52021, the ginkgolide PAF antagonist, inhibits ovalbumin-induced bronchial hyperresponsiveness, and eosinophil recovery in bronchoalveolar lavage fluid in ovalbumin-sensitized guinea pigs (34). These observations suggest that PAF may be involved in the pathogenesis of bronchial hyperresponsiveness through the recruitment and activation of circulating eosinophils.

To date, there are virtually no studies on the effects of PAF antagonists on the late phase response or the bronchial hyperresponsiveness after allergen challenge in man. Such studies are currently being conducted. The ginkgolide mixture BN 52063 has recently been shown to inhibit the late phase cutaneous response to allergen in atopic subjects without significantly altering the early wheal response, probably indicating an inhibitory effect of BN 52063 on eosinophil infiltration into the skin (35). Unfortunately, this oral dose of BN 52063 resulted in only a small inhibitory effect against PAF-induced bronchoconstriction in normal volunteers (36). PAF antagonists delivered directly as aerosols to the airways may be more effective. Chronic dosing with the PAF antagonists BN 52063 was associated with beneficial effects in patients with asthma. However, further clinical studies are needed with more potent PAF antagonists.

CONCLUSIONS

Much remains to be understood about the biology of PAF and about its possible role in the inflammatory process in asthma. The interactions of PAF with other mediators, such as those of the lipoxygenase and cyclooxygenase pathways, need to be further clarified. Regulation of the metabolism of PAF in normal and inflamed tissues has to be elucidated, and the localization of PAF receptors in the activation of normal and asthmatic subjects may contribute to our understanding of the mechanism of action of PAF. Interactions between PAF and eosinophil may be crucial in the pathogenesis of bronchial hyperresponsiveness of asthma. We need such information for the interpretation of the results of PAF antagonists in asthma and in planning the best use of PAF antagonists as possible antiasthma agents. The role of PAF and the potential use of PAF antagonists in asthma remain to be elucidated.

REVIEW

The Contribution of Platelet-Activating Factor to Allergen-Induced Eosinophil Infiltration and Bronchial Hyperresponsiveness[1]

C.P. Page*
Department of Pharmacology, King's College, University of London, London SW3 6LX, United Kingdom

Platelet-activating factor (PAF) is an ether-linked phospholipid having a range of biological properties of relevance to our understanding of the pathogenesis of bronchial asthma and related allergic diseases. In particular the ability of PAF to induce eosinophil activation and recruitment has received considerable attention. Since in experimental animals PAF and allergen-induced eosinophil infiltration are dependent upon platelet activation, it is suggested that platelet activation may be an important component of the allergic process. The ability of PAF antagonists to inhibit various aspects of the allergic response has been demonstrated in a number of animal models but not all of them have been extended into man. *Lipids 26,* **1280–1282 (1991).**

Eosinophil infiltration into airway tissue (1–3) and bronchial hyperresponsiveness (1–3) are now recognized as central features of bronchial asthma. Eosinophils and their products such as major basic protein and eosinophil cationic protein have been implicated in the pathogenesis of bronchial hyperresponsiveness, in part because they initiate damage to the respiratory epithelium (4–6) suggested as being an essential element of the physiological control of airway smooth muscle responsiveness (7). Despite the fact that many endogenous substances have been shown to be active as chemotactic agents for eosinophils including interleukin-5 (IL-5) (8), eosinophil chemotactic factor of anaphylaxis (ECF-A), and formyl methionyl leucyl phenylalanine (FMLP) (9), very little is known about the mechanisms whereby eosinophils are recruited into the lung following exposure of an allergic subject to an appropriate antigen. It is therefore of considerable interest that platelet-activating factor (PAF) has now been identified as a most potent endogenous chemotactic agent for eosinophils *in vitro* (9) as well as having the ability to induce eosinophil recruitment *in vivo* (10–13).

Additionally, PAF is now recognized as one of the few endogenous mediators capable of eliciting bronchial hyperresponsiveness in both experimental animals (11, 14–17) and in man (18,19). This article will review the contribution of PAF to allergen-induced eosinophil infiltration and bronchial hyperresponsiveness.

[1]Based on a paper presented at the Third International Conference on Platelet-Activating Factor and Structurally Related Alkyl Ether Lipids, Tokyo, Japan, May 1989.

ALLERGEN-INDUCED EOSINOPHIL INFILTRATION

Exposure of sensitized animals to an appropriate allergen results in an inflammatory response which is associated with the infiltration of leukocytes (primarily eosinophils) (11,12,20). Such animal models have therefore been used as possible models of allergic asthma as eosinophil infiltration is known to accompany the exposure of allergic subjects to allergen (1,2). Also, leukocyte infiltration into the lung of allergic animals has been shown to be reduced by pretreatment with clinically useful anti-allergic and anti-inflammatory drugs, such as disodium cromoglycate or glucocorticosteroids (20,21). A number of groups have reported that PAF antagonists will inhibit allergen-induced eosinophil infiltration into the lungs of allergic animals, measured both histologically (12) and by analysis of bronchoalveolar lavage fluid (11). Other investigators have reported that PAF antagonists are capable of inhibiting allergen-induced leukocyte infiltration associated with late-onset airways obstruction in allergic guinea pigs (22), sheep (23) and rabbits (24). It should be noted, however, that some investigators could not demonstrate any beneficial effect of PAF antagonists in models of allergen-induced eosinophil infiltration at concentrations that would inhibit PAF-induced eosinophil infiltration in the same species (25,26). The reasons for these discrepancies are presently not clear.

While corresponding studies have yet to be undertaken in man, PAF is known to induce the recruitment of eosinophils into the skin of allergic (3,27) but not normal subjects (12,28) suggesting that allergic eosinophils respond in a manner different from normal eosinophils, a conclusion borne out by recent *in vitro* data (29). PAF release is also known to accompany the late-onset cutaneous allergic response following i.d. allergen (30), a response believed to parallel in many respects the pulmonary late-onset response to allergen challenge (31) and known to be associated with eosinophil infiltration in both the skin (12,31) and the lung (1,2,31). It is therefore of interest that recently one of the PAF antagonists, BN 52063, has been reported to reduce the late-onset response to cutaneous allergen challenge (32) at a dose thought to be reasonably selective as a PAF antagonist in man (33).

ALLERGEN-INDUCED BRONCHIAL HYPERRESPONSIVENESS

Exposure of sensitized animals to an appropriate allergen results in increased bronchial hyperresponsiveness anything from 1 hr (11,20,34) to 24 hr and beyond (1,11,20) in a manner analogous to that observed in allergic asthmatics following exposure to allergen (1). Many of the mediators implicated in the pathogenesis of asthma (35) have been put forward because of their propensity to

induce bronchoconstriction. One of the interesting properties of PAF is its ability to induce long lasting bronchial hyperresponsiveness to other spasmogens in a number of species including man (14–21). The release of PAF into the lung following allergen exposure may therefore contribute to allergen-induced bronchial hyperresponsiveness. Such a conclusion is supported by experiments from a number of laboratories reporting that a variety of PAF antagonists will inhibit allergen-induced bronchial hyperresponsiveness in a number of experimental models, including the allergic rabbit (24), sheep (23) and guinea pig (11,26). Although PAF has been shown by some investigators (18), but not all (14), to induce bronchial hyperresponsiveness in man, early clinical studies with WEB 2086 have not shown any reduction in allergen-induced hyperresponsiveness in allergic subjects (36).

MECHANISM OF PAF AND ALLERGEN-INDUCED EOSINOPHIL INFILTRATION AND BRONCHIAL HYPERRESPONSIVENESS

It has been shown recently that PAF and allergen-induced eosinophil infiltration in the guinea pig is platelet-dependent because it can be significantly reduced by pretreatment of animals with a cytotoxic anti-platelet antibody or anti-platelet drugs (12). Similar observations have been made in allergic rabbits (37) and normal rabbits (38) although it is not yet known whether platelet dependent eosinophilia is a characteristic of human allergic disease. However, it is now recognized that human platelets can release eosinophil chemotactic factors such as platelet factor 4 and certain lipoxygenase metabolites of arachidonic acid metabolism (39). Furthermore, platelets are a good source of a variety of other chemoattractants such as platelet-derived growth factor and transforming growth factor beta, but it is not known whether these materials have chemotactic activity for eosinophils (39).

Likewise, PAF-induced hyperresponsiveness has been shown to be platelet-dependent in both the guinea pig (14) and rabbit (38), and very recently allergen-induced bronchial hyperresponsiveness in allergic rabbits has been shown to be significantly reduced by pretreatment of the rabbits with a cytotoxic anti-platelet antibody (37). The contribution of platelets to human asthma has been both postulated (39) and questioned (40), but to date there is no evidence for allergen-induced hyperresponsiveness in man being platelet-dependent as the definitive experiments required to prove this hypothesis are difficult to perform in man. Inhalation of PAF by normal volunteers is not associated with overt thrombocytopaenia (41) and this has led to the argument that platelets may not be involved in PAF-induced pulmonary effects in man (41). However, similar observations have been reported in the rabbit (38), yet removal of platelets from the rabbits reduces the ability of PAF to influence both hyperresponsiveness and eosinophil infiltration (38). This suggests therefore that we may have to find more subtle ways of evaluating platelets as inflammatory cells analogous to the experiments of others who have shown that immunoglobin E (IgE)-dependent activation of platelets is not associated with overt aggregation of platelets, but nonetheless is a physiological way of activating platelets which can be inhibited by anti-allergy drugs (reviewed in ref. 42).

CONCLUSION

It would therefore seem likely that platelets can contribute to PAF and allergen-induced bronchial hyperresponsiveness making these cell types legitimate targets for future anti-allergy drugs. While the precise relationships between these cell types remain to be resolved, it would seem prudent to investigate this area more fully, particularly as it relates to human allergic disease.

Platelet Activating Factor-Induced Pulmonary Accumulation of ^{111}Indium-Oxine Labelled Neutrophils in Anesthetized Guinea Pigs[1]

Ursula Hultkvist-Bengtsson[2], Gary P. Anderson[3], Madeleine Kings[4] and John Morley*
Preclinical Research, Sandoz AG, Basel, Switzerland

The thoracic accumulation of neutrophils labelled with ^{111}Indium-oxine in response to infusion of platelet activating factor (PAF, 18 ng/kg/min × 5 min, i.v.) was studied using an automated isotope monitoring system (AIMSplus) in anesthetized guinea-pigs. Loss of cell associated radioactivity *in vitro* was less than 1% over 4 hr. Labelled neutrophils maintained their functional capacity (oxidative response to the cell stimulants N-formyl-L-methionine-L-leucine-L-phenylalanine and phorbol myristate acetate) and >95% viability (ethidium bromide/acridine orange stain) *in vitro*. Total thoracic radioactivity increased significantly from baseline in response to PAF with a slight tachyphylaxia in the neutrophil-accumulation after a repeat PAF infusion. The highest ratios of radiolabel (tissue/blood) were found in the spleen >> liver > lung.
***Lipids 26,* 1283–1286 (1991).**

Polymorphonuclear leukocytes (PMNL), particularly neutrophils, are participants in the acute inflammatory response of the lungs to platelet activating factor (PAF) in experimental animals. Intratracheal instillation of PAF in rabbits causes dose-related structural derangement of the vascular endothelium and bronchial epithelium associated with aggregation of neutrophils within alveolar capillaries and, to a lesser extent, accumulation in alveolar septa (1). In the guinea-pig aggregates of neutrophils, often in association with platelets, within pulmonary arterioles and the submucosal microcirculation are evident histologically within 1 min of intravenous injection of 100 ng/kg PAF (2). In human volunteers, inhalation of PAF causes a transient, marked neutropenia (3).

Previous investigations of the responses of radiolabelled neutrophils to inflammatory mediators have concentrated on skin lesions or peritoneal accumulation *in vivo*, or on neutrophil adhesion to cultured endothelium obtained from large vessels *in vitro*. However, the lung is a highly specialized organ and the properties of the pulmonary vascular endothelium are likely to differ markedly from endothelium in other vascular beds. Currently it is difficult to isolate and culture endothelial cells *in vitro* from the lung microvasculature, a critical tissue in inflammatory reactions. Novel approaches are therefore required to investigate the interactions of the lung and leukocytes in living animals. The objective of the present study was to adapt the techniques of external monitoring of radiolabelled platelets (4) to the investigation of PAF-induced pulmonary neutrophil accumulation in the anesthetized guinea-pig.

MATERIALS AND METHODS

Animals. Male albino guinea-pigs (Dunkin-Hartley, KFM, Füllinsdorf, Switzerland), 400–500 g body weight, have been used in this study. The animals were initially anesthetized with a combination of ketamine (30 mg/kg s.c.) and xylazine (3 mg/kg i.m.). Anesthesia was maintained throughout the experiment by intravenous infusion of ketamine (15 mg/kg/hr). Catheters were inserted into two external jugular veins (for cell and drug administration) and one carotid artery (for blood pressure recordings, Statham-Gould P23 pressure-transducer and Buxco, model 6 analyzer). Body temperature was monitored rectally and maintained between 37–38°C by a heating pad.

Cell isolation and labelling. About 40 mL of blood was taken by heart puncture into citrate buffer from ether anesthetized donor animals. The blood was added to a mixture of Hypaque/methylcellulose and the red blood cells were allowed to sediment. The leukocyte rich plasma was removed and washed in HBSS (Hanks' balanced salt solution) buffered with HEPES containing bovine serum albumin (BSA). Centrifugation on a discontinuous Percoll gradient was used to separate the neutrophils from the other leukocytes. The resulting neutrophils were routinely checked for purity (differential counts) and viability using ethidium bromide/acridine orange stain (Becton-Dickinson, San Jose, CA). Functional testing of the neutrophils was performed repeatedly during the course of the methodological development using the nitroblue tetrazolium reduction (NBT) test on 1×10^6 cells/well in microtiter plates (Costar, Badhoeredorp, The Netherlands). This test provides an accurate spectrophotometric index of cell function and is based on the reduction of phagocytosed NBT dye to insoluble blue formazan during stimulus induced oxidative burst causing an increase in optical density (5).

^{111}Indium-oxine (^{111}In-ox: 25 μ Ci/3 × 10^6 cells) was used for radio-labelling of the neutrophils (incubated for 10 min at 37°C). About 10×10^6 neutrophils were injected into each recipient animal. Labelling efficiency and stability (radio-activity ratio of supernatant to cell pellet) were routinely checked. In two animals, the presence of labelled neutrophils in the blood was checked over two hr after cell injection.

External detection of radioactivity. An automated isotope monitoring system (AIMSplus Mumed Ltd., London, England) was used to evaluate the ^{111}In-ox

neutrophil accumulation in the lung. This system previously has been described in detail by Smith *et al.* (4). Four experiments were undertaken in parallel using labelled cells from the same batch. An NaI crystal scintillation detector was positioned over the thorax of a spontaneously breathing guinea-pig placed supine. Ten min after the injection of labelled neutrophils, when the cells were circulating, the spectrometer was normalized to count 10,000 cps (^{111}In-ox measured at 245 keV), in order to compare results between animals injected with slightly different amounts of radioactivity. Basal count rates were monitored for a further 30 min prior to challenge. The radioactivity was monitored continuously and count rates were stored on an IBM AT computer.

PAF administration. Two infusions of PAF (1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine; Nova Biochem, Läufelfingen, Switzerland) were given i.v. by a precision pump in a dose of 18 ng/kg/min for 5 min with 1-hr interval between doses. PAF was dissolved in ethanol and diluted in saline containing 0.25% BSA (final ethanol concentration <0.005%). The BSA-saline vehicle was used as a control infusion.

In vitro *gamma scintillation of dissected organs.* At the end of the experiment, the animals were killed by an overdose of pentobarbital and dissected. Samples (lung, liver, spleen, heart, kidney, ileum, skin, urine, plasma, bone marrow, whole blood) were counted in a well counter (LKB compugamma scintillator) and the ratio between the organ activity and the whole blood activity was calculated.

Statistics. Data are presented as mean ± SD. One-way analysis of variance (ANOVA) over time was used for statistical evaluation within the treatment and control groups.

RESULTS

The cell isolation technique utilized gave a >90 ± 5% pure neutrophil population with a viability of 95 ± 5%. Microscopic examination of the isolated neutrophils revealed that the cells comprised a single cell suspension. The phagocytic and metabolic functions of the isolated neutrophils were evaluated by the NBT-assay, indicating that the cells were still responsive to a stimulus and were not desensitized by *in vitro* handling. This was indicated by a dose-dependent free radical release induced by PMA (7.4×10^{-10}–10^{-6} M, increase in optical density at 540 nm up to 135% from the control value) and FMLP (1×10^{-10}–10^{-6} M, increase in optical density at 540 nm up to 82% from the control value).

Labelling efficiency was found to be> 50%, comparing the activity in the cell pellet with total added activity. The loss of activity from the cells *in vitro* was found to be <1% over a period of four hours. About 90% of the total activity injected into the animals was associated with the cells.

Total thoracic radioactivity in our experimental model represents the net pulmonary retention and efflux of radiolabelled neutrophils. Initially there was a quick release of labelled neutrophils from the lung that slowed after about 25 min from the time of injection. About 35% of the initial ^{111}In-activity had left the thorax region after 25 min. The presence of labelled neutrophils measured as ^{111}In-activity in peripheral blood was found to stabilize after 10 min at about 50% of the peak value determined just after cell injection. The response of radiolabelled neutrophils to intravenous PAF (18 ng/kg/min) is shown in Figure 1. Infusion of PAF caused an acute increase in thoracic radioactivity that peaked at 5 min and fell below pre-infusion levels over a 20-min period. Repeated doses of PAF confirmed that the neutrophils remained functional during the experiment and were only slightly desensitized to the agonist. The first PAF-infusion caused a transient decrease in basal blood pressure (base value 48 ± 8 mmHg) of 30% after 5 min. The second infusion induced a similar but deeper hypotension (45% of base-line) at 6 min.

The highest ratios of radiolabel (tissues/whole blood) in the samples were found in the spleen (52.4 ± 18.8), liver (21.4 ± 8.2) and lung (11.3 ± 9.0). The other samples showed ratios of less than 3.

DISCUSSION

The principal findings of this study are that ^{111}In-ox labelled neutrophils retain functional capacity and viability, and circulate in peripheral blood. In response to intravenous infusion of PAF, the neutrophils accumulated in the lungs of the guinea pigs. The use of external radiation detection of labelled cells has allowed the kinetics of this response to be monitored accurately in real time.

Under the experimental conditions employed in this study the neutrophils became only slightly desensitized to a repeat infusion of PAF. The data suggest that the accumulation of neutrophils in the thorax cannot be accounted for by removal of PAF-damaged neutrophils by the pulmonary circulation. A similar maintenance of functional capacity and lack of tachyphylaxis to leukotriene B_4-induced pulmonary accumulation of ^{111}In-tropolonate labelled neutrophils in the guinea pig *in vivo* has been reported (6). The organs with the highest radioactivity counts in the present study were the spleen and the liver, a finding consistent with the physiological role of these organs as the major clearance sites of neutrophils from the circulation (7). Our experiments cannot resolve whether neutrophils (which are normally short-lived) were damaged by the isolation and labelling procedures and were cleared by the spleen and liver prior to PAF infusion, or were removed from the circulation after PAF exposure. Under normal conditions, the lungs comprise the major pool of blood neutrophils, which may account for the relatively high basal radioactivity of this organ.

The mechanism of neutrophil accumulation after PAF infusion is not known. It is unlikely that the increase in thoracic radioactivity observed after infusion of PAF was an artifact secondary to an increase in thoracic blood volume since PAF infused at the same dose under identical conditions did not cause an increase in thoracic radioactivity when guinea pigs were injected with ^{111}In-labelled erythrocytes, a cell unresponsive to PAF and therefore suitable for use as a marker of thoracic blood volume (4).

Several possible mechanisms may cause neutrophils to be retained within the pulmonary vasculature in response to PAF with a time course consistent with the results of the present study. Firstly, PAF causes direct aggregation of neutrophils *in vitro* (8). Trapping of such aggregates within the microvasculature and their subsequent

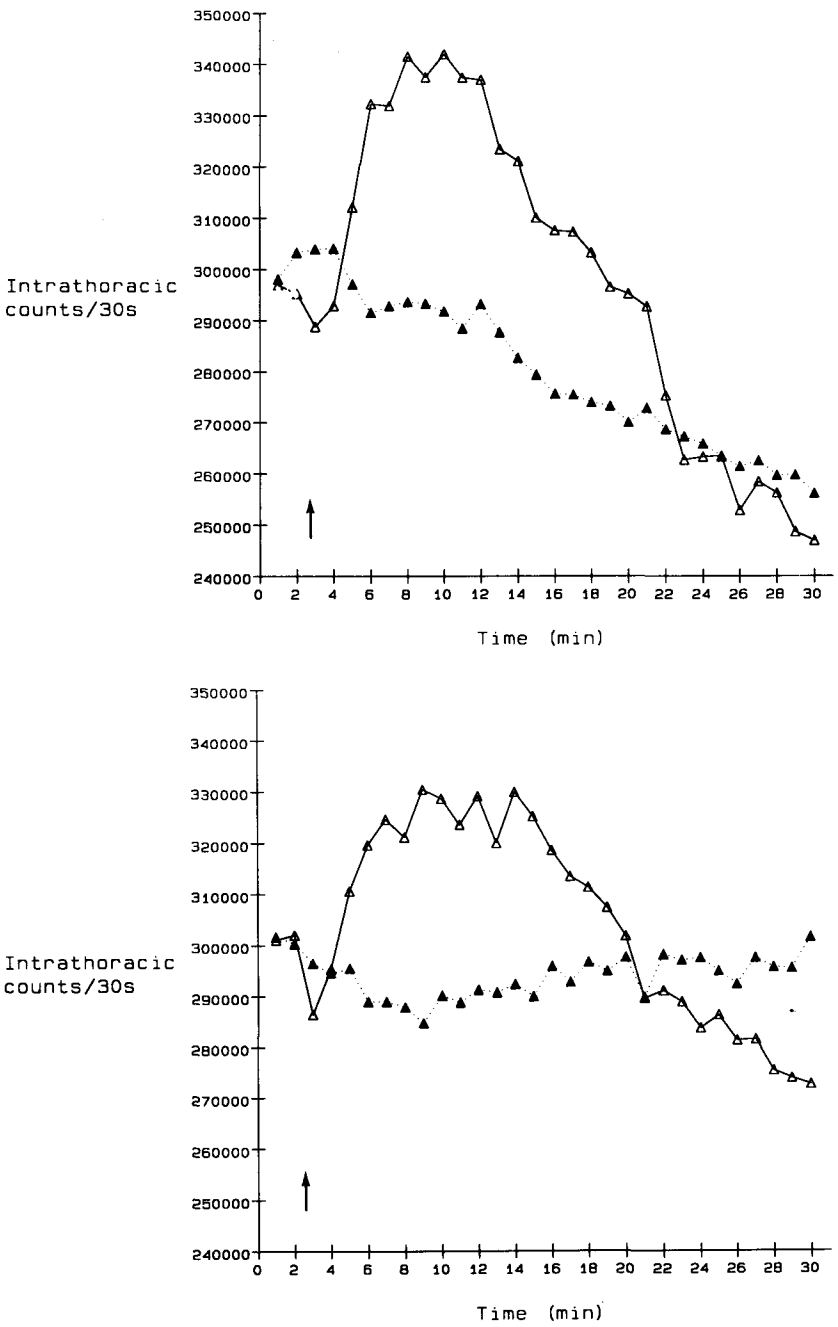

FIG. 1. Effect of i.v. PAF-infusion (18 ng/kg/min, 5 min) on thoracic accumulation of radiolabelled neutrophils. Points represent the mean group value. Top: First infusion (at arrow); Δ-Δ, PAF n=9 p<0.001; ▲-▲, BSA n=7 p<0.001. Bottom: Second infusion (at arrow); Δ-Δ, PAF n=9 p<0.001; ▲-▲, BSA n=6 n.s. One-way analysis of variance (ANOVA) over time was used within the treatment and control groups.

disassociation would account for both the peak and decline in radioactivity but may not explain the fall below the pre-challenge baseline count rate. The present study does not exclude the possibility that PAF simultaneously recruits circulating neutrophils into the lungs and causes detachment of pooled neutrophils altering the ratio between labelled and unlabelled cells that are retained within the pulmonary vasculature. Secondly, PAF also causes platelets to aggregate and to be retained within the lungs (4). Histological sections of guinea pig lungs exposed to PAF have revealed intravascular co-aggregates of neutrophils and platelets (2). Since platelets stimulated by PAF *in vivo* under similar experimental conditions to those of the present study spontaneously aggregate and disaggregate with a time course similar to that observed for neutrophils in the present study (4), it is possible that the increases in thoracic radioactivity we observed represent the trapping of neutrophils in intravascular platelet

aggregates. Finally, investigations into the mechanisms of neutrophil/endothelium interactions have revealed the existence of inducible adhesion molecules, termed leukocyte integrins, which may mediate rapid adhesion of neutrophils to endothelium in response to chemotactic stimuli (9). The contribution of such molecules to the effects of PAF observed in the present study remains to be determined.

Since the present studies suggest that PAF-induced accumulation of neutrophils in the lungs is a transient event, but histological evidence (2) indicates that neutrophils leave the vascular compartment rapidly after stimulation, several important questions remain to be answered. It will be of interest to determine whether inhibition of transient neutrophil accumulation can affect emigration of this cell type from intravascular spaces and whether those cells that emigrate through the endothelium are part of the marginated pool rather than newly recruited neutrophils. Further investigations into the mechanisms and implications of pulmonary neutrophil accumulation in response to PAF are in progress in this laboratory.

Platelet Activating Factor Induced Respiratory Mucosal Damage[1]

Ken-ichi Hisamatsu*, Tetsuya Ganbo, Tsutomu Nakazawa and Yoshihiko Murakami
Department of Otorhinolaryngology, Yamanashi College of Medicine, Tamaho-cho, Nakakoma-gun, Yamanashi 409-38, Japan

Human sinus mucosal specimens from eight normal individuals were exposed to platelet activating factor (PAF) at concentrations ranging from 10^{-6} M to 10^{-11} M in a humidified CO_2 chamber at 37°C. The mucosal surface of the specimens was recorded on video tapes and magnified 2,500 times on a 19-inch television (TV) monitor. Ciliary activity of each ciliated cell was photoelectrically measured on the TV monitor in real time. PAF induced mucosal damage which resulted in a coarse profile including ciliostasis and exfoliation of epithelial cells. The length of the incubation period in which the initial coarse profile occurred on the mucosal surface inversely correlated with the concentration of exposed PAF ranging from 10^{-6} M to 10^{-10} M with $r = -0.712$ ($p < 2 \times 10^{-4}$). Both the control medium and 10^{-8} M lysoPAF showed no effect on ciliary activity or mucosal surface alteration even after 24 hr of exposure. Significant ciliary inhibition was noted after 6 hr of exposure to PAF at concentrations of 10^{-8} M and 10^{-10} M ($p < 0.05$). After 10 hr of exposure, significant ciliary inhibition ($p < 0.01$) was noted at all concentrations. Inhibition occurred in a time- and dose-dependent manner. The length of the incubation period in which initial ciliostatis occurred and the level of PAF concentration showed an inverse correlation with $r = -0.918$ ($p < 10^{-6}$). These results indicate that PAF is cytotoxic to human respiratory mucosa.

***Lipids* 26, 1287–1291 (1991).**

Although various types of chemical mediators have been proposed in inflammatory disorders, there are few reports on their cytotoxic effect on the respiratory mucosa. In addition, there has only been limited research on inflammatory mediators and/or factors which have the capacity to damage the respiratory mucosa, *i.e.*, neutrophil-derived elastase, superoxide, and eosinophil granule cationic proteins.

Platelet activating factor (PAF) is thought to be an important chemical mediator in respiratory diseases, because it has various potent biological activities such as vasodilation, increased blood vessel permeability, enhanced mucosal gland secretion, and contraction of smooth muscles. Furthermore, PAF induces an accumulation of eosinophils (1) which have the capacity to generate more PAF (2), as well as leukotriene C_4 (3) and superoxide (4). Therefore, PAF has been thought to be involved in the pathogenesis of respiratory allergy through eosinophil-induced mucosal epithelial damage which leads to nonspecific hyperresponsiveness (5).

Although various pharmacological activities of PAF have been reported to date, there is little information on the effect of PAF on the mucosal epithelium.

The mucociliary transport system is an important respiratory defense mechanism. However, in patients suffering from chronic inflammation of the airway, infiltration of the respiratory mucosa by inflammatory cells can be observed. The system's dysfunction results in mucus being retained which contains a considerable number of inflammatory cells. Furthermore, these cells release PAF and LTB_4 resulting in a vicious cycle where the number of inflammatory cells is increased which further increases the release of mediators. This enhances and causes long-lasting clinical symptoms of the respiratory tract.

In the present paper we describe PAF-induced ciliary inhibition of normal human paranasal sinus mucosa *in vitro*. Ciliostasis and mucosal damage are also described. The lowest PAF concentration to induce mucosal damage in our experiments was 10^{-10} M, which is approximately the same as what occurs in nasal secretions (6).

MATERIALS AND METHODS

Mucosal specimens and testing solution. The mucosal specimens were obtained at the time of surgery from the paranasal sinuses of eight patients who had suffered trauma to that region as a consequence of traffic or sporting accidents. None of the eight patients were smokers or suffered from nasal diseases prior to the accidents.

The specimens were transferred to Eagle's minimal essential medium (MEM) containing Kanamycin, 60 mg/L and 20% fetal calf serum (FCS). They were rinsed in the culture medium and cut into pieces approximately 3 × 5 mm. The specimens were then transferred onto a collagen layer in 35 × 10 mm culture dishes which were prepared with collagen for tissue culture and maintained in Eagle's MEM under 5% CO_2 at 37°C.

Three solutions were used in the study. The PAF solution was made by dissolving PAF(C_{16}) in methanol at a concentration of 10^{-2} M. This solution was then diluted with Eagle's MEM without FCS from 10^{-6} M to 10^{-11} M. The 10^{-8} M lysoPAF(C_{16}) solution and the control solution of 10^{-8} M methanol / Eagle's MEM without PAF were prepared in the same manner.

Recording of the mucosal surface profile. The procedure for observation and recording of the mucosal surface profile was described in detail elsewhere (7). Briefly, the experiments were performed under 5% CO_2 at 37°C using a humidified CO_2 chamber equipped with an

Ciliary Activity of the Control and Test Groups at the Onset[a]

Group	N[b]	Hz (mean±SD)	
Control	4	11.0	0.54
10^{-6} M PAF	4	11.0	0.66
Control	3	11.3	0.20
10^{-8} M PAF	3	11.3	0.31
Control	4	10.9	0.51
10^{-9} M PAF	4	10.7	0.59
Control	4	10.8	0.45
10^{-10} M PAF	4	10.8	0.53
Control	3	10.9	0.38
10^{-11} M PAF	3	10.8	0.28
Control	3	11.2	0.12
10^{-10} M lysoPAF	3	11.3	0.14

[a]There were no significant differences at the onset of exposure to PAF between the ciliary activities of each control and test group nor among the test groups.

[b]"N" = the number of experiments performed.

inverted phase-contrast microscope and a television (TV) camera connected to a video tape recorder (VTR) system. The mucosal surface profile was recorded on a video tape and it was magnified approximately 2,500 times on a 19-inch TV screen. The magnified width of a single ciliated cell was about 25 to 30 mm on the screen. Ciliary activities of the individual cells on the TV monitor were measured photoelectrically. If the number of ciliostatic cells increased to more than 25% of all observed cells, the recording was discontinued. Portions of the mucosal specimens used in this study were examined under a light microscope. Only mucosal specimens which appeared to be normal, without inflammatory cell infiltration and with intact surfaces, were used for the tests.

Alterations of mucosal surface profiles were observed and categorized into three groups: i) coarse profile—early phase of exfoliation (may or may not include some exfoliated cells); ii) exfoliation—where xfoliation is clearly observed; iii) ciliostasis—a complete cessation of ciliary movement.

Statistical analysis. Student's t-test was used to compare the ciliary activity of each control specimen with the test group at the onset of exposure to PAF and lysoPAF. Analysis of variance for repeated measures was employed for the effect of PAF on the ciliary activity at concentrations of 10^{-8} M, 10^{-9} M and 10^{-10} M, and changes in the ciliary activity in the time course were analyzed by Scheffé's multiple comparison at the $p<0.05$ (*), $p<0.01$ (**) and $p<0.001$ (***) levels. Common regression lines were established between PAF levels and the length of the incubation period for the appearance of: i) coarsening of the mucosal surface and ii) initial ciliostasis. The correlation coefficients between PAF concentration and the length of the incubation periods were calculated.

RESULTS

Effect of PAF exposure on the mucosal surface profile. Mucosal damage which showed coarse profile, ciliostasis, and exfoliation of the epithelial cells was observed following exposure to PAF at concentrations ranging from 10^{-6} M to 10^{-10} M. PAF exposure caused mucosal cell swelling, increasing the volume of their cell body, resulting in coarsening mucosal surface profile and eventually exfoliation. The incubation period required for coarse profile to initially appear showed an inverse correlation with the concentration of PAF ranging from 10^{-6} M to 10^{-10} M with $r = -0.712$ ($N = 18$, $p< 2\times10^{-4}$). The regression equation was calculated

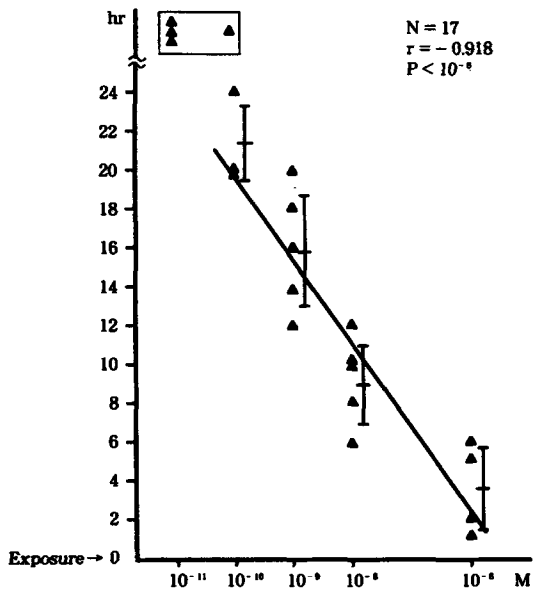

FIG. 2. The length of the incubation period for ciliostasis to initially occur and the PAF concentration showed an inverse correlation with r = − 0.918 (N = 17, p<10⁻⁶). The regression equation is Y = − 4.435 $\log_{10}$X + 24.261. Even after 24 hr, PAF failed to cause ciliostasis at a concentration of 10^{-11} M in all three test groups and in one of four test groups at 10^{-10} M (These groups are indicated inside the rectangle and were not considered in the statistical analysis).

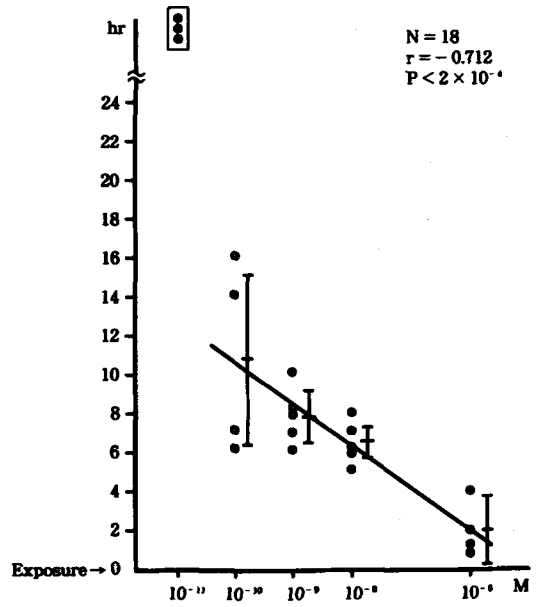

FIG. 3. PAF induced epithelial damage showing coarse profile and exfoliation at concentrations of 10^{-10} M and higher on human sinus mucosal specimens from normal individuals. The length of the incubation period for coarse profile of the mucosal surface to initially occur inversely correlated with the concentration of PAF with r = − 0.712 (N = 18, p<2 × 10^{-4}). PAF failed to cause mucosal damage at a concentration of 10^{-11} M even after 24 hr of exposure (These groups are indicated inside the rectangle and were not considered in the statistical analysis.).

between the incubation period (Y) and the PAF concentration (X): [Y = 10.682 + B $\log_{10}$X; B = −2.109, −3.278 < B < −0.812 (p = 0.01)]. PAF failed to cause alterations of mucosal surface at a concentration of 10^{-11} M even after 24 hr (Fig. 3).

LysoPAF/Eagle's MEM at a concentration of 10^{-8} M and the control groups showed no effect on mucosal surface profile throughout the experiments.

Effects of PAF on ciliary activity of human nasal sinus mucosa. Ciliary activity was measured to investigate cell viability of the ciliated cells of mucosal specimens. There were no significant differences at the onset of exposure to PAF between each control group and test group nor among the test groups (Table 1).

After 2, 6, 10, and 16 hr of exposure to PAF at concentrations of 10^{-8} M to 10^{-11} M, ciliary activity was analyzed in a time-dependent study. After 6 hr of exposure, significant ciliary inhibition ($p<0.05$) was noted at concentrations of 10^{-8} M and 10^{-10} M. After 10 hr of exposure, significant ciliary inhibition ($p<0.01$) was noted at all concentrations (Fig. 1). Ciliary inhibition was not noted in test groups with 10^{-11} M PAF and 10^{-8} M lysoPAF even after 24 hr of exposure.

The correlation between the incubation period required for ciliostasis to initially appear and PAF concentration was analyzed in 17 experiments and showed an inverse correlation with r = −0.918 ($N = 17, p < 10^{-6}$). The regression equation between the incubation period (Y) and the exposed PAF concentration (X) [Y = 24.261 + B $\log_{10}$X; B = −4.435, $-5.894 < B < -2.976$ ($p = 0.01$)] showed a linear relationship. The results clearly indicate that PAF induced slow reacting ciliary inhibition in a time- and dose-dependent manner at concentrations of 10^{-10} M or higher (Fig. 2).

DISCUSSION

One of the important clinical characteristics of respiratory allergic diseases is nonspecific hyperresponsiveness of the respiratory tract. Symptoms, such as sneezing attacks, hyperrhinorrhea, nasal obstruction, asthmatic attacks, etc. are even easily provoked by non-specific irritations. Therefore, it is necessary to understand the mechanisms of hyperresponsiveness of the respiratory tract for the clinical management of allergic patients.

Epithelial damage exposes sensory nerve endings resulting in mucosal nonspecific hyperresponsiveness. In addition it has been suggested that axon reflexes (8) exist at the sites of the exposed sensory nerve endings releasing neuropeptides such as substance P and calcitonin gene-related peptide, which may cause hypersecretion, smooth muscle contraction and also extravasation resulting in mucosal edema. Following epithelial damage, it is also suggested that putative epithelial-derived relaxant factor (9,10) and secretory inhibitory factor (11) might be reduced resulting in hyperresponsiveness of the lower respiratory tract. Thus, the mucosal epithelial damage and dysfunction are thought to be attributable not only to the disturbance of the muco-ciliary transport system resulting in exacerbation and sustained clinical symptoms, but also to the nonspecific hyperresponsiveness of the respiratory tract.

PAF is a unique chemical mediator because PAF inhalation causes not only immediate symptoms and sustained airway hyperresponsiveness but also long-lasting inflammation and eosinophilia, in animals (12) and humans (13). Eosinophil accumulation in the respiratory mucosa (14,15) and secretions (16,17) are also one of the distinctive clinical characteristics of respiratory allergic diseases.

Hyposensitivity of the airway to β-adrenergic agonists is a common characteristic found in allergic patients. It has been noted that the incubation of human trachea and lung tissue with PAF decreased the β-adrenergic bronchodilator responsiveness (18). Furthermore, in brain tissue, PAF decreased the density of β-adrenergic receptors (19). This suggests there is a mechanism by which PAF induces hyperresponsiveness by interfering with receptor sites of organ tissues. It is also suggested that PAF acts as a potent regulator of arachidonic acid metabolism and *vice versa* (20,21). Therefore, other inflammatory mediators such as leukotorienes and prostaglandins may possibly mediate PAF actions *in vivo*; however, they do not sustain airway hyperresponsiveness by themselves (22,23).

Presently it is believed that non-specific hyperresponsiveness of the respiratory tract is caused as a consequence of the inflammation following allergen challenge, *i.e.* the late phase response which is characterized by eosinophilic inflammation (24). This hypothesis has been further supported by the following advances in research on PAF and eosinophils. It has been reported that PAF is the most potent eosinophil chemotactic agent, with activity approximately one-hundred times stronger than that of eosinophil chemotactic factor of anaphylaxis released from mast cells following allergen challenge (25).

Eosinophils predominantly generate PAF (26) although various other inflammatory cells such as neutrophils, monocytes, platelets and macrophages also generate and relase PAF (2,27–29). Thus, there seems to be a "vicious cycle" between PAF and eosinophils. PAF activates eosinophils to release LTC_4 and superoxide. Eosinophil activation and degranulation are also possibly regulated by other inflammatory cells such as macrophages (30), T-cells (31), mast cells (32), basophil (31), etc. Recent studies have shown that eosinophils have cytotoxic proteins such as eosinophil granule major basic protein (MBP) (33), eosinophil cationic protein (ECP) (34), eosinophil peroxidase (EPO) (35) and eosinophil-derived neurotoxin (EDN) (36) which are released as a reaction to allergen challenge and/or other stimuli (31). MBP deposition and mucosal damage to the respiratory tract mucosa were observed in chronic sinusitis and/or asthmatic patients (15). Our recent study on MBP cytotoxicity showed human MBP induced human sinus mucosal damage *in vitro* at concentrations from one to ten μM which were achieved *in vivo* (7).

In the present study, living ciliary epithelium were investigated before and after exposure to PAF *in vitro*. Ciliary activity was measured, since it seems to be the best parameter for ciliated cell viability. One of the advantages of departing from the traditional forms of measurement and using our video tape recorder (VTR) system, which records mucosal surface profile in real time, is that the time course of up to 15 ciliated cells per mucosal specimen could be measured throughout the experimental period. Furthermore, since each single cell was magnified 2,500 times, we could easily observe morphological changes (*i.e.* swelling of the cell body which resulted in coarsening mucosal surface and eventually cell exfoliation, and ciliostasis) (7).

Although the mucosal specimens came from 8 normal subjects, all specimens showed a smooth profile, and data obtained showed no significant differences in ciliary activities at the onset of the experiment between controls and tested mucosa nor among the test groups. Furthermore, there were no significant changes in ciliary activity in the controls throughout the experiments, creating a high internal validity.

Cytotoxicity of PAF was noted *in vitro* in a time- and dose-dependent manner (Fig. 1, Fig. 2 and Fig. 3), whereas lysoPAF showed no effect on ciliary activity, nor caused mucosal surface alterations. Although PAF induces a slow reactive effect on sinus mucosa and possibly changes to lysoPAF during culture with mucosal tissues, we feel there is little if any possibility that second messengers induced the mucosal dysfunction and damage obtained in the present study because of the absence of inflammatory cells. In another study, we showed that after one-hour exposure to 10^{-8} M PAF followed by irrigation of the culture medium, ciliary inhibition and mucosal damage occurred. These data suggest that PAF exerts its impact on the mucosal epithelium within one hour of exposure, followed by slow reactive damage.

In order to verify that PAF exposure specifically induced ciliary inhibition and epithelial cell damage, we investigated the effect of CV-3988, a specific PAF receptor antagonist, on the slow reactive phenomenon following PAF exposure. CV-3988 completely inhibited PAF-induced slow reactive mucosal damage (Ganbo, T., and Hisamatsu, K., unpublished data). These results suggest that PAF directly induced mucosal damage through the receptor site of the respiratory mucosal cells.

The mechanism of PAF-induced cell damage is not known in detail. However, swelling of the cell body was consistently observed on the TV monitor during the process of mucosal surface alteration. This is possibly the result of an influx of extracellar liquid into the cell. Furthermore, in a previous paper we had reported that PAF induced ultrastructural alteration of epithelial cells, such as atypical vacuoles, swollen mitochondria, and increasing secondary lysosomes prior to significant ciliary inhibition and mucosal surface alteration (37).

In the present study, the lowest concentration of PAF that induced the mucosal damage appears to be 10^{-10} M. This is particularly interesting in light of a recent study that achieved an approximate concentration of 10^{-10} M in nasal washings from patients with allergic rhinitis (6).

Based on the data obtained in this study, we propose that PAF cytotoxicity may contribute to the dysfunction of the airway muco-ciliary transport system in inflammatory respiratory diseases. Especially in respiratory allergies, eosinophil-derived PAF may contribute to mucosal epithelial damage leading to nonspecific mucosal hyperresponsiveness and persistency associated with cytotoxicity of eosinophil cationic proteins. The results from the present study support that PAF cytotoxicity may also contribute to the mechanisms which induce tissue damages *in vivo* which have been reported recently

(38,39). Details of the mechanism of PAF-induced cytotoxicity and the regulation of cytotoxicity *in vivo* remain to be elucidated.

It recently has been recognized that platelet-activating factor (PAF) may be a mediator of asthma exacerbation. We had the opportunity to analyze bronchoalveolar lavage fluids from an asthmatic infant, which were characterized by neutrophil infiltration. The patient's lungs were washed on three occasions with saline during asthmatic attacks. PAF was found in each case on the basis of its ability to cause the immediate aggregation of washed rabbit platelets. The PAF detected was equivalent to 1-1.4 pmol of 1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine, three quarters of which were recovered in cell-associated form. By contrast, we did not detect PAF in bronchoalveolar exudates from patients with laryngeal stenosis or with respiratory distress syndrome. LysoPAF, the direct precursor as well as initial metabolite of PAF, was also analyzed after being converted to PAF by acetylation. There was a wide variation in the amount of lysoPAF present in individual patients, suggesting that lysoPAF levels cannot be taken as an indicator for the presence of PAF.

***Lipids 26,* 1292–1296 (1991).**

Platelet-activating factor (PAF) is attracting considerable attention as a potential mediator of bronchial asthma (1). Several findings suggest that PAF is involved in human asthma. Alveolar macrophages from asthmatic patients release PAF when stimulated with specific antigens (2). In addition, human inhalation of PAF as an aerosol causes an immediate dose-dependent bronchoconstriction, as well as an increase in nonspecific bronchial responsiveness (3). In bronchial provocation tests to allergens in asthmatic patients, BN 52063, a specific antagonist to PAF, significantly ameliorated early bronchoconstriction and showed a tendency to inhibit residual bronchial hyperreactivity (4). However, there has been no report of PAF being detected in bronchoalveolar lavage fluids (BALF) from asthmatic patients.

In relation to the development of lung function, we have analyzed surfactant phospholipids with special attention being paid to the perinatal period (5). The present study was undertaken to examine whether PAF can be detected in BALF from asthmatic patient.

MATERIALS AND METHODS

Chemicals. 1-*O*-Hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine (1-*O*-hexadecyl-2-acetyl GPC) and 1-*O*-hexadecyl GPC were purchased from Novabiochem AG (Läufelfingen, Switzerland). 1-Palmitoyl, 1-stearoyl and 1-oleoyl GPC were from Sigma Chemical Co. (St. Louis, MO). Acyl analogues of PAF were synthesized from acyl GPC by reaction with acetic anhydride in the presence of perchloric acid as catalyst (6). Bovine serum albumin (BSA) was obtained from Sigma. Silica Gel 60 and *tert*-butyldimethylchlorosilane were from Merck (Darmstadt, Germany) and Applied Science (State College, PA), respectively. Calcium ionophore A23187 (IoA23187) was from Calbiochem (San Diego, CA). Formyl-methionyl-leucyl-phenylalanine (fMLP) was obtained from the Protein Research Foundation (Osaka, Japan). IoA23187 and fMLP were each dissolved in dimethylsulfoxide at a concentration of 1×10^{-3} M. fMLP was diluted ten-fold with saline. CV-3988 and L-652,731 were kindly donated by Takeda Pharmaceutical Co. (Osaka, Japan) and Merck (Rahway, NJ), respectively. Phospholipase C (EC 3.1.4.3) was prepared from *Bacillus cereus* culture medium (7). All other chemicals were of reagent grade.

Patients. BALF and bronchoalveolar exudates were obtained from patients which were in our hospital for medical attention. These included an 11-month-old boy with the clinical symptoms of asthma of the non-atopic type, and a 4-month-old girl with laryngeal stenosis, but without loss of lung function. BALF was obtained from these patients by washing the lungs with a small volume of sterile saline by tracheal cannula. Other patients included newborn infants with respiratory distress syndrome (RDS) and one 14-year-old patient with pneumonia. Bronchoalveolar exudates were recovered from these patients by suction with a tracheal cannula.

Aliquots of BALF and lung exudates in saline were treated with May-Geimsa's stain before characterizing the inflammatory cells by microscopic examination (8). In the cases of asthma and pneumonia, neutrophils were observed; however, the exudates from patients with stenosis and RDS were essentially free of infiltrated inflammatory cells except for mononuclear cells. In each case, the remaining exudate was immediately subjected to lipid extraction.

Extraction and purification of PAF. Total lipids were extracted using the one- and two-phase systems described by Bligh and Dyer (9). Phospholipid content in extracts was determined by the method of Bartlett (10). Total lipids in minimal volumes of chloroform were then subjected to silicic acid column chromatography. Neutral lipids were eluted with chloroform, and phospholipids were recovered thereafter by methanol elution. More than 95% of lipid phosphorus was thus recovered. The total chloroform fraction and one-tenth of the methanol fraction were subjected to bioassay for PAF, but none of the preparations showed platelet aggregating activity. The remaining methanol

Abbreviations: BALF, bronchoalveolar lavage fluid; BSA, bovine serum albumin; IoA23187, Calcium Ionophore A23187; fMLP, formyl-methionyl-leucyl-phenylalanine; GPC, *sn*-glycero-3-phosphocholine; PAF, platelet-activating factor; PC, phosphatidylcholine; RDS, respiratory distress syndrome; SIM, selected ion monitoring; *t*-BDMS, *tert*-butyldimethylsilyl, TLC, thin-layer chromatography.

fractions were subjected to preparative thin-layer chromatography (TLC) on Silica Gel 60 plates together with a standard mixture of lysoPC, sphingomyelin and phosphatidylcholine (PC), and the plates were developed with chloroform/methanol/water (65:35:6, v/v/v). One-cm sections from the origin to the solvent front (16 fractions) were scraped off the plates and the lipids were extracted (9). The extracts were suspended in an appropriate volume of 2.5 mg BSA/mL saline solution. Recovery of PAF by TLC was examined by selected ion monitoring (SIM) (11). When 50 ng of 1-*O*-hexadecyl-2-acetyl GPC and 25 μg of standard phospholipid mixture were applied together to a TLC plate, the recovery, which was determined by measuring the ratio of the ions at *m/z* 117 of acetic acid and *m/z* 120 of perdeuteroacetic acid due to exogenously added internal standard after TLC, was 74 ± 4% (mean ± S.D., n=4). In the present experiment, PAF amounts were calculated using samples purified by TLC and are expressed without correction.

Isolation of neutrophils. Neutrophils were obtained from three healthy adult male volunteers. The isolation procedure, which involved dextran sedimentation, Ficoll gradient centrifugation and hypotonic treatment to lyse erythrocytes, was described previously (12). Both purity and viability of the polymorphonuclear leukocytes were greater than 97%.

PAF bioassay. Washed rabbit platelets were prepared by the method of Pinckard *et al.* (13). PAF was detected on the basis of its ability to cause the immediate aggregation of washed rabbit platelets which was monitored in an aggregometer (Nikko Hematracer PAT-4A, Osaka, Japan). PAF equivalents were determined as described (8), using 1-*O*-hexadecyl-2-acetyl GPC as standard.

Distribution of PAF. To determine the proportions of PAF that remained associated with cell components or were released, fresh BALF in 8 mL saline was centrifuged at 1,600 × g for 15 min at 0°C. The resulting sediment was suspended in 8 mL of cold saline. Both suspension and supernatant were extracted to isolate the PAF fraction which was bioassayed.

Stimulation of human neutrophils. Human neutrophils from citrated peripheral blood were suspended in Tyrode's gelatin solution, pH 7.2, containing 1.3 mM Ca^{2+} at a concentration of 5×10^6/mL. An aliquot was stimulated with 1×10^{-7} M of fMLP or 2.5×10^{-6} M of IoA23187 at 37°C. PAF production was measured at 2.5 min for fMLP and 15 min for IoA23187.

Acetylation of lysoPAF. LysoPAF[2] was measured as PAF after acetylation. The TLC fraction corresponding to lysoPAF was treated at room temperature overnight with 100 μL of acetic anhydride and 100 μL of pyridine (14). After evaporation of the reagent, the residue was suspended in an appropriate volume of 2.5 mg BSA/mL saline. The efficiency of conversion of 1-*O*-hexadecyl GPC to 1-*O*-hexadecyl-2-acetyl GPC was 76.5 ± 10.5% (mean ± S.D., n=6).

Selected ion monitoring. After conversion, the PAF was further subjected to hydrolysis with phospholipase C. The product was then quickly converted to *t*-BDMS derivatives and analyzed using a JEOL JMS-DX 300 instrument equipped with a JMS 3100 computer. The ion at *m/z* 117 was selected for quantitation. The conditions for gas chromatography and mass spectrometry were as described previously (6). The ionization energy was 70 eV.

RESULTS

Detection of PAF in BALF from asthmatic patient. Phospholipid fractions from lung exudates were applied to preparative TLC plates, and each 1-cm fraction was extracted and bioassayed for its ability to elicit platelet aggregation. With BALF from the asthmatic patient, the fraction which migrated directly below the sphingomyelin standard caused immediate and irreversible aggregation of washed rabbit platelets (Fig. 1). Moreover, the aggregating activity was almost completely lost by pretreatment of the platelets with 5×10^{-6} M CV-3988 or 5×10^{-7} M L-652,731, both of which are specific PAF receptor antagonists (Fig. 2).

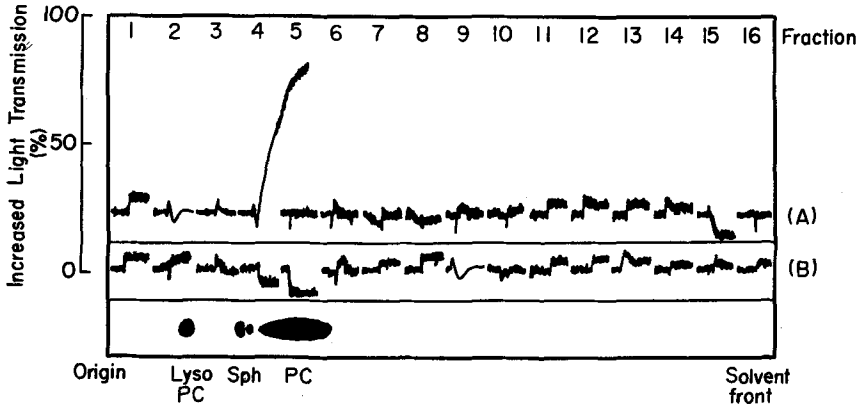

FIG. 1. Thin-layer chromatograms of phospholipid fractions from patients with asthma (A) and laryngeal stenosis (B). Phospholipid fractions, corresponding to 0.53 (A) and 2.41 μmol (B), were applied to Silica Gel 60 plates, developed, and extracted. One-cm fractions from the origin to the solvent front (16 fractions) were eluted and suspended in 200 μL of 2.5% BSA/saline. Ten μL of each fraction was used for bioassay.

[2]The lysoPAF fraction is a mixture of 1-acyl and 1-alkyl species. Upon acetylation, PAF and its 1-acyl analogue are produced, the latter being the major component but exhibiting only negligible biological activity.

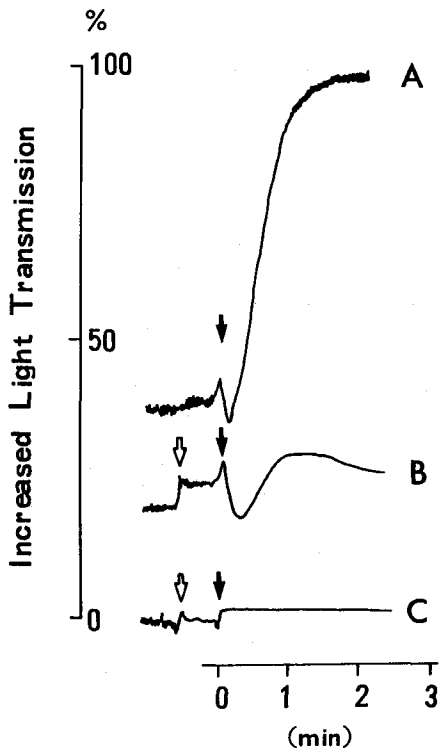

FIG. 2. Platelet aggregation induced by the fraction corresponding to PAF from the asthmatic patient A and its inhibition by antagonist B or C. Open arrows indicate the time when the antagonist L-652,731, B, or CV-3988, C, were added to platelets at the final concentrations of 5×10^{-7} M and 5×10^{-6} M, 1 min prior to the addition of stimuli (closed arrow).

BALF was obtained during three asthmatic attacks that occurred within about three months; in all cases, a similar degree of PAF activity was observed. In contrast, little or no PAF activity was observed in the BALF obtained from the patient with laryngeal stenosis. This was also true of the materials recovered by suction from the bronchoalveolar space of the infants with RDS (Table 1).

TABLE 1

PAF and LysoPAF Detected in Lung Exudates

	Age	Phospholipid (μmol)	PAF[a] (fmol)	LysoPAF (pmol)	Diagnosis
Case 1-1	11 M	1.63	1,206	77	Asthma
Cast 1-2		1.06	1,049	1,060	
Case 1-3		1.56	1,383	128	
Case 2-1	4M	4.84	*b*	53	Laryngeal

Case 5	Newborn	1.97	35	1,005	RDS

[a]1-*O*-Hexadecyl-2-acetyl GPC equivalents.

[b]Below detection threshold.

Distribution of PAF detected in BALF from asthmatic patient. PAF was detected in the supernatant and sediment fractions (327 fmol and 1,056 fmol, respectively) on the basis of its behavior in TLC and against antagonists.

PAF was also detected in the lung exudate from the patient with pneumonia. A level of PAF equivalent to 827 fmol of 1-*O*-hexadecyl-2-acetyl GPC was recovered from the sediment fraction, in which neutrophils were detected by microscopic examination. No PAF was detected in the bronchoalveolar exudates from patients with RDS. Moreover, the phospholipid distributions were quite different (Table 2).

PAF from stimulated human neutrophils. From 1×10^7 neutrophils, PAF activity equivalent to 272 ± 113 fmol (mean ± S.E., n=5) for fMLP and 57 ± 19.2 pmol (mean ± S.E., n=8) for IoA23187 was detected. This was expressed as 2,656 fmol and 556 pmol/μmol neutrophil phospholipids, respectively.

Characterization of lysoPAF. LysoPAF, which is both a direct precursor as well as an initial metabolite of PAF, was analyzed as PAF after acetylation. LysoPAF was more abundant than PAF, as is shown in Tables 1 and 2.

TABLE 2

Distribution of PAF and LysoPAF in Lung Exudates

		Age	Phospholipid (μmol)	PAF[a] (fmol)	LysoPAF (pmol)	Diagnosis
Cases 1-3	sup[b]	11 M	0.46	327	84	Asthma

	sed		0.04	*c*	*c*	

[a]1-*O*-Hexadecyl-2-acetyl GPC equivalents.

[b]In the supernatant fraction, a second platelet aggregating activity was observed on a TLC fraction migrating close to the solvent front. The aggregating pattern induced by this fraction was quite different from that of PAF; there was a delay in the induction of aggregation.

[c]Below detection threshold.

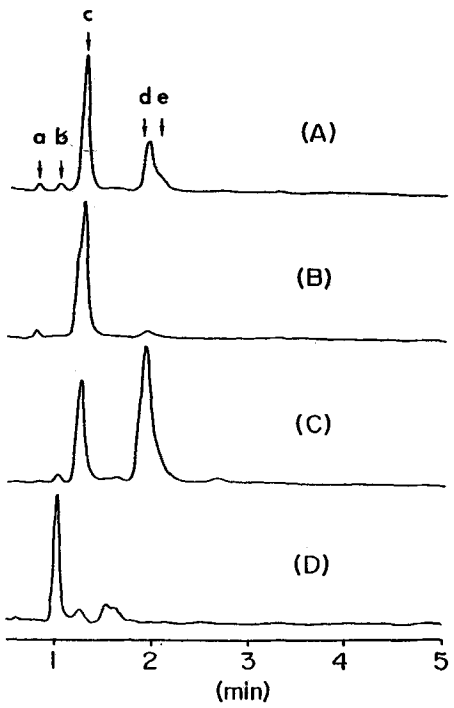

FIG. 3. Selected ion monitoring of lysoPAF. Lyso PAF fractions from patients with asthma (A) and laryngeal stenosis (B), and from human neutrophils (2.5×10^7 cells) (C) were converted to PAF by acetylation. The resulting PAF, as well as the PAF fraction from neutrophils (D), were subjected to hydrolysis with phospholipase C and derivatized. The ion derived from acetic acid at *m/z* 117 was used for selected ion monitoring. The elution times of 1-myristoyl (a), 1-hexadecyl (b), 1-palmitoyl (c), 1-oleoyl (d) and 1-stearoyl (e) derivatives are shown by arrows from left to right in ascending order.

The composition of lysoPAF was analyzed by selected ion monitoring (SIM). The lysoPAF fraction consisted mainly of the 1-acyl analogue with the major component being 1-palmitoyl GPC (Fig. 3). This was evident not only in the lung exudate from the patient with laryngeal stenosis but also in BALF from the asthmatic patient. Though minute in quantity, 1-*O*-hexadecyl species were detected in lysoPAF from the asthmatic patient as well as in the IoA23187-stimulated neutrophils.

DISCUSSION

Bronchial asthma, especially in children, has been thought of solely as an immunologic disorder involving degranulation of mast cells, triggered by antigen *via* an IgE-dependent mechanism. However, not all pathological aberrations in asthmatic patients can be accounted for by allergy (15). The possibility that inflammation is involved in the pathogenesis of asthma was demonstrated by the increased numbers of inflammatory cells in BALF from patients with asthma. We had the opportunity to obtain BALF that had been infiltrated by neutrophils from a child clinically diagnosed as having bronchial asthma. Of the chemical mediators, PAF is now suspected as one of the causative factors in asthma, because it is produced by neutrophils under stimulation (16) and is one of the most potent chemotactic factors of human eosinophils (17,18). In this context, we examined BALF from the asthmatic patient for PAF activity; PAF activity was detected in each of the three times when the patient's lungs were washed with saline during asthmatic attacks. In contrast, we did not detect significant PAF activity in the lung exudates from patients with laryngeal stenosis or RDS, the exudates being essentially free of infiltrated inflammatory cells in both cases.

The amount of PAF detected in the asthmatic patient was calculated as 1–1.4 pmol equivalents of 1-*O*-hexadecyl-2-acetyl GPC. Only one-fourth the amount of PAF was recovered from the supernatant fraction. Assuming that the volume of exudate was 100 μL, the concentration of PAF would be 3.27×10^{-9} M at most, which is insufficient to cause the accumulation of eosinophils (17). Furthermore, the patient was medicated with dexamethazone, which is known to decrease the number of eosinophils (19). The low PAF concentration for chemotaxis and the medication may have been the reasons why we did not detect any significant amount of eosinophils in the airway space. Eosinophils are characteristic inflammatory cells in the late phase of asthma (15).

In BALF from the asthmatic patient, about 1 pmol of PAF per μmol phospholipids was detected. PAF production by human peripheral neutrophils under fMLP stimulation was maximum after incubation for 2.5 min, and the amount was 2.7 pmol per μmol neutrophil phospholipid. Taken together, the PAF amount detected in the asthmatic patient was fairly high.

LysoPAF is a precursor of PAF as well as a metabolite, so it is widely expected that lysoPAF functions as an indicator for the presence of PAF. However, the amounts of lysoPAF varied in the present experiments. Furthermore, unstimulated neutrophils themselves had substantial amounts of lysoPAF; *i.e.*, 530 ± 65 pmol/1 × 10^7 neutrophils (mean ± S.E., n=5). Chemical analyses of the lysoPAF fraction from patients with laryngeal stenosis revealed that this fraction consisted mainly of the 1-palmitoyl analogue [Fig. 3(B)]. The molecular species of the lysoPAF fraction from neutrophils stimulated with IoA23187 also consisted mainly of the 1-acyl form, but the pattern was quite different from that observed in laryngeal stenosis [Fig. 3(C)]. Interestingly, the molecular species of PAF from the same neutrophils consisted mainly of the 1-alkyl form [Fig. 3(D)]. In lysoPAF from asthmatic patient, the percentage of palmitoyl species was decreased compared with that in laryngeal stenosis [Fig. 3(A)], possibly reflecting the contribution of neutrophils in the presence of lung surfactant.

In conclusion, PAF was detected in lung exudates that had been infiltrated with neutrophils from patients clinically diagnosed as having asthma and pneumonia. PAF was mainly cell-associated, as was PAF produced by human neutrophils (12). In contrast, PAF was not detected in the lung exudates that were essentially free of inflammatory cells. This observation is consistent with previous findings (20) that PAF commonly appears in lesions with inflammatory cells accumulation.

ACKNOWLEDGMENTS

This study was supported in part by a Grant-in-Aid for Scientific Research (63480132) and on Priority Areas (63636005) from the Ministry of Education, Science and Culture of Japan, and by the

Science Research Promotion Fund from the Japan Private School Promotion Foundation (1988). We thank M. Furukawa for preparing the washed rabbit platelets.

Platelet-Activating Factor (PAF) in Allergic Diseases: Inhibitory Effects of Anti-Allergic Drugs, Ketotifen and Three Kampo Medicines on PAF Production[1]

Tsuneyoshi Nakamura[a,*], Motoaki Kuriyama[a], Keiko Ishihara[a], Yukio Matsumura[b] and Terumasa Miyamoto[a]

[a]Department of Internal Medicine and Physical Therapy, School of Medicine, University of Tokyo, 7-3-1, Hongo, Bunkyo-ku, Tokyo and [b]Matsumura Clinic and Research Institute for Asthma and Immunological Diseases, 5-52-2, Higashinippori, Arakawa-ku, Tokyo, Japan

Platelet-activating factor (PAF) is considered an important mediator in allergic and inflammatory reactions. To further investigate the role of PAF in allergic diseases, we examined the *in vitro* and *ex vivo* effect of anti-allergic drugs on PAF production by human neutrophils. Ketotifen and three Kampo medicines, which are widely used in the treatment of allergic diseases in Japan, inhibited PAF production by normal human neutrophils dose-dependently, whereas disodium chromoglycate (DSCG) and tranilast did not have any inhibitory effect. Ketotifen also suppressed *ex vivo* PAF production by neutrophils from healthy subjects. PAF production decreased from 40.5 ± 5.0 units to 21.6 ± 4.7 units after oral administration of 2 mg of ketotifen per day for one week. We also measured the concentration of lysoPAF in serum from patients with Japanese cedar pollinosis during the pollen season and followed the effect of ketotifen on lysoPAF levels in the serum from these patients. We found that the concentration of lysoPAF, a precursor and degradation product of PAF, in patients with cedar pollinosis (87.8 ± 8.7 units) was significantly higher than in healthy subjects (54.7 ± 7.7 units). After two weeks, lysoPAF levels decreased significantly (82.6 units to 41.3 units) only in the group treated with nasal aerosol and ketotifen. These results suggest that PAF may play a role in allergic diseases and that the clinical effects of anti-allergic drugs may at least partially be due to their anti-PAF action. *Lipids 26,* 1297–1300 (1991).

Platelet-activating factor (PAF, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) has been recognized as an important mediator in hypersensitivity and inflammation (1). Evidence also suggests that PAF is involved in the pathogenesis of allergic diseases, especially of bronchial asthma in which PAF induces profound bronchospasms, increased vascular permeability, and leukocyte infiltration into the respiratory tract (2,3). Furthermore, the inhalation of PAF by experimental animals has been shown to cause bronchoconstriction and accumulation of inflammatory cells (4,5). We also reported that PAF may participate in the late asthmatic response following antigen inhalation challenge in patients with bronchial asthma (6).

Japanese cedar pollinosis was first reported by Horiguchi and Saito (7). The number of patients affected by this allergy has increased steadily over the years, and between the end of February and early April nearly 10% of the Japanese population suffer from this disease. The main symptoms are sneezing, rhinorrhea, nasal obstruction, anosmia, conjunctivitis, dermatitis, and throat irritation (7,8). The symptoms suggest that Japanese cedar pollinosis is an allergic disease.

In the present study, we examined the effects of anti-allergic drugs on PAF production by human neutrophils. We also measured serum lysoPAF levels of patients with Japanese cedar pollinosis during the pollen season and observed the changes that occurred after treatment with an anti-allergic drug.

MATERIALS AND METHODS

Materials. Neutrophils were separated from heparinized blood by dextran sedimentation. Contaminating lymphocytes were eliminated on a discontinuous gradient, and red blood cells by hypotonic shock. Ten million neutrophils were suspended in Tyrode-BSA (bovine serum albumin) solution to measure PAF production *in vitro*.

Disodium chromoglycate (DSCG), tranilast and ketotifen were kindly donated by Fujisawa Pharmaceutical Co. (Osaka, Japan), Kissei Pharmaceutical Co. (Matsumoto, Japan) and Sandoz-Japan Pharmaceutical (Tokyo, Japan), respectively. Kampo medicines (Shousaikoto, Shouseiryuto and Saibokuto) were donated by Tsumura Co. (Tokyo, Japan). Synthetic PAF was purchased from Funakoshi Pharmaceutical Co. (Tokyo, Japan).

DSCG, ketotifen and the three Kampo medicines were dissolved in phosphate-buffered saline (PBS), tranilast in 1% of $NaHCO_3$, and then diluted with PBS to the appropriate concentrations. The calcium ionophore A23187 (Calbiochem-Behring, La Jolla, CA) was dissolved in dimethylsulfoxide at 1 mg/mL and stored at −20°C until used.

Two milligrams of ketotifen per day were orally administered to ten healthy subjects for 21 days. Neutrophils were collected from these subjects at 0, 7 and 21 days after administration of Ketotifen to measure *in vitro* PAF production.

Venous blood samples were obtained by venipuncture from 30 untreated patients with cedar pollinosis during the Japanese pollen season. The subjects (8 males and 22 females, 19–57 years of age) were diagnosed as having Japanese cedar pollinosis based on their symptoms, disease history, serum IgE levels, number of eosinophils, positive skin test and/or RAST to Japanese cedar pollen. Serum was immediately separated and then stored at −20°C until assayed for lysoPAF.

[1]Based on a paper presented at Third International Conference on Platelet-Activating Factor and Structurally Related Alkyl Ether Lipids, Tokyo, Japan, May 1989.

Abbreviations: BSA, bovine serum albumin; DSCG, disodium chromoglycate; lysoPAF, lyso platelet-activating factor, 1-*O*-alkyl-*sn*-glycero-3-phosphocholine; PAF, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; PBS, phosphate-buffered saline.

Eighteen blood samples, taken in pairs, were obtained before and after the two-week-therapy with nasal beclomethasone dipropionate aerosol, with or without ketotifen treatment (2 mg/day).

Production of PAF by human neutrophils. PAF production by human neutrophils was stimulated as reported by Satouchi *et al.* (9). Briefly, 10×10^6 neutrophils suspended in Tyrode-BSA solution were stimulated with 10 μg/mL of calcium ionophore A23187 for 30 min at 37°C. The supernatants were collected and then stored at −20°C until assayed for PAF.

Acetylation of lysoPAF samples. Acetylation was done using methods reported previously (6,10). Briefly, 100 μL of serum was diluted with 500 μL of methanol and centrifuged at 3,000 rpm for 5 min to sediment protein. Total lipids were extracted from the supernatant by the method of Bligh and Dyer (11). One milliliter of chloroform solution containing the lipids was treated with 0.2 mL of acetic anhydride in the presence of 0.02 mL of perchloric acid for 60 sec at room temperature. The reaction was stopped by adding sodium bicarbonate, and the mixture was centrifuged at 3,000 rpm for 5 min. After a second lipid extraction, the chloroform layer was stored at −20°C until PAF activity was measured.

Measurement of PAF activity. PAF activity was assayed by measuring the aggregation of washed rabbit platelets in an aggregometer (Niko Hematracer, pat. 4A; Niko Biochemical Co., Tokyo, Japan) (6,9). For this purpose, 200 μL of washed rabbit platelets (4 to 6×10^6 mL) suspended in Tyrode-BSA solution were placed in aggregometer cuvettes. Twenty microliters of sample were added to the cuvettes, and platelet-aggregating activity was determined by following changes in light transmission. Platelet aggregating activity was inhibited by CV 3988 (kindly donated by Takeda Chemical Co., Osaka, Japan), a specific PAF antagonist (12). PAF activity was expressed in units calculated from a standard curve obtained for synthetic PAF at different concentrations. One unit was equivalent to 1 ng/mL of synthetic PAF (6).

RESULTS

Inhibitory effects of anti-allergic drugs on PAF production. DSCG, tranilast and ketotifen at concentrations lower than 1 μg/mL did not have any inhibitory effect on *in vitro* PAF production by human neutrophils. DSCG and tranilast did not inhibit *in vitro* PAF production at any of the concentrations measured (10 ng/mL to 100 μg/mL). In contrast, ketotifen inhibited PAF production significantly and in a dose-dependent manner at concentrations higher than 1 μg/mL (Fig. 1).

We also examined the effects of the Kampo medicines, Shousaikoto, Shouseiryuto and Saibokuto, on *in vitro* PAF production by human neutrophils. Figure 2 shows that these three Kampo medicines inhibited *in vitro* PAF production dose-dependently. However, there was no significant difference in the inhibitory effect between the three drugs.

Table 1 shows the changes in PAF production by human neutrophils that occurred after oral administration of ketotifen. PAF production decreased in six out of nine subjects at one week and five out of ten subjects at three weeks after administration of ketotifen. Oral administration of 2 mg of ketotifen, a dose used clinically for the

(2 mg/day) (n = 13), the other group was treated with nasal aerosol only (n = 5). The lysoPAF levels decreased from 82.6 units to 41.3 units ($p < 0.05$) after the two-week therapy with nasal aerosol and ketotifen. However, the level of lysoPAF did not change markedly in the group without ketotifen (from 97.2 units to 70.5 units; not significant) (Fig. 4).

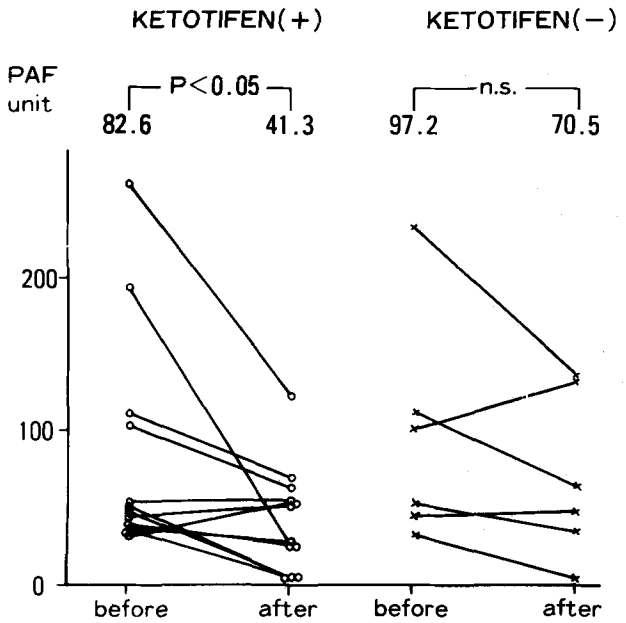

FIG. 4. Decrease in serum lysoPAF levels after treatment with ketotifen. Patients with Japanese cedar pollinosis were divided into two groups. One group was treated with nasal aerosol and ketotifen for 2 weeks (n = 13). The other group was treated with nasal aerosol only (n = 5).

DISCUSSION

Evidence suggests that PAF plays a role in the pathogenesis of allergic diseases, especially of bronchial asthma (1–5). In the present study, we examined the pharmacological effects of the anti-allergic drugs, DSCG, tranilast and ketotifen, on *in vitro* PAF production by human neutrophils, as these three drugs are widely used for the treatment of patients with allergic diseases. Our data show that ketotifen inhibited calcium ionophore-induced PAF production dose-dependently, whereas DSCG and tranilast had no inhibitory effect. The three drugs are known to inhibit histamine release from mast cells and slow-reacting substance of anaphylaxis (SRS-A) from neutrophils and basophils. Our results, however, indicate that there may be distinct differences in the modes of pharmacological action that suppress the allergic reactions.

We also examined the effect of the Kampo medicines, Shousaikoto, Shouseiryuto and Saibokuto, on *in vitro* PAF production by human neutrophils. The precise pharmacological mechanisms of these Kampo medicines are still obscure, but extensive experience in Japan and other Asian countries has established their clinical effectiveness for the treatment of allergic and liver diseases. Our results show that the three Kampo medicines inhibit *in vitro* PAF production dose-dependently and that there is no difference in inhibitory efficacy among these drugs. These Kampo medicines consist of seven to ten major natural components. Kanzo (a grass powder, glycryrrhiza), which shows a strong inhibitory effect on *in vitro* PAF production (data not shown), is a major common component of the three Kampo medicines. This may explain why the three Kampo medicines showed very similar inhibitory activity.

The *in vitro* experiments led us to initiate an oral anti-allergic drug administration trial with healthy subjects. Two milligrams of ketotifen, the usual clinical dose for the treatment of patients with allergic diseases, were administrated to ten healthy subjects for three weeks. PAF production by neutrophils was significantly suppressed after the one-week administration of ketotifen, and this suppression was sustained after three weeks of administration. This suggests that ketotifen inhibits not only *in vitro*, but also *in vivo* PAF production by human neutrophils.

It is of interest, therefore, to examine whether PAF plays a role in Japanese cedar pollinosis. We measured lysoPAF in serum from patients with Japanese cedar pollinosis, as PAF is rapidly metabolized to lysoPAF by the acetylhydrolase present in serum (13,14). To measure the lysoPAF levels, we acetylated the biologically inactive lysoPAF to PAF and measured its platelet aggregating activity. As the major metabolite of PAF in serum is lysoPAF, the level of lysoPAF present in serum may be considered to reflect the level of PAF produced (15). Based on the increased levels of lysoPAF found in serum from patients with Japanese cedar pollinosis, one may conclude that PAF may play a role in the pathogenesis and the clinical manifestation of this disease. Vascular activation and eosinophil accumulation due to PAF could easily account for the symptoms of nasal discharge and conjunctivitis associated with this disease. We compared the serum levels of lysoPAF from patients with Japanese cedar pollinosis before and after treatment with the anti-allergic drug, ketotifen, and nasal aerosol for two weeks. The lysoPAF levels were significantly decreased in the group treated with nasal aerosol and ketotifen. This also suggests that ketotifen inhibits *in vivo* PAF production and that the improvements of clinical symptoms may be partially due to its anti-PAF action.

Further studies are needed to evaluate the clinical significance of PAF in the pathogenesis of allergic diseases. However, our present results strongly suggest that PAF participates in allergic diseases and that the pharmacological benefit of anti-allergic drugs are partly due to their anti-PAF action. Our observations also may provide a new insight into the pathogenesis and the treatment of allergic diseases.

ACKNOWLEDGMENTS

We thank Dr. K. Satouchi for valuable discussions and Miss A. Furuya for excellent technical assistance in measuring PAF.

Effect of the Selective PAF Antagonist SM-10661 on an Asthmatic Model. 1. Effect on Passive Anaphylactic Bronchoconstriction in Guinea Pigs[1]

Masako Uchida, Noriaki Imanishi*, Toshinari Sugasawa and Shigeaki Morooka
Research Laboratories, Sumitomo Pharmaceuticals Co., Ltd., Osaka 554, Japan

The effect of SM-10661, a selective antagonist of platelet-activating factor (PAF), on passive anaphylactic bronchoconstriction was examined in guinea pigs. A challenge of ovalbumin to passively sensitized guinea pigs induced bronchoconstriction, which peaked at 4 min. When SM-10661 was administered intravenously 2 min before ovalbumin challenge, bronchoconstriction was inhibited dose-dependently with an ID_{50} of 68 mg/kg. In guinea pigs pretreated with 15 μg/kg mepyramine which is a suboptimal dose, antigen-induced bronchoconstriction peaked at 4–6 min, but was inhibited by SM-10661 with an ID_{50} of 21 mg/kg. When guinea pigs were pretreated intravenously with 2.5 mg/kg mepyramine, 1 mg/kg indomethacin and 0.01 mg/kg propranolol, the antigen-induced bronchoconstriction peaked at 6 min. SM-10661 inhibited the response with an ID_{50} of 45 mg/kg. Histamine- and leukotriene D_4-induced bronchoconstrictions were unaffected by up to 100 mg/kg SM-10661. Ovalbumin challenge of minced lungs from passively sensitized guinea pigs triggered the release of leukotrienes and histamine. SM-10661 had no effect on the antigen-induced release of peptide leukotrienes or histamine up to 10^{-4} M. These results indicate that SM-10661 may be a useful tool to investigate the role of PAF in antigen-induced anaphylactic bronchoconstriction.
***Lipids 26,* 1301–1304 (1991).**

Platelet-activating factor (PAF) is a phospholipid released from a variety of cell types in response to various stimuli (1). PAF has been causally implicated in several diseases, including shock, ischemia, inflammation and renal failure (2,3). PAF induces bronchoconstriction, non-specific increase in bronchial hyperreactivity and inflammatory cell recruitment to bronchoalveolar lavage (2,3), which suggests that PAF may play an important role in asthma. PAF antagonists have been used to examine PAF involvement in active and/or passive anaphylaxis in guinea pigs. PAF antagonists, BN-52021 and WEB-2086, inhibited antigen-induced bronchoconstriction (3,4–6), and antigen-induced releases of leukotriene D_4, thromboxane A_2 and histamine from perfused guinea pig lungs. Unfortunately, these compounds do not inhibit PAF alone, they also inhibit antigen-induced release of histamine and leukotriene. Therefore, it was not known whether the bronchoconstriction was induced only by PAF, and not by other factors.

We developed a selective, orally active PAF-receptor antagonist, SM-10661 ((±)-*cis*-3,5-dimethyl-2-(3-pyridyl)thiazolidin-4-one hydrochloride) which inhibits PAF induced rabbit platelet aggregation dose-dependently (IC_{50} 3.9 μM), and dissociates specific [^{3}H]PAF binding to rabbit platelets (7,8). *In vivo*, the responses induced by externally administered PAF, such as hypotension, death, bronchoconstriction and bronchial hyperreactivity, were inhibited by SM-10661 (ID_{50} 10–30 mg/kg p.o., 1–3 mg/kg i.v.) (7,8).

In the present study, we have examined the effect of SM-10661 (7,8) on passive anaphylactic bronchoconstriction in sensitized guinea pigs and on antigen-induced release of histamine and peptide leukotrienes from minced guinea pig lung *in vitro*.

MATERIALS AND METHODS

SM-10661 ((±)-*cis*-2-(3-pyridyl)-3,5-dimethylthiazolidin-4-one HCl), indomethacin and propranolol were synthetized, and fenoterol was extracted from Berotec-Tablets® (Dainippon Pharmaceuticals Co., Osaka, Japan). Rabbit anti-egg albumin antiserum (IgG type) and phenidone were purchased from Seikagaku Kogyo Co. (Tokyo, Japan) and Nakarai Chemicals, Ltd. (Osaka, Japan), respectively. Egg albumin (grade V), mepyramine maleate, and gallamine triethiodide were from Sigma Chemicals Co. (St. Louis, MO), and leukotriene D_4 was purchased from Daiichi Chemicals, Ltd. (Tokyo, Japan).

Studies on passive anaphylactic shock in guinea pig. Hartley male guinea pigs weighing 430 to 550 g (Japan SLC, Inc., Shizuoka, Japan) were sensitized with rabbit anti-egg albumin anti-serum (0.85 mg/kg) 24 hr before the antigen challenge according to the method of Lagente *et al.* (9). Passively sensitized animals were anesthetized with sodium pentobarbital (30 mg/kg i.p.) and sodium phenobarbital (120 mg/kg i.p.).

An intratracheal cannula was inserted into trachea and indwelling catheters were inserted into the left carotid artery and left jugular vein. Animals were ventilated with air supplemented with O_2 (1 L/min) using a small respirator (Harvard, Boston, MA) set at a stroke volume of 5–7 mL and a rate of 60 breaths/min. Then involuntary respiration was arrested by the administration of gallamine (10 mg/kg, i.m.). To monitor live and dead, mean arterial pressure (MAP) was measured continuously with a pressure transducer (Physiological Pressure Transducers 1280, Hewlett-Packard, Palo Alto, CA) connected to an amplifier (Hewlett-Packard) and recorder (Yokogawa Electric, Tokyo, Japan). Bronchoconstriction was measured according to the method of Konzett and Rössler (10). The rate of bronchoconstriction was measured as an increase in lung overflow with a bronchospasm transducer (Ugo Basile, Varse, Italy) from a side arm off the tracheal cannula, and expressed as a percentage of maximum bronchoconstriction obtained by clamping off the tracheal cannula. Bronchoconstriction values after antigen challenge

Abbreviations: MAP, mean arterial pressure; PAF, platelet-activating factor; phenidone, 1-phenyl-3-pyrazolidone, SM-10661, (±)-*cis*-2-(3-pyridyl)-3,5-dimethylthiazolidin-4-one HCl.

and maximum bronchoconstriction values were recorded with unirecorder (Model 7050, Ugo Basile).

Sensitized guinea pigs were divided into 3 groups. Animals in Group 1 were used for the experiment under no pretreatment. Animals in Group 2 or 3 were pretreated with a mixture of mepyramine (2.5 mg/kg i.v.), indomethacin (1.0 mg/kg i.v.) and propranolol (0.01 mg/kg i.v.) or mepyramine (15 μg/kg i.v.), respectively, 3 min before intravenous administration of SM-10661 or saline which was adjusted to pH 2 with 1 N HCl. Then ovalbumin (0.1 mg/kg) was injected 2 min later.

To investigate the effect of SM-10661 on LTD_4 (2 nmol/kg) or histamine (8 μg/kg)-induced bronchoconstriction, we used normal guinea pigs with pretreatment of a mixture of mepyramine (2.5 mg/kg i.v.), indomethacin (1.0 mg/kg i.v.) and propranolol (0.01 mg/kg i.v.), or without pretreatment, respectively.

Studies on the release of histamine and peptide leukotrienes from minced lung. Hartley guinea pigs were sensitized as described above, and the lungs were removed and perfused with ice-cold Tyrode's solution through the pulmonary artery. Lung parenchymal strips were dissected to about 0.5 × 0.5 × 1 mm with a tissue chopper (Mickel Laboratory Engineering Co., Guildford, England). Minced lungs (about 100 mg) were preincubated in 1 mL Tyrode's solution at 37°C for 5 min. And various drugs were added to these suspensions and incubated for 10 min. Then 0.01 μg/mL ovalbumin was added and incubation was continued for 15 min. The ice-cold suspensions were filtered through surgical gauze. The filtrate was centrifuged at 3000 × *g* for 15 min at 4°C, and histamine and leukotrienes were measured as described below.

Spectrofluorometric histamine assay. A 1-mL aliquot of the supernatant was mixed with 0.03 mL of 70% perchloric acid. After centrifugation for 10 min at 3000 × *g*, the supernatants were assayed for histamine according to the method of Shore *et al.* (11).

Radioimmunoassay of peptide leukotrienes. An aliquot of supernatant was assayed for total peptide leukotrienes using a [^{3}H]LTC_4, D_4, E_4 Radioimmunoassay Kit (Amersham, London, England).

Statistical analysis. The values in the figures represent the mean ± SEM. Individual differences between the control group and groups treated with drugs were analyzed by Student's t-test.

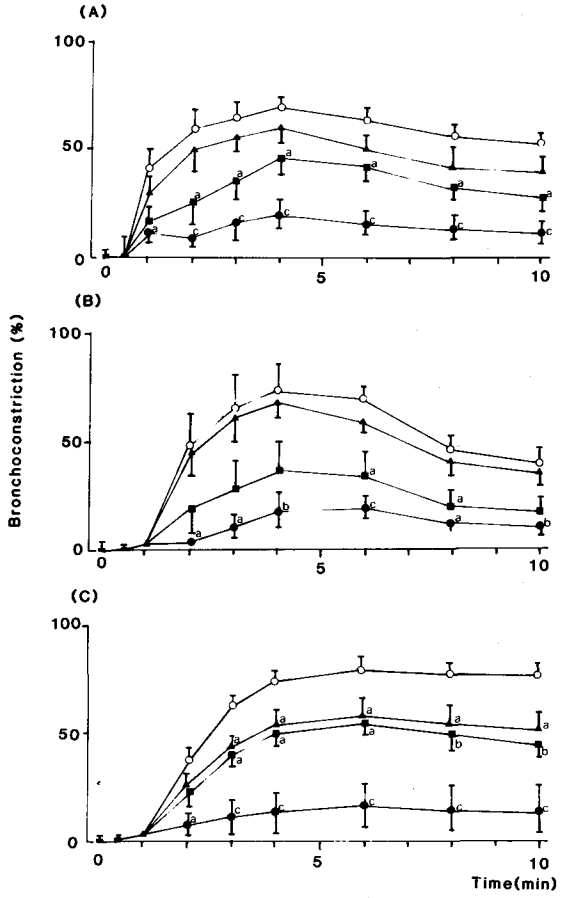

FIG. 1. Effect of SM-10661 on ovalbumin-induced bronchoconstriction in sensitized guinea pigs. (A) SM-10661 at 30 mg/kg (▲), 50 mg/kg (■), or 100 mg/kg (●), or saline (○; control) was given intravenously 2 min before antigen challenge. (B) After pretreatment with mepyramine (15.0 μg/kg i.v.), SM-10661 at 10 mg/kg (▲), 20 mg/kg (■), or 30 mg/kg (●) or saline (○; control) was given intravenously 2 min before antigen challenge. (C) After pretreated with mepyramine (2.5 mg/kg i.v.), indomethacin (1.0 mg/kg i.v.) and propranolol (0.01 mg/kg i.v.), SM-10661 (10 mg/kg (▲), 30 mg/kg (■), 100 mg/kg (●) or saline (○; control) was given intravenously 2 min before antigen challenge. Each value represents the mean ± SEM of 5 to 15 animals. Statistical significance; a: $p<0.05$, b: $p<0.01$, c: $p<0.001$ as compared to the control group.

RESULTS

Effect of SM-10661 on in vivo *passive anaphylactic shock in guinea pigs.* An injection of 0.1 mg/kg ovalbumin to passively sensitized guinea pigs induced bronchoconstriction which peaked at 4 min (71.0 ± 8.9%, n = 15). When SM-10661 was administered intravenously 2 min before ovalbumin challenge, bronchoconstriction was inhibited dose-dependently. Inhibition reached more than 70% when 100 mg/kg of SM-10661 was injected and ID_{50} was 68 mg/kg (Fig. 1 (a), Fig. 2).

Figure 3 shows the effect of the intravenously administered H_1-antagonist, mepyramine, on antigen-induced bronchoconstriction. Mepyramine inhibited maximal constriction of bronchi dose-dependently with an ID_{50} of 21 μg/kg and delayed the onset of bronchoconstriction.

The effect of SM-10661 on antigen-induced bronchoconstriction in guinea pigs previously treated with 15 μg/kg mepyramine was investigated to rule out the partial effect of histamine. Bronchoconstriction peaked at 4–6 min (70.0 ± 5.9 %, n = 6) but was inhibited 71.8% by 30 mg/kg SM-10661 with an ID_{50} of 21 mg/kg (Fig. 1 (b), Fig. 2).

Furthermore, when guinea pigs were pretreated intravenously with a mixture of 0.01 mg/kg propranolol, 1.0 mg/kg indomethacin and 2.5 mg/kg mepyramine to rule out the interference from other potential mediators of bronchoconstriction, antigen-induced bronchoconstriction peaked at 6 min (84.0 ± 5.4%, n = 13), and SM-10661 inhibited it with an ID_{50} of 45 mg/kg (Fig. 1 (c), Fig. 2).

Histamine- and leukotriene D_4-induced bronchoconstrictions were unaffected by SM-10661 up to 100 mg/kg i.v. (Fig. 4).

Effect of SM-10661 on antigen-induced release of histamine and peptide leukotrienes from minced lungs of passively sensitized guinea pigs. Ovalbumin challenge of minced lungs from passively sensitized guinea pigs

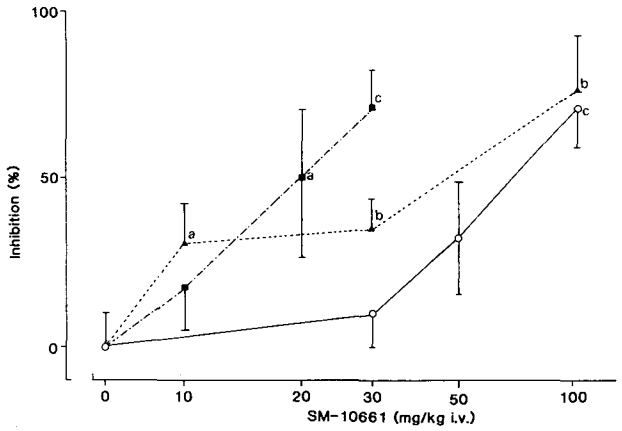

FIG. 2. Dose-dependent inhibitory effect of SM-10661 on antigen-induced bronchoconstriction in guinea pigs. SM-10661 was given to non-treated guinea pigs (○), and guinea pigs pretreated with mepyramine (15 μg/kg i.v.) (■), or mepyramine (2.5 mg/kg i.v.), indomethacin (1.0 mg/kg i.v.) and propranolol (0.01 mg/kg i.v.) (▲). Each value is the mean ± SEM calculated from Figure 1. Statistical significance; a: $p<0.05$, b: $p<0.01$, c: $p<0.001$ as compared to the control group.

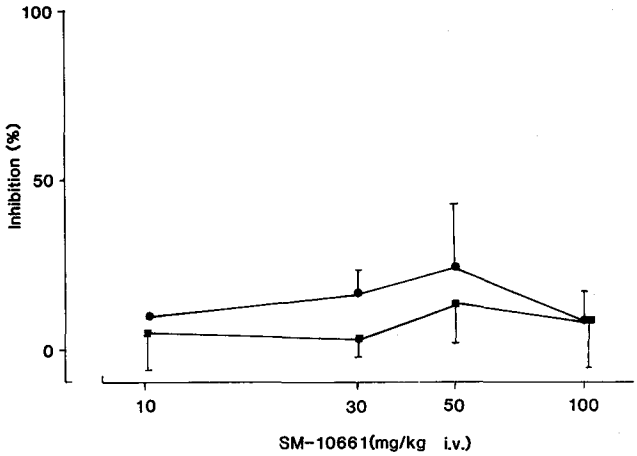

FIG. 4. Effect of SM-10661 on histamine and leukotriene D_4-induced bronchoconstriction. SM-10661 was administered intravenously 2 min before histamine (■) or leukotriene D_4 (●) to guinea pigs. Animals were pretreated with a mixture of mepyramine (2.5 mg/kg i.v.), indomethacin (1.0 mg/kg i.v.) and propranolol (0.01 mg/kg i.v.). Each value represents the mean ± SEM of 5 to 12 animals.

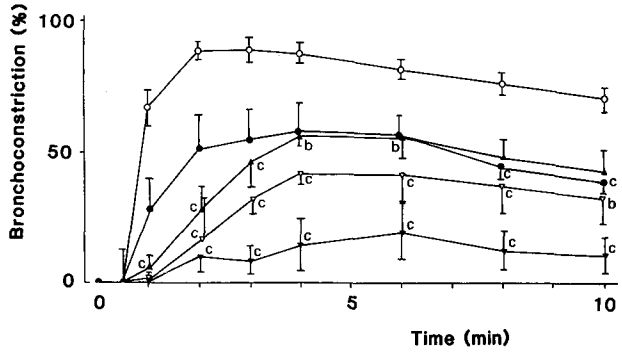

FIG. 3. Effect of mepyramine on ovalbumin-induced bronchoconstriction of sensitized guinea pigs. Mepyramine at 5 μg/kg (●), 10 μg/kg (△), 15 μg/kg (▲), 20 μg/kg (▽), or 50 μg/kg (▼) or saline (○) were administered intravenously 2 min before antigen challenge. Each value represents the mean ± SEM of 4 to 14 animals. Statistical significance; a: $p<0.05$, b: $p<0.01$, c: $p< 0.001$ as compared to the control group.

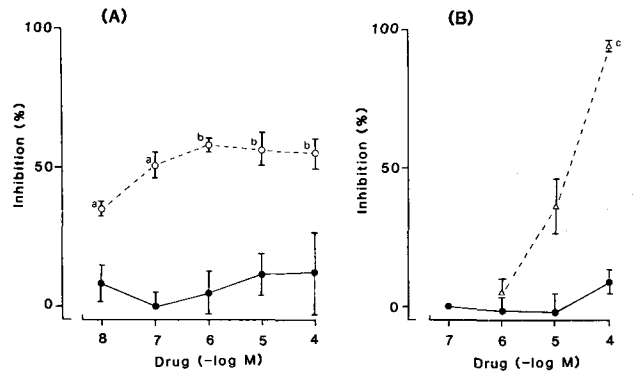

FIG. 5. Effects of SM-10661, fenoterol or phenidone on ovalbumin-induced release of histamine (A) and peptide leukotrienes (B) from minced lungs of sensitized guinea pigs. Dissected peripheral lung strips were preincubated in 1 mL Tyrode's solution at 37°C for 5 min. SM-10661 (●), fenoterol (○) or phenidone (△) were added and the suspensions were incubated for 10 min. Then 0.01 μg/mL ovalbumin was added and the suspensions were incubated at 37°C for 15 min, cooled on ice and filtered, and the filtrates were centrifuged. Histamine and peptide leukotriene levels in supernatants were measured by spectrofluorometric assay and radioimmunoassay, respectively. Each value represents the mean ± SEM of 3 samples. Statistical significance; a: $p<0.05$, b: $p<0.01$, c: $p<0.001$ as compared with the control group.

triggered the release of peptide leukotrienes and histamine. Fenoterol, a β_2-stimulant, significantly inhibited the release of histamine at concentrations above 10^{-8} M. Phenidone, a lipoxygenase inhibitor, significantly impaired the release of peptide leukotrienes at 10^{-4} M. However, SM-10661 had no effect on antigen-induced release of peptide leukotrienes or histamine up to 10^{-4} M (Fig. 5).

DISCUSSION

The present study demonstrated that the selective PAF antagonist, SM-10661, inhibits antigen-induced bronchoconstriction, but does not inhibit histamine- and leukotriene D_4-induced bronchoconstriction. These results indicate that PAF may play an important role in allergic asthma.

Intravenously administered SM-10661 inhibited antigen-induced bronchoconstriction with an ID_{50} of 68 mg/kg. Although guinea pigs are commonly used to study anti-asthmatic drugs, these animals respond differently than humans. For example, histamine is released in guinea pigs from lung and extra-lung sources and plays a major role in systemic anaphylaxis; therefore, anti-histamines are effective on anaphylaxis. By contrast, histamine H_1-antagonists are not effective in the treatment of clinical asthma (12–17). In our study, guinea pigs were pretreated with mepyramine to diminish the role of histamine.

Mepyramine inhibited antigen-induced bronchoconstriction dose-dependently, and at 50 μg/kg i.v., the bronchoconstriction was almost completely suppressed. In animals treated with a suboptimal dose of mepyramine (15 μg/kg i.v.), SM-10661 inhibited antigen-induced bronchoconstriction with an ID_{50} of 21 mg/kg. The inhibition by SM-10661 of bronchoconstriction in guinea pigs pretreated with mepyramine was stronger than that without mepyramine. These results may indicate that PAF produced by antigen challenge potentiates histamine-induced bronchoconstriction. The administration of PAF is reported to induce the bronchial hyperreactivity to histamine (18). In addition, antigen-induced bronchial hyperreactivity is inhibited by PAF antagonists (19–21).

SM-10661 inhibited antigen-induced bronchoconstriction with an ID_{50} of 45 mg/kg in animals pretreated with a mixture of mepyramine (2.5 mg/kg i.v.), indomethacin (1.0 mg/kg i.v.) and propranolol (0.01 mg/kg i.v.). This pretreatment was carried out to potentiate endogenous leukotriene-induced bronchoconstriction by antagonizing the effect of histamine, and inhibiting the cyclooxygenase pathway as well as the bronchodilating action of endogenous catecholamine (22). The inhibitory effect of SM-10661 on antigen-induced bronchoconstriction under these pretreatments was somewhat more pronounced than under no treatment. Considering that SM-10661 inhibited neither leukotriene D_4-induced bronchoconstriction nor the antigen-induced release of peptide leukotrienes, PAF may also be involved in bronchoconstriction under these pretreatments.

BN-52021 inhibited passive anaphylaxis in guinea pigs (3–5) and significantly reduced the anaphylactic release of histamine, leukotriene D_4 and thromboxane A_2 from isolated perfused lungs of passively sensitized guinea pigs (3,4). Another PAF antagonist, WEB-2086, also inhibited not only bronchoconstriction in both passively and actively sensitized guinea pigs, but also the antigen-induced release of histamine and thromboxane A_2 from perfused guinea pig lungs (6).

PAF is known to induce the release of peptide leukotrienes from isolated perfused rat lung (23), guinea pig lung (24) and human eosinophils (25). Thus, the inhibitory effects of BN-52021 and WEB-2086 on anaphylactic bronchoconstriction in guinea pigs may be due to the inhibition of their release.

However, whether PAF induces the release of histamine from lung mast cells at physiological concentrations is not clear (4,26,27). SM-10661 had no effect on the antigen-induced release of histamine from lung parenchyma, but fenoterol inhibited the release. Furthermore, PAF had no effect on histamine release from rat peritoneal mast cells at concentrations of 10^{-11} to 10^{-7} M, and SM-10661 did not inhibit antigen-induced release at concentrations of 10^{-8} to 10^{-5} M (Imanishi, N., unpublished data).

SM-10661 had no effects on antigen-induced release of peptide leukotrienes. Differences in the inhibition of leukotriene release by PAF antagonists may be due to differences of the pharmacological properties of the antagonists used. Also Pretolani *et al.* (26) used isolated perfused lungs to evaluate the effects of WEB-2086, whereas we used minced lungs. In our experiment, phenidone inhibited the release of peptide leukotrienes, and phenidone is known to inhibit antigen-induced bronchoconstriction in guinea pigs pretreated with mepyramine, indomethacin and propranolol (28,29). The inhibitory effect of phenidone on bronchoconstriction appears therefore to be associated with its inhibitory effect on the release of leukotrienes. Our results suggest that SM-10661 inhibits bronchoconstriction without inhibiting leukotriene release and that PAF may play an important role in anaphylactic bronchoconstriction other than that induced by leukotrienes.

Effect of the Selective PAF Antagonist SM-10661 on an Asthmatic Model. 2. Effect on Antigen-Induced Dual Asthmatic Response and Infiltration of Leukocytes into Airways in Actively Sensitized Conscious Guinea Pigs[1]

Toshinari Sugasawa*, Noriaki Imanishi and Shigeaki Morooka
Research Laboratories, Sumitomo Pharmaceuticals Co., Ltd., Osaka 554, Japan

The effect of a selective platelet-activating factor (PAF) receptor antagonist, SM-10661, on antigen-induced dual asthmatic response and leukocyte infiltration into the airways of actively sensitized conscious guinea pigs was investigated. The animals were pretreated with mepyramine maleate (10 mg/kg i.p.) and then challenged with ovalbumin. The inhalation of ovalbumin caused an immediate decline in specific airway conductance (sGaw) which peaked at 5 min after the challenge. sGaw gradually returned to the baseline 6 hr after the challenge. After the early asthmatic response (EAR), a second phase change, a late asthmatic response (LAR) in sGaw peaking at 17–20 hr was observed. When 1% w/v disodium cromoglycate was inhaled for 2 min on two occasions, EAR was not affected, but LAR was significantly inhibited. Oral administration of 50 mg/kg fenoterol (30 min before challenge) significantly inhibited EAR, but had no significant effect on LAR. SM-10661 administered orally 1 hr before the challenge inhibited EAR dose-dependently (50% inhibitory dose (ID_{50}); 59 mg/kg, but was even more effective against the LAR (ID_{50}); 13–16 mg/kg). When 30 mg/kg of SM-10661 was administered orally 6 hr after ovalbumin challenge, LAR was completely inhibited. The number of total cells, macrophages and eosinophils in bronchoalveolar lavage fluids rose significantly 17 hr after antigen challenge compared to that observed after saline challenge. The number of neutrophils and lymphocytes also increased in response to the ovalbumin challenge, but not significantly. SM-10661 (30 mg/kg) administered orally 1 hr before the challenge significantly inhibited the increase in total cells, macrophages and eosinophils. By comparison, when 30 mg/kg SM-10661 was administered orally 6 hr after the challenge, these increases were not significantly inhibited. These results suggest that PAF is involved in EAR and LAR, and that SM-10661 may be a useful therapeutic agent for the treatment of allergic asthma.
***Lipids 26,* 1305–1309 (1991).**

Inhalation of specific antigen causes immediate bronchoconstriction (early asthmatic response, EAR) in patients with allergic asthma. After the first response, a late asthmatic response (LAR) occurs in some allergic asthmatics within 4 to 8 hr and reaches a maximum within 6 to 12 hr (1,2). Although the pathophysiological mechanisms underlying LAR are not clear, the response is thought to be related to inflammatory reactions which are accompanied by infiltration of inflammatory cells, such as eosinophils, into the airways (3–5). The reactions are accompanied by bronchial hyperresponsiveness, *i.e.* an increase in bronchial responsiveness to nonspecific stimulation, such as inhaled histamine and methacholine (6,7).

Platelet-activating factor (PAF, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) is a membrane-derived phospholipid that is a potent inflammatory mediator with various biological activities (8). PAF activates leukocytes and mononuclear cells (9–12) and induces bronchoconstriction (13) and bronchial hyperresponsiveness (14). Furthermore, PAF is generated during pulmonary anaphylaxis (15,16). Recently, several animal models have been developed in which late responses occur in the airways after exposure to allergens (17–22) and PAF antagonists have been effective in reducing these responses (23–25).

In the present investigation, we studied the effect of the selective PAF-antagonist, SM-10661 (26,27) on antigen-induced dual asthmatic response and the role of PAF on late asthmatic response in guinea pigs.

MATERIALS AND METHODS

Materials. SM-10661 was synthesized by Sumitomo Pharmaceuticals Co. Ltd. (Osaka, Japan). Mepyramine maleate and ovalbumin grade III were purchased from Sigma Chemical Co. (St. Louis, MO). Sodium pentobarbital and disodium cromoglycate were purchased from Pitman-Moore (Washington Crossing, NJ) and Fujisawa Pharmaceuticals Co. (Osaka, Japan), respectively. Fenoterol HCl was extracted from Berotec-Tablets™ (Dainippon Pharmaceuticals Co., Osaka, Japan). SM-10661 and fenoterol were dissolved in saline.

Sensitization. Male Hartley guinea pigs weighing 430 to 550 g (Japan SLC, Inc., Shizuoka, Japan) were sensitized by exposure to aerosolized ovalbumin (2% w/v in saline) for 5 min on day 0 and day 7, respectively. The aerosol (particle diameter; about 5.0 μm) was generated by an ultrasonic nebulizer (NE-U11B, Omuron, Tokyo, Japan) at 1.5 mL/min. The animals were used 7 days after the second sensitization. Total arterial blood from 6 of the sensitized animals was obtained *via* an abdominal aorta under diethyl ether anesthesia. Antibody titer was measured by homologous passive cutaneous anaphylaxis

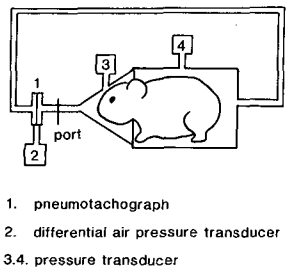
Abbreviations: EAR, early asthmatic response; ID_{50}, 50% inhibitory dose; LAR, late asthmatic response; PAF, platelet-activating factor; Pao, airway opening pressure; Pbox, box pressure; PCA, passive cutaneous anaphylaxis; Raw, airway resistance; sGaw, specific airway conductance; Vo, tidal air flow; Vtg, thoracic gas volume.

(PCA) according to the method described by Watanabe and Ovary (28).

Drug treatment and antigen challenge. Actively sensitized guinea pigs were fasted for about 24 hr before antigen challenge, and were pretreated with a H1-receptor antagonist mepyramine maleate (10 mg/kg i.p.) 1 hr before antigen challenge. Fenoterol (50 mg/kg) or SM-10661 (10–100 mg/kg) was orally administered 30 min or 1 hr before the challenge, respectively. Disodium cromoglycate (1% w/v) was inhaled for 2 min at both 15 min before and 6 hr after the challenge. In the other experiment, SM-10661 (30 mg/kg) was orally administered 6 hr after the challenge. The animals were placed in constant-volume pressure-compensated whole-body plethysmograph, which was made according to the method of Amdur and Mead (29) with slight modifications (Fig. 1). The animals were challenged for 5 min with 2% ovalbumin (control) or saline (negative control) aerosol 5 min after measuring the baseline of pulmonary function.

Measurements of pulmonary function. Specific airway conductance (sGaw) was measured according to the method of Hutson *et al.* (21,30) with slight modifications. Conscious animals were placed in the plethysmograph, with head and body compartments separated by a neck restrainer, then the head was inserted into a face mask.

Three transducers were set in the apparatus, a pneumotachograph (TV-241T, Nihon Koden, Tokyo, Japan) connected to a differential air pressure transducer (TP-602, Nihon Koden) to measure tidal air flow (Vo) and two pressure transducers (P10EZ, Nihon Koden) to measure box pressure (Pbox) and airway opening pressure (Pao). With the port open, Vo was recorded while breathing air trapped within the box. After 3 to 4 breaths, the port was clamped at the end of expiration, then Pbox and Pao were measured simultaneously during 3 to 4 breaths. Triplicate measurements were repeatedly performed. The mean values of three breaths were inserted into the following equations to calculate thoracic gas volume (Vtg), airway resistance (Raw) and sGaw. Using the mean of three values of each parameter, lung function was defined at each time point (Equations 1–3).



$$Vtg = (Pbox\ (a - w))/(b \times Pao) - c\ (mL) \quad [1]$$

$$Raw = (b \times Pao)/Vo - d\ (cm\ H_2O\ s/mL) \quad [2]$$

$$sGaw = 1/(Raw \times Vtg)\ (/cm\ H_2O\ s) \quad [3]$$

where a = box volume (1566.6 mL), b = correction factor for differences in temperature inside and outside of the animal (1.045), c = dead space volume of face mask (116 mL), d = apparatus resistance at no clamping (0.211 cm H_2O s/mL), w = body weight (g). Airway obstruction was expressed using sGaw as the percentage of change from the prechallenge baseline because the parameter included the difference of lung volume in each animal.

Cytological examination. Other sensitized animals were used for cytological examination. The animals were anesthetized with sodium pentobarbital (50 mg/kg i.p.) and killed by exsanguination from the abdominal aorta. The trachea was exposed, cannulated with a polyethylene tube connected to a syringe. Both lungs were lavaged with 5 mL of sterile saline at 37°C instilled through the tracheal cannula. After 3 min, the lavage fluid was recovered by gentle aspiration. A second lavage was performed with an additional 5 mL of saline. These fluids were combined, cooled to 4°C, and filtered through a stainless mesh (100 μm). The recovery was more than 70% of the total saline introduced. The bronchoalveolar lavage fluid was centrifuged at 200 × *g* for 5 min at 4°C, and red blood cells were lysed using 0.14 M NH_4Cl buffered with 0.017 M Tris (adjusted to pH 7.2 using 6 N HCl). The cells were washed twice with Ca^{2+}-free Dulbecco and Vogt buffer (31), then resuspended in 1 mL of the same buffer. Total leukocyte counts were measured from an aliquot of cell suspension using a microcell counter (CC-150 Toa Medical Co., Kobe, Japan). Differential leukocyte counts were performed using May-Grünwald-Giemsa staining (30). Three hundred cells were counted and classified as macrophages, neutrophils, eosinophils and lymphocytes.

FIG. 1. Whole-body plethysmograph used to measure pulmonary function in actively sensitized, conscious guinea pigs. Port represents area where tubing is clamped. The directions for use of this apparatus are described in the text.

Statistical analysis. All values in the figures are expressed as the mean ± SEM. Significant differences from the control group were determined using Dunnett's test or Student's t-test.

RESULTS

The effect of SM-10661 on early and late phase bronchoconstriction. The sera of 6 actively sensitized guinea pigs showed positive reaction at 4 hr-homologous passive cutaneous anaphylaxis (PCA) (titer; about 1:512 dilution), but no reaction at 7 days-homologous PCA. The titer at 4 hr-PCA was not affected by heat treatment at 56°C for 3 hr (data not shown). The mean baseline values ± SEM of the 52 sensitized guinea pigs for Raw, Vtg and sGaw were 739.1 ± 39.7 (cm H_2O:s/L), 20.4 ± 1.2 (mL) and 0.084 ± 0.004 (/cm H_2O·s), respectively.

The effects of saline and ovalbumin challenge on sGaw in sensitized animals are shown in Figure 2. Saline provocation produced small changes in sGaw, which were not significantly different from the baseline value. In contrast, inhalation of ovalbumin caused an immediate decline in sGaw of −67.3 ± 6.3% of the baseline value 5 min after the challenge. This change was significantly different from the baseline value ($p<0.01$). sGaw gradually returned to the baseline 6 hr after the challenge. A second phase change in sGaw was observed at 17–20 hr, which showed a significant decrease of −38.8 ± 7.2% at 17 hr ($p<0.05$) and of −38.2 ± 7.8% at 20 hr ($p<0.05$). Between the saline and ovalbumin challenged groups, significant differences

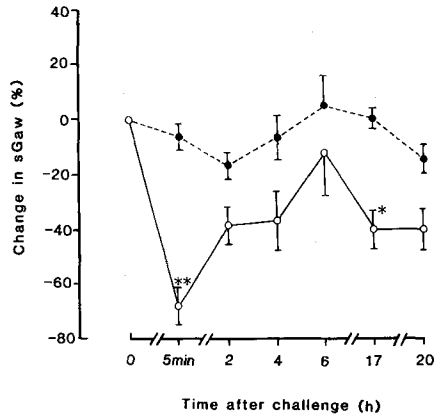

FIG. 2. Effects of challenge with saline (●; n = 5) or 2% ovalbumin (O; n = 10) on specific airway conductance (sGaw) in sensitized guinea pigs. Each point represents the mean ± SEM. Statistical significance: *p<0.05, **p<0.01.

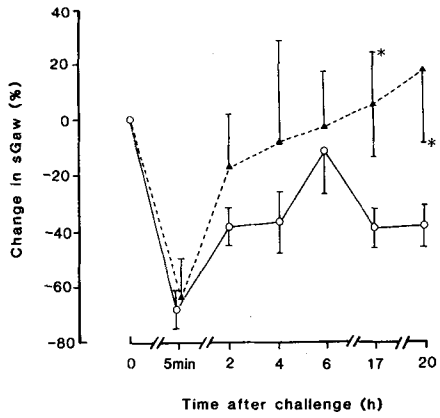

FIG. 3. Effect of disodium cromoglycate on the changes in specific airway conductance (sGaw) after inhalation challenge of 2% ovalbumin in sensitized guinea pigs. An aerosolized solution of 1% w/v disodium cromoglycate was inhalated for 2 min at 15 min before and 6 hr after challenge (▲; n = 5). The control animals (O; n = 10) received saline at the same time. Each value represents the mean ± SEM. Statistical significance: *p<0.05.

were observed at 5 min (p<0.01) and at 17 hr (p<0.05).

When guinea pigs inhaled 1% w/v disodium cromoglycate for 2 min (at both 15 min before and 6 hr after antigen challenge), EAR was not affected at 5 min after antigen challenge, but LAR was completely inhibited at 17 hr (p<0.05) and 20 hr (p<0.05) (Fig. 3).

Oral administration of 50 mg/kg fenoterol 30 min before antigen challenge significantly inhibited EAR measured up to 6 hr after antigen challenge (p<0.05-0.01), but had no significant effect on LAR at 17 hr and 20 hr (Fig. 4).

The effects of orally administered SM-10661 (1 hr before the challenge) on the dual asthmatic response are shown in Figure 5. EAR was inhibited by 10, 30 and 100 mg/kg SM-10661 at 5 min after antigen challenge with ID_{50} 59 mg/kg; this protection was significant (p<0.01) at the 100 mg/kg dose. LAR at 17 hr and 20 hr after antigen challenge was also inhibited dose-dependently by SM-10661 with ID_{50} values of 16 and 13 mg/kg, respectively. This inhibition was significant (p<0.05-0.01) at doses of 30 mg/kg or more. When administered 6 hr after antigen challenge, SM-10661 (30 mg/kg p.o.) almost completely inhibited LAR. The difference at 17 hr between the control and treatment groups was significant (p<0.01) when compared with the percent changes of sGaw from pretreatment values (values 6 hr after the challenge) (Fig. 6).

The effect of SM-10661 on antigen-induced changes of cellular content of bronchoalveolar lavage fluids. Figure 7 illustrates the total and differential leukocyte counts 17 hr after ovalbumin or saline challenge. When compared to the saline challenge, ovalbumin significantly (p<0.01) stimulated the increase in the number of total cells from (54.0 ± 6.34) × 10^5 to (127.3 ± 13.33) × 10^5 cells. The numbers of macrophages and eosinophils also rose significantly from (51.1 ± 5.49) × 10^5 to (96.9 ± 7.02) × 10^5 cells (p<0.01) and from (0.66 ± 0.237) × 10^5 to (11.9 ± 2.29) × 10^5 cells (p<0.01), respectively. The increase in neutrophils and lymphocytes was also stimulated, but not significantly, by ovalbumin challenge, from (0.37 ± 0.186) × 10^5 to (4.1 ± 1.28) × 10^5 cells and from (1.8 ± 0.87) × 10^5 to (14.3 ± 6.61) × 10^5 cells, respectively. SM-10661

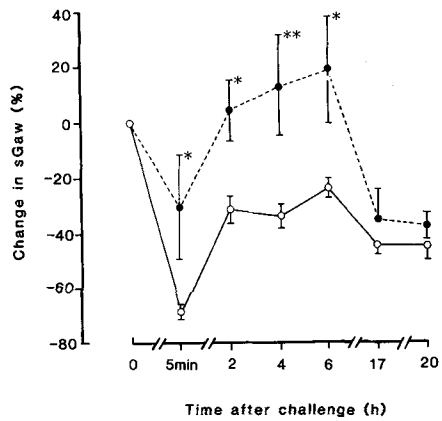

FIG. 4. Effect of fenoterol on the changes in specific airway conductance (sGaw) after inhalation challenge of 2% ovalbumin in sensitized guinea pigs. Fenoterol, 50 mg/kg, was given orally 30 min before challenge (●; n = 5). Control animals (O; n = 19) received distilled water at the same time. Each value represents the mean ± SEM. Statistical significance: *p<0.05, **p<0.01.

(30 mg/kg) administered orally 1 hr before the challenge significantly inhibited the rise in total cells, macrophages and eosinophils, by 87.9%, 81.2% and 79.2% (p<0.01), respectively. The number of lymphocytes was also reduced, but not significantly. When 30 mg/kg SM-10661 was administered 6 hr after the challenge, the increase in total cells, macrophages and eosinophils was slightly inhibited, and the lymphocyte count was reduced by the same level as with the SM-10661 pretreatment; these inhibitions were not significant.

DISCUSSION

In patients with dual allergic asthmatic responses, the early response is inhibited by cromoglycate and β2-adreno-

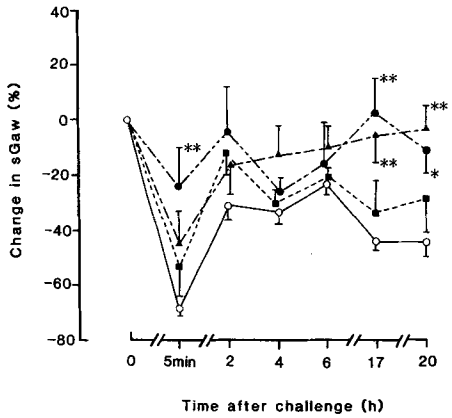

FIG. 5. Effect of SM-10661 on the changes in specific airway conductance (sGaw) after inhalation challenge of 2% ovalbumin in sensitized guinea pigs. SM-10661 (10 mg/kg (■; n = 6), 30 mg/kg (▲; n = 6), 100 mg/kg (●; n = 5)) was given orally 1 hr before challenge. Control animals (○; n = 19) received distilled water at the same time. Each value represents the mean ± SEM. Statistical significance: *p<0.05, **p<0.01.

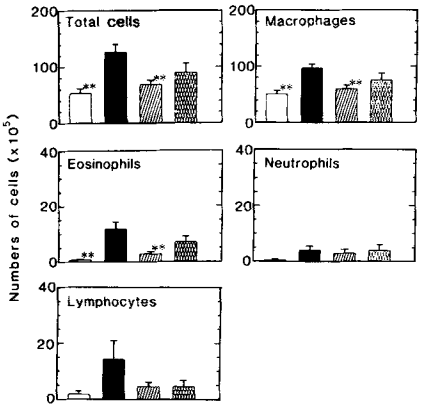

FIG. 7. Effect of SM-10661 on the changes in absolute numbers of total cells and differential cells in bronchoalveolar lavage fluids in sensitized guinea pigs 17 hr after inhalation challenge of 2% ovalbumin. SM-10661, 30 mg/kg, was given 1 hr before (hatched column; n = 10) or 6 hr after (cross-hatched column; n = 10) challenge. Control animals (solid column; n = 12) received distilled water at the same time. Saline (open column; n = 10) was challenged instead of 2% ovalbumin. Each column represents the mean ± SEM. Statistical significance: **p<0.01.

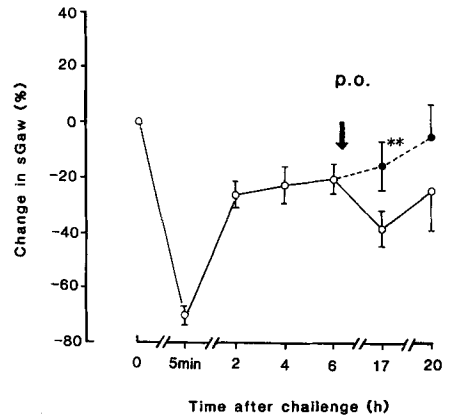

FIG. 6. Effect of SM-10661 (post-treatment) on the changes in specific airway conductance (sGaw) after inhalation challenge of 2% ovalbumin in sensitized guinea pigs. SM-10661, 30 mg/kg, was given orally 6 hr after challenge (●; n = 6). Control animals (○; n = 6) received distilled water at the same time. Arrow indicates the time of administration. Each value represents the mean ± SEM. Statistical significance: **p<0.01.

ceptor agonists, but not by corticosteroids (1, 32–34). Both late asthmatic response and associated airway hyperresponsiveness are inhibited by cromoglycate and corticosteroids, but not by β2-adrenoceptor agonists (1,32–34). Our observations with cromoglycate and a β2-adrenoceptor agonist, fenoterol, on late response agree with those of others.

Hutson *et al.* (30) reported that cromoglycate was effective on both the early and the late responses, but that the β2-adrenoceptor agonist, albuterol, was effective only on the early response in an asthmatic model similar to ours. These authors suggested that their model might be IgE-mediated because cromoglycate worked so well. However, cromoglycate had no effect on the early response in our model at the same dose and time of treatment. Cromoglycate was reported to be effective against IgE-mediated, but not IgG-mediated immediate anaphylactic bronchoconstriction in guinea pigs (35–37). In our model, the sera of the actively sensitized guinea pigs showed positive reaction at 4 hr-passive cutaneous anaphylaxis (PCA) when treated at 56°C for 3 hr, but no reaction at 7 days-PCA. These results indicate that our model was mainly IgG_1-mediated, thus explaining why cromoglycate had no effect on early bronchoconstriction in our studies. The differences in results of our study and previous ones may have been due to the differences in the concentrations of ovalbumin solution and inhalation times during sensitization between our model (2% for 5 min) and others (1% for 3 min).

The present study demonstrated that the selective PAF receptor antagonist, SM-10661, attenuated antigen-induced early and late asthmatic responses in guinea pigs. SM-10661 is a specific PAF receptor antagonist (26), and has no effect on either histamine- or leukotriene D_4-induced bronchoconstriction in guinea pigs (27). The latter also indicates that SM-10661 does not act as bronchodilator.

Hutson *et al.* (25) also reported that a PAF antagonist, WEB-2086, was effective on both early and late asthmatic responses in a model similar to ours. Interestingly, SM-10661 was more effective on the late asthmatic response (50% inhibitory dose (ID_{50}); 13–16 mg/kg) than on the early response (ID_{50}; 59 mg/kg). Treatment with SM-10661 6 hr after antigen challenge completely inhibited the late response, which was similar to the observations of Hutson *et al.* (25). This suggests that PAF is involved in both EAR and LAR, but plays a more important role in the late phase bronchial obstruction.

Late asthmatic response is thought to be related to inflammatory reactions. The analysis of the inflammatory cells recovered from bronchoalveolar lavage suggests that the allergen provocation induced infiltrations of leukocytes into the bronchial lumen, which is thought to injure the mucosa and the submucosa of the bronchi (3–5). The bronchoalveolar lavage technique was also used in this study to examine the local change of cellular composition in the airway lumen. Although there are some differences between the cellular composition of the lavage fluid and lung tissue itself, the lavage fluid is thought to reflect the inflammatory change of the airway lumen (38). The present study also demonstrated that antigens induced the infiltration of inflammatory cells such as eosinophils into the bronchial lumen during the late asthmatic response. SM-10661, at a sufficiently effective dose against late bronchial obstruction, inhibited cellular infiltration into the airway lumen when administered before antigen challenge. Post-treatment with SM-10661 inhibited late asthmatic response, but had no significant effect on cellular infiltration. This suggests that PAF, generated soon after antigen challenge, may induce the migration of inflammatory cells, and that PAF, generated after EAR, may trigger late phase airway obstruction.

Cromoglycate has been demonstrated to inhibit the activation of eosinophils and neutrophils by PAF and other mediators (39,40). In the present study, cromoglycate was effective on IgG_1-mediated late response. The inhibitory effect on the late response may be mediated *via* the inhibition of PAF-induced activation of the inflammatory cells.

PAF antagonists are capable of inhibiting late phase responses in rabbits and sheep (18,23,24,40–43). Using a sheep model, Abraham (43) carefully examined the effects of PAF and leukotriene antagonists. The author suggested that a large component of PAF induced responses in sheep may be mediated *via* leukotrienes (43). Peptide leukotrienes produced by PAF after EAR may induce late phase bronchoconstriction. Further studies are needed to determine whether LAR is mediated by leukotrienes in our model. Nevertheless, SM-10661 may be a useful therapeutic agent for the treatment of allergic asthma.

REVIEW

The Role of Platelet-Activating Factor (PAF) in Experimental Glomerular Injury[1]

A. Ortiz, M. Gomez-Chiarri, J.L. Lerma, E. Gonzalez and J. Egido*
Department of Nephrology, Fundacion Jimenez Diaz, 28040 Madrid, Spain

Platelet-activating factor (PAF) is a potent autacoid that participates in inflammation and other pathophysiological processes. In this review we deal with recent evidence suggesting that PAF is a mediator that is released early during glomerular injury. PAF can be synthesized in the glomerulus by infiltrating intrinsic glomerular cells. Normal glomeruli produce PAF upon stimulation, and glomerular PAF synthesis is increased in a variety of experimental glomerulopathies. The local infusion of PAF into the renal artery of isolated blood-free kidneys induces proteinuria. PAF attracts and activates inflammatory cells. Glomerular mesangial, endothelial and epithelial cells are also targets for PAF. Therapy with specific PAF receptor antagonists has prevented or reduced proteinuria and improved glomerular inflammation in several experimental models of proliferative glomerulonephritis and minimal change nephrosis. However, the beneficial effect of administration of PAF antagonists once proteinuria is fully developed has been minimal. PAF may also play a role in the recruitment of inflammatory interstitial cells. *Lipids 26,* **1310–1315 (1991).**

During the past decade it has been demonstrated that the renal glomerulus and its various cell types are active sites of synthesis of lipid compounds with vasoactive and proinflammatory activities. The first class is generally referred to as eicosanoids and consists of metabolites of arachidonic acid cyclooxygenation (prostaglandins and thromboxanes) and lipoxygenation (hydroxyeicosatetraenoic acids, leukotrienes and lipoxins). Enhanced glomerular synthesis of these lipids has been described in a variety of clinical and experimental forms of immune complex glomerulonephritis and non-immune experimental nephrosis (1,2). However, the contribution of these mediators to glomerular dysfunction remains unresolved and controversial.

The second class of lipid proinflammatory mediators of interest in glomerulonephritis are the alkyl ether glycerophospholipids, of which platelet-activating factor (PAF) has been the most studied. Recent data strongly suggest that PAF may be a mediator that is released early in glomerular injury, initiating the production of other mediators and expanding the possibility of further tissue damage (2-4). Thus, PAF induces an enhancement of vascular permeability (5) and proteinuria when injected into the abdominal aorta of rabbits (6), as well as into isolated perfused rat kidneys (7,8). Furthermore, treatment with PAF receptor antagonists induced improvement in proteinuria and in glomerular lesions in immune and nonimmune models of nephritis (9-11).

PAF may also be involved in proliferative, immune-mediated and non-proliferative, nonimmune-mediated experimental nephritis. Examples of proliferative, immune-mediated nephroses include acute serum sickness (rabbit), chronic serum sickness (rat), murine genetic lupus, nephrotoxic nephritis, *in situ* immune complex nephritis (rat) and hyperacute graft rejection (rabbit). Non-proliferative, non-immune-mediated nephroses include adriamycin nephropathy and aminonucleoside of puromycin nephropathy.

SOME BIOLOGICAL ASPECTS OF PAF

PAF is a potent autacoid that participates in physiopathological responses, such as inflammation, allergy, shock, and thrombosis (12). It was originally found to be released by antigen-sensitized basophils (13), but has since been shown to be produced by a variety of inflammatory cells, including neutrophils, monocytes, eosinophils, macrophages and platelets (12), as well as by endothelial (14) and mesangial cells (15). PAF is not known to be stored, and in many cells it is synthetized only after cell activation (16). However, the amount of PAF secreted varies considerably from cell to cell (17). PAF acts *via* receptors on the membranes of responsive cells (18). The binding of PAF to its receptor initiates a variety of intracellular responses, including stimulation of GTPase activity and activation of phospholipase C and protein kinase C (18). PAF also stimulates cells to release free arachidonic acid and thus induces formation of eicosanoid metabolites that may be responsible for some observed actions attributed to PAF (18). In addition, PAF induces further PAF synthesis in various cells (19,20). In addition to activating platelets, PAF activates polymorphonuclear leukocytes, monocytes and macrophages, attracts inflammatory cells, increases vascular permeability, and induces hypotension and decreased cardiac output (12). It should be noted that PAF is 1000-fold more potent than histamine in increasing vascular permeability (21). Several antagonists of PAF receptors have been described (12) and tried in experimental diseases, allowing insight into the pathophysiological role of PAF. Some of these antagonists have been employed to treat human diseases (22–24). However, a potent and selective antagonist of PAF synthesis is still lacking.

PAF PRODUCTION BY THE KIDNEY

The release from rabbit renal slices of a bioactive material with PAF characteristics was demonstrated after stimulation with antigen (25). PAF bioactivity was also recovered from the venous effluent of isolated rat kidneys perfused with the calcium ionophore A23187 (26). PAF production

Abbreviations: PAF, platelet-activating factor, PAN, aminonucleoside of puromycin; PG, prostaglandin; Tx, thromboxane.

has been shown to occur in isolated glomeruli and in suspensions of rat medullary cells and tubules (27). In the glomeruli, mesangial cells are a major source of PAF (15, 28,29), but endothelial and infiltrating inflammatory cells can also synthesize PAF (12). Pathophysiological stimuli known to induce PAF synthesis by mesangial cells include endotoxin, phagocytic opsonized substances, angiotensin II, cytokines such as IL-1 and TNF, C3a, PDGF, and PAF itself (15,30–33). The synthesis of PAF by glomerular epithelial cells has not been demonstrated (4).

Human and rat mesangial cells possess intracellular and predominantly extracellular acetylhydrolase activity that rapidly degrades PAF, generating lysoPAF, thus protecting the cells from the deleterious effects of PAF (28,29).

RENAL EFFECTS OF PAF

In vivo systemic administration of PAF induces decreased renal plasma flow, a decrease in glomerular filtration rate and decreased urine output when compared to kidney hypoperfusion (34). Sodium reabsorption is increased along the nephron (34). Increased capillary permeability with loss of intravascular volume to the interstitial space plays a significant role in the hemodynamic effects of PAF (34).

The local administration of PAF avoids the systemic effects. In isolated blood-free perfused kidneys, PAF increased prostaglandin and thromboxane (Tx) production and reduced glomerular filtration (8,35). Direct PAF infusion into the renal artery of anesthetized dogs led to a dose-dependent and reversible decrease in glomerular filtration, urinary flow and sodium excretion (3). There were no systemic hemodynamic changes, nor alterations in the functional parameters of the contralateral, nonperfused kidney. Treatment with indomethacin exacerbated the decline in glomerular filtration rate, suggesting that the vasoconstrictory effect of PAF was partially compensated by the action of vasodilatory prostaglandins (3). In contrast, although intraarterial PAF had similar effects in the rat, the changes were abolished by cyclooxygenase inhibitors, and treatment with a thromboxane synthase inhibitor led to increased glomerular filtration rates and renal plasma flow (36).

As it previously has been demonstrated for inflammatory and endothelial cells, cultured rat or human mesangial cells incubated with PAF display an early release of arachidonic acid *via* phospholipase A_2 stimulation, synthesis of prostaglandins, activation of phospholipase C, increase in intracellular calcium, and release of reactive oxygen species (37–41). PAF also seems to induce mesangial cell contraction, as evidenced by its capacity to cause shape changes in cultured mesangial cells and to reduce the surface area of glomeruli (37,38). This effect was exacerbated after prostaglandin synthesis blockade and reversed by PGE_2 (37).

Cultured endothelial cells express PAF in the outer membrane after stimulation with thrombin, and cell-associated PAF has been shown to be a potent promoter of neutrophil adhesion to these cells *in vitro* (42). PAF also induced changes in the shape of endothelial cells through rearrangement of the cytoskeleton, which leads to increased permeability to proteins *in vitro* (43). Finally, we recently have shown a direct cytotoxic effect of PAF on cultured rat glomerular epithelial cells (44).

PAF INDUCES PROTEINURIA

The injection of PAF into the renal artery of rabbits provoked structural and functional changes (6). In histological studies, an accumulation of neutrophils and platelets was noted. Glomerular endothelial cells appeared swelled and the number and size of the fenestrae were increased. Cationic proteins released by platelets and neutrophils were fixed to the glomerular capillary wall. Concomitantly, there was an increased permeability of the glomerular capillary wall, shown by transient proteinuria (6). This may be related to neutralization of fixed negative charges by cationic proteins released from infiltrating inflammatory cells or to a direct effect of PAF. Evidence for the latter mechanism came from experiments demonstrating increased glomerular permeability in platelet- and neutrophil-depleted rabbits (11). The discovery of a dose-dependent accumulation of [^{125}I]fibrinogen in isolated, blood-free perfused rat kidney further suggested that PAF increases renal vascular permeability in the absence of circulating blood cells (45). Recent studies on isolated, perfused rat kidneys confirmed that PAF alters the sieving properties of the glomerular capillary wall and induces proteinuria in the absence of inflammatory cells by a mechanism independent of alterations of the glomerular electrostatic barrier (7,8). PAF induced proteinuria was evident 5 min after beginning the infusion, increased further during the infusion, and returned to basal values 20 min after ceasing PAF infusion (46). PAF induced proteinuria was prevented by pretreatment with a specific PAF receptor antagonist, but was not influenced by lipoxygenase or cyclooxygenase inhibitors (7). Dexamethasone also prevented the increase in glomerular permeability induced by PAF, although the mechanism remains unclear (47). In this same model it has been demonstrated that PAF alters the glomerular barrier size selectivity and increases the permeability to large neutral dextran molecules (46). As already discussed, in other vascular beds PAF induced permeability is thought to depend on increased intracellular calcium and endothelial cell shape changes (43). In fact, PAF induced changes in glomerular permselectivity properties are dependent on the Ca^{++} concentration in the extracellular medium (46). However, the glomerular filtration barrier is a complex structure, and actions on epithelial cells also may be relevant (44).

A ROLE FOR PAF IN EXPERIMENTAL PROLIFERATIVE, LEUKOCYTE-DEPENDENT GLOMERULONEPHRITIS

Several studies have indicated that PAF acts as an important mediator of immune glomerular injury when leukocytes and platelets are the final effectors of inflammation (11).

The first suggestion of the involvement of PAF in renal pathology was made in acute serum sickness induced in the rabbit by a single injection of bovine serum albumin. In this model, the formation of immune complexes in glomeruli is preceded by the interaction of IgE anti-bovine serum albumin antibodies with basophils (48), leading to degranulation and intravascular release of PAF (49). Platelets were specifically desensitized to the action of PAF and platelet-derived cationic proteins localized in the glomeruli, causing focal neutralization of fixed anionic charges (50). Furthermore, the administration of synthetic

PAF aggravated the histological picture and PAF receptor antagonists markedly decreased proteinuria and glomerular hypercellularity (51).

Our group first suggested a role for PAF in the chronic serum sickness of rats sensitized by ovalbumin (52). In this model (coincidentally with the appearance of immune deposits in the capillary wall and the abrupt onset of proteinuria) there was a specific desensitization of platelets to PAF (52). In more recent studies, we have demonstrated increased synthesis of PAF by glomeruli of nephritic rats (unpublished results). Glomerular PAF synthesis was maximal in the phase of moderate proteinuria, characterized by the mesangial localization of immune deposits, and decreased in the phase of maximal proteinuria, which coincided with the deposit of immune complexes in the capillary wall. In this model, PAF antagonists appear to be effective in decreasing proteinuria only if administered within a short time frame (unpublished results) before the full-blown nephrotic syndrome has developed, suggesting that PAF synthesis may be an early event leading to the recruitment of cells and mediators.

Lupus nephritis is a proliferative nephritis characterized by massive immune deposits in the mesangium and glomerular capillary wall that resembles the model of chronic serum sickness. In NZBxW lupus mice, urinary PAF excretion increased significantly with age, and correlated with proteinuria (53). Treatment with the PAF receptor antagonist L-659,989 delayed the onset of proteinuria and improved survival (53). In the MRL/Mpj-lpr/lpr (lpr) mice with systemic lupus erythematosus, synthesis of PAF, TxA_2 (thromboxane A_2) and PGE_2 (prostaglandin E_2) by renal microsomes was increased (54). Treatment with a PAF receptor antagonist, L-659,989, beginning before the development of proteinuria and maintained for four weeks improved renal function and reduced urinary protein excretion. Renal microsomal eicosanoid synthesis was reduced and renal microsomal PAF was normalized, indicating that in some way PAF also induces its own release *in vivo* (19,20). Although the immune complex deposition was not prevented, mesangial cell proliferation and interstitial fibrosis were reduced, suggesting that PAF blockade in this model interferes with the processes that follow the deposition of immune complexes, rather than with formation and deposition itself (54).

Nephrotoxic nephritis results from the injection of antiglomerular basement membrane antibodies. The degree of glomerular injury is species-specific, being more severe in the rabbit. PAF receptor antagonists have proved to be effective in decreasing the manifestations of the disease in rabbits, rats and mice, but the antagonists were always administered before disease induction (55–59). In this model, renal damage is complement- and leukocyte-dependent, but the mechanisms of proteinuria have not been completely elucidated. The onset of proteinuria is preceded by loss of anionic charges of the glomerular basement membrane and the infiltration of monocytes (60). Both phenomena may be PAF related. In this sense, glomerular PAF synthesis peaked three hours after induction of the disease and was reduced by complement and platelet depletion, but not by neutrophil depletion (57). Both glomerular TxB_2 and PGE_2 were increased (56). In rabbits, PAF receptor antagonists did not alter the glomerular binding of antibody (55), but prevented the development of crescentic nephritis, increased glomerular filtration rate, and reduced proteinuria (55,56). Therapy with a thromboxane synthase inhibitor was also beneficial, but less so than with PAF antagonists (56). In rats, an increased spontaneous release of PAF by nephritic glomeruli has been demonstrated (58). In our experience, the PAF receptor antagonists BN52021 and alprazolam reduced proteinuria in the heterologous phase of the disease (Fig. 1) (9). These results are consistent with those of others (58). In another model of complement- and leukocyte-dependent nephritis caused by implantation of cationic antigen in the glomeruli of preimmunized rats, PAF receptor antagonists lessened the proteinuria and the accumulation of inflammatory cells in glomeruli, but not the activation of complement (61). Interestingly, leukocyte depletion also prevented glomerular injury. Thus, in this model, PAF seems to act as a chemoattractant for neutrophils and macrophages, that are the ultimate cause of tissue damage. The PAF receptor antagonist also rendered high plasma PAF levels undetectable, suggesting that PAF was inducing its own synthesis.

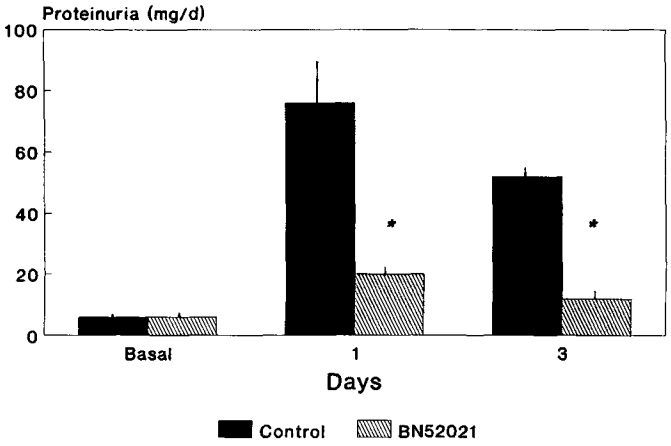

FIG. 1. PAF receptor antagonist BN52021 decreases proteinuria in the heterologous phase of rat nephrotoxic nephritis. Similar results were obtained with alprazolam; (*$p < 0.0025$); mean ± SEM.

PAF has been implicated in the pathogenesis of hyperacute kidney allograft rejection in the rabbit (62). In this model, preformed allotransplantation antibodies bind to the endothelium of glomerular and non-glomerular capillaries. PAF appeared rapidly in the venous effluent of the kidneys and was in close temporal relationship to the influx of platelets and neutrophils, with formation of intravascular thrombi (62). Both platelet and neutrophil-derived cationic proteins were located close to the anionic charges of the glomerular capillary wall, indicating the release of cell granules (62). PAF also possesses immunomodulatory effects that may affect graft survival (63); therapy with PAF receptor antagonists has resulted in improved survival of allografts (64).

PAF IN THE PATHOGENESIS OF NON-PROLIFERATIVE EXPERIMENTAL NEPHROTIC SYNDROME

The fact that PAF is capable of inducing proteinuria in the isolated perfused rat kidney model in the absence of inflammatory infiltrating cells led us to study the possible role of PAF in animal models of minimal change nephrotic syndrome. The experimental nephrosis induced

in rats by adriamycin (65) or aminonucleoside of puromycin (PAN) (66) is characterized by a virtual lack of inflammatory cells in the glomeruli and provides a useful model to study the participation of intrinsic glomerular cells in the genesis of proteinuria.

After receiving a single injection of adriamycin, rats developed severe proteinuria and degenerative lesions of epithelial glomerular cells (65). The toxic effect of adriamycin on the kidney requires only a few minutes of exposure to the drug (3); however, severe proteinuria persists and eventually leads to focal segmental glomerulosclerosis (67). We have hypothesized that adriamycin by itself, or through the release of some mediators from resident glomerular cells could damage epithelial glomerular cells (68–70). Several lines of evidence support the concept that PAF is one such mediator, released early in adriamycin-induced nephropathy.

The administration of PAF receptor antagonist BN 52021, begun the day before adriamycin injection and continued for three weeks, prevented the development of proteinuria (Fig. 2) as well as the biochemical manifestations of nephrotic syndrome (68). In treated rats, no alterations in epithelial glomerular cells were noted, while rats receiving vehicle displayed widespread effacement of podocytes, fusion of foot processes, and cytoplasmic vacuoles (68). Since the ginkgolide BN52021 also possesses antiprotease activities (22), we employed the synthetic specific PAF receptor antagonists, triazolam and the hetrazepine derivate, BN 52076, and obtained similar results (68). Therapy with PAF antagonists from day −1 to day +1 of adriamycin injection reduced proteinuria, although not to the extent observed with continued therapy (2). The administration of PAF receptor antagonists, once nephrotic syndrome was fully developed, had no effect on proteinuria. Together, these results suggest that PAF is an early mediator of proteinuria in this model of nephrosis. Cytokines or other lipid mediators, released in the cascade simultaneously or after PAF, could perpetuate renal damage (70).

We then evaluated the glomerular production of PAF and TNF_α, as both mediators have been shown to be closely related in several pathophysiological processes. Glomeruli obtained from adriamycin rats synthetized more PAF than those from healthy rats (70). The greatest production of PAF was on day 14, preceding maximal proteinuria and TNF_α production (both on day 21). Therapy with PAF receptor antagonists decreased glomerular PAF and TNF_α production (44). *In vitro* studies demonstrated that exposure of glomeruli and mesangial cells from healthy rats to adriamycin generated PAF production in a dose- and time-dependent fashion, peaking at 15 and 90 min (2; and unpublished data). Adriamycin also stimulates TNF_α synthesis by mesangial cells (44). A close relationship between PAF and TNF_α has been demonstrated in a variety of inflammatory responses (71).

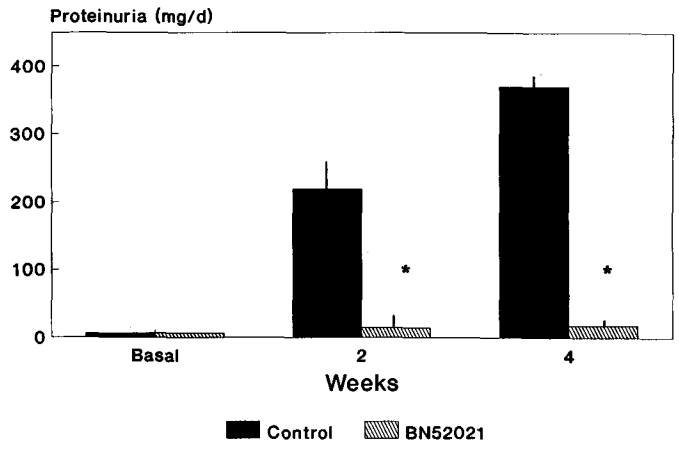

FIG. 2. PAF receptors antagonists prevent the development of proteinuria in adriamycin nephrosis; (*$p < 0.0005$); mean ± SEM.

The next question we addressed was whether PAF and TNF_α could induce epithelial cell damage. *In vitro* studies showed that both mediators were cytotoxic, cultured glomerular epithelial cells, as shown by a 6-hr ^{51}Cr release assay. PAF antagonists reduced TNF_α toxicity. Furthermore, adriamycin and PAN were also cytotoxic to epithelial cells, and there is preliminary evidence that this effect seems to be due to PAF and TNF_α (unpublished data).

A low protein diet is the only intervention, besides the use of PAF antagonists, that can prevent proteinuria in adriamycin nephropathy (72). Recent results from our laboratory suggest that a low protein diet may influence the glomerular production of PAF and TNF_α (73).

PAN nephrosis differs from adriamycin nephropathy in several aspects. Urinary protein excretion peaks earlier and then decreases only to rise again steadily in relation to the development of glomerulosclerosis (66). However, in both models epithelial cell damage is intense. In PAN nephrosis, PAF glomerular production peaked twice (days 1 and 15) before maximal proteinuria (day 11), and before the steady rise in proteinuria that follows, while TNF_α production peaked on day 2, and slowly declined until day 21. Treatment with the PAF receptor antagonist BN 52021 induced a striking decrease in proteinuria, a normalization of total serum proteins and serum cholesterol levels, and a diminution in TNF_α and PAF glomerular production (unpublished data).

Interstitial inflammation is associated with a variety of glomerular and non-glomerular renal diseases (74). The severity of interstitial damage correlates better with renal function than the severity of glomerular injury. However, the mechanisms involved are obscure. We recently characterized the interstitial cell infiltrates in adriamycin nephrosis as composed mainly of macrophages and T lymphocytes, that peaked on day 11, preceding maximal proteinuria (75). Previously, Eddy and Michael (76) had described a similar, but more severe, interstitial nephritis associated with puromycin nephrosis. In both models therapy with two structurally unrelated PAF antagonists decreased infiltration by leukocytes (75), suggesting a role for PAF in the interstitial nephritis associated with nephrosis.

By contrast, PAF receptor antagonists do not prevent proteinuria in passive Heymann nephritis and circulating PAF levels remain normal (77). Passive Heymann nephritis is an animal model of human membranous glomerulonephritis. The *in situ* formation of immune complexes on the subepithelial side of the glomerular basement membrane leads to epithelial cell damage and heavy proteinuria. There is no inflammatory cell recruitment in the glomerulus and the terminal sequences of complement are thought to be responsible for glomerular damage. The fact

that the pathological events take place in the subepithelial space may explain these findings. For this model we previously had reported the absence of an anaphylactic vasopermeability mechanism for immune complex deposition (78).

CONCLUSIONS

PAF has been shown to be released by a variety of renal and inflammatory cells. When administered systemically, PAF effects on the kidney depend on systemic hemodynamic changes. However, direct infusion of PAF into the renal artery induces changes in glomerular filtration and proteinuria both in the presence or absence of blood cells. The study of experimental models of glomerular injury has suggested a role for PAF in proliferative and nonproliferative, immune and toxic proteinuric nephritis. Increased glomerular PAF synthesis has been found to be an early event both in the absence or presence of infiltrating inflammatory cells. Prophylactic therapy with structurally different PAF receptor antagonists avoided or reduced proteinuria in experimental models of nephritis. On the other hand, therapy of established proteinuria has been disappointing so far. While the mechanisms of PAF induced proteinuria remains unknown, it may involve both loss of anionic charges and size selectivity of the glomerular filtration barrier, as well as epithelial cell damage and recruitment of other cells and mediators.

[Received November 9, 1989, and in revised form November 13, 1991; Revision accepted November 16, 1991]

The Effects of R-75,317 on Antiglomerular Basement Membrane Glomerulonephritis in Rats[1]

Platelet-activating factor (PAF) is a potent inflammatory mediator which is released by various inflammatory cells and produced by certain tissues, including the kidney. PAF has been shown to increase glomerular permeability to protein and to decrease glomerular filtration rate (GFR) by contracting mesangium. On the basis of these observations, it has been suspected that PAF may play a role as mediator of glomerular damage in glomerular nephritis. To examine this possibility, we studied the effects of a specific PAF antagonist, R-75,317, on the development of an experimental model of anti-glomerular basement membrane (anti-GBM) glomerulonephritis. Glomerulonephritis was initiated by injecting rabbit anti-rat GBM serum into rats. Proteinuria gradually developed after serum injection, plateaued at week 2, and remained at the high level of week 2 throughout the experimental period (6 wk). Chronic treatment with R-75,317 (10 mg/kg/day i.p.) tended to delay the onset of proteinuria and significantly accelerated the recovery phase. Creatinine clearance (Ccr) fell to 40% at week 3. R-75,317 treatment completely prevented this decline of Ccr. Histological changes in this model (glomerular hypertrophy, proliferation of mesangial matrix and interstitial fibrosis) were also ameliorated by the R-75,317 treatment. The results suggest that PAF may play a role in the development of glomerulonephritis and that PAF antagonists could be used in the treatment of human renal disease.

***Lipids 26*, 1316–1319 (1991).**

Glomerular nephritis is the major cause of end stage renal diseases. Despite considerable advances in the understanding of the immunologic mechanisms of this disease, factors responsible for the initiation and progression of glomerular damage have still not been identified. Recent studies have indicated that platelet-activating factor (PAF) is a potent inflammatory mediator released by various inflammatory cells (1–3). PAF causes proteinuria and a decrease in glomerular filtration rate (GFR) when directly injected into the renal artery (4–6). Specific renal tissues, including mesangial, medullary and glomerular endothelial cells, produce PAF (7–9). It has therefore been suspected that PAF may play a role in glomerular nephritis.

The purpose of the present study was to examine the role of PAF in the development of glomerular nephritis by studying the effects of a specific PAF antagonist, R-75,317. We used a model of antiglomerular basement membrane (anti-GBM) nephritis induced in rats by injection of anti-rat GBM rabbit antiserum. R-75,317 was administered for 6 wk and its effects on urinary protein excretion, urinary *N*-acetyl-β-D-glucosaminidase (NAG) activity, creatinine clearance (Ccr), and on histological changes in nephritic kidneys were examined.

MATERIALS AND METHODS

Preparation of rabbit anti-rat GBM antiserum. Details of this model have been described elsewhere (10,11). Rat glomeruli were isolated by sieving techniques; isolated glomeruli were washed by centrifugation followed by repeated sonication. The isolated and sonicated glomeruli were incubated with trypsin to obtain GBM. GBM was emulsified in Freund's complete adjuvant (Defco Laboratory, Detroit, MI) and injected intradermally into rabbits. After five boosting immunizations, the rabbit anti-rat GBM anti-serum was collected.

PAF antagonist. The chemical structure of R-75,317, 3-{2-[*O*-[(2*R*)-3-(*N*-heptadecylcarbamoyloxy)-2-(3-isoxazoyloxy)propyl]phosphonoxy]ethyl} thiazolium (inner salt), is shown in Figure 1. The efficacy of this compound has been reported both *in vitro* and *in vivo* (12). R-75,317 is active after oral as well as parenteral administration. PAF-induced hypotension was inhibited by 70% in rats injected p.o. with 30 mg/kg of R-75,317 (12).

Intravenous injection of anti-GBM serum causes transient but severe hypotension in anesthetized rats. Pretreatment with 10 mg/kg R-75,317 i.p. completely prevented this hypotension (Fig. 2).

Experimental design. Female Wistar rats weighing between 170–180 g were divided into three groups of 10 animals each. The control group (group I) received 4 mL/kg of normal rabbit serum in the tail vein. The nephritic group (group II) received 4 mL/kg of anti-GBM serum in the tail vein. The PAF antagonist treated group (group III) received the same amount of anti-GBM serum as group II, but was also treated i.p. with 10 mg/kg/day of R-75,317 throughout the experiment.

Animals were studied on the day of injection of anti-GBM serum (week 0) and at 7, 14, 21, 28, 35 and 42 days (weeks 1, 2, 3, 4, 5 and 6) after the injection. Animals were housed in metabolic cages and urine was collected over 24-hr periods. Blood samples were taken at weeks 0, 3 and 6 for the determination of creatinine concentration.

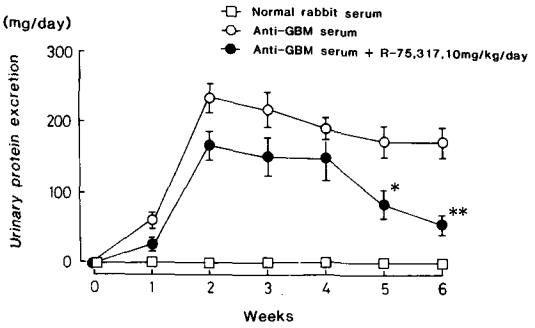

FIG. 3. Time course of urinary protein excretion. The number of animals in each group was 10. *p< 0.05, **p< 0.01, in comparison with the anti-GBM serum injected group (group II).

Histological study. All animals were sacrificed at week 6 to examine renal histology. For light microscopic examination, formalin-fixed sections were processed by routine methods and stained with hematoxylin and eosin or with periodic acid.

Analysis. Urinary protein concentration and urinary NAG activity were determined with a kit purchased from Wako, Osaka, Japan (Micro TP-test) and Shionogi, Osaka, Japan (NAG test), respectively. Plasma and urinary creatinine were measured by the enzyme colorimetric method (13); creatinine clearance was calculated by using standard formulae.

Statistical analysis. Results are expressed as mean ± SEM. Statistical analysis was by non-paired Student's t-test. Statistically significant differences were assumed to be $p < 0.05$.

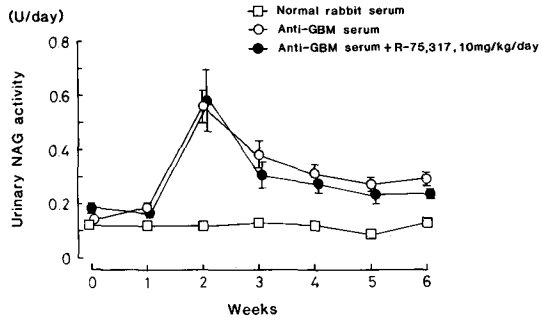

FIG. 4. Time course of urinary NAG activity. The number of animals in each group was 10.

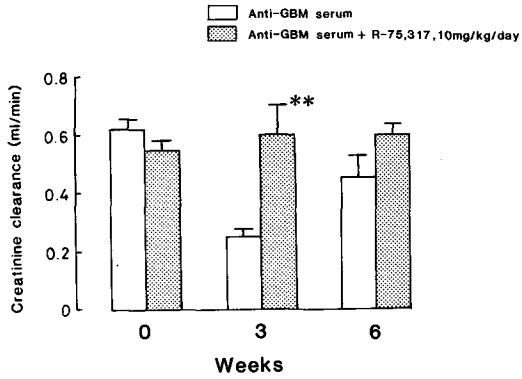

FIG. 5. Effects of R-75,317 on creatinine clearance in anti-GBM nephritic rats. The number of animals in each group was 10. **p<0.01, in comparison with the anti-GBM serum injected group (group II).

RESULTS

The time courses for urinary protein excretion in all groups are shown in Figure 3. Normal rabbit serum injection (group I) did not cause proteinuria at all. In group II, urinary protein excretion did not change on the day of anti-GBM serum injection, but gradually increased, reaching a peak at week 2 (230.4 ± 21.1 mg/24 hr) and maintained the week 2 level throughout the experimental period. Treatment with the PAF antagonist (group III) tended to suppress the onset of proteinuria and significantly accelerated the recovery phase.

The time course of urinary NAG activity after anti-GBM serum administration was similar to that of proteinuria (Fig. 4). Anti-GBM serum injection gradually increased urinary NAG activity in group II. R-75,317-treatment did not affect this enhanced activity.

Figure 5 shows the changes in Ccr in groups II and III. In group II, Ccr was reduced markedly at weeks 3 and 6 (0.62 ± 0.04, 0.25 ± 0.03, and 0.53 ± 0.08 mL/min for weeks 0, 3 and 6, respectively). Treatment with the PAF antagonist completely abolished this decline in Ccr.

Histologic changes in the kidneys were similar to those reported elsewhere for kidneys with anti-GBM nephritis (14–16). In the glomerular region, glomerular hypercellularity, mesangial expansion, thickening of GBM and

Bowman's capsule, and adhesion of glomeruli tuft to Bowman's capsule were obtained (Fig. 6, top). Thickened tubular basement membrane and interstitial fibrosis were observed in tubules. In the R-75,317 treated group, these histological changes were markedly improved (Fig. 6, bottom; Table 1).

DISCUSSION

Anti-GBM nephritis proceeds in two phases. First, the heterologous antibody binds to the glomerular basement membrane (GBM) within one hour after the injection of antiserum, and induces acute damage mediated mainly by complement and polymorphonuclear cells (17,18). In this heterologous phase, acute proteinuria and decrease in GFR are observed. The second phase (autologous phase) starts usually 7–10 days after the anti-GBM serum injection. In this phase, the host's immune responses to heterologous antibody bound to the GBM play an important role in deterioration of renal function and in bringing about morphological changes. Chronic proteinuria in the second phase is associated with enhanced glomerular permeability to protein.

The anti-GBM nephritic model in the present study has a different time course for urinary protein excretion. Proteinuria did not occur on the day of anti-GBM serum injection (week 0) but gradually developed thereafter, indicating that our model has a mild heterologous phase followed by a prominent autologous phase. The reason for the discrepancy between the results with our model and those of previous studies is not known. But it is quite possible that our anti-GBM serum has different activity or affinity from other anti-serum used by others since the GBM preparation is not pure and anti-GBM serum is polyclonal. The GBM-binding ability of our anti-serum might not have been potent enough to trigger the acute responses mentioned above. However, the injection of the anti-GBM serum did cause profound hypotension, an index of severe immuno-responses (Fig. 2). Another possibility is that the hypotension itself reduces proteinuria *via* the changes of intrarenal hemodynamics. Decrease of glomerular capillary pressure due to systemic hypotension is known to reduce glomerular filtration of macromolecules including protein. Therefore it is possible that reduction of glomerular capillary pressure induced by anti-GBM serum decreased the leakage of plasma protein. Treatment with the PAF antagonist partially, but significantly, enhanced the recovery phase of proteinuria. Proteinuria in this phase is associated with increased vascular permeability to proteins. Recent studies have indicated that PAF enhances vascular permeability (17) and causes proteinuria when directly injected into the renal artery (18,19). These findings suggest that PAF is involved in the proteinuria in this model through increased glomerular permeability.

NAG is a ubiquitous, lysosome-derived hydrolytic enzyme. Since proximal tubules are the major source of the enzyme in urine, urinary activity of NAG has been assumed to be a sensitive marker of tubular damage. The present results demonstrate that urinary NAG activity is increased in anti-GBM nephritic rats. This is in accord with histological findings that proximal tubules were injured in the nephritic kidneys. PAF may not be involved in NAG release from injured proximal tubules because the PAF antagonist did not affect the time course of urinary NAG activity.

The effects of R-75,317 on glomerular filtration rate (GFR) measured by Ccr were quite pronounced. Treatment with the PAF antagonist completely prevented the decrease of GFR in anti-GBM nephritic rats. Bertani *et al.* (20), using anti-GBM nephritic rabbits and L-652,731, another PAF antagonist, have found the PAF antagonist effective in preserving GFR. PAF has also been demonstrated to reduce GFR directly (5,6,19,21). These findings are in accord with the hypothesis that PAF plays an important role in the decrease of renal function in this model. However, other inflammatory mediators, namely thromboxane A_2 and leukotriene D_4, may also be responsible for the reduction of GFR in anti-GBM nephritis (22,23). Weisman *et al.* (24) have shown that PAF activates arachidonic acid (AA) metabolism in the kidney. The interrelationship between PAF and AA metabolites and their respective roles in nephritis induced by anti-GBM serum need to be determined.

TABLE 1

Effect of R-75,317 on Renal Morphology in Anti-GBM Nephritic Rats: Heterologous Phase[a]

	Anti-GBM serum	Anti-GBM serum + R-75,317 10 mg/kg/day
Glomerular hypercellularity	2.4 ± 0.5	1.9 ± 0.3
Mesangial expansion	2.2 ± 0.6	1.8 ± 0.4
Interstitial fibrosis	2.8 ± 0.8	1.8 ± 0.5

[a]Results were scored on a 0 to 4+ scale.

The histological changes of kidney observed in the present study are typically found in anti-GBM nephritis. The glomerular and tubular damages were moderately ameliorated by the R-75,317 treatment, which further supports the notion that PAF may play a role in the autologous phase of this model.

In summary, the present study has shown that R-75,317, a specific PAF antagonist, has preventive effects on the development of anti-GBM nephritis in rats. PAF may play an important role in this nephritic model. In order to clarify the role of PAF, the interrelationships between PAF and other inflammatory mediators and renal production of PAF in this model need to be examined.

Nephrotoxicity of Cyclosporine: The Role of Platelet-Activating Factor and Thromboxane[1]

Oscar F. Pavão dos Santos[a], Mirian A. Boim[a], Elvino J.G. Barros[a], Eduardo Pirotzky[b], Pierre Braquet[b] and Nestor Schor[a,*]

[a]Nephrology Division, Escola Paulista de Medicina, São Paulo, SP, Brazil and [b]Institut Henri Beaufour, Les Ulis, France

Cyclosporine (CsA), an immunosuppressive agent, is potentially nephrotoxic. We had previously observed that acute administration of CsA to Munich-Wistar rats induced a decrease in single nephron glomerular filtration rate, due to a decline in glomerular plasma flow, and in the glomerular ultrafiltration coefficient. Moreover, these alterations were prevented when an antagonist of platelet-activating factor (PAF) was administered. In the present study we examined whether the protective effect of the PAF blocker in CsA nephrotoxicity could have been mediated by thromboxane (TxA_2). Our data show that the PAF effects were not mediated by TxA_2, since administration of dazmegrel, a thromboxane synthetase inhibitor, did not ameliorate the acute renal failure caused by CsA. Thus, PAF appears to be a direct mediator of acute CsA nephrotoxicity, while TxA_2 is not significantly involved in this process.
Lipids 26, 1320–1323 (1991).

Platelet-activating factor (PAF) is produced by the glomeruli and by various kidney cell types, including mesangial and medullary renal cells (1–3). PAF is also involved in inflammatory and vasoactive response (4); PAF infusion during maintenance of mean arterial pressure decreases renal plasma flow (RPF) and whole kidney glomerular filtration rates (GFR) (5). These alterations in superficial glomerular hemodynamics were also observed after cyclosporine (CsA) administration, which suggests that PAF may be generated during CsA treatment. Moreover, both PAF and CsA cause contraction of isolated mesangial cells (6,7), probably leading to a decrease in the glomerular ultrafiltration coefficient (K_f) (8).

BN 52021, a terpene isolated from *Gingko biloba*, significantly inhibits the immune and vascular effects of PAF (4). This antagonist was also found to inhibit the effects of both PAF and CsA on isolated mesangial cells (7), and to protect spontaneous hypertensive (9) and Munich-Wistar rats (10) from the nephrotoxicity induced by CsA. Thus, PAF may be one of the humoral factors modulating CsA nephrotoxicity. Moreover, PAF may participate directly in CsA-induced toxicity by its actions on glomerular hemodynamics, or indirectly by stimulating platelets and/or plasma and renal cells to release thromboxane (TxA_2). After chronic treatment with CsA, urinary thromboxane excretion increases, while GFR decreases (11). Thus, in order to evaluate a possible role of TxA_2 as a second mediator in CsA nephrotoxicity, we employed a specific TxA_2 blocker, dazmegrel (DAZ), during acute CsA administration.

MATERIALS AND METHODS

Materials. Cyclosporine was from Sandoz (Basel, Switzerland), dazmegrel from Pfizer (Sandwich, United Kingdom), and PAF from Institut Henri Beaufour (Les Ulis, France). The Munich-Wistar rats were provided by the Central Animal Facility of the Escola Paulista de Medicina, São Paulo, Brazil.

Methods. The studies were performed using male Munich-Wistar (MW) rats weighing 265–350 g. All animals were submitted to two periods of study: First, a control period (except for Group 4 which received DAZ in the first period); and second, acute drug administration which was as follows: Group 1 (n = 12) was treated i.v. with CsA, 50 mg/kg body wt, in bolus. Group 2 (n = 7) received a continuous infusion of PAF (0.012 ± 0.001 μg/kg body wt/min, i.v.) up to a maximum dose which did not cause a decrease in mean arterial pressure below the renal autoregulation level. Group 3 (n = 6) received DAZ (UK-38485, 5 mg/kg body wt, i.v., in bolus). The dose of dazmegrel chosen was that recommended by Pfizer Laboratories. Finally, Group 4 (n = 7) received the same dose of DAZ (as Group 3), in the first period, and then the animals were treated with CsA (as Group 1) in the second period. Each period lasted approximately 40 min and additional 30–45 min equilibration periods followed after surgery and following the first period.

General protocol. Rats were anesthetized with Inactin, 100 mg/kg body wt, i.p., and submitted to micropuncture studies as previously described (8). Throughout the study, all rats received continuous i.v. infusion of 10% inulin and 2% *p*-aminohippuric acid (PAH) solution and of isotonic rat serum to replace surgical losses (12). After 30–45 min equilibration, the initial study period began. Two samples of urine, and blood samples of about 60 μL each were collected for measuring hematocrit (Hct), protein concentration (C_A), inulin and *p*-aminohippuric acid (PAH) in plasma and urine. After the control period collections, the drugs were administered to the respective groups as described above, and a new 30–45 min equilibration period was allowed. Thereafter, the same procedure was followed in the second study period.

Micropuncture studies were performed in both experimental periods. Samples of fluid from surface proximal tubule convolutions were collected for determination of flow rate and inulin concentration, and for calculation of the single nephron glomerular filtration rate (SNGFR).

Abbreviations: AP, mean arterial pressure; C_A, afferent arteriolar protein concentration; CsA, cyclosporine; DAZ, dazmegrel; ΔP, transcapillary hydraulic pressure difference; FF, filtration fraction; GFR, glomerular filtration rate; Hct, hematocrit; K_f, glomerular ultrafiltration coefficient; MW, Munich-Wistar; PAF, platelet-activating factor; P_{GC}, glomerular capillary hydraulic pressure; P_T, tubular hydraulic pressure; Q_A, glomerular plasma flow rate; R_A, afferent arteriolar resistance; R_E, efferent arteriolar resistance; R_T, total arteriolar resistance; RPF, renal plasma flow; SNFF, single nephron filtration fraction; SNGFR, single nephron glomerular filtration rate; TxA_2, thromboxane.

Hydraulic pressures were measured in surface glomerular capillaries (P_{GC}), proximal tubules (P_T), efferent arterioles (P_{EA}), and peritubular capillaries (P_C) by a continuous recording servonull micropipette transducer system (IPM Inc., San Diego, CA). Protein concentration in femoral arterial and efferent arteriolar plasma was measured, as described previously (13), to estimate colloid osmotic pressure. Colloid osmotic pressure was calculated according to the equation of Deen *et al.* (14). The estimates of pre- and post-glomerular protein concentrations permit calculation of colloid osmotic pressure, single nephron filtration fraction (SNFF), initial glomerular capillary plasma flow rate (Q_A), and afferent (R_A), efferent (R_E) and total (R_T) arteriolar resistances, as well as of glomerular capillary ultrafiltration coefficient (K_f) using equations previously described (14).

Analytical procedures. Plasma and urinary inulin concentration were determined by the macroanthrone method of Fuhr *et al.* (15). The concentration of inulin in the tubular fluid was measured by the microfluorescence method (16). Protein concentration in efferent arteriolar and femoral arterial plasma was determined by the fluorimetric method (13). Plasma and urinary *p*-aminohippuric acid concentrations were measured according to Smith *et al.* (17).

Statistical analyses were by Student's t-test. Significance was defined as $p<0.05$. Data were presented as mean ($\bar{X} \pm SE$).

RESULTS

Body weight, kidney weight, hematocrit and plasma protein were similar in all groups (data not shown). Table 1 summarizes various whole kidney functions. CsA caused a decline in GFR from 0.96 ± 0.04 to 0.47 ± 0.07 mL/min ($p<0.05$), and in RPF from 2.91 ± 0.19 to 1.30 ± 0.23 mL/min ($p<0.05$). Similarly, PAF provoked a decline in GFR (1.09 ± 0.03 to 0.43 ± 0.10 mL/min; $p<0.05$) and in RPF (3.59 ± 0.17 to 1.78 ± 0.34 mL/min; $p<0.05$). DAZ alone did not change GFR, RPF or FF. Pretreatment with DAZ did not modify the global renal effects induced by CsA. In Group 4, GFR decreased from 1.01 ± 0.03 mL/min to 0.50 ± 0.08 mL/min ($p<0.05$) in the second period, and RPF decreased from 2.71 ± 0.15 mL/min to 1.35 ± 0.24 mL/min ($p<0.05$).

The glomerular hemodynamic studies are presented in Table 2. CsA caused a decline in SNGFR from 27.9 ± 3.4 to 14.0 ± 3.5 nL/min ($p<0.05$) and in Q_A from 101.0 ± 17.1 to 44.4 ± 13.4 nL/min ($p<0.05$). Since P_T (14 ± 3 mmHg) remained constant and P_{GC} increased (45 ± 1 to 55 ± 4 mmHg; $p<0.05$), the transcapillary hydraulic pressure difference (ΔP) rose significantly ($p<0.05$). Both R_A and R_E increased, but mainly R_E ($p<0.05$) as shown in Table 2. The K_f decreased by 70% after CsA administration (from 0.096 ± 0.003 to 0.031 ± 0.010 $nL \cdot s^{-1} \cdot mmHg^{-1}$, $p<0.05$). PAF induced a decline in SNGFR (31.7 ± 2.7 to 13.4 ± 1.7 nL/min; $p<0.05$) and in Q_A (96.7 ± 7.6 to 41.5 ± 5.7 nL/min; $p<0.05$), and caused an increase in both R_A and R_E. After PAF infusion there was a significant decrease in AP (99 ± 2 to 87 ± 1 mmHg; $p<0.05$).

As shown in Table 2, DAZ alone did not affect the superficial nephrons. Pretreatment with DAZ did not reduce the effects of CsA in SNGFR (33.8 ± 3.1 to 17.0 ± 3.3 nL/min; $p<0.05$), in Q_A (92.1 ± 6.0 to 55.3 ± 10.6 nL/min; $p<0.05$) or in K_f (0.081 ± 0.007 to 0.045 ± 0.010 $nL \cdot s^{-1} \cdot mmHg^{-1}$; $p<0.05$). However, DAZ normalized ΔP (32 ± 1 mmHg) and decreased total arteriolar resistance, although not significantly.

DISCUSSION

Cyclosporine, an immunosuppressive agent that is used in organ transplants can show nephrotoxic effects (18,19). On the other hand, the absence of morphological glomerular lesions (20) suggests that the acute toxic effects are caused by humoral factors (18). Impairment of renal function evoked by CsA is mainly due to a decrease in Q_A and K_f (8), effects which are also observed after PAF infusion (5). PAF and CsA induce contraction of mesangial

cells (7), which can lead to decreased K_f, suggesting that PAF is involved in CsA-induced nephrotoxicity.

PAF induces the release of secondary mediators from various cell types and organs. Weissman *et al.* (21) showed that isolated perfused rabbit kidney stimulated by PAF generated PGE_2 and TxB_2. The release of these mediators was greater when the kidneys had been previously subjected to ureteral ligation. Increased production of renal thromboxane under chronic CsA treatment has been demonstrated (11). These data suggest that an interrelationship may exist between PAF, CsA, and TxA_2 which results in the development of acute renal failure (ARF) induced by CsA.

During acute CsA treatment, substantial increases in R_A and R_E (mainly R_E), leading to a significant increase ($p<0.05$) in P_{GC} (Table 2), were observed. As P_T remained unaffected there was also an increase in mean ΔP. Reduction in SNGFR resulted from arteriolar vasoconstriction, and consequently from a substantial decrease in Q_A. Moreover, our data indicate that SNGFR was also decreased due to a significant decrease in K_f. Thus, in spite of an increased ΔP, the SNGFR was reduced resulting from a significant decrease in Q_A and in K_f (70%). In previous studies (8), the effect of CsA vehicle (cremophor) was not considered because no glomerular hemodynamic alterations were observed upon cremophor administration.

PAF infusion provoked a significant decrease in AP, but AP was kept at renal autoregulation levels. PAF induced a reduction in FF, as would be expected in a predominantly pre-glomerular vasoconstriction. However, after acute PAF infusion, microcirculation studies suggested proportional incremental increases in R_A and R_E. These results may reflect the higher increment in R_A of the juxtamedullary nephrons. Despite the proportional increases in both arteriolar resistances R_A and R_E, PAF induced a moderate decrease in P_{GC} leading to a decline in mean ΔP. Moreover, PAF also induced a significant reduction in K_f. The effect of PAF on K_f may be caused by direct action on PAF receptors in mesangial cells, since it is known that PAF contracts mesangial cells (7). Thus, the hemodynamic mechanism responsible for the decrease in SNGFR appears to involve intrarenal vasoconstriction with a decrease in Q_A and K_f. The data suggest that a similar hemodynamic situation exists after acute CsA infusion, and would indicate a potential role of PAF in CsA nephrotoxicity. However, since PAF may stimulate the release of TxA_2 from activated platelets, the aim of the present work was to determine whether this vasoconstrictor prostaglandin participates as a second mediator in CsA-induced ARF, by administering a specific thromboxane synthetase inhibitor, dazmegrel, prior to CsA administration.

In our experimental model, DAZ alone did not change total or superficial kidney function. These results are very similar to those observed with other blockers, such as prostaglandin synthesis inhibitor (22) and angiotensin I converting enzyme inhibitor (23). Thus, when euvolemic normal Munich-Wistar rats undergo a hormonal blocking treatment, other vasoactive systems are activated and renal function is maintained. Therefore, DAZ which has no direct effects on kidney function may be used as a tool to study the pathophysiology of TxA_2 in various renal disorders, including CsA nephrotoxicity.

We observed that pretreatment with DAZ did not prevent the decline in GFR and SNGFR after acute cyclosporine administration, despite the increase in ΔP (Group 4). However, the normalization of ΔP was insufficient to compensate for the reduction in Q_A and K_f. In contrast, Perico *et al.* (11) observed that the administration of DAZ after chronic treatment with CsA was accompanied by an increase in GFR and a reduction in urinary excretion of TxB_2. However, there is a difference between the study made by Perico *et al.* (11) and the present work. We evaluated the acute effects of CsA and dazmegrel, while the earlier authors studied a chronic situation. We observed differences between acute and chronic (short term) effects of CsA on glomerular hemodynamics (24). Moreover, in Perico's study, urinary TxB_2 rose gradually during the

first month, and it was significantly elevated after one month of CsA treatment.

In summary, our data suggest that PAF is the direct mediator of acute CsA nephrotoxicity, and that TxA_2 does not contribute to a significant extent to the changes observed in whole kidney and single nephron hemodynamics upon CsA administration.

Cisplatin (DDP) is an effective anticancer agent that has been successfully applied against various solid tumors. However, DDP commonly causes nephrotoxicity. We observed that DDP led to significant alterations in renal microcirculation when administered to Munich-Wistar rats, with a concomitant decrease in single nephron glomerular filtration rate due to reduction in glomerular plasma flow and transcapillary hydraulic pressure difference. BN 52063, a platelet-activating factor antagonist, caused a striking change in acute renal failure induced by DDP leading toward normalization of all parameters of renal function. The results suggest that BN 52063 could be used as a novel drug to control DDP nephrotoxicity. ***Lipids 26,*** **1324-1328 (1991).**

cis-Diamminedichloroplatinum (DDP) has been proven to be a valuable agent in oncologic therapy. It is used, in particular, in the treatment of testicular and ovarian malignancy (1). DDP has also been useful in the treatment of head, neck, bladder, cervical, prostate and lung cancers (2,3). However, DDP treatment can cause a number of side effects with nephrotoxicity being the most common and most serious (4).

Observed reduction in glomerular filtration rate (GFR) due to cisplatin results from a decrease in renal blood flow and an increase in total renal vascular resistance (5) suggesting that cisplatin-induced acute renal failure (ARF) may be related to renal hemodynamic alterations (6). Therefore, one aim of this study was to characterize the changes that occur in renal microcirculation in response to DDP treatment in rats.

Platelet-activating factor (PAF) is a lipid mediator involved in various renal disorders (7) that causes inflammatory and vasoactive responses in the kidney. It was also observed that PAF causes a decline in GFR and in renal plasma flow (RPF) which can be ascribed to arteriolar vasoconstriction and/or mesangial cell contraction (8,9).

We have previously shown that BN 52063, a terpene isolated from *Gingko biloba* which inhibits the immune and vascular effects of PAF, is able to minimize cyclosporine (CsA) nephrotoxicity by ameliorating vasoconstriction induced by CsA (9). Thus, a second purpose of this study was to monitor the effect of the PAF antagonist BN 52063 on renal microcirculation in DDP treated rats.

MATERIALS AND METHODS

Methods. The studies were done using 29 male Munich-Wistar rats weighing between 240 and 320 g. Experimental rats received cisplatin (Group 1, n = 9) in a single dose of 6 mg/kg body wt, i.p. (10,11) (Laborterápica Bristol, São Paulo, Brazil), and control rats (Group 2, n = 6) received 0.5 mL of 0.9% NaCl i.p. The third group (Group 3, n = 7) received cisplatin, in the same dose as Group 1, and BN 52063 (Institut Henri Beaufour, Les Ulis, France) at 50 mg/kg body wt, p.o. for 4 days. Rats in the fourth group (Group 4, n = 7) received BN 52063 daily in the same dose as Group 3, to study the effects of chronic BN 52063 administration on renal microcirculation. Clearance and micropuncture studies were performed after four days following the administration of DDP.

Rats were anesthetized with Inactin, 100 mg/kg body wt, i.p. (BYK, Gulden, Konstanz, Germany) and were prepared in a routine fashion for micropuncture studies (12). All rats received an i.v. infusion of 10% inulin and 2% *p*-aminohippuric acid (PAH) at a rate of 1.2 mL/min, and isotonic rat serum to replace surgical losses and to maintain the animals in euvolemic condition (13). After 45 to 60 min equilibration, the experimental study period began. Two urine samples and arterial blood samples were collected for determination of inulin and PAH concentrations. Hematocrit (Hct) and plasma (C_A) were also measured.

Micropuncture studies. Timed (1 to 3 min) samples of fluid were collected from surface proximal convolutions of at least three nephrons for determining flow rate and inulin concentration and for calculating single nephron glomerular filtration rates (SNGFR). Coincident with these tubule fluid collections, two or three samples of femoral arterial blood were obtained for determination of systemic arterial Hct, C_A, inulin and PAH concentration in the plasma.

Hydraulic pressure was measured in single capillaries within surface glomeruli by a continuous recording servonull micropipette-transducer system (IPM Inc., San Diego, CA). Direct measurements of hydraulic pressure in glomerular capillaries (P_{GC}), proximal tubules (P_T), afferent arterioles (P_{EA}) and peritubular capillaries (P_C) were recorded for each rat.

To obtain estimations of colloid osmotic pressure (π) of plasma entering and leaving glomerular capillaries, we measured protein concentration in femoral arterial (C_A) and efferent arteriolar (C_E) plasma (14). C_A was taken as the protein concentration in the afferent arteriole. These

estimations of pre- and post-glomerular plasma protein concentrations permit the calculation of colloid osmotic pressure, single nephron filtration fraction (SNFF), glomerular capillary plasma flow rate (Q_A), afferent (R_A), efferent (R_E) and total (R_T) arteriolar resistances, as well as of the glomerular capillary ultrafiltration coefficient (K_f) using equations previously described (15).

Analytical procedures. The concentration of inulin in the tubular fluid was measured by the microfluorescence method (16). The inulin concentration in plasma and urine was determined by the macroanthrone method (17). Protein concentration in efferent arteriolar and femoral arterial blood was determined by a fluorcolorimetric method (14). Plasma and urinary PAH concentrations were measured by the method of Smith *et al.* (18). Total renal vascular resistance was calculated as the MAP/RPF ratio. The filtration fraction was calculated as the quotient of GFR and RPF.

Data were analyzed by Student's unpaired and paired two-tailed test. Statistical significance was taken as $p<0.05$; all data are reported as X ± SE.

RESULTS

Table 1 shows that initial body weight, kidney weight, Hct and C_A were not different between the groups. However, the animals treated with DDP showed a significant weight loss after 4 days, from 293 ± 8 to 267 ± 7 g ($p<0.05$). Table 2 shows the date on whole kidney function. GFR decreased 66% ($p<0.05$) after cisplatin treatment when compared to the vehicle group. We similarly observed a reduction in RPF from 3.02 ± 0.34 to 0.86 ± 0.27 mL/min ($p<0.05$). Since mean arterial pressure was not different in both groups, *i.e.* in vehicle and DDP, calculated total renal vascular resistance (TRVR) increased from 20.5 ± 2.7 to 93.3 ± 12.5 $mmHg \cdot min \cdot mL^{-1}$, ($p<0.05$). As GFR and RPF decreased proportionally, filtration fraction (FF) remained unchanged. Urinary volume was significantly higher in DDP rats compared to controls, 12.4 ± 0.2 *vs* 3.3 ± 0.3 μL/min ($p<0.05$). Chronic BN 52063 administration did not change whole glomerular function compared to controls. Concomitant treatment with BN 52063 and DDP normalized GFR (0.33 ± 0.04 *vs* 1.03 ± 0.05 mL/min; $p<0.05$), RPF (0.86 ± 0.27 *vs* 3.49 ± 0.17 mL/min; $p<0.05$) and TRVR (93.3 ± 12.5 *vs* 28.3 ± 1.3 $mmHg \cdot min \cdot mL^{-1}$; $p<0.05$) when compared with results obtained with DDP alone. However, urinary volume remained unchanged (12.4 ± 0.2 *vs* 12.8 ± 3.4 μL/min).

Tables 3 and 4 summarize the data on superficial nephron function. Mean values for SNGFR and Q_A were significantly lower in cisplatin-treated rats than in vehicle rats, 20.1 ± 2.3 *vs* 34.2 ± 2.1 nL/min ($p<0.05$) and 61 ± 6 *vs* 106 ± 9 nL/min ($p<0.05$), respectively. SNFF did not change 33 ± 3 *vs* 34 ± 3%. Since mean P_{GC} decreased from 46 ± 1 to 41 ± 1 mmHg ($p<0.05$) and mean P_T remained unchanged (from 15 ± 1 to 17 ± 2 mmHg), the mean transcapillary hydraulic pressure difference (ΔP) decreased significantly from 31 ± 1 to 27 ± 1 mmHg ($p<0.05$). Cisplatin treatment induced an impressive increase in total arteriolar resistance (R_T), 7.0 ± 0.4 *vs* 3.8 ± 0.2 × 10^{10} $dyn \cdot s \cdot cm^{-5}$ ($p<0.05$) which resulted from the rise in both R_A (88%) and R_E (77%), but mainly in R_A as shown in Table 4. The mean glomerular ultrafiltration coefficient (K_f) was similar for the vehicle and the DDP group.

[c]BN + DDP *vs* DDP.

Reminiscent of what was observed for whole kidney function, chronic BN 52063 administration alone did not change the superficial renal microcirculation. However, the treatment with BN 52063 in the group receiving DDP induced a marked increase in SNGFR (20.1 ± 2.3 *vs* 35.1 ± 2.1 nL/min; $p<0.05$). The normalization of SNGFR resulted from increases in Q_A (61 ± 6 *vs* 120 ± 12 nL/min; $p<0.05$) and ΔP (27 ± 1 to 32 ± 1 mmHg; $p<0.05$) with decreases in both arteriolar resistance, especially R_A (4.7 ± 0.5 *vs* 2.2 ± × 10^{10} dyn·s·cm^{-5}; $p<0.05$). K_f remained unchanged (0.0628 ± 0.0163 *vs* 0.0761 ± 0.0050 nL/s·mmHg; $p>0.05$).

DISCUSSION

Cisplatin has been shown to have potent chemotherapeutic effects in a variety of human neoplasms, impeding the development of many solid tumors, including testicular, ovarian and lung cancers (1). Since the kidney is highly susceptible to toxic injury, it is not surprising that antineoplasic agents may cause nephrotoxicity. Thus, we employed an experimental protocol in which the renal function was evaluated after 4 days of cisplatin administration. Moreover, we studied the role of PAF in DDP nephrotoxicity, by using BN 52063, a PAF antagonist.

Vehicle administration did not cause any alteration in renal hemodynamics when compared to control Munich-Wistar rats. After 4 days of short-term BN 52063 treatment in control rats (Group 4), we did not observe any alterations in total or superficial kidney functions under euvolemic conditions. Thus, BN 52063 may be useful in the study of the pathophysiology of PAF in various renal disorders.

In fact, our data suggest a possibly important involvement of PAF in DDP nephrotoxicity, because normalization of renal function was achieved when a PAF antagonist was co-administered. However, despite the protective effect of BN on glomerular hemodynamics, we did not observe reversion of the polyuria induced by DDP. This suggests that the mechanism(s) involved in the urinary concentration may be independent of the vasoconstriction that causes ARF in DDP rats. Actually the polyuria induced by cisplatin have been suggested to occur by two distinct mechanisms. In the first phase (24 to 48 hr), polyuria results from a reduction in vasopressin release

or synthesis and a rise in prostaglandin production (19). In the later phase, the mechanism is probably dependent on the lack of urea addition to the fluid in the loop of Henle (20).

In the present study, cisplatin administration caused a substantial decrease in GFR and RPF with a marked increase in TRVR. The decrease in GFR has been attributed to the vasoconstriction of renal vessels with a decrease in renal plasma flow and in effective filtration pressure (5). To clarify the pathophysiological mechanism(s) of ARF induced by cisplatin, the glomerular hemodynamics were studied in Munich-Wistar rats. We observed a marked increase in both afferent and efferent arteriolar resistance, mainly in R_A. The increase in R_A was associated with a significant decrease in intraglomerular hydraulic pressure (P_{GC}). Since P_T remained unchanged, ΔP decreased significantly. The latter data pinpoint intratubular obstruction as a main factor in cisplatin-induced ARF. Similarly, it was noted that intratubular obstruction did not play an important role in the early phase of ARF (5).

Clinical (21,22) and experimental (5,23,24) studies suggest that cisplatin-induced ARF is in part caused by reduced renal blood flow. Actually, we also observed significant decline in mean Q_A as measured by observed arteriolar vasoconstriction. After volume expansion, Winston and Safirstein (5) observed that renal plasma flow in cisplatin-treated rats increased, but GFR and SNGFR remained below control euvolemic values, suggesting that a reduction in K_f contributes to the decreased GFR. In the present study we observed a ~35% decrease in K_f, although this reduction did not reach statistical significance.

Similar to the observations reported by others (5,10,23), the decline in SNGFR (41%) was disproportionately lower than that observed for GFR (66%). Various possibilities should be considered to explain this finding. Safirstein *et al.* (10) demonstrated that inulin leaks (~30%) out of the tubule fluid beyond the site of proximal tubule puncture. However, the magnitude of this leak is not enough to explain the discrepancy between SNGFR and GFR. Another possibility is that we have preferentially chosen and punctured slightly affected nephrons and not more severely altered nephrons (bias selection). However, we did not observe apparent differences in the surface morphology. A likely mechanism may involve a predominant effect of DDP on juxtamedullary nephrons, leading to a greater decrease in GFR as compared to SNGFR, thus accounting for the observed difference.

Several compounds have been reported to limit cisplatin nephrotoxicity. Sodium thiosulfate (11), superoxide dismutase (25) and atrial natriuretic factor (26) administration have been shown to have some partial beneficial effect on the experimental model of ARF induced by cisplatin. However, acute or chronic administration of captopril, an angiotensin I converting enzyme inhibitor or verapamil, a calcium channel blocker, did not change the evolution of cisplatin nephrotoxicity (20). In contrast, the present study showed that the treatment with a PAF antagonist (BN 52063) completely prevented the alterations induced by DDP in both global and superficial nephron functions. The increases in mean arteriolar resistances and the decrease in ΔP were abolished by simultaneous treatment with BN 52063. Moreover, the glomerular plasma flow rate remained unchanged and the SNGFR returned to normal levels. Thus, BN 52063 treatment induced a striking change in ARF caused by DDP; it normalized all parameters of renal function and improved morphological parameters and overall mortality (Pirotzky, E., unpublished observations).

In summary, our data have shown that the reduction in SNGFR caused by cisplatin treatment resulted from intrarenal vasoconstriction, mainly in the pre-glomerular arteriole (R_A), leading to a decrease in Q_A and ΔP. K_f was not substantially altered. BN 52063 was able to normalize renal function in DDP treated rats, suggesting that PAF may have a potential role in cisplatin-induced nephrotoxicity. Thus, the PAF antagonist BN 52063 offers itself as a novel drug that can prevent the deleterious effects of DDP on renal microcirculation.

Effects of PAF Antagonists on Renal Vascular Escape and Tachyphylaxis in Perfused Rabbit Kidney[1]

M.G. Ferreira[a], P. Braquet[b] and M.C. Fonteles[a,*]

[a]Unidade de Pesquisas Clínicas, Centro de Ciencias da Saude, Universidade Federal do Ceará, Fortaleza, Brazil, and [b]Institut Henri Beaufour, F-92350, Le Plessis Robinson, France

Renal vascular escape is a physiological phenomenon of adaptation that occurs in vascular smooth muscle. It has been described in many preparations subjected to electrical stimulation or treated with vasoactive agents, such as noreprinephrine, angiotensin and vasopressin. We have recently demonstrated that a naturally occurring ginkgolide (BN 52021), which is a PAF antagonist, was able to block norepinephrine-induced escape in perfused rabbit kidney. In the present work other PAF antagonists, such as the ginkgolides BN 52022 and BN 52024, and the synthetic compounds 48740 RP and WEB 2086, were tested. Their effects on renal vascular escape, perfusion pressure and tachyphylaxis were evaluated. They all were shown to block the escape. Among the ginkgolides, BN 52024 is generally recognized as one of the weaker PAF antagonists. However, in spite of this, BN 52024 was able to significantly and simultaneously block renal vascular escape and tachyphylaxis in perfused rabbit kidney infused with norepinephrine.
***Lipids* 26, 1329–1332 (1991).**

In 1964, Folkow *et al.* (1) demonstrated in anesthetized cats that electric stimulation of sympathetic nerves of the mesenteric vascular bed produced an initial vasoconstriction followed by a return of flow toward control levels, even during continued nerve stimulation. This phenomenon was called "autoregulatory escape" and later defined as the failure of the vascular smooth muscle to maintain its contraction when a constant stimulus is applied (2).

The occurrence of escape in vascular beds of different animals, induced by direct stimulation of sympathetic nerves or by infusion of vasoconstricting substances, has been reported. Sites of vascular escape described include the mesenteric bed (1,3,4–7), hepatic and portal beds (8–10), and renal artery (5,11,12). In all these experiments, escape was induced by neural stimulation. Adrenergic stimuli facilitated vascular escape at the mesenteric (13–16), hepatic (8,10,16) and renal (5,17,18) sites.

Escape occurs during constant pressure or constant flow (3–5) and is not altered by β-receptor blockade (19,10), atropine (6), reserpine (20), adenosine (21), aspirin (20), or endothelium-derived relaxing factor (EDRF)-blocking agents (22). Indomethacin partially blocks noradrenergic-induced escape (20), but not the escape produced by sympathetic stimulation (6).

Previous reports suggest that the mechanism of escape may involve either the release of an unknown vasodilator (15,17) or a cellular mechanism which results in the inability of the arteriolar smooth muscle to maintain its contraction (23). Identification in kidney of platelet activating factor (PAF) being a vasodilator (24), as well as the discovery of PAF antagonists (25), led us to propose that PAF may be involved in vascular escape. We have therefore studied the role of several PAF antagonists in this phenomenon.

MATERIAL AND METHODS

Rabbits of both sexes, each weighing 1–2 kg, were fasted for 24 hr. The animals had access to water and were kept in the laboratory in the morning of the experiment. They were anesthetized intraperitoneally with sodium pentobarbital (50 mg/kg). After an abdominal incision, the left kidney was isolated from surrounding tissues and the ureter and renal penduncle were carefully dissected. The renal vein was then severed proximally to the kidney and the renal artery immediately cannulated. Perfusion was initiated in a Petri dish containing Krebs-Henseleit solution, with the pH adjusted to 7.3–7.4. The kidney was flushed with oxygenated perfusate and, after cannulation of the ureter, the organ was connected to an open perfusion system.

This system consisted of a previously calibrated Gilson (Paris, France) Minipuls perfusion pump, a heat exchanger, an Imbracrios (Ribeirão Preto, Brazil) infusion pump, a membrane oxygenator (Travenol, Deerfield, IL) and a pressure device to monitor perfusion pressure. Several physiological parameters were measured including perfusate flow, urinary flow, resistance, and perfusion pressure. Perfusate flow was measured at 10-min intervals by collecting the perfusion effluent. Urinary flow was also determined. To measure renal vascular resistance, the ratios of the mean perfusion pressure (mmHg) and the perfusate flow rate were followed. To evaluate vascular escape, the kidney was submitted to noradrenergic vasoconstriction for 20 min; escape was present when at the end of the α-agonist infusion the perfusion pressure was less than the maximal effect. Renal vascular escape was calculated according to Fonteles *et al.* (17) and Henrich and Lutz (13), and was expressed as (Pmx-Pmn)/(Pmx-Pi) × 100, where Pmx and Pmn were, respectively, the maximal and minimal perfusion pressures obtained during norepinephrine (NOR) infusion, and Pi was the initial pressure measured just prior to α-agonist infusion.

The effects of several PAF antagonists were evaluated, including the naturally occurring ginkgolides BN 52022 and BN 52024 (2.27×10^{-5} M and 2.35×10^{-6} M,

respectively), the synthetic compound 48740 RP (10^{-5} M) and a triazolobenzodiazepine WEB 2086 (10^{-6} M). These drugs were added to the perfusion fluid at the beginning of the experiment and the response of the kidney vessels to the agents was observed during three bursts of 20-min NOR (1.3×10^{-6} M) infusion. All salts and chemicals used were reagent grade. The ginkgolides were donated by Institut Henri Beaufour. 48740 RP was a gift of Dr. Boris B. Vargaftig from Institut Pasteur, and WEB 2086 was donated by Boehringer-Ingelheim. Data were analyzed by paired and unpaired t-tests.

RESULTS

Control kidneys. Infusion of NOR (1.3×10^{-6} M) resulted in a sudden increase in perfusion pressure and resistance, which was followed by escape and tachyphylaxis as seen in Tables 1, 2 and 3.

The increase in resistance was due to α-agonist administration. Resistance dropped below control values during the wash-out periods. Urinary flow decreased from 0.093 ± 0.015 mL/g/min to 0.059 ± 0.008 mL/g/min during NOR infusion, while the perfusate flow rate remained constant during the experiment.

Kidneys treated with ginkgolides. When two specific PAF receptor antagonists, BN 52022 (2.27×10^{-6} M) and BN 52024 (2.35×10^{-6} M) were added to the perfusate, renovascular escape produced by NOR infusion was partially blocked (Table 3). The magnitutde of this blockage was greater in kidneys treated with BN 52024, which was also more effective in reversing tachyphylaxis (Fig. 1). BN 52022 caused throughout the set of experiments a drop in resistance which reached values below control levels (Table 2). Urine flow decreased slightly in kidneys perfused with BN 52022 during the last period of NOR infusion, but perfusate flow remained unchanged. The opposite occurred with kidneys treated with BN 52024 which showed increased urinary flow.

Kidneys infused with synthetic PAF antagonists. In kidneys treated with 48740 RP, noradrenergic vascular escape and tachyphylaxis were also blocked, although less efficiently (Table 3). The resistance values, however, were always above the averages registered for the other groups, even during the wash-out period (Table 2). The perfusate flow was constant and the urinary flow rate decreased only during NOR infusion. WEB 2086 (10^{-6} M) partially blocked vascular escape (Table 3) while other parameters (resistance and perfusion pressure) of kidney perfusion remained unaltered (Tables 1 and 2). The effects of several PAF antagonists on renal vascular escape are shown in Table 3.

DISCUSSION

The failure of the kidney vascular smooth muscle to maintain its contraction during prolonged NOR infusion at a constant flow rate characterizes renal vascular escape, as described previously (17,18,20). The mechanism of this phenomenon remains elusive, and some workers have suggested that release of a vasodilator, in response to constrictor stimuli, may be involved in this process (15,17,23).

Since PAF promotes hypotension (26,27) and is produced by kidney tissues under various conditions

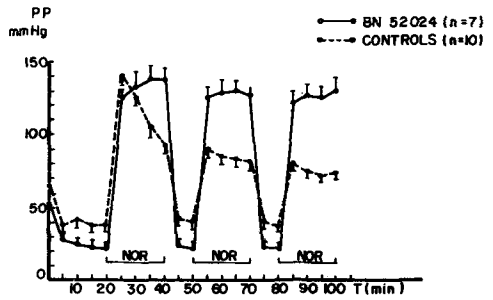

FIG. 1. Effects of repeated infusions of NOR (1.3×10^{-6}) on perfusion pressure of isolated rabbit kidney. Organs in this group were perfused with Krebs-Henseleit solution containing 2.35×10^{-6} M BN 52024. The control group was also plotted to demonstrate the complete reversal of tachyphylaxis.

(28,29), we hypothetized that PAF may be one such mediator.

Recently, we have demonstrated that the PAF antagonist ginkgolide B (BN 52021, 3.05×10^{-6} M) reduced vascular escape and blocked tachyphylaxis (30). BN 52021 is the most potent compound in displacing [^{3}H]PAF bound to its receptor and it has been considered to be the most potent PAF antagonist among the ginkgolides (31,32).

BN 52022 and BN 52024 share structural features which include the presence of a hydrophilic group close to lipophilic moiety, and this may well relate to their relative inability to displace bound [^{3}H]PAF (33). A recent study has compared the relative potencies of ginkgolides A, B and C (BN 52020, BN 52021 and BN 52022, respectively) in inhibiting PAF metabolism. These three compounds displayed in other systems the same order of potency as that described for platelet aggregation and PAF specific binding (32,34).

The fact that WEB 2086 and 48740 RP are also very active as escape blockers led us to believe that PAF is a mediator in this phenomenon.

In the present study, BN 52024 was used as a negative control because its PAF antagonistic effect is minimal. BN 52022 showed the ability to promote partial blockade of renovascular escape and tachyphylaxis. However, it was unexpected that BN 52024 would prove to be the most potent inhibitor of noradrenergic-induced escape and tachyphylaxis in rabbit kidney (Table 3).

Responses to NOR were always tachyphylatic in the present model (35). A high calcium concentration in the perfusate abolished NOR-promoted tachyphylaxis in rabbit kidney (36). Conversely, a low concentration of calcium and glucose in the infusate favors tachyphylaxis due to angiotensin II (37). Ginkgolides antagonize the rise in intracellular Ca^{2+} either by inhibiting calcium influx or calcium mobilization induced by PAF (38). It therefore seems unlikely that tachyphylaxis would be related to PAF antagonism and the effects observed here may be ascribed to a unique property of this compound. Escape could solely be dependent upon PAF receptor blockade. However, BN 52024 may possibly permeate the cell membrane and promote intracellular alterations which are linked to calcium mobilization, or it may act on a special PAF receptor.

The relationship between the occurrence of platelet-activating factor (PAF) and neutrophils in urine from patients with urinary tract infection was examined. PAF was detected in human pyuria, when leukocyte levels reached at least 300 cells/μL (n=45), but not in normal urine (n=12). The amount of PAF found in pyuria, measured by platelet aggregation assay, was 0.01 to 13.3 pmol/mL. A close correlation was seen between the amount of PAF present and the number of urinary leukocytes ($p < 0.01$, $r=0.70$). The leukocytes in pyuria consisted almost entirely of neutrophils (96 ± 4 %, mean ± S.D.). Our findings suggest that the occurrence of PAF is associated with the accumulation of neutrophils in urine.

Lipids 26, 1333–1335 (1991).

Platelet-activating factor (PAF) is generated by neutrophils, macrophages, monocytes, and endothelial cells, and is thought to play a role in the development of inflammation (1,2). However, the detailed mechanisms of PAF formation in these processes are not clear. Human neutrophils, which produce and are activated by PAF (3,4), are among the principal inflammatory cells. This suggests that the occurrence of PAF may be related to the accumulation of neutrophils in inflammatory lesions.

Sanchez-Crespo *et al.* (5) had found PAF at very low levels in the urine from normal volunteers. In the present study, the relationship between PAF and neutrophils in human urine was examined.

MATERIALS AND METHODS

1-*O*-Hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine (C_{16}PAF) and bovine serum albumin (BSA) were purchased from Sigma Chemical Co. (St. Louis, MO). CV-3988 (6) and CV-6209 (7) were gifts from Takeda Chemical Industries Ltd. (Osaka, Japan), and FR-900452 (8) was a gift from Fujisawa Pharmaceutical Co. (Osaka, Japan). Silica gel G plates (0.25 mm layer) were from Analtech (Newark, DE). Silicar (100–200 mesh type 60Å special) was obtained from Mallinckrodt Inc. (Paris, KY). Sources of other chemicals and other details are those described previously (9).

Fifty-seven samples of urine were obtained from 38 individuals as follows: 12 samples from 10 normal volunteers (6 male and 4 female; 51 ± 27 years of age, mean ± S.D.) and 45 samples from 28 patients with urinary tract infection (14 male and 14 female; 64 ± 20 years of age). The leukocytes in urine were counted using a blood cell counter. Pyuria is defined as urine containing more than or equal to 300 leukocytes/μL.

Total lipids were immediately extracted from 6 mL of fresh midstream urine by the method of Bligh and Dyer (10). Total lipids were applied to a silica gel column, and neutral lipids were eluted with chloroform. Phospholipids were recovered with methanol and suspended in 100 μL of 2.5 mg BSA/mL saline. For some samples, phospholipids were separated by preparative silica gel G thin-layer chromatography (TLC), using chloroform/methanol/water (65:35:6, v/v/v) as developing solvent. The silica gel was scraped from the TLC plates in 1 cm bands, and each fraction was extracted.

Washed rabbit platelets were prepared by the method of Pinckard *et al.* (11). The amount of PAF was quantified by measuring the ability of each sample to aggregate washed rabbit platelets using an aggregometer, as described previously (12). PAF levels are expressed as fmol/mL urine calculated from a calibration curve established for C_{16}PAF, which also is the major PAF species generated by human neutrophils (13). The minimum amount of PAF detectable by this method was 10 fmol/mL.

When the phospholipids from pyuria were diluted with BSA/saline and added to washed rabbit platelets, platelet aggregation decreased. By contrast, Nakayama *et al.* (14) reported that when similarly prepared samples from rat uterus were diluted with BSA/saline and added to washed rabbit platelets, platelet aggregation increased. This discrepancy was explained by the presence of endogenous inhibitors, such as lysophosphatidylcholine and sphingomyelin, in rat uterine samples. In our samples, the content of inhibitors was apparently insufficient to interfere with the platelet aggregation assay, even if endogenous inhibitors would have been present. The amount of PAF in urine was determined based on the aggregating activity of the phospholipid fraction obtained by column chromatography.

RESULTS AND DISCUSSION

When the phospholipid fraction from pyuria was reacted with washed rabbit platelets, immediate aggregation was observed. The aggregation curve was similar to that produced by authentic C_{16}PAF. The aggregation was completely inhibited upon preincubation with CV-3988, CV-6209, or FR-900452, which are specific antagonists of PAF (6–8) (Fig. 1).

The phospholipids from urine were also separated by thin-layer chromatography using chloroform/methanol/water (65:35:6, v/v/v) as solvent. Aggregation was induced by the fraction with the same migration rate (R_f) as that of C_{16}PAF, but not by the other fractions (Fig. 2). The results indicate that platelet-aggregating activity is associated with the PAF fraction isolated from the urine of human subjects with pyuria.

The amount of PAF in pyuria varied from 0.01 to 13.3 pmol/mL (n=45), but by our method PAF was not detected in normal urine (n=12). A close correlation was found between the amount of PAF and the number of

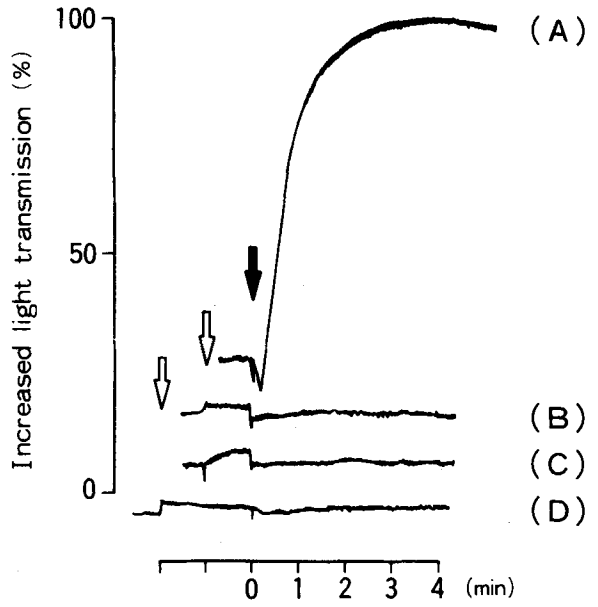

FIG. 1. Platelet aggregation by phospholipids extracted from urine of patients with pyuria. Phospholipids from 6 mL of urine were suspended in 100 μL of 2.5 mg BSA/saline solution. Washed rabbit platelets and 5 μL of the suspension were then allowed to react in an aggregometer (A). Washed rabbit platelets were preincubated with 50 nM CV-6209 for 1 min (B); 8 μM CV-3988 for 1 min (C); or 8 μM FR-900452 for 2 min (D); and the samples were then allowed to react with the platelets. The solid arrow indicates the time of sample addition; the outlined arrows indicate the time of CV-6209, CV-3988, or FR-900452 addition.

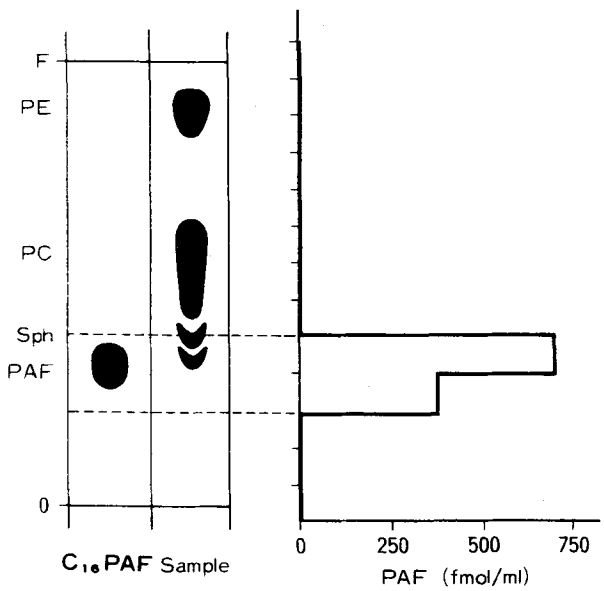

FIG. 2. The aggregating activity of the various fractions of phospholipids separated by TLC. The phospholipids from pyuria were separated by TLC using chloroform/methanol/water (65:35:6, v/v/v) as developing solvent. Fractions extracted from 1-cm silica gel bands were tested for their ability to promote platelet aggregation. Platelet aggregating activity was converted into amounts of C_{16}PAF. O, origin; F, front; PE, phosphatidylethanolamine; PC, phosphatidylcholine; Sph, sphingomyelin.

leukocytes in urine ($p < 0.01$, $r=0.70$) (Fig. 3). Light microscopic observation revealed that neutrophils were predominant among the leukocytes in pyuria (96 ± 4%, mean ± S.D., n=13). Hence, the presence of PAF appears to be related to the accumulation of neutrophils.

Sanchez-Crespo *et al.* (5) reported that urine from normal volunteers contained a platelet-activating component with characteristics similar to those of synthetic PAF. In contrast, our tests showed that normal urine which contained less than 300 leukocytes/μL contained no PAF. Reasons for the differences in the amounts of PAF observed in Sanchez-Crespo's study and ours may include differences in the initial volume of urine analyzed (about 1500 mL in their study and 6 mL in ours).

The observed relationship between the amount of PAF and the number of neutrophils present in urine appears to be reminiscent of what has been observed in scales from patients with psoriasis (15), and in pleural fluid from patients with pyothorax (16). There could be two explanations for this interrelationship between neutrophils and PAF. One is that PAF may be generated by neutrophils; the second is that PAF may be generated by other cells and that neutrophils may be accumulated in the inflammatory lesions. The source of PAF in pyuria is still unknown.

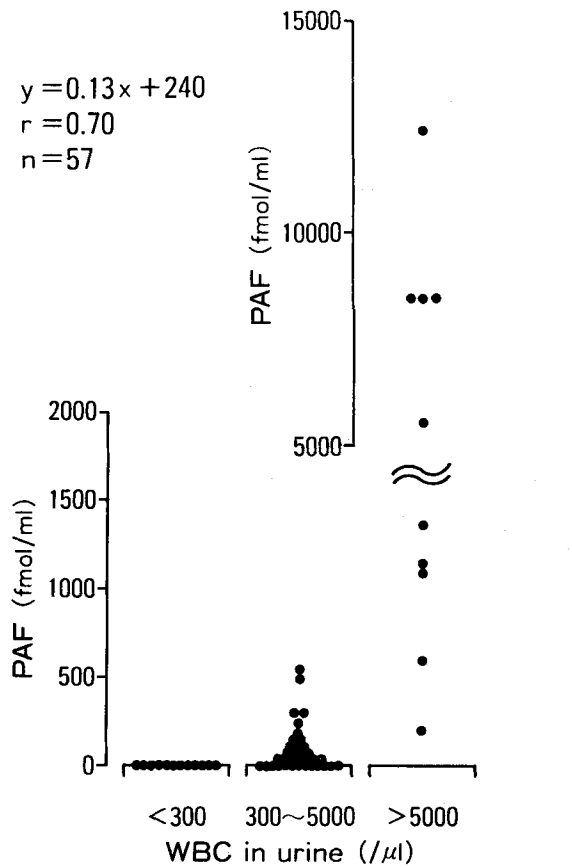

FIG. 3. Relationship between the amount of PAF and the number of leukocytes in urine. The amount of PAF was quantified by determining the ability of each sample to aggregate washed rabbit platelets in an aggregometer. The results are expressed as fmol/mL urine, calculated from a calibration curve established for C_{16}PAF. Pyuria was defined as urine containing more than or equal to 300 leukocytes/μL.

In conclusion, we found PAF in human pyuria and noted a close correlation between the amount of PAF and the number of neutrophils present. The occurrence of PAF appears to be associated with the accumulation of neutrophils in urine.

REVIEW

Significance of Platelet-Activating Factor in Mesenteric Ischemia-Reperfusion[1]

János Filep[a,*], Pierre Braquet[b] and Tibor Mózes[c]
Departments of [a]Pathophysiology and [c]Traumatology, Semmelweis University Medical School, 1445 Budapest, Hungary, and [b]Institut Henri Beaufour, 92350 Le Plessis Robinson, France

Reperfusion of the ischemic mesenterium is frequently followed by acute circulatory collapse. This review focuses on the possible role of platelet-activating factor (PAF) in ischemia-induced damage. It provides evidence that (i) PAF concentrations are elevated in the mesenteric circulation following temporary ischemia; (ii) administration of exogenous PAF into the superior mesenteric vein mimics many events observed during reperfusion; and (iii) pretreatment of the experimental animals with specific PAF receptor antagonists prevent the circulatory collapse. These findings suggest that PAF may play an important role in the development of circulatory collapse caused by mesenteric ischemia-reperfusion.
***Lipids 26,* 1336-1339 (1991).**

Reperfusion of an ischemic organ salvages some tissues that would have died if blood flow had not been restored. However, it results in prolonged but ultimately reversible dysfunction of the reperfused organ and often leads to acute circulatory collapse. Thus, reperfusion is a double-edged sword. During ischemia and reperfusion, various types of cells, including neutrophil granulocytes (1-3) and platelets (4), are activated. These cells are sources of numerous mediators, like free oxygen radicals (5,6), histamine (7), prostanoids (8-10), leukotrienes (9) and platelet-activating factor (PAF) (11). These mediators are thought to be responsible for the reperfusion injury and for the cardiovascular changes.

Since its identification in the early 1970's (12,13), PAF has emerged as a potential mediator of diverse pathological processes, such as airway hyperreactivity, shock, cardiac and systemic anaphylaxis, gastrointestinal mucosal damage and a variety of inflammatory conditions (11,14, 15). Evidence is accumulating which supports a role for PAF in ischemia-induced damage in various organs (16). PAF meets all of the major criteria required to define mediators of ischemia and shock: (i) it occurs in critical sites (i.e., in tissues or biological fluids of experimental animals) during the critical time; (ii) administration of exogenous PAF can mimic many events observed following ischemia; and (iii) PAF receptor antagonists protect against the reperfusion injury. This paper compiles available evidence on the possible role of PAF in the pathophysiology of mesenteric ischemia-reperfusion and analyzes the potential interactions of PAF and prostanoids.

REPERFUSION OF THE ISCHEMIC MESENTERIUM

Reperfusion of the ischemic mesenterium is frequently followed by an acute circulatory collapse (17). The hemodynamical changes may be reversible (i.e., correction of the impaired perfusion leads to restoration of systemic and organ functions) or irreversible (where uncorrectable changes have been produced during the ischemic state), depending on the duration of ischemia. One-hour occlusion of the superior mesenteric artery (SMA) in dogs resulted in reversible changes, while 2-hour occlusion evoked irreversible changes (18). Restoration of blood flow following 2-hour ischemia resulted in an immediate decrease in mean arterial blood pressure (MABP), and an increase in mean portal venous pressure (MPVP) and SMA blood flow (Fig. 1). The maximum reductions or elevations, respectively, were observed within 5-7 min. Then SMA blood flow returned to control levels, whereas MABP stabilized at low levels and MPVP remained elevated during the entire period of observation. Hematocrit values rose more than 30% during the first 5 min of reperfusion, and thereafter remained unchanged (19, 20). These changes were accompanied by a significant

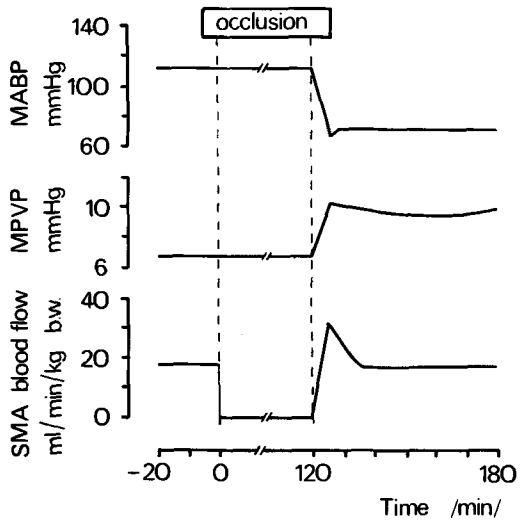

FIG. 1. Representative traces for the time course of changes in mean arterial blood pressure (MABP), mean portal venous pressure (MPVP) and superior mesenteric artery (SMA) blood flow in anesthetized dogs subjected to 2-hour occlusion of the superior mesenteric artery.

Abbreviations: MABP, mean arterial blood pressure; MPVP, mean portal venous pressure; PAF, platelet-activating factor; SMA, superior mesenteric artery.

decrease in the number of circulating platelets and serum calcium levels (20). Serum potassium and uric acid levels were elevated at 5 min of reperfusion, while their levels returned to control values at 60 min of reperfusion (20). Concentrations of $PGF_{2\alpha}$, TXB_2 and 6-keto $PGF_{1\alpha}$ in the superior mesenteric vein were two- to six-fold higher than control levels after 5 min of reperfusion (18). Then plasma levels of these prostanoids tended to decrease, but their concentrations remained above their preocclusion values even after 60 min of reperfusion (18). Ischemia-reperfusion increased the mucosal permeability of terminal ileum of rats, released lysosomal enzymes from the mucosa to the lumen (21) and resulted in neutrophil invasion of the intestinal wall (3,22).

OCCURRENCE OF PAF DURING ISCHEMIA-REPERFUSION

To accept PAF as a mediator of ischemia-reperfusion, either it or its metabolite should be present during the disease process itself. Since PAF radioimmunoassay became available only very recently, the measurement of PAF was based on bioassays (aggregation of rabbit platelets or release of labeled serotonin from preloaded platelets). Measurement of PAF in blood is further complicated by the fact that it is rapidly hydrolyzed to biologically inactive lysoPAF (11,14).

To date, only a few reports document the presence of PAF in organs or in circulation during shock and ischemic states. Elevated plasma levels of PAF were found in *E. coli* endotoxemia (23) and in gram-negative bacterial sepsis (24). Enhanced PAF production has also been reported in glomeruli isolated from rats subjected to 60 min renal ischemia (25). Recently, we measured PAF in the mesenteric vein of the dog during reperfusion (19). PAF was extracted from blood, purified and quantitated by a bioassay system (aggregation of rabbit platelets). PAF concentrations in the mesenteric vein were found to be about thirteen-fold and four-fold higher than the preocclusion values at 5 and 60 min of reperfusion, respectively (Fig. 2). Similarly enhanced PAF release was reported during myocardial ischemia-reperfusion in rabbits (26). It is worth mentioning that low amounts of PAF were detected in the blood of healthy volunteers (27) and experimental animals (19,20,28). Whether these low concentrations of PAF represent its basal level or indicate its generation during blood collection and extraction procedure is not clear. The biological significance of PAF, if present in blood under control conditions, remains to be determined.

EFFECTS OF EXOGENOUS PAF

Systemic administration of exogenous PAF to experimental animals produced severe hypotension, shock and even death (29,30). The shock syndrome involved altered pulmonary (31) and coronary circulation (32), increased vasopermeability and hemoconcentration (33) and activation of various cells (11,14,15). PAF was also shown to increase formation of thromboxane A_2 (32,34,35) and leukotrienes (35,36), suggesting that its effects may be partly mediated by eicosanoids.

Local administration of PAF can mimic many events characteristic for ischemia-reperfusion in brain (37), heart (35) and intestine (21). Administration of PAF at a dose of 0.1 μg/kg body weight into the superior mesenteric vein of the dog evoked similar changes in MABP, MPVP (Fig. 3), hematocrit values and platelet count as those observed during reperfusion (19,20). On the contrary,

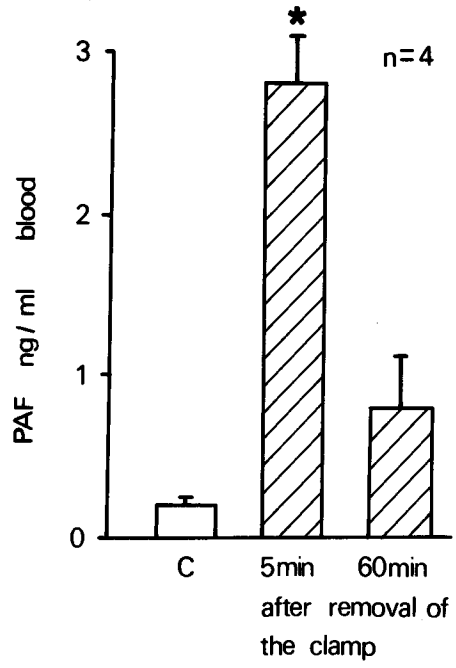

FIG. 2. PAF concentrations in the dog superior mesenteric vein during reperfusion. Blood was collected (a) 10 min before occlusion of the superior mesenteric artery (c, control); (b) at 5 min of reperfusion, when maximal hemodynamical changes were observed; and (c) at 60 min of reperfusion, when hemodynamical parameters had stabilized. PAF was extracted, purified and measured by using the rabbit platelet aggregation method. Identity of the PAF-bioactivity recovered from blood with authentic PAF was ascertained by thin-layer chromatography, high performance liquid chromatography and alkaline treatment (19,20).

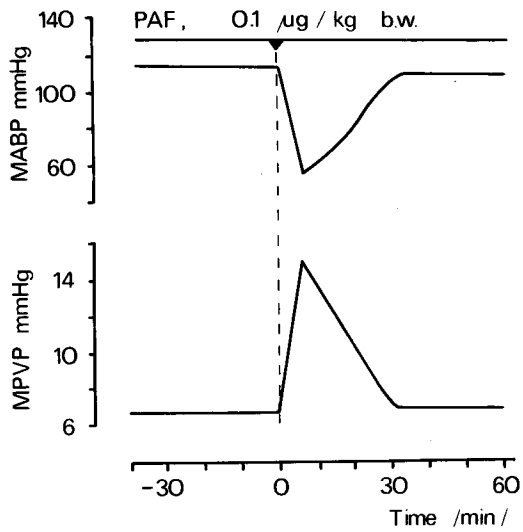

FIG. 3. Effects of exogenous PAF on mean arterial blood pressure (MABP) and mean portal venous pressure (MPVP) in anesthetized dogs. PAF, 0.1 μg/kg b.w. was injected into the superior mesenteric vein.

PAF did not effect serum uric acid, potassium and calcium levels (20). Since this dose of PAF was injected over a period of 1 min, and blood flow in the superior mesenteric vein was about 14–20 mL/min/kg body weight, peak concentrations of PAF in the mesenteric blood were calculated to be 5–7 ng/mL. These values are of the same order of magnitude as those measured at 5 min reperfusion (19,20) suggesting that the amount of PAF formed during reperfusion may be sufficient to evoke the observed changes.

PHARMACOLOGIC BLOCKADE OF PAF IN ISCHEMIA-REPERFUSION

Since the early 1980's, a group of specific PAF receptor antagonists have become available (38) that can be used to study the effects of PAF under various pathological conditions. There is accumulating evidence that the PAF receptor antagonists (e.g., BN 52021, kadsurenone, CV-6209) protected against reperfusion injury in brain (39–41), kidney (42) and heart (16,43,44). In mesenteric ischemia-reperfusion-induced shock, BN 52021, a competitive PAF receptor antagonist (45,46), prevented hypotension (19,20), hemoconcentration (19,20), activation of platelets (20), decrease in serum calcium concentration (20) and increases in serum potassium, uric acid (20), $PGF_{2\alpha}$, TXB_2 and 6-keto-$PGF_{1\alpha}$ levels (Filep *et al.*, unpublished observations). Furthermore, BN 52021 significantly reduced the increased intestinal permeability following ischemia (21) and attenuated the release of lysosomal enzymes from the mucosa to the lumen (21). Various PAF antagonists were found to exert a protective effect against mucosal damage similar to that observed with allopurinol, an inhibitor of xanthine oxidase in post-ischemic gastric lesion (22). However, BN 52021 had no effect on intestinal neutrophil accumulation following ischemia (21). Furthermore, it failed to modify the duration and the magnitude of reactive hyperemia in the mesenterium (20). This latter finding is consistent with the observation that BN 52021 has no effect on reactive hyperemia in gerbil brain (39).

SUMMARY AND CONCLUSIONS

Sufficient evidence has accumulated which suggest that PAF is an important mediator of reperfusion injury. Three major lines of observations support its role in mesenteric ischemia-reperfusion. PAF can be detected in mesenteric blood at concentrations sufficiently high enough to be responsible for many of the events observed during reperfusion. Secondly, exogenous PAF injected into the mesenteric circulation is able to produce acute circulatory collapse. Thirdly, pharmacological studies have shown that specific PAF receptor antagonists are capable of modifying the course of ischemia-reperfusion-induced shock. While any of these respective observations by themselves provide sufficient proof for a cause-effect relationship, the data taken together strongly suggest that PAF may play an important role in the early phase of ischemia-reperfusion. Figure 4 represents a simplified schematic diagram of the current understanding of PAF action during reperfusion. The cellular source(s) of the PAF released during ischemia-reperfusion is still unclear. Reperfusion injury is characterized by endothelial injury

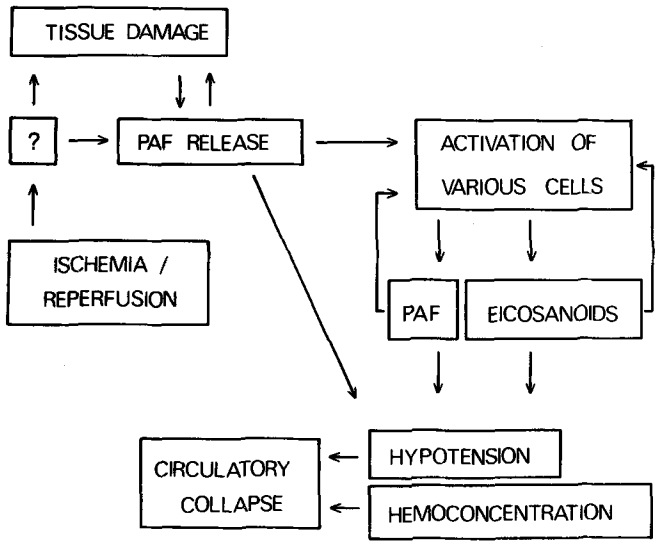

FIG. 4. Schematic presentation of the possible role of PAF in the early stage of mesenteric ischemia-reperfusion-induced shock. Reperfusion of the ischemic mesenterium leads to tissue damage and PAF release. The initial injury signal (questionmark) is still unknown. PAF released by either of the blood borne cells or by damaged tissues may cause further tissue destruction and activation of various cells. Stimulated cells, in turn, can release a wide range of vasoactive mediators, including PAF and eicosanoids. By activating the same and other cells, these lipid mediators can amplify the injury signal. Release of PAF and eicosanoids may lead to hypotension, hemoconcentration and to acute circulatory collapse.

(16) and ischemic tissues are infiltrated with different blood cells (3,16,22). All of these cells are capable of synthesizing PAF (11,14,15). Consequently, one or more of them may be responsible for the enhanced PAF concentrations in blood. Once released, PAF may exert a wide range of biological activities, including hypotension (29,30), hemoconcentration (33) and activation of various cells (11,14,15), which, in turn, release other vasoactive mediators, such as eicosanoids and oxygen radicals (6,32,34–36). Furthermore, PAF possesses the unique property of being able to induce its own synthesis *in vivo* (47,48), thus representing a self-generating, positive feedback system. However, one should keep in mind that none of the shock states are crucially dependent on any one class of lipid mediators. Indeed, PAF appears to play a minor (if any) role in reactive hyperemia (20,39), neutrophil infiltration (21) and tissue platelet accumulation (40). It remains to be established if the tissue damage is the cause or a consequence of PAF release. Although the signal that initiates reperfusion injury is not known, the data reviewed here suggest that PAF may serve as an early mediator to amplify the injury signal. As our understanding of the mediators and their complex interactions grows, the sequence of various events can be defined more precisely. The scheme may help to explain how the blockade of PAF can be an effective therapeutic modality in a complex multi-mediator system such as mesenteric ischemia-reperfusion-induced shock. Finally, more extensive experimental and clinical studies are needed to reveal whether the proposed role for PAF is correct and whether the PAF receptor antagonists developed so far have a therapeutic potential.

ACKNOWLEDGMENT

REVIEW

Hypoxia, PAF, and Necrotizing Enterocolitis[1]

Michael S. Caplan[2], Xiao-Ming Sun and Wei Hsueh*
Departments of Pediatrics and Pathology, Children's Memorial Hospital, Northwestern University Medical School, Chicago, Illinois 60614

Necrotizing enterocolitis (NEC) is an important neonatal disease with a high mortality rate. The pathophysiology is unclear but epidemiologic studies suggest that hypoxia and infection are important risk factors. In this review we discuss the effect of hypoxia and platelet-activating factor (PAF) on intestinal blood flow and intestinal necrosis, and implicate PAF as an important mediator in hypoxia-induced intestinal injury. Finally we provide evidence that PAF may be important in neonatal NEC. ***Lipids 26,*** **1340–1343 (1991).**

Necrotizing enterocolitis (NEC) is a neonatal disease that affects 1–5% of all neonates admitted to the intensive care nursery, and up to 12% of premature infants weighing less than 1500 grams (1). Despite intensive management, the morbidity and mortality rates remain distressingly high. Extensive investigations have failed to clarify the etiology of NEC; however, many risk factors have been implicated. These include prematurity (2), formula feeding (3), bacterial infection (4), hypoxia (5), and intestinal ischemia (6). In addition, experimental animal models have been developed to investigate the pathogenesis of ischemic bowel disease. These experimental models have supported the epidemiologic evidence implicating hypoxia and infection as risk factors for NEC but have failed to define the etiology. In this review, we will discuss the role of hypoxia on bowel necrosis, describe the association of platelet-activating factor (PAF) and intestinal injury, and summarize the possible role of PAF as a mediator for hypoxia-induced intestinal injury. Finally we will review the association of PAF in human, neonatal NEC.

THE ROLE OF HYPOXIA IN BOWEL NECROSIS

Hypoxia is regarded as an important risk factor for neonatal NEC (7). In animal models, hypoxia and/or asphyxia result in decreased gastrointestinal blood flow (8) which presumably leads to intestinal injury. Using newborn piglets, Nowicki *et al.* (9) have shown that a reduction in pO_2 from 85 to 18 mm Hg resulted in marked reductions of gastrointestinal blood flow. Karna *et al.* (10) demonstrated significant reductions in intestinal perfusion following alterations in respiratory function. It is of interest, that hypoxia was more deleterious than asphyxia or acidosis on intestinal blood flow and O_2 consumption. Although these studies suggest that hypoxia results in intestinal vasoconstriction, they did not demonstrate the development of intestinal necrosis.

In other animal models, intestinal injury has been induced by hypoxia and/or asphyxia (11). In the newborn rat pup, repeated asphyxial insult resulted in severe intestinal injury (12). Similarly, in the neonatal piglet, asphyxia for 2 hr produced decreased intestinal blood flow with early changes of intestinal necrosis (13). In the neonatal dog, pure hypoxia (10% O_2 for 2 hr) caused intestinal injury when specimens were evaluated 24 hr later (14). Others have shown mild intestinal injury followed hypoxia alone without asphyxia or acidosis (15). Although these reports confirm that hypoxia can lead to intestinal ischemia and focal intestinal necrosis, they do not describe the mechanism of the hypoxia-induced bowel injury.

THE ROLE OF PAF IN ISCHEMIC BOWEL NECROSIS

Platelet-activating factor (PAF, PAF-acether) is an endogenous phospholipid mediator with potent biological effects. In various animal models, PAF infusions have resulted in shock, bronchoconstriction, capillary leakage, neutrophil aggregation and degranulation, platelet aggregation and degranulation, and pulmonary hypertension (16,17). We have shown that intravascular injection of PAF in the rat produces ischemic bowel necrosis morphologically identical to neonatal NEC (18). In addition, low dose PAF and low dose bacterial endotoxin (LPS) synergistically induce bowel necrosis that can be prevented by pretreatment with PAF receptor antagonists (19). Further, we have shown that LPS injection in the rat causes increased intestinal PAF production which leads to bowel necrosis (20). In this model, we have shown that leukotriene C_4 (21), norepinephrine (22), oxygen radicals (23), and activated complement fragments (24) all may play a role in PAF-induced intestinal injury. Finally, we have shown that tumor necrosis factor-alpha (TNF) induced intestinal injury that was predominantly mediated by PAF (25).

Other investigators have studied the importance of PAF in gastrointestinal blood flow and injury. In the isolated, perfused rat stomach, PAF induced a dose-dependent reduction in gastric vascular flow which was effectively reversed with PAF receptor blockade (26). Furthermore, intravenous PAF administration in the rat produced extensive hemorrhagic erosions in the gastric mucosa (27). PAF-induced gastric ulceration appears to involve lipid peroxidation (28), oxygen free radicals (29), and increased gastric vascular permeability (30). Finally, in endotoxin-induced gastrointestinal damage, PAF was shown to be an important mediator of hypotension, plasma leakage, and intestinal ulceration (31). Similar to our findings, LPS-induced gastrointestinal lesions were prevented by PAF receptor antagonists (31,32). These studies all point to the importance of PAF in gastrointestinal injury.

THE ROLE OF HYPOXIA AND PAF IN INTESTINAL NECROSIS

Although hypoxia can result in intestinal ischemia and necrosis, the pathophysiology is not well understood. It is unclear whether hypoxia causes intestinal vasoconstriction directly or whether this process is mediated by compounds released following hypoxic exposure. In the rat model, hypoxia resulted in decreased gastric prostaglandin production (33). Recent evidence suggests that hypoxia leads to increased endothelial cell permeability and capillary leak, which are changes present in ischemic bowel necrosis (34,35).

It has also been shown that hypoxia results in increased PAF concentrations in rat bronchoalveolar lavage (36). Furthermore, hypoxia-induced increase in PAF concentrations appears to result from increased activity of phospholipase A_2, a key enzyme involved in the formation of precursor for PAF synthesis (37). Finally, in the ischemia-reperfusion model in the mesenteric circulation of the dog, systemic plasma PAF levels are increased (38). These findings suggest that hypoxia may increase PAF locally and/or in the systemic circulation. Since the association of PAF-induced intestinal injury is well known, we studied the role of PAF in hypoxia-induced intestinal ischemia and necrosis.

As seen in Table 1, acute hypoxia was accomplished following exposure to 100% N_2 for two minutes (mean ABG: pH/pCO_2/pO_2/base excess: 7.27/57/18/−2); sustained, moderate hypoxia (10% O_2) for thirty minutes resulted in hypoxia and acidosis (39). Plasma PAF levels were markedly elevated following only two minutes of severe, acute hypoxia (100% N_2, PAF level: 13.8 ± 2.9 ng/mL *vs* control: 2.1 ± 0.8 ng/mL, $p<0.01$, Fig. 1). Even with challenge of moderate hypoxia (10% O_2), a significant elevation was observed within 30 min. (41.0 ± 11.7 ng/mL, $p<0.01$, Fig. 1). The observed elevation of PAF in this model is much more rapid than what was reported by Prevost *et al.* (36) who showed that in rats following four hours of hypoxia the bronchoalveolar lavage fluid contained increased PAF concentrations.

The intestinal perfusion, as measured by the Evans blue dye method, was abnormal in all animals (n = 14) treated with hypoxia for 30 min. The mean percent bowel perfused was 40 ± 7% for the hypoxic animals, and ranged from 0 to 95% (Fig. 2). In contrast, all control animals showed normal (100%) intestinal perfusion. Pretreatment with the PAF receptor antagonists, SRI 63-441 (40) and WEB 2086 (41) (data not shown) prior to the hypoxic exposure, completely prevented the hypoxia-induced intestinal hypoperfusion (Fig. 2). This observation strongly suggests that PAF is an important mediator of hypoxia-induced intestinal vasoconstriction and hypoperfusion. Although hypoxia leading to intestinal ischemia is well known, to our knowledge these data are the first to suggest PAF as the important mediator.

We have shown that following 30 min of hypoxia there were early changes of intestinal necrosis, in addition to intestinal hypoperfusion (39). Histological examination of intestine from animals subjected to hypoxia alone revealed 6 of 14 animals with mild or moderate intestinal injury (Fig. 3, top), and 3 of 14 with minimal intestinal necrosis (Table 2). In contrast, microscopic examination of specimens from animals treated with two structurally different PAF antagonists, SRI 63-441 and WEB 2086, showed complete prevention of hypoxia-induced bowel injury (Fig. 3, bottom): none of the rats showed any necrotic changes except for one animal with focal, minimal injury (see legend, Table 2 for definition of microscopic intestinal

TABLE 1

Effect of Hypoxia on Arterial Blood Gas (pH/pCO_2/pO_2/base excess)

Treatment	Time of exposure	Number of animals	ABG (mean)
Air		5	7.34/43/96/−2
100% N_2	2 min	7	7.27/57/18/−2
10% O_2	15 min	5	6.99/95/23/−12
10% O_2	30 min	10	6.80/101/40/−22

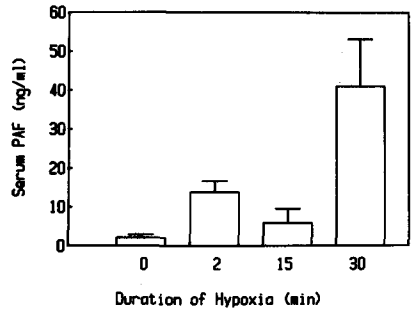

FIG. 1. The effect of hypoxia on serum PAF levels. The animals (male Sprague-Dawley rats, 60–90 g) were divided into four groups. The bars, from left to right, represent, rats breathing air (controls, n = 5); 100% N_2 for 2 min (severe hypoxia, n = 7); a mixture of 10% O_2, 15% CO_2, and 75% N_2 (moderate hypoxia) for 15 min (n = 5); the same gas mixture for 30 min (n = 10). Plasma PAF was extracted by the Folch method, purified by thin-layer chromatography, and quantitated with a rabbit platelet serotonin release assay. [^{3}H]PAF (10,000 cpm) was added at the start of each experiment to calculate extraction efficiency. Data are expressed as the mean ± SEM $P<0.05$ at 2 min, and $p<0.01$ at 30 min using analysis of variance with the Scheffe method to identify specific group differences.

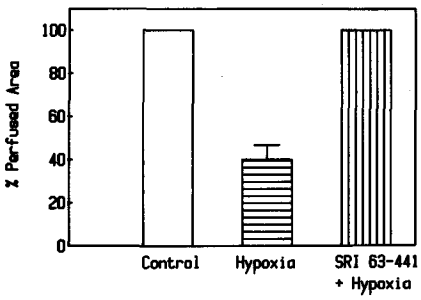

FIG. 2. Effect of hypoxia and PAF antagonist SRI 63-441 on intestinal perfusion. Intestinal perfusion was assessed after 30 min of hypoxia (n = 14) by the Evans blue dye method as described (39). Some animals were treated with the PAF receptor antagonist, SRI 63-441 (2.5 mg/kg i.v., Sandoz Research Institute, New Hanover, NJ), prior to hypoxic exposure (n = 5). The length of bowel not stained with Evans blue (hypoperfused) was measured and compared to the total intestinal length to calculate percent of perfused intestine (mean ± SEM). $P<0.01$ for hypoxia *vs* SRI pretreated groups.

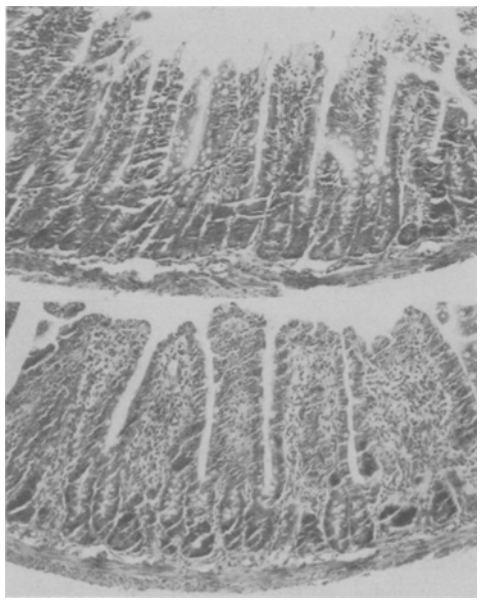

FIG. 3. Microscopic specimen from a rat. Top: treated with hypoxia (10% O_2) for 30 min. Bottom: pretreated with PAF receptor antagonist, SRI 63-441, 10 min prior to hypoxic exposure.

TABLE 2

Hypoxia-Induced Intestinal Injury and Its Prevention by PAF Antagonists

Treatment	Number of animals	Intestinal Injury[a]			
		None	Minimal	Mild	Moderate
Hypoxia 30 min	14	5	3	5	1
SRI 63-441 + Hypoxia	5	4	1	0	0
WEB 2086 + Hypoxia	5	5	0	0	0

[a]Intestinal injury was graded by microscopic examination. Sections were taken from the non-perfused areas of the small intestine; pathological changes of the most severe lesions are presented in the table (in animals pretreated with PAF antagonist in which no hypoperfused bowel was observed, random sections were taken for histological examination). Microscopic lesions were graded by one of the authors unaware of the codes. Minimal: Separation of the surface epithelial cells from lamina propria. Mild: Epithelial cell necrosis confined to the tips of villi. Moderate: Partial loss of intestinal villi. None of the animals showed necrosis beyond the mucosal layer. $P<0.05$ for antagonist *versus* hypoxia alone.

necrosis). Thus, PAF is probably an important mediator responsible for hypoxia-induced bowel injury. Interestingly, acidosis alone also increased PAF production, but failed to induce bowel necrosis (39). Thus it is probable that PAF and tissue hypoxia synergize in inducing tissue injury.

Acetylhydrolase is a PAF-specific enzyme that degrades PAF into biologically inert lysoPAF (42). This enzyme is found in most tissues, as well as in human serum (43). We found that serum acetylhydrolase activity was not significantly different between control and hypoxia-exposed rats at any time of blood sampling. However, intestinal acetylhydrolase activity increased following thirty minutes of hypoxia (3.8 ± 1.1 μmol/mL/min control *vs* 5.4 ± 0.6 μmol/mL/min hypoxia, $p<0.05$). Thus the acute rise in PAF must be a result of increased PAF production and not decreased degradation. This hypothesis is in accordance with the observation that hypoxia increases phospholipase A_2 activity, a key enzyme in the synthesis of PAF precursor (37).

In summary, severe hypoxia can rapidly (within two minutes) increase plasma PAF levels in the rat. In addition, following 30 min of moderate hypoxic challenge, intestinal hypoperfusion and mild ischemic bowel necrosis occurs, and can be prevented by PAF receptor antagonists. Although others have described the relationship of hypoxia inducing intestinal ischemia, hypoperfusion, and necrosis, these findings suggest that the changes are mediated by PAF.

PAF IN HUMAN NECROTIZING ENTEROCOLITIS

Although PAF is an important mediator of ischemic bowel necrosis in animal models, it is critical to investigate the role of PAF in human neonatal NEC. We have evaluated plasma PAF, plasma acetylhydrolase activity, and plasma TNF in 12 neonates with classic NEC and compared the levels to age-matched controls (44). Our findings showed that patients with NEC have higher plasma PAF (18.1 ± 3.6 ng/mL *vs* 3.1 ± 0.9 ng/mL control, $p<0.01$), lower acetylhydrolase activity (10.6 ± 0.7 nmol/mL/min *vs* 23.0 ± 1.4 nmol/mL/min control, $p<0.01$), and increased TNF (136 ± 75 U/mL *vs* 1.5 ± 0.8 U/mL control, $p<0.01$) compared to control infants. In these NEC patients, the individual plasma PAF concentrations did not correlate with plasma TNF levels. This pilot study shows that in human NEC, alterations in systemic PAF metabolism and TNF activity occur. The findings support the hypothesis derived from animal models, that PAF is a mediator in bowel necrosis. However, increased systemic PAF levels in neonates with NEC does not prove a cause and effect relationship. Further investigation of PAF in neonatal NEC is warranted. If follow-up studies are consistent with previous human and experimental reports describing the importance of PAF in ischemic bowel necrosis, then controlled trials of PAF receptor antagonists in this devastating disease would be indicated.

Antagonism of Platelet-Activating Factor in Isolated Rat Colon: Possible Mechanism[1]

Akira Tokumura*, Nobuyuki Yube, Motonori Terao and Hiroaki Tsukatani
Faculty of Pharmaceutical Sciences, The University of Tokushima, Tokushima 770, Japan

The contractions of three different regions of rat colon in response to platelet-activating factor (PAF) were compared. The ascending colon was found to be the most responsive. The slow contraction of the ascending colon induced by PAF was dependent on external Ca^{2+}. CV-3988, a structural analog of PAF, slowly induced irreversible inhibition of PAF-induced contraction, whereas FR-900452, which is structurally unrelated to PAF, caused rapid reversible inhibition of PAF-induced contraction. No inhibitory effects of CV-3988 were observed when the strip was washed with Tyrode's solution containing 1% bovine serum albumin (BSA). The results suggest that PAF and CV-3988 penetrate slowly into the outer half of the lipid bilayer of plasma membranes of cells in isolated rat colon, and then rapidly diffuse laterally to associate firmly with specific binding sites.
Lipids 26, 1344-1346 (1991).

Platelet-activating factor (PAF, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) has been implicated as a mediator of allergic and inflammatory processes (1,2). PAF has also been shown to cause contraction of smooth muscle of the gastrointestinal tract (3-6), lung (4,7-9) and uterus (10). However, the mechanism by which PAF induces smooth-muscle contraction is not fully understood. One problem in studies on this subject is the rapid tachyphylaxis of the isolated strips caused by PAF.

We previously developed a new method (11) for studies on isolated rat colon, the region most sensitive to PAF in the rat intestinal tract (5), by which tachyphylaxis was avoided. The binding of PAF to its putative sites seems to be very tight, because the contraction induced by this phospholipid agonist was not changed by repeated washings of the colon with Tyrode's solution (11). However, no contractions were observed when PAF bound to the specific binding sites was removed by treatment with bovine serum albumin (BSA). In the present study we further investigated the persistent contractile action of PAF on rat colon, using two different types of PAF antagonist.

MATERIALS AND METHODS

Materials. 1-*O*-Hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine (synthetic PAF) was purchased from Bachem Feinchemikalien AG (Bubendorf, Switzerland). CV-3988, *i.e. rac*-3-(*N*-octadecylcarbamoyloxy)-2-methoxypropyl-2-thiazolioethyl phosphate, was kindly provided by Dr. S. Tsushima Takeda Chemical Industries (Osaka, Japan). FR-900452, *i.e.* 1-methyl-3-(1-[5-methylthiomethyl-6-oxo-3-(2-oxo-3-cyclopenten-1-ylidine)-2-piperazinyl]ethyl)-2-indolinone, was a generous gift of Dr. M. Okamoto at Fujisawa Pharmaceutical Co. (Ibaraki, Japan). The other chemicals used in this study were as follows: acetylcholine hydrochloride (Daiichi Pharmaceutical Co., Tokyo, Japan), ethyleneglycol *bis*(β-aminoethylether)-*N,N,N',N'*-tetraacetic acid (EGTA; Nacalai Tesque, Kyoto, Japan), and fatty acid-free bovine serum albumin (BSA; Sigma Chemical Co., St. Louis, MO).

Measurement of contraction of rat colon. Male Wistar rats (200-300 g) were killed by a blow on the head, and colons were removed. Strips of colon (1.5-2 cm in length) were mounted in a 10-mL organ bath containing aerated Tyrode's solution (pH 7.8) of the following composition (mM): NaCl 136.9, KCl 2.7, $CaCl_2$ 2.5, $MgCl_2$ 1.0, $NaHCO_3$ 11.9, NaH_2PO_4 0.4, and glucose 5.5. After equilibration for 1 hr at 37°C, the colon was washed with Tyrode's solution containing 1% BSA, and remounted in Tyrode's solution with no BSA. After confirmation of constant responses of the strips to acetylcholine, they were exposed to PAF or PAF antagonist. The contractions produced by PAF were measured isotonically on a kymograph under 1-g load, and expressed as percentages of the maximal contraction produced by 100 μM acetylcholine. Results are shown as means ± S.E.M. Statistical analysis was performed by Student's t-test, and a value of $P<0.05$ was considered significant.

PAF was dissolved in saline with 0.1% BSA at various concentrations and a 0.1-mL aliquot of the PAF solution was added to a 10-mL organ bath. The final concentration of BSA was 0.001%. CV-3988 and FR-900452 were dissolved in ethanol. The final concentration of ethanol did not exceed 0.2%. Other chemicals were dissolved in saline.

RESULTS AND DISCUSSION

Regional differences in responses of rat colon to PAF. First we compared contractile responses to PAF of the ascending, transverse and descending regions of rat colon. The contraction of the ascending region in response to 0.3 nM PAF was 51.7 ± 2.4% (n = 14) of the maximal contraction induced by 100 μM acetylcholine. This response to PAF was significantly greater ($P<0.001$) than that of the transverse region (4.6 ± 1.4%, n = 7) or of the descending region (4.2 ± 1.25%, n = 8). Furthermore, the maximal contraction of the ascending region induced by PAF was 84.3 ± 1.7% (n = 20) of that induced by acetylcholine, whereas the maximal contractions of the transverse and descending regions induced by PAF were only 8.4 ± 0.8 (n = 7) and 12.5 ± 3.9% (n = 8), respectively, of those induced by acetylcholine. Therefore, the isolated ascending region of the colon was used in all subsequent studies.

Abbreviations: BSA, bovine serum albumin; CV-3988, *rac*-3-(*N*-octadecylcarbamoyloxy)-2-methoxypropyl-2-thiazolioethyl phosphate; EGTA, ethyleneglycol *bis*(β-aminoethylether)-*N,N,N',N'*-tetraacetic acid; FR-900452, 1-methyl-3-(1-[5-methylthiomethyl-6-oxo-3-(2-oxo-3-cyclopenten-1-ylidine)-2-piperazinyl]ethyl)-2-indolinone; PAF, platelet-activating factor.

Resistance of PAF-induced contraction of rat colon to washing. Previously, we reported that PAF-induced contraction of isolated rat colon persisted even after repeated washing of the strip with Tyrode's solution (11). One explanation for this observation may be that a substantial portion of the added PAF was adsorbed to the Magnus vessel used, diffused quickly into the fresh Tyrode's solution after replacement of the bath solution, and then was bound to its specific binding sites on the rat colon in the Magnus vessel. We examined this possibility. For this purpose, a rat colon strip was contracted half-maximally with PAF, and then restored to the basal tone by addition of 3 mM EGTA (Fig. 1, A) or 10 μM FR-900452 (data not shown). The strip was then transferred to another Magnus vessel with 10 mL of fresh Tyrode's solution containing 3 mM EGTA (Fig. 1, B) or 10 μM FR-900452 (data not shown). The bath solution in this second Magnus vessel was then replaced by fresh Tyrode's solution, resulting in rapid contraction (second contraction). When the bath solution was replaced with fresh Tyrode's solution, the time for half-contraction was 0.8 ± 0.2 min (n = 8) which was significantly ($P<0.01$) shorter than that for the first PAF-induced half-contraction (4.5 ± 1.1 min, n = 8). This cycle of relaxation of PAF-treated colon induced by EGTA followed by restoration of contraction by washing could be repeated at least twice in the second Magnus vessel without any significant reduction in the extent of contraction (Fig. 1, B). The fourth contraction was completely abolished when 3 μM FR-900452 was used, indicating that the contraction was due to PAF, which probably remained in the plasma membranes of the cells in the colon.

Effect of BSA on the inhibitory action of PAF antagonists. After the colon had been treated with 10 μM FR-900452 for 15 min, no increase in tone of the colon was seen upon subsequent treatment with 0.3 nM PAF. When the colon was subsequently washed with Tyrode's solution containing 1% BSA, it showed no increase in tone; however, when the colon was washed with Tyrode's solution without BSA, it showed spontaneous contraction (Fig. 2, A). After washing with Tyrode's solution containing BSA, the colon responded normally to a second addition of PAF (Fig. 2, A). These results indicated that FR-900452, but not PAF, was removed by washing the strip with Tyrode's solution, and so PAF was able to maintain its stimulatory effect on the strips.

Similar experiments were performed with 10 μM CV-3988 instead of FR-900452. When a set of strips was pretreated with CV-3988 for 20 min and then challenged with 0.3 μM PAF, they showed no significant contraction (Fig. 2, B). When one strip was then washed with Tyrode's solution, no spontaneous contraction was observed, unlike the results when FR-900452 was used. In addition, the strip did not respond to a second addition of 0.3 nM PAF. When the other strip was washed with Tyrode's solution containing BSA, no spontaneous contraction was observed, but the strip was able to contract in response to a second addition of 0.3 nM PAF, as shown in Fig. 2, B. These results indicate that the inhibitory action of CV-3988 was resistant to washing with Tyrode's solution alone.

The present results suggest tight binding of PAF and CV-3988, but not of FR-900452, to PAF binding sites on rat colon. As previously reported (11), FR-900452-induced-relaxation of colon pre-contracted by PAF was as fast as either EGTA-induced relaxation of the colon, but unlike CV-3988-induced relaxation. This may mean that FR-900452 rapidly replaces PAF molecules bound to their specific binding sites, resulting in rapid cessation of stimulus contraction coupling and relaxation of rat colon.

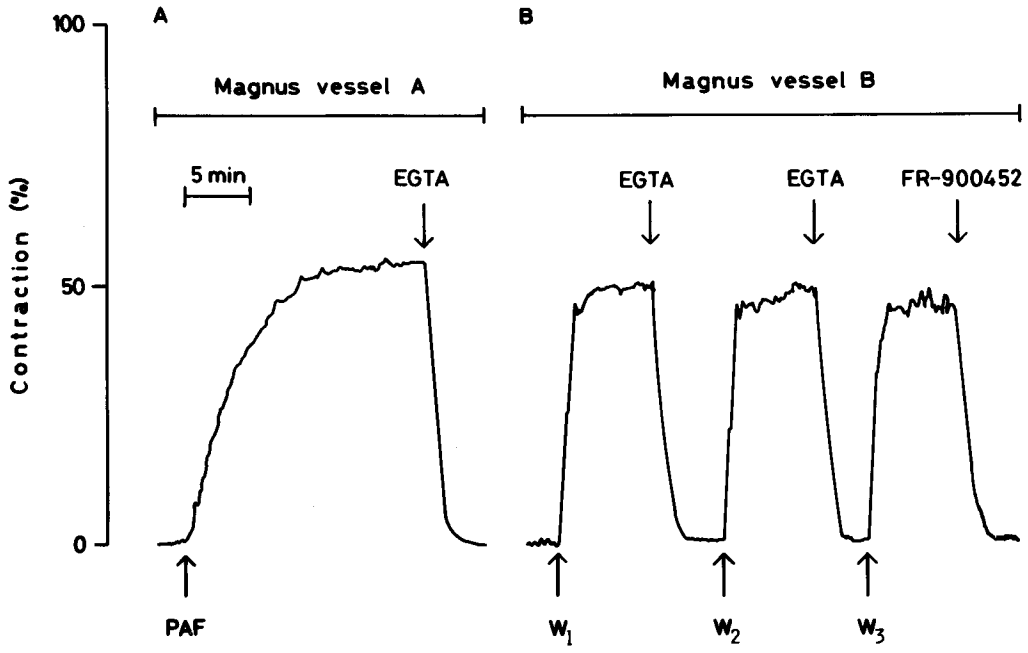

FIG. 1. Persistence of external Ca^{2+}-dependent contraction of rat colon induced by PAF after washing the colon with Tyrode's solution.

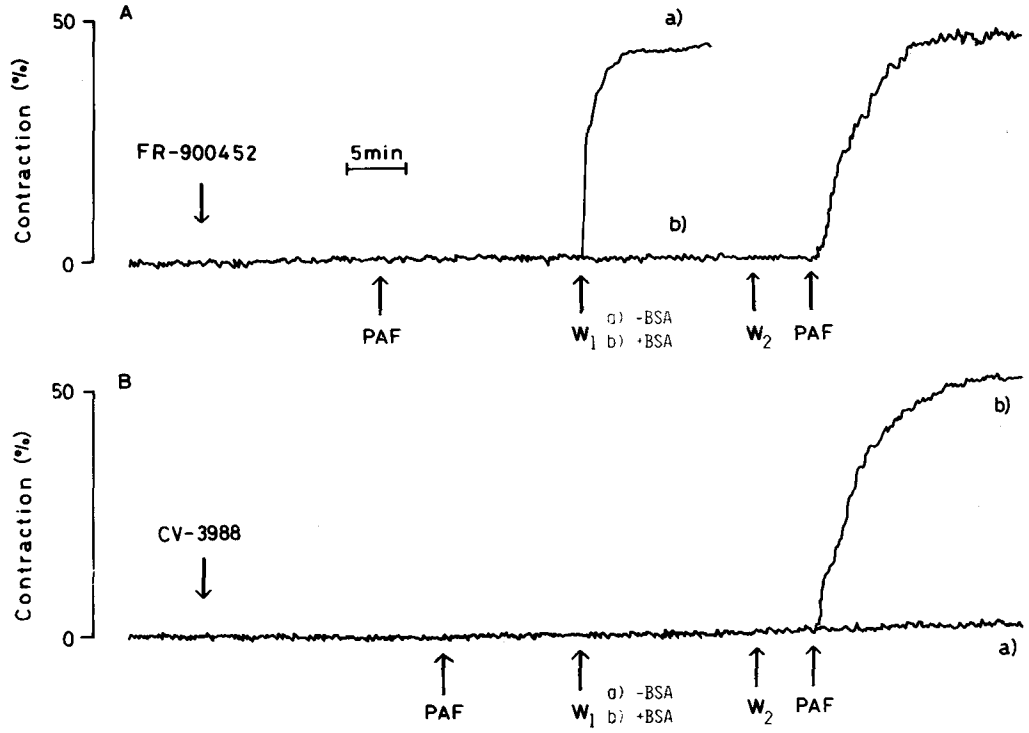

FIG. 2. Abolishment of the inhibitory action of FR-900452, but not of CV-3988, by washing rat colon with Tyrode's solution. A: Two strips of colon were pretreated with 10 μM FR-900452, and then challenged with 0.3 nM PAF. Strip a) was washed with Tyrode's solution (W_1). Strip b) was washed with Tyrode's solution containing 1% BSA (W_1), and then with Tyrode's solution with no BSA (W_2), and challenged with 0.3 nM PAF. B: Two strips of colon were pretreated with 10 μM CV-3988 and then challenged with 0.3 nM PAF. Strip a) was washed twice with Tyrode's solution (W_1 and W_2) and then rechallenged with 0.3 nM PAF. Strip b) was first washed with Tyrode's solution containing 1% BSA (W_1), and then with Tyrode's solution (W_2) to remove BSA. Strip b) was rechallenged with 0.3 nM PAF.

The binding sites for PAF are thought to be located near the interface between the plasma membrane and the extracellular fluid. Therefore, exogenously added PAF or its antagonists may be able to attach to binding sites either directly from the extracellular fluid (FR-900452) or after slow penetration into the outer half of the bilayer (PAF and CV-3988) followed by rapid lateral diffusion along the outer bilayer leaflet of the plasma membrane.

Molecular Heterogeneity of Platelet-Activating Factor (PAF) in Rat Glandular Stomach Determined by Gas Chromatography/Mass Spectrometry. PAF Molecular Species Changes upon Water-Immersion Stress[1]

Junko Sugatani[a,*], Kazuyo Fujimura[b], Masao Miwa[c], Kiyoshi Satouchi[a] and Kunihiko Saito[a]
[a]Department of Medical Chemistry and [b]The Third Department of Internal Medicine, Kansai Medical School, Moriguchi, Osaka 570, and [c]Department of Biochemistry, School of Pharmaceutical Science, University of Shizuoka, Shizuoka 422, Japan

The molecular heterogeneity of 1-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (alkylacetyl-GPC) and 1-acyl-2-acetyl-*sn*-glycero-3-phosphocholine (acylacetyl-GPC) in normal rat glandular stomach was studied by gas chromatography/mass spectrometry (GC/MS) and tandem mass spectrometry. The percentage compositions of the molecular species of 1-alkyl-2-acetyl-GPC and 1-acyl-2-acetyl-GPC in the antrum were, respectively, 1-alkyl [16:0 (34%) and 18:0 (66%)]-2-acetyl-GPC and 1-acyl [16:0 (60%), 18:0 (14%) and 18:1 (26%)]-2-acetyl-GPC. The alkyl chain composition of 1-alkyl-2-acetyl-GPC was quite different from that of 1-alkyl-2-acyl-GPC in both the antrum and corpus, demonstrating a high degree of selectivity of alkyl chain utilization in PAF biosynthesis. The amount of 1-acyl-2-acetyl-GPC was much greater than that of 1-alkyl-2-acetyl-GPC. The molecular heterogeneity of 1-alkyl-2-acetyl-GPC and 1-acyl-2-acetyl-GPC in the corpus was similar to that in the antrum. Water-immersion stress affected not only the amount of 1-alkyl-2-acetyl-GPC and 1-acyl-2-acetyl-GPC, but also their molecular heterogeneity in the antrum and corpus. Whereas the amounts of 1-hexadecyl-2-acetyl-GPC and 1-acyl [16:0, 18:0 and 18:1]-2-acetyl-GPC decreased markedly (to less than one-fifth) in the antrum after such stress for 1 hr, the amount of 1-octadecyl-2-acetyl-GPC increased markedly (up to 4-fold) in the corpus and severe lesions were observed after stress for 7 hr. The changes may be associated with the pathogenicity of gastric ulcers.
***Lipids* 26, 1347–1353 (1991).**

Platelet-activating factor [PAF, 1-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (1)] is a chemical mediator with a wide spectrum of biological activities, *e.g.*, stimulation of platelets and neutrophils, and enhancement of vascular permeability and smooth muscle contraction (2). PAF is not only generated in a variety of cells upon chemical or immune stimulation associated with inflammation and anaphylaxis (2), but is also found in normal animal tissues [bovine brain (3), rat uterus (4) and fetal rabbit lung (5)]. In a previous study, we found a significant amount of PAF in normal stomach (especially in the antral mucosa), and observed an alteration in the level of PAF upon water-immersion stress, as determined by a bioassay based on the release of [^{3}H]serotonin from washed rabbit platelets (6). Over the last several years, data have been accumulating that suggest a molecular heterogeneity of PAF in cells (7–9) and tissues (3,4) which is dependent on the pathophysiological state. Evidence exists that the different molecular species of PAF homologs and analogs may exert different biological activities (1,10). In the present study, we determined the molecular species of rat gastric PAF homologs [1-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (alkylacetyl-GPC)] and analogs [1-acyl-2-acetyl-*sn*-glycero-3-phosphocholine (acylacetyl-GPC)], and compared the compositions of their alkyl and acyl chains with those of alkyl and acyl chains at the 1-position of 1-akyl-2-acyl-GPC and 1,2-diacyl-GPC in order to investigate the selectivity of alkyl and acyl chain utilization in PAF biosynthesis. The influence of water-immersion stress on the molecular heterogeneity of PAF was also elucidated by gas chromatography/mass spectrometry (GC/MS).

MATERIALS AND METHODS

Materials. Male Wistar rats were deprived of food, but not water, for 24 hr before the experiments. Animals were placed in a stress cage and immersed in water (23°C ± 1°C) to the level of xiphoid process, in accordance with the method of Takagi and Okabe (11). Control rats were placed in a cage under no restraint at 25°C ± 1°C. The rats were then sacrificed by decapitation under light diethyl ether anesthesia unless otherwise stated.

Chemicals. 1-Hexadecyl-GPC, 1-hexadecyl- and 1-octadecyl-2-acetyl-GPC and 1-hexadecanoyl-GPC were purchased from Bachem Feinchemikalien AG, Bubendorf, Switzerland. 1-Octadecenyl-2-acetyl-GPC was prepared from human polymorphonuclear leukocytes (12). 1-Octadec-*cis*-9′-enoyl- and 1-octadecanoyl-GPC were obtained from Serdary Research Laboratories Inc., Ontario, Canada. Perdeuterated acetic anhydride(d_6) was a product of E. Merck, Darmstadt, Germany. 1-Hexadecyl-2-perdeuteroacetyl-GPC (internal standard for 1-akyl-2-acetyl-GPC) and 1-hexadecanoyl-, 1-octadec-*cis*-9′-enoyl- and 1-octadecanoyl-2-acetyl-GPC were synthesized by acetylating 1-hexadecyl-GPC and 1-hexadecanoyl-, 1-octadec-*cis*-9′-enoyl- and 1-octadecanoyl-GPC with perdeuterated acetic anhy-

[1]Based on a paper presented at the Third International Conference on Platelet-Activating Factor and Structurally Related Alkyl Ether Lipids, Tokyo, Japan, May 1989.

Abbreviations: GC/MS, gas chromatography/mass spectrometry; GPC, ***sn***-glycero-3-phosphocholine; PAF, platelet-activating factor; SIM, selected ion monitoring; *t*-BDMS, *tert*-butyldimethylsilyl; TLC, thin-layer chromotography; TNS, 6-*p*-toluidine-2-naphthalenesulfonic acid.

dride and acetic anhydride, respectively, in the presence of perchloric acid as a catalyst (13). 1-Heptadecanoyl-2-perdeuteroacetyl-GPC (internal standard for 1-acyl-2-acetyl-GPC) was synthesized as described previously (9). The *tert*-butyldimethylchlorosilane/imidazole reagent and all fatty acid methyl ester standards were obtained from Applied Science (State College, PA). Phospholipase C (EC 3.1.4.3) was partially purified from *Bacillus cereus* (14). Phospholipase A_2 (EC 3.1.1.4) from *Agkistrodon halys blomhoffi* was purified to homogeneity as reported previously (15).

Isolation of PAF, phosphatidylcholine and phosphatidylethanolamine from rat glandular stomach. The total lipids of antrum and corpus, respectively, were extracted by the method of Bligh and Dyer (16) at 4°C in the presence of 50 mM glycine-HCl buffer (pH 2.8) in a single-phase system to inactivate PAF acetylhydrolase, as described previously (6). The biological activity before and after the weak-acid treatment of the PAF extracted without acid treatment, as determined by rabbit platelet activation (17), was not altered, showing that only traces of the 1-alk-1′-enyl-type PAF, if any, were present. Lipid phosphorus was determined by the method of Bartlett (18). The lipids (*ca.* 2.5 mg phosphorus) were applied to a silic AR CC-7 column (8 × 90 mm). The neutral lipids were separated by elution with 40mL of chloroform. Phospholipids (*ca.* 500 μg phosphorus), eluted with 80 mL of methanol, were separated by thin-layer chromatography (TLC) on silica gel 60H plates (20 × 20 cm, 0.6 mm thick) using the solvent system chloroform/methanol/water (65:35:6, v/v/v). After spraying the plate with 1 mM 6-*p*-toluidine-2-naphthalenesulfonic acid (TNS) (19), the bands between lysophosphatidylcholine and sphingomyelin, and those of phosphatidylcholine and phosphatidylethanolamine, were localized under ultraviolet light, scraped off, and extracted. In order to separate acidic phospholipids, the phosphatidylcholine fraction (*ca.* 1 mg phosphorus) dissolved in chloroform was applied to a column of activated alumina 200 (8 × 16 mm) and eluted with 60 mL of chloroform/methanol (1:1, v/v).

Derivatization of PAF for mass spectrometry (MS) analysis. The isolated PAF fractions were digested with phospholipase C, and the resulting diradylglycerols were converted to *tert*-butyldimethylsilyl (*t*-BDMS) derivatives essentially as described previously (20). The *t*-BDMS derivatives were purified further by TLC (10 × 20 cm, 0.3 mm thick) using the solvent system hexane/diethyl ether (9:1, v/v).

Determination of 1-alkyl-2-acetyl-GPC and 1-acyl-2-acetyl-GPC by GC/MS coupled with selected ion monitoring (SIM). For measurement of 1-akyl-2-acetyl-GPC, the total lipids were mixed with 1-hexadecyl-2-perdeuteroacetyl-GPC ($4.2–4.8 \times 10^{-7}$ mol/mol total antrum phospholipds and 1.2×10^{-7} mol/mol total corpus phospholipids) as internal standard. For measurement of 1-acyl-2-acetyl-GPC, 1-heptadecanoyl-2-perdeuteroacetyl-GPC ($3.8–4.4 \times 10^{-6}$ mol/mol total antrum phospholipids and 2.4×10^{-7} mol/mol total corpus phospholipids) was used as internal standard.

A JEOL (Tokyo, Japan) JMS-DX300 instrument (ionization energy, 70 eV) with a JMA 3100 computer was coupled to a gas chromatograph equipped with a 1 m × 2 mm glass spiral packed with 1% OV-1 on Chromosorb W (80–100 mesh). The temperatures of the column, injection port, separator, inlet and ionization chamber were kept at 240, 290, 290, 290, and 270°C, respectively. The flow rate of helium was 55 mL/min. Ions $[M-57]^+$, produced by cleavage of the *tert*-butyl radical from the parent ion, and $[CH_3CO + 74]^+$ and $[RCO + 74]^+$, formed by rearrangements of the acetyl or acyl residue and dimethyl silanol, were selected for SIM. The abundance of each molecular species was calculated from the ratios of their peak areas to that of the internal standard.

Tandem mass spectrometry (MS/MS). MS/MS was performed on a JEOL HX110-HX110 tandem mass spectrometer equipped with a JMA-DA5000 computer. The instrument was used in the electron impact mode, and the sample was directly inserted into the ion source. The ionization energy, ionization current, ionization chamber temperature and accelerating voltage were 70 eV, 300 μA, 200°C and 10.0 kV, respectively. The selected $[M-57]^+$ ion was collided with helium.

Determination of the composition of ether-linked choline and ethanolamine glycerophospholipids. Choline and ethanolamine glycerophospholipids (358–587 μg phosphorus) were hydrolyzed with 2 mL of 0.1 N KOH in 90% methanol at room temperature for 60 min. The ether-linked type was recovered in the chloroform–soluble phase (32.2 and 28.7 μg phosphorus from choline glycerophospholipids of the antrum and corpus, and 154.7 and 113.6 μg phosphorus from ethanolamine glycerophospholipids of the antrum and corpus, respectively), and that derived from the diacyl type was recovered in the water-soluble phase (372.8 and 557.8 μg phosphorus from choline glycerophospholipids of the antrum and corpus, and 203.2 and 329.6 μg phosphorus from ethanolamine glycerophospholipids of the antrum and corpus, respectively) by the extraction method of Bligh and Dyer (16). Then the chloroform-soluble fraction was incubated in a mixture of 1 mL of chloroform, 2 mL of methanol and 0.8 mL of 0.5 N HCl at 37°C for 15 min. The products of alk-1′-enyl-GPC and alk-1′-enyl-*sn*-glycero-3-phosphoethanolamine (GPE) were recovered in the water-soluble phase (9.7 and 13.2 μg phosphorus from ether-linked choline lysoglycerophospholipids of the antrum and corpus, and 112.4 and 89.4 μg phosphorus from ether-linked ethanolamine lysoglycerophospholipids of the antrum and corpus, respectively), and alkyl-GPC and alkyl-GPE were recovered in the chloroform-soluble phase (20.9 and 13.8 μg phosphorus from ether-linked choline lysoglycerophospholipids of the antrum and corpus, and 31.2 and 20.7 μg phosphorus from ether-linked ethanolamine lysoglycerophospholipids of the antrum and corpus, respectively) in a two-phase system (16).

Analysis of the composition of acyl and alkyl chains at the 1-position of choline and ethanolamine glycerophospholipids. The composition of acyl and alkyl chains at the 1-position was determined by analysis of lysoglycerophospholipids obtained by phospholipase A_2 hydrolysis and of ether-linked lysoglycerophospholipids obtained by treatment with weak alkali and acid as described above, respectively. Choline and ethanolamine glycerophospholipids (6–7 μg phosphorus) were completely hydrolyzed with 50 μg purified phospholipase

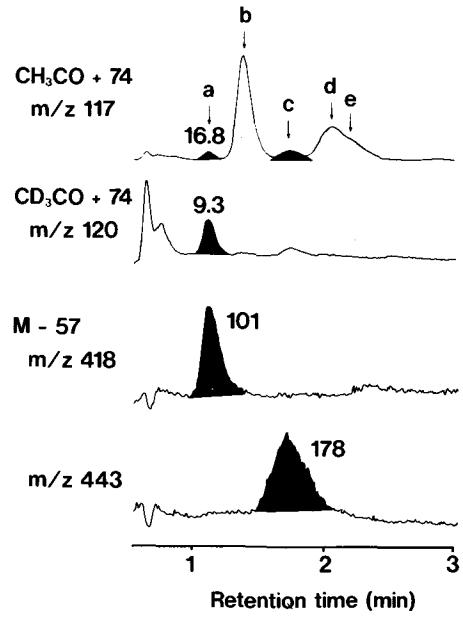

FIG. 1. Qualitative and quantitative analysis of 1-alkyl-2-acetyl-GPC in rat antrum by SIM analysis. Rats weighing 251 ± 31 g (157 animals), age 9–10 wk, were used (Experiment 1). The total antrum lipids were mixed with 1-hexadecyl-2-perdeuteroacetyl-GPC as internal standard. Peak areas are shown to the right of each of the peaks. Peaks of a, b, c, d and e correspond to those of *t*-BDMS derivatives of authentic 1-hexadecyl-2-acetyl-GPC and 1-hexadecanoyl-2-acetyl-GPC, 1-octadecyl-2-acetyl-GPC, 1-octadec-*cis*-9′-enoyl-2-acetyl-GPC and 1-octadecanoyl-2-acetyl-GPC, respectively. The result from one of 3 separate measurements is shown in the figure.

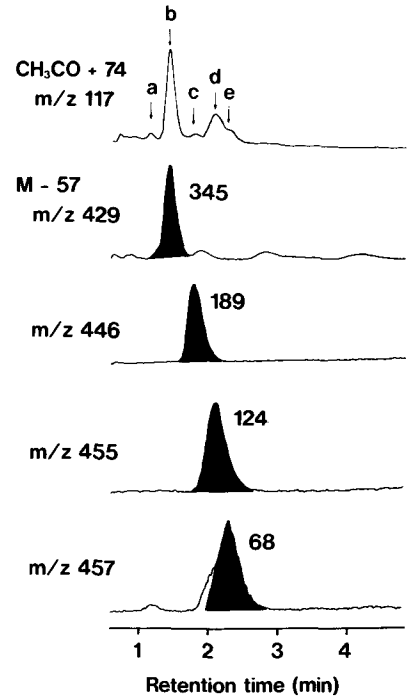

FIG. 2. Qualitative and quantitative analysis of 1-acyl-2-acetyl-GPC in rat antrum by SIM analysis. Rats weighing 223 ± 12 g (81 animals), age 9 wk, were used (Experiment 2). The total antrum lipids were mixed with both 1-hexadecyl-2-perdeuteroacetyl-GPC and 1-heptadecanoyl-2-perdeuteroacetyl-GPC as internal standards. Peak areas are shown to the right of each of the peaks. Peaks of a, b, c, d and e are as in Figure 1. The result from one of 3 separate measurements is shown in the figure.

A_2 (*Agkistrodon halys blomhoffi*) in a mixture of 3 mL of diethyl ether, 0.4 mL of 0.125 M Tris-HCl buffer (pH 8.2), 0.05 mL of 1.0 M NaCl and 10 mM $CaCl_2$ with vigorous shaking at room temperature for 16 hr. The lipid products were extracted and separated on a silica gel G plate in the solvent system chloroform/methanol/water (65:35:6, v/v/v). For analysis of the fatty acid composition of the purified lysoglycerophospholipids, the methyl esters derived by acid methanolysis were prepared (21). In order to determine the alkyl chain composition, the purified ether-linked lysoglycerophospholipids were mixed with 0.3 mL of acetic anhydride and 0.2 mL of glacial acetic acid at 150°C for 5 hr for conversion to 1-alkyl-2,3-diacetyl-glycerol (22). The fatty acid methyl esters and glyceryl ether diacetates were analyzed in a Shimadzu GC-7AG gas chromatograph (Kyoto, Japan) equipped with glass columns, packed 10% Silar 10C on Gas-Chrom Q (100-200 mesh) and 1% OV-1 on Chromosorb W (80–100 mesh) (both 2 m × 3 mm), respectively. The columns were operated at 185–215°C for analysis of fatty acid methyl esters and at 240°C for analysis of glyceryl ether diacetates. The peaks of each chromatogram were assigned on the basis of their retention times relative to those of standards.

RESULTS

Identification of 1-alkyl-2-acetyl-GPC and 1-acyl-2-acetyl-GPC in rat antrum. For GC/MS analysis, the *t*-BDMS derivative of the 'diglyceride' prepared enzymatically was used. The presence of both 1-alkyl-2-acetyl-GPC and 1-acyl-2-acetyl-GPG in rat antrum was demonstrated by SIM analysis (Figs. 1 and 2). Upon monitoring the ion at *m/z* 117, $[CH_3CO + 74]^+$, five peaks were detected with retention times of 1′07″, 1′24″, 1′44″, 2′04″ and 2′12″, which corresponded respectively to those of authentic 1-hexadecyl-2-acetyl-GPC, 1-hexadecanoyl-2-acetyl-GPC, 1-octadecyl-2-acetyl-GPC, 1-octadec-*cis*-9′-enoyl-2-acetyl-GPC and 1-octadecanoyl-2-acetyl-GPC. For determining the molecular species of 1-alkyl-2-acetyl-GPC, MS/MS analysis was performed. The $[M-57]^+$ ion was selected and collided with helium because this ion became more prominent than the $[M]^{+\cdot}$ ion in the electron ionization mass spectrum of the *t*-BDMS derivatives of the diglycerides (23). The collision-induced fragmentation of ions at *m/z* 415 and 443, due to $[M-57]^+$, yielded daughter ions at *m/z* 355 and 383, due to the characteristic $[R + 130]^+$ ion for the alkyl residue, and an ion at *m/z* 117, due to $[CH_3CO + 74]^+$ for the acetyl residue, for 1-hexadecyl-2-acetyl-3-*t*-BDMS-glycerol and 1-octadecyl-2-acetyl-3-*t*-BDMS-glycerol, respectively (Fig. 3). The collision-induced fragmentation of an ion at *m/z* 441 did not yield the

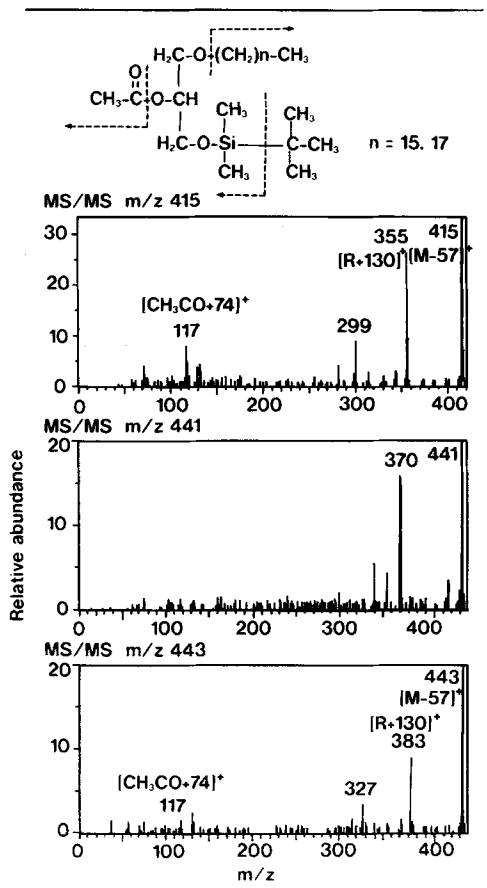

FIG. 3. MS/MS spectra of *t*-BDMS derivatives of antral 1-alkyl-2-acetyl-GPC in Experiment 2.

characteristic daughter ions for 1-octadecenyl-2-acetyl-3-*t*-BDMS-glycerol (Fig. 3). The observation indicates that 1-alkyl-2-acetyl-GPC was composed of 1-hexadecyl-2-acetyl-GPC and 1-octadecyl-2-acetyl-GPC. For the characterization of 1-acyl-2-acetyl-GPC, the ions at *m/z* 429, 455 and 457, due to $[M-57]^+$, and the ions at *m/z* 313, 339 and 341, due to $[RCO + 74]^+$, were selected. As shown in Figure 2, the peaks obtained by monitoring the ions at *m/z* 429, 455 and 457 were located at the same positions as those of authentic 1-hexadecanoyl-2-acetyl-GPC, 1-octadec-*cis*-9′-enoyl-2-acetyl-GPC, and 1-octadecanoyl-2-acetyl-GPC, respectively. Also, for the trace ions at *m/z* 313, 339 and 341, peaks were obtained at the same positions as those of 1-hexadecanoyl-2-acetyl-GPC, 1-octadec-*cis*-9′-enoyl-2-acetyl-GPC and 1-octadecanoyl-2-acetyl-GPC (data not shown).

Quantitation of 1-alkyl-2-acetyl-GPC and 1-acyl-2-acetyl-GPC in rat antrum. The amount of each molecular species was calculated from the ratios of their peak areas at $[M-57]^+$ relative to those of deuterated internal standards (1-hexadecyl-2-perdeuteroacetyl-GPC for measurement of 1-alkyl-2-acetyl-GPC and 1-heptadecanoyl-2-perdeuteroacetyl-GPC for measurement of 1-acyl-2-acetyl-GPC) using calibration curves (Figs. 1 and 2). In order to determine the amount of 1-hexadecyl-2-acetyl-GPC, the peak area at *m/z* $[CH_3CO + 74]^+$ relative to the internal standard was measured. The regression equations were $Y = 1.088X + 0.145$ and $Y = 0.583X + 0.121$ with correlation coefficients of $r = 1.000$ and 0.993 for 1-hexadecyl-2-acetyl-GPC and 1-octadecyl-2-acetyl-GPC, respectively, where X is the ratio by weight and Y is the ratio of peak areas. The regression equation for 1-hexadecanoyl-2-acetyl-GPC was $Y = 1.040X - 0.038$ with $r = 1.000$, which was coincident with the regression equation reported previously (14). Hence, for the calibration of 1-octadec-*cis*-9′-enoyl-2-acetyl-GPC and 1-octadecanoyl-2-acetyl-GPC, $Y = 0.871X - 0.044$ and $Y = 0.812X + 0.003$ were used as the regression equations, respectively, as reported previously (14). The results, presented as mol per mol total antrum phospholipids, are shown in Table 1. Thus, 1.9 ng of 1-alkyl [16:0 and 18:0]-2-acetyl-GPC and 15.6 ng of 1-acyl [16:0, 18:0 and 18:1]-2-acetyl-GPC were detected per rat antrum. The main species of 1-alkyl-2-acetyl-GPC was 1-octadecyl-2-acetyl-GPC, followed by 1-hexadecyl-2-acetyl-GPC. In contrast, the main species of 1-acyl-2-acetyl-GPC was 1-hexadecanoyl-2-acetyl-GPC, followed by 1-octadecenoyl-2-acetyl-GPC and 1-octadecanoyl-2-acetyl-GPC.

The composition of alkyl and acyl chains at the 1-position of choline and ethanolamine glycerophospholipids in perfused rat antrum and corpus. On analysis of choline and ethanolamine glycerophospholipids, rats were perfused with saline since it was necessary to remove phospholipids which might derive from blood cells and lipoproteins. As shown in Table 2, the composition of the diacyl, alkyl and alk-1′-enyl types of choline glycerophospholipids was quite different from that of ethanolamine glycerophospholipids in both the antrum and corpus. The amount of the alkylacyl type of both choline and ethanolamine glycerophospholipids was low (less than 5% of total phospholipids). The amount of the alkylacyl type in the antrum was about 2-fold greater than that in the corpus, which might be related to the localization of 1-alkyl-2-acetyl-GPC since the amount of PAF in the antrum was about 4-fold greater than that in the corpus (6). The alkyl chain distribution of choline glycerophospholipids in the antrum and corpus was 16:0, 18:0 and 18:1 with other components in less than trace amounts (Table 3). On the other hand, there was a significant difference in the fatty acid distribution between choline and ethanolamine glycerophospholipids. Whereas the predominant fatty acid in ethanolamine glycerophospholipids was 20:4 (28.9% in the antrum and 27.3% in the corpus), the predominant fatty acid in choline glycerophospholipids was 16:0 (25.8% in the antrum and 27.7% in the corpus) (data not shown). The acyl chain at the 1-position of diacyl type choline glycerophospholipids was composed mainly of 16:0 (36.3% in the antrum and 37.1% in the corpus) (Table 3), in contrast to the predominance of 18:0 (35.0% in the antrum and 28.8% in the corpus) in those of ethanolamine glycerophospholipids (data not shown).

Alteration in molecular species of 1-alkyl-2-acetyl-GPC and 1-acyl-2-acetyl-GPC associated with rat gastric ulcer induced by water-immersion stress. In a previous paper, we have reported that water-immersion stress for 1 hr and 3 hr, before the development of mucosal damage, produces a significant decrease in the gastric PAF level (39% of untreated controls), as determined by bioassay (6). The present study was done to confirm this observation physicochemically by GC/MS analysis. As shown

TABLE 1

Contents of Antral 1-Alkyl-2-acetyl-GPC and 1-Acyl-2-acetyl-GPC in Normal and Water-Immersion-Stressed Rats[a]

	Control		Water-immersion stress
	Experiment 1 9–10 wk old	Experiment 2 9 wk old	Experiment 3 9 wk old
	mol/mol total phospholipids

1-Octadecenoyl-2-acetyl-GPC	not determined	3.60×10^{-6}	0.51×10^{-6}

[a]Rats used in experiments 1 and 2 are shown in Figures 1 and 2. In Experiment 3, rats weighing 233 + 17 g (189 animals), age 9 wk, were restrained in water maintained at 23°C ± 1°C for 1 hr. The antral lipid-extracts from 157, 81 and 189 animals were combined and analyzed in Experiments 1, 2 and 3, repsectively. The lipid-phosphorus contents were 484.4, 467.5 and 458.9 μg phosphorus/g antrum tissue in Experiments 1, 2 and 3, respectively.

[b]$[CH_3CO + 74]^+$ was selected for the quantitation.

TABLE 2

Composition of Choline and Ethanolamine Glycerophospholipids in Perfused Rat Antrum and Corpus[a]

Phospholipids	Antrum	Corpus
	mol%	
Ethanolamine glycerophospholipids[b]	26.8, 34.0	28.8, 31.8
Diacyl type[c]	56.8	74.4
Alkylacyl type[c]	9.4	4.8
Alk-1′-enylacyl type[c]	33.8	20.8
Choline glycerophospholipids[b]	44.9, 39.6	42.5, 40.5
Diacyl type[c]	92.1	95.1
Alkylacyl type[c]	5.4	2.5
Alk-1′-enylacyl type[c]	2.5	2.4

[a]Rats weighing 242 ± 17 g (means ± SD) (39 animals), age 9 wk, were anesthetized with sodium pentobarbital (50 mg/kg, i.p.) and perfused with saline warmed at 37°C *via* the ventral aorta at a rate of 42.5 mL per min for 90 sec. The total lipids were extracted in a single phase of chloroform/methanol/water (1:2:0.8, v/v/v) in order to avoid cleavage of the alk-1′-enyl linkage. The lipid-phosphorus contents were 586.1 ± 13.5 μg phosphorus/g corpus tissue and 455.7 ± 27.0 μg phosphorus/g antrum tissue.

[b]The phospholipid fraction (60 μg phosphorus) after silic AR CC-7 column chromatography, as described in Material and Methods, was separated into phospholipid subclasses on a silica gel G plate (3 × 20 cm, 0.25 mm thick) (Analtech, Newark, NJ) in the solvent system chloroform/methanol/acetic acid/water (50:25:8:4, by vol). After spraying the plate with TNS reagent, PAF, phosphatidylcholine and phosphatidylethanolamine were scraped-off and extracted. Data are from combined samples from 19 and 20 rats.

[c]Diacyl, alkyl, and alk-1′-enyl types were determined as alkali-labile, alkali-stable and acid-stable, and alkali-stable and acid-labile phospholipids, respectively. Data are from combined samples from 39 rats.

in Figures 4-1 and 4-2, an alteration in the ratio of each molecular species of 1-alkyl-2-acetyl-GPC and 1-acyl-2-acetyl-GPC was observed 1 hr after commencement of stress. The levels of 1-hexadecyl-2-acetyl-GPC and 1-acyl [16:0, 18:0 and 18:1]-2-acetyl-GPC in the antrum (Experiment 3) decreased to 12–20% of those in untreated controls 1 hr after stress began (Experiment 2) (Table 1). Interestingly, the degree of decrease in the level of 1-octadecyl-2-acetyl-GPC was insignificant (62% of untreated control), in contrast to a remarkable decrease in the level of 1-hexadecyl-2-acetyl-GPC. Stress for 7 hr resulted in severe mucosal damage mainly in the corpus. The previous study, based on bioassay, demonstrated that the PAF content 7 hr after the stress was still decreased in the antrum (49% of the level in untreated controls), but was restored to normal in the corpus (6). The present SIM analysis revealed a remarkable alteration in the composition and amount of molecular species of 1-alkyl-2-acetyl-GPC and 1-acyl-2-acetyl-GPC during the 7-hr period of stress, as shown in Figures 4-3 and 4-4. In the corpus after 7 hr of stress, the amounts of 1-hexadecyl-2-acetyl-GPC and 1-hexadecanoyl-2-acetyl-GPC decreased. Surprisingly, the amount of 1-octadecyl-2-acetyl-GPC increased 4-fold (1.01×10^{-6} mol/mol total phospholipids). The EC_{50} values of 1-hexadecyl-2-acetyl-GPC and 1-octadecyl-2-acetyl-GPC for rabbit platelet activation ([^{3}H] serotonin release) were 1.0×10^{-10} M and 2.7×10^{-10} M, respectively. Therefore, the discrepancy between the results obtained by the bioassay and those by GC/MS analysis can be considered to result from the different biological activities of each of the molecular species of PAF.

DISCUSSION

In the present study we elucidated the molecular heterogeneity of PAF in the rat glandular stomach by GC/MS analysis. It was observed that odd-numbered 1-alkyl-2-acetyl-GPC eluted at the same position as even-numbered 1-acyl-2acetyl-GPC upon simultaneous

TABLE 3

Composition of Acyl and Alkyl Chains at the 1-Position of Choline Glycerophospholipids in Perfused Rat Antrum and Corpus After Digestion with Phospholipase A_2 and Treatment with Weak Alkali and Acid [a]

Chain length and number of double bonds	Antrum		Corpus	
	Acyl[b]	Alkyl[c]	Acyl[b]	Alkyl[c]
	weight%			
14:0	0.8, 2.1		0.3, 1.5	
14:1	2.8, 4.8		1.8, 1.5	
16:0	37.6, 35.0	42.0	34.1, 40.0	44.3
16:1	2.0, 1.3		0.5, 1.1	
18:0	21.8, 22.9	18.2	17.6, 15.6	16.7
18:1	15.0, 14.8	33.0	15.1, 14.1	32.4
18:2	7.6, 4.4		11.3, 9.5

[b]Data are from combined samples from 19 and 20 rats.

[c]Data are from combined samples from 39 rats.

analysis of 1-alkyl-2-acetyl-GPC and 1-acyl-2-acetyl GPC. In the SIM analysis of fractions corresponding to 1-alkyl-2-acetyl-3-*t*-BDMS-glycerol purified by TLC using hexane/diethyl ether (9:1, v/v), the peaks at 1′24″, 2′04″ and 2′12″ almost disappeared whereas the peaks at 1′07″ and 1′44″ were mostly retained. The observation indicates that there are only trace components, if any, of odd-numbered alkyl and acyl chains. As a consequence of this finding, it was possible to determine 1-alkyl-2-acetyl-GPC and 1-acyl-2-acetyl-GPC simultaneously by SIM. The amount of 1-acyl [16:0, 18:0 and 18:1]-2-acetyl-GPC was about 8-fold greater than that of 1-alkyl [16:0 and 18:0]-2-acetyl-GPC (Table 1). A preponderance of 1-acyl-2-acetyl-GPC over 1-alkyl-2-acetyl-GPC is a common feature of tissues such as bovine brain (3) and rat uterus (4). However, this is not true in stimulated cells such as polymorphonuclear leukocytes, in which the amount of 1-alkyl-2-actyl-GPC is five times higher than that of 1-acyl-2-acetyl-GPC (24). There was a great degree of similarity in the alkyl chain distributions of 1-alkyl-2-acyl-GPC between the antrum and corpus (Table 3). Furthermore, the molecular heterogeneity of 1-alkyl-2-acetyl-GPC and 1-acyl-2-acetyl-GPC in the corpus was quite similar to that in the antrum (Fig. 4). These observations suggest that the cells producing PAF in the corpus might be the same as those in the antrum. The acyl chain distribution at the 1-position of 1-acyl-2-acetyl-GPC remained more or less the same as that at the 1-position of 1,2-diacyl-GPC (Tables 1 and 3). However, the alkyl chain composition of 1-alkyl-2-acetyl-GPC did not seem to be dictated by that of 1-alkyl-2-acyl-GPC (Tables 1 and 3). Whereas 1-hexadecyl-2-acyl-GPC was the major molecular species of 1-alkyl-2-acyl-GPC (42% in the antrum and 44% in the corpus), 1-octadecyl-2-acetyl-GPC (66% in the antrum and 59% in the corpus) was the major molecular species of 1-alkyl-2-acetyl-GPC. This suggests that enzymes in PAF biosynthesis may have an extraordinary selectivity of alkyl chain utilization or that substrates located in an extraordinary position of stomach tissues (cells) may be utilized for PAF biosynthesis.

In a previous study (6), we found that water-immersion stress affected the gastric PAF content based on bioassay. The present GC/MS analysis revealed that such stress was associated with both qualitative and quantitative alterations in the molecular species of

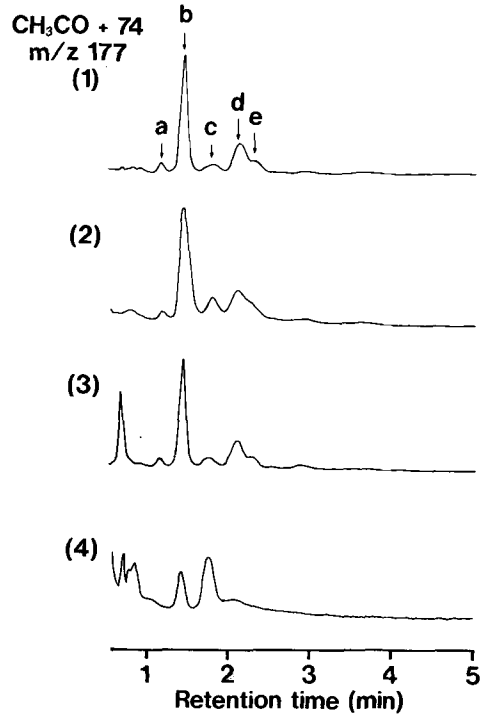

FIG. 4. SIM chromatograms of *t*-BDMS derivatives of gastric 1-alkyl-2-acetyl-GPC and 1-acyl-2-acetyl-GPC in control and water-immersion-stressed rats. 1. Control rat antrum (Experiment 1); 2. Antrum from 1-hr water-immersion-stressed rat (Experiment 3); 3. Control rat corpus (Experiment 4); 4. Corpus from 7-hr water-immersion-stressed rat (Experiment 5). In Experiments 4 and 5, rats weighing 225 ± 31 g (26 animals) and rats weighing 228 ± 14 g (22 animals) (age 9 wk) were used, respectively. The lipid-phosphorus contents were 702.5 and 722.8 μg phosphorus/g corpus tissue in Experiments 4 and 5, respectively. Peaks of a, b, c, d and e are as in Figure 1.

1-alkyl-2-acetyl-GPC and 1-acyl-2-acetyl-GPC in both the antrum and corpus. 1-Hexadecyl-2-acetyl-GPC and 1-acyl [16:0, 18:0 and 18:1]-2-acetyl-GPC showed a significant decrease before the development of mucosal damage in the glandular stomach upon application of water-immersion stress for 1 hr (Table 1 and Fig. 4). By contrast, 1-octadecyl-2-acetyl-GPC increased markedly in the corpus during a 7-hr period of stress, which resulted in severe mucosal damage to the corpus, characterized by hemorrhage and inflammatory infiltrates. The increased amount of 1-octadecyl-2-acetyl-GPC in the corpus may have been produced by stimulated resident cells or circulating blood cells. However, rat polymorphonuclear leukocytes and rat basophilic leukemia cells, either unstimulated or stimulated, have been reported to produce 1-hexadecyl-2-acetyl-GPC as the predominant molecular species of PAF (25). The cells producing endogenous 1-alkyl-2-acetyl-GPC and 1-acyl-2-acetyl-GPC in the rat glandular stomach and their biological significance still need to be clarified. However, our present observations may help in elucidating the biological function of gastric PAF. 1-Hexadecyl-2-acetyl-GPC and 1-octadecyl-2-acetyl-GPC may possibly play different roles in the stomach. The qualitative and quantitative alteration of specific molecular species of PAF might be associated with the pathogenesis of gastric ulceration. In order to clarify these aspects, it will be necessary to understand the intrinsic biological function of each molecular species of PAF homologs and analogs.

ACKNOWLEDGMENTS

This work was supported in part by grants-in-aid from the Ministry of Education, Science and Culture of Japan, and by The Science Research Promotion Fund of the Japan Private School Promotion Foundation. We thank Dr. Ittetsu Nojima, JEOL, for measuring MS/MS spectra.

The Effect of CV-3988 and CV-6209 on the Acute Gastric Erosions of Rats Due to Water-Immersion and Restraint Stress[1]

Makoto Nogami[a,*], Yoshio Hoshihara[a], Kunihiko Tsubura[a], Takashi Yamamoto[a], Masafumi Tabuchi[a], Terumasa Miyamoto[a] and Junji Shiga[b]

[a]Department of Medicine and Physical Therapy, and [b]Department of Pathology, Faculty of Medicine, University of Tokyo, 7-3-1, Hongo, Bunkyo-ku, Tokyo, 113, Japan

CV-3988 and CV-6209 inhibited gastric erosions in rats due to water-immersion and restraint stress in a dose-dependent manner. The above inhibitory effects of CV-3988 were observed in the presence of indomethacin, which may indicate that the inhibition is not prostaglandin dependent. The studies indicate that platelet-activating factor may be involved in the formation of erosions in rats under water-immersion and restraint stress. ***Lipids 26,*** **1354–1355 (1991).**

Platelet-activating factor (PAF) is a potent ulcerogenic agent (1). In the present investigation, the effect of the PAF antagonists CV-3988 and CV-6209 on acute gastric erosions due to water-immersion and restraint stress was studied in rats (2,3). The present study is an extension of our earlier work, in which the antagonist CV-3988 was used at relatively high concentrations (4,5).

CV-3988 (*rac*-3-(*N*-octadecylcarbamoyloxy)-2-methoxypropyl 2-thiazolioethyl phosphate) and CV-6209 (2-[*N*-acetyl-*N*-(2-methoxy-3-octadecylcarbamoyloxypropoxycarbonyl)aminomethyl]-1-ethylpyridinium chloride) were kindly provided by Takeda Pharmaceutical Company (Tokyo, Japan). Male Wistar rats (240–260 g for experiments 1 and 3), 190–210 g for experiment 2 were deprived of food for 24 hr. The drugs were then administered as follows: Experiment 1: CV-3988 was administered at doses of 0 mg, 10 mg, 20 mg, or 40 mg/kg body weight in saline (0.6 mL) by intravenous (i.v.) injection. Experiment 2: CV-3988 was administered i.v. in doses of 0 mg or 20 mg/kg body weight in saline (0.6 mL) and indomethacin (5 mg/kg in 0.6 mL of 8% $NaHCO_3$ adjusted to pH 9.0 by NaOH) were subcutaneously (s.c.) injected. As for the control, 0.6 mL of saline (i.v.) and the above solution used for indomethacin (s.c.) were administered. Experiment 3: CV-6209 was administered (i.v.) at doses of 0 mg, 0.1 mg, or 1 mg/kg in saline (0.6 mL).

After administration of the drugs, the rats were restrained in a cage and immersed in water at 22°C for 6 hr as described by Takagi and Okabe (6). Then the stomachs were fixed with 1% formalin and cut open by the great curvature. The lengths of linear hemorrhagic erosions were examined by one person unaware of the treatment, summed for each rat, and used as ulcer index.

The analysis of variances by F-test and Ryan's method were used for statistical analysis, $p < 0.05$ was regarded as statistically significant. Since the ulcer index varies between experiments, comparisons were made only within the same experiment and within the same group of rats.

[1]Based on a paper presented at the Third International Conference on Platelet-Activating Factor and Structurally Related Alkyl Ether Lipids, Tokyo, Japan, May 1989. The data on CV-3988 were originally reported in *Nippon Shokakibyo Gakkai Zasshi (Jap. J. Gastroenterol.) 85,* 2149–2154 (1988).

RESULTS AND DISCUSSION

The effect of CV-3988 on erosions due to water-immersion and restraint stress is shown in Table 1. CV-3988 inhibited the erosions in a dose-dependent manner. As shown in Table 2, CV-3988 also inhibited the enhanced erosions due to indomethacin administration. The effect of CV-6209 on the erosions due to water-immersion and restraint stress is shown in Table 3. CV-6209 also inhibited the erosions in a dose-dependent manner.

As shown here and reported earlier (4,5), CV-3988 significantly inhibited the erosions of rats caused by water-immersion and restraint stress. Since rather high doses were required for the inhibition, the possibility of a micellar effect of the drug could not be excluded (2). Micelles may injure cell membranes which, in turn, could possibly generate prostaglandins that could act as cytoprotective agents (7). However, the inhibitory effect of CV-3988 was also observed in the presence of indomethacin, which indicates that the inhibition is likely not to be mediated by prostaglandins (5,8). The more potent PAF antagonist CV-6209 also showed an inhibitory effect on the formation of erosions, but at much lower doses. At these drug concentrations, the inhibitory effect is observed well below the critical micelle concentration *in vivo*. Our data show that PAF might be involved in the formation of erosions in rats caused by water-immersion and restraint stress. Braquet *et al.* had earlier shown that BN 52021 and triazolam also reduced restraint-stress induced gastric damage (9). The data indicate that PAF may play a role in inducing gastric damage due to stress.

[Received July 24, 1989; Revision accepted March 9, 1990]

Platelet-Activating Factor May Mediate Dexamethasone-Induced Gastric Damage in the Rat[1]

János Filep[a,*], Ferenc Hermán[b] and Pierre Braquet[c]
Departments of [a]Pathophysiology and [b]Pharmacodynamics, Semmelweis University Medical School, 1445 Budapest, Hungary and [c]Institut Henri Beaufour, 92350 Le Plessis Robinson, France

The possible role of platelet-activating factor (PAF) in dexamethasone-induced gastric mucosal damage was studied in rats. PAF was measured by a platelet aggregation assay. The identity of the PAF-like product recovered from gastric tissues was ascertained by thin-layer chromatography and high-pressure liquid chromatography. Low levels of PAF were detected in the normal rat stomach, while in dexamethasone-treated animals PAF levels were significantly higher. Pretreatment of the animals with BN 52021, a specific PAF receptor antagonist, significantly attenuated dexamethasone-induced mucosal injury. These findings suggest that PAF may be a mediator of mucosal damage induced by glucocorticoids.
Lipids 26, **1356–1358 (1991).**

Platelet-activating factor (PAF) previously has been implicated as a mediator of allergic and inflammatory processes (1). Recent studies have identified PAF as the most potent endogenous ulcerogenic agent known to date (2–5). Further evidence suggesting a role for PAF in gastrointestinal damage comes from the observations that PAF predisposes the gastric mucosa to damage of topical irritants (6), and that PAF antagonists significantly reduce endotoxin-induced gastrointestinal damage (7–9) and prevent gastric lesions evoked by ethanol and stress (5,10).

Administration of glucocorticoids to experimental animals can result in acute gastric erosion formation (11,12). The mechanism of this damaging action of glucocorticoids is, however, far from being understood. Glucocorticoids have been reported to inhibit gastric mucus formation (13) and to affect epithelial cell turnover (14). Dexamethasone and prednisolone have been reported to be ineffective in blocking prostaglandin synthesis in rat stomach (12,15). The aim of the present experiments was to study the possible role of PAF in mediating gastric mucosal damage due to dexamethasone.

MATERIALS AND METHODS

Male Wistar rats (160–205 g) were used in all experiments. For six consecutive days (between 9:00 and 10:00 a.m. each day), the animals were given intraperitoneally 10 mg/kg of BN 52021 (ginkgolide B, Institut Henri Beaufour, Le Plessis Robinson, France), a specific PAF receptor antagonist (16,17) or its vehicle, and 30 min later they received a subcutaneous injection of dexamethasone sodium phosphate (Decadron, Merck, Sharp and Dohme-Chibret, Zürich, Switzerland) or vehicle. The animals were divided into four groups: (i) control (receiving vehicle only); (ii) 4 mg/kg dexamethasone; (iii) BN 52021; and (iv) BN 52021 plus dexamethasone. On day six, the animals were anesthetized with sodium pentobarbital 5 hr after the second injection. The stomach was immediately removed and examined. The severity of macroscopically visible damage was scored independently by two observers, who were unaware of the treatments, using a 0 to 3 scoring system (2,12). A score of 0 was assigned if the mucosa appeared to be normal; score 1, limited to diffuse superficial hyperemia; score 2, moderate hyperemia or focal hemorrhage; and score 3, multiple sites of bleeding or erosions. Scoring was completed within 2–3 min. Representative sections were taken, fixed in formalin, embedded into Durcupan ACM (Irvine, CA), and then 1 μm thick sections were made and stained with toluidine blue. The remaining glandular stomach was weighed, minced and homogenized in 10 mM morpholinoethansulfonic acid buffer containing 130 mM Na^+, 5.4 mM K^+, 1.8 mM Ca^{2+}, 112 mM Cl^- and 0.25% bovine serum albumin, pH 5.2. [^{3}H]PAF (220,000 dpm; 80 Ci/mmol, Amersham International, Amersham, U.K.) was added to monitor procedural losses. The lipids were extracted by the Bligh and Dyer method (18) and PAF was extracted on silica cartridges (Sep Pak, Waters Associates, Milford, MA) (19). PAF bioactivity was assayed by platelet aggregation as described (20). The identity of PAF bioactivity with authentic PAF was ascertained by thin-layer chromatography (TLC) and high-pressure liquid chromatography (HPLC) (20).

RESULTS AND DISCUSSION

As shown in Table 1, vehicle and BN 52021 treatment alone did not cause any gross or microscopic lesions. In contrast, all animals treated with dexamethasone developed extensive uniform hyperemia with multiple focal regions of petecchiae; in six out of nine animals mucosal erosions occurred in the glandular stomach. As evaluated histologically, dexamethasone treatment resulted in extravasation of erythrocytes, focal destruction of the surface epithelium, and necrosis extending down to one-fourth to one-third the depth of the mucosa.

Analysis of the PAF content showed that stomachs from rats treated with dexamethasone, at a dose which caused hemorrhagic mucosal damage, contained considerably higher amounts of PAF bioactivity than controls (Table 1). PAF was determined as a substance able to aggregate washed rabbit platelets in the presence of indomethacin and apyrase, an adenosine diphosphate (ADP) scavenger (20). Thus, it is unlikely that the aggregation observed was due to thromboxane A_2 or ADP. Furthermore, PAF bioactivity recovered from gastric extracts showed Rf values in TLC (0.24 ± 0.02, n=4) and

TABLE 1

Effects of Dexamethasone on Gastric Mucosa and PAF Content in the Rat Glandular Stomach, and Prevention by PAF Receptor Antagonist BN 52021

Treatment[a]	Gastric mucosal damage scores[b]	n	p[c]	PAF content ng/g tissue	n	p[c]
None	0.3 ± 0.2	9	—	0.14 ± 0.03	6	—
BN 52021, 10 mg/kg	0.4 ± 0.2	8	NS	0.12 ± 0.05	4	NS
Dexamethasone, 4 mg/kg	2.7 ± 0.2	9	0.001	5.31 ± 1.35	4	0.05
BN 52021, 10 mg/kg plus Dexamethasone, 4 mg/kg	0.7 ± 0.2	9	NS[d]	1.54 ± 0.60	4	0.05

Values are means ± SEM.

[a]The animals were given BN 52021, dexamethasone, or both drugs daily for six days. On day 6, the stomach was removed and examined. PAF was extracted, purified over silica cartridge and measured by a platelet aggregation assay (for details see Materials and Methods).

[b]Damage was scored on a 0 (normal) to 3 (severe, extensive hyperemia, multiple sites of bleeding/erosions) scale by two observers unaware of the treatments. The correlation between scores assigned by the two observers was r = 0.92 (n=35, p<0.001).

[c]Compared to untreated rats, [d]p<0.01 compared to dexamethasone treated animals (Dunn's multiple contrast test). NS, not significant; n, number of animals.

retention time (Rt) in HPLC (7.5 ± 0.2 min, n=4) identical to those of synthetic PAF (Rf 0.24 ± 0.02, n=3; Rt, 7.4 ± 0.2 min, n=4). Platelet aggregation induced by either synthetic PAF or by gastric extracts was completely abolished by pretreatment of the platelets with BN 52021, a specific PAF receptor blocker (16,17). Taken together, these findings strongly suggest that the material recovered from the rat stomach and assayed was indeed PAF.

In the present study, low amounts of PAF were detected in the stomach of untreated rats in five out of six cases. Although similar levels of PAF-like activity were detected in rat kidney (21) and uterus (22), it is still uncertain whether PAF is actually present *in situ*, or is generated by mechanical or chemical stimuli during the analytical procedure. The biological significance of endogenous PAF in the gastrointestinal area and the apparent contradiction that local injection of PAF can produce mucosal damage (2-5) remain to be clarified.

Pretreatment of the animals with BN 52021 (10 mg/kg) significantly reduced the severity of dexamethasone-induced gastric lesions (Table 1). In these animals no petecchiae or erosions were observed. BN 52021 also reduced the severity of hyperemia—in four out of nine rats, gastric mucosa appeared to be normal. Preliminary experiments showed that the protective effect of BN 52021 was dose-related. Pretreatment of the animals with 4 mg/kg of BN 52021 significantly reduced the number of erosions/petecchiae, but had little effect on hyperemia, while at a dose of 1 mg/kg, BN 52021 did not exert any protective effect (data not shown). PAF content of the stomach from BN 52021 plus dexamethasone-treated rats was significantly lower than PAF levels found in rats receiving dexamethasone alone (Table 1). Whether this difference mirrors a decrease in PAF formation and/or an increase in PAF metabolism secondary to its displacement from PAF receptors is not clear. The findings that BN 52021 is a competitive PAF receptor antagonist (16,17) and that it has a ten-fold lower affinity to PAF receptor than does PAF itself (17) seem to support the latter explanation. A further possibility might be that trace amounts of BN 52021 interacted in the platelet aggregation assay and that, consequently, PAF concentrations were underestimated.

The present data do not give any information on the source of PAF. However, it seems unlikely that PAF originated from neutrophil granulocytes since dexamethasone decreases gastric myeloperoxidase activity (12), a widely used index of neutrophil infiltration. On the other hand, dexamethasone treatment resulted in depletion and degranulation of mast cells in the gastric mucosa (23). Because these cells are capable of synthesizing PAF (1), it might be that mast cells are, at least partly, responsible for enhanced gastric PAF formation following dexamethasone treatment.

In conclusion, the present findings suggest that PAF may be an endogenous mediator of dexamethasone-induced gastric mucosal damage in the rat.

ACKNOWLEDGMENTS

We are grateful to Dr. F. Schneider for histological analyses and to Mr. A. Simon for excellent technical assistance. This work was partly supported by grants from the Hungarian Academy of Sciences (AKA 1-300-2-88-0-553) and from the Hungarian Ministry of Health (ETK 7-447).

[Received July 28, 1989; Revision accepted May 18, 1990]

Myoelectric Intestinal Disturbances in *Escherichia coli* Endotoxic Shock in Rats. Involvement of Platelet-Activating Factor[1]

Laurent Pons[a,*], Marié-Thèrese Droy-Lefaix[b], Pierre Braquet[b] and Lionel Buéno[a]
[a]Department of Pharmacology INRA, 31931 Toulouse Cédex, and [b]IPSEN/IHB Laboratories, 92350 Le Plessis-Robinson, France

Administration of BN 52021 (50 mg/kg *i.v.*), a specific antagonist of platelet-activating factor (PAF), significantly reduced the intestinal myoelectric disturbances induced by *E. coli* endotoxin injection (50 μg/kg *i.v.*) by 62%. Thus, PAF may be involved in the intestinal motor alterations observed in endotoxic shock. When given in combination with indomethacin (10 mg/kg *i.p.*), BN 52021 inhibited endotoxic shock intestinal disturbances. Indomethacin alone also reduced PAF induced (25 μg/kg *i.p.*) disruption of migrating myoelectric complexes. Endotoxins may act on intestinal motility *via* release of endogenous PAF and prostaglandins, the effects of PAF being mediated through the release of prostaglandins.
***Lipids 26,* 1359-1361 (1991).**

Platelet-activating factor (PAF) is thought to be involved in the pathophysiology of endotoxic shock because it displays a variety of effects likely to occur in endotoxemia, such as extensive necrosis and vascular congestion in the stomach and in the small intestine (1). Whittle *et al.* (2) demonstrated increased gastrointestinal PAF synthesis in a rat model of endotoxic shock. In addition to comparing the effects of endotoxin and PAF on intestinal myoelectric activity in fasted rats, the present study was conducted to determine if the release of endogenous PAF contributes to the genesis of intestinal motor disturbances observed in endotoxic shock using BN 52021, a specific PAF antagonist. The role of released endogenous prostaglandins was also examined.

MATERIALS AND METHODS

Under halothane (Fluothane ND, Coopers Vétérinaire S.A., Meaux, France) anesthesia, male Wistar rats (280–320 g) were chronically implanted with nichrome electrodes in

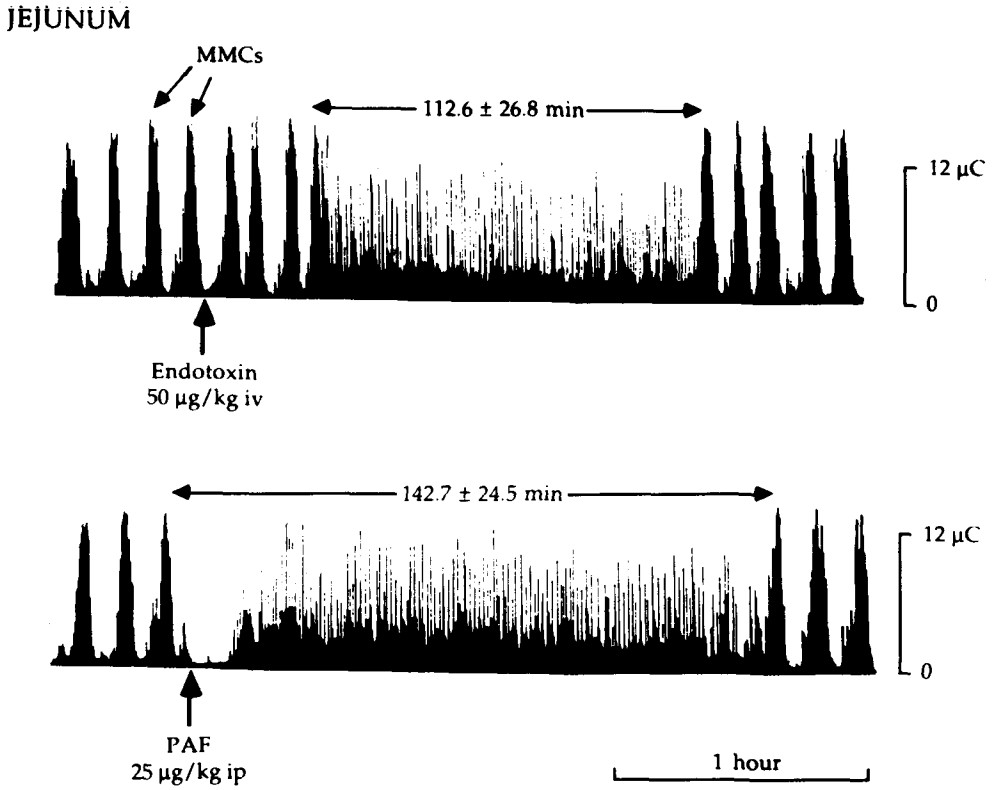

FIG. 1. Comparative effects of *E. coli* endotoxin (50 μg/kg *i.v.*) and PAF (25 μg/kg *i.p.*) administration on jejunal myoelectric activity (integrated records) in fasted rats.

[1]Based on a paper presented at the Third International Conference on Platelet-Activating Factor and Structurally Related Alkyl Ether Lipids, Tokyo, Japan, May 1989.

*To whom correspondence should be addressed at the Department of Pharmacology INRA, 180 chemin de Tournefeuille, B.P. 3, 31931 Toulouse Cédex, France.

Abbreviations: PAF, platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; MMC, migrating myoelectric complex.

the duodeno-jejunum, using a previously described technique (3). After one week, the experiments were performed in animals that were fasted for at least 8 hr, but were given free access to water. In the first series of experiments animals received *E. coli* endotoxin (S.O111:B4, Sigma, La Verpillière, France) injected intravenously in 0.2 mL saline at a dose of 50 μg/kg. Alternatively, animals were submitted to intraperitoneal administration of 0.2 mL saline containing PAF (Sigma, La Verpillière, France) at a dose of 25 μg/kg. Control animals received 0.2 mL saline. In the second series of experiments, BN 52021, a specific PAF antagonist, was dissolved in 0.2mL saline and injected intravenously at a dose of 50 mg/kg, 5 min before PAF (25 μg/kg *i.p.*) or endotoxin (50 μg/kg *i.v.*). BN 52021 was a gift from IPSEN/IHB Laboratories (Le Plessis-Robinson, France). In the last series of experiments, similar administrations of endotoxin and PAF were performed 10 min after intraperitoneal administration of indomethacin (Interchim, Montluçon, France), a cyclooxygenase inhibitor, dissolved in 0.2 mL $NaHCO_3$ (5%) and injected intraperitoneally at a dose of 10 mg/kg.

Myoelectrical activity of the small intestine was recorded using an electroencephalograph (Reega VIII, Alvar, Paris). Identification of the intestinal motor pattern was facilitated by the summation of spiking activity every 20 seconds (4). Effects on intestinal motility were evaluated by measuring the time elapsed from the injection to the recovery of a normal fasted pattern, *i.e.*, migrating myoelectric complexes (MMC) on integrated electromyographic records. Values are means ± S.D. These values were compared using one- or two-way ANOVA, followed by Student's *t*-test for fasted values.

RESULTS AND DISCUSSION

The myoelectric activity of conscious, 8 hr-fasted rats is characterized by the occurrence of MMC having a mean period of 16.2 ± 5.8 min. Each MMC consisted of irregular spiking activity (phase II) lasting 4–6 min, followed by a short (4–5 min) period of intense activity called regular spiking activity, or phase III. These two periods of activity were separated by a quiescent (phase I) period (Fig. 1).

Animals were injected *i.v.* with 50 μg/kg *E. coli* endotoxin. This resulted in a disruption of the MMC pattern, which was replaced by a continous spiking activity for 112.6 ± 26.8 min (Fig. 1). Such a disruption appeared within 20 min after injection. PAF administered *i.p.* at a dose of 25 μg/kg induced a transient inhibition of the spiking activity immediately followed by a long-lasting

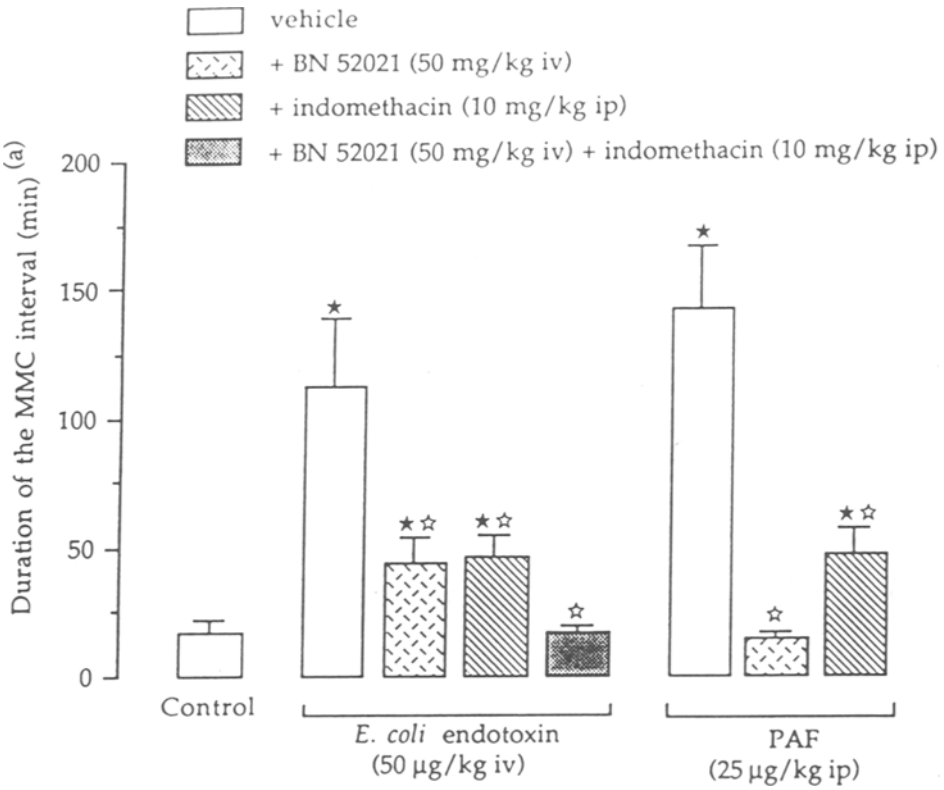

FIG. 2. Protective effects of BN 52021 (50 mg/kg *i.p.*), indomethacin (10 mg/kg *i.p.*) and a combination of both on endotoxin and PAF induced disruption of the MMC pattern in fasted rats. Values are means ± SD (n=6). A closed star and an open star indicate that values are significantly different from control and vehicle values, respectively. [a]Duration of the MMC interval was measured from the last phase III before to the first phase III after treatment at the jejunal level.

disruption of the MMC pattern for 142.7 ± 24.5 min (Fig. 1).

BN 52021, injected *i.v.* at a dose of 50 mg/kg 5 min prior to *i.p.* administration of PAF, abolished the effects of PAF on the intestinal myoelectric activity (Fig. 2). When BN 52021 was injected 5 min before endotoxin, the period of endotoxin-induced continous spiking activity persisted, but its duration was significantly reduced from 112.6 ± 26.8 min to 43.3 ± 10.7 min (Fig. 2). Injected 10 min before endotoxin, indomethacin (10 mg/kg *i.p.*) also significantly shortened the MMC disruption (Fig. 2). The same dose (10 mg/kg) also reduced the PAF induced intestinal myoelectric alterations (Fig. 2). A combination of indomethacin (10 mg/kg *i.p.*) and BN 52021 (50 mg/kg *i.v.*) injected 10 and 5 min before endotoxin, respectively, abolished the effects of endotoxin on the intestinal MMC pattern (Fig. 2).

Because of the similar effects of PAF to those of endotoxin, PAF is suspected to play a role in endotoxic shock. Our findings indicate that *i.v.* administration of endotoxin abolishes the normal pattern of intestinal myoelectric activity. The present work demonstrates that PAF is also able to induce a disruption of the MMC pattern. Furthermore, BN 52021 has been shown to affect endotoxin-induced lethality (5) or to prevent the hypotension induced upon PAF administration (6). In our model of endotoxic shock, BN 52021 appeared to be able to reduce endotoxin-induced alterations of the MMC pattern, consistent with an involvement of PAF in *E. coli* endotoxin-induced intestinal motor disturbances. In our experiments, PAF and endotoxin induced alterations are reduced by prior administration of indomethacin, a cyclooxygenase inhibitor, suggesting that prostaglandins are involved in endotoxin-induced motility alterations, but are also implicated in the action of PAF on the intestinal motor pattern. Prostaglandins appear to be involved in at least two levels, because indomethacin reduced PAF induced motor alterations, and a combination of indomethacin and BN 52021 abolished the effects of endotoxin.

REVIEW

Platelet-Activating Factor and Granulocyte-Mediated Oxidative Stress. Strategy for *in vivo* Oxyradical Visualization[1]

Makoto Suematsu and **Masaharu Tsuchiya***
Department of Internal Medicine, School of Medicine, Keio University, Tokyo 160, Japan

Platelet-activating factor (PAF) and leukotriene B_4 are potent lipid mediators of endothelium-granulocyte interaction which results in granulocyte-dependent increased microvascular permeability. The specific mechanism by which PAF induces granulocyte-mediated endothelial injury has not been fully investigated. Digital imaging photonic intensified microscopy has revealed that PAF effectively induces granulocyte-mediated oxidative stress on microvascular beds. The method has made it possible to visualize luminol-dependent photonic burst released from PAF-treated microvascular beds in the rat mesentery. The photonic activities clearly corresponded to the localization of sticking granulocytes in post-capillary venules. By contrast, no significant chemilumigenic response could be detected in the leukotriene B_4-induced activation of endothelium-granulocyte interaction *in vivo*. The present findings suggest that oxygen radicals are not prerequisites for granulocyte adhesion in the microcirculation and provide evidence for a dissociation of *in vivo* granulocyte function between leukotactic and oxidative activation in leukotriene B_4-induced microvascular changes.
***Lipids 26,* 1362–1368 (1991).**

Platelet-activating factor (PAF) is formed by many different cells and is believed to contribute to allergic and inflammatory processes (1,2). PAF shows a broad spectrum of pharmacological effects including platelet aggregation, granulocyte activation, bronchoconstriction, and increased microvascular permeability. The effect of PAF on hyperpermeability in microvascular beds is thought to be mediated by both granulocyte-independent and granulocyte-dependent mechanisms (3). In the latter mechanism, granulocytes are thought to adhere to the venular endothelial surface and in an unknown way induce macromolecular leakage. Björk and coworkers (3,4) first reported that pretreatment with anti-neutrophil sera reduced PAF-induced microvascular hyperpermeability in hamsters, which suggested the involvement of permeability-altering mediators derived from sticking granulocytes.

PAF is known to stimulate secretagogue activation of granulocyte *in vitro*, including the release of lysosomal enzymes, active oxygen metabolites, and leukotrienes (5). Among these mediators, active oxygen metabolites have attracted considerable interest as a tissue breakdown factor during acute inflammatory processes. Superoxide anion (O_2^-) is the primary product derived from NADPH oxidase (6) from which hydrogen peroxide (H_2O_2), hydroxyl radicals (•OH) and hypochlorous anions (ClO^-) are thought to be subsequently generated (7). Although there is a great deal of information on the mechanism by which granulocytes release active oxidants, whether oxidative activation of granulocytes actually occurs during inflammatory processes *in vivo* has not been fully established. Most observations that have suggested participation of active oxidants in tissue injury are based upon the preventive effects of antioxidants such as superoxide dismutase (SOD), catalase, or dimethyl sulfoxide (DMSO). It has been difficult to obtain direct evidence for oxidative stress that occurs during endothelium-granulocyte interaction in the disturbed microcirculation. Because oxygen radicals are highly reactive and short-lived compounds which react with the nearest target molecule, the cell membrane of endothelial cells is believed to be the primary site of granulocyte-mediated oxidative metabolite interaction (8). However, it has been technically impossible to evaluate spatial and temporal alterations of oxidant generation even *in vitro*.

This report is intended to summarize current methodology to *visualize* oxidative stress *in vitro* and *in vivo*, which may help in clarifying the topographic relationship between oxidant-generating sources and damaged sites. As an application, we discuss the role of PAF in granulocyte-mediated oxidative stress in microcirculatory disturbances.

CURRENT APPROACHES FOR OXYRADICAL VISUALIZATION

Chemical probes. Chemical probes intended to obtain spatial information on oxidative stress in biological systems require certain properties. An electron microscopic technique and use of cerium derivatives ($CeCl_3$) has first revealed the location of H_2O_2 in granulocytes stimulated by zymosan particles or soluble stimuli such as phorbol myristate acetate (PMA) or bacterial chemotactic peptide (FMLP). Karnovsky and coworkers (9) reported the spatial difference of H_2O_2 generation between PMA- and zymosan-treated cells. When granulocytes were stimulated by zymosan particles, H_2O_2-generating sites were observed to distribute in the contact surface between particles and the phagosome-forming membrane of granulocytes. By contrast, granulocytes stimulated by soluble stimuli produced a diffuse pattern of cerium deposits surrounding the entire membrane. Through this technique, the

oxyradical distribution during intercellular reaction between phagocytes and parenchymal cells can be investigated. Vissers *et al.* (10) clearly demonstrated that oxyradical burst could actually occur in the non-phagocytosable contact surface between granulocytes and the glomerular basement membrane *in vitro*. The electron microscopic approach helps to shed light on the topographic relationship between the oxidant-generating effector and target cells. However, it can not adequately trace the time history of oxidative stress.

Oxyradical-sensitive chemical probes may be useful tools for the analysis of the spatial distribution and temporal alteration of oxidant generation *in vitro* and *in vivo*. Table 1 lists previous reports which have provided quantification of oxidant generation from a single phagocyte through a microscope. The goal of these investigations is to clarify the spatial distribution of oxidant release and the heterogeneity of oxidative reactivity among cells. DiGregorio *et al.* (11) applied nitroblue tetrazolium (NBT), a chemical probe which is oxidized by O_2^- to form insoluble blue deposits (formazan), at the site of O_2^- generation. To determine the O_2^- generation, they quantified the optical turbidity of cells which was caused by formazan deposits by microscopic videodensitometry.

Another probe to visualize oxidant activities is dichlorofluorescin (DCFH), the usefulness of which was first established by Cathcart *et al.* (12). This method is based upon the original work of Keston and Brandt (13), in which DCFH is oxidized to the fluorescent, dichlorofluorescein (DCF) by H_2O_2 and peroxidase (13,14). Bass *et al.* (15) quantified intracellular oxidizing species in individual granulocytes using the ester-type precursor, DCFH diacetate. This reagent enters living cells to be catalyzed into DCFH by esterase. The technique has been applied to determine inorganic and organic hydroperoxide formation in renal epithelial cells (16) and hepatocytes (17). Using the fluorochrome, we have recently investigated the intralobular heterogeneity of carbon tetrachloride-induced hydroperoxide formation in perfused rat liver (18). The DCF-associated fluorescence was predominantly enhanced in the pericentral area, and was attenuated by SKF-525A, a potent inhibitor of cytochrome P-450. In order to use this technique for quantitative observation of oxidative stress *in vivo*, technical difficulties in fluorescence quantification such as a correction for photobleaching attenuation need to be solved (19).

Digital imaging photonic microscopy and chemiluminescence imaging. Besides the use of $CeCl_3$ and DCFH, the third strategy for oxidant visualization is the chemiluminescence method. Compared with the fluorescence method, this technique has several advantageous properties which prove useful for evaluation of oxidative stress *in vivo*: (i) the absence of a photobleaching effect; (ii) no need for excitation illumination, resulting in attenuation of cellular damages; (iii) availability of different chemilumigenic probes which makes it possible to pinpoint the active oxidants that are involved in different experimental models. However, the chemilumigenic response induced by the release of oxidants is generally too weak to be observed as a visible image even in the presence of chemiluminescence sensitizers. A special device for the low-level chemiluminescence visualization and an analytical evaluation is therefore required.

The objective of the conventional chemiluminescence study is to count oxidant-associated scintillating photonic activity by a photomultiplier. Since Tsuchiya *et al.* (20) first developed a two-dimensional photon-counting system equipped with a computer-assisted digital image processor, recent work with this system was aimed at the collection of quantitative information about the spatial distribution of chemiluminescence within a single cell. Figure 1 shows a system diagram of the ultrasensitive photonic image intensifier (C-2400-20, Hamamatsu Photonics, Hamamatsu, Japan). When an optical image from a microscope is focused on the bialkali photocathode in the front portion of camera head, photoelectrons are emitted in proportion to the intensity of the microscopic image. These photoelectrons are amplified in a 2-stage microchannel plate by a million-fold and transmitted to a phosphor screen. The scintillating photonic images on the screen are visualized by a low-lag vidicon and then digitally processed.

One major problem is the specificity of chemilumigenic probes. For example, the probe luminol is widely used to determine oxyradical generation from phagocytes. Using ultrasensitive photonic image intensified microscopy and a computer-assisted image processing device, we investigated the mechanism of luminol-dependent photoemission derived from single human neutrophils (21). This technology has revealed spatial differences of respiratory burst, heterogeneity of oxidative activation among neutrophils, and the crucial role of extracellular release of myeloperoxidase in this type of chemilumigenic reaction. When neutrophils were stimulated by opsonized zymosan, luminol-dependent photonic burst clearly corresponded to the distribution of cells in the microscopic field and each

chemilumigenic site was observed in a restricted region close to each active cell (Fig. 2). These photonic activities were completely attenuated by sodium azide or catalase, and were enhanced by adding exogeneous myeloperoxidase (22). It is therefore likely that extracellular and/or pericellular release of myeloperoxidase-associated oxidants such as ClO^- is involved in the luminol-dependent photoemission. To further elucidate the role of azulophilic degranulation and the extracellular release of myeloperoxidase, luminol-dependent chemiluminescence from neutrophils stimulated by PMA and calcium ionophore A 23187 was visually investigated (23). Neutrophils stimulated by PMA alone produced only a negligible level of photonic activities in the presence of luminol. The addition of calcium ionophore induced explosive changes of photonic burst which was closely correlated with the cellular distribution in the image. The photonic activities gradually spilled from the cells into the extracellular space. These findings suggest that degranulation and myeloperoxidase release is a prerequisite in luminol-dependent photoemission from stimulated neutrophils. This type of chemiluminescence was not detectable in neutrophils of patients with chronic granulomatous disease (complete cytochrome b558 deficiency) or myeloperoxidase deficiency (24). Taken together with these data, luminol was proposed to be a useful chemilumigenic probe to detect active oxidants derived from the H_2O_2-myeloperoxidase-chloride system.

IN VIVO OXYRADICAL VISUALIZATION DURING PAF-INDUCED MICROVASCULAR DAMAGE

Intravital microscopy is an indispensable technique to evaluate the dynamics of endothelium-granulocyte interaction *in vivo* (25). By using an intravital microscope equipped with an ultrasensitive photonic intensifier system, we observed spatial distribution and temporal changes of oxyradical-dependent chemilumigenic sites in damaged microvascular beds. Male Wistar rats were anesthetized and the ileocecal portion of the mesentery was carefully exposed and mounted on a plastic stage. The stage bottom was made of a non-fluorescent thin cover glass according to our methods described previously (21). The

preparation was continuously superfused (0.5 mL/min) with Krebs-Ringer bicarbonate-buffered solution. The dynamics of the mesenteric microcirculation was observed and visualized through an inverted microscope incorporated with a digital imaging photonic intensified system (C-2400-20 / ARGUS, Hamamatsu Photonics). After completing the preparation procedure, the luminol-containing Krebs-Ringer solution (final concentration 1.0 μg/mL) was superfused. After a control period of 10 min, the solution of vasoactive lipid mediators (PAF-acether or leukotriene B_4) was added to the superfusion buffer. The luminol-dependent chemiluminescence activity detected by the C-2400-20 through the intravital microscope was observed in a light-excluding chamber at 37°C. Real-time scintillating photonic activities were digitally accumulated for 180 sec and stored in a video frame memory of the image processor. Microvascular images were also recorded by using a transmission light source of the microscope immediately after the 180-sec photon-counting period. The stored photonic image was superimposed upon the vascular image to identify oxyradical-generating sites in the microvasculature. Temporal alterations of photonic activities were automatically calculated in preselected area of each microscopic field containing a 100 μm segment of a post-capillary venule (40 μm in diameter).

The photonic intensity derived from the microvascular segment is thought to depend on both the oxyradical-generating activity of individual granulocytes and the population of sticking cells. We therefore determined the number of sticking granulocytes in the preselected venular segment using acridine orange-associated fluorographic analysis (26). The acridine orange solution (0.1%, 0.2mL) was administered intravenously and the intravital fluorescence image in the microvascular segment was visualized by a silicon intensified target camera (C-2400-08, Hamamatsu Photonics).

Figure 3 indicates a representative study of endothelium-granulocyte interaction induced by leukotriene B_4 (100 nM superfusion for 5 min). The same concentration of PAF-acether also induced significant activation of granulocyte sticking in post-capillary venules (Fig. 4). These findings reflect the powerful stimulating effect of these reagents on granulocyte adherence as reported previously (3,4).

By contrast, the intravital photonic responses showed quite different pictures among the two groups. Figure 5

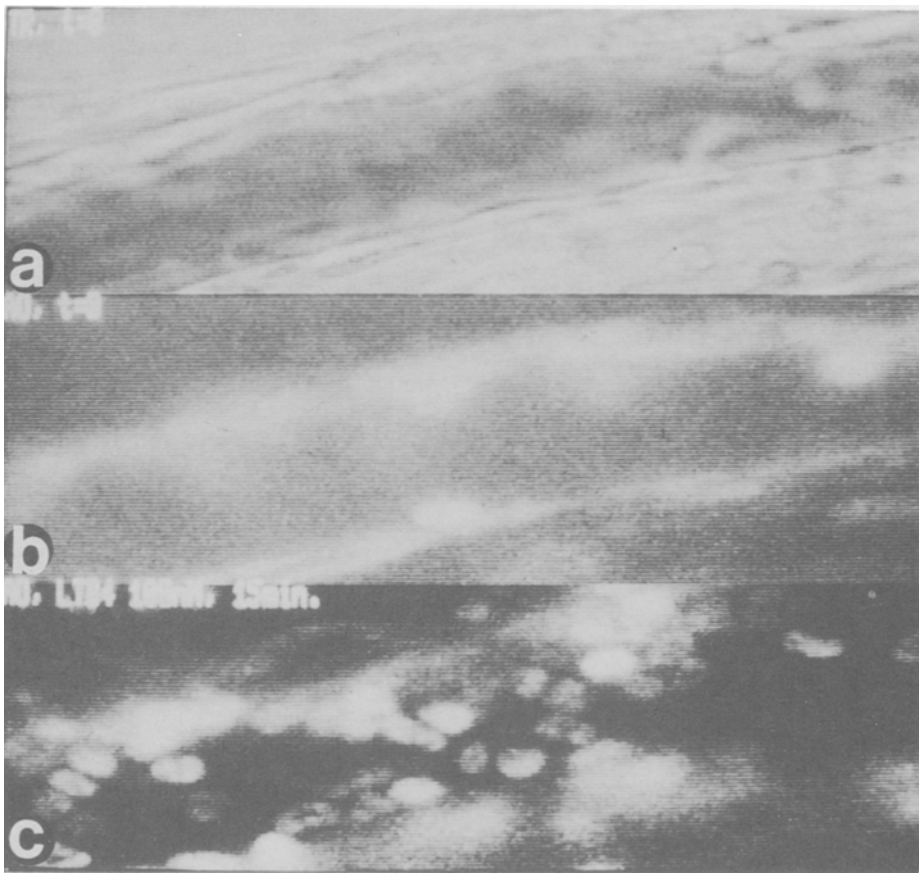

FIG. 3. Leukotriene B_4-induced granulocyte adherence in rat mesenteric microcirculation. Leukotriene B_4 (LTB_4) was superfused at 100 nM for 15 min. After the intravenous injection of acridine orange (AO) solution, rolling and sticking granulocytes were observed as spheroid-shaped fluorogenic cells in post-capillary venules. (a) A representative image of a venular segment visualized by transillumination (TR). (b) AO-associated epifluorescence image of the same venular segment before LTB_4 superfusion. (c) Granulocyte adherence induced by the LTB_4 superfusion for 15 min.

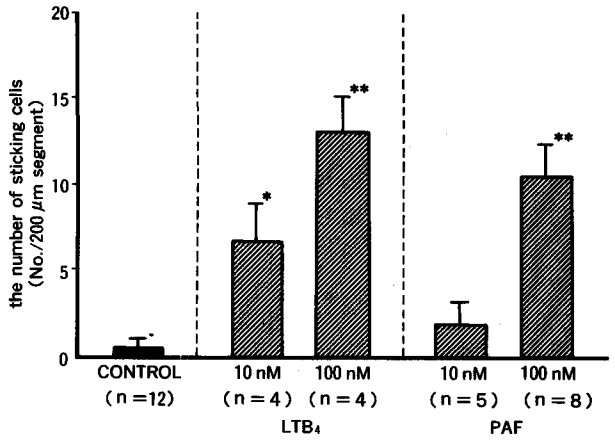

FIG. 4. *In vivo* morphometric analysis of the number of sticking granulocytes in rat mesenteric venules (200 μm segment, 40 μm in diameter) after 15 min superfusion of leukotriene B_4 or PAF-acether (PAF). Acridine orange-positive spheroid cells adhering to the endothelium and remaining in the same position for 1 min were considered to be 'sticking cells'.

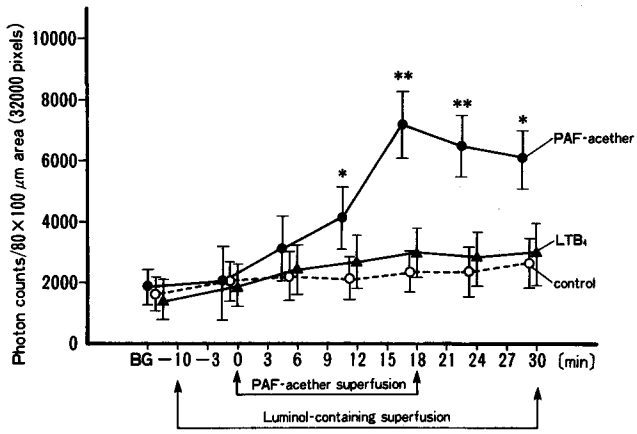

FIG. 6. Effects of PAF-acether and leukotriene B_4 (LTB_4) on luminol-dependent chemiluminescence activities derived from the preselected microscopic field (80 μm × 100 μm) containing a 100-μm venular segment. BG denotes background photonic activities before experiments in a light-excluding chamber. The photon-accumulating period is 180 sec, common in all experiments. Mean ± S.D. of 6 experiments. *$p<0.05$ and **$p<0.01$ as compared to the control.

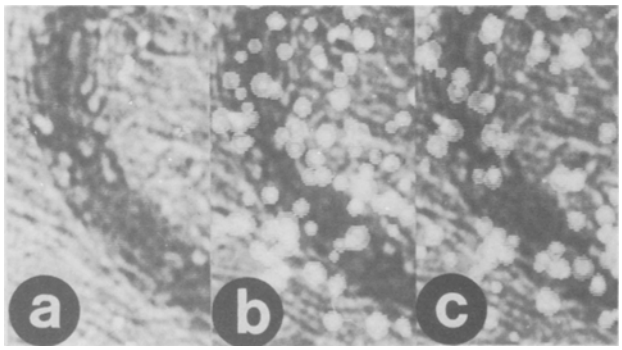

FIG. 5. Temporal and spatial alterations of luminol-dependent photoemission during endothelium-granulocyte interaction in a post-capillary venule treated with 100 nM PAF-acether. Parts a, b and c represent photonic images superimposed on microvascular frames in 3–6 min (a), 15–18 min (b) and 21–24 min (c) after starting the PAF-acether superfusion. (From ref. 27 with permission.)

represents temporal and spatial alterations of luminol-dependent photoemission derived from the venular segment treated with PAF-acether (100 nM). Six minutes after the start of PAF-acether superfusion, remarkable changes in granulocyte adherence were observed, but no significant elevation of chemiluminescence was detectable. However, the photonic activities gradually increased and their spatial distribution clearly corresponded to the localization of intravascular sticking cells (27). The photonic intensitometric analysis by the digital image processor indicated that approximately 15–18 min were required to obtain the maximum photonic counts. It was concluded that oxyradical-dependent photoemission in the luminol-perfused and PAF-treated microvascular beds reflects active oxidants derived from sticking and migrating granulocytes for the following reasons: (i) Luminol-dependent photoemission from PAF-stimulated granulocytes *in vitro* was attenuated by chlorpromazine, which is known to inhibit O_2^- generation by competing with oxygen for NADPH oxidase (28). Catalase (1000 units/mL) or sodium azide (1.0 mM) completely attenuated the photoemission, suggesting participation of the H_2O_2-myeloperoxidase-chloride system in this type of photoemission (27). (ii) The sites of photonic burst clearly corresponded to the location of sticking granulocytes in post-capillary venules. (iii) Luminol-dependent photoemission *in vivo* from sticking cells was also suppressed by the topical application of chlorpromazine or sodium azide (27). These results suggest that PAF is a powerful lipid mediator of endothelium-granulocyte interaction ensued by granulocyte-mediated oxidative stress *in vivo*.

By contrast, leukotriene B_4 did not cause any significant photonic activation at a concentration of 100 nM which is high enough to induce granulocyte adherence in post-capillary venules (Fig. 6). Although the luminol-dependent photoemission does not directly reflect O_2^- production in sticking granulocytes, our results may imply that secretagogue activation of the H_2O_2-myeloperoxidase-chloride system in granulocytes is not apparent in leukotriene B_4-induced leukotactic activation *in vivo*. The present findings raise the possibility that oxidative activation of granulocytes may not be a prerequisite for endothelium-granulocyte interaction in disturbed microvascular beds. The independence of granulocyte diapedesis from oxidant production is supported by the fact that NADPH oxidase-deficient granulocytes in patients with chronic granulomatous disease are accumulated in pus at the sites of infection (29). This idea is also consistent with the previous report by Harlan *et al.* (30) which demonstrated that granulocytes mediate the rapid nonlytic disruption of the endothelial monolayer integrity by an oxygen radical-independent mechanism.

ROLES OF PAF AND LEUKOTRIENE B_4 IN GRANULOCYTE-MEDIATED OXIDATIVE STRESS DURING MICROVASCULAR DAMAGE

Leukotaxis-inducible doses of leukotriene B_4 did not cause any significant activation of the photoemission from microvascular beds. Most inflammatory mediators with

chemotactic properties *in vitro* are known to increase microvascular permeability *in vivo* through a process entirely or partly dependent on granulocytes. Although the exact mechanism by which granulocytes damage the microvascular integrity remains unknown, recent studies have suggested the involvement of oxygen radicals in endothelial damages (31,32). Leukotriene B_4 is a potent chemotactic agent for granulocytes, and in high concentrations it can induce an oxyradical burst (33). It has also been reported that O_2^- and H_2O_2 may play a role in leukotriene B_4-induced granulocyte chemotaxis *in vitro* (34). However, there have been few reports suggesting that leukotriene B_4 may stimulate oxidant generation in adherent granulocytes *in vivo*. Rosengren *et al.* (35) demonstrated that SOD and/or catalase does not influence the leukotriene B_4-induced microvascular permeability and granulocyte sticking in the hamster cheek pouch microcirculation. This suggests that oxygen radicals may be not crucially involved in endothelium-granulocyte interaction and the resultant microvascular permeability changes. Our results showing the failure of leukotriene B_4 to produce photonic activities in sticking granulocytes *in vivo* provide evidence for a functional dissociation between leukotactic and secretagogue activation in leukotriene B_4-stimulated granulocytes.

The mechanism by which PAF-acether causes an increase in microvascular permeability seems different from that involved in leukotriene B_4-induced hyperpermeability. As shown in experiments with animals treated with a specific anti-neutrophil serum (36), the leukotriene B_4-induced plasma leakage is almost exclusively granulocyte-dependent. By contrast, PAF has been reported to cause a direct vasoactive effect on the microvascular endothelium. Humphrey *et al.* (37) have demonstrated that picomolar levels of PAF-acether induce an early, transiently increased microvascular permeability and that PAF-induced vasoactivity occurs in the absence of granulocyte, platelet or mast cell stimulation and during H_1 histamine blockade. With increasing amounts of PAF-acether, early granulocyte infiltration followed by relatively prolonged activation of vascular permeability has been documented (38). According to Kubes *et al.* (39), PAF-induced intestinal microvascular hyperpermeability was *partially* attenuated by pretreatment with a monoclonal antibody (IB_4) against the leukocyte adhesive glycoprotein complex. It should be noted that SOD attenuates the PAF-induced granulocyte adherence on the venular endothelium without changing microvascular hemodynamics, suggesting the involvement of O_2^- which may be generated at the interface between the venular endothelium and adherent granulocytes in PAF-induced granulocyte diapedesis (40). Taken together with these previous reports, the present study demonstrates that active oxidants from the H_2O_2-myeloperoxidase-halide system (*e.g.* ClO^-) may be possible candidates for PAF-induced and granulocyte-dependent microvascular hyperpermeability.

Our recent data showed that the PAF-induced granulocyte adherence and photonic burst are attenuated by pretreatment with AA-861, a specific 5-lipoxygenase inhibitor (41). This suggests involvement of leukotrienes in granulocyte-mediated oxidative stress in PAF-treated microvascular beds, and is supported by *in vitro* experiments showing the preventive effect of 5-lipoxygenase inhibitor on PAF-induced granulocyte chemotaxis through cultured endothelial cell monolayers (42). As shown previously, leukotriene B_4 *alone* did not show any significant photoemission at the sites of endothelium-granulocyte interaction. The potent stimulatory effect of PAF on the luminol-dependent photoemission from sticking granulocytes *in vivo* may be due to the concurrent action of PAF and endogenous leukotriene B_4, which is subsequently released from sticking granulocytes. Since H_2O_2 is known to stimulate PAF generation in umbilical venous endothelium *in vitro* (43), the exogenous PAF-induced granulocyte-mediated oxidative stress may stimulate the endothelium-dependent endogenous PAF generation at the sites of granulocyte adherence. Further *in vitro* investigations using cultured endothelium and granulocytes will be required to confirm this scenario. However, the reciprocal activation between venular endothelium and granulocytes *via* lipid mediators (PAF *plus* leukotriene B_4) may play an important role in secretagogue activation of sticking granulocytes in the PAF-treated microvascular beds.

In conclusion, the present findings which were obtained by digital imaging photonic intensified microscopy support the following concepts: (i) Oxygen radicals are not a prerequisite for endothelium-granulocyte interaction, and (ii) PAF is a potent lipid mediator of granulocyte-mediated oxidative stress upon venular endothelial integrity. Since our methods using luminol-dependent chemiluminescence can evaluate myeloperoxidase-mediated oxidants, it seems difficult to determine the direct activity of O_2^- produced by other oxidant-generating sources such as xanthine oxidase in endothelial cells. To determine and visualize intravital O_2^- generation, development of better chemilumigenic probes with O_2^--specific reactivity (44), high photonic efficiency, and low-level background photoemission are needed. Although the development of such an ideal chemilumigenic probe will be difficult, it would provide further insights into the cellular and subcellular mechanisms through which oxygen radicals exert their cytotoxic effects on tissues during microcirculatory disturbances.

ACKNOWLEDGMENTS

The authors thank Professor G. W. Schmid-Schönbein and Professor Y. Ishimura for their suggestions, and Dr. Fujiwake (Hamamatsu Photonics) for technical aid in the operation of the digital imaging photonic microscope. This study was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture of Japan, and by a grant from Keio University School of Medicine.

REVIEW

Involvement of Platelet-Activating Factor (PAF) in Septic Shock and Priming as Indicated by the Effect of Hetrazepinoic PAF Antagonists[1]

Hubert O. Heuer*
Department of Pharmacology, Boehringer Ingelheim KG, W-6507 Ingelheim/Rhein, Germany

Pharmacological data obtained with hetrazepinoic platelet-activating factor (PAF) antagonists, such as apafant (WEB 2086) and bepafant (WEB 2170), indicate a role for PAF in septic shock and in the priming process. The effect of PAF antagonists in different models of shock states favors a role for PAF in endotoxin associated lethality, activation of inflammatory blood cells with release of mediators, cardiovascular failure and increased vascular permeability, and in the development of shock organs and organ failure. The priming process (*e.g.*, by endotoxin or tumor necrosis factor) towards an increased susceptibility towards minute amounts of PAF has to be taken into account when considering the pathophysiological significance of PAF under *in vivo* conditions and in septic shock.
***Lipids 26*, 1369–1373 (1991).**

There is substantial evidence that platelet-activating factor (PAF) is one of the main mediators of shock states, including endotoxin-induced shock. PAF can induce most of the pathophysiological features associated with endotoxin shock, such as pulmonary hypertension and edema, cardiac failure, alteration of the microcirculation resulting in an increase in vascular permeability and tissue damage, activation of immune cells with associated mediator release, and systemic hypotension (for a review, see ref. 1). Figure 1 summarizes the pathophysiological derangements which can be mimicked by exogenously introduced PAF (1). Increased levels of PAF-like activity have been detected in blood from endotoxin-treated animals (2,3) and in septic patients (4–6). Tumor necrosis factor (TNF) can mimic most of the pathophysiologic features of endotoxin (7,8), and TNF has been shown to release PAF from endothelial and other cells (9).

Selective and potent PAF antagonists can be used to demonstrate a causative role of PAF in septicemia and septic shock. Partial effectiveness in animal models of septicemia suggests a contributory role of PAF in the pathophysiology, including interaction with other mediators.

The purpose of this synopsis is to summarize and evaluate the data available so far for hetrazepinoic PAF antagonists, exemplified by apafant (WEB 2086), bepafant (WEB 2170) and other hetrazepines (reviewed in refs. 10 and 11) in animal models of septic shock.

LETHAL EFFECT OF ENDOTOXIN AND/OR TUMOR NECROSIS FACTOR (TNF)

The role of PAF in the lethal effect of endotoxin, as indicated by a protective effect of selective PAF antagonists, including hetrazepines, remains somewhat controversial. Variable results may have been obtained because different animal species were used in different studies, and the routes of endotoxin administration varied. The kinetics, potency and bioavailability of PAF antagonists also differ. The lethal effect of endotoxin from *E. coli* in rats is inhibited dose-dependently by oral and intravenous treatment with WEB 2086 (12). Also, post-treatment with WEB 2086, starting at 2 hr after administration of endotoxin from *Salmonella enteritidis*, significantly improves survival as compared to vehicle treatment (13).

Animal susceptibility to endotoxin may be different even within the same species depending upon the age of the animals, and the dose and route of endotoxin administration. Although Balb/C mice seem to be sensitive to the lethal effect of endotoxin (14), younger Balb/C-mice do not have a high mortality rate when 10 mg/kg *i.v.* endotoxin alone is given (15). In addition, the lethal effect of endotoxin when given alone takes longer to manifest itself in younger mice (15). Oral WEB 2170 protected Balb/C mice from the lethal effect of the endotoxin even when a high dose (10 mg/kg *i.v.*) is used (15).

Experimental protocols which would produce clear-cut and reproducible high mortality rates 8–24 hr after administration of endotoxin, possibly at low doses, are desirable. Three different approaches have been chosen in previous studies (15,16). Human recombinant TNF (0.04 mg/kg *i.v.*) synergizes with endotoxin to increase its lethal effect (15,16). Rothstein and Schreiber (17) found that when both endotoxin and TNF are used, cytotoxicity, hemorrhagic necrosis in the skin, and lethal shock increase. Oral WEB 2170 inhibited the lethal effect of a combination of endotoxin and TNF in a dose-dependent manner, which suggests that PAF plays a role in this model (Fig. 2; refs 15,16).

Propranolol (0.1–0.5 mg/kg *i.v.*) administered 8 hr after endotoxin increases the toxic (lethal) potency of the endotoxin (15,16). The failure of co-administered propranolol to potentiate the lethal effect of endotoxin suggests that during the time interval between the administration of endotoxin and of propranolol, endotoxin may prime the generation of shock mediators such as thromboxanes, cytokines, leukotrienes, peptides, and PAF. Propranolol synergizes with a number of mediators (18). The ability of the selective PAF antagonist WEB 2170 to antagonize the propranolol-precipitated lethal effect of endotoxin (15,16) indicates that PAF may play a key role in the release of mediators and their interaction *in vivo*. Furthermore, the ability of propranolol to enhance the lethal and

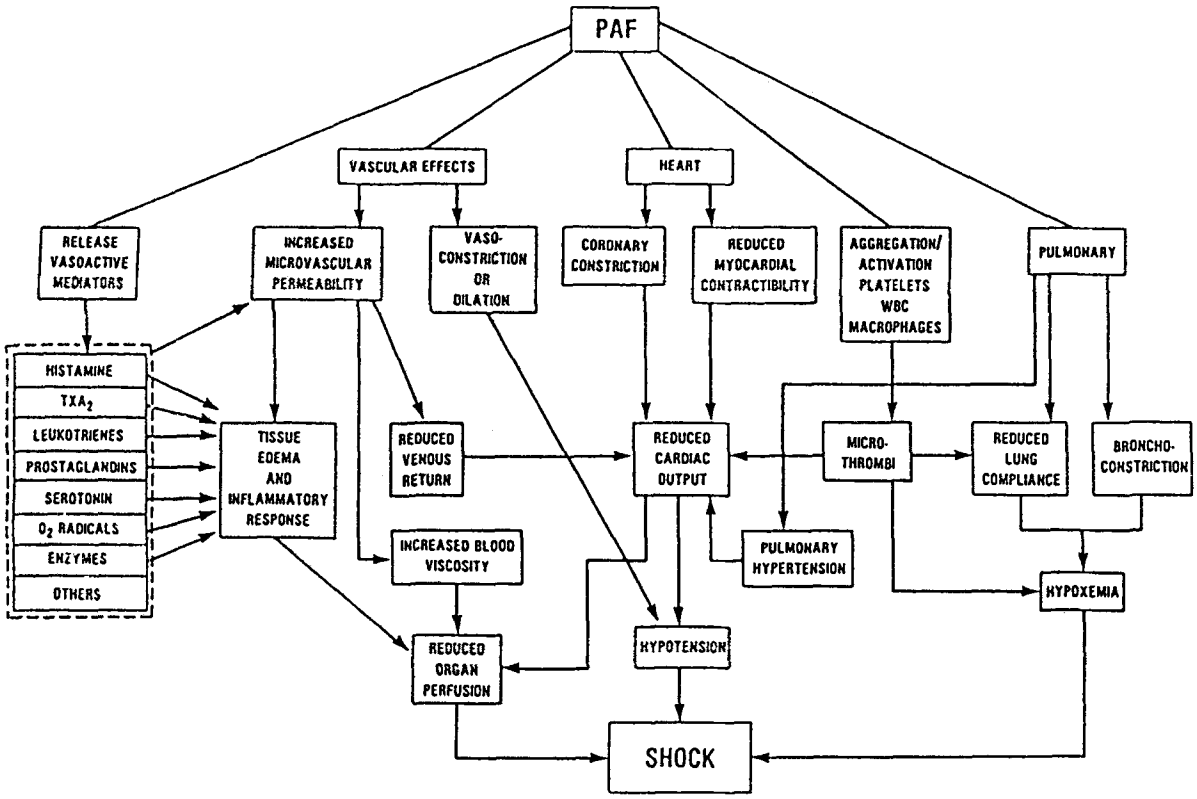

FIG. 1. Sequence of events and pathophysiology of PAF induced shock (adapted from ref. 1).

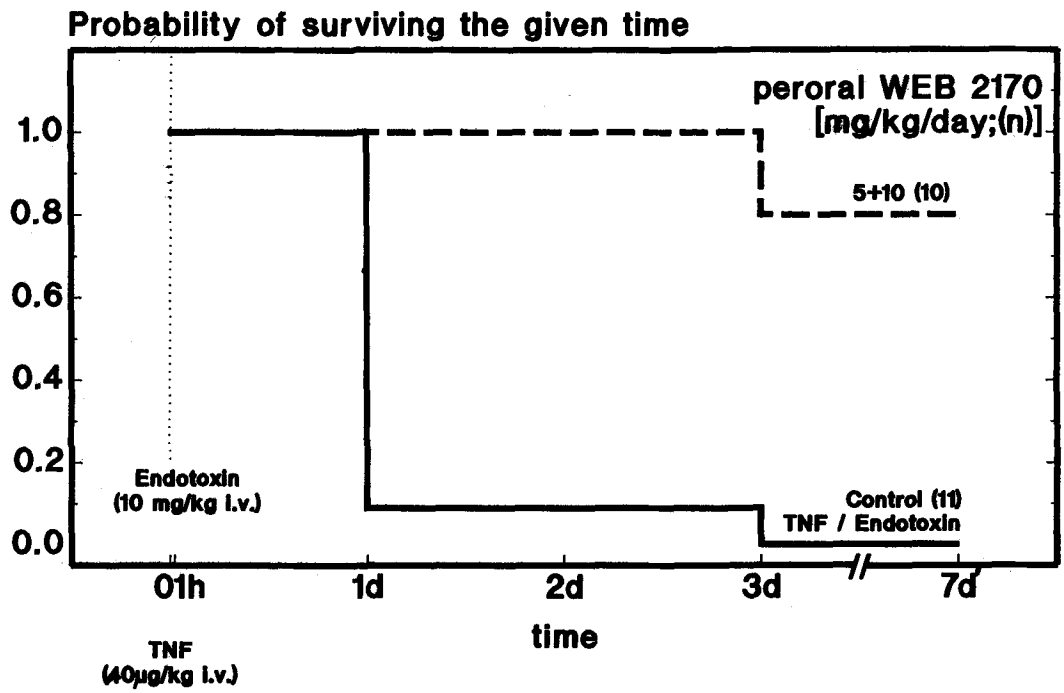

FIG. 2. Inhibition by oral WEB 2170 of the lethal effect of a combination of endotoxin (*E. coli* 0111:B_4, 10 mg/kg *i.v.*) and TNF (0.04 mg/kg *i.v.*). WEB 2170 was given in the morning and 8 hr later; 1 hr time interval between endotoxin and TNF; observation period, seven days; n is indicated in parentheses.

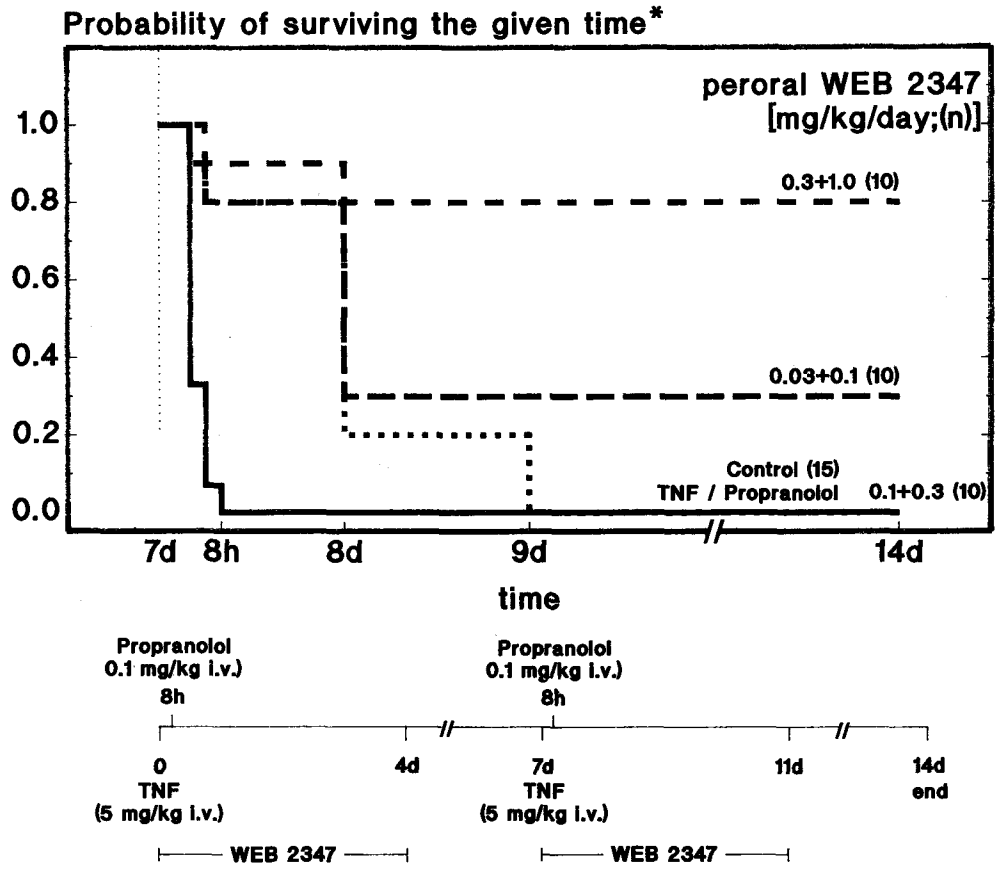

FIG. 3. Inhibition by oral WEB 2347 of the lethal effect of repeated human recombinant TNF/propranolol in Balb/C-mice; n indicated in parentheses.

toxic effects of exogenously introduced PAF (10,19) can be extended to endogenously released PAF *in vivo*; for example, the PAF antagonist, WEB 2170, blocks propranolol potentiated anaphylactic death in mice (16).

Although a single treatment with TNF and subsequent propranolol administration fails to have lethal effect on Balb/C-mice, it primes the mice for enhanced sensitivity to a second challenge with TNF (combined with subsequent administration of propranolol) one week later (15). This resembles a Sanarelli-Shwartzman-like phenomenon, which is induced here by TNF. The selective and very potent PAF antagonist [WEB 2347 (11)] protects Balb/C-mice from the lethal effect of TNF in the Sanarelli-Shwartzman-like phenomenon, which suggests a key role of PAF in this process (Fig. 3; ref. 15).

CARDIOVASCULAR EFFECTS OF ENDOTOXIN

The hypotensive action of endotoxin (from *E. Coli* 0111:B_4) in the rat is prevented by oral or intravenous treatment with WEB 2086, WEB 2170, or STY 2108 (12,20,21). In addition, therapeutic intervention at the nadir of endotoxin-induced hypotension (6 min after endotoxin) reverses endotoxin-induced hypotension in a dose-dependent fashion (12,21). In contrast to other pharmacological agents, PAF antagonists only increase blood pressure when the blood pressure is lowered by PAF or endotoxin. These results are in agreement with previously reported results for other PAF antagonists (2).

Tables 1 summarizes the ED_{50} values for prevention of endotoxin-induced hypotension by WEB 2086, WEB 2170, or STY 2108 (*p.o.*, *i.v.*) administered before endotoxin in comparison with those of the same drugs given after administration of endotoxin (12,21). The doses of PAF antagonists required to inhibit endotoxin-induced hypotension correlated with the doses needed to antagonize PAF induced hypotension in the rat (Table 2), which supports a specific involvement of PAF in this process.

In contrast, in endotoxin-induced shock, when WEB 2086 at the tested dose is given to pigs, the systemic hypotension occurring after infusion of endotoxin is not lessened (22). However, the pulmonary hypertension that occurred in the pig after infusion of endotoxin is significantly inhibited by treatment with WEB 2086 (22).

Perfusion of the hindlimb and systemic blood pressure in the rat are reduced by intravenous injection of 30 mg/kg *i.v.* endotoxin from *E. coli* 0111.B_4. Perfusion in the presence of WEB 2086 reverses the decreases in hindlimb perfusion and systemic blood pressure (23).

Endotoxin-induced microvascular leakage with edema formation is considered one of the earliest and most prominent symptoms in the development of adult respiratory distress syndrome (ARDS). WEB 2086 infused at 20 mg/kg/hr inhibits the endotoxin-induced lymph flow and

TABLE 1

ED_{50} Values of Hetrazepinoic PAF Antagonists Given Orally or Intravenously to Antagonize Hypotension Induced by Endotoxin from *E. coli*.

	Antagonism of endotoxin-induced hypotension[a]		
	Prophylactic[b] ED_{50} (mg/kg)		Curative[c]

STY 2108	0.011 (0.008-0.014)	0.52 (0.31-0.81)

[a]Inhibition of PAF induced [30 ng/(kg × min)] hypotension in the rat by hetrazepines given orally or intravenously; ED_{50}, effective dose of hetrazepine that antagonizes PAF induced hypotension by 50%.

[b]95% Confidence limits.

lymph protein clearance in conscious sheep (24). By contrast, WEB 2086 has little effect on early pulmonary hypertension and alterations in lung mechanics (24). In a recent study, Chang *et al.* (13) found that WEB 2086 inhibits lung vascular leakage not only when given before endotoxin but also when given 30 min after endotoxin. In the same study, post-treatment with WEB 2086, starting at 90 min after endotoxin, markedly attenuated the vascular lung leakage measured 6 hr after endotoxin (13).

In hypoxic pulmonary vasoconstriction in the rat, perfusion with WEB 2086 attenuated the pulmonary vasoconstrictor response in isolated and ventilated lung in a concentration dependent manner (25). The inhibition of the hypoxic pulmonary response is complete at the highest concentration (25). However, the involvement of PAF has not been fully clarified, as the result could not be reproduced in the pig (26).

In a traumatic shock model using anesthetized rats, WEB 2086 maintained a higher mean arterial blood pressure in traumatized rats than in rats receiving only physiologic saline (27). In addition, WEB 2086 increased the overall survival time of traumatized rats (27). Other indicators of traumatic shock, such as accumulation of lysosomal hydrolase, cathepsin D, and free amino-nitrogen compounds and increase of myocardial depressant factor were also inhibited by WEB 2086 (27).

The hetrazepine related benzodiazepine receptor antagonist and weak PAF antagonist, Ro 15-1788, had beneficial effects in a rat model of hemorrhagic shock (28). The specific PAF antagonist WEB 2086 attenuated hemorrhagic shock (survival and blood pressure drop) in another model of the rat (R. Reichl, personal communication).

ACTIVATION OF BLOOD CELLS AND ORGAN FAILURE

Activation of blood cells, including platelets and leukocytes, with mediator release may particularly contribute to the development of lung injury (ARDS). When conscious guinea pigs are exposed to an endotoxin aerosol, pretreatment with the hetrazepine brotizolam inhibits the endotoxin-induced pulmonary platelet recruitment dose-dependently (29). Also in the pig, WEB 2086 retards the sharp decline in peripheral white blood cell count occurring after the start of an infusion of endotoxin (22). In addition, the endotoxin associated deterioration in gas exchange and inspiratory pressure are also partially prevented by WEB 2086 (22).

Endotoxin-induced gastrointestinal ulceration is at least partially mediated *via* PAF, because it is blocked by PAF antagonists and PAF is released from the jejunum of endotoxin treated rats (30).

PRIMING OF PAF EFFECTS BY ENDOTOXIN/TNF

When PAF, endotoxin or TNF are given alone, high doses are necessary to induce any changes of transit velocity-index (TV-index) or mortality because mice are relatively resistant to PAF (31), TNF (7) and endotoxin (14).

Treatment with endotoxin (*S. typhosa*) primes mice for enhanced sensitivity towards PAF, resulting not only in decreased gastrointestinal transit velocity, but also in increased mortality (32). The same priming has been shown between tumor necrosis factor (TNF), which mimics pathophysiologic features of endotoxin, and PAF (33-35). The priming effect by endotoxin or TNF towards PAF occurs at doses at which PAF, endotoxin or TNF given alone do not significantly change lethality or TV-index (34,35). Furthermore, the priming effect of endotoxin/TNF towards PAF with respect to decreased gastrointestinal transit velocity and increased lethality is maximal when the time interval between administration of endotoxin/TNF and PAF is about 1-2 hr. WEB 2086 at 0.01-1 mg/kg *i.p.* prevents (in a dose-dependent manner) the enhanced sensitivity to PAF induced by endotoxin/TNF (34,35).

There may be several explanations for the need of a time interval between treatment with TNF or endotoxin and subsequent PAF challenge for maximum decreases in TV-index and survival rate. TNF or endotoxin may stimulate the synthesis of different mediators, such as PAF (9), leukotrienes, prostaglandins (36) and thromboxanes, dur-

ing the time period between administrations of TNF or endotoxin and PAF. These preformed mediators may be released upon PAF challenge and synergize with PAF to decrease TV-index and increase mortality. Thus both endotoxin and TNF prime effects of PAF *in vivo*. This is in accordance with the ability of TNF to prime PAF induced superoxide generation by human neutrophils *in vitro* (37). Interestingly, a similar time interval for the maximum priming response has been observed *in vitro* (37). TNF (38), like endotoxin (30), may induce intestinal damage which increases the susceptibility to PAF. Furthermore, TNF may be a mediatory of endotoxin shock (7) because the same synergism to PAF is also observed after treatment with endotoxin (32); the synergism is maximal when the time delay between endotoxin and PAF administration is about 1–2 hr, a "window phenomenon of dramatically enhanced sensitivity to PAF following a lag-time after pretreatment with endotoxin (32).

These results are in agreement with those reported by Salzer and McCall (39), namely that priming with endotoxin for 60–120 min leads to explosive enhancement of tissue injury caused by a triggering dose of PAF.

CONCLUSIONS

In summary, based on different models of shock states, the action of specific PAF antagonists of the hetrazepine series suggest a role for PAF in endotoxin-induced lethality, activation of blood cells with release of enzymes and mediators, cardiovascular derangements, edema formation, vascular permeability changes in the lung, development of shock organs, as well as in organ failure.

Since the pathophysiology of sepsis and septic shock is very complex, other mediators and mechanisms apart from PAF may have to be taken into account. In addition, contradictory results have been obtained in similar standardized animal models; the same PAF antagonists, given as a single therapeutic agent, have failed to show beneficial effects in some models, while in other models they have shown protective effects. Particular pathophysiological significance may have the ability of endotoxin and/or TNF to prime effects of PAF *in vivo*. This priming occurs at concentrations of the respective mediators at which they will not induce any pathophysiological change when given alone.

In conclusion, PAF may be a key mediator in endotoxin- and TNF-induced shock and in the Sanarelli-Shwartzman-like phenomenon. The effect of selective PAF antagonists in human sepsis and in TNF associated shock-like syndromes still needs to be examined further. When used in addition to the standard therapeutic treatments, PAF antagonists may provide a new therapeutic approach to the still severe and potentially fatal diseases of sepsis and septic shock.

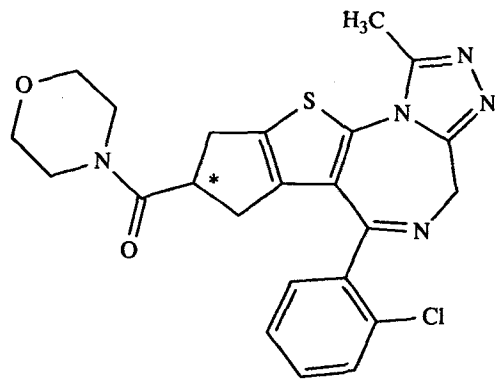
[Received August 31, 1989, and in revised form October 12, 1991; Revision accepted October 16, 1991]



Effect of the Hetrazepinoic Platelet-Activating Factor Antagonist Bepafant (WEB 2170) in Models of Active and Passive Anaphylaxis in Mice and Guinea Pigs[1]

H.O. Heuer
Department of Pharmacology, Boehringer Ingelheim KG, W-6507 Ingelheim/Rhein, Germany

The selective hetrazepinoic platelet-activating factor (PAF) antagonist WEB 2170 (Bepafant) was used to study the pathophysiological role of PAF in several models of anaphylaxis in mice and guinea pigs. In actively sensitized mice, the PAF antagonist WEB 2170 (1.0–10 mg/kg *p.o.*) protected mice from anaphylactic death in a dose-dependent manner when the anaphylactic response was potentiated by the beta-receptor antagonist propranolol. When active anaphylaxis in guinea pigs was induced intravenously by 100 mg/kg ovalbumin (OA) in the presence of small doses of the antihistamine mepyramine, additional treatment with oral or intravenous WEB 2170 protected the guinea pigs from anaphylactic death. Also, the remaining anaphylactic bronchoconstriction and blood pressure changes (including anaphylactic hypotension) were attenuated. When guinea pigs were passively sensitized with a heterologous antibody *via* the tracheal route and then challenged by ovalbumin (100 mg/kg *i.v.*) 24 hr after sensitization in the presence of 0.003 mg/kg *i.v.* mepyramine, additional treatment with tracheal WEB 2170 at 0.1–1 mg/kg protected the guinea pigs dose-dependently not only from anaphylactic death but also from a further decrease of respiratory flow and changes of blood pressure. Increased levels of PAF-like activity (20–50 ng PAF/whole lung) were detected in lungs removed from antigen-challenged animals. The results suggest a causative role for PAF in active and passive anaphylaxis. *Lipids 26,* 1374–1380 (1991).

Bronchoconstriction during anaphylactic shock in the guinea pig continues to be used as a model in the search of antiasthmatic drugs, although guinea pig anaphylaxis is mediated to a greater extent *via* histamine, particularly in its early phase (1), than it is in human asthma.

The results that have been obtained with platelet-activating factor (PAF) antagonists in models of *in vivo* anaphylaxis vary widely. Most investigators observed at least some protective effect by PAF antagonists during passive anaphylaxis in the guinea pig (2–6). On the other hand, in active anaphylaxis inhibition by PAF antagonists has been observed only in some instances (1,6–8). These results have to be considered in light of other findings where even the same PAF antagonists have failed to antagonize active anaphylaxis under differing experimental conditions, particularly without antihistamine supplementation (5,6,9).

WEB 2170

FIG. 1. Chemical structure of Bepafant (WEB 2170).

The purpose of the present study was to reinvestigate the role of PAF in several models of active and passive anaphylaxis and to define the conditions under which a protective effect by a PAF antagonist can be demonstrated. Since booster sensitization has been suggested to make active anaphylaxis refractory to treatment with PAF antagonists, the action of Bepafant in two series of boosted guinea pig anaphylaxis experiments was investigated. The selective hetrazepinoic PAF antagonist WEB 2170 (INN: Bepafant; Fig. 1) was used as a tool to investigate the role of PAF in *in vivo* anaphylaxis. Bepafant (WEB 2170) is one of the most potent antagonists of PAF *in vivo* (10).

MATERIALS AND METHODS

Five different series of experiments on active and passive anaphylaxis in mice and guinea pigs were carried out.

Active sensitization of mice. Fasting male mice (Chbi: NMRI, SPF; weight range 20–25 g at first sensitization) were given, on days 1, 3 and 5, injections *i.p.* of an ovalbumin (OA)/$Al(OH)_3$ suspension containing 40 μg/kg OA. OA (5 times re-crystallized, maximum purity; Serva, Heidelberg, Germany) and the aluminum hydroxide [2 g $Al(OH)_3$/10 mL] were suspended in physiological saline. The OA/$Al(OH)_3$ suspension was administered in a volume of 0.1 mL per animal *i.p.* per day [*i.e.,* 40 μg/kg OA and 100 mg $Al(OH)_3$ per mouse]. Because the mice failed to show any significant anaphylactic reaction upon antigen challenge 4 weeks after the first sensitization, the mice were sensitized again on days 30, 32 and 35 according to a protocol similar to that described above. Antigen

Abbreviations: AUC, area under the curve; MAP, mean arterial blood pressure; OA, ovalbumin; PAF, platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; TLC, thin-layer chromatography.

challenge with 100 mg/kg OA *i.v.* was carried out 115 days (mice then weighed 40–50 g) after the first day of sensitization in the presence of 0.1 mg/kg *i.v.* of propranolol.

Active sensitization of guinea pigs. Three groups of guinea pigs (Pirbright white Kisslegg, Ivanovas strain, weight range 250–350 g at first sensitization) were actively sensitized following three different protocols.

In the first group of anaphylaxis, female guinea pigs were sensitized using a modification of the method described by Andersson (11). Ovalbumin (OA) (40 μg/kg) and 100 mg $Al(OH)_3$ per guinea pig suspended in physiological saline (0.5 mL) were injected into each guinea pig *i.p.* Four weeks after this first sensitization, a booster sensitization followed using the same antigen-mixture as before. The animals were pretreated with cyclophosphamide (30 mg/kg *i.p.*) 2 days prior to this booster sensitization. Antigen challenge (100 mg/kg OA *i.v.*) was carried out approximately 30 weeks after the second sensitization in the presence of the antihistamine mepyramine (50 μg/kg *i.v.*). The weight of the guinea pigs at that time ranged from 750–970 g.

In the second group of active anaphylaxis, male guinea pigs of the same strain and weight as above were sensitized again using a modification of the method described for the first group. In the second group the booster sensitization after five weeks was not preceded by cyclophosphamide treatment. Antigen challenge with 100 mg/kg *i.v.* followed about 15 weeks after the first (10 weeks after the second) sensitization in the presence of a small dose of mepyramine. In the third group of active anaphylaxis a dose of 100 mg OA/guinea pig was injected *i.p.* and 100 mg OA/guinea pig *s.c.* (one site). Antigen challenge with 100 mg/kg *i.v.* was carried out approximately five weeks after sensitization in the presence of 15 μg/kg mepyramine *i.v.*

Passive sensitization of guinea pigs. Male albino guinea pigs (Pirbright white Kisslegg, Ivanovas strain, weight range 290–420 g) were passively sensitized by intratracheal instillation of 0.4 mL/kg of an heterologous anti-ovalbumin antibody (from rabbit) about 24 hr before antigen challenge (100 mg/kg OA *i.v.*) in the presence of 0.003 mg/kg of mepyramine *i.v.*

Measurement of respiratory flow and mean arterial blood pressure (MAP). The fasting guinea pigs were anaesthetized with urethane (1.5 g/kg *i.p.*) before insertion of an intra-arterial (carotid artery) and an intravenous (jugular vein) catheter and a tracheal cannula. Spontaneously breathing guinea pigs were used. The respiratory flow was monitored using a Fleisch pneumotachograph [Hugo Sachs Elektronik (HSE), Freiburg/Breisgau, Germany] attached to the intratracheal cannula and connected *via* a differential pressure transducer (MKS recorder) directly to a Servogor recorder, model 220 or SE 130 (HSE).

In the case of passive anaphylaxis, the spontaneously breathing guinea pigs were positioned in a body plethysmograph (HSE) and connected *via* a tracheal cannula to the outside, allowing the guinea pigs to breath air from outside the sealed plethysmography box. Respiratory flow was indirectly monitored by following the changes in the thorax volume, which, in turn, resulted in changes in the air flow measured with the pneumotachograph (HSE) mounted to the wall of the plethysmograph box.

The blood pressure (carotid artery) was recorded continuously with a pressure transducer (Statham P 23Db, HSE) connected to an amplifier (Burster) and a Servogor recorder 220 or SE 130 (HSE).

Experimental protocols. Animals were pretreated either intravenously (first group of active anaphylaxis) or *via* the intratracheal route (passive anaphylaxis) 10 min, or orally 60 min, before antigen challenge (ovalbumin at 100 mg/kg *i.v.*) with the PAF antagonist WEB 2170, *i.e.* (8-(R,S)-6-(2-chlorophenyl)-8,9-dihydro-1-methyl-8-[(4-morpholinyl]-carbonyl)-4H,7H-cyclopenta(4,5)thieno(3,2-f)(1,2,4)triazolo-(4,3-a)(1,4)diazepine. When intravenous or tracheal pretreatment was used, WEB 2170 was dissolved in 0.1 N HCl and further diluted with distilled water. For oral treatment WEB 2170 was dissolved in 0.5% Methocel (Tylose®) and further diluted with the same vehicle.

In the case of anaphylaxis in the guinea pig, the antihistamine mepyramine (Bayer, Leverkusen, Germany) was administered 5 min before antigen challenge by the intravenous route to protect the guinea pigs from immediate death upon antigen challenge. The indicated dose of mepyramine was individually titrated for each group of guinea pigs in such a way that immediate death was avoided, but a severe anaphylactic reaction was attained. Respiratory flow and mean arterial blood pressure were monitored after antigen challenge over a time period of 30 min.

Evaluation and statistical analysis. The results are expressed as the mean ± SEM. In mice, the experiments were evaluated by probit analysis, and the dose of WEB 2170 which protected 50% of the mice from anaphylactic death was calculated.

In the active anaphylaxis group of guinea pigs, the area under the curve (AUC) of peak respiratory flow during the 30-min evaluation period was referenced to AUC before antigen challenge.

In the group of passive anaphylaxis of guinea pigs, a representative baseline value was determined before each OA challenge. Respiratory flow and mean arterial blood pressure were evaluated at time points 2, 5, 10, 15, 20, 25 and 30 min after antigen challenge. A decrease in respiratory rate below 15/min marked the onset of gasping, and this respiratory flow was defined as zero.

An analysis of variance for respiratory flow and MAP was calculated. A Dunnett-Test comparing the mean values of the treated animals with the controls at any time point of measurement was applied.

Determination of PAF-like activity. For determination of PAF-like activity, lungs from control guinea pigs were removed immediately after death from active anaphylaxis, washed with saline, and homogenized in 0.25 M hydrochloric acid in methanol. After extraction according to Bligh and Dyer (12), with intermittent centrifugation to precipitate protein, this extract was further purified by thin-layer chromatography (TLC). TLC plates (Si 60 on alufoil, Merck, Darmstadt, Germany) were developed in chloroform/methanol/water (65:35:6, v/v/v). The band comigrating with synthetic C_{16}PAF was scraped off, extracted according to Bligh and Dyer (12), and further processed for measuring PAF-like activity using the aggregation assay described by Heuer *et al.* (13).

RESULTS

Active anaphylaxis in mice. In actively sensitized mice, the PAF antagonist WEB 2170 (1.0–10 mg/kg *p.o.*)

protected mice from anaphylactic death in a dose-dependent manner when the anaphylactic response was potentiated by the beta-adrenoreceptor antagonist propranolol. PD_{50} (dose of WEB 2170 which protects 50% of the mice from anaphylactic death) was determined as 3.3 (1.7–6.8) mg/kg *p.o.*

Active anaphylaxis in guinea pig. Preliminary tests in all three groups of active anaphylaxis failed to show a protective effect by WEB 2170 in the absence of an antihistamine. By contrast, control animals which had been treated with mepyramine (dose individually adjusted for each group of guinea pigs) were protected from immediate death. However, the guinea pigs still exhibited a very severe anaphylactic reaction, as shown by a decrease in respiratory flow (Figs. 2 and 3) and by an initial increase of MAP followed by a subsequent decline. The guinea pigs still died during the 30-min evaluation period.

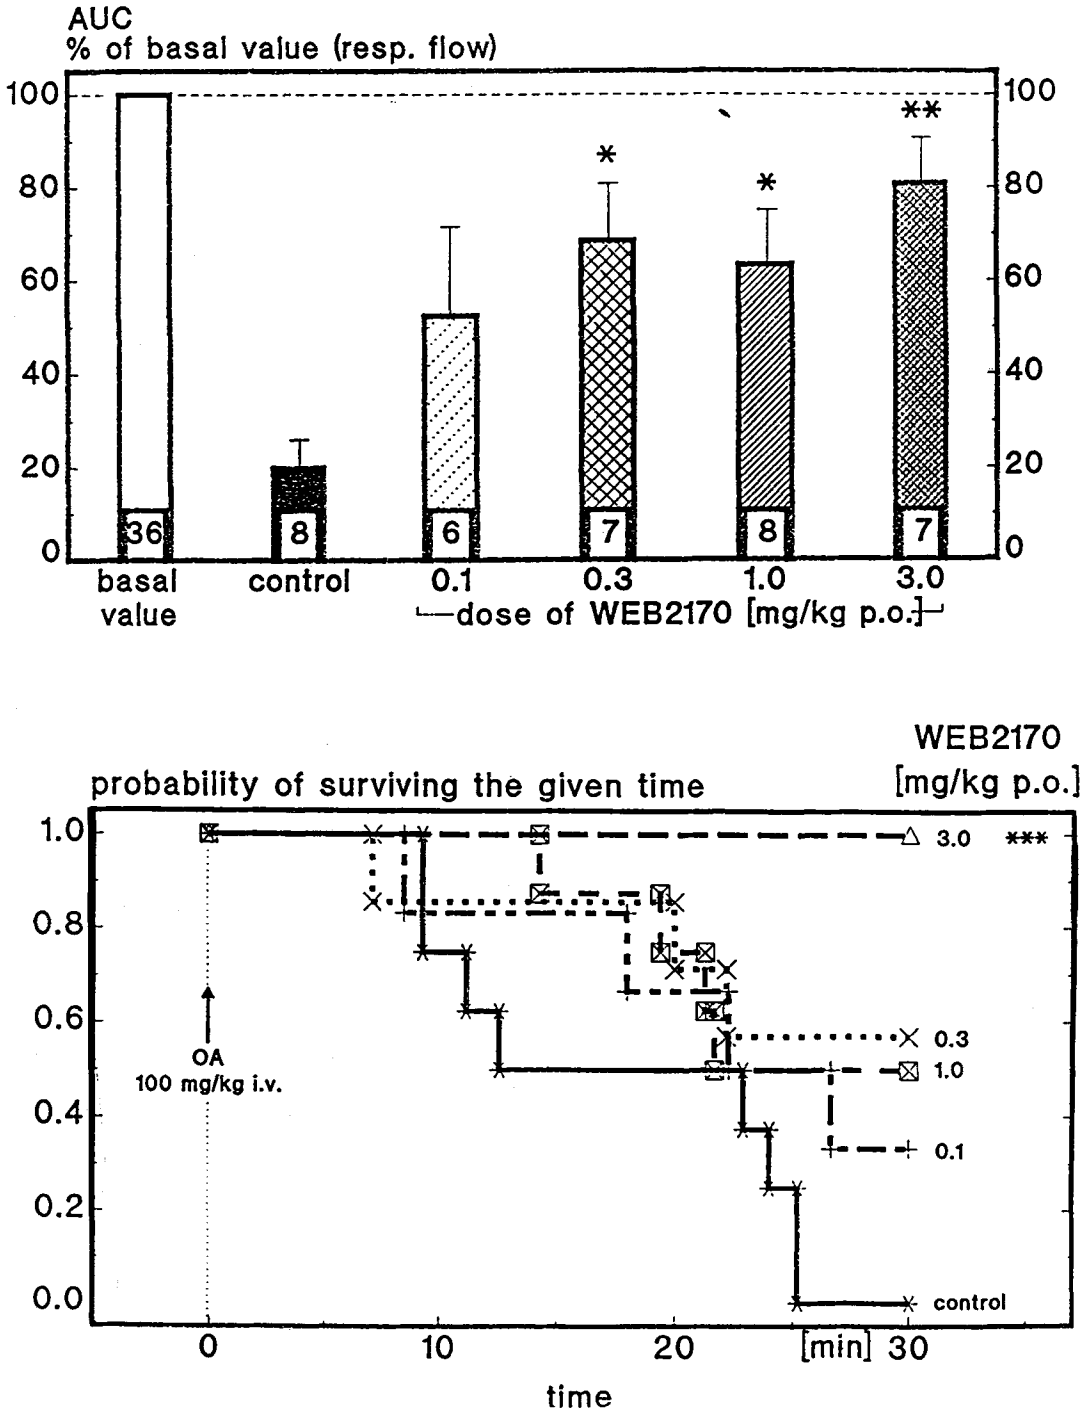

FIG. 2. Effect of oral WEB 2170 on anaphylaxis-associated decrease of respiratory flow (top, AUC, area under curve) and on mortality (bottom) during a 30-min observation period. Actively sensitized guinea pigs (second group) were challenged with 100 mg/kg *i.v.* ovalbumin in the presence of 10 μg/kg *i.v.* mepyramine; *p < 0.05, **p < 0.01, ***p < 0.001; n is indicated at the bottom of the bars; mean ± SEM.

When the guinea pigs were treated with WEB 2170 in addition to a small dose of mepyramine, the animals were protected from anaphylactic death (Figs. 2 and 3). The antigen-induced changes in respiratory flow (Figs. 2 and 3) and blood pressure were also attenuated significantly. In the first group, only one dose of WEB 2170 (5 mg/kg *i.v.*) was tested. In the latter two groups, oral Bepafant (WEB 2170) dose-dependently inhibited the remaining anaphylactic reaction in terms of lethality, decrease of respiratory flow, and blood pressure change (Figs. 2 and 3). With respect to the last group of active anaphylaxis, even 0.04 mg/kg *p.o.* WEB 2170 provided a very significant protection against antigen-induced bronchoconstriction (Fig. 3) and circulatory changes with protection being essentially complete at the highest dose (1 mg/kg *p.o.*).

Passive anaphylaxis in the guinea pig. Guinea pigs

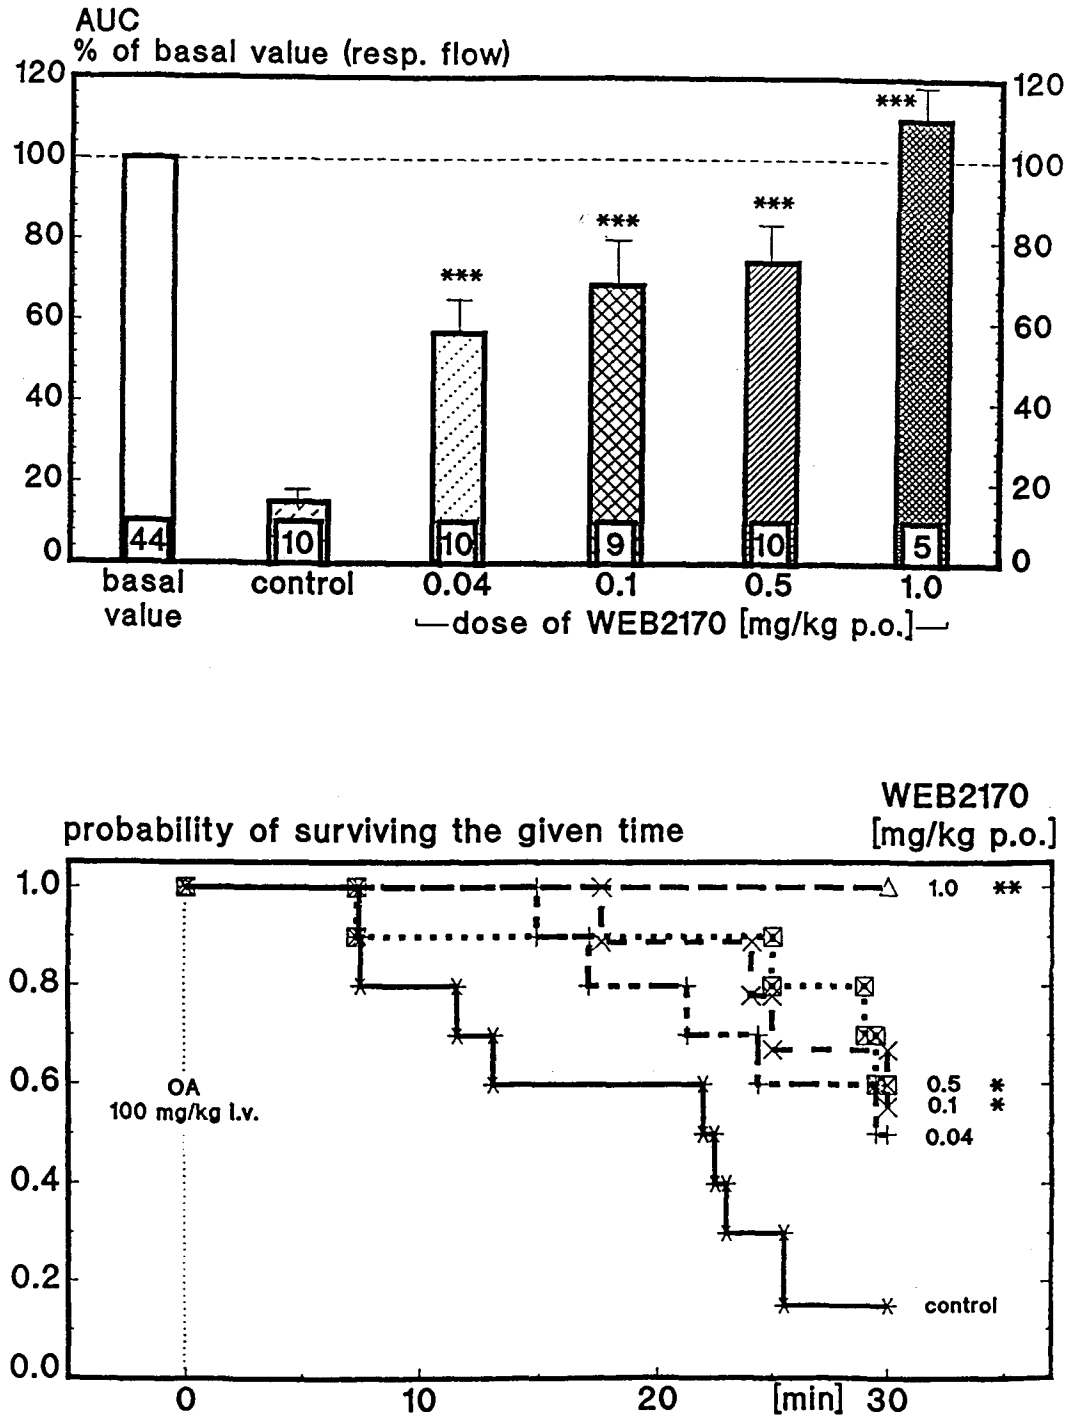

FIG. 3. Effect of oral WEB 2170 on anaphylaxis-associated decrease of respiratory flow (top) and mortality (bottom) during a 30-min observation period. Actively sensitized guinea pigs (third group) were challenged with 100 mg/kg *i.v.* ovalbumin in the presence of 15 μg/kg *i.v.* mepyramine, *$p < 0.05$, **$p < 0.01$, ***$p < 0.001$ indicates significant difference from control; n is indicated at the bottom of the bars; mean ± SEM.

passively sensitized *via* the tracheal route were dose-dependently protected by tracheal WEB 2170 (0.1–1 mg/kg) not only from anaphylactic death, but also from residual decrease in respiratory flow and changes in MAP (Fig. 4).

PAF-like activity in lungs from guinea pigs in anaphylaxis. Increased levels of PAF-like activity (20–50 ng PAF/whole lung) were detected in lungs removed from antigen-challenged animals (third group of active anaphylaxis) (Fig. 5). This PAF-like activity co-migrated with synthetic PAF and was completely suppressed by WEB 2086. Lungs from non-sensitized, non-challenged guinea pigs contained about 1–2 ng PAF/whole lung.

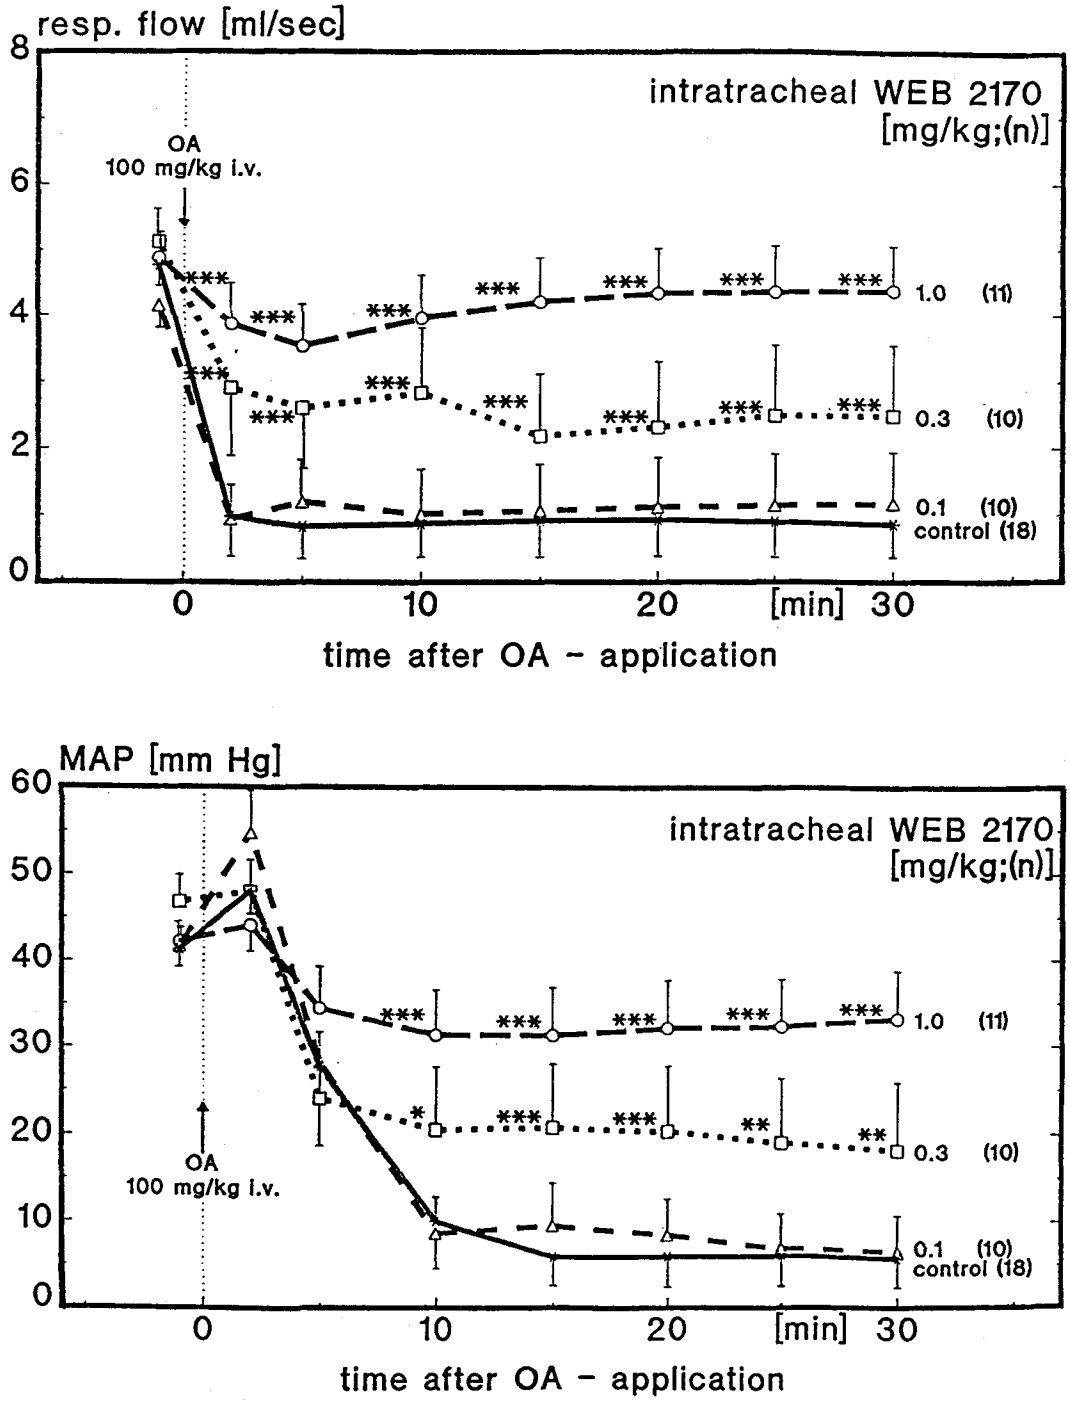

FIG. 4. Effect of tracheal WEB 2170 on anaphylaxis-associated decrease of respiratory flow (top) and blood pressure changes (bottom) induced by 100 mg/kg *i.v.* ovalbumin in the presence of 3 μg/kg *i.v.* mepyramine. Guinea pigs were passively sensitized by the tracheal route; n is given in parentheses; mean ± SEM; *p < 0.05, **p < 0.01, ***p < 0.001 indicates significant difference from control.

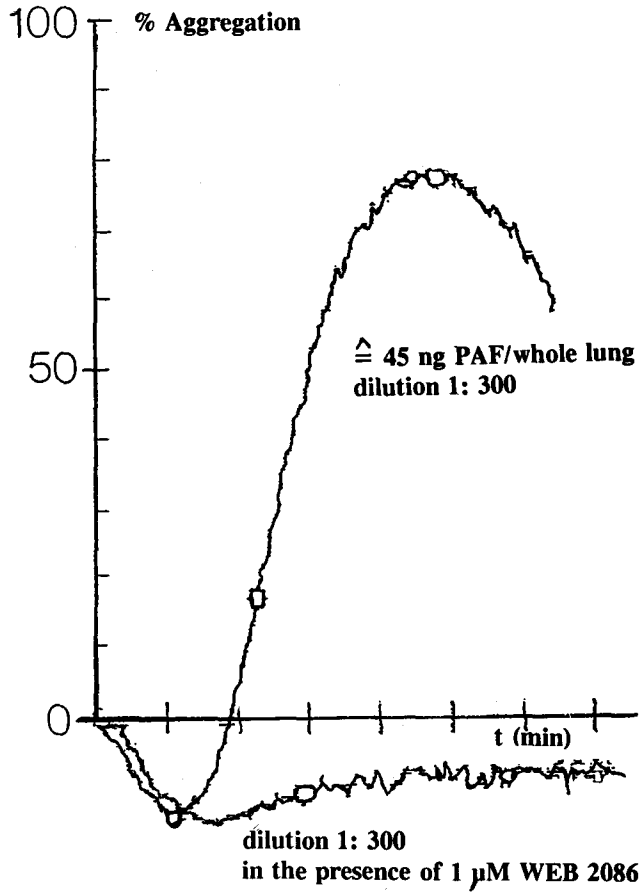

FIG. 5. PAF-like activity in the lung from active anaphylaxis in the guinea pig (third group). PAF-like activity co-migrated with synthetic PAF and could be completely suppressed by the selective PAF antagonist WEB 2086 (superimposed lower tracing). Control lungs from non-sensitized, non-challenged animals contained 1-2 ng PAF/lung.

DISCUSSION

The ability of WEB 2170 to protect actively sensitized mice from propranolol-potentiated anaphylactic death is the first report that a PAF antagonist can overcome an anaphylactic reaction when potentiated with propranolol. It is in contrast to results reported for guinea pig anaphylaxis (2). However, the finding is in agreement with the ability of the beta-antagonist propranolol to potentiate PAF effects in mice and guinea pigs (14,15).

The failure of WEB 2170 (given alone) to protect guinea pigs from anaphylaxis is in agreement with findings on actively sensitized guinea pigs (1,5,6) and actively sensitized rabbits (9) in which other PAF antagonists given alone neither attenuated anaphylactic bronchoconstriction nor circulatory anaphylaxis nor changes in blood cell count.

The characteristic of the protocols followed in the present study is the high antigen-load used for challenge. Higher doses of antigen during guinea pig anaphylaxis have been shown to reduce the relative contribution of histamine as a predominating mediator (16), and may favor a more prominent role of other mediators (such as PAF and leukotrienes) beside histamine, during guinea pig anaphylaxis.

Thus the presence of an antihistamine negates the early histamine-predominated phase of anaphylaxis, thereby revealing the subsequent PAF-predominated phase (see ref. 1). Discrepancies with other literature data (5,9) where PAF antagonists did not show a protective effect in active anaphylaxis may be due to the specific conditions used, such as a small dose of antihistamine in combination with a high challenging dose of ovalbumin, as we used here. Another reason for the failure of PAF antagonists to block active anaphylaxis has been suggested recently, namely the modification of the anti-anaphylactic action of PAF antagonists by a booster sensitization (17,18). By contrast, this report shows that even in boosted guinea pigs (first two series of active anaphylaxis) the hetrazepine Bepafant attenuated the anaphylactic reaction. This is in accordance with results obtained with WEB 2347 (19) which showed that in as often as five-times boosted guinea pigs anaphylaxis was inhibited dose-dependently (19). Thus, the booster would shift the already PAF-dependent anaphylaxis to an even more pronounced PAF-dependent process as indicated by the higher dose of PAF antagonists needed in boosted guinea pigs as compared to simply sensitized guinea pigs (third series of active anaphylaxis). Thus, the booster could modify the lung response to mediators, including PAF, and generate increased reactivity not only by activation of the lipoxygenase pathway but also *via* PAF.

The important role of PAF in passive anaphylaxis was confirmed in this study by use of tracheal Bepafant (WEB 2170). In addition, this is the first report describing guinea pigs to be passively sensitized by the tracheal route in an attempt to restrict the anaphylactic reaction to the lung. However, upon intravenous challenge with antigen, systemic anaphylactic reaction still occurred as documented by blood pressure changes. Tracheal Bepafant (WEB 2170) also antagonized the blood pressure changes, suggesting good systemic uptake of Bepafant from the lung and a role for PAF in passive anaphylaxis after intrapulmonary sensitization.

The present results suggest a causative role of PAF in active and passive anaphylaxis, because PAF cannot only mimic anaphylaxis but anaphylaxis also can be inhibited by the selective PAF antagonist Bepafant (WEB 2170). Furthermore, increased PAF-like activity can be detected in the lungs from antigen-challenged animals.

Platelet-Activating Factor Type Activity in Plasma from Patients with Septicemia and Other Diseases[1]

Hubert O. Heuer[a,*], Harald Darius[b], Helmut F. Lohmann[c], Juergen Meyer[b], Manuela Schierenberg[b] and Norbert Treese[b]

[a]Department of Pharmacology, Boehringer Ingelheim KG, 6507 Ingelheim, [b]University Clinic of Johannes Gutenberg University Mainz, 6500 Mainz, [c]Human Pharmacology Center, Boehringer Ingelheim KG, 6507 Ingelheim, Germany

The purpose of the present study was to determine whether increased levels of platelet-activating factor (PAF) type activity can be detected in plasma from patients with septicemia and other diseases. A level of PAF below 0.5 ng/mL of plasma was considered normal. We found that plasma from a patient with adverse anaphylactoidic reaction to intravenous analgetics contained 2.1 ng PAF/mL. In seven patients with septicemia, including urosepsis, endocarditis and peritonitis, and with positive blood culture, increased plasma PAF levels (1–20 ng PAF/mL) were observed. Other patients with clinical indications of septicemia had negative blood cultures and/or increased levels of C-reactive protein (CRP). Yet, in the plasma from these patients, no increased PAF levels were detected under the assay conditions used. Two patients with allergic asthma, requiring treatment with steroids, had no measurable plasma PAF. In the plasma from a patient with idiopathic thrombocytopenic purpura (ITP) only an "endogenous" inhibitor of PAF induced platelet aggregation was initially observed. In spite of this, the patient responded to treatment with the PAF antagonist WEB 2086 with a dramatic increase in platelet count (Lohmann *et al., Lancet ii,* 1147, 1988). Thereafter, also increased PAF levels (3.3 ng PAF/mL) were detected in plasma, although some "endogenous" inhibitor of PAF was still present. In conclusion, increased PAF levels in plasma from patients support a role of PAF in certain human disease states, such as in anaphylactoid reaction, sepsis and septic shock. The type, relevance and specificity of endogenous inhibitors of PAF deserve further study.

Lipids 26, **1381-1385 (1991).**

Increased levels of platelet-activating factor (PAF) type activity have been detected in blood from endotoxin treated animals (1,2). So far, there are only few reports on an increased level or turnover of PAF in human sepsis (3,4). This may be due in part to technical limitations in the measurement of PAF in human tissue and blood. Different approaches are conceivable to detect changes in turnover rates or levels of PAF under pathophysiological conditions in tissues and fluids, including blood, ascites, saliva, lavage fluid or urine, such as the measurement of lysoPAF or of PAF acetylhydrolase. However, any of these approaches has certain disadvantages, and the direct measurement of PAF may most likely reflect any relationship that may exist between PAF levels and various disease states. The purpose of the present study was to determine whether a modified aggregation assay for PAF type activity (5) may be suited for detecting and differentiating increased PAF-like activity in human plasma samples from patients with septicemia and other diseases.

MATERIALS AND METHODS

Blood samples from volunteers and patients were prepared for analysis of PAF-like activity by mixing 1 vol of whole blood with one volume of a modified ACD buffer (citric acid, 25 g; sodium citrate, 15 g; dextrose, 10 g; distilled water to a total volume of 1 L, pH 3.5). After centrifugation, the lipids of ACD plasma (pH 3.5) were extracted according to Bligh and Dyer (6), with intermittent centrifugation to precipitate protein. The chloroform phase of the Bligh and Dyer extract was taken to dryness and reconstituted in 0.8 mL of the aggregation buffer (see below).

Washed rabbit platelets were prepared according to a modification of described procedures (7–9). The washing solution/aggregation buffer had the following compositions (per 1 L distilled water): KCl (195 mg/195 mg), $MgCl_2 \times 6\ H_2O$ (212.5 mg/212.5 mg), NaCl (8 g/8 g), $NaHCO_3$ (1.015 g/–), Tris (–/1.21 g), $CaCl_2 \times 2\ H_2O$ (–/126.4 mg), EGTA 0.2 M; 76.07 g/L (1 mL/–), anhydrous glucose (1.0 g/1.0 g), bovine serum albumin (BSA) (fatty acid (FA) free) (2.5 g/2.5 g), HCl (pH 6.5/pH 7.4).

PAF-like activity was identified and quantitated by an aggregation assay using washed rabbit platelets under conditions described (5,10). PAF aggregatory activity was identified based on inhibition by the selective PAF antagonist WEB 2086, and in some cases was also confirmed by comigration in thin-layer chromatography (TLC) of PAF-like activity with synthetic PAF. Reproducibility and sensitivity of the PAF aggregation assay were improved by making some adjustments (5,10). Concentration response curves for PAF were well reproducible and independent of whether PAF was added to the assay system before (BAP) or after (AAP) addition of platelets. Aggregation was started according to the BAP procedure by addition of 50 μL of platelet suspension to 200 μL of PAF containing 1.0 aggregation buffer. The selective PAF antagonist WEB 2086 inhibited PAF induced aggregation in a specific and concentration-dependent manner with inhibition being complete above 1×10^{-7} M final concentration of WEB 2086 (IC_{50} 28 nM; PAF, 100 pg/mL). In the presence of subthreshold concentrations of cooperative aggregation stimuli, such as ADP or adrenaline, the concentration response curves for PAF were shifted to the left. Increase of pH (*e.g.*, pH 8.0) resulted in increased sensitivity for PAF, whereas a decrease in pH (pH 7.2) shifted the

concentration response curve to the right. Addition of fibrinogen to the aggregation buffer (0.01–0.06%) shifted the concentration response curves for PAF to the left (*e.g.*, final concentration, 0.02%). Consideration of these factors and appropriate choice of ion concentrations led to a sensitive PAF assay with a lower detection limit of about 1 pg/mL.

RESULTS

Under the conditions used for the extraction and assay of PAF in blood, no detection of PAF or a level of PAF below 0.5 ng/mL of plasma was considered normal.

Plasma from a patient who had collapsed due to adverse anaphylactoid reaction upon intravenous injection of a metamizol containing mixture of analgetics, exhibited a PAF level of 2.1 ng/mL (see Fig. 1). In seven plasma samples from patients with septicemia, including urosepsis, endocarditis and peritonitis, and with positive blood culture, increased levels of PAF (1–20 ng PAF/mL) were detected (see Fig. 2 and Table 1). In contrast, other patients with clinical indicators or suspicion of septicemia had negative blood cultures and/or increased levels of C-reactive protein (CRP); however, no increased levels of PAF were measured under the conditions used (see Tables 2 and 3). Two patients with allergic asthma, who required treatment with steroids, did not show measurable PAF in their plasma.

In plasma from a patient with idiopathic thrombocytopenic purpura (ITP), initially no PAF was detected. Instead an "endogenous" inhibitor of PAF induced platelet aggregation was identified. However, the patient responded to treatment with the PAF antagonist WEB 2086 with a dramatic increase in platelet count (Fig. 3). Thereafter and upon treatment with WEB 2086, also increased levels of PAF (3.3 ng PAF/mL) appeared in plasma (Fig. 4A). Upon purification by TLC, a yet higher level of PAF was measured in the same sample (Fig. 4B) suggesting the presence of some type of endogenous PAF inhibitor in ITP plasma.

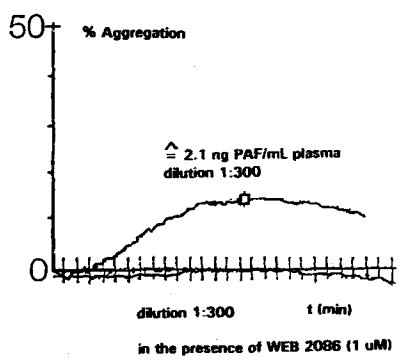

FIG. 1. PAF-like activity in plasma from a patient who collapsed upon anaphylactoid reaction after i.v. injection of a metamizol containing analgetic mixture. PAF-like activity is completely suppressed in the presence of the selective PAF antagonist WEB 2086 (superimposed tracing below).

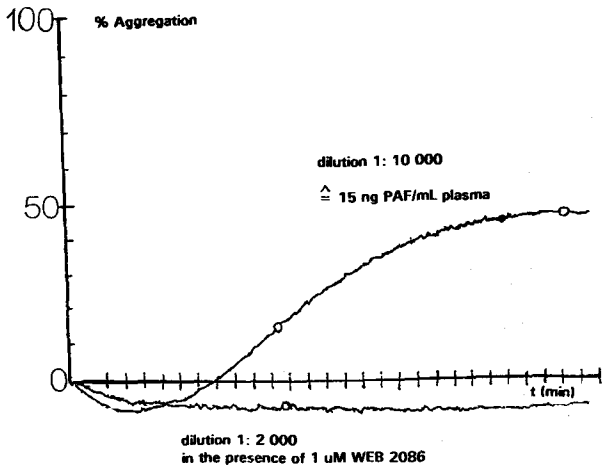

FIG. 2. Increased PAF-like activity in the plasma from a patient with acute myeloid leukemia and septicemia (severe peritonitis with necrosis of the bowel) from *Pseudomonas aeruginosa*. PAF-like activity comigrated with synthetic PAF in TLC and was completely suppressed in the presence of the selective PAF-antagonist WEB 2086 (superimposed tracing below). The patient died later in septic shock.

DISCUSSION

The bioassay used here to measure PAF type activity is highly sensitive and specific through use of the selective PAF antagonist WEB 2086. Under the modified conditions (pH 8.0, 0.02% fibrinogen, and cooperative stimuli), a detection limit of as low as 1 pg PAF/mL can be achieved, particularly when the Mg^{2+} and Ca^{2+} ion concentrations of the aggregation buffer (pH 8.0) are carefully adjusted (7,11,12).

Measurement of increased levels of PAF-like activity in plasma samples from patients in certain disease states illustrates that the bioassay can detect and differentiate PAF-like activity in plasma samples from patients. The level of PAF-like activity observed in this study is in the range found in the literature (3,13). The increased level of PAF-like activity found during an anaphylactoidic reaction after intravenous administration of analgesics is also in line with reports by others (14,15).

The increased level of PAF-like activity in septicemic patients (particularly those whose blood cultured gram-negative bacteria) is in agreement with previous studies in children (3) as well as studies in rats after infusion of endotoxin (1,2).

Our inability to find PAF-like activity in the plasma of asthmatic patients is consistent with earlier reports (16). On the other hand, changes in PAF metabolism in human allergies and asthma are indicated by the increased levels of lysoPAF found in plasma (16), by changes in PAF turnover, and/or by PAF occurrence in lung and other target sites of allergies (17–20). Furthermore, treatment with steroids may suppress PAF formation in asthmatics.

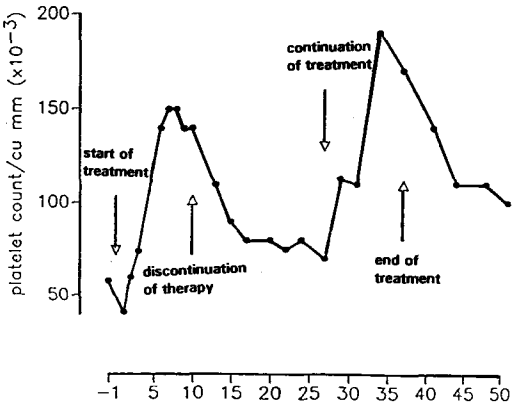

FIG. 3. Effect of repeated treatment with the PAF antagonist WEB 2086 (4 × 20 mg/day) on platelet count in a patient with idiopathic thrombocytopenic purpura (ITP; Morbus Werlhof).

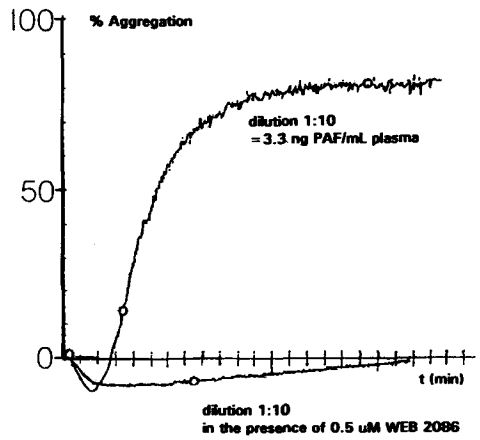

FIG. 4A. PAF-like activity in the plasma from a patient with idiopathic thrombocytopenic purpura (ITP) which came up after the second treatment cycle with WEB 2086 (see Fig. 3). Identification of platelet aggregating activity as PAF-like activity by WEB 2086 (superimposed tracing below).

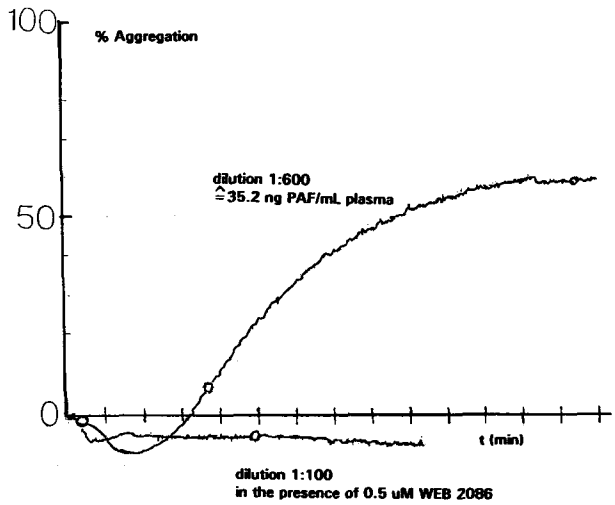

FIG. 4B. PAF-like activity in the plasma sample used above (see Fig. 4A) after purification by TLC. Increased PAF-like activity (35.2 ng PAF/mL plasma) compared to unpurified sample (3.3 ng PAF/mL plasma) suggests the presence of an endogenous inhibitor of PAF. PAF-like activity comigrated with synthetic PAF and was completely blocked by WEB 2086 (superimposed tracing below).

The functional bioassay using washed rabbit platelets allows the detection and quantification of specific and nonspecific inhibitors of PAF induced platelet aggregation, if in the apparent absence of platelet aggregating activity, added PAF is also inhibited. The amount of inhibitor present can then be estimated by serial dilution of the sample until the inhibitor disappears.

Different endogenous inhibitors of PAF, including certain phospholipids and C-reactive protein (CRP), have been described in the literature (21–27).

In some samples from patients suspected of septicemia, an endogenous inhibitor of PAF induced platelet aggregation was detected. In other samples where no PAF-like activity was identified, increased levels of CRP were found. It is entirely possible that PAF-like activity may be bound, and inactivated, by CRP and lipoproteins (25,27,28).

The dramatic increase in platelet count in a patient with idiopathic thrombocytopenic purpura (ITP) upon treatment with the selective PAF antagonist WEB 2086 (29) in the apparent absence of PAF and in the presence of an endogenous PAF inhibitor indicates that the apparent absence of PAF, as judged by the assay used, should not necessarily preclude the presence of PAF. In fact, the presence of an endogenous inhibitor of PAF may actually be indicative of a PAF-mediated process.

In conclusion, the very sensitive and selective aggregation assay for PAF-like activity as used here is suited to detect and differentiate PAF-like activity in plasma from patients. The results can provide additional support for a role of PAF in human disease, such as sepsis, anaphylaxis, and immunological disorders.

Various points should be taken into account when interpreting the data measured. For example, compartmentalization of PAF-mediated processes at the organ level (*e.g.*, in asthma) or binding and inactivation by lipoproteins or CRP may affect the level of unbound PAF in plasma, as suggested by the results presented here. Furthermore, the level of PAF relative to its metabolites, such as lysoPAF, the involvement of enzymes (*e.g.*, acetylhydrolase), and the presence of endogenous inhibitors (CRP, certain phospholipids) have to be considered. In addition, the level of PAF in relation to other inflammatory mediators, their interaction and synergism with PAF, and the sequence of their formation and release may have impact on the physiological and pathophysiological role of PAF.

Due to this complexity, the use of selective and potent PAF antagonists may be a more useful and convincing approach to pinpointing a causative role of PAF in human disease.

Differential Effect of a PAF Antagonist CV-3988 on Active and Passive Anaphylactic Shock in Various Mouse Strains[1]

Akinori Arimura* and **Minoru Harada**
Shionogi Research Laboratories, Shionogi & Co., Ltd., Osaka 553, Japan

To define the role of platelet-activating factor (PAF) in anaphylactic shock in the mouse, the suppressive effect of CV-3988, a PAF antagonist, on active and passive anaphylactic shock was studied. Various mouse strains treated or not treated with *Bordetella pertussis (B. pertussis)* were used. We found that the effect of CV-3988 on anaphylactic shock in the mice that were actively sensitized with bovine serum albumin plus *B. pertussis* differed markedly according to mouse strain. CV-3988 suppressed the anaphylactic shock in C3H/He and CBA/JN mice at a low dose of 3 mg/kg, whereas antagonists to other mediators such as histamine, serotonin, thromboxane A_2 and leukotrienes did not show a suppressive effect. This suggests that PAF plays a major role in anaphylactic shock in these strains. On the other hand, CV-3988 did not suppress active anaphylactic shock in cataract Shionogi (CTS), NOD and DS strains even at a high dose of 30 mg/kg, which could be interpreted to suggest that PAF is not active in these strains. However, this possibility was ruled out based on the similar results obtained in passive anaphylactic shock and PAF-induced shock in these mice. Passive anaphylactic shock in CTS mice mediated by IgG_1 antibody was markedly suppressed by CV-3988 but not at all by antagonists to other mediators. Furthermore, the suppressive action of CV-3988 against passive anaphylactic shock, and PAF-induced shock was greatly attenuated when the mice were pretreated with *B. pertussis*. From these results, the conclusion can be drawn that PAF is the main mediator of active and passive anaphylactic shock in the mouse in general, even though the effect of CV-3988 differs depending on the mouse strain and on whether or not *B. pertussis* treatment is used.
***Lipids 26,* 1386-1390 (1991).**

We have previously reported that the cataract Shionogi (CTS) mouse is T lymphocytopenic and that its *in vitro* and *in vivo* immune responses to T cell-dependent antigens are markedly impaired (1,2). For instance, the *in vivo* production of antibodies to bovine serum albumin (BSA) is minimal when the mouse is immunized with dead *Bordetella pertussis (B. pertussis)* organisms used as an adjuvant. Unexpectedly, however, lethal active anaphylactic shock was elicited in almost all mice 7 or more days after the immunization. These results suggest that CTS mice are very susceptible to the effector phase of active anaphylactic shock. This is supported by the finding that this strain is also highly susceptible to passive anaphylactic shock mediated by allogeneic IgE and IgG_1 antibodies (3). There are several possible explanations for the high susceptibility of CTS mice. Firstly, mast cells and other cell types may easily be sensitized by the antibodies. Secondly, a larger amount of mediators may be released from mast cells, or other cells, by antigen-antibody interactions in this strain than in others. Thirdly, CTS mice may be highly susceptible to the chemical mediators released. Before gaining some insight into the mechanism of the potent anaphylactic shock in CTS mice, we needed to identify the main mediator responsible for anaphylactic shock in the mouse. Using CV-3988 as a PAF antagonist, Terashita *et al.* (4) showed that PAF plays an important role in active anaphylactic shock in ICR mice. However, it is still unclear whether this is true for all mouse strains and all types of anaphylactic shock.

To examine whether or not the suppressive effect of CV-3988 against anaphylactic shock can be generally observed in the mouse, a systematic study was undertaken with various mouse strains which were sensitized by active and passive means with or without *B. pertussis* treatment.

MATERIALS AND METHODS

Animals. CTS, NOD, C3H/He, BALB/c, C57BL/6J, DS/Shi and BDF1 mice were bred under specific pathogen-free conditions at Shionogi Aburabi Laboratories (Shiga, Japan). CBA/JN and DBA/2 mice were purchased from Charles River Japan Inc. (Kanagawa, Japan), and Jcl:ICR mice were obtained from Clea Japan Inc. (Tokyo, Japan). Both sexes of NOD mice, and females of the other strains were used. Unless otherwise described, tests were done using mice 7 to 10 wk old. WS rats at 8 wk of age, which were bred at Shionogi Aburabi Laboratories, were used as recipients for passive cutaneous anaphylaxis (PCA) mediated by mouse IgE antibody.

Antigen and antibody. Ascitic fluids of BDF_1 mice containing IgE or IgG_1 monoclonal antibody to benzylpenicilloyl (BPO) haptens (5) were used. The antibody titers of both ascitic fluids were 1:1024 when assayed by means of 1-day PCA in rats (for IgE antibody) and 1-hr PCA in DS/Shi mice (for IgG_1 antibody). As a polyvalent eliciting antigen, BPO-GSA, the conjugate of BPO haptens with guinea pig serum albumin (GSA, Sigma Chemical Co., St. Louis, MO), was prepared according to the method of Levine and Ovary (6). In addition, to obtain anti-ovalbumin (OVA) serum, BALB/c mice were hyperimmunized by three intraperitoneal injections at 1-wk intervals of 1 mg of OVA (Seikagaku Kogyo, Tokyo, Japan) emulsified with complete Freund's adjuvant (CFA, Difco, Detroit, MI), and bled 1 wk after the last sensitization. The IgE and IgG_1 titers of the pooled serum were both

[1] Based on a paper presented at the Third International Conference on Platelet-Activating Factor and Structurally Related Alkyl Ether Lipids, Tokyo, Japan, May 1989.

Abbreviations: *B. pertussis, Bordetella pertussis*; BPO, benzylpenicilloyl; BSA, bovine serum albumin; CFA, complete Freund's adjuvant; GSA, guinea pig serum albumin; OVA, ovalbumin; PAF, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; PCA, passive cutaneous anaphylaxis.

1:1024. Anti-BPO ascites and anti-OVA serum were stored frozen at −20°C.

Active anaphylactic shock. Mice were sensitized by i.p. injection of 0.2 mL of saline containing 1 mg of bovine serum albumin (BSA, Nakarai Chemicals, Kyoto, Japan) and 2×10^9 cells of dead *B. pertussis* organisms (Nacarai Tesque, Tokyo, Japan). Shock was elicited by an intravenous challenge with 1 mg (0.2 mL in saline) of the homologous antigens 1 wk after sensitization in CBA/JN, C3H/He, DBA/2, BDF_1, BALB/c, NOD and Jcl:ICR mice and two weeks after sensitization in C57BL/6J, DS/Shi and CTS mice.

Passive anaphylactic shock. NOD and CTS mice were passively sensitized by an intravenous injection of 0.2 mL of ascitic fluid of BDF_1 mice containing anti-BPO IgE or IgG_1 monoclonal antibody or by an intravenous injection of 0.2 mL of anti-OVA hyperimmune serum, as these two strains are most susceptible to anaphylactic shock (3). To elevate susceptibility of mice to chemical mediators, some animals were injected intraperitoneally with *B. pertussis* (2×10^9 cells, unless otherwise stated) one week before the sensitization. IgG_1- and IgE-mediated anaphylactic reactions were elicited by an intravenous injection of BPO·GSA (1 mg) 3 to 5 hr and 1 day after sensitization, respectively. Anaphylaxis mediated by anti-OVA serum was caused by an injection of OVA (1 mg) after 3- to 5-day sensitization. The lethality was estimated at 60 min after antigen challenge in both active and passive shock tests, though lethal shock usually occurred within 30 min.

Platelet-activating factor (PAF)-induced shock. PAF (1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine, Sigma, 2 mg/mL in chloroform) was diluted with 0.9% saline solution to the concentrations needed. PAF was injected through the tail vein at 3.13 to 200 μg/kg (injection volume: 0.1 mL/10 g body weight). Intensity of PAF-induced shock was expressed in terms of the incidence of lethal shock within 1 hr after PAF injection, although death occurred usually within 30 min after the injection.

Drugs. CV-3988 [(RS)-2-methoxy-3-(octadecylcarbamoyloxy)-propyl-2-(3-thiazolioethylphosphate)], S-145 Na [sodium dl-(5Z)-7-(3-endo-(phenylsulfonyl)amino)bicyclo-[2.2.1]hept-2-exo-yl)heptenoic acid] (7) and FPL-55712 (sodium 7-[3(4-acetyl-3-hydroxy-2-propylphenoxy)-2-hydroxypropoxy]-4-oxo-8-propyl-4H-1-benzopyran-2-carboxylate were synthesized in our laboratories. Cyproheptadine (Sigma) was purchased. All drugs were dissolved in 0.9% saline and administered intravenously 5 min before the challenge with antigen or PAF.

RESULTS

Effect of various antagonists on active anaphylactic shock. To determine the dominant mediator in active anaphylactic shock, we examined the effects of various antagonists on lethality in C3H/He mice. Lethal shock occurred in almost all of the control mice within 30 min after antigen challenge, although it was somewhat delayed in a few cases. As shown in Table 1, cyproheptadine (histamine and serotonin antagonist), S-145 Na (thromboxane A_2 antagonist) and FPL-55712 (leukotriene antagonist) did not suppress the shock at all. In contrast, CV-3988 (PAF antagonist) protected mice from death caused by active anaphylactic shock at doses ranging from 1 to 10 mg/kg, when injected intravenously 5 min before the antigen challenge. These results are consistent with the previous report (4), and suggest that PAF plays a primary role in C3H/He mice. To see if this could be confirmed in general, the effect of CV-3988 was tested in other strains.

TABLE 1

Effect of Various Antagonists on Active Anaphylactic Shock in C3H/He Mice[a]

Drugs	Dose (mg/kg)	Lethality (death/total mice)
Control		27/31
CV-3988	1	5/12
	3	5/24
	10	0/4
Cyproheptadine	20	5/5
S-145 Na	10	5/5
FPL-55712	10	5/5

[a]Drugs were given i.v. 5 min before the antigen challenge.

As illustrated in Figure 1, the suppressive effect of CV-3988 differed according to mouse strain. Suppression was potent in C3H/He and CBA/JN mice and moderate in BALB/c, DBA/2, C57BL/6J, BDF_1 and Jcl:ICR mice. In CTS, NOD and DS mice, no suppression was observed even at a high dose of 30 mg/kg.

Effect of various antagonists on passive anaphylactic shock. As reported previously, CTS as well as NOD mice were much more susceptible to passive anaphylactic shock (3). Briefly, when the mice were sensitized with IgG_1 monoclonal antibody, lethal shock was easily produced in CTS and NOD strains regardless of the presence or absence of *B. pertussis* pretreatment. In some strains such as NON, C57BL/6J and DS/Shi, lethal shock was produced only when the mice had been treated with *B. pertussis*. In contrast, IgE antibody was less effective in sensitizing mice for anaphylactic shock than IgG_1 antibody. Lethal anaphylactic shock mediated by IgE antibody was observed in CTS, NOD, C57BL/6J and DS mice treated with *B. pertussis*. Based on these findings, the effects of

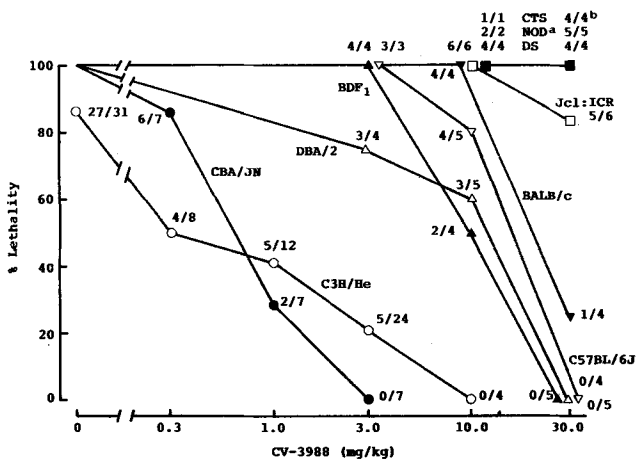

FIG. 1. Effect of CV-3988 on active anaphylactic shock in various mouse strains immunized with BSA and *B. pertussis*. CV-3988 was given i.v. 5 min before the antigen challenge. [a]Females aged 15 wk. [b]Incidence of lethal shock.

several drugs were examined against passive anaphylactic shock in *B. pertussis*-treated and untreated CTS and NOD mice.

Table 2 shows the drug effect against passive anaphylactic shock in untreated CTS mice sensitized with IgG_1 monoclonal antibody. Unlike active anaphylactic shock, this type of passive anaphylactic shock was markedly suppressed by the PAF antagonist CV-3988, but not by the antagonist to other mediators. Table 3 demonstrates the difference in the suppressive effect of CV-3988 between *B. pertussis*-treated and untreated mice sensitized with anti-OVA serum or anti-BPO ascites. CV-3988 suppressed the anaphylactic shock mediated by anti-OVA hyperimmune serum or anti-BPO IgG_1 antibody in the untreated NOD and CTS mice at lower dosages ranging from 3 to 10 mg/kg, but did not suppress shock in the *B. pertussis*-treated mice even at a high dose of 30 mg/kg. Because *B. pertussis* treatment is necessary to provoke lethal shock as far as IgE antibody is concerned, the suppressive effect of CV-3988 against IgE-mediated passive anaphylactic shock was compared between NOD mice treated with a low dose (2×10^8 cells) and a high dose of *B. pertussis* (2×10^9 cells). The suppressive effect was more pronounced in the mice treated with a low dose of *B. pertussis* than in those treated with a high dose. From these results, one could speculate that the suppressive effect of CV-3988 against passive anaphylactic shock is alleviated by *B. pertussis* treatment in general, even though PAF might play a crucial role.

Effect of B. pertussis *treatment on the antagonistic action of CV-3988 against PAF-induced shock in DS mice.* To support the aforementioned speculation, the effect of CV-3988 against PAF-induced shock between untreated and *B. pertussis*-treated DS mice was compared. In view of the observation that the minimal dose of PAF to produce 100% lethality in this strain was 25 μg/kg, the effect of CV-3988 was assessed against two doses of PAF, *i.e.,* 50 and 100 μg/kg. As shown in Table 4, protection of mice by CV-3988 from PAF-induced lethal shock decreased, accompanied by an increase in PAF dose, and was greatly reduced in the *B. pertussis*-treated animals.

Comparison of susceptibility to PAF-induced shock in untreated and B. pertussis*-treated mice of various strains.* The above described results that *B. pertussis* affects the suppressive action of CV-3988 against passive anaphylactic shock and PAF-induced shock suggest that differences between strains in the suppressive effect of CV-3988 against active anaphylactic shock depends on how much it is influenced by *B. pertussis.* To examine this possibility, we compared the PAF-induced shock in untreated and *B. pertussis*-treated mice of various strains. As demonstrated in Table 5, the susceptibility to PAF-induced shock in the untreated animals differed according to strain. However, the susceptibility was enhanced by *B. pertussis* in all the strains tested, although differing in intensity. The enhancement was minimal in C3H/He and CBA/JN strains as compared with the other strains. This may explain the potent suppressive action of CV-3988 against active anaphylactic shock in these strains. CTS mice were more susceptible than the other strains regardless of *B. pertussis* treatment.

[a]Drugs were given i.v. 5 min before the antigen challenge.

DISCUSSION

Our results show that the effect of CV-3988 against active anaphylactic shock differed widely according to mouse strain. The suppressive effect was potent in C3H/He and CBA/JN strains, moderate in BALB/c,

DBA/2 and BDF_1 strains and absent in CTS, NOD, C57BL/6J and DS strains. For the lack of suppression in CTS and some other strains, two explanations are possible. One is that mediators other than PAF are responsible. The other is that the action of CV-3988 can be greatly influenced by *B. pertussis* used as an adjuvant, even though PAF might be the main mediator for mouse anaphylactic shock in general. The first possibility can be disregarded on the basis of the analogy of the results with passive anaphylactic shock in CTS mice, where high dosages of antagonists to histamine, serotonin, thromboxane A_2 and leukotrienes sufficient to produce complete antagonism did not protect the mice from lethal shock. Involvement of histamine and serotonin can also be ruled out based on the finding that i.v. injection of a high dose (40 mg/kg) of exogenous histamine and serotonin failed to cause lethal shock in untreated mice (data not shown). By contrast, the second possibility is plausible in view of the observation that in these strains the suppressive effect of CV-3988 was markedly attenuated by *B. pertussis* treatment not only against passive anaphylactic shock, but also against PAF-induced shock. Actually, active anaphylactic shock in DS mice, which had been actively sensitized for 4 wk after an immunizing injection using CFA in place of *B. pertussis*, was dramatically suppressed by CV-3988 (data not shown).

It is known that *B. pertussis* and its components enhance the susceptibility to various chemical mediators

such as histamine, serotonin, methacholine and bradykinin and some immunological and physical stimuli in mice and rats (8), probably through the beta-adrenergic blockage (9–11). The present study demonstrated that the susceptibility to PAF was also enhanced by *B. pertussis* in all the mouse strains tested, probably due to its beta-blocking activity in view of the facts that plasma epinephrine and norepinephrine levels are markedly elevated by the injection of PAF in rats (12) and that PAF-induced shock is potentiated by propranolol, a beta-adrenergic blocker, and by adrenalectomy in mice (13,14). However, it should be noted that the *B. pertussis*-induced enhancement of the PAF-induced shock differed markedly according to strain, the enhancement being minimal in C3H/He and CBA/JN strains as compared to the others. This may explain why the potent suppression by CV-3988 was observed against active anaphylactic shock in these two strains even though they had been injected with *B. pertussis* as an adjuvant.

Effect of a Selective PAF Antagonist SM-10661 ((±)-*cis*-3,5-Dimethyl-2-(3-pyridyl)thiazolidin-4-one HCl) on Experimental Disseminated Intravascular Coagulation (DIC)[1]

Noriaki Imanishi*, Yoshihiro Komuro and Shigeaki Morooka
Research Laboratories, Sumitomo Pharmaceuticals Co., Ltd., Osaka, 554 Japan

Intravenous infusion of endotoxin (0.25 mg/kg/hr for 4 hr) was shown to induce disseminated intravascular coagulation (DIC) in rats, which resulted in hypofibrinogenemia, prolongation of prothrombin (PT) and partial thromboplastin time (PTT), thrombocytopenia, and elevated levels of fibrinogen/fibrin degradation products (FDP). Oral administration (100 mg/kg) of the selective PAF antagonist, SM-10661 ((±)-*cis*-3,5-dimethyl-2-(3-pyridyl)thiazolidin-4-one HCl), counteracted the changes caused by the endotoxin. Intravenous infusion of SM-10661 (6mg/kg bolus 2 min before endotoxin infusion + 6 mg/kg/hr for 4 hr infusion) also counteracted DIC. When suboptimal doses of gabexate mesilate, a synthetic protease inhibitor (3 mg/kg i.p.), and SM-10661 (2 mg/kg bolus + 2 mg/kg/hr for 4 hr infusion) were administered concomitantly, hematological parameters improved. The results suggest that PAF may play a role in the pathogenesis of DIC, and that together with the results already reported for other PAF antagonists, SM-10661 may be useful in the treatment of DIC.
***Lipids* 26, 1391–1395 (1991).**

Disseminated intravascular coagulation (DIC) is a pathological syndrome in which the formation of fibrin thrombi, the consumption of specific plasma proteins, the loss of platelets, and the activation of fibrinolytic systems occur. Clinically, these effects may manifest themselves as diffuse hemorrhage and, less frequently, as thrombosis (1).

The most common cause of DIC is infection (2–4). It is usually induced by endotoxin from gram negative bacteria (5–7). The principal goals in the treatment of DIC are to decrease the symptoms of the disease and to prevent the development and formation of fibrin thrombi.

The pathophysiology of DIC induced by endotoxin is complicated. Endotoxin activates platelets, leukocytes, blood coagulation-fibrinolytic systems and complement systems. The possible involvement of various chemical mediators such as reactive oxygen radicals, prostaglandins and thromboxane A_2 has been suggested (8–11).

It has been shown that injection of endotoxin increases the level of platelet-activating factor (PAF) in rats (12). *In vitro* studies have indicated that endotoxin-activated endothelial cells and monocytes produced PAF *via* the secretion of interleukin 1 and/or tumor necrosis factor (13–16). Therefore, PAF is thought to play a pathophysiological role in DIC caused by septic shock.

We previously developed an orally active PAF antagonist SM-10661 (17,18). We now have studied the effect of SM-10661 on endotoxin-induced DIC and the possibility of involvement of PAF in the pathogenesis of DIC.

MATERIALS AND METHODS

Materials. SM-10661 ((±)-*cis*-3,5-dimethyl-2-(3-pyridyl)-thiazolidin-4-one HCl) was synthesized by Sumitomo Pharmaceuticals Co. Ltd. (Osaka, Japan). Endotoxin (*S. typhimurium*) was purchased from Sigma Chemical Co. (St. Louis, MO). The fibrin/fibrinogen degradation products (FDP) test and gabexate mesilate were obtained from Teikoku Hormone Mfg. Co. (Tokyo, Japan), and Ono Pharmaceutical Co. Ltd. (Osaka, Japan), respectively. SM-10661 was dissolved in saline and adjusted to pH 5–6 by 1 N NaOH.

Effects of drugs on experimental DIC. The rat DIC model was developed according to Yoshikawa *et al.* (19), with slight modifications. Male Wistar rats, 7 to 8 wk old, were anesthetized with sodium pentobarbital (50 mg/kg i.p.), and right and left jugular veins were cannulated for injection of endotoxin and drugs (SM-10661 or saline). Gabexate mesilate was administered intraperitoneally before the start of endotoxin infusion. Endotoxin (0.25 mg/kg/hr) was infused at a flow rate of 0.6 mL/hr for 4 hr. SM-10661 was given both orally and by infusion to test its effect on DIC. In the first treatment, SM-10661 (5 mL/kg) was given orally 1 hr before the start of the endotoxin infusion. In the second treatment, 0.1 mL of SM-10661 was given in a bolus, and subsequently an additional 0.35 mL was infused. The control group was given saline instead of SM-10661, and the normal group was given saline instead of endotoxin and SM-10661. Blood samples (3 mL each) were taken from the abdominal artery into a plastic syringe containing citrate anticoagulant (final concentration 0.36%) 4 hr after the start of endotoxin infusion. Platelets were counted using an automatic counter (Sysmex PL Taiyodensi, Kobe, Japan). FDP was determined by the latex aggregation test and is reported in μg/mL of an equivalent of human fibrinogen base (20). Fibrinogen was determined according to the method of Ellis and Stransky (21); prothrombin time (PT) and partial thromboplastin time (PTT) were measured according to the methods of Quick *et al.* (22) and Langdell *et al.* (23), respectively, using a Blood Coagulation Analyzer (Sysmex PL Taiyodensi, Kobe, Japan).

Statistical analysis. The values in the text and figures represent the mean ± SEM. Student's t-test was used

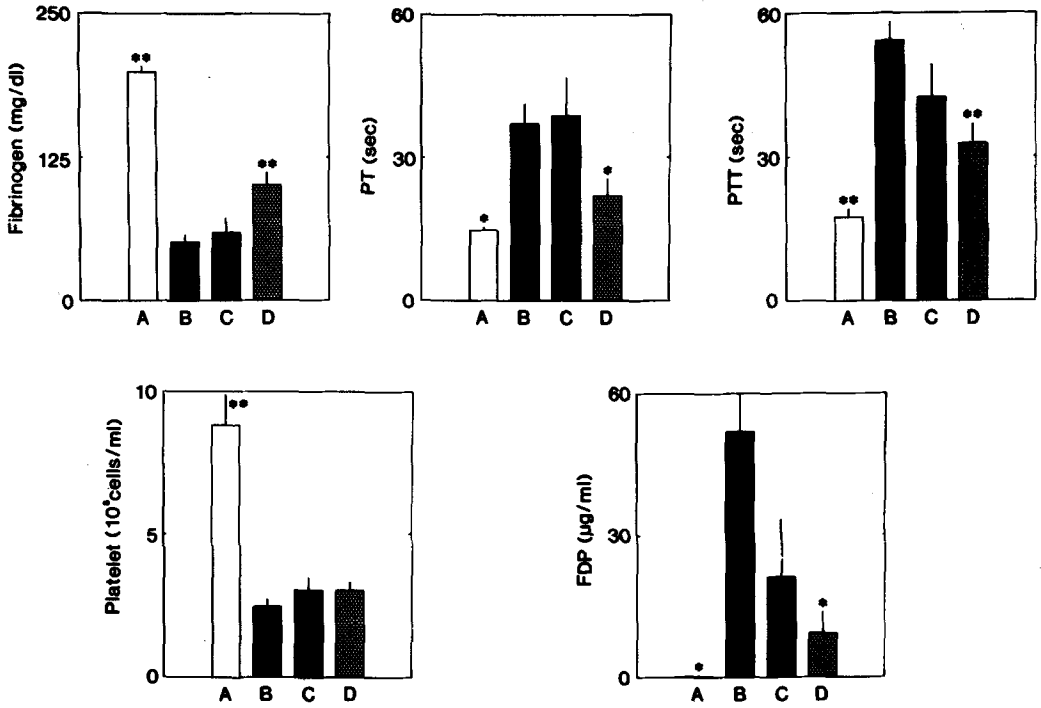

FIG. 1. Effect of orally administered SM-10661 on endotoxin-induced changes of the hematological parameters in rats. (A) Vehicle was administered and saline was infused intravenously for 4 hr (normal group) (n = 5). (B) Vehicle was administered and endotoxin (0.25 mg/kg/hr) was infused intravenously for 4 hr (control group) (n = 19). (C) SM-10661 (30 mg/kg) was administered and endotoxin was infused intravenously for 4 hr (n = 8). (D) SM-10661 (100 mg/kg) was administered and endotoxin was infused intravenously for 4 hr (n = 12). Statistical significance: *P<0.05, **P<0.01 as compared with the control group B.

for the statistical analysis. A value of less than 0.05 was considered significant.

RESULTS

A 4-hr sustained infusion of endotoxin (0.25 mg/kg/hr for 4 hr) caused DIC symptoms in rats (Fig. 1). Fibrinogen decreased from 199 ± 5 to 51 ± 6 mg/dL; PT and PTT were prolonged from 16.7 ± 0.5 sec and 26.1 ± 1.7 sec to 37.2 ± 4.1 sec and 54.2 ± 0.7 sec, respectively. Platelet counts decreased from 8.82 ±0.06×10^8 cells/mL to 2.47 ± 0.26 × 10^8 cells/mL, and FDP increased from 0.17 ± 0.17 μg/mL to 52.0 ± 13.7 μg/mL.

Orally administered SM-10661 partially inhibited endotoxin-induced DIC (Fig. 1). When 100 mg/kg of SM-10661 was administered, fibrinogen (101 ± 11 mg/dL), PT (22.0 ± 1.5 sec), PTT (32.8 ± 1.9 sec) and FDP (9.1 ± 1.5 μg/mL) were improved significantly, but platelet counts were not significantly affected (3.03 ± 1.28 × 10^8 cells/mL).

The effect of SM-10661 intravenous infusion on hematological parameters was examined in another series of experiments. A sustained 4-hr infusion of endotoxin caused DIC symptoms in rats (Fig. 2). Treatment with SM-10661 (6 mg/kg bolus + 24 mg/kg/4 hr infusion) improved fibrinogen (139 ± 8 mg/dL), PT (17.1 ± 0.4 sec), PTT (22.8 ± 0.7 sec), platelet counts (9.2 ± 8.1 × 10^8 cells/mL) and FDP (5.1 ± 1.0 μg/mL).

The effect of post-treatment with SM-10661 intravenous infusion on the hematological parameters was examined (Fig. 2). SM-10661 (6 mg/kg) was given in a bolus 2 hr after the start of endotoxin infusion, and subsequently 24 mg/kg was infused in addition to endotoxin. This treatment also improved fibrinogen (130 ± 10 mg/dL), PT (17.6 ± 0.3 sec) and FDP (9.2 ± 2.1 μg/mL), but did not significantly affect PTT and platelet.

The effect of intraperitoneally administered gabexate mesilate, a potent synthetic protease inhibitor, on hematological parameters is presented in Figure 3. Treatment with 10 mg/kg to 30 mg/kg gabexate mesilate improved the endotoxin-induced changes. The effects of gabexate mesilate were saturable.

To investigate whether co-administration of SM-10661 and gabexate mesilate is more effective than administration of each drug, both SM-10661 (2 mg/kg bolus + 6 mg/kg/4 hr infusion) and gabexate mesilate (3 mg/kg i.p.) were used (Fig. 3). Treatment with both drugs improved the parameters significantly in spite of the ineffectiveness of each drug at the same dose; fibrinogen (119 ± 11 mg/dL), PTT (23.2 ± 1.2 sec), platelet counts (5.85 ± 1.34 × 10^8 cells/mL) and FDP (3.4 ± 1.1 μg/mL). These results demonstrate that the co-administration of SM-10661 and gabexate mesilate had additive effects.

SM-10661 (final concentration; 10^{-9} to 10^{-3} M) did not prolong blood coagulation time *in vitro* (data not shown).

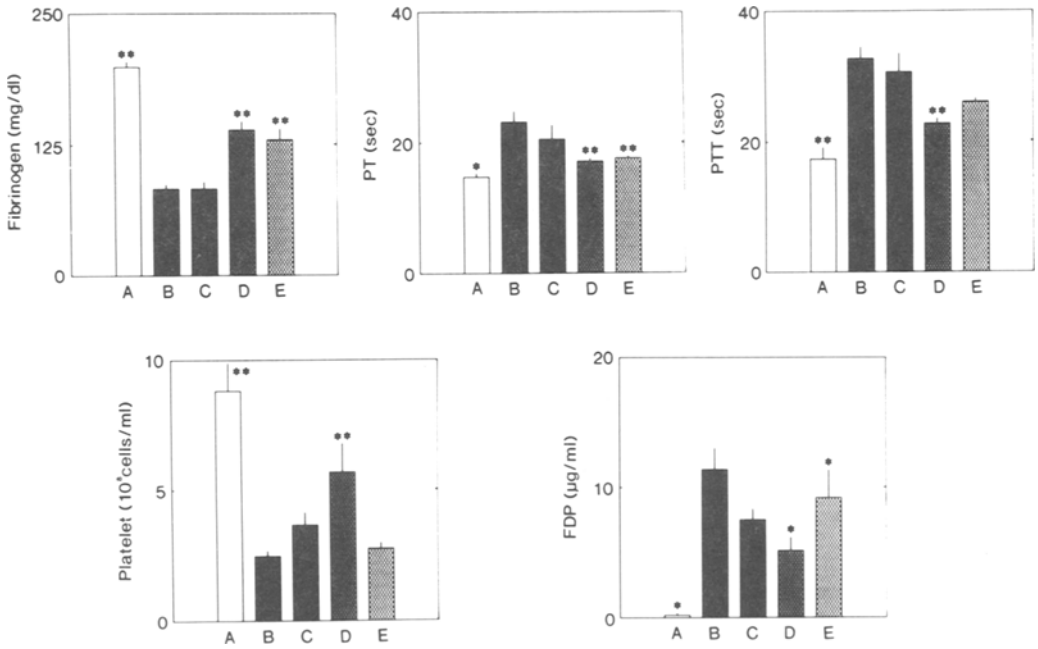

FIG. 2. Effect of intravenously administered of SM-10661 on endotoxin-induced changes of the hematological parameters in rats. SM-10661 or saline was administered in bolus and by infusion. (A) Saline was infused for 4 hr (normal group) (n = 5). (B) Saline was administered and endotoxin (0.25 mg/kg/hr) was infused for 4 hr (control group) (n = 52). (C) SM-10661 (2 mg/kg) was administered before the start of endotoxin infusion and infused (8 mg/kg) for 4 hr (n = 20). (D) SM-10661 (6 mg/kg) was administered before the start of endotoxin infusion and infused (24 mg/kg) for 4 hr (n = 19). (E) SM-10661 (6 mg/kg) was administered 2 hr after the start of endotoxin infusion and infused (24 mg/kg) for 2 hr (n = 15). Statistical significance: *P<0.05, **P<0.01 as compared with the control group B.

DISCUSSION

The intravenous administration of endotoxin evokes serious responses associated with systemic hypotension, shock, pulmonary hypertension, thrombocytopenia, leukopenia and increased vascular permeability. Similar responses were recently reported to be produced by PAF. Treatment by certain PAF antagonists, CV-3988, Kadsurenone and BN-52021 reduced these symptoms (12,24,25). Therefore, PAF is thought to be involved in the conditions induced by endotoxin. However, it is not clear whether PAF is involved in intravascular coagulation caused by endotoxin. Recently, Imura *et al.* (26) reported that CV-3988 prevented changes in all hematological parameters induced by endotoxin. Furthermore, in human patients with sepsis or DIC, high amounts of PAF have been described in blood or urine (27–29). These results suggest that PAF participates in the pathogenesis of endotoxin-induced DIC.

In the present studies, orally administered SM-10661 (100 mg/kg) reduced endotoxin-induced changes in the hematological parameters examined except for platelet counts. Intravenously administered SM-10661 affected these parameters, and thrombocytopenia was also improved. When SM-10661 was administered orally, anti-PAF activity in blood peaked at about 1–2 hr (17,18). Different effects on platelet counts may have resulted when SM-10661 was administered p.o. and i.v. because anti-PAF activity 1–2 hr after the onset of endotoxin infusion is necessary for thrombocytopenia inhibition. SM-10661, given in a bolus (6 mg/kg) 2 hr after the onset of endotoxin infusion and infused (24 mg/kg) with endotoxin for 2 hr, also improved the changes in hematological parameters except for platelet counts and PTT. Anti-PAF activity soon after the administration of endotoxin may therefore be important for the prevention of thrombocytopenia.

It is reported that the intravenous administration of endotoxin causes a transient neutropenia (30). The decrease of neutrophils in the blood is considered to be the result of adhesion of the cells to capillary vessels (31). Accumulation of neutrophils in the microvasculature may play an important role in endothelial damage because neutrophils produce a variety of vasoactive substances such as lysosomal enzymes and active oxygen metabolites (32-34). This injury induces blood coagulation, and is thought to be related to the etiology of DIC. Recent studies have indicated that endotoxin induces secretion of interleukin-1 and tumor necrosis factor in leukocytes (13,14) and that these cytokines activate the adhesion of leukocytes to cultured endothelial cells (35,36). This interaction is inhibited by various PAF antagonists (37,38), which suggests that PAF is involved.

In the present experiment, thrombocytopenia induced by endotoxin infusion may not be a direct effect of PAF because PAF has not been found to induce platelet aggregation in rats (39). However PAF does induce platelet aggregation in humans (40), and therefore PAF antagonists may be more effective in endotoxin-induced DIC in humans than in rats. Further investigation is needed using guinea pig or rabbit whose platelets are sensitive to PAF (40).

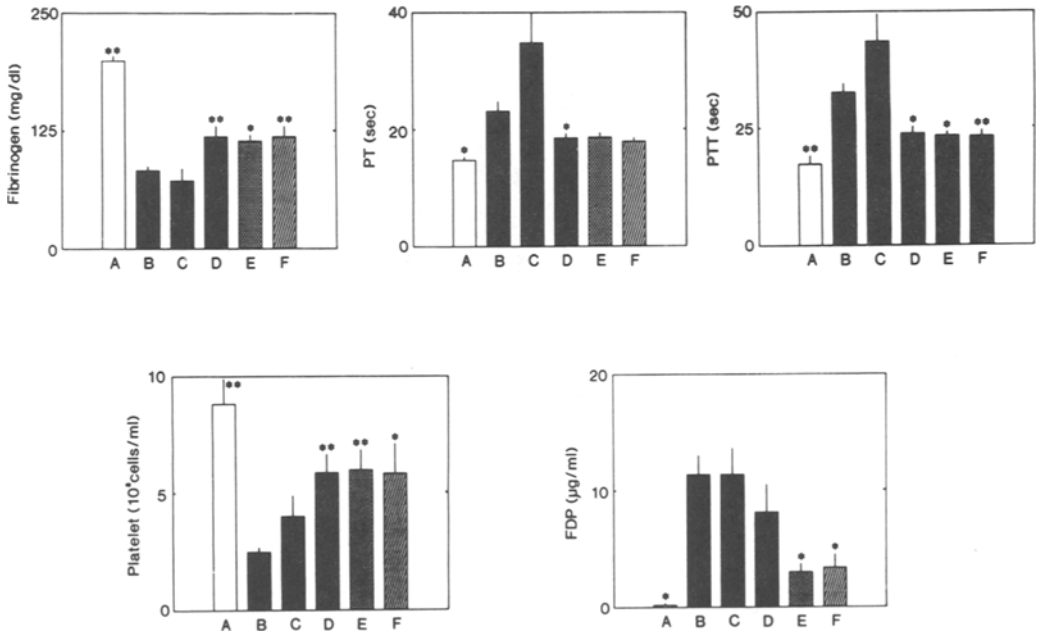

FIG. 3. Effects of intraperitoneally administered gabexate mesilate and intravenously administered SM-10661 on endotoxin-induced changes of the hematological parameters in rats. Gabexate mesilate was administered before the start of endotoxin infusion. (A) Saline was infused for 4 hr (normal group) (n = 5). (B) Saline was administered and endotoxin (0.25 mg/kg/hr) was infused for 4 hr (control group) (n = 52). (C) Gabexate mesilate (3 mg/kg) was administered before the start of endotoxin infusion (n = 11). (D) Gabexate mesilate (10 mg/kg) was administered before the start of endotoxin infusion (n = 9). (E) Gabexate mesilate (30 mg/kg) was administered before the start of endotoxin infusion (n = 6). (F) Gabexate mesilate (3 mg/kg) and SM-10661 (2 mg/kg bolus) were administered before the start of endotoxin infusion and SM-10661 (6 mg/kg) was infused for 4 hr (n = 9). Statistical significance: *P<0.05, **P<0.01 as compared with the control group B.

Several drugs which interfere with the activation of the coagulation system, or which remove fibrin (thrombosis or end-organ failure), are presently used for the treatment of DIC (41). These include synthetic inhibitors of coagulation enzymes such as heparin (42), gabexate mesilate (FOY) (43) and FUT-175 (44) and in some cases, thrombolytic agents (45).

The preventive effects of gabexate mesilate on the changes in hematological parameters were saturable with a bell-shaped dose response curve. Yoshikawa *et al.* (43) reported that an optimal dose of gabexate mesilate had to be administered to obtain the best results. Gabexate mesilate possesses not only anti-thrombin activity but also anti-plasmin activity. The requirement of the optimal dose is thought to be due to its anti-plasmin activity. The choice of optimal drug doses for clinical use may not always be easy. We demonstrated that coadministration of suboptimal doses of both SM-10661 and gabexate mesilate has additive effects. It is reported that protease inhibitors inhibited PAF production stimulated by phagocytosis in macrophages and induced with interleukin-1 in neutrophils or with tumor necrosis factor in vascular endothelial cells (46,47). Such additive effects may be due to the inhibitory effect of gabexate mesilate on PAF production. Therefore SM-10661, in combination with other protease inhibitor, may be useful for the treatment of DIC.

Effect of PAF-Acether Antagonists on Active Anaphylactic Mouse Paw Edema[1]

Claudia Zuany Amorim[a], Maria das Graças Muller de Oliveira Henriques[a], Vivian Baseches Weg[a], Renato Sérgio Balão Cordeiro[a,*] and B. Boris Vargaftig[b]

[a]Fundacao Oswaldo Cruz, IOC, Departamento de Fisiologia e Farmacodinâmica, CEP 20040, Rio de Janeiro, Brazil and [b]Unité de Pharmacologie Cellulaire, Unité Associee Institut Pasteur-INSERM U.285, 75015 Paris, France

A new model of active anaphylactic reaction in mice was developed. The edematogenic reaction appeared 5 min after the intraplantar injection of ovalbumin, peaked at 30 min after the antigenic challenge, and decreased thereafter. Using the non-steroidal, anti-inflammatory agents indomethacin and aspirin, we found that cyclooxygenase products do not participate in the reaction. In contrast, vasoactive amines appear to be involved, because meclizine and methysergide reduced the edema. Dexamethasone, BW755C, LY 171883 and WEB 2170 effectively interfered with the edematogenic reaction, which suggests that lipid mediators such as leukotrienes and PAF play a role in the active anaphylactic response.
***Lipids 26,* 1396–1399 (1991).**

Platelet-activating factor (PAF, PAF-acether, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) (1) is a mediator of allergic reactions which is involved in acute inflammatory processes (2,3). PAF is released by different cell types, including platelets, mast cells, endothelial cells, monocytes, macrophages, neutrophils and eosinophils (4). In addition, PAF promotes the activation of several inflammatory cells after immune and non-immune stimulation. Evidence suggests that PAF plays an important role in anaphylaxis. Its intravenous administration mimics different characteristics of systemic anaphylaxis, such as a drop in the number of circulating platelets and neutrophils, circulatory collapse with reduced coronary blood flow, and bronchoconstriction (5). Recent studies have also demonstrated the importance of PAF in shock, following the intravenous administration of human IgG aggregates to rats (6), and in mouse anaphylaxis, using the specific antagonist CV 3988 (7,8). Evans *et al.* (9), however, excluded a role for PAF in the increased vascular permeability induced by ovalbumin in actively sensitized guinea pigs. Furthermore, Yoshida *et al.* (10) argued that PAF does not participate in pulmonary anaphylactic dysfunction of guinea pigs or in passive cutaneous anaphylaxis of rats.

Since the role of PAF in mouse anaphylaxis is not fully understood, the focus of the present study was to investigate PAF participation in paw edema induced by intraplantar injection of ovalbumin in sensitized mice.

MATERIALS AND METHODS

Animals. Male Swiss Webster mice raised at the Oswaldo Cruz Foundation (Rio de Janeiro, Brazil) and weighing 25 to 30 g were used.

Sensitization. Animals were sensitized by the subcutaneous administration of 0.2 mL of 0.9% NaCl (saline) containing 10 μg ovalbumin and 1 mg aluminium hydroxide. The animals received two injections of the antigen separated by a 15-day interval (11).

Induction of paw edema. Seven days after the second antigen injection, the animals were challenged with 10 μg ovalbumin in 50 μL saline; the mixture was injected intraplantarly into one of the hind paws. The contralateral paw was injected with saline alone. Non-sensitized animals were injected with 2.5 μg of PAF or ovalbumin diluted with 50 μL saline. An equal volume of saline was injected into the contralateral paw. Animals injected with PAF were given intraperitoneally the PAF antagonist WEB 2170 (2, 4 or 8 mg/kg). The volume of the paw up to the tibiotarsal articulation was determined by plethysmography (12) 30 min after the challenge with ovalbumin or PAF; the results are expressed as increase in volume (μL). The control values obtained for the paws injected with saline alone were subtracted from the volume of the paws injected with the stimuli.

Treatments. Animals were treated intraperitoneally with the anti-inflammatory drugs indomethacin (0.25–0.5 mg/kg), aspirin (100–200 mg/kg), dexamethasone (0.25–2.5 mg/kg), and prednisolone (10–20 mg/kg), with the mixed cyclooxygenase and lipoxygenase inhibitor BW 755C (10–20 mg/kg), with the antihistaminic agents meclizine (12.5–25 mg/kg) and cimetidine (12.5–25 mg/kg), with the antiserotonin agent methysergide (1–5 mg/kg), with the anti-PAF agent WEB 2170 (2–16 mg/kg), and with the leukotriene D_4 antagonist LY 171883 (15–30 mg/kg). All drugs were administered 1 hr before the challenge, except that dexamethasone and prednisolone were administered 12 hr and 1 hr before the challenge, respectively, and meclizine was adminisitered 30 min before the challenge.

Drugs. Ovalbumin, indomethacin and methysergide were purchased from Sigma (St. Louis, MO). Aspirin was from Aspergic Egic Jouille (Paris, France). Dexamethasone was from Merck-Sharp and Dohme (Rio de Janeiro, Brazil) and prednisolone (Meticortem) was from Schering (Rio de Janeiro, Brazil). BW 755C was kindly provided by Dr. S. Moncada, Wellcome Research Laboratories (Beckenham, United Kingdom). Meclizine was from Pfizer (São Paulo, Brazil). Cimetidine was from CEME (Rio de Janeiro, Brazil). WEB 2170 (6-(2-chlorophenyl)-8,9-dihydro-1-methyl-8-(4-morpholinylcarbonyl)-4H, 7H-cyclopenta(4,5)thieno(3,2-f)(1,2,4)-triazolo-(4,3-a)(1,4)di-

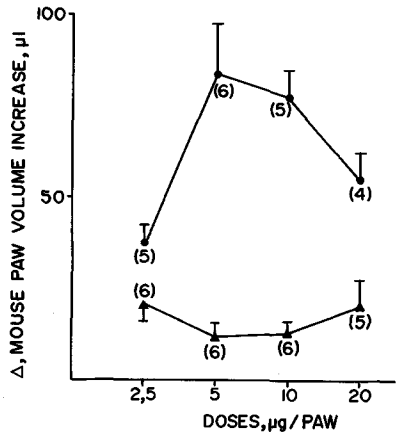

FIG. 1. Increase in mouse paw volume (µL) measured 30 min after intraplantar injection of ovalbumin (2.5–20 µg/paw); ●, sensitized animals; ▲, non-sensitized animals. Vertical bars indicate the mean ± SEM. Numerals in parentheses refer to the number of animals used.

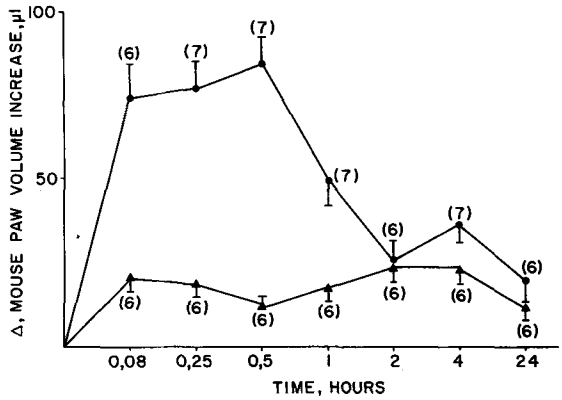

FIG. 2. Analysis of the time course of ovalbumin-induced edema in the mouse paw. The time is expressed in hr (0.08–24 hr). Each point represents the mean ± SEM of at least 5 animals; ●, sensitized animals; ▲, non-sensitized animals. The number of animals used is given in parentheses.

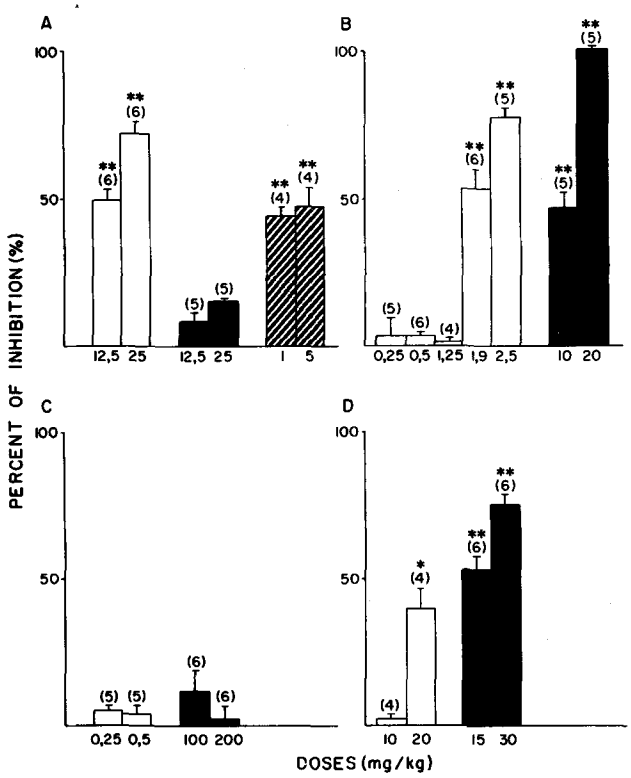

FIG. 3. Percent inhibition of ovalbumin-induced mouse paw edema by intraperitoneal pretreatment with synthesis and receptor antagonists. A, meclizine (12.5–25.0 mg/kg), open bar; cimetidine (12.5–25.0 mg/kg), solid bar; and methysergide (1–5 mg/kg), hatched bar. B, dexamethasone (0.25–2.5 mg/kg), open bar; prednisolone (10–20 mg/kg), solid bar. C, indomethacin (0.25–0.5 mg/kg), open bar; aspirin (100–200 mg/kg), solid bar. D, BW 755C (10–20 mg/kg), open bar; LY 171883 (15–30 mg/kg), solid bar. Vertical bars represent the mean ± SEM. The number of animals is given in parentheses; *, p< 0.01; **, p< 0.001 compared to control. Control groups consisted of at least six animals.

azepine) was kindly donated by Boehringer Ingelheim (Ingelheim, Germany) and the leukotriene D_4 antagonist LY 171883 (1-[2-hydroxy-3-propyl-4[4-(1H-tetrazol-5-yl)butoxy]pheny]ethanone) was kindly donated by Eli Lilly (Indianapolis, IN).

Statistical analysis. Results are reported as means ± standard error of the mean (SEM). The statistical significance of the differences between groups was calculated by analysis of variance by the method of Newman-Keuls.

RESULTS

Animals challenged with ovalbumin (2.5, 5, 10 or 20 µg) developed paw edema 21 days after sensitization (Fig.1). The maximal response, 80 µL, occurred with 5 and 10 µg ovalbumin; therefore 10 µg was used in further experiments. Analysis of the time course of this reaction (Fig. 2) showed an intense edematogenic reaction as early as 5 min after challenge, which reached a maximum at 30 min, and declined thereafter. In contrast, intraplantar injection of up to 20 µg ovalbumin failed to trigger edema in non-sensitized animals (Fig. 1).

Intraperitoneal administration of the H1 antihistaminic agent meclizine (12.5 or 25 mg/kg) and H2 antihistaminic agent cimetidine (12.5 or 25 mg/kg) to sensitized animals showed that only the H1 receptor inhibitor, meclizine, was effective in reducing the edema in a dose-dependent manner, with a maximum inhibition of 80% ($p < 0.001$) for 25 mg/kg (Fig. 3A). In addition, the figure shows that the anti-serotonin agent methysergide (1 or 5 mg/kg) caused a statistically significant inhibition (45%) of the response ($p < 0.001$) (Fig. 3A).

The cyclooxygenase inhibitors indomethacin (0.25 or 0.5 mg/kg) and aspirin (100 or 200 mg/kg), and the mixed cyclooxygenase and lipoxygenase inhibitor BW 755C (10 or 20 mg/kg) were used to examine the possible involve-

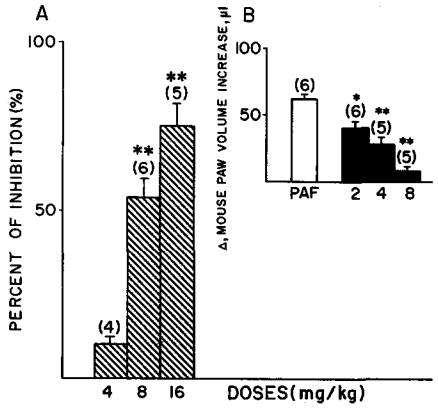

FIG. 4. A, Inhibition of ovalbumin-induced edema by WEB 2170, 4–16 mg/kg (hatched bar); B, Inhibition of PAF induced edema by saline (open bar) and WEB 2170, 2–8 mg/kg, (solid bar) in non-sensitized animals. The results are expressed as mean ± SEM. The number of animals is given in parentheses; *, p< 0.01; **, p< 0.001 compared to control. Control groups consisted of at least 6 animals.

ment of prostaglandins and leukotrienes. Indomethacin and aspirin did not interfere with edema, while BW 755C reduced it by 40% ($p < 0.01$) at 20 mg/kg (Fig. 3C, 3D). Dexamethasone was effective only at doses above 1.25 mg/kg (60% for 1.9 mg/kg and 80% for 2.5 mg/kg, $p < 0.001$). Prednisolone (10 and 20 mg/kg), reduced paw edema dose-dependently, with full suppression at 20 mg/kg ($p < 0.001$) (Fig. 3B). The intraperitoneal treatment of non-sensitized animals with the anti-PAF agent WEB 2170 (2, 4 and 8 mg/kg) inhibited dose-dependently ($p < 0.001$) the paw edema induced by the intraplantar injection of 2.5 μg PAF (Fig. 4A). Figure 4B shows that WEB 2170 8 and 16 mg/kg, administered i.p. caused a potent inhibition of ovalbumin-induced paw edema in sensitized mice ($p < 0.001$) at both doses. Finally, the LTD_4 inhibitor LY 171883 at a dose of 15 mg/kg reduced the increase of mouse paw edema by 55%, and reduced it by 75% at a dose of 30 mg/kg ($p < 0.001$) (Fig. 3D).

DISCUSSION

Administration of ovalbumin into the paw of sensitized mice triggered an edema which peaked within 30 min. The response started to decrease after intraplantar injection of 20 μg ovalbumin, probably because the antigen leaked into the circulation, triggering systemic shock. Shock was distinctly evident when antigen doses higher than 20 μg were injected, causing death of animals (data not shown). In contrast, control non-sensitized animals failed to respond to ovalbumin.

The use of specific antagonists indicated the participation of histamine *via* type H1 receptors, and of serotonin as reported by Kaneta *et al.* (13) in passive paw anaphylaxis of the mouse.

The fact that this reaction was not inhibited by the non-steroidal, anti-inflammatory agents indomethacin and aspirin, whereas both the cyclooxygenase and lipoxygenase mixed inhibitor BW 755C and the leukotriene D_4 antagonist compound LY 171883 interfered with edema, suggests that the cyclooxygenase metabolites of arachidonate are not involved in this type of anaphylactic model, in contrast to the lipoxygenase metabolites. These results differ from those observed in passive anaphylaxis of the rat by Ohuchi *et al.* (14) who found that leukotrienes do not participate in the reaction, but histamine and serotonin do.

The mechanism of action of steroidal anti-inflammatory drugs may involve the synthesis of phospholipase A_2 inhibitors, such as the lipocortins (15). The present results show that the glucocorticoid prednisolone suppresses the inflammatory response, whereas dexamethasone at doses that inhibit carrageenin-induced paw edema (0.25 and 0.5 mg/kg) (16) failed to interfere with the reaction and required doses as high as 1.9 mg/kg to be effective. Similar results were reported by Kaneta *et al.* (17) who showed that dexamethasone does not protect mice from passive paw anaphylaxis at doses of 0.1 mg/kg administered once a day for two days. On the basis of the model used by our group (edema by antigen *versus* edema by carrageenin), the different dose requirements for glucocorticosteroids confirm that these anti-inflammatory agents interfere with multiple targets and/or the synthesis of inhibitory proteins (18). In our study the specific antagonist WEB 2170 (19) was used. WEB 2170 has been recently found effective in inhibiting PAF-induced paw edema and pleurisy by Henriques *et al.* (20). Our present results confirm the previous data and show that the PAF antagonist WEB 2170 suppresses paw edema induced by PAF and by ovalbumin in sensitized animals, which suggests the participation of PAF in active anaphylaxis in mice.

[Received September 6, 1989, and in revised form July 1, 1991; Revision accepted August 31, 1991]

Pooling of Blood in Postischemic Shock Is Modulated by Platelet-Activating Factor (PAF)[1]

V.F. Sagach*[,a], A.V. Dmitrieva[a] and P. Braquet[b]
[a]A.A. Bogomolets Institute of Physiology, Kiev, USSR and [b]Institut Henri Beaufour, Le Plessis-Robinson, France

In experiments on dogs, *i.v.* administration of platelet-activating factor (PAF) (500 ng/kg) was shown to induce hypotension which, apart from decreased myocardial contractility, was characterized by blood pooling in veins (82.6 ± 6.8 mL/kg). This was accompanied by restriction of venous return to the heart and reduction of cardiac output (CO). During postischemic shock the cardio- and hemodynamic disturbances were similar to those induced by *i.v.* administration of PAF. In the postischemic shock model, preliminary blockage of PAF receptors with the PAF receptor antagonist BN 52021 (6 mg/kg, *i.v.*) significantly decreased the amount of blood pooled in shock from 38.7 ± 5 to 18.3 ± 2 mL/kg ($p<0.01$). Simultaneously, the reduction of CO and blood pressure, induced by reperfusion of the continuously ischemized tissues of a rear limb, was less significant in pretreated *vs.* the nontreated group. The data suggest that PAF may be involved in postischemic blood pooling and that PAF antagonists could be used to correct postischemic cardio- and hemodynamic disturbances.
***Lipids* 26, 1400–1403 (1991).**

In recent years, the development of a number of shock-related cardio- and hemodynamic disturbances has been attributed to lipid mediators, and particularly to platelet-activating factor (PAF). The administration of PAF to animals has been shown to produce systemic hypotension, inhibition of myocardial contractility, and reduction of cardiac output (CO). These disturbances are characteristic for shock (1,2). There is evidence for a protective effect by different PAF receptor antagonists on the cardiovascular system in endotoxic and anaphylactic shock. Terashita *et al.* (3) reported the protective effect of PAF antagonists in traumatic shock, while Sagach and Dmitrieva (4) noted similar effects in tourniquet shock. During traumatic shock, an increase of PAF content was found in peritoneal fluid (5). However, the precise mechanisms of the involvement of PAF in the shock-related development of cardio- and hemodynamic disturbances are still unclear.

The purpose of the present investigation was to clarify whether PAF is involved in postischemic blood pooling and in the development of hemodynamic disturbances.

MATERIALS AND METHODS

Twenty mongrel dogs were premedicated with Calipsol and then anesthetized with chloralose/urethane mixture (5 and 50 mg/kg, *i.v.*). Three series of experiments were carried out. In group 1 (n=13) postischemic shock was produced. Group 2 (n=5) was treated with PAF antagonist BN 52021 (6 mg/kg, *i.v.*) prior to reperfusion of the ischemic rear limb. PAF (500 ng/kg, *i.v.*) was administered in Group 3 (n=7).

Postischemic shock was modeled as follows. The left femoral artery and vein were ligated, and the left rear limb was ischemized using tourniquet for 3.5 hr. Then the ischemic rear limb was reperfused for 3 hr.

The right and left external jugular veins, main carotid arteries, subclavian arteries and right femoral artery and vein were exposed. A thermodilution CO catheter was positioned in the descending aorta through the left subclavian artery. The second catheter was placed in the left jugular vein for administration of cold solution. The left ventricle was catheterized through the left main carotid artery. The right and left external jugular veins were used for catheterization of the pulmonary artery and right atrium.

A special system for autoperfusion of coronary vessels was mounted. The right subclavian artery was catheterized, then the flow probe, offset to the pressure transducer, and a stiff metal catheter were connected in sequence. The metal catheter was placed in the aorta semi-lunar valves through the right main carotid artery, then turned around until it touched the opening of the left coronary vessels under pressure control. The amount of blood flowing from the subclavian artery to one of the left coronary artery branches was measured using an electromagnetic flow probe.

The vessels in the nonischemic rear limb were monitored by resistography, using pumps which perfused a constant volume of blood. The blood flowed from the femoral vein into a graduate burette, then was returned to the body by pumping through the proximal portion of the same vein.

The following hemodynamic parameters were measured: mean blood pressure, venous and pulmonary pressure, cardiac output (using the thermodilution method), coronary flow, left ventricular pressure and its first derivative (dP/dt), myocardial contractility (6), and total vascular, pulmonary and coronary resistance. In addition, we measured femoral mean filling pressure (7), compliance of venous vessels, and coefficient of capillary filtration (8). The amount of blood pooled was measured by means of a graduate burette in the resistography system. All indices were registered using a polycardiograph (Mingograph-82, Siemens-Elema, Berlin Germany).

C_{16}PAF (Novabiochem, Switzerland) was dissolved in dimethylsulfoxide (1 mg/mL) and diluted to the required concentration prior to injection. The PAF receptor antagonist BN 52021 (Institut Henri Beaufour, Plessis-Robinson, France) (6 mg/kg) was administered *i.v.* 15 min prior to reperfusion of the ischemic rear limb.

All data presented in the text and Figures are expressed as mean ± SEM of n observations. The differences within and between groups were analyzed using Student's *t*-test.

Abbreviations: CO, cardiac output; CVP, central venous pressure; LVEDP, left-ventricular end-diastolic pressure; MBP, mean blood pressure; PAF, platelet-activating factor; TVR, total vascular resistance.

A value of 0.05 or less was considered statistically significant.

RESULTS

The reperfusion of a continuously ischemic rear limb was accompanied by a gradual decline in mean blood pressure (MBP), which reached 52% of the initial level, or 68 ± 6.1 mm Hg ($p<0.001$), 3 hr after initiation of reperfusion. The development of hypotension was characterized by a drop of CO from 1864 ± 106 to 1003 ± 98 mL/min ($p<0.001$), which occurred without significant changes in total vascular resistance (TVR). The decrease in CO was associated with a reduction in myocardial contractility. Thus, the index of myocardial contractility decreased from 51.1 ± 3.2 to 33.3 ± 8 s^{-1} ($p<0.05$) 3 hr after initiation of the reperfusion. These changes were accompanied by a decrease in the circumflex coronary artery blood flow from 59.2 ± 5.8 to 37.4 ± 4.3 mL/min ($p<0.05$) without significant variation in coronary resistance.

Another major cause of reduced CO and subsequent hypotension was the restriction of venous blood return to the heart as exemplified by the decrease in central venous pressure from 2.2 ± 2 to −2.5 ± 1.1 mm Hg ($p<0.05$) and in left-ventricular end-diastolic pressure (LVEDP) to reach negative values. The decrease in venous return was associated with blood pooling in the periphery of the vascular bed, which resulted from the increase in compliance of venous vessels from 0.12 ± 0.01 to 0.56 ± 0.08 mL/mm Hg ($p<0.001$). The amount of blood pooled in the nonischemic rear limb was 38.7 ± 10 mL/kg. Decreased resistance and compliance of peripheral vessels could be attributed to the substantial fall in filling pressure of the rear limb's vascular bed, which decreased from 60.4 ± 3.3 to 13.2 ± 3.4 mm Hg at the end of the observation period (Fig. 1).

A similar pattern of cardio- and hemodynamic changes was noted following *i.v.* administration of PAF (500 ng/kg) (Fig. 2). Development of marked hypotension with a fall in MBP from 106 ± 6 to 47.4 ± 3.9 mm Hg ($p<0.001$) was accompanied by a sharp reduction in CO from 2251 ± 191

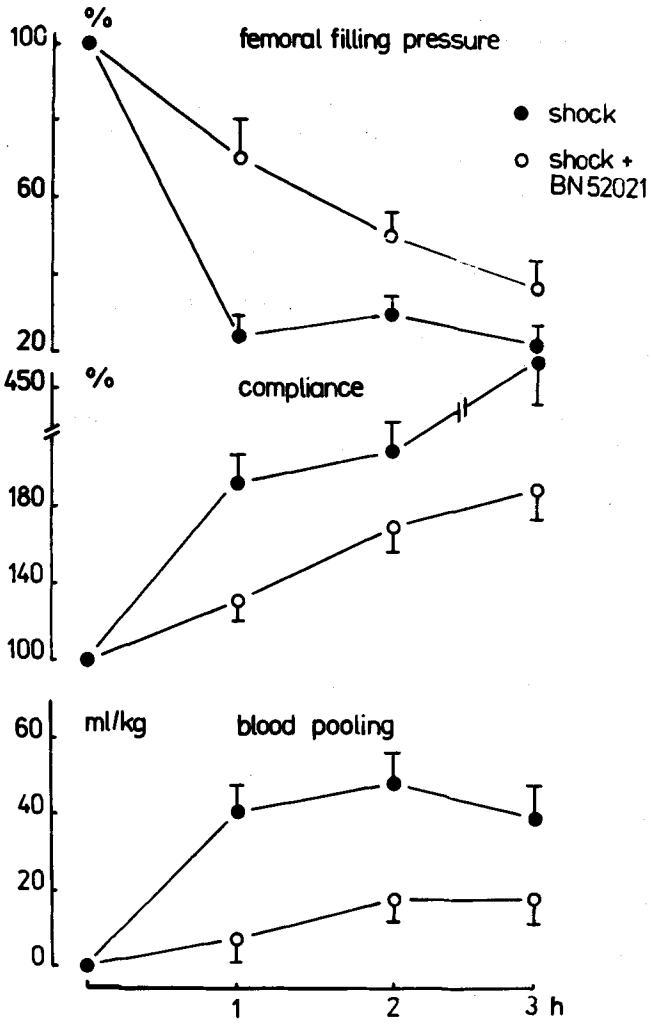

FIG. 1. Effect of the PAF antagonist BN 52021 on circulatory changes in the femoral vascular bed in postischemic shock reaction. The ordinates depict femoral filling pressure, compliance of venous vessels, and the amount of blood pooled; the abscissae depict the time of reperfusion. The data are expressed as means ± SEM.

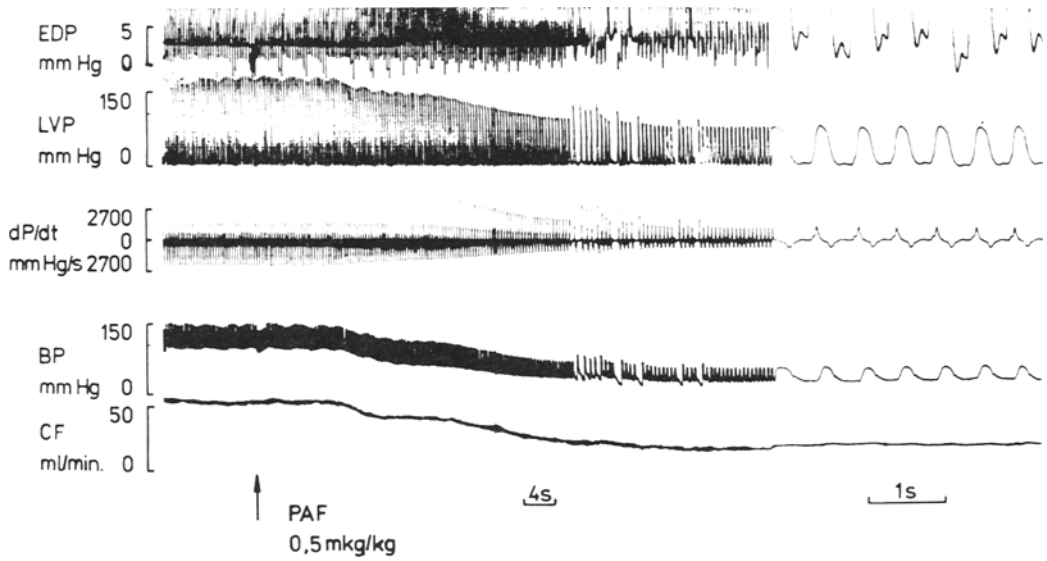

FIG. 2. Cardio- and hemodynamic changes in dog after *i.v.* PAF administration (500 ng/kg). Abbreviations: EDP, end-diastolic pressure; LVP, left-ventricular pressure; BP, arterial blood pressure; CF, coronary blood flow.

to 1181 ± 145 mL/min ($p<0.001$), and a decrease of the index of contractility from 55.8 ± 1.9 to 41.1 ± 2.7 s^{-1} ($p<0.001$). These animals showed marked signs of restriction of venous blood return to the heart due to blood pooling at the periphery of the vascular bed. The amount of blood pooled reached 86 ± 9.2 mL/kg and was accompanied by an increase of compliance of venous vessels from 0.27 ± 0.02 to 0.4 ± 0.037 mL/mm Hg ($p<0.01$) (Fig. 3). Apart from this, a significant increase in capillary permeability occurred: The coefficient of capillary filtration increased from 0.038 ± 0.005 to 0.055 ± 0.001 mL·mm $Hg^{-1}·g^{-1}·min^{-1}$ ($p<0.01$). The femoral filling pressure fell from 24.8 ± 3.8 to 11.7 ± 1.9 mm Hg ($p<0.02$); and central venous pressure (CVP) became negative.

Administration of BN 52021 prior to reperfusion of the ischemic rear limb significantly diminished both changes in cardiac function and in the phenomenon of blood pooling. In BN 52021 pretreated animals, the decrease in MBP was less marked, associated with a less significant reduction in CO, which fell from 1578 ± 118 to 1184 ± 131 mL/min ($p<0.05$). Inhibition of myocardial contractility was less pronounced in BN 52021 pretreated dogs. Thus, 3 hr after initiation of reperfusion, the left ventricular dP/dt was 37% lower than the initial value, while the inhibition in the nontreated group corresponded to 49%. In contrast to nontreated animals, the index of contractility changed from 52.8 ± 5.9 to 47.2 ± 5 s^{-1}. The decrease in CVR and LVEDP was only half of that of the nontreated group. These changes, indicative of restrictions in venous return and blood pooling, were less pronounced in BN52021 pretreated animals.

The compliance of venous vessels increased from 0.21 ± 0.02 to 0.4 ± 0.035 mL/mm Hg ($p<0.01$) *vs.* more than 400% in nontreated animals (Fig. 1). The amount of blood pooled was 18.3 ± 2.0 mL/kg.

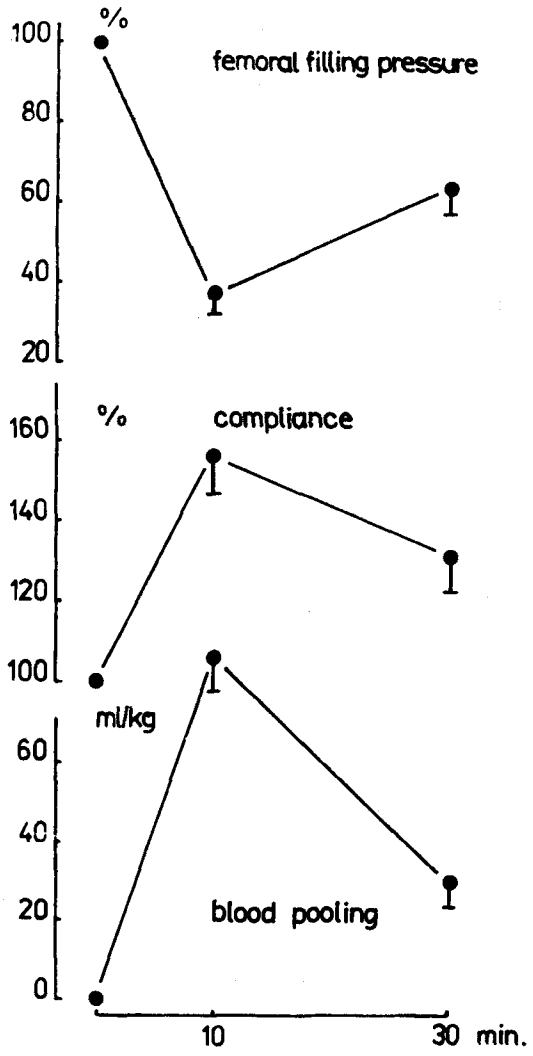

FIG. 3. Hemodynamic changes in the femoral vascular bed after PAF administration (500 ng/kg, *i.v.*). Coordinates and other details are as in Figure 1.

DISCUSSION

We have shown that hypotension, which develops following reperfusion of ischemic rear limb tissue, was associated with substantial blood pooling at the periphery of the vascular bed with subsequent restriction of venous return to the heart and decreased CO. PAF recently has been shown to participate in the development of lesions that occur in different organs and tissues in ischemia and subsequent reperfusion (9,10). PAF has been implicated as an important mediator in a variety of shock states, including anaphylactic (2,11), endotoxic (12), and traumatic shock (3,5). The capacity of PAF receptor antagonists to diminish hypotension and to preserve cardiac pumping and contractility functions suggest PAF involvement in shock reactions (1-3,12).

Our data show that blockage of PAF receptors by BN 52021 significantly decreased blood pooling, which developed due to increased compliance of peripheral venous vessels and due to increased capillary permeability, and thus reduced restrictions of venous return to the heart.

These effects of PAF on the cardiovascular system, namely its capacity to increase compliance of the veins, capillary permeability and pooling of blood in venous vessels, and the restriction imposed on venous return, have not been observed previously (1,13,14). Our results show that *i.v.* administration of PAF, apart from its known effects (systemic hypotension, decrease of coronary flow and myocardial contractility, pulmonary hypertension), may increase venous compliance, capillary permeability (*e.g.*, that of femoral vessels) and blood pooling. The latter is accompanied by the signs of restricted venous return to the heart (decrease of CVP, LVEDP, intravascular filling pressure) with subsequent reduction in CO. In a special series of experiments with stabilized venous flow to the heart, we showed that during *i.v.* administration of PAF the restriction of venous return to the heart was the major cause of reduced CO and hypotension (15). It is unclear whether this is a direct effect of PAF on the vessels, or whether it occurs *via* mediators capable of producing similar effects (16) that are released upon PAF stimulation.

In conclusion, it appears that blood pooling and subsequent hemodynamic disturbances in postischemic shock may be induced by PAF, and that PAF antagonists, such as BN52021, may be useful in attenuating these disturbances.

A neutral subfraction of mannan of bakers' yeast (WNM) was found to show a lethal effect in mice when administered intravenously. Symptoms caused by intravenous (i.v.) administration of WNM resembled those resulting from the administration of platelet-activating factor (PAF). CV-3988 and ONO-6240, selective PAF antagonists, prevented hypotension and death caused by the administration of WNM or PAF. A β-adrenoceptor agonist was shown to prevent death caused by WNM, whereas propranolol increased the lethal activity of WNM. Intravenous administration of WNM into mice produced PAF in gall bladder fluid which was determined by platelet aggregation assay. The findings indicate that WNM is able to induce PAF in mice and that the resultant PAF may participate in the WNM-induced lethal activity observed in mice.
***Lipids 26,* 1404–1407 (1991).**

A neutral subfraction of mannan of bakers' yeast (WNM) has been shown to cause various biological effects in mammalian systems such as antitumor effects against several transplantable tumors in mice (1–3), *Limulus* amoebocyte lysate-gelation activity (4), pyrogenicity in rabbits (5), and a mitogenic effect on murine splenic B-lymphocytes (6).

In the course of our studies of the biological effects of mannan, we found that WNM showed strong lethal activity in mice when it was administered intravenously (i.v.) (7), and that the acidic fraction of mannan from the same yeast containing phosphate, hexosamine, and chemically phosphorylated WNM was practically ineffective. We also demonstrated that the pretreatment of mice with D-mannose, D-galactose and dexamethasone (an anti-inflammatory steroid) protected the mice from death.

It is now well recognized that PAF shows a potent systemic hypotensive effect when administered either i.v. or orally (8,9). Myers *et al.* (10) reported that i.v. administration of PAF caused lethal shock in mice, and this could be prevented by pretreatment with cortisone acetate.

In the present paper, we report on the lethal effect of WNM in mice which we studied by using PAF agonists and antagonists.

Abbreviations: CV-3988, R,S-2-methoxy-3-(octadecylcarbamoyloxy)-propyl 2-(3-thiazolio)ethyl phosphate; DEAE, diethylaminoethyl; i.p., intraperitoneally; i.v., intravenous; LPS, lipopolysaccharides; ONO-6240, 1-*O*-hexadecyl-2R,S-*O*-ethyl-3-*O*-(7-thiazolipoheptyl)-glyceryl methanesulfonate; PAF, platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; WNM, a neutral subfraction of mannan of bakers' yeast (*Saccharomyces cerevisiae* wild type strain).

MATERIALS AND METHODS

Materials. C_{16} PAF (1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine) was purchased from BACHEM Feinchemikalien AG (Bubendorf, Switzerland). CV-3988, namely R,S-2-methoxy-3-(octadecylcarbamoyloxy)propyl 2-(3-thiazolio)ethyl phosphate, was provided by Takeda Chemical Industries, Co., Ltd. (Osaka, Japan). ONO-6240, namely 1-*O*-hexadecyl-2R,S-*O*-ethyl-3-*O*-(7-thiazolipoheptyl)glyceryl methanesulfonate was provided by ONO Pharmaceutical Co. (Osaka, Japan). Salbutamol, an agonist of β-adrenoceptors, and propranolol, an antagonist of β-adrenoceptors, were purchased from Sigma Chemical Co. (St. Louis, MO), and Nakarai Tesque, Inc. (Kyoto, Japan), respectively.

Preparation of the neutral fraction of mannan. The neutral mannan of bakers' yeast of a wild type strain of *Saccharomyces cerevisiae* (WNM) was prepared in accordance with the description by Suzuki *et al.* (3). Commercially available bakers' yeast was extracted with water at 140°C for 3 hr. After cooling, the extract was centrifuged and the residue was washed with water. The supernatant was concentrated *in vacuo*. The concentrated solution was poured into ethanol. The precipitate formed was collected and dissolved in water. Fehling solution then was added until the precipitation was completed. The mannan copper complex was washed several times with water, suspended in water, and concentrated HCl was added to dissolve the complex. The resultant solution was poured into ethanol, and the precipitate formed was collected by centrifugation. The crude polysaccharides were dissolved in water and passed through a column of Amberlite IR-120. The eluted solution was concentrated and precipitated with ethanol. The crude mannan fraction was dissolved in water, applied on a column of diethylaminoethyl (DEAE)-Sephadex (acetate type), and washed thoroughly with water. The eluate was concentrated and dialyzed against distilled water.

The results of the chemical analyses of WNM showed that the carbohydrate, phosphate, and nitrogen contents were 98.0, 0.0, and <0.3%, respectively. A *Limulus* amoebocyte lysate gelation assay showed that WNM was not contaminated with any bacterial lipopolysaccharides (LPS) (4).

Animals. ddY Strain male mice, 5 to 8 wk old, were obtained from Shizuoka Agricultural Cooperative Association for Laboratory Animals (Hamamatsu, Japan).

Assay of the effect of several drugs on the lethality of WNM in mice. The lethal effect of WNM was determined as described in a previous report (7). CV-3988 and ONO-6240 were administered i.v. to ddY mice, eight mice per group, at a dose of 10 mg/kg, 30 min before challenge with a lethal dose of WNM or at the time of WNM administration. The influence of β-adrenoceptors on lethality was measured as described by Criscuoli and Subissi (11). Salbutamol was used as an agonist and propranolol was used as an antagonist of β-adrenoceptors. Salbutamol and propranolol were administered intraperitoneally (i.p.) 30

min before WNM at doses of 1 mg/kg and 10 mg/kg, respectively. In all assays, mortality was expressed as the total number of dead mice from duplicate experiments, and percent of survival was calculated.

Assay of the effect of WNM and PAF on blood pressure of mice. Two groups of ddY strain mice, 10 mice per group, were given 10 mg/kg of CV-3988 or ONO-6240. Thirty minutes after CV-3988 treatment, or immediately after the administration of ONO-6240, 5 mg/kg of WNM was injected i.v. Blood pressure was measured until 30 min after the injection of WNM using the electric Rat-Mouse Manometer-Tachometer TK-350 (Unicom Co., Tokyo, Japan).

Detection of PAF in gall-bladder fluid from WNM-treated mice. The methods used were adopted from Doebber *et al.* (12). Mice were injected with 10 mg/kg of WNM i.v., and 10 min after injection, gall-bladder fluid was collected under anesthetized conditions. The lipid fraction in the bile was isolated according to the method of Bligh and Dyer (13) and was applied on a column of SEP-PAK Silica Cartridges (Waters Associates, Milford, MA) and eluted with chloroform, acetone, acetone/methanol (1:1, v/v), chloroform/methanol (7:3, v/v), and chloroform/methanol/water (10:20:8, v/v/v), subsequently. The finally eluted fraction was evaporated to dryness, and was designated as PAF specimen.

Bioassay of PAF by platelet aggregation. Rabbit blood, obtained by arterial puncture, was collected in a 3.8% trisodium citrate/citric acid buffer and processed as described by Benveniste *et al.* (14). The blood was centrifuged at room temperature for 10 min at 500 × *g* to obtain the platelet-rich fraction. Platelet aggregation by PAF was measured by a modified method described by Camussi *et al.* (15), using a platelet aggregation analyzer AA-100 (SYSMEX, Koube, Japan). A suspension of 0.25 mL containing 5 × 10^8 platelets/mL in HEPES-Tyrode buffer was added to a siliconized cuvette containing a Teflon stirbar revolving at 1000 rpm. After a 5-min delay to allow warming of cells to 37°C, 25 μL of aggregant was added and the resultant changes in light transmission were recorded as ΔT. Pretreatment of platelets with PAF inhibitor was also done with CV-3988, 25 ng, 30 min before treatment of samples.

RESULTS

Effects of selective PAF antagonists and β-adrenoceptor reagents on lethality of WNM in mice. As shown in Figure 1, CV-3988 (10 mg/kg) and ONO-6240 (10 mg/kg) lowered the lethality of WNM. CV-3988 increased the survival rate of mice from 25.0 to 77.7% and ONO-6240 from 25.0 to 100.0%. Following the administration of WNM at a dose of 20 mg/kg and propranolol at a dose of 20 mg/kg i.v., survival decreased. However, death of mice due to 50 mg/kg of WNM was completely prevented by salbutamol at a dose of 1 mg/kg, indicating that this β-adrenoceptor agonist is a very potent inhibitor of the WNM-induced lethal effect.

Inhibitory effects of PAF antagonists on hypotension induced by WNM. In order to test whether PAF was one of the substances causing hypotension in mice, the animals were pretreated with either of the two PAF antagonists. For this purpose, 10 mg/kg of CV-3988 or 10 mg/kg of ONO-6240 was administered 30 min before or simultaneously with WNM, and blood pressure changes

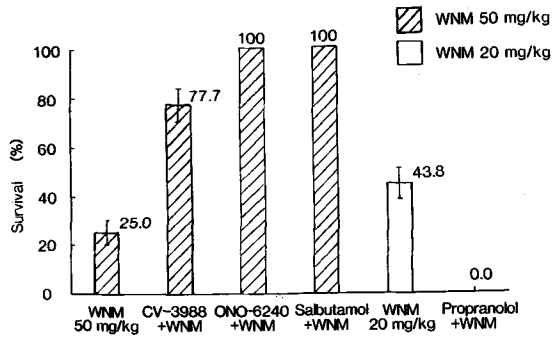

FIG. 1. Effect of several drugs on the lethal activity of WNM in mice. WNM (50 mg/kg): 50 mg/kg of WNM-treated group; CV-3988 + WNM, 10 mg/kg of CV-3988 was pretreated i.v. 30 min before 50 mg/kg of WNM administration; ONO-6240 + WNM, 10 mg/kg of ONO-6240 was administered i.v. at the same time with 50 mg/kg of WNM; Salbutamol + WNM, 1 mg/kg of salbutamol was pretreated i.p. 30 min before 50 mg/kg of WNM administration. WNM (20 mg/kg): 20 mg/kg of WNM-treated group; Propranolol + WNM, 10 mg/kg of propranolol was pretreated i.p. 30 min before 20 mg/kg of WNM administration. Figure shows mean survival percentage ± the standard error.

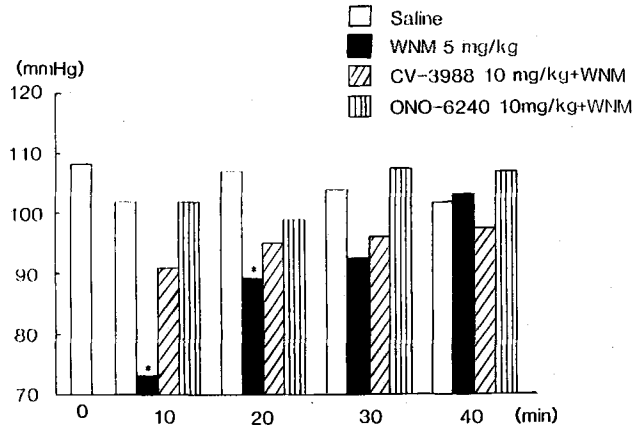

FIG. 2. Effect of PAF inhibitors on hypotension induced by WNM. Diagonal-lined bar, CV-39888 (10 mg/kg) pretreated i.v. 30 min before 5 mg/kg of WNM administration; vertical-lined bar, ONO-6240 (10 mg/kg) administered i.v. at the same time with 5 mg/kg of WNM; solid bar, WNM (5 mg/kg) in saline; open bar, saline control. * Indicates statistical significance between the experimental group and control group (P<0.05). Figure represents mean blood pressure of each sample.

in groups of mice given WNM alone or WNM plus PAF antagonists were measured. As shown in Figure 2, groups of PAF antagonist-treated mice showed no hypotension after receiving an i.v. injection of WNM at 50 mg/kg. The antagonists alone also showed no hypotensive effect.

Amount of PAF from gall-bladder fluid in WNM-treated mice. The results of this study indicate that i.v. administration of WNM induced *in vivo* PAF formation which caused various biological effects, including lethality. Therefore, we made an attempt to detect the PAF induced by WNM in gall-bladder fluid. The amount of PAF produced by administration of 10 mg/kg of WNM (0.13 pg/mouse) was estimated by measuring platelet aggregation and by comparing the aggregatory effect with that observed at various PAF concentrations (Fig. 3). Pretreatment with CV-3988 at a dose of 25 ng completely inhibited aggregation of platelets by gall-bladder fluid after the administration of WNM (data not shown).

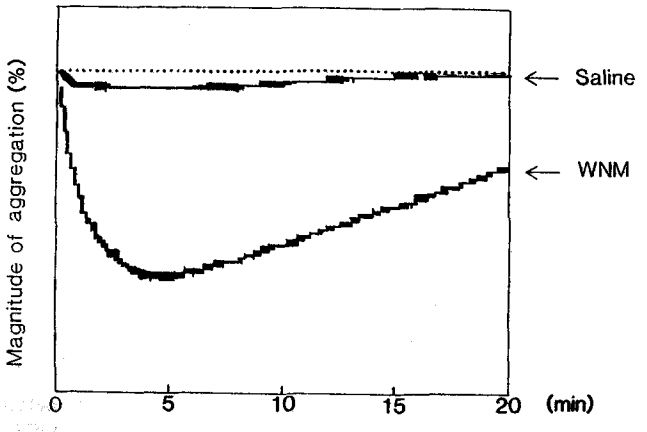

FIG. 3. Aggregation of rabbit platelets by gall-bladder fluid from WNM- or saline-treated mice. Platelet aggregation was assayed with a Sysmex AA-100 on 5 × 10^8 cells using 25 μL of sample at 37°C (20 min).

DISCUSSION

It has been reported (16–18) that cells of the yeasts *Candida albicans* and *Saccharomyces cerevisiae*, and an alkali-soluble extract of the mannan fraction from a cell wall preparation of *Candida albicans*, can elicit aggregation of rabbit platelets causing fibrin-platelet clots.

We previously also reported that WNM can act as a polyclonal B-cell mitogen, and that the effect was not due to contamination with bacterial lipopolysaccharides (LPS). The gelation activity of WNM was preserved upon treatment with 100 mM NaOH at 30°C for 48 hr, while bacterial LPS are not stable under these conditions. The results clearly demonstrated that *Limulus* amoebocyte lysate gelation activity of mannan was not due to contamination by bacterial LPS (4,6).

The present study revealed that the lethal effect of WNM is caused mainly by PAF produced by WNM. However, in a previous study (5) it was noted that the number of circulating platelets in mice treated with WNM did not change when compared with untreated-mice, and that administration of anti-platelet aggregating agents (*e.g.*, ticlopidine, indomethacin) did not inhibit the lethal effect of WNM. Mouse platelets cannot be aggregated by PAF (19) because these platelets lack PAF receptors (20). Therefore, WNM-induced lethality in mice must be mediated by some other mechanism.

Criscuoli and Subissi (11) reported that i.v. injection of PAF caused death in mice without causing platelet aggregation, and propranolol potentiated the effect of PAF (LD_{20}) in a dose-dependent fashion. On the other hand, salbutamol completely protected mice from PAF-induced death (LD_{80}). High doses of indomethacin, aspirin, benoxaprofen and FPL 55712 failed to counteract the lethal effect of PAF. Therefore, the authors concluded that manipulation of β-adrenoceptors affects PAF-induced death in mice, while 5-lipoxygenase and cyclooxygenase products derived from arachidonate do not appear to contribute to the lethal effect observed.

Biological and immunological effects of yeast mannan, containing a high-mannose type sugar chain, have been reported by several investigators (21,22). The existence of lectin-like proteins which bind with yeast mannan with high affinity has been demonstrated by Kawasaki *et al.* (23,24). One could further speculate that this mannan-binding protein serves as a carrier for the transport of glycoproteins by interacting with the oligomannoside-type carbohydrate chains. This transport is thought to occur, in the course of biosynthesis, from the rough endoplasmic reticulum to the Golgi.

In addition, IgE, an important allergic factor, has been shown to have high-mannose type sugar chains at its Fc portion which can react with the surface of mast cells (25). The structure of WNM, consisting of a linear chain with an α (1→ 6) linkage and side chains with α (1→ 2) and α (1→ 3) linkages, closely resembles the structure of high-mannose type sugar chains that are located on the cell surface of myeloid cells (26). The lethal effect of WNM in mice may thus involve the high-mannose type sugar chains that exist in mammalian glycoproteins.

Based on the results of our study, it appears reasonable to conclude that the factor that causes the lethal effect of WNM in mice is PAF. The observation points at the potential biological significance of high-mannose type carbohydrate chains located on various glycoproteins which may serve as the interacting sites.

ACKNOWLEDGMENTS

We are grateful to Takeda Chemical Industries Co., Ltd., and Ono Pharmaceutical Co., Ltd., Osaka, Japan, for kindly providing the PAF antagonists, CV-3988 and ONO-6240, respectively. We wish to thank Dr. W. J. Baumann for a critical reading and valuable advice for the manuscript.

Involvement of Platelet-Activating Factor in Zymosan-Induced Rat Pleurisy[1]

Yohsuke Imai, Masahiko Hayashi and Sachiko Oh-ishi*
Department of Pharmacology, School of Pharmaceutical Sciences, Kitasato University, Tokyo 108, Japan

The role of platelet-activating factor (PAF) in inflammatory reactions was studied in zymosan-induced rat pleurisy. Pleurisy was induced by injection of a 2% zymosan suspension into the pleural cavity of rats. The time course of pleural exudate accumulation, the exudation rate, and exudate leukocyte numbers were followed then for 96 hr. Peak pleural exudate accumulation was about 3 mL at 24 hr, whereas the exudation rate increased biphasically with peaks at 0.5 hr and 5 hr. The migration of leukocytes into the pleural cavity increased with time up to 48 hr. The polymorphonuclear leukocytes were the dominant white cells in the exudate between 5 and 16 hr, but mononuclear leukocytes started to outnumber them around 24 hr. Pretreatment with cyproheptadine (5 mg/kg), an inhibitor of both histamine and serotonin, significantly suppressed pleural fluid accumulation and the exudation rate at 0.5 hr. The PAF antagonist CV-6209 (1 mg/kg) significantly suppressed pleural fluid accumulation and the exudation rate at both 0.5 and 5 hr. At either time point, the parameters were not suppressed by indomethacin. We detected PAF activity in the high-performance liquid chromatography (HPLC) fraction (with a retention time corresponding to that of authentic PAF) of the exudates at 0.5 hr, 5 hr, and 16 hr using an aggregation bioassay with washed rabbit platelets. The results suggest that in zymosan-induced rat pleurisy, histamine and/or serotonin are the main mediators of exudation at 0.5 hr and that PAF may be partly responsible for exudation at 0.5 hr and later at 5 hr to 16 hr.
***Lipids 26,* 1408–1411 (1991).**

Platelet-activating factor (PAF) has been reported to exhibit a variety of biological effects including pro-inflammatory activities (1). PAF is synthesized by various types of cells, such as neutrophils (2), mononuclear leukocytes (3), and endothelial cells (4), as well as by lung (5) and amniotic (6) tissues. We previously suggested that PAF is a mediator for inflammatory exudation, based on our findings that a PAF-antagonist suppressed the exudation, and that PAF, in addition to histamine and PGI_2, was detected in the exudate when rat pleurisy was induced by phorbol myristate acetate (PMA) (7–9). When injected into the rat pleural cavity, PAF caused a vascular permeability increase and leukocyte accumulation (10,11). The factor also caused significant vascular permeability increases in rat skin and potentiated vascular permeability increases induced by other autacoids, such as histamine, bradykinin, and PGI_2 (8). In the present study, we further examined the role of PAF in the development of inflammatory exudation using zymosan-induced rat pleurisy.

Abbreviations: BSA, bovine serum albumin; HPLC, high-performance liquid chromatography; PAF, platelet-activating factor, 1-*O*-alkyl-2-*O*-acetyl-*sn*-glycero-3-phosphocholine; PMA, phorbol myristate acetate; UV, ultraviolet.

MATERIALS AND METHODS

Animals. Eight-week-old male Sprague-Dawley rats (Shizuoka Laboratory Animal Center, Hamamatsu, Japan) were used in this study. Male Japanese white rabbits (2–3 kg, Doken, Ibaragi, Japan) were used to prepare washed platelets.

Materials. 1-*O*-Hexadecyl- and 1-*O*-octadecyl-2-*O*-acetyl-*sn*-glycero-3-phosphocholine (C_{16}PAF, C_{18}PAF, Bachem Feinchemikalien, Bubendorf, Switzerland) were gifts from Funakoshi Pharmaceutical Co. (Tokyo, Japan). CV-6209 (2-[*N*-acetyl-*N*-(2-methoxy-3-octadecyl-carbamoyloxypropoxycarbonyl)aminomethyl]-1-ethyl-pyridinium chloride) and CV-3988 (*rac*-3-(*N*-n-octadecylcarbamoyloxy)-2-methoxypropyl 2-thiazolioethyl phosphate) were kindly supplied by Takeda Chemical Industries, Ltd. (Osaka, Japan). Zymosan A (Sigma, St. Louis, MO), indomethacin (Sigma), cyproheptadine (Nihon Merck Banyu Co., Tokyo, Japan), [^{3}H]C_{16}PAF (1-*O*-[^{3}H]hexadecyl-2-*O*-acetyl-*sn*-glycero-3-phosphocholine, 40 Ci/mmol)(New England Nuclear, Boston, MA), and SEP-PAK silica cartridges (Waters, Milford, MA) were obtained commercially.

The zymosan particles were washed with saline for 3 hr and autoclaved. Indomethacin and cyproheptadine were each prepared as emulsions in 0.5% sodium carboxy methyl cellulose solution at 5 mg/mL and injected intraperitoneally (i.p.) into the rats. CV-6209 was dissolved in saline (1 mg/mL) and intravenously (i.v.) injected.

Induction of rat pleurisy. Male Sprague-Dawley rats were intrapleurally injected with 0.1 mL of 2% zymosan suspension in saline under light diethyl ether anaesthesia and sacrificed by exsanguination at selected time points after injection in the same manner as for phorbol myristate acetate (PMA)-induced pleurisy (8). To assess the exudation rate, pontamine sky blue (PSB; Tokyo Kasei, Tokyo, Japan) solution (50 mg/kg) was injected intravenously 20 min before sacrifice (12). Either indomethacin or cyproheptadine was injected i.p. into rats at a dose of 5 mg/kg, 30 min before the zymosan injection. CV-6209 was injected i.v. at a dose of 1 mg/kg, 5 min before the inciter. The pleural exudate volume, the exudation rate, and the number and type of leukocytes in the exudate were measured as previously described (12).

PAF extraction and purification. PAF was extracted from the exudate and purified as described previously (7). The pleural exudates from 2–5 rats were pooled, immediately acidified to pH 3.0 in an ice bath, and centrifuged at 1,600 × *g* for 10 min at 4°C to separate the supernatant from the cell fraction. To determine recoveries, [^{3}H]C_{16}PAF was added as internal standard to the samples before extraction. The supernatants of the exudate and the cell pellets were extracted with methanol containing 2% acetic acid according to Bligh and Dyer (13). The lower layer was loaded on a SEP-PAK silica

cartridge, and the cartridge was washed sequentially with 10 mL aliquots of chloroform, acetone, acetone/methanol (1:1, v/v), and chloroform/methanol (7:3, v/v). PAF and choline-containing phospholipids were eluted with 11.4 mL of chloroform/methanol/water (1:2:0.8, v/v/v) and re-extracted by the Bligh and Dyer method (13). The combined chloroform layers were evaporated to dryness under reduced pressure. The residue was dissolved in 50 μL of isopropanol/hexane (1:2, v/v) for high-performance liquid chromatography (HPLC) separation. HPLC was performed with a Shimazu LC-3A system fitted with a μ-bondasphere silica column (Waters; 3.5 × 150 mm) and connected to a ultraviolet (UV) detector (Uvidec-V, Japan Spectroscopic Co., Tokyo, Japan). The fractions corresponding to the retention times of authentic C_{16}PAF and C_{18}PAF were eluted with isopropanol/hexane/water (110:100:20, v/v/v) at the flow rate of 0.4 mL/min, and the eluates were evaporated to dryness under reduced pressure. The residue was resuspended in Tyrode's solution containing 0.25% bovine serum albumin (BSA) and 1.3 mM Ca^{2+}, and used for the determination of PAF levels by the washed platelet aggregation method.

Washed rabbit platelet aggregation for PAF assay. Washed platelets were prepared from citrated rabbit blood as described previously (7). The number of platelets was adjusted to 10^6 cells/μL in Tyrode's solution containing 0.25% BSA and 1.3 mM Ca^{2+} (counted by Sysmex platelet counter PL-110, Tokyo, Japan), and aggregation was monitored with an aggregometer (Rikadenki RAM-31, Tokyo, Japan). The amount of PAF was calculated from the standard curve of authentic C_{16}PAF and corrected for losses in the extraction procedure. PAF in the sample was identified by the following criteria: i) inhibition of aggregation by CV-3988, and ii) suppression of the activity by treatment with phospholipase A_2, as previously reported (7).

Statistics. Statistical data evaluation was by Student's t-test. Differences with $p<0.05$ were considered significant.

RESULTS

Time course of zymosan-induced rat pleurisy. Figure 1 shows the time course of rat pleurisy induced by intrapleural injection of zymosan. The exudation volume, the exudation rate assessed by dye leakage during 20 min, and the leukocyte number in the exudate were examined up to 96 hr. The pleural exudate volume increased with time and peaked at 24 hr. The maximal volume was about 3 mL, and the volume then gradually decreased, but still amounted to about 0.13 mL even at 96 hr (Fig. 1). The exudation rate increased biphasically with peaks at 0.5 hr and 5 hr after the injection of zymosan, as shown in Figure 1. The first peak was transient but sharp, and corresponded to the initial rapid increase in exudate volume. The second peak at 5 hr was rather broad and corresponded to the gradual increase in exudate volume. Leukocyte migration into the pleural cavity occurred gradually and the total number increased until 48 hr, and slowly decreased thereafter up to 96 hr (Fig. 1). The total number of leukocytes in the exudate at 96 hr was still significantly higher than that of resident cells.

Classification of migrated leukocytes in the pleural exudate was done by microscopic examination of methanol-fixed specimens with Giemsa stain, as shown in Figure 2.

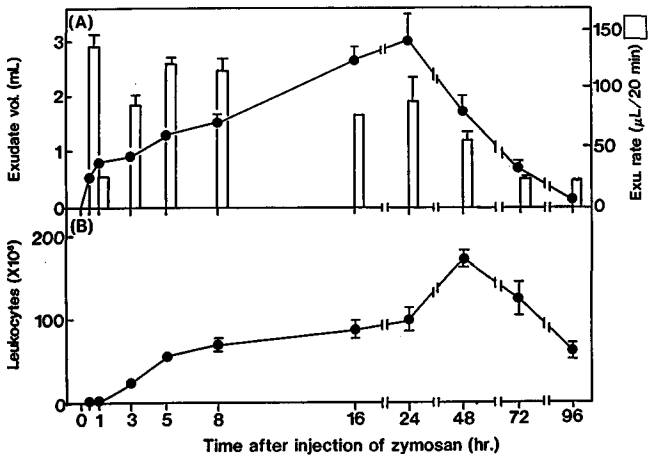

FIG. 1. Time course of zymosan-induced rat pleurisy. Rat pleurisy was induced by injection of 2% zymosan into the pleural cavity. The parameters indicated in panels (A) and (B) were determined at the indicated times after zymosan injection: (A) Pleural exudate volume (closed circles); exudation rate: rate of plasma exudation during 20 min before sacrifice (open column). (B) Infiltrated leukocytes counted in the exudate. Each value indicates the mean with standard error. The number of rats used were 4-16 for each group.

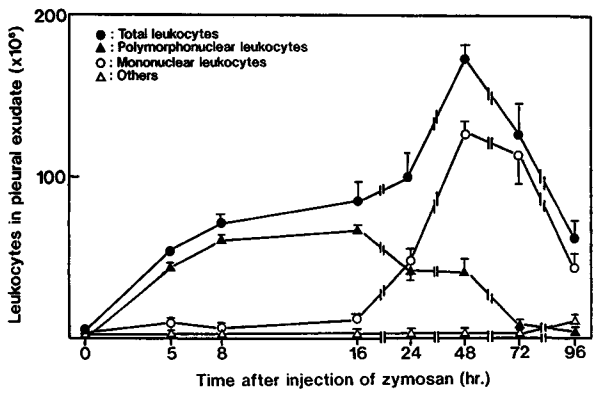

FIG. 2. Time course of leukocyte migration into the pleural cavity in zymosan-induced rat pleurisy. Classification of leukocytes was done on Giemsa-stained specimens of the exudate collected at the indicated times. The samples are the same as those in Figure 1. The type of leukocytes is shown by the following symbols: ●, total leukocytes; ○, polymorphonuclear leukocytes; ▲, mononuclear leukocytes; △, eosinophils and mast cells. Each value indicates the mean with standard error.

By this examination we could differentiate mast cells, eosinophils, polymorphonuclear leukocytes, and mononuclear cells. The latter cells included monocytes/macrophages and lymphocytes. Examination of a film sample of the exudate showed that polymorphonuclear leukocytes predominated up to 16 hr, and then decreased to half of their maximal number by 24 hr. After 16 hr, mononuclear cells started to increase in number and became predominant up to 96 hr. The number of mast cells and eosinophils did not change throughout the observation period until after 72 hr. The total number of eosinophils in the exudate at 96 hr was significantly higher than that at 72 hr.

Effect of selected inhibitors on rat zymosan pleurisy. As shown in Figure 3, the effects of indomethacin (5 mg/kg), CV-6209 (1 mg/kg), and cyproheptadine (5 mg/kg)

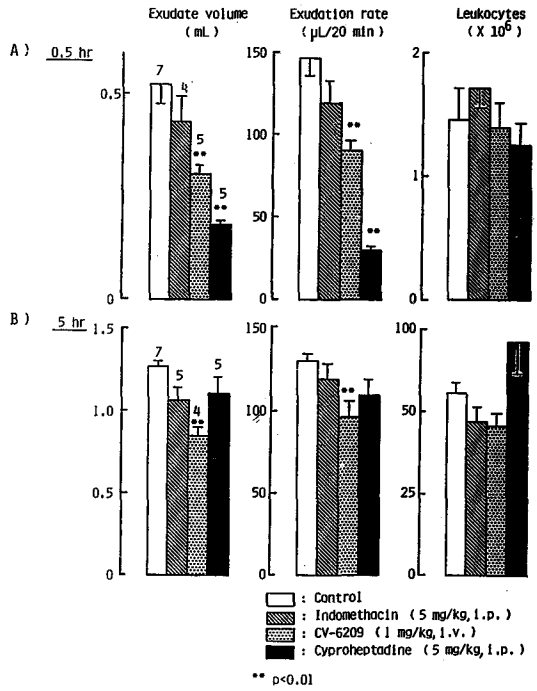

FIG. 3. Effect of various inhibitors on the rat zymosan pleurisy at 0.5 hr (A) and 5 hr (B). Cyproheptadine (5 mg/kg) and indomethacin (5 mg/kg) were injected intraperitoneally 30 min prior to the zymosan injection. CV-6209 (1 mg/kg) was injected into the tail vein 5 min prior to the zymosan injection. The data represent means with standard errors, with the number of rats examined indicated by the numerals above the columns. ** Values are significantly different at $p<0.01$ from those of the corresponding controls.

on the pleurisy were examined at 0.5 hr and 5 hr when the exudation rate peaked. Pretreatment with cyproheptadine, a dual inhibitor of histamine and serotonin, or CV-6209, a PAF antagonist, lowered the pleural exudate volume and the exudation rate significantly, but did not affect the leukocyte number of 0.5 hr pleurisy. Indomethacin had no effect. At 5 hr, only CV-6209 was significantly effective in reducing exudate volume and exudation rate.

Detection of PAF activity in the exudate of zymosan-induced rat pleurisy. Each supernatant and cellular fraction prepared from exudates pooled from 2–5 rats was extracted separately, and purified as described in Materials and Methods. PAF activity was detected and quantified in the pleural exudate of 0.5 hr, 5 hr, and 16 hr, as shown in Table 1. The HPLC fraction corresponding to authentic C_{16}PAF caused platelet aggregation, but no detectable activity was found in other fractions. The activity was suppressed by CV-3988 or treatment with phospholipase A_2 (data not shown), as indicated previously (7), suggesting that the activity in the exudate was due to intrinsic C_{16}PAF.

DISCUSSION

Rat pleurisy was induced by intrapleural injection of zymosan particles, which is known to activate an alternative pathway of the complement system (14). The time course of the accumulation of the pleural exudate of the

TABLE 1

PAF Activity in HPLC-Separated Fractions of Exudate of Rat Pleurisy Induced by Zymosan

Time after injection	Number of experiments[a]	ng/rat (C_{16}PAF equivalent)	
		Supernatant	Cell fraction
0.5 hr	5	0.662 ± 0.10	0.469 ± 0.16
5 hr	5	1.191 ± 0.20	3.068 ± 1.00
16 hr	5	0.590 ± 0.10	3.265 ± 0.94

[a]Each experiment was performed with a pooled sample from 2–5 rats. The amount of PAF, detected by the platelet aggregation method, was corrected for the percent recovery obtained by the extraction procedure. Final recovery rate was about 30–60%. Values indicate means with standard errors.

zymosan pleurisy was similar to that of carrageenin-induced pleurisy as previously reported (15). However, several details of the exudate formation were different. In the case of the zymosan-induced pleurisy, the exudation rate, assessed by dye leakage 20 min before sacrifice at the indicated time points, showed two peaks during the time course until 96 hr. The initial peak at 0.5 hr was sharp and of short duration; whereas the second one, at around 5 hr, showed a prolonged decay. However, in the case of carrageenin-induced pleurisy, the exudation rate showed only one peak, at 5 hr, and the exudation volume peaked at around 19–24 hr (15,16).

The main mediators of the exudation at the initial peak of the zymosan pleurisy seem to be histamine and/or serotonin and PAF, as judged by the result of pretreatment with cyproheptadine and CV-6209 (Fig. 3). Suppression of the pleural exudation by cyproheptadine was more pronounced than with CV-6209, suggesting that histamine and/or serotonin may be the main contributors to the exudation at 0.5 hr, with PAF being involved to a lesser extent. Simultaneous injection of cyproheptadine and CV-6209 lowered the exudate volume and exudation rate most significantly (data not shown). Exogenous PAF has previously been reported to induce exudate formation in the pleural cavity of rats (8). The fact that indomethacin did not affect exudation would indicate that cyclooxygenase products are not involved in exudation. The mediators involved at this stage appear to be similar to those involved in PMA pleurisy (except for cyclooxygenase products), as we reported earlier that histamine, PGI_2 and PAF were the main mediators of PMA pleurisy (7–9).

The exudation represented by the second peak was suppressed by CV-6209, but not by indomethacin or cyproheptadine. Even at 5 hr, the blood level of indomethacin may be effective, since the suppression of carrageenin-induced pleural exudation at 5 hr by indomethacin in rats has been reported (16). The specificity of CV-6209 was also shown, as this agent inhibited the effect of PAF, but did not inhibit histamine-, bradykinin-, or serotonin-induced vascular permeability increases in rat skin 0.5 hr or 5 hr after injection (data not shown).

PAF activity was detected and measured in the exudate at 0.5 hr, 5 hr, and 16 hr, and the PAF amounts were found to be similar to those found in PMA pleurisy (7). However, the amount of PAF found in the supernatant of the exudate did not parallel the exudate volumes at the

respective time points. This supports the idea that PAF is just one of the mediators responsible for the exudation, and agrees with our finding that histamine and/or serotonin may foremost be responsible for the exudation seen at 0.5 hr. It remains possible that mediators other than PAF may be involved in the exudation at 5 or 16 hr. This will need to be further investigated in the future.

As for the source of the mediators at these two stages of exudation, it seems likely that in the early stage (0.5 hr) the histamine and/or serotonin may be derived from mast cells and PAF may be synthesized from resident mononuclear leukocytes in the pleural cavity. We could only define the latter cells as those containing a round nucleus and being differentiable from polymorphonuclear leukocytes, mast cells, or eosinophils by Giemsa staining. We also recognized degranulated mast cells in the 0.5 hr specimens. The source of PAF at 5 and 16 hr may be the polymorphonuclear leukocytes, as the latter cells were the dominant type in the exudate at these time points. Furthermore, we detected a significant level of PAF synthesis by rat polymorphonuclear leukocytes *in vitro* (17). However, additional work will be required to accurately define the cells that synthesize PAF.

PAF was reported to induce eosinophil accumulation in the airways of guinea pig (18); however, we did not observe eosinophil accumulation in rat pleural cavity up to 72 hr and found only a slight increase at 96 hr. The reason for this difference is not clear but may be partly attributable to a species difference.

Our results agree with the report of Martins *et al.* (19), who demonstrated that the exudation of zymosan-induced rat pleurisy after 4 hr was suppressed by the PAF antagonist WEB-2086 and who hence suggested PAF involvement. By contrast, Vannier *et al.* (20) reported that indomethacin reduced pleural exudation and leukocyte numbers in pleurisy induced by the intrapleural injection of zymosan-activated serum (0.5 mL) into rats. Our data are consistent with the former results, but not with the latter. This may be due in part because we used boiled zymosan particles without pretreatment with serum (complement). However, the particles could make contact with serum components in the pleural fluid after injection, and then a small amount of complement activation could occur initially to induce histamine release (21). The involvement of the complement components in this pleurisy model needs to be studied further. Nevertheless, we can conclude that in the zymosan pleurisy model PAF is one of the main mediators of exudation.

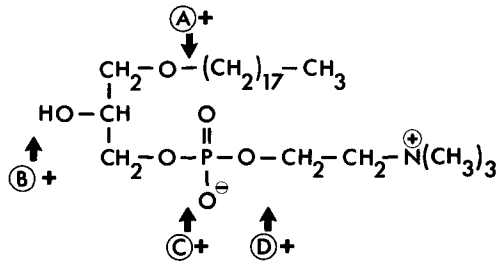
REVIEW

Hexadecylphosphocholine: Preclinical and the First Clinical Results of a New Antitumor Drug[1]

Clemens Unger[a,*] and **Hansjörg Eibl**[b]

[a]Division of Hematology/Oncology, Department of Internal Medicine, University Hospital Göttingen and [b]Max-Planck-Institute for Biophysical Chemistry, D-3400 Göttingen, Federal Republic of Germany



Dose-response studies on cytotoxic alkyl lysophospholipids with various chemical structures revealed that a long alkyl chain and a polar group are essential for antitumor activity. The combination of both the long alkyl chain and a phosphocholine group thus results in alkyl phosphocholines. Preclinical studies with hexadecylphosphocholine (He-PC) as a representative compound indicate distinct antineoplastic activity on leukemia cells of human origin. He-PC is highly effective in inhibiting the growth of chemically induced rat mammary carcinomas. Even more striking is the fact that a high percentage of the tumors regressed completely. In a clinical phase I trial on breast cancer patients with local recurrences, topically applied He-PC resulted in regression of skin metastases. A phase II trial for topical treatment and a phase I trial for orally applied He-PC have been initiated to further evaluate the antitumoral activity of this new compound. *Lipids 26,* **1412–1417 (1991).**

From the group of alkyl lysophospholipids, it is known that 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (PAF) is a thrombocyte stimulating and aggregating factor (1). The factor is mainly produced by blood cells and possesses biological activity in concentrations of as low as 10^{-10} moles/L. Furthermore, PAF has a strong blood pressure lowering effect, is produced *in vivo* during IgG induced shock and is an important mediator in allergies and inflammatory states (2).

The hydrolysis of a fatty acid chain in diacyl phospholipids by phospholipase A_2 leads to monoacyl phospholipids, the so-called lysophospholipids. A relatively constant concentration of lysophospholipids in cell membranes is maintained by the cell. This is necessitated by the fact that lysophospholipids have potent surface active properties and can destroy cell membranes at critical concentrations (approximately 20 mole% of cell membrane phospholipids) (3,4).

A number of observations made in recent years have underlined the importance of lysophospholipids in cell biology. Lysophospholipids stimulate macrophage phagocytosis (5,6), enhance the humoral immune response, and influence the development of delayed hypersensitivity reactions (7). Furthermore, lysophospholipids alter the surface properties of erythrocytes and thereby their agglutinating ability (8). They also promote cell fusion (9) and have been shown to affect the activity of several enzymes *in vitro* (10–12).

As already mentioned, the low and non-toxic level of lysophospholipids naturally present in biological membranes is maintained by the interplay of several phospholipid metabolizing enzymes. Under physiological conditions, membrane destruction and cell lysis do not occur. Correspondingly, the metabolic half-life of these structures is very short. For this reason, in the early 1970s, Westphal, Eibl and Weltzien synthesized ether analogs of lysophospholipids which were largely protected from attack by phospholipid metabolizing enzymes (13–16).

SCHEME 1. Chemical structure of alkyl lysophosphocholines and various attack sites of phospholipid metabolizing enzymes. A, alkyl cleavage enzyme; B, acyltransferase; C, phospholipase C; D, phospholipase D.

Scheme 1 shows the chemical structure of an ether lysolecithin and potential attack sites of phospholipid metabolizing enzymes. The replacement of the ester bond in the *sn*-1 position by an ether linkage endows this lysophospholipid with novel biological properties—it becomes antiproliferative and cytotoxic towards tumor cells, while its physicochemical properties remain largely unchanged. The cytotoxic properties can be considerably enhanced by substituting the *sn*-2 hydroxyl group, which results in compounds which cannot be reacylated. These structural characteristics are represented in the alkyl lysophospholipid prototype 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine (ET18-OCH_3). This ether lipid exhibits an unusually broad spectrum of biological

properties such as macrophage activation to cytotoxic effector cells, malignant cell differentiation, inhibition of tumor cell invasiveness in normal tissues and direct cytotoxic effects on tumor cells *in vitro* and *in vivo*. Comprehensive overviews have been presented by Berdel and Munder (17,18). Based on *in vivo* investigations, the direct cytotoxic effect of ET18-OCH_3 appears to be due to its accumulation in tumor cells. According to investigations by Snyder's group, many neoplastic cells are lacking an *O*-alkyl cleavage enzyme (19). It was suggested that lack of the enzyme in tumor cells may lead to an accumulation of alkyl lysophospholipids (ALP) in tumoral tissue, whereas normal cells would be able to metabolize ALP (18). However, more detailed studies on various tumor cells with different levels of *O*-alkyl cleavage enzyme showed that ET18-OCH_3 levels were not controlled by *O*-alkyl cleavage enzyme (20) and that ET18-OCH_3 is not a substrate for the *O*-alkyl cleavage system (21).

In recent years our Göttingen group has intensively studied the structure-activity relationship of alkyl lysophospholipids and has analyzed the structural requirements which determine the substrate properties of the most important phospholipid metabolizing enzymes, e.g., alkyl cleavage enzyme, acyl transferases and the phospholipases C and D (20–30). In summary, the results indicate that cytotoxic alkyl lysophospholipids have to fulfill two requirements: (i) reacylation in the *sn*-2-position must be prevented; and (ii) the substrate characteristics for phospholipase C and/or D must be preserved. These principles were translated and simple molecules which possess the suggested minimal structural requirements for cytotoxic activity were synthesized (31).

ALKYL PHOSPHOCHOLINES: A NEW CLASS OF ANTITUMORAL AGENTS

According to the rationale mentioned above, we prepared molecules which have a long alkyl chain directly connected to the phosphocholine moiety. Compared to the alkyl lysophospholipids, the alkyl phosphocholines lack the glycerol backbone, and they are only metabolized by action of the phospholipases C or D. All of the following investigations were carried out with hexadecylphosphocholine (He-PC) (Scheme 2).

SCHEME 2. Chemical structure of hexadecylphosphocholine (He-PC) as a representative of alkyl phosphocholines.

Preclinical investigations: physical properties. The physical properties of hexadecylphosphocholine were compared to 1-palmitoyl-*sn*-G-3-PC, which represents a lysophospholipid that occurs naturally in biomembranes (Table 1). The Table summarizes the critical micellar concentrations (CMC) and values for the hemolysis of human erythrocytes and for the oil/water partition. The similarity of the values for micelle formation and for hemolysis is not surprising, as both mechanisms depend on a common property—the surface activity which involves formation of micelles, but also results in the reorganization of lipid bilayer.

TABLE 1

Physical Properties of Hexadecylphosphocholine and 1-Palmitoyl-*sn*-Glycero-3-Phosphocholine

Parameter	Hexadecylphosphocholine	1-palmitoyl-*sn*-G-3-PC
log p[a] (olive oil/water)	−1.48	−1.52
log CMC[b] [mol/L]	−5.10	−5.22
log 50% hemolysis[c] [mol/L]	−5.22	−5.28

[a] Logarithm of the olive oil/water partition coefficient.

[b] Logarithm of the critical micelle concentration.

[c] Logarithm of the 50% hemolysis value after incubation of human erythrocytes with the compounds for 5 min.

As known from previous reports, micelle formation and the hemolytic properties of lysophospholipids critically depend on the length of the carbon chain (3,29). This particularly applies to the oil/water partition coefficients. Thus, the physical properties of hexadecylphosphocholine closely resemble those of the naturally occurring membrane lysophospholipid 1-palmitoyl-*sn*-G-3-PC.

However, despite the similarity of their physical properties, the two compounds behave quite differently with respect to antitumor activity. Whereas hexadecylphosphocholine is antitumor active, 1-palmitoyl-*sn*-G-3-PC is not. This suggests that the antineoplastic activity of hexadecylphosphocholine cannot be explained by its surface active property.

Cell experiments. The *in vitro* cytostatic and cytotoxic activity of He-PC was determined on four human leukemic cell lines: HL60 and U937 (promyelocytic leukemia) Raji (Burkitt's lymphoma) and K562 (erythroleukemia). The cells were incubated in RPMI medium at different concentrations of He-PC for up to 72 hr. The 50% growth inhibition dosage (ID-50) after 48-hr incubation was calculated by the loss of [^{3}H]thymidine incorporation into cellular DNA. The trypan blue dye exclusion assay was used to determine the half lethal dosage (LD-50). *In vitro* investigations of He-PC revealed concentration dependent cytotoxicity and growth inhibition for HL-60 cells (Fig. 1). ID-50 and LD-50 values (Table 2) were calculated from dose response curves after 48 hr of incubation when cell growth was in logarithmic phase. The data indicate that HL60 and U937 cells were highly sensitive, Raji were moderately sensitive and K562 were of low sensitivity in respect to He-PC. Susceptibility ranking of the four cell lines was similar in both test systems and corresponded to results obtained for alkyl lysophosphocholines such as ET18-OCH_3 in earlier experiments (20,21). It has to be stressed again that the cytotoxic effects observed in these experiments cannot be explained by the surface active properties of hexadecylphosphocholine. In fact, co-cultured erythrocytes remained viable up to the highest doses used (40 μg/mL, 72 hr) and did not show hemolysis.

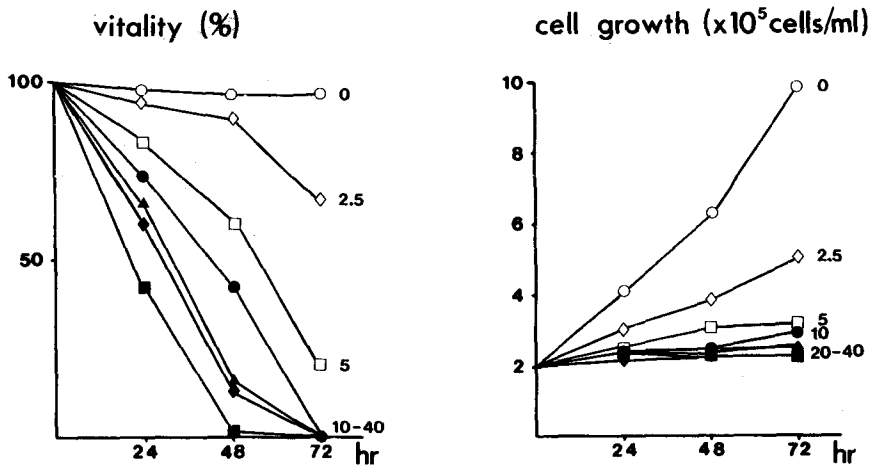

FIG. 1. He-PC dose dependent toxicity and inhibition of proliferation of the HL60 leukemia cell line. Cells (2×10^5) were cultured for 24, 48 and 72 hr in the presence of 2.5 to 40 μg/mL of He-PC. At each point in time, the number of total cells was counted and the number of dead and alive cells was determined. Data represents the mean for 3–6 independent experiments; S.D.s were less than ± 10%.

TABLE 2

Differential Sensitivity of Leukemia Cell Lines to Hexadecylphosphocholine[a]

Cell line	He-PC (μg/mL)	
	ID_{50}	LD_{50}
HL 60	5.0	7.7
U 937	3.0	16.0
Raji	10.0	26.0
K 562	15.0	>40.0

[a]Cells were incubated for 48 hr. ID_{50} values were obtained from [^{3}H]thymidine incorporation. LD_{50} values were obtained by trypan blue dye exclusion test.

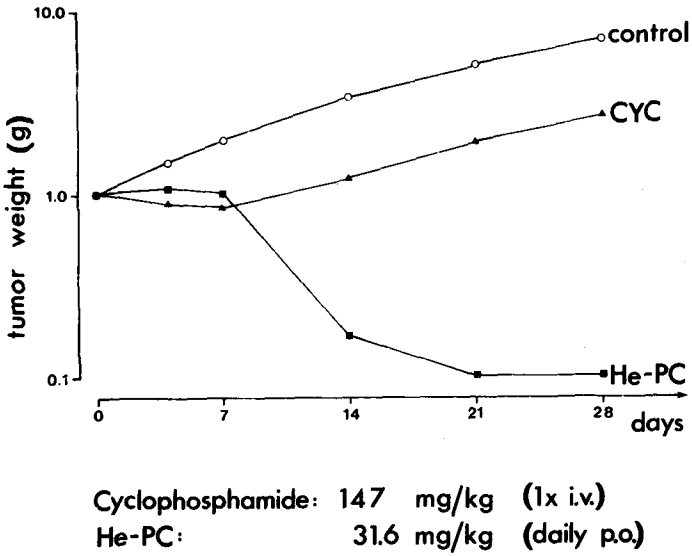

FIG. 2. Antineoplastic activity of He-PC in comparison to cyclophosphamide on DMBA induced rat mammary carcinoma. Dosages: He-PC 31.6 mg/kg body wt daily p.o. for 28 days; cyclophosphamide 147 mg/kg body wt as a single i.v. injection (maximally tolerated dosage).

Animal experiments. It has long been known that alkyl lysophospholipids (e.g., ET18-OCH_3) have reproducible cytostatic effects on chemically induced, autochthonous breast carcinomas in rats (32). In a series of experiments, two alkyl lysophospholipids (ET18-OCH_3 and the thioether BM41.440) were compared with octadecyl phosphocholine and hexadecyl phosphocholine on methylnitrosourea (MNU)-induced breast carcinoma in the rat (33,34). The optimally nontoxic dose was administered orally q.d. over a period of five weeks. All substances tested in this series showed distinct antitumor activity. Of particular interest is the fact that there was no mortality in the groups treated with alkyl phosphocholines, whereas in the groups treated with the alkyl lysophospholipids (ALP) 13% and 17% of the animals died. Another interesting observation was the complete tumor remission in the group treated with hexadecyl phosphocholine and octadecyl phosphocholine. This finding motivated us to further investigate the antineoplastic activity of He-PC in another carcinogen induced breast carcinoma (DMBA) in the rat (35). Also in this tumor model, the oral administration of He-PC in concentrations of 4–46 mg/kg BW led to a dose-dependent tumor growth inhibition and led to a high number of complete remissions at doses above 20 mg/kg BW. Figure 2 shows the effect of He-PC (31.6 mg/kg BW q.d., orally) compared to the maximal tolerable dose of cyclophosphamide (147 mg/kg BW once-time dose i.v.). One can see that in the first few days cyclophosphamide retards tumor growth, but after a week the tumor continues to grow. In the case of He-PC therapy, after about three weeks, complete tumor remission is achieved. Interestingly, all animals in which there was a complete disappearance of macroscopic tumors, suffered a relapse within a short time after cessation of therapy. Whether or not this represented regrowth of previously suppressed tumors, or the development of new tumors, is currently under investigation. In all experiments, tolerance of the

He-PC was extremely high and toxic effects were not observed. It must also be pointed out that hexadecyl phosphocholine shows no hematotoxicity (35). Leukocyte count in blood remains unchanged, but after one week the leukocyte count increases at doses of 46 mg/kg BW, remains constant for the remainder of the therapy, and then returns to normal after discontinuation of treatment. Microscopic studies revealed that the leukocyte increase can be attributed to mature granulocytes. The cause for the leukocyte increase remains unknown. It may be due to a cell redistribution from tissues to vasculature as could be observed after glucocorticoid therapy. On the other hand, granulocyte macrophage-colony stimulating factor (GM-CSF) release might be the cause.

Finally, it must be stressed that the activity of He-PC against experimental tumors appeared to be extremely selective. No response was seen against transplantable rat tumors such as DS-carcinosarcoma, the leukemias L5222, L1210, P388 or the Lewis lung carcinoma (35). Recently, however, we found that a human head and neck tumor transplanted into nude mice was highly sensitive to He-PC (data not shown).

Biodistribution and He-PC metabolism. Biodistributional studies after oral administration of He-PC in mice showed that He-PC is absorbed at high rates from the intestine. Based on this, clinical oral treatment regimens appear feasible (36). This finding is in line with other reports showing that ET18-OCH_3 and the thioether BM41.440 are well absorbed from the intestinal tract (37,38). The highest accumulation of He-PC was found in liver, kidney and lung, which is similar to what was observed for ET18-OCH_3.

The metabolism of He-PC was investigated in the mouse liver (36). After oral administration of He-PC labelled in the polar head group, the time-dependent formation of radiolabelled choline, phosphocholine and 1,2-diacyl-glycerophosphocholine was observed, which suggests the importance of phospholipases C and D in He-PC catabolism. Studies on the hydrolysis of He-PC *in vitro* carried out with phospholipase C *(bacillus cereus)* and phospholipase D (partially purified from cabbage) support the finding that He-PC is a substrate for these enzymes. Formation of 1,2-diacyl-glycerophosphocholine, labelled in the polar head group, is consistent with earlier results obtained with ET18-OCH_3 (24,25). In the latter study, we were able to demonstrate that the labelled phosphocholine group was transferred from ET18-OCH_3 to 1,2-diacylglycerol resulting in the formation of phosphatidylcholine.

Clinical investigations. The favorable results of the animal experiments on chemically induced breast carcinomas in the rat motivated us to use hexadecylphosphocholine as the first of the alkyl phosphocholines in clinical trials. After completion of the toxicological studies, two forms of administration were selected for clinical use. Firstly, topical application for treatment of skin metastases of the cutaneously metastasizing breast carcinoma (39) and, more recently, oral administration for testing the tolerance and effectiveness on solid metastasizing tumors.

Topical application. For the topical application, hexadecylphosphocholine was dissolved in a mixture of 1-*O*-alkylglycerols with C_3 (1-*O*-propylglycerol), C_6 (1-*O*-hexylglycerol) and C_9 (1-*O*-nonylglycerol) chain lengths in water. The resulting mixture called KASKADE for short (Table 3) is slightly viscous and can be applied to the skin easily. 1-*O*-Alkylglycerols were chosen as carrier for He-PC, because the amphiphilic molecules can permeate the membrane and thereby change membrane permeability. We were able to demonstrate this using the blood brain barrier model (40). For example, cyclophosphamide has an uptake index of 11% for rat brain. However, if cyclophosphamide is injected together with propylglycerol, butylglycerol or pentylglycerol into the arteria carotis of the rat, the brain uptake index is increased with increasing chain length (up to C_9) of the alkylglycerol carrier (40). Similar results were obtained with other cytostatic agents. As a possible mechanism of action, we suspect that short chain alkylglycerols can cause a short-term membrane perturbation and, as a consequence, cause increased permeability for the drugs. A second favorable characteristic of alkylglycerols is their bactericidal and fungicidal activity (39). Here, too, the longer chain alkylglycerols exhibit a greater antimicrobial effect. It should also be mentioned that the 1-*O*-alkylglycerols used in the formulation have some antineoplastic properties of their own (41) which might add to the therapeutic effects of the solution for topical treatment.

[a]20–80 mg He-PC/mL Kaskade.

Within the framework of the clinical phase I trial, local recurrences on the skin (partialiy exulcerated) in patients with metastatic breast carcinoma were treated with local cascade administration. After written consent, the substance was applied once a day for five days. In the case of proven local tolerance, the substance was applied twice a day for further treatment. The patient characteristics can be seen in Table 4. Altogether, 25 patients were treated in the phase-I trial, 24 were evaluated. All patients were extensively pre-treated. We observed three complete remissions, four partial remissions, eight no changes and nine progressive diseases. The good local tolerance of the mixture was striking. Cutaneous adverse effects observed were average dryness of the skin, epithelial scaling and, in individual cases, itching.

Reports on three of the patients treated. Patient 1. A 36-year-old woman with multiple, flat skin metastases in the peripheral area which had been treated with radiation therapy. Diameter of metastases was up to 2 cm; in the middle a large, solid node was visible. Chemotherapy was not possible as a consequence of hemolytic uremic syndrome. This patient showed a complete regression of the skin metastases, including the solid node, after eight weeks of topical treatment. The histological results from a skin biopsy after three months of treatment revealed normal architecture with a slight increase in collagen content.

TABLE 5

Pharmacokinetic Parameters of Hexadecylphosphocholine in Rats After a Single Oral Dose of 200 mg/kg Body Weight[a]

Parameter	
AUC, 0-240 hr (mg × hr × L^{-1})	6200
λ_z	0.0072
C_{max} (mg × L^{-1})	39.2
t_{max} (hr)	48
$t_{/2}$ (hr)	96
Cl (mL × min^{-1})	0.53
V_d (L × kg^{-1})	4.7

[a]AUC, area under the curve; λ_z, rate constant for terminal elimination; C_{max}, maximum serum concentration; t_{max}, time of maximum serum concentration; Cl, clearance; $t_{/2}$, half-life for the terminal elimination, V_d, distribution volume.

Patient 2. A 45-year-old woman had marked exulcerated local recurrence. She died five weeks after treatment was initiated. After five weeks of local therapy increasing epithelial proliferation occurred in the periphery of the exulceration. This patient's histological findings of an untreated area of skin showed large tumor cell clusters extending into the subcutaneous layer. In the treated area, one could see heavily damaged tumor cell clusters.

Patient 3. A 68-year-old patient had undergone a bilateral mastectomy with a marked local recurrence. After an 8-week course of therapy, a partial remission of metastases had occurred.

The general local tolerance of the cascade is striking. Systemic adverse effects are completely absent. It should be particularly stressed that neither hematotoxic nor other blood chemistry changes could be observed. Recently, a multicenter study on this type of topical skin carcinoma therapy has been initiated in the Federal Republic of Germany.

Oral administration. The goal of this phase I study was to test the tolerance and effectiveness of orally administered hexadecylphosphocholine in the treatment of advanced solid tumors. This study was just initiated, so we can only report on initial impressions. Before starting the phase I trial, pharmacokinetic investigations of He-PC in the rat after oral administration were carried out. A high performance liquid chromatography (HPLC) method was worked out to determine serum He-PC levels (42). The sensitivity of the method is approximately 5 nmol He-PC/mL serum. Table 5 shows the pharmacokinetic data of He-PC in the rat after oral administration.

The very long half-life of 96 hr is particularly noteworthy. Maximum levels after oral administration of 200 mg/kg He-PC were reached after 48 hr. This characteristic of hexadecylphosphocholine clearly differs from that of the alkyl lysophospholipids which are under current clinical study. It is also noteworthy that the one-time administration per week of the chosen dose led to a high percentage of complete remissions in DMBA induced breast carcinoma of the rat (35).

In the clinical pilot study, seven patients were treated with He-PC orally over a course of eight weeks. Two patients received a daily dose of 50 mg, five a dose of 100 mg. Until now, there has been no evidence of systemic toxicity; leukocytes in the peripheral blood also remained unaffected. We are planning to increase the dose in increments of 50 mg to reach maximal tolerable levels.

Evaluation and perspectives. Ether lipids and ether lysophospholipids are similar in structure to natural membrane components. Their antitumoral effect is one of the most interesting characteristics. The substances are completely different from the classical antitumor drugs, as their primary target appears to be the plasma membrane. As far as we know, they are not mutagenic or carcinogenic, nor do they possess immune suppressive properties. In addition, our work on the alkyl phosphocholines has shown that selective antitumoral effect can be achieved in animals which opens up new perspectives for a possible, specific treatment of individual tumors in man. A further interesting aspect is their possible molecular mode of action in that He-PC probably interferes with signal transmission from the cell membrane to the cell nucleus (manuscript in preparation). Particularly in the last years, the connection between phospholipid metabolism and signal transduction on cellular membranes has become quite evident. Research in the area of ether lipids is certainly only in the early stages of development, and further studies are necessary to clarify the potential significance of these compounds in cancer therapy.

[a]Emory University School of Medicine, Atlanta, Georgia 30322, [b]Max-Planck-Institut für Biophysikalische Chemie, 3400 Göttingen, Germany, [c]California State University, Northridge, California 91330 and [d]Takeda Chemical Industries, Ltd., Osaka 532, Japan

Alkyl lysophospholipids have been shown to be cytooxic to a number of neoplastic tissues. One, ET-18-OCH_3, has been used to selectively purge leukemic cells from mixtures with normal marrow progenitor cells, *in vitro* and *in vivo*. We have measured the 50% inhibitory (IC_{50}) effect of a series of ether lipids (EL) on leukemic cells (HL60, K562, Daudi, KG-1, KG-1a) and normal marrow progenitor cells. Cells were incubated with varying concentrations of EL for 4 hr and assayed for viability, [^{3}H]thymidine incorporation and clonogenicity in semi-solid media. The effect on protein kinase C (PKC) activity was assayed for each compound. Compounds tested included three glycerophosphocholine analogs—ET-18-OCH_3, ET-16-$NHCOCH_3$, and BM 41.440. In addition, a lipoidal amine, CP 46665, an ethyleneglycolphospholipid, AEPL, and four single chain alkylphosphocholine analogs, $HePC_2$, $HePC_3$, $HePC_4$ and $HePC_6$ were also tested. During the period of incubation, the cells remained viable (>70%) as judged by trypan blue dye exclusion. The glycerophosphocholines were the most active and showed the highest therapeutic index. The lipoidal amine was active, but toxic to normal marrow progenitor cells. The ethyleneglycolphospholipid was active against HL60, but not against the other cell lines. The single chain alkylphosphocholine analogs were less active. All of the compounds inhibited PKC activity; however, the glycerophosphocholines were the most inhibitory.
***Lipids* 26, 1418–1423 (1991).**

Alkyl lysophospholipids (ALP) are analogs of lysophosphatidylcholine which have been shown to be cytotoxic to a variety of neoplastic tissues *in vitro* (1–6). In addition, some antitumor activity has been demonstrated in humans (7). There has been some degree of selective cytotoxicity to neoplastic tissues and sparing of normal tissue (8). We have shown this selectivity in an animal model and an *in vitro* model by treating mixtures of normal bone marrow and leukemic cells *in vitro* with ET-18-OCH_3 and demonstrating elimination of leukemic cells and preservation of normal hematopoietic stem cells and progenitor cells (9–11).

The mechanism of action of this group of compounds is not clearly understood, but the site of action appears to be the cell membrane. Synthesis of membrane phospholipids, phosphatidylcholine, phosphatidylethanolamine and phosphatidylinositol are inhibited by ET-18-OCH_3 (12–15). Protein kinase C (PKC) activity and phorbol ester stimulation of PKC in tumor cells are inhibited by ET-18-OCH_3 (16), BM 41.440 (17) and the alkylphosphocholine analogs (18). $HePC_2$ inhibits inositol phosphate formation and PKC activity (19). Inhibition of (sodium plus potassium)-activated adenosine triphosphatase and the sodium pump has been described (20). Thus, multiple membrane associated enzymes are inhibited.

Modification of one of the more active ALP (ET-18-OCH_3) has resulted in a number of derivatives with varying degrees of antitumor activity *in vitro* (21–23). In studies on cell lines and fresh leukemic cells from patients, we observed a range of activity with ET-18-OCH_3. To determine the relationship of structure to activity, a number of ether lipids were tested and compared to ET-18-OCH_3. These consisted of three glycerophosphocholine analogs, a lipoidal amine, an alkyl ethylene glycophospholipid and four single chain alkylphosphocholine analogs. These compounds were tested against a spectrum of leukemic cell lines for antitumor activity, normal bone marrow progenitor cells to assess selectivity, and PKC to assess inhibitory activity.

MATERIALS AND METHODS

Compounds. Figure 1 shows the structures of the compounds and gives the letters assigned to each. ET-18-OCH_3 (A1), synthesized as described elsewhere (24–26), was obtained from Medmark Chemicals (Grünwald, Germany). ET-16-$NHCOCH_3$ (A2) was synthesized as previously described (27). 1-Hexadecylthio-2-methoxymethyl-2-deoxy-*rac*-glycero-3-phosphocholine, BM 41.440 (A3) was obtained from Boehringer Mannheim (Mannheim, Germany). 1-[2′-3′-(Di-n-decyloxy)-n-propyl]-4-aminomethyl-4-phenyl piperidine (CP-46665) (B) was a gift from Dr. K. Jensen, Pfizer Central Research (Groton, CT). 2-[2′-(Dodecyloxy)ethoxyl]ethyl 2-pyridinioethyl phosphate (AEPL) (C) was obtained from Takeda Chemical Industries, Ltd. (Osaka, Japan). Hexadecylphosphocholine (D1), hexadecylphospho-3-(*N,N,N*-trimethylamino)propanol (D2), hexadecylphospho-4-(*N,N,N*-trimethylamino)-butanol (D3), and hexadecylphospho-6-(*N,N,N*-trimethylamino)hexanol (D4) were prepared as previously described (28). The compounds were dissolved in RPMI 1640 medium (Gibco Laboratories, Grand Island, NY) containing 10% fetal bovine serum (FBS) (Gibco Laboratories), sterilized by acrodisc filtration (0.22 μm; Gelman Sciences, Inc., Ann Arbor, MI) and stored at −20°C until used.

Leukemic cell lines. The cell lines used in these studies were the myelocytic cell line HL60, obtained from Dr. Robert Gallo, NIH (Bethesda, MD) (29); the K562 cell line, obtained from Dr. Bismark Lozzio, University of Tennessee (Knoxville, TN) (30); the Daudi human B-cell leukemic

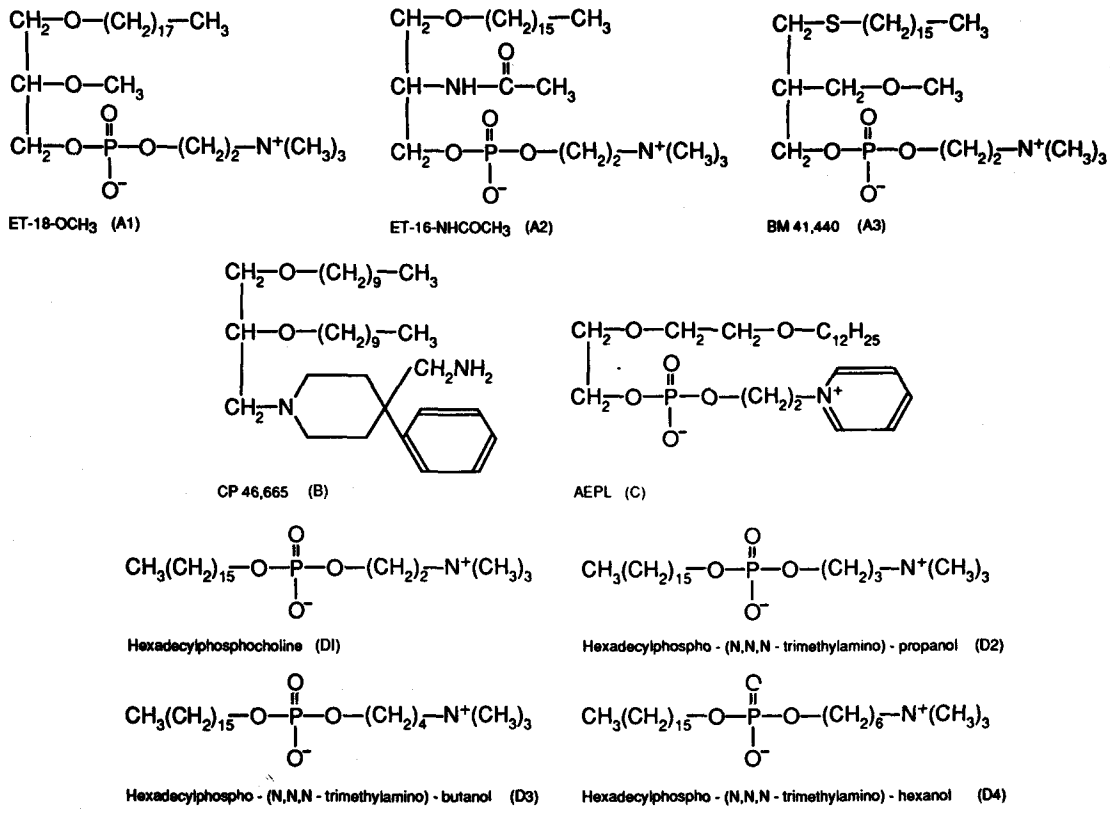

FIG. 1. Structures of ether lipids.

cell line, obtained from American Type Culture Collection (Rockville, MD) (31); and the myeloblastic leukemic cell lines KG-1 and KG-1a, kindly provided by Dr. H. Phillip Koeffler, University of California (Los Angeles, CA) (32, 33). All cells were continuously cultured at 37°C in 5% CO_2 in RPMI 1640 medium and 10% FBS (except KG-1, which required 20% FBS), and passaged twice weekly. Cells were in log phase of growth at the time the experiments were conducted.

Normal bone marrow cells. Cells were obtained by aspiration from posterior iliac crests of normal donors for allogeneic bone marrow transplantation giving informed consent or from bone marrow fragments following orthopedic procedures. Mononuclear cells were separated by Ficoll-Hypaque (Histopaque-1077, Sigma Chemical Co., St. Louis, MO).

Cytotoxicity assays. Two $\times$ 10^6 cells/mL were incubated with varying concentrations of EL for 4 hr at 37°C in RPMI 1640 medium, 10% FBS, 1% PSN or PS Antibiotic Mixture (Gibco) and 1% glutamine (RPMI-C). Following incubation, the cells were washed three times in RPMI 1640 medium, counted and resuspended in RPMI-C at a concentration of 1 $\times$ 10^6/mL. Viability was determined by trypan blue dye exclusion. Cells wre diluted in RPMI 1640-C for tritiated thymidine incorporation and clonogenicity in methylcellulose. For tritiated thymidine incorporation, 0.4 μCi of [*methyl*-^{3}H]thymidine (sp. act. 6.7 Ci/mmol) was incubated with 4 $\times$ 10^5 cells in 200 μL medium in triplicate or quadruplicate for 18 hr n 5% CO_2 at 37°C or incubated for 1 hr with 0.4 μCi of higher specific activity thymidine (89–90 Ci/mmol). Following incubation, the cells were harvested with a cell harvester, and upon addition of scintillation fluid, counted in a scintillation counter at an efficiency of 90%. The counts were expressed as CPM/4 $\times$ 10^5 cells.

Clonogenicity of cultured leukemic cells in methylcellulose was carried out as previously described (11). Briefly, 500 cells (1 $\times$ 10^4 for KG-1 and KG-1a) in RPMI-C were plated in triplicate in medium containing 0.8% methylcellulose, 30% FBS, 0.3% bovine serum albumin, 5 $\times$ 10^{-5}M mercaptoethanol, 5.6 $\times$ 10^{-8} M selenium and, in some instances, 5% phytohemagglutinin leucocyte conditioned medium (PHA-LCM or HPCM). The total volume was 1 mL. The plates were incubated in moist 5% CO_2 at 37°C for 7–14 days and colonies (>40 cells) scored.

Normal marrow progenitor cells were assayed in triplicate by a modification of the method of Fauser and Messner (34), as previously described (11), and counted on day 14. The total number of progenitors was defined as the sum of mixed colonies (GEMM), erythroid colonies (CFU-E), erythroid bursts (BFU-E), granulocyte-macrophage colonies (GM-CFU) (>40 cells) and GM clusters (<40 cells).

PKC assay. The activity of PKC was assayed as previously described (35). Briefly, PKC was partially purified from pig brain extract or purified to homogeneity from rat brain extracts (36,37). The reaction mixtures (0.2 mL) contained 5 μmol of piperazine-*N,N'-bis*(2-ethanesulfonic acid) (pH 6.5), 2 μmol $MgCl_2$, 5 μg of

phosphatidylserine, 40 μg of histone H1, 0.06 μmol of ethylene glycol-*bis*(β-aminoethyl ether)-*N,N,N'N'*-tetraacetic acid (EGTA), with or without 0.1 μmol of $CaCl_2$, 1.0 nmol of [γ-^{32}P] ATP (containing about 1 × 10^6 cpm) and various kinds and concentrations of EL. The reaction was carried out at 30°C for 5 min.

Statistical methods. The IC_{50} was defined as the concentration of EL causing 50% inhibition of the control value for the assay employed. Because of some variability in growth patterns of the cell cultures, the means of repeated experiments were averaged and plotted as percent of control for each dose. The IC_{50} was either read off the graph or calculated by the least-squares method. Triplicate samples were run in each assay and all assays were repeated a minimum of three times.

RESULTS

Figure 2 gives the IC_{50} for thymidine incorporation of eight of the compounds. Compound B (CP-46665) was not tested. As can be seen, the more active compounds contained the glycerol backbone. KG-1 was only tested with A1 (ET-18-OCH_3) and A2 (ET-16-$NHCOCH_3$), and the latter was more inhibiting. The reverse was observed in KG-1a, and C (AEPL) was essentially inactive.

Figure 3 shows the IC_{50} for the clonogenic assay. Colony formation by KG-1 cells was quite variable, usually yielding poor colony growth, and the data are not interpretable. The plating efficiency for each of the cell lines was as follows: HL60, 25.9 ± 12%; K562, 49.1 ± 14%; Daudi, 26.7 ± 9%; and KG-1a 11.7 ± 5%. In general, the glycerol EL were more active in HL60, K562 and Daudi. In KG-1a, A1 was more active than A2.

Figure 4 gives the IC_{50} for PKC activity. As shown, the glycerophospholipids were more active than the single chain hexadecylphosphocholine analogs. The lipoidal

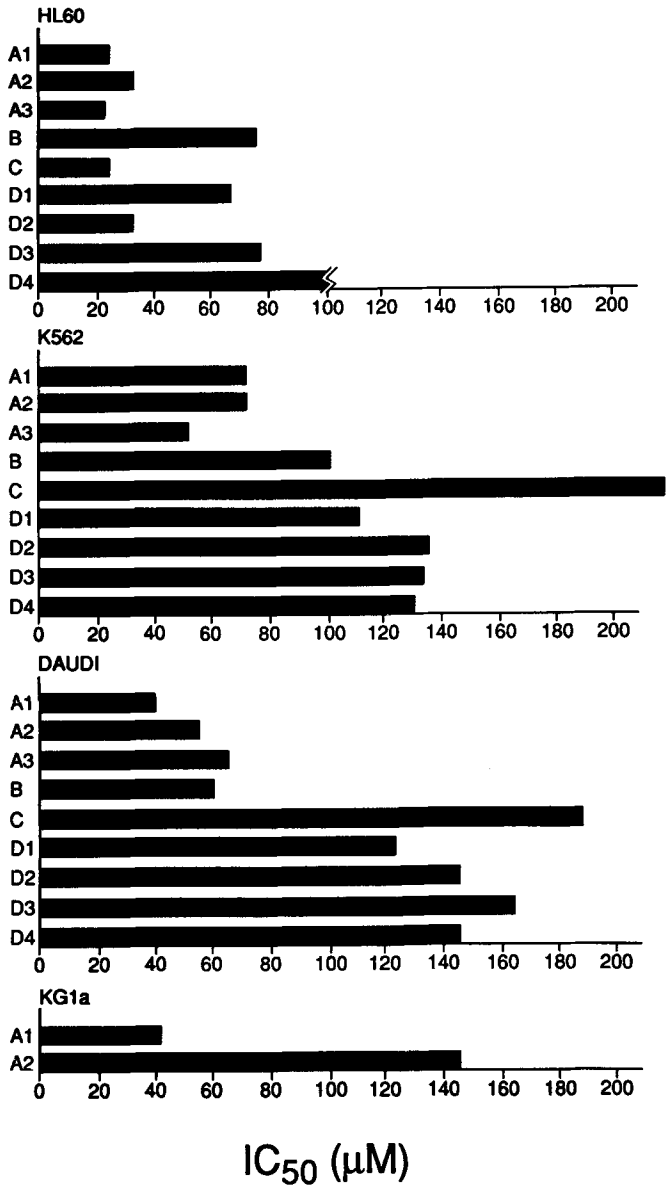

FIG. 3. Effect of EL on clonogenic assays in leukemic cell lines. Plotted are the mean IC_{50} (μM) for each compound. See text for identification of compounds.

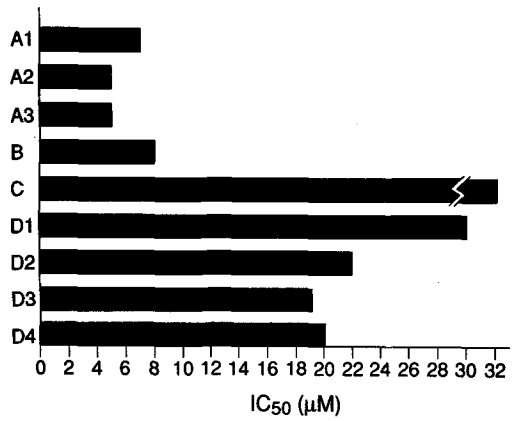

FIG. 4. Effect of EL on protein kinase C activity as described in text. Plotted are the IC_{50} for each compound tested.

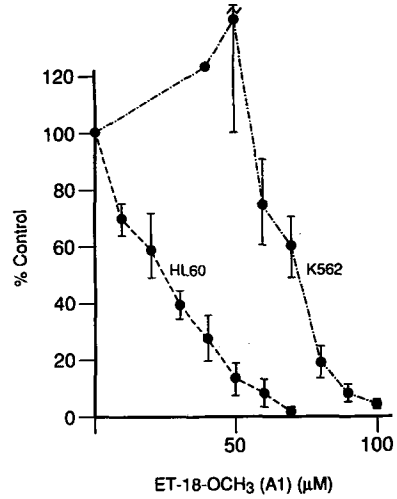

FIG. 6. Patterns of inhibition on colony formation by compound A1 on HL60 and K562 cells. Plotted are the mean and standard errors of 3–5 experiments per point.

amine (B) was also more active, but the ethylene compound (C) was relatively inactive with an IC_{50} of 177 μM.

The effect of these compounds on normal marrow progenitor cells is shown in Figure 5. As can be seen, except for the lipoidal amine, compound B, the IC_{50} was greater than 150 μM. There were no significant changes with increasing doses of drugs in the distribution of the types of colonies observed (data not shown).

Table 1 gives the calculated clonogenic therapeutic index for all of the compounds in HL60, K562 and Daudi cell lines. These were computed by dividing the IC_{50} for normal marrow progenitor cells by the IC_{50} for each of the cell lines for each of the drugs. As can be seen, the glycerol and ethylene compounds in general gave higher therapeutic ratios than the alkylphosphocholine analogs. Compound A3 gave the highest therapeutic index in all three cell lines. The lipoidal amine (compound B) was clearly toxic to normal cells.

There were two types of inhibitory patterns observed in the clonogenic assays. The first was a linear dose related inhibition. The second pattern was a non-linear inhibition characterized by an initial rise or plateau followed by rapid lysis. Figure 6 demonstrates these patterns with compound A1 in HL60 and K562 cells. In those instances, the IC_{50} was determined from the graph.

TABLE 1

Calculated Therapeutic Index[a]

Compounds	Cell Lines		
	HL60	K562	Daudi
A1 (ET-18-OCH_3)	6.08	2.03	3.65
A2 (ET-16-$NHCOCH_3$)	8.15	3.58	4.74
A3 (BM 41.440)	16.78	7.92	5.94
B (CP-46665)	0.74	0.55	0.95
C (AEPL)	24.56	2.57	3.28
D1 ($HePC_2$)	2.88	1.74	1.57
D2 ($HePC_2$)	12.00	2.91	2.75

[a]Ratio of IC_{50} of normal progenitor cells (CFU) *vs.* clonogenic leukemic cell lines.

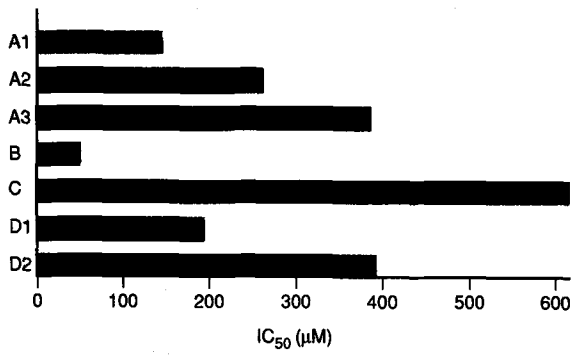

FIG. 5. Effect of EL on normal marrow progenitor cells. The IC_{50} of 3–5 separate marrow specimens were averaged and plotted for each compound. D3 and D4 were not tested because of limited antitumor activity.

At the IC_{50}, viability, as determined by trypan blue dye exclusion, was greater than 75% in all cell lines with all EL concentrations except Daudi which was 66% after exposure to compound A1. Despite the fact that the majority of cells present were viable, there was a significant effect on clonogenic cells.

DISCUSSION

This investigation attempted to explore relationships between structures and function in a series of ether lipids. Assays used included thymidine uptake as a measure of DNA synthesis, colony formation in semi-solid media as a measure of the leukemic stem cell and normal progenitor cells and PKC activity to assess potential mechanisms in regulation of cell growth.

Two myelogenous leukemic cell lines were employed. One, the HL60 cell line, was sensitive to A1, the reference compound which appeared from our own data and the literature to be the most active compound (8,38,39). The other, K562, was known to be resistant to the reference compound (6). Two other myeloid cell lines, KG-1 and KG-1a, differ in that the former can be induced to differentiate by phorbol esters (33) and the other cannot. Lastly,

Daudi represents a lymphoid leukemic cell line. Because of some difficulty in colony growth of KG-1 and KG-1a cells, only limited data are available.

From the results presented, A3 (BM 41.440) proved to be the most active compound and gave the highest therapeutic ratio in all of the cell lines tested. Although the ethylene compound (C) was active in HL60, it was inactive against K562 and Daudi, suggesting a limited spectrum of activity. The hexadecylphosphocholine analogs differ in the distance between the phosphorus and the tertiary ammonium group. The shorter the distance, the more active the compounds. The lesser activity, when compared to the A-groups, may be due to the relatively shorter alkyl chain, and synthesis of compounds with chainlengths of 18 to 20 carbons is in progress.

These agents are of interest because of their antitumor activity, in which they appear to be active through mechanisms differing from those of other chemotherapeutic agents. More importantly, they appear to be selectively toxic to neoplastic tissues sparing normal marrow progenitor cells. The reasons for the relative selectivity of the toxicity are poorly understood. The initial observation that ET-18-OCH_3 was more rapidly metabolized due to cleavage of the *O*-alkyl ether linkage in normal marrow cells and myelocytes of chronic myelocytic leukemia compared to leukemic blast cells (40,41) has not been confirmed in subsequent studies (6,15,42). Uptake of radiolabelled ET-18-OCH_3 and its concentration in the membrane of sensitive HL60 cells was greater than in the resistant K562 cells or normal granulocytes (6). The biochemical mechanisms involved remain to be elucidated.

Previous studies have indicated that the ether linkage or thio linkage in the *sn*-1 position of glycerophosphocholines is important for antitumor activity. The length of the alkyl chain in *sn*-1 is important, C_{16} or C_{18} compounds are more active (43). Substitution in *sn*-2 with a methoxy or acetamido group increases antitumor activity. Our data would suggest that the glycerophosphocholine-type compounds are more active than ethylene or alkylphosphocholine analogs. It is of interest that $HePC_2$, which lacks the glycerol backbone, shows antineoplastic activity (44,45). Further modification of their structure may enhance their activity.

ACKNOWLEDGMENT

This work was supported by Grant CA29850 from the National Institutes of Health, by Atlanta Leukemia Research, Inc., and by The Jill Andrews Memorial Leukemia Research Fund. The authors wish to thank Barbara Adair for typing the manuscript.

Stereospecific Synthesis of Antitumor Active Thioether PAF Analogs[1]

Suresh K. Bhatia[2] and Joseph Hajdu*
Department of Chemistry, California State University, Northridge, Northridge, California 91330

A novel stereospecific synthesis of antitumor active thioether analogs of platelet-activating factor (PAF) is reported. The synthesis is based upon: i) the use of *D*-serine to provide the chiral center for the construction of the optically active phospholipid molecule; ii) development of the *sn*-1-thioalkyl function via thioacetate displacement of methanesulfonate-activated primary hydroxyl group followed by alkylation of the *sn*-1-thiolate function; and iii) introduction of the phosphocholine moiety through the 2-chloro-2-oxo-1,3,2-dioxaphospholane/trimethylamine sequence. The entire scheme relies on the use of a single protecting group. The synthetic thioether phospholipid 1-*S*-hexadecyl-2-*N*-acetamidodeoxy-*sn*-glycero-3-phosphocholine has been shown to be a potent antitumor active phospholipid, exhibiting tumor cytotoxicity against a lymphoblastoid lymphoma (Li-A) cell line and a malignant histiocytic (DHL-4) cell line of human origin at the same level of potency as ET-18-OMe and 1-*O*-octadecyl-2-*N*-acetamidodeoxy-*sn*-glycero-3-phosphocholine. The synthetic method described has a great deal of flexibility, providing a convenient general route to a wide range of thioether PAF analogs.
***Lipids 26,* 1424–1430 (1991).**

Stereospecific synthesis of antitumor active platelet-activating factor (PAF) analogs is one of the key steps toward elucidating the structural basis of their biological mechanism of action (1). Specifically, a number of structurally modified alkyl ether derivatives of PAF have been shown to exhibit selective cytotoxicity against a series of different human cancer cells (1–3). These synthetic phospholipid compounds appear to act at the cell membrane inhibiting phosphatidylcholine biosynthesis (4), protein kinase C activity (5), as well as phorbol ester stimulation of protein kinase C (6). While most early attempts to prepare antitumor active phospholipids have led to *racemic* mixtures of the target compounds (1–3), studies which employed enantiomerically pure ether lipids seem to indicate significant differences both in potency and selectivity of the respective stereoisomers (7,8). Therefore, availability of facile and efficient synthetic methods for the preparation of structurally variable chiral PAF analogs is a prerequisite for establishing structure-activity relationships, as well as for the design of new phospholipid compounds with targeted antineoplastic activities.

Thioether analogs of platelet-activating factor represent a particularly useful series of anticancer phospholipids, since in contrast to the corresponding *sn*-1-*O*-alkyl derivatives, the sulfur compounds have been reported to possess lower platelet-aggregating potency and show less immunosuppression, two noted side effects in antileukemic phospholipid chemotherapy (9). Indeed, one such compound, Ilmofosine (BM 41,440, 1-hexadecylthio-2-methoxymethyl-*rac*-glycero-3-phosphocholine), is currently in clinical trials as a potential anticancer drug (10). As part of our research toward developing new synthetic methods for the preparation of phospholipid derivatives (11–15) we have recently introduced a stereospecific sequence leading to 1-thioalkyl-2-acylaminodeoxy-*sn*-glycero-3-phosphocholines (1) (13). In this paper we describe the synthesis in detail and demonstrate the applicability of the method to the preparation of other structurally related phospholipid analogs.

MATERIALS AND METHODS

General methods. Melting points were determined on a Mel-Temp apparatus (Laboratory Devices, Hollistow, MA) and are uncorrected. IR spectra were recorded on a Beckman Acculab 2 spectrophotometer Beckman Instruments (Fullerton, CA). ^{1}H NMR (internal Me_4Si) were taken on an IBM NR-80 instrument. Optical rotations were determined either on a Perkin Elmer 241 MC (Perkin Elmer, Norwalk, CT) or Rudolph AutoPol III polarimeter. 4-(Dimethylamino)pyridine, triphenylchloromethane, acetyl chloride, palmitoyl chloride, *p*-nitrophenyl chloroformate, sodium methoxide and potassium thioacetate were obtained from Fluka Chemical Corporation (Ronkonkoma, NY). *D*-serine from Sigma Chemical Co. (St. Louis, MO) and trimethylamine from Kodak Laboratory Chemicals (Rochester, NY) were used as received. Tetradecanol, methanesulfonyl chloride and hexadecyl iodide were obtained from Aldrich Chemical Co. (Milwaukee, WI). Anhydrous trifluoroacetic acid (Pierce Chemical Co., Rockford, IL), methanol (Burdick and Jackson, Muskegon, MI) and anhydrous diethyl ether (Mallinckrodt, St. Louis, MO) were used as received. Acetonitrile (Burdick and Jackson) and triethylamine (Fluka) were dried over activated Linde 4A molecular sieves (Fluka). Benzene (Burdick and Jackson) was kept over sodium wire; chloroform and methylene chloride (Mallinckrodt) were distilled from phosphorus pentoxide (Baker Chemical Co., Phillipsburg, NJ) just prior to use. 2-Chloro-2-oxo-1,3,2-dioxaphospholane was prepared by procedures in the literature (16). Column chromatography was carried out with silica gel 60 (70–230 mesh ASTM, E.M. Laboratories, Cherry Hill, NJ). The silica gel support was constantly kept at 120°C and was cooled to room temperature only prior to use in a desiccator over P_2O_5. Thin-layer chromatography was carried out on Whatman MK6F plates. The phospholipids were visualized by molybdic acid spray (17) and by charring (50% aq.

sulfuric acid). Trityl compounds were visualized by UV light, and all other compounds were detected by iodine vapor. The thiols were additionally visualized by dipping into methanolic solution of 5,5′-dithio*bis*(2-nitrobenzoic acid) (18). Elemental analyses were performed by Galbraith Laboratories, Inc. (Knoxville, TN) and by Desert Analytics (Tucson, AZ).

N-*triphenylmethyl*-D-*serine methyl ester* (4). Triethylamine (6.39 mmol) was added to a cooled (ice-water bath) suspension of *D*-serine methyl ester hydrochloride (4.65 g, 30.0 mmol) in 70 mL dry chloroform. After 5 min, triphenylmethyl chloride (8.65 g, 31.0 mmol) was added and the resulting solution was stirred at room temperature for 24 hr. The solution was washed with water (3 × 50 mL), the organic layer was dried over anhydrous $MgSO_4$ and the solvent was flash-evaporated. The oily residue was triturated with hexane. The solidified product was filtered and dried in vacuum, yielding 9.9 g (91.4%) of chromatographically pure triphenylmethyl ether 4 R_f($CHCl_3$/CH_3OH, 98:2, v/v) 0.48. Crystallization from chloroform/petroleum ether gave a white solid; m.p. 141-2°C.^{1}H NMR ($CDCl_3$) δ 3.29 (*s*, 3H,OCH_3), 3.59 (*m*, 3H, OCH_2CHN), 7.20-7.45 (*m*, 15H, phenyl); $[\alpha]_D^{23}$ −17.63 (c 1.6, CH_3OH/$CHCl_3$, 1:4 v/v) *Anal.* Calcd. for $C_{23}H_{23}NO_3$:C, 76.43; H, 6.41, N, 3.87. Found: C, 76.64, H, 6.24; N, 3.76.

N-*triphenylmethyl*-O-*methanesulfonyl*-D-*serine methyl ester* (5). Methanesulfonyl chloride (1.26 g, 11.0 mmol) was added to a cooled (ice-water bath) solution of alcohol 4 (4.36 g, 10.0 mmol) in 50 mL anhydrous methylene chloride containing triethylamine (1.21 g, 12.0 mmol) and the resulting mixture was stirred at 0°C for 2 hr. Thin-layer chromatography showed disappearance of the starting material. The solution was washed three times with 50 mL water followed by brine (50 mL), dried over $MgSO_4$, and the solvent was flash-evaporated at 30°C to give 4.0 g (91%) of methanesulfonate (5) as a viscous oil: R_f($CHCl_3$) 0.4; ^{1}H NMR ($CDCl_3$) δ 2.97 (*s*, 3H, O_3SCH_3), 3.27 (*s*, 3H, OCH_3), 3.60-4.38 (*m*, 4H, OCH_2CHN, NH), 7.22-7.44 (*m*, 15H, phenyl). The compound is unstable on storage; therefore, it was used as soon as possible for the next reaction step.

N-*triphenylmethyl*-S-*acetyl*-D-*cysteine methyl ester* (6). A solution of mesylate 5 (3.9 g, 8.88 mmol) in dry acetonitrile (80 mL) was stirred with $KSCOCH_3$ (1.71 g, 15.0 mmol) at room temperature for two days. The dark brown precipitate that formed was filtered and the acetonitrile was evaporated *in vacuo*. The residue was treated with 100 mL chloroform and filtered. The chloroform solution was washed with 1% aq. $NaHCO_3$ (60 mL) and saline (60 mL) and dried over anhydrous $MgSO_4$. Evaporation of the solvent gave a brown semisolid as a chromatographically pure product 6 (5.15 g, 84.6%): R_f ($CHCl_3$) 0.59; ^{1}H NMR ($CDCl_3$) δ 2.39 (*s*, 3H, $SCOCH_3$), 3.18 (*s*, 3H, OCH_3), 3.28-3.51 (*m*, 4H, $NCHCH_2SCO$, NH), 7.24-7.46 (*m*, 15H, phenyl) which was used directly for the next reaction.

N-*triphenylmethyl*-D-*cysteinol* (7). Lithium aluminum hydride (0.5 g, 13-15 mmol) in one portion was added to a cooled solution (0°C, ice-water bath) of ester 6 (3.15 g, 7.52 mmol) in dry ether (150 mL). The mixture was stirred at 0°C for 30 min, then at room temperature for 3 hr. Excess hydride was decomposed by slow addition of water at 0°C. The insoluble inorganic material was filtered over a pad of celite and washed with ether. The combined etheral layer was washed with 60 mL saline and dried over anhydrous $MgSO_4$. The solvent was evaporated *in vacuo* and the residue was chromatographed on freshly activated silica gel using chloroform. The product 7 was obtained as a semisolid (1.78 g, 68%) R_f($CHCl_3$) 0.60; ^{1}H NMR ($CDCl_3$) δ 1.73 (*br s*, 1H, OH), 2.13 (*br s*, 1H, SH), 2.76 (*m*, 2H, CH_2S), 3.27-3.50 (*m*, 3H, OCH_2CHN), 7.24-7.50 (*m*, 15H, phenyl), which was used for the next step as soon as possible.

S-*hexadecyl*-N-*triphenylmethyl*-D-*cysteinol* (8). A solution of compound 7 (1.78 g, 5.0 mmol) in absolute methanol (50 mL) containing sodium methoxide (0.28 g, 5.2 mmol) was stirred with hexadecyl iodide (1.76 g, 5.0 mmol) at room temperature for 16 hr. The methanol was then evaporated *in vacuo*, the residue was suspended in 50 mL water and extracted with 50 mL chloroform. The organic layer was washed with saline and dried over $MgSO_4$. Evaporation of the solvent gave the crude hexadecyl thioether 8, which was chromatographed on freshly activated silica gel using chloroform to give analytically pure product 8 (1.8 g, 61%) as a strongly hygroscopic viscous oil: ^{1}H NMR ($CDCl_3$) δ 0.88 (*t*, 3H, CH_3), 1.25 [*s*, 28H, $(CH_2)_{14}$], 2.14-2.22 (*m*, 5H, CH_2SCH_2, OH), 2.75-3.58 (*m*, 4H, OCH_2CHN, NH), 7.24-7.51 (*m*, 15H, phenyl); $[\delta]_D^{23}$ −20.72 (c 1.53, CH_3OH/$CHCl_3$ 1:4 v/v). *Anal.* Calcd. for $C_{38}H_{55}NOS$: C, 79.52; H, 9.66; N, 2.44; S, 5.59. Found: C, 79.64; H, 9.62; N, 2.29; S, 5.52.

1-Thiohexadecyl-2-N-*triphenylmethylaminodeoxy*-sn-*glycerol-3-phosphocholine* (10). 2-Cloro-2-oxo-1,3,2,-dioxaphospholane (0.64 g, 4.5 mmol) in dry benzene (5 mL) was added to a cooled solution (0°C) of alcohol 8 (2.4 g, 4.2 mmol) in dry benzene (95 mL) containing triethylamine (0.465 g, 4.6 mmol). The reaction mixture was stirred at room temperature for 24 hr. The precipitated triethylamine hydrochloride was filtered off and the solvent was removed under reduced pressure. The resulting semisolid, 2-(1-*S*-hexadecyl-2-*N*-triphenylmethylaminodeoxy-*sn*-glyceryl)-2-oxo-1,3,2-dioxaphospholane 9, formed as a single phosphate positive product ^{1}H NMR ($CDCl_3$) δ 0.87 (*t*, 3H, CH_3), 1.26 [*s*, 28H, $(CH_2)_{14}$], 2.14-2.22 (*m*, 4H, CH_2SCH_2) 3.10 (*m*, 2H, HCNH), 3.60-4.34 (*m*, 6H $(CH_2O)_3$), 7.24-7.52 (*m*, 15H, phenyl). This cyclic phosphotriester intermediate is moisture sensitive and readily undergoes hydrolytic decomposition; therefore, it was used directly for the next step.

The semisolid obtained (9) was suspended in dry acetonitrile (50 mL) and transferred to a pressure bottle. The pressure bottle was cooled in a dry-ice bath and to this, anhydrous trimethylamine (3 mL) was added. The content of the pressure bottle was heated at 65°C in an oil bath for 20 hr. Acetonitrile was then removed and crude product was chromatographed on activated silica gel with $CHCl_3$/CH_3OH/H_2O (65:25:4, v/v/v) to give analytically pure phospholipid 10 (1.9 g, 61.3%) as a strongly hygroscopic white solid. ^{1}H NMR ($CDCl_3$) δ 0.88 (*t*, 3H, CH_3) 1.25 [*s*, 28H, $(CH_2)_{14}$], 2.10 (*m*, 4H, CH_2SCH_2), 2.92-4.15 [*m*, 16H with *s* at 3.24 $N(CH_3)_3$, OCH_2CHN, OCH_2CH_2N]; $[\alpha]_D^{23}$-10.84° (c 1.31, CH_3OH/$CHCl_3$ 1:4, v/v); R_f($CHCl_3$/CH_3OH/water, 65:25:4, v/v/

v) 0.52. *Anal.* Calcd. for $C_{43}H_{67}N_2O_4PS \cdot \frac{1}{2}H_2O$: C, 69.04; H, 9.16; N, 3.74; P, 4.15; S, 4.28. Found: C, 68.86; H, 9.33; N, 3.67; P, 3.86; S, 4.39.

*1-Thiohexadecyl-2-*N*-acetamidodeoxy-*sn*-glycero-3-phosphocholine (1)*[3].

i) By detritylation-acylation method (Scheme I). Anhydrous CF_3COOH (0.4 g, 3.5 mmol) from a freshly opened vial was added to a solution of compound **10** (1.0 g, 1.35 mmol) in dry chloroform (30 mL). The resulting solution was stirred at room temperature for 1 hr. Thin-layer chromatography showed complete disappearance of the starting material (**10**). 4-(Dimethylamino)pyridine (0.465 g, 3.81 mmol) and acetyl chloride (0.120 g, 1.5 mmol) were added to this solution and the reaction mixture was stirred at room temperature for 20 hr. The chloroform was then evaporated and the residue was passed through Rexyn I-300 (25 mL bed volume) with $CHCl_3/CH_3OH$/water (4:5:1, v/v/v) using 60 mL total volume of eluant. Ten-mL fractions were collected and analyzed for phospholipid. The phosphate-positive fractions were combined, the solvent was evaporated *in vacuo*, and the residue was redissolved in benzene and freeze-dried. Finally, the freeze-dried product was dissolved in $CHCl_3/CH_3OH$/water (65:25:4, v/v/v) and chromatographed on activated silica gel to afford 0.45 g (62%) analytically pure phospholipid **1** as a hygroscopic white solid. ^{1}H NMR ($CDCl_3$) δ 0.88 (*t*, 3H, CH_3), 1.25 [*s*, 28H, $(CH_2)_{14}$], 1.98 (*s*, 3H, $NCOCH_3$), 2.52–2.64 (*m*, 4H, CH_2SCH_2), 3.34 [s, 9H, $N(CH_3)_3$], 3.74–4.27 (*m*, 7H, $NCHCH_2O$, OCH_2CH_2N); $[\alpha]_D^{23}$ −4.07° (c 1.08, $CH_3OH/CHCl_3$, 1:4, v/v), + 7.57° (c 1.4, CH_3OH). *Anal.* Calcd. for $C_{26}H_{55}N_2O_5PS \cdot H_2O$: C, 56.09; H, 10.32; N, 5.03; P, 5.56; S, 5.76. Found: C, 56.03; H, 10.22; N, 4.65; P, 5.50; S, 5.69.

ii) By the acylation-phosphorylation method (Scheme II). HCl was bubbled through a solution of chloroform-methanol (1:1, 100 mL) for a period of 45 min. Trityl compound **8** (2.2 g, 3.84 mmol) was added to this and the resulting solution was stirred at room temperature for 1 hr. The solvent was removed under reduced pressure, and the residue was treated with 150 mL saturated K_2CO_3 and 150 mL ether. After stirring for 30 min, the ether layer was separated, washed with aq. K_2CO_3 (100 mL), brine (100 mL), and then dried over anhydrous $MgSO_4$. The crude product was chromatographed on silica gel (20 g), eluting first with $CHCl_3/CH_3OH$ (95:5, v/v), then with $CHCl_3/CH_3OH$ (9:1, v/v). The amino alcohol (**12**) was obtained as a white solid (1.06 g, 84%) which was freeze-dried from benzene prior to the next step. ^{1}H NMR ($CDCl_3$ + D_2O) δ 0.87 (*t*, 3H, CH_3), 1.26 [*s*, 28H, $(CH_2)_{14}$], 2.56 (*m*, 4H, CH_2SCH_2), 3.0–3.6 (*m*, 3H, $NCH\text{-}CH_2O$); $[\alpha]_D^{23}$ + 21.13 (c 1.41, $CH_3OH/CHCl_3$, 1:4, v/v).

A solution of alcohol **12** (0.600 g, 1.81 mmol) in dry chloroform (25 mL) containing 4-(dimethylamino)pyridine (0.230 g 1.89 mmol) and acetyl chloride (0.141 g, 1.79 mmol) was stirred at room temperature for two days. The solvent was removed under reduced pressure and the residue was chromatographed on silica gel (20 g) with $CHCl_3/CH_3OH$ (94:6, v/v). The *N*-acetyl compound **13** (0.480 g, 71%) was obtained as a white solid: ^{1}H NMR ($CDCl_3$) δ 0.87 (*t*, 3H, CH_3), 1.25 [*s*, 28H, $(CH_2)_{14}$], 2.02 (*s*, 3H, $COCH_3$), 2.45–2.76 (*m*, 4H, CH_2SCH_2), 3.75–4.01 (*m* 4H $NCHCH_2O$, OH), 5.97 (*m*, 1H, NH); $[\alpha]_D^{23}$ + 6.92 (c 1.2, $CH_3OH/CHCl_3$, 1:4, v/v).

A suspension of alcohol **13** (0.430 g, 1.16 mmol) in dry benzene (30 mL) containing triethylamine (0.136 g, 1.34 mmol) and 2-chloro-2-oxo-1,3,2-dioxaphospholane (0.180 g, 1.27 mmol) was stirred at room temperature for two days. The precipitated triethylamine hydrochloride was filtered off and the filtrate was evaporated to dryness. The semisolid residue was transferred to a pressure bottle with anhydrous acetonitrile (25 mL), and trimethylamine (3 mL) was added to the mixture. The pressure bottle was sealed and the solution was kept at 65°C in an oil bath for two days. The solvent was then evaporated and the residue was chromatographed on silica gel using $CHCl_3/CH_3OH$/water (65:25:4, v/v/v) as eluant. The fractions containing the pure phospholipid (**1**) were combined, the solvent was evaporated and the product freeze-dried from benzene. Compound **1** was obtained as a hygroscopic white solid (0.322 g, 52%). Spectroscopic data for this compound are given above.

Compounds **1′** and **1″** with the corresponding palmitoyl and tetradecyloxycarbonyl substitutents at the *sn*-2 position were prepared by employing the same experimental conditions as described for the acetyl compounds.

*1-Thiohexadecyl-2-*N*-palmitoylaminodeoxy-*sn*-glycero-3-phosphocholine (1′).*

i) *By detritylation-acylation method (Scheme I).* Compound **1′** was obtained as a white hygroscopic solid in 51% yield from **10**. ^{1}H NMR ($CDCl_3$) δ 0.87 [t 6H, $(CH_3)_2$] 1.25 [*s*, 54H, $(CH_2)_{27}$], 2.13 (*br t*, 3H, $COCH_2$), 2.48–2.78 (*m*, 4H, CH_2SCH_2), 3.33 [*s*, 9H, $N(CH_3)_3$], 3.78–4.37 (*m*, 7H, $NCHCH_2O$, OCH_2CH_2N); $[\alpha]_D^{23}$ + 9.62° (c 1.32, CH_3OH); *Anal.* Calcd. for $C_{40}H_{83}N_2O_5PS \cdot 3H_2O$: C, 60.88; H, 11.37; N, 3.55; P, 3.92; S, 4.06. Found: C, 60.59; H, 11.53; N, 3.54; P, 3.78; S, 4.44.

ii) *By the acylation-phosphorylation method (Scheme II).* The *N*-palmitoyl analog of **13** was obtained in 64% yield from the corresponding amino alcohol precursor (**12**). Compound **13′** was isolated as a hygroscopic solid ^{1}H NMR ($CDCl_3$) δ 0.87 [*t*, 6H, $(CH_3)_2$] 1.25 [*s*, 54H, $(CH_2)_{27}$], 2.12 (*br t*, 2H $COCH_2$), 2.44–2.75 (*m*, 4H, CH_2SCH_2), 3.73 (*m*, 3H, $NCHCH_2O$); $[\alpha]_D^{23}$ + 9.58 (c 1.2 CH_3OH-$CHCl_3$, 1:4, v/v).

Phosphorylation of the *sn*-2-palmitoyl alcohol (**13′**) with 2-chloro-2-oxo-1,3,2-dioxaphospholane, followed by ring-opening with trimethylamine as outlined above afforded the corresponding phospholipid **1′** in 41% yield. Spectroscopic data for this compound are given above.

*1-Thiohexadecyl-2-*N*-tetradecyloxycarbonylaminodeoxy-*sn*-glycero-3-phosphocholine (1″).*

i) By detritylation-acylation method (Scheme I). Compound **1″** was obtained in 57% yield from **10**. ^{1}H NMR ($CDCl_3$ + D_2O) δ 0.88 [*t*, 6H, $(CH_3)_2$], 1.25 [*s*, 52H, $(CH_2)_{26}$], 2.52–2.65 (*m*, 4H, CH_2SCH_2), 3.37 [*s*, 9H, $N(CH_3)_3$], 3.74–4.32 (*m*, 9H, OCH_2CHN, OCH_2CH_2N, $NCOOCH_2$); $[\alpha]_D^{23}$ + 6.36° (c 1.21, CH_3OH). *Anal.* Calcd.

[3]For the synthesis of *rac-(1)* and D-*(2)* from cysteine see Reference 26.

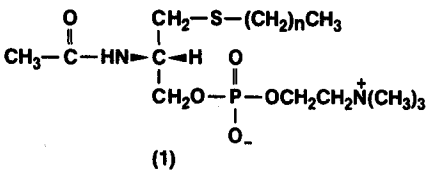
for $C_{39}H_{81}N_2O_6PS•3H_2$): C, 59.21; H, 11.08; N, 3.54; P, 3.91; S, 4.05. Found: C, 59.11; H, 11.05; N, 3.51; P, 3.87; S, 3.87.

ii) *By the acylation-phosphorylation method (Scheme II): 1-Thiohexadecyl-*N*-tetradecyloxycarbonylaminodeoxy-*sn*-glycerol (13″).* A solution of alcohol 12 (0.500 g, 1.51 mmol) in 20 mL anhydrous chloroform containing 4-(dimethylamino)pyridine (0.195 g, 1.6 mmol) and *p*-nitrophenyl tetradecyl carbonate (14, 0.568 g, 1.5 mmol) was kept at room temperature for 30 hr. The solution was diluted with chloroform (50 mL) and washed with 5% K_2CO_3 until the aqueous solution became colorless. The organic layer was washed with saline, dried over anhydrous $MgSO_4$, and the solvent was evaporated. The crude product (13″) was chromatographed on silica gel (20 g) with $CHCl_3/CH_3OH$ (94:6 v/v) to afford the target compound as a crystalline solid (13″, 0.610 g, 71%). ^1H NMR ($CDCl_3$) δ 0.87 [*t*, 6H, $(CH_3)_2$], 1.25 [*s*, 52H, $(CH_2)_{26}$], 2.46–2.75 (*m*, 4H, CH_2SCH_2), 3.77–4.12 (*m*, 5H, OCH_2CHN, $NCOOCH_2$); $[\alpha]_D^{23}$ + 7.54.

p-*Nitrophenyl tetradecyl carbonate (14).* Tetradecanol (2.14 g, 10 mmol) was added to a solution containing *p*-nitrophenyl chloroformate (2.2 g, 10.9 mmol) in 70 mL dry chloroform. 4-(Dimethylamino)pyridine (1.342 g, 11.0 mmol) was added and the reaction mixture was stirred at room temperature for 16 hr. The solvent was then evaporated under reduced pressure and the residue was chromatographed on silica gel with chloroform-hexane (3:1). The product (14, 3.7 g, 97.5%) was obtained as a liquid which solidified on standing. ^1H NMR ($CDCl_3$) δ 0.87 (*t*, 3H, CH_3), 1.26 [*s*, 24H, $(CH_2)_{12}$], 4.28 (*t*, 2H, OCH_2), 7.27–8.33 (*dd*, H_{arom}). *Anal.* Calcd. for $C_{21}H_{33}NO_5$: C, 66.47; H, 8.76; N, 3.69. Found: C, 66.62; H, 8.87; N, 3.64.

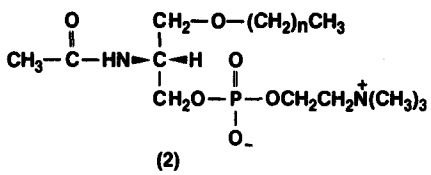
*1-Thiohexadecyl-2-*N*-tetradecyloxycarbonylamino-*sn*-glycero-3-phosphocholine (1″).* A suspension of alcohol 13″ (0.50 g, 0.88 mmol) in dry benzene (30 mL) containing triethylamine (0.110 g, 1.1 mmol) and 2-chloro-2-oxo-1,3,2-dioxaphospholane (0.142 g, 1.0 mmol) was stirred at room temperature for two days. The precipitated triethylamine was filtered, and the solvent was evaporated *in vacuo*. The residue was transferred into a pressure bottle with anhydrous acetonitrile (30 mL), and trimethylamine (3 mL) was added while the mixture was cooled in a dry-ice bath. The pressure bottle was sealed and the solution was kept at 65°C for two days. The solvent was then evaporated and the product (1″) was chromatographed on activated silica gel with $CHCl_3/CH_3OH$/water (54:25:4 v/v/v). The product was then freeze-dried from benzene to give 0.320 g (49.3%) analytically pure phospholipid 1″. Spectroscopic data for the product (1″) are given above.

RESULTS AND DISCUSSION



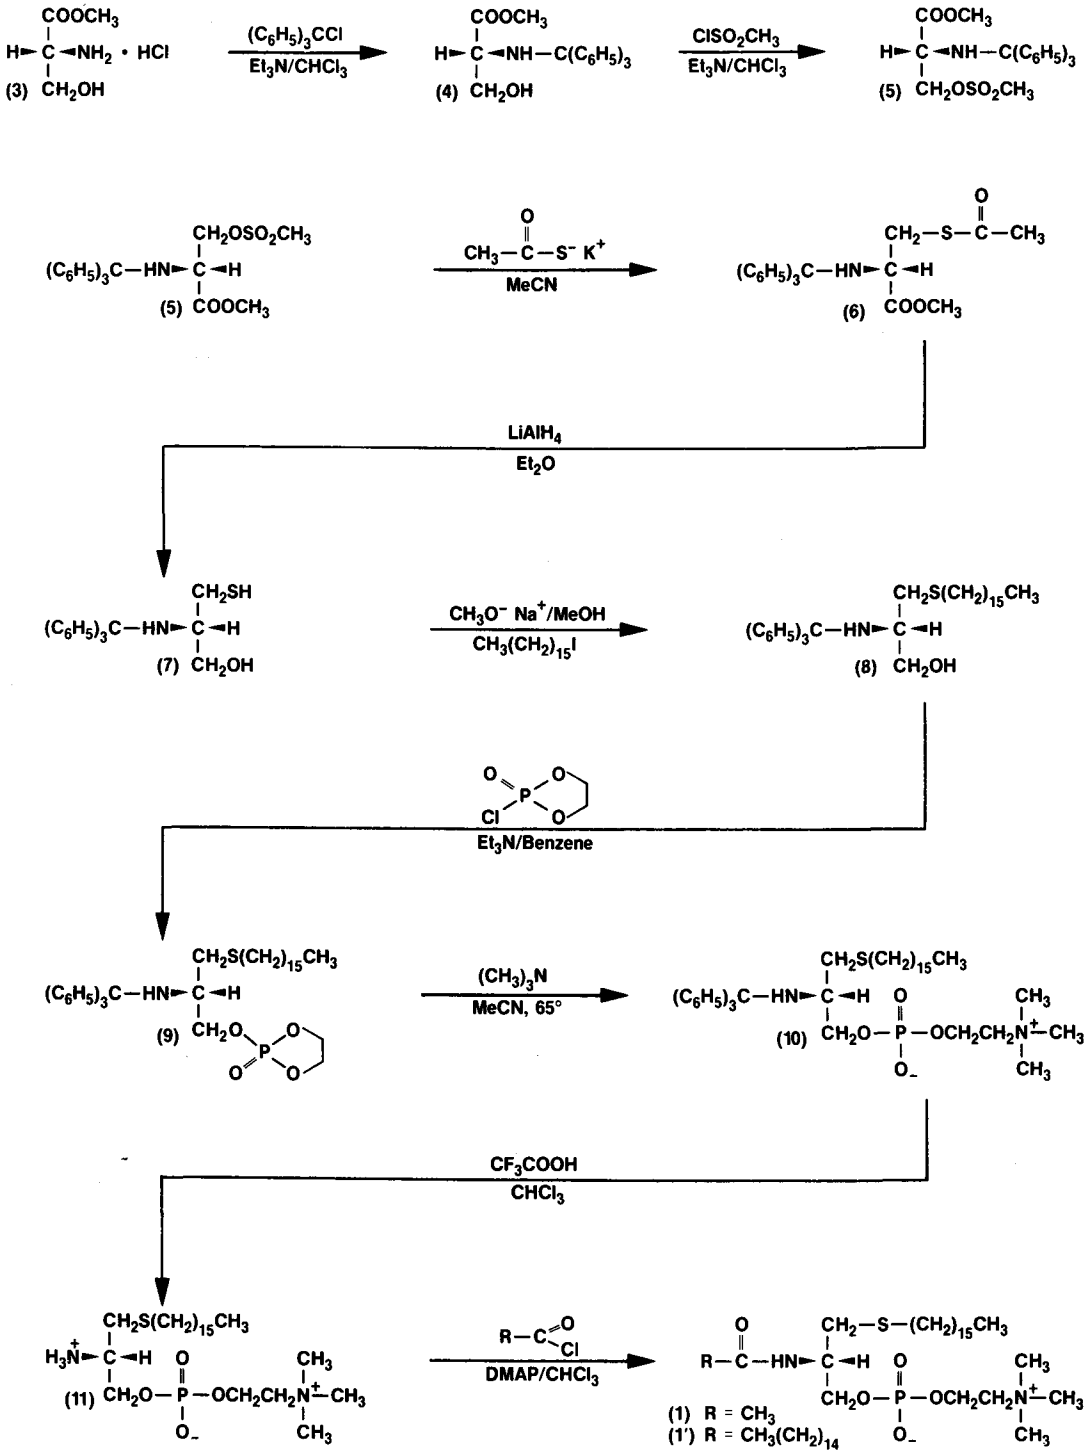
The structural design of (1) and (2) as our target compound has relied on studies showing that: i) the antitumor activity of 1-*O*-octadecyl-2-acetamidodeoxy-*sn*-glycero-3-phosphocholine (2, n = 17) is comparable to that of ET-18-OMe (1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine) (1,7); and ii) the 1-*S*-alkyl analogs of ET-18-OMe and related 1,2-dialkylphospholipids appear to exceed the tumor cytotoxicity of the 1-*O*-alkyl series yet, at the same time, exhibit diminished platelet-aggregating activity (9,19). Thus, by replacing the *sn*-1-*O*-alkyl substituent of (1) with the corresponding thioether function, we sought to achieve high antineoplastic potency with decreased immunosuppressive and platelet activating capacity.

Our approach to the synthesis of (1) is based on construction of the chiral phosphodiester molecule around the α-carbon of *D*-serine using a sequence of reactions that keeps the stereochemistry of the optically active center unchanged (Scheme I). Based on the structural relationship between the starting amino acid (3) and the target phospholipid (1), the synthesis must involve: i) reduction and thioalkylation at the incipient *sn*-1-position; ii) selective *N*-acylation of the amino group at the secondary carbon; and iii) phosphorylation of the hydroxymethyl function with subsequent elaboration of the phosphodiester head group.



In order to achieve these objectives, we first prepared *N*-trityl-*D*-serine methyl ester (4). This intermediate allows facile manipulation of the primary carbon functions for developing the thioalkyl and phosphocholine residues, respectively. Thus, activation of the alcohol function by treatment of (4) with methanesulfonyl chloride/triethylamine in chloroform gave the corresponding methanesulfonate (5) in excellent yield (91%). Compound (5) was then allowed to react with potassium thioacetate in anhydrous acetonitrile at room temperature for introduction of the sulfur atom at the incipient *sn*-1-position of the target phospholipid (84%). Reduction of both the thioester and the carbomethoxy functions of (6) with lithium aluminum hydride gave the γ-hydroxy thiol (7) in one step (68%). This compound (7) was then selectively *S*-alkylated using hexadecyl iodide/1 equiv. sodium methoxide in methanol (75%).

The sequence here employed for elaboration of the thioether function via thioacetate-displacement, followed by reduction and subsequent alkylation, turned out to be a convenient route to sulfur-substituted lipid derivatives, since the intermediates are readily obtained, isolated and purified. The alternative method involving direct coupling between the methanesulfonate (5) and sodium hexadecyl thiolate (20) appeared to be much less efficient.



Phosphorylation of alcohol 8 with 2-chloro-2-oxo-1,3,2-dioxaphospholane in benzene in the presence of 1 equiv. triethylamine, followed by treatment of the cyclic triester (9) with anhydrous trimethylamine in

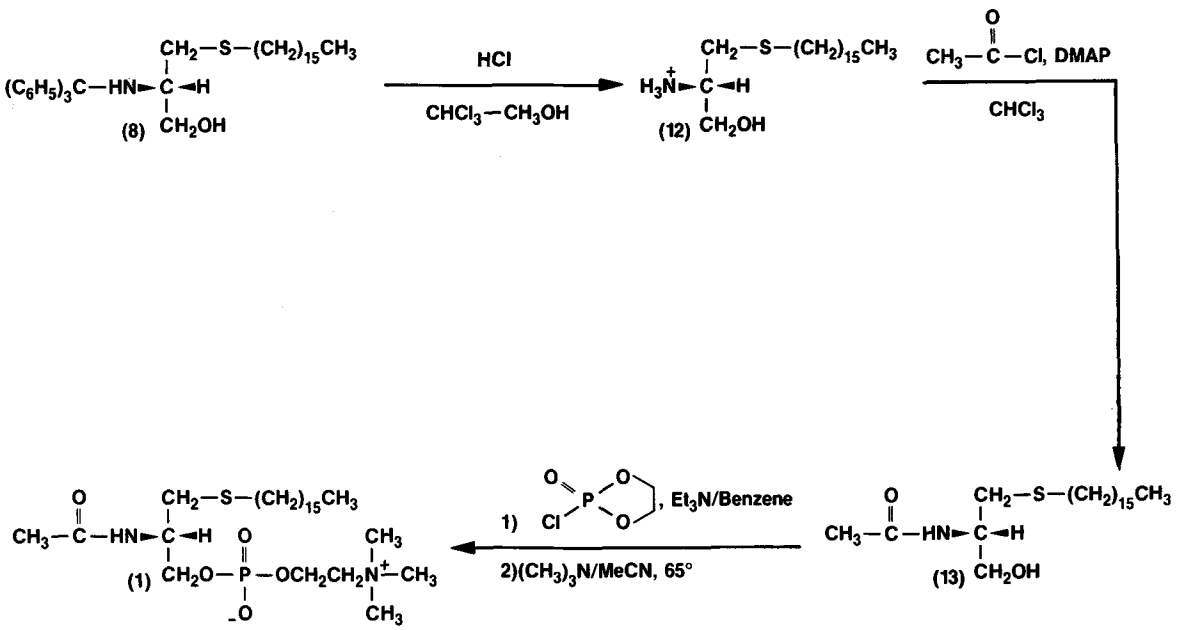
(1)

(2)

SCHEME I. Synthesis of 1-thiohexadecyl-2-acetamidodeoxy-*sn*-glycero-3-phosphocholine.

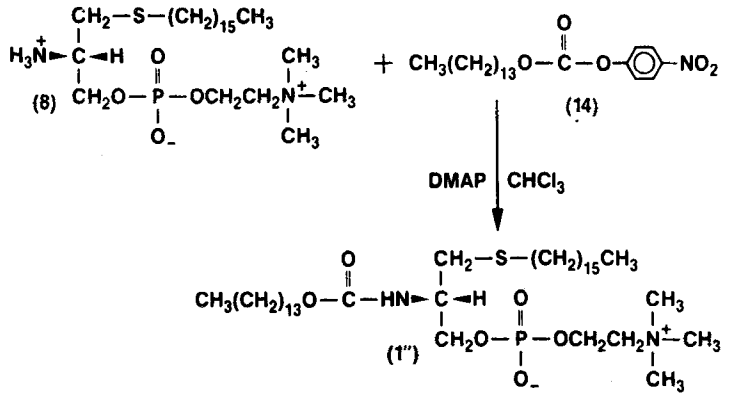
acetonitrile at 65°C for 16 hr gave the corresponding phosphocholine (10). The compound (10) obtained as a single phosphate-positive product from the reaction mixture, was readily purified by silica gel chromatography to give a strongly hygroscopic white solid (61%). Detritylation of (10) was carried out with anhydrous trifluoracetic acid in chloroform, and the resulting aminophospholipid (11) was acetylated *in situ* using acetyl chloride/4-(dimethylamino)pyridine at room temperature, to afford the target PAF analog 1 in 62% yield.

The main synthetic strategy that has emerged from Scheme I is the use of the *N*-trityl protecting group for the preparation of substituted *sn*-2 aminodeoxyglycerophospholipids. This intermediate is likely to become



a useful precursor for the synthesis of other structurally related derivatives, where electrophilic neighboring group activation might be required. Specifically, in contrast to carbonyl-carrying protecting groups, the *N*-trityl function eliminates the possibility of intramolecular side-reactions (*e.g.*, oxazoline formation; refs. 21,22) potentiated by the nucleophilic carbonyl oxygen of *t*-butoxycarbonyl- or carbobenzoxy-substituted amino derivatives. Furthermore, *N*-trityl protected amino alcohols provide hydrophobic substrates that turned out to be highly suitable for efficient phosphorylation. In addition, the resulting *N*-trityl phospholipids are readily purified by silica gel chromatography, yielding much better recoveries than the corresponding aliphatic derivatives (23,24). Finally, due to the ease with which the amino group is deprotected, the desired *sn*-2 substituent of the target phospholipid can be introduced after the polar headgroup had been elaborated.

We have also explored the use of an alternative strategy for the synthesis of 1 through introduction of the *sn*-2 acyl substituent prior to elaboration of the phosphocholine moiety of the target phospholipid. As shown in Scheme II, compound 8 was first detritylated with HCl in anhydrous methanol/chloroform solution to give the corresponding amino alcohol (12, 84%), which was then selectively *N*-acetylated (25) in 71% yield. The product, suspended in dry benzene, was phosphorylated with 2-chloro-2-oxo-1,3,2-dioxaphospholane/triethylamine at room temperature for two days. Ring opening of the ethylene-bridged phosphodiester portion of the molecule by anhydrous trimethylamine in acetonitrile at 65°C for two days yielded compound (1). The phospholipid product was isolated by filtration and purified by silica gel chromatography (52%).



The sequence outlined in Scheme II provides an efficient alternative route to a number of thioether phospholipids, with two important constraints: i) the nature of the *sn*-2 substituent must be committed prior to phosphorylation; and ii) the functional group introduced in the 2-position must be stable under the phosphorylation conditions. It should be pointed out that the key to successful application of the sequence is to provide rigorously anhydrous conditions both during *N*-acylation of the amino alcohol (12) and phosphorylation of the corresponding amide (13). Specifically, anhydrous conditions are required for preferential *N*-acylation in converting compound 12 to 13, preventing the formation of the corresponding diacyl compound (23). The latter has been shown to occur in the reaction mixture as the minor product, isolated in 10–15% yield. Similarly, efficient phosphorylation of alcohol 13 greatly depends on anhydrous conditions; even traces of water appear to cause substantial decrease in yield of 1, most likely due to oxazoline formation (21,22) at the incipient *sn*-3 position.

Synthesis of related analogs. Availability of the *sn*-2 amino intermediate (11) from the sequence described in Scheme I prompted us to extend the scope of the synthesis to the preparation of related derivatives by varying the *sn*-3 substituents. Along these lines we have prepared two closely related *sn*-2 analogs: i) the corresponding long-chain amide (1′); and ii) an *sn*-2 carbamoyl-(tetradecyloxycarbonylamino)phosphocholine 1″. Thus, electrophilic trapping of the sn-2 amino group of 11 by *p*-nitrophenyl tetradecyl carbonate (14)/4-dimethylaminopyridine in chloroform afforded 1″ in 57% yield, (eq. [1]).

The *sn*-2 palmitoyl compound (1′) was obtained under similar reaction conditions (51%). Therefore, it appears that in analogous reactions using other functionalized electrophilic segments, new structurally re-

SCHEME II. Alternative synthesis of 1-thiohexadecyl-2-acetamidodeoxy-*sn*-glycero-3-phosphocholine via acylamino alcohol intermediate.

lated phospholipid derivatives might be preparable. As introduction of the *sn*-2 substituents occurs in the final step of the synthesis, functional groups, that are sensitive to the experimental conditions involved in phosphorylation or interfere with elaboration of the polar headgroup may now be incorporated.

Antitumor activity of compound (1). Comparison of the antineoplastic activity of 1-thiohexadecyl-2-acetamideodeoxy-*sn*-glycero-3-phosphocholine (1) to those exhibited by the 1-*O*-alkyl ether PAF analog (2) and ET-18-OMe indicates that the three compounds are about equipotent. Preliminary studies using a lymphoblastoid lymphoma cell line (Li-A) and a malignant histiocytic cell line (DHL-4) of human origin indicate that both cell lines have about the same sensitivity to the thioether PAF-analog (1) as to the two reference compounds, which are among the most active anticancer phospholipids to date. These results seem to suggest that structurally related analogs of compound (1) might become suitable candidates for future studies of antineoplastic phospholipids.

In conclusion, it might be noted that the strength of the synthetic methods presented is in their simplicity and efficiency; flexibility in terms of the substituents that can be introduced; and applicability to the development of other structurally variable thioether PAF analogs. Synthetic work along these lines is currently under way in our laboratory.

ACKNOWLEDGMENTS

We thank Professor W.E. Berdel of the Technical University of Munich, Germany, for determination of the antitumor activity of compound (1). We are grateful to the National Institutes of Health (DK36215 and CA 46750) for financial support.

Antitumor Activity of Ilmofosine (BM 41.440) in the [3]Lewis-Lung Carcinoma Model[1]

Dieter B.J. Herrmann[a,*], Hans-George Opitz[a] and Paul G. Munder[b]

[a]Boehringer Mannheim GmbH, Department of Immunopharmacology, 6800 Mannheim and [b]Max-Planck-Institute for Immunobiology, 7800 Freiburg, Germany

Ilmofosine (1-hexadecylthio-2-methoxymethyl-1,3-propanediol-phosphocholine, BM 41.440) is a thioether phospholipid with cytostatic/cytotoxic properties. The antineoplastic activity of this compound was investigated *in vivo* in the [3]Lewis-lung carcinoma system. [3]Lewis lung tumor-bearing C57Bl/6 mice were treated with 0.625 to 40 mg Ilmofosine/kg per day *p.o.* either from days 1 to 9 or from days 11 to 28 after intrafoot-pad tumor cell inoculation. Ilmofosine caused a significant dose-related response on tumor growth and metastases, expressed in terms of tumor diameter, tumor weight, survival time and number of metastases-free animals as compared to sham-treated and positive (cyclophosphamide) controls. The results suggest that direct cytostatic/cytotoxic effects, rather than immune-modulatory mechanisms, preferentially contribute to the antitumor activity of Ilmofosine *in vivo*.
***Lipids* 26, 1431–1436 (1991).**

Alkyl lysophospholipids (ALP) are synthetic analogues of naturally-occurring lysophosphatidylcholine, which is a minor but important intermediate in the continuous exchange and renewal of phospholipids in cellular membranes (1, 2). ALP represent a new class of antitumor agents (3,4).

Ilmofosine is a thioether lysophosphatidylcholine analogue which has recently been tested in clinical phase I tolerability studies in adult patients with refractory cancers (5,6). The physiological lysophosphatidylcholine molecule was modified at two sites. Firstly, the ester bond at the *sn*-1 position of the glycerol moiety was replaced by a thioether linkage that is not cleaved by phospholipases; secondly, the hydroxyl group at the *sn*-2 position was replaced by a methoxymethyl group, thereby preventing acylation at position 2 of the lysophospholipid *via* acyltransferases (7,8).

The most frequently considered principal mechanisms to account for the antitumor activity of ALP *in vivo* are the direct and selective cytostatic and cytotoxic effects on malignant cells (9–13) and/or an induction of tumoricidal, immuno-competent cells of the monocyte/macrophage lineage (4,9,14). The molecular mechanism by which ALP deploy their direct tumor cell destructive effect appears to be attributable to a very selective interference of these compounds which cellular phosphatidylcholine metabolism (12,15–17), but it remains uncertain whether this effect is related to a specific inhibition of protein kinase C (PKC) activity (18,19). It was the aim of the present study to shed light on the mode of action of the thioether phospholipid derivative Ilmofosine *in vivo*.

MATERIALS AND METHODS

Compounds. Ilmofosine was synthesized by Boehringer Mannheim GmbH (Mannheim, Germany). Details on the synthesis of this and related alkyl lysophospholipids (ALP) have been published (7). Figure 1 shows the chemical structure of Ilmofosine. The compound was supplied as a crystalline, white powder. The chemical purity of each batch used for the experiments was greater than 98%. Cyclophosphamide (Endoxan^R), used as a reference compound, was obtained from ASTA Pharma AG (Bielefeld, Germany). Ilmofosine and cyclophosphamide were dissolved in phosphate-buffered saline (PBS) immediately before use and diluted as required.

Animals. Syngeneic C57Bl/6 mice, 2–3-months-old, with a body weight of 20–25 g, were used in all experiments. The animals were obtained from our own specific pathogen-free (SPF) unit and were kept under standard laboratory conditions (room temperature, 23 ±1°C; humidity, 50–70%; day/night rhythm, 12 hr, 6 a.m. to 6 p.m.). Food (Altromin^R 1324) and water were provided *ad libitum*.

[3]Lewis-lung carcinoma model. The [3]Lewis-lung carcinoma was maintained by serial passage in C57Bl/6 mice, transplanting 1×10^6 viable tumor cells *s.c.* into the axilla. Seven days later, the animals were killed, the tu-

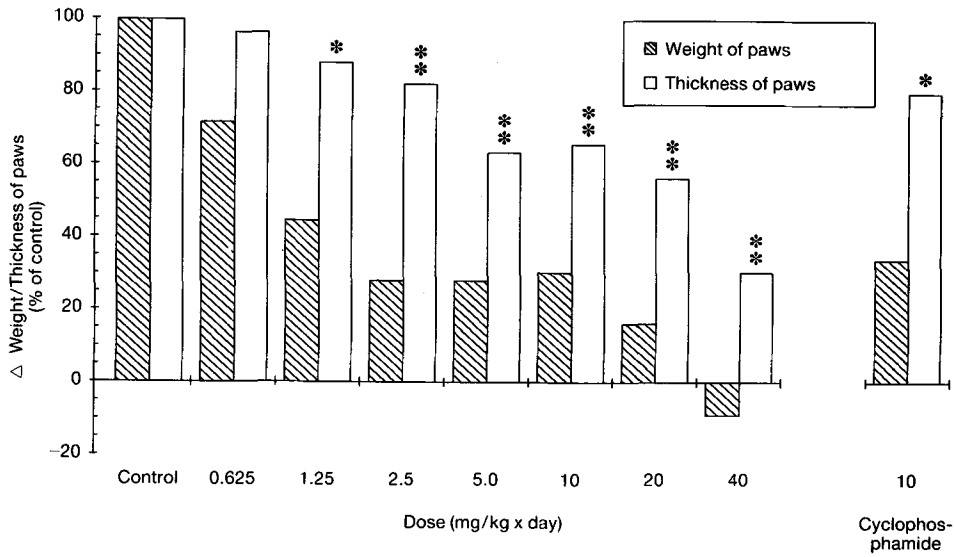

FIG. 2. Effect of Ilmofosine on primary ^{3}Lewis-lung carcinoma growth. Female C57Bl/6 mice, n = 20, were inoculated with 1 × 10^6 tumor cells/mouse on day 0. Surgical removal of the primary tumor was done on day 10. Animals were daily treated *p.o.* from day 1 through day 9 (Schedule I). For mean weight and mean diameter of normal, uninoculated hind paws of C57Bl/6 mice refer to Materials and Methods. *, p≤0.01; **, p≤0.001.

mors excised, and a single cell suspension was prepared by a combined mechanical and enzymatic technique according to Treves *et al.* (20). Briefly, after removal of necrotized parts, tumor fragments were minced with scissors into small pieces which were then suspended in 50 mL cold PBS under continuous slight stirring for 15 min at room temperature. Subsequently the supernatant was sucked off and the sediment trypsinized (15 min, 37°C) with 50 mL of a 0.25% solution of trypsin (Boehringer Mannheim GmbH). After spontaneous sedimentation, the supernatant was discarded and the remaining tissue fragments trypsinized again (30 min, 37°C). Trypsinization was stopped by adding 10 mL fetal calf serum (FCS). The cell suspension was filtered through a stainless steel sieve, underlayered with 5 mL FCS and then centrifuged for 10 min at 1,500 rpm. The cell pellet was washed twice with ice-cold PBS. Cell viability was determined by the trypan blue dye exclusion test and was usually greater than 90%.

Trypan blue dye exclusion test. The trypan blue dye exclusion test for checking cell viability was performed according to the method of Hudson and Hay (21).

Tumor transplantation and surgical removal. In order to study the effect of test and standard compounds, washed, viable ^{3}Lewis-lung carcinoma cells (1 × 10^6 cells/mouse) were injected into the right hind foot pad of female C57Bl/6 mice in a volume of 0.05 mL PBS. Primary tumor growth in controls and in drug-treated mice was determined by caliper measurements of the diameters of the tumor-bearing hind legs. Within 8 to 10 days the inoculated foot usually reached a diameter of 0.5–0.6 cm. In some experiments, tumors were then surgically removed by amputating the primary tumor-bearing hind leg just above the knee joint under phenobarbital anaesthesia (22). The weights of amputated, primary tumor-bearing hind-feet were determined. The differences in weight and diameter, respectively, in comparison to feet of non-tumor-bearing C57Bl/6 mice represent a measurement for primary tumor growth (mean weight and mean diameter ± SD of normal, uninoculated hind paws of C57Bl/6 mice: 134 ± 0.5 mg, 2.1 ± 0.1 mm, n = 10).

Drug treatment schedules. In a first series of experiments, animals were daily treated orally with Ilmofosine, cyclophosphamide or with the drug-free vehicle (PBS), respectively, from day 1 through day 9 after tumor cell inoculation, *i.e.,* treatment was stopped 1 day prior to amputation of the tumor-bearing hind leg on day 10 (Schedule I). In a second set of experiments, treatment started on day 11, *i.e.,* 1 day after amputation, through day 28 after tumor cell inoculation (Schedule II). Ilmofosine and cyclophosphamide were administered by gavage in 0.2 mL PBS. The *in vivo* experiments were usually terminated on day 55 or day 60. Animals treated according to Schedule I were randomly assigned to treatment and control groups immediately after tumor cell inoculation. Mice treated according to Schedule II were randomized 1 day after amputation prior to start of the treatment.

Examination of pulmonary metastases. All animals were examined for pulmonary metastases by injecting diluted India ink into the trachea before fixation of the whole lung, as described in detail by Wexler (23). Metastases appeared as white nodules against black-stained normal lungs.

Statistics. Statistical comparisons of *in vivo* results *vs.* the appropriate negative (PBS) or positive (cyclophosphamide) control groups were performed according to the Mann-Whitney test by using the RS/1 program (BBN Software Products Corp., Cambridge, MA) and a Hewlett-Packard/Vectra ES computer (Microsoft GmbH, Aschheim/Dornach, Germany).

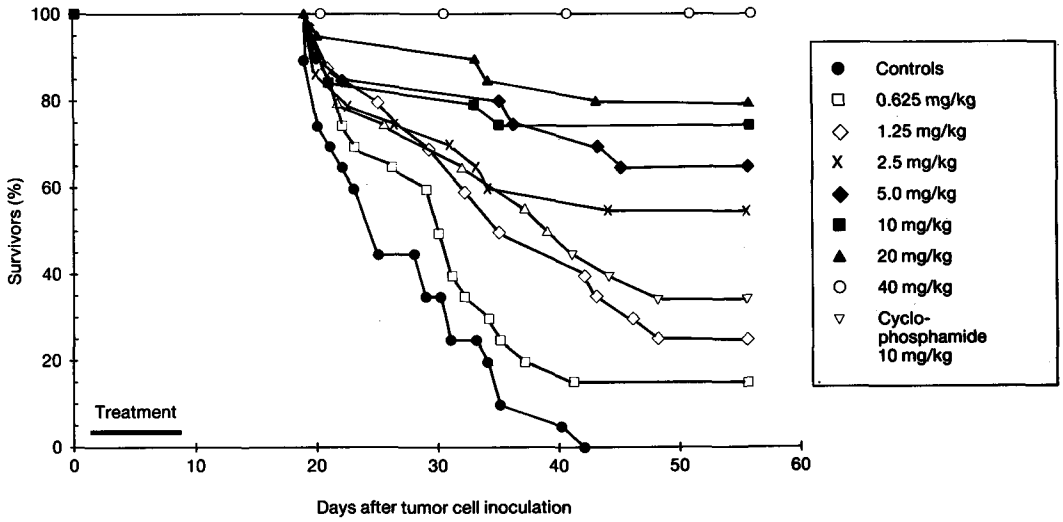

FIG. 3. Influence of Ilmofosine on survival time of ^{3}Lewis-lung carcinoma-bearing mice. Same experiment as shown in Figure 2.

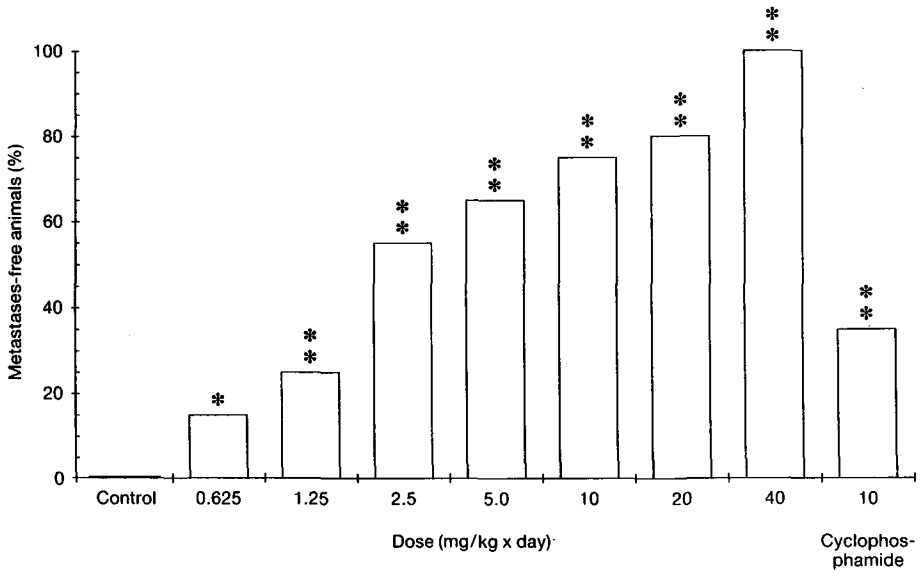

FIG. 4. Influence of Ilmofosine on the number of metastases-free animals. Same experiment as shown in Figure 2. *, $p \leq 0.01$; **$p \leq 0.001$.

RESULTS

The first series of experiments were aimed at testing the influence of Ilmofosine on the growth and metastatic spread of the primary tumor in the ^{3}Lewis-lung model. Groups of 20 mice were inoculated *s.c.* with 1×10^6 ^{3}Lewis-lung tumor cells into the foot pad of the right hind leg. Animals were then treated with doses ranging from 0.625 to 40 mg/kg daily *p.o.* from day 1 through day 9 after tumor cell inoculation. Corresponding control mice were either treated with PBS or cyclophosphamide (10 mg/kg × day). Figures 2–4 show the dose dependent effect on several tumor parameters from a characteristic experiment. These parameters included: i) primary tumor growth, expressed as reduction in weight and thickness of inoculated hind paws (Fig. 2); ii) survival time (Fig. 3); and iii) cumulative numbers of metastases-free animals (Fig. 4).

From this type of experiment (Figs. 2–4) it can be seen that the therapeutic effect of Ilmofosine is clearly dose-related. Even doses as low as 1.25 and 2.5 mg/kg resulted in a significant inhibition of primary tumor growth ($p \leq 0.01$ and $p \leq 0.001$, respectively; Fig. 2). Cyclophosphamide (10 mg/kg × day) also inhibited primary tumor growth, but was always less effective as compared to 5 mg/kg Ilmofosine. This dose of cyclophosphamide was selected based on results of preceding dose response experiments, and proved always to induce survival of 30–40% of the animals under the experimental conditions used (Fig. 3).

In accordance with its inhibitory effect on primary tumor growth, Ilmofosine dose-dependently increased

TABLE 1

Dose-Dependent Effect of Ilmofosine on Mean Survival Time in the ^{3}Lewis-Lung Carcinoma Model

Compound	Dose (mg/kg × day)	MST (Days) [a] Schedule I [b] (Days 1–9)	MST (Days) [a] Schedule II [c] (Days 11–28)
Control (PBS)	—	24	24
Cyclophosphamide	10	39	34
Ilmofosine	0.625	30	27
	1.25	35	36
	2.5	> 55	38
	5.0	> 55	> 60
	10	> 55	> 60
	20	> 55	> 60
	40	> 55	> 60

[a]MST, mean survival time, as calculated from Figures 3 and 5.

[b]Schedule I, daily treatment *p.o.*, days 1–9 after tumor cell inoculation.

[c]Schedule II, daily treatment *p.o.*, days 11–28 after tumor cell inoculation.

survival time in the same experiment (Fig. 3). Control mice began to die from metastases 18–19 days after tumor cell inoculation; 50% of the animals died within 24–26 days, and none of the control animals was alive after 40–42 days. Even the lowest doses of Ilmofosine tested were able to increase mean survival time (Table 1). Cyclophosphamide (10 mg/kg × day) also increased mean survival time up to 39 days as compared to sham-created controls (24 days), but was always less effective compared to 2.5 mg/kg Ilmofosine (Table 1). All 20 animals which were treated daily with 40 mg/kg *p.o.* from day 1 through day 9 after tumor cell inoculation survived the whole observation period up to 55 days. Furthermore, the cumulative numbers of metastases-free animals increased dose-dependently in the same experiment (Fig. 4).

The next set of experiments was aimed at evaluating the therapeutic efficacy of Ilmofosine in this model when treatment started 1 day after removal of the primary tumor by amputation of the tumor-bearing hind leg. The ^{3}Lewis-lung tumors were surgically removed after having reached a diameter of about 0.5–0.6 cm, *i.e.*, on day 10 after tumor cell inoculation. After randomization the animals were then treated with doses of Ilmofosine ranging from 0.625 to 40 mg/kg daily *p.o.* from day 11 through day 28. Once again, cyclophosphamide served as positive control. Figures 5 and 6 show the dose-dependent influence of Ilmofosine on survival time and on the number of metastases-free animals from the same characteristic experiment, respectively.

As can be seen from Figures 5 and 6, as well as Table 1, Ilmofosine again caused a dose-dependent increase of survival time and in the number of metastases-free animals over the total observation period of 60 days as compared to sham-treated and positive (cyclophosphamide) controls.

In all *in vivo* experiments described here Ilmofosine was well tolerated. No noticeable toxic effects and no deaths from toxicity were observed.

DISCUSSION

1-*O*-Alkyl and 1-*S*-alkyl lysophospholipids are structurally related to the membrane component 2-lysophosphatidylcholine as well as to platelet-activating factor (PAF), a naturally occurring lipid mediator, which appears to be involved in the mediation of acute inflammatory and allergic reactions (24,25). Some of these synthetic ether phospholipids previously have been shown to possess antitumor activity *in vitro* (9–12) and *in vivo* (9,14,26). The explanations for these antineoplastic effects include: i) direct cytotoxicity (9,12); ii) generation of tumoricidal immunecompetent cells such as macrophages (9,14); iii) anti-invasiveness (27) and anti-metastatic properties (4,9,14); and iv) induction of differentiation (28,29).

One of these compounds, the thioether lipid Ilmofosine (BM 41.440), has recently been tested in short- and long-term clinical phase I tolerability studies in refractory cancer patients (5,6). Ilmofosine exerts antitumor activity in several *in vivo* tumor systems, including the methylcholanthrene-induced fibrosarcoma (MethA), the L 1210 leukemia, the ^{3}Lewis-lung carcinoma (4) and the methylnitroso-urea (MNU)-induced mammary carcinoma (30). Compared to 1-*O*-alkyl lysophospholipids, thioether-type compounds such as Ilmofosine have certain advantages—for instance, lack of platelet aggregating properties (31,32), a higher therapeutic index *in vitro* (13), and pharmacokinetic detectability at clinically relevant concentrations (5,33).

The question, whether or not the known antitumor effect of Ilmofosine *in vivo* may be attributable to direct cytotoxicity and/or be mediated by the activation of immune-competent cells, such as macrophages or natural killer cells, prompted us to extend our former investigations (4,34) on the activity of this compound in the ^{3}Lewis-lung carcinoma model *in vivo*.

The *in vivo* data presented here indicate that the thioether phospholipid Ilmofosine shows an almost linear and reproducible, dose-dependent dose response relationship in the^{3}Lewis-lung carcinoma model. This is true for all tumor parameters monitored, *i.e.*, primary tumor volume, expressed in terms of weight and thickness of tumor-bearing paws, mean survival time, and numbers of metastases-free animals. Oral administration of Ilmofosine immediately after tumor cell inoculation as well as immediately after amputation of the primary tumor proved to be effective at clinically relevant doses (5,6). At the time of surgical removal of the primary tumor-bearing hind leg, *i.e.*, 10 days after tumor cell inoculation, the metastatic spread in the ^{3}Lewis-lung system has already occurred and tumor cells can be found in the lungs (35; also D.B.J. Herrmann, unpublished results). Thus, Ilmofosine exerts a direct inhibitory effect on the local metastatic growth in the lungs, resulting in a dose-dependent increase in the number of metastases-free animals and, subsequently, in a dose-dependent increase in mean survival time.

Stimulation of cellular or humoral host immune mechanisms frequently show a "bell-shaped" dose-response curve with a decrease of activity at higher dose levels. Therefore, the *in vivo* data shown here make it very unlikely that the postulated immune-modulating mechanisms of ALP (3,9,14) significantly contribute to the

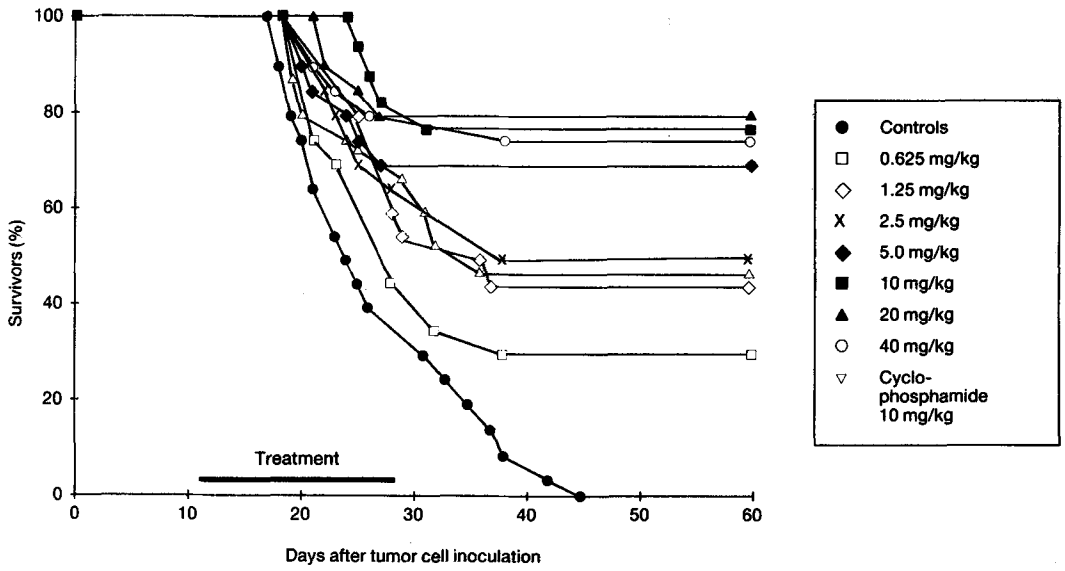

FIG. 5. Influence of Ilmofosine on survival time of ^{3}Lewis-lung carcinoma-bearing mice under an adjuvant treatment schedule. Female C57Bl/6 mice, n = 20, were inoculated with 1×10^6 tumor cells/mouse on day 0. Surgical removal of the primary tumor was done on day 10. Animals were daily treated *p.o.* from day 11 through day 28 (Schedule II).

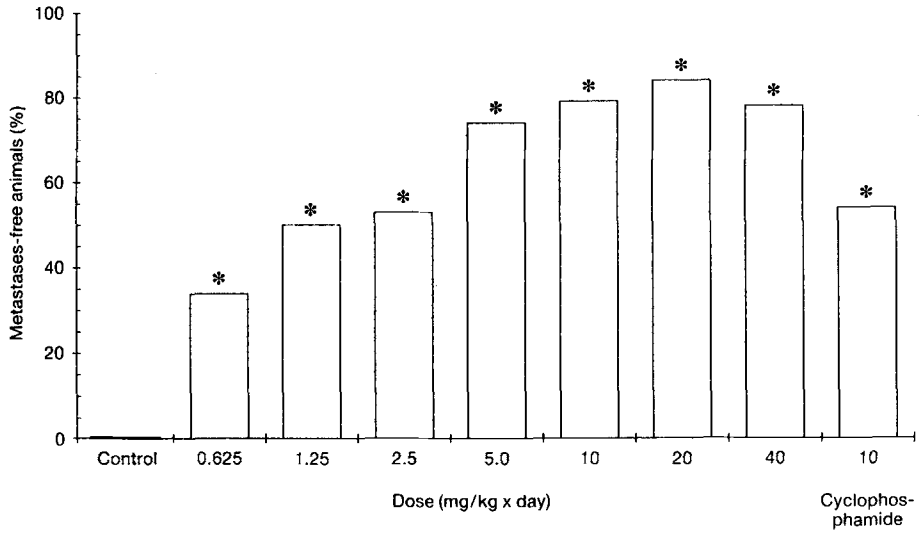

FIG. 6. Influence of Ilmofosine on the number of metastases-free animals. Same experiment as shown in Figure 5. *p≤0.001.

antitumor activity of Ilmofosine, at least in this *in vivo* tumor system.

Our results are well in accordance with the dose-dependent anti-tumor activity of Ilmofosine in the methylnitroso-urea (MNU)-induced mammary carcinoma model (30), and with our recent findings in a methylcholanthrene (MethA)-induced fibrosarcoma model (36). Studies on the antitumor activity of ET – 18 – OCH_3, a structurally related ALP, also revealed dose-related effects in different *in vivo* models, including MethA sarcoma (37), MNU-induced mammary carcinoma (30,38), myeloma MPC-11 (3,9), and L 1210 leukemia (39). Moreover, after a comprehensive evaluation, Talmadge *et al.* (40) did not find convincing evidence for immunomodulatory properties of ALP in mice.

Among all the animal models for testing new anticancer drugs *in vivo*, the ^{3}Lewis-lung carcinoma system is of particular relevance because some of its biological features are very similar to human solid tumors. The ^{3}Lewis-lung carcinoma that arose spontaneously in 1951 in a C57Bl/6 mouse (41) is highly malignant and metastasizes regularly to the lungs (41–43), probably due to its lack of immunogenicity in syngeneic recipients (44,45). Furthermore, this tumor is, as are human solid cancers, characterized by a primary resistance to a majority of chemotherapeutics (46-50).

Ilmofosine was very well tolerated in all *in vivo* experiments reported here. This confirms our earlier observations made during preclinical toxicology studies where a high LD_{50} value of 615 mg/kg was determined for oral

administration of the drug to mice (4). Good tolerance also was seen in the first clinical short- and long-term tolerability studies in cancer patients (5,6). No systemic toxicities were observed (5, 6). Therefore, Ilmofosine appears to have a broad therapeutic range compared to conventional cytostatics.

In conclusion, the data presented here strongly suggest that the therapeutic activity of Ilmofosine *in vivo* relates to its direct cytostatic/cytotoxic effect against tumor cells rather than to immunomodulatory properties as reported for ALP, mainly based on *in vitro* studies. If our observations can be extrapolated to humans, the present results will have a major impact on the designs of further clinical phase II studies. Low toxicity, lack of mutagenicity (4), together with its dose-dependent antitumor and antimetastatic activity, observed in this study under a post-surgical, oral treatment schedule make Ilmofosine an interesting candidate for adjuvant cancer chemotherapy.

1-β-D-Arabinofuranosylcytosine Conjugates of Ether and Thioether Phospholipids. A New Class of Ara-C Prodrug with Improved Antitumor Activity[1]

Chung Il Hong[a,*], Charles R. West[a], Ralph J. Bernacki[b], Cameron K. Tebbi[c] and Wolfgang E. Berdel[d]

Departments of [a]Neurosurgery, [b]Experimental Therapeutics and [c]Pediatrics, Roswell Park Cancer Institute, Buffalo, New York 14263, and [d]Department of Hematology and Oncology, Free University of Berlin, Berlin 45, Germany

The 1-β-D-arabinofuranosylcytosine (ara-C) conjugates 1-*O*-alkyl (ether) and 1-*S*-alkyl (thioether) phospholipids, being analogues of ara-CDP-*sn*-1,2-*O*-dipalmitoylglycerol (1), showed significant antitumor activity against L1210 and P388 leukemia *in vivo*. The more active conjugates include the 1-*O*-alkyl analogues, ara-CDP-*rac*-1-*O*-hexadecyl-2-*O*-palmitoylglycerol (2) and ara-CDP-*rac*-1-*O*-octadecyl-2-*O*-palmitoylglycerol (3), and the corresponding 1-*S*-alkyl analogues, ara-CDP-*rac*-1-*S*-hexadecyl-2-*O*-palmitoyl-1-thioglycerol (4) and ara-CDP-*rac*-1-*S*-octadecyl-2-*O*-palmitoyl-1-thioglycerol (5, Cytoros). The conjugates were formulated by sonication, in which the conjugates existed as discs (size 0.01–0.04 μm). Among the conjugates of the three different phospholipids, the 1-*S*-alkyl analogues 4 and 5 displayed the strongest antitumor activity against L1210 leukemia in mice, followed by the 1-*O*-alkyl (2 and 3) and the 1-*O*-acyl (1) analogues. The 1-*S*-alkyl analogue 5 was considerably more effective than the 1-*O*-acyl analogue 1 against myelomonocytic WEHI-3B leukemia in mice. Conjugate 5 (Cytoros) showed a significant therapeutic activity in mice with colon 26 carcinoma, M5076 sarcoma, and C-1300 neuroblastoma. Furthermore, this agent inhibited liver metastases of M5076 sarcoma. Conjugates 3 and 5 also inhibited the metastasis of 3-Lewis lung carcinoma to the lungs of mice. Cytoros (5) and its analogues, with other ether and thioether phospholipids, appear to offer increased therapeutic benefit to mice with tumors.

***Lipids* 26, 1437–1444 (1991).**

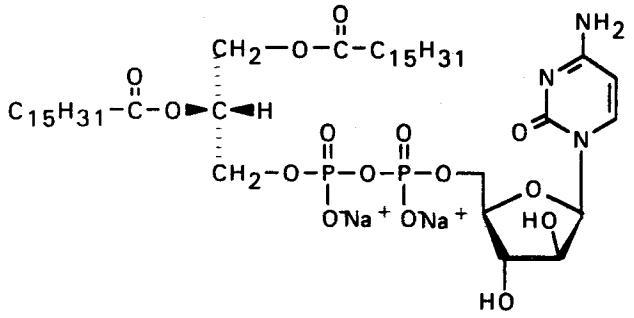
Favorable activity of 1-β-D-arabinofuranosylcytosine (ara-C) conjugates of nontoxic 1-*O*-acylphospholipids such as ara-CDP-L-DP (1) (1–3) and antineoplastic properties of certain ether and thioether phospholipids such as ET-18-OCH_3 (4) and BM 41.400 (5) led us to synthesize a series of ara-C conjugates of 1-*O*-alkyl (ether) and 1-*S*-alkyl (thioether) phospholipids (6–8). The rationale is that the conjugates are not only new prodrugs of ara-C, but also may generate two cytotoxic groups with different target sites in neoplastic cells. Most of them displayed significant antitumor activity against L1210 and P388 leukemia *in vivo* (6,8). The conjugates of ether and thioether phospholipids significantly inhibited 3-Lewis lung carcinoma (3-LL) growth and also increased survival of mice bearing these tumor cells (9,10).

This paper reports on the therapeutic effects of the selected ara-C conjugates from the three different phospholipids (Fig. 1), and also describes further effects of the more active conjugates on various animal solid tumor models.

MATERIALS AND METHODS

Drugs. The chemical structures of the selected conjugates are depicted in Figure 1. The conjugates include: i) the 1-*O*-acyl analogue, ara-CDP-L-DP (1); ii) the 1-*O*-alkyl analogues, ara-CDP-DL-PCA (2) and ara-CDP-DL-PBA (3); and iii) the 1-*S*-alkyl analogues, ara-CDP-DL-PTCA (4) and ara-CDP-DL-PTBA (Cytoros, 5). Details on synthesis (2,6, 11,12) and chemical properties (2,6,11–13), and preliminary antitumor activity data (1–3,6–14) have been published. The conjugates were synthesized in 30% yield by condensation of ara-CMP morpholidate with the phosphatidic acids in anhydrous pyridine (6,12). The conjugate was formulated by sonication in sterile water followed by filtration through a 0.22-μm membrane filter into a sterile receiving container using a laminar flow cabinet (13).

Animals and tumors. DBA/2J mice (male), weighing 23–30 g, in groups of five or six were inoculated *i.p.* with 1×10^6 L1210 lymphoid leukemia cells (or *i.c.* with 1×10^5 L1210 cells), and each drug was given *i.p.* once daily as a single or multiple injections, starting at day 1 as outlined previously (8,15). Survival time and animal weights were recorded and the %ILS (% increase in life span) was compared with the median survival of the untreated mice. Statistical significance was determined by using the Cox-Mantel test. The data calculations were performed using software prepared previously (16).



For antitumor studies with animal solid tumor models, such as colon 26 carcinoma and M5076 carcinoma, the methodology was described previously (17). A 50-mg piece of the tumors was transplanted *s.c.* by trochar implant into the abdominal flank of female BALB/C or C57BL/6 mice (wt 20–25 g). Drugs were administered *i.p.* or *i.v.* on day 7, or on days 7 and 14. Tumor growth, animal weight, and survival were checked using procedures described previously (16,17). Data were analyzed, where required, by analysis of variance (ANOVA) and by the Mann-Whitney

FIG. 1. Chemical structures of ara-C conjugates of various phospholipids.

U test. The 0.05 level of probability was taken as significant.

The antitumor study with C-1300 neuroblastoma was carried out following the published method (18). A/Strong Ros mice (wt 20–25 g) were inoculated *s.c.* in the scruff of the neck with 2×10^6 C-1300 neuroblastoma cells on day 0, and drug was injected *i.p.* once every 10 days, a total of 6 times, starting on day 3. Tumor growth, animal weight and survival were checked as outlined previously (18).

For metastases experiments of 3-LL, the viable cells

(1×10^6) in 0.05 mL PBS were injected *s.c.* into the left hind foot pad of C57BL/6 mice (wt 20–25 g). Within 7–10 days, the injected foot bore a tumor with a diameter of 0.6 cm. The tumors were then surgically removed under pentobarbital anesthesia. Drugs were given *i.p.* after randomization on days 1–5 after the operation. The end-point of the experiments was either death from metastasis or survival (10).

RESULTS

Drug formulation. The conjugates in sonicated solution existed as discs with diameters varying from 0.01 μm to 0.04 μm as judged by electron microscopy after negative-staining or freeze-fracture (13,19). The formulation, when stored at 3–4°C, was chemically stable for more than six months.

L1210 lymphoid leukemia. Table 1 summarizes the effects of the ara-C conjugates of 1-*O*-acyl, 1-*O*-alkyl (ether) and 1-*S*-alkyl (thioether) phospholipids against *i.p.* implanted L1210 lymphoid leukemia in DBA/2J mice according to the procedure outlined in the NCI protocols (15), with some modifications (8). Both the optimal single doses (300–400 mg/kg) and the five consecutive doses (40–80 mg/kg/day × 5) produced significant antitumor activity with increases in life span by 215–371% as compared with survival of the control group ($p < 0.01$). Ara-CDP-L-DP (1), ara-CDP-DL-PTCA (4) and ara-CDP-DL-PTBA (Cytoros, 5) gave one out of six long-term suvivors >45 days. In Figure 2, the antileukemic effectiveness of ara-CDP-L-DP, ara-CDP-DL-PBA, and ara-CDP-DL-PTBA are compared. The results indicate that the conjugate of thioether phospholipid, ara-CDP-DL-PTBA (Cytoros), showed stronger therapeutic efficacy than did the others. In fact, 26 out of 90 animals treated with a single dose of ara-CDP-DL-PTBA (400 mg/kg) survived more than 45 days (Fig. 3). Furthermore, it appeared that toxicity, as reflected in weight loss, was low (Fig. 3).

Table 2 summarizes the effects of ara-CDP-L-DP, ara-CDP-DL-PCA, and ara-CDP-DL-PTBA against *i.c.* implanted L1210 lymphoid leukemia in DBA/2J mice. The optimal single doses (300–500 mg/kg) produced significant antitumor activity with ILS of 200–229%. Multiple courses of drug therapy resulted in no gain in animal life span. However, five consecutive doses (60 mg/kg/day × 5) of ara-CDP-DL-PTBA produced two long-term survivors out of six animals.

Colon 26 carcinoma. Administration (*i.p.*) of a single dose of ara-CDP-DL-PTBA on day 7 to BALB/C female mice, implanted *s.c.* in the abdominal flank with colon 26 carcinoma on day 0 resulted in significant (>100% ILS) increases in life span and decreases in tumor size (Table 3). Median life span more than doubled (day 15 to 33) following the *i.p.* administration of 200–600 mg/kg of ara-CDP-DL-PTBA. Additionally, tumor growth was significantly retarded in the drug-treated animals with half maximal growth tumor size occurring more than three days later (16.5 to 20 days or more). Table 4 shows the effects of *i.v.* administration of ara-CDP-DL-PTBA on day 7, or on days 7 and 14, to the tumor bearing mice. The *i.v.* drug therapy also resulted in tumor size reduction, but little increase in animal lifespan. Treatment with a single dose (300 mg/kg) resulted in some reduction in tumor sizes (84% control tumor size at day 21), but with minimal effect on animal lifespan (ILS 21%). Multiple courses of drug therapy (300 mg/kg/day, days 7 and 21) resulted in improved tumor size reduction (58% control tumor size at day 21) and gain in animal life-span (ILS 84%). Two toxic deaths at day 7 and the loss in weight may be attributable to greater drug toxicity by *i.v.* administration *vs. i.p.*

M5076 sarcoma. Table 5 shows the effects of *i.p.* administration of ara-CDP-DL-PTBA on day 7 to C57BL/6

[a] DBA/2J mice (23–38 g) were implanted *i.p.* with 1×10^6 L1210 leukemia cells on day 0. Treatments (*i.p.*) were initiated 24 hr after tumor inoculation. Animal survival was checked daily until death or 45 days.

[b] Dose producing greatest increase in life span.

[c] Statistical significance was determined by using the Cox-Mantel test, and they are all statistically significant with $p < 0.01$.

[d] Calculated based on survivors according to the NCI protocols (15).

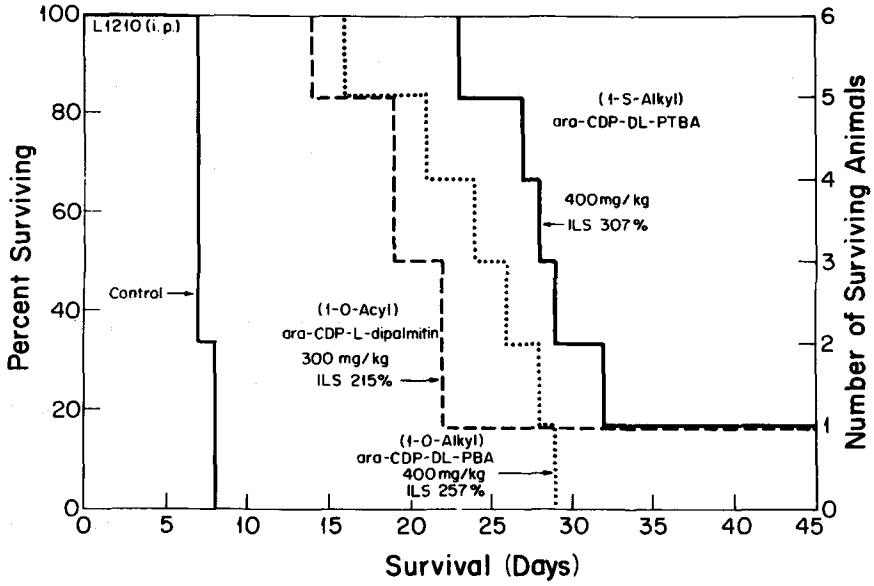

FIG. 2. Effects of changes in *sn*-1 substituent of the conjugate on antitumor activity against *i.p.* implanted L1210 lymphoid leukemia in DBA/2J mice. Experimental details are the same as described in Table 1.

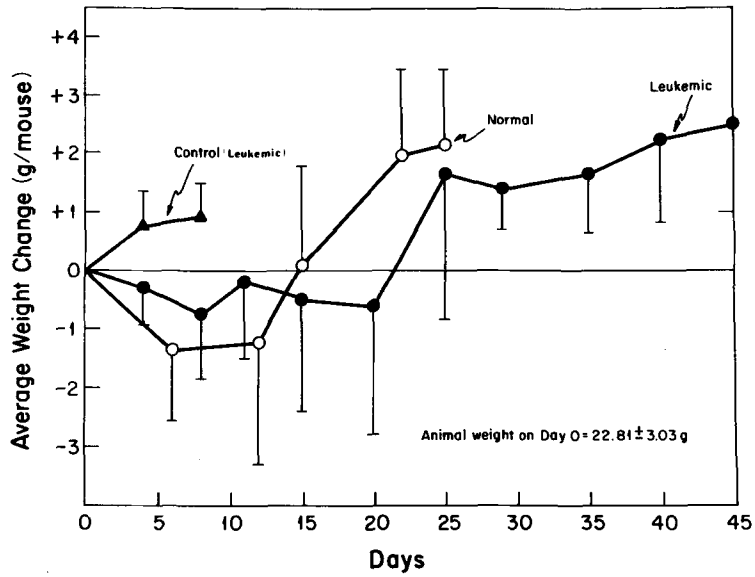

FIG. 3. Average weight changes of normal and *i.p.* inoculated L1210 leukemic DBA/2J mice during *i.p.* treatment with ara-CDP-DL-PTBA (qd 1, 400 mg/kg). Leukemic DBA/2J male mice (av. wt 22.81 ± 3.03 g, total 90 animals) and non-leukemic normal mice (total 5) received drug on day 1. Control leukemic mice (total 54) received saline. All of the normal mice survived more than 45 days. Out of 90 treated leukemic mice, 26 survived more than 45 days.

mice implanted *s.c.* with M5076 sarcoma. A single dose of area-CDP-DL-PTBA (200 or 400 mg/kg) resulted in negligible increases in life span of the tumor bearing mice. The higher dose (800 mg/kg) was severely toxic and caused early death. However, a significant therapeutic effect of drug administration was noted on tumor size. There was also a corresponding decrease in liver metastases observed on day 33, as noted by a decrease in the number of macroscopic tumor foci in liver from animals administered 400 mg/kg drug.

C-1300 neuroblastoma. Administration (*i.p.*) of multiple courses of drug therapy (250 mg/kg/10 days × 6), starting on day 3 to A/Strong Ros male mice, implanted *s.c.* in the scruff of the neck with C-1300 neuroblastoma on day 0, resulted in tumor-free treated animals at least for four weeks as compared to the control ($p < 0.001$) (Fig. 4).

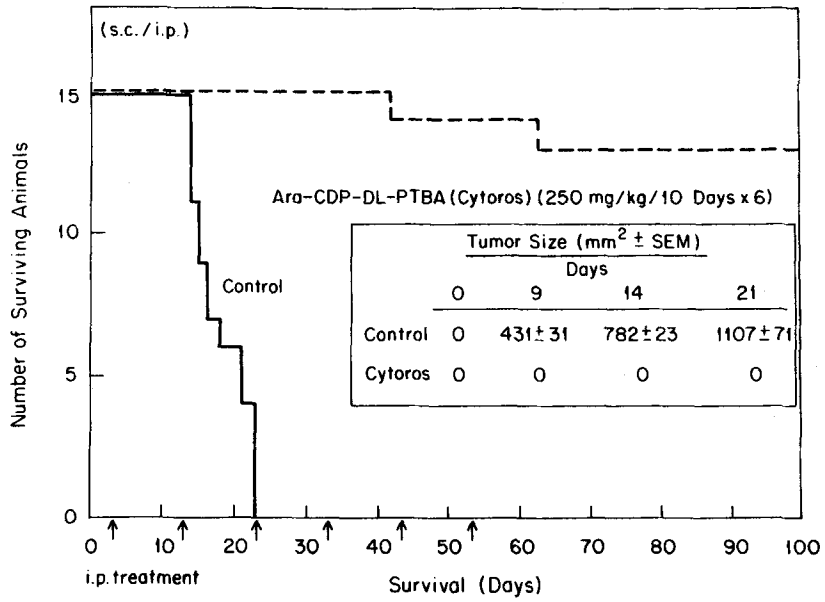

FIG. 4. Therapeutic effects of ara-CDP-DL-PTBA on *s.c.* implanted C-1300 neuroblastoma in A/Strong Ros mice. Mice (20–25 g) were inoculated *s.c.* in the scruff of the neck with 2×10^6 tumor cells on day 0. Drug was injected *i.p.* once every 10 days, a total of 6 times, starting on day 3. Experimental details were as described previously (18).

The survival of this group was significantly greater than the mean of 18 ± 3.7 days for the control group ($p < 0.001$). Weight loss was observed in treated animals, ranging from 10–20% of body weight ($p < 0.001$).

3-LL metastasis. Figure 5 shows the effects of ara-CDP-DL-PBA, ara-CDP-DL-PTBA and equimolar mixtures of ara-C and ET-18-OCH_3 on 3-LL metastasis by giving the drugs as adjuvant chemotherapy shortly after removal of the primary tumor. Administration (*i.p.*) of five consecutive daily doses (80–100 mg/kg/day; days 1–5 postoperatively) of ara-CDP-DL-PBA and ara-CDP-DL-PTBA produced moderate therapeutic effects as measured by an increase in survival time and absolute numbers of surviving animals in comparison to controls. Equimolar

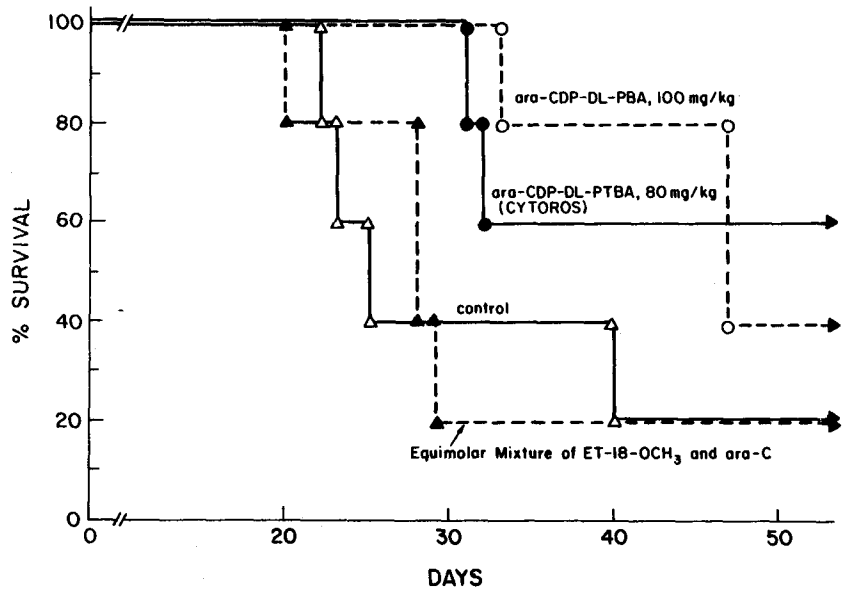

FIG. 5. Therapeutic effects on metastatic 3-LL. C57BL/6 female mice (20–25 g, 5 mice per group) were implanted *s.c.* into the left hind foot pad with 1×10^6 tumor cells on day 0. On days 7–10, the tumors (diameter 0.6 cm) were surgically removed. Drugs were given *i.p.* for five consecutive days shortly after the primary tumor was removed. Equimolar mixture of ara-C and ET-18-OCH_3 was 1:1 mixture of 98.8 mole/kg of each compound, which was the same dose level of ara-CDP-DL-PBA, 100 mg (98.8 μmole/kg. Further details have been outlined previously (10).

mixtures of ara-C and ET-18-OCH_3 were less effective than the conjugates.

DISCUSSION

The conjugates used in this study are amphiphiles (20) that form micelles in water. Upon sonication, the conjugates appear as discs (size 0.01–0.04 μm) when observed by electron microscopy after negative-staining or freeze-fracture (13,19); similar discs are formed by CDP-diacylglycerol (21). The conjugates in micellar form were chemically stable when stored at 3–4°C for a period of more than six months (13). Thus, the conjugates can be formulated safely in micellar solution and stored in a refrigerator.

All of the conjugates shown in Figure 1 displayed a significant therapeutic activity in L1210 leukemic mice. Among them, the thioether phospholipid conjugate, ara-CDP-DL-PTBA (Cytoros), revealed the strongest antitumor activity. Ara-CDP-DL-PTBA also showed considerably higher efficacy than the 1-*O*-acyl phospholipid conjugate, ara-CDP-L-DP, against myelomonocytic WEHI-3B leukemia in mice (22).

Ara-CDP-DL-PTBA also displayed a significant therapeutic activity in mice with various solid tumors such as colon 26 carcinoma, M5076 sarcoma, C-1300 neuroblastoma and 3-LL (5). Multiple doses of ara-CDP-DL-PTBA produced greater therapeutic benefits in mice with colon 26 carcinoma (Table 4) and C-1300 neuroblastoma (Fig. 4). Furthermore, this agent inhibited liver metastases of M5076 sarcoma as noted by the decreased number of macroscopic tumor foci in the treated animals (Table 5). The drug also inhibited the metastases of 3-LL to the lungs of mice as demonstrated by an increase in survival time and in the number of surviving animals (Fig. 5).

The mode of action of the ara-C conjugates remains largely unknown. They may act as lipophilic prodrugs with sustained release of ara-C because of the effectiveness by a single dose treatment (Tables 1 and 2), or they may facilitate transfer of the active moiety across the tumor cell membranes because of their amphiphilic nature. However, there is experimental evidence that the administration of ara-CDP-DL-PTBA leads to a greater intracellular retention of ara-CTP than that resulting from ara-C (23). Some other possible pharmacologically favorable properties of the conjugates include resistance to hydrolysis by cytidine deaminase (1), rapid interaction with serum lipoproteins (24), rapid uptake by cells (25), and effects on lipid biosynthesis (26,27). In addition, the conjugates of 1-*O*-alkyl (ether) and 1-*S*-alkyl (thioether) phospholipids may enhance their therapeutic activity by releasing an additional cytotoxic moiety, namely a 1-*O*-(or-*S*-)alkyl lysophospholipid (28,29). Thus, superior antitumor activity of ara-CDP-DL-PTBA compared to that of ara-CDP-L-DP may be attributed, in part, to the release of two cytotoxic compounds, *viz.* ara-C and 1-*S*-alkyl lysophospholipid. From the present and previous studies (6,8), we can draw the conclusion that the conjugate should resemble the naturally occurring CDP-diacylglycerols which are immediate precursors of phosphatidylinositol (30,31), and that long aliphatic side chains, together with the 1-*O*-alkyl- or 1-*S*-alkyl linkage and long fatty acyl group at *sn*-2 position of glycerol, seem to enhance activity. Further studies are necessary to elucidate the mode of action of these agents.

In summary, the enhanced therapeutic activity of ara-CDP-DL-PTBA (Cytoros) and its 1-*O*-alkyl analogues and their broad therapeutic spectra in both mouse leukemia and solid tumor models suggest that clinical investigations would be warranted.

ACKNOWLEDGMENTS

We are grateful to Roswell Park Cancer Institute for providing DBA/2J mice. We acknowledge the excellent technical assistance of David J. Buchheit, Alan J. Kirisits, Alexander Nechaev, David Chervinsky, and Alice Atwood in various aspects of these studies. The excellent secretarial assistance of Donna Strain is also appreciated.

We synthesized a new series of nonphosphorus alkyl ether glycerolipids, in which the 2-acetyl group of platelet-activating factor was replaced by a pyrimidin-2-yl group and the 3-phosphocholine portion by an ω-(substituted ammonio)ethoxyethyl side-chain including ω-thiazolio-, imidazolio- and pyridinio groups with or without a carboxyl substituent, respectively (compound I–XI). Their effects on cell proliferation and differentiation of human myeloid leukemia HL-60 cells were examined. Incubation of HL-60 cells with these cationic and zwitterionic alkyl ether lipids inhibited proliferation of HL-60 cells with IC_{50} values ranging from 10 to 500 ng/mL. The cells were induced by the lipids to differentiate into morphologically and functionally mature granulocytes. Among the compounds we tested, 1-octadecyl-2-pyrimidinyl-3-[3-(5-carboxylatepentyl)imidazolioethoxyethyl]glycerol (compound I) was the most effective in inducing differentiation of HL-60 cells. Compound I showed on a molar basis, an inhibitory effect on the leukemic cells over 50 times greater than did 2-(2-dodecyloxyethoxy)ethyl 2-pyridinioethyl phosphate, the antileukemic alkyl ether phospholipid.

Lipids 26, 1445–1449 (1991).

Several human and murine myeloid leukemia cells can be induced to differentiate *in vitro* into mature granulocytes and macrophages by various inducers (1,2). Syngeneic mice inoculated with myeloid leukemia M1 cells all died of leukemia, but their survival was significantly enhanced by injection of several differentiation inducers including an alkyl ether phospholipid (3). These findings suggest that treatment of differentiation inducers could be a new approach to the control of leukemia.

Some long-chain alkyl ether phospholipids induced differentiation of human myeloid leukemia HL-60 cells and mouse myeloid leukemia M1 cells (4,5). Although the experimental therapeutic effects of these ether phospholipids were definite, the therapeutic index was not sufficient to be acceptable for clinical trials in the treatment of leukemia (6).

To search a new antitumor agent with a better drug therapeutic index, we synthesized a new series of alkyl ether lipids, 1-*O*-octadecyl-2-*O*-substituted glycerolipids with a 3-(ω-(trimethylammonio)ethoxyethyl group and found that the highest *in vitro* antiproliferative activity was obtained when the 2-substituent was the pyrimidin-2-yl group (7). Based on this study, we continued functional modifications at the polar head base of the 1-*O*-octadecyl-2-*O*-pyrimidinyl glycerolipids by replacing the ω-trimethylammonio group with a thiazo, imidazolio or pyridinio group with or without a carboxyl substituent. These procedures yielded two groups of compounds, zwitterionic (seven) and cationic (five) ones, depending upon whether the polar head base was a heteroaromatic quaternary ammonium group with or without a carboxylate function. This paper deals with the potent growth-inhibitory effects of these new alkyl ether glycerolipids and their ability to induce differentiation of human myeloid leukemia cells.

MATERIALS AND METHODS

Chemicals. The compounds used in this study were 1-*O*-octadecyl-2-*O*-pyrimidin-2-yl 3-*O*-ω-substituted ethoxyethyl glycerols in which a quaternary heteroaromatic ammonio group (thiazolio, imidazolio and pyridinio) with or without a carboxyl moiety was introduced at the ω-position of the 3-polar head side-chain (compounds I–XI). The other compound used was 1-*O*-octadecyl-2-*O*-acetonyl-3-[2-[2-(3-(5-carboxypentyl)imidazolio)ethoxyl]ethyl]glycerol (compound XII). These cationic (compound III, IV, V, VIII and IX) and zwitterionic alkyl ether lipids (compounds I, II, VI, VII, X, XI and IX) were synthesized in our laboratories (7). The purity and chemical structure of each compound were confirmed by thin-layer chromatography (TLC), nuclear magnetic resonance (NMR) and elemental analysis.

Cells and cell culture. Human myeloid leukemia HL-60, K562, ML-1, HEL, U937 and KU812 cells were maintained in RPMI-1640 medium supplemented with 10% fetal bovine serum at 37°C in a humidified atmosphere of 5% CO_2 in air (8–12). Bone marrow cells were obtained from the femurs of 8-week-old mice. Immature myeloid cells were enriched using Lympholyte-M, a separation medium for isolation of mouse lymphocytes, at a density of 1.087–1.088 g/mL (Cedarlane Laboratories, Hornby, Canada). Bone marrow nucleated cells were cultured in RPMI-1640 medium supplemented with 10% fetal bovine serum, 50 units/mL recombinant GM colony-stimulating factor and 50 units/mL recombinant interleukin 3 (Genzyme Co., Boston, MA). The cells were seeded in suspension at a concentration of 3×10^5/mL in a multidish (Nunc, Roskilde, Denmark). All the test compounds were dissolved in absolute ethanol and added to the culture (final ethanol concentration, 0.1 to 0.5%). This concentration range of ethanol had no apparent effect on cell growth or differentiation.

Assay of cell growth and the properties of differentiated cells. Cells (10^5/mL) were suspended in 2 mL of culture medium and were cultured with or without alkyl ether lipids in a multidish (Nunc). The cell number was counted with a Model ZBI Coulter Counter (Coulter Electronics,

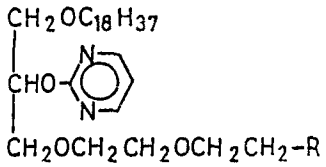
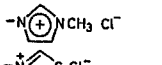
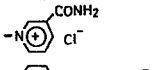
Abbreviations: ET18-OMe, 1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine; NBT, nitroblue tetrazolium; NMR, nuclear magnetic resonance; ST-023, 1-*O*-tetradecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine; ST-029, 2-(2-octadecyloxyethoxy)ethyl 2-pyridinioethyl phosphate; TLC, thin-layer chromatography.

Hialeah, FL) 6 days after treatment. Nitroblue tetrazolium (NBT) reduction was assayed as reported previously (4). The percentage of cells containing intracellular blue-black formazan deposits was then determined by examination of at least 200 cells. Lysozyme activity was determined by a lysoplate method with lysoplates containing 1% agar, 67 mM sodium phosphate buffer (pH 6.6), 50 mM NaCl, and heat-killed *Micrococcus lysodeikticus* (0.5 mg/mL) (4). The percentages of cells that were morphologically similar to mature granulocytes were determined in smears treated with May-Gruenwald-Giemsa stain.



RESULTS





We synthesized novel alkyl ether lipids which differ from known alkyl lysophospholipids in that they contain no phosphoric acid ester group. In the course of screening, we found that these lipids induced differentiation of HL-60 cells. Then we examined the effects of various analogs on growth inhibition and differentiation of HL-60 cells (Table 1). The growth-inhibiting effects of the compounds were estimated by determining the concentrations required to reduce the cell number to half that of untreated cultures (IC_{50}). Nitroblue tetrazolium (NBT) reduction is a typical functional marker of differentiation of HL-60 cells (13), and the cells were cultured with IC_{50} concentration of each compound for assay of NBT reduction. These 1-*O*-octadecyl-2-*O*-pyrimidin-2-yl glycerolipids which are characterized by the absence of a phosphoryl group in the 3-polar head side-chain (compounds I–XI) showed dramatically potent activities on growth and differentiation of HL-60 cells, as compared to alkyl ether phospholipids including the reference compound, ET18-OMe (4,5). Among the compounds tested, most of the cationic lipids showed greater activity than those with the zwitterionic structure, with a few exceptions. The maximal activity was observed with the *N*-methylimidazolio compound (IV) with the IC_{50} value of 10.5 ng/mL. However, the *n*-carboxypentylimidazolio compound (I) with the IC_{50} value of 96.7 ng/mL was more effective than compound IV in inducing NBT reduction of the cells (Table 1). This led us to synthesize and test further analogs of compound I having an appropriate substituent at position 2 and/or 3 of the glycerol backbone. A change in the structure of the polar head base (ω-heteroaromatic ammonio group) did not yield a more favorable inducer of cell differentiation than compound I, although only a limited number of compounds was tested. Figure 1 shows the chemical structures of the compounds obtained by modification of the substituent at position 2 (compound XII) and the repeated ethyleneoxy unit at position 3 (compound X and XI). These compounds did not show any significant increase in either the growth inhibition or the ability to induce NBT reduction as compared to compound I (Table 2). Consequently, among the compounds tested, compound I was the most effective in inducing NBT reduction of the cells.

Lysozyme activity also is a typical marker of functional differentiation of the cells (4). Lysozyme activity was induced in a dose-dependent manner by compound I, as was

XI	237.5	39.6
XII	412.5	35.5

[a]HL-60 cells were treated with analogs (Fig. 1), as shown in Table 1.

NBT reduction (Fig. 2). When HL-60 cells were cultured without inducers, most of them were promyelocytic, whereas when the cells were cultured with increasing concentrations of the compound, mature granulocytes appeared and increased in number (Fig. 3). After culture for 6 days, more than 90% of the cells were induced to differentiate into myelocytic and more mature cells.

The growth-inhibitory effect of the new ether lipid was compared with known ether lipids. Figure 4 shows compound I was more effective in inhibiting growth of HL-60 cells than the previously known alkyl phospholipids (ET18-OMe, ST-023 and 029). The inhibitory effect of compound I was about 50 times greater on a molar basis than that of the dodecyl ethyleneglycophospholipid (ST-029), which had been proved to be therapeutically effective on leukemic mice in our laboratories (6).

The chemical structure of compound I is quite different from those of alkyl ether phospholipids, and this difference was expected to be reflected in differences in antileukemic properties. Therefore we examined the growth-inhibitory effect of this compound on several human myeloid leukemia cell lines (ML-1, HEL, KU812, U937 and K562) in direct comparison with alkyl ether lysophospholipid (ST-023). K562 cells are known to be resistant to ET18-MOe alkyl ether phospholipid (14). Figure 5 and Table 3 show that normal mouse bone marrow cells are fairly resistant to compound I, as well as ST-023, and compound I represents a similar selective effect on several

human leukemia cell lines although it was much less active against K562 cells. This inhibition pattern was similar to that of ST-023 (4).

DISCUSSION

Aiming to obtain a better therapeutic inducer of human leukemia, we synthesized a new class of nonphosphorus alkyl ether lipids, cationic (compound III, IV, V, VIII and IX) and zwitterionic types (compound I, II, VI, VII, X, XI and XII), and examined their growth-inhibitory activity and ability to induce differentiation of HL-60 cells. The structural features of the present alkyl ether lipids are: (i) a long-chain alkyl ether linked to position 1 of the glycerol backbone, (ii) an ether-linked pyrimidin-2-yl group at position 2 (in the case of compound XII, the acetoacetyl group was introduced), and (iii) the absence of a phosphate group and the presence of an ω-(heteroaromatic quaternary ammonio)ethoxyethyl unit in the polar head side-chain at position 3 of glycerol.

The ether lipids examined were much more potent than the alkyl ether lysophospholipids (ET18-OMe and ST-023) in inhibiting cell growth and inducing cell differentiation on a molar concentration basis. This emphasizes the importance of the nonphosphorus alkyl ether lipids in this series. An increase in growth-inhibiting activity appeared to be associated with the metabolic stability of the lipids which is attributed to the absence of a phosphate group and the presence of an ω-(substituted ammonio)ethoxyethyl function in place of the phosphocholine moiety. In view of the substrate specificities of phospholipases (A_1, A_2, C and D) (15), the present class of ether lipids should be resistant to the action of phospholipases and thus can be expected to accumulate more readily in the cell membrane than alkyl lysophospholipids, as the latter are thought to be cleaved by phospholipases C and D (16). Recently, we reported that a labeled nonphosphorus alkyl ether lipid,[2] similar in structure to ET18-OMe, was not degraded at all (no formation of radiolabeled choline or choline phosphate) during incubation with HL-60 cells, when compared with an alkyl ether phospholipid (17). These results suggest that the nonphosphorus alkyl ether lipids are metabolically stable and cannot be substrates for phospholipases C and D.

Marked individual variation occurs among different human leukemias with respect to their sensitivity to the antiproliferative effect of alkyl lysophospholipids (18,19). This series of alkyl glycerolipids has similar target specificity on proliferation of human myeloid leukemia cells (Table 3). Compound I showed high inhibitory activities, except against K562 cells, and the potencies against HL-60, ML-1, HEL, and KU812 cells were more than 15 times higher than that of ST-023. The results suggest that the mode of action of the new types of lipids may be similar to that of alkyl lysophospholipids.

Our findings showed that the cationic ether lipids were generally more inhibitory against leukemia cells than those with zwitterionic structure, presumably due to a higher affinity of the cationic type for malignant cells. Compound I and IV inhibited the proliferation of HL-60 cells at 10^{-7} and 10^{-8} M, respectively. The high efficiency of the lipids in inhibiting cell growth may suggest the presence of specific binding sites for the lipids, which would presumably be located on the surface of the plasma membrane of HL-60 cells (20). The initial target site still remains to be identified.

Alkyl lysophospholipids and the analogs have aroused increasing interest as a new class of potential anticancer agents. Clinical pilot studies of several alkyl ether lipids have been undertaken on patients suffering from a variety of malignant diseases (21,22). In general, alkyl ether lipids tend to inhibit proliferation of certain types of leukemia cells at a low concentration and to inhibit the growth of normal bone marrow cells only at a high concentration (4,23). The difference in response of leukemic and normal cells indicates the potential advantages of using alkyl ether lipids as antileukemic agents. Our preliminary experiments have shown that compound I is active against *in vivo* experimental tumors (S180 and MM46) with less acute toxicity in mice when compared with ST-023 (in preparation). Further *in vivo* studies on the antileukemic properties of compound I are underway.

[2]1-*O*-octadecyl-2-*O*-methyl-3-*O*-(ω-trimethylammonioethoxyethyl)-glycerol, tritium-labeled in the *N*-methyl group of the 3-polar-head side-chain.

ACKNOWLEDGMENTS

We are grateful to the Japanese Cancer Research Resources Bank for the supply of HEL and KU812 cell lines. This work was supported in part by a Grant-in-Aid for Cancer Research from the Ministry of Education, Science and Culture of Japan, and a grant from the Ministry of Health and Welfare for a Comprehensive 10-year Strategy of Cancer Control, Japan.

[Received July 21, 1989; Revision accepted September 18, 1990]

PREFACE

This special *Lipids* issue represents a thorough, state-of-the-art account on platelet activating factor (PAF) and structurally related alkyl lysophospholipids (ALP). The present collection contains some hundred peer-reviewed research articles and reviews by the world's leading authorities in this field. The contributions are based on papers and posters which were originally presented at the Third International Conference on Platelet-Activating Factor and Structurally Related Alkyl Ether Lipids held in Tokyo, Japan, in May 1989. Most of the original research papers and focused in-depth review articles have since been updated and provide a detailed overview of the state of current research on ether lipid mediators covering biochemical, cell biological, physiological and pathological aspects of PAF function as well as the role of ether lipids (ALP) in cancer therapy.

The present volume covers a wide range of specialized topics including PAF metabolism and its regulation; PAF and PAF analogs and their metabolic effects; PAF analysis by spectrometric and immunological assay; PAF receptor and PAF antagonists; cell biology of PAF; PAF and the cerebral system; PAF, the cardiovascular system, and hypotension; PAF, the respiratory system, allergy, and asthma; PAF and the renal system; PAF and the gastrointestinal system; the pathophysiology of PAF; and alkyl lysophospholipids in cancer therapy. This timely collection is the most comprehensive compendium of peer-reviewed papers published in the PAF field to date.

I wish to express my sincere thanks to Professor Shoshichi Nojima, Chairman of the Conference, and to the Members of the Organizing Committee for their commitment and for making the Conference a most memorable experience. Thanks are also due to the colleagues who have co-edited the papers. I am deeply indebted to the many referees for their enormous efforts and their expert advice; without them peer-review would not have been possible. My cordial thanks also to Dr. Barbara Malewicz, Kerry McParland and Kerry Ruck at the Hormel Institute for their tireless efforts and encouragement, and to Annette Wall and the entire *Lipids* Production Staff for their extraordinary dedication and care. Last but not least, I would like to thank each of the authors for their contributions and for their cooperation and patience in revising and updating their papers. This special issue is the result of a special team effort. All involved can be proud of it.

This special issue of *Lipids*, which is also available as hardcover copy, should become a key reference source for researchers in a broad range of biochemical, biological and biomedical disciplines concerned with the role of PAF, ALP, and related ether lipid mediators and their respective modes of action.
