Our objective was to determine the relative rates of *in vivo* triglyceride (TG) secretion and the composition of very low density lipoproteins (VLDL) in rats fed different dietary saturated fats. Male Sprague-Dawley rats (150–200 g) were fed diets containing 16% corn oil, or 14% butterfat, 14% beef tallow, 14% olive oil, or 14% coconut oil plus 2% corn oil for 5 wk. Changes in plasma TG specific radioactivity were determined in individual, unanesthetized fasted rats after injection of 100 μCi [2-^{3}H]glycerol. Nonlinear regression analysis using a 2-compartment model was used to determine the fractional rate constant for TG turnover in plasma. The plasma TG pool was 33–40% larger with beef tallow than with corn, olive or coconut oil feeding ($p<0.05$), and 20% larger with beef tallow than with butterfat feeding. The rate of TG secretion into plasma (mg/min/100 g body weight) was 60% higher in animals fed beef tallow than corn or coconut oil ($p<0.05$) and 26–33% higher in animals fed beef tallow than olive oil or butterfat. Differences in VLDL composition (% wt) were also noted. Our data suggest that greater TG secretion is the primary factor contributing to the larger TG pool with ingestion of beef tallow relative to butterfat, corn or coconut oil. These results suggest that different dietary saturated fats have unique effects on TG metabolism in rats.
***Lipids* 26, 824–830 (1991).**

The influence of diet on plasma triglyceride (TG) levels has received recent attention, in part, because of a better appreciation of how TG-rich lipoproteins may promote atherogenesis (2). Ingestion of saturated or monounsaturated fats has been associated with higher plasma TG concentrations compared to ingestion of polyunsaturated fats in humans (3,4) and in rats (5–9). Possible mechanisms contributing to higher plasma TG levels with ingestion of saturated fat relative to unsaturated fat include an increase in very low density lipoprotein (VLDL) secretion (4,10–12) and hepatic lipogenesis (13,14) and a decrease in the rate of clearance of VLDL or chylomicrons from plasma (7,8). An increase in hepatic TG secretion has been demonstrated to be the primary factor associated with the hypertriglyceridemic effect of saturated fats in humans (4,10).

The mechanism(s) underlying high plasma TG levels with ingestion of saturated fats in the rat remain controversial. *In vitro* studies with liver perfusion demonstrated an increase (11,12) or no difference (6) in TG secretion when long-chain saturated fatty acids replaced unsaturated fatty acids in the perfusate. However, *in vivo* studies using Triton WR 1339 demonstrated similar rates of TG secretion in rats fed palm oil relative to sunflower seed oil (8). Other work suggests that saturated TG in chylomicrons (7) and VLDL (8) are cleared more slowly from plasma than unsaturated TG.

The relative effects of different types of dietary saturated fats on *in vivo* rates of TG secretion and the composition of TG-rich VLDL have not been compared concurrently in one study. In addition, previous methods used to determine TG secretion such as liver perfusion and the Triton technique have limitations which may not reflect the *in vivo* response. Moreover, these methods often require the use of anesthesia or restraint which has been shown to significantly decrease TG production (15,16).

Therefore, our objectives were to determine the relative rates of *in vivo* TG secretion and plasma VLDL composition in rats fed corn oil, butterfat, beef tallow, olive oil or coconut oil. Rates of TG secretion were determined using 2-[^{3}H]glycerol and a two-compartment model (17) with sequential blood sampling of individual, unanesthetized animals using minimal restraint.

MATERIALS AND METHODS

Animals and diets. Male, Sprague-Dawley rats (Harlan Sprague-Dawley, Madison, WI) weighing 138–176 g were housed in individual stainless steel cages and maintained at 25°C with a 12-hr (7 a.m. to 7 p.m.) light-dark cycle. Rats were assigned to dietary groups ($n = 15$) by controlled randomization 5 days after delivery so that initial body weights were not different among groups.

Rats were fed *ad libitum* one of five AIN 76A diets containing 16% fat and equal amounts of sucrose and cornstarch (9). The five diets contained 16% corn oil or 14% butterfat, 14% beef tallow, 14% olive oil or 14% coconut oil plus 2% corn oil to prevent essential fatty acid deficiency (Table 1). Cholesterol was added to provide a similar amount of dietary cholesterol based on the cholesterol content of anhydrous butterfat, 0.25 g cholesterol/100 g butterfat (9). The fatty acid composition of the diet was determined (9) using a Varian 3400 gas chromatograph (Varian, Sugarland, TX) equipped with an on-column temperature programmable injector (Table 2). Diets were stored at 4°C and fresh diets were presented to animals biweekly. Food intakes were calculated weekly based on a 4-day period, and body weights were measured biweekly.

After feeding the diets for 5 wk, 7 rats from each group were randomly selected and killed for analysis of plasma, VLDL and liver lipid concentrations. Rats were fasted

overnight, anesthetized with CO_2, and blood (8–10 mL) was collected by cardiac puncture into syringes containing 1 mg EDTA and 0.1 mg gentamicin sulfate per mL blood. Livers were excised, blotted dry, weighed, and kept at −20°C for analysis. The remaining animals were used for determination of TG secretion.

Determination of in vivo triglyceride secretion. In vivo TG secretion was determined in individual, unanesthetized fasted rats by multicompartment analysis of the changes in plasma TG specific radioactivity (dpm/mg TG) after injection of 100 μCi [2-^{3}H]glycerol (5–10 Ci/mmol; New England Nuclear, Boston, MA). Animals underwent surgical placement of cannula in the left carotid artery (18) after ingesting the diets for 5 wk. After being anesthetized by intramuscular injection of a mixture providing 50 mg ketamine plus 10 mg xylazine per kg body weight, a polyethylene catheter (15 cm, PE-50, ID 0.58 mm, OD 0.97 mm, Dow Corning Corp., Midland, MI) was inserted 2.5 cm into the left carotid artery and sutured securely to the artery (18). The free end of the catheter was tunneled under the skin and secured in the midscapular area with two surgical staples. The catheters were pretreated with 2% TDMAC-Heparin solution (1000 usp units/mL; Polysciences Inc., Warrington, PA) and sterilized. Animals were allowed 1 wk to recover from surgery and to regain their presurgical weights. All experiments were conducted at 8 a.m. on unanesthetized rats that were fasted for 10 hr. Minimal restraint was used during injection of isotope and repeated blood sampling.

Prior to the injection of isotope, a baseline blood sample (300 μL) was collected into a 1-mL syringe containing 0.3 mg EDTA and 0.03 mg gentamicin sulfate. Each animal then received 100 μCi [2-^{3}H]glycerol diluted in 300 μL saline followed by flushing the cannula 3 times with 200 μL of saline to displace any remaining isotope. A preliminary *in vitro* experiment demonstrated little residual isotope after this flushing procedure.

Blood samples (300 μL) were obtained 10, 15, 20, 25, 30, 40, 60, and 80 min after injection of isotope as described for baseline blood samples. These time points were chosen (17) to sample 3–4 times during both the ascending and descending parts of the TG specific activity curve. After each sample was obtained, the cannula was flushed with 300 μL saline which was then removed and discarded prior to obtaining the next sample. After the experiment, cannulae were dissected from selected animals and counted for ^{3}H; results demonstrated minimal residual contamination with isotope. The repeated blood sampling resulted in a 14–18% decrease in blood hematocrit with no significant differences among groups.

Determination of plasma triglyceride specific activity. Plasma was separated by centrifugation at 1200 × *g* for 20 min. Lipids were extracted twice from plasma samples (120 μL) with 2.5 mL chloroform/methanol (2:1, v/v) (19) and triglycerides were separated and identified by thin-layer chromatography on Whatman Silica Gel H (American Scientific Products, Mc Gaw Park, IL) (20). TG concentrations were determined in TG extracts from chromatography plates based on saponification and measurement of free glycerol (21).

Radioactivity was counted with an accuracy of ± 2% in a Packard 2000 CA Tri-carb Liquid Scintillation Analyzer, with Opti-fluor (Packard Instrument Inc., Downers Grove, IL) as scintillation fluid. The TG specific activity was calculated for each sample and expressed as dpm/mg TG. A known amount of tritiated tripalmitin was added to selected plasma samples before lipid extraction; recovery of radioactivity ranged from 85–90%.

Kinetic analysis. The kinetic model used to evaluate changes in plasma TG specific activity was based on a two-compartment system with irreversible flow, time delay between the compartments and equal fractional rate constants (17). The equation describing the model is:

$$SA_{(2)} = A(t-t_{lag})e^{-k(t-t_{lag})} \quad [1]$$

where $SA_{(2)}$ = specific activity of TG in compartment 2;

A = a constant; k = the fractional rate constant; t = time of sampling; t_{lag} = lag time (delay in appearance of labeled TG in plasma).

For each animal, the coefficients A and k were determined by nonlinear regression analysis using the SAS NLIN procedure (22) on a Hewlett-Packard 9000/825 computer. Plots of residual *versus* predicted values were used to assess fit of the model (23). Plasma TG pool size was calculated as baseline plasma TG concentration multiplied by plasma volume, where plasma volume = (body weight × 0.041) − 1.59 (17). The half life ($t_{1/2}$) for plasma TG turnover was calculated from the equation: $t_{1/2} = \ln 2/k$. The rate of TG secretion into plasma was calculated by multiplying k by the plasma TG pool size.

Analyses of liver and plasma lipids. Plasma was obtained by centrifugation at 4°C for 20 min at 1200 × *g*. VLDL were fractionated from 3 mL plasma by sequential ultracentrifugation (9) with the following modifications to improve recovery of TG. The VLDL fraction was initially isolated by spinning at d = 1.006 g/mL for 18 hr. A tube slicer was then used to help remove the top two mL containing VLDL followed by repeated rinsing of the inside wall of the tube with d = 1.006 g/mL solution to recover lipid clinging to the tubes. The VLDL fraction was then ultracentrifuged for another 18 hr to minimize albumin contamination and the top one mL containing VLDL was carefully removed and saved for analysis.

Concentrations of cholesterol and TG (Sigma TG Kit, No. 336, Sigma Chemical Company, St. Louis, MO) were determined in plasma and VLDL (5). Concentrations of VLDL protein, total and free cholesterol and phospholipid were determined (5). The concentration of esterified cholesterol was multiplied by 1.68 when VLDL composition was expressed as % by weight to account for the fatty acid moiety. Lipids were extracted from 1 g hepatic samples with chloroform/methanol (2:1, v/v) (19) and assayed for cholesterol (5) and TG (21) contents.

Concentrations of apolipoprotein B and E in plasma VLDL were determined by the Laurell electroimmunoassay technique (24) and expressed as mg apolipoprotein/dL plasma. Standard curves were calculated using standardized rat plasma of known apolipoprotein concentration.

Statistical analysis. Differences among dietary treatment groups were assessed by one-way analysis of variance (ANOVA) using the SAS general linear models program (22). Group means were considered to be significantly different at $p \leq 0.05$ as determined by the least significant difference technique (25). Values are expressed as mean ± SEM.

RESULTS

Final body weight, liver weight and lipid contents of plasma and liver are summarized in Table 3 for nonsurgical rats fed for 5 wk. Food intake (14.6–15.3 g/d) and final body weight were not significantly different among dietary groups. However, liver weight was significantly higher with ingestion of olive or coconut oil than with ingestion of corn oil, butterfat or beef tallow.

In vivo triglyceride secretion. Figure 1 illustrates the changes in plasma TG specific activity after administration of 100 μCi [2-^{3}H]glycerol to rats fed different dietary fats. Illustrated data were taken from representative animals. Examination of residual plots indicated that our model gave an adequate fit to the data. Steady state plasma TG levels were maintained throughout the experiment satisfying an assumption of the kinetic model.

The magnitude of plasma [2-^{3}H]TG specific activity differed from animal to animal. For example, plasma TG specific activity ranged from 1555 to 39682 dpm/mg TG in one animal fed corn oil and from 833 to 66227 dpm/mg TG in another animal fed beef tallow. Differences within a dietary treatment were also present indicating a large intra animal variation with respect to the extent of tracer incorporation. This suggests the importance of doing compartmental kinetic analysis on sequential samples from individual animals rather than killing multiple animals at specific time points.

The effects of dietary saturated fats on plasma TG pool size, the rate of TG secretion, the fractional rate constant (k), lag time (t_{lag}) and half life ($t_{1/2}$) are shown in Table 4. The plasma TG pool was 33–40% larger with beef tallow than with corn, olive or coconut oil feeding ($p<0.05$), and 20% larger with beef tallow than with butterfat feeding. The rate of TG secretion into plasma (mg/min/100 g body weight) was 60% higher in animals fed beef tallow than corn or coconut oil ($p<0.05$) and 26–33% higher in animals fed beef tallow than olive oil or butterfat. Values for fractional rate constants (0.048–0.060 min^{-1}), t_{lag} (10.9–11.9 min) or $t_{1/2}$ (10.8–15.0 min) were not significantly different among the dietary groups.

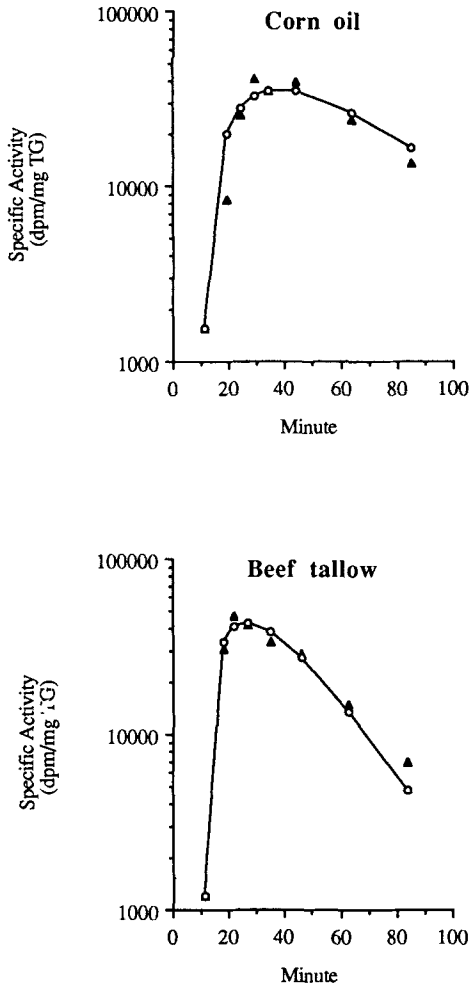

FIG. 1. Plasma triglyceride specific radioactivity after injection of 100 μCi [2-^{3}H]glycerol (5–10 Ci/mmol) into rats fed different dietary saturated fats. Data were taken from representative animals from the corn oil and beef tallow groups. ▲, observed triglyceride specific radioactivity; O, predicted triglyceride specific radioactivity based on the model: $SA_{(2)} = A(t-t_{lag})e^{-k(t-t_{lag})}$.

Analysis of plasma VLDL. VLDL concentration (mg/dL plasma) and composition (% by weight) are shown in Table 5. VLDL total mass was significantly higher with ingestion of beef tallow or olive oil than corn oil, as indicated by significantly higher individual concentrations of VLDL-TG, protein, phospholipid (PL) and cholesterol. VLDL-TG, protein and cholesterol concentrations were not significantly different among corn oil, butterfat or coconut groups. Ingestion of butterfat, olive or coconut oil resulted in VLDL with less % by weight TG than beef tallow.

VLDL from animals fed beef tallow demonstrated a significantly higher ratio of core-to-surface components (TG + esterified cholesterol/free cholesterol + PL + protein) than all fats except corn oil. This suggests the presence of larger TG-enriched VLDL with ingestion of beef tallow than with ingestion of butterfat, olive or coconut oil. Ingestion of butterfat was associated with relatively smaller VLDL particles than beef tallow or corn oil based on a significantly lower ratio of VLDL core-to-surface components.

Concentrations of apolipoprotein (apo) B and E in plasma VLDL are shown in Table 6. Apo B was 3–4 fold higher ($p<0.0001$), and apo E was 1.8–2 fold higher ($p<0.01$) with ingestion of beef tallow or olive oil than corn oil. However, no significant differences in apo B and E levels were noted in rats fed butterfat, coconut or corn oil.

Overall, the data suggest distinct effects on VLDL concentration, composition and relative size with ingestion of different dietary fats. Beef tallow and olive oil feeding appeared to be associated with a greater number of VLDL particles than corn oil because of a significantly higher VLDL mass without a significant difference in VLDL size based on the relative ratios of VLDL core-to-surface components.

Plasma and hepatic cholesterol and triglyceride contents. Fasting total plasma cholesterol levels were not significantly different among the groups after ingestion of the diets for 5 wk. Fasting plasma TG levels were 30–54% higher with ingestion of beef tallow, olive or coconut oil than corn oil ($p<0.05$). Rats fed corn oil or butterfat demonstrated similar plasma TG levels. Consistently lower concentrations of hepatic total cholesterol (25–35% lower) and TG (30–50% lower) were noted with ingestion of butterfat, beef tallow or coconut oil relative to corn oil. Rats fed olive oil demonstrated similar levels of hepatic cholesterol and TG when compared with corn oil feeding but significantly higher levels of hepatic cholesterol and TG when compared with feeding saturated fats.

DISCUSSION

The present study utilized two unique features to determine if a greater rate of hepatic TG secretion contributes to higher plasma TG levels with ingestion of dietary saturated fats rather than unsaturated fats in fasted rats. First, three saturated fats, butterfat, beef tallow and coconut oil, the monounsaturated olive oil and polyunsaturated corn oil were compared concurrently. Second, *in vivo* TG secretion was determined in individual, unanesthetized unrestrained rats using [2-^{3}H]glycerol and a two-compartment model (17). The most pronounced response was noted in the beef tallow group which demonstrated a 60% higher rate of TG secretion than the corn or coconut oil groups ($p<0.05$).

Measurement of plasma TG kinetics by tracer techniques assumes a steady state condition, *i.e.* balanced secretion and clearance of the plasma TG pool (26), as we have confirmed. A greater relative rate of TG secretion due to ingestion of specific dietary fats would result in an expanded TG pool without differences in the fractional rate constant (26). Therefore, our observation of a larger TG pool with no significant difference in fractional rate constants (Table 4) suggests that greater TG secretion is the primary factor contributing to the larger TG pool associated with ingestion of beef tallow relative to butterfat, corn or coconut oil. This conclusion is supported by lower hepatic TG content (Table 3) and higher VLDL concentrations of TG, protein, apo B and apo E (Table 5,6) with ingestion of beef tallow relative to corn or coconut oil.

Further examination of the magnitude of increases in the rate of TG secretion and TG pool size provides indirect

TABLE 4

Effects of Dietary Saturated Fats on Triglyceride Secretion into Plasma[a]

	Final body weight (g)	Plasma TG pool size (mg/100 g body wt)	TG secretion (mg/min/100 g body wt)	k (min^{-1})	t_{lag} (min)	$t_{1/2}$ (min)

evidence of different rates of TG clearance from plasma with ingestion of beef tallow relative to corn or coconut oil. For example, a 60% higher rate of TG secretion but only a 33% larger TG pool size were observed with ingestion of beef tallow relative to corn or coconut oil. This suggests that the rate of TG clearance was also higher in association with the expanded TG pool with ingestion of beef tallow relative to corn or coconut oil.

The TG response to olive oil feeding differed from effects associated with feeding saturated fats or corn oil. The rate of TG secretion into plasma was 20% higher than the rate observed with corn or coconut oil with no difference in plasma TG pool size. This could be related to a higher rate of TG clearance as indicated by the fractional rate constant which was 20% higher with ingestion of olive oil compared to corn or coconut oil. Similar to previous reports (5,27), higher hepatic cholesterol and TG contents were noted with ingestion of olive oil compared to all of the saturated fats.

Proposed mechanism(s) underlying high plasma TG levels with ingestion of saturated fats in the rat provide conflicting evidence which is due, in part, to different experimental conditions (6–8,11–14). Liver perfusion studies by Nestel and Steinberg (11) and by Kohout *et al.* (12) suggested that an increase in hepatic VLDL productions was the primary factor contributing to the high plasma TG levels associated with saturated fatty acids. In their studies (11,12), the secretion of TG into the media and the accumulation of TG by liver were higher when palmitate rather than linoleate was perfused. Higher activities of

hepatic lipogenic enzymes have also been noted with ingestion of saturated rather than unsaturated fats (13,14). In contrast, Groot *et al.* (8) suggested that less efficient VLDL catabolism is responsible for the higher plasma TG levels with ingestion of palm oil relative to sunflower seed oil. Their conclusion (8) reflected lower lipoprotein lipase activity and slower chylomicron catabolism with no differences in hepatic VLDL production using the Triton technique. Interestingly, Green *et al.* (7) also noted slower chylomicron catabolism with ingestion of palm relative to corn oil using multicompartmental analysis. They concluded (7) that slowly catabolized chylomicrons enriched in saturated fatty acids would increase hepatic uptake of TG, stimulate hepatic production of VLDL-TG and thus, contribute to higher plasma TG levels.

As demonstrated in our study, different types of dietary saturated fats do not increase the TG pool or rate of TG secretion and alter VLDL composition to the same extent when compared to monounsaturated or polyunsaturated fats. For example, ingestion of saturated beef tallow or monounsaturated olive oil resulted in 33-60% higher rates of TG secretion and significant increases of VLDL-mass with little change in VLDL composition (mg %) or relative particle size compared to ingestion of corn oil. On the other hand, ingestion of butterfat resulted in only a 20% higher rate of TG secretion with little change in VLDL mass but relatively smaller VLDL particles than ingestion of corn oil. Based on our observations comparing 5 different dietary fats, it is not surprising that previous reports comparing only 2 or 3 dietary fats provide conflicting results regarding the relative contribution of secretion and clearance to elevated plasma TG levels with ingestion of saturated fats. Moreover, different VLDL compositions as a result of ingesting different dietary saturated fats are likely to affect VLDL-TG clearance and hepatic uptake of VLDL remnants, which may impact on hepatic VLDL secretion (7).

The kinetic model used for our data is a variation of that used by Bird *et al.* (17). Written in a form slightly different from theirs, it is $SA_{(2)} = C[e^{-\alpha(t-t_{lag})} - e^{-\beta(t-t_{lag})}]/(\alpha-\beta)$. Using calculus it is possible to derive our model as a special case of theirs by taking the limit $\alpha \rightarrow \beta$. Preliminary data analyses confirmed that this modification was more appropriate for fitting the data of our experiment. Several differences in our experimental conditions may explain the need for this modified model. Baker (28) has commented more broadly on the effects of experimental conditions on modeling of TG secretion.

First, anesthesia was not given during repeated blood sampling, and minimal animal restraint was used. The effects of anesthesia, restraint and surgery have been reported to lower TG production in anesthetized animals when compared to unanesthetized, unrestrained animals (15,16). Second, the [2-^{3}H]glycerol was injected *via* the left carotid artery into the aorta, which provided more direct and rapid delivery of the tracer to the liver than does injection *via* the jugular vein (17). Given these two differences in experimental approach, it seems likely that the value of β in Bird *et al.* (17), which represents the fractional rate constant of hepatic TG secretion, might very well be increased because of more rapid delivery to, and turnover of, the label in hepatic pools. Our observation of a shorter lag time for appearance of isotope, 10.9-11.9 min *versus* 14-17 min reported by others (16,17,29), supports the idea of less hepatic delay in TG secretion.

Our observation of a greater rate of TG secretion in association with higher plasma TG levels with ingestion of saturated *versus* polyunsaturated fat is consistent with some human studies (4,10). However, consumption of a diet rich in saturated fat rather than polyunsaturated fat does not consistently result in higher plasma TG levels in humans (2,30). In addition, the saturated diets used in human studies often consist of only one type of saturated fat, or a mixture of saturated fats whose fatty acid profile is not always defined (4). We have demonstrated in the rat that ingestion of different types of dietary saturated fats results in unique effects on VLDL composition, TG pool size and TG secretion. These observations challenge generalizations about the hypertriglyceridemic effects of saturated fats in human diets. Further research is needed utilizing controlled diets containing a variety of naturally-occurring fats of defined fatty acid composition in order to better understand how TG-rich lipoproteins may promote atherogenesis.

ACKNOWLEDGMENTS

This research was supported by a research grant from the Wisconsin Milk Marketing Board (project No. 88-39) and by funds from the College of Agricultural and Life Sciences, University of Wisconsin-Madison (project No. 3096). The authors would like to thank Gary Ecelbarger and Jannette Rivera for technical assistance. We would also like to thank Dr. Michael Bird, Glaxo, Inc., United Kingdom and Dr. Mary Ann Williams, University of California—Berkeley, for their suggestions regarding the preparation of this manuscript.

Geotrichum candidum NRRL Y-553 Lipase: Purification, Characterization and Fatty Acid Specificity

Mary Welch Baillargeon* and **Stephen G. McCarthy**
U.S. Department of Agriculture, Agricultural Research Service, Eastern Regional Research Center, Philadelphia, Pennsylvania 19118

Lipases from *Geotrichum candidum* NRRL Y-553 are of interest because of their unique specificity for *cis*-9-unsaturated fatty acids relative to both stearic and palmitic acids. The lipases were partially purified by chromatography on Octyl Sepharose, AG MP-1 macroporous anion exchanger, and chromatofocusing resin. The preparation was found to contain multiple, glycosylated lipases varying slightly in pI (pI 4.88, 4.78, 4.65, 4.57 and 4.52) as judged by both activity and silver staining. The molecular mass determined by sodium dodecyl sulfate polyacrylamide gel electrophoresis was 64 kilodaltons for the main species, with minor species of 60 and 57 kilodaltons present as well. The specificity of the crude lipases for hydrolysis of 4-methylumbelliferyl esters of oleic *vs.* palmitic acid was 20-to-1. The specificity of the purified, partially separated lipases was similar to that of the crude preparation. Thus the lipases could be used even in crude form for the hydrolysis and restructuring of triacylglycerols on a large scale.
***Lipids 26*, 831-836 (1991).**

Lipases (EC 3.1.1.3) from *Geotrichum candidum* are known to show preference for unsaturated fatty acids with a *cis*-double bond at the 9-position (oleic, linoleic, linolenic, palmitoleic acids) (1). The extent of specificity for *cis*-9-unsaturated fatty acids in comparison to saturated fatty acids varies between strains. Among the saturated fatty acids, palmitic acid (16:0) is hydrolyzed more readily by some strains than others. Since palmitic acid and stearic acid are among the most plentiful saturated fatty acids of common fats and oils, a lipase which would preferentially react with unsaturated fatty acids in the presence of these saturated fatty acids could be of commercial use for the splitting and restructuring of natural triacylglycerols. The utility of such a process would ultimately depend on the selectivity of the enzyme employed.

We have previously reported the relative specificity constants for the competitive hydrolysis of oleic and palmitic methyl or butyl esters for several strains of *G. candidum* (2). The relative specificity constants ranged from 1.0 (no specificity shown) to 50 (highly specific). Two preparations showed high specificity: strain NRRL Y-553 and lipase 26557 RP, a proprietary enzyme preparation from Rhône-Poulenc. The original strain of *G. candidum* (3), characterized by Jensen and co-workers (4), but no longer available, released 23 ± 14 times as much oleic acid (18:1) as palmitic acid (average of four triacylglycerols containing only these two fatty acids). Of the strains available (5-8), *G. candidum* NRRL Y-553 produces one of the lipases that is most specific for oleic acid relative to palmitic acid.

Continuing our efforts to obtain *G. candidum* lipases that are highly selective against both stearic and palmitic acids, we report here the purification and further characterization of *G. candidum* NRRL Y-553 lipases. We have modified our previous purification scheme for separating *G. candidum* lipases (9) to accomplish the separation of a relatively low concentration of lipases from a complex medium.

MATERIALS AND METHODS

Lipase production. G. candidum NRRL Y-553 was obtained from the Agricultural Research Service Culture Collection (Peoria, IL). The culture was stored on silica gel according to Perkins (10) and plated onto acidified potato dextrose agar (Difco Laboratories, Detroit, MI) as needed. Lipase was produced under the conditions previously optimized (2). A liquid medium was used consisting of 5% peptone (Difco), 0.1% $NaNO_3$, and 0.1% $MgSO_4 \cdot 7H_2O$, adjusted to pH 7.0 before sterilization. Sterile soybean oil (0.75% v/v) was added as a carbon source. A single colony was transferred to 65 mL of medium in a 250-mL Erlenmeyer flask and incubated about 24 hr at 30°C (300 rpm). An aliquot (0.5-1.0 mL) was used to inoculate similar flasks for lipase production. Lipase activity peaked at about 40 hr after inoculation under these conditions.

The crude lipase broth was tested for protease activity using an agar diffusion method with casein as substrate (kit from Bio-Rad Laboratories, Richmond, CA); no protease activity was found even after extended incubation times.

Materials. Endoglycosidase F/N-glycosidase (Endo F), N-glycosidase F and the glycan detection kit were obtained from Boehringer Mannheim (Indianapolis, IN). Purified olive oil, 4-methylumbelliferyl (4-MUMB) esters and concanavalin A (Con A) labeled with peroxidase were obtained from Sigma Chemical Company (St. Louis, MO). Chromatography media were obtained from Pharmacia LKB Biotechnology Inc. (Piscataway, NJ) or Bio-Rad. All other materials were reagent grade or better.

Assays. Lipase activity was quantitated titrimetrically by an initial rate assay at pH 8.2 using an olive oil-gum arabic emulsion containing 11 mM $CaCl_2$, as described previously (11). A unit of lipase activity (U) was defined as the release of one micromole of free fatty acid (FFA)/min at room temperature. Lipase activity of column fractions and native electrophoretic gels were qualitatively measured on Rhodamine-olive oil-agar plates (12), as previously described (9).

Protein was assayed by the bicinchoninic acid (BCA) method (13) (Pierce, Rockford, IL) when detergent was present, or by the Bradford method (14) (Bio-Rad), with bovine serum albumin (BSA) (Sigma) as standard.

The specificity of lipase for oleate *vs.* palmitate was

*To whom correspondence should be addressed at: USDA, ARS, ERRC, 600 East Mermaid Lane, Philadelphia, PA 19118.

Abbreviations: BCA, bicinchoninic acid; BSA, bovine serum albumin; Con A, concanavalin A; Endo F, endoglycosidase F/N-glycosidase; FFA, free fatty acids; IEF, isoelectric focusing; 4-MUMB, 4-methylumbelliferyl; SDS PAGE, sodium dodecyl sulfate polyacrylamide gel electrophoresis; U, unit of lipase activity.

calculated from the initial rate of non-competitive hydrolysis of the respective esters of 4-methylumbelliferone (15), as previously described (9). To avoid loss of enzyme activity, enzyme samples were diluted as needed with cold buffer [0.1 M tris(hydroxymethyl)aminomethane hydrochloride (Tris), 5 mM $CaCl_2$, pH 8.0] containing 0.1 mg/mL BSA.

The specificity for one substrate (A) *vs.* another substrate (B) at one minute reaction time was calculated using Eq. [1] (16):

$$\text{Specificity A/B} = \frac{V_A\,[B]}{V_B\,[A]} \qquad [1]$$

where the rate, V, was multiplied by the substrate concentration at one min. Low values of specificity (around 1) can be measured much more accurately than large values (around 100). This method produces the same values of specificity 18:1/16:0 as obtained by non-competitive hydrolysis of emulsified methyl esters of oleic and palmitic acids (measured by initial rate titration at 35°C), but is much more rapid and sensitive.

Electrophoresis. Polyacrylamide gel electrophoresis was performed using the PhastSystem (Pharmacia) and the gels were silver stained (17) or activity stained as previously described (9,11). Standards for pI measurements were obtained from Sigma (pI 3.6–6.6) and molecular weight standards were from Diversified Biotech (Newton Centre, MA). Molecular weight measurements have a standard deviation of 2 kilodaltons (kDa).

Carbohydrate analysis. Carbohydrate was removed by treatment of native lipase with Endo F (pH 6.0) (18) or of denatured lipase with N-glycosidase F (pH 7.5) according to the instructions of the manufacturer. Two to three units of glycosidase activity were added to the lipase sample in aliquots over an extended incubation period. After IEF or sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS PAGE), samples were transferred to Immobilon transfer membranes (Millipore Corp., Bedford, MA) by diffusion blotting, and glycosylation was detected with the glycan detection kit according to the manufacturer's instructions, or by peroxidase-labeled Con A (18).

Purification. The procedure previously used for purifying commercial *G. candidum* lipases (9) was modified to accommodate dilute lipases in a broth of high peptone concentration. All steps were performed at room temperature (21–25°C). When lipase activity was maximal (about 14 U/mL), the broth was centrifuged for 200,000 $g \times$ min, decanted, and filtered under a slight vacuum through Whatman No. 2 filter paper. The supernatant (approximately 1 L) was incubated with Octyl Sepharose in an affinity rather than hydrophobic interaction mode (80 mL preequilibrated in 0.01 M imidazole buffer, pH 6.8) for 30 min with gentle agitation. The resin was then placed in a Buchner funnel with a fritted disc, and washed with the imidazole buffer to remove the colored peptone; negligible lipase activity was washed from the column by this procedure. A limited amount of water (250 mL) was used to wash the resin, which was then placed into a 1.5 × 50 cm column, and briefly packed with water (flow rate of 25 mL/hr). Lipase activity was eluted by a linear gradient of 250 mL each of water and 0.5% polyoxyethylene 10-tridecyl ether (Emulphogene BC-720, Sigma) in water.

The fractions containing the main lipase activity were pooled and applied directly to an AG MP-1 column (1.5 × 12 cm) equilibrated in 0.05 M histidine buffer (pH 6.0). After washing with the histidine buffer (flow rate of 50 mL/hr), the lipase activity was eluted by a linear gradient of 50 mL each of histidine buffer and histidine buffer with 0.4 or 0.5 M NaCl.

Chromatofocusing was used for separation of the molecular forms of lipases with varying charge as previously described (9), with a pH gradient from 5.4 to 3.8. The pH gradient was later narrowed (pH 5.2 to pH 4.1), resulting in increased resolution of the multiple lipase species.

Attempts to desalt the chromatofocusing buffer from column fractions by gel filtration on Bio-Gel P-30 were abandoned because lipase activity was retained on the column and trailed severely. Activity was also lost during dialysis; this was attributed to binding to the dialysis membrane.

RESULTS

Isoelectric focusing. Analytical IEF gels of *G. candidum* NRRL Y-553 lipases are shown in Figure 1. The lipases consisted of three major forms of pI 4.78, 4.65 and 4.57, named b, c, d; and of two minor forms of pI 4.88 and 4.52, named a and e, respectively. Additional minor species are also identifiable in more concentrated samples. All forms were identified as lipases by lipase activity stain, and were also stained with silver stain and esterase stain. Analysis by two-dimensional electrophoresis (not shown) showed charge heterogeneity among lipases of the same or very similar molecular mass. Glycosylation of the lipases was confirmed with the glycan detection kit and Con A-peroxidase.

Purification. The high concentration of peptone in the growth medium interfered with the purification procedure used previously (9). The peptone bound to the Octyl Sepharose at salt levels that promoted hydrophobic interactions (1 M ammonium sulfate), reducing the capacity of the column. The peptone also bound to the AG MP-1 anion exchanger. We therefore developed a rapid and relatively simple procedure for purification of lipases in peptone broth using Octyl Sepharose, AG MP-1, and chromatofocusing. Affinity chromatography on Octyl Sepharose using low ionic strength buffer allowed lipase to bind while the peptone was washed off. This was followed by anion exchange on AG MP-1, accomplishing a rapid concentration and at least partial removal of the detergent. Chromatofocusing was then used to separate the multiple lipase forms.

Elution of lipases from Octyl Sepharose by a detergent gradient is shown in Figure 2. A contaminant and a small amount of lipase activity are eluted at low detergent concentrations. The main lipase activity is eluted in a broad peak from about 0.25 to 0.50% detergent. Fractions 63 to 121 were pooled and applied directly to the AG MP-1 anion exchanger.

Chromatography on AG MP-1 is shown in Figure 3. The lipase activity eluted as a sharp peak (fractions 40–48), with some trailing which included contaminating proteins. Fractions 40 to 48 were pooled, dialyzed against 0.025 M piperazine (pH 5.4), applied to the chromatofocusing

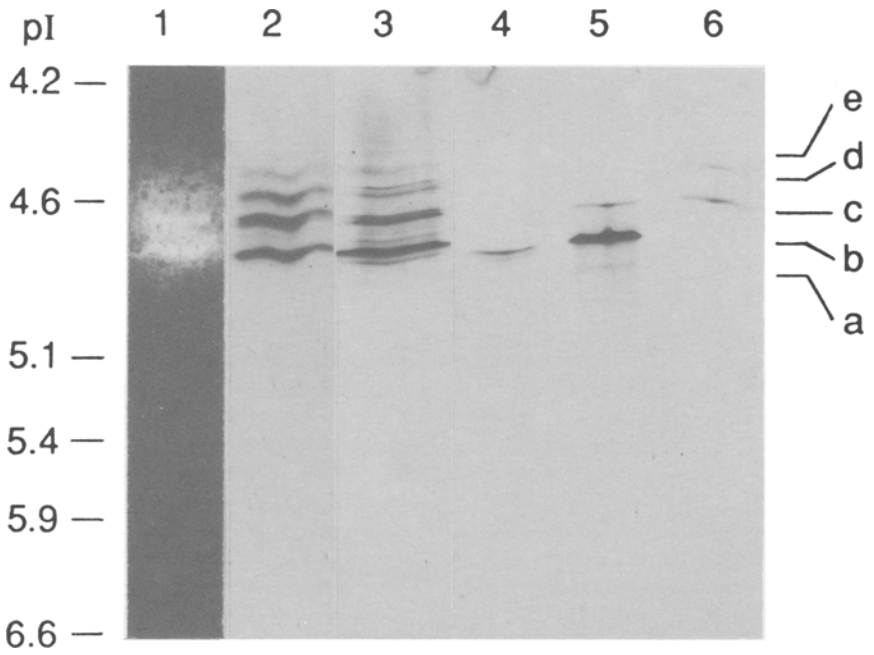

FIG. 1. Isoelectric focusing of *G. candidum* NRRL Y-553 lipases at 15°C. Lipases a through e are identified. Lane 1, AG MP-1 fraction 49 with lipase activity stain photographed under ultraviolet light; the scale is slightly reduced compared to lanes 2–6. Lipases b and c are of much stronger intensity. Lane 2, same sample with esterase stain; lane 3, same sample with silver stain; lane 4, chromatofocusing, fraction 44; lane 5, chromatofocusing, fraction 48; lane 6, chromatofocusing, fraction 57. Lanes 4 through 6 are silver stained.

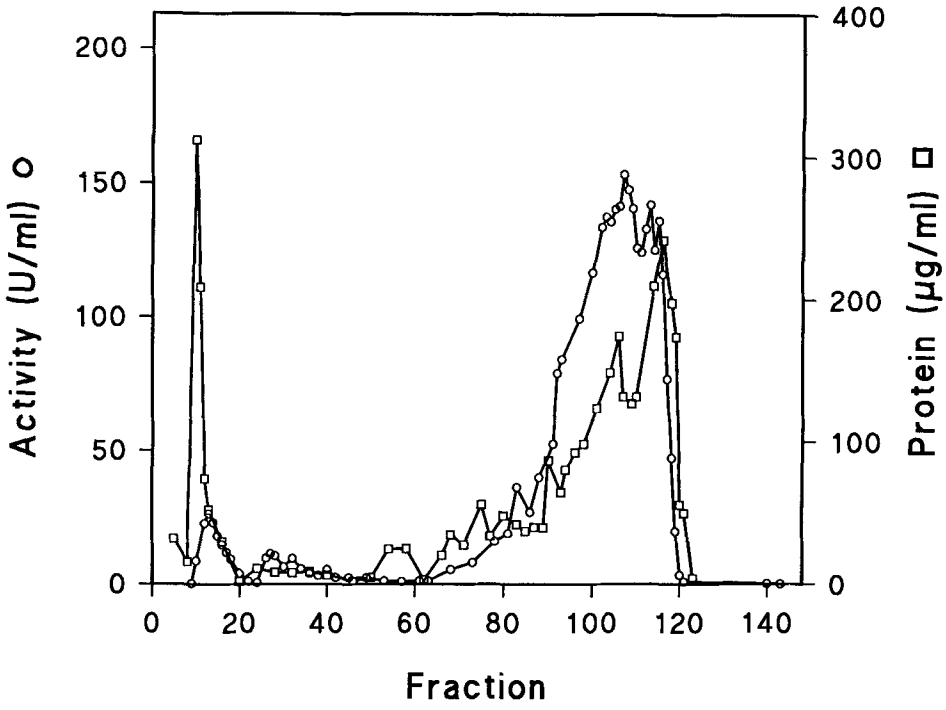

FIG. 2. Chromatography of *G. candidum* NRRL Y-553 lipases on Octyl Sepharose. Lipases were eluted with a detergent gradient from 0 to 0.5% which was started at fraction 1. See text for details.

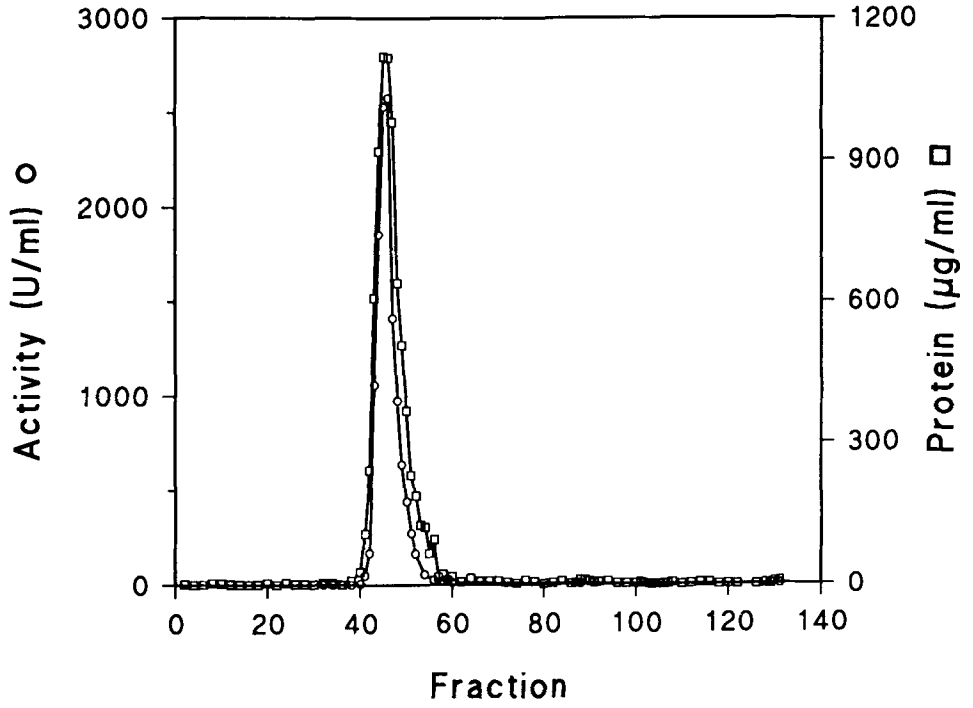

FIG. 3. Anion exchange chromatography of *G. candidum* NRRL Y-553 lipases on AG MP-1. Lipases were eluted with a salt gradient from 0 to 0.5 M NaCl starting at fraction 1.

column, and eluted with Polybuffer (pH 3.8) (Fig. 4). Lipases a and b eluted first (fractions 41–45), followed by lipases b and c at the main peak (fractions 46–52). The small second peak (fractions 53–62) contained lipases c, d, e, and a minor amount of lipase b. The lipases trail together such that no single form is completely isolated from others close in pI. Elution using a narrower pH gradient increases the resolution; however, the lipases are so similar that it is not possible to isolate each one.

The purification achieved is shown in Table 1. A 14-fold purification with 96% recovery of activity was obtained with the Octyl Sepharose column. The anion exchange and chromatofocusing steps resulted in a 23-fold purification with a 46% total recovery of activity.

Figure 5 shows SDS PAGE of the lipases at each purification step. The purified lipases contain a main component of 64 kDa, and minor components of 60 and 57 kDa; glycosylation of all three components was confirmed using both the glycan detection kit and Con A-peroxidase.

Carbohydrate analysis. The various species of *G. candidum* NRRL Y-553 lipase separated by either SDS PAGE or IEF were all found to be glycosylated. In order to study the contribution of glycosylation to lipase heterogeneity, lipases purified by Octyl Sepharose and anion exchange was subjected to enzymatic deglycosylation (data not shown). Endo F was used to deglycosylate the lipases under native conditions. The susceptibility of proteins to deglycosylation by endo F varies; indeed, even after extended incubation, only partial deglycosylation of NRRL Y-553 lipases could be achieved, as measured with Con A-peroxidase detection. The partially deglycosylated lipases contained lipases b and c, with a small amount of lipase d, as detected by IEF gels using lipase and esterase activity stain, and silver stain; however, only lipases b and c were detected with Con A-peroxidase. Two-dimensional electrophoresis of the partially deglycosylated native lipases confirmed the presence of lipases b and c, respectively, at two slightly different molecular masses at constant pI, indicating partial removal of uncharged carbohydrate. The concentration of lipase d was too low to be detected on the 2D gel.

N-Glycosidase was used to deglycosylate denatured *G. candidum* NRRL Y-553 lipases; more complete deglycosylation would be expected under these conditions. Approximately 90% of the lipases were converted to species of lower molecular mass which were no longer detected by Con A-peroxidase or the glycan detection kit, indicating removal of the carbohydrate. A decrease of molecular mass of 2.5 kDa, representing 4% by weight of the main lipase component on SDS PAGE, was obtained. It appeared that the reaction was incomplete, with about 10% of the lipase remaining with unchanged molecular mass and carbohydrate intact.

Specificity. The specificity of *G. candidum* NRRL Y-553 lipases at various stages of purification is summarized in Table 2. The specificity of lipases partially separated by chromatofocusing is given and graphed in Figure 4. The crude lipases have a specificity of 20 ± 4. Fractions eluting from the chromatofocusing column at pH 4.4 (the beginning of lipase elution) and composed of lipases a and b consistently have a slightly higher specificity 18:1/16:0. However, the specificity values are the same within two standard deviations for all stages of purification.

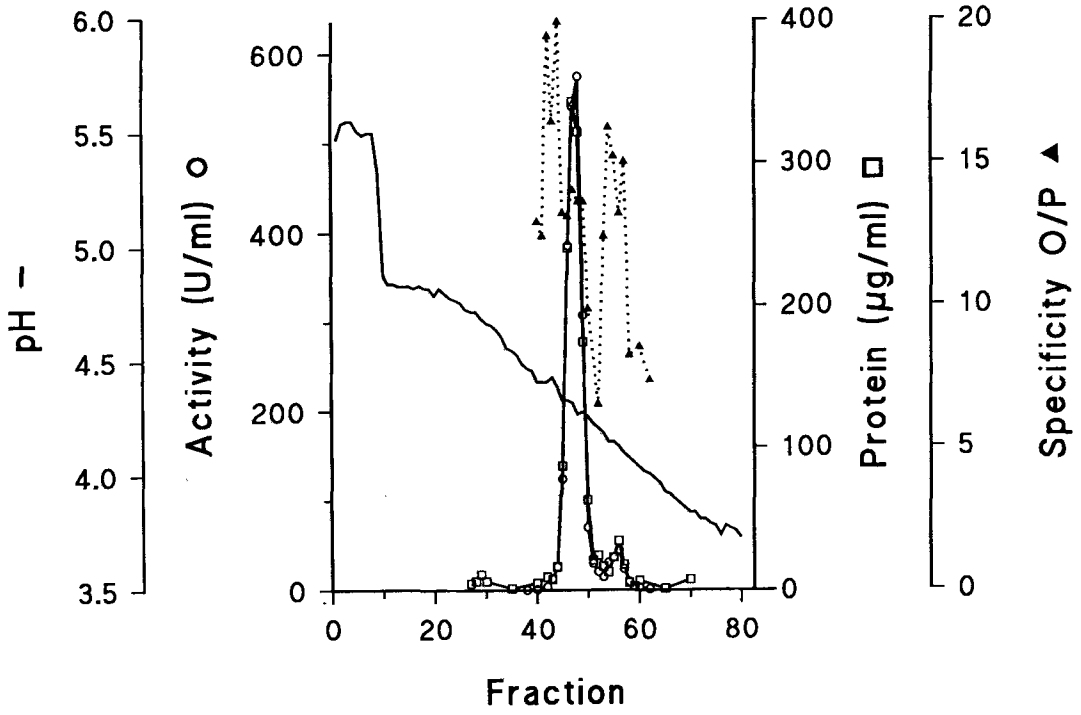

FIG. 4. Chromatofocusing of *G. candidum* NRRL Y-553 lipases. Elution conditions are given in Materials and Methods. The lipase activity closely coincides with the protein concentration.

DISCUSSION

The lipases produced by the fungus *G. candidum* are a complex mixture varying in molecular mass, pI and specificity. The *G. candidum* NRRL Y-553 lipases partially isolated here are quite similar in molecular weight and pI to those recently reported for three other strains—ATCC 34614 (5,19), commercial GC-20 lipases from Amano (9) and an isolate *G. candidum* Link ex Pers. emend. Carmichael from waste water (8,20). However, the specificity varies among the strains—lipases from ATCC 34614 show very little specificity 18:1/16:0 (2,5); while lipase from *G. candidum* Link ex Pers. emend. Carmichael shows intermediate specificity (8). We previously found that although crude GC-20 contains little specificity 18:1/16:0, it contains a low level of an isozyme which is specific (specificity 18:1/16:0 is 29 ± 8) (9). *G. candidum* NRRL Y-553 produces a group of specific lipases (specificity 18:1/16:0 is 20 ± 4) whose specificity approaches that of the original strain of *G. candidum* (specificity 18:1/16:0 is 23 ± 14) (4).

G. candidum NRRL Y-553 lipases consist of five glycosylated species of molecular mass 64 kDa (major component), and 60 and 57 kDa (minor components). Heterogeneity in size due to non-specific proteolytic degradation seems unlikely, since no proteases were detected in the crude lipase broth. Differential glycosylation contributes to the heterogeneity, since partial deglycosylation reduces the molecular mass of the main lipase component to about that of the smaller species, and reduces the number of species from five to three. Additional heterogeneity could be due to actual differences in amino acid sequence; the presence of two genes coding for two closely-related lipases, each containing two potential

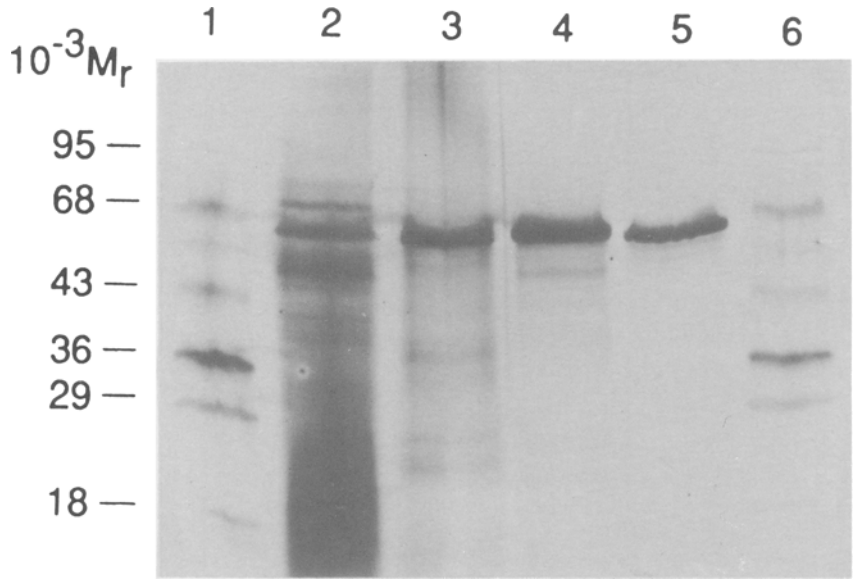

FIG. 5. SDS PAGE of *G. candidum* NRRL Y-553 lipases at various stages of purification with silver staining. Specificity of *G. candidum* NRRL Y-553 Lipases at Various Stages of Purification

Sample	Specificity 18:1/16:0
Crude lipase	20.0 ± 4.4
Lipases (a), b[a]	18.6 ± 1.9
Lipases (a), b, c	13.5 ± 0.4
Lipases b, c	8.2 ± 2.4
Lipases (b), c, d	14.4 ± 1.6

[a]Lipases in parentheses are minor components. Purified lipases are from the chromatofocusing column.

sites for *N*-glycosylation, has recently been reported for *G. candidum* ATTC 34614 (5,21).

G. candidum NRRL Y-553 lipases could be useful for large-scale splitting and restructuring of unsaturated fatty acids from triacylglycerols, and the lipases could be used in crude form without prior purification. We are currently testing the lipases for such practical applications.

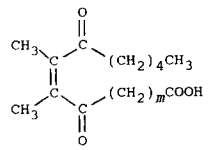
A Novel Method for the Introduction of a Methyl Group into the Furan Ring of a 2,5-Disubstituted C_{18} Furanoid Fatty Ester *via* a Malonic Acid Function



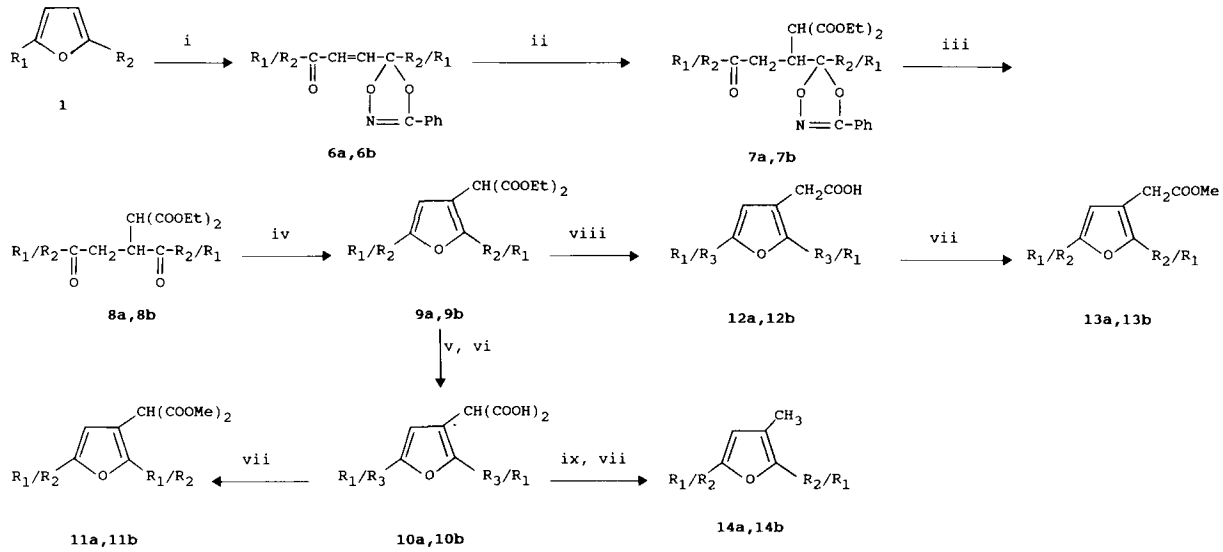
Marcel S.F. Lie Ken Jie* and **Ka-Po Wong**
Department of Chemistry, University of Hong Kong, Hong Kong

Furan ring opening with benzohydroxamic acid of methyl 9,12-epoxy-9,11-octadecadienoate gave a mixture of positional isomers of conjugated methyl 3-phenyl-1,4,2-dioxazolyl C_{18}-enone esters 6a,6b. Michael addition of diethyl malonate anion to the conjugated enone system of 6a,6b furnished the corresponding malonyl intermediates 7a,7b, which upon removal of the dioxazole ring by hydrolysis gave methyl 10- and 11-dicarbethoxymethyl-9,12-dioxooctadecanoate 8a,8b. Cyclization of the latter gave the trisubstituted C_{18} furanoid fatty esters 9a,9b, containing the malonate ester function at the 3-/4-position of the furan ring. Base hydrolysis of compounds 9a,9b gave the corresponding tricarboxylic acid derivatives 10a,10b, which were esterified to the trimethyl esters 11a,11b in BF_3/MeOH. When a mixture of 9a,9b was refluxed with Na_2CO_3/MeOH, hydrolysis of the malonate ester function was followed by decarboxylation to yield a $-CH_2COOH$ substituent at the 3-/4-position of the furan ring (12a,12b). Esterification of the latter with BF_3/MeOH gave the corresponding methyl diester derivatives 13a,13b. When a mixture of tricarboxylic acids 10a,10b was heated at 160–180°C for 6 hr, exhaustive decarboxylation of malonic acid function furnished a methyl group at the 3-/4-position of the furan nucleus. Esterification of the decarboxylated product gave a mixture of trisubstituted furanoid compounds 14a,14b (overall yield 28%). The procedure constitutes a novel method for the introduction of a methyl group *via* a malonic acid group to the 3-/4-position of the furan ring of a 2,5-disubstituted C_{18} furanoid fatty ester.
***Lipids 26*, 837–841 (1991).**

Morris *et al.* (1) reported the first isolation of a 2,5-disubstituted C_{18} furanoid fatty acid (1) (Scheme 1) from the seed oil of *Exocarpus cupressiformis*. A trisubstituted C_{18} furanoid acid (2) containing a methyl group at the 3-position of the furan nucleus was identified as the major fatty acid component (95%) in the triglyceride fraction of the latex of the rubber plant (*Hevea brasiliensis*) (2,3). More recently, long-chain tri- and tetrasubstituted furanoid fatty acids have been found in small quantities in a large variety of common plant species (4). Furanoid fatty acids in animals were first recorded by Glass *et al.* (5) to occur in fish, and later were found in soft corals (6), crayfish (7), amphibians and reptiles (8), human blood plasma (9,10) and in bovine liver extracts (11). The role of these natural furanoid fatty acids remains unclear. Biosynthetic experiments by Sand *et al.* (12)

1, R_1 = H, R_2 = H, n = 5, m = 7;
2, R_1 = H, R_2 = CH_3, n = 5, m = 7;
3, R_1 = H, R_2 = COOH, n = 4, m = 2;
4, R_1 = CH_3, R_2 = CH_3, n = 4, m = 6,8,10.

5, m = 6,8,10.



SCHEME 1

failed to show that furanoid fatty acids in fish were produced by acetate *de novo*, while Gorst-Allman *et al.* (13) ruled out 10,13-nonadecadienoic acid as a possible precursor of furanoid fatty acids in animals. Furanoid fatty acids were metabolized to urofuranic acids (3) in human feeding experiments (14). *In vitro* incubation of furanoid fatty acids (4) with lipoxidase gave unstable dioxo ethylenic products (5) (15).

We have synthesized all positional isomers of the 2,5-disubstituted C_{18} furanoid fatty acids (16) and have also produced furanoid fatty acids with one or two methyl groups in the 3- and/or 4-position of the furan ring from ricinoleic acid (17,18). Preliminary screening tests for compound (1) have shown that this compound possesses potent anti-microbial properties against certain microorganisms (Lie Ken Jie, M.S.F., Shortridge, K.F., and Tam, J., unpublished results). In view of the potential therapeutic properties of this class of fatty acids, the aim of this project was to develop chemical means of incorporating different substituents into the 3- or 4-position of the furan ring of the furanoid fatty acid for further antimicrobial investigations. We have selected the malonyl function, as this versatile dicarboxylate system can be readily transformed into an array of other interesting chemical functions. The synthetic route leading to the malonyl substituted C_{18} furanoid fatty ester derivative and the various chemical transformations of this substrate to yield trisubstituted furanoid fatty acid derivatives are presented in Scheme 2 — R_1 = $CH_3(CH_2)_5$; R_2 = $(CH_2)_7COOCH_3$; R_3 = $(CH_2)_7COOH$. Its reagents are: i) benzohydroxamic acid, Pb(IV) oxide, EtOAc; ii) diethyl malonate, NaOMe, Et_2O; iii) H_2O, EtOH; iv) BF_3/etherate, $CHCl_3$; v) KOH, H_2O, EtOH; vi) dilute HCl; vii) BF_3/MeOH; viii) Na_2CO_3, H_2O, MeOH; and ix) 160–180°C, 6 hr.

Abbreviations: ECL, equivalent chain length; IR, infrared spectroscopy; NMR, nuclear magnetic resonance; R_F, retardation factor; TLC, thin-layer chromatography.

SCHEME 2

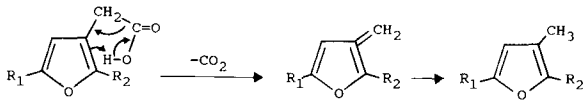
MATERIALS AND METHODS

Thin-layer chromatographic (TLC) analyses were carried out on silica gel coated microscope slides (*ca.* 0.1 mm thickness). Column chromatographic purifications were carried out on silica gel and mixtures of light petroleum (b.p. 60–80°C)/diethyl ether were used as eluant. [PE30 denotes a mixture of light petroleum/diethyl ether (70:30, v/v) where the numeral stands for the percentage of diethyl ether in the solvent mixture]. Gas chromatographic analyses were conducted on a Hewlett-Packard 5970 gas chromatograph (Hewlett-Packard, Palo Alto, CA) fitted with a 10-m microbore glass column (0.53 mm diam., 2.65 μm film coating thickness SE-30 stationary phase) and a flame ionization detector. Nitrogen (20 mL/min) was used as the carrier gas and the column temperature was maintained at 190°C. External standards of methyl myristate, palmitate and stearate were used as reference compounds and the equivalent chain length (ECL) value was calculated accordingly for each component (19). Elemental analyses were by Butterworth Laboratories Ltd. (Teddington, Middlesex, England, U.K.); all compounds gave acceptable value determined for C, H, and N (±0.3) percent. Infrared (IR) spectra were obtained with a Perkin-Elmer 577 (Perkin-Elmer, Norwalk, CT) spectrophotometer. Nuclear magnetic resonance (NMR) spectra were recorded with a JEOL FX-90Q (90 MHz) (JEOL Ltd., Tokyo, Japan) Fourier transform spectrometer at 89.56 MHz for protons and at 22.5 MHz for carbon. Alternatively, a JEOL GSX-270 (270 MHz) spectrometer with proton observation at 270.05 MHz and carbon observation at 67.8 MHz was used. Chemical shifts (ppm) are reported relative to Me_4Si as internal standard. Connectivities in the ^1H-^{13}C NMR spectra were established at 270.05 MHz using a combination of spin-spin decoupling, COSY and double quantum filter experiments. Carbon atom types were established in ^{13}C NMR using a combination of broad-band proton decoupling and DEPT experiments. Melting points were measured on a Reichert Thermovar hot-stage microscope (Reichert Co., Vienna, Austria) and are uncorrected. Methyl 9,12-epoxy-9,11-octadecadienoate was prepared from methyl ricinoleate as described elsewhere (20). Benzohydroxamic acid was prepared by the method described by Hauser and Renfrow (21). Diethyl malonate and sodium methoxide were purchased from Aldrich Chemical Co. (Milwaukee, WI).

*Synthesis of methyl 3-phenyl-1,4,2-dioxazolyl C_{18}-enone esters (**6a,6b**).* A mixture of methyl 9,12-epoxy-9,11-octadecadienoate (14 g, 45.5 mmol), benzohydroxamic acid (9 g, 65 mmol), Pb (IV) oxide (60 g, 0.25 mol) and ethyl acetate (150 mL) was stirred at room temperature for 24 hr. The reaction mixture was filtered and the solvent was evaporated under reduced pressure. The residue was chromatographed on a silica gel column (PE30) to give a mixture of compounds **6a,6b** (14.7 g, 73%) as an oil. R_F (PE40) 0.35; IR (cm^{-1}) (film) 1630(m, C=N), 1705(s, C=O), 1740(s, C=O ester). ^1H NMR (δ) 0.9(*t*, 3H, CH_3), 1.2–1.4(*m*, 12H, CH_2), 1.6–1.8(*m*, 6H, CH_2), 2.2–2.5(*m*, 6H, CH_2COOCH_3, $CH_2C{=}O$, $CH_2COOCNPh$), 3.6(*s*, 3H, $COOCH_3$), 6.0(*d*, J = 13Hz, 2H, $CH{=}CH$), 7.3–7.5(*m*, 3H, arom), and 7.6–7.8(*m*, 2H, arom). ^{13}C NMR ($CDCl_3$) 14.0(C-18), 22.5(C-17), 23.4($COCH_2CH_2$), 24.9(C-3), 28.9, 29.0, 29.1, 29.3, 31.7(C-16), 34.0(C-2), 37.8(CH_2 COOCNPh), 43.4($COCH_2$), 51.2($COOCH_3$), 115.4 (*C*OOCNPh), 123.4(arom), 126.8(arom), 128.7(arom), 131.4(arom), 132.4, 134.7(*C*H=*C*H), 158.1(*C*=N), 173.8(C-1) and 203.0 (*C*=O, oxo) ppm.

*Reaction of sodium diethyl malonate anion with compounds **6a,6b**.* A mixture of diethyl malonate (3.2 g, 20 mmol), sodium methoxide (1.2 g, 22 mmol) and diethyl ether (100 mL) was stirred at room temperature for 3 hr. Compounds **6a,6b** (7.3 g, 16.4 mmol) in diethyl ether (20 mL) were added and the reaction mixture stirred for an additional 24 hr. Diluted acetic acid (1M, 10 mL) was added and the reaction mixture was extracted with diethyl ether (3 × 50 mL). The organic extract was washed with water (20 mL), and dried (Na_2SO_4). The solvent was

evaporated; silica gel column chromatography of the residue yielded a mixture of the triesters **7a,7b** (8.5 g, 86%) as an oil. R_F (PE40) 0.25; IR (cm^{-1}) (film) 1626(m, C=N), 1735(s, C=O). ^1H NMR (δ) 0.9(*t*, 3H, CH_3), 1.2-1.4(*m*, 18H, CH_2), 1.4-2.0(*m*, 6H, CH_2), 2.3(*t*, 2H, CH_2COOCH_3), 2.5-2.9(*m*, 8H), 3.6(*s*, 3H, $COOCH_3$), 4.1(*q*, J = 7.2 Hz, 4H, $COOCH_2CH_3$), 7.3-7.5(*m*, 3H, arom) and 7.7-7.8(*m*, 2H, arom). ^{13}C NMR ($CDCl_3$) 14.0(3C, C-18, 2 × $COOCH_2CH_3$), 22.1, 22.5(C-17), 23.8($COCH_2CH_2$), 24.9(C-3), 29.0, 29.2, 29.3, 31.6(C-16), 34.1(C-2), 36.0($CH_2COOCNPh$), 40.6($CHCOOCNPh$), 42.9(CH_2CO), 50.9[$CH(COOEt)_2$], 51.3($COOCH_3$); 61.4, 61.8[2C, 2 × $CH(COOCH_2CH_3)_2$], 119.0($COOCNPh$), 123.1(arom), 126.8(arom), 128.7(arom), 131.5(arom), 158.6(C=N), 168.3(2C, 2 × COOEt), 174.0(C-1) and 207.6(C=O, oxo) ppm.



*Hydrolysis of the dioxazole ring in compounds **7a,7b**.* A mixture of compounds **7a,7b** (4.0 g, 6.6 mmol) and aqueous ethanol (50%, 100 mL) was refluxed for 10 hr. Water (100 mL) was added and the reaction mixture was extracted with diethyl ether (3 × 50 mL). The organic extract was washed with water (30 mL) and dried (Na_2SO_4). The solvent was evaporated and the residue chromatographed on a silica gel column (PE30) to give a mixture of methyl 10- and 11-dicarbethoxymethyl-9,12-dioxooctadecanoate (**8a,8b**) (2.6 g, 80%) as an oil. R_F (PE40) 0.4; IR (cm^{-1}) (film) 1368(m), 1736(s, C=O). ^1H NMR (δ) 0.9(*t*, 3H, CH_3), 1.2-1.4(*m*, 18H, CH_2), 1.5-1.8(*m*, 6H, CH_2), 2.3(*t*, 2H, CH_2COOCH_3), 2.5-2.8(*m*, 8H), 3.65(*s*, 3H, $COOCH_3$), 4.16(*q*, J = 7.1 Hz, 4H, $COOCH_2CH_3$). ^{13}C NMR ($CDCl_3$) 14.0(3C, C-18, 2 × $COOCH_2CH_3$), 22.5(C-17), 23.5, 23.8($COCH_2CH_2$), 25.0(C-3), 29.0-29.1(4C), 31.7(C-16), 34.1(C-2), 42.2, 42.9(CH_2CO), 45.2(CHCO), 51.3($COOCH_3$), 53.0[$CH(COOEt)_2$], 61.7 [$CH(COOCH_2CH_3)_2$], 168.1(2C, 2 × COOEt), 174.1(C-1), 207.8(C=O, oxo) and 210.0(C=O, oxo) ppm.

*Synthesis of methyl 9,12-epoxy-10(11)-dicarbethoxymethyl-9-11-octadecadienoate (**9a,9b**).* A mixture of compounds **8a,8b** (6g, 12.4 mmol), boron trifluoride etherate (2.4 mL, 18.6 mmol) and chloroform (50 mL) was stirred at room temperature for 3 hr. Aqueous sodium carbonate (10%, 20 mL) was added and the organic mixture was extracted with diethyl ether (2 × 50 mL). Purification of the organic product on a short silica gel column gave a mixture of compounds **9a,9b** (5.4 g, 94%) as an oil. R_F (PE40) 0.5; IR (cm^{-1}) (film) 1736(s, C=O), 1036(s, furan ring breathing). ^1H NMR (δ) 0.9(*t*, 3H, CH_3), 1.2-1.4(*m*, 18H, CH_2), 1.6-1.8(*m*, 6H, CH_2), 2.30(*t*, 2H, CH_2COOCH_3), 2.54(*t*, J = 7.5Hz, 4H, CH_2-furan), 3.66(*s*, 3H, $COOCH_3$), 4.20(*q*, J = 7Hz, 4H, $COOCH_2CH_3$), 4.41[*s*, 1H, $CH(COOEt)_2$] and 6.06(*s*, 1H, CH furan). ^{13}C NMR ($CDCl_3$) 13.9(C-18), 14.1(2C, $COOCH_2CH_3$), 22.6(C-17), 25.0(C-3), 26.1, 27.9, 28.1, 28.5, 28.9, 29.0, 29.1, 31.6(C-16), 34.1(C-2), 49.4[$CH(COOEt)_2$], 51.3($COOCH_3$), 61.5(2C, 2 × $COOCH_2CH_3$), 106.2(C-4′ of furan, assuming malonate ester substituent at C-3′ of furan ring), 112.0(C-3′ of furan), 151.7, 151.9(C-5′ of furan), 154.2, 154.4(C-2′ of furan), 168.2(2C, 2 × COOEt) and 174.1(C-1) ppm.

*Hydrolysis of compounds **9a,9b** to the tricarboxylic acids **10,10b**.* A mixture of compounds **9a,9b** (4.0 g, 10.1 mmol), KOH (2 g, 35 mmol) and aqueous ethanol (95%, 50 mL) was refluxed for 1 hr. Concentrated HCl (10 mL) was added and the cooled reaction mixture was extracted with diethyl ether (3 × 50 mL). The organic extract was washed with brine (30 mL) and dried (Na_2SO_4). The solvent was evaporated and the residue crystallized from PE40 to give a mixture of compounds **10a,10b** (3.5 g, 88%) as light yellow amorphous solid. Melting point 102-104°C; IR (cm^{-1}) (nujol) 3400(s, br), 1713(s), 925(m). ^1H NMR (δ) 0.89(*t*, 3H, CH_3), 1.2-1.4(*m*, 12H, CH_2), 1.5-1.8(*m*, 6H, CH_2), 2.27(*t*, 2H, CH_2COOH), 2.56(*t*, J = 7.5Hz, 4H, CH_2-furan), 4.4[*s*, 1H, $CH(COOH)_2$], 6.05(*s*, 1H, CH furan) and 10.4(*s*, 3H, 3 × COOH). ^{13}C NMR (CD_3OD) 14.3(C-18), 23.5(C-17), 25.9(C-3), 26.7, 28.7, 29.0, 29.3, 29.6, 29.7, 29.9, 30.0, 32.6(C-16), 34.9(C-2), 50.1[$CH(COOH)_2$], 107.4(C-4′ of furan), 113.9(C-3′ of furan), 152.8(C-2′ of furan), 155.0(C-5′ of furan), 171.8(2C, 2 × COOH) and 177.5(C-1) ppm. Methylation of compounds **10a,10b** using boron trifluoride methanol complex gave the corresponding methyl triester derivatives **11a,11b** (98%) as an oil. R_F (PE40) 0.5; IR (cm^{-1}) 1741(s), 1021(m). ^1H NMR (δ) 0.87(*t*, 3H, CH_3), 1.2-1.4(*m*, 12H, CH_2), 1.5-1.8(*m*, 6H, CH_2), 2.3(*t*, 2H, CH_2COOCH_3), 2.53(*t*, J = 7.3 Hz, 4H, CH_2-furan), 3.64(*s*, 3H, $COOCH_3$), 3.73(*s*, 6H, 2 × $COOCH_3$ or malonate), 4.46[*s*, 1H, $CH(COOMe)_2$], 6.05(*s*, 1H, CH furan). ^{13}C NMR ($CDCl_3$) 14.0(C-18), 22.6(C-17), 25.0, 26.1, 27.9, 28.1, 28.5, 28.8, 29.0, 29.1, 31.6(C-16), 34.1(C-2), 48.9[$CH(COOMe)_2$], 51.2($COOCH_3$), 52.5[2C, 2 × $CH(COOCH_3)_2$], 106.1(C-4′ of furan), 111.8(C-3′ of furan), 151.8, 151.9(C-2′ of furan), 154.3, 154.5(C-5′ of furan), 168.6(2C, 2 × $COOCH_3$ malonate), and 174.0(C-1) ppm.

*Decarboxylation of compounds **9a,9b**.* A mixture of compounds **9a,9b** (4.0 g, 6.4 mmol), methanol (35 mL), water (15 mL) and Na_2CO_3 (10 g) was refluxed for 12 hr. The reaction mixture was acidified with dilute HCl (2M, 10 mL) and extracted with diethyl ether (2 × 30 mL). The organic extract was washed with water (10 mL) and dried (Na_2SO_4). The solvent was evaporated and the residue crystallized from PE50 to give compounds **12a,12b** (1.8 g, 79%) as light yellow amorphous solid. Melting point 63-65°C; IR (cm^{-1}) (nujol) 3400(v.br), 1700, 1220, 1010. ^1H NMR (δ) 0.88(*t*, 3H, CH_3), 1.2-1.4(*m*, 12H, CH_2), 1.5-1.8(*m*, 6H, CH_2), 2.26(*t*, 2H, CH_2COOH), 2.5(*t*, J = 7Hz, 4H, CH_2-furan), 3.3(*s*, 2H, furan-CH_2-COOH), 5.87(s, 1H, CH furan), and 10.5 (*s*, 2H, COOH). ^{13}C NMR (CD_3OD) 14.3 (C-18), 23.4(C-17), 25.9(C-3), 26.6, 28.7, 29.0, 29.4, 29.5, 29.7, 29.9, 31.6, 32.5(C-16), 34.8(C-2), 108.0(C-4′ of furan) 113.1(C-3′of furan), 151.7, 151.8(C-2′ of furan), 154.7, 154.8(C-5′ of furan), 175.2(COOH) and 177.3(C-1) ppm. Methylation of compounds **12a,12b** using boron trifluoride methanol complex gave the corresponding methyl diester derivatives **13a,13b** as an oil. R_F (PE30) 0.5; IR (cm^{-1}) (film) 1740(s), 1580(m), 1010(s). ^1H NMR (δ) 0.88(*t*, 3H, CH_3), 1.2-1.4(*m*, 12H, CH_2), 1.5-1.8(*m*, 6H, CH_2), 2.3(*t*, 2H, CH_2COOCH_3), 2.5(*t*, J = 7.3 Hz, 4H, CH_2-furan), 3.29(*s*, 2H, furan-CH_2COOCH_3), 3.64(*s*, 3H, $COOCH_3$), 3.66(*s*, 3H, furan-$COOCH_3$) and 5.87(*s*, 1H, CH furan). ^{13}C NMR ($CDCl_3$) 14.0(C-18), 22.6(C-17), 25.0(C-3), 26.0, 28.0, 28.5, 28.6, 28.9, 29.0, 29.1, 31.0, 31.7(C-16), 34.1(C-2), 51.2($COOCH_3$), 51.7(furan-$COOCH_3$), 106.9(C-4′ of furan), 111.9(C-3′ of furan), 150.8, 151.0(C-2′ of furan), 154.0, 154.2(C-5′ of furan), 171.9(furan-$COOCH_3$) and 173.9(C-1) ppm.

*Thermal decarboxylation of compounds **10a,10b**.* A mixture of compounds **10a,10b** (2.0 g, 5.1 mmol) was heated at 160-180°C under nitrogen for 6 hr. The resulting reddish oil was refluxed with boron trifluoride methanol com-

$R_1 = CH_3(CH_2)_5$; $R_2 = (CH_2)_7COOH$

SCHEME 3

plex (15%, w/w, 10 mL) and methanol (30 mL) for 10 min. Water (50 mL) was added and the reaction mixture was extracted with light petroleum (3 × 30 mL). The organic extract was washed with water (20 mL) and dried (Na_2SO_4). The solvent was evaporated under reduced pressure and silica gel column chromatography of the residue yielded a mixture of the trisubstituted furanoid fatty ester derivatives **14a,14b** (1.3 g, 83%) as an oil (17,18). R_F (PE10) 0.9; ECL = 18.7 (SE-30); IR (cm^{-1}) (film) 3010(w), 1740(s), 1010(m, furan ring breathing). ^1H NMR (δ) 0.88(*t*, 3H, CH_3), 1.2-1.4(*m*, 14H, CH_2), 1.5-1.8(*m*, 4H,CH_2), 1.88(*s*, 3H, furan-CH_3), 2.28(*t*, 2H, CH_2COOCH_3), 2.49(*t*, J = 7.3 Hz, 4H, CH_2-furan), 3.63(*s*, 3H, $COOCH_3$) and 5.7(*s*, 1H, *CH* furan). ^{13}C NMR ($CDCl_3$) 9.9(furan-CH_3), 14.0(C-18), 22.7(C-17), 25.1(C-3), 26.0, 28.2, 28.3, 28.7, 28.9, 29.0, 29.1, 31.8(C-16), 34.1(C-2), 51.2($COOCH_3$), 107.9(C-3′ of furan), 113.9(C-4′ of furan), 149.3, 149.5(C-2′ of furan) 153.3, 153.5(C-5′ of furan) and 173.9(C-1) ppm.

When a mixture of compounds **10a,10b** (2.0 g, 5.1 mmol) was heated under nitrogen at 160-180°C for 3 hr, silica gel column chromatographic separation of the methyl ester derivatives of the isolated product gave compounds **13a,13b** (1.2 g, 62%) and compounds **14a,14b** (0.44 g, 27%).

RESULTS AND DISCUSSION

As the objective of this project was to incorporate reactive chemical functions to either the 3- or 4-position of the furan ring, no effort was made to develop synthetic methods to obtain regiospecific positional isomers. Thus, treatment of methyl 9,12-epoxy-9,11-octadecadienoate with benzohydroxamic acid in the presence of Pb(IV) oxide gave a mixture of the half-blocked dioxazole-keto esters **6a,6b** in good yield (73%), as described by Mackay *et al.* (22). This reaction was non-regiospecific with the dioxazole ring attached to either C-9 or C-12 of the C_{18} fatty ester chain and the keto group at C-12 or C-9, respectively.

A subsequent 1,4-Michael addition reaction involving compounds **6a,6b** with diethyl malonate anion furnished the malonate ester derivatives **7a,7b**. Hydrolysis of the dioxazole ring in compounds **7a,7b** gave a mixture of the dioxo-malonate ester intermediates **8a,8b**, which was readily cyclized to the corresponding trisubstituted C_{18} furanoid fatty esters **9a,9b**. Hydrolysis of compounds **9a,9b** gave the tricarboxylic furanoid acids **10a,10b**, which were converted to the methyl esters **11a,11b** using boron trifluoride methanol complex. When a mixture of compounds **9a,9b** was refluxed with aqueous sodium carbonate in methanol, hydrolysis of the ester functions was followed by decarboxylation of one of the two carboxylic acid groups of the malonic acid function to yield compounds **12a,12b** containing a -CH_2COOH substituent at the 3-/4-position of the furan ring. Esterification of the latter gave the corresponding methyl diester derivatives **13a,13b**.

When a mixture of compounds **10a,10b** was heated at 160-180°C for 6 hr, an unexpected *bis*-decarboxylation reaction took place, which transformed the malonic acid group to that of a methyl function. Esterification of the isolated decarboxylated product gave the trisubstituted furanoid fatty esters **14a,14b** containing a methyl group at the 3-/4-position of the furan ring in high yield (83%). However, when the same reaction was repeated at the same temperature for 3 hr instead of 6 hr, a mixture of compounds **13a,13b** (62%) and **14a,14b** (27%) was obtained after esterification. The ratio of the products was verified by gas chromatographic analysis.

It appears from these results that the *bis*-decarboxylation process involving compounds **10a,10b** was made possible by the availability of *pi*-electrons in the furan system. The mechanism of this reaction was considered analogous to the decarboxylation process of β,γ-unsaturated carboxylic acids (23) as outlined in Scheme 3. This reaction constitutes a novel method for the introduction of a methyl group *via* a malonic acid group to the 3-/4-position of the furan ring of a 2,5-disubstituted C_{18} furanoid fatty esters.

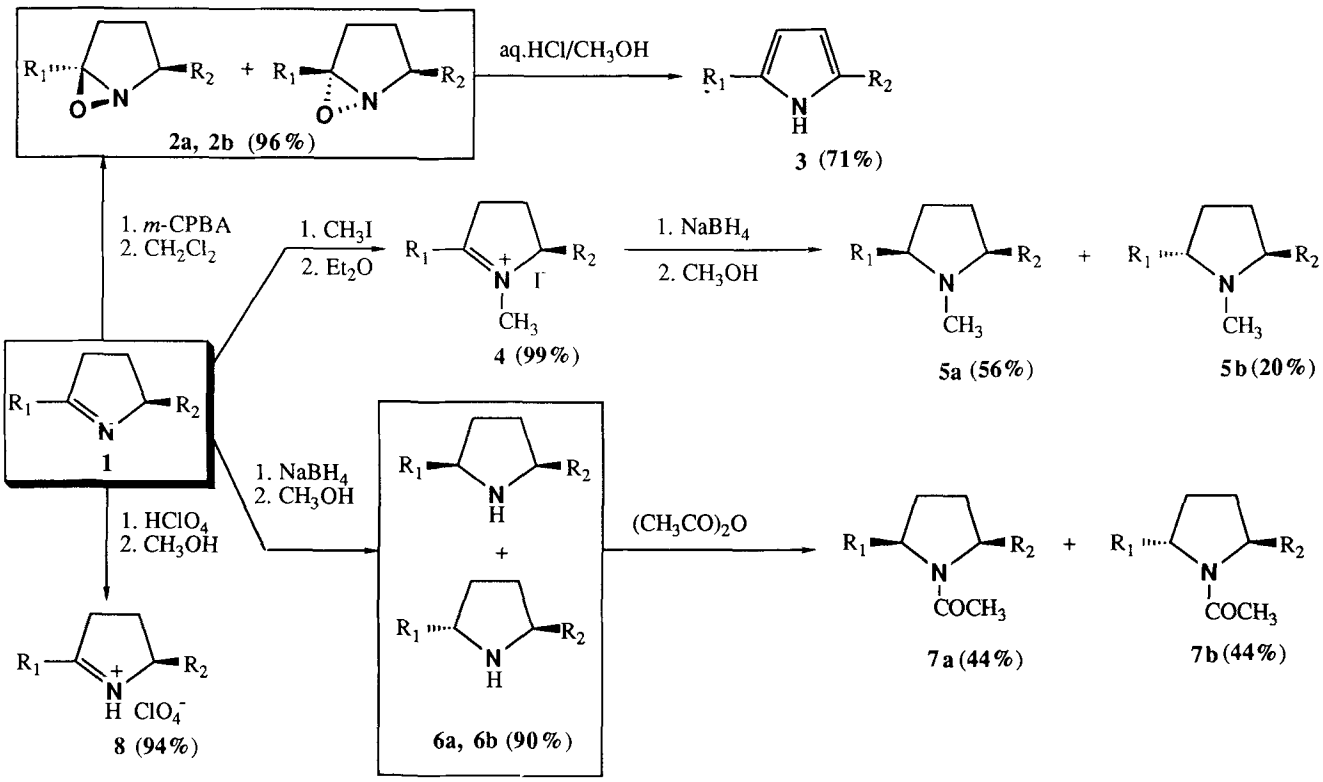
Preparation and Some Spectroscopic Properties of *N*-Heterocyclic Derivatives of a Novel 1-Pyrroline C_{18} Fatty Ester

Marcel S.F. Lie Ken Jie* and **M.S.K. Syed-Rahmatullah**
Department of Chemistry, University of Hong Kong, Hong Kong

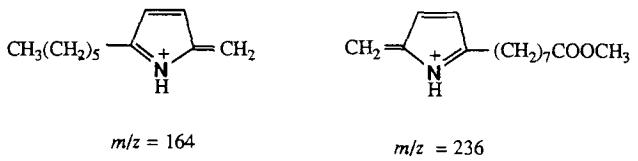
A C_{18} 1-pyrroline fatty ester, methyl 8-(5-hexyl-2-pyrrolin-1-yl)octanoate (1), was prepared from methyl *iso*-ricinoleate. The C=N bond of the pyrroline ring was oxidized by *m*-chloroperoxy-benzoic acid to yield a mixture of oxaziridine isomers 2a,2b, which decomposed during gas chromatographic analysis to a 2,5-disubstituted pyrrole derivative, methyl 8-(5-hexyl-1*H*-pyrrole-2-)octanoate (3). Compound 3 was also obtained by reaction of 2a,2b with dilute HCl in methanol. Reaction of compound 1 with iodo-methane formed an *N*-methyl iminium iodide intermediate 4, which on reduction with sodium borohydride furnished a mixture of *cis/trans*-*N*-methyl-2,5-disubstituted pyrrolidine derivatives, methyl 8-(*cis/trans*-5-hexyl-*N*-methyl-pyrrolidine-2-)octanoates 5a,5b. Reduction of compound 1 with $NaBH_4$ gave a mixture of *cis/trans*-isomers of 2,5-disubstituted pyrrolidine derivatives, methyl 8-(5-hexyl-pyrrolidine-2-)octanoates 6a,6b. Acetylation of compounds 6a,6b with acetic anhydride furnished the corresponding *N*-acetyl pyrrolidines 7a,7b. When compound 1 was treated with perchloric acid, the corresponding iminium perchlorate derivative, methyl 8-(5-hexyl-1-pyrrolinium perchlorate-2-)octanoate 8 was obtained. The structures of the various derivatives were characterized by a combination of chromatographic, mass spectral and spectroscopic techniques.
Lipids 26, **842–846 (1991).**



Long-chain *N*-heterocyclic fatty acids have not been found in nature. We have recently reported the synthesis of a novel 1-pyrroline C_{18} fatty ester derivative, methyl 8-(5-hexyl-2-pyrrolin-1-yl)octanoate, from methyl *iso*-ricinoleate (methyl 9-hydroxy-12-*cis*-octadecenoate) (1). The facile method developed for the preparation of this unusual fatty acid derivative provides a unique opportunity to explore the chemical, physical and biological properties of a new class of lipid molecules containing a five-membered *N*-heterocyclic system. 1-Pyrrolines are classified as cyclic imines and possess a chemically reactive C=N bond system. The formation of imine linkages has often been exploited by nature in various biochemical processes, including the condensation of 11-retinal with the amino group of lysine to form a visual pigment (rhodopsin) (2). The chemistry and physical properties of imines have been extensively reviewed (3,4).

In this paper we present some basic reactions involving the C=N (imine) bond of the 1-pyrroline system in the fatty ester derivative to obtain various related *N*-heterocyclic derivatives, in order to study the physical and chemical properties of this new class of five-membered *N*-heterocyclic fatty esters. The reactions carried out include oxidation (*m*-chloroperoxybenzoic acid) and reduction ($NaBH_4$) of the C=N linkage of the 1-pyrroline system, *N*-methylation, *N*-protonation and *N*-acetylation of the derived disubstituted pyrrolidine derivative, and the preparation of a pyrrole fatty ester derivative as outlined in Scheme 1 (derivatives of methyl 8-(5-hexyl-2-pyrrolin-1-yl)-octanoate (1)).

RESULTS AND DISCUSSION



The novel C_{18} 1-pyrroline fatty ester derivative 1 was prepared by reaction of the mesyl derivative of methyl *iso*-ricinoleate (methyl 9-hydroxy-12-*cis*-octadecenoate) with sodium azide, and the structure of compound 1 was unequivocally characterized as reported elsewhere (1). Reaction of compound 1 with *m*-chloroperoxybenzoic acid gave almost quantitative yield of a mixture of the corresponding oxaziridine derivatives **2a,2b.** This oxidation process of the C=N (imine) bond of the 1-pyrroline substrate was non-stereospecific and resulted in the formation of a mixture of *cis/trans*-isomers. The presence of geometric isomers in the product was reflected in the ^1H nuclear magnetic resonance (NMR) spectrum of compounds **2a,2b,** which gave signals at δ3.0(*m*) and 3.3(*m*) for the shift of the proton at the C-9 of the *cis*- and *trans*-isomers, respectively. These values were similar to results reported by Belzecki and Mostowicz (5) for asymmetric oxaziridines. Attempts were not directed to produce optically active oxaziridine derivatives, as such an approach would require optically active (1*S*)-(+)-percamphoric acid (6). The existence of a mixture of stereoisomers was also reflected in the ^{13}C NMR spectrum of compounds **2a,2b,** which showed signals at 67.34 and 65.74 ppm for the chemical shifts of the carbon atom C-9 for the *cis*- and *trans*-isomers respectively. Compounds **2a,2b** were found to be unstable when injected onto a gas chromatographic (GC) column (SE-30, 190°C), forming the pyrrole derivative **3** during the analysis. The latter compound was characterized by gas chromatography/mass spectrometry (GC/MS). Compound 3 was also readily obtained by mild acid-catalyzed dehydration of compounds **2a,2b.** Preparation of the same pyrrole derivative **3** from methyl 9,12-dioxostearate *via* the Paal-Knorr reaction was previously reported by us (7). The pyrrole nucleus in compound **3** was confirmed by ^{13}C NMR analysis, which showed the shift of the hetero-aromatic carbon atoms at 104.6 (C-10, C-11, 2C) and 131.1 (C-9, C-12, 2C) ppm. In the ^1H NMR spectrum of compound 3 the chemical shift of the protons of the hetero-aromatic ring appeared at δ 5.73 (*d*, J = 2.6 Hz). GC/MS confirmed the position of the pyrrole ring between C-9 and C-12 of the alkyl chain from the ion peaks at m/z = 164 (100%, base peak) and m/z = 236 (54%) (Scheme 2). Compound 3 decomposed gradually into a dark red polymeric

SCHEME 1

SCHEME 2

Substance even at low temperature, but the free acid form could be preserved under nitrogen at 0°C for a considerable period.

Reaction of compound **1** with iodomethane formed an *N*-methyl iminium iodide intermediate **4**, which furnished a mixture of *cis/trans*-*N*-methyl-2,5-disubstituted pyrrolidine derivatives **5a, 5b** when treated with $NaBH_4$. The mixture of compounds **5a** and **5b** was separated by silica gel column chromatography into two fractions. Based on results published on the chromatographic and NMR spectroscopic properties of *cis*- and *trans*-isomers of 2,5-dialkyl and *N*-methyl-2,5-dialkyl pyrrolidines (8,9), the less polar fraction comprised the *cis*-isomer **5a**, while the more polar fraction consisted of the *trans*-isomer **5b**. ^1H and ^{13}C NMR spectral analyses confirmed the structure of these geometric isomers. The chemical shift of the *N*-methyl protons in the *cis*-isomer **5a** appeared at δ2.24(*s*), while that of the *trans*-isomer was found further downfield at δ 2.33(*s*). In the ^{13}C NMR spectrum the shift of the *N*-methyl carbon atom of the *cis*-isomer **5a** appeared at 39.00 ppm, while the same carbon in the *trans*-isomer **5b** was more shielded and appeared at 35.13 ppm instead. The shifts for the chemically equivalent C-9 and C-12 carbon atoms of the *cis*-isomer **5a** appeared at 67.80 ppm, while those of the *trans*-isomer were shifted more upfield to 63.38 ppm. 2,5-Dialkylpyrrolidines were isolated from the venom of ants (10).

Reduction of compound **1** with $NaBH_4$ gave a mixture of *cis*- and *trans*-isomers of 2,5-disubstituted pyrrolidine derivatives **6a,6b**, which could not be separated into individual geometric isomers by silica gel chromatography. However, the presence of the *cis*- and *trans*-isomers in the reaction product was confirmed by ^1H and ^{13}C NMR spectral analyses. By referring to NMR spectroscopic data published (11–13) for the proton chemical shifts associated with the methine groups of the 5-membered *N*-heterocyclic ring of 2,5-dialkylated pyrrolidines, the signals at δ2.93(*m*) and 3.12(*m*) in the spectrum of compounds **6a,6b** were assigned to the protons of the ring methine groups of the *cis*-isomer **6a** and *trans*-isomer **6b** respectively. The ^{13}C NMR spectrum of the mixture of compounds **6a,6b** further confirmed the presence of the *cis*- and *trans*-isomers. The chemical shifts of the ring methine carbon atoms (C-9 and C-12) of the *cis*-isomer **6a** appeared at 59.48, while the

same carbon atoms of the *trans*-isomer **6b** were shifted to 58.21 ppm. Signals at 31.42 and 32.42 ppm corresponded to the shifts of the methylene carbon atoms of the heterocyclic ring (C-10 and C-11) of the *cis*- and *trans*-isomer, respectively.

Acetylation of compounds **6a,6b** was achieved with acetic anhydride to give a mixture of *cis/trans-N*-acetyl pyrrolidine derivatives **7a,7b,** which was readily separated by silica thin-layer chromatography (TLC) into the *cis*-isomer **7a** and *trans*-isomer **7b**. The ^1H NMR analysis gave a characteristic signal at δ 2.05(*s*) for the chemical shift of the protons of the acetyl ($COCH_3$) group, while in the ^{13}C NMR spectrum the shift for the carbon atom of the same group appeared at 23.00 (*q*) ppm. When compound 1 was treated with perchloric acid in methanol, the iminium perchlorate derivative 8 was obtained as a viscous oil. In the ^1H NMR analysis of compound 8, the deshielding effect of the proton on the nitrogen atom of the pyrroline ring caused the chemical shift of the methine proton at C-9 to appear at δ 4.45(*m*). In the ^{13}C NMR spectrum of compound 8, the shifts of the carbon atom at C-12 appeared downfield at 197.67 ppm.

The results of these reactions demonstrate the facile chemical transformations of the 1-pyrroline fatty ester to a range of interesting pyrrolidine and pyrrole fatty ester derivatives.

EXPERIMENTAL PROCEDURES

Iso-ricinoleic acid was isolated from the seed oil of *Wrightia tinctoria* according to the partition method described by Gunstone (14). Methyl *iso*-ricinoleate was prepared by treatment of the acid with methanol in the presence of BF_3/CH_3OH (15). Thin-layer chromatography was performed on microscope glass plates coated with silica gel (*ca.* 0.1 mm thickness) and a mixture of light petroleum (b.p. 40–60 °C)/diethyl ether used as the developing solvent, unless otherwise stated. Column chromatographic purifications were carried out on silica gel using gradient elution of mixtures of light petroleum/diethyl ether as eluant. Gas chromatography (GC) was conducted on a Hewlett-Packard (Hewlett-Packard, Palto Alto, CA) model 5970 gas chromatograph fitted with a 10-m microbore glass column (0.53 mm internal diameter, 2.65 μm film thickness, SE-30 stationary phase) using nitrogen (20 mL/min) as the carrier gas at an isothermal column temperature of 220°C with a flame ionization detector. External standards of methyl myristate, palmitate and stearate were used as reference compounds and equivalent chain length (ECL) values were calculated for each component (16). Elemental analyses were carried out by Butterworth Laboratories Ltd. (Teddington, Middlesex, England, U.K.). Infrared (IR) spectra were obtained on a Perkin-Elmer model 577 (Perkin Elmer, Norwalk, CT) spectrophotometer. NMR spectra were measured on either a Jeol FX-90Z (Jeol Ltd., Tokyo, Japan) Fourier transform spectrometer with proton observation at 90 MHz and carbon observation at 22.5 MHz, or a Jeol GSX-270 instrument with proton observation at 270 MHz and carbon observation at 67.8 MHz. GC/MS analyses were carried out on a Hewlett-Packard model 5970 gas chromatograph fitted with a 12-m capillary glass column (0.2 mm internal diameter, 0.33 μm film thickness, crosslinked methyl silicone gum) using helium (*ca.* 2 mL/min) as the carrier gas under temperature programmed conditions (initial temperature, 140°C; final temperature, 240°C; programmed at a rate of 5°C/min). The outlet of the column was connected to a Hewlett-Packard Mass Selective Detector™.

Methyl 8-(5-hexyl-2-pyrrolin-1-yl)octanoate (1). Methanesulfonyl chloride (1.5 g, 13 mmol) was added to a cooled mixture of methyl *iso*-ricinoleate (2.0 g, 6.4 mmol), triethylamine (2 mL) and CH_2Cl_2 (25 mL) at 0°C. The reaction mixture was stirred at 0°C for an additional 30 min. Water (25 mL) was added and the reaction mixture was extracted with CH_2Cl_2 (2 × 30 mL), washed with dil. HCl (2M, 10 mL), and then with water (2 × 20 mL) and was dried over anhydrous Na_2SO_4. Evaporation of the solvent under reduced pressure furnished methyl 9-mesyloxy-12-*cis*-octadecenoate (2.45 g, 99%) as an oil. The latter compound was dissolved in *N,N*-dimethyl formamide (25 mL) and NaN_3 (0.6 g, 9.2 mmol) was added. The mixture was stirred vigorously at 80°C for 6 hr. Water (40 mL) was added and the reaction mixture was extracted with Et_2O (2 × 50 mL). The ethereal extract was washed with water (2 × 20 mL) and dried over anhydrous Na_2SO_4. Silica gel column chromatography of the extract using Solvent C as eluant yielded compound 1 (1.8 g, 91%) as an oil. Elemental analysis: Found, C, 73.7; H, 11.5; N, 4.8. Calculated for $C_{19}H_{35}NO_2$: C, 73.7; H,11.4, N, 4.5%; R_f 0.5 (Solvent D); ECL 18.4 (SE-30). ^1H NMR (270 MHz, $CDCl_3$) δ 0.89 (*t*, 3H), 1.2–1.5 (*m*, 14H), 1.5–1.8 (*m*, 6H), 2.03 (*m*, 2H, 10-H ring), 2.30(*t*, J = 7.0 Hz, 4H, 2-H, 13-H), 2.45 (*q*, J = 7.0 Hz, 2H, 11-H ring), 3.65 (*s*, 3H, CO_2CH_3) and 3.90 (*m*, 1H, N-CH ring); ^{13}C NMR (67.5 MHz, $CDCl_3$) 14.05(*q*, C-18), 22.60(*t*, C-17), 25.00(*t*, C-3), 26.62(*t*, C-7,C-14 2C), 28.64(*t*, C-10 ring), 29.14(*t*), 29.21(*t*), 29.25(*t*), 29.63(*t*), 31.65(*t*, C-16), 34.07(*t*, C-2 and C-13, 2C), 36.71(*t*, C-8), 36.95(*t*, C-11 ring), 51.34(*q*, CO_2CH_3), 72.50(*d*, C-9 *ring*), 174.13(*s*, C-1) and 177.07(*s*, *C*=N ring) ppm. Reaction of 1 with m-*chloroperoxybenzoic acid. m*-Chloroperoxybenzoic acid (0.6 g, 3.5 mmol) was added to a stirred solution of compound 1 (1.0 g, 3.24 mmol) in CH_2Cl_2 (30 mL), and the reaction mixture was stirred at room temperature for 30 min. Aqueous Na_2SO_3 (5%, 20 mL) was added, and the reaction mixture was extracted with CH_2Cl_2 (30 mL). The organic extract was washed with dil. $NaHCO_3$ (10%, 20 mL), and then with water (3 × 20 mL) and dried over anhydrous Na_2SO_4. The solvent was evaporated and the residue was chromatographed on silica gel using Solvent A as the eluant to give a mixture of methyl 8-[5-hexyl-6-oxa-1-azabicyclo(3.1.0)-hexane-2-]octanoates (**2a,2b,** 1.0 g, 96%). Elemental analysis: Found, C, 70.2; H, 11.2; N, 4.3. Calculated for $C_{19}H_{35}NO_3$: C, 70.1; H, 10.9; N, 4.5%; R_f 0.6 (Solvent A); ECL 20.0 (SE-30); ^1H NMR (90 MHz, $CDCl_3$) δ 0.9 (*t*, J = 7 Hz, 3H), 1.2–1.6 (*m*, 16H), 1.6–1.9 (*m*, 8H), 1.9–2.2 (*m*, 2H), 2.3 (*t*, J = 7 Hz, 2H), 3.0, 3.3 (*m*, broad, 1H, 9-*H*) and 3.6 (*s*, 3H); ^{13}C NMR (22.5 MHz, $CDCl_3$) 14.06(*q*), 22.56(*t*), 24.65(*t*, C-7), 24.96(*t*), 25.65(*t*, C-14), 26.8(*t*), 27.14, 27.55(*t*, C-10), 29.12(*t*), 29.40(*t*), 29.50(*t*), 31.70(*t*), 31.99(*t*), 32.83(*t*, C-11), 32.91(*t*, C-13), 34.07(*t*), 51.38(*t*), 65.74(*d*, C-9 ring, *trans*), 67.34(*d*, C-9 ring, *cis*), 90.00 (*s*, C-12) and 174.17(*s*, C-1) ppm.

*Conversion of compounds **2a,2b** to methyl 8-(5-hexyl-1H-pyrrole-2-)octanoate (**3**).* A mixture of compounds **2a,2b** (0.15 g, 0.46 mmol), dil.HCl (0.1 M, 1 mL) and methanol (15 mL) was refluxed for 20 min. The reaction mixture turned brick red in color. Water (30 mL) was added and the reaction mixture was extracted with Et_2O (2 × 20 mL). The organic extract was washed with water (2 × 20 mL) and dried over anhydrous Na_2SO_4. Silica gel column chromatography using Solvent A as eluant gave compound 3 (0.1 g, 71%) as an oil. [Received November 26, 1990, and in revised form July 1, 1991; Revision accepted July 25, 1991]

Further Oxidation Products of 2,2,5,7,8-Pentamethyl-6-chromanol

Cacang Suarna, Manuel Baca, Donald C. Craig, Marcia Scudder and **Peter T. Southwell-Keely***
Department of Organic Chemistry, University of New South Wales, Kensington, N.S.W., 2033, Australia

In order to undertake a quantitative study by high-performance liquid chromatography of the rate of oxidation of 2,2,5,7,8-pentamethyl-6-chromanol (1), the model compound of α-tocopherol, a number of potential products were required as standards. Among these compounds were 2,2,7,8-tetramethylchroman-5,6-dione (10) and 2,2,7-trimethyl-6-hydroxychroman-5,8-dione (17), the model compounds of tocored and tocopurple, respectively. Attempts to synthesize 10 and 17 led to the isolation of 8-hydroxymethyl-2,2,7-trimethylchroman-5,6-dione (14) and 1,2-*bis*(2,2,7-trimethylchroman-5,6-dione-8-)ethane (19) a dimer of 10. Purification by thin-layer chromatography of the spirodimer (20) of 1 resulted in an acid-catalyzed decomposition to 1-(2,2,7,8-tetramethyl-6-chromanol-5-)2-[2-(3-methyl-3-hydroxybutyl)-5,6-dimethyl-1,4-benzoquinone-3-]ethane (23), a new chromanol-quinone dimer.
***Lipids 26*, 847-852 (1991).**

α-Tocoquinone and tocored were the first oxidation products of α-tocopherol to have been isolated, and they form the bases of the well known Emmerie-Engel and Furter-Meyer colorimetric assays for vitamin E (1,2). According to the literature, the conditions required to produce tocored are more vigorous than those needed for tocoquinone and represent an overoxidation.

Our experience with oxidations of 2,2,5,7,8-pentamethyl-6-chromanol (1), the model compound of α-tocopherol, showed that 2,2,7,8-tetramethylchroman-5,6-dione (10), the model compound of tocored, and 2,2,7-trimethyl-6-hydroxychroman-5,8-dione (17), the model compound of tocopurple, were almost always among the products. Since we desired to make a detailed kinetic study of the rate of formation of various oxidation products of 1 by high-performance liquid chromatography (HPLC), it was necessary to prepare a number of these compounds in a high degree of purity for use as standards. During the preparation of 10 and 17, two new compounds were isolated, one of which was a hydroxylated form of 10, and the second a dimer of 10.

The second part of this work arose from the observation that attempts to purify the spirodimer of 1(20) by repeated chromatography on silica gel thin-layer chromatography (TLC) plates led to its apparent decomposition. It was hypothesized that the decomposition may have been due to acid-catalyzed ring opening of 20 on the TLC plate. This indeed proved to be true and led to the isolation of two new dimers.

Abbreviations: E.I., electron impact; F_o, observed structure amplitude; HPLC, high-performance liquid chromatography; IR, infrared; I_o, observed intensity; MS, mass spectrum; NMR, nuclear magnetic resonance; σ, standard deviation; θ, diffraction angle; TLC, thin-layer chromatography.

MATERIALS AND METHODS

Infrared (IR) spectra were determined on a Perkin-Elmer (Norwalk, CT) 580B spectrometer, ultraviolet (UV) spectra on a Perkin-Elmer 124 double beam spectrophotometer. ^1H and ^{13}C nuclear magnetic resonance (NMR) spectra were recorded on a Bruker (Karlsruhe, Germany) AM 500 spectrometer. NMR spectra were taken in $CDCl_3$ and are reported in parts per million downfield from tetramethylsilane as internal standard. Electron impact (E.I.) mass spectra were determined at 70 eV on an A.E.I. (Manchester, England) MS 12 spectrometer.

Compound 1 together with its spirodimer (20) and spirotrimer, 5-hydroxymethyl-2,2,7,8-tetramethyl-6-chromanol (5), 5-formyl-2,2,7,8-tetramethyl-6-chromanol (6) and 5-ethoxymethyl-2,2,7,8-tetramethyl-6-chromanol (4) were prepared as reference compounds by known methods (3-8).

Oxidation of 1 by silver nitrate in absolute ethanol. Compound 1 (105 mg, 0.48 mmol) was dissolved in absolute ethanol (5 mL) and heated to 65°C for 5 min. Silver nitrate (358 mg, 2.11 mmol) was then added and the solution kept at 65°C for 2 hr during which time the color changed to blood red, and silver precipitated. The solution was filtered, the silver precipitate washed with chloroform (3 × 10 mL) and the chloroform washings added to the ethanol filtrate. The chloroform caused further precipitation in the combined chloroform/ethanol filtrate which was refiltered, washed with distilled water (4 × 5 mL), dried (Na_2SO_4) and the solvent removed *in vacuo*.

The residue was chromatographed on thin layers of silica gel GF_{254} (solvent, petroleum hydrocarbon (b.p. 60-80°C)/ethyl acetate, 9:1, v/v). The fractions were located under ultraviolet light and eluted with distilled chloroform. The solvent was removed under a stream of nitrogen.

Major bands with the following R_f values were isolated: 0.00 (pink, 1.6 mg), 0.03 (purple, 3.9 mg), 0.13 (red, tocored model compound 10, 39.5 mg), 0.28 (3.3 mg), 0.37 (9.1 mg), 0.44 (1, 10.7 mg), 0.56 (5-ethoxymethyl-2,2,7,8-tetramethyl-6-chromanol, 4, 29.6 mg), 0.62 (5-formyl-2,2,7,8-tetramethyl-6-chromanol, 6, 11.3 mg) and 0.69 (1.0 mg).

The major bands with R_f values of 0.00, 0.03 and 0.13 were combined and rechromatographed on silica gel GF_{254} (solvent, petroleum hydrocarbon (b.p. 60-80°C/ethyl acetate, 1:1 v/v) yielding 5 minor bands with R_f values of 0.02 (pale purple, trace), 0.16 (purple, 3.9 mg), 0.26 (pink, 0.8 mg), 0.40 (pink, 5.4 mg) and 0.72 (red, 36.8 mg).

The minor bands with R_f values of 0.02 and 0.26 were not purified further.

Minor band R_f 0.16 separated as orange crystals (purple on silica gel) from petroleum hydrocarbon and was identified as 2,2,7-trimethyl-6-hydroxychroman-5,8-dione (model compound of tocopurple, 17). Compound 17 had the following spectral data: UV (λ_{max}, methanol) 295 mm; IR (KBr) (cm^{-1}): 3371 (OH), 2976, 2936, 2859 (CH_3), 1732, 1654 (C=O), 1639, 1625, 1612, 1463, 1407, 1376, 1356, 1287, 1267, 1240, 1158, 1120, 1097, 1064 (C—O—C), 983, 943, 883, 837, 764. Mass spectra (MS) (E.I.) (*m/z*) (rel. in-

tensity): 222 (M^+) (24), 207 (75), 167 (13), 139 (26), 123 (15), 109 (23), 95 (32), 81 (33), 69 (44), 55 (64) and 41 (100). ^1H NMR ($CDCl_3$) δ 1.3985 (*s*, 6H, 2 × CH_3), 1.7580 (*t*, 2H, J = 6.6 Hz, =C−CH_2−CH_2−), 1.9100 (*s*, 3H, =C−CH_3), 2.4412 (*t*, 2H, J = 6.6 Hz, =C−CH_2−CH_2−) and 7.23 (*s*, 1H, OH). ^{13}C NMR. ($CDCl_3$) δ 182.205 (2 peaks), 154.988, 151.301, 113.898, 112.133, 79.159, 31.403, 26.495 (2 peaks), 15.540, 7.71.

Minor band R_f 0.40 separated as blood red-purple crystals from absolute ethanol/ethyl acetate (pink on silica gel). The UV spectrum showed that it was contaminated with 2-(3-hydroxy-3-methylbutyl)-3,5,6-trimethyl-1,4-benzoquinone at 268 nm and 258 nm. Purification was achieved by adding n-hexane which dissolved the quinone easily but not the red compound. The compound, which had m.p. 169–171°C, was identified as 1,2-*bis*(2,2,7-trimethyl-chroman-5,6-dione-8-)ethane (**19**) and had UV-Vis (λ_{max}, methanol) 287, 468 nm; IR (KBr) (cm^{-1}) 2926, 2855 (CH_3), 1680, 1644 (C=O), 1581, 1458, 1403, 1375, 1325, 1293, 1264, 1243, 1198, 1172, 1121 (C−O−C), 1078, 938, 882; MS (E.I.) (*m/z*) (rel. intensity): 438 (M^+) (2), 222 (38), 208 (16), 205 (17), 166 (100), 152 (61), 138 (16); ^1H NMR ($CDCl_3$) δ 1.4014 (*s*, 12H, 4 × CH_3), 1.7659 (*t*, 4H, 2 × CH_2, J = 6.7 Hz, =C−CH_2−CH_2−), 2.0741 (*s*, 6H, 2 × CH_3, =C−CH_3), 2.4543 (*t*, 4H, 2 × CH_2, J = 6.7 Hz, =C−CH_2−CH_2−) and 2.6202 (*s*, 4H, 2 × CH_2, =C−CH_2); ^{13}C NMR. ($CDCl_3$) δ 180.929, 177.730, 162.283, 145.355, 134.901, 111.044, 79.758, 31.475, 26.806 (2 peaks), 26.429, 15.809 11.728. As the molecule (**19**) is a symmetrical dimer, each of the peaks actually represents the signals of two carbons.

Crystal data. $C_{26}H_{30}O_6$, M 438.5, monoclinic, space group C2/c, a 26.098 (3), b 6.068 (1), c 18.414 (2)Å, β 129.05 (1)°, V 2264.7 (3)Å^3, D_c 1.29 g cm^{-3}, Z 4, μ_{Cu} 7.00 cm^{-1}. Crystal size 0.04 by 0.48 by 0.46 mm, 2 diffraction angle (θ_{max}) 70°, minimum and maximum transmission factors 0.77 and 0.98. The number of reflexions was 1431 considered observed out of 2156 unique data, with R_{merge} 0.015 for 54 pairs of equivalent hk0 reflexions. Final residuals R, R_w were 0.049, 0.062.

Structure determination. Reflexion data were measured with an Enraf-Nonius (Delft, Holland) CAD-4 diffractometer in $\theta/2\theta$ scan mode using nickel filtered copper radiation (λ 1.5418 Å). Data were corrected for absorption. Reflexions with I>3 standard deviation (σ) (I) were considered observed. The structure was determined by direct phasing and Fourier methods. Hydrogen atoms were located in a difference Fourier, included in idealized positions, and were assigned thermal parameters equal to those of the atom to which they were bonded. Positional and anisotropic thermal parameters for the non-hydrogen atoms and an isotropic extinction parameter were refined using full matrix least squares. Reflexion weights used were $1/\sigma^2$ observed structure amplitude (F_o), with $\sigma(F_o)$ being derived from $\sigma(I_o) = [\sigma^2(I_o) + (0.04I_o)^2]^{1/2}$. The weighted residual is defined as $R_w=(\Sigma w\Delta^2/\Sigma wF_o^2)^{1/2}$. Atomic scattering factors and anomalous dispersion parameters were from *International Tables for X-ray Crystallography* (9). Structure solution was by *MULTAN80* (10). Initial refinement used *BLOCKLS*, a local version of *ORFLS* (11) and was completed using *RAELS88* (12) when disorder was identified. Alternate positions for C(2), and hence for C(10) and C(11), were refined, with slack constraints ensuring that the dimensions of the two components were approximately equal. The proportions of the two components were refined, but their sum was kept at 1.0. As a result of the disorder, ten hydrogen atoms had alternate positions included in the refinement. Thermal parameters of each atom of the minor disorder component were equated to those of the equivalent atom of the major component. *ORTEPII* (13) running on a Macintosh IIcx was used for the structural diagram, and an IBM 3090 computer was used for calculations.

The structure and atom numbering scheme is shown in Figure 1, with the minor disorder component, comprising 16%, omitted. The molecule has a crystallographic center of symmetry in the C(13)—C(13) bond, and only the asymmetric portion is labeled. Material deposited with this journal comprises all atom and thermal parameters, interatomic distances and angles, and observed and calculated structure factors.

Minor band R_f 0.72 separated from petroleum hydrocarbon (b.p. 40–60°C) as blood-red crystals (pink on silica gel) and was identified as 2,2,7,8-tetramethyl-chroman-5,6-dione (**10**). Compound **10** had the following spectral data: UV-Vis (λ_{max}, hexane) 270, 438; (λ_{max}, methanol) 282, 468 nm; IR (KBr) (cm^{-1}); 2975, 2931, 2857 (CH_3), 1676, 1645 (C=O), 1586, 1455, 1401, 1378, 1324, 1288, 1242, 1185, 1121, 1109 (C−O−C) 1047, 923, 897, 880. MS (E.I.) (*m/z*) (rel. intensity): 220 (M^+) (17), 205 (28), 192 (63), 177 (20), 159 (16), 137 (100), 109 (15). ^1H NMR ($CDCl_3$) δ 1.3730 (*s*, 6H, 2 × CH_3), 1.7306 (*t*, 2H, J = 6.7 Hz, =C−CH_2−CH_2−), 1.9431 (*s*, 3H, =C−CH_3), 2.0256 (*s*, 3H, =C−CH_3), 2.424 (*t*, 2H, J = 6.7 Hz, =C−CH_2−CH_2−). ^{13}C NMR ($CDCl_3$) δ 180.825, 177.915, 163.307, 143.724, 134.149, 110.058, 79.088, 31.392, 26.694 (2 peaks), 15.657, 13.721, 11.558. The analysis of the ^1H NMR spectrum was completed by means of a two-dimensional long-range, proton-carbon correlation spectrum (14).

When **10** (36.8 mg) was kept in chloroform solution for a few days, it decomposed into five compounds which were separated on thin layers of silica gel (solvent, petroleum hydrocarbon/ethyl acetate, 1:1, v/v). The compounds had R_f 0.00 (yellow, trace), 0.26 (pink, 1.3 mg), 0.40 (pink, **19**, 3.2 mg), 0.49 (colorless, quinone, trace) and 0.73 (pink-red, **10**, 31.6 mg).

The band with R_f 0.26 (pink) was combined with minor band R_f 0.26 from the silver nitrate reaction and was tentatively identified as 8-hydroxymethyl-2,2,7-trimethyl-chroman-5,6-dione (**14**). It had UV-Vis (λ_{max}, n-hexane): 268, 434; IR (KBr) (cm^{-1}); 3451 (OH), 2958, 2929, 2858 (CH_3), 1734, 1684, 1651 (C=O), 1586, 1458, 1397, 1377, 1326, 1291, 1175, 1117, 1032, 1016, 979, 924, 898, 878; MS (E.I.) (*m/z*) (rel. intensity): 236 (M^+) (13), 220 (55), 207 (23), 205 (100), 191 (13), 180 (24), 177 (33), 165 (32), 149 (16); ^1H NMR ($CDCl_3$) δ 1.4234 (*s*, 6H, 2 × CH_3), 1.7879 (*t*, 2H, J = 6.6 Hz, =C−CH_2−CH_2−), 2.0450 (*s*, 3H, =C−CH_3), 2.4533 (*t*, 2H, J = 6.6 Hz, =C−CH_2−CH_2−) and 4.5175 (*d*, 2H, J = 5.2 Hz, =C−CH_2−OH). On shaking with D_2O the doublet at 4.5175 ppm changed to a singlet peak suggesting that it was bound to an OH.

Hydrolysis of the spirodimer of 1. To the spirodimer of **1** (12 mg) in ethanol/chloroform (3:1, v/v, 2 mL) was added hydrochloric acid in ethanol (150 μL of 1M) and the solution was left at room temperature for 30 min with occasional stirring. The solution was then diluted with

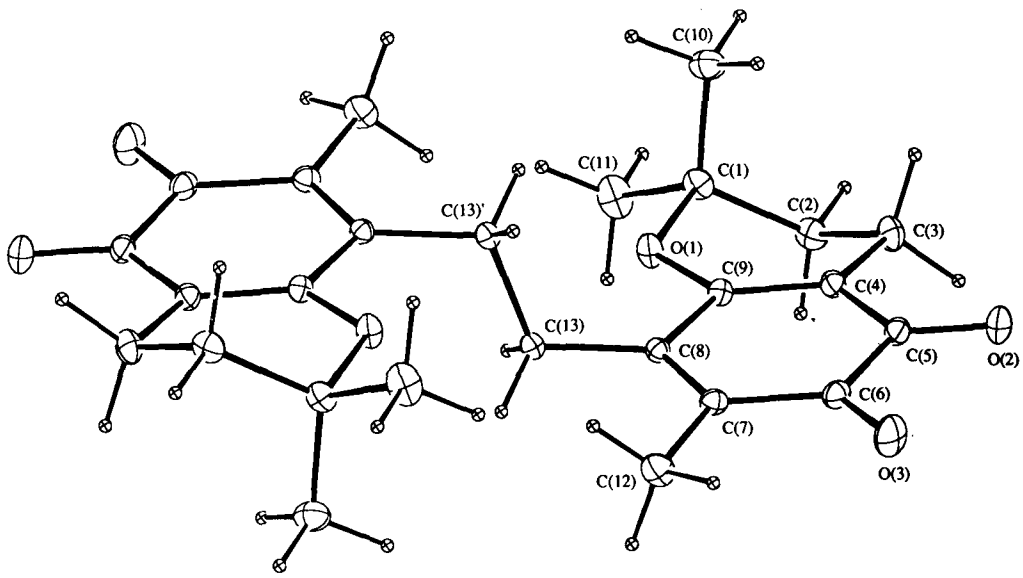

FIG. 1. X-ray crystal structure of 1,2-*bis*(2,2,7-trimethylchroman-5,6-dione-8-)ethane (19).

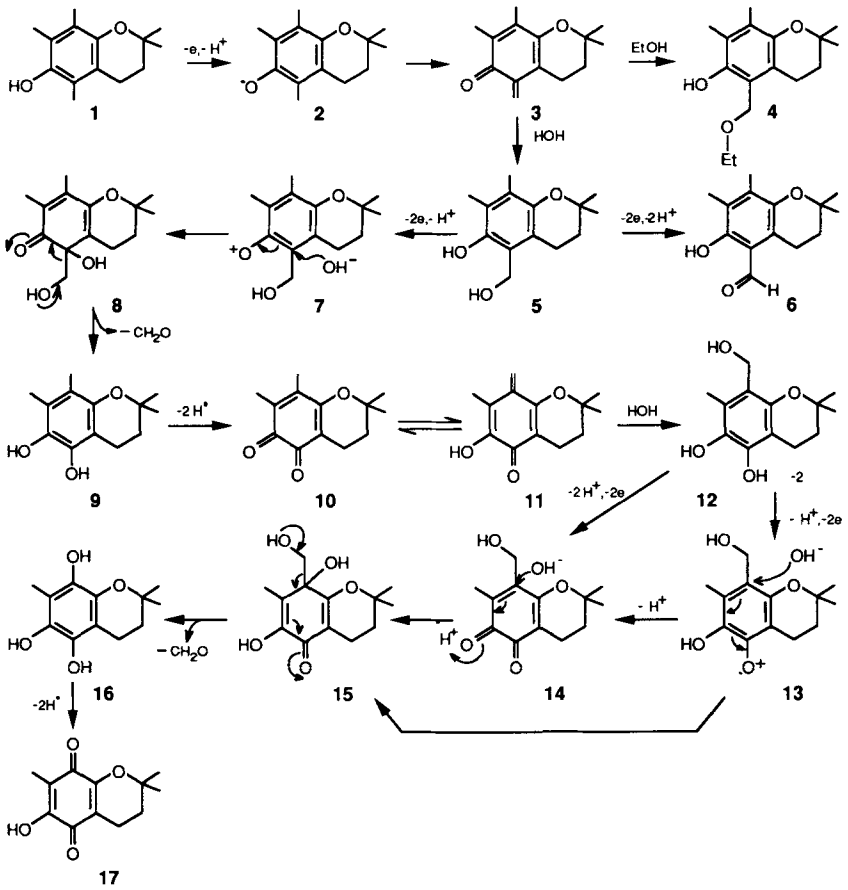
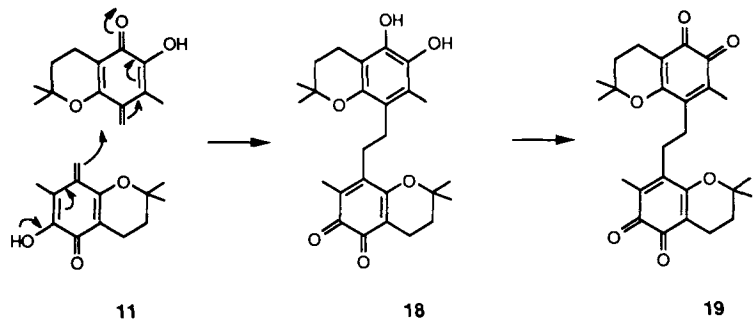


petroleum hydrocarbon (25 mL), washed with water (2 × 10 mL) and the solvent removed *in vacuo*. The residue was chromatographed on thin layers of silica gel GF_{254} (solvent, petroleum hydrocarbon (b.p. 60–80°C)/ethyl acetate 9:1, v/v) yielding bands with R_f values of 0.00 (1.6 mg), 0.05 (6.7 mg) and 0.56 (starting material, 4.0 mg). The compounds with R_f values of 0.00 and 0.05 were combined and rechromatographed on thin layers of silica gel (solvent, chloroform/methanol, 24:1, v/v) to give bands with R_f values of 0.50 and 0.72. Compound R_f 0.72 was identified as 1-(2,2,7,8-tetramethyl-6-chromanol-5-)2-[2-(3-methyl-3-hydroxybutyl)-5,6-dimethyl-1,4-benzoquinone-3-]-ethane (**23**). It had UV λ_{max} (hexane): 263, 270, 294 nm; IR (KBr) (cm^{-1}) 3463 (OH), 2976, 2932 (CH_3), 1726, 1646 (C=C–C=O), 1454, 1384, 1266, 1227, 1170, 1128, 1111, 1091, 1035, 930, 905, 759, 729; MS (E.I.) (*m/z*) (rel. intensity) 454 [M^+] (10), 436 (49), 421 (14), 380 (8), 337, (8), 324 (8), 311 (8), 260 (10), 219 (100); ^1H NMR ($CDCl_3$) δ 1.29 (*s*, 12H, 4 × CH_3), 1.57 (*m*, 2H, =C–CH_2–CH_2–), 1.81 (*t*, 2H, Ar–CH_2–CH_2–, J = 6.8 Hz), 2.04 (*s*, 3H, =C–CH_3), 2.06 (*s*, 3H, =C–CH_3), 2.11 (*s*, 3H, Ar–CH_3), 2.20 (*s*, 3H, Ar–CH_3), 2.65 (*m*, 6H, =C–CH_2–CH_2– & =C–CH_2–CH_2–Ar), 2.78 (*t*, 2H, Ar–CH_2–CH_2–, J = 6.8 Hz), 6.01 (*s*, 1H, OH); ^{13}C NMR ($CDCl_3$) δ 188.53, 187.42, 145.66, 145.23, 144.87, 142.92, 141.17, 140.75, 123.85, 122.86, 122.33, 116.11, 72.58, 71.09, 43.29, 33.12, 29.73, 29.25, 29.25, 26.79, 26.79, 26.17, 21.54, 20.45, 12.45, 12.45, 12.37, 11.95.

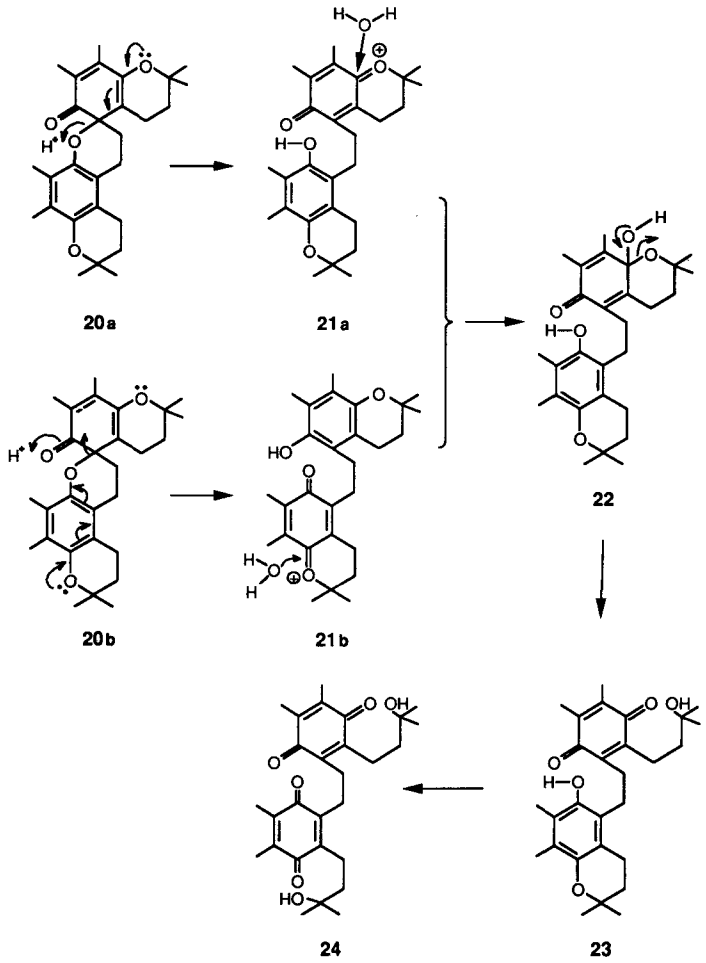
Compound R_f 0.5 was identified as 1,2-*bis*[2-(3-methyl-3-hydroxybutyl)-5,6-dimethyl-1,4-benzoquinone-3-]ethane (**24**). Compound **24** had the following spectra data: UV λ_{max} (hexane): 263 nm; IR (KBr) (cm^{-1}) 3396, (OH), 2974, 2930, 2859 (CH_3), 1737, 1648 (C=C–C=O), 1622, 1463, 1448, 1382, 1359, 1294, 1282, 1195, 1147, 1110, 1033, 1007, 941, 888; MS (E.I.) (*m/z*) (rel. intensity) 470 [M^+] (10), 452 (100), 436 (23), 419 (27), 394 (23), 379 (59), 363 (13), 335 (20), 323 (29), 322 (26), 232 (35), 219 (63), 203 (26), 189 (24), 177 (33); ^1H NMR ($CDCl_3$) δ 1.34 (*s*, 12H, 4 × CH_3), 1.67 (*m*, 4H, 2 × =C–CH_2–CH_2–), 2.012 (*s*, 6H, 2 × =C–CH_3), 2.018 (*s*, 6H, 2 × =C–CH_3), 2.56 (*s*, 4H, =C–CH_2–CH_2–C=), 2.73 (*m*, 4H, 2 × =C–CH_2–CH_2–); ^{13}C NMR ($CDCl_3$) δ (each resonance, 2 carbons) 187.86, 187.41, 145.74, 142.57, 141.10, 140.66, 70.71, 43.67, 29.07, 29.07, 26.81, 21.65, 12.43, 12.37.



RESULTS AND DISCUSSION

The structure of **14** is tentative since there was insufficient material for a long-range, proton-carbon correlation spectrum which would have fixed the position of the alcohol group. However comparison of the ^1H NMR spectra of **10** and **19** with that of **14** suggests the structure which has been proposed.

Formation of **10** and **17** may occur as outlined in Scheme 1. Oxidation of **1** leads progressively to the chromanoxy radical **2** and the quinone methide **3** (15,16). It seems likely that **3** results from the disproportionation of two molecules of **2** (17). The quinone methide **3** may add ethanol to form **4** (8), the second most abundant product, or water to form **5** (18). The water probably comes from the "absolute ethanol" which contains 0.5% (1.1 mmol). Oxidation of **5** may produce the aldehyde **6**, which is stable and is found as one of the products, or it may form the phenoxylium ion **7**. Addition of OH^- (from water) to **7** could then form **8**. Conversion of **8** to 2,2,7,8-tetramethyl-5,6-dihydroxychroman (**9**) with the loss of formaldehyde is a typical retro-aldol type of reaction where the driving force is the reestablishment of aromaticity in **9**. Compound **9** contains the very labile catechol structure and would be oxidized rapidly to **10**, the major product. This pathway has been proposed previously for the C-demethylation of methyl phenols (19) and is analogous to the C-demethylation of methyl quinones by amines (20). Recent results have shown that compound **4** can also be oxidized



SCHEME 1

SCHEME 2

to **10**, though not as rapidly as can **5** (Kohar, I., and Southwell-Keely, P.T., unpublished results). Thus an alternative, but strictly analogous, pathway (not shown) may be proposed in which **4** substitutes for **5** and either the diethylacetal of formaldehyde or formaldehyde plus ethanol is eliminated instead of formaldehyde itself. In fact it seems likely that both pathways operate simultaneously.

Conversion of **10** into **17** appears to be a repetition of the formation of **10**. Enolization of **10** would produce the *para* quinone methide **11** which could add water as before to form the hydroxymethyl catechol **12**. Oxidation of **12** to 8-hydroxymethyl-2,2,7-trimethylchroman-5,6-dione (**14**) and addition of water would form **15**. Loss of formaldehyde from **15**, as above, would give the trihydroxychroman **16** which could be oxidized readily to **17**. An alternative route from **10** to **17** may involve the production of a second phenoxylium ion **13**. Compound **13** could then either lose

SCHEME 3

a proton to form **14** or add OH^- to form **15**. Compound **15** could then lose formaldehyde as before. Whether **12** goes directly to **14** or first to **13** and then to **14**, or to **13** and then to **15**, remains to be proved. The fact that **14** has been isolated suggests the pathway **12-13-15** may not be a major one.

Formation of **19** (Scheme 2, Fig. 1) may be readily understood as following the enolization of **10** to **11** and its dimerization to **18**, a reaction typical of quinone methides (21). Oxidation of **18** would produce **19**.

Attempted purification of **20** by repeated chromatography on silica gel (solvent, petroleum hydrocarbon/carbon tetrachloride/ethyl acetate, 16:9:1, v/v) failed to produce a single spot and gave, in addition to **20**, an orange band at R_f 0.0. Rechromatography of the R_f 0.0 band (solvent, chloroform/methanol, 24:1, v/v) yielded an orange band at R_f 0.58 whose UV and mass spectra suggested that it was chromanol quinone dimer. It was believed that such a compound could originate by hydrolysis of **20** on the slightly acidic surface of the silica gel. In order to test this hypothesis, **20** was deliberately hydrolyzed in acidic ethanol/chloroform solution. Two compounds were isolated from the hydrolysis, **23**, which was identical to that isolated from the TLC plate, and **24**. The α-tocopherol analogue of **23** has been isolated previously although structural assignment was based on an approximate molecular weight plus UV and IR spectra data (22).

Formation of **23** and **24** may be understood as the direct consequence of an acid catalyzed ring opening of **20** (Scheme 3). Protonation of **20** may occur on the spiropyran oxygen (**20a**) or on the carbonyl oxygen (**20b**) to give the same oxonium ion intermediate (**21a-21b**). Although both sites of protonation are possible, it seems likely that the carbonyl oxygen would be more basic than the spiropyran oxygen particularly because the latter would tend to conjugate with the aromatic ring (23). Addition of water to **21** would form the hemi-ketal **22** which may be thought of as a substituted 8a-hydroxy-α-tocopherone. Compound **22** would be expected to undergo ring opening in the same way as 8a-hydroxy-α-tocopherone and to form **23** (24). Oxidation of **23** would produce **24**.

ACKNOWLEDGMENTS

Thanks are due to Mrs. N. Juranario for running the IR spectra, to Mrs. H. Stender for the NMR spectra, and to Dr. J. Brophy for the mass spectra.

METHOD

Lipid Hydroperoxide Measurement by Oxidation of Fe^{2+} in the Presence of Xylenol Orange. Comparison with the TBA Assay and an Iodometric Method

Zhen-Yue Jiang, Alison C.S. Woollard and **Simon P. Wolff***
Toxicology Laboratory, Department of Clinical Pharmacology, University College and Middlesex School of Medicine, London WC1E 6JJ, United Kingdom

Study of the role of hydroperoxides and lipid peroxidation in disease requires simple and sensitive methods for direct hydroperoxide measurement. We report on a technique for measuring hydroperoxide which relies upon the rapid hydroperoxide-mediated oxidation of Fe^{2+} under acidic conditions. Fe^{3+} forms a chromophore with xylenol orange which absorbs strongly at 560 nm, yielding an apparent E_{560} (for H_2O_2, butyl hydroperoxide and cumene hydroperoxide) of 4.3×10^4 M^{-1} cm^{-1}. The assay was validated in a study of liposomal lipid peroxidation and shown to give results comparable with those obtained by an iodometric method or by measuring conjugated dienes. The assay involving thiobarbituric acid, by comparison, underestimates lipid peroxidation and does not measure hydroperoxide *per se*.
***Lipids* 26, 853–856 (1991).**

Lipid peroxidation has been proposed to contribute to various pathophysiological cell and tissue abnormalities. The assessment of oxidative damage in tissue exposed to oxidative stress has been difficult to achieve by direct measurement of oxidative alterations, such as hydroxyl radical damage, or accumulation of lipid peroxidation products (1,2). Methods for the direct determination of hydroperoxides (*e.g.*, based on iodine oxidation, enzymatic or non-enzymatic catalytic oxidation of dyes, or coupled oxidation of NADPH) can often be insensitive and unreliable, particularly if they require strict anoxia (3–5). Methods for measuring hydroperoxide using initiation of the cyclooxygenase reaction (6) or microperoxidase-catalyzed isoluminol luminescence (7) have the potential for excellent sensitivity, but can be subject to various confounding factors, in the former case, and require specialized equipment and materials in the latter. Also, doubts exist about the usefulness and general validity of the widely employed thiobarbituric acid (TBA) assay for lipid peroxidation (8–14).

We have previously modified a method for measuring hydroperoxide initially described by Gupta (see ref. 15) which involves the oxidation of Fe^{2+} by hydroperoxides at low pH in the presence of the Fe^{3+}-complexing dye xylenol orange [*o*-cresolsulfonphthalein-3′,3″-*bis*(methyliminodiacetic acid sodium salt)]. We used this ferrous oxidation/xylenol orange method (which we term FOX) in a study of nanomolar H_2O_2 formation during transition metal-catalyzed glucose oxidation (16). We adapted the method for the study of lipid peroxidation and found that it can be used to quantify lipid hydroperoxides at the nanomolar level. The method is simple and straightforward.

EXPERIMENTAL PROCEDURES

Ammonium ferrous sulfate, hydrogen peroxide, glutathione (GSH), cumene hydroperoxide, butyl hydroperoxide, butylated hydroxytoluene (BHT) and thiobarbituric acid (TBA) were obtained from Sigma (Poole, Dorset, U.K.) or Aldrich (Gillingham, Dorset, U.K.). Phosphatidylcholine (egg yolk, Sigma Type V-E), catalase (Type C-40), glutathione peroxidase (bovine erythrocyte Type G6137) and phospholipase A_2 (porcine pancreas Type P6534) also were obtained from Sigma. Xylenol orange [*o*-cresolsulfonphthalein-3′,3″-bis(methyliminodiacetic acid sodium salt)] was obtained from Aldrich. The fatty acid composition of the phosphatidylcholine used was given by the manufacturer as 16:0 (31.6%), 18:0 (13.4%), 18:1 (29.7%), 18:2 (15.5%), 20:4 (4.3%) and total minor components (5.5%).

Preparation of liposomes and liposome incubations. Two mL of phosphatidylcholine (100 mg/mL) were dried under nitrogen and then hydrated in 10 mL of glucose-free phosphate-buffered saline (10 mM, pH 7.4; PBS) in the dark for 1 hr. The resulting dispersion was ultrasonicated for 3 min while cooling on ice (17). The small liposomes were then incubated at a final concentration of 10 mg/mL in PBS with respective agents in a shaking water bath at 37°C. At defined time intervals, 100 μL of the incubation mixture was removed and 900 μL methanol was added to dissolve the dispersion.

Measurement of stable products of lipid peroxidation by thiobarbituric acid assay and measurement of conjugated dienes. Aldehyde products of lipid peroxidation were measured using TBA. Methanol-solubilized liposomal incubation mixture (200 μL) was incubated with 800 μL of 0.67% TBA (adjusted to pH 4) at 100°C for 5 min. The reaction was complete at this point as judged by comparison with results obtained for malondialdehyde (MDA), prepared by acid hydrolysis of tetramethoxypropane. After cooling, the reaction mixture was centrifuged (12000 × *g*, 10 min) and the absorbance of the supernatant was read at 532 nm. The concentration of MDA was calculated from TBA-reactive material (TBARM) using the extinction coefficient of 1.56×10^5 M^{-1} cm^{-1} given for the MDA-TBA adduct (18). Conjugated diene (CD) concentration was estimated by difference spectroscopy of the methanol extract using an extinction coefficient of 2.8×10^4 M^{-1} cm^{-1} at 233 nm for the methanol extract (19).

Abbreviations: BHT, butylated hydroxytoluene; CD, conjugated diene; DTPA, diethylenetriaminepentaacetic acid; FOX, ferrous oxidation/xylenol orange; GSH, reduced gluthathione; MDA, malondialdehyde; PBS, phosphate-buffered saline; TBA, thiobarbituric acid; TBARM, TBA-reactive material; TCA, trichloroacetic acid.

Iodometric determination of hydroperoxide. Hydroperoxide content of liposomes was also determined by an established iodometric method (3). Solution A consisted of a mixture of HPLC-grade methanol (British Drug Houses, Poole, Dorset) and glacial acetic acid (Sigma) (1:1, v/v) containing 1 mg/mL of ethylenediaminetetraacetic acid (disodium salt) degassed with a stream of nitrogen for 20 min. Solution B consisted of HPLC-grade methanol degassed with N_2 for 20 min followed by addition of 20% w/v potassium iodide (Sigma), and degassed for a further 20 min.

One mL of solution A was added to 1.5 mL of solution B in a 3-mL cuvette adapted to permit degassing with nitrogen as well as addition of small volumes of fluid under anoxic conditions. The cuvette contents were treated with N_2 for 5 min and the cuvette was sealed. Absorbance was monitored at 290 nm for 4 min. The solution was discarded if absorbance increased by more than 0.005 AU. A small volume (1–10 μL) of an N_2-treated standard hydroperoxide solution, or methanol-solubilized liposomes, was then injected. The cuvette contents were gently mixed by careful agitation. Absorbance at 290 nm was monitored for 5 min after which time no further absorbance change was observed. A standard curve generated with H_2O_2 gave an extinction coefficient for tri-iodide at 290 nm of 4.7×10^4 M^{-1} cm^{-1}, in good agreement with the value published previously.

Composition of the hydroperoxide-measuring reagent (FOX). The FOX assay described previously (16) requires modification for measurement of lipid hydroperoxides. Sorbitol (which was previously added to stimulate chain-oxidation of Fe^{2+}) causes extensive peroxidation of lipid in the assay itself leading to a false signal (data not shown). This undesirable chain oxidation was prevented by omission of sorbitol and inclusion of the lipid-soluble chain-breaking antioxidant butylated hydroxytoluene (BHT). One hundred μL of methanol-solubilized sample was added to 900 μL of the following reaction mixtures and incubated for 30 min at room temperature prior to measurement at 560 nm: 100 μM xylenol orange, 250 μM Fe^{2+}, 25 mM H_2SO_4, and 4 mM BHT in 90% (v/v) methanol. The reaction is essentially complete after 15 min and the color is stable overnight at room temperature. The apparent extinction coefficients (estimated by curve fitting to a first-degree function) for H_2O_2, cumene hydroperoxide and butyl hydroperoxide at 560 nm were found to be 4.3×10^4 M^{-1} cm^{-1} with little difference in the color yields for the different hydroperoxides. The actual extinction coefficient of the Fe^{3+}-xylenol orange complex at 560 nm (the absorbance maximum) was determined using freshly-made acidic solutions of ferric chloride and determined to be 1.5×10^4 M^{-1} cm^{-1}, indicating that there is some chain oxidation of ferrous by hydroperoxide (approximately 3 mol ferrous ion per mol hydroperoxide) in the assay system.

Unless otherwise indicated, the data are presented as the mean ± standard deviation of duplicate/triplicate determinations and are representative of at least two experiments.

RESULTS AND DISCUSSION

Application of FOX to studies of lipid peroxidation and comparison with TBA and conjugated diene measurements. Figure 1 shows results obtained by application of FOX to the measurement of liposome peroxidation, and compares the results with those obtained using the TBA assay and conjugated diene (CD) measurement. In all instances, peroxidation was catalyzed by Cu^{2+} and inhibited by BHT (Fig. 1). Assuming that lipid hydroperoxides derived from phosphatidylcholine have an apparent extinction coefficient of approximately 4.3×10^4 M^{-1} cm^{-1} (the mean value for those obtained for H_2O_2, butyl hydroperoxide and cumene hydroperoxide), and using an extinction coefficient for the MDA-TBA adduct of 1.56×10^5 M^{-1} cm^{-1}, it is clear that the measurement of TBARM greatly underestimates the extent of lipid peroxidation (Fig. 1). The assumption that the apparent extinction coefficient of the lipid hydroperoxide can be derived directly from that found for the standard hydroperoxides is supported by the close agreement of the zero time CD and lipid hydroperoxide measurements (Fig. 1). After initiation of lipid peroxidation, however, hydroperoxide content increases twice as rapidly as CD content. Hydroperoxide formation in the presence of Cu^{2+} thus appears to occur by a chemical pathway which is antagonistic to CD formation (9).

Confirmation of liposome hydroperoxide content. The material reactive with FOX in the liposomes was established as lipid hydroperoxide by pre-treatment with enzymes known to be involved in hydroperoxide metabolism. To a sample of liposome (pre-incubated with Cu^{2+}) were added catalase alone; catalase; glutathione (GSH) and glutathione peroxidase; catalase, GSH, glutathione peroxidase and phospholipase A_2; or phospholipase A_2 alone (Fig. 2). The yields of FOX-reactive and TBA-reactive material were then compared. Catalase produced an approximately 29% decrease in the yield of color in the FOX assay which indicates the formation of some H_2O_2 during lipid peroxidation. This compares with an 88% decrease when catalase was added together with GSH and glutathione peroxidase. Phospholipase A_2 did not further decrease the color in the presence of these enzymes, but increased it slightly (13%) when present alone, probably due to the presence of contaminating lipoxygenase (Fig. 2). GSH in the absence of glutathione peroxidase caused a slight increase in color yield in the FOX assay at its final concentration (10 μM) as compared to the control (not shown). It is surprising that a combination of glutathione peroxidase and GSH caused a decrease in hydroperoxide signal in the absence of phospholipase because esterified lipid hydroperoxides are generally regarded to be poorly metabolized by glutathione peroxidase in the absence of phospholipase (20). However, esterified hydroperoxides are poor substrates for glutathione peroxidase as opposed to being non-substrates (21). There is also the possibility that the liposomes contained a high proportion of highly peroxidizable, non-esterified polyunsaturated fatty acid.

Hydroperoxides are not precursors of TBARM in the TBA assay. The data show that the FOX assay measures predominantly lipid hydroperoxide. In contrast, the level of malondialdehyde (Fig. 2) was not affected by pretreatment with the enzymes, with the exception of a slight increase produced by phospholipase A_2. Essentially the same results were obtained when the TBA was incubated at 100°C with an acidified methanol extract of the liposomes, or when the liposome incubation mixture was

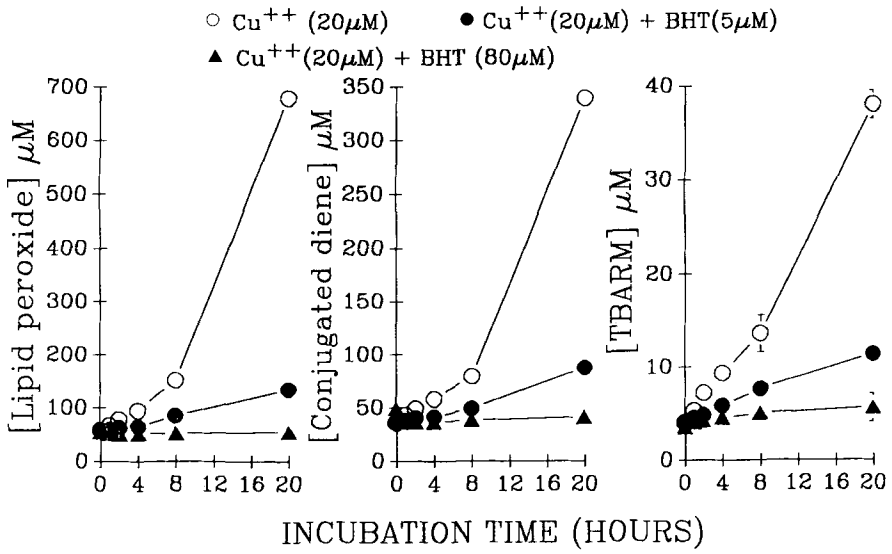

FIG. 1. The accumulation of hydroperoxide and TBA-reactive material in liposomes. Liposomes (10 mg/mL) were incubated with 20 μM Cu^{2+} alone or in the presence of BHT (5 μM or 80 μM) in PBS at 37°C for 20 hr. Samples were taken at zero time (and at various time intervals up to 20 hr) and analyzed for hydroperoxide content. The liposome incubation mixture was diluted 1:4 with methanol and centrifuged at 12,000 × *g* for 2 min at room temperature. TBARM, conjugated dienes and hydroperoxides were measured as described in Materials and Methods.

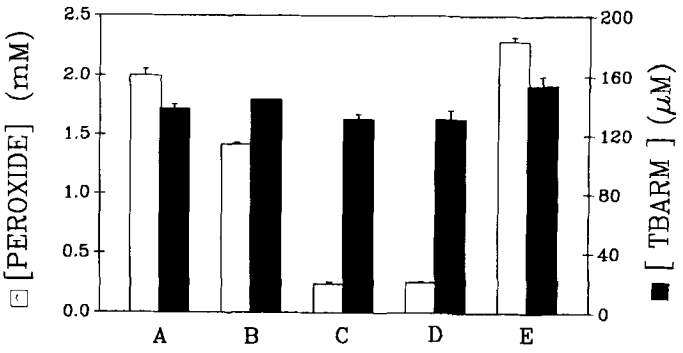

FIG. 2. Enzyme treatment of hydroperoxide and TBA-reactive material in liposomes. Liposomes (preincubated at a concentration of 10 mg/ML for 24 hr with 20 μM potassium phosphate, pH 7.4) were exposed at a concentration of 1 mg/mL in PBS for 20 min at 37°C to (B) catalase (10 units/mL); (C) catalase (10 units/mL, GSH (500 μM) and glutathione peroxidase (5 units/mL); (D) catalase (10 units/mL), glutathione (500 μM), glutathione peroxidase (5 units/mL) and phospholipase A_2 (5 units/mL); or (E) phospholipase A_2 without further additions. (A) represents the control. The phospholipase incubations contained, in addition, 1 mM calcium chloride and 3 mM magnesium chloride. At the end of the incubation period, the samples were diluted 1:4 with methanol and centrifuged at 12,000 × *g* for 2 min. Samples were then analyzed for hydroperoxides and TBARM as described in Materials and Methods.

precipitated with 5% trichloroacetic acid (TCA) prior to boiling of the TCA supernatant with TBA (not shown). Malondialdehyde is thus not formed from hydroperoxide under the conditions of the TBA-assay, as has been postulated (22), but must be present in the sample prior to incubation with TBA.

This suggestion is supported by examination of the rate of decay of hydroperoxide under conditions in which the TBA assay is performed (Fig. 3). When pre-peroxidized liposomes were incubated at 100°C in methanol (adjusted to pH 4) there was a decay in the concentration of material reactive in the FOX assay over a 40-min time period. Consistent with the identity of this material as hydroperoxide, the decay was rapid in the presence of Cu^{2+} but inhibited by BHT and the metal-chelating agent diethylenetriaminepentaacetic acid (DTPA). In contrast, the level of TBARM was unaffected by these treatments (Fig. 3).

Comparison of the FOX assay with an iodometric method. The FOX assay was compared directly with the iodometric method described in Methods and Materials using liposomes incubated in PBS at 37°C for 20 hr in the presence and absence of 10 μM Cu^{2+} (Fig. 4). Assuming that the hydroperoxides present in the incubated liposomes were equally reactive towards iodide and ferrous ions, then the methods are comparable with respect to sensitivity and reproducibility.

We have previously applied this method to the study of lipid peroxidation induced in low density lipoprotein by glucose and have found that measurement of TBARM greatly underestimates hydroperoxide content in this case as well (23). The FOX method also appears suitable for use in more complex biological samples, such as for the

METHOD

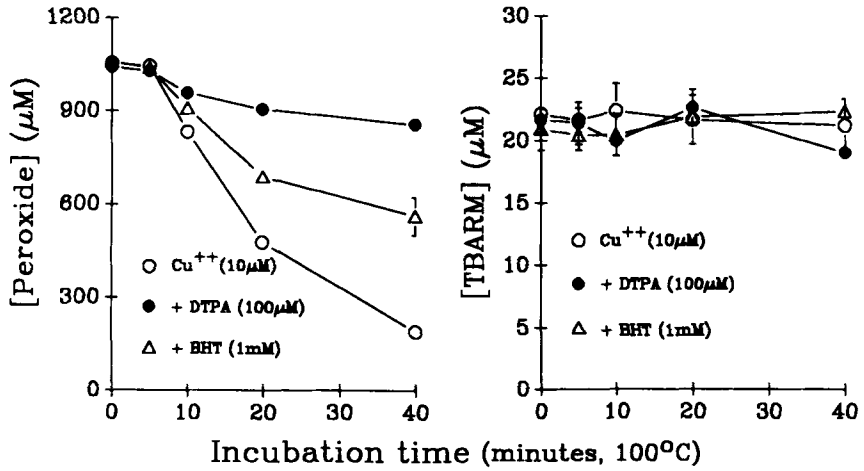

FIG. 3. Hydroperoxides are not precursors of TBARM in the TBA assay. Liposomes (10 mg/mL) were pre-incubated for 22 hr with 10 μM Cu^{2+} in PBS. The liposome incubation mixture was then adjusted to pH 4 and divided into three aliquots. BHT (1 mM) and DTPA (100 μM) were then added separately to two of the aliquots, and the three new liposome incubation mixtures were incubated at 100°C for a total of 40 min. Samples were withdrawn at various time intervals and diluted 1:9 with methanol. Samples were then analyzed for hydroperoxides and TBARM as described in Materials and Methods.

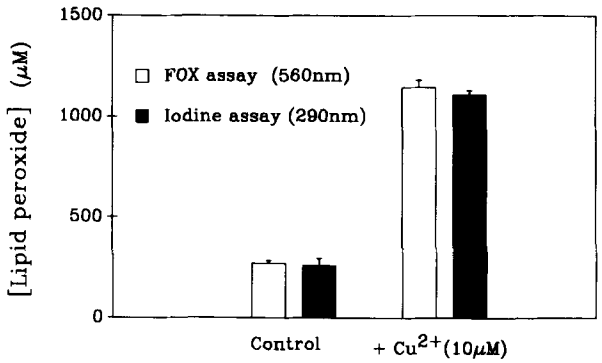

FIG. 4. Comparison of the FOX assay and the iodometric technique. Liposomes (10 mg/mL) were incubated in PBS in the presence or absence of 10 μm Cu^{2+} at 37°C for 20 hr. The samples were then solubilized in methanol and analyzed for material reactive in the FOX assay or the iodometric assay as described in Materials and Methods.

measurement of hydroperoxides in erythrocyte and hepatocyte membranes (Jiang, Z.-Y., Hunt, J.V., Birlouez, I., and Wolff, S.P., unpublished data). However, we find that it is important to perform hydroperoxide recovery experiments in any system of interest and to confirm that the signal is related to hydroperoxide presence using the pre-treatment with enzymes as described above.

COMMUNICATION

Effects of Perfluorodecanoic Acid on *de novo* Fatty Acid and Cholesterol Synthesis in the Rat

John W. Davis, II[a], John P. Vanden Heuvel[b] and Richard E. Peterson[a,*]
[a]School of Pharmacy and [b]Environmental Toxicology Center, University of Wisconsin, Madison, Wisconsin 53706

Perfluorodecanoic acid (PFDA) is a peroxisome proliferator that causes a dose-dependent (20–80 mg/kg) increase in hepatic triacylglycerol and cholesteryl ester levels in the rat. We hypothesized that PFDA may cause an increase in the *de novo* synthesis of fatty acids and cholesterol in this species, which would explain observed effects. The incorporation of ^3H_2O into tissue lipids was examined 7 days after rats received vehicle or 20 or 80 mg/kg of PFDA. PFDA treatment decreased the rate of synthesis of cholesterol and fatty acids in the liver and in epididymal fat pad. At a PFDA dose (20 mg/kg) that decreased *de novo* synthesis of fatty acids and cholesterol, there was no effect on the concentration of fatty acids and cholesterol in the liver, epididymal fat pads, and plasma. We conclude that PFDA induced fatty liver is due to either a decrease in the oxidation of fatty acids in the liver, or an impairment of triacylglycerol catabolism and/or export from the liver, and is not the result of an increase in *de novo* synthesis of fatty acids and cholesterol.
Lipids 26, 857–859 (1991).

Perfluorodecanoic acid (PFDA) is a straight-chain fatty acid analog representative of the perfluorinated carboxylic acids used industrially as lubricants, wetting agents, plasticizers and corrosion inhibitors (1). We have previously shown that PFDA alters energy utilization (2) and lipid metabolism (3) in the rat. Despite a decrease in caloric intake, PFDA treated rats maintain a relatively high amount of carcass and liver triacylglycerols. There is 17-fold increase in hepatic triacylglycerols in rats treated with 80 mg PFDA/kg body weight when compared to their pair-fed counterparts (3). A similar, but less dramatic increase in cholesteryl esters is observed. This increase in neutral lipids may be due either to decreased catabolism or alternatively to increased synthesis of fatty acids.

This report examines the hypothesis that PFDA causes an increase in the synthesis of fatty acids, which would explain the increase in triacylglycerols and cholesteryl esters observed following treatment with PFDA. The incorporation of ^3H_2O into liver and fat pad lipids was examined 7 days after treating male rats with PFDA. We will demonstrate that PFDA does not increase the synthetic rates of free fatty acids or cholesterol, and that inhibition of fatty acid oxidation is a more likely explanation for the observed alterations in lipid metabolism.

Abbreviations: ANOVA, analysis of variation; PFDA, perfluorodecanoic acid; TLC, thin-layer chromatography.

MATERIALS AND METHODS

Chemicals. Perfluorodecanoic acid (PFDA) was purchased from Aldrich Chemical Company (Milwaukee, WI) and was further purified as described previously (4). ^3H_2O (sp. act. 5 mCi/mL), [7(n)-^{3}H]cholesterol (sp. act. 5.5 Ci/mmol), and [9,10(n)-^{3}H]palmitic acid (sp. act. 56 Ci/mmol) were purchased from Amersham (Arlington Heights, IL). All enzymes and cofactors were obtained from Boehringer Corp. (Indianapolis, IN), with the exception of cholesterol oxidase and *o*-dianisidine, which were purchased from Sigma Chemical Co. (St. Louis, MO). Plates for thin-layer chromatography (TLC) and 2′,7′-dichlorofluorescein were purchased from J.T. Baker Inc. (Phillipsburg, NJ). Hionic-Fluor and Soluene-350 were purchased from Packard Instrument Co. (Downers Grove, IL).

Experimental design. Six-week-old male (170–195 g) rats, obtained from Harlan Sprague-Dawley (Indianapolis, IN), were individually housed in suspended stainless-steel cages in a temperature-controlled room with a 12-hr light/dark cycle (lighted 0500–1700 hr). After an acclimation period of one week, rats were administered PFDA (20 or 80 mg/kg) in propylene glycol/water (1/1, v/v; 1 mL/kg, i.p.). All rats were given access to feed (Purina Rat Chow, #5012, Ralston Purina Co., St. Louis, MO) during the meal period (1700–0900 hr). Water was available *ad libitum.*

One week after PFDA treatment, rats were administered ^3H_2O (1 mCi/kg, i.p.). After 60 min, the rats were decapitated and trunk blood was collected in lightly heparinized tubes. The liver and fat pads were removed, weighed, and freeze-clamped. Samples were stored at −70°C until the radioactivity could be quantitated.

Analytical procedures. Total lipids were extracted from the liver, fat pads, and plasma as previously described (5). Simple lipids were separated using a TLC system described by Kelley (6) and visualized under ultraviolet light after plates were sprayed with 2′,7′-dichlorofluorescein (0.1% in methanol). The free fatty acids and cholesterol bands, as determined using authentic standards, were scraped off and counted directly in 10 mL Hionic-Fluor. The synthetic rates of cholesterol and free fatty acids were calculated as described by Andersen and Dietschy (7), and expressed as nmol of ^3H_2O incorporated per g of tissue per hr (nmol/g/hr). The use of ^3H_2O to estimate lipid synthetic rates in the rat has been validated by several investigators (8–10). Incorporation of ^{3}H from ^3H_2O into lipids has been demonstrated to give accurate lipid synthetic rates because the specific activity of body water can be correctly determined as the precursor pool does not change (10). Cholesterol was quantitated in the total lipid extract as described by Salè *et al.* (11). Free fatty acids were measured using a sensitive micro method (12).

Statistical analysis. Differences between treatment groups were analyzed using one-way analysis of variation

(ANOVA) and, if the ANOVA was significant, differences between the means were evaluated by Dunnett's t-test. Significance was set at the $p<0.05$.

RESULTS AND DISCUSSION

The effects of PFDA treatment on body weight change and tissue weights are shown in Table 1. During the 7-day posttreatment period, rats receiving 20 mg/kg of PFDA gained slightly less weight than vehicle control rats. Rats treated with 80 mg/kg of PFDA showed a significant decrease in body weight. Relative liver weight was increased by both doses of PFDA. Although there was a slight increase in absolute liver weight, the weights were not significantly different from controls.

Hepatomegaly and alterations in hepatic lipid metabolism are sensitive indices of PFDA exposure in rats (3,13, 14). PFDA treated rats have increased hepatic triacylglycerol and cholesteryl ester contents, despite a decrease in food intake (3). In addition, PFDA causes alterations in long-chain fatty acid profiles with a relative increase in palmitic and oleic acids (14).

Several explanations for these PFDA induced changes in lipid metabolism are possible, including an increase in the rate of fatty acid synthesis. Increased synthesis of fatty acids has been proposed as the cause of fatty livers in acute ethanol intoxication, phenobarbital treatment, and essential fatty acid deficiency (15). Support for the hypothesis that PFDA treatment increases hepatic fatty acid synthesis is based on the observations that PFDA treatment increases both hepatic triacylglycerol levels (3) and the activity of hepatic malic enzyme [1-malate: $NADP^+$ oxidoreductase (decarboxylating); EC 1.1.1.40] (16). Malic enzyme is a NADPH producing enzyme whose activity has been shown to correlate with lipogenesis (17,18).

Tritium incorporation into free fatty acids and cholesterol of liver and fat pads was much higher than incorporation into triacylglycerol and cholesteryl esters (data not shown). In fact, ^3H incorporation into triacylglycerol and cholesteryl esters within 1 hr was too low to be quantified. Therefore, only the synthetic rates of fatty acids and cholesterol are presented.

The rate of hepatic cholesterol synthesis was not increased by PFDA, as hypothesized, but rather was decreased (Table 2). The rate of hepatic *de novo* synthesis of cholesterol or fatty acids in PFDA treated rats was similarly reduced to about one-third of that of controls. Hepatic cholesterol and fatty acid concentrations were not affected by PFDA treatment (Table 2), except in the high dose PFDA group, where cholesterol was higher.

An increase in fatty acid synthesis in adipocytes and subsequent fatty acid release into the circulation and uptake by the liver may contribute to the hepatomegaly caused by PFDA. For this reason, incorporation of ^3H_2O derived label into fatty acid and cholesterol was examined in epididymal fat pads (Table 3). We found that the rate of cholesterol synthesis in the fat pads was significantly lower in PFDA treated rats, and that the rate of fatty acid synthesis in this tissue followed a similar pattern. However, the levels of cholesterol and free fatty acids in epididymal fat pads were not affected by PFDA treatment.

PFDA had little effect on the concentrations of cholesterol and free fatty acids in plasma (Table 4). Rats receiving 20 mg/kg of PFDA had a lower plasma cholesterol concentration; however, the difference was not significant. The amount of ^3H_2O label incorporated into fatty acids and cholesterol of plasma was not affected by either dose of PFDA (data not shown).

We conclude that the PFDA induced increase in hepatic triacylglycerol and cholesterol concentration in rats treated with PFDA is not caused by an increase in *de novo* synthesis of fatty acids or cholesterol in hepatocytes or adipocytes. Hepatic, epididymal fat pad and plasma concentrations of fatty acids and cholesterol were not altered by 20 mg PFDA/kg, and hepatic cholesterol concentration was increased at 80 mg PFDA/kg. Therefore, *de novo* synthesis of fatty acids and cholesterol is decreased while their tissue concentrations either remain constant or are increased. We conclude that the most likely cause of PFDA induced fatty liver is either a decrease in hepatic fatty acid oxidation and/or a decrease in hepatic VLDL export. PFDA induced fatty liver does not result from increased synthesis of fatty acids, even though the activity of the lipogenic enzyme, malic enzyme, is increased by PFDA (16).

TABLE 1

Effects of PFDA Treatment on Body, Liver and Epididymal Fat Pads Weight[a]

Treatment	Body weight change (g)[b]	Liver weight		Fat pads weight	
		Absolute (g)	Relative[c] (g/kg)	Absolute (g)	Relative[c] (g/kg)
Vehicle	+17 ± 1	8.8 ± 0.5	33.4 ± 1.6	1.8 ± 0.1	7.2 ± 0.2
PFDA (20 mg/kg)	+12 ± 5	10.9 ± 0.2	42.5 ± 1.2[d]	1.8 ± 0.2	6.7 ± 0.8
PFDA (80 mg/kg)	−59 ± 10[d]	10.4 ± 0.8	56.4 ± 2.8[d]	1.5 ± 0.1	8.3 ± 0.3

Transient Activation of 1-*O*-Alkyl-*sn*-glycero-3-phosphocholine: Acetyl-CoA Acetyltransferase During the Incubation of Macrophages

Takayuki Sugiura*, Teruo Fukuda, Neng-neng Cheng and Keizo Waku
Faculty of Pharmaceutical Sciences, Teikyo University, Sagamiko, Kanagawa 199-01, Japan

The activity of the platelet-activating factor (PAF)-synthesizing enzyme, 1-*O*-alkyl-*sn*-glycero-3-phosphocholine (lysoPAF):acetyl-CoA acetyltransferase (EC 2.3.1.67) in alveolar macrophage lysate was found to be elevated after warming the cells to 37°C. Such an increase in enzyme activity was detectable only when intact cells were warmed. The stimulation was transient, reaching a peak at 2 min, and then gradually decreased to the control level. We could not find increased PAF formation in warmed cells which had increased acetyltransferase activity, even though substantial amounts of lysoPAF were shown to be present within cells. In contrast, considerable amounts of PAF were formed after treatment of the cells with exogenous lysoPAF. These results suggest that the activation of acetyltransferase is not sufficient to induce PAF formation and that the increased availability of substrates, especially lysoPAF, in the cells is indispensable for triggering PAF biosynthesis in this type of cells. *Lipids 26*, 861–865 (1991).

Platelet-activating factor (PAF), originally described as a mediator of acute hypersensitivity (1), is a unique bioactive ether phospholipid whose structure was elucidated in 1979 as 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (2–4). PAF is known to elicit a variety of biological responses, such as platelet activation, neutrophil and eosinophil activation, and increased vascular permeability and hypotension, and is regarded as an important lipid mediator in various inflammatory and allergic reactions (5,6). Recent evidence specifically suggests that PAF plays a central role in inflammatory or allergic reactions, especially in asthma (7).

Various types of mammalian cells including alveolar macrophages have been reported to produce PAF (8). Several groups have studied the biosynthetic routes for PAF in mammalian tissues (8). Until now, dual synthetic pathways have been proposed, one involving the hydrolysis of 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholine by phospholipase A_2 to produce lysoPAF followed by the acetylation of this lysophospholipid by acetyltransferase (EC 2.3.1.67), the other involving cholinephosphotransferase (EC 2.7.8.16) using 1-alkyl-2-acetyl-*sn*-glycerol and CDPcholine as substrates. The former pathway is thought to be responsible for the production of PAF in inflammatory cells upon stimulation.

Much attention has been directed to the regulatory mechanism of PAF biosynthesis in white blood cells (9–25). Albert and Snyder (10) suggested that the acetyltransferase activity, which was shown to increase upon stimulation, has a regulatory function in PAF biosynthesis in rat alveolar macrophages. Similar assumptions have been made by various investigators for other cell types (8), although the precise mechanism triggering PAF synthesis is not yet fully understood. Recently, we observed that the addition of lysoPAF (20 μM) *per se* elicits PAF formation in rabbit alveolar macrophages (23) and human polymorphonuclear leukocytes (25) without apparent activation of the acetyltransferase. Thus, the question remains as to the relative importance of the activation of acetyltransferase *versus* increased availability of substrates, such as lysoPAF, in the triggering of PAF biosynthesis.

In the present study we tried to address this question. We found that the enzyme activity of acetyltransferase increased transiently during preincubation of macrophages, although we observed negligible PAF production and negligible increase in lysoPAF levels. The relative importance of substrate availability *versus* activation of acetyltransferase in the induction of PAF synthesis in this type of cells is discussed.

MATERIALS AND METHODS

[1-^{14}C]Acetyl-CoA (50 mCi/mmol) was purchased from ICN Radiochemicals (Irvine, CA). 1-*O*-Hexadecyl-2-[^{3}H]acetyl-*sn*-glycero-3-phosphocholine (GPC) was synthesized from 1-*O*-hexadecyl-GPC and [^{3}H]acetic anhydride (ICN Radiochemicals) in the presence of pyridine. [^{3}H]LysoPAF (1-*O*-[^{3}H]hexadecyl-GPC) was prepared from 1-*O*-[^{3}H]hexadecyl-2-acetyl-GPC (Dupont-New England Nuclear, Boston, MA) by mild alkaline treatment. LysoPAF (1-*O*-hexadecyl-GPC) and acetyl-CoA were from Sigma (St. Louis, MO). PAF (1-*O*-hexadecyl-2-acetyl-GPC) was from Bachem (Bubendorf, Switzerland). A23187 was obtained from Calbiochem (La Jolla, CA) and dissolved in dimethylsulfoxide (DMSO).

Alveolar macrophages were prepared from normal rabbits (Japan white) as described earlier (26). Cells were suspended at 2×10^6 cells/mL in ice-cold 20 mM HEPES-Hanks balanced salt solution (HBSS). In order to examine the effect of warming of cells, the cell suspension (0.5 mL) was warmed for various periods of time in a water bath (37°C) with gentle shaking. The temperature of the cell suspension reached 25°C within 20 sec and 37°C within 45 sec. After warming the cells for the indicated periods (30 sec–5 min), the cells were cooled and sonicated with a Branson Sonifier (setting 3, 20 sec, 50% pulse). In another experiment, the cells were sonicated before warming at 37°C. In order to examine the effect of A23187 on acetyltransferase activity, the cells were first prewarmed to 37°C for 10 min and then challenged with A23187 (final 0.1–2 μM, final DMSO concentration was 0.5%) for 2 min. After the addition of ice-cold HBSS, the

Abbreviations: DMSO, dimethylsulfoxide; GPC, *sn*-glycero-3-phosphocholine; HBSS, Hanks balanced salt solution; lysoPAF, lyso platelet-activating factor, 1-*O*-alkyl-*sn*-glycero-3-phosphocholine; PAF, platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; PMA, phorbol myristate acetate.

cells were centrifuged at 1200 rpm for 6 min, resuspended at 2 × 10^6 cells/mL in HBSS and sonicated. To compare the effects of A23187 and warming, 2 min-warmed cells (without prewarming and without A23187) were also centrifuged, resuspended and sonicated. Acetyltransferase activity was measured at 37°C, using 20 μM lysoPAF, 100 μM [^{14}C]acetyl-CoA (2 × 10^5 dpm) and 0.5 mL cell lysate as described earlier (23). The incubation was carried out for 5 min and the total lipids were extracted by the method of Bligh and Dyer (27). The radioactivity recovered in the chloroform layer was measured and the enzyme activity was calculated as described in (23,25).

In some experiments, the amount of PAF produced by intact cells was determined. After the extraction of total lipids, the PAF fraction was separated by thin-layer chromatography (TLC) using chloroform/methanol/water (65:35:6, v/v/v) as developing solvent and quantified by bioassay with washed rabbit platelets, using hexadecyl PAF as a standard (28). The lysoPAF content was also measured by bioassay following the chemical acetylation (12) of the 1-radyl-GPC fraction which was treated in advance with 0.5 N NaOH and then with 0.5 N HCl.

RESULTS

Figure 1 shows the effect of warming the cells on the activity of acetyltransferase as a function of time. We found that the enzyme activity of acetyltransferase in cell lysate rapidly increased when the intact cells were warmed to 37°C (Fig. 1 (a)). Similar activation was observed when ^{3}H-labeled lysoPAF (20 μM) and acetyl-CoA (100 μM) were used instead of unlabeled lysoPAF and ^{14}C-labeled acetyl-CoA. This increase in enzyme activity was transient, reaching a peak at 2 min, and then acetyltransferase activity gradually declined to control levels. By contrast, only a gradual decline in enzyme activity was observed when cells were sonicated prior to warming (Fig. 1 (b)).

The effects of warming and A23187-treatment of cells on the activity of acetyltransferase are compared in Figure 2. After warming the cells for 2 min followed by the centrifugation and washing, the acetyltransferase activity in cell lysate was still elevated *ca.* 2-fold over controls. Similar activation was observed for A23187- (0.5 μM and 2μM) treated cells, although the increase was less prominent when a low concentration of ionophore (0.1 μM) was used. In any event, the observation that warming the cells and treatment with A23187 resulted in a similar activation of acetyltransferase prompted us to examine PAF production in these cells; it is assumed that the activation of acetyltransferase is a key event in the regulation of PAF biosynthesis in several types of stimulated cells.

Figure 3 shows the amounts of PAF (cell-associated plus released) in warmed (a) and A23187-treated (b) macrophages. Cells immediately after preparation from lung contain a small amount of PAF (a), which may have been formed during cell preparation or when handling animals. However, we did not find any PAF production following the warming of the cells at 37°C. Only a gradual decrease in the PAF level was observed during the incubation. In contrast, cells produced large amounts of PAF if challenged with A23187 (0.5 μM and 2 μM)(b). The production was detectable within 1 min after stimulation and the PAF level increased almost linearly at least up to 4 min. Thus,

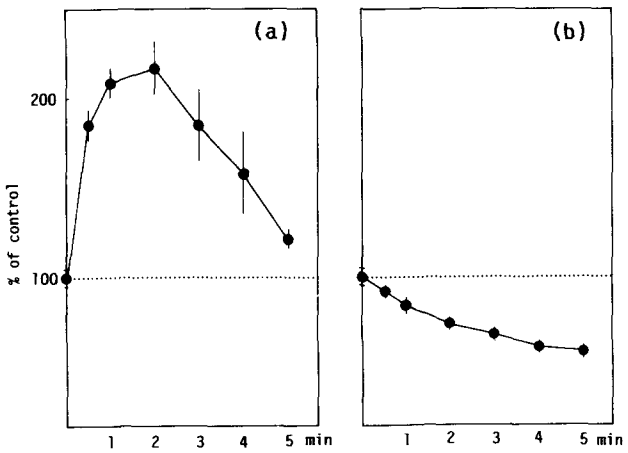

FIG. 1. Effects of warming of intact cells (a) and lysed cells (b) on the activity of acetyltransferase. Cells suspended in ice-cold HBSS were incubated in a water bath (37°C) for the indicated periods of time prior to (a) or after (b) sonication. Cell lysate was then incubated with 100 μM lysoPAF and 20 μM [^{14}C]acetyl-CoA at 37°C for 5 min. Acetyltransferase activity was assessed as described in Materials and Methods. Each value (% of control) is the mean ± SD from three to four determinations. The enzyme activities for controls were (a) 1.13 nmol/5 min/10^6 cell lysate and (b) 1.18 nmol/5 min/10^6 cell lysate.

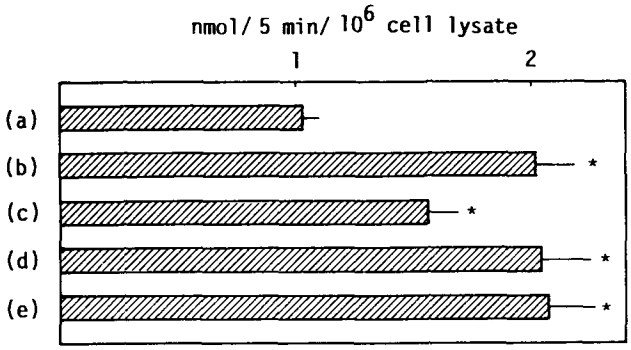

FIG. 2. Comparison of effects of warming and A23187-treatment of cells on cellular acetyltransferase activity. (a) Cells suspended in ice-cold HBSS were washed once with ice-cold HBSS by centrifugation and resuspended in the same solution. (b) Cells suspended in ice-cold HBSS were warmed in a water bath (37°C) for 2 min and then cooled with ice-cold HBSS followed by centrifugation. (c)(d)(e) Cells prewarmed at 37°C for 10 min were further incubated at 37°C in the presence of 0.1 μM (c), 0.5 μM (d) and 2 μM (e) A23187. After 2 min, cells were washed once with ice-cold HBSS. All resuspended cells were sonicated and acetyltransferase activity was measured at 37°C as described in Materials and Methods. Each value is the mean ± SD from five determinations. *P<0.001, compared to (a).

these two cases were quite different in terms of the initiation of PAF synthesis.

We then examined the cellular level of lysoPAF, a substrate for PAF synthesis. As shown in Figure 4, alveolar macrophages contain considerable amounts of lysoPAF. The amounts of lysoPAF did not change markedly during the incubation at 37°C at least for 2 to 10 min. However, the level of lysoPAF increased *ca.* 1.5-fold following stimulation with A23187 for 2 min. The amount of PAF also increased under the same condition as shown in Figure 3. These observations suggest that the increas-

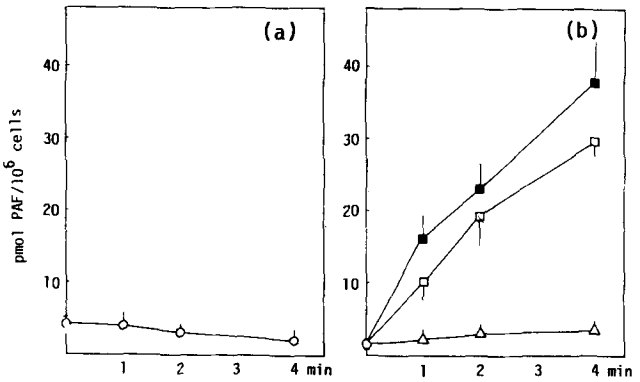

FIG. 3. Amounts of PAF in warmed cells (without preincubation)(a) and in A23187-stimulated cells (b). (a) Cells suspended in ice-cold HBSS were warmed in a water bath (37°C) for the indicated time periods. (b) Cells prewarmed at 37°C for 10 min were further incubated with 0.1 μM (△), 0.5 μM (□) and 2 μM (■) A23187. The incubation was terminated by adding chloroform/methanol (1:2, v/v). PAF levels were determined by bioassay as described in Materials and Methods. Each value is the mean ± SD from four determinations.

TABLE 1

Effects of Acetyl-CoA and LysoPAF on the PAF Level in Alveolar Macrophages[a]

	No addition	+ Acetyl-CoA	+ LysoPAF
	pmol PAF/10^6 cells		
Without preincubation	1.58 ± 0.25 (0)	3.36 ± 0.69[b] (1.78)	41.66 ± 3.97[c] (40.08)
With preincubation	0.51 ± 0.04 (0)	1.44 ± 0.13[c] (0.93)	25.70 ± 3.91[c] (25.19)

[a]Cooled (without preincubation, 4°C) or prewarmed (with incubation, 37°C for 10 min) macrophages (10^6 cells/0.5 mL) were incubated in the presence of acetyl-CoA (100 μM) or lysoPAF (20 μM) at 37°C for 4 min. The incubation was terminated by adding chloroform/methanol (1:2, v/v). The PAF content was estimated as described in Materials and Methods. The values in parentheses represent increments of cellular PAF upon the addition of exogenous substrates. Each value is the mean ± SD from five determinations.

[b]P<0.01, compared to control (no addition).

[c]P<0.001, compared to control (no addition).

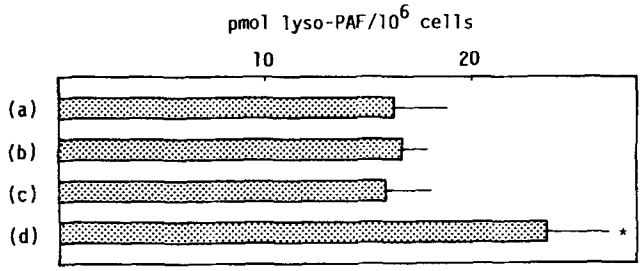

FIG. 4. LysoPAF levels in cells. (a) Cells suspended in ice-cold HBSS. (b) Cells suspended in ice-cold HBSS were warmed in a water bath (37°C) for 2 min. (c)(d) Cells prewarmed at 37°C for 10 min were further incubated in the absence (c) or presence of 2 μM (d) A23187 for 2 min. The incubation was terminated by adding chloroform/methanol (1:2, v/v). The amounts of lysoPAF were estimated by bioassay after conversion of lysoPAF to PAF by chemical acetylation as described in Materials and Methods. *P<0.05, compared to (c). Each value is the mean ± SD from four determinations.

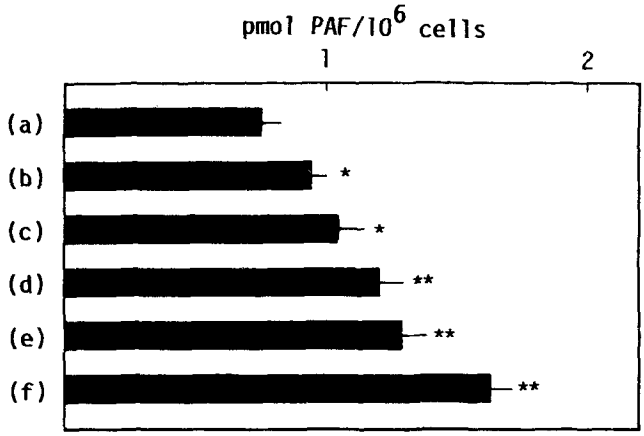

FIG. 5. Formation of PAF in cells treated with various concentrations of lysoPAF. Prewarmed (at 37°C for 10 min) cells were incubated with various concentrations of lysoPAF for 4 min. The incubation was terminated by adding chloroform/methanol (1:2, v/v). The amounts of PAF were estimated by bioassay as described in Materials and Methods. (a) No addition, (b) with 0.2 μM lysoPAF, (c) with 0.5 μM lysoPAF, (d) with 1 μM lysoPAF, (e) with 2 μM lysoPAF and (f) with 5 μM lysoPAF. Each value is the mean ± SD from four to five determinations. *P<0.001.

ed level of lysoPAF within cells is important in the triggering of PAF synthesis.

In order to examine this possibility, we compared the effects of supplementation of substrates on the PAF level in macrophages (Table 1). We found that a small amount of PAF was formed when cells were exposed to a relatively high concentration of acetyl-CoA (100 μM) for 4 min following 10 min preincubation. However, the formation of PAF was more pronounced if cells were incubated with lysoPAF (20 μM) indicating that the increased availability of lysoPAF *per se* is enough to trigger the formation of considerable amounts of PAF. The augmented production of PAF was detectable even after brief treatment of cells with as low as 0.5 μM lysoPAF (Fig. 5). We also found that PAF production induced by the addition of either acetyl-CoA or lysoPAF was remarkably enhanced if the preincubation was omitted (Table 1). Under such a condition the acetyltransferase activity was augmented *ca.* 2-fold as shown in Figure 1, suggesting that the increased acetyltransferase activity is effective in producing larger amounts of PAF.

DISCUSSION

The mechanism of regulation of PAF biosynthesis, including the triggering mechanism, has been studied by many investigators (9–25). It has generally been assumed that acetyltransferase is an important regulatory

enzyme in PAF biosynthesis in various tissues and cells following stimulation (8), although the control mechanism seems to be rather complicated (18) and may somewhat differ from tissue to tissue.

In this study, we found that the activity of acetyltransferase in alveolar macrophages was transiently elevated if the cells were warmed at 37°C. Similar transient activation of acetyltransferase (*ca.* 2-fold) was also observed for human polymorphonuclear leukocytes (Sugiura, T., unpublished data). By contrast, acetylhydrolase activity in cell lysate was not influenced by warming cells (data not shown). The mechanism of the augmentation of acetyltransferase activity after warming is not yet clear. The enzyme activity was increased even when exogenous Ca^{2+} was omitted during the warming of macrophages (data not shown), indicating that the entry of Ca^{2+} into the cell is not the direct cause of the increase of acetyltransferase activity during warming. On the other hand, when cells were sonicated before warming, acetyltransferase was not activated (Fig. 1 (b)). This suggests that the intact organization of cellular components and/or metabolic integrity is required to enhance enzyme activity. Several investigators have already demonstrated that the activation of acetyltransferase in several tissues and cells upon stimulation with appropriate agonists is due to the phosphorylation of enzyme protein (29–32). It would be possible, therefore, that the phosphorylation of the enzyme protein may also account for the transient activation of acetyltransferase in warmed cells. The possible metabolic changes induced by transferring intact cells from 4°C to 37°C may be responsible for the transient modification of enzyme. Further studies are still needed to clarify the exact mechanism of the transient activation of acetyltransferase in warmed cells.

The activation of acetyltransferase is not sufficient to induce PAF formation in this type of cell. We did not find any PAF production in warmed cells in which the activity of acetyltransferase was elevated. Recently, Leyravaud *et al.* (22) also demonstrated that human neutrophils do not produce PAF when challenged with a high concentration of phorbol myristate acetate (PMA), though the activity of acetyltransferase increases under this condition. They suggested that the reduced availability of lysoPAF in a high concentration of PMA-treated cells may be responsible for the diminished production of PAF. Under the condition of the present study, considerable amounts of lysoPAF were present within the cells. A possible explanation for the failure of PAF production in warmed cells shown in this study is that the preexisting lysoPAF is topologically isolated from acetyltransferase or masked with proteins or other macromolecules, preventing acetyltransferase from interacting with lysoPAF. Recently, Burrier and Brecher (33) demonstrated that the fatty acid binding protein obtained from rat liver is also able to bind lysophosphatidylcholine. Furthermore, a protein which binds PAF and catalyzes the transfer of PAF was found in the cytosolic fraction of macrophages (34), although it is not clear whether this protein is capable of binding lysoPAF as well and of interfering with the action of acetyltransferase.

In contrast to warmed cells, the addition of A23187 to cells was shown to increase the cellular level of lysoPAF *ca.* 1.5-fold (Fig. 4). Total amounts of generated lysoPAF may be higher than the actually observed level of lysoPAF, because a portion of generated lysoPAF had rapidly been acetylated to form PAF as shown in Figure 3. Also, large amounts of lysoPAF can be acylated to form long-chain fatty acid-containing choline glycerophospholipids. We have already shown that lysoPAF is rapidly acylated with polyunsaturated fatty acids through a transacylation system in alveolar macrophage microsomes (35). It seems very likely that the increased availability of intracellular lysoPAF, as observed in A23187-stimulated cells but not in warmed cells, is one of the important factors for eliciting PAF synthesis. This was supported by the results of other experiments (Table 1 and Fig. 5) showing that the addition of exogenous lysoPAF to cells induces PAF formation, although the levels of lysoPAF-induced PAF formation in intact cells were considerably lower compared with those observed in A23187-stimulated cells.

From these results we conclude that the activation of acetyltransferase can be favorable for the increase in PAF synthesis in stimulated cells but is not *per se* sufficient to induce PAF formation. Furthermore, it is possible that the increased availability of substrates, especially lysoPAF, is indispensable in the triggering of PAF synthesis, although the involvement of other factors in this process should also be taken into account. More detailed aspects of the regulatory mechanism of PAF biosynthesis including intracellular processing will need to be clarified in the future.

The effects of the n-3 fatty acids, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), on the growth of a human lung mucoepidermoid carcinoma (HLMC) in athymic mice were studied. The mice were divided into three groups which were given either a control chow diet (C), a chow diet supplemented with EPA/DHA (P) (25 or 50 mg of free n-3 fatty acids/g of pellet/day), or chow diet supplemented with palmitic acid (S) (isocaloric with P). Two independent experimental schedules were followed: i) host mice bearing either tumors that were allowed to reach 4000 mm^3, or only 35 mm^3, were fed C, P or S for 21 or 41 days; ii) animals were fed C, P and S for 9 days before tumor implant and were maintained on these diets throughout tumor growth. Food consumption, mouse weight and liver/body weight ratio showed no significant differences between supplemented diets and chow. Tumor growth was markedly inhibited (45%) in both experiments by the EPA/DHA supplemented diet. In Experiment 2, only 60% of mice fed diet P had tumors. The fatty acid composition of neutral and polar lipids of host liver and tumor reflected the dietary intake of n-3 fatty acids; the content of arachidonic acid was reduced by 50%, and EPA/DHA was increased 3- to 5-fold. Tumor prostaglandin E_2 levels were reduced 7.4-fold in the P group. The reduced PGE_2 content may be a factor in tumor growth inhibition.
Lipids 26, 866-870 (1991).

Fish oil consumption is considered to be a promising nutritional approach in the prevention of cardiovascular diseases (1-4), in the control of inflammation (5), and in the treatment of tumors (6-11). Several studies have indicated that a fish oil supplemented diet significantly decreases the growth rate of rat or mouse mammary (6-8) and colon (9) carcinomas and human melanoma (10), prostatic (11) and mammary carcinomas (12), as well as the size and number of rat pancreatic preneoplastic lesions (13). The reason for these effects may be the high content of n-3 polyunsaturated fatty acids found in fish oil (6,14).

It has recently been proposed that enhanced effects can be observed when eicosapentaenoic (EPA, 20:5n-3) or docosahexaenoic (DHA, 22:6n-3) acids are given as free fatty acids, because polyunsaturated n-3 free fatty acids are absorbed more efficiently than the corresponding triglycerides (15).

EPA and DHA can depress prostaglandin E_2 (PGE_2) production by reducing stored phospholipid arachidonate (20:4n-6). EPA also competes with 20:4n-6 for cyclooxygenase (16). The eicosanoids produced *via* cyclooxygenase from 20:4n-6 may modulate biochemical pathways involved in cancer initiation and promotion, cell proliferation, and differentiation (17,18). In particular, high levels of PGE_2 have been associated with aggressive growth rates of human skin carcinomas (19). PGE_2 has also been shown to suppress the cytotoxic activities of various immune cells, such as natural killer cells (20). Because n-3 fatty acids may affect PGE_2 metabolism and therefore tumor growth, we examined whether a diet supplemented with EPA/DHA concentrate reduces the growth rate of a human lung mucoepidermoid carcinoma (HLMC) grown in athymic nude mice. The tumor content of PGE_2 and the fatty acid composition of liver and tumor were also studied.

MATERIALS AND METHODS

Chemicals. All organic solvents and chemicals were reagent grade and were obtained from Mallinkrodt (St. Louis, MO). Lipid standards and gas-liquid chromatographic supplies were purchased from Nu-Chek-Prep (Elysian, MN) and Supelco (Bellefonte, PA). Palmitic acid was obtained from Riedel de Haen A.G. (Hannover, Germany). Silica gel 60G and 60HR for thin-layer chromatography (TLC) was purchased from Merck (Darmstadt, Germany). Prostaglandin E_2 was measured using a [^{125}I] radioimmunoassay (RIA) Kit obtained from NEN Research Products-DuPont (Wilmington, DE).

EPA/DHA concentrate. A free fatty acid concentrate of EPA and DHA was prepared from South Atlantic hake body oil as described elsewhere (21) employing urea inclusion and further purification by silicic acid chromatography. The free fatty acid concentrate was regularly checked for peroxide content by ultraviolet (UV) absorption spectroscopy and kept under N_2 with 0.02% butylated hydroxytoluene at −20°C until use. The fatty acid composition of the concentrate is shown in Table 1.

Source of tumoral tissue. A human lung mucoepidermoid carcinoma (HLMC) was obtained by surgery from a local hospital. Non-cancerous and obviously necrotic tissues were dissected away before transplantation within 1 to 2 hr after resection. The tumor specimen was finely minced in sterile isotonic NaCl solution and inoculated subcutaneously on the back of the nude mice. Host animals were killed by cervical dislocation 9 mon after the primary implant. Tumor (2 g) was minced through a

22:6n-3	1.1	41.4

stainless steel 1 mm^2 mesh and suspended in 3 mL of isotonic NaCl solution. A volume of 250 μL of this suspension was injected into nude mice. Tumor growth could be recognized between 15–20 days following inoculation. The mass doubling time during the log growth phase was 6–7 days. The tumor was serially transplanted every two months and histopathologically controlled as previously described (22).

The present experiments were performed with tumors weighing between 2.54 g (small tumors) and 5.13 g (large tumors).

Animals and diets. One-month-old athymic Balb-C female mice bearing nu/nu genotype were provided by the Comision Nacional de Energia Atomica, seccion Bioterio (Ezeiza, Argentina). Host animals were maintained *ad libitum* on a gamma-irradiated chow diet until the tumor average size was 35 mm^3 or 4000 mm^3, and then were randomly separated into three dietary groups: C, control chow diet containing 70 mg/g of fat; P, chow diet supplemented with 50 mg/g of EPA/DHA concentrate, and S, chow diet supplemented with 50 mg/g of palmitic acid. The fatty acid composition of the chow diet is shown in Table 1.

At least three animals were used per dietary group in all experiments. Animals with tumors that were allowed to reach 4000 mm^3 or with small tumors of 35 mm^3 were fed for 21 days or 41 days, respectively, with the different diets.

Further experiments were performed with other groups of 5 animals per diet fed either the C diet, the chow diet supplemented with 25 mg/g of EPA/DHA concentrate (P') or the chow diet supplemented with 25 mg of palmitic acid (S') for 9 days before tumor implant and then maintained on the same diets until they were killed by cervical dislocation. Fresh diet was made and fed every two days and leftover feed was discarded.

Testing. When tumors became palpable, they were measured twice weekly with calipers and the volume was calculated for an ellipsoid by the formula $V = a^2 \times b/2$, where a is the width and b is the length, in millimeters. The tumor sizes were expressed as relative tumor volume. This was calculated by the formula Vi/Vo, where Vi is the mean tumor volume at any given time and Vo is the mean initial tumor volume at the start of each experiment (23).

Animals were weighed twice weekly. Relative animal weight was calculated by the formula Wi/Wo, where Wi is the mean animal weight of each group at any given time and Wo is the mean initial animal weight when treatment was begun.

Lipid analysis. Total lipids from 500 mg of liver or tumor were extracted according to Folch-Pi *et al.* (24) and fractionated into phospholipids and neutral lipids by silicic acid column chromatography (25). Further separation into classes was accomplished by TLC on silica gel HR (26) and G (27) for phospholipids and neutral lipids, respectively. Fatty acid composition of individual lipid classes was determined by gas-liquid chromatography of methyl esters as previously described (22).

Prostaglandin (PG) analysis. Tumor prostaglandins (PG) were extracted essentially according to the method of Powell (28) using Sep-Pak C18 cartridges in the presence of indomethacin 10 μg/mL. PG were purified by TLC as previously described (29). The PGE zone was detected by comparing the R value with authentic standard and was eluted from the silica gel with methanol (30).

PGE_2 ^{125}I radioimmunoassay (RIA) was performed on the PGE extract according to the procedure described in the DuPont PGE_2 ^{125}I-RIA Kit.

RESULTS

Animals in all groups consumed similar amounts of food (3.6 g/day on average), and although the mean body weight of the mice fed diet P was lower than of those fed diets C or S, the differences were not significant (Table 2). The ratio of liver to body weight was also not significantly affected by diets P and S (Table 2). EPA and DHA excretion in the feces (data not shown) was not significantly altered.

Tumor growth. The data in Figure 1 for small tumors (35 mm^3) show that feeding 175 mg/day of the EPA/DHA mixture to the host animals significantly depressed the growth rate of the human lung mucoepidermoid carcinoma when compared to C or S groups. After 41 days, the relative volume of the P group tumors was 52% lower than that of the C group, whereas the S group tumors increased in relative volume (147%) when compared to group C. There were no significant differences in animals bearing large tumors (4000 mm^3) during the experiment (data not shown).

TABLE 2

Effect of Different Diets on Food Consumption, Body Weight and Liver Weight[a]

Diet	Food consumption (g/day)	Body weight (g)	Liver weight/body weight × 100
C	3.70 ± 0.23	21.50 ± 0.75	5.60 ± 0.29
P	3.40 ± 0.23	17.51 ± 1.09	7.32 ± 1.27
S	3.60 ± 0.29	20.53 ± 0.69	6.20 ± 0.63

[a]Each value represents the mean ± SE from 3 animals. Differences are not significant. Diets: chow (C), chow + EPA/DHA (50 mg/g diet) (P), chow + palmitic acid (50 mg/g diet) (S).

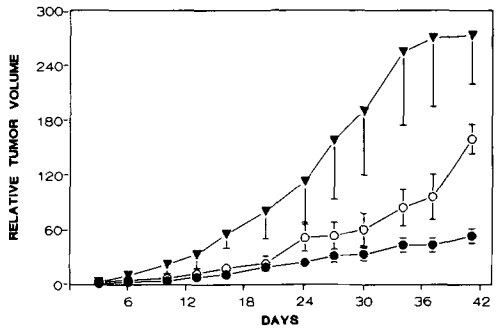

FIG. 1. Growth rate of human lung mucoepidermoid carcinoma xenografts in nude mice. Mice were fed the control and supplemented diets when the tumor size was 35 mm^3. Diets: ○, Control chow (C); ▼, Control chow + palmitic acid (50 mg/g diet) (S); ●, Control chow + EPA/DHA (50 mg/g diet) (P). Values are the mean of 3 animals ± SE. After day 36 and day 16, tumors in P group were significantly smaller than in C and S groups, respectively (P<0.05) (Student t-test).

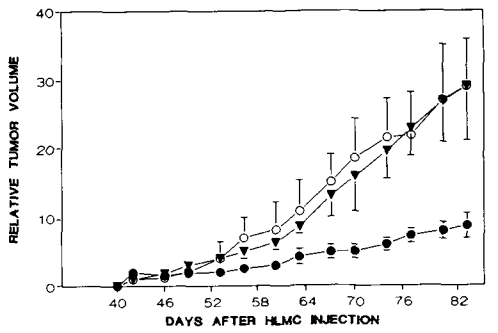

FIG. 2. Growth rate of human lung mucoepidermoid carcinoma xenografts in nude mice previously fed supplemented diets. Mice were fed for 9 days: ○, Control diet (C); ▼, Control chow diet + palmitic acid (25 mg/g diet) (S'); ●, Control chow diet + EPA/DHA (25 mg/g diet) (P') before tumor injection. Tumor size was measured 40 days thereafter. Values are the mean of 5 animals ± SE. After day 46 and day 67, tumors in P group were significantly smaller than in S and C groups, respectively (P<0.05) (Student t-test).

When animals were fed the diets before tumor implantation, the tumor was detected in all mice of groups C and S' but only in 60% of those in the P' group (3 out of 5) receiving 87.5 mg/day of EPA/DHA mixture. As can be seen in Figure 2, the relative volume of tumors in the P' group was 80% lower than in group C or S' after 42 days of tumor development and no differences were seen between groups S' and C.

Liver and tumor fatty acid analysis. Table 3 shows that feeding the EPA/DHA supplemented diet markedly increased the content of both EPA and DHA in host liver lipids. This increase appeared to be at the expense of 20:4n-6 and eicosatrienoic acid (20:3n-6) as well as hexadecenoic acid (16:1) and ocatadecenoic acid (18:1). A similar trend is seen for linoleic acid (18:2n-6) though these data were significant at P<0.10. The content of 20:3n-9 was decreased below detectable levels. Fatty acid composition of total tumor lipids also reflected the dietary intake of EPA/DHA. Significant increases in the content of EPA/DHA were found in phosphatidylcholine, phosphatidylethanolamine and triglycerides (Fig. 3) when compared to controls. Phosphatidylinositol was also analyzed, but showed no significant differences compared to groups C or S.

TABLE 3

Fatty Acid Composition of Total Liver Lipids (μg/g wet tissue)[a]

[a]Each value represents the mean ± SE from 3 animals. Comparison was made between P and C diet and between P and S diet (Student t-test). TA, trace amounts.

[b]P<0.05 P *vs* C.

[c]P<0.05 P *vs* C and P *vs* S.

Prostaglandin analysis. Measurements of urinary or plasma levels are likely to have little relevance because PG act locally. As already proposed by Turini *et al.* (31), these measurements are not representative of a specific site of synthesis and thus may explain why frequently no correlations have been observed. Therefore, we have focused our studies on the tumor content of PGE_2. Table 4 illustrates that in tumors of the P group the PGE_2 content was 14% of that measured in groups C or S.

DISCUSSION

In this study we have examined the effects of an EPA/DHA concentrate obtained from hake body oil on the development of a human lung mucoepidermoid carcinoma grown in nude mice. As already reported for mammary, pancreatic and colon tumors (6–13), we have shown that n-3 fatty acids provided as free fatty acids can inhibit the growth of a human lung carcinoma. This was true not only in animals with small tumors fed the EPA/DHA supplemented diet but also, more noticeably, when animals were fed the EPA/DHA diet prior to tumor implantation. High fat diets are rich in calories, and it is interesting to consider whether the effects on tumor development are related to the quality of the fats or to an increased supply of calories (32,33). In the experiments described here, diets P (chow supplemented with 50 mg/g of EPA/DHA) and S (chow supplemented with 50 mg/g of palmitic acid) exhibited opposite effects although they are isocaloric. Our results indicate that fatty acid supplemented diets can depress or enhance the development of this human carcinoma depending on both the dose and type of fatty acid supplied.

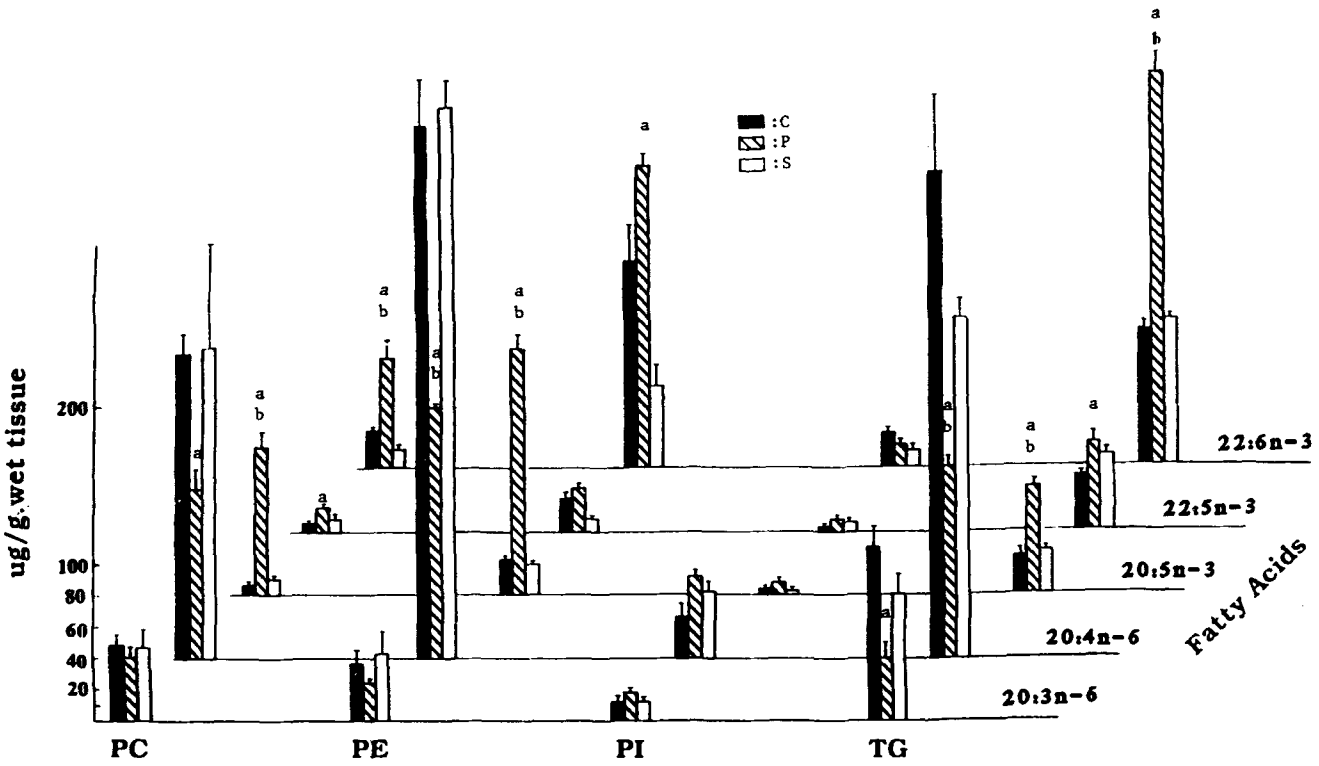

FIG. 3. Polyunsaturated fatty acid content of tumor phospholipids and triglycerides from mice fed control and supplemented diets. Diets: C, Control chow; P, Control chow + EPA/DHA (50 mg/g diet); S, Control chow + palmitic acid (50 mg/g diet). PE, phosphatidylethanolamine; PC, phosphatidylcholine; PI, phosphatidylinositol; TG, triglycerides. Values are the mean of at least 3 animals ± SE. a: P<0.05 P *vs* C; b: P<0.05 P *vs* S.

TABLE 4

Prostaglandin E_2 Tumor Content in Mice on Chow and Supplemented Diets[a]

Diet	PGE_2 ng/g wet tissue
C	30.72 ± 4.73
P	4.20 ± 0.56
S	36.00 ± 9.80

[a]The values are the mean of 3 tumors ± SE. P<0.01 P *vs* C and P *vs* S (Student t-test). Diets: chow (C), chow + EPA/DHA (50 mg/g diet) (P), chow + palmitic acid (50 mg/g diet) (S).

We have also demonstrated that an n-3 fatty acid supplemented diet changes the pattern of 20:4n-6, 20:5n-3 and 22:6n-3 in liver and tumor lipids. The reduced content of 20:4n-6, together with the disappearance of 20:3n-9 may also be caused by the inhibition of Δ6 and/or Δ5 desaturase activity as reported *in vitro* (34) and *in vivo* for rat liver following fish oil feeding (35,36). However, Borgeson *et al.* (12) found an increase in Δ6 and Δ5 desaturase in a human mammary tumor and liver of nude mice fed fish oil. This difference may lie in the genotype of the mice, the tumor origin, as well as the precursors used for the enzyme measurements. The reduced 16:1 and 18:1 content of the liver lipids (shown in Table 3) may be a consequence of reduced Δ9 desaturase activity as previously demonstrated (12,37).

The change in fatty acid profile certainly modifies the substrate for prostaglandin synthesis. The decreased 20:4n-6 content of tumor phosphatidylcholine and phosphatidylethanolamine probably resulted in a decrease of 2-series PG synthesis.

We have previously described the capacity of HLMC homogenates to synthesize PGE_1 and PGE_2 when ^{14}C-labeled fatty acid precursors were added to the incubation medium (21). Now, we find a marked decrease in PGE_2 content of tumors from animals fed an EPA/DHA supplemented diet which may be beneficial to the host. This diminished ability of the tumor to synthesize PG *in vivo* may be the result of the competition between n-3 fatty acids and n-6 fatty acids for cyclooxygenase (17,38). Furthermore, EPA and DHA could probably act synergistically in the inhibition of this enzyme (21). PGE_2 has been shown to elicit unfavorable effects in tumor-bearing animals through the suppression of lymphocyte proliferation and the inhibition of both macrophage and natural killer cell cytotoxicity toward tumor cells (30,39). In the present studies, we have used athymic nude mice which lack T cells but have natural killer (NK) cells (23). The latter cells may be a key factor in the immunosuppressive status of the tumor-bearing host fed n-3 fatty acids. It should be pointed out that Bennett *et al.* (40) have shown that fish oil enriched diets did not modify NK functions in mice even when given carcinogens. However, in our model, the presence of a PG secreting tumor may alter the sensitivity of the host NK

cells. Further data is needed to conclusively state that the slower HLMC development in nude mice fed EPA/DHA results from a decrease in PGE_2 levels. It is also possible that endogenous lipid peroxidation in the presence of increased n-3 polyunsaturated fatty acids could be responsible for the slower tumor growth observed (12).

In summary, the present study demonstrates that supplementing the host diet with EPA/DHA as free fatty acids leads to significant growth inhibition of this human lung carcinoma. The use of free n-3 fatty acids instead of fish oil causes significant effects, suggesting that free fatty acid administration may be helpful in future human experiments by reducing the volume of active components to be ingested.

ACKNOWLEDGMENTS

This study was supported by grants from Consejo Nacional de Investigaciones Cientificas y Tecnicas (CONICET), and Comision de Investigaciones Cientificas de la Provincia de Buenos Aires (CIC), Argentina. The authors are indebted to Dr. R.C. Cantrill for corrections and suggestions in the preparation of the manuscript, and Dr. D.F. Horrobin for his interest and encouragement with these studies. Specific Accumulation of Docosahexaenoic Acid (22:6n-3) in Brain Lipids During Development of Juvenile Turbot *Scophthalmus maximus* L.

Gabriel Mourente[1], **Douglas R. Tocher*** and **John R. Sargent**
NERC Unit of Aquatic Biochemistry, Department of Molecular and Biological Sciences, School of Natural Sciences, University of Stirling, Stirling FK9 4LA, Scotland

The changes in the lipid class and the fatty acid compositions of total lipids and individual glycerophospholipids which occur in brain during development of juvenile turbot (*Scophthalmus maximus* L.) were investigated. Fish were sampled during a 10-week period immediately following weaning from a live feed to a pellet diet. During this period, brain dry weight increased over 6-fold. The percentages of protein, cholesterol and galactolipids increased in brain during development, presumably reflecting increased membrane maturation and myelination processes. The percentages of docosahexaenoic acid (DHA; 22:6n-3) were low at the beginning of the study period. However, DHA specifically accumulated in juvenile turbot brain during development. The percentages of DHA increased in total lipid, total diradyl glycerophosphocholine (GPC), total diradyl glycerophosphoethanolamine (GPE), phosphatidylserine (PS) and phosphatidylinositol (PI) reaching 26.1%, 25.8%, 40.8%, 47.1% and 17.9% of the total fatty acids, respectively, by the end of the 10-week period. The percentages of other n-3 polyunsaturated fatty acids (PUFA) and n-6 PUFA generally decreased during this period, as did that of monoenes; the percentages of saturated fatty acids remained relatively constant. Non-linear regression analysis showed that the increase in DHA in total lipid, GPC, GPE and PS fitted 1st order rate kinetics (plus offset) allowing maximum values for the percentages of DHA in each lipid class to be estimated.
Lipids 26, 871–877 (1991).

Recent research has established a critical role for n-3 polyunsaturated fatty acids (PUFA) and docosahexaenoic acid (DHA) in neural and retinal tissue functions in mammals (1,2). During dietary n-3 PUFA deprivation studies, DHA is tenaciously retained by mammalian neural tissues (3) and at least two generations of deprivation are required to significantly reduce DHA levels in brain or retina (4–7). Depletion of neural DHA levels is accompanied by alterations in physiological parameters and functional defects such as reduced visual acuity and impaired learning abilities (4–7). As evidence of the important role of DHA in development of neural tissues grows, so does support for the nutritional requirement for n-3 PUFA in mammals (8,9).

Tissue lipids in most fish generally contain high levels of n-3 PUFA, especially eicosapentaenoic acid (EPA; 20:5n-3) and DHA (10,11). A recent study has suggested that fish accumulate more DHA in neural tissues (12) than in non-neural tissues (13). Although fish neural tissue lipids can have extremely high levels of n-3 PUFA and DHA (12,14,15), the accretion of DHA by fish brain has not been demonstrated. In fish, considerable growth and development of neural tissues occurs after hatching and during independent feeding of the offspring. Therefore, the vast majority of n-3 PUFA and DHA required for normal development of the brain must be obtained in the diet. The individual contributions of dietary 18:3n-3, EPA and DHA to the final DHA content of adult fish brain are not known. Some marine fish, such as the turbot (*Scophthalmus maximus* L.), have incomplete desaturase pathways and therefore require preformed EPA and DHA in their diet for growth and development (16). Therefore, dietary 18:3n-3 cannot contribute to the DHA content in turbot brain. The developmental stage and diet of turbot can be precisely known because turbot are cultured commercially. Thus, the turbot is a particularly useful species in which to study the role of DHA during development.

Our aims were to determine (i) whether DHA was specifically accumulated in the brain during development of fish and, if so, (ii) what, if any, preferences occurred for individual glycerophospholipid classes and (iii) what, if any, fatty acids were discriminated against in the accumulation processes. The lipid class and fatty acid compositions of total lipid and individual glycerophospholipid classes were determined in juvenile turbot over a 10-week period immediately after weaning from a live feed to a dry pellet diet. The results are discussed in relation to current understanding of the role of lipids in neural development obtained from studies in other vertebrates and in relation to existing data on fatty acid metabolism in fish.

MATERIALS AND METHODS

Materials. Turbot (*Scophthalmus maximus* L.) were obtained from Golden Sea Produce Ltd. (Hunterston, Scotland, United Kingdom). Larvae were fed live foods through metamorphosis until they were large enough to accept dry food. The batch of fish used in this study was weaned from enriched *Artemia* to a dry pellet diet on day 37 post-hatch. Enriched *Artemia* had been supplemented with n-3 PUFA, according to a commercial protocol, to increase the n-3 highly unsaturated fatty acid (HUFA, $\geq C_{20}$ and with at least 3 double bonds) content. The lipid contents and fatty acid compositions of the *Artemia* and the pellet diet are given in Table 1. Triplicate samples of weaned fish

Total n-3 PUFA	18.2 ± 1.6	31.2 ± 2.8
Total n-6 HUFA	1.1 ± 0.1	2.0 ± 0.2
Total n-3 HUFA	6.2 ± 0.4	24.8 ± 2.4

[a]*Artemia* were enriched with n-3 PUFA for 60 hr prior to being fed to fish. Data are means ± SD of three samples. Totals include some minor components (<0.1%) not shown. PUFA, polyunsaturated fatty acids; HUFA, highly unsaturated fatty acids ($\geq C_{20}$ and with at least 3 double bonds); tr, trace.

(varying from 20 fish/sample for 38-day fish to 10 fish/sample for 105-day fish) were collected at 38, 56, 70, 90 and 105 days post-hatch. Fish were killed by decapitation, and the brains were dissected out on ice, frozen in liquid nitrogen and stored at −80°C until analysis. Butylated hydroxytoluene (BHT), fatty acid-free bovine serum albumin (BSA) and nonadecanoic acid (19:0) were purchased from Sigma Chemical Co. (Poole, Dorset, United Kingdom). Thin-layer chromatographic (20 × 20 cm × 0.25 mm) and high-performance thin-layer chromatographic (10 × 10 cm × 0.15 mm) plates precoated with silica gel 60 (without fluorescent indicator) were obtained from Merck (Darmstadt, Germany). Analar-grade glacial acetic acid, sulfuric acid and isopropanol were purchased from BDH Ltd. (Poole, Dorset, United Kingdom). All other solvents of high-performance liquid chromatography (HPLC) grade were from Rathburn Chemicals (Walkerburn, Scotland, United Kingdom).

Dry weight determination. Pre-weighed samples of 5 brains each were heated at 110°C for 24 hr. Dry weight was determined after cooling the sample *in vacuo* for at least 1 hr.

Protein determination. Protein concentration was measured in fresh brain by the Folin-phenol reagent method, according to Lowry *et al.* (17).

Total lipid extraction. Brain samples (50–500 mg wet wt) were homogenized in a Teflon pestle glass homogenizer in 10 mL of chloroform/methanol (2:1, v/v) containing 0.05% BHT. Total lipids were extracted according to the method of Folch *et al.* (18) as detailed previously (12).

Lipid class and fatty acid analysis. Lipid classes were separated by high-performance thin-layer chromatography (HPTLC) using a single-dimension double-development method described previously (12,19) and were quantified by calibrated densitometry after charring using a Shimadzu CS-9000 dual-wavelength flying spot scanner and DR-13 data handling system (Kyoto, Japan) (19). For fatty acid analyses, glycerophospholipid classes were separated according to the method of Vitiello and Zanetta (20). Fatty acid methyl esters were prepared by acid-catalyzed transmethylation overnight at 50°C using nonadecanoic acid (19:0) as internal standard (21). Methyl esters were extracted and purified by thin-layer chromatography (TLC) as described previously (12) and analyzed in a Packard 436 gas chromatograph equipped with a chemically bonded CP Wax 52 CB fused silica capillary column (50 m × 0.34 mm i.d.; Chrompack UK Ltd., Millharbour, London, United Kingdom). Chromatography was performed with on-column injection, hydrogen as carrier gas and a two-stage thermal gradient from 50°C to 235°C. Individual methyl esters were identified as described previously (12) and quantified using a Shimadzu CR-3A recording integrator. The percentage by weight of total unidentified peaks was 7.7 ± 2.9 (n = 30 analyses).

Statistical analysis. All results are expressed as means ± SD (n = 3), and the differences between means were analyzed by a paired t-test (small group of samples), indicating with an asterisk (*) when $P < 0.05$. The correlations between developmental age and the levels of various fatty acids were studied by linear regression analysis. The evolution of the levels of DHA in various classes was analyzed by non-linear regression and fitted 1st order rate equations, plus offset of the type (Equation 1):

$$WP = \text{limit} \times (1-e^{-kt}) + \text{offset} \quad [1]$$

Where WP = weight percentage; limit = the theoretical maximum value for WP calculated from the intercept with the y-axis; k = rate ($days^{-1}$); t = time (days); offset is the value of the ordinate from the y intercept to y = zero. The offset is necessary as the data which start on day 38 do not pass through zero. This equation simplifies to (Equation 2):

$$WP = a - be^{-kt} \quad [2]$$

where; a = limit value + offset value, and represents the actual maximum percentage; b = limit value.

RESULTS

Total lipid contents and fatty acid compositions of enriched *Artemia* and the pellet diet used to wean turbot larvae are shown in Table 1. The dry weight percentage is ~12 times higher in the pellet diet but the total lipid contents, as percentages of the dry weight, were identical in the diets. *Artemia* total lipid contains relatively large proportions of cholesterol and pigments. Therefore, the *Artemia* diet supply only 62.0 μg total fatty acid/mg diet dry weight compared to 103.4 μg total fatty acid/mg diet dry weight for the pellet diet (Table 1). Only 18:3n-3 and 18:1n-7 were more abundant in the *Artemia* diet. The absolute amount of DHA was almost 13-fold greater in the pellet diet.

The dry weights of the turbot brains increased by a factor of 6.4 from day 38 to day 105 (Table 2). Between 38 and 70 days the protein content as a percentage of the dry weight increased with a concomitant decrease in the percentage of total lipids. However, from 70 days the percentages of protein and lipids in the brain remained generally constant. The total polar lipid content of turbot brain was approximately 1.5 times that of total neutral lipids although there was a trend toward decreasing percentages of polar lipids as development proceeded (Table 2). The predominant polar lipid classes were total diradyl (includes diacyl, alkylacyl and alkenylacyl) glycerophosphocholine (GPC) and total diradyl (includes diacyl, alkylacyl and alkenylacyl) glycerophosphoethanolamine (GPE) (each approximately 20% of total lipids), followed by phosphatidylserine (PS) (~7–10%), phosphatidic acid/cardiolipin (PA/CL) (2–3%) and phosphatidylinositol (PI) (~2.5%). The percentages of sulfatides and cerebrosides were more variable. Cholesterol was the predominant neutral lipid and tended to increase and was primarily responsible for the increasing percentage of total neutral lipids (Table 2). The concomitant decrease in the percentage of polar lipids was due to decreases in GPC, PS and PA/CL.

The fatty acid compositions of total lipids and individual glycerophospholipids in brains of turbot on days 38 and 105 post-hatch are shown in Table 3. In total lipids, saturated fatty acids did not show significant differences between day 38 and day 105, whereas total monoenes decreased significantly. Fatty acids such as 18:3n-3, 18:4n-3, 20:4n-6, 20:3n-3 and EPA decreased significantly whereas DHA increased over 3-fold. Total dimethylacetals (DMA) in total lipid showed a slight, but significant increase.

The percentage of total saturated fatty acids in GPC was higher than that in total lipids, but was not significantly different between day 38 and day 105, whereas the percentage of total monoenes decreased (Table 3). GPC had the lowest percentage of total PUFA of all the glycerophospholipids at both days 38 and 105, but the percentage on day 38 was almost doubled by day 105. The percentages of 18:2n-6, 18:3n-3 and 20:3n-3 decreased in GPC, whereas 20:4n-6, 20:4n-3 and 22:5n-3 increased. However, the largest effect observed in GPC was a 10-fold increase in DHA.

In GPE, the percentage of total saturated fatty acids significantly increased and total monoenes significantly decreased (Table 3). Total PUFA accounted for ~50% of total fatty acids, but there was no significant difference between days 38 and 105. However, the percentages of most PUFA significantly decreased, whereas that of DHA increased from day 38 to day 105.

In PS, the percentage of total monoenes decreased and the percentage of total PUFA increased significantly by day 105. The percentages of PUFA in PS significantly

TABLE 2

Gross Composition and Lipid Class Composition of Brains of Turbot *Scophthalmus maximus* L.[a]

Composition	Time post-hatch days				
	38	56	70	90	105

[a]Data are expressed as wt percentage of total fatty acids and represent the mean ± SD (n=3). SD = 0.0 implies an SD of <0.05. Totals include some other minor components not shown. *, significantly different ($P < 0.05$); nd, not detected; tr, trace < 0.1%; GPC, total diradyl glycerophosphocholine; GPE, total diradyl glycerophosphoethanolamine; SFA, saturated fatty acid; MUFA, monounsaturated fatty acid; PUFA, polyunsaturated fatty acid; DMA, dimethyl acetal.

decreased, except that of DHA which more than doubled by day 105.

The percentage of total saturated fatty acids increased significantly in PI, whereas that of total monoenes decreased significantly from day 38 to day 105. The percentage of DHA in PI more than doubled over this period. PI was characterized by the highest percentage of 20:4n-6 of all the glycerophospholipids and also the highest percentage of EPA other than GPE on day 38.

Brain dry weight was not correlated directly with changes in proportions of 20:4n-6 in total lipid during development ($r = -0.50$; $p = 0.08$) but, in contrast, brain dry weights and the percentages of DHA in total lipid presented a significant, direct correlation ($r = 0.79$; $p < 0.01$) during the study period.

The time courses for the most significant fatty acid changes observed during the period from 38 to 105 days post-hatch are shown in Figures 1-3. In total lipid the largest increase in the percentage of DHA occurred between days 38 and 56 (Fig. 1). In contrast, the percentages of EPA and total monoenes decreased between days 38 and 56 (Fig. 1). The 1st order rate equation (Equation 3) that fitted the evolution of DHA in total lipid was:

$$WP = 27.7 - 69.1e^{-0.032\,t} \quad (k = 0.032 \pm 0.001) \quad [3]$$

where the initial rate at day 38 was very high and the net forward rate decreased, approaching zero at the equilibrium position, and 27.7 is the estimated maximum value for the percentage of DHA in total lipid at the end of development.

In GPC, the percentages of DHA and total monoenes were inversely correlated ($r = -1.1$; $p < 0.01$) during the observed period of development (Fig. 2). The 1st order rate equation (Equation 4) fitting the changes in the percentages of DHA in brain GPC was:

$$WP = 24.9 - 131.5e^{-0.046\,t} \quad (k = 0.046 \pm 0.016) \quad [4]$$

showing a very high initial rate and defining a maximum percentage of DHA in GPC of approximately 25%.

The percentages of EPA and DHA in GPE were inversely correlated ($r = -0.73$; $p = 0.017$) with the initial value of EPA higher than that of DHA (Fig. 2). The

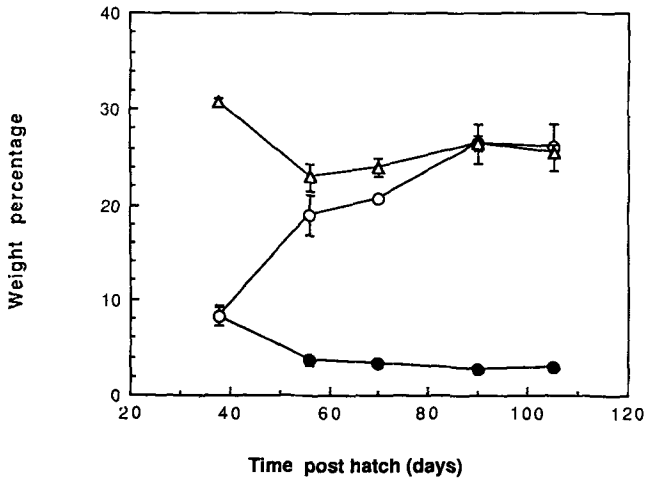

FIG. 1. Variation in the proportions of fatty acids of brain total lipids from turbot during development. (●) 20:5n-3; (○) 22:6n-3; (△) total monounsaturated fatty acids.

proportion of EPA decreased throughout the remaining period. In contrast, the proportion of DHA was increased reaching 40% of GPE fatty acids by day 105. The 1st order rate equation (Equation 5) defining the evolution of DHA in GPE during development was:

$$WP = 40.2 - 193.2e^{-0.054\,t} \quad (k = 0.054 \pm 0.017) \quad [5]$$

showing an estimated maximum percentage of DHA in brain GPE of 40.2% with a higher initial rate than GPC.

PS showed the highest levels of DHA, which increased throughout development, whereas other n-3 PUFA decreased between days 38 and 70 (Fig. 3). The equation (Equation 6) representing the evolution of DHA levels in PS was:

$$WP = 51.0 - 74.4e^{-0.026\,t} \quad (k = 0.026 \pm 0.013) \quad [6]$$

giving an estimated maximum percentage of DHA retained in PS of 51%.

The percentages of 20:4n-6 and EPA in PI remained relatively constant during the study period (Fig. 3). The

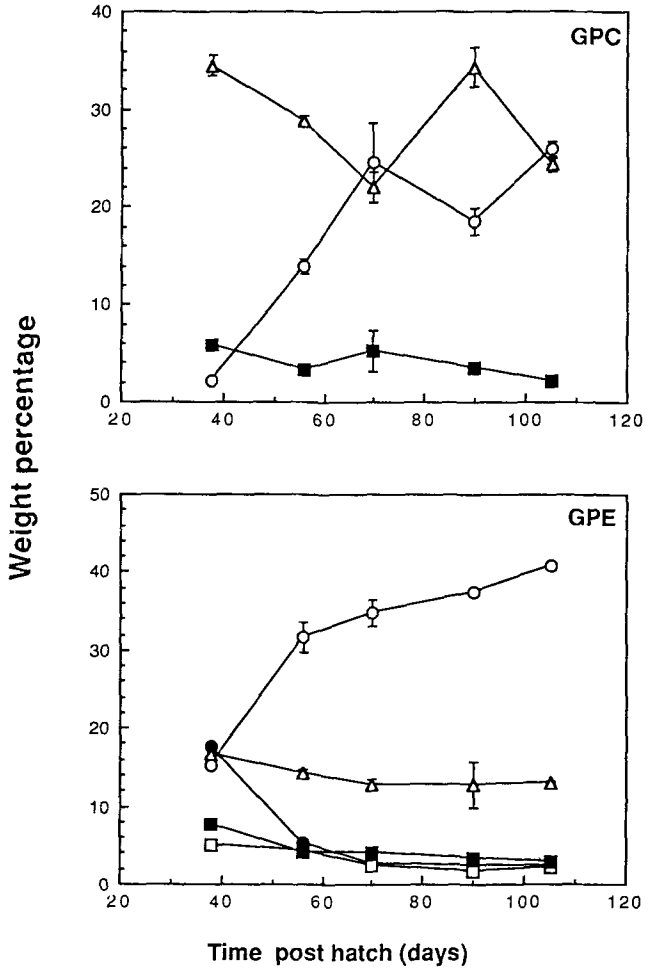

FIG. 2. Variation in the proportions of fatty acids in total diradyl glycerophosphocholine (GPC) and total diradyl glycerophosphoethanolamine (GPE) from turbot brain during development. (●) 20:5n-3; (□) 22:5n-3; (○) 22:6n-3; (△) total monounsaturated fatty acids; (■) total n-6 fatty acids.

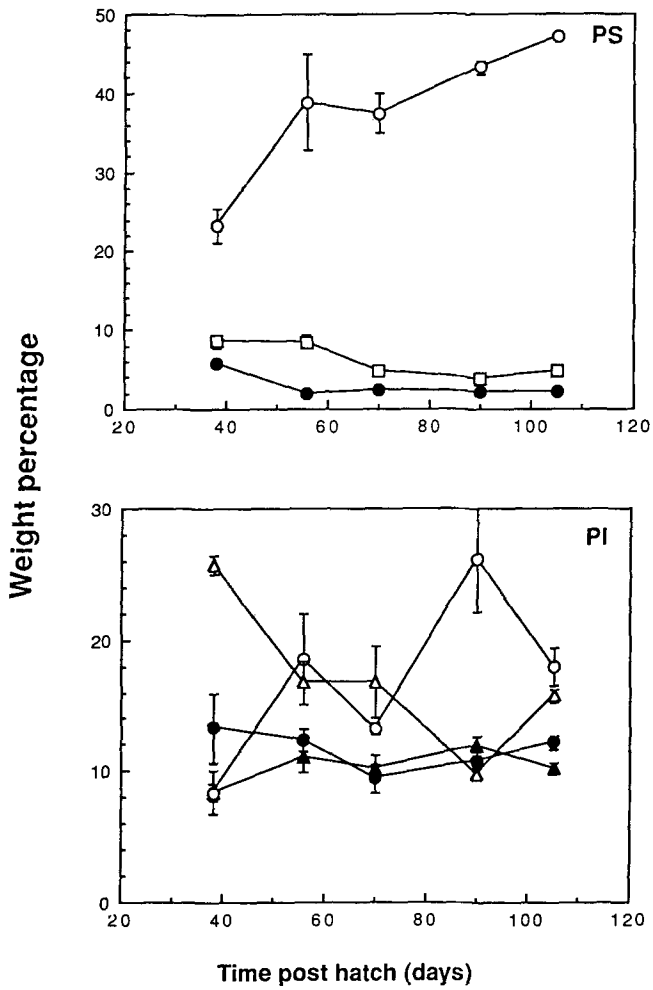

FIG. 3. Variation in the proportions of fatty acids in phosphatidylserine (PS) and phosphatidylinositol (PI) from turbot brain during development. (●) 20:5n-3; (□) 22:5n-3; (○) 22:6n-3; (▲) 20:4n-6; (△) total monounsaturated fatty acids.

percentage of DHA in PI fluctuated, but was inversely correlated to that of total monoenes ($r = -0.7$; $p < 0.01$).

DISCUSSION

Anatomical and biochemical development of brain are sequential processes characterized by specific stages of growth and maturation. The period of brain development under study in the present work may correspond to Period IIa as described by Ansell (22) in mammalian species. This period or "growth spurt" includes the processes of axonal and dendritic growth, glial multiplication, myelination and the development of enzyme systems (22,23). Therefore, the increases in the proportions of total protein, total cholesterol and galactolipids observed in the present study may be due to these processes of growth, restructuring and maturation of brain membranes combined with increasing myelination. Myelination in trout occurs over several months and is accompanied by an increasing ratio of galactolipids to phospholipids, although the ratio of cholesterol to phospholipids in developing trout brain is more constant than the values observed here (24). Trout are similar to turbot in that the proportions of phospholipid classes do not change throughout development (24). Although the data in the present study are consistent with Period IIa of development, it is not clear when Period I, characterized by neuronal multiplication, is complete in fish.

The most significant aspect of lipid metabolism in the developing brain of juvenile turbot is the accumulation of DHA. Accumulation of PUFA during the development of mammalian brain occurs during periods of cell division (25) and, although it is unclear at what stage of development the turbot brains are (see above), both Periods I and IIa are characterized by cell division (22). However, the comparatively low level of DHA in the turbot brain at day 38 and its subsequent enrichment in brain lipids may also reflect factors other than development. The pellet diet contained more DHA, gram for gram, than the *Artemia* diet, the fish may consume more of the pellet diet and there may be differences in the relative ability of turbot to digest the different diets.

The accumulation of DHA was extremely specific, with no other fatty acid increasing in percentage in total lipid other than a small increase in 24:1. In particular, there was no evidence for selective accumulation of arachidonic acid in the fish brain; no correlation was found between this fatty acid and brain dry weight. In comparison, both DHA and arachidonic acid specifically accumulate during development of mammalian brains (25–28).

The accumulation of DHA in turbot brain was rapid and quantitatively very large. From the data for brain dry weights, brain lipid contents, fatty acid content of lipid classes (*e.g.* approximately 35% of the weight of glycerophospholipids is due to the fatty acid components, for triacylglycerols the figure is 90%, etc.) and the percentage of DHA in total lipid, we can calculate the DHA content per brain. On day 38, an individual brain contained <10 μg DHA, whereas on day 105 each brain contained almost 125 μg DHA. This represents an accretion rate of, on average, 1.7 μg DHA per day. The kinetic data show that the rate of accumulation is initially much higher and indicate that the brain DHA content was increasing by >20% every day in the first few days on the pellet diet.

The percentage of DHA had attained its estimated maximal value in total lipid by approximately 7 wk and in GPC and GPE by 10 wk, after placing turbot on the pellet diet. In comparison, the DHA levels in brain cells of rats switched to a soybean oil diet at 60 days of age (after being fed sunflower oil for 4 generations) had not reached control values after 10 wk (29). In n-3 PUFA-deficient rhesus monkeys, brain DHA levels recovered to the levels of control animals after 12 wk on a diet supplemented with fish oil (30). However, the initial levels of brain DHA before changing to n-3 PUFA-containing diets and the dietary compositions (*e.g.* DHA content) in these studies are not directly comparable to those in the present study. Furthermore, no evidence for n-3 PUFA deficiency was found in the turbot at the start of the present study. Nevertheless, the accumulation of DHA in the developing turbot was not dramatically different from the accumulation of DHA in the brains of n-3 PUFA-deficient mammals.

The accumulation of DHA in turbot brain was accompanied by decreases in the percentages of all other fatty acids except saturated fatty acids and, in PI, n-6 PUFA. All the individual monoenes and PUFA generally contributed to the decreases, although to different extents in different glycerophospholipids. In contrast, saturated fatty acids were generally conserved relative to DHA. This is different from the situation in n-3 PUFA-deficient mammalian brains during dietary n-3 PUFA supplementation. There the accumulation of DHA is compensated almost solely by decreasing levels of 22:5n-6 (29,30). Furthermore, other n-3 PUFA also increase, particularly EPA and 22:5n-3, especially when fish oil is fed (29,30). Changes in total saturated fatty acids and monoenes in the mammalian studies are not dramatic and are variable, depending upon the fatty acid compositions of the diets fed.

The data in the present study suggest that juvenile turbot have low Δ5 and limited Δ4 desaturase activities. The *Artemia* diet contained a high level of 18:3n-3 and this was reflected in the levels of 18:3, 18:4, 20:3 and 20:4n-3 observed in day-38 fish, consistent with very low Δ5 desaturase activity. In addition, *Artemia* also contained 4.4 μg EPA/mg diet dry weight which would avoid the Δ5 block. However, the levels of EPA in the brains of day-38 fish were much higher than expected and exceeded the levels of DHA in all glycerophospholipid classes except PS. The levels of EPA in brains were reduced after 10 wk on the pellet diet, although this diet contained higher levels of EPA than the *Artemia* diet. These data suggest that preformed DHA is required by the brain and that liver, as well as brain, in turbot has low Δ4 desaturase activity. Therefore, only DHA present in the diet can contribute to the accumulation of DHA in turbot brain.

The rank order of the glycerophospholipid classes in initial rates of accumulation of DHA was GPE > GPC > PS. However, the decrease in DHA at day 90 in GPC affected the fit of the line and tended to lower the estimated initial rate value. Therefore, there is no evidence in this study that any glycerophospholipid class, either *via de novo* biosynthesis and/or *via* turnover (deacylation/reacylation), is preferentially acylated with dietary DHA. Ether-linked glycerophospholipid may have a role in the initial incorporation of long-chain PUFA, especially DHA, into neural tissues (31,32). However, further analyses of ether-linked ethanolamine and choline glycerophospholipids are required.

By day 105, GPE and PS contained the highest percentages of DHA in the turbot brain. High levels of DHA in GPE and PS are common characteristics of mammalian cerebral cortex (1) and vertebrate retinal photoreceptors (1,2,14,33). The total PUFA contents of GPE and PS in turbot brain, at >50%, suggest the presence of di-PUFA molecular species and possibly of di-docosahexaenoyl GPE and PS. Di-PUFA and di-22:6n-3 species of GPE and PS are found in relatively large amounts in both trout brain (14) and cod brain (34). The properties that di-22:6n-3 phospholipids confer on membrane structure and the precise nature of their role(s) in the specialized functions of these tissues remain to be elucidated (14). However, among subcellular fractions of mammalian neural tissue, the highest levels of DHA and di-22:6n-3 molecular species are found in synaptosomes and synaptic vesicles, as well as in mitochondria and microsomes (1,2). Therefore, DHA may be involved in action potentials or fast signal transmission. However, the signal transduction process is mainly associated with the rapid turnover of inositol phospholipids in which 20:4n-6 is a major component in mammals. PI in fish brain contains the highest level of 20:4n-6 of all the glycerophospholipids and substantial levels of EPA (12). Turbot brain PI also had relatively high levels of both 20:4n-6 and EPA, which remained relatively constant during development.

DHA in neural tissues may have diverse roles related to the biophysical properties of membranes, (1,2,35), as a modulator of lipid-protein interaction and neural enzyme activity (1), and as a precursor of lipoxygenase products (36). The results of the present study have shown that DHA was rapidly accumulated by the developing fish brain during development post-hatch. The accumulation was specific for DHA, and no selective accumulation of 20:4n-6 was apparent. DHA was accumulated at the expense of monoenes and other n-3 and n-6 PUFA, but the percentage of saturated fatty acids was maintained. The accumulation of DHA was maximal 10 wk after transfer to a diet supplying excess DHA. No individual glycerophospholipid class played any specific role in the accumulation process.

Fatty Acid Composition of Subcellular Particles from Sheep Platelets and Topological Distribution of Phosphatidylethanolamine Fatty Acids in the Plasma Membrane

J. Sánchez-Yagüe, J.A. Cabezas and M. Llanillo*
Department of Biochemistry and Molecular Biology, Faculty of Biology, University of Salamanca, 37008 Salamanca, Spain

The fatty acid composition of individual phospholipids in subcellular fractions of sheep platelets and the asymmetrical distribution of phosphatidylethanolamine (PE) fatty acyl chains across the plasma membrane were examined. The main fatty acids of total lipid extracts were oleic (18:1; 32–41%), linoleic (18:2, 10–17%), stearic (18:0; 13–15%), palmitic (16:0; 11–15%) and arachidonic (20:4; 8–12%) acids, with a saturated/unsaturated ratio of about 0.4. Each phospholipid class had a distinct fatty acid pattern. Sphingomyelin (SM) showed the highest degree of saturation (50%), with large proportions of behenic (22:0), 18:0 and 16:0 acids. The main fatty acid in PE, phosphatidylserine (PS) and phosphatidylcholine (PC) was 18:1n-9. Our findings suggest that fatty acids are asymmetrically distributed between the choline *versus* the non-choline phospholipids, and also between plasma membranes and intracellular membranes. The transbilayer distribution of PE fatty acids in plasma membranes from non-stimulated sheep platelets was investigated using trinitrobenzenesulfonic acid (TNBS). A significant degree of asymmetry was found, which is a new observation in a non-polar cell. The PE molecules from the inner monolayer contained higher amounts of 18:2 and significantly less 18:1 and 20:5 than those found in the outer monolayer, although no major differences were detected in the transbilayer distribution of total unsaturated *versus* saturated PE acyl chains.

Lipids 26, 878–883 (1991).

The platelet plasma membrane plays an important role in hemostatic phenomena (1,2). In human platelets, changes in saturated/unsaturated fatty acid ratios have been shown to be associated with platelet hyperfunction (3) and antithrombotic action (4,5). Interest has increased considerably in recent years in determining the nature of the relationship between fatty acid group composition, membrane physical properties and membrane function. Fatty acid compositions of red blood cell phospholipids in many animal species (6) and also of several purified membrane fractions of human platelets have been reported (7–10). Additionally, the fatty acid distribution between the two halves of the bilayer has been described in plasma membranes from different sources (11–14). The fatty acid asymmetric location found in these studies raises the possibility that membrane properties may be modulated in different ways in the bilayer leaflets.

Prediction of the physical and dynamic properties of a biological membrane requires previous knowledge of the distribution of different lipid classes and fatty acid moieties in the two halves of the bilayer. However, the distribution of the aminophospholipid fatty acids in the platelet plasma membrane, a subcellular fraction where aminophospholipids constitute a very important lipid class involved in the coagulation process (15), has not yet been elucidated. The fatty acid composition of the different subcellular fractions isolated from sheep platelets is also not known, and only limited data are available on the fatty acid composition of individual phospholipids from platelet plasma membranes.

The aim of the present study was to examine the phosphatidylethanolamine (PE) fatty acid distribution in platelet plasma membranes, using trinitrobenzenesulfonic acid as a probe. The fatty acid composition of lipid extracts and of individual phospholipids of intact sheep platelets and their subcellular fractions were also established.

MATERIALS AND METHODS

Materials. Essentially fatty acid- and globulin-free bovine serum albumin (BSA), phenylmethylsulfonyl fluoride (PMSF) and tris(hydroxymethyl)aminomethane were purchased from Sigma (St. Louis, MO). D-Sucrose was obtained from Aldrich-Europe (Beerse, Belgium). Phospray, phospholipid and fatty acid methyl ester (FAME) standards, and methanolic-base were obtained from Supelco (Gland, Switzerland); 2,4,6-trinitrobenzenesulfonate (TNBS) was purchased from Serva Feinbiochemica (Heidelberg, Germany). Thin-layer chromatographic plates (Silica gel G, type 60) were obtained from E. Merck (Darmstadt, Germany). Other products were from Probus or Panreac (Barcelona, Spain). All organic solvents were of high quality and glass-distilled twice.

Preparation of platelets and isolation of subcellular fractions. Platelets were isolated from freshly collected blood of adult sheep (*Ovis aries* L. var. *domestica*) according to the procedure of Barber and Jamieson (16), slightly modified as indicated previously (17). Platelet preparations were sedimented at 3,000 × *g* for 30 min, then gently suspended in solution 1 (5 mM $Na_2PO_4H/NaPO_4H_2$, 0.154 M NaCl pH 7.4 containing 0.2% glucose, 0.05% BSA and 0.05 mM PMSF), and washed once in the same solution. Three main subcellular fractions were isolated from whole platelets using a discontinuous sucrose gradient under conditions similar to those used by Llanillo and Cabezas (18). The characterization of the fractions was described in previous papers (18,19). The upper fraction in the gradient was enriched in plasma membranes. The middle fraction consisted of endoplasmic reticulum, and the lower fraction comprised mitochondria and most of

Abbreviations: ANOVA, analysis of variance; BSA, bovine serum albumin; CGLC, capillary gas-liquid chromatography; FAME, fatty acid methyl esters; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PS, phosphatidylserine; SM, sphingomyelin; TLC, thin-layer chromatography; TNBS, trinitrobenzenesulfonic acid.

the granules. The protein content of the different fractions was determined by the method of Lowry *et al.* (20), using BSA as standard.

Trinitrophenylation of the aminophospholipids. The platelet labeling procedure was carried out under conditions identical to those described by Sánchez-Yagüe and Llanillo (21). TNBS (150 mM solution buffered with 5% $NaHCO_3$) was added to whole platelets (5-6 μmol TNBS/mg protein) to a final TNBS/lipid phosphorus molar ratio of 35. Labeled platelets were washed twice with solution 1 to remove free TNBS and then the plasma membrane fraction was obtained as indicated above. The supernatant from the labeling incubation system was used to measure platelet lysis by assay of lactate dehydrogenase activity (22).

Lipid extraction, fractionation and identification. Total lipid extraction from labeled or unlabeled materials, separation and identification of phospholipid classes, determination of their lipid phosphorus, and calculation of labeled phosphatidylserine and phosphatidylethanolamine were carried out as reported by Sánchez-Yagüe and Llanillo (21). Special care was taken in maintaining a nitrogen atmosphere during all steps of the extraction and fractionation procedures.

Capillary gas-liquid chromatography (CGLC). An aliquot of lipid extracts from each fraction (100 μg lipid phosphorus) was transmethylated using a sodium methoxide/methanol reagent (methanolic base), as reported elsewhere (23). Phosphatidylcholine (PC), phosphatidylserine (PS), phosphatidylethanolamine (PE), and sphingomyelin (SM), separated by thin-layer chromatography (TLC) as indicated above, were localized by staining with "phospray." Wet silica gel areas containing the phosphatides were rapidly scraped into dry tubes and treated with methanolic base. The fatty acid methyl esters (FAME) of unfractionated lipids and individual phospholipids were partitioned in a water/petroleum hydrocarbon system, brought to dryness under nitrogen in small conical tubes, and dissolved in 10-μL aliquots of isooctane for analysis by CGLC. FAME were determined in a Konik (model 3000, Barcelona, Spain) apparatus equipped with a flame ionization detector (FID) and a capillary column of the chemical bond type (BP5, SGE, 50 m × 0.25 mm) programmed as follows: initial 5 min hold at 180°C, 2°C/min 180-230°C, final 20 min hold at 250°C; carrier gas, H_2 (inlet pressure 2 atmospheres); splitless 1:60. Injector port and detector temperatures were 240°C and 280°C, respectively. Appropriate blank areas of silica gel or aliquots of chloroform/methanol (2:1, v/v) without lipids were transmethylated; the products were also gas chromatographed. The areas of the peaks were subtracted from those of the sample under study to account for background contamination. The fatty acid peaks were identified by comparison of their retention times with those of known FAME standards. FAME (23:0 and 24:0; 22:6, 24:0 and 24:1) with similar retention times in CGLC, were resolved into individual esters by argentation TLC (24), extracted with diethyl ether, and determined by CGLC as indicated above. Peak areas were measured with an electronic integrator (Konik model SP 4290).

Statistical analysis. Analysis of variance (ANOVA I) complemented with the Scheffé and Newman-Keuls multiple-range tests were used as statistical methods on an IBM-PS/2 computer.

RESULTS AND DISCUSSION

Fatty acid composition of sheep platelets and their subcellular fractions. Table 1 shows the fatty acyl chain profiles of lipids extracted from sheep platelets and their subcellular fractions. The major fatty acids, representing about 90% of total, were 18:1n-9 (32-41%), 18:2 (10-17%), 16:0 (11-15%), 18:0 (13-15%) and 20:4 (8-12%). Other fatty acids were present at percentages below 5%. These compositions were quite similar in whole platelets, in granule-mitochondria fractions, and in membranes. However, statistically significant differences ($p<0.05$) were found in the percentages of 18:1n-9 and 18:2, which increased progressively in the following order: whole platelets, plasma membranes, endoplasmic reticulum and granule-mitochondria fractions. Other fatty acids (16:1, 18:3, 20:1 and 20:0) occurring in low percentages (<2%) also showed significant differences. Total fatty acids were mainly unsaturated (68-73%), with saturated/unsaturated ratios of about 0.4. Previously published data indicate that the acyl chains of platelet total lipids from different animal species, such as the guinea pig (25), the miniature pig (26), humans (9,10,27) and the rat (28), are composed of the same fatty acids (16:0, 18:0, 18:1, 18:2 and 20:4) as those found in sheep platelets. However, the relative content of individual fatty acid changes somewhat with the species studied. The similarities in the phospholipid composition and in the individual phospholipid fatty acid composition between megakaryocytes and platelets (25) suggest that megakaryocyte are responsible for the overall phospholipid and fatty acid content of the platelets. The greatest difference between these two cell types is the higher concentration of arachidonic acid and a lower concentration of oleic acid in the platelets. This difference is probably due to an accumulation of arachidonic acid by the megakaryocyte in membranes destined to become part of the platelet, *i.e.*, the plasma and certain granule membranes (25).

The fatty acid composition of phospholipid classes from sheep platelets shows more pronounced differences than those of the total lipid extracts; the aminophospholipids show the largest variation (Table 2). The main fatty acid components of PE in all fractions are 18:1n-9 (42.5-47%), 18:0 and 18:2 (12-16%), 20:4 (11-18%) and 16:0 (4-5%). The most significant differences were found in the percentage increase ($p<0.05$) of 18:0 and 20:4 in PE of the plasma membranes compared to the percentage increase of these fatty acids in PE from intracellular membranes. The same five acids accounted for approximately 90% of the total in PS. However, PS had considerably more 18:0, less 20:4, slightly less 18:1n-9, and similar 16:0 and 18:2 levels as compared to PE. Stearic and 18:1n-9 acids increased ($p<0.05$) in PS from plasma membranes and endoplasmic reticulum. PE had the highest unsaturation index compared to the other phospholipids and a saturated/unsaturated ratio of about 0.2, while in PS this ratio was increased to 0.6. PE of subcellular fractions shows a significant increase in the unsaturation index compared to the PE of whole platelets. By contrast, this index decreases in the PS fractions. Table 3 shows the fatty acid composition of choline phospholipids. The major PC fatty acids, representing about 90% of the total, are 16:0 and 18:1n-9 (30-38%), 18:2 (11-13%) and 18:0 (9-11%), with a significant increase ($p<0.05$) in 16:0 in the plasma

[a]Data shown are given in percentages of total fatty acid content and are means ± S.D. (n = 5, at each point). CGLC determinations were done in triplicate on each sample. By rows, the significance of the results was assessed by ANOVA I of compounded data (superindices without coinciding letters [b,c]: $p<0.05$) as well as by the Scheffé and Newman-Keuls tests. Trace amounts (less than 1%) of 14:0, 18:4, 20:0, 20:3, 23:0, 22:4, 22:6 and 24:0 fatty acids were present. N.D. not detected; Sat., saturated; Unsat., unsaturated.

[d]Unsaturation Index (U.I.) was calculated as the sum of the percentage by weight of each fatty acid times the number of olefinic bonds.

membrane fraction. SM contains a large proportion of long-chain saturated fatty acids (50%) and has the smallest unsaturation index among the different phospholipid classes. SM has less 18:1n-9 (14–18%), 18:2 (8–9%) and 16:0 (8–11%) compared to the PC fractions and a similar 18:0 (11–14%) content; 22:0 (16–19%) and 22:1 increased ($p<0.05$) in the plasma membrane fractions. SM was the only phospholipid class in which 23:0 and 24:0 were identified. This appears to be a general characteristic of SM that has also been observed in other sources (6,9,10,29). The individual fatty acid patterns in sheep platelets are very different from those found in human platelets and erythrocytes (6,7,9,10,27,30). Certain fatty acids of human platelets and erythrocytes are predominant in specific phospholipids: 20:4 in PE, 18:0 in PS, 20:4 and 18:0 in phosphatidylinositol, and 16:0 and 18:1 in PC. The highest abundance of 20:4 in sheep platelets is found in PE (11–18%); however, this percentage is significantly lower than that found in platelets from other sources (7,9,25,26).

The present study demonstrates that fatty acids of sheep platelets are asymmetrically distributed among the phospholipids of the different particulate fractions. The concentration of 20:4, 18:0 and 18:1n-9 was twice as high in aminophospholipids than in choline phospholipids while the concentration of 16:0 was five times smaller. The amounts of linoleic acid were identical in both phospholipid classes. The saturated/unsaturated ratios of the non-choline phospholipids were considerably smaller than those of the choline phospholipids. However, the asymmetry of sheep platelet plasma membrane is not as pronounced as that described by Broekman *et al.* (10) for human platelets. Differences in some fatty acids, such as 20:4 from PE (significantly more enriched in the plasma membrane), exist between plasma membranes and intracellular membranes of sheep platelets. The data are in agreement with those reported for human platelets (7). By contrast, PC from the plasma membrane of human platelets is less enriched in 20:4 than are intracellular membranes (7). However, these latter differences have not been found in sheep platelets.

Studies on the contribution of each phospholipid to the saturation level in whole sheep platelets and their subcellular particles show that aminophospholipids lead to the smallest saturation percentage in each membrane fraction. The data can be calculated by the following expression: % "a" from "b," where "a" represents the saturated fatty acid percentage of a phospholipid class in a specific subcellular fraction (data given in Tables 2 and 3), and "b" is the relative percentage of this phospholipid in the same fraction [values given in Table 2 of our previous paper (21)]. Thus, the phospholipid yielding the highest percentage of saturation is PC

[a]Data (mean ± S.D.; n = 5 at each point) are given in percentages of total fatty acids in each phospholipid. CGLC assays were carried out in triplicate on each sample. By rows, the significance of results was assessed by ANOVA I of compounded data (superindices without coinciding letters [b,c,d]: $p<0.05$) as well as by the Scheffé and Newman-Keuls tests. N.D., not detected; Sat., saturated; Unsat., unsaturated.

[e]Unsaturation Index (U.I.) was calculated as in Table 1.

TABLE 3

Fatty Acid Composition of Choline Phospholipids from Sheep Platelets and Their Subcellular Fractions[a]

[a]Data (mean ± S.D.; n = 5 at each point) are given in percentages of total fatty acids in each phospholipid. CGLC assays were carried out in triplicate on each sample. By rows, the significance of results was assessed by ANOVA I of compounded data (superindices without coinciding letters [b,c]: $p<0.05$) as well as by the Scheffé and Newman-Keuls tests. N.D., not detected; Sat., saturated; Unsat., unsaturated.

[d]Unsaturation Index (U.I.) was calculated as in Table 1.

(12-14%), followed by SM (7-8%), PE (5-8%) and PS (5-6%) (data not shown). Both aminophospholipids contribute about 5-6% to the total saturation, even though the percentage of PE is 2.5-3.0 times greater than that of PS in all subcellular fractions (21). The smallest amount of saturated fatty acids from PE with respect to PS is consistent with these values.

Topological distribution of PE fatty acids across the sheep platelet plasma membranes. These studies were carried out using TNBS to separate the PE of the outer monolayer (trinitrophenylated aminophospholipids) from those associated with the inner monolayer (non-reactive with TNBS). The fatty acyl chains of the isolated individual PE were analyzed. In our previous study (21), the topological distribution of aminophospholipids was determined with regard to the polar head groups. Whole sheep platelets were incubated with TNBS under conditions identical to those described in the present paper. This treatment essentially conserves platelet integrity (below 7% of lactate dehydrogenase found in the supernatant), thus preventing TNBS penetration into the platelets, as has been demonstrated previously (21,31). Accordingly, only external aminophospholipids are trinitrophenylated. After labeling, plasma membranes were obtained, and lipids were extracted. The plasma membrane separation procedure that was applied after labeling did not modify the fatty acid pattern of PE located on the external leaflet of the lipid bilayer (data not shown). All PS were located on the internal leaflet (21); therefore, only the distribution of the PE fatty acyl chains across the lipid bilayer were studied by analyzing the fatty acyl chains from trinitrophenylated PE and non-reactive PE. The PE fatty acid composition of the outer leaflet corresponded to the fatty acids found in the labeled PE. The fatty acyl chains from non-reactive PE were located in the inner leaflet of the lipid bilayer. These data are given in Table 4. The results demonstrate, for the first time, that in the plasma membrane of non-stimulated platelets, the two PE pools are different in their fatty acid composition. The PE molecules from the inner monolayer contain a higher amount of 18:2 and significantly ($p<0.05$) less 18:1n-9 and 20:5 than those from the outer monolayer. Nevertheless, the PE unsaturation indices are similar across the plasma membrane, a value not statistically different from that obtained when the total PE from the plasma membrane fraction was analyzed (Table 2).

Perret *et al.* (14) have shown that 20:4 is mostly located on the inside of human platelets in both intracellular membranes and in the inner leaflet of the plasma membranes. Thus the arachidonic acid used as a precursor for prostaglandin and thromboxane synthesis should come from intracellular phospholipids (4). Pelletier *et al.* (13) have found that in the posterior trout intestine, PS and PE fatty acid chains from the brush-border membrane are asymmetrically distributed, the inner phospholipid species having a higher content of 22:6n-3 than the outer ones. By contrast, the PC from the external leaflet is enriched in 20:5n-3 and 22:6n-3 (12). The important fluidizing role played by 22:6n-3 (32) suggests that it may regulate and possibly equalize the fluidity of each of the membrane leaflets. In other systems (11,33,34), an asymmetric distribution in saturated fatty acids between the two leaflets of the plasma membranes has also been reported, although with different results in function. Recently, the molecular species composition of PE on the inner and outer leaflet of the human erythrocyte membrane has been postulated (35), suggesting an asymmetric distribution across the plasma membrane. The PE pool in the outer monolayer displays a higher degree of unsaturation than the inner one, which may be compensated for by the relatively low degree of unsaturation of SM and PC in this bilayer (36,37).

The topological distributions described have numerous repercusions on structure (38) and membrane physical properties (39), and may help membrane enzymes to be modulated in different ways in the two bilayer leaflets. This has been explored in detail for adenylate cyclase (34). Plasma membrane acetylcholinesterase of sheep platelets, an enzyme associated with the external surface, changes its catalytic properties by progressive inclusion of free cholesterol into the plasma membrane (40). This increase in cholesterol causes a gradual shift of aminophospholipids from the inner to the outer side of the lipid bilayer (41), which may also produce changes in the distribution of individual phospholipid fatty acyl chains across the plasma membrane. These modifications in the lipid environment in which the enzyme is embedded may be responsible for the changes observed in acetylcholinesterase, as has been reported for several enzymes (42).

TABLE 4

Fatty Acid Composition of Phosphatidylethanolamines Distributed Between the Two Leaflets of the Lipid Bilayer from Sheep Platelet Plasma Membranes[a]

Fatty acid	External leaflet	Internal leaflet
16:0	5.0 ± 0.5	4.5 ± 1.0
18:0	10.1 ± 1.0	9.7 ± 0.3
18:1n-9	39.3 ± 0.5[b]	37.5 ± 1.2[c]
18:2	16.5 ± 1.1[c]	19.8 ± 1.2[b]
20:4	19.9 ± 1.1	19.9 ± 2.0
20:5	4.8 ± 0.3[b]	4.0 ± 0.3[c]
U.I.[d]	163.0 ± 14.5	170.3 ± 18.5

[a]Results (mean ± S.D.; n = 5 at each point) are given in percentages of total fatty acids in each sample. CGLC determinations were carried out three times on each sample. By rows, the significance of the results was assessed by ANOVA I of compounded data (superindices without coinciding letters [b,c]:$p<0.05$) as well as by the Scheffé and Newman-Keuls tests. 18:1n-7, 20:1, 20:2, 20:3, 22:4, 22:5 and 22:6-fatty acids were also detected at percentages less than 2%. The remaining fatty acids found in trace amounts in the plasma membrane (14:0, 16:1, 18:3, 18:4) were not detected in these assays.

[d]Unsaturation Index (U.I.) was calculated as in Table 1.

[a]Lipid Research Laboratory, Department of Biological Sciences, University of Lowell, Lowell, Massachusetts 01854, [b]Zablocki Veterans Administration Medical Center, Milwaukee, Wisconsin 53295, and [c]Eli Lilly and Co., Indianapolis, Indiana 46285

The present study was designed to investigate the effect of ethanol (EtOH) dose on low density lipoprotein (LDL) and platelet composition. Male squirrel monkeys were divided into three groups designated Control, Low, and High EtOH, and fed isocaloric liquid diets containing 0%, 12%, and 24% of calories as EtOH, respectively. After four months of treatment, monkeys fed the 12% alcohol dose had LDL and platelet cholesterol concentrations similar to Controls. By contrast, platelet membranes from High EtOH animals contained significantly more cholesterol which was associated with higher levels of plasma LDL cholesterol and apolipoprotein B. Blood platelet count, size, and mass were similar for all groups and circulating platelet aggregates were absent in the two alcohol cohorts. Despite elevations in platelet cholesterol mass and thromboxane A_2 (TXA_2) precursor, phospholipid arachidonate, platelet responsiveness, measured as thromboxane formed in response to a collagen challenge *in vitro*, and the cholesterol/phospholipid molar ratio, were not significantly altered by high dose alcohol. Normal platelet activity in High EtOH monkeys may have resulted from a significant increase in the platelet phospholipid polyunsaturated/saturated fatty acid ratio and a non-significant increase in platelet phospholipid mass, both of which would have a fluidizing effect on platelet membranes. Our data indicate that low EtOH intake has no effect on platelet composition and function while unfavorable platelet cholesterol enrichment following consumption of high dose ethanol may arise from elevations in plasma LDL. Potentially thrombogenic (TXA_2 formation, platelet aggregate formation) consequences of increased platelet cholesterol in squirrel monkeys fed high levels of alcohol may be averted by compensatory physicochemical changes in platelet membrane lipid composition although persistent elevations in circulating LDL may contribute to increased risk of cardiovascular disease. *Lipids 26,* 884-890 (1991).

While moderate ethanol consumption may protect against coronary heart disease (CHD) (1,2), chronic alcohol abuse is associated with hypertension (3), vasospasm (4), stroke (5), and cardiomyopathy (3,6). In an effort to define the underlying mechanisms responsible for these disparate effects of ethanol on the cardiovascular system as related to its lipid modifying properties, we developed a non-human primate model which exhibits dramatically different lipoprotein profiles when these animals are fed low *vs* high dose ethanol (7-10). At low (12% of calories) alcohol levels, atherosclerosis susceptible squirrel monkeys show a coronary protective lipoprotein response in terms of an elevated plasma high density lipoprotein$_2$ (HDL_2/high density lipoprotein$_3$ (HDL_3) ratio and low concentrations of atherogenic low density lipoprotein (LDL) cholesterol and apolipoprotein B (9,10). When this species is given higher alcohol doses (24% calories), they demonstrate a further increment in HDL_2 along with elevations in HDL_3 and significant increases in LDL cholesterol and apolipoprotein B (10). As a point of reference, population surveys have estimated that nonalcoholics may consume 5-18% ethanol calories/day while EtOH intake, as a percentage of total calories, may range from 35-50% in alcoholics (11,12). While these observations may partially explain the differences in coronary risk between moderate drinkers *vs* alcoholics, other studies suggest that ethanol may also exert its cardiovascular effects by modifying the concentration of vasoactive prostanoids and by altering platelet function (13-17). Depending on dose and treatment period, ethanol produces variable alterations in vascular prostacyclin (PGI_2) and platelet thromboxane A_2 (TXA_2) (4,13,16-19). The relative production of these prostanoids may be of clinical importance because of the potent platelet anti-aggregatory, vasodilatory (PGI_2) *vs* pro-aggregatory/vasoconstrictory (TXA_2) properties of these compounds (20,21).

Very recently, several studies have implicated lipoproteins as important modulators of prostanoid production (22-26). Specifically, HDL may provide precursor (arachidonic acid) for PGI_2 synthesis and reduce platelet aggregation (27-31), while LDL may inhibit PGI_2 production (22,32-34) and contribute to platelet enrichment with cholesterol, hyperactivity, and enhanced TXA_2 formation (30,35). While some recent effort has been directed at understanding the relationship between alcohol, HDL, and PGI_2 (31), virtually nothing is known about the effect of ethanol on LDL levels and subsequent changes in platelet composition and function. Consequently, since our non-human primates show divergent responses to low EtOH (low LDL) *vs* high EtOH (high LDL) intake, the present study was designed to employ the squirrel monkey dietary ethanol model to examine the lipoprotein-platelet relationship as a function of alcohol dose.

EXPERIMENTAL PROCEDURES

Adult male squirrel monkeys *(Saimiri sciureus)* were maintained on isocaloric Primate Liquid Diet #19 (Bio-Serv, Inc., Frenchtown, NJ) for 5 mon after which a series of baseline measurements was performed to ensure initial between-group homogeneity. There were no significant differences between animals in platelet count, or plasma lipid parameters (cholesterol, triglyceride, HDL, and LDL

Abbreviations: ACD, acid citrate dextrose; CHD, coronary heart disease; C/PL, cholesterol/phospholipid; EDTA, ethylenediamine tetraacetate; EtOH, ethanol; GGT, gamma glutamyltranspeptidase; HDL, high density lipoprotein; LDL, low density lipoprotein; P/S, polyunsaturated/saturated; PGI_2, prostacyclin; PRP, platelet rich plasma; SGOT, serum glutamate oxaloacetate transaminase; TLC, thin-layer chromatography; TXA_2, thromboxane A_2; VLDL, very low density lipoprotein.

cholesterol). Animals were then randomly assigned to three treatment groups consisting of six to eight monkeys per group: (i) Controls fed isocaloric liquid diet; (ii) Low Ethanol monkeys given liquid diet with 100 proof vodka substituted isocalorically for carbohydrate at 12% of calories (2.36 g EtOH/day); and (iii) High Ethanol animals fed diet plus vodka at 24% of calories. Vodka was chosen as the source of ethanol to mimic an alcoholic beverage typically consumed by humans and because of its low concentration of congeners. The control diet had a caloric density of 0.87 kcal/mL, a caloric distribution of 18.4% protein, 52.2% carbohydrate, and 29.4% fat with a polyunsaturated/saturated (P/S) fatty acid ratio of 1.00 and a cholesterol content of 0.14 mg/kcal. Corn oil, coconut oil, chicken fat and soy lecithin were the sources of fat, and casein was the protein component of Liquid Diet #19. Diet consumed was measured after each feeding.

All measurements were performed after four months of treatment because we have previously determined that ethanol-fed squirrel monkeys exhibit stable lipoprotein profiles at this time (10), and because other studies indicate that the short-term (several weeks) platelet response to alcohol may differ appreciably from more long-term (months) exposure suggesting a process of "physiological adaptation" (4,17,18,36,37).

Lipoprotein measurements. After an overnight fast, blood was collected from the femoral vein of unanesthetized monkeys and transferred to tubes containing disodium EDTA. Plasma was isolated and aliquots were removed for triglyceride (Sclavo Diagnostics, Wayne, NJ) and cholesterol analyses (38). Following precipitation of very low density (VLDL) and low density (LDL) lipoproteins with heparin-manganese (39), the supernatant was collected and HDL cholesterol (38) was measured colorimetrically. LDL cholesterol was determined using the formula: (VLDL + LDL cholesterol) − plasma triglyceride/5 which provides values identical to those obtained for LDL separated by ultracentrifugation (40,41). Since VLDL lipid mass represents a minor component of the lower density lipoproteins in squirrel monkeys at these alcohol doses (42), alcohol-related alterations in the VLDL-LDL pellet were taken to represent quantitative changes in LDL. Lipids in the pellet were subsequently extracted (43), phospholipid was separated by thin-layer chromatography (44), and phospholipid fatty acids were transesterified (45) using methanolic HCl (Alltech Associates, Inc., State College, PA). Fatty acid methyl esters were analyzed by gas-liquid chromatography as described earlier (46). Phospholipid mass in another aliquot was determined by the Bartlett procedure (47).

Plasma apolipoprotein B-100 was measured by the Tago radial immunodiffusion method (Tago, Inc., Burlingame, CA) using human anti-apolipoprotein B sera which cross-reacts with squirrel monkey apolipoprotein B antigen. Sample apolipoprotein B was determined from a standard calibration curve prepared by microscopic measurement of ring diameters. The intra- and inter-assay coefficients of variation for this procedure were 6.23% and 6.25%, respectively.

Platelet parameters. Platelet counts and average size were measured in whole blood collected in 15% disodium EDTA using a Coulter S+4 counter (Coulter Electronics, Inc., Hialeah, FL). Platelet mass was calculated by multiplying count by size.

Platelet isolation and extraction. Blood was collected from the femoral vein of unanesthetized monkeys with a 23 gauge butterfly cannula into plastic tubes containing 1/6 volume acid citrate dextrose (ACD). After mixing, samples were centrifuged (150 × *g*) for 15 min and platelet-rich plasma (PRP) was collected, placed in polypropylene conical tubes and centrifuged (1500 × *g*) for 15 min at 22°C to sediment the platelets. The platelet pellet was washed twice and the final pellet resuspended in 0.5 mL platelet washing buffer (pH 6.5) (48). Separate aliquots were then removed to measure platelet counts (Coulter Counter Model ZBI equipped with a 70 μm aperture), to test for the presence of apolipoprotein B using the Tago radial immunodiffusion procedure, and to extract lipids (43). Phospholipid mass in one aliquot of the lipid extract was measured by the Bartlett procedure (47). Lipids in the remainder of the extract were resolved by thin-layer chromatography (44), nonesterified cholesterol was quantitated colorimetrically (38), and phospholipid fatty acid methyl esters were prepared and analyzed as described above for LDL.

TXB_2 formation by collagen-stimulated platelets. Free flowing blood was collected into 1/10 vol 3.8% trisodium citrate *via* a 23 gauge cannula. Aliquots of citrated whole blood were then incubated with 10 μg/mL collagen in a shaking water bath at 37°C for exactly 5 min after which 10 μM indomethacin was added. Following centrifugation (2500 × *g*) at 4°C for 15 min, plasma was aspirated and TXB_2 (the stable hydration product of TXA_2) was quantitated by radioimmunoassay using rabbit anti-TXB_2 antisera (49). Antiserum and tritiated TXB_2 were added to samples and known standards, followed by an overnight incubation (4°C). Unbound [^{3}H]TXB_2 was subsequently adsorbed and sedimented on dextran-coated charcoal, and antibody-bound radioactivity was measured by liquid scintillation spectroscopy. Detection limit of the assay was 500 pg/mL serum. Cross-reactivity with other eicosanoids was 0.1% or less.

Circulating platelet aggregates. Circulating platelet aggregates were measured by the method of Wu and Hoak (50). Briefly, 0.5 mL of blood was collected (as described above for platelet isolation) into two separate tubes, one containing 2 mL of buffered EDTA solution only; the other containing 2 mL of buffered EDTA-formalin solution. Both solutions were isotonic and at pH 7.4. Samples were mixed, maintained at 22°C for 15 min, and then centrifuged (150 × *g*) for 8 min to generate PRP. Platelet counts in the mid-fraction of the PRP were determined using a Coulter Counter Model ZBI. The platelet count ratio was calculated as follows: PRP count in EDTA-formalin/PRP count in EDTA. When platelet aggregates are present, they are fixed with formalin and sediment during centrifugation, thus producing a platelet count ratio of less than 1.0 (50).

Liver function tests. Serum glutamate-oxaloacetate transaminase (SGOT) and gamma-glutamyltranspeptidase (GGT) were measured with Dade test kits (Dade Diagnostics, Inc., Miami, FL).

Statistical analyses. Data were expressed as the mean plus or minus the standard error of the mean. Mean values were analyzed for significant differences ($P<0.05$) by one-way analysis of variance and Duncan's multiple range test. Correlation coefficients and corresponding P values were calculated for the platelet lipid *vs* LDL relationship.

RESULTS

There were no significant differences between the treatment groups for SGOT (Control, 54 ± 3, Low EtOH, 56 ± 5, High EtOH, 58 ± 7 U/mL). However, High EtOH primates showed a significant increase in GTT (27 ± 3 IU/L) compared to Control (14 ± 2), but not compared to Low EtOH monkeys (21 ± 2). All serum liver enzymes were within the normal range for human subjects (51).

As shown in Table 1, platelet parameters (count, size, mass) were similar for the three regimens, and platelet responsiveness (TXB_2 formation) to a collagen challenge was not significantly altered by ethanol dose (Controls 61 ± 15, Low EtOH 66 ± 6, High EtOH 72 ± 5 ng/10^8 platelets). The platelet count ratio for Control primates tended to be the lowest while the ratios for both alcohol groups approximated unity indicating an absence of circulating platelet aggregates (Fig. 1). However, neither measure of platelet function (TXB_2 formation, circulating platelet aggregates) was significantly altered by alcohol treatment. As indicated in Figure 2, platelets from monkeys fed high levels of EtOH had significantly more

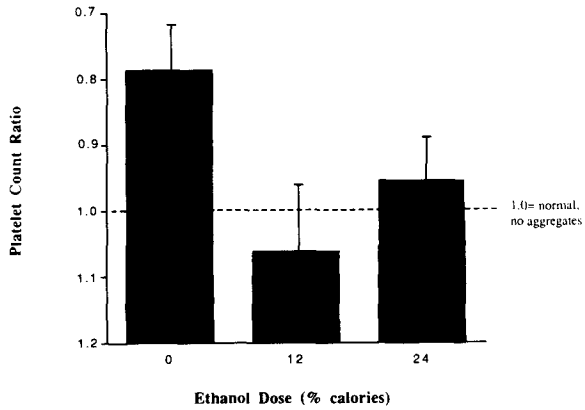

FIG. 1. Effect of ethanol dose on circulating platelet aggregates. Values represent mean ± SEM for 6–8 monkeys/group expressed as platelet-rich plasma count in EDTA-formalin divided by the platelet-rich plasma count in EDTA (50). A platelet count ratio of less than 1.0 indicates the presence of circulating platelet aggregates.

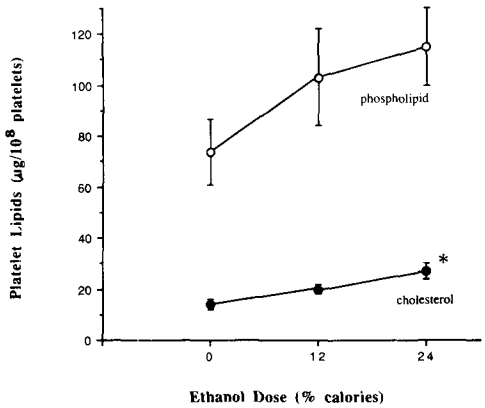

FIG. 2. Effect of ethanol dose on platelet cholesterol and phospholipid concentrations. Values represent mean ± SEM for 6–8 monkeys/group expressed as μg/10^8 platelets. * indicates significant difference (P<0.05) between 24% and 0% EtOH means.

TABLE 1

Effect of Ethanol Dose on Platelet Parameters[a]

Parameter	Treatment groups		
	Control (0%)	Low ethanol (12%)	High ethanol (24%)
Platelet count (10^8/mL)	3.0 ± 0.4	3.4 ± 0.2	3.4 ± 0.2
Size (mean platelet vol, μm^3)	11.7 ± 0.7	12.2 ± 0.6	11.3 ± 0.4
Mass (count × size)	33.8 ± 4.1	41.5 ± 3.1	38.8 ± 3.1

[a]Values represent mean ± SEM for 6–8 monkeys per group.

TABLE 2

Comparison of Platelet and Low Density Lipoprotein Lipid Composition as a Function of Ethanol Dose[a]

	Treatment groups		
	Control	Low ethanol	High ethanol
Platelet component			
Phospholipid 18:2 (μ/10^8 platelets)	4.4 ± 0.6	5.0 ± 0.3	6.3 ± 1.2
Phospholipid 20:4 (μg/10^8 platelets)	7.2 ± 0.6	9.6 ± 0.4	11.3 ± 1.5
Phospholipid 20:4 (% distribution)	17.7 ± 0.3[b,c]	22.0 ± 0.7[c]	25.4 ± 0.4[b]
Phospholipid polyunsaturated/saturated fatty acid ratio	0.623 ± 0.003[b]	0.805 ± 0.005	0.985 ± 0.094[b]
Low density lipoprotein component			
Phospholipid (mg/dL)	52 ± 4[b]	53 ± 2[b]	68 ± 6[b]
Phospholipid 18:2 (mg/dL)	9.0 ± 0.6	8.5 ± 0.5	8.9 ± 0.2
Phospholipid 20:4 (mg/dL)	6.2 ± 0.7[b]	5.6 ± 0.4[b]	8.3 ± 0.7[b]
Phospholipid 20:4 (% distribution)	18.2 ± 1.4[b]	17.6 ± 0.4[b]	21.9 ± 1.6[b]

[a]Values represent mean ± SEM for 6–8 monkeys per group.
[b]High ethanol mean significantly different (P<0.05) from means of other groups with superscript b.
[c]Low ethanol mean significantly different (P<0.05) from means of other groups with superscript c.

cholesterol, a non-significant increase in phospholipid mass, a significant elevation in the percentage of phospholipid arachidonate (Table 2), and the highest polyunsaturated/saturated (P/S) fatty acid ratio (Table 2). Platelet cholesterol/phospholipid molar ratios for Control (0.34 ± 0.08), Low (0.48 ± 0.10), and High (0.49 ± 0.04) EtOH primates were not significantly different. No apolipoprotein B was detected in washed platelet pellets. In addition, there was no evidence of essential fatty acid deficiency as indicated by the similar concentration of arachidonic acid and its precursor, linoleic acid, in all treatment groups for both platelets and LDL phospholipid (Table 2).

Monkeys fed the 24% EtOH dose exhibited a significant increase in LDL cholesterol while consumption of alcohol at 12% of calories had no effect on this parameter (Fig. 3). As noted in Figures 4 and 5, respectively, animals with the highest plasma LDL cholesterol and apolipoprotein B (High EtOH group) also had the greatest amount of platelet cholesterol. HDL cholesterol values for Control, Low, and High EtOH primates were 114 ± 7, 120 ± 10, and 167 ± 21 mg/dL, respectively, with significant differences appearing between the High alcohol group *vs* the other two treatments.

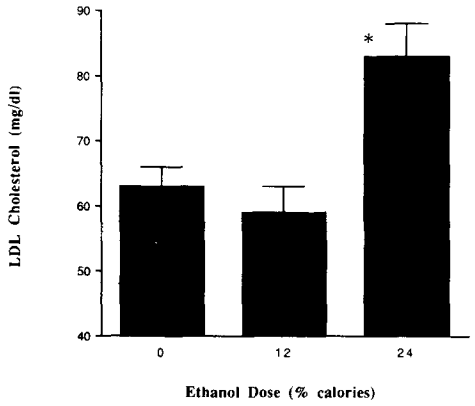

FIG. 3. Effect of ethanol dose on low density lipoprotein cholesterol concentration. Values represent mean ± SEM for 6–8 monkeys/group expressed as mg/dL. * indicates significant difference (P<0.05) between 24% EtOH dose and both 0 and 12% means.

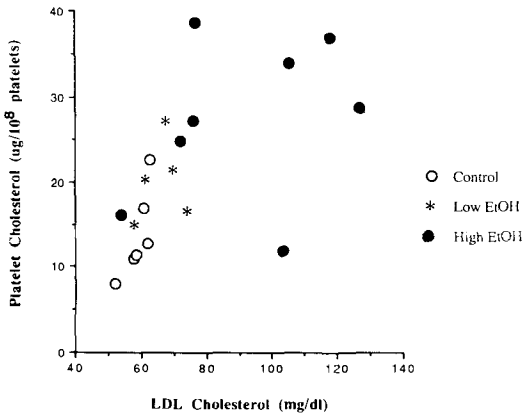

FIG. 4. Relationship between low density lipoprotein cholesterol and platelet cholesterol as a function of ethanol dose. Values for platelet cholesterol ($\mu g/10^8$ platelets) plotted against LDL cholesterol (mg/dL). P = 0.007, r = 0.601.

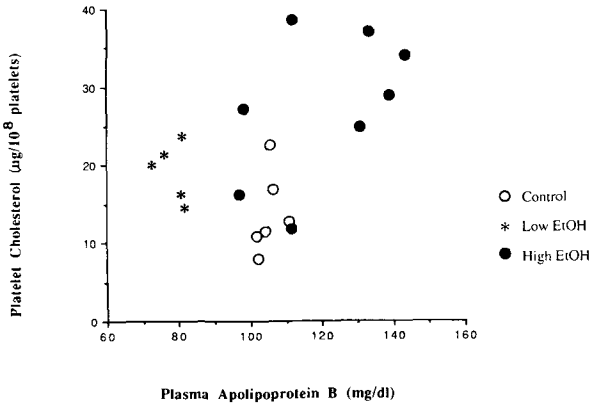

FIG. 5. Relationship between plasma apolipoprotein B and platelet cholesterol as a function of ethanol dose. Values for platelet cholesterol ($\mu g/10^8$ platelets) plotted against plasma apolipoprotein B (mg/dL). P = 0.058, r = 0.441.

DISCUSSION

Several pathophysiologic mechanisms may be responsible for increased or decreased risk of atherosclerosis and cardiovascular disease associated with alcohol consumption. Plasma lipoproteins can either act as a "circulating insult" to the vascular wall and initiate and promote atherogenesis (low density lipoproteins), or participate in the removal of cholesterol from arteries and its transport to the liver for excretion (high density lipoproteins) (52,53). There is a variety of evidence that demonstrates that moderate ethanol consumption raises HDL resulting in (at least in part) a "coronary protective" effect (2, 54–56) while excessive intake may elevate plasma triglyceride and LDL and thus increase coronary risk (57–61). A second potential mechanism involves the hemostatic process and the relationship between the generation of vascular prostacyclin (PGI_2), a potent vasodilatory, platelet antiaggregatory eicosanoid, and platelet thromboxane A_2 (TXA_2), which has proaggregatory/vasoconstrictory properties (20,21). A predominant number of studies in the literature indicate that a moderate alcohol dose favors a shift to an increased PGI_2/TXA_2 ratio (14–18,21,62,63), while long-term, excessive consumption patterns may retard PGI_2 synthesis (64,65) and contribute to hyperactive platelets and enhanced TXA_2 formation (19,66). The latter sequence may thus explain the correlation between vasospasm/stroke and alcohol abuse (3,4,13).

Recently, a number of investigations have shown that lipoproteins may influence eicosanoid production (22–24). Moreover, both LDL and HDL are capable of altering platelet function (26,67–70). However, virtually no studies have examined the relationship between alcohol consumption, alterations in LDL, and changes in platelet activity. Consequently, we hypothesized that since alcohol causes dose-dependent modifications in atherogenic LDL in squirrel monkeys (Fig. 3), these alterations would influence platelet composition/function, which in turn might explain alcohol's observed effects on cardiovascular disease risk. Since platelets do not retain their capacity

for *de novo* sterol synthesis, they may obtain their membrane cholesterol from the surrounding circulatory environment *via* receptor mediated binding and uptake of the LDL ligand, apolipoprotein B-100 (30,71-73). Abnormal platelet cholesterol/phospholipid ratios and concomitant platelet dysfunction have been observed in patients with atherosclerosis and in individuals with familial hypercholesterolemia (69,74-76), both of which may result from excessively high levels of circulating LDL. In addition, the cholesterol/phospholipid (C/PL) ratio in normal platelets is increased following *in vitro* incubation with serum from patients with liver disease which contains a high LDL C/PL ratio (77). Consequently, the elevation in platelet cholesterol in High EtOH primates may be related to a concurrent increase in the circulating pool of LDL (Fig. 3) as suggested by the data presented in Figures 4 and 5. Alternatively, the increased platelet sterol mass in our monkeys could have originated from elevated concentrations of cholesterol in precursor megakaryocytes (78).

The greater amount of platelet cholesterol present in High EtOH primates (Fig. 2) should cause increased membrane rigidity, increased platelet TXA_2 formation and promote aggregation (35,74,76,79-81). However, increased platelet responsiveness was not observed during the collagen stimulated platelet-TXB_2 experiments (Results). Consequently, some type of adaptive response(s) may have taken place to offset the elevated platelet membrane cholesterol. For example, repeated exposure of circulating platelets to plasma ethanol (49-68 mg/dL, Low EtOH primates, 142-159 mg/dL, High EtOH animals) (10,82) would have a fluidizing effect on their membranes over the short-term and could thus influence platelet activity (79,81,83,84). However, chronic exposure of cell membranes to EtOH may, by contrast, increase their rigidity (85). Therefore, of greater importance may be the compensatory physicochemical changes in platelet membrane lipid composition which occurred in our high alcohol primates after four months of treatment. Indeed, with increasing alcohol dose, there was also a commensurate increase in membrane phospholipid (Fig. 2), which although not significantly different from Controls, apparently was elevated enough to modulate the cholesterol/phospholipid molar ratio which did not change appreciably (Results). Therefore, it is possible that the elevated platelet phospholipid in High EtOH monkeys would offset the cholesterol increase, maintain membrane fluidity, and thus contribute to an equilibrium between these lipids in the membrane structure (74,76). And finally, an increase in the platelet phospholipid polyunsaturated/saturated (P/S) fatty acid ratio in the High EtOH treatment group (Table 2) would render the membrane bilayer structure less rigid, increase membrane molecular motion (fluidity) (76,81), and thus counterbalance the cholesterol increase.

Another interesting finding was that High EtOH platelets tended to have elevated absolute and relative concentrations of phospholipid arachidonic acid (20:4), a precursor in TXA_2 synthesis (Table 2). Increased incorporation of 20:4 into phospholipids of cerebral cortical membranes has also recently been reported in mice fed ethanol for chronic periods (86). The source of the platelet 20:4 may be circulating LDL since High EtOH monkeys showed significant elevations in LDL phospholipid arachidonate (Table 2) and because earlier work has documented that platelets may acquire phospholipid components *via* transfer from plasma lipoproteins (87). This observation is significant for two reasons. First, the presence of adequate amounts fo 20:4 and its precursor (linoleic acid, 18:2) (Table 2) in platelets indicates that our animals did not exhibit essential fatty acid deficiency or prostanoid precursor depletion as has been reported in other studies involving long-term alcohol consumption (88-90). Second, although *in vitro* platelet aggregation, and presumably TXA_2 formation, is positively correlated with platelet 20:4 concentration (91), High EtOH platelets showed normal collagen-stimulated TXB_2 formation (Results) which was probably related to the lipid matrix fluidizing effects described above. The observed platelet lipid alterations in High EtOH primates (Table 2) would thus attenuate a potentially adverse increase in TXA_2 formation which has been observed in rats fed alcohol for chronic periods (19), and temper changes in phospholipase A_2 activity which may be stimulated in response to elevated concentrations of low density lipoproteins (Fig. 3) (35).

In conclusion, results from our experiments are consistent with a growing body of evidence that a relationship exists between platelet composition and plasma lipoproteins (22-35,68-73,75,92-105). Our study has advanced present knowledge of this relationship by showing that alterations in the former may be linked to alcohol-mediated changes in the latter. In general, the low alcohol dose (12%) fed to squirrel monkeys had little effect on plasma lipids or platelet parameters. By contrast, although high level alcohol (24%) consumption over a chronic drinking period increased platelet cholesterol and produced an elevation in plasma LDL cholesterol and apolipoprotein B (10), potentially thrombogenic effects (platelet aggregate and TXB_2 formation) may have been averted by adaptive changes in platelet lipid composition. Nevertheless, persistent, high circulating levels of LDL may be particularly detrimental not only because of their well documented role in arterial lipid deposition (52) and their adverse effect on platelet and endothelial cell function (30,35,71,106), but also because this lipoprotein class has recently been shown to be capable of inducing aortic vasoconstriction (107).

Metabolic Transformation of Intracraneally Injected [1-^{14}C]Linoleic and [1-^{14}C]α-Linolenic Acids in Malnourished Developing Rats

Maria Elena De Tomás*, Osvaldo Mercuri[1] and Cristina Serres
Instituto de Investigaciones Bioquimicas de La Plata (INIBIOLP), Facultad de Ciencias Medicas, (1900) La Plata, Argentina

The effect of a low protein diet during pregnancy and lactation on the fatty acid composition of phosphatidylcholine (PC) and phosphatidylethanolamine (PE) from brains of ten-day-old rats was studied. The results indicated that partial deprivation of protein during early development was associated with an increase in the fatty acids of the n-9 family in PC. The fatty acids of the linoleic acid series decreased in PE but were not modified in PC. These minor changes did not affect the double bond index values either in PC or in PE. The effect of protein depletion on the *in vivo* metabolic transformation of intracraneally injected [1-^{14}C]linoleic and [1-^{14}C]α-linolenic acids was also studied. The percentage distribution of the labeled precursors and their derivatives among PC and PE differed from that of mass distribution. These results indicate that the direct uptake of polyunsaturated fatty acids from the blood and/or the low turnover rate of these acids incorporated into PC and PE might be involved in maintaining the fatty acid pattern of these brain lipids. *Lipids 26,* 891-894 (1991).

Neither linoleic (18:2n-6) nor α-linolenic (18:3n-3) acid can be synthesized by animals; therefore, they are defined as essential fatty acids (EFA). Nevertheless, these acids are precursors of longer chain endogenously synthesized n-6 and n-3 fatty acids which are important constituents of tissue lipids.

Long-chain polyunsaturated fatty acids (PUFA) of both series are synthesized through processes which include chain desaturation and elongation. The desaturation steps are influenced by dietary and hormonal changes described previously (1).

In earlier experiments (2) we demonstrated that liver fatty acid desaturase activities are greatly affected by maternal protein deficiency and suggested that this fact would alter the normal supply of PUFA to the fetus. Furthermore, the adverse influence of protein restriction during pregnancy and lactation upon the activities of the desaturases may contribute to the lack of PUFA observed in the liver of the early developing rat (3,4). Narce *et al.* (5) reported that the effects of protein deprivation in the adult rat on the activities of liver desaturases were not strictly paralleled by changes in the lipid fatty acid composition.

The desaturating enzymes were also studied in brain, because PUFA constitutes the major proportion of the brain phospholipid fatty acids. It was demonstrated that the activity of desaturating enzymes in brain falls very rapidly in the rat after the first week of post-natal life (6-11). Thus, malnutrition during the critical stage of brain growth can cause defects in the metabolism of EFA. Moreover, *in vitro* experiments using brain microsomes (12) clearly demonstrated a deleterious effect of protein deficiency on EFA metabolism when the enzymatic systems were still active.

We undertook this study to determine the effect of a low protein diet during both the prenatal and postnatal periods (until 10 days after birth) on the *in vivo* brain metabolism of intracraneally injected [1-^{14}C]linoleic and [1-^{14}C]α-linolenic acids.

MATERIALS AND METHODS

[1-^{14}C]linoleic acid (specific activity 52 mCi/mmol) and [1-^{14}C]α-linolenic acid (specific activity 41.5 mCi/mmol) were purchased from Radiochemical Centre (Amersham, England). They were 98% radiochemically pure. Gas-liquid chromatographic supplies were purchased from Nu-Chek Prep (Elysian, MN) and Supelco (Bellefonte, PA). All organic solvents were reagent grade and were obtained from Mallinkrodt (St. Louis, MO).

Fatty acid methyl esters used as standards in gas-liquid chromatography were purchased from Sigma Chemical Company (St. Louis, MO).

Animals and diets. Female Wistar rats weighing 150-170 g were divided into two groups after mating. The dams were fed the diets given in Table 1 throughout gestation and lactation. On parturition, five pups of both sexes from each group were allowed to remain with the mother.

In vivo *tracer experiments employing 10-day-old pups.* Five μCi of [1-^{14}C]linoleic acid or 10 μCi of [1-^{14}C]α-linolenic acid as an albumin complex in 5 μL of saline solution was injected intracraneally slightly above and between the eyes by means of a Hamilton microsyringe as described by Dhopeshwarkar and Subramanian (7). The pups were returned to the mother and 8 hr later they were sacrified. The brains were excised, washed in distilled water, and blotted. The brains were then cut through the olfactory lobes and the cerebral peduncles and weighed. Only the cerebrum was used for analyses.

Cerebral lipid analyses. The cerebral lipids were extracted according to Folch-Pi *et al.* (13), and the mixture was stirred overnight at room temperature under a N_2 atmosphere (7). Lipid classes of the extract were fractionated by thin-layer chromatography according to Wagner *et al.* (14). The plates were scanned in a Berthold II Scanner to obtain the distribution of radioactivity in the lipid fractions, and by comparing their R_f values with those of authentic standards.

Phosphatidylcholine (PC) and phosphatidylethanolamine (PE) fractions were isolated and extracted from the silica-gel using the method of Arvidson (15). Plasmalogen-free PE was obtained according to Waku and Lands (16). Fatty acid methyl esters were obtained by transesterifica-

[d]Each kilogram of diet contained the following vitamins (in milligrams): thiamin, 10; riboflavin, 10; pyridoxine, 10; Ca pantothenate, 50; niacin, 25; inositol, 1000; biotin, 20; choline chloride, 1000; vitamin B-12, 0.1; dl-α-tocopherol, 30; menadione, 50; vitamin A, 3000 IU; and vitamin D, 800 IU.

tion (17) and analyzed (before and after hydrogenation over platinum oxide) in a Panax radio-gas chromatograph with a glass column (1.50 m × 4 mm) packed with 10% SP 2330 and programmed temperature from 140–220°C at 3°C/min.

The fatty acid compositions of PC and PE were determined by gas-liquid chromatography (GLC) using a Shimadzu GC-RIA chromatograph (Kyoto, Japan).

RESULTS

Table 2 shows the fatty acid composition of PC and PE fractions from brains of control and malnourished ten-day-old pups. A striking finding was the similarity in the fatty acid composition of PC from the two dietary groups with the exception of a small but significant increase in the fatty acids from the n-9 family in the malnourished group. The effect of protein deficiency on the n-6 fatty acids was apparently different between PE and PC, because the concentration of fatty acids of the linoleic acid series decreased in PE but was not modified in PC. Minor changes in the n-3 fatty acid concentrations were observed in the brain PC and PE from rats on the low protein diet compared to the control diet. These minor changes in the long-chain unsaturated fatty acid composition promoted by protein depletion did not affect the double bond index values either in PC or in PE.

Table 3 shows the percent distribution of radioactivity of [1-^{14}C]18:2n-6 and its derivatives incorporated into PC and PE. In the PC fraction, the linoleic acid fraction retained the major radioactivity in both groups of rats. Nevertheless, the malnourished group showed a significant increase in the proportion of this radioactive substrate that remained without metabolic transformations. The n-6 acids, other than 18:2n-6, incorporated in PC and PE were the desaturation products of Δ6, Δ5 and Δ4 desaturases and/or of chain elongation (Fig. 1). Gamma-linolenic acid (γ-18:3n-6), the product of Δ6 desaturation of 18:2n-6 and dihomogamma linolenic acid (20:3n-6), the product of elongation of γ-18:3n-6, were decreased in the malnourished group. Arachidonic acid (20:4n-6), the product of Δ5 desaturation of 20:3n-6, was also decreased as a consequence of protein malnutrition. The activity of the Δ4 desaturase was practically negligible because no radioactivity was detected in the 22:5 n-6 incorporated into the PC fraction. Despite the decrease in the radioactivity incorporated into 20:2n-6, ^{14}C in the other fatty acids derived by the elongation pathway, 22:3n-6 and 22:4n-6, was increased in the malnourished group. The ratio ^{14}C in 18:2n-6/Σn-6 − 18:2n-6, increased from 1.47 in the control group to 2.38 in the malnourished group. The [1-^{14}C]18:2n-6 that was not metabolically transformed was drastically increased in the brain PE of malnourished animals. Meanwhile, the desaturation products of 18:2n-6 were significantly diminished with the exception of 22:4n-6 which remained at the same level as in the control group. The ratio ^{14}C in 18:2n-6/Σn-6 −

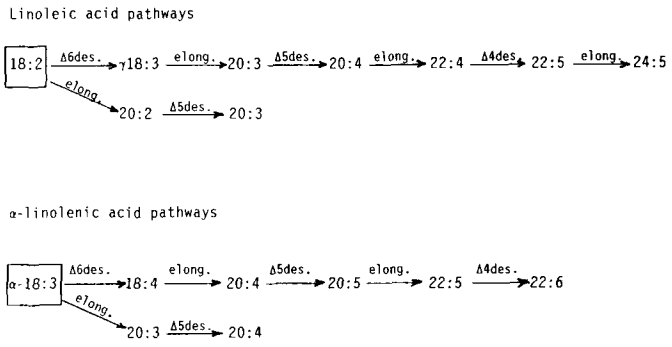

FIG. 1. Steps in the metabolism of linoleic and α-linolenic acids.

18:2n-6 increased in the PE fraction from 0.30 in the control group to 1.39 in the malnourished group.

Table 4 shows the incorporation of the intracraneally injected [1-^{14}C]α-linolenic acid into brain PC and PE fatty acids. Of the total radioactivity incorporated into brain fatty acids in the control group, sixty percent in PC and thirty percent in PE were in the fatty acids synthesized *de novo* from labeled acetate, a product of the β-oxidation of [1-^{14}C]α-18:3n-3. The radioactive tracer that was not metabolically transformed was significantly increased in the PC fraction from the malnourished group. A decrease in the radioactivity incorporated in PE as 22:6n-3 and an increase in the incorporation of labeled 22:4n-3 were observed. Protein depletion promoted an increase in the ratio ^{14}C in α-18:3n-3/Σn-3 − α18:3n-3 in PC and PE from 0.40 to 0.69 and 0.24 to 0.36, respectively.

DISCUSSION

It is clear from the data presented that only minor changes in the fatty acid pattern of brain PC and PE were observed in the malnourished rats. These findings indicate the stability of these structural lipids in this highly differentiated tissue.

A question addressed by our study was the degree to which intracraneally injected [1-^{14}C]18:2n-6 was desaturated and chain elongated. The increase in the ratio 18:2n-6/Σn-6 − 18:2n-6 in the PC and PE fractions promoted by protein depletion indicated that the amount of *in vivo* desaturation/elongation products from 18:2n-6 was significantly diminished in the brain of malnourished animals. Nevertheless the ^{14}C in the fatty acids derived by the elongation pathway, 22:3n-6 and 22:4n-6, was increased in the malnourished group.

The present data and results from other laboratories using *in vivo* techniques (18–20) do not as yet permit conclusion as to the elongation pathways that lead to the formation of PUFA in brain. The major uncertainty in our study is the extent to which malnutrition contributes to the alteration of the normal pattern of fatty acid elongation.

^{14}C-Incorporation of the intracraneally injected [1-^{14}C]α-18:3n-3 into PC and PE fatty acids illustrated the special susceptibility of α-18:3n-3 to oxidation as was previously noted (21,22). The results are consistent with those reported by Anderson and Connor (23) and Crawford and Harbige (24). Only the radioactivity of 18:0 decreased in PC of the malnourished group, while an increase in radioactivity in PE 16:0 was promoted by protein depletion during early development.

The precursor/product ratio of PUFA derived from [1-^{14}C]α-18:3n-3 supports the assumption that the activities of the enzymes involved are diminished in the

brain of malnourished animals. On the other hand, the decreased amount of radioactivity incorporated in PE as 22:6n-3 was apparently compensated in part by an increase in the incorporation of labeled 22:4n-3, the product of elongation of 20:4n-3.

The present data do not allow conclusion as to the extent to which EFA metabolism would contribute to the maintenance of the fatty acid pattern of brain PC and PE. It is also not clear to what extent the direct uptake of PUFA from the blood (25) and/or a low turnover rate of these acids would be involved.

Arachidonic Acid, Prostaglandin E_2 and Leukotriene C_4 Levels in Gingiva and Submandibular Salivary Glands of Rats Fed Diets Containing n-3 Fatty Acids[1]

S.Q. Alam*, B.M. Bergens and **B.S. Alam**
Department of Biochemistry and Molecular Biology, LSU Medical Center, New Orleans, Louisiana 70119

The effect of dietary n-3 fatty acids on prostaglandin E_2 (PGE_2) and leukotriene C_4 (LTC_4) levels in rat salivary glands and gingiva was examined in two separate nutritional studies. In the first set of experiments, two groups of male weanling Sprague-Dawley rats were fed semipurified diets containing 10% corn oil (control group) or 10% menhaden oil (experimental group). Rats were killed after 8 wk on the diets; the fatty acid composition of total phospholipids and the concentrations of PGE_2 and its precursor, arachidonic acid, were measured in gingiva and submandibular salivary glands (SMSG). Dietary n-3 fatty acids were incorporated into the tissue phospholipids. Arachidonic acid levels were reduced by 56% in gingiva and SMSG of rats fed menhaden oil compared with the control rats fed the diet containing corn oil. The concentrations of PGE_2 in SMSG and gingiva of rats fed the diet containing menhaden oil were reduced by 74% and 83%, respectively. In a subsequent nutritional study, we tested whether the diet-induced reduction in tissue arachidonic acid levels would also result in a corresponding decrease in LTC_4 production. Three groups of rats were fed diets containing 5% corn oil (group 1), 4% ethyl ester concentrate of n-3 fatty acids plus 1% corn oil (group 2), or 5% ethyl ester concentrate of n-3 fatty acids (group 3). After 6 wk of feeding, gingiva and SMSG were analyzed for arachidonic acid content and *in vitro* production of LTC_4. Arachidonic acid content of total phospholipids was about 60% lower in gingiva and 69% lower in SMSG of rats fed the ethyl ester concentrate of n-3 fatty acids (groups 2 and 3) than those of the control group fed the corn oil diet (group 1). Upon incubation with calcium ionophore, gingiva and SMSG from rats fed the n-3 fatty acids rich diet produced significantly less LTC_4 than those from rats of the control group. Because PGE_2 and LTC_4 are believed to be important biochemical mediators of periodontal disease, one may speculate that a diet-induced reduction in their levels may have a beneficial effect upon the course of the disease. The function of salivary glands may also be altered because of the role of these eicosanoids in salivary secretions.
***Lipids* 26, 895-900 (1991).**

Arachidonic acid is released from cell membrane phospholipids mainly *via* the action of a calcium-dependent phospholipase A_2 (1). To a lesser extent, some arachidonic acid is released by diacylglycerol lipase action upon diacylglycerol, which is one of the products of phospholipid degradation by phospholipase C. There are basically two pathways for arachidonic acid metabolism. One is the cyclooxygenase pathway which produces prostaglandins (PG), thromboxanes (TX), and prostacyclins (2). The other pathway is the lipoxygenase pathway which results in the production of a variety of biologically active hydroxyeicosatetraenoic (HETE) acids and the leukotrienes, which are known mediators of the acute vascular changes that accompany the process of inflammation (3,4). Many reports show that cyclooxygenase products of arachidonic acid are present in much higher concentrations in inflamed than in healthy tissue (5,6). The products of arachidonic acid metabolism also contribute to bone resorption (7). A several-fold increase in the content of PGE_2 in gingival fluid and gingival tissue from patients with periodontal disease has been observed compared to the PGE_2 content in normal healthy gingiva (8-10).

An excess of arachidonic acid metabolites can be potentially injurious to gingival tissues. The n-3 fatty acids have been shown to reduce or counteract the effects of arachidonic acid metabolites. A previous study from our laboratory had shown an incorporation of these fatty acid into the submandibular salivary gland lipids (11). The n-3 fatty acids give rise to the series of prostaglandins 3 and thromboxane 3, which inhibit the release of arachidonate from phospholipids and the formation of PGE_2 and thromboxane 2 (12). The eicosanoids derived from n-3 fatty acids exhibit a spectrum of biological activity that differs from that of the arachidonic acid metabolites. Thus, research into the effects of n-3 fatty acids on arachidonic acid and its metabolites in gingiva is important. These fatty acids from the dietary sources could possibly improve gingival health by decreasing inflammation and bone loss in periodontal disease. One of the objectives of the present investigation was to determine if the levels of prostaglandin E_2 (PGE_2), leukotriene C_4 (LTC_4) and their precursor, arachidonic acid, can be altered in gingiva as a result of feeding diets rich in n-3 fatty acids.

Prostaglandins and leukotrienes have also been shown to influence the secretion of saliva. An increase in cAMP content of rat salivary acini *in vitro* (13), and a decrease in salivary flow (14,15) have been reported by PGE_1 and PGE_2. Similarly, it was reported that physiological levels of PGI_2, PGE_2 and $PGF_{2\alpha}$ stimulated the release of rennin from the mouse submandibular salivary gland (SMSG) slices *in vitro* (16). The products of the lipoxygenase pathway of arachidonic acid metabolism, such as LTC_4 and LTD_4, reduced methacholine- and substance P-induced salivary flow in rats (17). It has been reported that among several murine tissues, the SMSG, had the highest ability to synthesize PGE_2 *in vitro* (18). The presence of

Abbreviations: EEC, ethyl ester concentrate; FAME, fatty acid methyl esters; GC/MS, gas chromatography/mass spectrometry; HETE, hydroxyeicosatetraenoid(s); L, leukotriene; PG, prostaglandin(s); SMSG, submandibular salivary glands; TX, thromboxane(s).

PGE_2, $PGF_{2\alpha}$, PGI_2, TXB_2 and HETE in rat, rabbit and human saliva has been reported (19–21). In view of the important role of eicosanoids in salivary gland secretion, another objective of our studies was to determine the effects of feeding diets rich in n-3 fatty acids on the levels of arachidonic acid, PGE_2 and LTC_4 in SMSG.

MATERIALS AND METHODS

Experiment 1. Male weanling Sprague-Dawley rats (Holtzman Co., Madison, WI) were fed regular rat ration for 7 days to acclimate them to the laboratory conditions. Rats were weighed and randomly divided into two groups with the same average body weight per group. Rats were housed individually in suspended stainless-steel cages in a temperature and light-controlled room (22–23°C, 12-hr light-dark cycle) and were given diets and tap water *ad libitum*. Rats were weighed weekly and their food intake was also measured. Diets were prepared every week and stored at 4°C. Unused diet before each feeding was discarded to minimize rancidity of the fed oils. The diets were similar to the American Institute of Nutrition (AIN-76A) diet (22,23), with 10% corn oil added to the control group and 10% menhaden fish oil added to the experimental group. Composition of the diets was as follows (in wt %): casein, 20.0; DL-methionine, 0.3; choline, 0.2; mineral mixture, 3.5; cellulose, 5.0; sucrose, 45.0; starch, 15.0; oil, 10.0; vitamin mixture (AIN-76A), 1.0. Menhaden oil, which was obtained under the Fish Oil Test Material Program, National Institutes of Health (NIH), Bethesda, MD, contained supplements of antioxidants to prevent autooxidation. Therefore, in order to equalize the antioxidant content of the two diets, α-tocopherol (0.1%), γ-tocopherol (0.1%) and *t*-butylhydroquinone (0.02%) were added to the diet containing corn oil. The fatty acid composition of the two diets has been previously reported (11). The corn oil diet contained 58% of 18:2n-6 as the main fatty acid and only trace amounts of n-3 fatty acids. The menhaden oil-diet had high levels of n-3 fatty acids (20:5, 15.5%; 22:5, 2.2%, and 22:6, 8.6%; all values are as % of the total fatty acids) and low levels of n-6 fatty acids (1% 18:2).

Rats were killed at the end of 8 wk of feeding the diets. Gingivae and SMSG were quickly dissected while the tissues were immersed in ice-cold physiological saline-indomethacin solution (5 μg/mL) to inhibit prostaglandin synthesis. The tissues were blotted dry, weighed, and immediately frozen in liquid nitrogen.

Extraction and measurement of PGE_2. Gingivae and SMSG from each rat were separately homogenized in glass homogenizer with ethanol (4 × 1 mL). The ethanolic extracts were filtered and the filtrates were dried under nitrogen. Water (1 mL) was added and the pH was adjusted to 3.5 with 2 N HCl. The acidified extracts were passed through a C-18 column (Sep-Pak, J.T. Baker Chemical Co., Phillipsburg, NJ) and PGE_2 was eluted with 0.5 mL of methanol. The solvent was evaporated under nitrogen and the residue was dissolved in an assay buffer. Suitable aliquots were assayed by radioimmunoassay (Prostaglandin E_2 [^{125}I] RIA Kit, NEN, Dupont, Boston, MA). According to the supplier, the stated cross-reactivity of the antiserum was 100% for PGE_2, 3.7% for PGE_1 and <1% for other prostaglandins. The cross-reactivity against PGE_3 was not measured. In separate experiments, the recovery of PGE_2 was also measured in triplicate samples after the addition of [^{3}H]PGE_2 to the tissue homogenates following the above procedure. Methanolic eluates containing [^{3}H]PGE_2 from the C-18 columns were counted for radioactivity using a liquid scintillation counter (Beckman LS 6800, Fullerton, CA). The recovery of [^{3}H]PGE_2 was 38% for gingiva and 43% for SMSG. The recovery of PGE_2 was not influenced by the previous dietary treatment.

Fatty acid composition and arachidonic acid levels (Experiment 1). Lipids were extracted from aliquots of tissue homogenates by homogenizing with chloroform/methanol (2:1, v/v) containing butylated hydroxytoluene (5 mg/100 mL) as an antioxidant. The concentrations of arachidonic acid in the total lipid extracts were measured by gas chromatography, using an internal standard (6,9,12,15-octadecatetraenoic acid, 18:4), which was added prior to lipid extraction. Phospholipids were separated by column chromatography (Bio-Sil A, 100-200 mesh, Bio-Rad Laboratories, Richmond, CA), and fatty acid methyl esters (FAME) were prepared using boron trifluoride/methanol (24). The fatty acid composition was determined by gas chromatography on a 15% Silar 10 C column (3.66 m × 2 mm i.d.) using isothermal conditions as previously described (25).

Experiment 2. The purpose of this study was to determine whether a diet-induced reduction in arachidonic acid concentrations of phospholipids would result in a concomitant reduction in the *in vitro* production of leukotriene C_4 by gingiva and the SMSG. Three groups of male weanling Sprague-Dawley rats were fed semipurified diets (Basal diet was AIN-76A) containing 5% corn oil (group 1), 1% corn oil plus 4% ethyl ester concentrate of n-3 fatty acids (group 2), or 5% ethyl ester concentrate of n-3 fatty acids (group 3). The ethyl ester concentrate (EEC) of n-3 fatty acids, which was obtained from the Fish Oil Test Material Program, NIH, had 78.5% of the total fatty acids as n-3, with 20:5 (43.9%) and 22:6 (24.0%) as the major fatty acids. The EEC also contained 3.4% of the total fatty acids as n-6, with 20:4 constituting 2.3% of the total. Our reason for using the EEC n-3 instead of menhaden oil, which was used in Experiment 1, was that the EEC n-3 contained 3-fold higher levels of n-3 fatty acids than menhaden oil. In this nutritional study we included an additional group (4% EEC n-3 plus 1% corn oil) to exclude the possibility of inadvertently inducing essential fatty acid deficiency. Although EEC of n-3 fatty acids contained only 0.1% 18:2n-6, the addition of 1% corn oil supplied adequate amounts (1.5% of total calories) of 18:2n-6.

Rats were killed after 6 wk of feeding the various diets, SMSG and gingivae were dissected. About one-half of the tissue was frozen immediately in liquid nitrogen, the remaining (0.05–0.1 g for gingiva and 0.2–0.3 g for SMSG) was cut into small pieces with a razor blade and incubated at 37°C for 10 min in 1 mL of Tris buffer, pH 7.4, 0.05 M, in the presence of calcium ionophore, A23187 (10 μM). After incubation, 20 μL of 4.75 M formic acid was added and the contents were frozen at −75°C until analyzed.

Extraction and assay of LTC_4. The contents (tissue plus the incubation medium) were homogenized with 1 × 3 mL of ice-cold absolute ethanol in a ground glass tissue homogenizer. After centrifugation at 12,000 × *g* for 20 min in a refrigerated centrifuge, the supernatant was transferred to a graduated tube. Ethanol was evaporated under N_2 by heating the tube at a temperature less than

40°C. The volume was reduced to 1 mL, and 2.3 mL of H_2O was added to bring the ethanol concentration to about 15% according to the method of Powell (26). The pH of the extract was between 3–3.5.

Partial purification of LTC_4 was obtained by column chromatography over Amprep Ethyl C2 minicolumns (100 mg size, Amersham Corp., Arlington Heights, IL). The columns were washed with 2 mL methanol, followed by 2 mL of H_2O. The tissue extracts containing LTC_4 were applied to the column and then washed sequentially with 1 mL of 15% ethanol, 1.5 mL of H_2O, 2 mL of hexane, and 1.5 mL of 10% ethanol/8% HCl. The LTC_4 fraction was collected by eluting the column with 2 mL of methyl formate. Aliquots of the methyl formate fraction containing LTC_4 were dried under nitrogen, the residue was dissolved in the assay buffer and analyzed by radioimmunoassay. The recovery of a standard of [^{3}H]-LTC_4, when added to duplicate samples, by using the above column chromatographic procedure, was 35% for gingiva and 40% for SMSG. The recovery was not affected by the dietary treatment.

The LTC_4 concentrations in methyl formate fractions eluted from the columns were measured by using the leukotriene C_4 specific [^{3}H]assay system (monoclonal antibody) purchased from Amersham and the radioactivity was measured using a liquid scintillation counter. The stated cross-reactivity of the LTC_4 antibody, as provided by the supplier, was 5.4% against LTD_4, 0.5% against LTE_4 and <0.001% against LTB_4. The cross-reactivity against LTC_5 was not measured.

Fatty acid composition and arachidonic acid concentrations of phospholipids (Experiment 2). Lipids were extracted by the method of Folch *et al.* (27) from the tissues which were frozen in liquid nitrogen immediately after dissection. Total lipid extracts were filtered under nitrogen over a sintered glass funnel, extracts were washed with 0.2 vol of 0.9% KCl, and the volume was adjusted to 6 mL with chloroform. Aliquots (2 mL) of this total lipid extract were subjected to column chromatography on silicic acid columns, and the phospholipid fraction was isolated. The fatty acid composition of total phospholipids was determined after transesterification with 14% BF_3/methanol (24). To quantitate the levels of arachidonic acid in total phospholipids, 10–20 μg of an internal standard (6,9,12,15-octadecatetraenoic acid, 18:4n-3) was added prior to transesterification. This fatty acid could be safely used as an internal standard because it behaves like arachidonic acid in terms of its chemical properties and it was not found in tissue phospholipids or in blood plasma phospholipids of rats fed diets containing corn oil or n-3 fatty acids (Alam, S.Q., unpublished observations).

For gingival phospholipids, FAME were analyzed by gas chromatography on a megabore column (15 m × 0.53 mm FSOT, DB-Wax, 1.0 μm, J & W Scientific, Folsom, CA). Column temperature was programmed from 70°C (initial temperature for 1 min) to 210°C at 8°C/min. The detector temperature was 250°C and the injection port temperature was 225°C. Under these conditions, all FAME could be readily separated within 30 min. The identification was based upon relative retention data using standards.

The fatty acid composition of phospholipids from SMSG was determined by gas chromatography/mass spectrometry. A Hewlett-Packard gas chromatograph, Palo Alto, CA, (Model 5890) with a mass selective detector (Model 5970) was used. FAME were analyzed on a fused silica capillary column (DB-23, 20 m × 0.172 mm, i.d., J & W Scientific). The samples were injected in a split mode. The column temperature was programmed from a 3-min hold at 140°C to 220°C at 5°C/min. The detector and injector temperatures were 280°C and 250°C, respectively. Electron impact spectra were obtained at 70 electron volt. FAME were quantitated by monitoring total ion currents.

Statistical analyses. Data on the fatty acid composition, arachidonic acid level and prostaglandin E_2 levels were analyzed for significance between the corn oil group and the menhaden oil group by using Student's t-test (Experiment 1). Similar comparisons were made for phospholipid fatty acid compositions, arachidonic acid levels and LTC_4 production in SMSG and gingiva between the corn oil group *versus* the two experimental groups fed diets containing EEC of n-3 fatty acids using Student's t-test (Experiment 2).

RESULTS

Two separate sets of animal studies were carried out during the last two years. The purpose of the first study (Experiment 1) was to determine the effects of feeding a diet rich in n-3 fatty acids on arachidonic acid and PGE_2 levels in gingiva and SMSG. The second study (Experiment 2) dealt primarily with the *in vitro* production of LTC_4 in these tissues as modulated by altering the *in vivo* concentration of arachidonic acid.

The fatty acid composition of phospholipids in the SMSG and gingiva of rats fed menhaden oil diet (Experiment 1) is shown in Table 1. Dietary n-3 fatty acids from menhaden oil were incorporated into the SMSG and gingival phospholipids. In phospholipids from tissue of

TABLE 1

Fatty Acid Composition of Phospholipids in Submandibular Salivary Gland and Gingival Homogenates of Rats Fed Diets Containing 10% Corn Oil or Menhaden Oil (Experiment 1)[a]

Fatty acid	SMSG		Gingiva

22:5n-3	tr	2.6 ± 0.1[d]	3.2 ± 0.2[d]
22:6n-3	tr	5.5 ± 0.4[d]	7.3 ± 0.4[d]

[a]Values are area percent (mean ± SEM of 3 rats/group). FAME were analyzed by gas chromatography/mass spectrometry (GC/MS). Values with superscripts in the same row are significantly different from those in the control group (5% corn oil) using Student's t-test. [b]P<0.05, [c]P<0.01, [d]P<0.001. [e]Significantly different (P<0.001) from the corresponding value in the 4% EEC n-3 plus 1% corn oil group. DMA, dimethylacetal; tr, trace.

TABLE 4

Major Fatty Acids in Total Phospholipids in Gingiva of Rats Fed Diets Containing Ethyl Ester Concentrate (EEC) of n-3 Fatty Acids (Experiment 2)[a]

Fatty acid	5% Corn oil	4% EEC n-3 + 1% corn oil	5% EEC n-3
16:0	17.4 ± 2.3	18.6 ± 1.9	16.8 ± 2.1
16:1	1.9 ± 0.2	3.4 ± 0.4[b]	3.9 ± 0.3[c]
18:0	17.1 ± 1.1	15.6 ± 1.0	16.3 ± 0.8
18:1	16.1 ± 1.0	16.5 ± 1.5	19.3 ± 1.1
18:2n-6	13.4 ± 0.8	7.1 ± 0.5[c]	1.7 ± 0.1[c,d]
20:4n-6	14.7 ± 1.5	6.1 ± 0.4[c]	6.3 ± 0.5[c]
20:5n-3	tr	5.2 ± 0.6[c]	6.6 ± 0.3[c]
22:4n-6	2.2 ± 0.5	tr	tr
22:5n-3	tr	1.0 ± 0.3[e]	2.9 ± 0.7[e]
22:6n-3	tr	9.0 ± 1.9[b]	11.5 ± 1.2[c]

[a]Values are area percent (mean ± SEM of 4-5 rats/group). Only the major fatty acids are reported. There were several minor fatty acids in each group which made up the remainder of the total fatty acids. Values with superscripts in the same row are significantly different from the corresponding values in the control group (5% corn oil) using Student's t-test. [e]P<0.05, [b]P<0.01, [c]P<0.001. [d]Significantly different (P<0.001) from the corresponding value in the 4% EEC n-3 plus 1% corn oil group; tr, trace.

rats fed the corn oil-diet, these fatty acids were present only in small amounts (<1.0%). The levels of linoleic and arachidonic acid were significantly lower (P<0.001) in phospholipids of SMSG or gingiva of rats fed 10% menhaden oil than those fed the 10% corn oil diet. The concentrations of arachidonic acid in total lipids were 2-2.5 fold lower and the endogenous PGE_2 levels were 4-6 fold lower in SMSG and gingiva of rats fed the diet containing menhaden oil than those fed the corn oil diet (Table 2).

The fatty acid composition of total phospholipids in SMSG and gingiva of rats fed ethyl ester concentrate (EEC) of n-3 fatty acids is shown in Tables 3 and 4, respectively. When compared with the control group (5% corn oil), phospholipids from the two experimental groups contained higher levels of n-3 and lower levels of n-6 fatty acids. The levels of linoleic acid in phospholipids of rats fed diets containing 4% EEC plus 1% corn oil were 33% lower in SMSG and 47% lower in gingiva than the corresponding levels in the control group. In the group fed 5% EEC without corn oil, the linoleic acid levels were only 7% of the control group (5% corn oil) in the SMSG and 13% of the control group in the gingiva. Arachidonic acid levels in the two experimental groups were 33% of the control values in the SMSG and 42-43% in gingiva. Similar to the total phospholipids, lower levels of n-6 fatty acids (18:2 and 20:4) and higher levels of n-3 fatty acids (20:5, 22:5 and 22:6) were observed in the phosphatidylcholine, phosphatidylethanolamine, and the phosphatidylserine plus phosphatidylinositol fractions which were isolated from SMSG and gingiva of rats fed the two experimental diets containing EEC of n-3 fatty acids (data not shown).

The concentrations of arachidonic acid in total phospholipids and the stimulated *in vitro* production of LTC_4

TABLE 5

***In vitro* Production of Leukotriene C_4 and Endogenous Arachidonic Acid Levels in Total Phospholipids of SMSG and Gingiva of Rats Fed Diets Containing Ethyl Ester Concentrate (EEC) of n-3 Fatty Acids (Experiment 2)[a]**

Dietary fat	SMSG		Gingiva	
	Arachidonic acid	LTC_4	Arachidonic acid	LTC_4
	(mg/g)	(ng/g)	(mg/g)	(ng/g)
5% Corn oil	4.5 ± 0.5	28.0 ± 2.4	0.70 ± 0.11	2.0 ± 0.22
4% EEC n-3 plus 1% corn oil	1.3 ± 0[b]	17.4 ± 1.7[d]	0.28 ± 0.03[b]	1.1 ± 0.06[b]
5% EEC n-3	1.4 ± 0.1[b]	1.5 ± 0.3[c]	0.28 ± 0.03[b]	1.1 ± 0.21[d]

[a]Values are mean ± SEM of 3–5 rats in each group. LTC_4 production was measured by radioimmunoassay after 10 min incubation of the SMSG or gingival tissue at 37°C in the presence of 10 μM calcium ionophore, A23187. Arachidonic acid concentrations in total phospholipids were measured using 18:4 as an internal standard. Values with superscripts in the same column are significantly different from those in the control group (5% corn oil) using Student's t-test ([d]P<0.02, [b]P<0.01, [c]P<0.001).

were significantly lower in the SMSG and gingiva of rats fed 4% EEC plus 1% corn oil or 5% EEC of n-3 fatty acids than those fed 5% corn oil (Table 5). In gingiva, the LTC_4 production in the two experimental groups was the same, 55% of the control group. However, in the SMSG, the LTC_4 levels were several fold lower in the group fed 5% EEC than in the group fed 4% EEC plus 1% corn oil.

DISCUSSION

Although there are a number of studies on the effects of dietary n-3 fatty acids on eicosanoid levels in tissues, this is the first report on gingiva and salivary glands. Our results with gingiva and SMSG are consistent with the observations made on several other tissues that the levels of arachidonic acid in phospholipids are decreased by feeding diets rich in n-3 fatty acids (28–32). This may partly be due to the lower linoleic acid levels in the fish oil diets and partly due to the inhibitory effects of n-3 fatty acids on the metabolic conversion of linoleic acid to arachidonic acid. The n-3 fatty acids have been shown to inhibit the activity of Δ6 desaturase (28), a rate-limiting enzyme for the synthesis of arachidonic acid from linoleic acid (33,34). There is some evidence that the n-3 fatty acids also inhibit the rate of conversion of eicosatrienoic acid (20:3n-6) into arachidonic acid by inhibiting Δ5 desaturase activity (29).

The endogenous levels of PGE_2 in gingiva and the SMSG were also significantly lower in rats fed a menhaden oil-containing diet than a corn oil diet. Similar observations have been made in other tissues (35–38). Eicosapentaenoic acid and docosahexaenoic acid, the major n-3 fatty acids present in fish oils, are known to competitively inhibit the utilization of arachidonic acid by cyclooxygenase (12,39,40). The reduction observed in PGE_2 levels was about 4-fold in SMSG and 6-fold in the gingiva. The corresponding reduction in arachidonic acid levels was 2–2.5 fold. Thus, in both tissues there was a greater reduction in the endogenous PGE_2 levels than in the arachidonic acid levels. Similar observations were made with respect to the stimulated *in vitro* production of LTC_4 in the SMSG (Table 5). Although the experimental group fed 5% EEC of n-3 fatty acids had arachidonic acid concentrations which were about one-third of those in the control group fed 5% corn oil, the LTC_4 production was 19–20 fold lower in the experimental group than the control group. Similar results have been reported for other tissues (41). A reduction of 87% in the levels of the stimulated LTB_4 production was reported in neutrophils from essential fatty acid-deficient rats as compared with the control rats, even though the arachidonic acid content was reduced by only 34%.

The SMSG from rats fed 1% corn oil with 4% EEC of n-3 fatty acids did not show a reduction of the same magnitude as did the rats fed 5% EEC in the production of LTC_4. This may partly be due to the conversion of 18:2n-6 to 20:4n-6 during the incubation period (10 min at 37°C), thus resulting in an increase in the arachidonic acid pool. At this point, however, we do not have experimental evidence for this.

A number of investigators (42–49) have shown that nonsteroidal anti-inflammatory drugs which inhibit cyclooxygenase can retard the progression of periodontal disease in experimental animals and humans. In view of a significant reduction in the levels of endogenous PGE_2 and lower *in vitro* production of LTC_4 in gingiva of rats fed diets containing n-3 fatty acids, it is possible that the progression of periodontal disease may be retarded in humans ingesting supplements of n-3 fatty acids or those consuming large amounts of fish. Further investigations are needed to determine if the production of other arachidonic acid metabolites of the cyclooxygenase and lipoxygenase pathways in gingiva is also decreased by a diet rich in n-3 fatty acids. If so, this may provide a practical approach to decrease the production of the biochemical mediators of inflammation and thereby affect the course of periodontal disease. Because the feeding of a diet containing n-3 fatty acids was associated with significant reductions in the levels of PGE_2 and LTC_4 in SMSG, it is possible that gland function may also be altered. PGE_2 and LTC_4 have been shown to affect salivary secretion (14–17).

Cholesterol Metabolism in the Rat Lactating Mammary Gland: The Role of Cholesteryl Ester Hydrolase

Kathleen M. Botham*
Department of Veterinary Basic Sciences, The Royal Veterinary College, London, NW1 OTU, United Kingdom

An acid cholesteryl ester hydrolase activity associated with a fraction containing mitochondria and lysosomes from rat lactating mammary glands was found to have a pH optimum of 5.0. Its sedimentation pattern was closely related to that of the lysosomal enzyme markers acid phosphatase and β-glucuronidase, suggesting that the activity is associated with the lysosomes. The enzyme was strongly inhibited by Cu^{2+}, but was inhibited little by other divalent metal ions. Acid cholesteryl ester hydrolase activity was almost completely abolished by *p*-hydroxymercuribenzoate, but this effect was reversed in the presence of an equimolar concentration of reduced glutathione (GSH), indicating that the enzyme requires free sulfhydryl groups for activity. These properties are similar to those of acid, lysosomal cholesteryl ester hydrolases found in other tissues. Acid cholesteryl ester hydrolase activity was 8–14 fold higher in mammary tissue from lactating as compared to virgin rats. Neutral cholesteryl ester hydrolase activities associated with the microsomal and cytosolic subcellular fractions were also increased in lactating glands, but to a lesser extent. In addition, a 2-fold increase in the activities of both the acid and microsomal neutral enzymes was seen during the first few days of lactation, while the cytosolic neutral activity remained constant. These results suggest that mammary gland cholesteryl ester hydrolases have a role in the regulation of cholesterol metabolism in mammary cells, and in the provision of cholesterol for secretion into milk. *Lipids 26,* **901–906 (1991).**

Cholesterol, an important component of milk fat, is secreted into milk during lactation in both esterified and unesterified form. Approximately 20–40% of milk cholesterol originates from *de novo* synthesis within the mammary gland, while the remaining 60–80% is derived from plasma lipoproteins (1–3). Cholesterol from both these sources, however, may be esterified and stored in the mammary gland as cholesteryl esters (4,5), which may in turn be hydrolyzed to unesterified cholesterol when required. In other tissues the immediate fate of lipoprotein cholesteryl esters after uptake is hydrolysis by an acid cholesteryl ester hydrolase located in the lysosomes (6). By contrast, intracellular stores of cholesteryl ester are hydrolyzed by enzymes with pH optima near neutral, located in the microsomal and soluble cell fractions (7,8). As both these types of cholesteryl ester hydrolase have regulatory roles in intracellular cholesterol metabolism in some tissues (6,7,9), similar enzymes in the mammary gland may play an important part in determining the cholesterol content of milk by regulating the amount available for secretion.

We have shown previously that the rat lactating mammary gland contains an acid cholesteryl ester hydrolase associated with the mitochondrial/lysosomal subcellular fraction, and two neutral activities found in the microsomal and cytosolic compartments (10). Tawil *et al.* (11) have also found cholesteryl ester hydrolases with pH optima near neutral in rat mammary tissue. Studies of the microsomal and cytosolic enzymes provide evidence for modulation of their activity by phosphorylation-dephosphorylation (12), suggesting that these enzymes are under hormonal control and have a regulatory role in mammary gland cholesterol metabolism.

In the current work, the properties of the acid cholesteryl ester hydrolase found in lactating glands in our earlier report (10) were investigated, and the activities of the acid and neutral enzymes in non-lactating tissue were compared to those of lactating tissue. In addition, changes in the activities of the three cholesteryl ester hydrolases, which occur during the early lactation period, were examined.

MATERIALS AND METHODS

Cholesteryl oleate, phosphatidylcholine (type XI-E), oleic acid, sodium taurocholate, *p*-hydroxymercuribenzoate (sodium salt), phenylmethylsulfonyl fluoride, glutathione (reduced form) (GSH), bovine serum albumin (essentially fatty acid free) and 4-morpholino-ethanesulfonic acid (MES) (free acid and sodium salt) were obtained from Sigma (Poole, Dorset, United Kingdom). Cholesteryl [1-^{14}C]oleate and [1-^{14}C]oleic acid were supplied by Amersham International (Aylesbury, Bucks., United Kingdom).

Animals. Abdominal and inguinal glands were excised from lactating Wistar rats 2–9 days post-partum, or from virgin rats 15–20 weeks old. The glands were cleaned of fat and connective tissue, finely minced with scissors and homogenized using a glass Teflon homogenizer in 5 vol of Tris-HCl buffer pH 7.2 (50 mM), containing 0.25 M sucrose (homogenizing buffer).

Preparation of subcellular fractions. The homogenate was centrifuged at 800 × *g* for 10 min (4°C) in a swing-out rotor and the floating fat layer was removed and discarded. The supernatant was then centrifuged at 12,000 × *g* for 10 min (4°C) using a fixed angle rotor. After careful removal of the floating fat layer and the supernatant, the pellet was washed with 5 mL homogenizing buffer and resuspended in MES buffer pH 5.0 (100 mM). This fraction containing the mitochondria and lysosomes was used in all experiments with the acid cholesteryl ester hydrolase, except where indicated otherwise. Microsomal and cytosolic subcellular fractions were prepared from the 12,000 × *g* supernatant as before (12). For partial separation of mitochondrial and lysosomal enzyme activities in some experiments, the supernatant from the first centrifugation (800 × *g*) was centrifuged sequentially at 2,500 × *g*, 8,000 × *g* and 12,000 × *g* (10 min, 4°C) using a fixed-angle rotor, and the resulting pellets were washed and resuspended as described above.

Assay of cholesteryl ester hydrolase. Cholesteryl ester hydrolase activities were determined by measuring the

release of [1-^{14}C]oleic acid from cholesteryl [1-^{14}C]oleate. The substrate was used as a mixed micelle with phosphatidylcholine and sodium taurocholate in molar ratios of 1:4:2 respectively, essentially as described by Hajjar *et al.* (13). Cholesteryl [1-^{14}C]oleate (185 KBq, 1.92 GBq/mmol) was added to a toluene solution containing phosphatidylcholine (57.6 μmol) and non-radioactive cholesteryl oleate (14.4 μmol) and the solvent was removed under a stream of nitrogen. Lipids were then resuspended in 5 mL Tris-HCl buffer pH 7.0 (50 mM) containing sodium taurocholate (28.8 μmol, 5.76 mM) and sonicated using a 0.5-inch horn for a total time of 30 min at 46°C. The resulting solution was centrifuged at 1,500 × *g* (10 min, room temperature) to remove metal fragments from the sonicator horn. Cholesteryl oleate/phosphatidylcholine vesicles were prepared in the same way, except that sodium taurocholate was omitted. Recovery of radioactivity in the substrate preparations was routinely >95%. The activity of acid cholesteryl ester hydrolase was assayed as follows: 150 μL MES buffer (pH 5.0, 100 mM) containing bovine serum albumin (essentially fatty acid free, 7.5 mg) was added to 200 μL of the mitochondrial/lysosomal subcellular fraction (approximately 0.2 mg protein) and incubated at 37°C for 10 min. The substrate (50 μL, 144 nmol cholesteryl oleate, 12.95 KBq/μmol) was then added to start the reaction. The final volume in the assay was 400 μL and the final concentrations of cholesteryl oleate, phosphatidylcholine and sodium taurocholate were 360 μM, 1440 μM and 720 μM respectively. After 15-min incubation at 37°C, the reaction was stopped with 1.5 mL chloroform/methanol/toluene (2:2.4:1, v/v/v) containing 0.29 mM oleic acid as carrier. Sodium hydroxide (50 μL, 1 M) was then added. The mixture was vortexed for 20 sec and finally centrifuged at 1,500 × *g* (25 min, 20°C) to separate the phases. The amount of sodium [1-^{14}C]oleate released into the upper phase was determined by liquid scintillation counting. Blank tubes containing substrate but no enzyme protein were included in each experiment. The efficiency of extraction of sodium [1-^{14}C]oleate was also estimated in each experiment, using mixed micelles prepared in the same way as the substrate except that [1-^{14}C]oleic acid was substituted for cholesteryl [1-^{14}C]oleate. Extraction efficiency was >85% and was unaffected by the amount of enzyme protein present. Cytosolic and microsomal neutral cholesteryl ester hydrolase activities were also assayed by this method using MES buffer (100 mM) at pH 6.6 and Tris-HCl (100 mM) at pH 7.0, respectively. Endogenous cholesteryl ester in the mitochondrial/lysosomal and microsomal fractions represented <2% of the total amount of substrate present in the assays. No cholesteryl ester was detected in the cytosolic fraction. Mixed micelles were used as substrate in all experiments except where indicated otherwise.

Other assays. The activities of glutamate dehydrogenase (14), acid phosphatase (15) and β-glucuronidase (16) were determined as described previously. Proteins were estimated by the method of Lowry *et al.* (17). Significance limits were calculated using Student's t-test or Pearson's correlation coefficient.

RESULTS

Previous studies have shown that rat lactating mammary glands contain a cholesteryl ester hydrolase activity with a pH optimum of about 5 associated with the subcellular fraction containing mitochondria and lysosomes (10). The effect of pH in the range 4–6.5 on the activity of this enzyme was tested to determine the pH optimum more precisely (Fig. 1), and a clear, sharp pH optimum at 5.0 was found. The rate of hydrolysis of cholesteryl ester at pH 5.0 was linear with both the time of incubation, up to approximately 30 min (Fig. 2, A), and with the amount of subcellular fraction protein added, up to about 0.2 mg (Fig. 2, B).

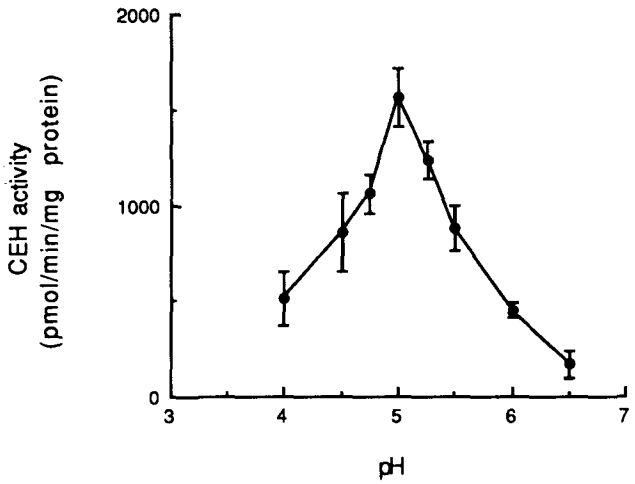

FIG. 1. The effect of pH on acid cholesteryl ester hydrolase activity. The activity of cholesteryl ester hydrolase in the subcellular fraction containing lysosomes and mitochondria prepared from rat lactating mammary tissue was assayed using sodium acetate (100 mM, pH 4.0–4.75) or MES (100 mM, pH 5.0–6.5) buffer. Each point is the mean from 3 experiments. Error bars show the standard error of the mean.

The low pH optimum and sedimentation pattern (10) of the acid cholesteryl ester hydrolase suggest that it may be a lysosomal enzyme. To test this possibility, three subcellular fractions containing mitochondria and lysosomes of increasing density were prepared from rat lactating mammary tissue and the activity of cholesteryl ester hydrolase in each fraction was compared to that of marker enzymes for mitochondria (glutamate dehydrogenase) and lysosomes (acid phosphatase and β-glucuronidase). The specific activities of the marker enzymes in each fraction relative to their specific activities in the whole mitochondrial pellet were consistent in preparations from four animals. Approximately 50% of the total activities (sum of the activities in the three fractions) of cholesteryl hydrolase (50.2 ± 2.1%), acid phosphatase (47.9 ± 1.5%) and β-glucuronidase (48.5 ± 15.4%) were associated with the pellet sedimenting at 8,000 × *g*. In contrast, only 27.0 ± 5.7% of the activity of glutamate dehydrogenase sedimented with this fraction. Over a number of experiments (data not shown), the percentage of the total activity of cholesteryl ester hydrolase associated with each fraction was much more strongly correlated with the percentage activities of acid phosphatase (Pearson's correlation coefficient, $r = 0.95$ $p<0.001$) and β-glucuronidase ($r = 0.95$ $p<0.001$) than with those of glutamate dehydrogenase ($r = 0.6$), suggesting

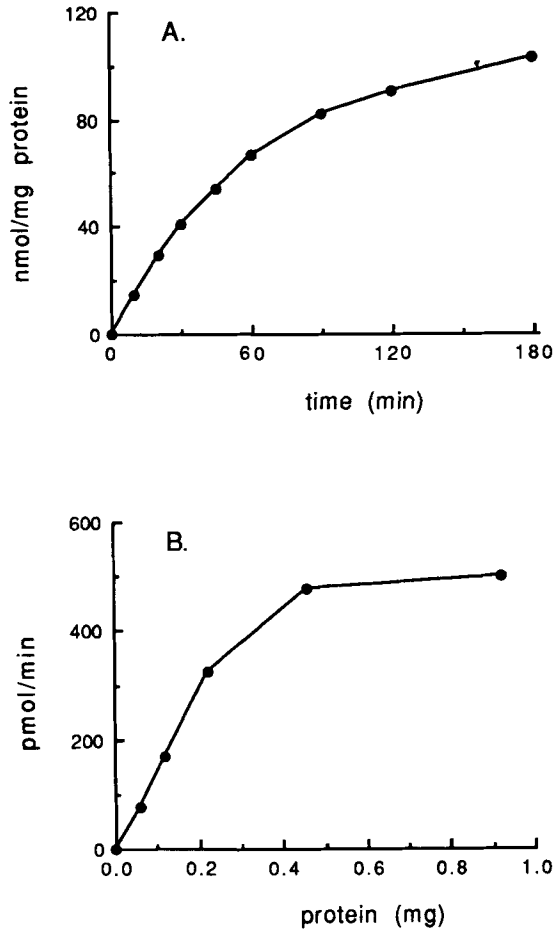

FIG. 2. The effect of time of incubation and enzyme protein concentration on acid cholesteryl ester hydrolase activity. The activity of cholesteryl ester hydrolase in the subcellular fraction containing lysosomes and mitochondria prepared from rat lactating mammary glands was assayed using the standard conditions described in Materials and Methods except that the time of incubation in the presence of the substrate (A), or the amount of subcellular fraction protein added (B), was varied as indicated. Each point is the mean from duplicate determinations and the experiment shown is typical of 4 performed in each case.

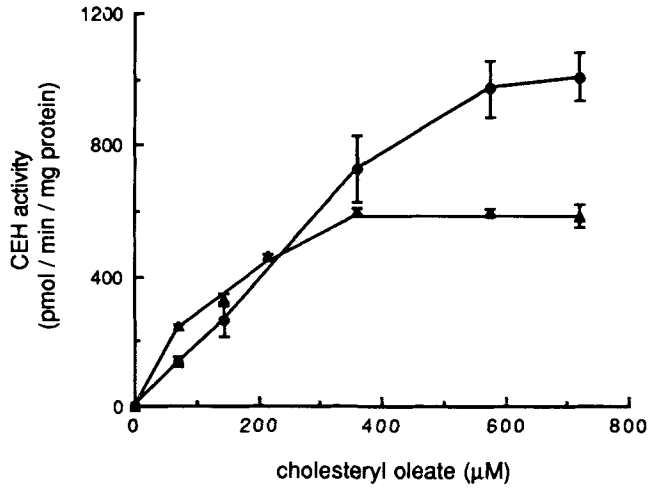

FIG. 3. The effect of substrate concentration on acid cholesteryl ester hydrolase activity. The activity of cholesteryl ester hydrolase in the subcellular fraction containing lysosomes and mitochondria prepared from rat lactating mammary tissue was determined using the concentrations of cholesteryl oleate indicated. Assays were carried out with the substrate in the form of mixed micelles (●) or cholesteryl oleate/phosphatidylcholine vesicles (molar ratio 1:4) in the presence of sodium taurocholate (720 μM) (▲). Each point is the mean from 3 experiments. Error bars show the standard error of the mean.

that the acid cholesteryl ester hydrolase is associated with the lysosomes in rat mammary tissue.

The activity of acid, lysosomal cholesteryl ester hydrolases in some tissues is influenced by the mode of presentation of the substrate (18). The highest activity is usually found when the cholesteryl ester is dispersed with phospholipid in micelles or vesicles with or without sodium taurocholate and/or digitonin (18,19). Previous experiments have shown that mammary gland acid cholesteryl ester hydrolase activity is decreased considerably when sodium taurocholate is omitted from the mixed micelle substrate, but can be substantially restored by separate addition of the bile salt (20). Addition of digitonin (50–250 μg/mL) to the assays did not significantly alter the observed activity in the presence or absence of sodium taurocholate (data not shown). In the experiment shown in Figure 3, the activity of acid cholesteryl ester hydrolase was assayed using different concentrations of cholesteryl oleate dispersed either as mixed micelles, or with phosphatidylcholine only (molar ratio 1:4) in the presence of sodium taurocholate (720 μM) added separately. The kinetics of the enzyme were markedly different with the two substrate presentation modes. These differences may be explained by the variation in the concentrations of sodium taurocholate which are added with the different cholesteryl oleate concentrations when the mixed micelle substrate is used. The detergent effect of the bile salt is likely to influence the size of the lipid/water interface between the enzyme and the substrate and thus modify the activity (18).

The effect of divalent metal ions (1 mM) on the activity of the acid cholesteryl ester hydrolase is shown in Table 1. The enzyme was strongly inhibited by Cu^{2+}, but was inhibited little by other divalent metal ions at the concentration used. Furthermore, ethylenediaminetetraacetic acid (EDTA) (1 mM) did not change the enzyme activity significantly (Table 2). The enzyme was inhibited by NaCl (10–100 mM) and NaF (10–50 mM) in a concentration-dependent way (Table 2). A concentration of 1 mM *p*-hydroxymercuribenzoate almost completely abolished the activity, while 1 mM GSH had only a small inhibitory effect. In the presence of equimolar concentrations of *p*-hydroxymercuribenzoate and GSH, however, activity of the enzyme was restored to the level found with GSH alone (Table 2). Finally, the serine esterase inhibitor phenylmethylsulfonyl fluoride (1 mM) caused a decrease in acid cholesteryl ester hydrolase activity of approximately 25% (Table 2).

Figure 4 shows the changes in the activities of the mam-

TABLE 1

The Effect of Divalent Metal Ions on Acid Cholesteryl Ester Hydrolase Activity[a]

Additions	Cholesteryl ester hydrolase activity (% control value)
None	100
$MgCl_2$	88.6 ± 2.2(5)
$MnCl_2$	83.3 ± 6.1(5)
$NiCl_2$	84.8 ± 5.2(5)
$CaCl_2$	74.7 ± 3.4(5)
$ZnCl_2$	80.9 ± 4.8(4)
$CuCl_2$	10.8 ± 1.5(4)

[a]The subcellular fraction containing lysosomes and mitochondria was prepared from rat lactating mammary tissue as described in Materials and Methods. Acid cholesteryl ester hydrolase activity was determined in the presence and absence of the metal ions indicated. The metal salts were added to the assays in the MES buffer prior to the preincubation period. Data are expressed as a percentage of the values found in the absence of added metal ions, and are the mean ± standard error of the mean from 4 or 5 experiments (indicated in brackets). Control values (pmol/min/mg protein) were 1054 ± 115 (4 experiments) and 1010 ± 99 (5 experiments).

TABLE 2

The Effect of Enzyme Inhibitors on Acid Cholesteryl Ester Hydrolase Activity[a]

Additions	Cholesteryl ester hydrolase activity (% control value)
None	100
NaF (10 mM)	46.0 ± 4.6(4)
NaF (50 mM)	16.1 ± 0.9(5)
NaCl (10 mM)	79.3 ± 4.1(4)
NaCl (100 mM)	52.8 ± 7.4(4)
EDTA (1 mM)	98.2 ± 2.5(5)
Phenylmethylsulfonyl fluoride (1 mM)	75.4 ± 1.3(4)
p-Hydroxymercuribenzoate (0.1 mM)	79.2 ± 2.1(5)
p-Hydroxymercuribenzoate (1 mM)	0.2 ± 0.1(5)
GSH (1 mM)	84.8 ± 1.5(4)
p-Hydroxymercuribenzoate (1 mM) + GSH (1 mM)	79.7 ± 3.2(4)

[a]The subcellular fraction containing mitochondria and lysosomes was prepared from rat lactating mammary tissue as described in Materials and Methods. Acid cholesteryl ester hydrolase activity was determined in the presence and absence of the compounds shown. Additions were made to the assays in the MES buffer prior to the preincubation period. Data are expressed as a percentage of the values found without additions, and are the mean ± standard error of the mean from 4 or 5 experiments (indicated in brackets). Control values (pmol/min/mg protein) were 1192 ± 87 (4 experiments) and 1132 ± 90 (5 experiments).

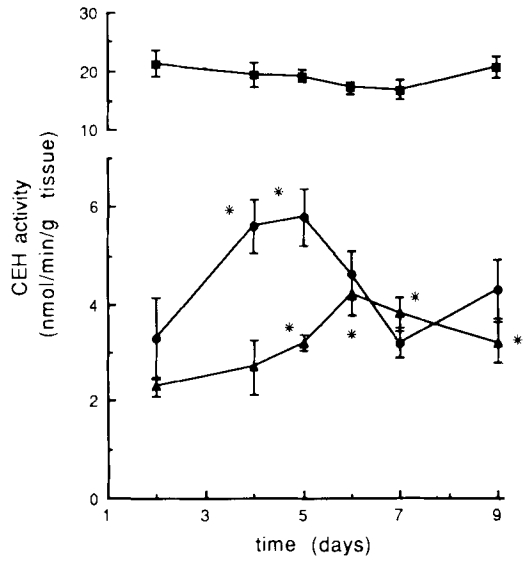

FIG. 4. The effect of time of lactation on acid and neutral cholesteryl ester hydrolase activities. The activities of acid and neutral cholesteryl ester hydrolases (CEH) in the subcellular fractions containing mitochondria and lysosomes (●), microsomes (▲) and cytosol (■) prepared from mammary glands taken from rats after the period of lactation shown were determined as described in Materials and Methods. Each point is the mean from at least 4 experiments. Error bars show the standard error of the mean. *Value is significantly different ($p<0.05$) from value at 2 days.

mary gland acid and neutral cholesteryl ester hydrolases which occur during the first 9 days of lactation. The results are expressed as nmol/min/g tissue so that their relative activities in whole tissue can be compared. The activity of the cytosolic neutral cholesteryl ester hydrolase was higher than that of the other two enzymes at all time points, and did not change significantly during the period studied. Acid cholesteryl ester hydrolase activity, however, increased significantly during the first few days of lactation, reaching a peak after 5 days, then declined to a value close to that seen at the start of the experiment after 7 days. The activity of the microsomal neutral enzyme also increased steadily during early lactation, reaching a maximum after 6 days. The relative specific activities of marker enzymes for lysosomes (acid phosphatase, 1.88 ± 0.15), microsomes (NADPH:cytochrome C reductase, 3.55 ± 0.21) and cytosol (lactate dehydrogenase, 1.71 ± 0.07) varied little in subcellular fractions of glands from seven rats between 2 and 9 days post-partum. No relationship between the relative specific activities of the enzymes and the number of days lactating was detected. Recovery of the marker enzymes in the appropriate fractions as a percentage of the total activity found in the homogenate was also consistent (± 5%). These results indicate that the changes in the activities of the three cholesteryl ester hydrolases during lactation are not caused by differences in purity or recovery of the individual preparations.

When subcellular fractions were prepared from mammary tissue from virgin rats, the activities of the three cholesteryl ester hydrolases under investigation were decreased considerably compared to the values obtained with lactating glands. The greatest difference, 8–14 fold, was seen in the activity of the acid cholesteryl ester hydrolase (non-lactating, 0.42 ± 0.11 nmol/min/g; peak lactating at 5 days, 5.8 ± 0.6 nmol/min/g) followed by the

microsomal enzyme, 3–5 fold (non-lactating, 0.75 ± 0.25; peak lactating at 6 days, 4.2 ± 0.4 nmol/min/g), while the cytosolic activity showed the smallest change, 2-fold (non-lactating, 9.3 ± 0.9; lactating at 2 days, 21.3 ± 2.3 nmol/min/g). The non-lactating values were obtained using tissue pooled from two or three rats because very much less mammary tissue is present in virgin rats. The data given are the mean ± standard error of the mean from three experiments using a total of eight animals.

DISCUSSION

Cholesteryl ester hydrolase activities with pH optima between 4.0 and 5.0 are associated with the lysosomes in a wide variety of tissue and cell types including liver (21,22), heart (23), aorta (24), fibroblasts (25,26), adrenal cortex (27) and adipose tissue (23). Our earlier experiments had suggested that a similar activity may be present in the rat lactating mammary gland (10). The results reported here confirm the presence in such tissue of an acid cholesteryl ester hydrolase with a pH optimum of 5.0 which sediments with lysosomal enzyme markers. Similar to the acid, lysosomal cholesteryl ester hydrolases in other tissues, the mammary gland enzyme is inhibited by Cu^{2+} (27–29), NaCl, and NaF (19,21,25). Furthermore, the inhibition of the mammary gland activity by *p*-hydroxymercuribenzoate, and its almost complete reversal by GSH (Table 2) indicates that the enzyme requires free sulfhydryl groups for activity, as has been found with similar enzymes in other cell types (21,22,24,25,30).

In a number of previous studies the activity of lysosomal cholesteryl ester hydrolase, even after extensive purification, could not be separated from that of lysosomal acid lipase, which is responsible for the hydrolysis of triglycerides, and it is believed that the same enzyme catalyzes both reactions (21,24,31). If this were the case with the mammary gland cholesteryl ester hydrolase, then the observed 25% inhibition by phenylmethylsulfonyl fluoride may indicate contamination of the preparation with other lipases, as lysosomal, acid lipases are not believed to be affected by serine esterase inhibitors. Imanaka *et al.* (32), however, have reported that the cholesteryl ester hydrolase activity of partially purified rabbit liver lysosomal lipase was inhibited by about 20% by 0.2 mM phenylmethylsulfonyl fluoride. The subcellular fraction used in the experiments described here may contain lipoprotein lipase, which is present in rat mammary tissue (33). This enzyme, however, has an alkaline pH optimum at about 8.5, and has virtually no activity below pH 6 (34). The milk of some species contains a bile salt-stimulated lipase (35), but this has not been detected in rat milk (36). Although the presence of other lipases in rat mammary tissue has not been reported, the possibility of some contamination by unknown lipases cannot be ruled out.

The lysosomal cholesteryl ester hydrolase has an important function in the regulation of cholesterol metabolism in some tissues (6,37). Increased flux of cholesterol from the plasma leads to decreased cholesterol synthesis and increased storage as esters. Feeding lactating rats a hypercholesterolemic diet has been shown to decrease cholesterol synthesis in the mammary gland (38), suggesting that cholesterol taken up from the plasma and processed by the acid cholesteryl ester hydrolase may also regulate cholesterol metabolism in mammary cells. In addition, neutral cholesteryl ester hydrolases in the adrenal cortex (7,9), liver (39) and adipose tissue (40) have been shown to be hormonally controlled by a mechanism involving phosphorylation-dephosphorylation. Thus they are believed to be involved in the regulation of the supply of unesterified cholesterol for metabolism in these tissue. Recent experiments in this laboratory (12) have suggested that the microsomal and cytosolic neutral cholesteryl ester hydrolases from rat mammary glands may be modulated by similar phosphorylation-dephosphorylation mechanisms. These enzymes, therefore, may play a part in regulating mammary gland cholesterol metabolism.

If the mammary gland cholesteryl ester hydrolases were important in the provision of unesterified cholesterol for secretion into milk, their activities would be expected to be higher in lactating as compared to non-lactating tissue. This was found to be the case for all three enzymes studied. The acid activity, however, showed the greatest increase (8–14 fold). A large proportion (60–80%) of milk cholesterol is derived from plasma lipoproteins (1–3), and the uptake of cholesterol from this source has been shown to be increased approximately 8-fold at the onset of lactation (41). Cholesteryl esters from chylomicrons have been shown to be internalized by mammary cells without prior hydrolysis (42). In addition, Raphael *et al.* (3) have reported that radioactivity from low density lipoprotein and very low density lipoprotein cholesteryl esters is transferred into milk. The results of the current work, therefore, suggest that the mammary gland acid cholesteryl ester hydrolase has a role in hydrolyzing lipoprotein cholesteryl ester to provide unesterified cholesterol for secretion into milk.

The experiments reported here demonstrate that the acid cholesteryl ester hydrolase activity found in the mammary gland has characteristics similar to those of acid, lysosomal cholesteryl ester hydrolases found in other tissues. In addition, the findings support the idea that the mammary gland acid and neutral cholesteryl ester hydrolases, like those found in other tissues, play a part in regulating intracellular cholesterol metabolism, and thus help control the availability of cholesterol for secretion into milk.

Effects of Perturbations in Hepatic Free and Esterified Cholesterol Pools on Bile Acid Synthesis, Cholesterol 7α-Hydroxylase, HMG-CoA Reductase, Acyl-CoA:Cholesterol Acyltransferase and Cytosolic Cholesteryl Ester Hydrolase

W.M. Grogan[a,*], M.L. Bailey[b], D.M. Heuman[b] and Z.R. Vlahcevic[b]

[a]Department of Biochemistry and Molecular Biophysics and [b]Division of Gastroenterology, McGuire Veterans Administration Hospital, Medical College of Virginia, Virginia Commonwealth University, Richmond, Virginia 23298-0614

Effects of expansion of the hepatic free cholesterol pool on bile acid and cholesterol metabolism and homeostasis were examined in rats fed cholesterol in high-fat diets or treated with oleyl-*p*-(n-decyl)-benzenesulfonate (ODS) or progesterone. Cholesterol feeding for 10–16 days, which increased free (33%) and esterified (6-fold) cholesterol, had no effect on cholate synthesis, total bile acid synthesis, or cholate turnover, whereas these activities were increased 60–80% by ODS and progesterone, which produced only small increases (19%) in free cholesterol. Cholesterol feeding reduced β-hydroxy-β-methylglutaryl (HMG)-CoA reductase (72%) and cholesteryl ester hydrolase (48%) and increased acyl-CoA:cholesterol acyltransferase (184%), whereas ODS and progesterone reversed these compensatory responses in cholesterol-fed rats. Cholesterol 7α-hydroxylase was changed no more than 22% by any treatment. A bolus of ODS elevated biliary cholesterol output 41% and shifted biliary bile acid synthesis and composition toward 12-deoxy bile acids. These effects were not seen in ODS-fed or progesterone-treated rats, in which cholesteryl ester stores were depleted. It is concluded that effects of free cholesterol on bile acid synthesis and biliary cholesterol are probably mediated by specific precursor or regulatory pools which can be independently regulated and which represent a relatively small fraction of hepatic free cholesterol.
***Lipids* 26, 907–914 (1991).**

The role of hepatic free cholesterol in the regulation of bile acid synthesis is controversial. Bile acid synthesis, the major metabolic fate of cholesterol, is thought to be regulated by modulation of cholesterol 7α-hydroxylase (C7AH), a rate-limiting enzyme in this pathway (1), by a poorly understood feedback mechanism involving bile acid and sterol (2,3) and by availability of free cholesteryl substrate (4). Some studies have suggested that C7AH is not saturated by cholesterol levels present in microsomes (4–7). Moreover, cholesterol feeding, which increases bile acid synthesis in several species, may or may not increase C7AH activity (8–10). Other studies have suggested that microsomal free cholesterol levels are near saturation and, thus, not rate-limiting for C7AH under most conditions, that increased C7AH activity can be decoupled from increased cholesterol synthesis (11–14), and that increases in bile acid synthesis with cholesterol feeding are dependent on receptor-mediated uptake of cholesterol (15). Although some studies suggest that changes in size of the hepatic free cholesterol pool affect biliary cholesterol secretion (16,17), the effects of manipulation of the free cholesterol pool on bile acid synthesis have not been studied.

Compensatory mechanisms maintain intracellular free cholesterol levels within relatively narrow ranges, even when challenged by large influxes of dietary cholesterol (18–22). Best characterized of these mechanisms is gene level coordinate repression of serum lipoprotein receptors and HMG-CoA reductase (β-hydroxy-β-methylglutaryl-CoA reductase, HMGCR), the rate-limiting enzyme in cholesterol biosynthesis (23). Although detailed mechanisms are unclear, free cholesterol is also regulated by hepatic microsomal acyl-CoA:cholesterol acyltransferase (ACAT), the major cholesterol esterifying enzyme (24–26), cholesteryl ester hydrolases (CEH) (22,27–29) and C7AH, the initial rate-limiting enzyme in bile acid synthesis (1). HMGCR, ACAT, CEH and C7AH are apparently all subject to short-term regulation by protein kinases (28–32).

Precursor cholesterol for both bile acid synthesis and biliary cholesterol secretion seems to derive from intracellular pools of free cholesterol which can be distinguished under appropriate experimental conditions (16, 33–36). For example, free cholesterol derived from lipoprotein is apparently the preferred substrate for bile acid synthesis in man (33–35), whereas newly synthesized cholesterol seems to be the preferred substrate in rat (6,7,36). Biliary cholesterol seems to be derived preferentially from a free cholesterol pool in rapid equilibration with cholesteryl ester (16,17).

We have examined the effects of manipulation of hepatic free cholesterol pools on bile acid synthesis, biliary cholesterol secretion and the four key regulatory enzymes of cholesterol homeostasis, using oleyl-*p*-(n-decyl)-benzenesulfonate (ODS), a CEH activator (37), and progesterone, an ACAT inhibitor (16,17). In order to accentuate effects related to storage and mobilization of cholesteryl ester, liver cholesteryl ester stores have been mildly elevated by cholesterol feeding.

MATERIALS AND METHODS

Animals and diets. Adult male Sprague-Dawley rats (Charles River Breeding Laboratories, Cambridge, MA) were maintained on rat chow until weighing 200–250 g and then fed *ad libitum* 10 days on rat chow (Prolab RMH 3000, Agway Corp., Syracuse, NY) or rat chow supplemented with 10% (w/w) commercial vegetable fat (Crisco, Procter and Gamble, Cincinnati, OH) or 10% fat + 1%

Abbreviations: ACAT, acyl-CoA:cholesterol acyltransferase; C7AH, cholesterol 7α-hydroxylase; CEH, cholesteryl ester hydrolase; HPLC, high-performance liquid chromatography; HMGCR, β-hydroxy-β-methylglutaryl-CoA reductase; ODS, oleyl-*p*-(n-decyl)-benzenesulfonate.

cholesterol (Sigma Chemical Co., St. Louis, MO). Fat was melted at 50°C and mixed with feed to achieve uniform distribution. Cholesterol was dissolved in molten fat prior to mixing with feed. Rats were regularly monitored for appearance, activity, feed and water consumption and bile, urine and fecal output. Rats used in these experiments had reached a weight of 250–350 g prior to surgery. Rats consuming less than 10 g feed or 15 mL water or producing less than 5 mL urine per day were eliminated from the study. Rats exhibiting a decline in bile flow due to catheter occlusion were excluded from data analysis.

Treatments. Oleyl-*p*-(n-decyl)-benzenesulfonate (ODS), synthesized as described previously by Quackenbush *et al.* (38), was administered either intraduodenally as a 40 μg bolus or as 0.01% of diet (w/w) dissolved in dietary fat prior to mixing of fat with chow. Treatment was normally begun 48 hr following surgery or 48 hr after addition of [26-^{14}C]-cholesterol, to permit recovery from surgery and equilibration of cholesterol pools. Whereas [^{3}H]cholate was normally given 24 hr after initiation of treatment, one group of 7 rats was given an ODS bolus 3–4 days after administration of radiolabel to permit monitoring of isotope dilution before and after treatment. Progesterone treated rats received intraduodenal boluses of 40 μg/kg progesterone (Sigma) dissolved in 500 μL corn oil. Bolus ODS or progesterone was injected in the duodenal return line of bile duct cannulated rats (see below) and bile flow was monitored for at least 30 min thereafter, with no diminution in flow rate.

Surgical techniques. Rats were provided with exteriorized enterohepatic circulation as described by Weis and Barth (39) and Kuipers *et al.* (40). A bile duct cannula was routed outside of the body, and joined to an intraduodenal cannula, for continuous reinfusion of bile. The simple overlapping junction of the two lines could be disconnected briefly for collection of bile or injection of an air bubble for flow rate determination. Details of the surgical procedure as carried out in this laboratory are described in Heuman *et al.* (41).

Bile acid synthesis and turnover by isotope dilution. As described by Heuman *et al.* (41), rats were given 1 μCi [2,4-^{3}H(N)]cholic acid (New England Nuclear-Dupont, Boston, MA; 25 Ci/mmol) or [24-^{14}C]cholic acid (40–60 mCi/mmol) 24 hr after surgery or initial treatment with ODS or progesterone. Twice each day, 20–40 mg bile was drained and weighed for measurement of mass and radioactivity of bile acids and cholesterol as described below. Cholate pool, intestinal absorption efficiency and fractional turnover were calculated from isotope dilution by the method of Linstedt (42). Bile salt secretion was calculated as the product of biliary bile salt concentration and bile flow rate, measured by timing movement of a bubble through a defined volume of cannula.

Bile acid synthesis by [26-^{14}C]cholesterol oxidation. At 24 hr after surgery, rats were given 10 μCi [26-^{14}C]cholesterol (New England Nuclear-Dupont; 53 mCi/mmol) in 400 μL corn oil as an intraduodenal bolus. Following a 48-hr waiting period to allow equilibration of radiolabel with cholesterol pools, rats were placed in CO_2 collection chambers at 6, 8 or 12 hr intervals, 2–4 times each day for 4 days. Details of procedure and collection apparatus are given in Duane *et al.* (43,44). Air was drawn through the sealed chamber under slightly negative pressure, into a series of 3 bubble traps containing monomethylamine, which traps >95% of expired CO_2. Rats were accommodated to chambers for approximately 15 min, prior to CO_2 collection for 30 min. ^{14}C was measured in aliquots of collection fluid by liquid scintillation counting, correcting for quenching by addition of internal standard. Bile acid synthesis was calculated as dpm expired $^{14}CO_2$/specific radioactivity of precursor pool. Specific radioactivity of the precursor pool was obtained two ways. Specific radioactivity of biliary cholesterol was calculated from concentrations of ^{14}C and cholesterol in bile samples and fitted to a log/linear decay curve by linear regression analysis, in order to calculate values for times at which bile samples were unavailable. Specific radioactivity of liver total and free cholesterol was also measured for 20 rats at termination of the experiment (see below). These values agreed with those obtained for biliary cholesterol from the final bile collection.

Biliary cholesterol determination. Bile samples were extracted with 25 mL $CHCl_3$/MeOH (2:1, v/v) according to the method of Folch *et al.* (45), as described previously (41). Following partitioning, the $CHCl_3$ phase was drawn off and brought to 25 mL with $CHCl_3$. A 5-mL aliquot was evaporated to dryness, redissolved in scintillation fluid and assayed for ^{14}C by liquid scintillation counting. A 10-mL aliquot was dried and assayed for cholesterol using a commercial kit, based on the cholesterol oxidase colorimetric determination (Sigma). Approximately 5% of samples were lost or discarded due to contamination. The MeOH/H_2O phase was saved for bile acid analysis.

Biliary bile acid determination. Biliary bile acid analysis was carried out as described previously (41). A 5-mL aliquot of MeOH/H_2O from bile extraction was assayed for ^{3}H by liquid scintillation counting. Taurine and glycine conjugates of cholate, deoxycholate, chenodeoxycholate, ursodeoxycholate and muricholate were measured in 1-mL aliquots by the high-performance liquid chromatography (HPLC) method of Nakayama and Nakagaki (46) as adapted by Heuman *et al.* (41).

Liver total and free cholesterol. Livers were extracted with $CHCl_3$/MeOH by the method of Folch *et al.* (45). Extract was dried under N_2 and redissolved in 25 mL $CHCl_3$. Radioactivity of total cholesterol was measured in 1-mL aliquots by liquid scintillation counting. Total cholesterol was determined in 1-mL aliquots as described by Klauda *et al.* (37). Free cholesterol was precipitated from duplicate 2-mL aliquots with digitonin as described by Klauda *et al.* (37). One precipitate was analyzed for cholesterol as described by Klauda *et al.* (37); the other was redissolved in 1 mL MeOH and assayed for radioactivity by liquid scintillation counting. Cholesteryl ester was calculated as the difference between total cholesterol and free cholesterol.

Enzyme assays. Neutral cytosolic CEH was measured at pH 7.4 in 104,000 × g supernatant essentially by the method of Deykin and Goodman (27). Cholesteryl oleate (Sigma), 100 nmol, containing 100,000 dpm [1,2,6,7-^{3}H(N)]cholesteryl oleate (New England Nuclear-Dupont; 83 Ci/mmol) was added in 100 μL acetone to 1 mL of cytosol containing 100 μg protein, and incubated for 30 min at 37°C. The reaction was terminated by extraction with $CHCl_3$/MeOH (2:1, v/v). Solvent was evaporated under N_2 and the residue was dissolved in $CHCl_3$. Unreacted cholesteryl oleate and free cholesterol product were separated by thin-layer chromatography, visualized with

I_2, scraped from the plate and assayed for radioactivity by liquid scintillation counting. Lysosomal acid CEH activity is not detected under conditions used for this assay (29).

Microsomal enzymes were measured by radiometric procedures used by Heuman *et al.* (47). Acyl-CoA:cholesterol acyltransferase was measured by the method of Erickson *et al.* (48). β-Hydroxy-β-methylglutaryl-CoA reductase was assayed by the procedure of Shefer *et al.* (1) as modified by Whitehead *et al.* (49). Cholesterol-7α-hydroxylase was assayed as described by Shefer *et al.* (50). Protein was determined by the method of Bradford (51). Whereas enzymes could only be assayed at termination, additional groups of 3–6 rats were sacrificed for measurement of enzyme activity, 1, 2, 3 and 4 days after administration of ODS (bolus).

RESULTS

Hepatic total and free cholesterol. As expected, cholesterol feeding increased hepatic total cholesterol levels 273% over fat-fed controls ($p<0.025$; see Table 1). Free cholesterol was increased by 33%, whereas the balance of increase was in cholesteryl ester. Administration of ODS in a single bolus produced no significant decrease in total cholesterol, but elevated free cholesterol by an additional 19% ($p<0.01$). Addition of 0.01% ODS to diet for 4 days lowered total hepatic cholesterol to the level of non-cholesterol-fed controls, whereas free cholesterol was much more variable and not significantly different from either cholesterol-fed or ODS (bolus) treated rats (Table 1). A similar result was obtained with progesterone, which reduced total cholesterol below non-cholesterol-fed control levels and gave final free cholesterol levels equivalent to cholesterol-fed controls. Both ODS-feeding and progesterone depleted cholesteryl ester to only 17–20% of total cholesterol, whereas cholesteryl ester was >50% of total cholesterol in all other groups. There were no significant differences in microsomal cholesterol levels at termination of the experiment.

Hepatic enzymes of cholesterol homeostasis. As shown in Table 2, cholesterol feeding reduced CEH and HMGCR activities 48% ($p<0.05$) and 72% ($p<0.001$), respectively, while elevating ACAT 184% ($p<0.001$) in comparison to controls. These effects were consistent with a compensatory response to increased influx of dietary cholesterol. In contrast, there was no significant effect on C7AH.

Administration of ODS as a bolus to cholesterol-fed rats increased CEH, HMGCR, and C7AH 160% ($p<0.001$), 250% ($p<0.001$) and 32% ($p<0.025$), respectively, and decreased ACAT 52% ($p<0.001$). Thus, ODS appeared to reverse the effects of cholesterol feeding on CEH, HMGCR and ACAT. However, only with CEH did the change more than compensate for effects of cholesterol feeding. Essentially the same results were obtained from rats (N = 3–6) sacrificed 1, 2, 3, 4, or 5 days post-treatment (data not shown).

ODS feeding and progesterone produced similar changes ($p<0.001$) in CEH, HMGCR and ACAT, but had no significant effect on C7AH (Table 2). Interestingly, the vehicle fat for dietary cholesterol by itself produced significant increases in ACAT ($p<0.005$) and C7AH ($p<0.001$), in comparison to rats fed unmodified rat chow. Thus, with one or more diets, each potential regulatory enzyme of cholesterol homeostasis and bile acid synthesis varied independently with respect to the other three enzymes.

Bile synthesis and cholate turnover. Figure 1 shows a typical isotope decay curve for seven rats which were monitored both before and after administration of ODS bolus. Decay of [^{14}C]cholate specific radioactivity was log-linear with respect to time both before and within 48 hr after ODS treatment but exhibited a sharp change in slope at 24–48 hr post-treatment, consistent with rapid equilibration to a new steady state with a higher turnover rate. [^{3}H]Cholate given 48 hr after ODS treatment (Fig. 1, 2nd isotope) produced a decay curve parallel to that of [^{14}C]cholate. In contrast, cholesterol-fed controls exhibited log-linear decay throughout the test period. As shown in Table 3, cholate pool size did not change with any treatment, which serves as further evidence that this

10% fat, 1% cholesterol, progesterone bolus	1.6 ± 0.2	0.4 ± 0.1[e]	29 ± 3

[a]Rats were fed chow, chow + 10% fat or chow + 10% fat + 1% cholesterol for 10 days. Following surgery as described in Materials and Methods, chow, fat and cholesterol groups were continued on respective diets for an additional 6 days before measurement of free and total cholesterol. Other groups were treated as cholesterol-fed rats, except for treatments. ODS bolus and progesterone groups received a single bolus of ODS or progesterone, respectively, 2 days after surgery. ODS was added to diet of ODS-fed, beginning 2 days after surgery. Esterified cholesterol was calculated by difference. Values are mean ± SEM (N = 4–12).

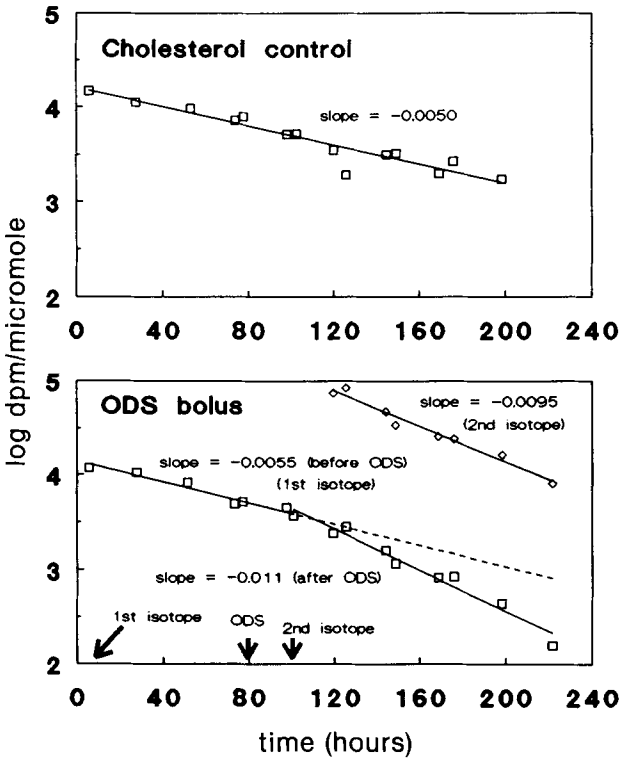

FIG. 1. Typical isotope dilution plot for radiolabeled cholate showing log-linear decay of specific radioactivity before and after treatment with ODS. As indicated by arrows [^{14}C]cholate (1st isotope) was given 1 day after surgery; a single bolus of ODS was given 3 days later; [^{3}H]cholate (second isotope) was given 1 day after ODS. Bile samples were taken at times indicated and analyzed for cholate and radioactivity (double isotope counting) as described in Materials and Methods. Solid line is fitted to data points shown by linear regression analysis. Dotted line is extrapolation of decay before ODS. A total of 7 rats were treated in this way with similar results. Upper panel shows simultaneous control.

pool was in steady state during linear phases of decay. Inasmuch as mean before and after ODS values were virtually identical to those obtained from all cholesterol-fed or ODS treated rats, respectively, isotope dilution and biliary composition data from these studies, in which rats were used as their own controls, are not reported separately.

As shown in Table 4, neither cholate synthesis, determined by isotope dilution, nor total bile acid synthesis, measured by [26-^{14}C]cholesterol oxidation, was significantly affected by either fat feeding or cholesterol feeding. In contrast, ODS, whether given as a bolus or fed, and progesterone increased cholate and bile acid synthesis 64-83%. However, only in the case of ODS bolus was the increase accompanied by a significant increase in C7AH (Table 2).

As shown in Table 3, cholate pool size was not significantly affected by any diet or treatment. Cholesterol feeding did not significantly alter fractional turnover (half-life) of cholate, but did produce a trend toward lower ($p<0.2$) absorption efficiency and pool size. In contrast, ODS, given as a bolus or fed, and progesterone reduced half-life 33% ($p<0.01$). This increased turnover was apparently due to a small but highly significant decline in absorption efficiency (Table 3), *i.e.*, the fraction of radiolabel from cholate reabsorbed on each passage through the enterohepatic circulation.

Biliary cholesterol secretion. As shown in Figure 2, biliary cholesterol output was not significantly changed by fat or cholesterol feeding. Following ODS bolus, which did not deplete liver cholesteryl ester stores (Table 1), biliary cholesterol exhibited a significant 41% increase ($p<0.025$). In contrast, ODS feeding and progesterone, which depleted cholesteryl ester stores, increased output 7% and 35%, respectively, but neither increase was statistically significant. Output was highly variable in individual rats over four days of collection but was not correlated with time after initiation of treatments (data not shown). Whereas bile flow rate was not changed significantly by any treatment (1.85 ± 0.10 mL/hr for cholesterol-fed,

TABLE 3

Parameters of Cholic Acid Turnover as a Function of Fat and Cholesterol Feeding and Treatment with ODS or Progesterone[a]

Diet/treatment (N)	Half-life	Absorption efficiency	Cholate pool
	(days)	(%)	(μmol/100 g)
Chow (6)	2.8 ± 0.2	95.8 ± 0.5	86 ± 6
10% fat (9)	2.8 ± 0.5	95.9 ± 0.3	87 ± 12
10% fat, 1% cholesterol (16)	2.4 ± 0.2	95.2 ± 0.4	72 ± 8
10% fat, 1% cholesterol, ODS bolus (11)	1.6 ± 0.2[b]	92.9 ± 0.9[c]	88 ± 23
10% fat, 1% cholesterol, 0.01% ODS-fed (7)	1.6 ± 0.2[b]	92.3 ± 0.9[d]	88 ± 11
10% fat, 1% cholesterol, progesterone bolus (9)	1.6 ± 0.2[d]	91.6 ± 2.0	82 ± 16

[a]Rats were fed indicated diets for 10 days, prior to cannulation of bile duct. Treatments were begun 48 hr after surgery and 24 hr after administration of radiolabeled cholate. Bile samples were collected twice daily for 4-5 days and turnover parameters were determined by isotope dilution as described in Materials and Methods. Values are mean ± SEM for individual rats.

TABLE 4

Effects of Cholesterol Feeding, ODS and Progesterone on Cholate Synthesis and Total Bile Acid Synthesis (μmol/hr/100 g rat)[a]

Diet/treatment	Cholate	Total bile acid
Chow	0.9 ± 0.1	1.4 ± 0.2
10% fat	0.9 ± 0.1	1.3 ± 0.1
10% fat, 1% cholesterol	0.9 ± 0.1	1.4 ± 0.2
10% fat, 1% cholesterol, ODS bolus	1.5 ± 0.2 ($p<0.05$)	2.6 ± 0.2 ($p<0.001$)
10% fat, 1% cholesterol, 0.01% ODS-fed	1.6 ± 0.2 ($p<0.005$)	2.1 ± 0.2 ($p<0.025$)
10% fat, 1% cholesterol, progesterone bolus	1.7 ± 0.4 ($p<0.1$)	2.2 ± 0.3 ($p<0.025$)

[a]Diets and treatments are as described in Table 1. Cholate synthesis was determined by isotope dilution and total bile acid synthesis, by [26-^{14}C]cholesterol oxidation, measured 2-3 times daily for 4-5 days after initiation of treatment, as described in Materials and Methods. Values are mean ± SEM of average outputs from individual rats (N = 6-16 rats). P values are given for significance of differences between treated and cholesterol-fed.

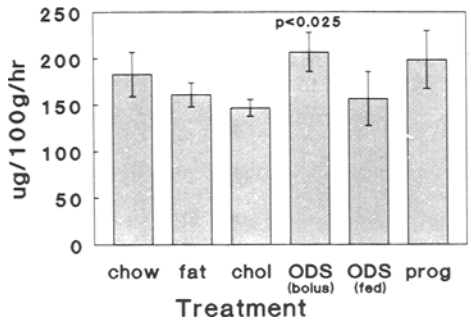

FIG. 2. Effects of cholesterol feeding, ODS and progesterone on biliary cholesterol output. Diets and treatments are as described in Figure 1. Cholesterol was measured in bile samples collected twice daily for 4-5 days after initiation of treatment. Values are mean ± SEM of average output from individual rats (N = 7-15 rats). P value is given for significance of difference between ODS bolus and cholesterol-fed.

1.88 ± 0.13, for ODS bolus), biliary cholesterol concentration paralleled output.

Biliary bile acid output. As shown in Table 5, decline in biliary cholate output and increase in output of chenodeoxycholate and its metabolites (12-deoxy bile acids) with fat and cholesterol feeding resulted in a highly significant increase in the ratio 12-deoxy bile acids/cholate ($p<0.005$). ODS bolus further increased 12-deoxy bile acids to a value 67% higher than chow controls ($p<0.01$) and 17% higher than cholesterol-fed. The ratio also increased still further but not significantly. In contrast, ODS feeding and progesterone, which depleted cholesteryl ester stores (Table 1), essentially reversed the effects of cholesterol loading, increasing cholate and decreasing 12-deoxy bile acids, with a resultant decrease in ratio ($p<0.005$). No significant differences occurred in total bile acid output (Table 5) or concentration among any of the groups, consistent with decreased absorption efficiency.

DISCUSSION

Previous studies have suggested that hepatic free cholesterol levels, which are tightly regulated over a wide range of dietary influx (18-22,37), may play a role in regulation of bile acid synthesis (5-7) and biliary cholesterol secretion (16,17,34,35). We have examined effects of cholesterol

TABLE 5

Effects of Cholesterol Feeding, ODS and Progesterone on Biliary Bile Acid Output (μg/hr/100 g rat)[a]

Group/treatment	Cholate	12-Deoxy bile acids	Total bile acids	12-Deoxy bile acids/cholate
Chow	23 ± 3	20 ± 3	55 ± 8	0.8 ± 0.06
10% fat	23 ± 2	23 ± 2	55 ± 4	1.0 ± 0.07
10% fat, 1% cholesterol	20 ± 2	28 ± 2[b]	57 ± 4	1.6 ± 0.13[c]
10% fat, 1% cholesterol, ODS bolus	21 ± 2	33 ± 3[d]	65 ± 4	1.7 ± 0.20
10% fat, 1% cholesterol, 0.01% ODS-fed	22 ± 1	24 ± 2[e]	54 ± 4	1.1 ± 0.06[e]
10% fat, 1% cholesterol, progesterone bolus	26 ± 2[f]	25 ± 2[g]	60 ± 4	1.0 ± 0.10[h]

[a]Diets and treatments are as described in Figure 1. Taurine and glycine conjugates of biliary bile acids were measured in bile samples collected twice daily for 4-5 days after initiation of treatment. 12-Deoxy bile acids include conjugates of chenodeoxycholate and its metabolites. Values are mean ± SEM of averages from individual rats (N = 7-16 rats).

feeding, ODS and progesterone, all of which are known to perturb cholesterol homeostasis and elevate free cholesterol levels in liver (16,17,37), on key enzymes of cholesterol metabolism (CEH, ACAT, HMGCR and C7AH), biliary cholesterol, and bile acid synthesis and turnover. Earlier studies by us suggested that stimulation of bile acid turnover by ODS, though seen without cholesterol feeding, is enhanced in cholesterol-fed rats and that any effects of ODS or progesterone which are mediated by mobilization of cholesteryl ester should be enhanced by cholesterol loading (16,37,52). Thus, cholesterol was added to diets of all treated groups.

Role of free cholesterol in bile acid synthesis and cholesterol homeostasis. Cholesterol feeding, ODS and progesterone produced substantial changes in bile acid synthesis, cholate turnover, biliary cholesterol secretion, bile acid composition, and key regulatory enzymes of cholesterol homeostasis. However, none of these effects correlated well with the measured hepatic pool of free cholesterol. In fact, elevations of free cholesterol were modest and statistically significant only with cholesterol-feeding and ODS-bolus (Table 1). Thus, it is unlikely that the observed effects can be ascribed to increases in free cholesterol unless those increases are highly localized. In fact, metabolically non-equivalent intracellular pools of free cholesterol can be demonstrated under appropriate experimental conditions (16,33-35,53). In rat, one such pool appears to be in rapid equilibrium with cholesteryl esters (16), which, in the current study, varied 20-fold among the various groups and were virtually depleted by ODS-feeding and progesterone (Table 1). It follows that the size of this free cholesterol pool would be affected by relative rates of esterification/hydrolysis and limited by the supply of cholesteryl esters.

With cholesterol feeding, metabolic compensatory responses are apparent in suppressed CEH, suppressed HMGCR and activated ACAT (Table 2). Accompanying this metabolic state are accumulation of cholesteryl esters and a substantial increase in 12-deoxy bile acids/cholate (Table 5). There is considerable evidence for existence of multiple pathways for bile acid synthesis, drawing on different precursor pools (53-55). The current data might be seen as evidence that newly absorbed cholesterol comprises a pool that is preferentially metabolized to chenodeoxycholate rather than cholate. However, results of ODS and progesterone treatment suggest a somewhat more complex interpretation.

Administration of a single ODS bolus abolished the compensatory response to cholesterol feeding, stimulating CEH and HMGCR and suppressing ACAT (Table 2), despite a further increase in free cholesterol. C7AH activity increased, but not in proportion to increases in bile acid synthesis (Table 4). Increases in biliary cholesterol secretion (Fig. 2) and bile acid synthesis in absence of a normal compensatory response to increased free cholesterol or commensurate increase in C7AH suggest augmentation of specific precursor pools, which do not induce strong compensatory responses, perhaps free cholesterol released locally from cholesteryl ester. Whereas 12-deoxy bile acids/cholate (Table 5) and total bile acid synthesis, but not cholate synthesis, are highest with the ODS bolus, a free cholesterol pool, already enlarged by cholesterol feeding and providing substrate preferentially for chenodeoxycholate synthesis, may be further increased. This view is supported by Klauda *et al.* (37), who found that ODS elevated chenodeoxycholate/cholate in non-cholesterol-fed rats.

With ODS feeding, a similar pattern of reversal of effects of cholesterol feeding was seen, with respect to three of the enzymes, CEH, ACAT and HMGCR. Bile acid synthesis was also substantially elevated, but in absence of any elevation of C7AH. Although hepatic free cholesterol remained elevated, it was not significantly higher than cholesterol-fed controls, despite enzyme levels favoring elevation. This was probably due to depletion of cholesteryl ester stores (Table 1). With depletion of cholesteryl ester, biliary cholesterol reached a minimum (Fig. 2) and 12-deoxy bile acids/cholate dropped to levels of fat-fed

controls (Table 5), despite elevated HMGCR (Table 2) and free cholesterol (Table 1). This suggests that free cholesterol derived from hydrolysis of cholesteryl ester may be preferentially used for chenodeoxycholate synthesis and biliary cholesterol. Stone *et al.* (16) have proposed such a precursor pool for biliary cholesterol, on the basis of short-term effects of progesterone on microsomal cholesterol and biliary cholesterol secretion. This view was also supported by current results with progesterone.

Like ODS feeding, progesterone abolished the compensatory responses of CEH, HMGCR and ACAT to cholesterol feeding, although free cholesterol levels were the same as cholesterol-fed. Bile acid synthesis was elevated by progesterone, without elevated C7AH. Biliary cholesterol output was not significantly different from that of any other group and 12-deoxy-bile acids/cholate was significantly lower than that of cholesterol-fed or ODS-bolus. Here, too, the cholesteryl ester pool was greatly reduced, limiting any free cholesterol pool dependent on hydrolysis for maintenance. Inasmuch as cholesterol synthesis is not impaired and cholesterol dietary intake should not be impaired by a single progesterone bolus, these results also suggest that precursor pools for chenodeoxycholate and biliary cholesterol secretion derive preferentially from hydrolysis of cholesteryl ester.

Implications for regulation of bile acid synthesis. As microsomal C7AH did not correlate with *in vivo* bile acid synthesis, these studies lend support for the view that the free cholesterol substrate pool may limit rates of bile acid synthesis (4–7). It is apparent that the conditions of this study prevented the increase in bile acid synthesis normally seen with cholesterol feeding (8–10). This is perhaps due to limitation of a critical substrate or regulatory free cholesterol pool by an exaggerated compensatory response, of one or more of the key regulatory enzymes, to cholesterol feeding (Table 2). In this regard, the 10% vehicle fat added to all test diets elevated ACAT 56% over Chow control (Table 2), demonstrating a significant effect on the regulatory environment and calling for further study of the role of dietary fat in regulation of bile acid synthesis. Supporting this view is the recent report from this laboratory showing induction of C7AH in cholesterol-fed rats on low-fat diets (2). Even in the absence of increased bile acid synthesis, compensatory responses of CEH, HMGCR and ACAT to cholesterol feeding persisted (Table 2). Moreover, the increased ratio, 12-deoxy bile acids/cholate, reported by other investigators (21,56), also persisted (Table 5). Thus, several of the effects associated with cholesterol feeding were apparently uncoupled from increased bile acid synthesis. However, cholesterol-fed rats showed a trend ($p<0.2$) toward lower cholate absorption efficiency (Table 3), which, upon longer-term feeding, might have led to a measurable compensatory increase in synthesis.

Although bile acid synthesis did not correlate well with free cholesterol levels in this study, it did increase with metabolic conditions favoring increases in free cholesterol levels, *i.e.*, elevated CEH and HMGCR, and suppressed ACAT. Thus, reversal by ODS and progesterone of the normal homeostatic compensatory responses to increased free cholesterol may result in augmentation of a precursor or regulatory pool which is more accessible to C7AH than the larger intracellular free cholesterol pool.

Elevated output of 12-deoxy bile acids was seen with elevated cholesteryl ester (cholesterol-fed, ODS bolus) but not with depleted cholesteryl ester stores (ODS-fed, progesterone) (Table 5). Moreover, cholate synthesis accounted for essentially all increase in bile acid synthesis in treated groups with depleted cholesteryl ester, suggesting that chenodeoxycholate synthesis may be limited by cholesteryl ester stores.

Implications for mode of action of ODS. Earlier studies on mode of action of ODS and its analogs suggested that these compounds lower serum and liver cholesterol in hypercholesterolemic rats by inhibiting intestinal cholesterol absorption but not bile acid absorption (37,52). Although the mechanism for inhibition of cholesterol absorption was unclear, an analog increased CEH activity in intestinal mucosa. Whereas synthesis of cholesteryl ester is an essential step in cholesterol transport, *i.e.*, chylomicron formation, this enhanced hydrolysis may be responsible for decreased absorption. Hypocholesterolemic effect persisted when the analog was administered intravenously or remained in the liver for as long as three weeks after termination of treatment. Moreover, these compounds increased cholate and chenodeoxycholate turnover and [26-^{14}C]cholesterol oxidation, *in vivo*. Coinciding with these effects was a 2–3 fold increase in hepatic neutral CEH and both serum and liver free cholesterol. Thus, activation of CEH may be a common mechanism for metabolic effects in liver and absorption effects in intestinal mucosa.

The current studies lend support to a parenteral mode of action for ODS, inasmuch as action persisted for several days after administration of a bolus, and effects on bile acid turnover were delayed for at least 24 hr (Fig. 1). Moreover, effects of ODS on compensatory responses by liver enzymes to cholesterol feeding were not appreciably different between ODS-bolus and ODS-fed. Differences in biliary cholesterol secretion and bile acid composition with ODS as well as progesterone seem to have been related to size of the cholesteryl ester storage pool as well as influx of dietary cholesterol. Thus, it seems likely that the mode of action of ODS is related to a shift in equilibration between hepatic free cholesterol and cholesteryl ester and perhaps augmentation of precursor pools for biliary cholesterol and bile acid synthesis. However, the pattern of changes in enzyme activity clearly suggests disruption of compensatory responses to influx of dietary cholesterol, which include decreased HMGCR and CEH and increased ACAT. It is difficult to suggest a mechanism for this disruption, which seems to persist, even with elevated levels of free cholesterol, and, apparently, with or without impairment of intestinal absorption. However, Pandak *et al.* (57,58) have reported decreased CEH, HMGCR and C7AH and increased ACAT in response to mevinolin or AY9944, both inhibitors of cholesterol synthesis. Both these and the current studies suggest coordinate regulation of these enzymes, which has been confounded to produce paradoxical patterns of regulation under the respective experimental conditions.

A somewhat unexpected outcome of this study is the similarity in detail between effects of ODS and progesterone on bile acid synthesis and turnover and cholesterol homeostasis. As already noted, earlier studies (52) suggested that inhibition of cholesterol absorption plays a prominent role in the hypocholesterolemic effect of ODS, whereas effects of progesterone are thought to

be mediated at the transcriptional level. However, in view of progesterone's inhibitory effect on ACAT and stimulatory effect on CEH, seen by us and others (16,59), ODS and progesterone may share a common mode of action, based on a shift in steady state equilibration point between free cholesterol and cholesteryl ester, to which other effects could also be ascribed. Stone *et al.* (16) have suggested such a mode of action for progesterone. Although their primary mechanisms of action need not be the same, interaction of ODS with steroid receptors is not out of the question, especially in view of the substantial metabolic effects of ODS. While highly speculative, such a mechanism of action might play a role in disruption of compensatory response to cholesterol feeding, which is apparently mediated by a steroid repressor (60,61).

[a]Department of Biochemistry, Arrhenius Laboratories, University of Stockholm, S-106 91 Stockholm, [b]Department of Cell Biology, Faculty of Health Sciences, University of Linköping, S-581 85 Linköping and [c]Division for Basic Research in Dementia, Clinical Research Center at Huddinge Hospital, Karolinska Institutet, S-141 86 Huddinge, Sweden

The influence of different fat diets on liver phospholipid, cholesterol and dolichol was studied. Rats were separated into four groups and fed standard laboratory chow (control), a diet containing linolenic acid, a coconut oil diet, or a corn oil-containing diet. After five weeks, microsomes and mitochondrial/lysosomal fractions were prepared from the liver, and lipid compositions were analyzed. No changes in phospholipid content were observed. In control animals, the fatty acid compositions of phosphatidylcholine and phosphatidylethanolamine in the two subfractions were similar. However, these two phospholipids showed different fatty acid patterns, which were altered independently upon dietary treatment. The dietary treatments resulted, in most cases, in decreased cholesterol and dolichol contents and, especially in microsomes, in a decreased level of esterification of both lipids. The fatty acid compositions of cholesteryl esters in the two subfractions showed significant differences and cholesterol was esterified to a large extent with linolenic acid when this fatty acid was supplied in the diet. The same dietary treatment exerted different effects on the cholesterol localized in the two different intracellular compartments. This difference was most pronounced in rats fed the corn oil-containing diet; microsomal cholesteryl esters exhibited increased saturation, whereas cholesteryl esters in the mitochondrial/lysosomal fraction displayed decreased saturation. Dolichyl esters in the two cellular compartments had different fatty acyl compositions, with a considerably higher degree of saturation in microsomes. The various diets influenced the nature of the fatty acid moieties present in the isolated fractions and the effects on the two subfractions were opposite. The diet containing linolenic acid decreased the degree of saturation in microsomal dolichyl esters and increased the degree of saturation in the mitochondrial/lysosomal fraction. The results demonstrate that the fatty acid compositions of both dolichyl and cholesteryl esters display organelle specificity. Both the content of these lipids and their fatty acid compositions are greatly influenced by dietary conditions, and the esterification processes at different cellular locations exhibit independent regulation, regardless of the fatty acid content of the diet.

Lipids 26, 915–921 (1991).

The lipid compositions of biological membranes are quite stable and dietary or experimental pathological conditions are usually thought to cause only limited changes in membrane phospholipid content and composition. The effect of phospholipids on cellular properties, including membrane architecture, fluidity, stability and enzyme activation, explains why large changes in composition are not compatible with cell survival (1). However, a number of investigations in recent years have shown that the fatty acid compositions of phospholipids can be manipulated by dietary treatment. Most of the *in vivo* studies examined either the liver or the brain of the rat (2–7). In these experiments the effect of standard diet was compared with fat-free diets and diets containing lard or various types of oils.

The effects described for total or individual phospholipids and for homogenates or isolated subfractions vary somewhat, in part because of differences in the experimental conditions employed. The modifications described are quite moderate and, depending on the type of diet employed, 5–10% increases or decreases in certain monosaturated or polyunsaturated fatty acids (FA) are observed. In most experiments the relative amount of saturated FA did not change significantly. In those experiments where larger changes in the fatty acid pattern were observed after only a short dietary regime, the FA composition of the total lipid extract was analyzed (8,9). These changes are likely to be present primarily in triglycerides and not in phospholipids.

Modifications in the FA compositions of phospholipids need not be large to result in changes in membrane and enzymatic functions. Furthermore, these changes may influence the structure, composition and amount of components other than phospholipids. Such modifications have important effects on protein configurations and distributions, thereby influencing a number of membrane-associated functions.

In the present experiments young developing rats were subjected to dietary treatment in an attempt to change the phospholipid compositions of major liver organelles. The aim was to determine to what extent these modifications are accompanied by changes in cholesterol and dolichol contents, as well as in the extent of esterification of these two lipids. In addition, the possible influence of dietary conditions on the fatty acid compositions of cholesteryl and dolichyl esters was determined.

MATERIALS AND METHODS

Chemicals and diet. Ergosterol was purchased from Steraloids Inc. (Wilton, NH). Dolichol-23 was isolated from the bovine pituitary gland (10) and the cholesteryl ester standard was synthesized using [^{14}C]cholestereol (Radiochemical Centre, Amersham, England) and hepta-

decanoyl chloride (11) (Sigma, St. Louis, MO). Borontrifluoride (in methanol) and linolenic acid were purchased from Merck (Darmstadt, Germany) and Kodak (Rochester, NY), respectively. The "fat-free" test diet was purchased from U.S. Biochemical Corporation (Cleveland, OH).

Animals. Male Sprague-Dawley rats weighing 60 g at the start of the experiment were used. Control rats received the basal diet consisting of 24% protein, 49% carbohydrate and 5.4% total fat, including 0.2% cholesterol. For the preparation of specific diets, a "fat-free" test diet was mixed either with 20% linolenic acid, 20% coconut oil or 20% corn oil by weight and then formed into pellets. The fat-free diet consisted of 17% cellufil, 59% sucrose, 21% casein, 4% salt mixture and vitamins. Rats received the diets *ad libitum* for five weeks.

At the end of the dietary period, the rats were decapitated and their livers homogenized. The microsomal and mitochondrial/lysosomal fractions were prepared as described earlier (12). The mitochondrial fraction isolated by differential centrifugation contains the majority of the lysosomes (13). The combined mitochondrial/lysosomal fraction is suitable for assaying lysosomal polyprenol content, because polyisoprenols are present only in very low concentrations in mitochondria. Protein was measured using the Biuret procedure with bovine serum albumin as the standard (14).

Lipid extraction and separation. For extraction of lipids, one mL of the isolated subfractions or 1 mL of dietary chow dissolved in 0.25 M sucrose was mixed with 21 mL chloroform/methanol (CM, 14:7, v/v). After 30 min at 37°C, the solvent was removed and the proteins reextracted with 9 mL CM (2:1, v/v). All solvent mixtures contained 0.15% butylated hydroxytoluene as antioxidant. The two extraction mixtures were combined and filtered, and the internal standards ergosterol, [^{14}C]cholesteryl heptadecanoate and dolichol-23 were added. The extract was partitioned by the addition of 6.5 mL of water, and the chloroform phase was washed twice with theoretical upper phase chloroform/methanol/water (CMW, 3:48:47, v/v/v). After evaporation of the solvent under N_2, the lipids were dissolved in 4 mL chloroform and placed on an aminopropyl column (Supelco, Bellefonte, PA). Neutral lipids were removed with 4 mL chloroform/2-propanol (2:1, v/v) and the free fatty acids were eluted with 4 mL 2% acetic acid in diethyl ether. Phospholipids were eluted with 8 mL methanol.

The mixture containing neutral lipids was evaporated and the lipids were dissolved in 100 μL chloroform. Methanol (4 mL) was added and the mixture was placed onto a C-18 reversed phase column (Supelco). Cholesterol and cholesteryl esters were eluted with 21 mL methanol and dolichol and dolichyl esters were removed with 8 mL n-hexane. The methanol eluate was evaporated and the lipids were dissolved in n-hexane and transferred to a silica gel column [Silica gel 60 (Merck), packed in a Pasteur pipette]. Cholesteryl esters were eluted with 8 mL 2% diethyl ether in n-hexane, followed by the elution of cholesterol with 8 mL chloroform.

The mixture containing free FA was evaporated under N_2. The residue was dissolved in CM (2:1, v/v) and placed onto silica thin-layer chromatography (TLC) plates (Merck), which were then developed with petroleum ether/diethyl ether/acetic acid (90:10:2, v/v/v). After visualization with Rhodamine 6G, the fatty acid-containing spot was scraped off and extracted with CM (2:1, v/v) for gas chromatographic (GC) analysis.

Phospholipids were resolved using silica thin-layer chromatographic (TLC) plates with a concentrating zone (Merck). The phospholipids were eluted first with chloroform/diethyl ether/acetic acid (70:30:2, v/v/v) and thereafter with chloroform/methanol/H_2O (70:30:4, v/v/v) in the same direction. The lipid spots containing phosphatidylcholine (PC) and phosphatidylethanolamine (PE) were visualized with Rhodamine 6G and removed for the determination of phosphorus (15). A schematic representation of the course of lipid separation is presented in Figure 1.

High-performance liquid chromatography (HPLC). HP Hypersil ODS (3 μm) was the HPLC column used for reversed phase separation. For the isolation and quantitation of dolichol and dolichyl esters, a convex gradient was applied from the initial methanol/2-propanol/water (60:40:5, v/v/v) in pump system A to 60% *n*-hexane/2-propanol (70:30, v/v) in pump system B at a flow rate of 2 mL per min with a program time of 20 min. The absorbance of the eluate at 210 nm was monitored. In this system the individual dolichols were eluted first, followed by the dolichyl esters. Since dolichol is present as a series of polyisoprenes with different UV spectra, the total amount of dolichol was calculated as described earlier (16).

Cholesterol was separated using a linear gradient with methanol/water (9:1, v/v) in pump system A to methanol/2-propanol (4:1, v/v) in pump system B at a flow rate of 1.5 mL per min. The isolated cholesteryl ester fractin was hydrolyzed in 0.8 mL tetrahydrofuran with 0.2 mL 0.66 M KOH in methanol, and cholesterol was quantitated by HPLC.

Gas chromatography. Phospholipids, dolichyl esters,

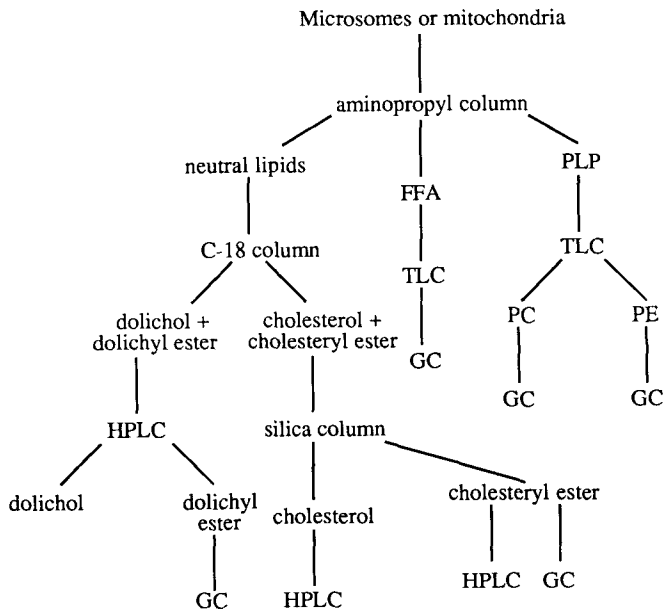

FIG. 1. Schematic illustration of the course of lipid separation and quantitation.

TABLE 1

Fatty Acid Compositions of the Different Dietary Components[a]

FA	Control diet	Linolenic acid	Coconut oil	Corn oil
	(% of total)			
14:0	1.7	0.1	48.3	0.1
16:0	21.3	5.2	23.9	10.9
18:0	4.1	2.3	6.8	
18:1	16.0	22.3	16.6	31.3
18:2	46.2	17.2	4.4	56.6
18:3	5.9	52.9		0.7
20:0	2.2			0.3
22:6	2.6			0.1
Total				
Saturated	27.1	7.6	79.0	11.0
Monounsaturated	16.0	22.3	16.6	31.3
Polyunsaturated	56.8	70.1	4.4	57.7

[a]For determination of the FA compositions, the control laboratory chow, linolenic acid mixture, coconut oil and corn oil samples were extracted and the fatty acid methyl esters were quantitated using GC.

free fatty acids and cholesteryl esters were dissolved in a borontrifluoride/methanol mixture for hydrolysis and methylation. The tubes were sealed under N_2 and kept in a boiling water bath for 15–45 min. The methylated fatty acids were extracted three times with *n*-hexane/diethyl ether (1:1, v/v). The analysis was performed by capillary gas chromatography using cyanosiloxane 60 as the stationary phase (17).

RESULTS

Diet. Lipids in the standard laboratory chow (control diet) were extracted and the total fatty acid composition was determined (Table 1). The control diet contained a relatively low level of saturated fatty acids, almost 50% 18:2 and low levels of other polyunsaturated fatty acids. Linolenic acid, a commercial product, consisted of 53% 18:3 and 47% 18:1 and 18:2. Half the fatty acids in coconut oil were myristic acid and the other two major components were 16:0 and 18:1. Only about 11% of the FA in corn oil were saturated; the remainder consisted of 18:1 and 18:2.

Phospholipids. Lipids were analyzed in the isolated microsomes and mitochondrial/lysosomal fractions. The various diets did not affect the protein content of these fractions (not shown in Table). The two major phospholipids in the isolated subfractions were PC and PE. The total and relative amounts of these phospholipids did not change under the various dietary conditions.

The distributions of saturated, monounsaturated and polyunsaturated fatty acids in microsomal PC and PE were similar, but substantial differences in the detailed compositions of these lipids were observed (Table 2). The ratio of 16:0/18:0 was approximately 0.9 in microsomal PC, while the corresponding value for PE was 0.5. In PE, the 18:2 content was less than in PC, whereas the content of 22:6 was twice as much as that of PC. When 18:3 was supplied in the diet, the degree of saturation increased as well as the relative amounts of 18:1 and 18:2. These increases were compensated for by a 53% reduction in the content of arachidonic acid. Coconut oil in the diet led to increased levels of saturated and monounsaturated FA and to lowered amounts of polyunsaturated FA. The corn oil-containing diet resulted in a moderate decrease in 16:0 and a 25% elevation in the arachidonic acid level. The diet containing 18:3 increased the levels of 18:0 and 22:6 and decreased that of 20:4 in microsomal PE. In rats given the coconut oil diet, the levels of saturated FA were elevated, while those of 18:2 and 22:6 decreased.

The fatty acid compositions of PC and PE in the mitochondrial/lysosomal fraction were very similar to those in their microsomal counterparts (Table 3). Consequently, substantial differences between these two lipids in the mitochondria/lysosomes were also present. Changes similar to those which occurred in microsomal PC and PE were observed in the PC and PE of mitochondria/lysosomes after various dietary treatments.

Cholesterol. Microsomal cholesterol was found primarily in free form, with only about 9% being esterified with a fatty acid (Table 4). Significant decreases in the content

Corn oil	14.8 ± 2.7	0.5 ± 0.1	3

[a]Cholesterol and cholesteryl FA were quantitated as described in Materials and Methods. The values are the means ± S.D. for six animals.

of microsomal cholesterol and in the degree of esterification were found after feeding rats the coconut oil or corn oil diet. When the corn oil-containing diet was fed to rats, the cholesterol content decreased moderately in the mitochondrial/lysosomal fraction; the other two diets increased the cholesterol content moderately. Only a small portion of cholesterol was esterified.

The fatty acid compositions of cholesterol in microsomes and mitochondria/lysosomes were very different (Table 5). While the degree of saturation in microsomes was 25%, this value in mitochondria/lysosomes was 51%, and the relative amount of palmitoleic acid was four times greater. The amount of 18:1 was much less in mitochondria/lysosomes and polyunsaturated FA constituted 13% of the total, whereas the corresponding value for microsomes was 42%. Microsomal cholesterol was, to a high degree, esterified with 18:3 in rats fed the diet containing linolenic acid. Dietary linolenic acid increased the degree of saturation, doubled the relative amount of 16:1, and decreased the content of 18:2 + 20:4 + 22:6 from 41% to 13%. The coconut oil diet elevated both the relative amounts of saturated and monounsaturated FA and decreased the levels of polyunsaturated FA. Surprisingly, the corn oil diet increased the relative amounts of saturated FA and 16:1 in microsomal cholesterol and reduced the level of polyunsaturated FA. When rats were given a diet enriched in 18:3, the content of 16:0 decreased, while the levels of 18:2 and 18:3 increased in mitochondrial/lysosomal cholesteryl esters. This diet also caused a decrease in total saturation and an elevation in total polyunsaturated FA. Larger changes occurred in the microsomal fraction than in the mitochondrial/lysosomal fraction when rats were fed the coconut oil diet. In rats fed the corn oil diet, changes in mitochondrial/lysosomal cholesteryl esters were similar to those which occurred in phospholipids; the levels of saturated FA decreased and those of polyunsaturated FA increased.

Dolichol. The three diets, particularly the one containing 18:3, significantly decreased dolichol and dolichyl ester levels in both the microsomal and mitochondrial/lysosomal fractions (Table 6). Furthermore, the degree of esterification decreased in microsomes of rats fed the 18:3 or the coconut oil diet. These diets, however, did not affect the degree of esterification in the mitochondrial/lysosomal fraction. Dolichyl esters in microsomes from control rats have a FA composition which is quite different from that of the other lipids (Table 7). One-third of the total FA is 18:0 and one-fourth is 16:0. The only polyunsaturated FA present, besides trace amounts of 18:3, is 6% of 18:2. In the mitochondrial/lysosomal dolichyl ester fraction the relative amount of 18:0 is 50% less than in microsomes, and one-third of the total is polyunsaturated FA. Rats fed the 18:3 diet had decreased levels of 18:0 in microsomes and increased levels of 16:0 in the mitochondrial/lysosomal fraction. The relative amounts of both monounsaturated and polyunsaturated FA increased in microsomes, but decreased in mitochondrial/lysosomal dolichyl esters. The total relative levels of saturated and unsaturated FA in microsomes of rats fed the coconut oil diet were not affected, but that of monounsaturated FA doubled in the mitochondrial/lysosomal frac-

[a]Dolichol and dolichyl esters were isolated by aminopropyl and C-18 column chromatography, followed by quantitation on reversed phase HPLC. The values are the means ± S.D. for six animals.

tion. Dolichol esters in both fractions were only slightly changed in rats fed corn oil, but in microsomes the level of 16:0 increased greatly and the level of 18:0 decreased. The isoprenoid patterns of dolichol and dolichyl esters were similar in microsomes and in the mitochondrial/lysosomal fraction, and no modification in these patterns was observed after the various dietary treatments.

DISCUSSION

Most of the dolichol, and part of the cholesterol, in liver and blood are esterified with a fatty acid. Esterification changes the properties of these lipids considerably, but the exact functional role(s) of the esterified derivative is not known. It is often claimed that association with fatty acids is necessary for storage, but no direct evidence is presently available (18).

A number of data indicate that fatty acids may serve as targeting signals, directing lipids to appropriate cellular locations (17). Uptake of cholesterol from the intestine (19) and secretion of low-density lipoprotein (LDL) to the blood (20) require esterification. In addition, the extensive esterification associated with high-density lipoprotein (HDL) may also regulate the distribution of cholesterol in the blood (21). Most dolichol is esterified in the endoplasmic reticulum by a specific transferase (10), and subsequent hydrolysis of the esters may occur both in lysosomes and plasma membranes (22). A number of experiments have demonstrated that intracellular targeting of dolichol requires esterification.

The type of phospholipid and the FA composition of these lipids are important for both the distribution and for the biosynthesis of cholesterol and dolichol. It has been demonstrated that cholesterol is associated preferentially with PC (23), while dolichol favors PE (24). Increasing concentrations of dolichol and dolichyl esters affect model membranes containing PE with unsaturated FA, causing destabilization, increased fluidity of phospholipid FA, and increased permeability (25,26). The nature of phospholipids and their FA compositions directly regulate enzymes of cholesterol biosynthesis (27,28) and of dolichol biosynthesis (29–31) and thereby regulate the levels of these two lipids. Cholesterol, dolichol and ubiquinone have a common initial biosynthetic pathway terminating with farnesyl-PP. It has been established that these three lipids have a common regulatory step at the level of the hydroxymethylglutaryl-CoA reductase (32), and an increase or decrease in biosynthesis of one of these lipids has well-characterized effects on the biosynthesis of the other two lipids.

A number of studies have shown that dietary changes can significantly influence the fatty acid compositions of phospholipids in the liver, as well as in other tissues (2,5,6). In our study, the effects of four diets (control, 18:3, coconut oil and corn oil) on microsomal and mitochondrial/lysosomal fractions were examined. We have found changes in the FA compositions of phospholipids and of two esterified products of the mevalonate pathway, but the mechanisms for these dietary changes are obviously different. *De novo* synthesis of phospholipids, cholesterol

[a]The total dolichyl ester fractions were isolated by HPLC and used to prepare fatty acid methyl esters for GC. The values are the means ± S.D. for six animals.

and dolichol is localized primarily in the endoplasmic reticulum, from where these lipids are transported both to the mitochondria and lysosomes to serve as membrane components or metabolic substrates (33). Modification of FA moieties in phospholipids can be achieved by *de novo* synthesis of new species, but most of FA are exchanged through transacylation reactions (34,35). No such exchange reactions occur with cholesterol or dolichol in liver, and modification of their FA patterns thus involves exclusively esterification of the free lipid.

The FA compositions of PC and PE in the microsomes and in the mitochondrial/lysosomal fraction were identical. However, these two lipids are modified independently during dietary treatment.

The dietary treatments employed here, particularly with coconut and corn oils, clearly depress the biosynthesis of products of the mevalonate pathway. The independent regulation of cholesterol esterification, in comparison with phospholipids and dolichol, is apparent from its high degree of unsaturation and the uptake of 18:3 from the diet. Furthermore, the degree of polyunsaturation decreased in microsomes of rats fed the coconut oil or corn oil diet, while mitochondrial/lysosomal cholesteryl esters were unchanged or enriched in polyunsaturated FA.

An independent regulation of the esterification process for dolichol is also apparent. Microsomes from control rats possess dolichyl esters with as much as 70% saturation, while the mitochondrial/lysosomal lipids show only about 40% saturation. The level of saturation decreased in microsomes of rats given the 18:3 diet, but increased in the mitochondrial/lysosomal fraction.

Our results show that the metabolic turnover of the fatty acyl moieties of various lipids in hepatocytes are regulated independently. The levels of phospholipids are constant, while those of cholesterol and dolichol are variable. The decreased levels of cholesterol and dolichol indicate inhibition of the mevalonate pathway. Decreased synthesis of these two lipids is probably compensated for, to some extent, by a decreased excretion of cholesterol and dolichol from the cell, thereby maintaining a basic cellular level of these lipids necessary for basic functions. Characteristically, phospholipid fatty acid compositions are species specific, but not organelle specific (36), while cholesterol and dolichol in the different organelles represent different pools which are regulated independently.

Both the properties of the fatty acyl transferases of the different lipids and their regulation are quite different. The large and opposite changes in the distribution of lipid esters in the subfractions suggest that in our experiments, modifications in FA compositions are not caused by an excess or deficiency of specific fatty acids in the substrate pool. The dietary treatments had a direct influence on the enzymes of the biosynthetic pathways.

Intracellular transport of newly synthesized cholesteryl and dolichyl esters occurs rapidly and effectively *via* the cytoplasm, independently of protein transport, and specific protein carriers for this purpose have not been identified (22,37,38). For these reasons, transport mechanisms other than those involving exclusive protein carriers should exist. It has been proposed repeatedly and also is supported by experimental findings that FA participate in the lipid transport process. The observations that the FA compositions of cholesteryl and dolichyl esters are different in various cellular organelles and that the FA present in the diet do not directly determine the FA composition of these two mevalonate pathway lipids favor the proposal that individual FA in the esterified forms function as targeting signals during the movement from the endoplasmic reticulum to specific cellular membranes.

Formation of Dityrosine and Other Fluorescent Amino Acids by Reaction of Amino Acids with Lipid Hydroperoxides

Kiyomi Kikugawa*, Tetsuta Kato and **Akira Hayasaka**
Tokyo College of Pharmacy, Tokyo 192-03, Japan

Formation of fluorescence by the reaction of various amino acids with lipid hydroperoxides, *i.e.*, linoleic acid 13-monohydroperoxide, methyl linoleate 13-monohydroperoxide and phosphatidylcholine hydroperoxide, in the presence of methemoglobin was investigated. Two types of fluorescence were produced: fluorescent dityrosine (3,3′-dityrosine) from tyrosine, and unidentified fluorophores with α- and ε-amino groups of various amino acids. While the former was stable after treatment with borohydride, the latter fluorophores were readily destroyed. The rate of dityrosine formation was rapid, and the yield of dityrosine was dependent on the concentrations of tyrosine and the lipid hydroperoxides. Butylated hydroxytoluene and tocopherol inhibited the formation of dityrosine, but did not affect the formation of fluorophores on the amino groups. Dityrosine appears to be formed by radical reaction of the lipid hydroperoxides, while the other fluorophores seem to be created by non-radical mechanisms.
***Lipids* 26, 922-929 (1991).**

Fluorescent lipofuscin pigments accumulate with age in tissues and cells (1). Pigment formation has been thought to be due to lipid peroxidation, as incubation of tissues or cells under aerobic conditions is known to produce fluorescence (2). Several mechanistic studies on fluorescence formation during lipid peroxidation have been undertaken (3-5). Peroxidation of lipids yields various reactive species including lipid peroxyl radicals, alkoxyl radicals, lipid hydroperoxides, and aldehydes (6). Among the products identified monofunctional aldehydes have been considered as possible candidates that contribute to the development of fluorescence (4,5,7-12). It is known that more reactive lipid peroxyl and alkoxyl radical species cause damage on proteins (13-15), but no evidence of their contribution to the formation of fluorescence has been brought forward.

Lipid hydroperoxides (ROOH) undergo heterolytic or homolytic cleavage to produce peroxyl radicals (ROO•) or alkoxyl radicals (RO•) when they react with metals or metal complexes (16-19). In the present study, we investigated the formation of fluorescence by reaction of various amino acids with lipid hydroperoxides in the presence of methemoglobin. This paper describes two possible reaction pathways to fluorescence formation: a radical pathway which yields fluorescent dityrosine (3,3′-dityrosine) and a non-radical pathway which produces fluorophores by reaction with amino groups of amino acids.

MATERIALS AND METHODS

Materials. Amino acids, L-arginine (Arg), L-histidine (His), L-lysine (Lys) hydrochloride, L-methionine (Met) and L-phenylalanine (Phe) were obtained from Ajinomoto Company, Ltd. (Tokyo, Japan). Glycine (Gly), L-tryptophan (Trp) and L-tyrosine (Tyr) were obtained from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). L-Cysteine (Cys) was the product of Kanto Chemical Company, Ltd. (Tokyo, Japan). Carbobenzoxy (Z)-amino acids, Z-Arg, Z-L-aspartic acid (Z-Asp), Z-L-isoleucine (Z-Ileu), Z-Phe, Z-L-proline (Z-Pro), Z-L-serine (Z-Ser), Z-Trp and Z-L-valine (Z-Val) were obtained from Wako Pure Chemical Industries. Z-His was from Sigma Chemical Company (St. Louis, MO). Nα-Z-Lys was from Fluka Chemie AG, Buchs, Switzerland. Z-Tyr was from Peptide Institute, Inc. (Osaka, Japan).

Commercial reagent-grade hydrogen peroxide (31% in water) used was estimated to be 9.11 M by iodometric titration. dl-α-Tocopherol was a product of Eisai Company, Ltd. (Tokyo, Japan). Butylated hydroxytoluene (BHT) was obtained from Nikki Universal Company (Tokyo, Japan). Horseradish peroxidase (HRP) [EC 1.11.1.7], methemoglobin (MetHb) from human, and superoxide dismutase Type I from bovine blood [EC 1.15.1.1] were obtained from Sigma. The concentration of MetHb was determined by use of a molecular extinction coefficient of MetHb subunit at 630 nm, 4010 (20), and expressed on a basis of MetHb tetramer.

Analysis. Ultraviolet absorption spectra were taken with a Hitachi (Tokyo, Japan) U-2000 double beam spectrophotometer. Fluorescence spectra were measured on a Hitachi 650-40 fluorescence photospectrometer. Fluorescence intensity at maximum excitation and emission relative to the intensity of 0.1 μM quinine sulfate in 0.1 N sulfuric acid was determined. Chemiluminescence intensity was counted on a Lumicounter 1000 machine (Nition Rikakikai Seisakusho, Ltd., Tokyo, Japan). High-performance liquid chromatography (HPLC) was carried out on a Shimadzu (Osaka, Japan) LC-2, a Hitachi 655A-11 or a Hitachi L-6000 liquid chromatograph equipped with an Inertsil ODS column (4.6 mm i.d. × 25 cm) (Gasukuro Kogyo Company, Ltd., Tokyo, Japan) or a YMC A-303 ODS column (4.6 mm i.d. × 25 cm) (Yamamura Research Laboratories, Kyoto, Japan). Elution solvents employed were: Solvent A, 0.5% acetic acid/methanol (29:1, v/v); Solvent B, 0.1 M ammonium formate/methanol (6:4, v/v); Solvent C, 0.1 M ammonium formate/methanol (1:1, v/v); and Solvent D, 0.1 M ammonium formate/methanol (4:6, v/v). Ultraviolet absorbing peaks were detected by a Shimadzu SPD-6A or a Hitachi 638-41 spectrophotometric detector. Fluorescent peaks were detected using a Shimadzu RF-530 fluorescence spectromonitor.

Peroxide values were determined according to the method of Wheeler (21).

Linoleic acid 13-monohydroperoxide (LOOH) and its

*To whom correspondence should be addressed at Tokyo College of Pharmacy, 1432-1 Horinouchi, Hachioji, Tokyo 192-03, Japan.

Abbreviations: BHT, butylated hydroxytoluene; HPLC, high-performance liquid chromatography; HRP, horseradish peroxidase; LOOH, linoleic acid 13-monohydroperoxide; MetHb, methemoglonin; MLOOH, methyl linoleate 13-monohydroperoxide; PC, phosphatidylcholine; PCOOH, phosphatidylcholine hydroperoxide; ROOH, lipid hydroperoxide; Z, carbobenzoxy.

methyl ester (MLOOH). Linoleic acid 13-monohydroperoxide (LOOH) was prepared according to the method of Gardner (22) using linoleic acid (Nippon Oil and Fats Company, Ltd., Tokyo, Japan) and lipoxygenase Type I from soybean [EC 1.13.11.12] (Sigma). Briefly, the solution of linoleic acid in borate buffer (pH 10) containing Tween 20 was purged with oxygen gas in the presence of lipoxygenase. The chloroform/methanol extract of the acidified reaction mixture was applied to a column of silicic acid, which was eluted with diethyl ether/*n*-hexane mixture. The ultraviolet absorption spectrum of each fraction was carefully monitored, and the fractions containing LOOH with a maximum absorption at 234 nm were collected. The purity of the hydroperoxide was 95–105% when estimated on the basis of its extinction coefficient at 234 nm, 24500 (23), and 97–106% when estimated on the basis of its theoretical peroxide value, 6400 meq/kg.

Methyl linoleate 13-monohydroperoxide (MLOOH) was prepared as follows. LOOH (500 mg) was dissolved in 20 mL of diethyl ether, and then an excess of diazomethane in diethyl ether was added. The mixture was kept at room temperature for 5 min and evaporated *in vacuo* to dryness. The methylated product was applied to a column (2 cm i.d. × 25 cm) of silica gel, and the column was eluted with diethyl ether/*n*-hexane (15:85, v/v). The peak fractions detected at 234 nm were collected and evaporated *in vacuo* to dryness. MLOOH was obtained in a yield of 320 mg. The product showed a single spot at R_f 0.1 on a silica gel thin-layer chromatogram developed with diethyl ether/*n*-hexane (15:85, v/v), when detected by potassium iodide. The purity of the product was 94.3% based on its theoretical peroxide value, 6140 meq/kg.

Phosphatidylcholine hydroperoxide (PCOOH). Egg yolk phosphatidylcholine (PC) (Coatsome NC-10 from Nippon Oil and Fats Company) was photoxidized in the presence of methylene blue according to the method of Miyazawa *et al.* (24). The reaction mixture was subjected to preparative reverse phase thin-layer chromatography, using DC-Fertigplatten RP-8F_{254}S (E. Merck, Darmstadt, Germany) and methanol/chloroform/water (10:1.5:0.5, v/v/v) as developing solvent. Phosphatidylcholine (PC) appeared at R_f 0.21 when detected by iodine vapor; the product appeared at R_f 0.27 when detected with iodine vapor, potassium iodide and ultraviolet light. The product was extracted with chloroform/methanol (1:1, v/v), and the extract was evaporated to dryness (73 mg). The product showed an absorption maximum at 233 nm in ethanol, and a peroxide value of 2600–3200 meq/kg.

Dityrosine. Dityrosine (3,3′-dityrosine) was prepared according to a previously reported method (25). A mixture of 5 mM Tyr, 5.25 mM hydrogen peroxide and 3 mg HRP in 0.2 M borate buffer (pH 9.5) (200 mL) was incubated at 37°C for 2 hr. Dityrosine was separated from small amounts of Tyr, and its trimer through a column of cellulose phosphate P-10 (Whatman Inc., Clifton, NJ). About 20 mg of dityrosine was obtained as a brownish colored powder. HPLC analysis of the preparation, using an Inertsil ODS column and Solvent A at a flow rate of 0.8 mL/min, showed a single ultraviolet and fluorescent peak at a retention time of 13.5 min. Ultraviolet absorption and fluorescence spectra (Fig. 1) of the preparation were identical with those reported (25–27). The concentration of dityrosine was determined based on its molar extinction coefficient at 284 nm (0.02 N HCl), 5400 (26).

Loss of Z-amino acids by LOOH/MetHb. A mixture of 1.0 mM Z-amino acid and LOOH (10 mM)/MetHb (1.3 μM) in 0.1 M phosphate buffer (pH 7.5) was incubated at 37°C for 24 hr. The Z-amino acid that remained unchanged was determined by HPLC of the reaction mixture using a YMC A-303 ODS column and Solvent B (for Z-Ser, Arg, Asp, Lys and His), Solvent C (for Z-Tyr) and Solvent D (for Z-Trp) at a flow rate of 0.8 mL/min. The peak due to Z-amino acid was detected at 260 nm, and its peak height was compared with that of the standard Z-amino acid solution.

Formation of fluorescence in reaction of amino acids (Z-amino acids) with lipid hydroperoxide/MetHb. A mixture of amino acid (Z-amino acid) and LOOH (MLOOH or PCOOH)/MetHb in 0.1 M phosphate buffer (pH 7.0, 7.5) or 0.2 M borate buffer (pH 9.5) was incubated at 37°C for 24 hr. The reaction mixture was then treated with 88 mM sodium borohydride at 0°C for 4 hr. Fluorescence spectra and relative intensities of the mixture were measured before and after the treatment with borohydride.

Formation of dityrosine and loss of Tyr in reaction of Tyr with LOOH/MetHb or hydrogen peroxide/HRP. A mixture of Tyr and LOOH/MetHb or hydrogen peroxide/HRP in the buffer was incubated at 37°C for the indicated period. The amount of dityrosine produced was determined by direct fluorescence measurement and HPLC analysis of the reaction mixture. Fluorescence intensity of the reaction mixture was measured after dilution into the same buffer, and the amount of dityrosine was obtained by comparison of the intensity with that of the standard dityrosine in the same buffer. HPLC analysis was done using an Inertsil ODS column and Solvent A at a flow rate of 0.8 mL/min. The peak due to dityrosine was detected at a retention time of 13.5 min by fluorescence at 300 (excitation) and 400 nm (emission), and by absorption at 280 nm. The amount of dityrosine was determined by comparing the peak heights estimated by both fluorescence and absorption with those obtained from the standard dityrosine solution. The amount of Tyr that remained unchanged was determined similarly. The height of the peak due to Tyr detected at 280 nm and of that which appeared at a retention time of 10.5 min were compared with that of a standard Tyr solution.

RESULTS

Formation of fluorescence in the reaction of amino acids and lipid hydroperoxides in the presence of MetHb. Lipid hydroperoxides (ROOH) are cleaved into radical species, lipid peroxyl radicals (ROO•) or alkoxyl radicals (RO•), by interaction with ferric complexes (16–19). In the present investigation, these lipid radicals were generated when hydroperoxides of linoleic acid (LOOH), methyl linoleate (MLOOH) and phosphatidylcholine (PCOOH) interacted with MetHb.

The decrease in Z-amino acids (1mM) caused by the reaction of an excess amount of LOOH (10 mM)/MetHb (1.3 μM) in phosphate buffer (pH 7.5) was investigated (Table 1). Loss of Nα-Z-Lys, Z-Tyr, Z-His and Z-Trp was significant but relatively small. The result, however, indicated that heterocyclic, amino and phenolic groups in amino acids were more susceptible to LOOH/

TABLE 1

Loss of Z-amino Acids Caused by Reaction with LOOH/MetHb[a]

Z-Amino acid	% Loss	
	2 hr	24 hr
Z-Ser	nd[b]	0
Z-Arg	nd[b]	2.9
Z-Asp	nd[b]	0
Nα-Z-Lys[c]	9.7	12.9
Z-Tyr[c]	3.6	5.7
Z-His[c]	13.0	nd[b]
Z-Trp[c]	9.1	17.6

[a]A mixture of 1.0 mM Z-amino acid and LOOH (10 mM)/MetHb (1.3 μM) in 0.1 M phosphate buffer (pH 7.5) was incubated at 37°C, and % loss of Z-amino acid was determined by HPLC analysis (See Materials and Methods).

[b]nd, not determined.

[c]Control experiments of the Z-amino acid alone and with MetHb (1.3 μM) did not show any significant loss after 24 hr.

MetHb than alkyl groups, which is consistent with earlier observations (14).

Formation of fluorescence in the reaction of amino acids or Z-amino acids with lesser amounts of lipid hydroperoxides/MetHb was investigated (Table 2). In the reaction of amino acids with LOOH/MetHb in phosphate buffer (pH 7.5), the reaction mixtures of Gly, Arg, Lys, Phe and His produced fluorescence with relative intensities slightly higher than those of the controls without the amino acids. They showed spectra with excitation maxima at 353–360 nm and emission maxima at 430–435 nm. The reaction mixture of Tyr produced fluorescence whose relative intensity was much higher than that of the control. The mixture showed a spectrum with an excitation maximum at 320 nm and an emission maximum at 410 nm. In similar reactions with Z-amino acids, only Nα-Z-Lys and Z-Tyr produced fluorescence, and no marked fluorescence was produced from other Z-amino acids. Hence, the amino groups in amino acids and the phenolic function in Tyr may be responsible for fluorescence development.

The formation of fluorescence was more significant in the reactions of amino acids and Z-amino acids with LOOH/MetHb in borate buffer (pH 9.5). While the fluorescence spectra of the reaction mixtures of Gly, Arg, Lys, Phe, His and Nα-Z-Lys were similar to those observed with the reaction mixtures in phosphate buffer, the maximum wavelengths of fluorescence from the reaction mixtures of Tyr and Z-Tyr were shorter than those observed with the reaction mixtures in phosphate buffer. This spectral difference of the reaction mixtures of Tyr and Z-Tyr in borate buffer may be due to the effect of borate on the fluorescence. While fluorescence from amino acids except for Tyr, and from Nα-Z-Lys was readily lost upon borohydride treatment, fluorescence from Tyr and Z-Tyr remained stable.

The reactions of Nα-Z-Lys and Z-Tyr with MLOOH/MetHb or PCOOH/MetHb in borate buffer (pH 9.5) gave marked fluorescence with characteristics similar to those obtained from the reaction of LOOH/MetHb.

Hence, two types of fluorescence were produced in the reaction of amino acids with the lipid hydroperoxides: the fluorescence on α- and ε- amino groups of the amino acids which was readily destroyed by borohydride treatment and the fluorescence on Tyr which was resistant to the treatment.

Formation of dityrosine in reaction of Tyr with LOOH in the presence of MetHb. Fluorescent dityrosine (3,3′-dityrosine) is a known oxidation product of Tyr (25–27). Standard dityrosine, prepared by oxidation of Tyr with hydrogen peroxide/HRP (25), showed absorption maxima at 285 (in acid) and 315 nm (in alkali). It exhibited the characteristic fluorescence spectra shown in Figure 1. Fluorescence spectra and intensities were influenced by pH and solvent. Fluorescence in acidic media showed maxima at 285 (excitation) and 410 nm (emission) and a relative molar intensity of 0.05. Fluorescence in alkaline medium showed maxima at 320 (excitation) and 410 nm (emission) and relative molar intensities of about 0.40. Fluorescence in borate buffer (pH 9.5) showed maxima at 298 (excitation) and 384 nm (emission) and a relative intensity of 0.10. The spectral difference in borate buffer may be due to the formation of some type of complex between dityrosine and borate (26).

The fluorescence data of the reaction mixtures of Tyr and Z-Tyr with lipid hydroperoxides/MetHb in phosphate and borate buffers listed in Table 2 were similar to those of standard dityrosine in the buffers (Fig. 1). As standard dityrosine is resistant to borohydride treatment, the stability of fluorescence of the reaction mixtures of Tyr and Z-Tyr upon borohydride treatment (Table 2) supported the idea that the reactions produced dityrosine and Z-dityrosine, respectively. HPLC of the reaction mixture of Tyr and an excess amount of LOOH/MetHb in borate buffer revealed a single fluorescent peak at a retention time of 13.5 min (Fig. 2A), which coincided with that of dityrosine formed by the reaction of Tyr with hydrogen peroxide/HRP (Fig. 2B). Ultraviolet absorption and fluorescence spectra of the peak fraction in various solvents were the same as those of standard dityrosine. Hence, the fluorophore formed in the reaction of Tyr with LOOH/MetHb was dityrosine.

The yield of dityrosine and the loss of Tyr in the reaction of Tyr with LOOH/MetHb under various conditions was estimated (Table 3). In the reaction of 5 mM Tyr with an excess amount of LOOH/MetHb at pH 9.5, the yield of dityrosine amounted to 20% accompanied by about 30% loss of Tyr. A similar reaction of Tyr with hydrogen peroxide/HRP yielded a higher amount of dityrosine (50%) accompanied by an extensive loss of Tyr (about 95%). The yield of dityrosine in the reaction of 1.35 mM Tyr with LOOH/MetHb at pH 7.5 increased as the concentration of LOOH/MetHb increased, but the yield was only 1.5% even at the high concentration of LOOH (10 mM)/MetHb (1.3 μM). In a similar reaction with hydrogen peroxide/HRP, the yield of dityrosine was maximal (8.4%) at the lower concentration of hydrogen peroxide (1 mM)/HRP (10 μg/mL) and decreased at the higher concentrations.

The time course of the formation of dityrosine and the loss of Tyr in the reaction of 1.4 mM Tyr with an excess amount of LOOH/MetHb at pH 7.5 were followed (Fig. 3). The formation of dityrosine rapidly reached a maximum after 2 min, whereas the loss of Tyr continued over 24 hr. In a similar reaction with hydrogen peroxide/HRP, the formation of dityrosine was gradual and reached a maximum after 2 hr, whereas the loss of Tyr continued over 24 hr. The results indicate that the formation of dityrosine in the reaction of Tyr with LOOH/MetHb de-

[a]A mixture of amino acid (Z-amino acid) at the indicated concentration and hydroperoxide/MetHb at the indicated concentration in 0.1 M phosphate buffer (pH 7.5 or 7.0) or 0.2 M borate buffer (pH 9.5) was incubated at 37°C for 24 hr. Fluorescence spectra and intensities of the reaction mixture before and after borohydride treatment were measured. Control experiment of amino acid (Z-amino acid) alone, or a mixture of amino acid (Z-amino acid) with MetHb (14 μM) did not produce any detectable fluorescence under the conditions.

[b]The relative fluorescence intensities underlined indicate increased fluorescence as compared with the value obtained without the amino acid (Z-amino acid) [none].

[c]The reaction mixture was treated with borohydride as described in Materials and Methods.

[d]Control experiment without amino acid (Z-amino acid) [none] produced fluorescence probably due to the globin moiety of MetHb.

pended on the concentrations of the substrate and of the hydroperoxide, and that the rate of dityrosine formation was rapid.

Contribution of radical species to dityrosine formation. Effect of radical scavengers on fluorescence formation in the reaction of Lys and Tyr with LOOH/MetHb at pH 9.5 was investigated (Table 4). Sodium azide that scavenges singlet oxygen (28), superoxide dismutase that destroys superoxide (29), methanol and mannitol that scavenge hydroxyl radicals (30), and dl-α-tocopherol and BHT as chain breaking antioxidants (31) were added to the reaction mixtures. The formation of fluorescence from Lys did not appear to be prevented by any of these scavengers. In contrast, the formation of dityrosine was dramatically inhibited by dl-α-tocopherol and BHT. Dityrosine formation in the reaction of Tyr with hydrogen peroxide/HRP was similarly inhibited by the antioxidants. The formation of dityrosine from Tyr appears to be caused by the radical species generated from LOOH/MetHb.

Tyr phenoxy radical, which emits chemiluminescence,

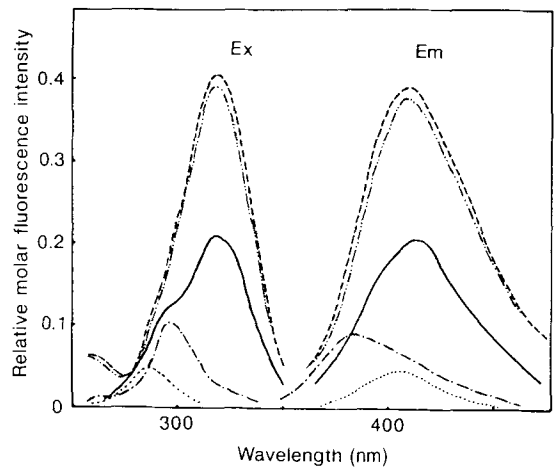

FIG. 1. Fluorescence spectra of dityrosine and its molar fluorescence intensities relative to quinine sulfate, in 0.02 N HCl (.....), 0.1 M phosphate buffer (pH 7.0) (——), 0.2 M carbonate buffer (pH 9.5) (– – –), 0.2 M borate buffer (pH 9.5) (—·—), and 0.02 N NaOH (—··—).

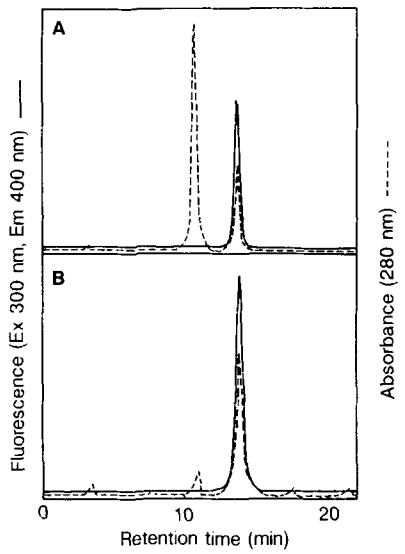

FIG. 2. HPLC of the reaction mixtures of 5.0 mM Tyr and LOOH (16 mM)/MetHb (54 μM) (A) and hydrogen peroxide (5 mM)/HRP (15 μg/mL) (B) in 0.2 M borate buffer (pH 9.5) incubated at 37°C for 2 hr. HPLC was performed using an Inertsil ODS column and 0.5% acetic acid/methanol (29:1, v/v) at a flow rate of 0.8 mL/min.

has been detected in the reaction of Tyr with hydrogen peroxide/HRP (32). The reaction mixtures of Tyr and LOOH/MetHb at pH 7.5 and pH 9.5 emitted intense chemiluminescence (Fig. 4A). Emission of chemiluminescence was maximal at 3 min of the reaction and ceased after 40 min. Similar reaction mixtures of Tyr with hydrogen peroxide/HRP emitted chemiluminescence (Fig. 4B), and the intensities gradually increased during 40 min. The results suggest that the radical species from LOOH abstracted a hydrogen radical from Tyr to give a Tyr phenoxy radical, which in turn condensed to dityrosine.

DISCUSSION

Fluorescence formation in aged tissues has received considerable attention as it is regarded an index for aging (1-5). There is considerable evidence that lipid peroxidation of tissues and cells can lead to the development of fluorescence. Lipid peroxidation generally proceeds through the formation of lipid hydroperoxides (ROOH) as primary products, which are subsequently cleaved into peroxyl (ROO•) and alkoxyl radicals (RO•). The latter are then decomposed to aldehydes (6).

Various aldehyde species can produce fluorescence by interaction with amino acids and proteins (3-5). Malonaldehyde had long been considered to be responsible for fluorescence formation (3), although it is only of minor consequence because its levels in peroxidized tissues are typically much lower than generally expected. Also the fluorescence characteristics produced from malonaldehyde are quite different from those produced from peroxidized lipids (4,5). Aldehyde species other than malonaldehyde are now being considered as more likely candidates for fluorescence formation (4,5,7-12).

TABLE 3

Formation of Dityrosine and Loss of Tyr in Reaction of Tyr with LOOH/MetHb and Hydrogen Peroxide/HRP

Reaction mixture[a]					Dityrosine μM			
						By HPLC analysis[b]		
Tyr mM	LOOH/MetHb mM/μM	Hydrogen peroxide/HRP mM/μg/mL	pH	Reaction time hr	By fluorescence intensity[b]	Fluorescence detection	Ultraviolet detection	Tyr mM By HPLC analysis[b]
5.0	16/54		9.5	2	540	470	460	3.36
5.0		5/15	9.5	2	1390	1290	1310	0.22
1.35	1/0.13		7.5	24		1		
1.35	5/0.65		7.5	24		4		
1.35	10/1.3		7.5	24		10.5		
1.35		1/10	7.5	24		58		
1.35		5/50	7.5	24		31		
1.35		10/100	7.5	24		31		

[a]A mixture of Tyr and LOOH/MetHb or hydrogen peroxide/HRP in 0.1 M phosphate buffer (pH 7.5) or 0.2 M borate buffer (pH 9.5) was incubated at 37°C for the indicated period.

[b]See Materials and Methods.

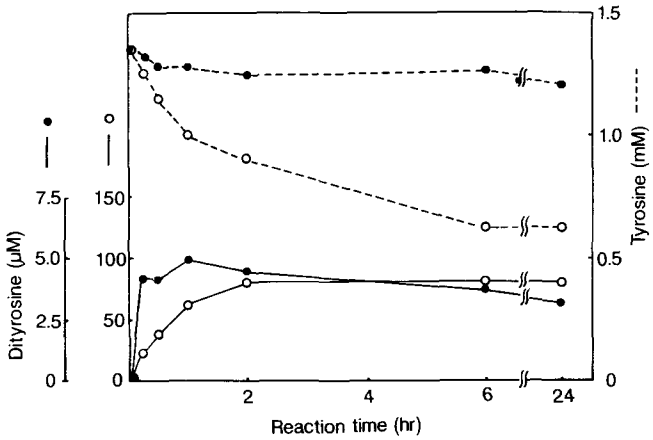

FIG. 3. Time course of the formation of dityrosine (—) and the loss of Tyr (---) in the reaction of 1.35 mM Tyr with LOOH (10 mM)/MetHb (1.3 μM) (●) and hydrogen peroxide (1 mM)/HRP (10 μg/mL) (○) in 0.1 M phosphate buffer (pH 7.5) at 37°C. Dityrosine and Tyr were determined by HPLC as described in Materials and Methods.

In the present investigation, an alternative mechanism for fluorescence formation during lipid peroxidation emerged. The reactive lipid peroxyl (ROO·) or alkoxyl (RO·) radicals generated from lipid hydroperoxides (ROOH) produced by reaction with amino acids, two types of fluorescence. One was due to fluorescent dityrosine from Tyr, the other was due to fluorescence derived from α- and ε-amino groups of the amino acids (Scheme 1). The first appears to be produced by a radical reaction. The peroxyl and alkoxyl radicals seem to abstract a hydrogen radical from Tyr to produce the Tyr phenoxy radical which in turn condenses to fluorescent dityrosine. This mechanism is consistent with the facts that antioxidants prevent the formation of dityrosine, and that chemiluminescence due to the phenoxy radical (32) is emitted during the reaction. The second type of fluorescence seems to be produced by a non-radical reaction. Since the fluorescence spectra of the fluorophores that are produced on the amino groups are similar to those obtained by reaction of amino acids with LOOH in the absence of ferric complexes (33), lipid hydroperoxides as such or some types of their non-radical degradation products seem to be involved in the formation of fluorophores on the amino groups.

TABLE 4

Effect of Scavengers on Fluorescence Formation in the Reaction of Lys and Tyr with LOOH/MetHb and Hydrogen Peroxide/HRP[a]

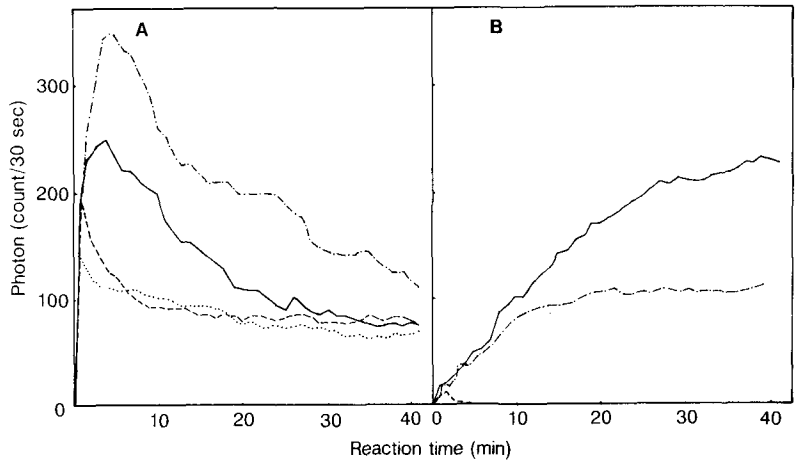
	LOOH/MetHb		Hydrogen peroxide/HRP
Scavenger added	Fluorescence from Lys[b]	Dityrosine from Tyr[c]	Dityrosine from Tyr[c]
None	100	100	100
Sodium azide 10 mM	88	101	114
Superoxide dismutase 0.1 mg/mL	104	109	109
Methanol 4%	96	114	69
Mannitol 100 mM	94	98	109
dl-α-Tocopherol 100 μM[d]	80	24	1
BHT 100 μM[d]	113	0	0

[a]Mixtures of 1.0 mM Lys or Tyr, and LOOH (1.0 mM)/MetHb (1.5 μM) or hydrogen peroxide (1.0 mM)/HRP (3 μg/mL) in 0.2 M borate buffer (pH 9.5) was incubated at 37°C for 24 hr in the presence of scavenger.

[b]Fluorescence intensity at 350 (excitation) and 430 nm (emission) was compared.

[c]The amount of dityrosine determined by HPLC analysis (fluorescence) was compared.

[d]Acetonitrile (30%) was incorporated into the reaction mixture to dissolve the agents.



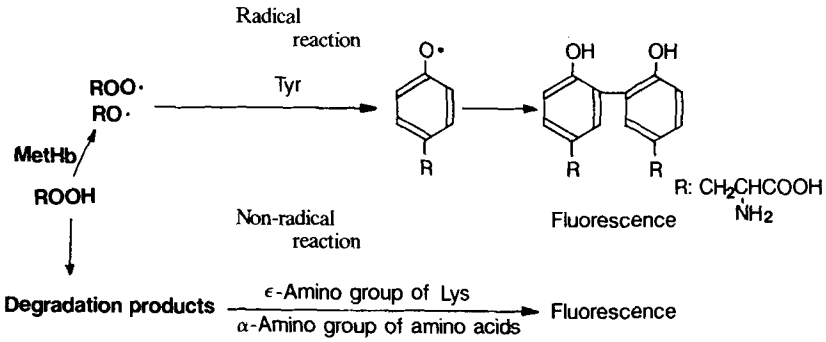


FIG. 4. Chemiluminescence intensities of the reaction mixtures of 1.35 mM Tyr and LOOH (10 mM)/MetHb (1.3 μM) (A) and hydrogen peroxide (1 mM)/HRP (10 μg/mL) (B) in 0.1 M phosphate buffer (pH 7.5) (—) and in 0.2 M borate buffer (pH 9.5) (——) incubated at 37°C. The controls without Tyr at pH 7.5 (– – –) and at pH 9.5 (·····) were similarly counted.

SCHEME 1

The fluorescence spectra of dityrosine and of the fluorophores produced on the amino groups are different. The wavelengths of maximum excitation and emission of dityrosine are shorter than those of the fluorophores on the amino groups. Furthermore, both can be distinguished by borohydride treatment. Dityrosine is resistant to borohydride treatment, whereas the fluorophores on the amino groups are not.

The present findings on the formation of dityrosine by lipid peroxyl or alkoxyl radicals appear important also from another point of view. Although dityrosine was first recognized some 30 years ago (34), there is renewed interest in its occurrence in natural proteins (26,35-44). Although dityrosine can be produced by reaction with hydrogen peroxide/HRP or with ovoperoxidase (25,26, 34,42), by radiolysis (45), by ultraviolet irradiation (27), by reaction with tetranitromethane (46), ozone (47), periodate (48), or by reaction with bromine radicals (49), most of these reactions do not seem to take place in *in vivo* systems. In a previous paper (50), we described the formation of fluorescence and intermolecular cross-links in α-crystallin by reaction with lipid hydroperoxides, and suggested the formation of fluorescent dityrosine and other fluorophores in the protein. The present findings suggest that lipid peroxidation contributes to dityrosine formation in tissues. Induction of lipid peroxidation in tissues generates lipid peroxyl and alkoxyl radicals, which could play an important role in the formation of dityrosine in natural proteins.

[Received April 25, 1990, and in revised form April 29, 1991; Revision accepted September 23, 1991]

Changes in Lipids of Pigeon "Milk" in the First Week of Its Secretion

Sreerama Shetty and **S.N. Hegde***
Division of Applied Zoology, Department of Biosciences, Mangalore University, Mangala Gangotri, 574 199, India

Pigeon "milk" (PM) collected from the crop of 1- to 5-day-old squabs was analyzed to examine whether there were changes in lipid composition during the first week of secretion. The high PM fat content (9–11%) remained fairly constant in the first 5 days of secretion. The mean percentage of neutral lipids, glycolipids and phospholipids was 80, 12 and 8%, respectively. Unlike the content of neutral lipids, glycolipid and phospholipid levels increased significantly between day 1 and day 5 of secretion. Triglycerides, the major neutral lipids, decreased by 24% between day 1 and day 5, while free sterols, monoglycerides and hydrocarbons increased by 8%, 11% and 2.5%, respectively, during the same period; diglycerides and sterol esters, however, remained unchanged. The ratio of saturated to unsaturated fatty acids was 0.27 and it remained unchanged. Medium-chain (C_{10}, C_{12} and C_{14}) and odd-chain (C_{15} and C_{17}) fatty acid contents were low. Fatty acids longer than C_{20} were absent. Palmitic acid, the major saturated fatty acid, increased by 42% from day 1 to day 5, whereas stearic acid decreased by 48% during the same period. Oleic acid, the predominant unsaturated fatty acid, also decreased from 51 to 45% between the first and fifth day of PM secretion. Polyunsaturated acids (18:2, 18:3 and 20:4) accounted for 26% and 30% of the total fatty acids on day 1 and day 5, respectively. Although lipid changes in the crop of squabs prior to collection of samples cannot totally be ruled out, the nature of lipid changes is likely to reflect cellular breakdown that precedes PM secretion by parent pigeons.
***Lipids* 26, 930–933 (1991).**

Pigeon "milk" (PM) is an avian crop secretion exuded by pigeons and doves of the family Columbidae (1). The altricial birds called squabs are fed by regurgitation with PM by female and male parents in the first three post-hatching weeks (1,2). However, after day 5 of secretion, PM becomes mixed with increasing quantities of grains which makes it more difficult to obtain PM in satisfactorily pure form.

Earlier PM analyses suggested that PM contains about 8% lipid, 14% protein, 0.05% glycogen (3,4), and 2.6% minerals (5). More recently it has been reported that PM lipids consist primarily of triglycerides (81.2%) and phospholipids (12.7%) (6,7). As the squabs increase their body weight 8-fold in the first week, and because fat is the principal energy source (60%) in the PM diet (Shetty, S., and Hegde, S.N., unpublished data), it was of interest to determine whether the lipid composition would change during this period. The occurrence of certain types of glycolipids of PM is also reported here for the first time.

Abbreviations: DG, diglyceride(s); FID, flame ionization detector; PM, pigeon "milk"; TG, triglyceride(s); TLC, thin-layer chromatography.

MATERIALS AND METHODS

Rock or house pigeons (*Columba livia*) that were bred and maintained on a mixed-grain cereal based diet (3.5% lipids), supplemented with minerals and vitamins, were used. PM was collected as a semi-solid material once a day through small, surgically made slits on the crop of the squabs as described by Pase *et al.* (8). The slits were closed by double sutures after extraction of the milk (a maximum of 4–6 g of milk could be collected at a time). Samples contaminated by grains were sorted by hand. PM samples obtained on different days of secretion were separately pooled and stored in the cold (−20°C). Total lipids were extracted from small samples with a mixture of chloroform/methanol (2:1, v/v) and washed with water to remove non-lipid contaminants following the method of Folch *et al.* (9). Non-lipid contaminants were also removed by passing the extracts through Sephadex G-25 (Pharmacia Fine Chemicals, Uppsala, Sweden) columns (10). Lipids were concentrated on a rotary flash evaporator under vacuum. The lipid content was estimated spectrophotometrically based on organic carbon using stearic acid as standard (11). Total lipids in a minimum volume of chloroform were separated into neutral lipids, glycolipids and phospholipids by eluting with chloroform, acetone and methanol, respectively, using silicic acid columns (12). The lipid classes were estimated on the basis of organic carbon as mentioned above.

Neutral lipids loaded onto heat-activated silicic acid columns were fractionated into hydrocarbons, steryl esters, triacylglycerols, free sterols, diacylglycerols and monoacylglycerols by successive elution with hexane, 15% benzene, 5% diethyl ether, 15% diethyl ether, 30% diethyl ether (all in hexane) and finally with pure diethyl ether (13). Glycolipids were separated into acylsterol glycosides, monogalactosyl diglycerides, sterol glycosides and digalactosyl diglycerides by eluting with a mixture of chloroform/acetone (9:1, v/v, 8:2, v/v, 7:2, v/v, and 2:8, v/v, respectively) (14). Phospholipids were separated into phosphatidic acid plus cardiolipin, phosphatidylethanolamine plus phosphatidylserine, phosphatidylinositol plus phosphatidylcholine, and sphingomyelin plus lysophosphatidylcholine using chloroform/methanol 95:5, v/v, 80:2, v/v, 50:50, v/v and pure methanol, respectively (15). Neutral lipid and phospholipid fractions were identified on thin-layer chromatography (TLC) plates by comparison with standards (Sigma Chemical Company, St. Louis, MO) using petroleum hydrocarbon (b.p. 60–80°C)/diethyl ether/acetic acid (80:20:1, v/v/v) and chloroform/methanol/water (65:25:4, v/v/v) as solvent systems, respectively. However, in respect to glycolipids, only the homogeneity was checked by TLC employing chloroform/methanol/water (65:25:4, v/v/v) as solvent system. For estimation of fatty acids, the total lipids were saponified with alcoholic potassium hydroxide and methylated with diazomethane (16). Fatty acid methyl esters were analyzed using a gas chromatograph (Schimadzu Gc-9A, Kyoto, Japan) fitted with flame ionization detector (FID) and recorder C-R3A.

TABLE 1

Changes in the Lipids of Pigeon "Milk" in the First Five Days of Its Secretion

Day of secretion	Total lipid (g/100 g wet wt)	Percentage of 3 major lipid classes		
		Neutral lipids	Glycolipids	Phospholipids
1	9.24 ± 0.71[a]	84.55 ± 6.75	9.50 ± 1.72	5.95 ± 1.14
2	10.40 ± 0.65	81.94 ± 6.33	10.51 ± 1.53	7.55 ± 1.32
3	10.83 ± 0.89	80.65 ± 8.14	13.22 ± 1.63	6.13 ± 1.80
4	11.23 ± 0.70	77.98 ± 5.20	14.06 ± 4.36	7.95 ± 1.72
5	11.36 ± 0.98	72.53 ± 3.98	15.05 ± 4.35	12.42 ± 2.81
P[b]	NS[c]	NS[c]	<0.05	<0.05

[a]Values are mean ± SE of 8 determinations on samples pooled from 10 collections.
[b]Significance of difference between day 1 and day 5 sample.
[c]NS, not significant.

Separation was achieved on 3 m × 2 mm columns of 10% EGSS-Y on Chromosorb W (100–200 mesh, acid washed) operated isothermally at 190°C. Different components were identified with reference to known standards (Sigma) by plotting the logarithm of their retention times against carbon numbers. The data were statistically processed by applying Student's t-test.

RESULTS

Changes in different classes of PM lipids in the first five days of secretion are shown in Table 1. PM has about 9–11% total lipid which did not undergo significant change between day 1 and day 5. Total lipid content determined upon removal of non-lipid contaminants by Folch washing was not different from that obtained by passing chloroform/methanol extracts through Sephadex-G columns. Hence the former procedure was adopted in the present work. Neutral lipids were in the range of 73–85% with a mean value of about 80%; their level decreased slightly but not significantly in the first week. Glycolipids were in the range of 10–15% (mean 12%) and increased significantly ($P<0.05$) between day 1 and day 5. Similarly phospholipids accounted for about 6–12% (mean 8%) and increased significantly ($P<0.05$) in the first week of secretion. Among neutral lipids of PM, the level of major triglyceride fractions decreased from 59% to 35% ($P<0.001$) whereas that of free sterols, monoglycerides and hydrocarbons increased from 16% to 24% ($P<0.01$), 8–19% ($P<0.001$) and 1.5–4% ($P<0.01$), respectively. Steryl esters (2.3%) and diglycerides (14%) remained constant, however (Fig. 1).

As illustrated in Figure 2, the digalactosyl diglycerides and acylsterol glycosides decreased from 33 to 25% ($P<0.01$) and 28 to 23% ($P<0.05$), respectively, while monogalactosyl diglycerides increased from 11 to 26% ($P<0.001$) of glycolipids between day 1 and day 5. In contrast, sterol glycosides (25–27%) did not change significantly during this period. Changes in the phospholipids are shown in Figure 3. Phosphatidylcholine (plus phosphatidylinositol) and phosphatidylethanolamine (plus phosphatidylserine) decreased from 41 to 35% ($P<0.02$) and 27 to 22% ($P<0.05$) of phospholipids between day 1 and day 5, respectively. Whereas sphingomyelin plus lysophosphatidylcholine increased significantly from 17 to 27% ($P<0.01$), phosphatidic acid plus cardiolipin

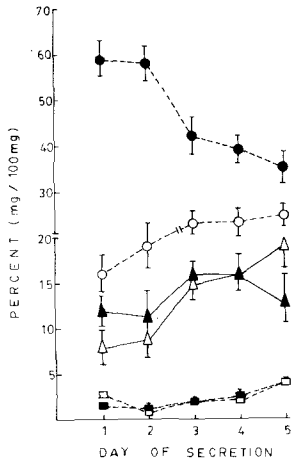

FIG. 1. Changes in the relative proportion of neutral lipid classes in pigeon milk during the first five days of secretion. Symbols: ●--●, triglycerides; ○--○, free sterols; ▲—▲, diglycerides; △—△, monoglycerides; □--□, steryl esters; ■--■, hydrocarbons. Vertical bars indicate SE of 4 determinations.

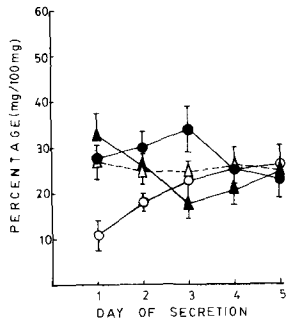

FIG. 2. Changes in the relative proportion of glycolipid classes in pigeon milk during the first five days of secretion. Symbols: ▲—▲, digalactosyl DGS; ●—●, acylsterol glycoside; △--△, Sterol glycoside; ○—○, monogalactosyl DGS. Vertical bars indicate SE of 4 determinations.

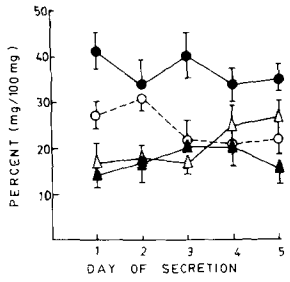

FIG. 3. Changes in the relative proportion of phospholipid classes in pigeon milk during the first five days of secretion. Symbols: ●—●, phosphatidylcholine (plus phosphatidylinositol); ○--○, phosphatidylethanolamine; △—△, sphingomyelin plus lysophosphatidylcholine; ▲—▲, phosphatidic acid plus cardiolipin. Vertical bars indicate SE of 4 determinations.

TABLE 2

Fatty Acid Composition (% total) of Pigeon "Milk" Total Lipids[a]

	Day of secretion				
Fatty acid	1	2	3	4	5
10:0	0.2	0.3	0.6	0.9	0.7
12:0	0.1	0.1	0.2	0.6	0.9
14:0	0.9	0.6	0.9	1.1	0.9
15:0	0.6	0.1	0.5	0.3	0.3
16:0	11.0	12.9	15.4	14.8	15.7

18:3	3.3	1.6	2.5	2.0	2.0
20:0	Tr	Tr	Tr	Tr	Tr
20:4	Tr	2.3	Tr	Tr	Tr

[a]Mean percentage values of two determinations made on samples pooled from 10 collections. Tr, trace.

(14-15%) remained almost constant between day 1 and day 5.

Due to small sample size, the fatty acid changes could not be tested statistically. However, the apparent trends indicated that between day 1 and day 5, oleic, stearic and linolenic acids decreased, from 51 to 45%, from 8 to 4%, and from 3 to 2%, respectively (Table 2). In contrast, linoleic and palmitic acids appeared to increase from 23 to 28% and from 11 to 16%, respectively; palmitoleic acid (2%) remained almost constant.

DISCUSSION

It should be pointed out that the parent pigeons do not store PM at any time in their crop cavity and hence the samples had to be extracted (once a day, normally between 11:00-12:00) from the crop of squabs. The time elapsed from parental feeding to surgical collection was about 1-2 hr. During this period it is possible that PM undergoes certain changes in the squab crop due to microbial action as both PM and parent pigeon crop mucosa were found to harbor lactobacilli and streptococci (17). Endogenous lipolytic activity was unlikely because neither the crop and saliva of parents nor those of squabs is a source of lipase (1). Likewise, retrograde flow of digesta containing pancreatic lipase was also ruled out because of the presence of a gizzard and a long proventriculus between crop and duodenum of squabs (1). Although our definition of pigeon "milk" is restricted to crop contents of freshly fed squabs, the samples, as used in the present study and for reasons outlined above, were assumed to represent nearly true parental secretions. Secondly, beyond day 5 of secretion the small quantity of PM gets mixed up with large quantities of parent's food with the result that the milk/grain ratio of 20 on day 1 is reduced to 0.5 on day 5 (Shetty, S., and Hegde, S.N., unpublished data). It was for this reason that the analyses were restricted to the first 5 days.

Lactation by mammals is believed to have evolved primarily to maximize growth and viability of the young. PM bears similarity with mammalian milk inasmuch as it provides virtually all nutrients during the initial phase of postnatal growth; however, unlike mammalian milk which has been analyzed from a large number of species [see review by Jenness and Sloan (18) and Oftedal (19)], relatively little is known about PM. The high lipid content (9-11%) together with moderate amounts of dry matter (26%) appear to contribute much to the high energy value (25 KJ/g) of PM (Shetty, S., and Hegde, S.N., unpublished data).

The postnatal increase in body weight of squabs was 8-, 18- and 22-fold in the first, second and third week, respectively (Shetty, S., and Hegde, S.N., unpublished data). This growth rate surpasses even that of the fastest growing seal pups (20). The carbohydrate content of PM was only 1.5%, and free lactose was absent. Another feature of PM is that despite the significant decrease in protein content, fat levels did not change in the first week of secretion (Shetty, S., and Hegde, S.N., unpublished data).

Although there was a decrease in triglycerides (TG), neutral lipid content of PM remained unchanged because of the increase in the proportion of free sterols and monoglycerides. As PM was extracted from the squabs, some, if not all of the partial glycerides could be the products of TG lipolysis by PM bacteria (17). The free sterol content, which was higher than that of esterified sterols, increased from day 1 to day 5. This could possibly be due to increased cellular turnover in the parent crop gland. The polar lipid content of PM was higher than that of mammalian milk (21). As polar lipids are generally associated with cell membranes, an increase in their proportion also suggests increased cellular breakdown in the crop. Although PM lipids have been studied previously (6,7), the presence of glycolipids was not reported; the latter increased from day 1 to day 5 with carbohydrate contents of 24-37% (Shetty, S., and Hegde, S.N., unpublished data). Their source could be either bacteria (17) or plausibly the sloughed-off cells of parent crop mucosa of which PM is composed. PM glycolipids probably serve as precursors of structural components of cells and tissues in fast developing squabs. Phosphatidylcholine (plus trace amount of phosphatidylinositol) and phosphatidylethanolamine were the major phospholipid fractions of PM. Like glycolipids, phospholipids of PM also increased in the first week (Table 1). Although their content was greater than

that of mammalian milk (19,21), it was comparable to that of mammalian saliva (22). An increase in phospholipid content in the first 5 days of secretion was again indicative of higher tissue turnover in parent pigeons during this period.

The saturated fatty acid proportion of 21-25% in PM though comparable to that of the northern fur seal (*Collorhinus ursinus*) milk (27.3%), was lower than that of the milk of sow (35.7%), human (55.7%) and cow (57.5%) (23). Medium-chain fatty acids (C_{10}, C_{12} and C_{14}) were in low proportions unlike those found in the milk of ruminants, elephants and rabbits (24). C_{15} and C_{17} acids were the only odd-chain fatty acids detected and their content was also much less than that in mammalian milk. Oleic acid (18:1) and linoleic (18:2) acid contents of PM were higher than those of most mammalian milk. Fatty acids with a carbon chain longer than 20 were absent in PM. About 80% of the fatty acids of PM were unsaturated which compared well with fur seal milk (23). The levels of linoleic and linolenic acids were much higher in PM than human colostrum (25). This property may contribute to the fast postnatal development of squabs because of the importance of the metabolites of linoleic and linolenic acids in cell membranes of tissues, such as brain and retina, and as precursors of eicosanoids.

ACKNOWLEDGMENTS

The authors thank Dr. J.V. Prabhakar (Area Co-ordinator) and Dr. J. Hemavathi, Scientist, Lipid Technology, CFTRI, Mysore and Dr. E.V. Daniel, Scientist, CPCRI, Vittal for their help and expertise in analyzing lipids and fatty acids. The work was supported by DST Grant No. 22 (9P-42).

Free Sterols, Steryl Esters, and Lipid Phosphorus in Needles of Scot's Pine (*Pinus sylvestris* L.)

Christine Fischer* and **Wolfgang Höll**
Institut für Botanik und Mikrobiologie, Technische Universität München, München, Germany

Free sterols, steryl esters, and lipid phosphorus were measured in new (current year) needles of Scot's pine during an annual cycle, and also in one-, two-, and three-year-old needles collected shortly after bud break. Sterols were identified and quantified by capillary gas chromatography and gas chromatography/mass spectrometry. Steryl esters were hydrolyzed enzymatically. Newly emerged needles contained highest amounts of free sterols and lipid phosphorus, probably reflecting increased membrane and organelle production, but low levels of steryl esters. Mature needles contained approximately equal amounts of free and esterified sterols. The molar phospholipid/free sterol ratio was 3:1 at all the time periods studied. A dramatic increase of steryl esters was observed in the one-, two-, and three-year-old needles at times when new needles emerged. The individual free and esterified sterols were sitosterol, campesterol (presumably together with its C-24 epimer), and cholesterol at approximately 88, 10, and 2%, respectively. Isofucosterol, an intermediate in sitosterol biosynthesis, was present almost exclusively in newly emerged needles. Esterified sterols contained only trace amounts of isofucosterol. Shifts in favor of cholesterol and 24ξ-methyl cholesterol occurred in the steryl esters during needle differentiation, and saturation grade of esterified fatty acids decreased. In mature needles, the composition of free sterols and steryl esters remained constant throughout the year.
***Lipids 26,* 934-939 (1991).**

The importance of sterols on membrane stability, fluidity and permeability is well known (1-6). In addition, there appear to be developmentally regulated functions for sterols to control ontogenetic changes like growth or reproduction (7,8). The different sterols presumably reflect different roles (9).

Pines and all other trees examined belong to the "main line" plants, in that they have the characteristic type of dominant Δ^5-sterols (9). Sitosterol, campesterol (presumably with its C-24 epimer dihydrobrassicasterol), 5α-sitostanol, and traces of cholesterol have been detected in the wood and the bark of different species of the genus *Pinus* (10-13). The levels of free and esterified sterols increase towards the center of the trunk (14,15). Only traces of steryl glycosides and acylated steryl glycosides are detectable in Scot's pine wood (16).

Because the amounts and composition of tree sterols are well known, comparatively little information is available about the fluctuation of sterols during ontogenetic changes like bud break or heartwood formation (17,18). The present paper describes the annual fluctuations of free sterols, steryl esters, and lipid phosphorus in developing needles of Scot's pine, and also in one-, two-, and three-year-old needles collected shortly after bud break.

MATERIALS AND METHODS

Needle material. Newly emerged needles of seven (30-year-old) Scot's pine trees were collected monthly in a forest near Munich, Germany. The collection dates in 1988 were: February 2, March 23, April 24, May 24, June 24, July 22, August 23, September 23, October 25, November 24, and December 23. In 1989, needles were collected on January 26, May 19, and June 26. On May 19, 89 newly emerged, one-, two-, and three-year-old needles were collected. Immediately after collection, the needles were frozen in dry ice, lyophilized and homogenized with liquid nitrogen using a micro dismembrator (Braun, Melsungen, Germany).

Extraction of free sterols. The needle powder (20 mg) was extracted for 20 min with 1 mL chloroform/methanol (2:1, v/v) containing 10 μM 5α-cholestan-3β-ol as an internal standard and washed twice with 0.5 mL chloroform/methanol (2:1, v/v). The combined extracts were dried under a stream of nitrogen.

Isolation, purification and enzymatic hydrolysis of steryl esters. The needle powder (20 mg) was extracted with 1 mL chloroform/methanol (2:1, v/v) for 30 min, and washed twice with 0.5 mL of the chloroform/methanol mixture. In addition, every third sample was extracted with 1 mL chloroform/methanol (2:1, v/v) containing 20 μM cholesteryl oleate as an internal standard. The combined extracts were dried under nitrogen and redissolved in 50 μL chloroform/methanol (2:1, v/v) for thin-layer chromatography (TLC). Samples were applied quantitatively to TLC plates (0.2 mm Silica gel 60 on aluminum). Authentic cholesteryl palmitate served as marker. Plates were developed twice in petroleum hydrocarbon (b.p. 40-60°C)/diethyl ether/acetic acid (90:10:1, v/v/v) (19). Spots carrying the cholesteryl palmitate standard were made visible by spraying with sulfuric acid/acetic acid (1:1, v/v) and by heating for 3 min at 160°C (20). Unsprayed plate areas corresponding to cholesteryl palmitate were scraped off and eluted with chloroform/methanol (2:1, v/v) as described above.

For enzymatic hydrolysis, 200 μL potassium phosphate buffer (0.05 M, pH 8.0) containing sodium taurocholate (7.8 mM) and Triton X-100 (0.1%) were added to the dry samples. After vigorous mixing for 30 seconds (Vortex mixer), specimens were treated with lipoprotein lipase (7.5 U/mL, E. Merck, Darmstadt, Germany) and incubated for 17 hr at 37°C (21). For gas chromatography, 20 nmol 5α-cholestan-3β-ol and 40 nmol pentadecanoic acid were added as external standards to each sample. Samples were then taken to dryness again.

Derivatization and gas chromatography of sterols.

Bis(trimethylsilyl)trifluoroacetamide (0.1 mL) in anhydrous pyridine (1:5, v/v) was added to the samples. The solutions were heated for 15 min at 80°C. Before injection into the gas chromatograph, samples were diluted with chloroform to a final concentration of approximately 50 ng sterol derivatives per 1 μL (injection volume).

A DANI 8500 Capillary Gas Chromatograph (Monza, Italy) was equipped with a Programmed Temperature Vaporizer (PTV) injection system, a flame ionization detector (FID) and a 25-m fused silica capillary column coated with DB-1 (J&W Scientific, Folsom, CA) with an internal diameter of 0.25 mm and a film thickness of 0.25 μm. The chromatographic conditions used were as follows: Carrier gas, helium at 2 mL/min; detector gases, hydrogen at 56 mL/min and air at 180 mL/min; make-up gas, nitrogen at 40 mL/min. Splitless injection mode with solvent split was used; the split ratio was 1:20. The column temperature was programmed with a 2-min hold at 200°C, followed by heating at 15°C/min to 280°C and a final 10-min hold at 280°C. The temperature of the PTV was 60°C for 6 seconds, followed by a very rapid heating (900°C/min) to 300°C. This final temperature was held for 15 min. The detector temperature was 300°C. Sterol derivatives were quantified using a Shimadzu C-R3A integrator (Kyoto, Japan).

Derivatization and gas chromatography of fatty acids. For synthesis of fatty acid methyl esters (FAME), steryl ester samples (after hydrolysis) were treated with 0.1 mL of boron trifluoride (14% in methanol) for 30 min at 80°C. After adding 1 mL of water, the mixtures were extracted three times with 1 mL of diethyl ether. The combined extracts were washed two times with 1 mL of water and then taken to dryness under a stream of nitrogen. Before gas chromatography, samples were diluted with chloroform to a final concentration of 50 ng FAME/μL.

FAME were determined on a fused silica 30-m DB-225 (J&W) with an internal diameter of 0.25 mm and a film thickness of 0.25 μm. The column temperature program was a 2-min hold at 150°C, followed by heating at 10°C/min at 210°C. This final temperature was held for 10 min. The carrier gas was helium at 3 mL/min. All other conditions were as described above, with the exception of the final PTV-temperature and the detector temperature at 230°C.

Lipid phosphorus. TLC areas corresponding to phospholipids were scraped off, and phosphorus was determined according to Chen *et al.* (22).

Gas chromatography/mass spectrometry (GC/MS). GC/MS was performed with a Finnigan model M112S (Sunnyvale, CA) operated in the electron impact mode. The ion source was operated at 70eV and with a 700 μA ionization current. The ion source temperature was approximately 200°C, and the interface temperature was about 250°C. The gas chromatograph was a Carlo Erba model 4160 (Milano, Italy). Carrier gas and oven temperature program were as described above.

Experimental design and statistics. Experiments were designed as single factor experiments with repeated measures. Populations were checked for Gauss distribution using the Kolmogoroff-Smirnoff test. Homogeneity of variance was checked using the F_{max} test. Means were tested for significance using a single factor analysis of variance for repeated measures. For multiple comparisons, the LSR test was performed. Regression lines were ascertained using the least square method. Pearson's correlation coefficient was tested for significance using the *t*-test according to Fisher.

Experimental errors of three different measurements using the same sample (expressed as coefficients of variation) were 2–4% for free sterols, 4–6% for steryl esters, and 10–15% for lipid phosphorus, respectively. Tree-to-tree variations were quite large and are specified in the legends to the Figures.

RESULTS

Total amounts. Figure 1 shows that newly emerged needles (May) contained much higher amounts of free sterols than do older needles (differences are significant on the 99.9% level). In subsequent months, the amounts of free sterols decreased and remained more or less constant until the end of the year. Compared to the preceding months, February and March needles contained significantly higher amounts (95% level) of free sterols. No significant changes were detectable in the total amounts of free sterols in one-, two-, and three-year-old needles collected shortly after bud break (Table 1).

When compared with differentiated needles, newly emerged needles contained small amounts of steryl esters (Fig. 1). During the summer the concentration of steryl esters increased and then remained constant till bud break at the end of April. In May, the now one-year-old needles showed very high amounts of steryl esters (differences were significant on the 99.9% level). Four weeks later, steryl esters decreased again, but the needles showed still significantly higher amounts (95% level) than in most of the months before bud break. This increase in the esterified sterols during bud break was also true for needles older than one year (Table 1). The amounts of steryl esters in May increased as needle age increased.

The seasonal fluctuation of lipid phosphorus in needles of Scot's pine during their first year of life is shown in Figure 2. Newly emerged needles contained the highest amounts of lipid phosphorus. Needles collected in October and November showed higher amounts than needles collected in February and March (95% level). No differences were observed between one-, two-, and three-year-old needles collected in May (Table 1).

Composition of sterols and steryl esters. 24ξ-Ethyl cholesterol, probably sitosterol (configuration at C-24 was

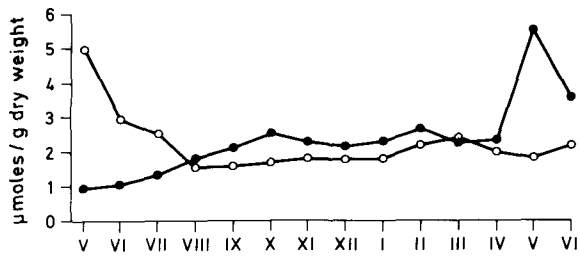

FIG. 1. Seasonal changes of free sterols (○) and steryl esters (●) in newly emerged needles of Scot's pine (n=7). Tree-to-tree variations, expressed as 95% confidence interval, were 6–20% of the mean for free sterols, and 11–38% for steryl esters. Bud break occurred at the end of April and needle maturation was in August. Roman numbers indicate months of collection. For significance of differences between means see the Results section.

TABLE 1

Free Sterols, Steryl Esters, and Lipid Phosphorus in Newly Emerged, One-, Two-, and Three-Year-Old Needles of Scot's Pine Collected Shortly After Bud Break

[d] Percent of total amounts.
[e] Not detectable.

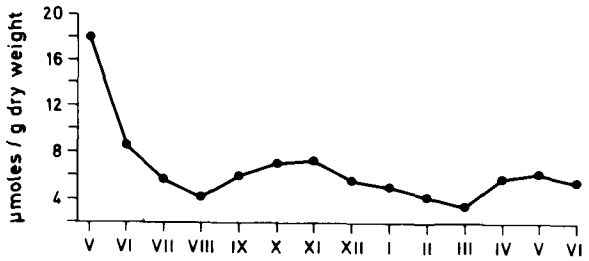

FIG. 2. Seasonal changes of lipid phosphorus in newly emerged needles of Scot's pine (n=7). Tree-to-tree variation, expressed as 95% confidence interval, was 9–45% of the mean. See Figure 1 for further explanations.

not determined), is the principal free sterol throughout the investigated period (Fig. 3). Campesterol (presumably with its C-24 epimer) was about 10% in all months investigated. Cholesterol was present only in minor amounts. In newly emerged needles, isofucosterol accounted for 25% of the total free sterols. Needles collected in subsequent months contained only trace amounts of isofucosterol.

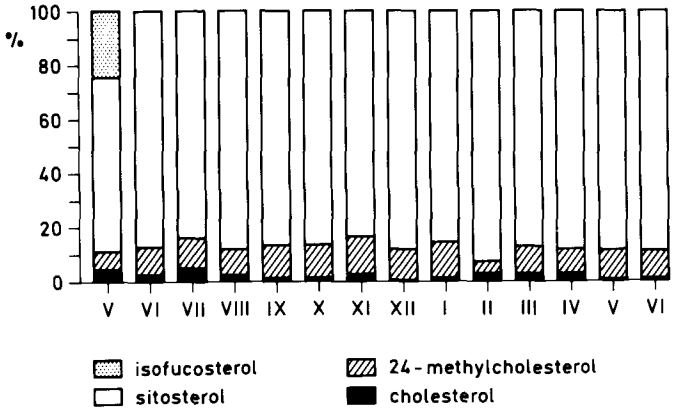

FIG. 3. Seasonal changes in the individual free sterols (relative amounts) in newly emerged needles of Scot's pine (n=7). Tree-to-tree variations, given as 95% confidence interval, were: cholesterol, 19–100%; 24-methyl cholesterol, 8–95%; sitosterol, 1–12%; and isofucosterol, 6%. See Figure 1 for further explanations.

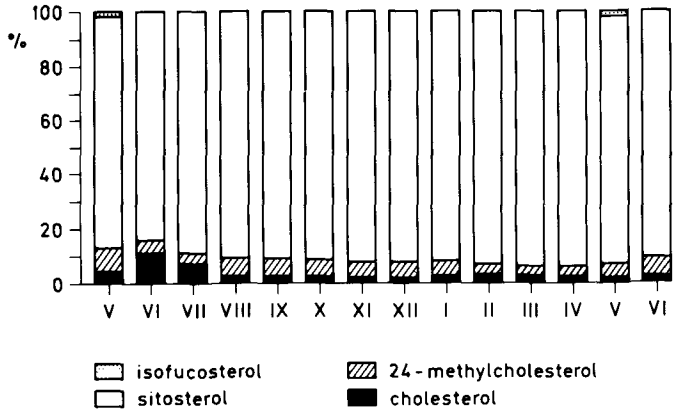

FIG. 4. Seasonal changes in the individual esterified sterols (relative amounts) in newly emerged needles of Scot's pine (n=7). Tree-to-tree variations, given as 95% confidence interval, were: cholesterol, 26–74%; 24-methyl cholesterol, 8–42%; sitosterol, 1–5%; isofucosterol, 50–100%. See Figure 1 for further explanations.

The steryl composition of the steryl ester fraction (Fig. 4) reflected the composition of the free sterol fraction. Sitosterol accounted for 85–95% of the steryl ester fraction throughout the year. The relative amounts of 24ξ-methyl cholesteryl esters and cholesteryl esters were 4–7% and 2–10%, respectively. Only trace amounts of isofucosteryl esters were detectable. Significant differences (mostly 99.9% level) in the steryl ester composition occurred between newly emerged and differentiated needles. Young needles contained relatively large amounts of 24ξ-methyl cholesteryl (in the first four weeks) and cholesteryl esters (in the first three months).

The major constituent fatty acids in the steryl ester fraction (Table 1) were palmitic (16:0), oleic (18:1ω9), and linoleic (18:2ω6) acid, together with two nonmethylene-interrupted polyunsaturated acids, $18:2\Delta^{5.9}$ and $20:3\text{-}\Delta^{5.11.14}$. Myristic (14:0), stearic (18:0), linolenic (18:3ω3), octadecatetraenoic ($18:4\Delta^{5.9.12.15}$), arachidic (20:0), eicosenoic (20:1ω9), eicosadienoic (20:2ω6), and eicosatrienoic (20:3ω3) acids were detected in minor amounts. Traces

(below 0.5%) of lauric acid (12:0) and various C_{16} polyunsaturated acids were present, but are not included in Table 1. Myristic, stearic, and eicosadienoic esters did not show any seasonal fluctuations (Table 2). The youngest needles (May) contained highest amounts of palmitic, oleic, arachidic, and eicosenoic acid and lowest amounts of linolenic, octadecatrienoic, and the two eicosatrienoic acids (99.9% level). The relative amounts of linoleic ester were higher in summer needles than in winter needles; those of the 18:2Δ5.9 acid esters were high in winter, but low in summer needles (99% level).

One-, two-, and three-year-old needles collected shortly after bud break were very similar in their free sterol and steryl ester compositions (Table 1).

DISCUSSION

Our results show that needles newly emerged in May contained high amounts of free sterols (Fig. 1) and lipid phosphorus (Fig. 2). Lipid phosphorus was associated with phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine (traces), and probably phosphatidylinositol (unpublished data). Differentiated needles of conifers synthesize cell walls, resin ducts, cuticle, etc., associated with organelles, such as Golgi vesicles. Thus, the high amounts of free sterols and phospholipids probably indicate a high density of biomembranes which are typical for young and growing plant tissue (2). During maturation, the free sterol content decreased, which is in accordance with what has been observed for apple trees (17), but contrasts with what has been reported for herbaceous plants (23).

In Scot's pine, however, high amounts of sterols do not necessarily indicate the presence of biomembranes. Towards the center of the trunk, the free sterol/phospholipid ratio increases and the dead heartwood contains considerable amounts of free sterols, but no phospholipids (14,15). The free sterol/phospholipid ratio of needles remained constant (1:3) at all time periods studied. This may indicate that needle sterols are predominantly membrane constituents, while heartwood sterols have different functions. It has been suggested that they are part of a defense mechanism against pathogens (24,25).

In apple buds, an increase in free sterols and a decrease in steryl esters (possibly due to hydrolysis) was shown to occur at the end of dormancy and during spring (17). High levels of sterols in developing Scot's pine needles may also result from steryl ester hydrolysis in buds before bud break. Total amounts of steryl esters were low in newly emerged needles of Scot's pine (Fig. 1). In the subsequent months, they increased and remained constant from August to April of the following year. With the exception of the one-, two-, and three-year-old needles collected in May, there was a remarkable correlation between the amounts of free and esterified sterols ($r=0.708$; $P<0.01$; Fig. 5)—the higher the concentration of free sterols, the lower the concentration of esterified sterols.

The significance of steryl ester changes in needles of Scot's pine is difficult to assess because of the lack of information about the physiological role of these molecules in plants. The relationship between free and

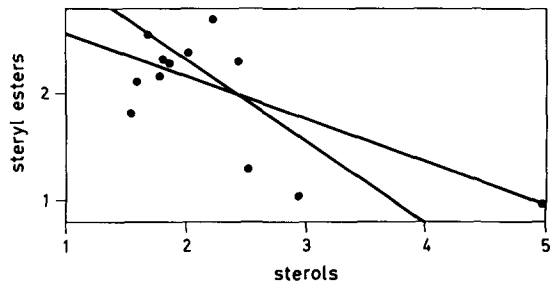

FIG. 5. Relationship between free sterols and steryl esters (μmoles/g dry weight) in Scot's pine needles during their first year. Both regression lines are given (YSE = 2.99 − 0.44XS and XS = 4.56 − 1.15 YSE).

esterified sterols in young pine needles may indicate that steryl esters serve as a store for sterols, as it is suggested for yeast steryl esters (26). It seems unlikely that the dramatic increase of steryl esters in the older pine needles during bud break (Table 1) is due to senescence.

When steryl esters increase in the older needles, stored or newly synthesized energy rich products, such as triglycerides and carbohydrates, are mobilized and translocated into the emerging twigs (27-29). Steryl esters may play a role in the mobilization of food reserves in mature needles, *e.g.*, in regulating lipolytic enzymes. It is an open question as to whether newly emerging needles obtain sterols from older needles, in addition to carbohydrates and triglycerides. Steryl esters may be involved in intercellular sterol transport, as it occurs in mammals and is postulated to occur in plants (2,30,31).

In accordance with earlier reports (10-13), sitosterol represented by far the largest amounts both in the free and esterified form. The relative amounts of 24ξ-methyl cholesterol (campesterol and dihydrobrassicasterol) were somewhat higher in the free sterols than in the steryl esters. In contrast, more cholesterol was found in esterified form. We did not detect 5α-sitostanol in Scot's pine needles, although this stanol is present in *Pinus sylvestris* wood in considerable amounts (10,15). Tissue specialization affecting the presence or absence of stanols has been reported from two species of *Larix* (9)—24ξ-methylstanol was present only in the wood, not in the bark. Nes (9) suggested that reduction of the Δ^5-bond plays some important role in wood. Stigmasterol, another common "main line" plant sterol, could not be detected in Scot's pine needles and is also absent in pine wood and bark (10-13,15).

Isofucosterol has not been reported in *Pinus* species before. In newly emerged needles, isofucosterol contributed about 25% of total free sterols. Only trace amounts of this sterol could be detected in needles collected in the subsequent months. In the steryl ester fraction, isofucosterol is negligible. 24(Z)-Ethylidene sterols, such as isofucosterol, are precursors of 24α-sterol products in higher plants (32-34). Since isofucosterol occurred almost exclusively in newly emerged needles, one can conclude that free sterols are formed *de novo* and are only (if at all) partly translocated from other parts (*e.g.*, older needles, wood) of the tree. The absence of isofucosterol in the steryl ester fraction indicates that reduction of the Δ24(28) double bond takes place prior to esterification in sitosteryl ester biosynthesis.

The composition of individual steryl ester fatty acids is complex and does not differ from the fatty acid composition of total needle lipids reported by Jamieson and Reid (35). In addition to the common methylene-interrupted fatty acids, four unusual, nonmethylene-interrupted polyunsaturated acids with Δ^5 unsaturation were present in Scot's pine needles. Δ^5 Acids have been found in all conifer leaf lipids examined (35).

The composition of individual free sterols did not (with the exception of newly emerging needles; Fig. 3) change during the course of the year. This contrasts with the results of studies on plants other than conifers; in tobacco (23), sorghum (7), and maize (30), the level of Δ^{22}-sterols like stigmasterol increased with plant age. Without using techniques such as ^1H nuclear magnetic resonance (NMR) or ^{13}C NMR, no information is available about

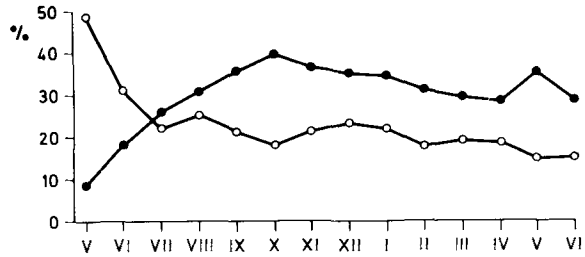

FIG. 6. Seasonal changes of steryl ester fatty acids differing in their degree of unsaturation (relative amounts) in newly emerged needles of Scot's pine (n=7). 16:0+20:0+18:1ω9+20:1ω9 (○); 18:3ω3+18:4$\Delta^{5.9.12.15}$+20:3ω3+20:3$\Delta^{5.11.14}$ (●). See Figure 1 for further explanations.

changes in the level of C-24 epimers during needle maturation. In *Cucurbita maxima*, an ontogenetic shift occurred from approximately equal amounts of 24α- and 24β-ethyl sterols to a predominance of the former during seedling development (36).

There was a shift in favor of 24ξ-methyl cholesterol and cholesterol in steryl ester composition during needle maturation (Fig. 4), but more pronounced changes occurred in the esterified fatty acids (Table 2). The proportion of polyunsaturated acids with three or four double bonds increased rapidly. This increase was accompanied by a rapid decrease of saturated or monounsaturated steryl ester fatty acids ($r=-0.825$; $P<0.001$; Fig. 6). Similar changes of fatty acids differing in their degree of unsaturation occurred on the leaf lipids of *Larix* during the early part of the growing season (35). The changes of the two 18:2-isomers in the steryl esters (Table 2) seemed to depend on needle development rather than on season. The relative amount of linoleic ester increased ($r=0.850$, $P<0.01$), and that of the 18:2$\Delta^{5.9}$ acid ester decreased ($r=-0.734$, $P<0.01$) with rising temperature. In other lipid fractions of Scot's pine needles, the seasonal changes of linoleic acid differed from those found in the steryl ester fraction; in the triglycerides, linoleic acid increased in winter and decreased in summer needles ($r=-0.670$, $P<0.01$; unpublished data).

The total amounts and the fatty acid composition of steryl esters extracted from *P. sylvestris* sapwood and heartwood did not change during the course of the year (18). Changes within the steryl esters described here for Scot's pine needles, however, are striking, and could reflect the physiology of needle differentiation.

METHOD

Selected Ion Monitoring Gas Chromatography/Mass Spectrometry of 1,2-Diacylglycerol *tert*-Butyldimethylsilyl Ethers Derived from Glycerophospholipids

Toshiaki Ohshima* and **Chiaki Koizumi**
Department of Food Science and Technology, The Tokyo University of Fisheries, Tokyo, Japan

Selected ion monitoring was used in conjunction with gas chromatography/mass spectrometry to analyze *tert*-butyldimethylsilyl ethers (*tert*-BDMS) of 1,2-diacyl-*sn*-glycerols derived from naturally occurring glycerophospholipids, including those of *Escherichia coli*, soybean, egg yolks and porcine liver. First, the fatty acid composition of the unknown glycerophospholipid was determined by gas-liquid chromatography (GLC) and, based on that, the fatty acids (mostly >0.5 wt%) were selected for monitoring the characteristic fragmentation ions produced from the fatty acid residues of the corresponding *tert*-BDMS derivatives of 1,2-diacyl-*sn*-glycerols. Next, the *tert*-BDMS derivatives were separated by GLC on a 65% methylphenylsilicone gum wall-coated open-tubular (WCOT) column according to the degree of unsaturation and the chain length of the fatty acid residues, and then directly introduced into the ion source of the mass spectrometer. The selected fragmentation ions, $[RCO+74]^+$ representative of the fatty acid residues, and $[M-57]^+$ indicative of the molecular weight of the derivatives, were monitored simultaneously. It thus became possible to determine the molecular species of the *tert*-BDMS derivatives by measuring a specific combination of two $[RCO+74]^+$ and an $[M-57]^+$ ion with the same retention time on the selected ion monitoring (SIM) profile. High background noise caused by volatilization of stationary phase at high temperature was largely overcome by selected ion monitoring. However, the fragmentation ion peaks produced from *tert*-BDMS derivatives of highly unsaturated glycerophospholipids showed a distorted SIM profile, which was attributed to interaction between the *tert*-BDMS derivatives and the methylphenylsilicone phase of the column. Use of a WCOT column with a more polar liquid phase is therefore recommended for the analysis of highly unsaturated molecular species.
***Lipids* 26, 940-947 (1991).**

In the past decade, wall-coated open-tubular (WCOT) column gas-liquid chromatography (GLC) has become a well accepted tool for the analysis of lipids. Earlier, apolar phases such as OV-1 and SE-30 were used in WCOT columns for the separation of triacylglycerols and related compounds based on the number of total carbon atoms present in the molecule (1-7). The subsequent development of "polar" phases such as methylphenylsilicone gum (equivalent to OV-17) with high temperature stability (up to 370°C) allowed for the separation of triacylglycerols not only according to chain length, but also according to the number of ethylenic bonds in the fatty acid residues (4,8-12). More polar cyanopropyl-phenylsilicone phases, such as SP 2330, have been applied to the resolution of trimethylsilylated and *tert*-butyldimethylsilylated 1,2-diradyl glycerols derived from glycerophospholipids (13-18). To accomplish assignments of peak components with a degree of certainty, ordinary mass spectrometry coupled with gas chromatography (GC/MS) on apolar phase WCOT columns have successfully been used (6,19, 20). Our preliminary studies with polar phase columns showed that high background noise caused by volatilization of stationary phase from the column, especially at high temperatures, interfered with the feeble signals arising from the samples. When the injected sample size was increased to improve the ratio of sample signal over background noise, sample-overload on the WCOT column occurred, and peak resolution suffered. Although the application of GC/MS on apolar columns can provide useful information (21,22), it requires time-consuming preliminary separations, such as by argentation thin-layer chromatography; furthermore, GLC retention times need to be assigned based on those of authentic standards. Selected ion monitoring (SIM) in GC/MS generally provides specificity and sensitivity for the selected ions which are characteristic of the constituent compounds. We recently separated vegetable oil triacylglycerols (23) and *tert*-BDMS of 1,2-diacyl-*sn*-glycerols derived from glycerophospholipids of marine origin (24-26) by GLC on a 65% methylphenylsilicone phase WCOT column, and demonstrated the applicability of SIM in GC/MS to the assignment of components separated by GLC on such a polar column. In the present study, selected ion monitoring in GC/MS was applied to the analysis of *tert*-BDMS of 1,2-diacyl-*sn*-glycerols derived from various naturally occurring glycerophospholipids.

MATERIALS AND METHODS

Glycerophospholipids. 1,2-Diacyl choline glycerophospholipids (CPL) from soybean, 1,2-diacyl ethanolamine glycerophospholipids (EPL) from *Escherichia coli*, and authentic 1-palmitoyl-2-stearoyl, 1-palmitoyl-2-oleoyl, 1-palmitoyl-2-linoleoyl, 1-palmitoyl-2-arachidonoyl, 1,2-dilinolenoyl and 1-stearoyl-2-linoleoyl CPL were purchased from Avanti Polar Lipids, Inc. (Pelham, AL). Turkey egg yolk CPL (60% purity) and porcine liver EPL (98% purity) were obtained from Sigma Chemical Company (St. Louis, MO). Hen egg yolk EPL and authentic 1,2-distearoyl CPL

*To whom correspondence should be addressed at Dept. of Food Science and Technology, The Tokyo University of Fisheries, Konan 4, Minato-ku, Tokyo 108, Japan.

Abbreviations: *tert*-BDMS, *tert*-butyldimethylsilyl ether; CPL, choline glycerophospholipid; EPL, ethanolamine glycerophospholipid; FID, flame ionization detector; GC/MS, gas chromatography/mass spectrometry; GLC, gas-liquid chromatography; SIM, selected ion monitoring; TC/DB, total acyl carbons *vs.* double bonds; WCOT; wall-coated open-tubular; Δ, cycropropanoic fatty acid, *e.g.*, 17:0Δ represents 17:0 fatty acid with a cyclopropanoid ring.

were purchased from Serdary Research Laboratories Inc. (London, Ontario, Canada).

Lipid derivatization. A 10-mg portion of CPL or EPL was mixed with 2 mL of 0.1 M Tris-HCl buffer (pH 7.2), containing 5 mM $CaCl_2$ and 1 mL diethyl ether/ethanol (98:2, v/v), and 400 units (0.1 mL in the above buffer) of phospholipase C of *Bacillus cereus* (Boehringer Mannheim, Germany) was added. The mixture was shaken vigorously for 2 hr at 37°C (27). The 1,2-diacylglycerol thus obtained was isolated from the reaction mixture by preparative thin-layer chromatography (TLC) on Silica Gel G (E. Merck, Darmstadt, Germany) using petroleum hydrocarbon (b.p. 30–60°C)/diethyl ether/acetic acid (70:30:1, v/v/v) as developing solvent. The 1,2-diacylglycerol was recovered from the silicic acid with diethyl ether, the extract was transferred into a reaction vial, and the solvent was evaporated under a nitrogen stream. An aliquot of *tert*-butyldimethylchlorosilane/imidazole reagent (Gasukuro Kogyo, Tokyo, Japan) was added to the reaction vial and the mixture was incubated at 80°C for 1 hr to obtain *tert*-butyldimethylsilyl ether (*tert*-BDMS) of 1,2-diacyl-*sn*-glycerol (28,29). The product was subsequently purified by preparative TLC on Silica Gel G using petroleum hydrocarbon/diethyl ether/acetic acid (90:10:1, v/v/v) as the first developing solvent and toluene as the second solvent in the same direction.

For the analysis of the fatty acid composition of the glycerophospholipids, an aliquot of CPL or EPL was mixed in a reaction vial with 3 mL 14% BF_3 in methanol (Wako Pure Chemical, Osaka, Japan) and heated at 100°C for 1 hr to obtain the corresponding fatty acid methyl esters (30).

Lipid analyses. The *tert*-BDMS derivatives of 1,2-diacyl-*sn*-glycerols were analyzed by GLC using a Shimadzu GC 12A instrument (Shimadzu Seisakusho, Kyoto, Japan), equipped with a flame ionization detector (FID), a MP65HT fused silica WCOT column (65% methylphenylsilicone, 0.1 μm film thickness, 0.25 mm i.d. × 25 m; Quadrex, New Haven, CT), and a Shimadzu movable on-column injector. The injector temperature was held at 370°C. The column oven was programmed from 230 to 350°C at 5°C/min. Helium was used as carrier gas at a constant inlet pressure of 1.7 Kg/cm^2. Usually 1–2 μL of a 0.02% hexane solution of a *tert*-BDMS derivative was injected.

Selected ion monitoring in the mass spectrometric analysis of *tert*-BDMS derivatives of 1,2-diacyl-*sn*-glycerols was done on a Shimadzu QP 1000 quadrupole mass spectrometer fitted with an electron impact ionization (EI) source to which the outlet of the MP65HT column (0.1 μm film-thickness, 0.25 mm i.d. × 15 m) was directly connected. Mass spectra were acquired at 0.4 second intervals using 3 KV accelerating energy, 70 eV electron beam energy, and a source temperature of 310°C.

The fatty acid compositions of CPL and EPL were determined by GLC using a Shimadzu GC 12A instrument equipped with an FID and a Supelcowax-10 fused silica WCOT column (0.25 μm film-thickness, 0.25 mm i.d. × 30 m, Supelco Japan, Tokyo) at 195°C with helium as carrier gas.

The molecular species are designated, for example, as 16:0-18:0, which describes the palmitoyl-stearoyl *tert*-BDMS derivative. It should be noted that the designation does not specify the positional distribution of the component fatty acids on the glycerol moiety.

RESULTS AND DISCUSSION

Selected ion monitoring of tert-BDMS derivatives prepared from authentic phospholipids. It is well established that the characteristic fragmentation ions produced by EI mass spectrometry of *tert*-BDMS of 1,2-diacyl-*sn*-glycerols include $[R+148]^+$, $[R+130]^+$, $[RCO+74]^+$, $[RCO]^+$ and $[R]^+$, indicative of the acyl chains, and $[M-57]^+$, $[M-RO]^+$ and $[M-RCOO]^+$ indicative of the molecular weight of the compounds (28,29). Observed ion intensities depend on the number of carbons and ethylenic bonds in the fatty acyl chains linked to the *sn*-1 and *sn*-2 positions of the glycerol backbone (31). Our preliminary studies indicated that neither $[RCO+74]^+$ nor $[M-57]^+$ overlapped with any other ions. Therefore, we chose $[RCO+74]^+$ and $[M-57]^+$ for selected ion monitoring. The calculated *m/z* of the selected fragmentation ions produced from typical *tert*-BDMS of 1,2-diacyl-*sn*-glycerols are summarized in Table 1.

[b] Δ Designates cyclopropanoic fatty acid.

Typical SIM profiles of the molecular species derived from authentic 1,2-diacyl glycerophospholipids are shown in Figure 1 (a) and (b). Prior to SIM of *tert*-BDMS of 1,2-diacyl-*sn*-glycerols derived from unknown glycerophospholipids, a preliminary analysis of the constituent fatty acids would be needed to determine the ions to be monitored. However, this was not necessary for the authentic phospholipids shown here (Fig. 1). At 8.2 min after injection, the unresolved peaks Nos. 1 and 2 were detected when the fragmentation ion at *m/z* 313 was selectively monitored. When the ions at *m/z* 341 and *m/z* 653 were monitored, two additional ion peaks, each having the same retention time as ion peak No. 1 shown on the trace of *m/z* 313, appeared on the SIM profile. The characteristic combination of these selected ion peaks is indicative of the molecular species 16:0-18:0, as predicted from the specific combinations of fragmentation ions listed in Table 1. For peak No. 2, from the two ion peaks with the same retention time at *m/z* 339 due to $[RCO+74]^+$ arising from an oleic acid (18:1) residue and at *m/z* 651 due to $[M-57]^+$ indicative of a total carbon/double bond ratio (TC/DB) of 34:1, a molecular species of 16:0-18:1 is suggested. For peak No. 6, a molecular species of 16:0-20:4 is indicated, because the fragmentation ions at *m/z* 313 due to the palmitic acid (16:0) residue, at *m/z* 361 due to the arachidonic acid (20:4) residue, and at *m/z* 673 indicative of $[M-57]^+$ of the molecular species of 36:4, were detected at the same retention time. The relative ion intensity of only 19 at *m/z* 361 was noticeably lower than that of 1770 at *m/z* 313, although both fragmentation ions were originally present at the same abundance in the molecule. The ion peak at *m/z* 673 due to $[M-57]^+$ of 36:4 was detected, as well as the peak at *m/z* 675, but the intensity of *m/z* 673 was twice as high as that of *m/z* 675; this is probably due to the more complex fragmentation patterns of polyunsaturated fatty acid residues (31). The lower stability of unsaturated molecular species of triacylglycerols in EI mass spectrometry previously has been pointed out (23). We conclude from the above results that not only the combination of the characteristic fragmentation ions shown in Table 1, but also the intensity of the ions should be considered to substantiate the assignment of peaks that reflect the molecular species.

Molecular species of tert-*BDMS of 1,2-diacyl-*sn*-glycerols from* E. coli *glycerophospholipids.* The ethanolamine glycerophospholipids of *E. coli* were taken as an example of a naturally occurring phospholipid. A typical gas chromatogram of the *tert*-BDMS of the 1,2-diacyl-*sn*-glycerols derived from EPL of *E. coli* is shown in Figure 2. In order to determine the $[RCO+74]^+$ ions suitable for selective ion monitoring in GC/MS, the fatty acid composition of *E. coli* EPL was determined by GLC/FID; the results obtained are shown in Table 2. Based on these data, the more prominent (mostly >0.5 wt%) fatty acid residues were chosen and their characteristic fragmentation ions were selectively monitored, as shown in Figure 3. The WCOT columns used in GLC/FID (Fig. 2) and in GC/MS (Fig. 3) had the same liquid phase, although the column lengths were different. Therefore, the elution orders of the *tert*-BDMS of 1,2-diacylglycerols in both GLC/FID and

[a]Data are presented as mean ± S.D. (n=3).

[b]Positional isomers (ref. 37).

GC/MS could be expected to be similar. The procedure for peak assignments was as follows:

Peak No. 1 in Figure 3 posesses three characteristic fragmentation ions at *m/z* 285, *m/z* 313 and *m/z* 597. These are due to the $[RCO+74]^+$ from the myristic acid (14:0) residue, $[RCO+74]^+$ from the palmitic acid (16:0) residue, and $[M-57]^+$ of the molecular species with a TC/DB ratio of 30:0, respectively. Consequently, the species corresponding to peak No. 1 was identified as 14:0-16:0.

For peak No. 2, the combination of the fragmentation ion peaks at *m/z* 285 due to the myristic acid residue and at *m/z* 311 due to palmitoleic acid (16:1) suggested that the peak component may be 14:0-16:1; however the ion intensity at *m/z* 595 due to $[M-57]^+$ of the molecular species 30:1 was feeble.

The fragmentation ion at *m/z* 285 of peak No. 3 was considered to be due to a myristic acid residue. It was difficult to confirm the precursors of the corresponding fragmentation ion *m/z* 325 based on mass spectrometric data only because the EI mass spectra of cyclopropanoic fatty acids and of the corresponding normal-chain fatty acids are generally quite similar. There are two possibilities in regard to the origin of the fragmentation ion at *m/z* 325; $[RCO+74]^+$ could represent a 17:1 residue or a cyclopropanoic fatty acid (17:0Δ) residue. EPL of *E. coli* contains 17:0Δ as one of the prominent constituent fatty acids as shown in Table 2. The fatty acid composition confirms that most of the fragmentation ions at *m/z* 325 were therefore derived from 17:0Δ cyclopropanoic acids. In general, cyclopropanoic fatty acids are relatively resistant to electron impact ionization (32), and therefore their fragmentation becomes similar to that of normal fatty acids (32). In the present case, 17:0Δ acid is esterified to the glycerol moiety, and the esterified 17:0Δ would be

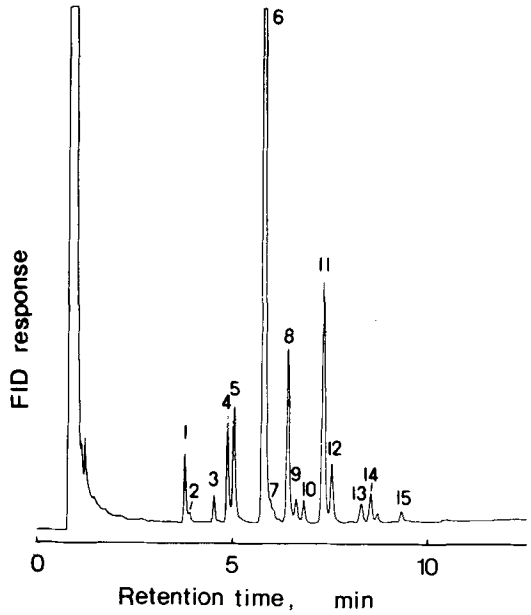

FIG. 2. FID open-tubular gas chromatogram of *tert*-butyldimethylsilyl ether of 1,2-diacyl-*sn*-glycerol derived from *Escherichia coli* ethanolamine glycerophospholipids. Column, MP65HT (0.1 μm film-thickness, 0.25 mm i.d. × 25 m) at 230–350°C programmed at 5°C/min; injector, a solventless moveable on-column injector at 370°C; carrier gas, helium at 1.75 Kg/cm^2.

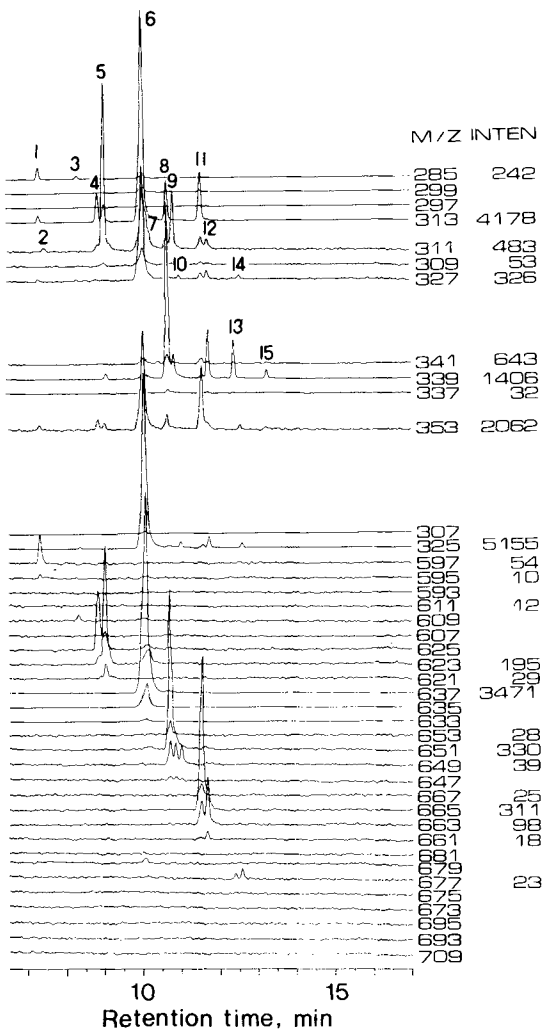

FIG. 3. Selected ion monitoring profiles arising from *tert*-butyldimethysilyl ether of 1,2-diacyl-*sn*-glycerols derived from *Escherichia coli* ethanolamine glycerophospholipids. The conditions are as in Figure 1. See the text for peak assignments.

expected to be more stable against EI ionization than the corresponding free fatty acids or methyl esters. Consequently, the molecular species of peak No. 3 was identified as 14:0-17:0Δ with the ions at *m/z* 325 and *m/z* 609 being mainly due to the 17:0Δ acid residue and to a molecular species of 31:0Δ, respectively. A small amount of 14:0-17:1 would also expected to exist in peak No. 3.

The dominant molecular species of peak No. 4 was identified as 16:0-16:0, since *m/z* 313 due to $[RCO+74]^+$ of the palmitic acid residues and *m/z* 625 due to $[M-57]^+$ of molecular species were selectively monitored.

Peak No. 5 consists mainly of 16:0-16:1, since *m/z* 311 due to the palmitoleic acid residue and *m/z* 313 due to the palmitic acid residue were observed with *m/z* 623 due to the molecular species 32:1. A fragmentation in peak at *m/z* 353 with weak intensity showed that 13:0-19:0Δ was indicated as a minor component of peak No. 5.

Peak No. 6 was a prominent component of *E. coli* EPL as estimated from the FID gas chromatogram in Figure 3. The fragmentation ions detected were relatively complicated. The fatty acid composition of the EPL shown in Table 2 clearly shows that the fragmentation ion at *m/z* 325 was mainly due to the 17:0Δ acid residue. Similarly, the ion at *m/z* 353 was due to a cyclopropanoic 19:0Δ acid residue. Consequently, there were four molecular species in peak No. 6—16:0-17:0Δ and 16:0-17:1 based on ions *m/z* 313, *m/z* 325 and *m/z* 637, 16:1-17:0 based on ions *m/z* 311, *m/z* 327 and *m/z* 637, and 14:0-19:0Δ based on ions *m/z* 285, *m/z* 353 and *m/z* 637. From the intensity of the ions, we estimated that 16:0-17:0Δ was the most prominent molecular species in peak No. 6.

Peak assignments of Nos. 7, 8 and 9 were relatively easy. Peak No. 7 was assigned to the molecular species 16:1-17:0Δ and 16:1-17:1. Peaks Nos. 8 and 9 were 16:0-18:1 and 16:1-18:1, respectively.

It was difficult to identify all components contained in peak No. 10 in detail, since the combinations of fragmentation ions at *m/z* 325 due to 17:0Δ and/or 17:1 and *m/z* 649 due to 34:1Δ and/or 34:2 indicate the following possibilities—17:1-17:1, 17:0Δ-17:0Δ and 17:1-17:0Δ. Based on the fatty acid composition given in Table 2, 17:0Δ-17:0Δ would be the most prominent component of peak No. 10.

The characteristic fragmentation ions of peak No. 11 suggested that 16:0-19:0Δ would be a prominent molecular species; 18:0-17:0Δ also was included in the peak as a minor component.

Peak Nos. 12, 13, 14 and 15 were easily identified as 18:1-17:0Δ and 18:1-17:1, 18:1-18:1, 17:0Δ-19:0Δ and 17:1-19:0Δ, and 18:1-19:0Δ, respectively.

Molecular species of glycerophospholipids with one cyclopropanoic fatty acid residue, such as 16:0-17:0Δ and 16:0-19:0Δ, have been reported in *E. coli* phosphatidylglycerol (33) and EPL (34). The molecular species composition of glycerophospholipids are known to be affected by

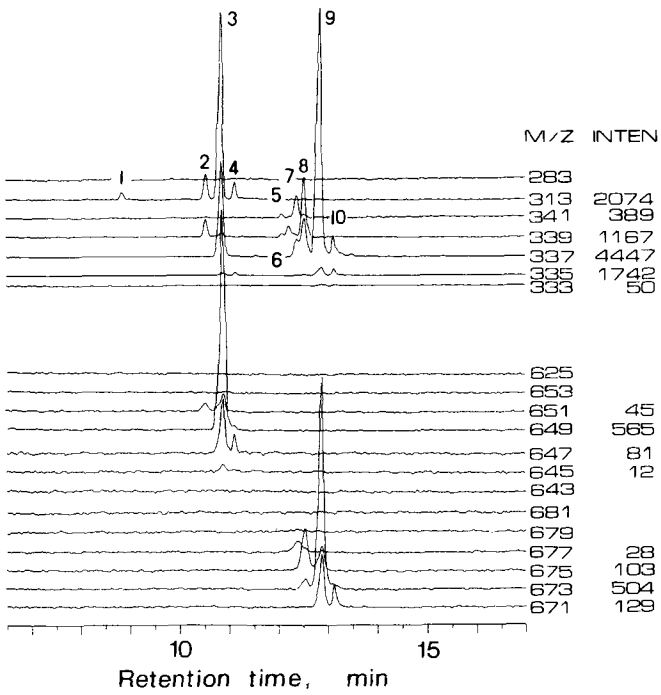

FIG. 4. Selected ion monitoring profiles arising from *tert*-butyldimethysilyl ether of 1,2-diacyl-*sn*-glycerols derived from soybean choline glycerophospholipids. 1, 16:0-16:0; 2, 16:0-18:1; 3, 16:0-18:2; 4, 16:0-18:3, 5, 18:0-18:0; 6, 18:1-18:0; 7, 18:0-18:2; 8, 18:1-18:2; 9, 18:2-18:2; 10, 18:2-18:3. The conditions were those given in Figure 1.

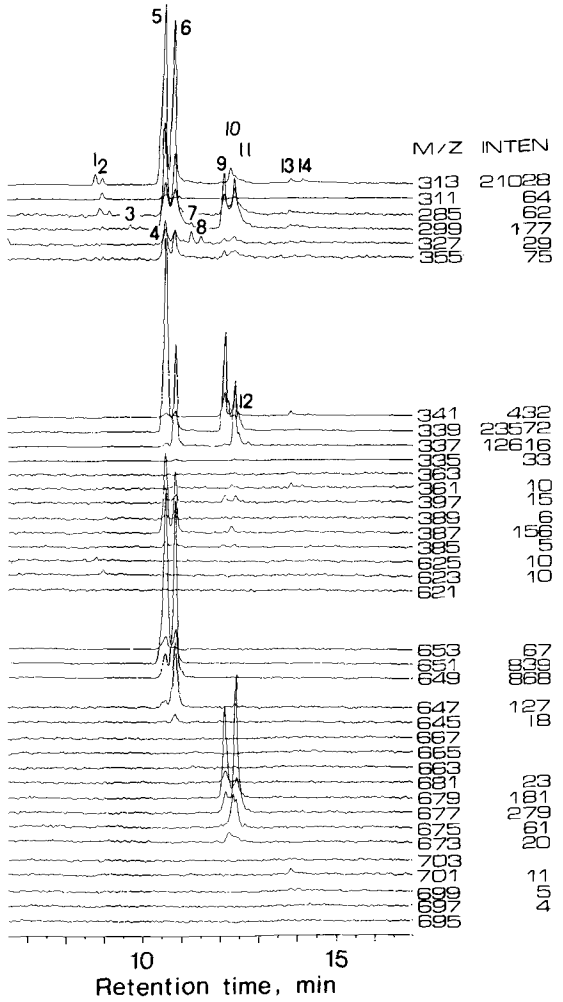

FIG. 5. Selected ion monitoring profiles arising from *tert*-butyldimethysilyl ether of 1,2-diacyl-*sn*-glycerols derived from turkey egg yolk choline glycerophospholipids. 1, 16:0-16:0, 2, 16:0-16:1; 3, 15:0-18:1; 4, 16:0-18:0; 5, 16:0-18:1; 6, 16:0-18:2; 7, 17:0-18:1; 8, 17:0-18:2; 9, 18:0-18:1n-9; 10, 18:0-18:1n-7; 11, 18:0-18:2; 12, 18:1-18:2; 13, 18:0-20:4; 14, 18:1-20:4. The conditions were those given in Figure 1.

changes in environmental conditions (33,34). However, molecular species containing cyclopropanoic fatty acid residues on both the *sn*-1 and the *sn*-2 positions of the glycerol moiety, such as 17:0Δ-17:0Δ and 17:0Δ-19:0Δ, as we determined in the present study, are novel findings in the *E. coli* EPL. Under our experimental conditions, a molecular species having a cyclopropanoic fatty acid residue gives the same retention time in GLC as a species having fatty acid with one ethylenic double bond.

Further applications. The SIM profiles of *tert*-BDMS derivatives of 1,2-diacyl-*sn*-glycerols prepared from glycerophospholipids of soybean, turkey egg yolk, hen egg yolk, and porcine liver are shown in Figures 4, 5, 6 and 7, respectively. The results of previous fatty acid analyses are shown in Table 2. Applications of the present techniques demonstrated that complete separation between highly unsaturated molecular species was difficult on the liquid phase used, as has been pointed out elsewhere (12,23). The derivatives from soybean CPL, possessing up to three ethylenic bonds per fatty acid residue, were separated well under the present experimental conditions. However, hen egg yolk EPL (Fig. 6), rich in 20:4n-6 (Table 2), showed poorer resolution than did turkey egg yolk CPL (Fig. 5). The results shown in Figure 7 are consistent with the above description: porcine liver EPL with higher levels of polyunsaturated fatty acids (PUFA), probably from an animal fed a fish meal diet (35), showed relatively poor resolutions between highly unsaturated molecular species such as 18:0-20:4 (peak No. 10) and 16:0-22:6 (peak No. 11). This could be attributed to a partial polymerization of the PUFA residues on the WCOT column in the high temperature range (12), or be due to geometric isomer artifacts produced at higher elution temperature (36).

Usually the SIM approach has been restricted to the quantitative analysis of known materials. In this study, however, SIM was applied to unknown materials. Reliable quantification can be accomplished by the combination of GLC/FID and GC/MS-SIM. One of the strong points of the present technique is that peak assignment is possible despite high background levels caused by column bleeding, which appears unavoidable with polar phase columns. A comparison of the retention times between authentic standards and samples, which are indispensable in apolar phase WCOT column GLC, is not always required in the present technique. Once the fatty acid composition of an unknown glycerophospholipid is known, then exact peak assignments become possible. However, severe distortions of peaks corresponding to highly unsaturated molecular species can occur under present conditions. This means that the method has somewhat limited practicality for such samples. Therefore, even more

Double-Bond Localization in Heneicosapentaenoic Acid by a Gas Chromatography/Mass Spectrometry (GC/MS) Method

Kohei Yamamoto[a,1], **Akira Shibahara**[b,*], **Takao Nakayama**[a,1] and **Goro Kajimoto**[b,2]
[a]General Testing Research Institute of Japan Oil Stuff Inspectors' Corporation, Kobe 658, and [b]Department of Nutrition, Kobe-Gakuin University, Kobe 651-21, Japan

Double-bond locations in heneicosapentaenoic acid from eel lipids were determined by a method involving gas chromatography/mass spectrometry (GC/MS). The methyl esters of the pentaenoate fraction were first partially reduced with hydrazine. The resulting *cis*-monoenoates were then methylthiolated, and the resultant adducts were analyzed by GC/MS. The key fragmentation ions generated by the cleavage between the methylthio-substituted carbons were used to ascertain the original double-bond positions in the native fatty acid esters. Based on mass spectral evidence, the acid was identified as all-*cis*-6,9,12,15,18-heneicosapentaenoic acid.
***Lipids 26,* 948–950 (1991).**

We have recently reported a convenient method for determining the double-bond positions in polyenoic fatty acids using gas chromatography/mass spectrometry (GC/MS) (1). The method involves partial reduction of methyl polyenoate(s) with hydrazine, methylthiolation of the resulting monoenoates, and GC/MS analysis of the resultant adducts. With this method, it is only necessary to prior isolate the methyl polyenoate(s) from the other methyl esters. This is accomplished by conventional fractionation based on the degree of unsaturation before partial reduction with hydrazine. In the present paper, we describe the application of this approach to the determination of the double-bond positions in heneicosapentaenoic acid (21:5), which was recently detected in trace amounts in eel lipids using capillary gas chromatography (GC).

Fatty acids with odd-numbered carbon chains have been recognized as normal but minor components of many natural lipids (2). Mayzaud and Ackman (3) focused on an odd-chain polyenoic acid, 21:5, in marine lipids and identified the acid in seal oil as all-*cis*-21:5(Δ6,9,12,15,18). These researchers (3) also cited and discussed the previous data which their group had obtained concerning the occurrence of 21:5 in several marine organisms (3; and references therein). Other structures of 21:5 that had been suggested previously include 21:5n-2 in herring oil (4) and 21:5n-5 in *Euglena gracilis* lipids (5).

MATERIALS AND METHODS

All chemicals were analytical reagent grade, and solvents were distilled before use.

The edible parts of eels *(Anguilla japonica),* grown in Lake Hamana (in Shizuoka prefecture), were homogenized with chloroform/methanol (2:1, v/v) (6). The lipids obtained were converted to fatty acid methyl esters (FAME) by methanolysis (0.5 N KOH/methanol) and successive methylation (BF_3/methanol) (6). The resulting FAME were purified by silica gel column chromatography (6).

An aliquot (*ca.* 0.2 g) of the purified FAME was dissolved in 50 mL of methanol containing 5 g of urea, stirred for 20 min at 50°C, and allowed to stand for 60 min at −20°C. The non-urea-complexing FAME mixture was filtered while below 0°C. After adding water, the filtrate was extracted twice with hexane. The recovered fraction, rich in polyenoates, was then fractionated by argentation thin-layer chromatography (AgTLC) (6) with hexane/diethyl ether (50:50, v/v), and the pentaenoate band corresponding to authentic all-*cis*-20:5(Δ5,8,11,14,17) methyl ester was recovered.

The pentaenoate fraction (*ca.* 5 mg) was dissolved in 1.2 mL of an 8.3% (v/v) methanolic hydrazine hydrate solution, containing 0.1 mL of 30% H_2O_2, and was stirred for 90 min at 50°C. After acidification with 6 N HCl, the resultant products were extracted with hexane and separated by AgTLC with hexane/diethyl ether (80:20, v/v) as developing solvent. The monoenoate band corresponding to authentic methyl *cis*-monoenoates was scraped off and extracted with diethyl ether. The extract was then washed several times with a saturated NaCl solution to remove trace amounts of contaminating $AgNO_3$, which would be strongly inhibitory to the formation of dimethyl disulfide (DMDS) adducts. The separations were monitored by capillary GC (7), capillary GC/MS (7), and packed-column GC/MS using the chemical-ionization mode (100 eV) with isobutane as a reactant gas.

The purified monoenoate fraction was methylthiolated according to our earlier procedure (6,8) with the following modifications. The fraction (*ca.* 0.5 mg) was incubated with 0.3 mL of DMDS containing 4 mg of I_2 for 30 min at 35°C. After adding 1 mL of hexane/diethyl ether (1:1, v/v) with stirring, a 10% (w/v) aqueous $Na_2S_2O_3$ solution was added with vigorous vortexing until the color of I_2 disappeared. The mixture was allowed to stand for a few minutes, and then an aliquot of the upper phase containing the resultant adducts was withdrawn and injected directly into a packed-column GC/MS system. The GC/MS system was operated in the electron impact ionization mode (20 eV) under conditions similar to those reported earlier (6).

Other analytical procedures were the same as those used in our previous work (6).

RESULTS AND DISCUSSION

Figure 1 shows a capillary gas chromatogram of the pentaenoate fraction prepared from eel lipids. Authentic

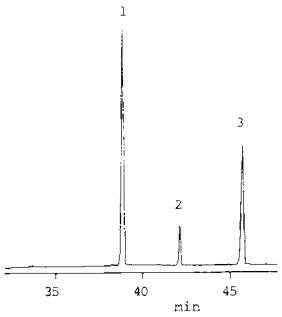

FIG. 1. Capillary gas chromatogram of fatty acid methyl esters of the pentaenoate fraction prepared from eel lipids. Peak identifications are discussed in the text. Peak 1, 20:5; 2, 21:5; 3, 22:5. Column, fused silica ULBON HR-SS-10 (50 m × 0.25 mm i.d., chemically bonded type); column temperature, isothermal at 100°C for 5 min, programmed at 4°C/min to 210°C and held for an additional 20 min; carrier gas, helium at 18.2 cm/s.

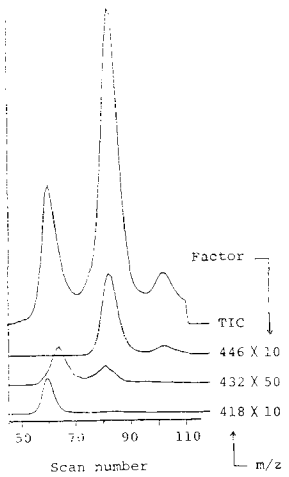

FIG. 2. Mass chromatogram of dimethyl disulfide adducts of methyl monoenoates formed by partial hydrazine reduction of the pentaenoate fraction. The ions at *m/z* 418, 432 and 446 are the molecular ions of the adducts of 20:1, 21:1 and 22:1 methyl esters, respectively. The predominant adducts of major 20:1 methyl esters are cut off from the analytical line by using an automated pre-cut valve to prevent ion source contamination. Column, 1 m × 3 mm i.d. glass column packed with 2% OV-101 on 100–120 mesh Chromosorb WHP; column temperature, 250°C; carrier gas, helium at 40 mL/min; ionization energy, 20 eV; scan range, 0–450 a.m.u. at 5.1 s/cycle.

all-*cis*-20:5(Δ5,8,11,14,17) methyl ester eluted at the same position as peak 1. For peaks 1, 2 and 3 in Figure 1, GC/MS analysis, using the chemical-ionization mode, showed quasi-molecular ions (M + 1) at *m/z* 317 (for peak 1), 331 (for peak 2) and 345 (for peak 3); the ions indicated the presence of 20:5, 21:5 and 22:5 methyl esters. In the other fractions, none of the peaks coincided with peak 2 and no quasi-molecular ion at *m/z* 331 was detected by capillary GC and GC/MS using chemical-ionization.

The infrared and ultraviolet spectra (data not included) of the pentaenoate fraction showed no absorption in the 960–970 cm^{-1} region or in the 230–235 nm region, which indicated that the fraction contained neither *trans* double bonds nor conjugated double bonds. The unsaturated ester corresponding to peak 2 in Figure 1 had the same mobility in AgTLC as did authentic all-*cis*-20:5(Δ5,8,11,14,17) methyl ester (see Materials and Methods). These results suggested that the three esters (peaks 1, 2 and 3 in Fig. 1) had similar double-bond configurations and methylene-interrupted arrangements.

After complete hydrogenation of an aliquot of the pentaenoate fraction in the presence of platinum black (6), three peaks were detected in capillary GC. The retention times of the peaks agreed with those of authentic straight chain 20:0, 21:0 and 22:0 methyl esters, respectively. Capillary GC/MS analysis of the hydrogenated products gave the same mass spectra as did the authentic standards. Hence, the unsaturated ester corresponding to peak 2 in Figure 1 was determined to be 21:5 methyl ester with a straight fatty acid chain.

The pentaenoate fraction was then partially reduced with hydrazine. From the reduced products, a *cis*-monoenoate fraction was recovered by AgTLC. No band for *trans*-monoenoate was observed. After methylthiolation, the DMDS adducts of the monoenoates were analyzed by packed-column GC/MS. Figure 2 shows the mass chromatogram, in which the ions at *m/z* 418, 432 and 446 are the molecular ions of the adducts of 20:1, 21:1 and 22:1 methyl esters, respectively.

Two peaks were registered at scan numbers 63 and 79 on the mass chromatogram of the molecular ion at *m/z* 432. In general, DMDS adducts of monoenoic positional isomers having an identical chain length are partially separated even on a short packed-column; this is due to the position of the carbons to which two methylthio groups are attached. As shown in Figure 2, the DMDS adducts (*m/z* 446) of 22:1 methyl esters (originating from 22:5 methyl ester) eluted as two peaks, and the DMDS adducts (*m/z* 418) of 20:1 methyl esters (originating from 20:5 methyl ester) eluted in the same pattern. In this mass chromatogram, the predominant DMDS adducts of major 20:1 methyl esters, which would be expected to elute before scan number 50, were cut off by using an automated pre-cut valve to prevent ion source contamination.

Figure 3 shows the mass spectra used for confirming the original double-bond positions in the 21:5 methyl ester and illustrates the fragmentation patterns of the individual adducts. The electron impact ionization of the adducts produced the recognizable molecular ion at *m/z* 432 and the three representative key fragmentation ions. Of the three definitive fragmentation ions, two were generated by the cleavage between the methylthio-substituted carbons at the original double-bond position in the molecule, and the remaining ion was derived by loss of methanol from the ion containing the ester group (6–8).

In spectrum A, the presence of DMDS adducts of 21:1(Δ6), 21:1(Δ9) and 21:1(Δ12) methyl esters was confirmed based on the detection of sets of the key fragmentation ions at *m/z* 257, 175 and 143, at *m/z* 215, 217 and 185, and at *m/z* 173, 259 and 227, respectively (*cf.* structures in Fig. 3). The presence of DMDS adducts of 21:1(Δ15) methyl ester (spectrum B) and 21:1(Δ18) methyl ester (spectrum C) was confirmed in the same manner based on mass spectral evidence (*cf.* structures in Fig. 3). The peaks of the unmarked ions in spectrum B were those overlapping in spectrum A; the peaks of the unmarked ions in spectrum C were due to the fragmentation of DMDS adducts of 22:1 methyl esters which co-eluted in the mass chromatogram (*cf.* Fig. 2). These results suggested that the original double-bond positions in these

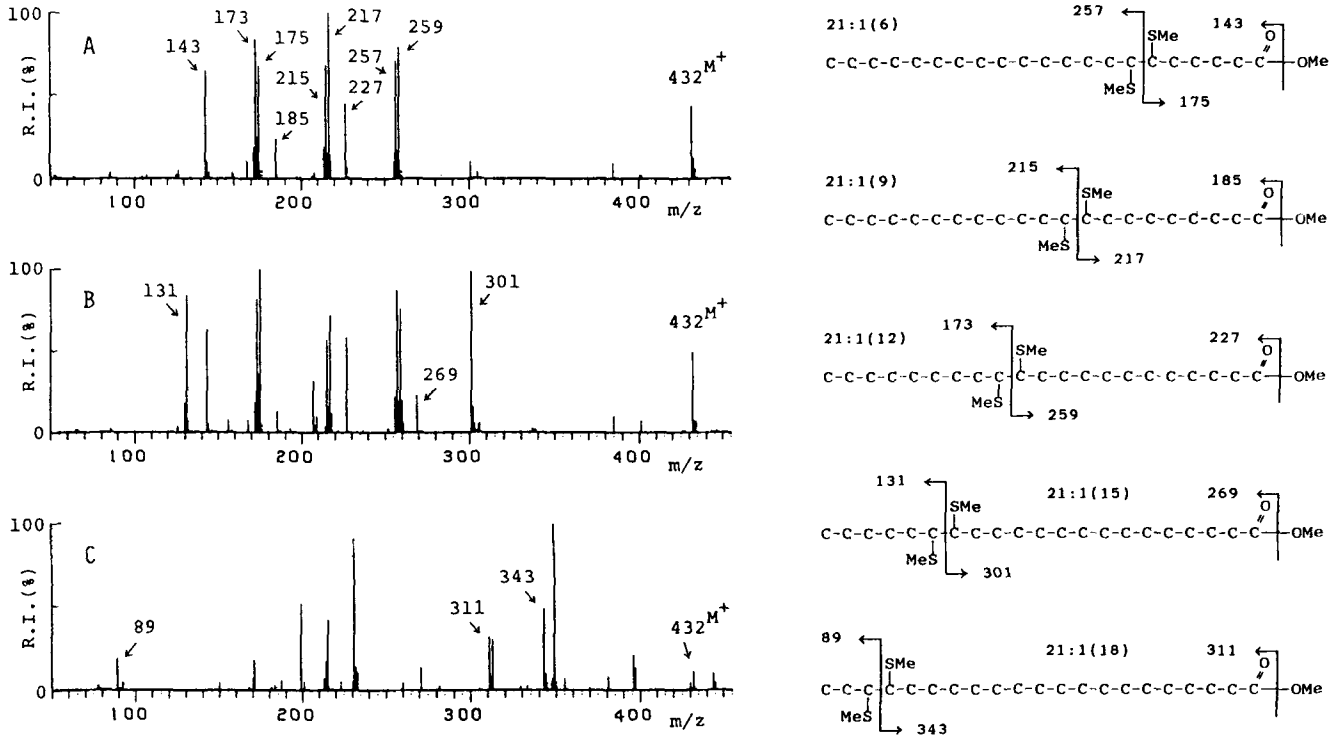

FIG. 3. Mass spectra of dimethyl disulfide adducts of 21:1 methyl esters. Spectra A, B and C are measured at scan numbers 63, 65 and 79, respectively, in the mass chromatogram shown in Figure 2. The schemes illustrate the fragmentation patterns of the individual adducts.

21:1 methyl esters were at the C-6, C-9, C-12, C-15 and C-18 carbons, respectively.

The five types of 21:1 methyl esters recovered from the *cis*-monoenoate fraction (see above) were formed from the 21:5 methyl ester by partial reduction with hydrazine, which is known to reduce double bonds without geometrical or positional isomerization of the remaining double bonds (9). Consequently, the 21:5 could be identified as all-*cis*-21:5(Δ6,9,12,15,18).

The structure of this methylene-interrupted all-*cis*-21:5n-3 in the eel lipids agrees with that reported previously in seal oil (3). No other double-bond positional isomers could be detected in the 21:5 fraction, and no other odd-chain polyenoic acids having more than five double bonds could be detected in these lipids. The proportion of 21:5n-3 relative to total fatty acids is very low in the eel lipids (below 0.5%) as it is in other marine lipids (below 1%) (3; and references therein). Possible explanations for the occurrence of 21:5n-3 in marine lipids have been discussed by Mayzaud and Ackman (3). The acid might be formed from 22:5n-3 by an α-oxidation pathway or from a hydrocarbon (3,6,9,12,15,18-heneicosahexaene and so forth) by an ω-oxidation route. However, the pathways of 21:5n-3 formation and also the reasons for 21:5n-3 accumulation have not yet been determined. The occurrence of 21:5n-3 in the lipids of cultivated eels might have resulted from a partial marine fish meal diet.

In the present study, we have employed our recently devised method (1) to locate the double-bond positions in trace amounts of 21:5n-3. This convenient method is very useful for confirming the structures of polyenoic fatty acids. The original data on the method for polyenoic acid analysis (*i.e.*, its reliability and applicability) are summarized in our recent paper (1).

ACKNOWLEDGMENT

We wish to thank Professor M. Noda (Kinki University) for helpful discussions.

Identification of Natural Diacylglycerols as the 3,5-Dinitrophenylurethanes by Chiral Phase Liquid Chromatography with Mass Spectrometry

Y. Itabashi[1], **L. Marai** and **A. Kuksis***
Banting and Best Department of Medical Research, University of Toronto, C.H. Best Institute, Toronto, Canada M5G 1L6

This study reports a facile identification of the molecular species of enantiomeric diacylglycerols by combining chiral phase high-performance liquid chromatography with positive chemical ionization mass spectrometry. For this purpose the 3,5-dinitrophenylurethane (DNPU) derivatives of *sn*-1,2(2,3)-diacylglycerols are separated on an R(+)-naphthylethylamine polymer column (25 cm × 0.46 cm ID) using an isocratic solvent system made up of hexane/dichloroethane/acetonitrile (85:10:5, by vol) or isooctane/*tert*-butyl methyl ether/acetonitrile/isopropanol (80:10:5:5, by vol). About 1% of the column effluent (1 mL/min) was admitted to a quadrupole mass spectrometer (Hewlett-Packard, Palo Alto, CA) *via* direct liquid inlet interface, and positive chemical ionization spectra were recorded over the range of 200–900 mass units. The DNPU derivatives of diacylglycerols yield characteristic $[M-DNPU]^+$ and $[RCO+74]^+$ ions for each diacylglycerol species from which the molecular weight and exact pairing of fatty acids can be unequivocally obtained. The characteristic ions appear to be generated in nearly correct mass proportions as indicated by preliminary quantitative comparisons.
***Lipids* 26, 951–956 (1991).**

The chiral phase high-performance liquid chromatography (HPLC) described by Takagi and Itabashi (1) provides a rapid and complete resolution as the 3,5-dinitrophenylurethane (DNPU) derivatives of enantiomeric diacylglycerols with identical fatty acids, but separation of enantiomers containing different fatty acids results in overlap or interdigitation of many molecular species, and identification of individual *sn*-1,2- and *sn*-2,3-enantiomers becomes difficult or impossible. Furthermore, the chiral stationary phases thus far developed fail to provide a complete separation of molecular species within either enantiomer class.

We have recently overcome this difficulty by collecting separately the enantiomeric fractions by chiral phase HPLC, regenerating the diacylglycerols without isomerization, converting them to the TMS ethers, and identifying the molecular species of the diacylglycerols by polar capillary gas-liquid chromatography (GLC) (2). Although this method yields excellent results, the procedure is laborious and could lead to isomerization and loss of sample.

In the present study we have combined chiral phase HPLC with mass spectrometry (LC/MS) for the identification and quantitation of molecular species overlapping between enantiomers and within each enantiomer class. For this purpose we have employed positive chemical ionization mass spectrometry (CIMS), which provides significant $[RCO+74]^+$ and $[M-DNPU]^+$ fragments necessary for unequivocal identification of diacylglycerol DNPU derivatives in the effluents of chiral phase HPLC columns. Under the LC/MS conditions, significant intensities are also obtained for the negative ions corresponding to $[M]^-$, $[DG+Cl]^-$, $[DNPU]^-$, and $[DNPU+Cl]^-$, which do not provide additional structural information, although they increase the sensitivity of detection of the diacylglycerol derivatives in the LC/MS effluent (3). A preliminary report has appeared (4).

MATERIALS AND METHODS

rac-1,2-Dioleoylglycerol was prepared by Grignard degradation from standard trioleoylglycerol (Sigma Chemical Co., St. Louis, MO). Cocoa butter, corn oil and a hydrogenated low molecular weight fraction of butteroil were those used by our laboratory in previous studies (3,5,6). In each instance, the triacylglycerols were isolated by normal phase thin-layer chromatography (TLC) using a neutral solvent system (6). The mixed *sn*-1,2(2,3)-diacylglycerols were prepared from the purified triacylglycerols by Grignard degradation and purified by boric acid TLC (7), which also removed any X-1,3-diacylglycerols. The dinitrophenylurethanes were prepared by reacting the purified diacylglycerols with 3,5-dinitrophenylisocyanate in dry toluene in the presence of pyridine, as described by Itabashi and Takagi (1).

Chiral phase HPLC. The chiral phase HPLC analyses were performed on a Hewlett-Packard Model 1084 liquid chromatograph (Palo Alto, CA) equipped with a column (25 cm × 4.6 mm ID) containing R-(+)-naphthylethylamine polymer as the liquid phase (YMC-Pack A-KO3, YMC Inc., Tokyo, Japan) (8). For combined LC/MS

Abbreviations: CIMS, chemical ionization mass spectrometry; DNPU, dinitrophenylurethanes; GLC, gas-liquid chromatography; HPLC, high-performance liquid chromatography; LC/MS, liquid chromatography/mass spectrometry; TLC, thin-layer chromatography.

The abbreviations 14:0, 16:1, 18:2, etc. represent normal chain fatty acids of 14, 16, 18, etc. acyl carbons and 0, 1, 2, etc. double bonds, respectively; 16:0-18:1, etc. represent diacylglycerols containing 16:0 and 18:1 fatty acids of unspecified positional distribution; *sn* indicates stereospecific numbering of glycerol carbons; *sn*-1,2-diacylglycerols and *sn*-2,3-diacylglycerols are enantiomeric diacylglycerols of unspecified fatty acid composition; *rac*-1,2-diacylglycerols are racemic diacylglycerols representing equal amounts of *sn*-1,2- and *sn*-2,3- enantiomers; *sn*-1,2(2,3)-diacylglycerols are a mixture of *sn*-1,2- and *sn*-2,3-diacylglycerols of unspecified proportion of enantiomers and unspecified fatty acid composition and positional distribution; X-1,3-diacylglycerols are diacylglycerols of unspecified fatty acid composition and reverse isomer content.

analyses the original solvent system was modified to contain either hexane/dichloroethane/acetonitrile (85:10:5, by vol) or isooctane/*tert*-butyl methyl ether/acetonitrile/isopropanol (80:10:5:5, by vol). The columns were operated at a flow rate of 1.0 mL/min or less and at 25°C oven temperature. About 30–50 μg of the DNPU derivative dissolved in the same solvent as the mobile phase was admitted to the column using an automatic sample injector.

LC/MS. For LC/MS, about 1% of the HPLC effluent was admitted to a Hewlett-Packard Model 5985B quadrupole mass spectrometer *via* a direct liquid inlet interface (9). Positive chemical ionization mass spectra were taken every 5 s over the entire chromatogram in the mass range 200–900, and the data were recorded by a computer. Chloride attachment negative chemical ionization spectra of the dinitrophenylurethanes were recorded over a similar mass range. The HPLC solvent served as the reagent gas and the source of chloride for chloride attachment negative chemical ionization (3). The stored data were recalled and analyzed with the help of a Hewlett-Packard data system (Model HP-1000E) and a graphics terminal (Model HP 2648A) as previously described (9,10).

RESULTS AND DISCUSSION

Figure 1 shows the chiral phase LC/MS profile of the DNPU derivatives of *rac*-1,2-dioleoylglycerols derived from trioleoylglycerol. Previous work has established the earlier elution of the *sn*-1,2-enantiomer (8). The single ion plots show the presence of the $[RCO+74]^+$ (*m/z* 339) and the $[M-DNPU]^+$ (*m/z* 603) fragments in both enantiomeric peaks. The total mass spectra recorded in Figure 2 indicate the absence of any other significant positive ions, and are similar for both enantiomers. An identical LC/MS spectrum was obtained for the DNPU derivative of X-1,3-dioleoylglycerol, which emerges ahead of the *sn*-1,2-isomer (results not shown). Interestingly, the $[M-RCOO]^+$ ion is not obtained under the LC/MS conditions. The *sn*-1,2- and *sn*-2,3-dioleoylglycerols were derived from the trioleoylglycerol in the anticipated 1:1 mass proportion as indicated by the peak area ratios.

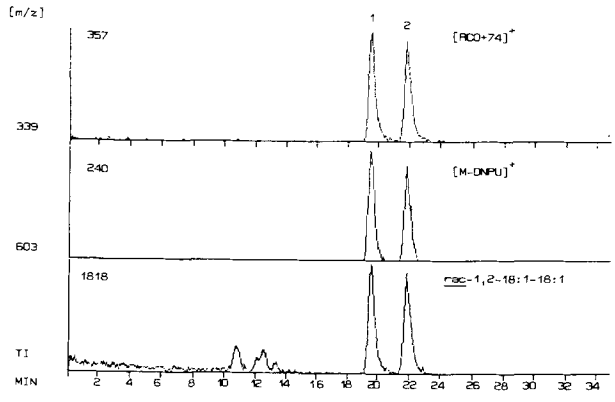

FIG. 1. Chiral phase LC/MS profile of the DNPU derivatives of *rac*-1,2-dioleoylglycerol. TI, total ion current; *m/z* 339, $[RCO+74]^+$ (oleic acid); *m/z* 603, $[M-DNPU]^+$ (dioleoylglycerol). HPLC solvent system: isooctane/*tert*-butyl methyl ether/acetonitrile/isopropanol (80:10:5:5, by vol). Other LC/MS conditions are as given in Materials and Methods.

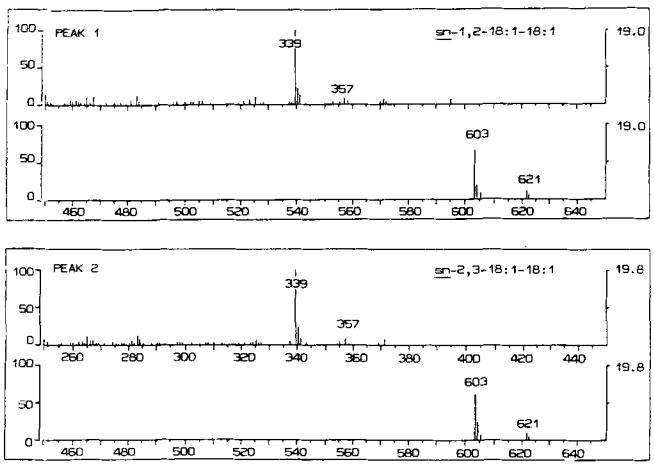

FIG. 2. Full mass spectra of Peaks 1 and 2 (Fig. 1) as recorded over the range of 250–650 mass units. LC/MS conditions as in Figure 1.

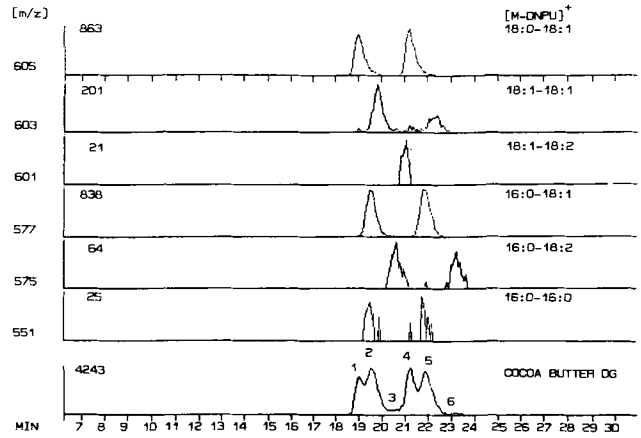

FIG. 3. Chiral phase LC/MS profile of the DNPU derivatives of *sn*-1,2(2,3)-diacylglycerols derived from cocoa butter triacylglycerols by Grignard degradation. TI, total ion current; *m/z* 551, 575, 577, 601, 603, 605 represent $[M-DNPU]^+$ of 16:0-16:0, 16:0-18:2, 16:0-18:1, 18:1-18:2, 18:1-18:1 and 18:0-18:1 diacylglycerols, respectively. LC/MS conditions as in Figure 1.

Figure 3 shows the chiral phase LC/MS profile of the DNPU derivatives of *sn*-1,2(2,3)-diacylglycerols derived from cocoa butter triacylglycerols by Grignard degradation. In this instance the diacylglycerols are resolved into the *sn*-1,2- and *sn*-2,3-enantiomers, each of which represents several molecular species of diacylglycerols, as demonstrated by the single ion ($[M-DNPU]^+$) plots recorded in Figure 3. On the basis of these ions it is possible to recognize 18:0-18:1 (*m/z* 605), 16:0-18:1 (*m/z* 577) and 18:1-18:1 (*m/z* 603) as the major components and 16:0-18:2 (*m/z* 575), 16:0-16:0 (*m/z* 551) and 18:1-18:2 (*m/z* 601) as minor components. (Corresponding $[RCO+74]^+$ ions not shown). Figure 4 shows the full mass spectra of Peaks 1 and 4 (Fig. 3). Peak 1 contains 18:0-18:1 as the major species as indicated by the $[RCO+74]^+$ ions at *m/z* 339 and 341 and the $[M-DNPU]^+$ ion at *m/z* 605. Peak 4 is identical to Peak 1 in composition, as it contains the corresponding *sn*-2,3-enantiomer. Since the cocoa butter triacylglycerols are asymmetric, the proportions of the

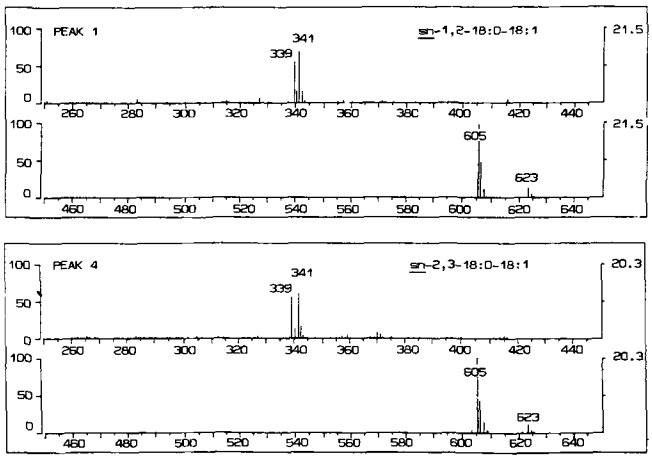

FIG. 4. Full mass spectra of Peaks 1 and 4 (Fig. 3) as recorded in the range of 250–650 mass units. LC/MS conditions as in Figure 1.

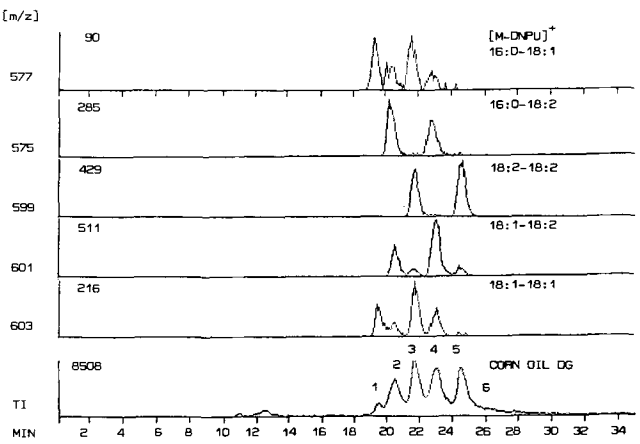

FIG. 5. Chiral phase LC/MS of the DNPU derivatives of *sn*-1,2(2,3)-diacylglycerols derived from corn oil triacylglycerols by Grignard degradation. TI, total ion current; *m/z* 575, 577, 599, 601 and 603 represent $[M-DNPU]^+$ of 16:0-18:2, 16:0-18:1, 18:2-18:2, 18:1-18:2 and 18:1-18:1, respectively. LC/MS conditions as in Figure 1.

two enantiomers in the two peaks are different. A complete identification of all the molecular species is given in Table 1 along with the characteristic fragment ions. The proportions of the individual components in any overlapping diacylglycerol species were obtained from the uncorrected ratios of the characteristic $[RCO+74]^+$ ions as previously described for the $[MH-RCOOH]^+$ ions of the silyl ethers of diacylglycerols (9,10). It should be noted that Peak 4 also contained the minor *sn*-1,2-18:1-18:2 species, which overlapped with the *sn*-2,3-diacylglycerols. The relative proportions of the *sn*-1,2- and *sn*-2,3-diacylglycerols given by the uncorrected peak areas and the estimates from overlapping species correspond closely to the peak area ratios determined earlier (2) by polar capillary GLC, following removal of the DNPU groups from the enantiomeric *sn*-1,2- and *sn*-2,3-diacylglycerols recovered from the chiral column. The slight preference observed for the association of the mono- and diunsaturated fatty acids with the *sn*-1,2-enantiomers would be anticipated from the earlier stereospecific analyses of Brockerhoff and Yurkowski (11).

Figure 5 shows the chiral phase LC/MS profile of the DNPU derivatives of *sn*-1,2(2,3)-diacylglycerols derived from corn oil triacylglycerols. In this instance there is

	341,337	603	*sn*-2,3-18:0-18:2	2.5	1.6
	339	603	*sn*-2,3-18:1-18:1	1.0	1.2
6	313,337	575	*sn*-2,3-16:0-18:2	1.2	1.8

[a] The diacylglycerol species are identified only by enantiomeric configuration and molecular association of fatty acids; positional distribution of fatty acids is not specified. Note late elution of *sn*-1,2 enantiomer containing the 18:1-18:2 pair of fatty acids.

[b] Uncalibrated $[M-DNPU]^+$.

[c] Combined chiral phase HPLC and polar capillary GLC (2). The GLC analysis revealed the presence of 0.3% *sn*-1,2-20:1-18:1 and 1.4% *sn*-2,3-20:1-18:1.

considerable overlap and interdigitation of the *sn*-1,2- and *sn*-2,3-diacylglycerols, as demonstrated by the single ion ([M−DNPU]$^+$) plots recorded in Figure 5. On the basis of these ions it is possible to recognize 18:1-18:2 (*m/z* 601), 18:2-18:2 (*m/z* 599), 16:0-18:2 (*m/z* 575) and 18:1-18:1 (*m/z* 603) as major components, and 16:0-18:1 (*m/z* 577) as a minor component. (Corresponding [RCO+74]$^+$ ions not shown). Figure 6 shows the complete mass spectra of Peaks 2 and 4 (Fig. 5). Peak 2 contains two major molecular species: 16:0-18:2, as indicated by the [RCO+74]$^+$ ions at *m/z* 313 and 337, and an [M−DNPU]$^+$ ion at *m/z* 575, and 18:1-18:2, as indicated by the [RCO+74]$^+$ ions at *m/z* 339 and 337, and an [M−DNPU]$^+$ ion at *m/z* 601. The diacylglycerol types of ions were observed to appear as 18 mass units higher fragment ions due to the addition of water. The composition of Peak 4 is identical to that of Peak 2, except for differences in the proportions of the molecular species. A complete identification of all the molecular species is given in Table 2, along with the characteristic fragment ions. The relative proportions of the individual *sn*-1,2- and *sn*-2,3-diacylglycerols given by the uncorrected peak areas correspond rather closely to the peak area ratios determined earlier by combined chiral phase HPLC and polar capillary GLC (2).

Figure 7 shows the chiral phase LC/MS profile of the DNPU derivatives of the *sn*-2,3-diacylglycerols derived from a hydrogenated short chain triacylglycerol fraction of a butteroil distillate. The triacylglycerols in this distillate had been shown to contain butyric acid in the *sn*-3 position (12). Following Grignard degradation the butyric

[c]UV response of HPLC detector at 254 nm.

acid-containing diacylglycerols yielded a separate TLC band which migrated more slowly than the longer chain diacylglycerols. Preparation of the DNPU derivatives and chiral phase HPLC revealed only the presence of the *sn*-2,3-diacylglycerols, as established by parallel analyses of standards. The composition of the molecular species of these diacylglycerols was determined by LC/MS. The single ion plots indicate the elution times of the major components identified as 18:0-4:0 (*m/z* 411), 16:0-4:0 (*m/z* 383), and 14:0-4:0 (*m/z* 355) on the basis of the $[RCO+74]^+$ and $[M-DNPU]^+$ fragments. (Corresponding $[RCO+74]^+$ ions for butyric acid not shown). Figure 8 shows the full mass spectra for Peaks 2 and 7 (Fig. 7), which contain single diacylglycerol species, as demonstrated by the ion plots recorded in Figure 7. On the basis of these ions it is possible to recognize the $[RCO+74]^+$ corresponding to stearic acid (*m/z* 341) and the $[M-DNPU]^+$ corresponding to 18:0-4:0 (*m/z* 411) in Peak 2. Although the $[RCO+74]^+$ corresponding to butyric acid (*m/z* 161) is not seen, the detection of the long chain acid along with the correct molecular weight and chiral phase HPLC retention time is sufficient to identify the molecular species in Peak 2. Likewise, the $[RCO+74]^+$ corresponding to myristic acid (*m/z* 285) and the $[M-DNPU]^+$ corresponding to 14:0-4:0 (*m/z* 355), along with the anticipated HPLC retention time, establish the identity of the diacylglycerol in Peak 7. In both instances a minor peak was seen for the $[M-DNPU+18]^+$ ion.

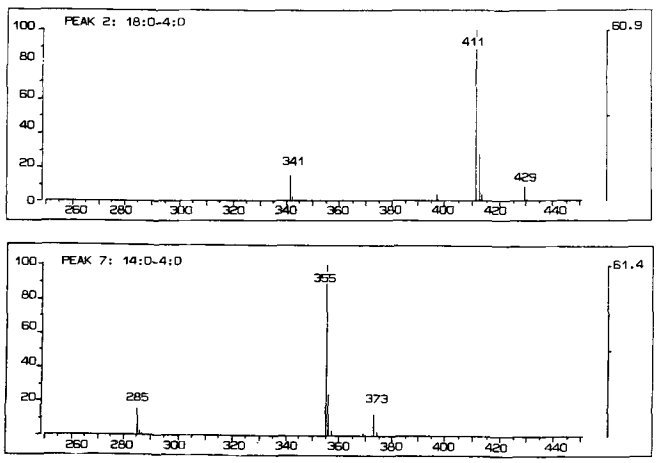

FIG. 8. Full mass spectra of Peaks 2 and 7 (Fig. 7) as recorded in the range of 250–500 mass units. LC/MS conditions as in Figure 1.

Table 3 lists the molecular species of diacylglycerols identified by chiral phase LC/MS in the short chain triacylglycerols of the butteroil distillate. The uncalibrated quantitative LC/MS response differs significantly from the UV signal of the HPLC detector and requires correction.

In conclusion, chiral phase LC/MS with positive chemical ionization provides an effective method for the unequivocal identification of molecular species of enantiomeric diacylglycerols from natural sources. The method establishes the order of elution of the species, which is the same for the *sn*-1,2 and the *sn*-2,3 isomers. The higher molecular weight and more unsaturated species are eluted last. Accurate quantitation, however, may require calibration of the LC/MS response.

ACKNOWLEDGMENT

These studies were supported by funds from the Medical Research Council of Canada, Ottawa, and the Heart and Stroke Foundation of Ontario, Toronto, Canada. The authors are indebted to Professor Toru Takagi for interest and support.

COMMUNICATION

Inhibition of the *Clostridium perfringens* Phospholipase C Hydrolysis of a Thiophosphate Analog of Lysophosphatidylcholine by Micelle-Bound Ammonium and Sulfonium Cations

Paul R. Young,* William R. Snyder and **Rosemary F. McMahon**
Department of Chemistry, University of Illinois at Chicago, Chicago, Illinois 60680

Cetyltrimethylammonium and *n*-octadecyldimethylsulfonium bromides inhibit the *Clostridium perfringens* phospholipase C-catalyzed hydrolysis of 1-*S*-phosphocholine-2-*O*-hexadecanoyl-1-mercapto-2-ethanol (1) at pH 7.5, 37°C, μ = 0.15 with KCl. Mixed micelles containing 1 and either inhibitor are substrates for the enzyme and the fraction of activity remaining is a monotonic, but non-linear function of the mole fraction of inhibitor. Simple saturation kinetics are observed as the concentration of 1 is increased in mixed micelles containing a constant mole fraction of inhibitor. Inhibition constants for cetyltrimethylammonium and *n*-octadecyldimethylsulfonium bromides are 0.66 ± 0.04 and 0.25 ± 0.02 mM, respectively. The data suggest that the significant inhibition previously observed for soluble alkyldisulfonium salts (K_{50} for dodecamethylene-*bis*(dimethylsulfonium) bromide, 27 μM) is dependent upon bifunctional cationic interactions rather than hydrophobic binding.
***Lipids* 26, 957-959 (1991).**

Phospholipase C (PLC, phosphatidylcholine choline phosphohydrolase, EC 3.1.4.3) catalyzes the hydrolysis of the glycerophosphate ester bond in phospholipids. The PLC enzymes from *Bacillus cereus* and *Clostridium perfringens* have been widely studied and reviewed (1-4). Because of the central role of phospholipases C in inflammation, there has been considerable interest in the regulation and inhibition of phospholipase C activity (5). We have recently reported (6) that the hydrolysis of 1-*S*-phosphocholine-2-*O*-hexadecanoyl-1-mercapto-2-ethanol (1) Scheme 1 (8,9), catalyzed by *C. perfringens* phospholipase C, follows simple saturation kinetics which are consistent with an ordered, rapid equilibrium mechanism in which Ca^{2+} binds to the enzyme followed by 1. Further, the hydrolysis of 1 was found to be inhibited by alkyldiamines, alkyldiammonium and alkyldisulfonium salts by a simple non-competitive mechanism in which inhibitor binds reversibly to all enzyme forms (6; Young, P.R., Snyder, W.R. and McMahon, R.F., submitted for publication). The alkyldisulfonium salts (*i.e.*, dodecamethylene-*bis*(dimethylsulfonium) bromide, K_{50} = 27 μM) are among the most active soluble phospholipase C inhibitors thus far reported. In the present study, we examined the inhibition of the hydrolysis of 1 by insoluble, micelle-bound, alkylammonium and alkylsulfonium salts. Unlike the soluble sulfonium salts examined previously, *n*-octadecyldimethylsulfonium bromide is only slightly more effective in inhibiting the enzyme than a comparable trimethylammonium salt.

SCHEME 1

MATERIALS AND METHODS

Materials. All chemicals used were readily available commercial products and were used without further purification unless otherwise noted. 1-*S*-Phosphocholine-2-*O*-hexadecanoyl-1-mercapto-2-ethanol (1) was prepared by the method described by Cox *et al.* (7), as modified by Snyder (8). *n*-Octadecyldimethylsulfonium bromide was prepared by reaction of *n*-octadecyl mercaptan with a large excess of CH_3I in methanol containing $NaHCO_3$ at room temperature, for three days (10). The resulting oil was chromatographed over Dowex-1 chloride in methanol and was characterized by nuclear magnetic resonance (NMR) spectroscopy; elemental analyses were found to be within standard limits. Phospholipase C (*C. perfringens*, 300 units/mg protein) was from Sigma Chemical Co. (St. Louis, MO) and was used as supplied.

Kinetics. The critical micelle concentration (CMC) of 1 was determined to be 20 μM at 37°C and an ionic strength of 0.15 (maintained with KCl) (6). Kinetic determinations were performed at 37°C, μ = 0.15 (KCl), [S] > 20 μM, pH 7.5 [10 mM 3-(*N*-morpholino)propanesulfonic acid (MOPS)] and dithio-*bis*(2-nitrobenzoic acid) (DTNB) = 500 μM, using a Hitachi (Hitachi, Ltd., Tokyo, Japan) 100-40 spectrophotometer equipped with an automatic cell changer and a thermostated cell compartment, as described previously (6). Substrate micelles, prepared by mixing stock solutions of 1, benzalkonium chloride and inhibitors, produced clear solutions and did not require sonication. All kinetic determinations were run in duplicate, and kinetic parameters were determined by non-linear least squares fit of the data to the appropriate equation. No induction period was observed during initial rate studies. The initial rate of hydrolysis of 1 was found to be a simple linear function of enzyme concentration over the concentration range [E] = 12-96 μg/mL, based on enzyme solid, as supplied.

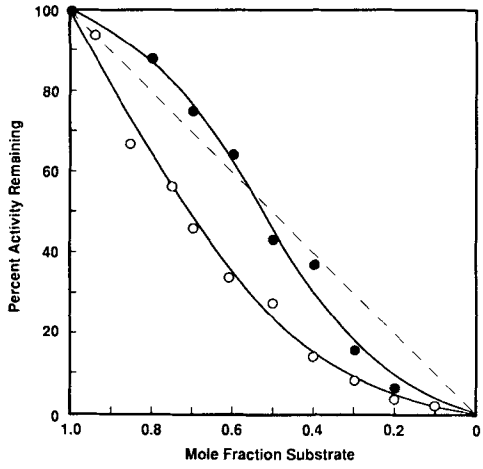
Abbreviations: BAC, benzalkonium chloride; CMC, critical micelle concentration; CTAB, cetyltrimethylammonium bromide; DTNB, dithio-*bis*(2-nitrobenzoic acid); MOPS, 3-(*N*-morpholino)propanesulfonic acid; NMR, nuclear magnetic resonance; ODSB, *n*-octadecyldimethylsulfonium bromide; PLC, phospholipase C; TNB, dianion of thio-(2-nitrobenzoic acid).

RESULTS AND DISCUSSION

The hydrolysis of the thiolester linkage in **1** by *C. perfringens* phospholipase C results in the release of phosphocholine and one equivalent of free thiol (7,9) (Scheme 2). In the presence of 5,5′-dithio-*bis*(2-nitrobenzoic acid) (DTNB), the thiol produced reacts to release one mole of 5-thio-2-nitrobenzoate (TNB) and form mixed disulfide. This intermediate can react with a second mole of free thiol, releasing another mole of TNB and forming the disulfide shown in Scheme 2. The initial velocity of DTNB reduction, monitored at 412 nm in the presence of 70 μM **1** (37°C, μ = 0.15 and [Ca^{2+}] = 50 mM) followed simple saturation kinetics with increasing DTNB concentration, with an apparent half-maximum at [DTNB] = 20 μM; kinetic determinations were routinely performed at [DTNB] = 500 μM where the reaction rate is independent of [DTNB] (6).

Initial velocities for the enzyme-catalyzed hydrolysis of **1** have been found to follow simple saturation kinetics under the conditions cited above, and generate linear double reciprocal plots (6). Linear mixed-type slope-intercept effects are observed for the hydrolysis of **1** with variable [Ca^{2+}] at fixed concentrations of **1**, and a simple slope effect is observed as the concentration of **1** is varied at several fixed concentrations of Ca^{2+}, consistent with a simple ordered rapid equilibrium mechanism in which Ca^{2+} binds to the enzyme first followed by the substrate (6).

Because of the simplicity of this system, we have previously examined the inhibition of the *C. perfringens* phospholipase C-catalyzed hydrolysis of **1** by a series of alkyldiamines (*i.e.*, 1,12-diaminododecane), by natural polyamines and by alkyldiammonium and alkyldisulfonium salts (6). The inhibition by the *bis*(dimethylsulfonium) compounds was especially striking with half-maximum inhibition occurring at 222 and 27 μM for the decyl- and dodecyl- compounds, respectively (Young, P.R., Snyder, W.R. and McMahon, R.F., submitted for publication). Further, there was a significant difference in inhibition constant between analogous ammonium and sulfonium compounds, the sulfonium compounds being over 300-fold more effective and ranking as some of the most powerful soluble phospholipase C inhibitors known. For alkyldiamines, previous work (6) has shown that the intervening alkyl chain bound to the enzyme in a manner that was non-competitive with substrate, and that the dissociation constant for the E|[S]|[Ca^{2+}]|[I] complex was a simple function of alkyl chain length with ≈ 74% of the available binding energy being utilized toward the stabilization of the inhibitory complex (6, 11-13). To examine the possibility that a simple alkyl sulfonium salt may bind to the enzyme in a similar manner and allow full utilization of hydrophobic binding potential towards inhibition, we have examined the inhibition of the hydrolysis of **1** by cetyltrimethylammonium bromide (CTAB) and by *n*-octadecyldimethylsulfonium bromide (ODSB) incorporated into mixed micelles containing substrate. Such micelles are substrates for the enzyme and the fraction of activity remaining is a monotonic, but non-linear function of the mole fraction of inhibitor (Fig. 1). For CTAB, the rate of the reaction decreases linearly to approximately 40% mole fraction inhibitor. The fact that the data are *below* the dashed line connecting 100% and zero activity, means that inhibition by CTAB is being observed, not simply substrate dilution within the



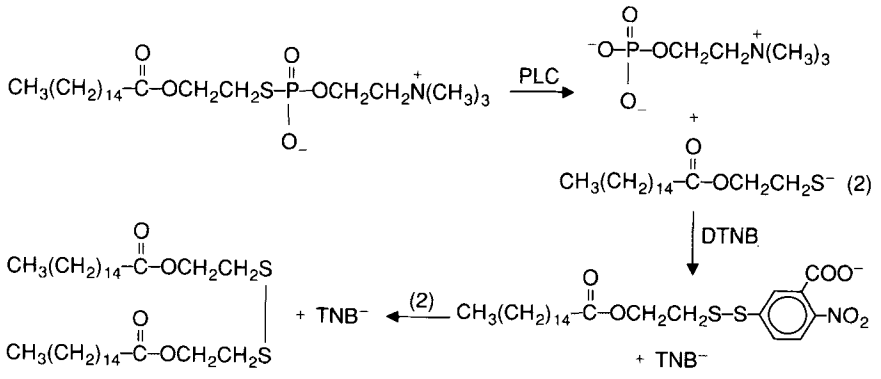


FIG. 1. The effect of the mole fraction of inhibitor present within micelles of 1-*S*-phosphocholine-2-*O*-hexadecanoyl-1-mercapto-2-ethanol (1), on the hydrolysis of 1 by *C. perfringens* phospholipase C, for cetyltrimethylammonium bromide (○) and *n*-octadecyldimethylsulfonium bromide (●). Assays were under the following conditions; pH 7.5, 37°C, μ = 0.15 (KCl), [Ca^{2+}] = 50 mM, [1] = 50 μM, 5,5′-dithio*bis*(2-nitrobenzoic acid) [DTNB] = 500 μM, and the reduction of DTNB was monitored at 412 nm.

SCHEME 2

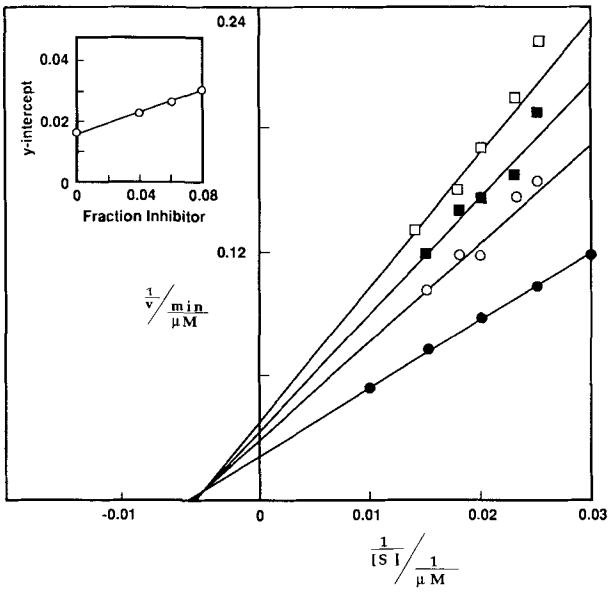

FIG. 2. Double reciprocal plots of 1/v *vs* 1/[S] for the hydrolysis of 1-*S*-phosphocholine-2-*O*-hexadecanoyl-1-mercapto-2-ethanol catalyzed by *C. perfringens* phospholipase C at the following fixed mole fractions of *n*-octadecyldimethylsulfonium bromide; (●), zero; (○), 0.04; (■), 0.06; (□), 0.08. Assays were under the following conditions; pH 7.5, 37°C, μ = 0.15 (KCl), [Ca^{2+}] = 50 mM, 5,5'-dithiobis(2-nitrobenzoic acid) [DTNB] = 500 μM, and the reduction of DTNB was monitored at 412 nm. Benzalkonium chloride (BAC) constituted 70% of the ternary micelles and was varied such that [1] + [BAC] was constant. *Inset*: Replot of (y-intercept) *vs* fraction *n*-octadecyldimethylsulfonium bromide.

mixed micelle. For ODSB, low mole fractions of the "inhibitor" stimulate enzyme activity, as demonstrated by the slight positive deviations above the 0-100% line. This effect is readily reproducible in duplicate experiments, and might result from effects of the sulfonium salt on gross micelle structure. The fact that the sulfonium compound is actually an inhibitor of the enzyme is shown clearly in Figure 2 where the mole fraction of inhibitor in the complex is maintained as a constant by substituting benzalkonium chloride (BAC) for 1 in a three-component mixed micelle. At the mole fraction of BAC used in these experiments (0.70), BAC has no effect on the rate of hydrolysis of 1 and simply functions as an inert diluent. Using this approach, simple saturation kinetics are observed at low concentrations of 1 as demonstrated in Figure 2 and the analogous plot for CTAB. In these plots, the common intersection point which is observed gives the approximate dissociation constant for the E|[Inhibitor] complex (14). Inhibition constants for CTAB and OSDB (obtained from negative x-intercept replots) are 0.66 ± 0.04 and 0.25 ± 0.02 mM, respectively. Although these constants are for binary BAC/inhibitor micelles, it is clear that the large difference in inhibition constant previously observed between structurally similar ammonium and sulfonium compounds (Young, P.R., Snyder, W.R. and McMahon, R.F., submitted for publication) is not observed in the present case. If the origin of the previously observed differences lies in the ability of sulfonium salts to form tight contact ion-pairs or tetracoordinate sulfuranes (15) with anionic groups on the enzyme surface, the present data suggest that the formation of these complexes is dependent upon bifunctional cationic interactions rather than hydrophobic binding to the enzyme surface.

An Aldehyde-Containing Galactolipid from the Red Alga *Gracilariopsis lemaneiformis*

Zhi D. Jiang and **William H. Gerwick***
College of Pharmacy, Oregon State University, Corvallis, Oregon 97331

An unprecedented aldehyde-containing digalactosyldiacylglycerol (DGDAG) has been isolated from the red alga *Gracilariopsis lemaneiformis* and structurally defined. Its structure was determined as 1-*O*-[5-hydroxy-12-oxo-dodeca-6(E),8(E),10(E)-trienoyl]-2-*O*-palmitoyl-3-*O*-[-β-D-galactopyranosyl-6,1-α-D-galactopyranosyl]-glycerol by nuclear magnetic resonance (NMR) spectroscopy, mass spectrometry and degradation to simple fragments. The identification of this aldehyde-containing DGDAG from *G. lemaneiformis*, in addition to our previous findings of unusual galactolipids, further indicates that this alga has unique lipoxygenase capacities.
***Lipids* 26, 960-963 (1991).**

Galactolipids are major constituents of the chloroplast membrane in higher plants (1). The biosynthesis of galactolipids occurs *via* two separate metabolic routes, termed the eukaryotic and prokaryotic pathways, which occur at different locations in the cell and result in the incorporation of different acyl groups in the resultant complex lipid species (2). Our previous work has shown that the red alga *Gracilariopsis lemaneiformis* is both a rich source of oxylipins (3,9) as well as of unusual oxygenated galactolipids (4). The continuation of our investigation of these lipid products from *G. lemaneiformis* has led us to isolate another unusual galactolipid which possesses an aldehyde-containing fatty acid as an acyl substituent.

EXPERIMENTAL PROCEDURES

General. Nuclear magnetic resonance (NMR) spectra were recorded on Bruker (Karlsruhe, Germany) AM 400 and AC 300 spectrometers. All shifts are reported relative to an internal tetramethylsilane (TMS) standard. Mass spectra were recorded on a Kratos (Manchester, England) MS 50TC. Infrared spectra were obtained on a Nicolet (Madison, WI) 510 spectrometer. Merck (Darmstadt, Germany) aluminum-backed thin-layer chromatography (TLC) sheets were used for TLC, and all solvents were distilled prior to use.

Collection, extraction and isolation. Gracilariopsis lemaneiformis was collected from exposed intertidal pools at Cape Perpetua on the Oregon coast on May 17, 1988. A preserved specimen of this alga is deposited in the herbarium at the Department of Botany, University of California, Berkeley, CA. The seaweed was immediately frozen with CO_2 (solid) and stored frozen until used. The freshly defrosted alga (350 g dry wt) was homogenized in $CHCl_3$/MeOH (2:1, v/v), steeped for 30 min, and then filtered. Solvent was removed *in vacuo* to give 3.15 g of a dark green oil.

The organic extract was acetylated overnight at room temperature with excess acetic anhydride in pyridine (1:1, v/v). The excess reagents were removed *in vacuo* to yield *ca.* 3.5 g of a residue. This was fractionated by vacuum silica gel chromatography using a gradient of EtOAc in isooctane. The materials eluting with EtOAc/isooctane (1:1, v/v) were further purified by normal phase high-performance liquid chromatography (HPLC) [Alltech RSIL 10μ, 50 cm × 10 mm, EtOAc/isooctane (1:1, v/v)] and reverse phase HPLC [Lichrosorb RP-18 7μ, 25 cm × 10 mm, MeOH/H_2O (9:1, v/v)] to give 5.5 mg of compound 2.

Compound 2. A colorless oil, $[\alpha]_D^{23}$ + 52.3° (c = 0.81, MeOH); ultraviolet (UV) (MeOH) λ_{max} = 306 nm (ε = 4.9 × 10^4); infrared (IR) (neat) 3024.5, 3021.7, 2924.2, 2853.2, 1746.1, 1678.5, 1370.2, 1222.8, 1158.2, 1059.7, 1021.7, 665.0 cm^{-1}; FAB MS (positive ion) *m/z* (rel. intensity) 1196 (M^+, 0.5), 1137 (M^+−AcO, 4.6), 931 (6.7), 619 (4.6), 561 (2.7), 501 (2.0), 411 (1.2), 331 (100), 289 (8.6), 229 (8.6); High resolution fast atom bombardment mass spectrometry (FAB MS) (positive ion) obs. 1196.56050 ($C_{59}H_{88}O_{25}$, 0.92 mmu dev.); ^1H NMR (benzene-d_6, 400 MHz) δ 9.40 (1H, *d*,*J* = 7.8 Hz), 6.48 (1H, *ddd*,*J* = 3.5, 11.3, 14.8 Hz), 6.19 (1H, *m*), 6.13 (1H, *m*), 6.02 (1H, *dd*,*J* = 7.9, 15.4 Hz), 5.8 (3H, *m*), 5.7 (3H, *m*), 5.5 (2H, *m*), 5.4 (1H, *m*), 5.2 (2H, *m*), 4.57 (1H, *dd*,*J* = 2.6, 12.2 Hz), 4.4 (3H, *m*), 4.3 (2H, *m*), 4.1 (1H, *m*), 3.83 (1H, *dd*, 1H, *J* = 6.5, 10.1 Hz), 3.70 (1H, *dd*,*J* = 5.8, 10.8 Hz), 3.40 (1H, *t*,*J* = 5.9 Hz), 3.24 (1H, *dd*,*J* = 5.3, 10.2 Hz), 2.40 (1H, *m*), 2.32 (1H, *m*), 2.21 (2H, *t*,*J* = 6.9 Hz), 2.01 (3H, *s*), 1.97 (3H, *s*), 1.83 (3H, *s*), 1.81 (3H, *s*), 1.80 (3H, *s*), 1.77 (3H, *s*), 1.7 (4H, *m*), 1.67 (3H, *s*), 1.62 (3H, *s*), 1.3-1.5 (26H, *m*), 0.97 (3H, *t*,*J* = 6.9 Hz); for ^1H and ^{13}C NMR data in $CDCl_3$ see Table 1.

Acid hydrolysis of compound 2. Compound 2 (7 mg, partially obtained from a subsequent recollection of the alga) was dissolved in 2 mL of MeOH and 1 mL of 6% H_2SO_4 and refluxed for 3 hr. The mixture was diluted with 2 mL of H_2O, MeOH was removed *in vacuo*, and the residue was extracted with CH_2Cl_2 (3 × 1 mL). The extract was treated with CH_2N_2 in diethyl ether (30 min, RT) and then separated by preparative TLC (EtOAc/hexane, 1:1, v/v) to give compound 3 as a colorless oil (0.8 mg, 55% yield); UV (MeOH) λ_{max} = 310 nm (ε = 2.1 × 10^4); ^1H NMR ($CDCl_3$) δ 9.58 (1H, *d*, 8.0 Hz), 7.14 (1H, *dd*, 15.3, 11.1 Hz), 6.68 (1H, *dd*, 14.8, 10.8 Hz), 6.45 (1H, *dd*, 14.9, 11.1 Hz), 6.34 (1H, *dd*, 15.3, 10.8 Hz), 6.18 (1H, *dd*, 15.3, 8.1 Hz), 5.84 (1H, *dd*, 15.8, 8.1 Hz), 3.67 (3H, *s*), 3.65 (1H, *m*), 3.29 (3H, *s*), 2.34 (2H, *t*, 7.1 Hz), 1.55-1.75 (4H, *m*); electron impact mass spectra (EI MS) (rel. intensity) obs M^+ *m/z* 252 (40.7), 184 (9.5), 151 (32.8), 145 (10.1), 129 (16.7), 110 (16.6), 105 (13.3), 91 (68.4), 85 (19.5). The aqueous solution after CH_2Cl_2 extraction was neutralized with $Ba(OH)_2$. Precipitated $BaSO_4$ was removed by centrifugation, and the H_2O was concentrated *in vacuo* to a

[c] Not assigned.

volume of 1 mL. The solution showed a positive optical rotation (+ 0.055, c = 0.69, 33% sugar yield). Paper chromatography (H_2O/butanol/HOAc, 5:4:1, v/v/v) of the residue gave a band which matched a galactose standard after being made visible with aniline phthalate (5).

RESULTS AND DISCUSSION

The lipid extract of an early summer collection of the temperate alga *Gracilariopsis lemaneiformis* was acetylated to improve the stability and chromatographic characteristics of its polar metabolites. Vacuum silica gel chromatography yielded a fraction which contained a yellow acid-charring compound even more polar than previously reported galactolipids from this alga (4). Further purification of this fraction by HPLC yielded pure compound 2 as *ca.* 0.2% of the extract (Fig. 1).

3

FIG. 1. Formulae.

Compound 2, $[\alpha]_D^{23}$ + 52.3° (c = 0.81, MeOH), gave a strong UV absorption at 306 nm. A molecular formula of $C_{59}H_{88}O_{25}$ was generated by positive ion HR FAB MS, and therefore, compound 2 possessed 16 degrees of unsaturation. Eight of these could be easily assigned to 8 acetate carbonyl functionalities which were readily observed by ^{1}H NMR and ^{13}C NMR analysis. Seven of these eight acetates were localized to an acetylated digalactosyl substituent (see Table 1), which accounted for an additional two degrees of unsaturation.

The digalactosyldiacylglycerol (DGDAG) nature of compound 2, including the sugar linkages and relative stereochemistry, was revealed by comparison of ^{1}H NMR and ^{13}C NMR data with those of previously identified galactolipids from *G. lemaneiformis* (4). Further, in similarity to MS data obtained for other DGDAG (4), the positive ion FAB MS of compound 2 showed key fragment ions at *m/z* 931 (loss of *sn*-1 substituent, $C_{14}H_{17}O_5$) and *m/z* 941 (loss of *sn*-2 substituent, $C_{16}H_{31}O_2$) which indicated that palmitic acid was one of the acyl substituents. The possibility that this was present as an *iso* or *anteiso* acid was ruled out by observation of a single high field methyl group in the ^{1}H NMR spectrum of 2.

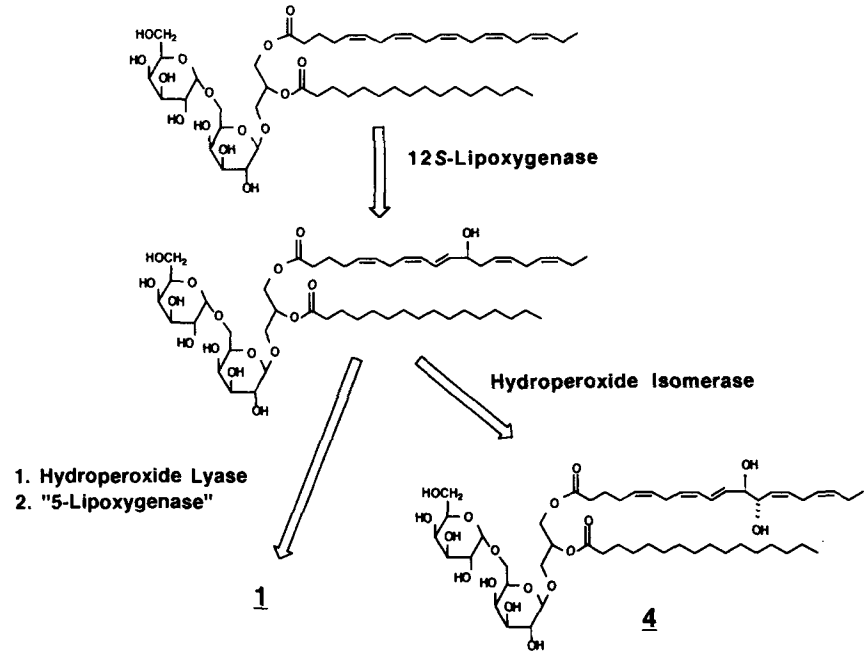

FIG. 2. Proposed biogenesis of *Gracilariopsis lemaneiformis* metabolites 1 and 4 (4) showing the intermediacy of a 12-hydroperoxide species.

Further, the ^{1}H NMR spectrum of compound 2 showed that the second acyl substituent contained an aldehyde at δ 9.57 which was connected to an all *trans* triene by ^{1}H-^{1}H COSY and coupling constants analysis (Table 1). The last remaining secondary acetate was positioned to the carboxyl side of this conjugated trienal. However, due to overlap in the high field region of the ^{1}H NMR for 2, it was not possible to unequivocally determine the number of methylene groups between this acetoxy functionality and the carboxylic ester. Hence, acid hydrolysis of compound 2 was carried out to give, following extraction, methylation and purification, this unusual acyl substituent as a pure compound (3). The EI MS of the derivatized fragment gave a molecular ion at *m/z* 252 indicating a formula of $C_{14}H_{20}O_4$. A methoxyl group could now be placed adjacent to the triene functionality based on ^{1}H NMR analysis, a fact confirmed by a major fragment ion at *m/z* 151 resulting from cleavage of the C(4)-C(5) bond. Apparently, the acetate ester was also removed by acid hydrolysis, and the resulting allylic alcohol was sufficiently activated to be methylated with CH_2N_2. In this isolated fragment, methylene groups at C(2), C(3) and C(4) could be confidently assigned, and hence, defined 3 as methyl 5-methoxy-12-oxo-dodeca-6(E),8(E),10(E)-trienoate.

In the ^{1}H NMR spectrum of compound 2 in benzene-d_6, the *sn*-2 C(2)″ protons of the palmitoyl group appeared as a second order ABX_2 pattern. This is likely the result of sterically hindered rotation of the *sn*-2 acyl chain, as previously seen in related galactolipids (4). Further, the aqueous fraction resulting from acid hydrolysis of compound 2 contained only galactose as judged by TLC and showed a positive optical rotation which indicated their D-configurations. Assembly of the above components yielded the natural product structure as 1-*O*-[5-hydroxy-12-oxo-dodeca-6(E),8(E),10(E)-trienoyl]-2-*O*-palmitoyl-3-*O*-[-β-D-galactopyranosyl-6,1-α-D-galactopyranosyl]-glycerol (1).

The acyl substituent at *sn*-1 in metabolite 1 is interesting because oxidized acyl substituents are extremely rare in galactolipids and because the positions of oxygenation and unsaturation in the chain suggest a unique biogenesis. Specifically, the aldehyde at *sn*-1 C(12)′ is likely generated by action of hydroperoxide lyase (6,7)[1] on a 12-lipoxygenase introduced hydroperoxide (8,9) in a 20 carbon polyunsaturated fatty acid substituent (either arachidonoyl or eicosapentaenoyl (4)). Oxidation at C(5)′ may be arising through separate action of an unknown 5-lipoxygenase (Fig. 2). It is interesting to note, in analogy to the biosynthesis which we have recently shown for free 12*R*,13*S*-dihydroxy-5*Z*,8*Z*,11*E*,14*Z*-eicosatetraenoic acid in this same alga (9), that the previously reported *G. lemaneiformis* DGDAG (*e.g.* 4) which contain the ω3 analog of this unusual acyl substituent (4) as a component, likely also arise through a 12-hydroperoxide intermediate. Consequently, this hypothesis predicts that natural products 1 and 4 could both be metabolites of a common intermediate (Fig. 1).

[1]The hydroperoxide lyase product 12-oxo-5*Z*,8*Z*,10*E*-dodecatrienoic acid was recently characterized as a product of arachidonic acid added to a cell free preparation of *G. lemaneiformis* (10). Further, the 100,000 × *g* supernatant from fresh tissue homogenates of *G. lemaneiformis* metabolizes, in a time-dependent manner, exogenous arachidonic acid to materials which absorb in the ultraviolet (UV) at λ_{max} = 237 (conjugated diene, major absorbance) and λ_{max} = 282 (conjugated dienal, minor absorbance) (Wise, M., and Gerwick, W.H., unpublished data). The latter provides further evidence for the occurrence of hydroperoxide lyase in this alga.

Platelet-Activating Factor (PAF): An Introduction[1]

Shoshichi Nojima
Faculty of Pharmaceutical Sciences, Teikyo University, Kanagawa, Japan

Acidic lipid mediators, such as prostaglandins and leukotrienes, play important physiological roles and are generally regarded as autacoids or local hormones. One of the most potent autacoids, platelet-activating factor (PAF), belongs to a more recently discovered class of mediators with a broad range of biological activities. Research by three independent groups led to the discovery of PAF as the first example of a complex phospholipid, a minute amount of which exhibits potent bioactions. Earlier studies on ether-linked glycerophospholipids provided the basis for establishing the chemical structure of PAF as a 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine. Two significant biological activities, platelet activation and hypotensive activity, of this unique lipid factor were independently discovered and further defined by the groups of prominent scientists who opened up this interesting research field.

In 1922, the first structural determination of an ether-linked lipid was made by Tsujimoto and Toyama (1), who isolated three types of alkyl glycerol ethers from the unsaponifiable lipids of liver oil of ray, shark and rat fish. The first ether-linked glycerophospholipids were isolated in 1958 by Carter and his associates (2), who identified 1-*O*-octadecylglycerophosphoethanolamine derived from egg yolk phosphatides.

It is now known that significant amounts of alkylacylglycerophosphocholine, a precursor of PAF, occur in a variety of animal tissues, cells and microorganisms, including various blood cells such as macrophages, platelets and neutrophils. In 1972, Benveniste, Henson and Cochrane (3) reported the leukocyte-dependent aggregation of rabbit platelets. When leukocytes were prepared from IgE-sensitized rabbits and treated with the specific antigen, platelets were strongly aggregated. The investigators reasoned that, upon stimulation, IgE-sensitized basophils degranulated and released a soluble factor that caused the platelet aggregation. Benveniste *et al.* (3) called this soluble factor platelet-activating factor and suggested a possible role of PAF in acute allergic reactions.

In 1979, Demopoulos, Pinckard and Hanahan (14) found that a synthetic glycerophospholipid, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (AAGPC) had the same physicochemical and biological properties as native PAF. AAGPC elicited the secretion of serotonin from rabbit platelets. They also showed that both AAGPC and PAF were converted to inactive forms through base-catalyzed methanolysis and restored to functional forms by reacetylation. In 1980, Hanahan and his group (5) purified native PAF from activated basophils and characterized it extensively. The authors concluded that naturally occurring PAF is indeed AAGPC.

Long before the discovery of "PAF" through the cultivation of activated basophils, Muirhead, Jones and Stirman (6) found in 1960 that two lipid fractions of renomedullary tissue with different polarity exerted a hypotensive effect. Since these fractions protected animals from the development of experimental hypertension, they were called antihypertensive polar renomedullary lipid (APRL) and antihypertensive neutral renomedullary lipid (ANRL). In 1979, Blank, Snyder, Byers, Brooks and Muirhead (7) reported that the structure of APRL is 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine. They showed that semisynthetic PAF exhibited potent antihypertensive action in experimentally hypertensive rats with the same effectiveness as did natural APRL.

PAF is a very potent autacoid; the ED_{50} value for guinea pig platelet activation is about 3×10^{-10} M. An intravenous injection into rat of about 60 ng/body PAF causes severe hypotension. In addition to activation of platelets and induction of hypotension, PAF has a wide spectrum of biological activities. PAF induces contraction of smooth muscle cells, cardiac effects and increase of vascular permeability. It also activates neutrophils, and induces monocyte aggregation, eosinophil chemotaxis, macrophage activation, an increase in liver glycogenolysis, and many other effects. It is now widely accepted that PAF-sensitive cells and tissues are activated upon binding of PAF to a specific binding site, which is probably a PAF receptor present on the cell surface.

PAF is generated, upon appropriate stimulation, by basophils, monocytes-macrophages, neutrophils, platelets and endothelial cells. Several organs, including lung and kidney, have been shown to produce PAF. So far, the assay of the amount of PAF present in biological materials has been done by bioassay or gas chromatography-mass spectrometry. A new radioimmunoassay method recently has been developed, enabling us to quantify the amount of PAF in a more reliable and sensitive manner than before.

The precursor of PAF, alkylacylglycerophosphocholine, is stored in the cell membrane and, upon stimulation of the cell, is immediately utilized to generate PAF. So far two routes of PAF biosynthesis have been demonstrated. In the "remodelling pathway", lysoPAF is formed by deacylation of alkylacylglycerophosphocholine. Subsequent acetylation of lysoPAF is catalyzed by a PAF acetyltransferase, which is assumed to be activated by stimulus-coupled phosphorylation. In the "*de novo* pathway", alkylacetylglycerol serves as a substrate for a cholinephosphotransferase. Degradation and inactivation of PAF is mainly catalyzed by PAF acetylhydrolase (known to be present in both plasma and various tissues) to yield lysoPAF. In target cells, lysoPAF is often converted further to alkylacylglycerophosphocholine by an arachidonoyl-specific transferase. It has therefore been argued that the synthesis and degradation of PAF is coupled with arachidonic acid metabolism.

Although the precise role of PAF *in vivo* is still not fully understood, PAF has been implicated in a number of pathological reactions, such as gram-negative septic shock and asthma. Several anti-PAF drugs (receptor antagonists) which are expected to be utilized as either

therapeutic or prophylactic medications against these PAF-related disorders have been developed.

Recent research on PAF bioaction has led to a better understanding of the roles of PAF in many physiological and pathological reactions. Further studies are obviously required to determine the precise *in vivo* involvement of PAF in inflammation, allergy-asthma, nephritis, reproductive processes, hypotension, neuropathology and other biological processes in which PAF is though to be involved.

Studies on the Selectivity of Enzymes Involved in Platelet-Activating Factor Formation in Stimulated Cells[1]

H. van den Bosch[a,*], A. Sturk[b], J.W. ten Cate[b] and A.J. Aarsman[a]
[a]Centre for Biomembranes and Lipid Enzymology, University of Utrecht, Padualaan 8, 3584 CH Utrecht, and [b]Department of Hematology, Division of Hemostasis and Thrombosis, Academic Medical Centre, 1105 AZ Amsterdam, The Netherlands

The present studies were undertaken to obtain further insight into the selectivities of the enzymes, i.e., phospholipase A_2 and acetyltransferase, involved in platelet-activating factor (PAF) production upon stimulation of human polymorphonuclear leukocytes (PMN) and platelets. After appropriate stimulation of the cells in the presence of [^{3}H]acetate the total PAF and analogs, i.e., 1-alkyl-2-acetyl-, 1-alkenyl-2-acetyl-, and 1-acyl-2-acetyl-glycero-3-phosphocholine were isolated by high performance liquid chromatography. The isolated mixture was subjected to treatment with phospholipase A_1 to differentiate acetate incorporation into 1-ether linked and 1-ester linked species. The ratio of acetate incorporation into 1-ether linked vs 1-ester linked PAF analogs amounted to 13.8 ± 1.0 and 1.3 ± 0.1 for PMN and platelets, respectively. When compared to the ratio of 1-ether linked and 1-ester linked species in the diradylglycerophosphocholine precursors in each cell type, i.e., 1.13 for PMN and 0.22 for platelets, these data suggested a pronounced selectivity for the phospholipase A_2 and/or acetyltransferase in the process of PAF production. When the experiments were repeated with cells that had been pretreated with phenylmethanesulfonylfluoride (PMSF) to block the acetylhydrolase, the most dramatic effects were observed on acetate incorporation into 1-acyl-2-acetyl-glycero-3-phosphocholine, which increased much more than that into 1-alk(en)yl-2-acetyl-glycero-3-phosphocholine. Under these conditions, the ratio of acetate incorporation into 1-ether linked vs 1-ester linked PAF analogs became 1.4 ± 0.2 and 0.17 ± 0.02 for PMN and platelets, respectively. These values are very close to the 1-ether linked vs 1-ester linked species in the diradylglycerophosphocholine precursors for PAF in the respective cell type. These data suggested that the selectivities of phospholipase A_2 and/or acetyl transferase for ether-linked species, as observed in non-PMSF treated cells, are only apparent and caused by rapid degradation of the 1-acyl analog either before or after acetylation. In line with this interpretation, we demonstrated that 1-acyl-2-acetyl-GPC can be deacylated to water-soluble acetyl-GPC and GPC by sonicated PMN and platelets and that this deacylation is completely blocked in sonicates from PMSF-pretreated cells. In addition, evidence is presented which indicates that the enzyme responsible for deacylation may be a lysophospholipase.
***Lipids 26,* 967-973 (1991).**

The synthesis of platelet-activating factor (PAF) upon appropriate stimulation of a large variety of cell types involves a deacylation of the cellular PAF precursor, i.e., 1-*O*-alkyl-2-acyl-GPC, to lysoPAF by a phospholipase A_2 and subsequent acetylation of lysoPAF to PAF by an acetyltransferase (1). Studies on the selectivity of these enzymes, both in intact cells and in cell free systems, have indicated that both are not completely discriminatory against the 1-ester linked analogs of the substrates. Using cell free systems, the Ca^{2+}-dependent cytosolic phospholipase A_2 from human neutrophils (2) and human platelets (3) appeared to use 1-acyl- and 1-alkyl-2-arachidonoyl-GPC equally well. The increased activity of this enzyme in cytosol prepared from A23187-stimulated cells suggests that this phospholipase A_2 may be involved in PAF production upon cell stimulation, but there is no further proof for this. Likewise, the membrane-bound acetyltransferase shows increased activity after cell stimulation (4-7), and the enzyme from spleen microsomes utilized both 1-alkyl- and 1-acyl-lyso-GPC, although the former at a two-fold higher rate (8,9). As suggested by the specificities of the phospholipase A_2 and the acetyltransferase, PAF synthesis in rabbit (10) and human (7) platelets and in rabbit (11,12) and human (11) neutrophils concomitantly produced the 1-acyl-2-acetyl-GPC analog to various extents.

PAF is inactivated through catabolism by acetylhydrolase. This enzyme is localized in the cytosol of cells (13), shows an increased activity upon stimulation of some cells (4) and also metabolizes both 1-alkyl- and 1-acyl-2-acetyl-GPC (13). Acetylhydrolase is inhibited by diisopropylfluorophosphate (13) and phenylmethanesulfonylfluoride (PMSF) (14) and treatment of platelets with PMSF resulted in an increased PAF recovery upon thrombin stimulation (15). However, acetate incorporation into PAF analogs was not differentiated into incorporation into 1-alkyl-and 1-acyl-2-acetyl-GPC. In attempts to increase PAF recovery from stimulated human PMN and platelets by pretreatment of the cells with PMSF, we noticed to our surprise that acetate incorporation in 1-acyl-2-acetyl-GPC increased much more dramatically than that in PAF. This observation led to a careful analysis of the relative amounts of 1-alk(en)yl-2-acetyl-GPC and 1-acyl-2-acetyl-GPC in non-PMSF-treated and PMSF-treated cells. The results easily can be interpreted by assuming that under cellular conditions neither the phospholipase A_2 nor the acetyltransferase involved in PAF production shows much selectivity for 1-ether linked *vs* 1-ester linked substrates, and that the 1-ester linked species in control cells, but not in PMSF-treated cells, are rapidly

degraded by PMSF-sensitive deacylases. This hypothesis will be further elaborated upon in the Results and Discussion section.

EXPERIMENTAL

The source of chemicals and the detailed experimental procedures have been described elsewhere (16), and only a brief description will be given here.

Cell isolation. Gelfiltered platelets and PMN-enriched leukocytes were isolated from acid-citrate-dextrose anticoagulated human blood, as described previously (17).

PMSF-treatment and cell stimulation. Platelets ($1-3 \times 10^8$ cells/mL) and leukocytes ($2-3 \times 10^7$ cells/mL) were incubated 15 min at 37°C with 2 mM PMSF (15) added from a 2 M stock solution in dimethylsulfoxide. Control cells only received the solvent. Excess PMSF was removed by centrifugation and washing of the cells. Leukocytes (0.4×10^7 cells) and platelets (6×10^8 cells) were stimulated at 37°C with 10 μM A23187 and 2.5 U/mL bovine thrombin, respectively. Just prior to stimulation, 10 μCi/mL of [^{3}H]acetate (sodium salt, spec. activity 3.4 Ci/mmol) was added.

Isolation and characterization of PAF and analogs. Cell stimulation was stopped by addition of chloroform and methanol, and lipids were extracted according to Bligh and Dyer (18). The chloroform layer was dried, and lipids were dissolved in hexane/isopropanol (50:50, v/v) for HPLC separation essentially as described by Blank and Snyder (19). Fractions were dried, the residues dissolved in 0.2 mL ethanol and aliquots were used for radioactivity determination, biological measurement of PAF activity using a rabbit platelet aggregation assay (17) and for phospholipase A_1 treatment to differentiate between acetate incorporation into ether-linked and ester-linked PAF and analogs. The overall recovery of the PAF isolation procedure was 65% (range 58–68%, n = 8) as determined from simultaneously tested samples receiving [^{3}H]PAF at the time of lipid extraction of cells stimulated in the absence of [^{3}H]acetate, and values were corrected for this recovery. PAF was characterized as previously described (17).

Differentiation of [^{3}H]acetate incorporation into 1-alk(en)yl-2-acetyl-GPC and 1-acyl-2-acetyl-GPC was done by treatment of the total PAF analog mixture as isolated from the HPLC column with *Rhizopus arrhizus* lipase with phospholipase A_1 activity as described (16,20). The percentage [^{3}H]acetate incorporation into analogs was established by Bligh and Dyer extraction (18) and measurement of the radioactivity in the chloroform layer (1-alk(en)yl-2-acetyl-GPC) and the methanol/water layer (1-hydroxyl-2-acetyl-GPC derived from 1-acyl-2-acetyl-GPC). Control experiments with 1-acyl-2-acetyl-GP[^{14}C]C indicated nearly quantitative (mean 97%, range 96.5–97.5%, n = 4) conversion of the 1-acyl-2-acetyl-GPC. By contrast, 1-[^{3}H]alkyl-2-acetyl-GPC was completely resistant to phospholipase A_1 treatment since little lysoPAF (mean 2.3%, range 1.2–3.0%, n = 4) was formed by this procedure, indicating that the phospholipase A_1 was not contaminated by phospholipase A_2.

Preparation and metabolism of 1-acyl-2-acetyl-GP[^{14}C]C. The title compound was prepared by phospholipase A_2 degradation of dipalmitoyl-GP[^{14}C]C and subsequent reacetylation of the isolated lyso-compound by established procedures (21). The purified compound was mixed with 1-[^{3}H]alkyl-2-acetyl-GPC and incubated with cell sonicates prepared from control and PMSF-treated leukocytes and gelfiltered platelets.

RESULTS AND DISCUSSION

Figure 1 shows a time course of PAF production in control PMN after stimulation with Ca^{2+}-ionophore, measured as biological activity and *via* [^{3}H]acetate incorporation. As can be seen, acetate incorporation into the total mixture of PAF and analogs is essen-

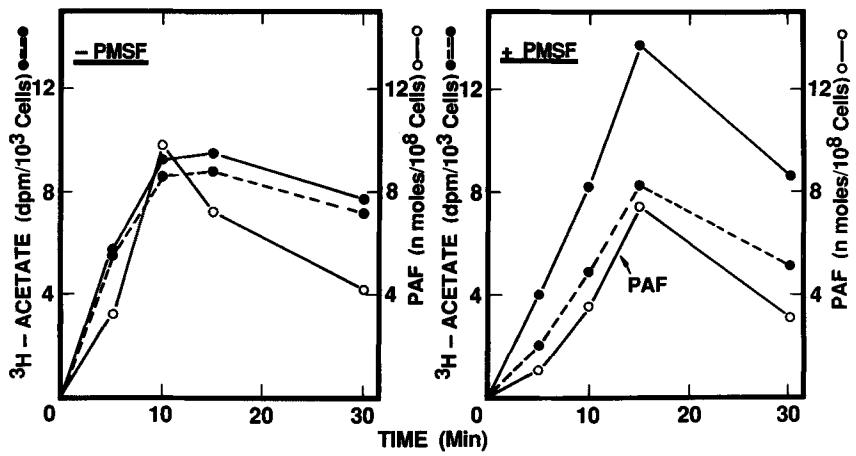

FIG. 1. PAF production in A23187-stimulated PMN. PAF production was measured as biological activity (open symbols) and via [^{3}H]acetate incorporation (closed symbols). In the latter case, the solid line represents incorporation into total PAF and analogs, i.e., 1-alk(en)yl- plus 1-acyl-2-acetyl-GPC, whereas the dashed line indicates incorporation into 1-alk(en)yl-2-acetyl-GPC remaining after phospholipase A_1 treatment of the total mixture.

tially confined to the 1-ether linked species (closed symbols, dashed line). Acetate incorporation into total analogs, including 1-acyl-2-acetyl-GPC, is only slightly higher. These data suggest that the total process of PAF production in stimulated PMN is somehow specific for ether linked species.

The experiments were repeated with PMSF-pretreated cells to block the acetylhydrolase to increase the yield of PAF. Surprisingly, PAF production, both when measured as biological activity and via acetate incorporation into 1-alk(en)yl-2-acetyl-GPC, did not increase as compared to the non-PMSF treated controls. Rather, what increased was the total [^{3}H]acetate incorporation due to an extra incorporation in the 1-acyl-2-acetyl-GPC. The latter became labeled to extents approaching those observed for 1-alk(en)yl-2-acetyl-GPC (Fig. 1, right panel).

The above phenomenon was even more pronounced in human platelets (Fig. 2). Upon stimulation with thrombin, very little PAF is produced in control cells and no attempts were made in this experiment to differentiate acetate incorporation into ether linked and ester linked species of PAF and analogs. Notably, PMSF-treatment resulted in dramatically increased total [^{3}H]acetate incorporation. Some of this additional incorporation was PAF, presumably due to inhibition of acetylhydrolase by PMSF, but the vast majority appeared to be present in the acyl analog of PAF as indicated by the large difference between the solid and the dashed line through the closed symbols (Fig. 2, right panel).

We considered it unlikely that PMSF would stimulate a biosynthetic reaction, i.e., acetate incorporation into 1-acyl-2-acetyl-GPC. First, it did not stimulate acetate incorporation into 1-alkyl-2-acetyl-GPC in PMN (Fig. 1), but only into 1-acyl-2-acetyl-GPC. Second, PMSF reacts with serine residues in the active site of enzymes, and by doing so acts as an inhibitor rather than as a stimulator of enzymes. To reconcile the accumulation of 1-acyl-2-acetyl-GPC in PMSF-treated cells with this general mode of action of PMSF, we hypothesized that it would prevent a normally occurring breakdown of this 1-acyl-2-acetyl-GPC. A further suggestion for this hypothesis was obtained when we realized that the relatively much higher accumulation of the 1-acyl analog, as compared to the 1-alkyl analog, in platelets likely reflected the fact that platelet diradylglycerophosphocholine (diradylGPC) consists for a much larger proportion of diacyl species than PMN diradylGPC. Thus, if this hypothesis were correct, the [^{3}H]acetate incorporation data may have an important message on the specificities of the enzymes involved in PAF synthesis as summarized in Figure 3. The ratio of 1-ether linked and 1-ester linked species in total PMN diradylGPC amounts to 1.13. This ether/ester ratio in the total PAF analogs accumulating after stimulation of the cells became 13.8, suggesting at least a ten-fold preference for either phospholipase A_2 or acetyltransferase for ether linked species. However, in cells pretreated with PMSF this ratio became 1.4, a value very close to that of the diradylGPC precursor for PAF and PAF analog synthesis. Similarly, the ratio of 1-ether linked and 1-ester linked PAF and analogs in PMSF-treated platelets showed a value of 0.17, i.e., much lower than the ratio of 1.4 in PMN, but very close to the ratio of 0.22 in the total platelet diradylGPC. Again, the ether/ester ratio of 1.3 in PAF and analogs accumulating in non-PMSF-treated platelets was much higher, suggesting a six-fold preference for ether linked species in PAF production in platelets. However, we interpret the data given in Figure 3 as indicating that neither the phospholipase A_2 nor the acetyltransferase under cellular conditions exhibits much specificity for ether linked species. LysoPAF and 1-acyl-glycerophosphocholine are apparently formed in a ratio that is close to that in the precursor diradylGPC of each cell type, whereafter the acyl analog is rapidly degraded, either before or after the acetylation step, to give the suggestion of selectivity for ether linked species. This normally occurring degradation of the acyl analogs (in non-PMSF-treated cells) is prevented by PMSF treatment and, due to the lack of selectivity of phospholipase A_2 and acetyltransferase, the ether/ester ratio in PAF analogs approaches that in the precursor diradylGPC of the respective cells.

To investigate whether the cells contain enzymes capable of specifically degrading 1-acyl-2-acetyl-GPC,

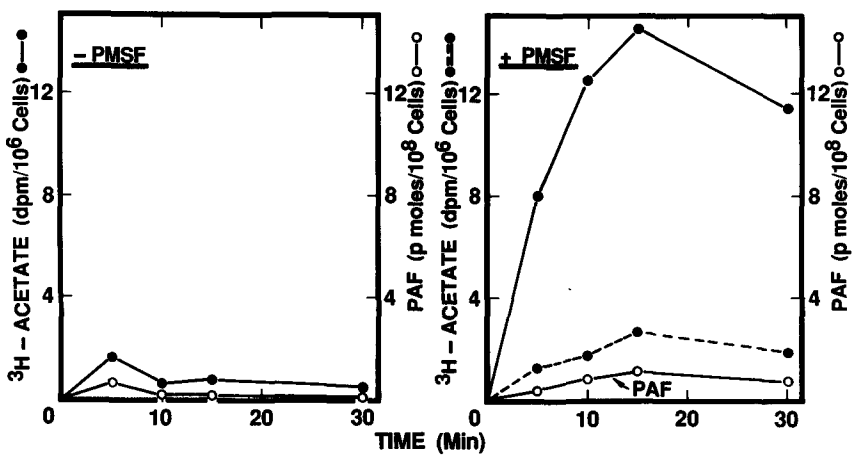

FIG. 2. PAF production in thrombin-stimulated platelets. Symbols as in Figure 1.

experiments were done with sonicates prepared from control and PMSF-pretreated PMN and platelets. These cell-free systems were incubated with a mixture of 1-[^{3}H]alkyl-2-acetyl-GPC and 1-acyl-2-acetyl-GP[^{14}C]C for different time periods as indicated in Figure 4. The incubations were stopped by a Bligh and Dyer lipid extraction and radioactivity in the chloroform and methanol/water layers were analyzed. As can be seen in Figure 4, the [^{14}C]choline-labeled acyl analog is time-dependently converted into a water-soluble component, both by PMN and platelet sonicates, and this process is completely blocked in sonicates from PMSF-pretreated cells. Two types of experiments were done to obtain further insight into the pathway for the degradation of 1-acyl-2-acetyl-GPC. First, the chloroform layers of the incubations as described in Figure 4 were analyzed by HPLC. As can be seen in Figure 5, both the ^{3}H- and the ^{14}C-radioactivity gave a single coinciding peak. The ^{3}H/^{14}C-ratio in this peak from 60 min incubations performed with sonicates from PMSF-treated PMN (Fig. 5, right panel) was identical to that in zero-time controls (Fig. 5, left panel). However, the peak of PAF and lysoPAF analogs, which were not resolved in this experiment, obtained from 60 min in-

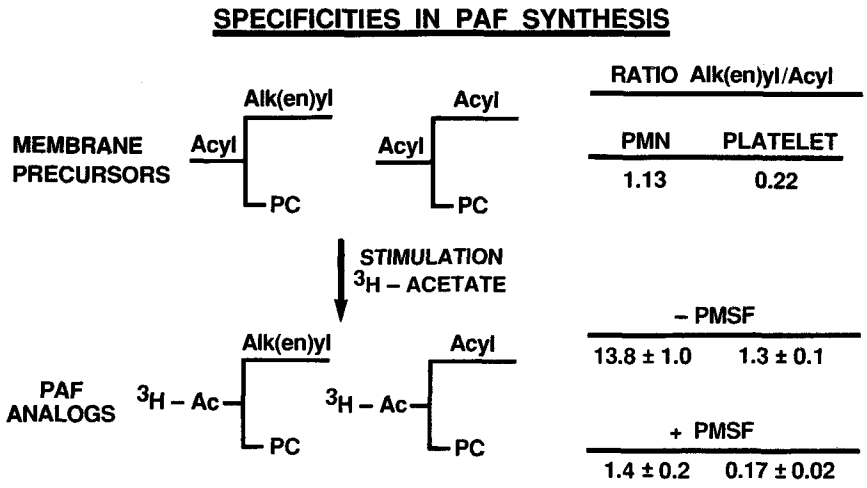

FIG. 3. Enzyme specificities in PAF synthesis. The ratio of 1-ether linked (alk(en)yl) to 1-ester linked (acyl) species in PMN and platelet diradylGPC precursors for PAF and PAF analog synthesis was calculated from the compositional data given in references 22 and 23, respectively. The ratio in total PAF and analogs accumulating in control (-PMSF) and PMSF-treated cells was determined (n=5) as described under Experimental.

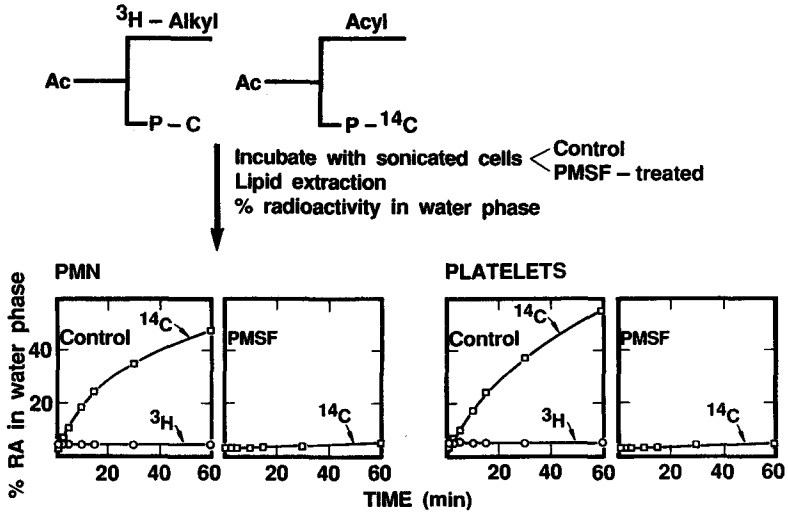

FIG. 4. PMSF prevents degradation of 1-acyl-2-acetyl-GPC. Cell sonicates were incubated with trace amounts of 1-[^{3}H]alkyl-2-acetyl-GPC (0.03 pmoles) and 1-acyl-2-acetyl-GP[^{14}C]C (25 pmoles), each containing 3000 dpm of radioactivity and representing less than 0.1% of the endogenous substrates. After incubation for the indicated time periods the reactions were stopped by lipid extraction and aliquots of the chloroform (Fig. 5) and methanol/water layer were analyzed for radioactivity.

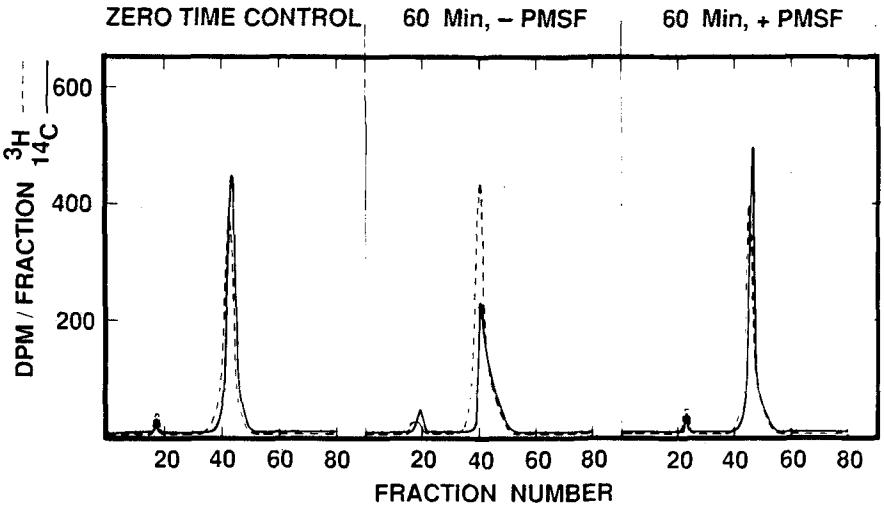

FIG. 5. HPLC of lipid extracts. The chloroform layer of incubations as described in the legend of Figure 4 was subjected to HPLC analysis as described under Experimental. Left: zero-time control; Middle: 60 min incubation with sonicate from non-PMSF-treated PMN; Right: 60 min incubation with sonicate from PMSF-treated PMN.

cubations performed with non-PMSF-treated PMN (Fig. 5, middle panel) had lost a considerable amount of the ^{14}C-label in full agreement with the appearance of about 50% of the ^{14}C-label in the methanol/H_2O layer (Fig. 4). Very similar patterns were observed for the chloroform layers obtained from incubations with platelet sonicates (data not shown). Most importantly, the fact that single ^{3}H-radioactivity peaks are observed indicates that 1-[^{3}H]alkyl-2-acetyl-GPC is not degraded by phospholipase C or D-type enzymes under the conditions of the experiments. This also suggests that the 1-acyl-2-acetyl-GP[^{14}C]C is not metabolized by such enzymes and that the appearance of water-soluble ^{14}C-radioactivity (Fig. 4) is not due to [^{14}C]phosphocholine or [^{14}C]choline formation. This was confirmed in the second type of experiment to identify the pathway of 1-acyl-2-acetyl-GPC degradation, i.e., identification of the water-soluble degradation product. The results (Table 1) clearly indicate the formation of GPC, along with a component that was tentatively identified as acetyl-GPC (*vide infra*). Collectively, the results demonstrate that control PMN and platelets contain enzyme(s) capable of deacylating the acyl analog of PAF, and this process is blocked in PMSF-treated cells. These findings provide additional support for the notion that the selectivity of phospholipase A_2 and acetyltransferase for ether linked species in PAF production is only apparent and explainable by degradation of the simultaneously produced acyl analogs, either 1-acyl-2-lyso-GPC or 1-acyl-2-acetyl-GPC. Of course, any other biochemical pathway that selectively removes the 1-acyl-2-lyso-GPC prior to acetylation could also contribute to the apparent specificity for ether linked species in PAF production. In this respect, it is interesting to note that the acyl-CoA-dependent acylation of 1-radyl-2-lyso-GPC generally proceeds several-fold faster with the 1-acyl analog than with the 1-ether linked derivatives (24–26). Thus, the selective reacylation of the acyl analog after phospholipase A_2-catalyzed formation of the lyso intermediates could leave a mixture of 1-radyl-2-lyso-GPC that is enriched in 1-alkyl-2-lyso-GPC for subsequent reacetylation. Although this mechanism could contribute to the selective accumulation of 1-alkyl-2-acetyl-GPC in non-PMSF-treated cells, it is more difficult to reconcile with the loss of this selectivity in PMSF-treated cells, unless PMSF inhibited completely the acyl-CoA:1-acyl-2-lyso-GPC acyltransferase. This possibility is less likely, based on experimental evidence indicating that this biosynthetic enzyme from the liver of various species is not inhibited by diisopropylfluorophosphate (27).

By contrast, it is demonstrated in this paper (Fig. 4) that the enzyme that deacylates 1-acyl-2-acetyl-GPC is completely blocked in PMSF-treated cells. In attempts to further identify the responsible enzyme,

TABLE 1

Identification of Water-soluble Product Formed from 1-Acyl-2-Acetyl-GP[^{14}C]C

Compound	Rf values[a]	
	System I	System II
Choline	0.57	0.79
Glycerophosphocholine	0.66	0.19
Phosphocholine	0.38	0.44
PMN product	0.64	0.20; 0.32[b]
Platelet product	0.65	0.21; 0.34[b]

[a]The water-soluble product formed in incubations with sonicates from non-PMSF-treated cells was identified by cellulose thin-layer chromatography along with reference compounds as indicated. Identical results were obtained in two separate experiments. Solvent system I: ethanol/ammonia/water (6:3:1, v/v/v). Solvent system II: t-butanol/picric acid/water (20:1:5, v/w/v).

[b]Tentatively identified as acetyl-GPC. Mild alkaline hydrolysis of this compound quantitatively converted it into glycerophosphocholine.

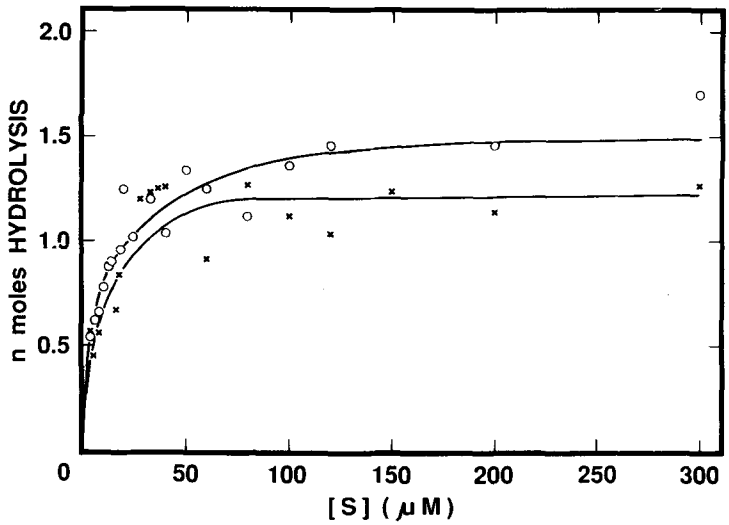

FIG. 6. Deacylation of 1-acyl-2-acetyl-GPC by lysophospholipase. The indicated concentrations of 1-palmitoyl-2-lyso-GP[^{14}C]C (o) and 1-palmitoyl-2-acetyl-GP[^{14}C]C (x) (spec. radioact. 5200 dpm/nmol) were incubated for 10 min at 37°C with 0.3 μg bovine liver lysophospholipase II in 0.5 mL of 20 mM potassium phosphate buffer (pH 7.5). Lysophospholipase II was purified as described (32). Hydrolysis of the 1-ester bond was calculated from the appearance of water-soluble radioactivity after lipid extraction and was corrected for blanks without enzyme.

we considered the possibility that it might be a lysophospholipase. These enzymes are not very specific (28) and do not require a free hydroxyl-function at the *sn*-2-position as evidenced by the fact that 1-palmitoylpropane-3-phosphocholine was hydrolyzed at a rate comparable to that of 1-palmitoyl-2-hydroxy-GPC (29). In addition, these enzymes are known to be inhibited by the serine-blocker diisopropylfluorophosphate (30,31). Therefore, we investigated whether 1-acyl-2-acetyl-GPC could be deacylated by a purified, homogeneous lysophospholipase from bovine liver (32). The results (Fig. 6) showed this to be the case. Indeed, 1-acyl-2-acetyl-GPC was deacylated at a rate comparable to that of 1-acyl-2-lyso-GPC. The water-soluble compound obtained from 1-acyl-2-acetyl-GP[^{14}C]C migrated on cellulose thin-layer plates developed with solvent system II (compare Table 1) with an Rf value of 0.34. Mild alkaline hydrolysis of this product yielded GPC (Rf 0.20), indicating that acetyl-GPC had been formed in the incubation with lysophospholipase (A.J. Aarsman, unpublished observations). The fact that the initially formed 1-lyso-2-acetyl-GPC has partially migrated into 1-acetyl-2-lyso-GPC cannot be excluded from the thin-layer chromatographic data.

These results and those of Table 1 imply that 1-acyl-2-acetyl-GPC was metabolized by sonicated non-PMSF-treated PMN and platelets both by direct deacylation and by deacylation of 1-acyl-2-lyso-GPC produced after removal of the 2-acetyl group by acetylhydrolase. As shown in Figure 6, both deacylations can be catalyzed by a lysophospholipase. Inhibition of this deacylation in PMSF-treated cells caused production of 1-ether linked and 1-ester linked analogs of PAF in a ratio nearly identical to that present in the cellular diradylGPC. This phenomenon disclosed the lack of selectivity for ether linked species of the phospholipase A_2 and acetyltransferase involved in PAF production under cellular conditions. This interpretation could only be developed by using a combination of PMSF-treatment and differentiating acetate incorporation into ether linked and ester linked analogs of PAF by phospholipase A_1 treatment. Previous reports have either studied the effect of PMSF without differentiating acetate incorporation in ether linked and ester linked PAF analogs (14,15), or have used this differentiation solely in non-PMSF treated cells (7,10-12). The results of these and our data are summarized in Table 2, and all indicate a four- to ten-fold selective utilization of ether linked species. However, based on evidence with PMSF-treated cells presented in this paper, we propose that

TABLE 2

Apparent Selectivity of Phospholipase A_2 and Acetyltransferase for Ether Linked Species in PAF Production in Non-PMSF-Treated Cells

Cell type	Ratio of 1-ether/1-ester linked species[a]		Ref.
	DiradylGPC	PAF analogs	
Rabbit platelet	0.15	0.7-1.3	10
Human platelet	0.22	2.3	7
	0.22	1.3	this paper
Rabbit neutrophil	0.35	3.0	11
	0.35	1.3	12
Human neutrophil	1.13	6.7	11
	1.13	13.8	this paper

[a]Comparison of 1-ether linked vs 1-ester linked species in cellular diradylGPC and accumulated PAF analogs upon stimulation of the indicated cell types. Ratios in cellular diradylGPC were calculated from published data: rabbit platelet (33), human platelet (23), rabbit neutrophil (12) and human neutrophil (22).

this selective accumulation of 1-ether linked PAF analogs is caused by a selective deacylation of the concomitantly produced 1-acyl analogs and intermediates, rather than by selective utilization of the 1-ether linked species by phospholipase A_2 and acetyltransferase. This interpretation would be in line with the observation that thrombin treatment of human platelets prelabelled with [^{14}C]stearic or [^{14}C]palmitic acid induced the formation of both radioactive lysophosphatidylcholine and free fatty acids (34). As suggested (34), the hydrolysis of the lysophosphatidylcholine by lysophospholipase also would explain why the amounts of lysophosphatidylcholine that accumulate in thrombin-treated platelets (35) are considerably lower than the amounts of arachidonate which are released. Likewise, A23187-stimulation of human neutrophils not only caused release of [^{3}H]arachidonate, but also of [^{14}C]palmitate from the diradylGPC pool of prelabelled cells (36).

Activities of enzymes which metabolize lysoplatelet-activating factor (lysoPAF) and platelet-activating factor (PAF) were studied in rabbit alveolar macrophage lysates. Substantial acetyltransferase activity was noted in the presence of 100 μM acetyl-coenzyme A (CoA), and this activity was increased in A23187-stimulated cell lysate. On the other hand, in the absence of exogenous acetyl-CoA, lysoPAF was mainly acylated through a transacylation pathway rather than by acetyltransferase in both control and A23187-stimulated cell lysates. We confirmed that the intracellular concentration of acetyl-CoA is relatively low. The observations suggest that the transacylation system may play an equally important role in the regulation of the availability of lysoPAF in intact cells. Intracellular lysoPAF was also maintained at relatively low levels. Interestingly, large amounts of PAF were produced even in unstimulated cells upon addition of an excess of exogenous lysoPAF, suggesting that generation of an adequate amount of lysoPAF within cells may be sufficient to trigger PAF synthesis in this type of cells.

***Lipids 26,* 974-978 (1991).**

Platelet-activating factor (PAF) (1), chemically identified as 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (2-4), is a potent lipid mediator with a variety of biological activities. For instance, PAF was shown to induce aggregation, degranulation and infiltration of blood cells, increased vascular permeability, hypotension, bronchoconstriction and bronchial hyperreactivity *in vitro* or *in vivo* (5-7), and is now assumed to be an important mediator in various inflammatory and allergic reactions such as endotoxin shock and asthma.

Various types of mammalian cells, including polymorphonuclear leukocytes and macrophages, are known to generate considerable amounts of PAF upon stimulation (5-7). The mechanism of the biosynthesis of PAF in mammalian tissues and cells has been studied by several groups in the 1980s (5-7). The remodeling of the preexisting 1-alkyl-2-acyl-*sn*-glycero-3-phosphocholine (GPC) with a long acyl chain in position 2 to alkylacetyl-GPC (PAF) by action of phospholipase A_2 and acetyl-coenzyme A (CoA):1-alkyl-GPC acetyltransferase is considered to be the most important biosynthetic pathway for PAF in inflammatory cells upon stimulation.

The properties of the acetyltransferase have been studied by several investigators (8-13). Acetyltransferase activity was shown to increase in various stimulated cells and tissues (14-24) and is considered important in controlling the biosynthesis of PAF. A unique feature of the acetyltransferase is its ability to utilize only very short-chain acyl-CoA, such as acetyl-CoA, in the acylation of lysoPAF (1-alkyl-GPC) (8,9,12). Recent studies have also provided evidence for the presence of another enzyme which acylates lysoPAF with long-chain fatty acids derived from diacylglycerophospholipids (25-28). This enzyme, a cofactor-independent transacylase, transfers C_{20} and C_{22} polyunsaturated fatty acids from donor phospholipids to lysoPAF (25-29). Both the acetylation and the transacylation pathways may be operative and may metabolize lysoPAF in certain cell types, such as inflammatory cells.

However, precise comparative data on the activities of acetyltransferase and transacylase either in unstimulated cells or in stimulated cells are lacking. In fact, little information is available concerning the effect of cellular activation on the activity of the transacylase. It therefore seemed important to investigate these points in some detail in order to gain a better understanding of the regulation of the biosynthesis of PAF, as lysoPAF is a common substrate for both acetyltransferase and transacylase and because substrate availability could affect the amount of PAF formed.

In the present study, we first examined the activities of the enzymes which metabolize lysoPAF in rabbit alveolar macrophages. Secondly, we examined the effect of substrate availability on the biosynthesis of PAF. We found that lysoPAF was mainly acylated by transacylase rather than by acetyltransferase and that a considerable amount of PAF was formed even in unstimulated cells when a sufficient amount of lysoPAF was supplemented.

MATERIALS AND METHODS

Chemicals. All chemicals were of reagent grade. Acetyl-CoA, 1-hexadecyl-GPC (lysoPAF), alkaline phosphatase *(E. coli),* acetoacetate (lithium salt) and DL-β-hydroxybutyrate (sodium salt) were obtained from Sigma (St. Louis, MO). A23187 was from Calbiochem (La Jolla, CA). Eagle's minimal essential medium was from Nissui (Tokyo, Japan). PAF (16:0) was purchased from Bachem (Bubendorf, Switzerland). Pre-coated silica gel thin-layer chromatography (TLC) plates were from Merck (Darmstadt, Germany). 1-[^{3}H]Hexadecyl-2-acetyl-GPC ([^{3}H]-PAF) (40Ci/mmol) was purchased from New England Nuclear (Boston, MA). In order to obtain [^{3}H]lysoPAF, [^{3}H]PAF was deacetylated by brief treatment with sodium methoxide. After neutralization, the resultant [^{3}H]-lysoPAF was extracted and purified by TLC before use.

Cells. Alveolar macrophages were prepared from the pulmonary lavage of normal healthy rabbits (Japan white) as described earlier (30). For measurement of endogenous

Abbreviations: BSA, bovine serum albumin; CoA, coenzyme A; GPC, *sn*-glycero-3-phosphocholine; GPE, *sn*-glycero-3-phosphoethanolamine; Hepes, *N*-2-hydroxyethyl piperazine-*N*'-2-ethane sulfonic acid; MEM, minimum essential medium; PAF, platelet-activating factor; PMN, polymorphonuclear leukocytes; TLC, thin-layer chromatography.

substrates, rabbits injected with 1 mL of Freund's complete adjuvant were used (27). Cells were suspended at 2×10^6 cells/mL in 20 mM *N*-2-hydroxyethyl piperazine-*N'*-2-ethane sulfonic acid-minimum essential medium (Hepes-MEM) (pH 7.4) and preincubated at 37°C for 10 min.

Enzyme assay. Macrophages were stimulated with A23187 (10 μM) for 2 min and subsequently cooled by adding ice-cold medium (4°C). After centrifugation at 1,200 rpm for 6 min, the supernatant was discarded and the sedimented cells were resuspended at 2×10^6 cells/mL in 20 mM Hepes-MEM. Then, the cell suspension was sonicated with a Branson Sonifier (setting 3, 20 sec, 50% pulse). The cell lysate (0.5 mL) was incubated with 20 μM 1-[^{3}H]alkyl-GPC (25,000 dpm) for 5 min in the presence (for acetyltransferase assay) or absence (for transacylase assay) of 100 μM acetyl-CoA. In an experiment where endogenous acetyl-CoA was used as the substrate, a more concentrated cell lysate (2×10^7 cells/mL) was incubated with [^{3}H]lysoPAF (70,000 dpm) for 2 min. The amount of acetyl-CoA was estimated by the method of Wieland and Weiss (31). In order to study the degradation of [^{3}H]lysoPAF and [^{3}H]PAF, the incubation was carried out for 5 min in the presence of 20 μM [^{3}H]lysoPAF (25,000 dpm) and [^{3}H]PAF (25,000 dpm), respectively, the latter of which was sonicated prior to the addition to the incubation mixture. The reactions were terminated by adding chloroform/methanol (1:2, v/v), and small amounts (10 nmol) of nonradiolabeled lysoPAF and PAF were added as carriers. After the extraction of total lipids by the method of Bligh and Dyer (32), neutral lipids, phosphatidylcholine, PAF and lysoPAF were separated from each other by TLC using chloroform/methanol/water (50:25:4, v/v/v) as developing solvent. In some experiments, lipids were separated by TLC with petroleum ether/diethyl ether/acetic acid (30:70:1, v/v/v) as solvent. Lipid spots were made visible with primuline, and the silica gel was scraped off into vials. Radioactivity was measured as described earlier (33).

PAF production. Macrophages (10^6 cells) were suspended in 0.5 mL of 20 mM Hepes-MEM and preincubated at 37°C for 10 min. Then cells were incubated in the presence or absence of A23187 (final 0.5 μM or 10 μM) or lysoPAF (final 20 μM) for a further 7.5–30 min. The incubation was terminated by adding chloroform/methanol (1:2, v/v), and total lipids were extracted by the method of Bligh and Dyer (32). Individual phospholipids were separated by TLC with chloroform/methanol/water (40:24:4, v/v/v). The area corresponding to authentic PAF was scraped off and the adsorbent extracted with chloroform/methanol/water (1:2:0.8, v/v/v). After Bligh and Dyer extraction (32), the chloroform layer was evaporated to dryness. The residue was resuspended in Hepes-buffered Tyrode's solution (pH 7.4) containing 0.25% bovine serum albumin (BSA). Amounts of PAF were estimated by measuring the aggregating activity toward washed rabbit platelets (34), using 16:0-PAF as standard. LysoPAF content was estimated by measuring lipid phosphorus of the lysolecithin fraction after treatment with HCl and NaOH.

RESULTS AND DISCUSSION

The enzymatic basis for PAF metabolism has been studied by many investigators (35). However, there apparently has not been a precise study in which individual enzyme activities in the same cells were compared. In the present study, we compared in detail the activities of the enzymes involved in PAF metabolism in alveolar macrophages. The cells are regarded as an important source of PAF in pulmonary tissue (36).

Table 1 shows the activities of various enzymes which metabolize 1-alkyl-GPC (lysoPAF) and PAF in macrophage lysate. Acetyltransferase activity was shown to be the highest, with the incubation mixture being supplemental with 100 μM acetyl-CoA. Acetyltransferase activity was increased 3.6-fold in A23187-stimulated cell lysate. This increase in enzyme activity may be due to protein phosphorylation as treatment of the microsomes from stimulated cells with alkaline phosphatase *(E. coli)* abolished the increase in enzyme activity (data not shown) as had previously been demonstrated for other cell types (19,24,37,38). On the other hand, the activities of the enzymes of lysoPAF degradation and acylation (with long-chain fatty acids), as well as of PAF degradation by acetylhydrolase were considerably lower than was acetyltransferase activity and did not increase in A23187-stimulated cell lysate, which would tend to favor PAF accumulation in stimulated cells. The product of the degradation of lysoPAF was mainly 1-alkylglycerol (data not shown), suggesting that the combined actions of lysophospholipase D and phosphatase are involved as they are in other tissues (39,40). The transacylation pathway could be responsible for the rapid acylation of lysoPAF with long-chain fatty acids, as has already been suggested by us (26,27,29) and by other groups (25,28).

The metabolic fate of lysoPAF in the absence of exogenous acetyl-CoA was shown to be, however, considerably different from the results obtained above. Table 2 shows the metabolism of lysoPAF in concentrated cell lysate in the absence of exogenous acetyl-CoA. LysoPAF was mainly metabolized through the transacylation pathway to form alkylacyl-GPC, and only a small amount of PAF was produced, though the formation of PAF increased in A23187-stimulated cell lysate.

The effects of acetyl-CoA concentration on the activities of acetyltransferase and transacylase are shown in Figure 1. The activity of acetyltransferase depends quite markedly on the concentration of acetyl-CoA, while this is not the case for transacylase. The Km values of acetyltransferase for acetyl-CoA were calculated to be

TABLE 1

Activities of Enzymes Involved in the Biosynthesis and Degradation of PAF in Alveolar Macrophage Lysate[a]

	pmol/min/10^6 cell lysate	
	Control	A23187
PAF formation (acetyltransferase)	280 ± 17	1021 ± 21
PAF degradation (acetylhydrolase)	87 ± 10	78 ± 14
LysoPAF degradation (lysophospholipase D + phosphatase)	62 ± 7	47 ± 14
LysoPAF acylation (transacylase)	86 ± 18	66 ± 10

[a]Cell lysate (10^6 cells/0.5 mL) obtained from unstimulated or A23187-stimulated macrophages was incubated in the presence of 20 μM [^{3}H]lysoPAF or [^{3}H]PAF (25,000 dpm) with (for the acetyltransferase assay) or without (for other assays) 100 μM acetyl-CoA. The data represent the means ± SD from three determinations.

TABLE 2

Metabolic Fate of [^{3}H]LysoPAF in Concentrated Macrophage Lysate[a]

Product	pmol/min/10^7 cell lysate	
	Control	A23187
PAF	5 ± 1	34 ± 5
Alkylglycerol	100 ± 6	115 ± 3
Alkylacyl-GPC	975 ± 70	805 ± 115

[a]Cell lysate (10^7 cells/0.5 mL) obtained from unstimulated or A23187-stimulated macrophages was incubated in the presence of 20 μM [^{3}H]lysoPAF (70,000 dpm) for 2 min. The data represent the means ± SD from three determinations.

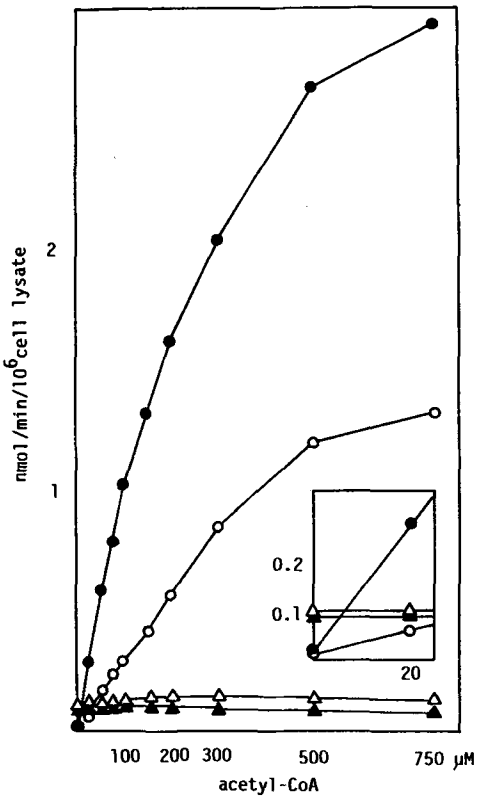

FIG. 1. Effects of the concentration of acetyl-CoA on the activities of acetyltransferase and transacylase. Macrophage lysate (10^6 cells/0.5 mL) was incubated with various concentrations of acetyl-CoA in the presence of 20 μM [^{3}H]lyso-PAF (25,000 dpm) for 5 min. After the extraction of total lipids, individual phospholipids were separated by TLC and radioactivities were estimated as described in the text. The data represent the means of three determinations. Acetyltransferase activities in control cell lysate (○—○) and in A23187-stimulated cell lysate (●—●), transacylase activities in control cell lystate (△—△) and in A23187-stimulated cell lysate (▲—▲).

around 320 μM and 250 μM in control and A23187-stimulated cell lysate, respectively. This observation is in general agreement with previous reports on other tissues and cells (9,13). However, the intracellular levels of acetyl-CoA in mammalian tissues are known to be usually low (41). A very low level of acetyl-CoA in macrophage lysate is also suggested by the results in Table 2. In fact, we found that the amount of acetyl-CoA in

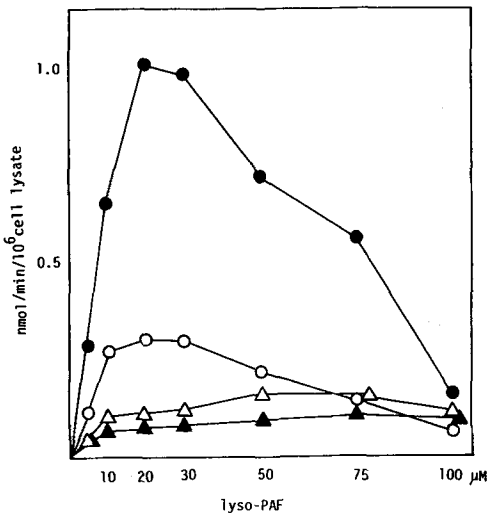

FIG. 2. Effect of lysoPAF concentration on the activities of acetyltransferase and transacylase. Macrophage lysate (10^6 cell lysate/0.5 mL) was incubated with various concentrations of [^{3}H]lysoPAF (25,000 dpm) in the presence of 100 μM acetyl-CoA. The data represent the means of three determinations. Acetyltransferase activities in control cell lysate (○—○) and in A23187-stimulated cell lysate (●—●), transacylase activities in control cell lysate (△—△) and in A23187-stimulated cell lysate (▲—▲).

rabbit alveolar macrophages is less than 4 nmol/10^8 cells (the packed volume of 10^8 cells corresponds to *ca.* 0.5 mL), using the method of Wieland and Weiss (31). It can be possible, therefore, that lysoPAF is preferentially metabolized by transacylase rather than by acetyltransferase also in living cells.

Figure 2 shows the effects of lysoPAF concentration on the activities of acetyltransferase and transacylase in the presence of 100 μM exogenous acetyl-CoA. The activities of both acetyltransferase and transacylase increased with the concentration of lysoPAF. However, the activity of acetyltransferase became maximal at 20 μM, and its activity was rather reduced at a higher concentration of lysoPAF, such as 50 μM or 100 μM, both in control and A23187-stimulated cell lysates. Such an inhibition was not observed in the case of transacylase, suggesting that acetyltransferase is much more sensitive to the detergent effect of lysoPAF. The inhibition of the activity of acetyltransferase by a high concentration of lysoPAF has also been observed in other types of cells (8,9,12,13). We measured the intracellular pool of lysoPAF by estimating the lipid phosphorus of unsaponifiable material of the lysophosphatidylcholine fraction and obtained values of 4.2 ± 0.8 nmol/10^8 cells and 6.2 ± 0.8 nmol/10^8 cells for control and A23187-stimulated cell lysate, respectively (the means ± SD from three determinations), both of which may be suboptimal concentrations for acetyltransferase, as shown in Figure 2.

Then we examined the effects of substrate availability on the PAF production. First we studied the effects, on the production of PAF, of ketone bodies which are known to be transporters of acetyl units in blood and are metabolized by various peripheral tissues to yield acetyl-CoA. As shown in Figure 3, the addition of 5 mM acetoacetate, β-hydroxybutyrate or acetate augmented PAF production. On the other hand, a relatively inactive

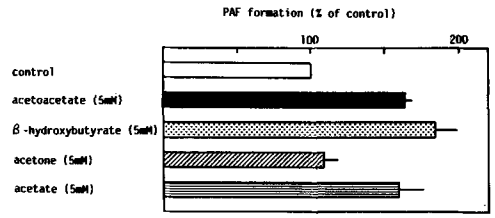

FIG. 3. Effects of ketone bodies and acetate on the production of PAF in A23187-stimulated macrophages. Macrophages (10^6 cells/0.5 mL) were stimulated with A23187 (10 μM) for 10 min in the presence of 5 mM ketone bodies or acetate. After the extraction of total lipids, PAF fraction was separated by TLC. The amounts of PAF were estimated by bioassay with washed rabbit platelets as described in the text. The data represent the means ± SD from three determinations.

ketone body, acetone, failed to enhance the formation of PAF. The addition of 5 mM acetoacetate to unstimulated cells did not affect the basal level of PAF (data not shown). The increased production of PAF induced by acetoacetate, β-hydroxybutyrate and acetate in A23187-stimulated cells may be due to the changes in acetyl-CoA level in cells induced by these materials. Several investigators have already shown that the treatment of sheep kidney with 5 mM acetoacetate (42) or rat heart with 5.5 mM β-hydroxybutyrate (43) resulted in a dramatic increase of acetyl-CoA in these tissues. The intracellular level of acetyl-CoA in rabbit alveolar macrophages is considerably lower than the optimal concentration for acetyltransferase as demonstrated in Figure 1 and Table 2. Thus, it is very likely that the increased level of acetyl-CoA in cells leads to the enhanced formation of PAF when these cells are stimulated. We also found that ionophore or opsonized zymosan-stimulated human peripheral polymorphonuclear leukocytes (PMN) produce much more PAF in the presence of acetoacetate, β-hydroxybutyrate or acetate (44). The effect of acetate or acetyl-CoA on the production of PAF has already been reported by Benveniste and his colleagues (17,45–47). In any case, the fact that the amount of PAF produced is affected by exogenous ketone bodies strongly suggests that the biosynthesis of PAF in peripheral tissues and cells is closely related to the status of lipid metabolism in the whole body, especially the liver.

The effects of lysoPAF on the biosynthesis of PAF are illustrated in Figure 4. Formation of PAF in A23187 (0.5 μM)-stimulated cells was considerably increased in the presence of 2 μM lysoPAF, suggesting that the availability of lysoPAF is not yet optimal for PAF synthesis, at least at this concentration of ionophore. On the other hand, the stimulative effect of lysoPAF was not as prominent in the case of a higher concentration of A23187 (10 μM). This is probably due to the fact that a sufficient amount of lysoPAF was available to the PAF-synthesizing enzyme, acetyltransferase. The enhanced synthesis of PAF in the presence of lysoPAF has already been reported for human polymorphonuclear leukocytes (46) and endothelial cells (48) exposed to various stimuli. In contrast, Mencia-Huerta *et al.* (45) found that the addition of lysoPAF did not accelerate PAF formation in murine peritoneal macrophages. The most striking observation in this study was, however, that considerable

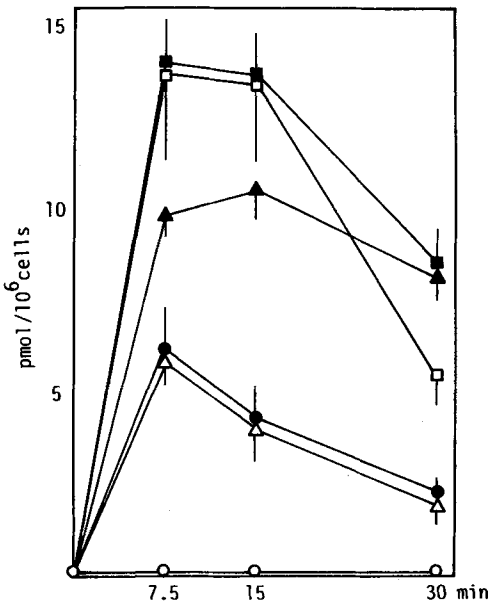

FIG. 4. Effects of exogenous lysoPAF on PAF production in unstimulated macrophages and in A23187-stimulated macrophages. Macrophages (10^6 cells/0.5 mL) were incubated with or without A23187 (0.5 μM or 10 μM) for 7.5–30 min in the presence or absence of lysoPAF (2 μM or 20 μM). The amounts of PAF were estimated by bioassay with washed rabbit platelets as described in the text. The data represent the means ± SD from three determinations. Unstimulated cells + no lysoPAF (○—○) and + 20 μM lysoPAF (●—●), A23187 (0.5 μM) + no lysoPAF (△—△) and + 2 μM lysoPAF (▲—▲), A23187 (10 μM) + no lysoPAF (□—□) and + 2 μM lysoPAF (■—■).

amounts of PAF were formed even in unstimulated cells, if these cells are incubated with a relatively high concentration of lysoPAF (Fig. 4). In fact, the amount of PAF produced in the presence of 20 μM lysoPAF alone was almost equal to that produced by 0.5 μM A23187 stimulation. This is quite different from the case for ketone bodies. We also confirmed that unstimulated human polymorphonuclear leukocytes can produce large amounts of PAF without increase in acetyltransferase activity, if these cells are incubated in the presence of lysoPAF, especially in the absence of albumin (Sugiura, T., manuscript in preparation).

These observations are of particular importance in considering the mechanism of the regulation of PAF synthesis. The level or localization of lysoPAF in unstimulated cells seems to be under strict regulation and only a small amount of PAF can be produced. Such a small amount of PAF may be rapidly degraded by acetylhydrolase, since rabbit alveolar macrophages contain relatively high acetylhydrolase activity (Table 1). In fact, the PAF level in stimulated macrophages also decreased with time (Fig. 4), suggesting that the degradation of PAF could be very important in the regulation of PAF levels, as suggested by other investigators (17,49). On the other hand, if excess amounts of lysoPAF were present within cells or near cells, significant amounts of PAF could be formed without additional stimulation, since a high activity of acetyltransferase was noted even in control cells. The elevation of acetyltransferase activity in stimulated cells shown in this study (Figs. 1 and 2 and Table 1) and in

others (14-24) could be favorable for the formation of additional PAF. However, this might not be necessary in some situations as described above. We also found that the treatment of human polymorphonuclear leukocytes with exogenous phospholipase A_2 and l-alkenyl-*sn*-glycero-3-phosphoethanolamine (GPE), the latter of which was shown to cause the degradation of alkylacyl-GPC to provide l-alkyl-GPC, produces small but significant amounts of PAF (Sugiura, T., manuscript in preparation). Taking all these results together, it would appear that the cellular availability of lysoPAF, which may be controlled by phospholipase A_2, the transacylation system, lysoPAF degrading activity, and intracellular localization, is one of the important factors which modulate the magnitude of PAF production.

In conclusion, we found that i) the concentrations of both acetyl-CoA and lysoPAF in living cells are suboptimal for acetyltransfer and that ii) increase of these substrates within cells augments PAF synthesis in ionophore-stimulated alveolar macrophages. We furthermore found that iii) the addition of an excess amount of lysoPAF *per se* triggers PAF production in unstimulated cells, which suggests that the generation of lysoPAF within cells can be enough to elicit for PAF synthesis in this type of cell, and that iv) the transacylation system could play a possible important role in regulating intracellular levels of lysoPAF.

ACKNOWLEDGMENT

This study was supported in part by a Grant-in-Aid for Scientific Research (No. 63771977) from the Ministry of Education, Science and Culture of Japan.

Human tissues, blood cells, and plasma have enzymes that catalyze the hydrolysis of PAF (1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine). The activities are not due to phospholipases A_2 that hydrolyze long chain acyl groups at the *sn*-2 position of glycerophospholipids, since they are calcium-independent and are specific for hydrolysis of short chain acyl groups. We examined the biochemical properties of these PAF acetylhydrolase activities (EC 3.1.1.47) in homogenates of human liver and spleen, in white blood cells (neutrophils and monocytes), and in erythrocytes. The data suggest that the plasma and intracellular PAF acetylhydrolase activities are likely due to different proteins. Second, the intracellular PAF acetylhydrolase activities in liver and spleen share several biochemical features that differentiate them from the activities in blood cells. Third, the activities in monocytes and neutrophils have properties that differentiate them from the activity present in human erythrocytes. Finally, the erythrocyte activity has unique properties that place it in a separate category of short chain acylhydrolases. In conclusion, there is a family of distinct enzymes that can be identified as PAF acetylhydrolases based on their calcium-independence and specificity for a short residue at the *sn*-2 position of phospholipids.
***Lipids* 26, 979-985 (1991).**

Platelet-activating factor (PAF, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) is a bioactive phospholipid that is synthesized by a variety of mammalian cells (1-6). The biological effects mediated by PAF have been reviewed by Snyder (7) and Hanahan (8) and they include, among many other effects, aggregation of platelets, monocytes, and neutrophils; induction of hypotension; vasopermeability; and smooth muscle contraction. It has been suggested that PAF synthesized by endothelial cells mediates the adherence of neutrophils to the endothelium (9). PAF biosynthesis is under tight regulatory control (10), but there is also evidence that the accumulation of PAF is regulated by the rate of degradation in certain cells (11). Thus, the metabolism of PAF is an area of current interest. It has been recognized since 1980 that the degradation of PAF occurs by removal of the acetyl group at the *sn*-2 position of the glycerol backbone to produce the biologically inactive lysoPAF [1-*O*-alkyl-*sn*-glycero-3-phosphocholine, (12)]. This reaction is catalyzed by a specific PAF acetylhydrolase (1-alkyl-2-acetyl-glycerophosphocholine esterase, 1-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine acetohydrolase, EC 3.1.1.47) present in plasma (13,14), in the cytosolic fraction of various mammalian tissues (12), and human blood cells (15).

We previously purified and characterized the human plasma PAF acetylhydrolase (16) and determined that PAF degradation in human blood and in plasma is entirely accounted for by this activity (17). However, the relationship of the plasma PAF acetylhydrolase and the intracellular PAF acetylhydrolase activities is currently undefined. The activities may be the expression of a single protein present in cells and fluids such as plasma, or there can be two or more proteins with the ability to specifically degrade PAF. The latter possibility is more likely, since inhibitor studies have shown a different response of the activities present in cells as compared to the plasma activity (18-20).

Blank *et al.* (12) described PAF acetylhydrolase activities in the cytosolic fractions of rat tissues. The activity present in kidney cortex was specific for hydrolysis of phospholipids with short chain acyl groups at the *sn*-2 position and the liver activity was calcium-independent. Thus, the plasma and the tissue PAF acetylhydrolases had properties that differentiated them from phospholipases A_2 that hydrolyzed phospholipids with long chain acyl groups at the *sn*-2 position. The substrate specificity and the Km of the activities present in rat tissues and in plasma were similar. However, the plasma activity had a higher apparent molecular weight than the intracellular activity (18). In addition, the rat plasma PAF acetylhydrolase was resistant to protease treatment, while the intracellular activity was sensitive (18). Nijssen *et al.* (19) described the presence of a calcium-independent PAF acetylhydrolase activity in rat lung cytosol. The activity was sensitive to treatment with serine esterase inhibitors but was not affected by the alkylating agent *p*-bromophenacylbromide. Recently, Yanoshita *et al.* examined the substrate specificity of PAF acetylhydrolases and found that the tissue-originated activities could be differentiated from the activities in blood cells and in plasma based on the rates with which the enzymes degraded PAF vs 1*S*-methyl-1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine (20). These observations suggest that there are at least two PAF acetylhydrolase activities—plasma and intracellular—but do not define their relationship to one another, nor do they suggest if there is more than one intracellular PAF acetylhydrolase.

In this paper we examine the biochemical properties of PAF acetylhydrolase activities in homogenates of human liver and spleen, and in blood cells. A comparison of the properties of plasma vs intracellular PAF acetylhydrolase activities suggests that they are likely due to different proteins. In addition, the PAF acetylhydrolase activities in liver and spleen share several biochemical features that differentiate them from the PAF acetylhydrolase activities in monocytes and neutrophils. Finally, the

erythrocyte activity has unique properties that place it in a separate category of short chain acylhydrolases. We conclude that there is a family of distinct enzymes that can be identified as PAF acetylhydrolases based on their calcium-independence and specificity for a short residue at the *sn*-2 position of phospholipids.

MATERIALS AND METHODS

Materials. 1-*O*-Alkyl-2-[^{3}H]acetyl-*sn*-glycero-3-phosphocholine ([^{3}H-*acetyl*]PAF) and 1-palmitoyl-2-[^{14}C]arachidonoyl-*sn*-glycero-3-phosphocholine were purchased from New England Nuclear (Boston, MA). 1-*O*-Alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (PAF), and 1-palmitoyl-2-arachidonoyl phosphatidylcholine were from Avanti Polar Lipids (Birmingham, AL). Bovine trypsin was from Calbiochem-Behring (La Jolla, CA).

Assays. PAF acetylhydrolase assays were performed as described previously (16), except that the incubation time, unless otherwise stated, was 15 min rather than 30 min. The assays were performed at saturating concentrations of PAF, which ensured zero order kinetics with respect to substrate. A unit of enzymatic activity was defined as 1 μmol of acetate produced per hour at 37°C. Phospholipase A_2 assays were carried out as described (21), using 1-palmitoyl-2-arachidonoyl phosphatidylcholine as substrate. Protein content was determined by the method of Lowry *et al.* (22).

Preparation of tissue homogenates. Human polymorphonuclear neutrophils were isolated as described (23), and human monocytes were obtained by elutriation (11). Tissue samples of human liver and spleen were obtained from unused specimens removed by the Organ Transplantation Service, University of Utah Medical Center, and the tissues were frozen immediately after extraction. Homogenates were prepared by first slicing the tissues (1 g) into small pieces, and then homogenizing them with the aid of a Potter-Elvehjem homogenizer, in 10 mL of 50 mM Tris-HCl buffer (pH 7.5) containing 1% aprotinin and 0.1 mg/mL soybean trypsin inhibitor. When the homogenates were used to test the effect of proteases, aprotinin and trypsin inhibitor were omitted from the buffer. The preparations were centrifuged at 130,000 × *g* for 60 min at 4°C and the supernatants were used as the source of PAF acetylhydrolase.

For preparation of erythrocyte PAF acetylhydrolase, human blood was drawn from healthy volunteers using EDTA as anticoagulant. The cellular fraction was isolated by centrifugation at 2,000 × *g* for 20 min. After removing the plasma fraction, the buffy coat was aspirated and discarded. The red cells were washed three times with 0.9% NaCl and then lysed by osmotic shock in 0.83% NH_4Cl, sonication or freezing-thawing. For some experiments, the PAF acetylhydrolase activities were partially purified by ion exchange chromatography on DEAE-Sepharose CL-6B.

Chromatography and electrophoresis. Gel permeation chromatography was carried out on Sephacryl S-200 columns (1.5 × 60 cm) equilibrated with 50 mM Tris-HCl buffer (pH 7.5), at a flow rate of 10 mL/hr. Packed erythrocytes (500 μL of a preparation containing 278 mg/mL of protein) were diluted ten-fold in equilibrating buffer, lysed by sonication, and then centrifuged at 130,000 × *g* for 60 min. The supernatant, containing 0.5 U of PAF acetylhydrolase activity, was loaded on the column. Similarly, a liver homogenate prepared as described above was centrifuged at 130,000 × *g* for 60 min and 5 mL of the supernatant fraction containing 2.9 mg of protein and 0.2 U of PAF acetylhydrolase activity was loaded on the column. Human plasma low density lipoprotein fraction was prepared as described (17). A preparation containing 0.24 mg of protein and 0.28 U of PAF acetylhydrolase activity, in a total volume of 5 mL, was loaded on the column. Elution took place at 4°C. Fractions (1.8 mL) were collected and assayed for PAF acetylhydrolase activity.

Native polyacrylamide gel electrophoresis was performed under reducing conditions by the method of Davis (24). Samples of high speed supernatants from erythroctes and liver and a neutrophil lysate were separately loaded on slab gels (1.5 mm × 18 cm × 16 cm) of 7% acrylamide and electrophoresed at a constant current of 20 mA. After electrophoresis, the individual lanes were excised and sliced into 20–25 fragments of equal size. The gel slices then were assayed for PAF acetylhydrolase activity for 60 min at 37°C, in 0.1 M Hepes buffer (pH 7.2) using 50 μL of 0.1 mM [^{3}H-*acetyl*]PAF, in a total volume of 100 μL.

RESULTS

Human tissue homogenates and blood cells have PAF acetylhydrolase activity. We first determined that homogenates from human tissues and blood cells catalyze the hydrolysis of PAF. The assay developed for the determination of PAF acetylhydrolase activity in plasma was adequate for the assay of intracellular PAF acetylhydrolase activities. For example, using this assay we found that the time course of PAF hydrolysis catalyzed by a human erythrocyte lysate was linear up to 20 min and leveled off with longer incubation times (Fig. 1A). PAF hydrolysis increased linearly with the amount of protein added, up to 0.5 μL of erthrocyte lystate (Fig. 1B). The enzymatic activity increased with substrate concentration and then reached a plateau level (Fig. 1C). Optimal hydrolysis of PAF was observed at pH 7.6. Using this assay, we determined that human spleen and liver homogenates, as well as human monocytes and neutrophils, had detectable levels of PAF acetylhydrolase activity (not shown).

Since the activity we were measuring could have been the expression of phospholipase A_2-like activities that hydrolyze long as well as short fatty acyl chains at the *sn*-2 position of glycerophospholipids, we tested the effect of calcium ions added to the incubations. Calcium is an obligatory cofactor for activity of many phospholipases A_2 (25); however, addition of supplemental calcium did not stimulate PAF hydrolysis by intracellular PAF acetylhydrolases (Table 1). Furthermore, the chelating agents EDTA and EGTA did not significantly affect PAF hydrolysis. In addition, phosphatidylcholine (which had a long chain fatty acid at the *sn*-2 position) did not inhibit PAF hydrolysis by human neutrophils, monocytes, or erythrocytes. The liver and spleen PAF acetylhydrolase activities were only slightly inhibited by phosphatidylcholine.

Biochemical comparison of tissue PAF acetylhydrolase activities with the plasma activity. Agents known to

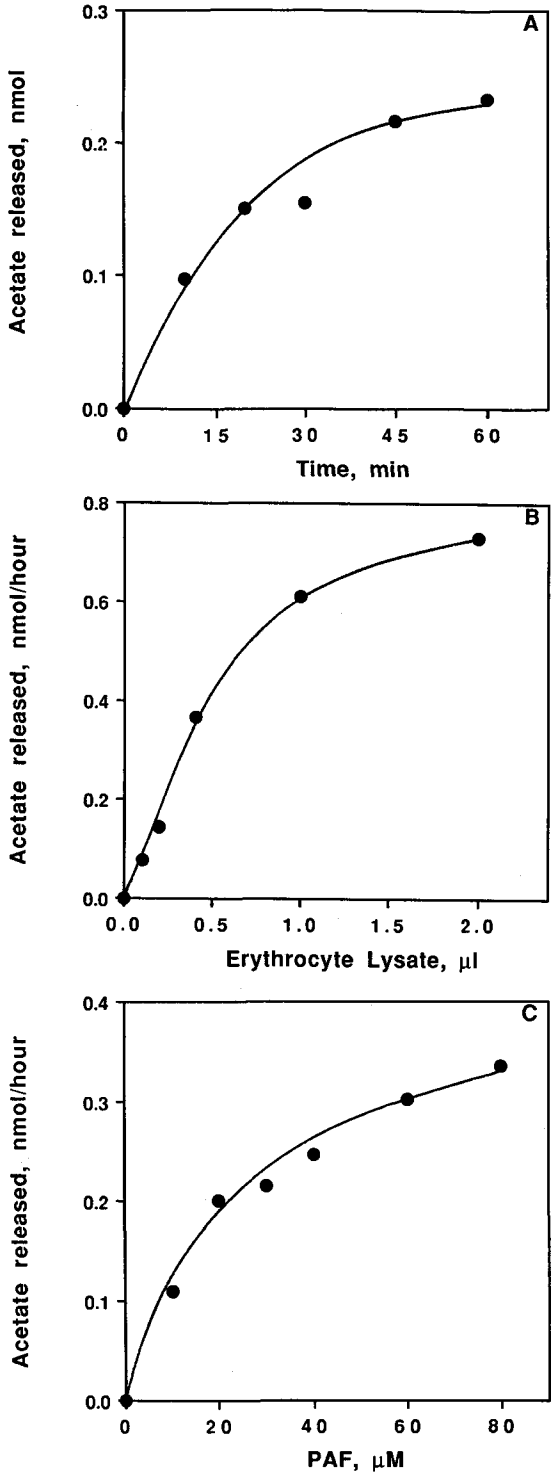

FIG. 1. Dependence of PAF hydrolysis on time, protein, and substrate concentration. (A) Time course: A fresh erythrocyte lysate (0.4 µL of a total lysate containing a protein concentration of 277 mg/mL) was incubated with 80 µM PAF at 37°C for the indicated periods of time (0–60 min). The assays were then continued as described (16). (B) Protein concentration: Varying amounts of a fresh erythrocyte lysate (containing 277 mg/mL of protein, 0–2 µL) were incubated for 30 min at 37°C in the presence of 80 µM [^{3}H-*acetyl*]-PAF. The assays were then continued as described (16). (C) Substrate concentration: Varying amounts of [^{3}H-*acetyl*]PAF (0–80 µM) were incubated for 30 min at 37°C using 0.4 µL of a fresh erythrocyte lystate containing a protein concentration of 277 mg/mL, as the enzyme source. The assays were then continued as described (16). Results are representative of at least two determinations.

TABLE 1

Effect of Calcium, EDTA, EGTA, and Phosphatidylcholine on Various Cellular PAF Acetylhydrolase Activities

	PAF acetylhydrolase activity[a] % of Control			
Tissue tested	$CaCl_2$ 2 mM	EDTA 10 mM	EGTA 10 mM	PC[b] 0.4 mM
Erythrocyte lysate	97	70	94	99
Neutrophil lysate	95	83	105	105
Monocyte lystate	81	96	101	91
Liver homogenate	96	108	102	79
Spleen homogenate	90	98	100	67

[a]Control values were obtained by adding buffer instead of the reagent indicated in each case. Results are representative of at least two determinations.

[b]PC: phosphatidylcholine.

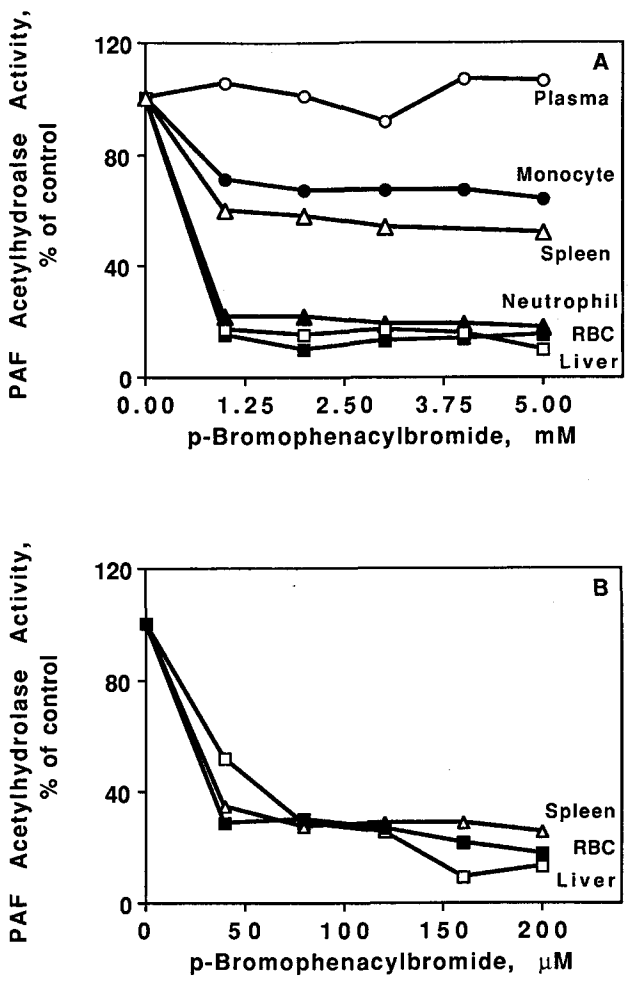

FIG. 2. Effect of *p*-bromophenacylbromide on PAF acetylhydrolase activity. Samples from various cellular fractions, prepared as described in Materials and Methods, were preincubated for 15 min at 37°C with *p*-bromophenacylbromide (*p*-BPB), at the concentrations shown. The assays then were continued as described (16). (A): crude homogenates or plasma; (B) partially purified preparations of PAF acetylhydrolase were used. Symbols: ○, plasma; ●, monocytes; △, spleen; ▲, neutrophils; ■, erythrocytes; and □, liver. Results are representative of at least two determinations.

inhibit phospholipase A_2 activity were tested for their effects on the various intracellular PAF acetylhydrolase activities. We first tested the effect of *p*-bromophenacylbromide (*p*-BPB), a nucleophilic reagent that has been shown to block phospholipase A_2 activity by derivatizing a histidine at the active site (Fig. 2A). The PAF acetylhydrolase activities from neutrophils, erythrocytes, and liver resembled one another in that they were almost completely inhibited by *p*-BPB. The monocyte and spleen activities were partially sensitive and the plasma activity was completely resistant to *p*-BPB. The partial inhibition obtained with the monocyte and spleen extracts could have been due to the presence of other proteins that bound the reagent, thus preventing it from fully inhibiting enzymatic activity. To address this issue, we subjected erythrocyte lysates and tissue homogenates to gel permeation chromatography on Sephacryl S-200 or ion exchange chromatography on DEAE Sepharose. Partial purification of the PAF acetylhydrolase activity in spleen resulted in higher sensitivity to *p*-BPB; the partially purified erythrocyte and liver activities remained sensitive to treatment with the inhibitor (Fig. 2B). In contrast, the purified plasma PAF acetylhydrolase (specific activity, 500 μmol/mg/hr) was resistant; concentrations of *p*-BPB up to 3 mM had no effect (not shown). Thus, the intracellular and plasma PAF acetylhydrolase activities had opposite sensitivities to *p*-BPB, suggesting that the activities were due to different proteins.

The presence of essential histidine residues at the active site of intracellular PAF acetylhydrolase activities was further examined by testing the effect of diethylpyrocarbonate (DEPC) on the enzymatic activities (Table 2). DEPC inhibited the partially purified intracellular PAF acetylhydrolase activities from human erythrocytes, neutrophils, and spleen, but it had no effect on the purified plasma activity (Table 2). Thus, the inhibitory effects of DEPC and *p*-BPB were in agreement and suggested the presence of essential histidine residues at the active sites of intracellular PAF acetylhydrolases, but apparently not the plasma activity.

We next examined the effect of 5,5′-dithio-*bis*(2-nitrobenzoic acid) (DTNB), an agent that inactivates enzymes containing essential sulfhydryl groups at the active site. We found that the activities in blood cells were sensitive to treatment with DTNB, in contrast to the tissue activities, which were only partially sensitive. The plasma PAF acetylhydrolase activity was resistant (Table 2). This suggested the occurrence of at least two kinds of intracellular PAF acetylhydrolase activities—the activity in blood cells such as neutrophils, erythrocytes and monocytes, which seemed to contain sensitive sulfhydryl groups, and the activity in tissues such as spleen and liver, with sulfhydryl groups partially protected from attack by DTNB or removed from the active site. The plasma activity did not seem to contain essential sulfhydryl groups.

Sodium fluoride has been reported to inhibit bee venom phospholipase A_2 (25) and Nijssen *et al.* (19) have reported that sodium fluoride partially inhibits the PAF acetylhydrolase activity in rat lung cytosol. We tested the effect of sodium fluoride on the PAF acetylhydrolase activities from plasma, tissues and blood cells (Table 2). The human erythrocyte activity was inhibited by sodium fluoride. In contrast, the intracellular PAF acetylhydrolase activities of every other source were quite resistant over a wide range of concentrations. Thus, the PAF acetylhydrolase in red blood cells has properties that differentiate it from the activity in white blood cells and from the plasma and tissue activities.

TABLE 2

Effect of Diethylpyrocarbonate, 5,5′-Dithio*bis*(2-Nitrobenzoic Acid), and Sodium Fluoride on PAF Acetylhydrolase Activities[a]

Enzyme source	Inhibitor	Activity % of Control
Plasma[b]	DEPC	80

Erythrocyte	NaF	7

[a]The enzyme source indicated in each case was preincubated with diethylpyrocarbonate (DEPC), 0.2–0.8 mM, 5,5′-Dithio*bis*(2-nitrobenzoic acid), DTNB, 1–2 mM, or NaF, 9–20 mM. The mixtures were preincubated for 15–30 min at 37°C. Then, [^{3}H-*acetyl*]PAF was added and the incubations were continued for 15–30 min at 37°C, as described (16). Results are representative of at least two determinations.

[b]The plasma PAF acetylhydrolase was purified from LDL to a final specific activity of 300 U/mg, as described (15). Each assay contained 0.4 ng of protein. Control activity, 12 nmol/mL/hr.

[c]The PAF acetylhydrolase activity present in high speed supernatants of spleen homogenates was purified two-fold by gel filtration on Sephacryl S-200, as described in Materials and Methods. The amount of protein per assay was 4.8 μg. Control activity, 30 nmol/mL/hr.

[d]Each assay contained 3×10^6 lysed neutrophils. Control activity, 2.3 nmol/mL/hr.

[e]The PAF acetylhydrolase activity in high speed supernatants of erythrocyte lysates was purified two-fold by gel filtration on Sephacryl S-200, as described in Materials and Methods. The amount of protein per assay was 28 μg. Control activity, 20 nmol/mL/hr.

[f]The PAF acetylhydrolase activity in high speed supernatants of liver homogenates was purified two-fold by gel filtration on DEAE Sepharose CL-6B, as described in Materials and Methods. The amount of protein per assay was 3.6 μg. Control activity, 12.2 nmol/mL/hr.

[g]Each assay contained 6×10^5 lysed peripheral blood monocytes. Control activity, 3.8 nmol/mL/hr.

Susceptibility of PAF acetylhydrolases to trypsin. Trypsin was tested for its effect on various PAF acetylhydrolase activities (Table 3). The plasma PAF acetylhydrolase activity was resistant to trypsin treatment, in contrast to the erythrocyte, liver, and spleen activities, which were sensitive. The activities in neutrophils and monocytes were only partially inhibited by trypsin

treatment. Thus, the tissue activities resembled one another and the activity present in red blood cells and were differentiated from the monocyte, neutrophil, and plasma activities.

Physical separation of various PAF acetylhydrolase activities. The cellular PAF acetylhydrolase activities were further compared by gel filtration and electrophoresis on non-denaturing polyacrylamide gels. The elution profiles of cellular PAF acetylhydrolase activities upon gel filtration chromatography on Sephacryl S-200 showed that the

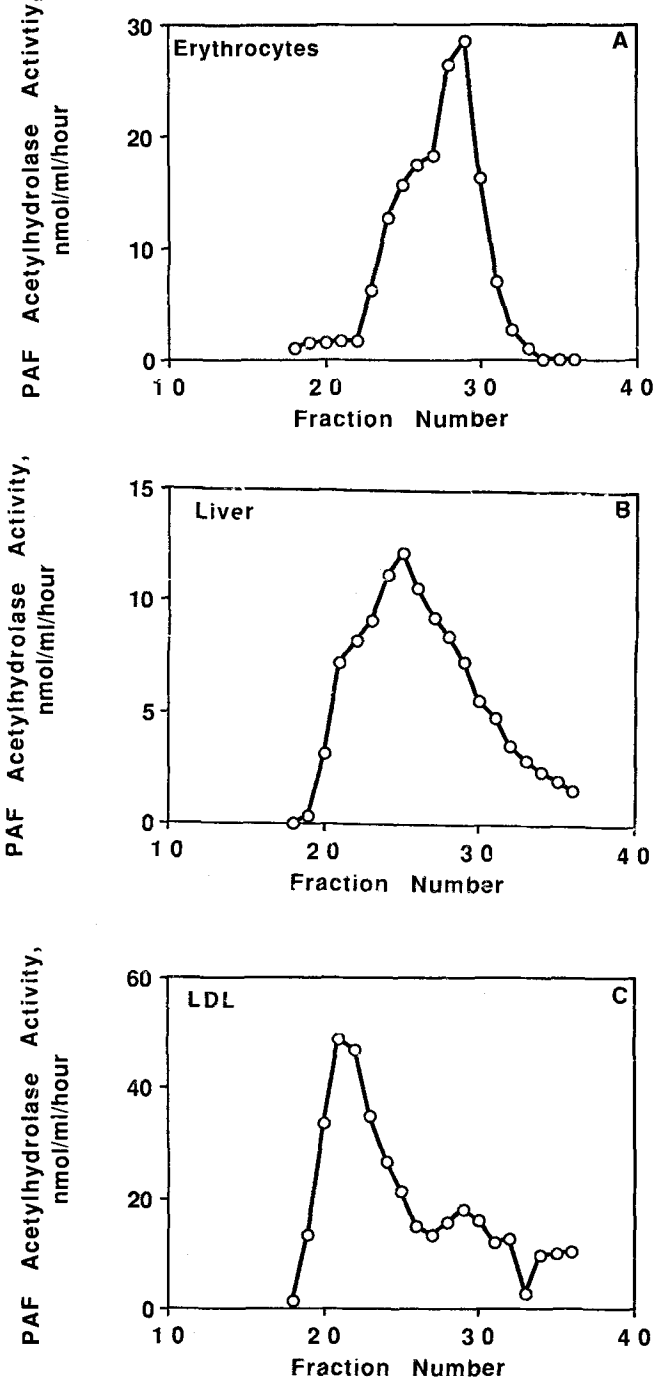

FIG. 3. Sephacryl S-200 column chromatography of human erythrocyte, liver, and LDL-associated PAF acetylhydrolase activities. Samples from the cellular fractions indicated were loaded on a Sephacryl S-200 column as described in Materials and Methods. (A) erythrocytes; (B) liver; and (C) LDL.

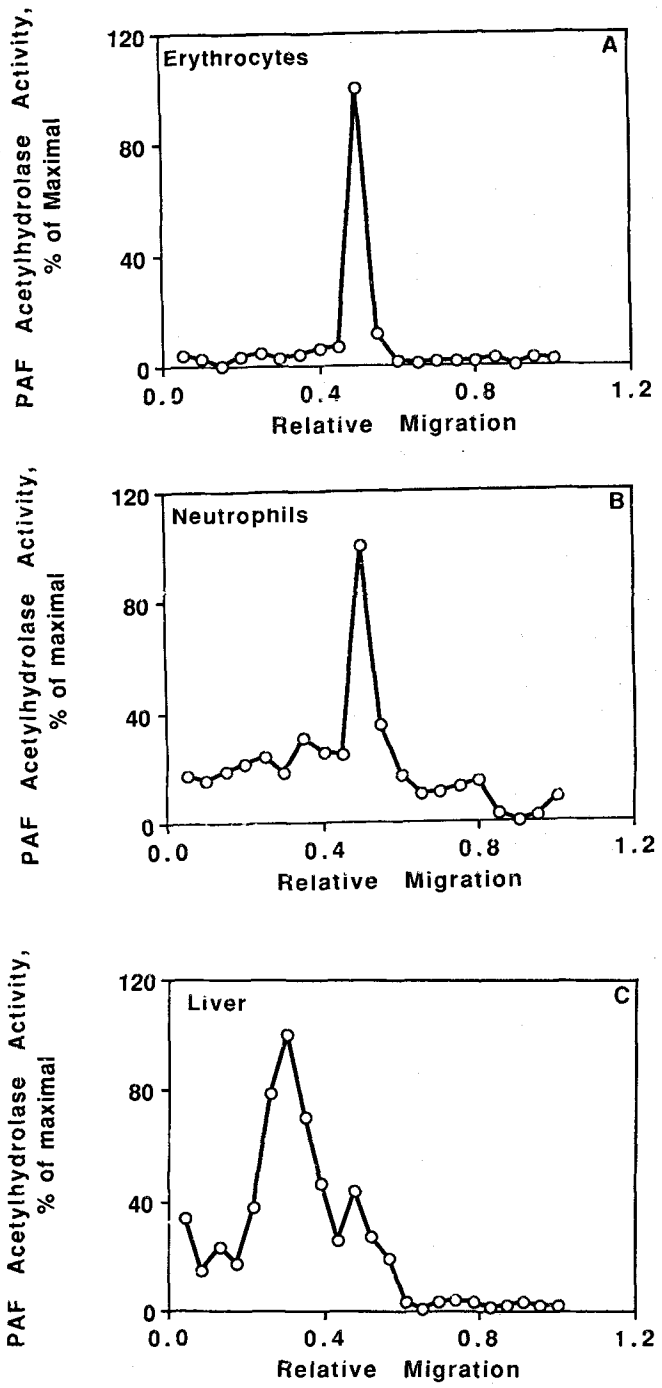

FIG. 4. Non-denaturing polyacrylamide gel electrophoresis of human erythrocyte, neutrophil, and liver PAF acetylhydrolase activities. Samples (5–100 μL) were loaded on native slab gels and electrophoresed as described in Materials and Methods. (A) Erythrocytes. The erythrocyte lysate sample (130,000 × *g* supernatant) contained 692 μg of protein; maximal activity—0.15 nmol/h. (B) Neutrophils. A total of 2×10^7 neutrophils were lysed by sonication and then subjected to electrophoresis; maximal activity—0.04 nmol/hr. (C): Liver. A crude homogenate containing 29 μg of protein was centrifuged at 130,000 × *g* for 60 min. The supernatant fraction then was subjected to electrophoresis. Maximal activity, 0.11 nmol/hr.

TABLE 3

Effect of Trypsin on PAF Acetylhydrolase Activity

Enzyme source	PAF acetylhydrolase activity[a] % of Control
Plasma	88
Spleen[b]	0
Liver[b]	7
Neutrophils	57
Monocytes	59
Erythrocytes	4

[a]Equal amounts of activity from each enzyme source were preincubated with buffer or various amounts of trypsin (0–0.025%), for 60 min at 37°C, in a total volume of 50 μL. Then, 20 μL-aliquots were incubated with 30 μL of 0.1 mM [^{3}H-*acetyl*]PAF for 60 min at 37°C, as described (16). Results reported represent the residual amount of PAF acetylhydrolase activity determined after trypsin action had reached a plateau. Results are representative of at least two determinations.

[b]The activities were partially purified as described in the legend to Table 2.

TABLE 4

Comparison of Intracellular and Plasma PAF Acetylhydrolase Activities

Location	Characteristics			
	Histidine reagents	Sulfhydryl reagents	Trypsin	NaF
Extracellular (e.g., plasma)	Resistant	Resistant	Resistant	Resistant
Intracellular				
Tissues (e.g., liver and spleen)	Sensitive	Partially sensitive	Sensitive	Resistant
Blood cells				
White blood cells (e.g., neutrophils and monocytes)	Sensitive	Sensitive	Partially sensitive	Resistant
Red blood cells (e.g., erythrocytes)	Sensitive	Sensitive	Sensitive	Sensitive

erythrocyte activity was eluted with a lower apparent molecular weight than the liver acetylhydrolase (Fig. 3). The plasma PAF acetylhydrolase was eluted at the void volume, since the activity associates with much larger lipoprotein particles (16). The elution positions of the liver and erythrocyte PAF acetylhydrolases indicated that the two activities could be differentiated from each other, in agreement with the inhibitor results. To compare the mass/charge ratio of the erythrocyte and neutrophil activities, we subjected cell lysates to electrophoresis in polyacrylamide gels that did not contain detergent (Fig. 4). The erythrocyte and neutrophil activities migrated with the same relative mobilities. The liver activity had a higher apparent mass/charge ratio, in agreement with the gel filtration results. Thus, in addition to the inhibitory profiles, the blood cell PAF acetylhydrolases can be differentiated from the tissue and plasma activities on the basis of size and mass/charge ratios.

CONCLUSION

We have shown that human tissues, white blood cells, and red blood cells have enzymes that catalyze the hydrolysis of PAF. The activities share two features with the plasma PAF acetylhydrolase activity—they are calcium-independent and only hydrolyze phospholipids with a short chain acyl group at the *sn*-2 position of the glycerol backbone. Thus, the activities are not an expression of phospholipase A_2 activities that can hydrolyze phospholipids with long chain acyl residues at the *sn*-2 position of the glycerol backbone.

The functional similarities between the plasma and intracellular PAF acetylhydrolase activities contrasted with our finding of marked differences in the physical and biochemical behavior of the enzymes (Table 4). First, the intracellular activities were differentiated from the plasma activity since the former are sensitive to histidine reagents and trypsin treatment, in contrast to the plasma activity, which is resistant. These differences were emphasized when comparisons where made with the partially purified preparations, where contamination with other proteins was less likely to contribute to the observed effects. Second, the tissue activities were differentiated from the blood cell activities, based on their size or mass/charge ratios and resistance to sulfhydryl reagents. Third, the activity in red blood cells is extremely sensitive to proteolysis and treatment with sodium fluoride, in contrast to the activities in white blood cells, which are only partially sensitive to these agents (Table 4).

It remains to be established whether the intracellular PAF acetylhydrolase activities are the expression of more than one protein, or whether their different behaviors are due to various stages in the processing of a single protein. However, it is apparent that a variety of cells and tissues express PAF acetylhydrolase activity, and that these various activities can be grouped into at least four species, according to their kinetic and physical behavior. It appears that the extracellular plasma activity, intracellular erythrocyte, white blood cell, and tissue activities comprise a family of PAF acetylhydrolases.

Properties of PAF-Synthesizing Phosphocholinetransferase and Evidence for LysoPAF Acetyltransferase Activity in Rat Brain[1]

Gianfrancesco Goracci* and **Ermelinda Francescangeli**
Dipartimento di Medicina Sperimentale e Scienze Biochimiche, Università di Perugia, 06100 Perugia, Italy

Several reports have indicated that platelet-activating factor (PAF) may play a role in the physiopathology of nervous tissue. We previously have demonstrated the presence, in the microsomal fractions of rat brain, of a phosphocholinetransferase which is able to synthesize PAF by the *de novo* pathway. The presence of dithiothreitol in the medium increases the rate of PAF biosynthesis, whereas it inhibits the synthesis of long-chain alkylacyl- and diacyl-glycerophosphocholines (GPC), including dioctanoyl-GPC. This and other properties, such as pH dependence and thermal stability, indicate that rat brain may have two distinct enzymes for the synthesis of PAF and other choline phospholipids. The affinity of these enzymes for CDPcholine is similar to that reported for other tissues, the K_m being 42 μm and 55 μm with alkylacetylglycerol and dioctanoylglycerol as lipid substrates, respectively. The V_{max} values were 3.0 and 2.2 nmol/mg prot/min for PAF and dioctanoyl-GPC, respectively. In addition, it was shown that the microsomal fraction of rat brain contains an acetyltransferase which can convert lysoPAF to PAF. Since it has been reported previously that brain tissue possesses phospholipase A_2 activity that can hydrolyze alkylacyl-GPC to lysoPAF, we conclude that brain tissue has all enzymic activities for the synthesis of PAF by the "remodeling pathway". The role of the two routes of PAF biosynthesis in nervous tissue remains to be established.
***Lipids 26,* 986–991 (1991).**

Different molecular species of PAF (1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) have been detected in lipid extracts of bovine brain together with ten 1-acyl analogues (1,2). In brain of rats the basal level of PAF, as determined by bioassay, is about 0.25 pmol/g wet weight, but the concentration greatly increases upon treatment with chemoconvulsant drugs or upon electroconvulsion (3).

The role of PAF in the nervous tissue is not known, but several reports have indicated that this lipid mediator may serve some function under physiological and pathological conditions. In fact, it has been shown by Bussolino and colleagues (4) that neurotransmitters induce PAF biosynthesis in chick retina. Furthermore, Kornecki and Ehrlich (5) have shown that, at nanomolar concentrations, PAF can stimulate morphological differentiation of neural cells, but becomes cytotoxic at higher concentrations. On the basis of these findings, it was postulated that PAF might play a physiological role in neuronal development, but might also be involved in some pathological events. The latter possibility is consistent with the observations on the effect of the PAF antagonist BN52021 on cerebral ischemia-reperfusion damages in the gerbil (6). In fact, the injection of the antagonist at the onset of reperfusion clearly reduced brain free fatty acid levels (6), an increase of which has been considered as one of the biochemical indicators for ischemic brain damage (7,8).

Two pathways have been described for PAF biosynthesis in various cell types and tissues (9)—the *de novo* pathway, which produces PAF from CDPcholine and 1-*O*-alkyl-2-acetyl-*sn*-glycerol (alkylacetylG) *via* a diothiothreitol (DTT)-insensitive phosphocholinetransferase (10), and the "remodeling pathway" which leads to the formation of PAF from acetylCoA and 1-*O*-alkyl-*sn*-glycero-3-phosphocholine (lysoPAF) by a lysoPAF acetyltransferase (11).

We have recently demonstrated that a rat brain microsomal fraction contained a phosphocholinetransferase which could convert alkylacetylG and CDPcholine into PAF (12). Since Lee *et al.* (13,14) had previously reported that rat brain tissue can produce alkylacetylG, one can expect that brain should be able to synthesize PAF by the *de novo* route.

In the present study, we have further characterized the rat brain PAF-synthesizing phosphocholinetransferase which was compared with the enzyme responsible for the synthesis of other choline glycerophospholipids. Knowledge of the enzyme properties is essential for the correct assay of enzyme activities.

It is not clear whether nervous tissue can synthesize PAF by the "remodeling pathway". In fact, lysoPAF acetyltransferase activity has not been detected in the microsomal fraction from brain (11) or in synaptosomal preparations (3). On the other hand, PAF biosynthesis by lysoPAF acetyltransferase has been reported in chick retina (4).

In the present study, we provide some evidence for the presence of lysoPAF acetyltransferase in a rat brain microsomal fraction. This finding would indicate that brain tissue is able to synthesize PAF by the "remodeling pathway" as well.

MATERIALS AND METHODS

Brain microsomes were prepared from Sprague-Dawley rats (28–30-days-old) after intracardiac perfusion under light anesthesia (12). Protein concentrations were determined using bovine serum albumin as standard (15). Radioactivity of the products was measured by liquid scintillation counting.

Assay of phosphocholinetransferase. 1-*O*-Hexadecyl-2-acetyl-*sn*-glycerol and 1,2-dioctanoyl-*sn*-glycerol were from Novabiochem (Läufelfingen, Switzerland). Long-chain 1,2-diacyl-*sn*-glycerols were prepared from soybean lecithin and long-chain 1-*O*-alkyl-2-acyl-*sn*-glycerols from ratfish liver oil (16). Diradylglycerols were dispersed by sonication in a convenient volume of 0.03–0.12% Tween-20

[1]Based on a paper presented at the Third International Conference on Platelet-Activating Factor and Structurally Related Alkyl Ether Lipids, Tokyo, Japan, May 1989.

Abbreviations: DO, dioctanoyl; DTT, dithiothreitol; G, glycerol; GPC, glycero-3-phosphocholine; PAF, platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine.

depending on the experiments (12). Unless specified otherwise, phosphocholinetransferase activity was determined by incubating rat brain microsomes (0.05–0.3 mg protein) with 0.1 mM CDP[*methyl*-^{14}C]choline (spec. act. 1–2 nCi/nmol, Amersham, Little Chalfont, England) and 0.2-0.5 mM 1,2-diradylglycerol in a medium containing 60 mM Tris/HCl buffer (pH 8) and 20 mM $MgCl_2$ at 37°C using a final volume of 0.3 mL. Twenty mM DTT (Sigma, St. Louis, MO) was included when activity for PAF synthesis was tested; otherwise DTT was omitted. The concentration of Tween-20 in the incubation medium was 0.005%. Extraction, isolation of labeled choline glycerophospholipids, and their identification were as previously described (12). Lipids were separated by TLC on Silica gel G using chloroform/methanol/acetic acid/water (50:25:8:4, v/v/v/v) as developing solvent (10).

Assay of lysoPAF acetyltransferase. The enzymic activity was assayed as reported by Wykle *et al.* (11) by incubating the homogenate or microsomes from rat brain (0.3–0.5 mg protein) with 0.2 mM [1-^{14}C]acetyl-CoA (Amersham, Little Chalfont, England) and 0.03 mM 1-*O*-alkyl-*sn*-glycero-3-phosphocholine (lysoPAF, Novabiochem) in 100 mM Tris/HCl buffer (pH 6.9). The incubation was carried out at 37°C in a final volume of 0.5 mL. In some experiments acetyltransferase activity was measured in rat spleen microsomes which were prepared according to Wykle *et al.* (11) after having rinsed the isolated organ three times in 0.25 M sucrose containing 1 mM DTT.

The extraction of lipids was performed by the procedure of Bligh and Dyer (17), and labeled PAF was isolated as mentioned above. The reaction product, having the same R_F as authentic 1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine (PAF, Novabiochem), was further purified by TLC and/or HPLC (12) and then hydrolyzed by phospholipase C (*B. cereus*, Boehringer, Mannheim, Germany). The diethyl ether extract was then fractionated by TLC (silica gel G; chloroform/methanol, 98:2, v/v) and radioactivity was recovered together with authentic 1-*O*-hexadecyl-2-acetyl-*sn*-glycerol. The reaction product was able to induce aggregation of washed rabbit platelets, which, in turn, could be completely prevented in the presence of the specific antagonist of PAF receptor binding, BN 52021 (18).

RESULTS

We have previously reported some properties of rat brain phosphocholinetransferase activity which catalyzes the conversion of alkylacetylG to PAF (12). The enzyme is located in the microsomal fraction, requires Mg^{2+} to exhibit activity, and is inhibited by Ca^{2+}. These characteristics are identical to those of the enzymic activity responsible for the synthesis of long-chain diradyl-GPC in this tissue (19,20). Maximal activity of PAF-synthesizing phosphocholinetransferase activity was attained at pH 8 (12) and with 20 mM $MgCl_2$ (data not shown). We have also shown the effect of DTT on the synthesis of PAF, long-chain alkylacyl-GPC and long-chain diacyl-GPC (12). The data are summarized in Figure 1. The effect of DTT on the synthesis of dioctanoyl-GPC is also reported. Our results demonstrate that the presence of DTT in the incubation mixture increases the rate of PAF biosynthesis, whereas it inhibits the synthesis of the ether analogue

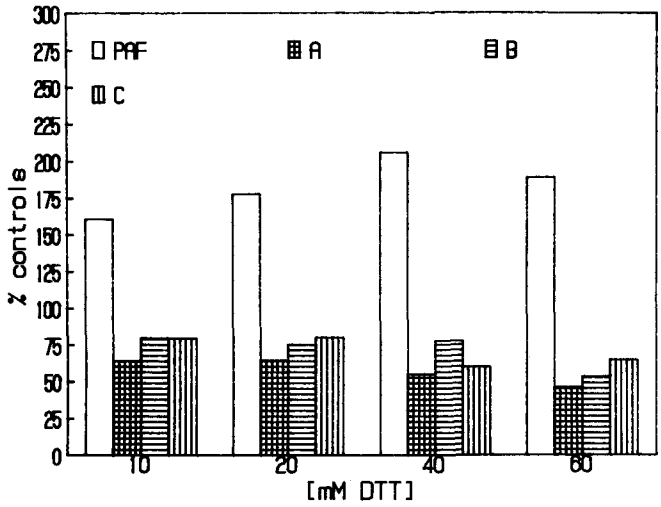

FIG. 1. The effect of DTT on the synthesis of PAF and other choline glycerophospholipids. A, long-chain alkylacyl-GPC; B, long-chain diacyl-GPC; C, dioctanoyl-GPC. Incubation conditions: for PAF, A and B, see reference 12; for dioctanoyl-GPC, 60 mM Tris-HCl buffer (pH 8), 20 mM $MgCl_2$, 0.5 mM dioctanoylG, 0.005% Tween-20, 0.1 mM labeled CDPcholine (spec. act. 1.4 nCi/nmol), 44 μg microsomal protein, 15 min at 37°C, final volume 0.3 mL. Data are representative of four experiments giving similar results.

with a long-chain fatty acid in C-2 position of the glycerol moiety. DTT also inhibits the synthesis of long-chain diacyl choline glycerophospholipids and dioctanoyl-GPC. However, this inhibition was not complete, even at relatively high DTT concentrations.

Because the physical properties of lipid substrates can greatly affect the rate of lipid incorporation into phospholipids by the phosphotransferase reaction, we have in some experiments assayed phosphocholinetransferase activity using 1,2-dioctanoylG as the lipid substrate and have compared the rate of its conversion to dioctanoyl-GPC with the rate of PAF biosynthesis under similar conditions.

Data on the effect of microsomal protein concentration on phosphocholinetransferase activity are presented in Figure 2. Under the conditions indicated, the rate of PAF biosynthesis is essentially linear up to 0.3 mg protein/mL, whereas the rate of 1,2-dioctanoyl-GPC synthesis can be considered proportional to protein concentration at least up to 1 mg protein/mL.

The dependence on CDPcholine concentration of PAF and dioctanoyl-GPC biosynthesis by brain phosphocholinetransferase is shown in Figure 3. Typical Michaelis-Menten kinetics have been obtained with either alkylacetylG or dioctanoylG as substrate. The K_m for CDPcholine was 42 μM with alkylacetylG. This value is similar to that reported for DTT-insensitive phosphocholinetransferase from rat renal inner medulla (21).

We have obtained a slightly higher K_m for CDPcholine when dioctanoylG was used as the lipid substrate (55 μM). Reddy and Horrocks (22) have measured the apparent K_m values for CDPcholine with dioctanoylG using microsomes from rat brain gray and white matter as function of age by assaying the enzyme activity at pH 7.6. With both preparations from 30-day-old rats the K_m was 32 μM.

Under the conditions indicated, the V_{max} values for PAF and dioctanoyl-GPC were 3.0 and 2.2 nmol/mg

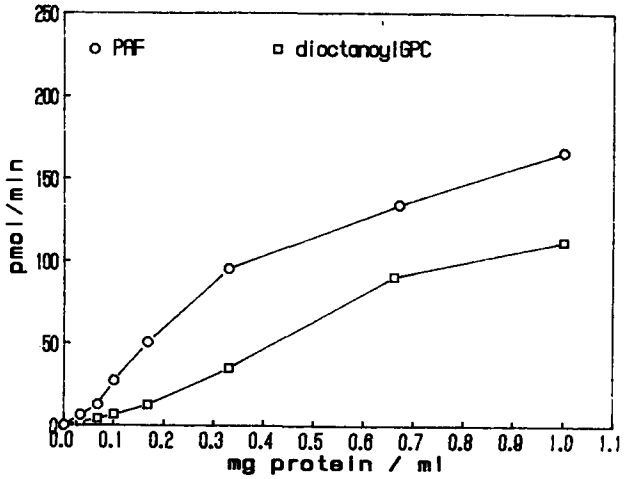

FIG. 2. Effect of microsomal protein concentration on the synthesis of PAF and dioctanoyl-GPC. Incubation conditions: 60 mM Tris-HCl buffer (pH 8), 1 mM alkylacetylG or dioctanoylG, 0.005% Tween 20, 10 mM $MgCl_2$, 0.1 mM labeled CDPcholine (spec. act. 2 nCi/nmol), microsomal protein at the indicated concentrations, at 37°C for 15 min in a final volume of 0.3 mL. PAF-synthesizing phosphocholine-transferase was assayed in the presence of 20 mM DTT. Data are from one experiment in duplicate.

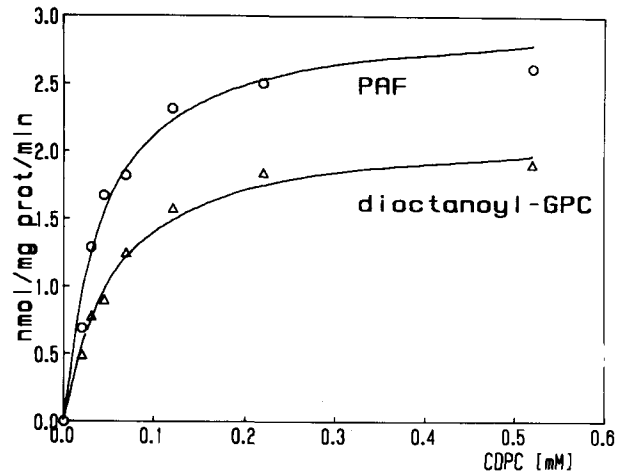

FIG. 3. Dependence of brain phosphocholinetransferase activity on CDPcholine concentration. Incubation conditions: 60 mM Tris-HCl buffer (pH 8), 0.5 mM diradylG, 0.005% Tween 20, 20 mM $MgCl_2$, labeled CDPcholine (spec. act. 50–1.9 nCi/nmol), 90 μg microsomal protein, 37°C for 5 min, in a final volume of 0.3 mL. PAF-synthesizing phosphocholinetransferase was assayed in the presence of 20 mM DTT. Data are the mean of duplicate measurements from one experiment which is representative of two others.

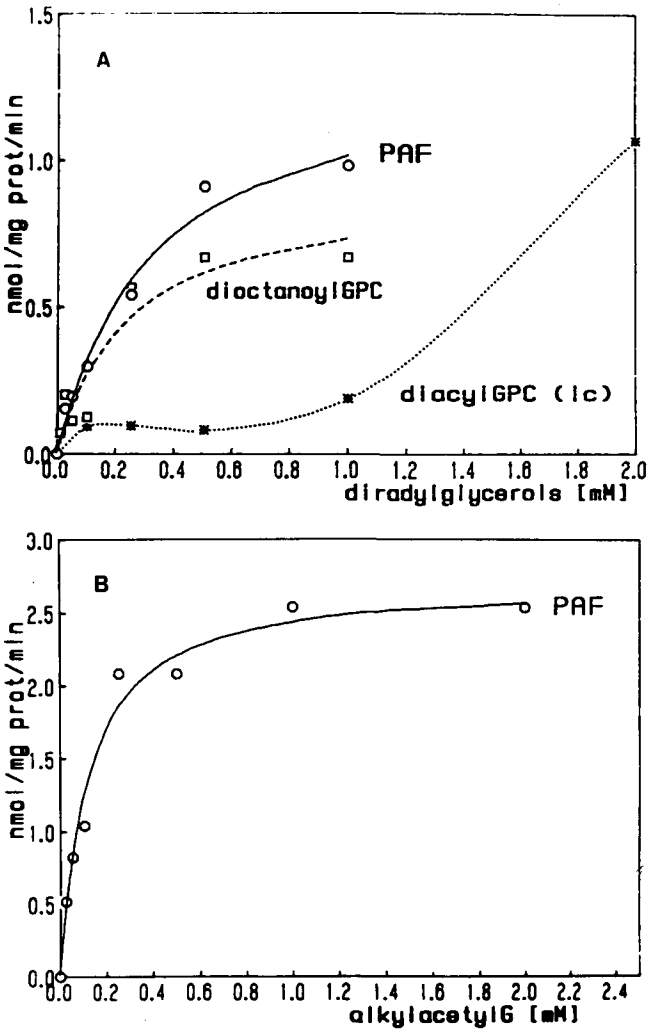

FIG. 4. Dependence of brain phosphocholinetransferase activity on diradylglycerols concentration. A, 60 mM Tris-HCl buffer (pH 8), alkylacetylG and dioctanoylG at the indicated concentrations, 0.005% Tween 20, 10 mM $MgCl_2$, 0.5 mM labeled CDPcholine (spec. act. 0.9 nCi/nmol), 0.12 mg microsomal protein, 37°C for 5 min, in a final volume of 0.3 mL. Data for long-chain diacylglycerol are from reference 12. PAF-synthesizing phosphocholinetransferase was assayed in the presence of 20 mM DTT. B, as above, but 20 mM $MgCl_2$ was used.

prot/min, respectively. Woodard *et al.* (21) found a V_{max} of 9.6 nmol/mg prot/min for PAF biosynthesis by the renal enzyme. Higher values of V_{max} than those given in the present paper have been reported using dioctanoylG as substrate and microsomal preparations from gray (5.1 nmol/mg protein/min) and white matter (4.7 nmol/mg protein/min) of brain from 30-day-old rats (22).

The dependence of brain phosphocholinetransferase activity on diradylG concentration is reported in Figure 4. Under the conditions indicated, saturation of the enzyme was achieved with 0.5 mM alkylacetylG or dioctanoylG. Using long-chain diacylG as the lipid substrate, kinetics did not satisfy the Michaelis-Menten equation (Fig. 4A). The apparent K_m for dioctanoylG (230 μM) was lower than that for alkylacetylG (312 μM). However, both values are much higher than those reported by Woodard *et al.* (21) for 1,2-dioleoylG and alkylacetylG with microsomes from rat inner renal medulla. The V_{max} values for alkylacetylG were higher than those for dioctanoylG, averaging 1.3 and 0.9 nmol/mg prot/min, respectively. However, at higher Mg^{2+} concentration (20 mM), V_{max} for alkylacetylG was 2.7 nmol/mg prot/min and the apparent K_m was 115 μM (Fig. 4B).

We have carried out experiments for studying thermal stability of phosphocholinetransferase using alkylacetylG or dioctanoylG as substrates. Preliminary experiments had indicated that preincubation of the microsomes for

15 min at 60°C caused an essentially complete inactivation of PAF-synthesizing enzyme and of DTT-sensitive phosphocholinetransferase. Further experiments were carried out by preincubating microsomes for various time-intervals at 60°C and then measuring phosphocholine-transferase activity with alkylacetylG or dioctanoylG as the lipid substrates (Table 1). In the absence of DTT, preincubation of microsomes for 5 min at 60°C did not cause inhibition of PAF biosynthesis, whereas synthesis of dioctanoyl-GPC was reduced to 80% of the control sample, which had not been preincubated. Preincubation of microsomes for 10 min or 15 min without DTT inhibited the synthesis of dioctanoyl-GPC more than that of PAF.

When DTT was present in the medium during the preincubation period at 60°C, incorporation of both dioctanoylG and alkylacetylG into the corresponding cholinephospholipids was much reduced and this became evident after 5 min. Similar results have been obtained by preincubating microsomes at 55°C. In this case, complete inactivation of the enzymic activities was achieved after 8 min when DTT was included in the incubation system. In its absence, the synthesis of dioctanoyl-GPC was reduced by about 35% after 15 min and no effect was observed on PAF biosynthesis.

Another series of experiments was performed to estimate the capability of rat brain microsomes to synthesize PAF by acetylCoA:lysoPAF acetyltransferase, the enzyme catalyzing the last step of the "remodeling pathway". The enzyme activity was determined according to the procedure described by Wykle *et al.* (11). The rate of the incorporation of the labeled acetyl group into PAF was three-fold higher in the microsomes than in the homogenate. As shown in Figure 5, the incorporation of the labeled precursor into PAF was essentially linear with time up to 10 min. No radioactivity co-migrated with authentic PAF after TLC analysis of samples that had not been incubated or had been incubated for 30 min with microsomes which had been boiled for 5 min. The acetyltransferase activity measured was proportional to microsomal protein concentration up to 0.6 mg prot/mL (Fig. 6).

The specific activity of rat brain microsomal acetyltransferase was 0.12 ± 0.013 (n=5) nmol/mg prot/min.

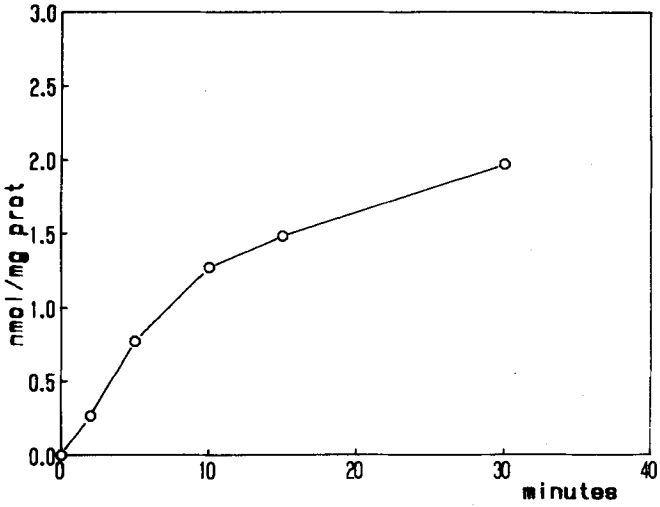

FIG. 5. Time course for the incorporation of labeled acetyl into PAF. Incubation conditions: 0.1 M Tris/HCl (pH 6.9), 0.03 mM 1-*O*-hexadecyl-*sn*-glycero-3-phosphocholine (lysoPAF), 0.2 mM [1-^{14}C]acetyl-CoA (spec. act. 2.04 nCi/nmol), 0.25 mg microsomal proteins, in a final volume of 0.5 mL. The incubation was carried out at 37°C. Data represent the mean of duplicate determinations from one experiment which is representative of another which gave similar results.

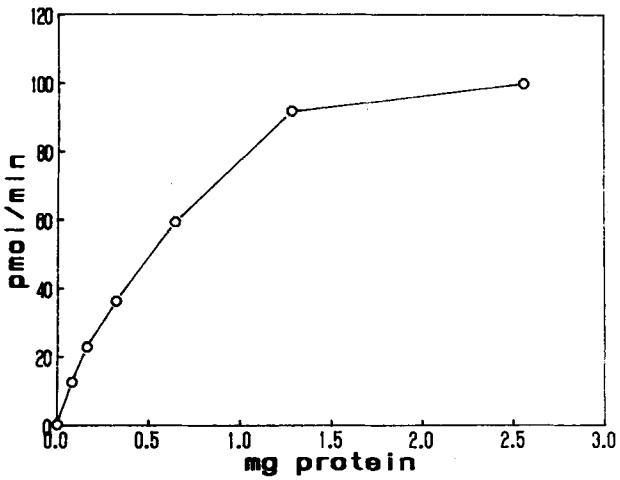

FIG. 6. Dependence of brain acetyltransferase activity on protein concentration. Incubation conditions: 0.1M Tris/HCl (pH 6.9), 0.03 mM lysoPAF, 0.2 mM [1-^{14}C]acetyl-CoA (spec. act. 2.04 nCi/nmol), microsomal protein at the indicated concentrations, 15 min, 37°C, 0.5 mL final volume. Data are the mean of duplicate determinations.

TABLE 1

Effect of Preincubation at 60°C of Brain Microsomes on Phosphocholinetransferase Activity[a]

Product	Addition	Preincubation time (min) 2	5	10	15
PAF	None	—	113.0	54.4	24.8
	DTT	95.5	5.5	1.6	1.5
DO-GPC	None	—	78.0	17.2	18.0
	DTT	87.7	3.9	1.4	1.2

[a]Microsomes were resuspended in 90 mM Tris/HCl (pH 8), or in the same buffer containing 20 mM DTT, and preincubated at 60°C for the indicated periods of time. The incubation was carried out at 37°C for 15 min in a medium containing: 60 mM Tris/HCl buffer (pH 8), 20 mM $MgCl_2$, 0.5 mM alkylacetylG or dioctanoylG, 0.005% Tween-20, 0.1 mM labeled CDPcholine (spec. act. 1.66 nCi/nmol) and 70 μg microsomal protein. Data (mean of duplicate samples) are expressed as % of the enzyme specific activity of non preincubated samples. DO-GPC, dioctanoyl-GPC.

This value is much lower than that reported for the enzyme in microsomes of rat spleen (11), but is very similar to that reported by Bussolino *et al.* (4) for the retina. We have done two experiments to assay acetyltransferase activity in rat spleen microsomes and, under our conditions, we measured a specific activity of 0.23 nmol/mg protein/min, which is very low with respect to the value reported by Wykle *et al.* (11), but closer to that reported by others (23).

DISCUSSION

There is some evidence (24,25) that in nervous tissue long-chain diacyl-GPC and long-chain alkylacyl-GPC are

synthesized by the same phosphocholinetransferase, but it is not known whether or not this enzyme catalyzes the conversion of alkylacetylG to PAF. We earlier reported the presence in rat brain of a phosphocholinetransferase activity that can convert CDPcholine and alkylacetylG to PAF (12). We also described some of its characteristics (*i.e.*, subcellular localization, Mg^{2+} requirement, inhibition by Ca^{2+}) that are similar to those identified for the synthesis of long-chain choline glycerophospholipids (19,20). However, other properties, such as the dependence of enzyme activity on pH and, more evidently, the effect of DTT, have indicated the possibility that a distinct enzyme catalyzes the biosynthesis of PAF in brain tissue (12). In fact, the presence of DTT in the incubation medium inhibits the incorporation of long-chain alkylacylG, long-chain diacylG and dioctanoylG into the corresponding choline glycerophospholipids, whereas it has a stimulatory effect on the incorporation of alkylacetylG into PAF. These findings confirm previous data obtained with microsomal preparations from other tissues (10,21) which suggested that the DTT-insensitive phosphocholinetransferase possesses a strong specificity for alkylglycerol having a very short carbon chain at the 2-position of the glycerol moiety. In addition, it should be pointed out that, even at relatively high concentrations, DTT is not able to completely inhibit the activity of the brain phosphocholinetransferase which synthesizes long-chain choline glycerophospholipids and dioctanoyl-GPC. Due to this, we cannot exclude a certain contribution of DTT-sensitive phosphocholinetransferase activity to the synthesis of PAF in our assay system where we have included 20 mM DTT, which inhibits this enzyme activity by 25–30% only. In the future, other sulfhydryl reagents should be tested to find a more discriminatory tool to distinguish the two phosphocholinetransferase activities.

The possibility that two distinct enzymes are present in rat brain with different specificity for alkylacetylG and other diradylG is substantiated by the studies on the thermal stability of the enzymes. In fact, the data reported in Table 1 indicate that the PAF-synthesizing enzyme possesses a higher stability since the preincubation of microsomes at 60°C causes an earlier inhibition of the synthesis of dioctanoyl-GPC with respect to that of PAF. This finding is in agreement with data by Woodard *et al.* (21) who also reported a higher thermal stability of PAF-synthesizing enzyme of rat kidney medulla by pretreating microsomes for 15 min at various temperatures. It is also of interest to re-emphasize the rapid inhibition of the synthesis of PAF and of dioctanoyl-GPC at 60°C when DTT was present in the incubation system. At present, we have no explanation for this phenomenon.

The studies of the kinetic properties of brain phosphocholinetransferase have shown that the K_m values for CDPcholine are very similar when alkylacetylG or dioctanoylG are used as the lipid substrates and that the values are also very close to those reported for microsomes from inner renal medulla with alkylacetylG or long-chain diacylglycerol (21). The V_{max} for the synthesis of PAF in brain is three times lower than that measured for the renal enzyme (21).

Brain tissue contains 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholine which represents about 5% of the total choline glycerophospholipids (26). This ether lipid is considered to be the metabolic precursor for the synthesis of PAF by the "remodeling pathway" (27). In brain, it is synthesized by a phosphocholinetransferase which utilizes long-chain alkylacylG as the lipid precursor (25).

It has also been demonstrated that brain tissue possesses a phospholipase A_2 activity which hydrolyzes 1-*O*-alkyl-2-acyl-GPC to produce the corresponding 2-lyso derivative (28,29).

The present paper reports preliminary results showing the presence in the rat brain of an acetyltransferase activity which is able to convert lysoPAF into PAF. Its specific activity is very low if compared to the activities reported for other tissues, but it is possible that it has been underestimated since conditions have not been optimized. Furthermore, it is known that acetyltransferase of rat spleen microsomes is activated by phosphorylation (23), and it cannot be excluded that the brain enzyme is regulated by the same mechanism. In this case, a loss of activity might have occurred during homogenization by dephosphorylation of the enzyme.

On the basis of our findings, we can conclude that rat brain possesses the capability of synthesizing PAF by the "remodeling pathway" in addition to the *de novo* pathway. It will be necessary to establish the role of the two metabolic routes in the brain. This task is made more difficult because different brain areas and different cell populations are known to have very different functions and it is quite possible that the enzymic activities responsible for PAF biosynthesis by the two pathways may be of different importance in glial and neuronal cells and in different brain regions. For instance, we have demonstrated that the specific activity of phosphocholinetransferase for the synthesis of long-chain diacylGPC is higher in neuronal cells than in glial cells (20). The same is true for phospholipase A_2, which is about five-fold higher in neurons than in glia (30).

The regulation of brain choline glycerophospholipid synthesis takes place mainly at the level of the cytidylyltransferase reaction (20,31) which produces CDPcholine from phosphocholine and CTP. CDPcholine is a common substrate for the synthesis of long-chain choline glycerophospholipids and PAF by the *de novo* pathway. Since the affinity for CDPcholine of PAF-synthesizing phosphocholinetransferase is very similar to that of the enzyme responsible for the synthesis of diradyl-GPC, having a longer chain at C-2 of the glycerol moiety, the relative rate of PAF biosynthesis might depend on the availability of the lipid substrate alkylacetylG. This hypothesis is supported by the data reported by Bussolino *et al.* (32) who found an increase of the concentration of alkylacetylG after stimulation of the retina with acetylcholine or dopamine in parallel with an increased rate of PAF biosynthesis *via* phosphocholinetransferase.

The mechanism for the regulation of brain phospholipase A_2 is not known and it remains to be established whether the same enzyme is responsible for the degradation of diacyl-, alkenylacyl- and alkylacyl-GPC. However, it is known that under certain pathological conditions (*e.g.*, ischemia and epilepsy), brain phospholipase A_2 becames more active and releases fatty acids from membrane phospholipids (7,8,33). As in other cell types and tissues, the activation of phospholipase A_2 would lead to the production of lysoPAF for the synthesis of PAF by the activated form of acetyltransferase (27,34,35). It also should be considered that PAF levels in brain are

regulated by the activity of acetylhydrolase which inactivates specifically PAF (3,36).

In conclusion, it appears that brain tissue is capable of synthesizing PAF by the DTT-insensitive phosphocholine-transferase and by the "remodeling pathway". As proposed by Snyder (9), the first pathway might be responsible for the production of PAF to maintain physiological levels, whereas the second pathway might be responsible for the abnormal PAF levels produced under pathological conditions or/and in situations of metabolic stress.

The Metabolism of 1-Acyl-PAF in Rabbit Platelets And Its Possible Interaction With PAF[1]

Lhousseine Touqui*, Clystenes Soares Silva[2] and Bernardo Boris Vargaftig
Unite de Pharmacologie Cellulaire, Unite Associee INSERM/Pasteur U.285, Institut Pasteur, 75015 Paris, France

The metabolism of 1-acyl-2-acetyl-*sn*-glycero-3-phosphocholine (1-acyl-PAF), a naturally occurring analogue of platelet activating factor (PAF), was investigated in rabbit platelets. Our studies showed that 1-acyl-[^{3}H]PAF (1-palmitoyl-2-acetyl-*sn*-glycero-3-phospho[*N-methyl*-^{3}H]-choline) was converted by platelets into phosphatidyl-[^{3}H]choline ([^{3}H]PC) in a time-dependent fashion. The formation of [^{3}H]PC occurred at a rate similar to that observed when lyso-[^{3}H]PC (palmitoyl-*sn*-glycero-3-phospho[*N-methyl*-^{3}H]choline) was used as substrate. In addition, a time-dependent increase in the level of water-soluble radioactivity was observed during the incubation of platelets with either 1-acyl-[^{3}H]PAF or lyso-[^{3}H]PC. This increase was parallel to the formation of [^{3}H]PC and was not observed in the presence of [^{14}C]PAF (1-octadecyl-2-acetyl-*sn*-glycero-3-phospho[*N methyl*-^{14}C]-choline). Analysis by thin-layer chromatography showed that the soluble radioactivity was mainly associated with glycerophosphocholine (GPC). On the other hand, the preincubation of platelets with phenylmethylsulfonyl fluoride, an inhibitor of the acetylhydrolase, reduced the hydrolysis of 1-acyl-[^{3}H]PAF to [^{3}H]GPC with a concomitant accumulation of radioactivity in 1-acyl-PAF. These findings suggest that 1-acyl-PAF is converted into PC through deacetylation-reacylation with lysoPC as an obligatory intermediate. The findings also indicate that the lysoPC resulting from 1-acyl-PAF is either reacylated to phosphatidylcholine (PC) or hydrolyzed to GPC by lysophospholipase. Finally, we showed that the stimulation of platelets with PAF led to a time- and concentration-dependent increase in the conversion of 1-acyl-[^{3}H]PAF to [^{3}H]PC. The stimulatory effect of PAF was not observed when platelets were lysed before incubation, suggesting that PAF enhances the metabolism of 1-acyl-PAF, probably by accelerating its translocation through the plasma membrane.
***Lipids 26,* 992–996 (1991).**

PAF (platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) is a potent mediator of platelet aggregation involved in inflammation and allergy. It is actively produced by a variety of cells, including platelets, through a calcium-dependent mechanism. The biosynthesis of PAF involves the deacylation-reacetylation of its inactive precursor 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholine (alkylacyl-GPC) by a phospholipase A_2 and an acetyltransferase. Conversely, PAF is inactivated by a deacetylation reaction catalyzed by a calcium-independent acetylhydrolase found both in plasma and in the cytosolic fraction of the cell. This reaction leads to the generation of the inactive metabolite lysoPAF which, in turn, is reacylated by transacylases into alkylacyl-GPC (1,2). Polymorphonuclear leukocytes (PMN) (3,4) and platelets (5,6) produce a 1-acyl analogue of PAF (containing an ester linkage at the *sn*-1 position) upon stimulation with the calcium ionophore A23187. 1-Acyl-PAF (1-acyl-acetyl-*sn*-glycero-3-phosphocholine) represents approximately 40% and 30% of the total amount of PAF-like materials produced by stimulated PMN and platelets, respectively. Rat spleen microsomes contain an acetyltransferase activity which converts lysophosphatidylcholine (lysoPC) into 1-acyl-PAF (7,8). This enzyme seems to be identical to the acetyltransferase involved in the acetylation of lysoPAF. Unlike PAF, 1-acyl-PAF can be hydrolyzed by a phospholipase A_1 (PLA_1) leading to the formation of water-soluble acetylglycerophosphocholine (6). It has been shown that 1-acyl-PAF is 200- to 500-fold less active than PAF in inducing platelet aggregation (9,10), suggesting that this analogue might not have physiological functions. Although the biological role of this unique lipid molecule is not yet clear, it represents an important part of the total amount of PAF-like material produced in stimulated PMN and platelets (3–6) and probably in other cells. So, it will be of importance to compare the biochemical properties of PAF and that of 1-acyl-PAF in various types of cells.

MATERIALS AND METHODS

Materials. [^{3}H]PC (1,2 dipalmitoyl-*sn*-glycero-3-phospho-[*N-methyl*-^{3}H]choline, 40–80 Ci/mmol) and [^{14}C]PAF (1-*O*-octadecyl-2-acetyl-*sn*-glycero-3-phospho[*N-methyl*-^{14}C]choline, 50–60 mCi/mmol) were from Amersham Corp. (Arlington Heights, IL). 1-Acyl-[^{3}H]PAF (1-palmitoyl-2-acetyl-*sn*-glycero-3-phospho[*N-methyl*-^{3}H]-choline) and lyso[^{3}H]PC (1-palmitoyl-*sn*-glycero-3-phospho[*N-methyl*-^{3}H]choline) were prepared as indicated below. Unlabelled phospholipids (PC, lysoPC, PAF), bee venom phospholipase A_2 (PLA_2), and bovine serum albumin (BSA) were from Sigma Chemical Co. (St. Louis, MO). Synthetic 1-acyl-PAF was the generous gift of Dr. F. Heymans (Laboratoire de Pharmacochimie Moléculaire, Université Paris VII, France). Plastic silica gel plates for thin-layer chromatography (TLC) and organic solvents were from Merck, Ltd. (Darmstadt, West Germany).

Preparation of radioactive 1-acyl-PAF. [^{3}H]PC (50 μCi) was hydrolyzed by 30-min incubation with 10 μg of bee venom PLA_2 in Tyrode's buffer containing 2 mM Ca^{2+}. The lyso-[^{3}H]PC produced by this hydrolysis was then converted into 1-acyl-[^{3}H]PAF (1-palmitoyl-2-acetyl-*sn*-

Abbreviations: 1-acyl-PAF, 1-acyl-2-acetyl-*sn*-glycero-3-phosphocholine; DMSO, dimethylsulfoxide; EDTA, ethylenediaminetetraacetic acid; EGTA, ethylene glycol *bis*(aminoethyl ether)*N,N,N',N'*-tetraacetic acid; GPC, glycerophosphocholine; lysoPC, lysophosphatidylcholine; PAF, platelet activating factor; PC, phosphatidylcholine; PLA_1, phospholipase A_1; PLA_2, phospholipase A_2; PMN, polymorphonuclear leukocytes; PMSF, phenylmethylsulfonyl fluoride; TLC, thin-layer chromatography.

glycero-3-phospho[*N-methyl*-^{3}H]choline) by acetylation according to the method of Wientzek *et al.* (11). Briefly, 120 μL of pyridine, 80 μL of acetic anhydride and 2 μL of perchloric acid were added sequentially to a glass tube containing 30 μCi of radioactive lysoPC. After 60 min incubation at 70°C, the solvents were evaporated to dryness with nitrogen, and lipids were separated by phase partition according to Bligh and Dyer (12). The solvent of the organic (lower) phase was evaporated to dryness and the residue redissolved in 50 μL of chloroform/methanol (2:1, v/v) and subjected to TLC with chloroform/methanol/ammonia (70:35:7, v/v/v) as mobile phase. Unlabelled phospholipids (PAF, lysoPAF, 1-acyl-PAF and lysoPC) were applied onto the same plate as standards and visualized with iodine vapors. The plates were divided into 34 bands (0.5 cm width) which were scraped into scintillation vials containing 5 mL of ACS II and radioactivity was determined by scintillation counting. Radioactive 1-acyl-PAF migrated as a single band closely corresponding to PAF (Rf = 0.41). The fractions containing radioactive 1-acyl-PAF were scraped off and extracted as indicated above. The solvent of the organic phase was evaporated to dryness and the residue resuspended in 100 μL of ethanol and stored at −20°C until use.

Preparation and lysis of platelets. Blood was collected from the central ear artery of adult New Zealand rabbits directly into a 5 mM solution of ethylenediaminetetraacetic acid (EDTA) and the platelets were washed according to the method of Ardlie *et al.* (13). The final suspension (5 × 10^8 platelets/mL) was in calcium-free Tyrode's buffer containing 1 mM ethylene glycol *bis*(aminoethyl ether)*N,N,N',N'*-tetraacetic acid (EGTA) and 2.5 mg/mL gelatin. Aliquots of platelet suspensions were kept in an ice bath, lysed by sonication (30 seconds, twice), using a MSE sonifier at its maximum output, and then kept at −80°C until use.

Metabolic studies. Suspensions (2.5 mL) from intact or lysed platelets were incubated with 5 × 10^4 cpm/mL of 1-acyl-[^{3}H]PAF, lyso-[^{3}H]PC or [^{14}C]PAF added in ethanol solution (0.1% final). The final concentration of each lipid was adjusted to 10 nM by the addition of unlabelled compound. In some experiments, unlabelled PAF was added to platelets at the concentrations indicated in Figure 5 immediately before incubation with 1-acyl-[^{3}H]PAF (in the absence of unlabelled 1-acyl-PAF). At the times indicated (see Figures), aliquots (0.5 mL) were transfered into Eppendorf tubes containing 1 mL of methanol/chloroform (1:1, v/v) and maintained at 4°C. Phase partition was promoted by 2-min centrifugation at 12,000 rpm. Samples (100 μL) from the aqueous phases were carefully aspirated and their radioactivity measured by liquid scintillation counting. Finally, the lipids were extracted from the organic phases according to Bligh and Dyer (12). The radioactivity associated with the organic and aqueous phases were analyzed by TLC, as indicated below.

In other experiments, suspensions from lysed platelets were treated for 10 min at 37°C with increasing concentrations of phenylmethylsulfonyl fluoride (PMSF) or with dimethylsulfoxide (DMSO, 0.25% v/v) before addition of 1-acyl-[^{3}H]PAF or lyso[^{3}H]PC. After 30 min incubation, the reactions were stopped and the extracts were analyzed as indicated above.

TLC analysis. The organic phases of platelet extracts were evaporated to dryness under nitrogen and resuspended in 50 μL of chloroform:methanol (2:1, v/v). The radioactivity contained in 5 μL of these suspensions was measured by liquid scintillation spectrophotometry to determine the yield of extraction. The remaining suspensions (45 μL) were submitted to TLC on plastic silica gel plates using chloroform/methanol/ammonia (70:35:7, v/v/v; System A) as mobile phase. Unlabelled PAF, lysoPAF, lysoPC, 1-acyl-PAF and PC were also applied onto the same plates as standards. Hundred-μL aliquots from aqueous phases were boiled for 10 min (100°C) and then applied to plastic silica gel plates. The plates were developed in a solvent system consisting of methanol/2.4% NaCl/water/ammonia (50:12.5:17.5:5, v/v/v/v) (System B). This system was adapted from that described by Vance *et al.* (14) and allowed good separation of phosphocholine and glycerophocholine (Rf = 0.35 and 0.47, respectively). The plates were then divided into 17 bands and radioactivity of the fractions was determined by liquid scintillation counting.

RESULTS AND DISCUSSION

Rabbit platelets were incubated with radioactive 1-acyl-PAF for various time periods and then extracted by addition of chloroform/methanol (see Methods). The radioactivity associated with the organic phase was analyzed by TLC. It was shown that the content of 1-acyl-PAF decreased progressively with a concomitant increase in PC (Fig. 1). The radioactivity associated with lysoPC

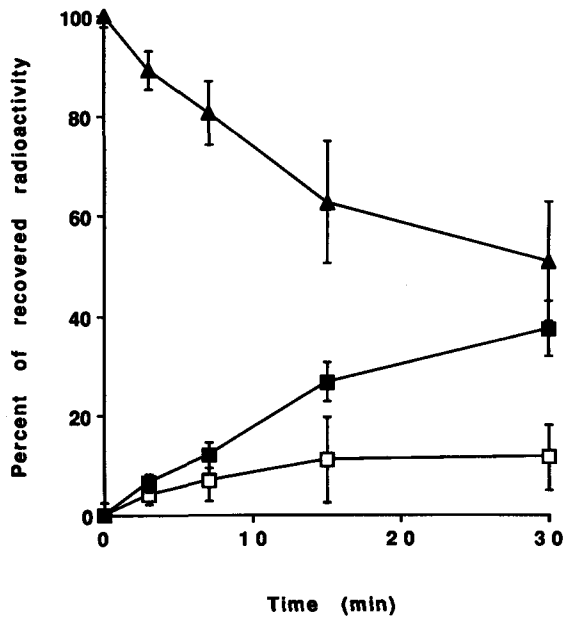

FIG. 1. Conversion of 1-acyl-PAF by intact platelets. The platelet suspension was incubated at 37°C with 1-acyl-[^{3}H]PAF (10 nM, 5 × 10^4 cpm/mL, final conc.). Aliquots (0.5 mL) were collected at the times indicated. The lipids were extracted and analyzed by TLC as described in the Methods section. The Figure shows the variation in the radioactivity associated to 1-acyl-PAF (▲), PC (■) and lysoPC (□) expressed as percentage of the radioactivity recovered from the organic phase. The results are representative for four separate experiments.

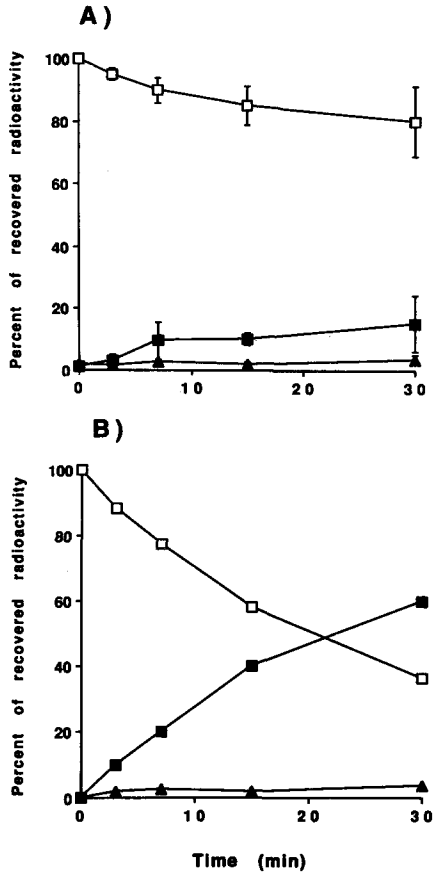

FIG. 2. Comparative metabolism of lysoPC in intact and lysed platelets. Suspensions from intact (A) or lysed (B) platelets were incubated at 37°C with lyso-[^{3}H]PC (10 nM, 5×10^4 cpm/mL). Lipid extraction and analysis were carried out as detailed in the Methods section. The Figure shows the radioactivity associated to PC (■) and lysoPC (□) expressed as percent of the radioactivity recovered from the organic phase. No significant radioactivity was associated with 1-acyl-PAF (▲).

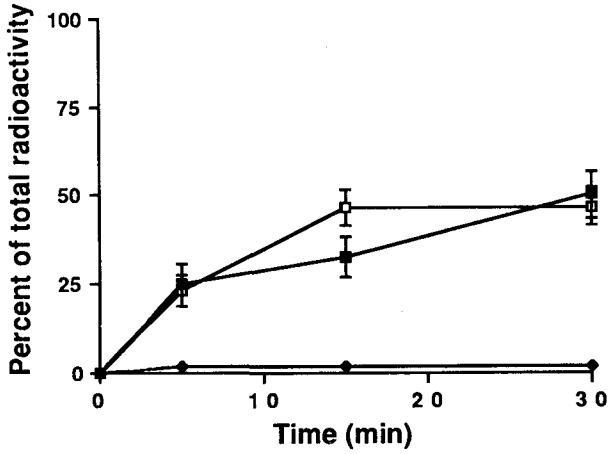

FIG. 3. Release of water-soluble radioactivity during the incubation of platelet lysates with 1-acyl-PAF, lysoPC or PAF. Platelet lysates were incubated separately with 1-acyl-[^{3}H]PAF, lyso-[^{3}H]PC or [^{14}C]PAF as indicated in the Methods section. After 30 min incubation, aliquots (0.5 mL) were transferred into Eppendorf tubes containing 1 mL of chloroform/methanol (1:1) and maintained at 4°C. Phase partition was promoted by centrifugation at 12,000 rpm for 2 min. Samples (100 μL) from the aqueous phases were carefully aspirated and their radioactivity measured by liquid scintillation counting. The Figure shows the recovery of radioactivity from the aqueous phase during incubation of platelet lysates with 1-acyl-[^{3}H]PAF (■), lyso-[^{3}H]PC (□) or [^{14}C]PAF (◆). All lipids were radiolabelled at the *sn*-3 position in the choline group.

remained constant over the time period examined. This suggests that platelets convert 1-acyl-PAF into PC through a deacetylation-reacylation reaction and that lysoPC is a transient intermediate in this conversion. However, intact platelets convert exogenous lysoPC into PC to a much lesser extent that is observed with 1-acyl-PAF (Fig. 2A); this conversion was markedly increased when platelets were lysed by ultrasonication before the addition of lysoPC (Fig. 2B). This result is in accordance with our previous findings (15) and supports the hypothesis that the platelet plasma membrane is poorly permeable to exogenous lysophospholipids. On the other hand, the recovery of radioactivity associated with the organic phase decreased following the incubation of platelets with 1-acyl-[^{3}H]PAF (data not shown), suggesting that 1-acyl-PAF was hydrolyzed to yield water-soluble products. Indeed, in contrast to PAF, 1-acyl-PAF can be hydrolyzed at the *sn*-1 position by *in vitro* incubation with PLA_1, which leads to the generation of water-soluble products (6). This procedure was used in the present study to investigate the ability of platelets to hydrolyze 1-acyl-PAF at the *sn*-1 position (i.e., PLA_1 or lysophospholipase). We showed that the incubation of platelet lysates with 1-acyl-[^{3}H]PAF led to a time-dependent increase of the water-soluble radioactivity which reached 35–45% of the total radioactivity added after 30 min (Fig. 3). This increase was parallel to that observed when platelets were incubated with lyso[^{3}H]PC instead of 1-acyl-[^{3}H]PAF (Fig. 3). However, no significant increase of water-soluble radioactivity was observed when platelets were incubated with [^{14}C]PAF (also labelled at the *sn*-3 position). TLC analysis (System B) showed that the water-soluble radioactivity derived either from 1-acyl-[^{3}H]PAF or lyso[^{3}H]PC comigrated with glycerophosphocholine (GPC) (Fig. 4). This suggests that a lysophospholipase-type activity was involved in the hydrolysis of 1-acyl-PAF. One would expect that 1-acyl-PAF is first deacetylated by the acetylhydrolase and that the resulting lysoPC is subsequently hydrolyzed by a lysophospholipase to produce GPC. However, it could be argued that 1-acyl-PAF could be first hydrolyzed at the *sn*-1 position by a PLA_1-like enzyme before its deacetylation. The results of Figure 5 show that preincubation of platelets with phenylmethylsulfonyl fluoride (PMSF), a potent inhibitor of acetylhydrolase (15), led to the inhibition of the hydrolysis of 1-acyl-[^{3}H]PAF to [^{3}H]GPC (Fig. 5) with a concomitant accumulation of radioactivity in 1-acyl-PAF (data not shown). This would support the hypothesis that 1-acyl-PAF is first deacetylated before its hydrolysis to GPC. However, this interepretation must be considered with caution because PMSF also inhibited lysophospholipase activity (i.e., hydrolysis of lysoPC to GPC) (Fig. 5). The sensitivity of this enzyme to serine protease inhibitors has been previously reported by van den Bosch *et al.* (16).

Finally, we examined whether the metabolism of 1-acyl-PAF could be regulated by the stimulation of platelets

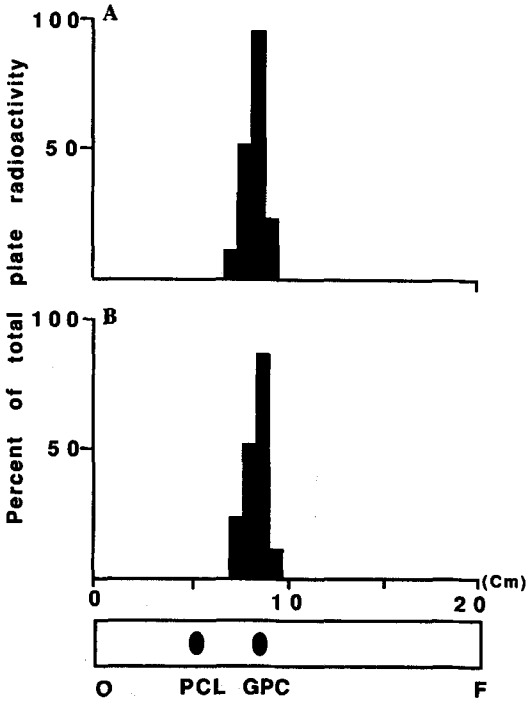

FIG. 4. Thin-layer chromatographic analysis of the water-soluble radioactivity released from 1-acyl-PAF (A) and lysoPC (B). Aliquots (0.5 mL) from platelet lysates were incubated with 1-acyl-[^{3}H]PAF or lyso-[^{3}H]PC for 30 min at 37°C. After phase partition (see above), samples (200 μL) were collected from the aqueous phase, boiled for 10 min and then applied onto plastic silica gel plates. The solvent system (System B) consisted of methanol/NaCl 2.5%/water/ammonia (50:12.5:17.5:5). The Figure shows thin-layer chromatographic distribution of the water-soluble radioactivity derived from 1-acyl-PAF (A) or from lysoPC (B). Similar results were obtained in three separate experiments. GPC and PCL refer to glycerophosphocholine and phosphocholine standards, respectively. O, origin; F, front.

with PAF. Figure 6 shows that addition of unlabelled PAF to intact platelets led to a marked increase of the conversion of 1-acyl-[^{3}H]PAF to [^{3}H]PC. This effect was dependent on the concentration of PAF added and reached maximal levels within 30 min. It occurred in the absence of extracellular calcium and was not

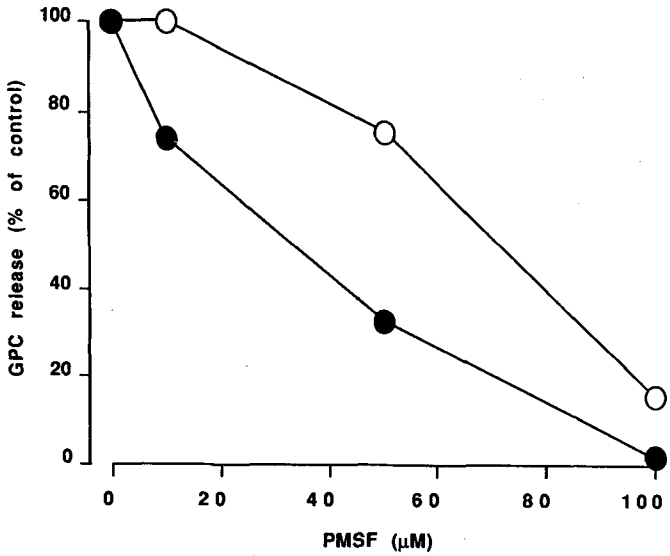

FIG. 5. Effect of PMSF on the hydrolysis of 1-acyl-PAF and lysoPC to GPC by lysed platelets. Suspensions from lysed platelets were pretreated for 10 min with increasing concentrations of PMSF or DMSO (0.25% final conc.) as control and then incubated for 30 min at 37°C with 1-acyl-[^{3}H]PAF or lyso-[^{3}H]PC. The recovery of [^{3}H]GPC in the aqueous phase was measured as indicated in the Methods section. The results show the effect of PMSF on the hydrolysis of 1-acyl-[^{3}H]PAF (○) or lyso-[^{3}H]PC (●) to [^{3}H]GPC and are expressed as percent of control (DMSO-treated platelets).

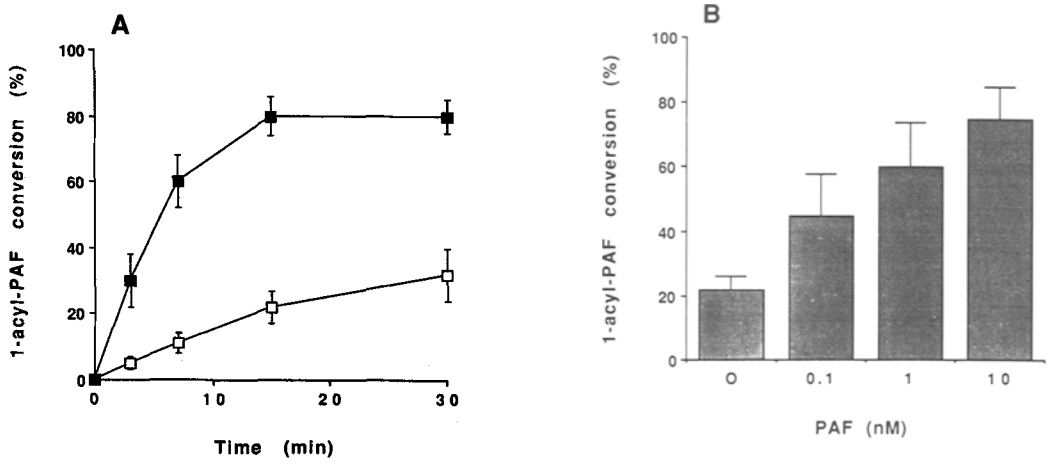

FIG. 6. Effect of PAF on the conversion of 1-acyl-PAF into PC by intact platelets. The time-course (A) and the concentration-dependent effect (B) are shown. (A) Platelets were incubated with 10 nM of unlabelled PAF or with BSA (0.25% final conc., as control) before addition of 1-acyl-[^{3}H]PAF. At the indicated time points, the reactions were stopped and the formation of [^{3}H]PC was measured as indicated above; [control (□), PAF-stimulated platelets (■)]. (B) 1-Acyl-[^{3}H]PAF was incubated together with platelets for 20 min in the presence of PAF at increasing concentrations. The results are expressed as percentage of the radioactivity recovered from the organic phase.

accompanyied by an aggregation or release reaction (data not shown). Thus, the effect of PAF on the conversion of 1-acyl-PAF seems to be independent of the platelet activation. On the other hand, the addition of PAF to lysed platelets had no significant effect on the conversion of 1-acyl-PAF (data not shown), suggesting that PAF stimulates the metabolism of 1-acyl-PAF, probably by accelerating its transmembrane movements. Such a process has been reported to be involved in the regulation by PAF of its own metabolism (17,18).

We conclude that rabbit platelets metabolize 1-acyl-PAF to PC through a deacetylation/reacylation reaction with lysoPC as intermediate. The deacetylation of 1-acyl-PAF is probably catalyzed by an acetylhydrolase similar to that involved in the hydrolysis of PAF. The ability of this enzyme to deacetylate 1-acyl-PAF has been suggested earlier by the studies of Blank *et al.* (19). Other studies (7) have shown that 1-acyl-PAF is formed by the acetylation of lysoPC, which, in turn, results from the hydrolysis of PC by PLA_2. Taken together, these findings suggest that 1-acyl-PAF is metabolized through a metabolic cycle similar to that previously described for PAF (1,2,14) and that 1-acyl-PAF may actively participate in the turnover of PC (Lands pathway). In addition, the lysoPC formed by hydrolysis of 1-acyl-PAF is also cleaved at the *sn*-1 position by a lysophospholipase-dependent reaction leading to the generation of GPC. However, the possibility that 1-acyl-PAF could be hydrolyzed at the *sn*-1 position before its deacetylation cannot be excluded. The presence of the ester linkage at the *sn*-1 position confer to 1-acyl-PAF a metabolic behavior different from that of PAF. The physiological significance of the catabolism of 1-acyl-PAF is not clear. Because intact platelets are more permeable to 1-acyl-PAF than to lysoPC, one could speculate that 1-acyl-PAF may play a role as a transport vehicle for lysoPC through the plasma membrane of platelets. Although the biological role of this unique lipid molecule is not yet clear, 1-acyl-PAF represents 40% of the total amount of PAF-like material produced in stimulated PMN and platelets. So, it will be of importance to compare the biochemical properties of PAF and 1-acyl-PAF in various types of cells.

ACKNOWLEDGMENTS

Dr. Clystenes S. Silva received financial support from the Fundação de Amparo à Pesquisa do Estado de São Paulo. We are also grateful to Dr. Françoise Heymans (Laboratoire de Pharmacochimie Moléculaire, Université Paris VII France) for the preparation of unlabelled 1-acyl-PAF.

Platelet-Activating Factor (PAF) Stimulates the LysoPAF Acetyltransferase in Leukocyte-Rich Plasma: Use in PAF Antagonist Studies[1]

Thomas W. Doebber*, Margaret S. Wu, Anthony Mauriello and Alfred Alberts
Department of Biochemical Regulation, Merck Sharp & Dohme Research Laboratories, Rahway, New Jersey 07065-0900

Addition of platelet-activating factor (PAF; 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) to leukocyte-rich plasma from several species resulted in the rapid and pronounced activation of the PAF biosynthetic enzyme acetyl-CoA:1-*O*-alkyl-*sn*-glycero-3-phosphocholine acetyltransferase (EC 2.3.1.67). Activation of acetyltransferase by PAF occurred in leukocyte-rich plasma from human, chimpanzee, rhesus monkey, and dog. The neutrophil was indicated to be the major cellular source of the activatable acetyltransferase in leukocyte-rich plasma. The induction of acetyltransferase was substantial with 10 nM PAF, and maximal at 10–30 seconds. Measurable acetyltransferase activation was significantly greater when the PAF-activated cells were separated from the plasma by centrifugation before the acetyltransferase assay. This may be due in part to the removal of the PAF-specific acetylhydrolase present in plasma which can cleave the acetyl group from PAF. Measuring PAF activation of acetyltransferase in leukocyte-rich plasma can be useful to determine the potency of PAF antagonists with neutrophils in plasma compared to isolated neutrophils in aqueous buffer, and as an *ex vivo* assay to determine the efficacy and plasma concentration equivalents of antagonists administered to whole animals. The PAF antagonist L-659,989 was shown to be 3–5 times more potent in inhibiting PAF induction of acetyltransferase in isolated human neutrophils than in human leukocyte-rich plasma, with IC_{50} values of 10 nM and 40 nM, respectively. In the *ex vivo* assay, oral administration of the PAF antagonist L-667,131 to dogs resulted in very substantial inhibition of PAF induction of acetyltransferase in the leukocyte-rich plasma. Utilizing the *ex vivo* assay, oral administration of 1 mg/kg L-659,989 to rats was found to result in plasma concentration equivalents of approximately 200–300 nM L-659,989. Our findings offer a new approach for characterizing the *in vitro* and *in vivo* efficacy of PAF receptor antagonists and demonstrate that PAF may be able to activate neutrophils in the blood *in vivo*, further enhancing PAF synthesis.
***Lipids* 26, 997–1003 (1991).**

Platelet-activating factor (PAF) synthesis is induced by specific agonist-receptor interactions in several cell types. Such interactions include those of antigen-stimulated mast cells (1), immune complex-activated and opsonized zymosan-activated macrophages (2), complement component C5a-stimulated eosinophils (3), and opsonized zymosan-stimulated and complement component C5a-stimulated neutrophils (4,5). Cellular PAF synthesis results from a two-step pathway involving: (i) phospholipase A_2 cleavage of the fatty acid from 1-*O*-alkyl-2-acyl-glycero-3-phosphocholine to form 1-*O*-alkyl-glycero-3-phosphocholine (lysoPAF); and (ii) acetylation of lysoPAF to PAF by a specific acetyl-CoA:1-*O*-alkyl-*sn*-glycero-3-phosphocholine acetyltransferase (EC 2.3.1.67) which utilizes acetyl-CoA as the acetyl donor (6). This acetyltransferase is a highly regulated enzyme and its activation in intact cells by specific agonists closely parallels large increases observed in the synthesis of PAF. Specifically, opsonized zymosan stimulation of human neutrophils resulted in activation of the acetyltransferase that correlated closely with the induction of PAF synthesis with regard to agonist concentration and time of stimulation (7). Similar studies with human eosinophils demonstrated a close correlation between acetyltransferase activation and increased PAF synthesis upon cell stimulation with formyl-methionyl-leucyl-phenylalamine (fMet-Leu-Phe), complement component C5a, eosinophil chemotactic factor of anaphylaxis, and the calcium ionophore A23187 (3). The combined evidence, at least for leukocytes, indicates that activation of the acetyltransferase is a prerequisite for increased PAF synthesis.

More recently, we demonstrated that PAF itself is a potent stimulator of this specific acetyltransferase in isolated rat and human neutrophils, resulting in the *de novo* synthesis of very substantial amounts of PAF in rat neutrophils (8). The induction of PAF synthesis by PAF in human neutrophils has since been documented (9). We also discovered that PAF activation of acetyltransferase occurs in leukocyte-rich plasma from several different species. In the present study, we characterized this leukoctye-rich plasma response to PAF. We also describe the utility of measuring this PAF response for characterizing PAF receptor antagonists.

MATERIALS AND METHODS

Blood was collected from experimental animals and normal human volunteers by venipuncture using heparinized syringes or heparinized vacutainer tubes. Leukocyte-rich plasma was prepared by mixing whole blood with 1/3 volume of 3% dextran (average molecular weight of 510,000) in 0.15 M NaCl and then letting this mixture stand at room temperature for 1 hr. The resulting leukocyte-rich plasma was then pipetted from above the sedimented erythrocytes. Rat elicited polymorphonuclear PMN neutrophils (utilized in experiments described in Fig. 9 and Table 1) were prepared by the method of

Abbreviations: BSA, bovine serum albumin; fMet-Leu-Phe, formyl-methionyl-leucyl-phenylalamine; lysoPAF, 1-*O*-alkyl-*sn*-glycero-3-phosphocholine; PAF, platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; PMN, polymorphonuclear.

Cunningham *et al.* (10) using intraperitoneal injections of 9 mL of 12% sodium caseinate per rat. Human neutrophils were isolated from blood by methods previously described (8,11). Leukocyte concentrations were determined as described previously (12). Leukocyte DNA was measured by use of the Hoechst Dye H33258.

For determination of PAF stimulation of acetyltransferase, 0.4 mL of a leukocyte suspension (leukocyte-rich plasma or isolated neutrophils suspended in Hanks balanced salt solution) was transferred to 1.5 mL polypropylene tubes. To the leukocyte suspension was added 100 μL of Hanks containing 0.25% bovine serum albumin (BSA), 3 mM $CaCl_2$, 5 mM $MgCl_2$, and the indicated concentration of PAF. For measurement of the basal (unstimulated) level of acetyltransferase, 100 μL of the same solution without PAF was used. The resulting cell suspension was incubated at room temperature for the time period indicated. The cells were then rapidly pelleted in a microcentrifuge for 7 seconds and the plasma supernatant was completely removed. The packed cells were resuspended in 1 mL of a mixture of Hanks containing 0.25% BSA/0.1M Tris-HCl, pH 7.2 (1:1, v/v), and then lysed by sonication for 10 seconds (Branson Sonifier Cell Disruptor, W-350, Branson, Danbury, CT). If acetyltransferase activity was to be assayed soon thereafter, lysed cell suspensions were stored in ice. Otherwise, the suspensions were quick-frozen in dry-ice/ethanol and then stored at −70°C for later assay. The loss in acetyltransferase catalytic activity using the latter freeze treatment was 5% or less when compared to the assay on the fresh samples immediately after sonication. Acetyltransferase activity was determined as described previously utilizing 5 μM 1-*O*-alkyl-*sn*-glycero-3-phosphocholine and 100 μM [^{3}H]-acetyl-CoA (0.3 μCi, New England Nuclear, Boston, MA) (8,13). Acetyltransferase activity is expressed as the amount of [^{3}H]PAF synthesized per min by the equivalent of 10^7 lysed cells. Any deviation from this protocol and other details of the assay are given in the Figure legends.

For the oral administration of the PAF antagonist L-667,131 to dogs, an ethanol solution of L-667,131 was mixed with starch. After evaporation of the ethanol, the L-667,131 starch mixture was packed into gelatin capsules. A pre-dose blood sample was obtained followed by oral administration of the capsules to the dogs.

For the study of the L-659,989 concentration equivalents in plasma from rats dosed orally with L-659,989, this compound was suspended in a solution containing 0.9% NaCl, 0.5% carboxymethylcellulose, 0.4% Tween 80, and 0.9% benzyl alcohol to a final concentration of 0.1 mg/mL. This suspension was administered orally *via* stomach tube to female CD rats (Charles River Breeding Labs, St. Constant, Quebec, Canada). Blood samples were obtained by cardiac puncture, 30 min later, and plasma was prepared by centrifugation.

1-*O*-Alkyl-2-[*acetyl*-^{3}H(N)]-acetyl-*sn*-glycero-3-phosphocholine, for measuring acetylhydrolase activity was prepared enzymatically by incubation of rat spleen microsomal acetyltransferase with 1-*O*-alkyl-*sn*-glycero-3-phosphocholine and [^{3}H]acetyl coenzyme A. The resulting [^{3}H]PAF was extracted according to the procedure of Bligh and Dyer (16). L-659,989 was prepared and supplied by Dr. M. Ponipom (14). L-667,131 was prepared and supplied by Dr. D. Graham and Dr. Y.-C. Chiang (15).

RESULTS

Addition of increasing concentrations of PAF to leukocyte-rich plasma from different species resulted in concentration-dependent increases in acetyltransferase activity as demonstrated for human, rhesus monkey, dog, and chimpanzee (Fig. 1). While there were modest increases with 1 nM PAF, 10 nM PAF induced substantial increases in acetyltransferase activity, and the activity plateaued between 10^{-7} and 10^{-6} PAF. The exception was the human acetyltransferase, which continued to increase in activity with PAF concentrations up to 10^{-5}M. The increase in maximal acetyltransferase activity compared to basal activity ranged from 3.3-fold for the rhesus monkey to 10.6-fold for the human. The chimpanzee basal activity was zero.

For the human leukocyte-rich plasma, evidence indicates that the PMN neutrophil is the cell type predominantly responsible for the PAF-activatable acetyltransferase. Firstly, PMN neutrophils isolated from human blood displayed an acetyltransferase that is substantially activated by PAF (8). Secondly, the selective removal of PMN neutrophils from human leukocyte-rich plasma greatly reduced the amount of PAF-activatable acetyltransferase on a per cell basis. Specifically, in one experiment, the leukocyte-rich plasma, in which 76% of all leukocytes were PMN neutrophils, displayed a basal and a PAF-stimulated acetyltransferase activity of 1405 and 5272 pmole/min/10^7 cells, respectively. The net PAF-activatable acetyltransferase activity was thus 3867 pmole/min/10^7 cells. When PMN neutrophils were specifically pelleted from the leukocyte-rich plasma by layering the leukocyte-rich plasma over lymphocyte separation medium followed by centrifugation, 100% of the pelleted cells were PMN neutrophils (200 out of 200 cells counted) and 0% of the leukocytes in the remaining supernatant were PMN neutrophils (0 out of 205 cells counted). The latter supernatant exhibited a basal and a PAF-stimulated acetyl-

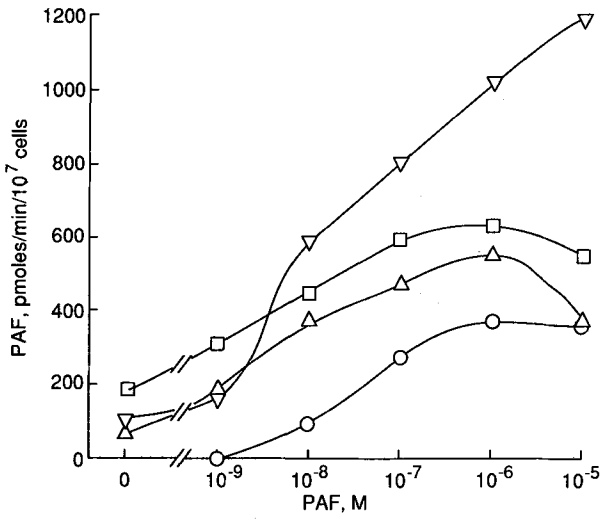

FIG. 1. PAF concentration-dependent induction of acetyltransferase activity in leukocyte-rich plasma samples from human (▽), rhesus monkey (□), dog (△), and chimpanzee (○). Leukocyte-rich plasma samples were activated for 30 seconds after addition of PAF. The reaction was stopped by the addition of 0.5 mL of 0.1M Tris-HCl, pH 7.2, followed by sonication to lyse the cells. The individual values represent the mean of triplicate determinations.

transferase activity of 1152 and 2088 pmoles/min/10^7 cells, respectively, for a net PAF-activatable acetyltransferase activity of 936 pmole/min/10^7 cells. Thus, the PMN-containing leukocyte-rich plasma on a cell basis had four times more PAF-activatable acetyltransferase than the PMN-free leukocyte-rich plasma. While this type of analysis was not performed on the three other species presented in Figure 1, the PMN differential counts in the leukocyte-rich plasma were quite similar to that for human—77% for chimpanzee, 68% for rhesus, and 78% for dog.

The PAF concentration-dependent increase in acetyltransferase differed considerably for leukocyte-rich plasmas from different human donors, as shown for three donors in Figure 2. Both the threshold PAF concentration that activated the acetyltransferase and the PAF concentration at which the activity plateaued differed for the three leukocyte-rich plasma samples. While there is variability among different human donors, the pattern for leukocyte-rich plasma samples obtained at different times from the same donor was much more consistent.

The effect of plasma on the acetyltransferase assay was followed by measuring the PAF concentration-dependent increase in acetyltransferase in cells that had been separated from plasma by centrifugation after PAF activation and in cells that remained in the plasma. The results depicted in Figure 3 demonstrate that the measurable acetyltransferase activation was considerably greater when the plasma was removed from the cells. The lower activity with plasma present may be due to the steady deacetylation of [^{3}H]PAF formed by the PAF-specific acetylhydrolase. This interpretation is consistent with the data shown in Figure 4 which demonstrate that human plasma, human leukocyte-rich plasma, and sonicated human leukocyte-rich plasma each degrade [^{3}H]PAF in a time-dependent manner. Plasma and leukocyte-rich plasma were about equally active in their ability to degrade [^{3}H]PAF, while the sonicated leukocyte-rich plasma was slightly less active. Because the undiluted sonicated leukocyte-rich plasma deacetylated only 28% of the [^{3}H]PAF by 10 min and because the leukocyte-rich plasma assayed (Fig. 3) was diluted five-fold for the

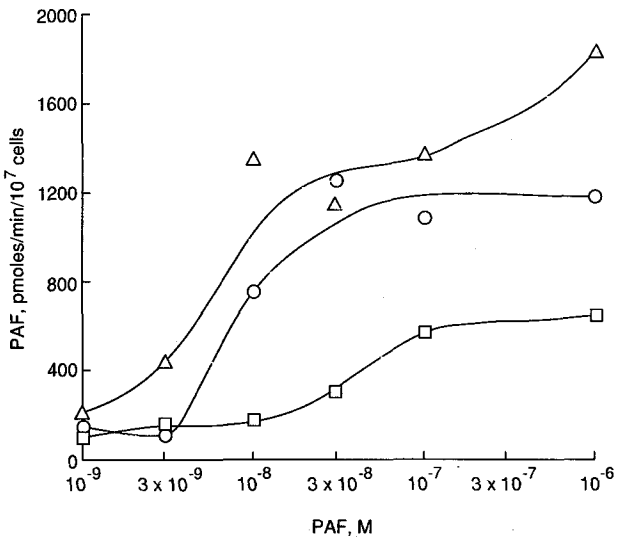

FIG. 2. PAF concentration-dependent stimulation of acetyltransferase activity in leukocyte-rich plasmas from three human donors. The PAF activation of the leukocyte-rich plasma was for 30 seconds. The individual values represent the mean of duplicate determinations.

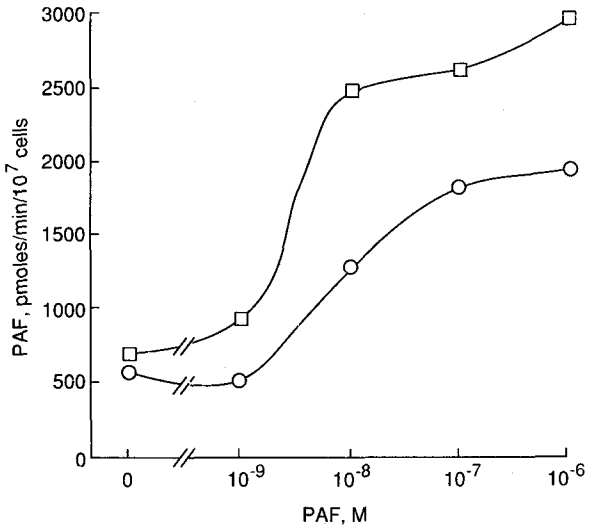

FIG. 3. Effect of plasma on the determination of human leukocyte-rich plasma acetyltransferase that was activated by different concentrations of PAF. Following a 1-min incubation with PAF, the cell suspensions were either diluted with 0.5 mL of 0.1 M Tris-HCl (pH 7.2) and then sonicated (○), or the cells were rapidly pelleted in a microcentrifuge, the plasma supernatant was removed, and the packed cells were then sonicated in 1 mL of a mixture of Hanks containing 0.25% BSA/0.1 M Tris-HCl, pH 7.2 (1:1, v/v) (□). The individual values represent the mean of triplicate determinations.

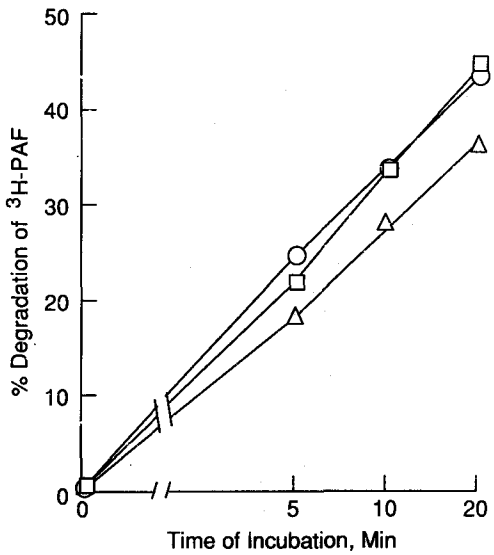

FIG. 4. Time-dependent deacetylation of [^{3}H]PAF by human plasma (○), human leukocyte-rich plasma (□), and human leukocyte-rich plasma in which the cells had been lysed by sonication (△). [^{3}H]PAF with the ^{3}H label in the acetate moiety (80,000 dpm) was added to 1.1 mL of human plasma or leukocyte-rich plasma and the mixture was incubated at 37°C. At 0, 5, 10, and 20 min of incubation, duplicate 0.1-mL aliquots were withdrawn and subjected to Bligh-Dyer extraction. The ^{3}H activity in the aqueous layer was counted as a measure of the [^{3}H]acetate released from [^{3}H]PAF. A control incubation of [^{3}H]PAF in Hanks containing 0.25% BSA resulted in negligible release of [^{3}H]acetate into the aqueous layer.

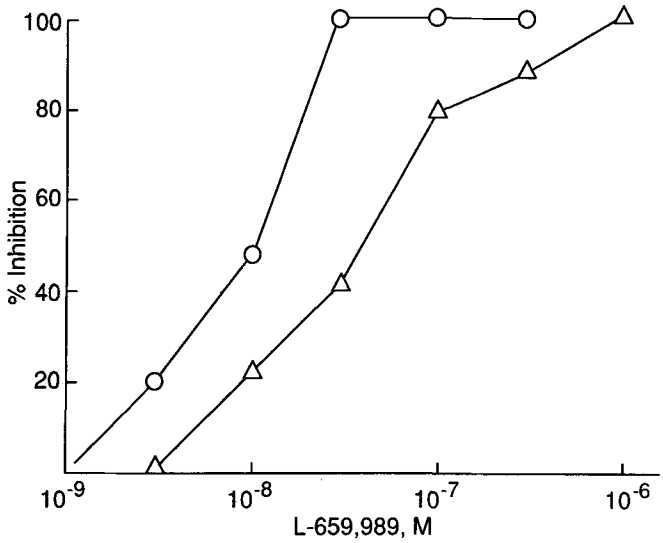
acetyltransferase assay, there appear to be other factors responsible for the much lower acetyltransferase activity that resulted when the plasma was not removed from the leukocytes before sonication and enzyme assay.

The time dependence for the 10 nM PAF induction of acetyltransferase in human leukocyte-rich plasma at room temperature and at 37°C is presented in Figure 5. At room temperature, the activation was discernable but not maximal at 10 seconds, and reached maximal values at 0.5 to 1 min. The state of activation steadily decreased at 3, 10, and 20 min. A different pattern occurred at 37°C with maximal activity at 10 seconds and substantial decreases at 0.5 and 1 min. The decrease in activity at 3, 10, and 20 min was quite parallel to the pattern that was seen at room temperature.

One of the applications of measuring PAF activation of acetyltransferase is the ability to determine the inhibition by PAF antagonists of this response to PAF in neutrophils in plasma compared to isolated neutrophils in buffer. Figure 6 shows the concentration-dependent inhibition of PAF activation of acetyltransferase in human leukocyte-rich plasma and isolated human neutrophils by the PAF antagonist L-659,989 (Scheme 1). Approximately three- to five-fold higher concentrations of L-659,989 were required to inhibit this response to PAF in human leukocyte-rich plasma as compared with isolated human neutrophils prepared from the same leukocyte-rich plasma. The L-659,989 concentration required for 50% inhibition of the PAF induction of acetyltransferase was 10 nM for isolated neutrophils and 40 nM for leukocyte-rich plasma. The decreased potency of L-659,989 in the leukocyte-rich plasma compared to isolated neutrophils is probably due to the fact that 97% of L-659,989 added to plasma is bound to plasma proteins. The inhibitory action of L-659,989 on PAF activation of acetyltransferase in human leukocyte-rich plasma was not due to inhibition of the acetyltransferase catalytic activity and was specific



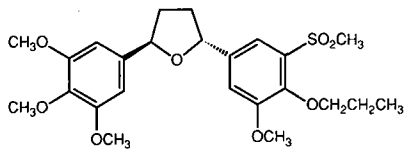


FIG. 6. Concentration-dependent inhibition by PAF antagonist L-659,989 of 10 nM PAF induction of acetyltransferase in isolated human neutrophils (○) and human leukocyte-rich plasma (△). The L-659,989 was preincubated with the cells 15 min before addition of PAF. The PAF activation of the cells was for 30 seconds. Each value depicts the mean of duplicate determinations for the isolated neutrophils and of triplicate determinations for the leukocyte-rich plasma.

SCHEME 1. Structure of L-659,989.

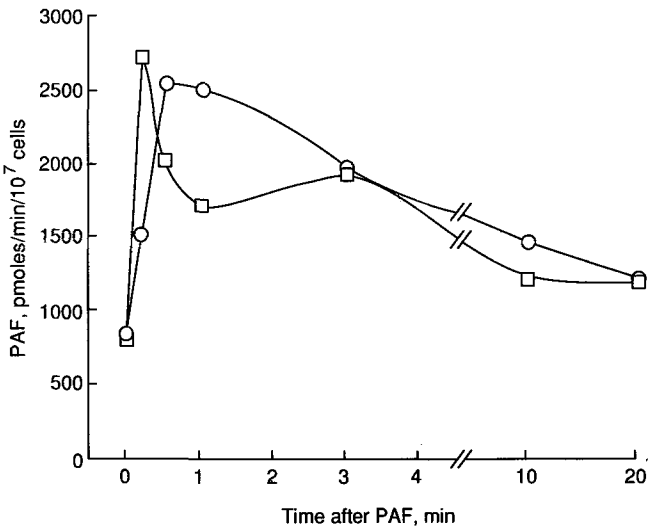

FIG. 5. Time-dependent activation of acetyltransferase in human leukocyte-rich plasma by 10 nM PAF at room temperature (○) and 37°C (□). For the 37°C study, the leukocyte-rich plasmas were preincubated at 37°C for 15 min before addition of PAF. All values represent the mean of triplicate determinations.

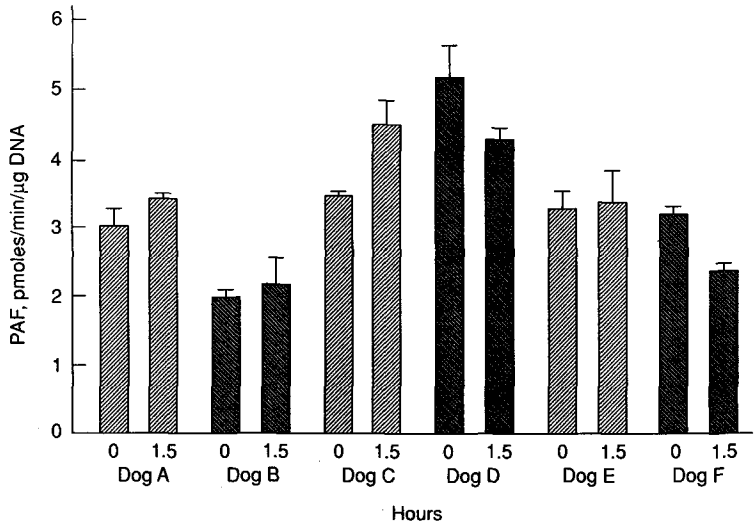
to PAF: i) The addition of L-659,989 (1 μM final concentration) to sonicated leukocytes from either unactivated or PAF-activated human leukocyte-rich plasma had essentially no inhibitory action on the acetyltransferase catalytic activity; and ii) the activation of acetyltransferase in human leukocyte-rich plasma by 10^{-8}M fMet-Leu-Phe was unaffected by the addition of 1 μM L-659,989 to the leukocyte-rich plasma before the fMet-Leu-Phe challenge.

Another application of the PAF activation of acetyltransferase in leukocyte-rich plasma is the *ex vivo* determination of the efficacy of PAF antagonists administered to experimental subjects. In this procedure, a control blood sample is taken followed by dosing with the antagonist and then subsequent blood samples are obtained at desired times. Leukocyte-rich plasma samples which are prepared from each blood sample are challenged with buffer and 10 nM PAF and the level of activation of acetyltransferase is determined. If a PAF antagonist is efficacious in this assay, the level of PAF activation of acetyltransferase in the leukocyte-rich plasma obtained after dosing of antagonist would be substantially lower than that in the pre-dose leukocyte-rich plasma. A prerequisite for results from such an assay to be meaningful is that the level of PAF activation of acetyltransferase be quite reproducible for leukocyte-rich plasma obtained from the same donor at different times. This requirement was



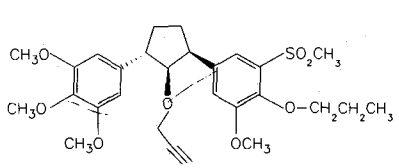


FIG. 7. Reproducibility of PAF activation of acetyltransferase in leukocyte-rich plasmas from six dogs. Two blood samples were obtained from each dog with 1.5 hr between blood drawings. The resulting leukocyte-rich plasma samples were stimulated with 10 nM PAF and buffer (for determination of basal activity) for 30 seconds. The acetyltransferase activity was calculated on the basis of μg of cellular DNA. The results are expressed as the net PAF activated acetyltransferase having subtracted the basal activity. The values represent the mean of triplicate determinations and the error bars depict the standard deviations. The basal activities ranged from 0.54 pmole/min/μg DNA for the 0 hr blood sample of dog B to 1.44 pmole/min/μg DNA for the 1.5 hr blood sample of dog D.

tested in dogs followed by the full *ex vivo* assay of the efficacy of a PAF antagonist administered orally to dogs. The reproducibility of the PAF activation of acetyltransferase in leukocyte-rich plasma obtained at two different time points was determined in six pure-bred beagles. The results in Figure 7 show the net PAF activation of acetyltransferase (after subtracting basal activity) for two blood samples obtained with a 1.5-hr interval. The leukocyte-rich plasma from dogs A, B, and E showed very good reproducibility. In comparing the 1.5-hr sample to the 0-hr sample, dog C exhibited a 28% increase and dogs D and F exhibited a 17% and 25% decrease, respectively. Next, the efficacy of the PAF antagonist L-667,131 upon oral administration at 1 mg/kg in two pure-bred beagles was determined (Scheme 2). The results in Figure 8, again expressed as the net PAF activation, demonstrate a very substantial reduction in the PAF activation of acetyltransferase in leukocyte-rich plasmas from blood samples obtained 0.5, 2 and 4 hr after the antagonist dosing as compared to the predose level of PAF activatable acetyltransferase. Dog A showed decreases in PAF activatable acetyltransferase of 85%, 93%, and 99% for the 0.5, 2, and 4 hr blood samples, respectively, compared to the 0 hr predose level, while the corresponding decreases for dog B were 28%, 56%, and 56%. Except for the 0.5 hr value of dog B, these decreases are clearly much larger than the variability displayed in the activatable acetyltransferase

SCHEME 2. Structure of L-667,131.

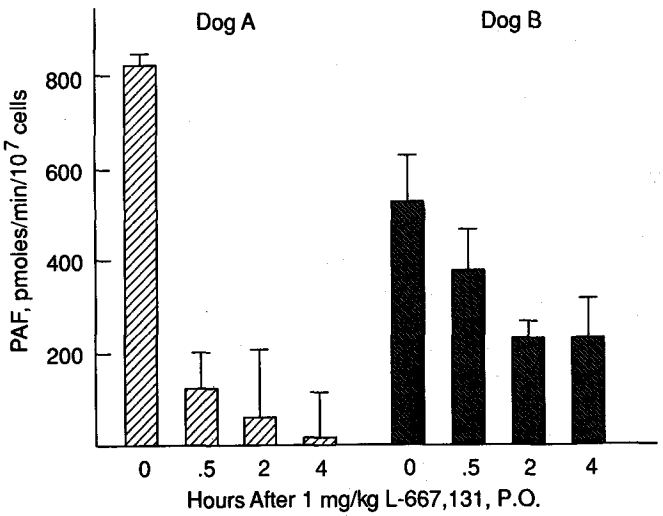

FIG. 8. PAF activation of acetyltransferase in leukocyte-rich plasma from dogs that were orally dosed with L-667,131. Immediately after the 0 hr blood sample was drawn, each dog was dosed with the capsule that contained L-667,131. Subsequent blood samples were obtained at 0.5, 2, and 4 hr after dosing. The leukocyte-rich plasma derived from each blood sample was stimulated with 10 nM PAF for 30 seconds. The results are expressed as the net PAF activated acetyltransferase after subtraction of the basal activity. The values indicate the mean of triplicate determinations and the error bars represent the standard deviations. The basal activities ranged from 144 pmole/min/10^7 cells for the 2 hr blood sample of dog B to 576 pmole/min/10^7 cells for the 0 hr blood sample of dog A.

TABLE 1

Inhibition of PAF Activation of Rat Neutrophil Acetyltransferase by Plasma from Rats Dosed Orally with L-659,989[a]

Plasma sample	Net PAF activatable acetyltransferase	% Inhibition
Control rat	318 ± 51 pmole PAF/min/10^7 cells	—
L-659,989-dosed Rat 1	215 ± 17 pmole PAF/min/10^7 cells	32%
L-659-989-dosed Rat 2	236 ± 6 pmole PAF/min/10^7 cells	26%

[a]Rat neutrophils were preincubated at room temperature with diluted plasma from the control rat or L-659-989-dosed rats for 15 min before addition of PAF to a final concentration of 10 nM. The time of PAF stimulation was 1 min. The results are expressed as the net PAF activated acetyltransferase after subtraction of the basal activity and represent the mean of triplicate determinations along with the standard deviation. The basal acetyltransferase values were 64, 56, and 53 pmole PAF/min/10^7 cells for the incubations with plasma from the control rat, rat 1, and rat 2, respectively.

in the two blood samples from each of the six control animals in Figure 7.

A modification of this latter assay permits the determination of the concentration equivalents of a PAF antagonist in plasma of animals that were dosed with the antagonist. For this assay, two rats were dosed orally with 1 mg/kg of L-659,989 and then bled 1/2 hr later. A control rat received an equal volume of vehicle. The resulting plasma samples from L-659,989-dosed rats and control rats were diluted 16.7-fold with Hanks containing 0.25% BSA, and these dilutions were added to isolated neutrophils prepared from other rats. The neutrophil suspensions were challenged with 10 nM PAF and the extent of activation of the acetyltransferase was determined. The results in Table 1 demonstrate that the plasma samples from the L-659,989-dosed rats inhibited the PAF activation of neutrophil acetyltransferase by 32% and 26%. The concentration-dependent inhibition by exogenously added L-659,989 of PAF activation of acetyltransferase in neutrophils suspended in the same dilution (16.7-fold) of control plasma was performed and the results are presented in Figure 9. By knowing the amount of inhibition given by the plasma from the L-659,989-treated rats (Table 1), the factor of the dilution of plasma added to the neutrophils, and the amount of inhibition by known amounts of L-659,989 (Fig. 9), the L-659,989 concentration equivalents in the plasma from the L-659,989-dosed rats can be determined. The 32% inhibition exhibited by the diluted plasma from rat 1 that received the oral dose of L-659,989 (Table 1) is the interpolated level of inhibition given by 16 nM L-659,989 added exogenously to neutrophils (Fig. 9). Multiplication of the 16 nM value by the 16.7-fold dilution of the plasma added to the neutrophils results in a value of 267 nM plasma equivalents of L-659,989 for rat 1. The same exercise performed for rat 2 indicates a plasma equivalents level of 225 nM L-659,989. The term equivalents is used since it is not known if intact L-659,989 or a metabolite that is an active PAF antagonist is the inhibitory component in the plasma from the orally-dosed rats.

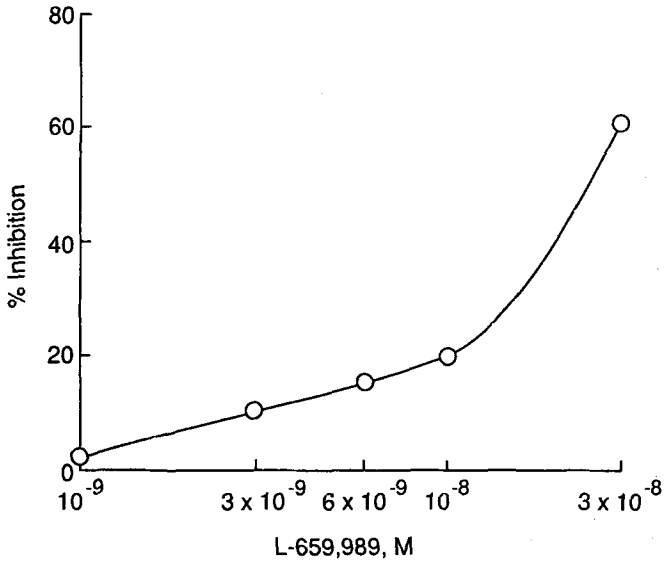

FIG. 9. Concentration-dependent inhibition by L-659,989 of 10 nM PAF induction of acetyltransferase in isolated rat neutrophils. The L-659,989 dilutions and control plasma were preincubated with the neutrophils for 15 min. The PAF activation was for 1 min. All samples contained 6% control rat plasma, the same plasma concentration present in the acetyltransferase assays of Table 1. Each point is the mean of triplicate determinations.

DISCUSSION

As we demonstrated previously with isolated human and rat neutrophils (8), PAF was now shown to activate the PAF synthesizing acetyltransferase in leukocyte-rich plasma from several species, including human, rhesus monkey, dog, and chimpanzee. This activation occurred at rather low PAF concentrations (10 nM) and reached maximal levels of activation after very brief exposure to PAF (10 seconds at 37°C and 30 seconds at room temperature), as was true for the activation of acetyltransferase in isolated neutrophils (8). For human leukocyte-rich plasma, the neutrophil was the primary cell responsible for the increased acetyltransferase levels following PAF stimulation.

The detectability of the level of activation of the PAF-stimulated acetyltransferase in human leukocyte-rich plasma was substantially greater when the plasma was removed from the cells before cell lysis by sonication (Fig. 3). The continued deacetylation by the PAF-specific

acetylhydrolase in plasma of the [^{3}H]PAF formed during the acetyltransferase assay was considered a partial factor for the dampening effect of plasma. Other explanations could include the deactivation of the stimulated acetyltransferase and alternate uses of the substrates used for the acetyltransferase assay by enzymes present in the plasma.

While the extent of acetyltransferase activation is almost the same for PAF stimulation of human leukocyte-rich plasma at room temperature and 37°C, the time-dependency is quite different. The activation and subsequent deactivation occur more rapidly at 37°C than at room temperature. Other laboratories have indicated that the acetyltransferase in spleen microsomes and human neutrophils is activated by kinases and deactivated by phosphatases (17-19). Possibly, the more rapid activation and deactivation of acetyltransferase at 37°C compared to room temperature may be due to the higher catalytic activity at 37°C of neutrophil kinases and phosphatases that may be responsible for activation and deactivation, respectively, of the acetyltransferase.

While PAF does activate the acetyltransferase in human leukocyte-rich plasma up to 10-fold over the basal level, we were unable to detect any PAF stimulation of PAF synthesis in human leukocyte-rich plasma as measured by incorporation of [^{3}H]acetate into PAF. A major reason for not detecting any PAF synthesis is that the [^{3}H]acetate method requires a neutrophil concentration of at least 10^7 cells/mL for significant synthesis by isolated neutrophils of [^{3}H]PAF to occur. Typical neutrophil concentrations in human leukocyte-rich plasmas are only 1-3 × 10^6 cells/mL.

A main benefit of this response of the leukocyte-rich plasma acetyltransferase to PAF is the ability to characterize PAF antagonists. The potencies of antagonists in inhibiting the PAF induction of acetyltransferase in leukocyte-rich plasma can be compared with that in isolated neutrophils. This is quite important since an antagonist that is quite potent with isolated cells in plasma-free buffers may be much less potent in the presence of plasma because of extensive binding of antagonist to plasma proteins and/or metabolism by enzymes present in plasma. Indeed, this was the case for the studies with L-659,989 (Fig. 6). These studies can be performed by examining antagonist inhibition of PAF induction of aggregation of washed platelets and platelet-rich plasma. However, it is important to examine the neutrophil system as well as the platelet system since the studies of Hwang (20) indicate that PAF receptors on platelets may be different from those on neutrophils.

The PAF induction of acetyltransferase in leukocyte-rich plasma also provides a useful *ex vivo* assay for determining the efficacy and plasma concentration equivalents of antagonists administered to whole animals. This capability was demonstrated here for the PAF antagonists L-667,131 and L-659,989. The very good efficacy of the PAF antagonist WEB 2086 was demonstrated in humans utilizing the *ex vivo* efficacy of PAF induction of aggregation of platelet-rich plasma (21). Similar studies can be performed in humans or experimental animals using the PAF induction of leukocyte-rich plasma acetyltransferase. The advantages of the latter assay are: i) Only 4 mL of blood are needed for triplicate determinations of basal and PAF activatable acetyltransferase; ii) the PAF challenge of the leukocyte-rich plasma can be performed very quickly and the sonicated neutrophils can be quick-frozen and then assayed for acetyltransferase activity at a later time; and iii) determination of the neutrophil DNA concentration provides a convenient basis for expression of the acetyltransferase activity.

ACKNOWLEDGMENTS

The authors are grateful to Dr. D. Graham and Dr. Y.-C. Chiang for providing L-667,131, to Dr. M. Ponpipom for a sample of L-659,989, and to Ms. Madeline Spencer for typing the manuscript.

Enzyme kinetic studies of lysoPAF acetyltransferase from microsomal preparations of human and rat neutrophils were carried out using lysoPAF or dansyllysoPAF as substrate. With the human enzyme, incomplete conversion of the substrate into the product was observed at 37°C with both substrates. The acetyltransferase was inactivated at 37°C in the absence of substrate with a half-life of 7.5 min. However, the initial rate of product formation under the assay conditions was linear up to 10 min. Both enzymes were optimally active at 40 μM concentration with either substrate, but enzyme activity was inhibited at higher substrate levels. At a constant substrate concentration (40 μM), the K_m (μM) and V_{max} (nmol product/min/mg protein) values for the human acetyltransferase, with respect to acetyl-CoA were 132 and 23.1, respectively, with lysoPAF as substrate, and 105 and 26.7, respectively, when dansyllysoPAF was used. The K_m and V_{max} values for the rat enzyme were 105 and 6.5, respectively, with lysoPAF as substrate, and 120 and 5.4, respectively, when dansyllysoPAF was used. Under our standard conditions, lysoPAF required 1 mg of BSA per mL in the assay, whereas full activity of both enzymes was seen with dansyllysoPAF even in the absence of BSA. The results show that dansyllysoPAF can replace lysoPAF in the assay without any significant changes in kinetic parameters.

Lipids 26, 1004–1010 (1991).

Paf-acether (platelet-activating factor, PAF) has been implicated in the development of a variety of pathological conditions, such as endotoxic shock (1), anaphylaxis (2), asthma (3), and thrombi formation (4). Thus, interest has grown in recent years in the development of PAF antagonists with pharmacological potential (2). However, little attention has been paid to inhibitors of PAF biosynthesis. Acetyl-CoA:1-*O*-alkyl-*sn*-glycero-3-phosphocholine acetyltransferase (EC 2.3.1.67) is an enzyme which plays a key role in Paf-acether formation (5,6) Inhibition of this enzyme could decrease Paf-acether production, and thus lessen certain disease symptoms. Only one preliminary report has been published on inhibitors of microsomal acetyltransferase (7), and only few compounds have been shown to inhibit PAF biosynthesis in neutrophils (8–10). The mode of action of these inhibitors is not yet fully understood.

Large-scale screening for enzyme-specific inhibitors requires that a high number of assays can be performed within a short period of time. A newly developed assay for measuring acetyltransferase activity based on a fluorophore-labeled lysoPAF derivative, *i.e.*, dansyllysoPAF, was recently described (11). This acetyltransferase assay appears useful for the screening of potential enzyme inhibitors. In the present study, the dansyllysoPAF assay was compared with a standard assay based on the incorporation of [^{3}H]acetyl from [^{3}H]acetyl-CoA into lysoPAF (12). It was our objective to compare the kinetics of the acetyltransferase reaction for both substrates, and for the enzymes from both human and rat neutrophils.

EXPERIMENTAL PROCEDURES

1-(*N*-Dansyl-11-amino-1-undecyl)-*sn*-glycero-3-phosphocholine (dansyllysoPAF) and its acetylated derivative (dansylPAF) were prepared as previously described (11). LysoPAF (1-*O*-octadecyl-*sn*-glycero-3-phosphocholine) and [^{3}H]-acetyl-CoA were purchased from Bachem (Bubendorf, Switzerland) and New England Nuclear (Boston, MA), respectively. [^{14}C]PAF was the product of Amersham International (Amersham, U.K.), and Ficoll-Hypaque was obtained from Pharmacia (Uppsala, Sweden). Plasmagel® was the product of Laboratoire R. Bellon (Neilly s/Seine, France). Acetyl-CoA, essentially fatty acid free bovine serum albumin (BSA), leupeptin and soybean trypsin inhibitor were purchased from Sigma (Deisenhofen, Germany). Hank's balanced salt solution (HBSS), sodium caseinate and ionophore A23187 were purchased from Gibco (Karlsruhe, Germany), Roth (Karlsruhe, Germany) and Calbiochem (La Jolla, CA), respectively. Thin-layer plates (type 5641) were purchased from Merck (Darmstadt, Germany). All other chemicals were reagent grade. Stock solutions of lysoPAF (1 mM) and dansyllysoPAF (1.6 mM) were prepared in 0.9% NaCl containing 0.25% BSA and water, respectively, and further diluted as indicated.

Protein was quantified by the method of Lowry *et al.* (13). Bovine serum albumin was used as the protein standard.

Preparation of acetyltransferase from human polymorphonuclear leukocytes (PMN). Venous blood from healthy donors was collected in tubes containing ethylenediaminetetraacetic acid (EDTA) (5 mM, final concentration) as anticoagulant. After sedimentation for 30 to 45 min in the presence of 3% gelatin (Plasmagel®), the supernatant (20 mL) was layered onto 10 mL Ficoll-Hypaque (density 1.077) and centrifuged at 400 × *g* for 20 min at 20°C. The cell pellet was washed in washing buffer, pH 7.4, containing (in mM) KCl (2.6), NaCl (137), glucose (5.6), and HEPES (4.2). Erythrocytes were lysed by adding 3 vol of distilled water per 1 vol of cell suspension for 40

Abbreviations: BSA, bovine serum albumin; dansyllysoPAF, 1-(*N*-dansyl-11-amino-1-undecyl)-GPC; dansylPAF, 1-(*N*-dansyl-11-amino-1-undecyl)-2-acetyl-GPC; EDTA, ethylene diamine tetraacetic acid; GPC, *sn*-glycero-3-phosphocholine; HBSS, Hank's balanced salt solution; lysoPAF, 1-*O*-alkyl-GPC; PAF, platelet-activating factor, Paf-acether, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; PMN, polymorphonuclear leukocytes; PMSF, phenylmethylsulfonyl fluoride; TLC, thin-layer chromatography.

sec, and lysis was stopped by the addition of 1 vol of NaCl (3.5%). The cells were then washed twice with washing buffer (400 × *g* × 10 min at 20°C) and resuspended in washing buffer supplemented with $CaCl_2$ (1.3 mM) and $MgCl_2$ (1 mM) at a cell concentration of 1×10^6/mL. All preparations contained more than 98% PMN as determined by the examination of May Grunwald-Giemsa-stained smears. Cells (8×10^6 in 8 mL) were preincubated for 5 min at 37°C and then challenged with ionophore A23187 (3 μg/mL) for 5 min. Stimulation was stopped by washing with 0.15 NaCl at 4°C. Cell lysates were obtained from the ionophore-stimulated PMN (8×10^7 cells), and suspended in 0.5 mL of 0.25 M sucrose containing phenylmethylsulfonyl fluoride (PMSF) (2 mM) and leupeptin (20 μg/mL) by sonication in an ice bath (3 pulses of 15 sec). The postnuclear supernatant was fractionated by centrifuging twice at 500 × *g* for 10 min at 4°C in 0.25 M sucrose. Granules and mitochondria were first removed by centrifugation (15,000 × *g* for 10 min) at 4°C. The 15,000 × *g* supernatant was collected and centrifuged at 200,000 × *g* for 30 min at 4°C to separate the microsomal fraction (pellet) from the cytosol (supernatant). The microsomal fraction was resuspended in 0.15 N NaCl to yield a final concentration of approximately 1 mg protein/mL.

Preparation of acetyltransferase from rat peritoneal PMN. Rat peritoneal PMN were obtained 16 hr after intraperitoneal injection of 2% sodium caseinate (14). The cells were lavaged from the peritoneum with HBSS buffer, centrifuged, and exposed to hypotonic medium to remove erythrocytes as described above. The cells were washed twice with HBSS buffer and resuspended in the same buffer at 10^8 cells/mL. The purity of PMN was better than 95% based on May Grunwald-Giemsa-stained smears. PMN were stimulated with ionophore A23187 (3 μg/mL) for 5 min at 37°C (12). All subsequent steps were performed at 4°C. The stimulated cells were washed with ice-cold buffer A [HBSS buffer pH 7.0 which contained 0.5 mg/mL of soybean trypsin inhibitor (15) and 25 mM NaF (16)]. The cell-free preparations were obtained by sonication of the cells suspended in buffer A in an ice bath (3 pulses of 10 sec). Cell debris was removed from crude lysate by pelleting at 1,000 × *g* for 10 min. The resulting supernatant was further fractionated by centrifugation at 15,000 × *g* for 30 min. The microsomal fraction was obtained from the 15,000 × *g* supernatant by centrifugation at 105,000 × *g* for 1 hr. The microsomal fraction was resuspended in buffer A to yield a final concentration of approximately 1 mg protein/mL.

Acetyltransferase assay. The acetyltransferase activity of microsomal fractions obtained from ionophore-stimulated PMN was measured using two different substrates. The radiolabeled assay (assay 1) was performed as previously described (12). Briefly, 50 μL of microsomal fraction containing approximately 50 μg protein was added to the reaction mixture (0.5 mL final volume, pH 7.0) containing (in mM): HEPES (4.2), NaCl (137), KCl (2.6), $CaCl_2$ (0.65), $MgCl_2$ (0.5), 0.5 μCi [^{3}H]acetyl-CoA, and acetyl-CoA and lysoPAF as indicated in the legends to the Figures. When not stated otherwise, the assay contained BSA at a concentration of 1 mg per mL of assay. Samples without lysoPAF served as blanks. The reaction was carried out at 37°C for 10 min, and was stopped by the addition of 2 mL of chloroform/methanol (1:1, v/v) containing [^{14}C]PAF (3,000 dpm) as internal standard. The extraction procedures used were those described in ref. 12. After substraction of blanks, the amount of [^{3}H]PAF assayed also was corrected for isolation losses. Acetyltransferase activity was calculated as the average of duplicate determinations with an intraexperimental variation of less than 10%. The fluorophore assay (assay 2) for acetyltransferase was performed at 37°C in 60 μL of buffer A, which contained dansyllysoPAF (40 μM), acetyl-CoA (200 μM) and enzyme as previously described (11). The standard assay 2 was run in the absence of BSA. Incubations were carried out up to the indicated time points and terminated by directly spotting a 5-μL aliquot of the reaction mixture onto thin-layer plates. Substrate and product were separated using the solvent system chloroform/methanol/acetic acid/water (50:25:4.5:4.5, by vol) and were quantified by scanning plates in a fluorescence densitometer (CD 50, Desaga, Heidelberg, Germany) with the excitation wave length set at 256 nm and an emission cut-off filter at 400 nm. Both microsomal preparations of human and rat enzyme were devoid of transacylase activity when tested as previously described (11).

When not stated otherwise, results are expressed as nmol product formed per min per mg of protein. Kinetic data were analyzed by weighted fits to the appropriate function with a non-linear regression analysis program adapted from KINFIT (17).

RESULTS AND DISCUSSION

Time course experiments. Typical results of the time course experiments for human acetyltransferase using assay 1 and assay 2 are shown in Figure 1. Both assays gave similar results with respect to product formation over time. A linear relationship between initial velocity and human leukocyte microsomal protein concentration has already been established previously for assay 1 (18). A similar linear relationship was found in a plot of initial velocities of dansylPAF formation (calculated from the progress curves in Fig. 1b) as a function of protein up to 56 μg protein (data not shown). However, in both assays, the total amount of PAF or dansylPAF formed at the end of the incubation time decreased as protein concentrations decreased. Incomplete conversion of lysoPAF to PAF has previously been observed (18,19). Similar results were obtained for rat PMN acetyltransferase (P.W. Schindler, unpublished results).

Effects of assay temperature on the activity of the human enzyme. Since the microsomal preparation of acetyltransferase was devoid of any significant PAF acetylhydrolase (data not shown), the possibility could be excluded that PAF or dansylPAF were hydrolyzed again after being formed in the assay. Therefore, we addressed the question whether the observed incomplete production formation may be due to thermal instability of the enzyme at the incubation temperature. As shown in Figure 2, preincubating the stock microsomal fraction (0.676 mg/mL) at 37°C for up to 50 min resulted in a rapid loss of enzyme activity. A plot of log [fractional enzyme activity] *vs.* time gave a straight line, regardless of the type of substrate used. In both cases, the half life of the human enzyme was 7.5 min. Thus, the rapid inactivation of human acetyltransferase at 37°C may account for the incomplete product formation which is apparent from Figure 1. We presently do not know whether the loss of

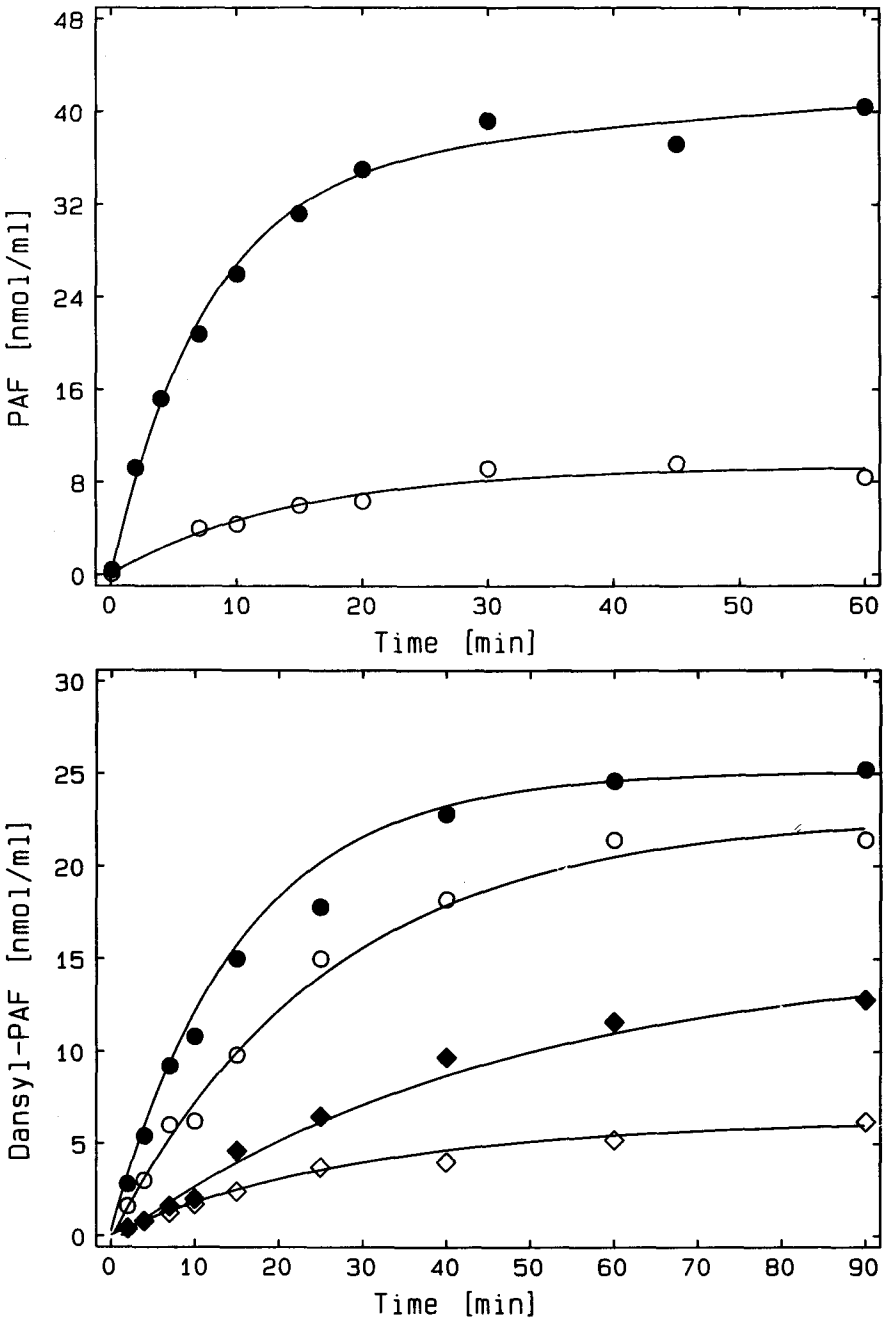

FIG. 1. Time course of paf-acether formation as a function of human acetyltransferase concentration. a) Standard assay 1 using lysoPAF (40 μM); the assay mixture (500 μL) contained 120 μg of protein (closed circles) and 24 μg of protein (open circle), respectively. b) Standard assay 2 with dansyllysoPAF as the substrate; the assay mixture (60 μL) contained the following amount of protein (μg): 56.4 (closed circles), 28.2 (open circles), 11.3 (closed squares), and 5.7 (open squares).

enzyme activity is due to intrinsic thermal instability of the protein at 37°C, to facilitated deactivation [for example, by dephosphorylation of the enzyme (15,16,20)], or to other factors. Recently Ninio *et al.* (18) showed that complete conversion could be achieved when microsomal proteins of high specific activity from ionophore-stimulated human neutrophils are used.

Effect of BSA. Assays of acetyltransferase with lysoPAF as substrate are routinely performed in the presence of BSA, which binds PAF as it is formed (18). By comparison, BSA was found dispensable in assay 2 when rat PMN acetyltransferase with dansyllysoPAF as substrate was measured (11). When we compared the effect of various BSA concentrations on the activity of human acetyltransferase measured by the two assays (Fig. 3), we found that human acetyltransferase was virtually inactive in the absence of BSA with lysoPAF as substrate. The activity sharply rose when BSA was added at concentra-

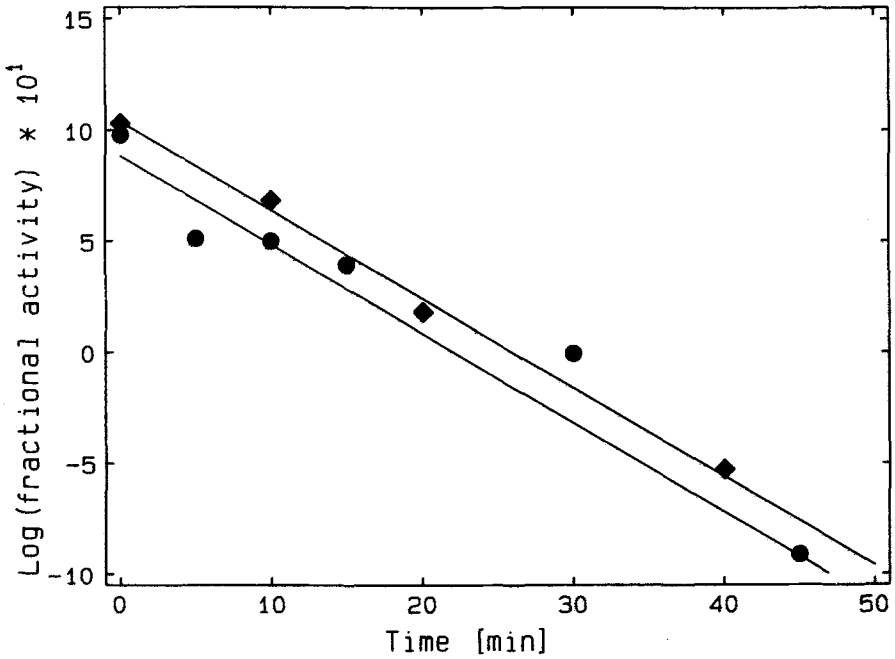

FIG. 2. Time course of the inactivation of human acetyltransferase at 37°C. A stock microsomal fraction (0.676 mg/mL) was incubated at 37°C. At the intervals indicated, samples were withdrawn and assayed using lysoPAF (closed circles) or dansyllysoPAF (closed squares).

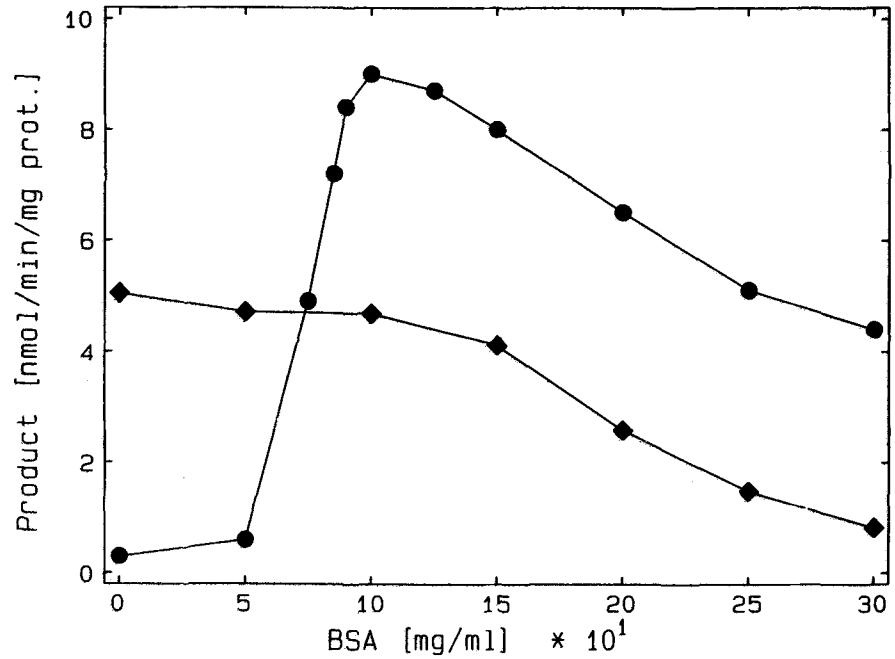

FIG. 3. Activity of human acetyltransferase as a function of BSA assayed with lysoPAF (closed circles) or dansyllysoPAF (closed squares).

tions above 0.5 mg/mL. Maximum enzyme activity occurred at 1 mg BSA per mL assay. At BSA concentrations ranging from 1–3 mg/mL, enzyme activity declined rapidly. Since lysoPAF is quite insoluble in aqueous medium below its critical micellar concentration (18), the results suggest that a critical BSA/lysoPAF ratio exists in assay 1 which provides for an optimal dispersion of the lysoPAF substrate. Contrary to the results from assay 1, full acetyltransferase activity was observed in assay 2 in the absence of BSA. However, BSA concentrations exceeding 1 mg/mL led to diminution of dansylPAF formation. Contrary to lysoPAF, dansyllysoPAF is readily soluble in water at least up to 1.6 mM. Therefore, the data using assay 2 suggest that BSA-mediated dispersion of substrate is not required if the substrate is readily soluble. The decline in activity of the enzyme observed with both substrates at BSA concentrations exceeding 1 mg/mL was beyond the scope of our present study. However,

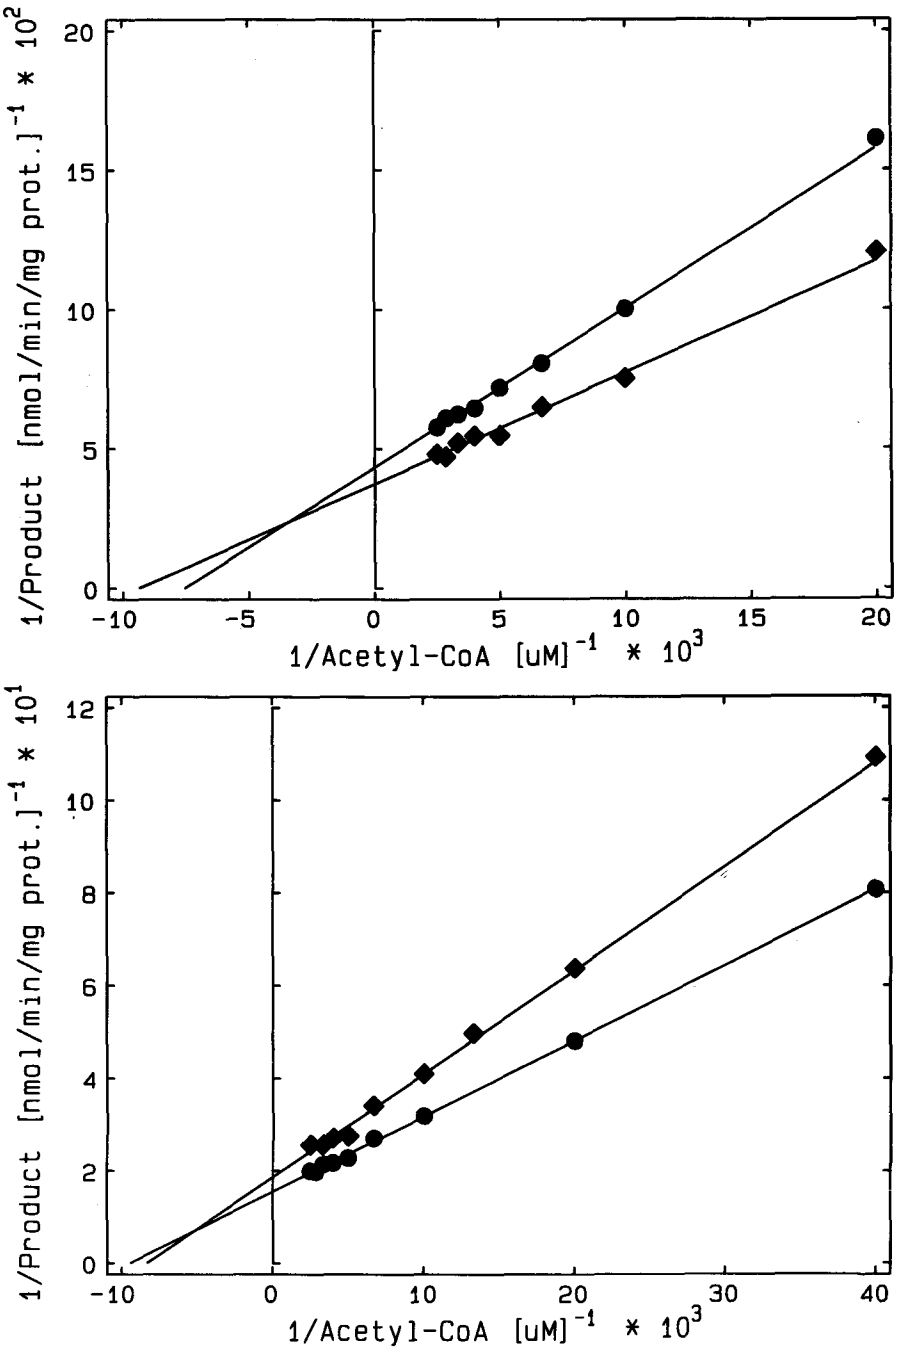

FIG. 4. a) Activity of human acetyltransferase as a function of acetyl-CoA at fixed concentrations (40 μM) of lysoPAF (closed circles, assay 1) or dansyllysoPAF (closed squares, assay 2). b) Activity of rat acetyltransferase as a function of acetyl-CoA at fixed concentrations (40 μM) of lysoPAF (closed circles, assay 1) or dansyllysoPAF (closed squares, assay 2).

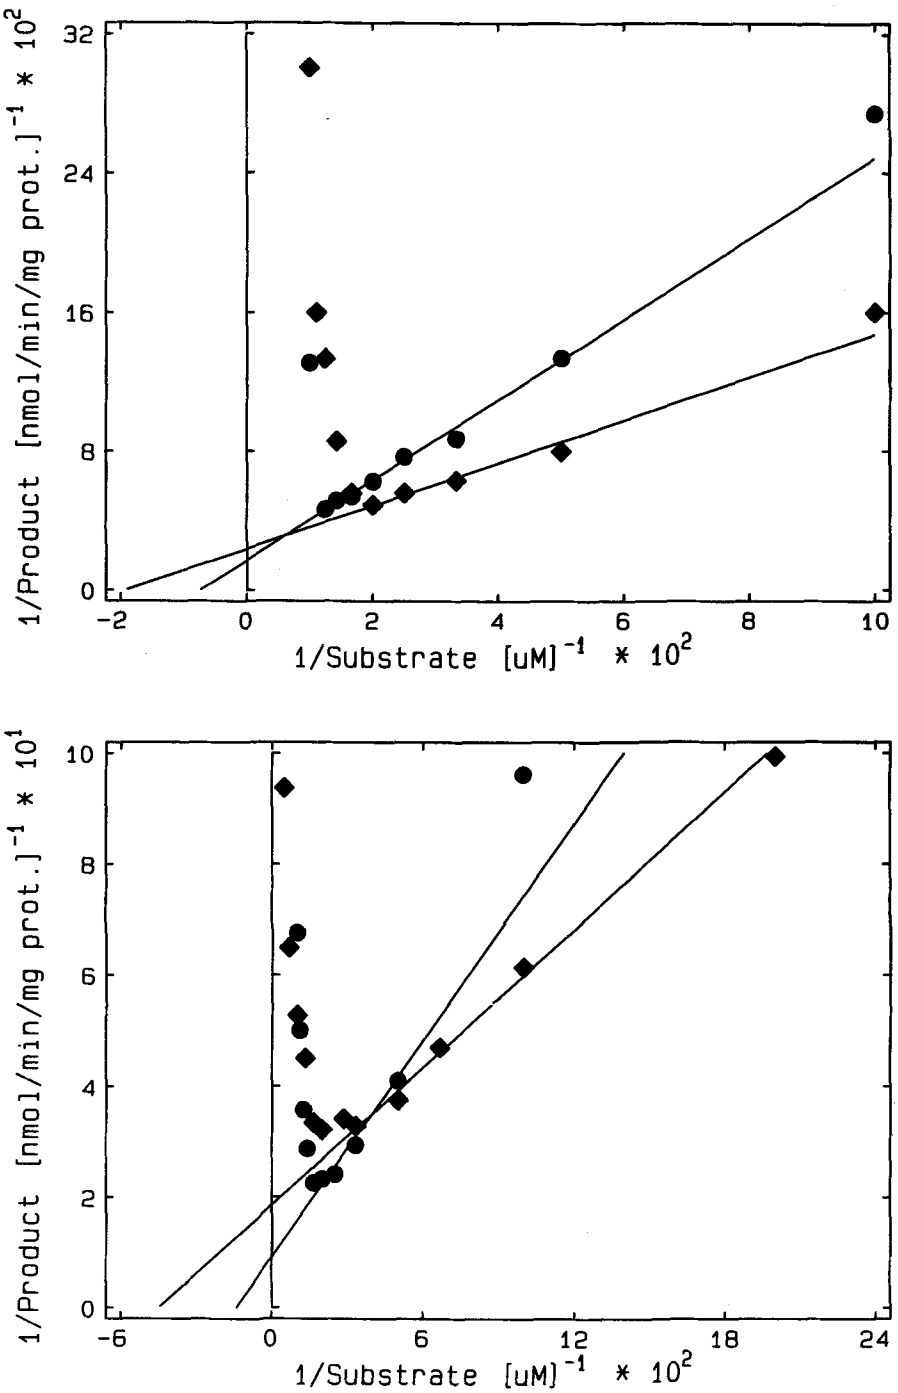

FIG. 5. a) Activity of human acetyltransferase as a function of lysoPAF (closed circles) or dansyllysoPAF (closed squares) at fixed concentrations (200 μM) of acetyl-CoA. b) Activity of rat acetyltransferase as a function of lysoPAF (closed circles) or dansyllysoPAF (closed squares) at fixed concentrations (200 μM) of acetyl-CoA.

TABLE 1

Comparison of Kinetic Parameters for Human and Rat PMN Acetyltransferase Activity as a Function of Acetyl-CoA[a]

Substrate		K_m for Acetyl-CoA (μM)		V_{max} nmol × mg^{-1} × mg^{-1}	
		Human	Rat	Human	Rat
LysoPAF	(+BSA)	132	105	23.1	6.5
DansyllysoPAF	(−BSA)	105	120	26.7	5.4

[a]Kinetic data were obtained from experiments shown in Figure 4. Initial velocity data were analyzed by weighted fits to the Michaelis-Menten equation using a non-linear regression analysis program adapted from KINFIT (17).

this effect may have been caused from the formation of tightly BSA-bound substrates unavailable to the substrate-binding site of the enzyme.

Activity of acetyltransferase as a function of acetyl-CoA. When the activity of acetyltransferase was determined at acetyl-CoA concentrations ranging from 25 to 400 μM at a fixed concentration of lysoPAF or dansyllysoPAF (40 μM), both human and rat acetyltransferase exhibited classical Michaelis-Menten kinetics with this cosubstrate (Fig. 4). The kinetic parameters derived from these experiments are summarized in Table 1. As can be seen from the data, both enzymes exhibited similar K_m values for acetyl-CoA regardless of which substrate was used. Also, the V_{max} values for the human or rat acetyltransferase were similar when assayed with either lysoPAF or dansyllysoPAF. However, the specific activity of rat PMN microsomal acetyltransferase is considerably less than the specific activity of the human enzyme.

Activity of acetyltransferase as a function of lyso ether lipid. Figure 5 shows data of experiments obtained when the concentration of lysoPAF or dansyllysoPAF was varied between 5 and 100 μM, and the concentration of acetyl-CoA (200 μM) was fixed. As can be seen from this Figure, the increase in the activity of lysoPAF acetyltransferase with increasing substrate concentrations apparently followed simple saturation kinetics only up to about 50 μM. At concentrations of lyso compound exceeding 50 μM a drop in enzyme activity was observed that was consistent with previously published data (19,21,22). However, the limited range of substrate concentrations that seemed to follow Michaelis-Menten kinetics was not suitable to calculate meaningful values for K_m or V_{max}. Since the data obtained could not be fitted to a function representing substrate inhibition, factors other than unproductive substrate binding may be responsible for the drop in activity at higher substrate concentrations.

The data presented in this paper demonstrate that no significant differences in the kinetic behavior of acetyltransferase are apparent when either lysoPAF or dansyllysoPAF serve as the substrate. Therefore, the introduction of the dansylamino group into the omega position of the alkyl side chain of lysoPAF does not affect the rate-limiting step of product formation with either human or rat acetyltransferase. Thus, dansyllysoPAF should be a suitable substrate for high throughput screening of potential inhibitors of acetyltransferase from both rat and human neutrophils.

The Effect of Inhibitors of Platelet Aggregation on the Metabolism of Platelet-Activating Factor (PAF) in Washed Rabbit Platelets[1]

The rabbit platelet metabolizes platelet-activating factor (PAF) intracellularly. PAF is deacetylated to produce lysoPAF which, in turn, can be acylated to produce 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholine (alkylacyl GPC). Some PAF receptor antagonists have been shown to inhibit this metabolic conversion. In the present study we examined whether the PAF receptor antagonists SRI 63-441 and WEB 2086 would inhibit the metabolism of PAF by intact rabbit platelets. In addition, we examined whether iloprost, a stable analogue of prostaglandin I_2 (PGI_2), and a potent inhibitor of platelet activation induced by a range of agonists, would also inhibit PAF metabolism. We found that SRI 63-441 and WEB 2086 caused an almost complete inhibition of the conversion of PAF to alkylacyl GPC. Iloprost caused up to a 50% inhibition of PAF metabolism compared to antagonist-free controls. Iloprost (and PGI_2) is thought to inhibit platelet response by elevation of cAMP, while receptor antagonists act by blocking PAF binding to its receptor. Since iloprost caused partial inhibition of PAF metabolism, the results of this study suggest that inhibition of PAF metabolism does not occur solely due to competitive inhibition of PAF binding to its receptor.
***Lipids* 26, 1011-1014 (1991).**

Platelet-activating factor (PAF) is generally acknowledged to have a short half-life *in vivo*. This is due to the broad distribution of the enzyme PAF acetylhydrolase (1), both extracellularly and intracellularly. Acetyl hydrolysis results in the conversion of PAF to lysoPAF, the latter being cytotoxic (2). To avoid cell and tissue damage, rapid processing of lysoPAF is therefore required. LysoPAF in cells is usually reacylated *via* a transacylase to form 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholine (alkylacyl GPC). The fatty acid utilized in this esterification in most cells is preferentially, but not exclusively, arachidonic acid (3,4). Membrane alkylacyl GPC may then serve as a precursor for PAF synthesis *via* phospholipase A_2 and acetyltransferase (E.C. 2.3.1.67), thus creating the PAF cycle (5). However, this pattern of metabolism may not be universal. Activation of washed human platelets by PAF does not result in this type of cellular PAF metabolism (6).

Some PAF receptor antagonists inhibit the metabolism of PAF by rabbit platelets (7,8) and a variety of other cell types, preventing the production of both lysoPAF and alkylacyl GPC. The dose of antagonist required is generally higher than that needed to inhibit platelet activation (8). It has been suggested that the PAF receptor antagonist prevents internalization of PAF by rabbit platelets, and thus exposure of PAF to intracellular metabolic enzymes (7,8). In the case of human platelets, however, PAF receptor antagonists, such as WEB 2086 or ginkgolides, did not inhibit PAF metabolism, nor did they inhibit serum acetylhydrolase (6,9).

The present study, examined (for the first time) the capacity of the PAF receptor antagonists SRI 63-441 and WEB 2086 to inhibit the metabolism of PAF by washed rabbit platelets. Since other agents which activate platelets, such as thrombin, can also promote metabolism of PAF by platelets (10), the ability of the prostaglandin I_2 (PGI_2) stable analogue, iloprost (ZK 36374), which is a very potent inhibitor of platelet activation, was also examined.

MATERIALS AND METHODS

Preparation of platelets. Blood (7 vol) from a male New Zealand white rabbit was collected into 1 vol of acidified citrate dextrose (ACD; pH 6.4, 4°C) (6). The platelets were centrifuged at 100 × *g* for 15 min to produce platelet-rich plasma (PRP). They were then washed three times in Tyrodes buffer containing ACD (9:1, v/v; pH 6.4) (6). After the last wash, the platelets were resuspended ($250 \times 10^3/\mu L$) in Tyrodes buffer. Tyrodes buffer contained 137 mM NaCl, 2.6 mM KCl, 11.9 mM $NaHCO_3$, 1.0 mM $MgCl_2$, 0.41 mM NaH_2PO_4, 0.5 mM dextrose, and 5.0 mM HEPES (Sigma Chemical Co., St. Louis, MO). The buffer was supplemented with 0.25% (w/v) bovine serum albumin (BSA, CSL, Melbourne, Australia) and adjusted to pH 7.4. This medium is referred to as Tyrodes-BSA (6).

[^{3}H]PAF and inhibitors. [^{3}H]PAF (1-*O*-[hexadecyl-1′, 2′-^{3}H(N)]-; 56.7 Ci/mmol) was obtained from NEN Research Products (Wilmington, DE). [^{3}H]PAF in chloroform was placed into siliconized glass test tubes, the solvent was evaporated under N_2, and PAF was resuspended in Tyrodes-BSA. Three inhibitors were used in the study: i) SRI 63-441 which is *cis*-(±)-1-[2-hydroxy [tetrahydro-5-[(octadecylaminocarbonyl)oxy]methyl]-furan-2-yl]methoxy-phosphinyloxy]ethyl]quinolinium hydroxide, inner salt (Sandoz Research Institute, East Hanover, NJ); ii) WEB 2086 which is 3-[4-(2-chlorophenyl)-9-methyl-6H-thieno[3,2-f][1,2,4]triazolo-[4,3-a][1,4]-diazepin-2-yl]-1-(4-morpholinyl)-1-propanone (Boehringer Ingelheim, Ingelheim, Germany); and iii) iloprost which is 5-(E)-(1S,5S,6R,7R)-7-hydroxy-6-(E)-(3S,4RS)-3-hydroxy-4-methyl-oct-1-en-6-yn-yl-bicyclo-3.3.0-octano-3-yliden-pentanoic acid (Schering AG, Berlin, Germany). Iloprost was provided as a 0.1 mg/mL saline solution, and SRI 63-441 and WEB 2086 were prepared as 1 mg/mL solutions

Abbreviations: ACD, acidified citrate dextrose; alkylacyl GPC, 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholine; BSA, bovine serum albumin; HPLC, high-performance liquid chromatography; PAF, platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; PGI_2, prostaglandin I_2; PRP, platelet-rich plasma.

in phosphate buffered saline. The inhibitor concentrations required were attained by serial dilution with saline. The potency of the three inhibitors was tested in a platelet aggregation assay as previously described (11).

PAF metabolism assay. The washed platelet suspension (250 μL) was placed into a 37°C teflon chamber and stirred using a magnetic stirrer (approximately 500 rpm). [^{3}H]PAF (5 μL) in Tyrodes-BSA was added to give a final concentration of 1.3 nM. Immediately thereafter, 45 μL of saline containing the appropriate concentration of inhibitor was added. For zero time assessment, 125 μL of the platelet suspension was removed and added immediately to 19 vol of methanol to stop metabolism and to extract the lipids. The remaining platelet suspension was incubated, and the reaction was stopped at various time points by addition to methanol.

Lipid extraction. The addition of methanol caused precipitation of proteins which were removed by centrifugation (2,500 × *g*, 4°C, 30 min). The supernatant (1 vol) was added to H_2O and chloroform (0.8:0.95, v/v) to effect phase separation. The chloroform phase was recovered and solvent was removed in a rotary evaporator; the lipids were resuspended in 100 μL of methanol and chromatographed by high-performance liquid chromatography (HPLC).

Chromatography. Ion exchange HPLC was used to separate PAF from its metabolites (adapted from ref. 12), utilizing an LKB system with a Whatman Partisil SCX (covalently bound benzene sulfonate residues) column (250 × 4.6 mm, 10 μM silica; Activon, Sydney, Australia). The mobile phase was $CH_3CN/CH_3OH/H_2O$ (300:150:35, v/v/v) at a flow rate of 1.5 mL/min. Fractions (1.5 mL) were collected for 40 min and the radioactivity in each fraction was quantitated by scintillation counting. Figure 1 shows a typical elution profile for a number of phospholipids, including [^{3}H]lysoPAF. The putative acylated derivative of lysoPAF (alkylacyl GPC) eluted at approximately 11–12 min, PAF at 18–21 min and lysoPAF at 28–31 min. Over 85% of all counts recovered were associated with these three regions. Counts eluting at the solvent front were generally less than 10%.

RESULTS

The first experiments were designed to determine the time dependence of PAF metabolism by washed rabbit platelets. These experiments were done in the absence of PAF antagonists (Fig. 2). A significant amount of PAF conversion had already occurred by 15 min when most of the PAF-derived label was found in the lysoPAF fraction. PAF degradation proceeded in an almost linear fashion between 15 and 65 min, and by 80 min most of the label migrated close to the phosphatidylcholine fraction. Based on the results of previous studies, it appeared likely that the latter fraction was alkylacyl GPC (13). Only a small amount of lysoPAF was present at this time, confirming that lysoPAF does not accumulate in platelets. Further experiments used 80 min as the end-point, and the conversion of [^{3}H]PAF to putative alkylacyl GPC was used as a measure of metabolic activity.

Figure 3 shows the relative potency of inhibition of PAF induced platelet aggregation by the three antagonists used in this study. Both iloprost and WEB 2086 were more potent than SRI 63-441, while iloprost was significantly more potent than WEB 2086 (iloprost IC_{50} 13.9 nM; WEB 2086 IC_{50} 55 nM).

Figure 4 shows that the PAF receptor antagonists SRI 63-441 and WEB 2086 almost completely inhibited conversion of [^{3}H]PAF to putative alkylacyl GPC at the highest concentrations tested. The amount of lysoPAF present was not different from the zero time control or inhibitor-free preparation (results not shown). There was

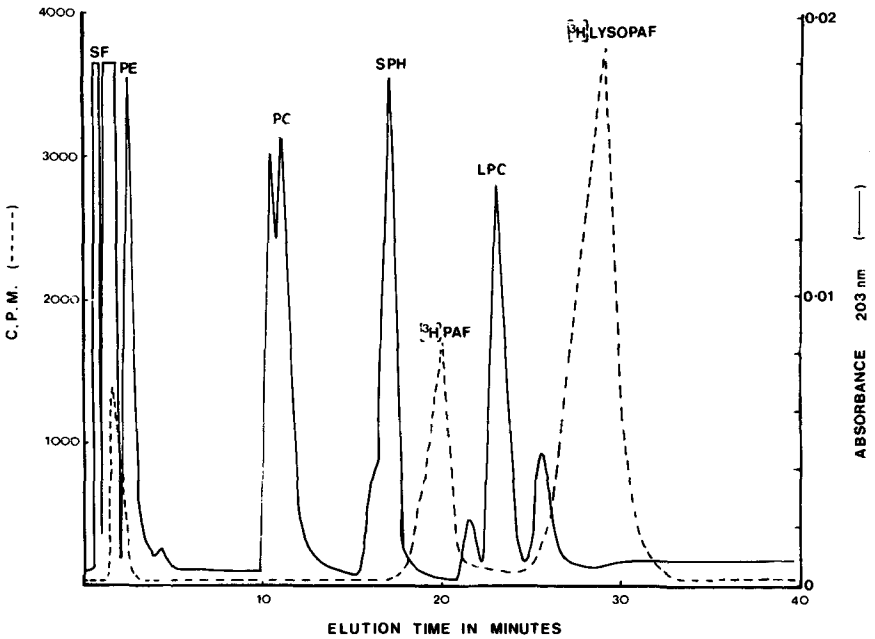

FIG. 1. Typical elution of [^{3}H]PAF and [^{3}H]lysoPAF (broken line) and phospholipid standards (solid line) from a Whatman Partisil strong cation-exchange column with acetonitrile/methanol/water (300:150:35, v/v/v) at a flow rate of 1.5 mL/min.

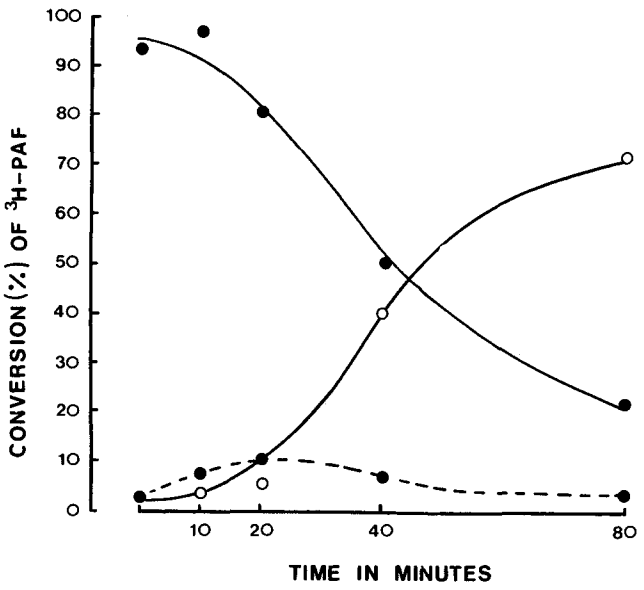

FIG. 2. Redistribution of label from [^{3}H]PAF by washed rabbit platelets as percentage of radioactivity added as a function of time. PAF (●-●), lysoPAF (●--●), or alkylacyl GPC fraction (O-O). Each point is the mean of three replicates.

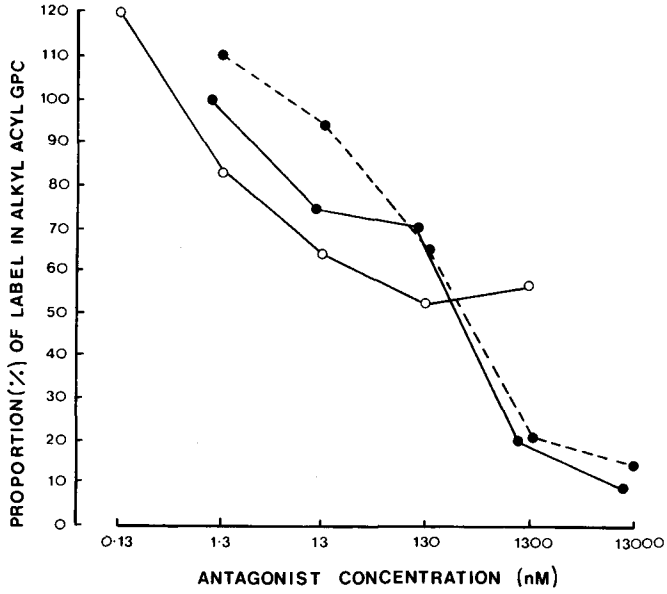

FIG. 4. The effect of PAF inhibitors (iloprost O-O; WEB 2086 ●-●; SRI 63-441 ●- -●) on the conversion of [^{3}H]PAF to putative alkylacyl GPC relative to its conversion in the absence of inhibitors, *i.e.*, % conversion with inhibitor/% conversion without inhibitor × 100. Each point is the mean of three replicates, except for WEB 2086 g, which was the mean of four replicates.

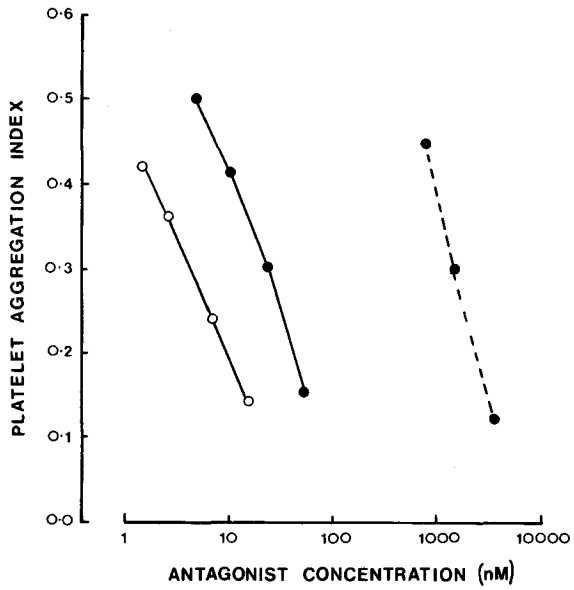

FIG. 3. The effect of increasing concentrations of the PAF inhibitors, iloprost (O-O), WEB 2086 (●-●) and SRI 63-441 (●- -●) on the platelet aggregation induced by the EC_{50} for PAF (0.023 μM) after 15 min incubation with citrated rabbit blood. Each point is the mean of at least three replicates. The platelet aggregation index is 1−(platelet count at 15 min/platelet count at 0 min). An index of 0 signifies no aggregation, and 1 is complete aggregation.

little difference in the relative potencies of response of the two receptor antagonists (which is in contrast to the relative potencies of inhibition of platelet aggregation by these two agents; Fig. 3). For both of these antagonists, the maximum inhibition of metabolism was at a 1,000-fold higher dose than its non-effective concentration. Iloprost caused significant inhibition of metabolism at lower doses than SRI 63-441 and WEB 2086. In contrast to that of the two receptor antagonists, the maximum inhibition caused by iloprost was only approximately 50% of that of antagonist-free controls. WEB 2086 and SRI 63-441 caused a 90% inhibition of metabolism as compared with controls. As with the receptor antagonists, iloprost displayed its maximum inhibitory effect at a 1,000-fold higher dose than its non-effective concentration.

DISCUSSION

The action of PAF on blood platelets is receptor mediated (6,9,14). This signal is transduced by a GTPase (G protein) (15,16) which appears to activate phospholipase C (17). The consequent generation of inositol polyphosphates and diacylglycerol is well documented, as is the resulting increase in cellular calcium concentration and activation of protein kinase C (for a review, see ref. 18).

PAF receptor antagonists compete with PAF for platelet receptors, but do not stimulate GTPase activity upon binding (19), thus inhibiting signal transduction and preventing cell activation. By comparison, iloprost is a potent stimulant of adenylate cyclase (20), resulting in increased cellular cAMP concentrations. Treatment of platelets with dibutyryl cAMP suppresses their response to PAF, and also suppresses PAF induced GTPase activity (19). cAMP also inhibits diacylglycerol dependent activation of protein kinase C (21). Thus, by different mechanisms, the PAF receptor antagonists and iloprost prevent PAF induced activation of cells by inhibition of its signal transduction and secondary messengers.

It was suggested that the binding of PAF to its receptor stimulates the internalization of PAF (and other phospholipids), resulting in its exposure to metabolic enzymes (8,22). The PAF receptor antagonist, BN 52021, inhibited conversion of PAF to putative alkylacyl GPC in intact platelets, but not with cell lysates (7).

A possible explanation for the inhibition of PAF metabolism by receptor antagonists is that the antagonists compete with PAF for the receptor, thus reducing the amount of PAF that can be internalized. It was shown that structural analogues of PAF, U66985 and lysoPAF had only marginal effects on the metabolism of PAF (10). However, these agents also compete for the receptor, but had either minimal or no inhibitory effect on platelet activation, respectively (10). Furthermore, desensitization of platelets to PAF, by prior exposure in the absence of calcium, actually enhanced the metabolism of PAF upon stimulation of platelets with thrombin, collagen or A23187 (9). From such results it appears that the effects of receptor antagonists on PAF metabolism are not simply due to competitive inhibition at the receptor level, but are also dependent upon inhibition of platelet activation.

If this is the case, it may be expected that other inhibitors of platelet activation would also inhibit PAF metabolism. To test this hypothesis we have examined the effect of iloprost on PAF metabolism. Iloprost was the most potent inhibitor of platelet aggregation, with an IC_{50} of 13.9 nM (Fig. 3), and was also the most potent inhibitor of PAF metabolism by platelets (Fig. 4).

All three inhibitors showed a similar pattern of response at low concentrations. For iloprost, however, a maximum response of only about 50% inhibition of metabolism was observed. Further increases in the concentration caused no additional effect. At low doses, iloprost stimulates intracellular platelet cAMP levels (23). At higher concentrations, however, while there was a rapid production of cAMP, the concentration subsequently returned to normal (14). Such a biphasic response is consistent with our inability to completely inhibit PAF metabolism with iloprost. It was not determined in this study whether iloprost affected PAF binding to platelets, although it previously has been shown that iloprost increases intracellular cAMP (24) and that dibutyryl cAMP may indirectly reduce PAF binding by platelets (19). Since iloprost caused partial inhibition of metabolism, the results of this study suggest that inhibition of PAF metabolism does not occur solely due to competitive inhibition of PAF binding to its receptor.

In situ, there is extensive extracellular metabolism of PAF to lysoPAF by serum acetylhydrolase (1). The resulting lysoPAF can cross membranes independently of the PAF receptor (8), albeit at a slower rate than PAF. Therefore, the inhibition of metabolism by PAF antagonists at the cellular level may be of limited significance. However, PAF binding molecules in serum (molecular weight 160–180 kilodalton) which protect PAF from metabolism by serum acetylhydrolase and, hence, limit extracellular metabolism, has been reported (25). If PAF were bound to a molecule protecting it from serum acetylhydrolase, the presence of a high concentration of an inhibitor of PAFs action (and hence cellular metabolism) would extend the half-life of PAF *in situ* considerably. This could facilitate PAFs local accumulation and potentially accentuate its action.

ACKNOWLEDGMENT

This work was funded by a grant from the Special Programme of Research, Development and Research Training in Human Reproduction, World Health Organisation. We thank Schering AG, Boehringer Ingelheim and Sandoz Research Institute for the gifts of antagonists, and Mrs. D. Gillespie for her help in the preparation of the manuscript.

The Hormonal Regulation of Platelet-Activating Factor Acetylhydrolase Activity in Plasma[1]

Shuichi Miyaura, Noriei Maki, William Byrd and **John M. Johnston***
The Departments of Biochemistry, Obstetrics-Gynecology and The Cecil H. & Ida Green Center for Reproductive Biology Sciences, The University of Texas Southwestern Medical Center, Dallas, Texas 75235-9038

We have previously reported that certain fetal tissues including the lung and kidney have an increased platelet-activating factor (PAF) content and enzymatic mechanism for its elevated biosynthesis during the latter stages of pregnancy. In contrast, in the maternal plasma compartment of both the rabbit and human, a decreased capacity to inactivate PAF has been demonstrated. The PAF acetylhydrolase in the fetal plasma is also suppressed. The present study was undertaken to determine the mechanism(s) involved in the regulation of PAF acetylhydrolase. The 17α-ethynylestradiol was administered (intraperitoneal [i.p.] 2.5 mg/kg body wt 5 days) to female and male rats. The plasma PAF acetylhydrolase activity decreased 5-fold. A decrease was observed when a concentration of the estrogen as low as 50 μg/kg was employed. The injection of dexamethasone (i.p., 1.3 mg/kg body wt, 5 days) to male and female rats resulted in a 3-fold increase in the plasma PAF acetylhydrolase activity. The activity returned to the values prior to hormone treatment 4 days after cessation of treatment. Testosterone and progesterone were without effect on plasma acetylhydrolase activity. The change in PAF acetylhydrolase activity caused by estrogen and the glucocorticoid was reflected by a change in the activity in the HDL fraction and not due to the presence of an inhibitor or activator in the plasma of the hormone-treated animals. Human serum obtained from a group of women, in which the 17β-estradiol concentration was elevated in preparation for an *in vitro* fertilization procedure, showed an inverse relationship between the plasma estrogen concentration and the PAF acetylhydrolase activity. It is suggested that estrogen is responsible for the regulation of PAF acetylhydrolase and the decrease in the plasma PAF acetylhydrolase during the latter stages of pregnancy in both the maternal and fetal plasma caused by the hyperestrogenic state that occurs during this period. The observed increase in PAF acetylhydrolase by dexamethasone may account for, in part, the known anti-inflammatory properties of this steroid by decreasing the concentration of this potent autacoid.
***Lipids 26,* 1015-1020 (1991).**

The name "platelet-activating factor (PAF)" was first utilized to describe a mediator that was released from basophils following IgE sensitization which would cause platelet aggregation (1). The structure was subsequently shown to be 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine by Demopoulos *et al.* (2) and Benveniste *et al.* (3). During this same period, Snyder and colleagues demonstrated that the polar renal-medullary antihypertensive lipid was PAF (4). Subsequently it was demonstrated that a variety of cells release PAF upon stimulation (for recent reviews, see ref. 5-7). It is now well established that this active autocoid is involved in a variety of biological phenomena including anaphylaxis and the inflammatory response including neutrophil and eosinophil stimulation (8-10), vascular permeability (11-13), and induction of hypotension (4). Its physiological role has also been suggested in reproductive biology in both animals and humans including implantation (14) and fetal lung maturation, and the initiation and maintenance of parturition (15). Other investigators have suggested a role for PAF in ovulation (16) and spermogenesis (17).

The enzymatic mechanisms involved in PAF biosynthesis in various tissues have been reported (for review, see ref. 18). PAF can be synthesized by two distinct mechanisms referred to as the remodeling and the *de novo* pathways. Until recently, the regulation of PAF concentration in most tissues has focused on the biosynthetic pathways. The key regulatory enzymes of the remodeling pathway and *de novo* pathway are thought to be acetylCoA:lysoPAF acetyltransferase and acetylCoA: 1-alkyl-2-lyso-*sn*-glycero-3-P acetyltransferase, respectively (7).

The inactivation of PAF is catalyzed by the enzyme PAF acetylhydrolase (18). Two forms of the enzyme exist: one is found in the cytosolic fraction of most cells, and an extracellular form of the enzyme is present in plasma. Several reports have appeared concerning the change in activity of PAF acetylhydrolase in plasma in association with certain biological events. A significant increase in activity has been reported during a "stress" reaction of the lizard (19). The activity also increased during platelet aggregation (20) and in patients with ischemic cerebrovascular disease (21). A decrease in PAF acetylhydrolase activity in maternal plasma was found during the latter half of pregnancy in the rabbit (22) and human (23). The activity of this enzyme is increased dramatically in the plasma of the rabbit neonate shortly after delivery (22). A decrease in plasma acetylhydrolase activity has also been reported in asthmatic children (24), and the deficiency in serum PAF acetylhydrolase is transmitted as an autosomal recessive trait. An increase in PAF acetylhydrolase has been reported in insulin-dependent diabetes mellitus (25) and also in spontaneously hypertensive rats (26) and hypertensive Caucasian males (27). The properties of PAF acetylhydrolase and its potential role in human disease have recently been reviewed in detail (28).

To investigate the regulation of the circulating or tissue levels of PAF, we have examined the activity of PAF acetylhydrolase as it may be regulated by various hormones during pregnancy. Increases in estrogens and progesterone are known to occur in both the fetal and maternal compartments during the latter stages of pregnancy. During this time period the activity of PAF acetylhydrolase

[1]Based on a paper presented at the Third International Conference on Platelet-Activating Factor and Structurally Related Alkyl Ether Lipids, Tokyo, Japan, May 1989.

Abbreviation: PAF, platelet-activating factor.

is low in fetal plasma and decreasing in the maternal plasma (22). We have examined the role of various steroid hormones on the activity of PAF acetylhydrolase in rat plasma and in the plasma of women undergoing hormonal manipulation in preparation for an *in vitro* fertilization procedure.

MATERIALS AND METHODS

Chemicals. [^{3}H]PAF (1-*O*-hexadecyl-2-[^{3}H]acetyl-*sn*-glycero-3-phosphocholine; 10 Ci/mmol; 1 Ci = 37 GBq) was purchased from New England Nuclear, Boston, MA. Nonradiolabeled PAF was obtained from Avanti Polar Lipids, Pelham, AL. Bovine serum albumin (fatty acid-poor), 17α-ethynylestradiol, progresterone, testosterone and dexamethasone were purchased from Sigma Chemical, St. Louis, MO.

Treatment of rats with hormones. Hormones were dissolved in ethanol and made up to desired concentrations with dimethylsulfoxide. The final concentration of ethanol was 18%. Hormones were administered to both male and female Wistar rats (270 g) for 5 days by daily intraperitoneal injection. Control rats received the vehicle only. Blood was collected from the tail vein into heparinized capillary tubes. Samples were collected 22 hr prior to the first, second and fourth injections and after the last injection. The plasma was immediately separated by centrifugation.

Patient selection. Twelve patients requesting treatment by *in vitro* fertilization and embryo transfer were given luprolide acetate (TAP Pharmaceuticals, North Chicago, IL) subcutaneously to inhibit gonadotrophin secretion, 1 mg/day for a minimum of 14 days followed by 0.5 mg a day until the administration of human chorionic gonadotrophin. Follicular development was stimulated following suppression of endogenous luteinizing hormone (LH) and follicle stimulating hormone (FSH) by injection of 3 ampoules of Pergonal (preparation of human gonadotrophins containing equal amounts of LH and FSH) per day (Serono, Randolf, MA) for the three days, followed by variable doses of Perganol depending on the patient's estradiol response. Ovulation was induced by 5,000 IU of hCG when two or more follicles reached 18 mm in diameter as determined by sonography.

Hormone assays. Estradiol and progesterone were measured using the Delfia (Pharmacia ENI, Columbia, MD) solid phase fluoroimmunoassay procedure. Blood samples were taken from patients at indicated times, and allowed to clot at room temperature. The serum separated by centrifugation. Intra-assay variation was 5.7% for progesterone and 8.7% for estradiol. Inter-assay variation was 7.1 and 9.9%, respectively.

Assay for PAF acetylhydrolase activity. The activity of PAF acetylhydrolase (EC 3.1.1.48) in plasma was assayed according to the method of Miwa *et al.* (24) with minor modifications. The assay mixture contained Tris-HCl (30 mM, pH 7.5), 1-*O*-hexadecyl-2-[^{3}H]acetyl-*sn*-glycero-3-phosphocholine (50 μM, 4.0 μCi/μmol) in bovine serum albumin (0.13% final concentration), and various amounts of plasma in a total vol of 0.5 mL. The assay mixtures and controls (without enzyme) were incubated for 20 min at 37°C and terminated by addition of 0.5 mL of 14% trichloroacetic acid. The supernatant was obtained by centrifugation for 5 min at 3,000 × *g* at 4°C. A 0.1 mL aliquot of the supernatant was removed and mixed with 5 mL scintillation cocktail (Budget-Solve; Research Products International Corp.). The water-soluble [^{3}H]acetate released from [^{3}H]PAF was assayed by liquid scintillation spectroscopy.

Preparation of cytosolic and lipoprotein fractions. Liver, kidney, lung, spleen and brain were removed following hormone treatments and stored at −70°C until used for assay. Tissues were homogenized in 6 vol of a cold 0.25 M sucrose using a PT 10/20 Polytron homogenizer at maximum speed. All procedures were performed at 4°C. The homogenate was centrifuged at 600 × *g* for 10 min. The resulting supernatant fraction was further centrifuged at 18,000 × *g* for 15 min and then at 105,000 × *g* for 60 min to obtain the cytosolic fraction. The lipoprotein fractions were prepared by ultracentrifugation on a KBr density gradient as described (29). PAF acetylhydrolase activity in the cytosolic fraction was assayed as described above.

RESULTS

Effect of hormones on PAF acetylhydrolase. Previously Pritchard (30) had injected 17α-ethynylestradiol to male rats in order to establish that the activity of PAF acetylhydrolase was closely associated with the lipoprotein fraction. In our initial studies, 2.5 mg/kg of 17α-ethynylestradiol, 50 mg/kg of progesterone, 5 mg/kg of testosterone and 1.3 mg/kg of dexamethasone were injected

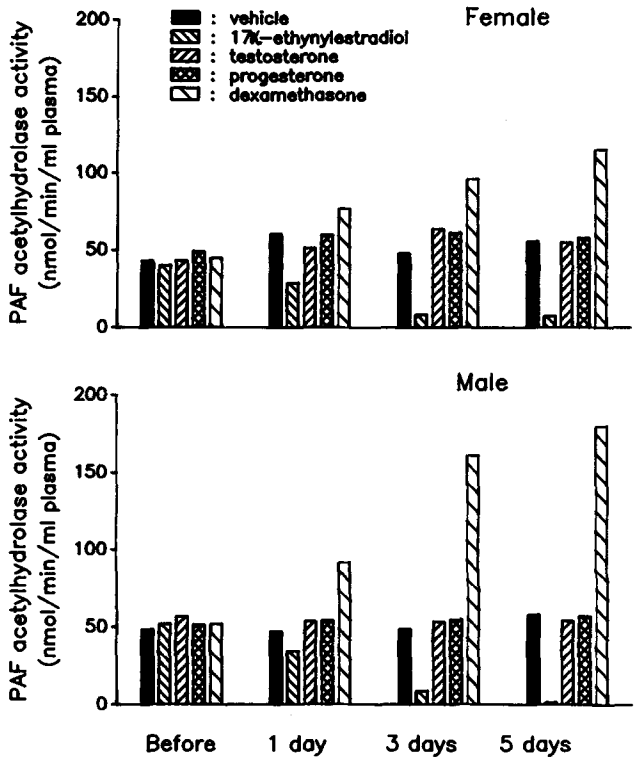

FIG. 1. Effect of various steroid hormones on the plasma PAF acetylhydrolase activity of the rat. Rats received vehicle, 17α-ethynylestradiol (2.5 mg/kg), testosterone (5 mg/kg), progesterone (40 mg/kg) or dexamethasone (1.3 mg/kg) as detailed in Experimental Procedures. PAF acetylhydrolase activities in plasma were assayed periodically, and the values are the averages of results from two rats.

i.p. in male and female rats for 5 days, and the plasma PAF acetylhydrolase was assayed (Fig. 1). The specific activities of PAF acetylhydrolase in male and female rats before treatment were 52 ± 1.5 (means ± SEM; n = 10) and 50 ± 2.1 nmol × min^{-1} × mL^{-1} of plasma (n = 10), respectively. The activity of the enzyme decreased during the 5 days of treatment with 17α-ethynylestradiol to 1.2 and 7.5 nmol × min^{-1} × mL^{-1} plasma in male and female rats, respectively. When dexamethasone was administered for similar time periods, a significant increase in PAF acetylhydrolase activity was observed: from 52 to 180 nmol × min^{-1} × mL^{-1} plasma in male rats and from 50 to 115 in female rats after a 5-day treatment. Progesterone (50 mg/kg) or testosterone (5 mg/kg) administration under similar conditions did not alter the activity of PAF acetylhydrolase in either male or female rats. This experiment was repeated several times and similar results were obtained. In addition, we observed no effect of progesterone when given in combination with 17α-ethynylestradiol over and above the predicted decrease in activity when 17α-ethynylestradiol was administered alone (data not shown). However, when 17α-ethynylestradiol and dexamethasone were administered simultaneously, no change in PAF acetylhydrolase activity was observed (Fig. 2). It is suggested that the combination of these two hormones, one of which inhibits and one of which increases PAF acetylhydrolase activity, resulted in no net change in the activity of this enzyme.

To clarify whether or not hormones have some effect on the intracellular PAF acetylhydrolase activity, we determined the activity of the cytosolic enzyme in various tissues obtained from rats treated with the various hormones. In control male rats, specific activities of PAF acetylhydrolase were: kidney 4.2, lung 3.0, brain 1.4, spleen 0.88 and liver 0.28 nmol × min^{-1} × mg^{-1} protein. Although these values were lower than that previously reported (31), the relative distribution pattern among tissues was very similar. No change of intracellular PAF acetylhydrolase activity in any tissues was observed after hormone treatment.

In order to determine whether the changes of the enzyme activity in plasma from rats treated with either 17α-ethynylestradiol or dexamethasone were due to an activator or inhibitor, a mixing experiment was performed (Table 1). The activity of PAF acetylhydrolase was assayed following the mixing of plasma samples obtained from the hormone-treated group with the control samples in various proportions. The specific activities in the plasmas obtained following treatment for 5 days with 17α-ethynylestradiol from the 17α-ethynylestradiol and control rats were 4.5 and 57 nmol × min^{-1} × mL^{-1} plasma, respectively. When equal volumes of each plasma were mixed and assayed, the specific activity was 31 nmol × min^{-1} × mL^{-1} plasma (theoretical value, 31). Similar theoretical values were obtained when samples from a variety of known mixtures were analyzed. When mixtures of control and dexamethasone plasma were assayed in a similar manner, the results again agreed with the theoretical values. It is, therefore, concluded that the plasma obtained from the 17α-ethynylestradiol- and dexamethasone-treated animals contained neither activators nor inhibitors of PAF acetylhydrolase that account for the change in activity following hormone treatment.

TABLE 1

PAF Acetylhydrolase Activity in Mixtures of Plasma from Rats Treated with Hormones[a]

Combinations	Mixing ratio by vol				
	1:0	3:1	1:1	1:3	0:1
Vehicle/estrogen	57	45	31	18	4.5
Vehicle/dexamethasone	57	93	120	154	177
Dexamethasone/estrogen	177	131	101	50	4.5

[a]Plasma obtained from rats injected with either vehicle, 17α-ethynylestradiol or dexamethasone (see Experimental Procedures) was mixed in the ratios indicated and their PAF acetylhydrolase activities were determined. Activities are expressed as nmol × min^{-1} × mL^{-1} plasma.

We next examined the dose response of 17α-ethynylestradiol and dexamethasone on PAF acetylhydrolase activity. As indicated in Figure 3, the administration of 17α-ethynylestradiol at doses as low as 0.05 mg/kg resulted in a significant decrease of enzyme activity. Maximum inhibition was observed at doses of 0.25 mg/kg. Dexamethasone increased PAF acetylhydrolase when this hormone was administered at doses as low as 0.65 mg/kg. Within three days following the suppression or induction of PAF acetylhydrolase activity by either hormone, the values returned to the levels observed prior to hormone treatment.

Distribution of PAF acetylhydrolase activity in lipoprotein fractions. It was previously reported that in the human plasma PAF acetylhydrolase is a Ca^{2+}-independent phospholipase A_2 associated with the lipoprotein fraction with specificity for substrates with a short-chain acyl group (7,32,33). In the human, PAF acetylhydrolase activity is primarily associated with the LDL fractions (28,32,33), while in the rabbit (22) and rat (30) the activity is present in the HDL fraction. The distribution of PAF acetylhydrolase in the various plasma fractions of the rat is illustrated in Figure 4. The PAF acetylhydrolase activity in the control samples following hormone treatment is present in the HDL fraction in rat plasma (85%) and less than 5% in the LDL fraction. PAF acetylhydrolase activities in plasma obtained from the 17α-ethynylestradiol- and dexamethasone-treated animals were altered to 6 and 216 % of the control animals, respectively.

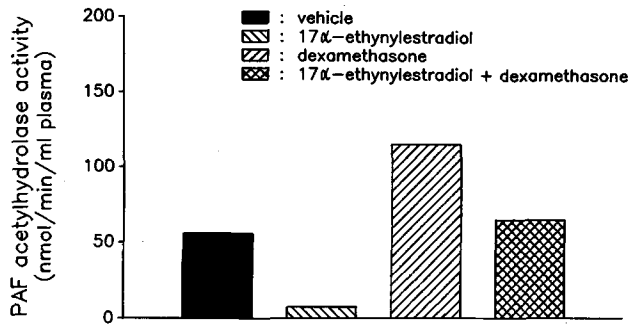

FIG. 2. Effect of combination hormone treatment on the plasma PAF acetylhydrolase activity of the rat. Rats received vehicle, 17α-ethynylestradiol (2.5 mg/kg), dexamethasone (1.3 mg/kg) or a mixture of 17α-ethynylestradiol and dexamethasone for 5 days. PAF acetylhydrolase activity in plasma was assayed 22 hr after the last injection (experiment repeated 3 times with similar results).

However, the activity was still primarily associated with the HDL fraction. Based on these findings, it is suggested that the suppression and induction of the enzyme by these hormones resulted in a change in the activity without changing the plasma distribution of the enzyme from that present in the untreated animal.

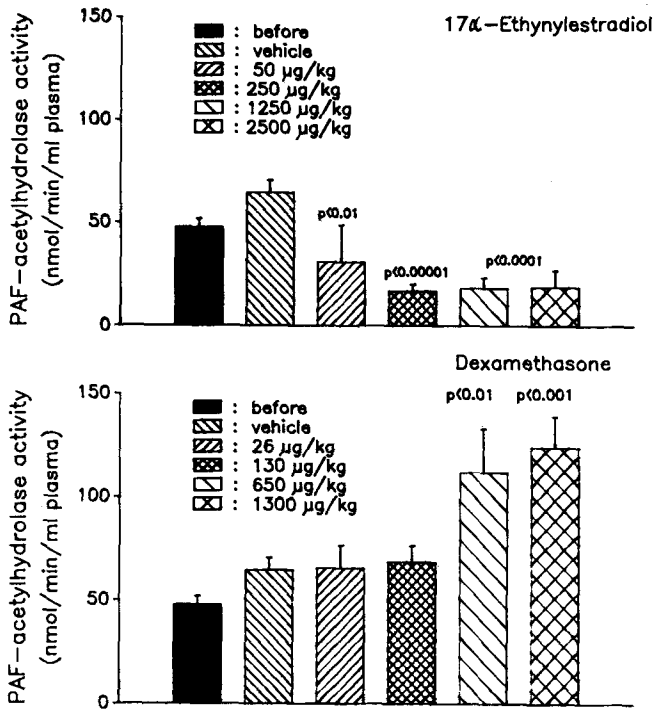

FIG. 3. Dose response of 17α-ethynylestradiol and dexamethasone on the plasma PAF acetylhydrolase in male rat plasma. Male rats received vehicle, 17α-ethynylestradiol or dexamethasone at various concentrations for 3 days by daily intraperitoneal injection. Blood was collected from the tail vein 22 hr before the 1st injection and after the last injection. PAF acetylhydrolase activity in plasma was assayed, and statistical analysis was carried out by Student's t-test for unpaired samples. Values are the means ± SD of results from 4 rats.

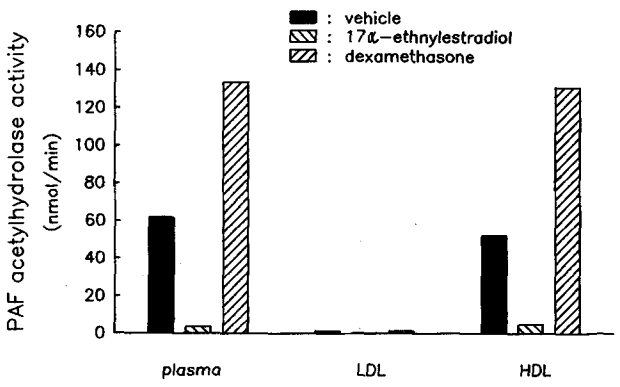

FIG. 4. Distribution of PAF acetylhydrolase activity in rat plasma. Rats received 17α-ethynylestradiol at 0.25 mg/kg or dexamethasone at 0.65 mg/kg for 5 days. Blood was collected from heart of unanesthetized rats, mixed with 1 mg EDTA per mL and placed on ice. Lipoproteins were separated by ultracentrifugation on a KBr density gradient as described (29). Values in plasma and lipoprotein fractions are expressed as total activities obtained from 1 mL of plasma (experiment repeated 2 times with similar results).

Plasma PAF acetylhydrolase activity and estrogen concentration in the human. In an attempt to determine whether or not the activity of PAF acetylhydrolase could be correlated to circulating hormone concentrations in the human, we examined the serum PAF acetylhydrolase activity in a group of women whose serum 17β-estradiol concentrations were known. These women were undergoing follicular stimulation in preparation for *in vitro* fertilization. Serum 17β-estradiol levels were suppressed to less than 0.2 nmol/L following the subcutaneous administration of Lupron prior to follicular stimulation with Pergonal. Following Pergonal stimulation, samples were taken throughout the cycle, and the estradiol and progesterone were measured. The PAF acetylhydrolase activity expressed as a function of the serum 17β-estradiol concentration in these women is illustrated in Figure 5. As can be seen, there is an inverse relationship between the serum estradiol concentration and the activity of PAF acetylhydrolase. In Table 2 the relationship of progesterone and estradiol was examined in these same women. The activity of the PAF acetylhydrolase in the first three groups was significantly different from each other ($p < 0.001$). We found no relationship between the serum progesterone levels and the activity of plasma PAF acetylhydrolase activity.

We have also determined the level of estradiol and PAF acetylhydrolase activity in aspirates from preovulatory follicles in women undergoing *in vitro* fertilization. We found that the estradiol levels in the follicular aspirates had a mean value of 140.9 ± 25.3 nmol/L with a corresponding value of 1.3 ± 0.8 nmol × min^{-1} × mL^{-1} of PAF acetylhydrolase activity. When the estradiol levels from serum and follicular fluid were compared to PAF acetylhydrolase activities, there was a correlation of $r = 0.856$ ($p < 0.0001$).

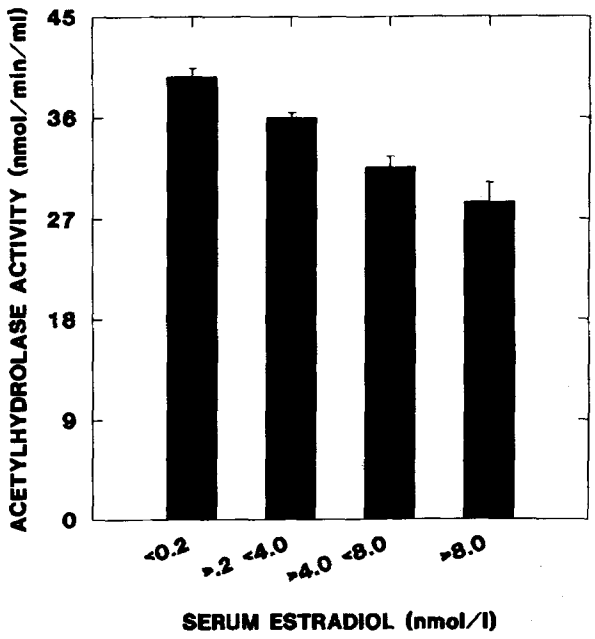

FIG. 5. Acetylhydrolase activity and estradiol levels in women undergoing follicular stimulation wtih Pergonal. Serum samples were obtained daily from 12 women undergoing follicular stimulation.

TABLE 2

Plasma PAF Acetylhydrolase Activity During the Menstrual Cycle in Women

	Estradiol nmol/L	Progesterone nmol/L	PAF Acetylhydrolase nmole × min^{-1} × mL^{-1}
Day 1 (start Pergonal)	0.01 ± 0.01[b]	0.8 ± 0.49[d]	40.05 ± 31[f]
Day 11 (hCG)	7.35 ± 4.45[a]	2.14 ± 0.93[d]	30.24 ± 6.41[e]
Day 21 (Mid-Luteal)	0.055 ± 0.35[b]	45.37 ± 12.55[c]	38.56 ± 7.56[f]

Mean ± SD.

[a]Significantly different from b ($p < 0.001$) ANOVA (analysis of variance).

[c]Significantly different from d ($p < 0.001$) ANOVA.

[e]Significantly different from f ($p < 0.02$) ANOVA.

DISCUSSION

The importance of PAF in reproductive and developmental biology has recently been reviewed (14,15,34). We have previously observed that PAF is present in the amniotic fluid of women at term and in labor but not present in the amniotic fluid of women at term and not in labor (35). These findings were confirmed by Nishihara *et al.* (36). We also reported that PAF is present in the amniotic fluid of women with preterm labor and premature rupture of membranes (37). The source of the PAF in amniotic fluid is thought to be at least, in part, the fetal lung (38). It has been observed that PAF will stimulate PGE_2 formation in amnion tissue (39) and amnion cells in culture (40). PAF is also one of the most potent stimuli of myometrial contraction in rat (36), guinea pig (41) and human (42). In support of its role in stimulating myometrial contraction, we have recently demonstrated the presence of PAF receptors in myometrium, and shown that PAF is a potent stimulator of Ca^{2+} uptake and myosin light-chain phosphorylation in isolated human myometrial cells (43). It has also been demonstrated that the length of labor in rats was increased 3- to 5-fold by the administration of the PAF receptor antagonist L-659,989 (44).

We have suggested that the increase in PAF production occurs in several fetal tissues, including the lung, during the latter stages of gestation (15,38). The increase in PAF is most likely due to an elevation in its biosynthesis due to an increase in the activities of the enzymes of both the remodeling and *de novo* pathways in fetal tissue (38,45). No change in the intracellular activity of PAF acetylhydrolase in fetal lung tissues was observed during this period. Thus, the capacity for PAF biosynthesis is increased in certain fetal tissues during the latter stages of pregnancy (23).

In contrast, it is suggested that there is a decreased capacity to inactivate PAF in the maternal plasma during the latter stages of pregnancy in the rabbit (22) as well as the human (23) since the activity of PAF acetylhydrolase is significantly reduced. It is suggested that the combination of an increase in the biosynthesis of PAF in fetal tissues and a decrease in the capacity of the maternal plasma to inactivate PAF is of critical importance in the initiation and maintenance of parturition (23). The decidua may be the site in which the PAF is inactivated in early and mid-pregnancy because of its "lush" blood supply. During the latter stages of pregnancy, a decrease in the capacity to inactivate PAF occurs due to the reduced activity of PAF acetylhydrolase in maternal plasma (22). The mechanism involved in the regulation of this potent autacoid during development is of importance. It is well documented that during the latter stages of pregnancy dramatic hormonal changes occur in both the fetal and maternal compartments. Estrogen would be a prime candidate for hormonal regulation of plasma PAF acetylhydrolase since its concentration increases at a similar time as the changes in PAF acetylhydrolase. Support for a possible role for estrogen in regulating PAF acetylhydrolase was provided by the observation by Pritchard (30) who injected 17 α-ethynylestradiol to male rats, and demonstrated a decrease in the lipoprotein fraction and PAF acetylhydrolase activity in plasma.

In the present study, it has been demonstrated that the intraperitoneal administration of 17α-ethynylestradiol to both male and female rats results in a significant decrease in the plasma PAF acetylhydrolase activity. The decrease was noted within the first 24 hr and was maximal following 3 days of estrogen administration. The activity returns to pretreatment levels (within 3 days) when the hormone treatment was discontinued. The administration of progesterone by itself or in combination with the estrogen did not alter the activity over that expected by 17α-ethynylestradiol injection. Thus, the combined treatment was not necessary for the decreased expression of the enzyme activity. Testosterone administration was also without effect.

In contrast, the administration of dexamethasone to both male and female rats resulted in an increase in the specific activity of plasma PAF acetylhydrolase. The increase was seen within 24 hr, and was maximal after 3 days of treatment. Like estrogen administration, the activity returned to the preinjection levels within 3 days following the suspension of dexamethasone treatment. The importance of PAF as an autacoid in the inflammatory response is well established (6). As discussed, the activity of PAF acetylhydrolase increases during a "stress" reaction in the lizard which is related to an increase in glucocorticoids (19). Based on the reported observations that dexamethasone increases PAF acetylhydrolase activity, it is suggested that this synthetic glucocorticoid may function, in part, as an anti-inflammatory agent by increasing the activity of PAF acetylhydrolase, and thus decrease the concentration of this potent mediator of the inflammatory response in plasma and certain tissues.

During pregnancy the estrogen levels in the maternal compartment are increasing. In this study we have demonstrated a decrease in PAF acetylhydrolase activity by estrogen administration which would be consistent with a central role for estrogens in the regulation of this enzyme during the latter stages of pregnancy. An additional role for estrogen in the regulation of the activity of this enzyme in fetal plasma might also be invoked. The PAF acetylhydrolase activity in rabbit fetal plasma is low during most of gestation (22) and then increases to values which are two to three times that of the adult nonpregnant rabbit within 10 days after birth (23). The activity remains elevated in the newborn until the time of sexual maturity. This would be the expected pattern of PAF acetylhydrolase activity of the neonate and maturing rabbit if the plasma enzyme were regulated by estrogen, since the estrogen concentration in the fetus is high during the latter stages of gestation. Following delivery, the estrogen concentration decreses in the newborn since the placenta is the primary site of its biosynthesis. It is suggested that the high circulating levels of PAF acetylhydrolase present in neonatal rabbits may be the explanation of the increased resistance of neonate and young animals to PAF administration when compared to adult animals (45). We have also noted an inverse relationship between the serum 17β-estradiol levels in women in which the estrogen level has been significantly elevated in preparation for *in vitro* fertilization (Table 2, Fig. 5). The role of estrogens in the regulation of PAF acetylhydrolase in relation to the initiation and maintenance of parturition and to certain complications of pregnancy is presently under investigation.

REVIEW

Recent Advances in Our Understanding of the Biochemical Interactions Between Platelet-Activating Factor and Arachidonic Acid[1]

Floyd H. Chilton*, Marc Cluzel and Massimo Triggiani
The Johns Hopkins University School of Medicine, The Johns Hopkins Asthma and Allergy Center, Baltimore, Maryland 21224

In the last few years, it has become increasingly apparent that the biochemistry of PAF (platelet-activating factor) and that of arachidonic acid are interrelated in a number of inflammatory cells. Experiments presented here further point out that arachidonic acid plays a crucial role in the catabolism and biosynthesis of PAF. In addition, they suggest that the same phospholipid molecular species may serve as a source for both arachidonic acid and 1-alkyl-2-lyso-*sn*-glycero-3-phosphocholine during cell activation. Finally, they reveal that there may be common regulatory mechanisms for the biosynthesis of PAF and arachidonic acid metabolites. Taken together, studies examining the relationship between PAF and arachidonic acid suggest it may be difficult to consider the biochemistry of PAF without considering arachidonic acid metabolism and vice versa.
Lipids 26, 1021–1027 (1991).

Five years ago, we and others proposed that the biochemistry of PAF (platelet-activating factor) and arachidonic acid may overlap at several points (Fig. 1). Two observations strongly supported this hypothesis: (i) PAF is catabolized by several inflammatory cells by removing the 2-acetyl group and specifically replacing it with arachidonate; and (ii) cells mobilize 1-alkyl-2-lyso-GPC (glycerophosphocholine) and free arachidonic acid from a common precursor molecule, 1-*O*-alkyl-2-arachidonoyl-GPC by a phospholipase A_2 reaction upon Ca^{++} stimulation. Both 1-alkyl-2-lyso-GPC and free arachidonic acid may then serve as precursors for bioactive lipids, PAF and eicosanoids, respectively. Since these initial findings, several studies have been performed in a number of cells to test and to better characterize these pathways. Progress has been made in several areas which support the hypothesis; these areas include our understanding of: (i) the role of arachidonate in the catabolism of PAF; (ii) the role of arachidonate in the biosynthesis of PAF; (iii) phospholipid sources of arachidonic acid used for eicosanoid biosynthesis and their relationship to PAF sources; and (iv) common regulatory mechanisms for PAF and arachidonic acid metabolites. This review briefly examines some recent developments in each of these areas.

ROLE FOR ARACHIDONATE IN THE CATABOLISM OF PAF

Several cells and tissues including human neutrophils (1), rabbit macrophages (2–4), human (5) and rabbit (6) platelets, human (7) and mouse (8) mast cells and the isolated perfused lung (9) have been shown to metabolize PAF by removing the acetate moiety at the *sn*-2 position and replacing it with arachidonate. Studies utilizing microsomal preparations from a variety of cells now indicate that the key enzyme responsible for the selective acylation of 1-alkyl-2-lyso-GPC with arachidonate is a CoA-independent transacylase (2–4). This enzyme selectively transfers arachidonate from 1-*O*-acyl-2-arachidonoyl-GPC to 1-alkyl-2-lyso-GPC to form 1-alkyl-2-arachidonoyl-GPC. In addition to arachidonate, other C_{20}–C_{22} fatty acids such as 20:5, 22:4, and 22:6 are transferred as well from 1,2-diacyl-GPC to 1-alkyl-2-lyso-GPC in a CoA-independent manner (10). In support of these data, whole cell studies indicate that certain C_{20}–C_{22} carbon fatty acids can replace arachidonate in the acylation reaction of 1-alkyl-2-lyso-GPC if they are present at comparable levels with arachidonate within the cellular phosphoglycerides (8,11). In these studies, the membrane content of ω-3 fatty acids was increased in cells *in vitro* by supplementing them in culture or *in vivo* with diets enriched in ω-3 fatty acids such as 22:6 or 20:5. Subsequently, the cells were examined for their ability to catabolize PAF. Shown in Figure 2 are the HPLC (high performance liquid chromatography) separations of molecular species of newly synthesized 1-alkyl-2-acyl-GPC produced during the catabolism of PAF by mast cells supplemented in culture with arachidonic acid (A), docosahexaenoic acid (B) or linoleic acid (C). Data from this study demonstrate that docosahexaenoate can replace arachidonate in the transacylation reaction if it is present at comparable levels within the cellular phospholipids. In the case of linoleic acid (C), HPLC profiles were identical to cells that had not been supplemented in culture. All of these findings suggest that the nature of the acylation in the whole cell depends on both the fatty acid specificity of the transacylase (C_{20}–C_{22} fatty acids) and also the availability of C_{20}–C_{22} fatty acids within cellular phospholipids.

The CoA-independent transacylation reaction may

explain how C_{20}–C_{22} fatty acids such as arachidonic acid accumulate in the large 1-alkyl pools of certain inflammatory cells. Until recently, little was known about this process. There is now evidence that arachidonic acid is incorporated into choline-linked subclasses by three different enzymatic steps (12). Initially, arachidonic acid is converted to arachidonoyl-CoA by a specific arachidonoyl-CoA synthetase step (13–15). The arachidonoyl-CoA is then incorporated into 1-acyl-2-lyso-GPC in a step that involves an arachidonoyl-CoA:lysophosphatidylcholine acyltransferase reaction that is selective for 1-acyl-linked glycerophosphocholine (12,16). These pathways help explain why free arachidonic acid or arachidonic acid from arachidonoyl-CoA is initially incorporated into 1,2-diacyl-linked species (12,17–19). Furthermore, there is now evidence that the initial acylation of 1-acyl-2-lyso-GPC may be regulated during cell activation (20,21). As discussed above, arachidonate is subsequently transferred from 1-acyl-2-arachidonoyl-GPC into the 1-alkyl-linked fraction by a CoA-independent transacylation step. Figure 3 shows the distribution of exogenously-provided arachidonic acid in choline-linked phospholipid molecular species of the neutrophil after addition for 5 min or 120 min. It is clear from these data that 1-acyl-linked pools are initially labelled; however, this arachidonate shifts into the larger 1-alkyl-linked pools during an additional 120 min incubation period. Further experiments will be necessary to determine which steps in the turnover of arachidonate are altered during cell activation.

THE ROLE OF ARACHIDONIC ACID IN THE BIOSYNTHESIS OF PAF

The discovery of the selectivity for arachidonate in acylation of 1-alkyl-2-lyso-GPC during PAF catabolism led to the question of whether the reversal of this reaction might take place during cell activation. Specifically, would 1-*O*-alkyl-2-arachidonoyl-*sn*-glycero-3-phosphocholine serve as a common source to 1-alkyl-2-lyso-GPC and arachidonic acid? The fact that approximately 65% of the total arachidonate in choline containing lipids is associated with 1-alkyl-2-arachidonoyl-GPC suggests that the neutrophil contains ample substrate to support such a pathway (22,23). Moreover, composition studies in other cell types indicate that arachidonate is preferentially associated with 1-ether-linked phospholipids when 1-ether-linked phospholipids are present within the cell (24–29). In order to test this

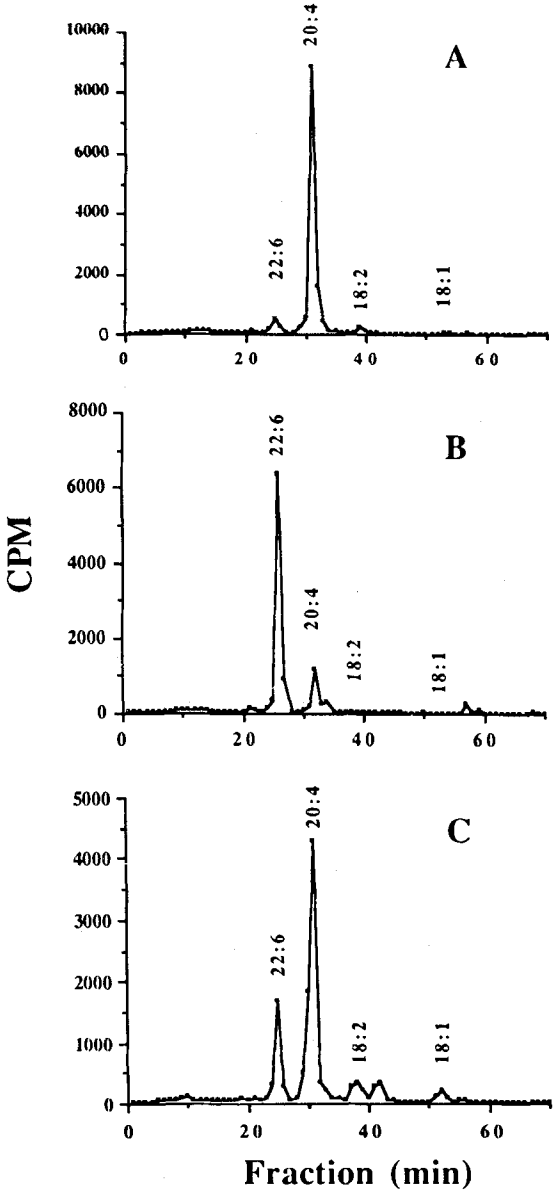

FIG. 2. HPLC separation of molecular species of 1-alkyl-2-acyl-glycerobenzoate derived from newly-synthesized 1-alkyl-2-acyl-GPC formed during the catabolism of PAF by mast cells supplemented in culture with arachidonic acid (A), docosahexaenoic acid (B) or linoleic acid (C). Murine mast cells (PT-18) were supplemented in culture with arachidonic acid, docosahexaenoic acid or linoleic acid (10 μM for 5 days) in addition to fetal calf serum. These cells were removed from culture, washed and incubated with 1-[^{3}H]hexadecyl-2-acetyl-GPC for 30 min. Newly synthesized 1-*O*-hexadecyl-2-acyl-GPC was isolated and converted to benzoate derivatives. The various glycero-benzoate molecular species containing different fatty acyl chains at the *sn*-2 position were isolated by HPLC. The retention times of the 1-alkyl-2-acyl-glycerobenzoate derivatives containing 22:6, 20:4, 18:2 and 18:1 at the *sn*-2 position are indicated on the chromatogram. (Triggiani, M., and Chilton, F.H., *Biochim. Biophys. Acta. 1006*, 41, 1989).

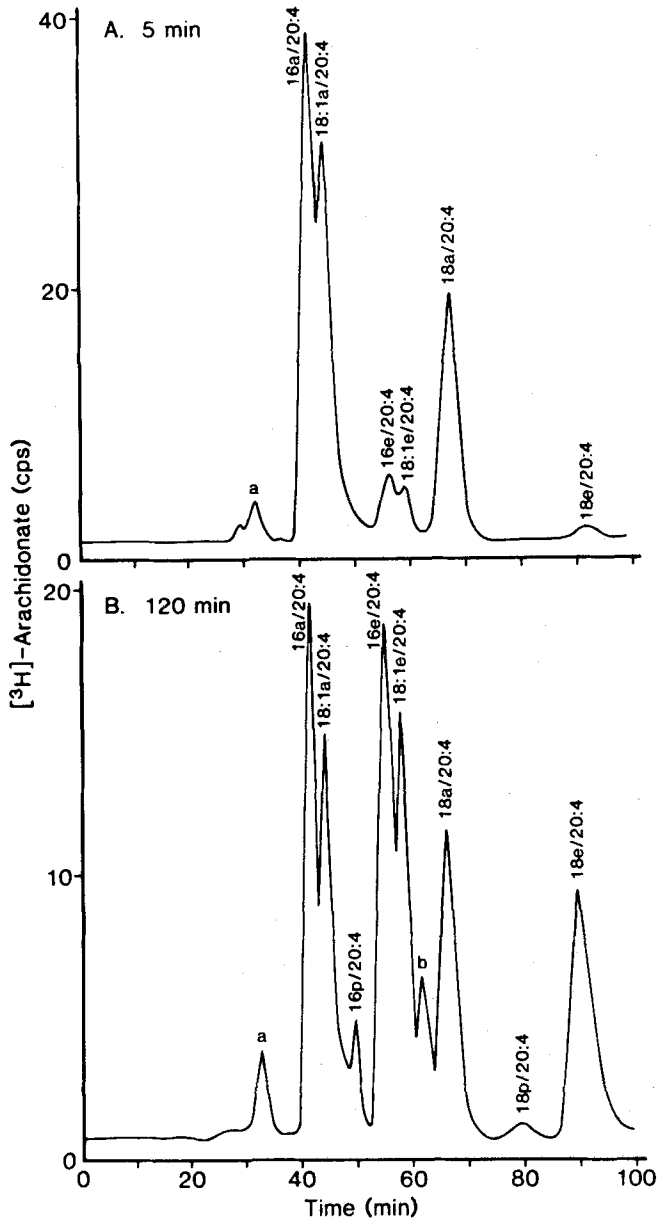

FIG. 3. Incorporation of exogenous arachidonic acid into choline-linked phosphoglyceride molecular species. Neutrophils were labeled for 5 min and 120 min as described (Chilton, F.H., and Murphy, R.C., *J. Biol. Chem. 261*, 7771, 1986). Choline-linked phosphoglycerides were purified by normal phase HPLC. The various 1-radyl-2-[^{3}H]arachidonoyl-GPC species were separated by reverse phase HPLC. The *top panel* shows the distribution of label in the various molecular species from cells which were pulse-labeled for 5 min. The *bottom panel* shows the distribution of label in the various molecular species from cells which were pulse-labeled followed by an additional 120-min incubation. The newly synthesized 1-radyl-[^{3}H]arachidonoyl-GPC contained 16:0, 18:0, and 18:1 fatty acid chains at the *sn*-1 position with *a* representing an acyl linkage at the *sn*-1 position, *e* representing an alkyl ether linkage at the *sn*-1 position, and *p* representing an alk-1-enyl ether linkage at the *sn*-1 position. Arachidonic acid (20:4) esterified at *sn*-2 is indicated following the terminal number. These data are representative of five separate experiments. (Chilton, F.H., and Murphy, R.C., *J. Biol. Chem. 261*, 7771, 1986).

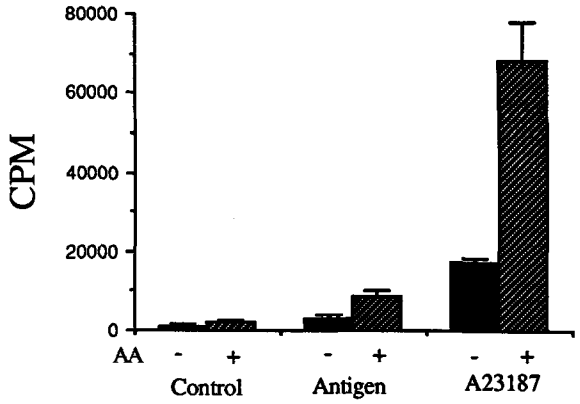

FIG. 4. PAF biosynthesis by mast cells supplemented in culture with arachidonic acid. Murine mast cells (PT-18) were supplemented in culture with (+) and without (−) arachidonic acid (10 μM for 5 days) in addition to fetal calf serum. These cells were removed from culture, washed and then stimulated in the presence of 7 μCi of [^{3}H]acetate with antigen (DNP7-HSA, 2μg/mL) or ionophore A23187 (5 μM). Labeled phospholipids were separated by TLC on silica gel G plates developed in chloroform/methanol/acetic acid/water (50:25:8:3, by vol). The radioactivity in the PAF region was determined by liquid scintillation counting. The data are the mean ± SEM of four experiments.

common precursor hypothesis, we labeled neutrophils with 1-alkyl-2-lyso-GPC. This rapidly converted to 1-alkyl-2-arachidonoyl-GPC which was incorporated into cellular phospholipids. Subsequently, these cells were stimulated, and a large portion of 1-alkyl-2-arachidonoyl-GPC was deacylated at the *sn*-2 position to form arachidonic acid and 1-alkyl-2-lyso-GPC. The 1-alkyl-2-lyso-GPC was then either converted to products such as PAF, or rapidly reacylated with unsaturated fatty acids (primarily 18:1 and 18:2) (30). This provided evidence that 1-alkyl-2-arachidonoyl-GPC could be a primary source of precursors for PAF and arachidonic acid. Studies in using similar prelabeling strategies suggest this pathway is functional in other cells (31).

While the aforementioned experiments suggest that 1-alkyl-2-arachidonoyl-GPC could be a source of 1-alkyl-2-lyso GPC which forms PAF, these experiments provide little evidence that arachidonate at the *sn*-2 position is an absolute requirement for PAF biosynthesis. However, circumstantial evidence suggests that arachidonate at the *sn*-2 position of a phospholipid may be an important factor in whether PAF is formed from that phospholipid. The requirement of arachidonate for PAF biosynthesis has been tested in an indirect manner in dietary and culture supplementation experiments where PAF production is measured in cells in which the composition of fatty acids within phospholipids is altered. Ramesha and Pickett (32) have demonstrated that rat neutrophils depleted of arachidonic acid produce substantially less PAF and leukotriene B_4 than normal neutrophils. In addition, PAF and leukotriene B_4 biosynthesis could be partially restored by incubating the cells with arachidonic acid. We have performed similar experiments in mast cells supplemented in culture with arachidonic acid, and found that the amount of PAF produced correlates with the levels of arachidonate in choline-containing phospholipids of the mast cell (Fig. 4). Similar findings have been reported by Suga and colleagues (33) in the cultured HL-60 cell.

We have recently found that the human lung mast cell produces primarily 1-acyl-2-acetyl-GPC and not 1-alkyl-2-acetyl-GPC upon immunologic activation (34). This finding raises new questions about the relationship of arachidonate to other PAF-like molecules such as 1-acyl-2-acetyl-GPC. Preliminary data indicate that most of the arachidonate found in choline-linked phospholipids of the human lung mast cell is associated with 1-acyl-2-arachidonoyl-GPC subclasses. In contrast to the human lung mast cell, the murine mast cell (PT-18) synthesizes primarily 1-alkyl-2-acetyl-GPC during antigen stimulation. As with the neutrophils, the bulk of arachidonate found in choline-linked phospholipids of the murine mast cell is found with 1-alkyl-2-acyl-GPC. These data support the hypothesis that the relative distribution of arachidonic acid within phospholipid subclasses might influence the subclass of PAF produced.

In addition to 1-alkyl-2-lyso-GPC, 1-alkyl-2-acetyl-GPC and arachidonic acid, 1-alkyl-2-acyl-glycerol was also formed from 1-alkyl-2-arachidonoyl-GPC during cell activation (30). A great deal of research activity has recently gone into understanding the biosynthesis and the biological function of 1-alkyl-2-acyl-glycerol. These studies suggest that this molecule may be formed either by a novel PC (phosphatidylcholine)-specific phospholipase C reaction (35) or a phospholipase D reaction followed by phosphohydrolase activity (36,37). However, it is not yet known if the phospholipase(s) C or D shows any specificity for 1-alkyl-2-acyl-GPC with arachidonate at the *sn*-2 position. Recent studies have compared the mole quantities of alkyl-acyl-glycerol and diacyl-glycerol produced upon cell stimulation (38–40). These studies indicate that a large proportion of radylglycerols formed during cell activation is 1-alkyl-linked. The 1-alkyl-2-acyl glycerols have been proposed to inhibit diacylglycerol-stimulated protein kinase C activity (41–43), to modulate the respiratory burst in neutrophils (44,45), to cause differentiation of human myeloid leukemia cells in culture (46) and to regulate arachidonic acid release in human neutrophils (47). Taken together, these studies suggest that the stimulated degradation of 1-alkyl-2-arachidonoyl-GPC eventually results in the production of at least three—PAF, arachidonic acid, and 1-alkyl-2-acyl glycerol—potentially bioactive molecules.

PHOSPHOLIPID SOURCES OF ARACHIDONIC ACID USED FOR EICOSANOID BIOSYNTHESIS AND THEIR RELATIONSHIP TO PAF SOURCES

There is little concrete information regarding the source of endogenous arachidonate which enters into eicosanoid pathways during cell activation. A major question which has been asked in relation to 1-alkyl-2-arachidonoyl-GPC is whether arachidonic acid which is lost from this molecule during cell activation is important in eicosanoid biosynthesis. We have found that there are at least 16 major arachidonate-containing

phospholipid molecular species in the human neutrophil (17). This large diversity of arachidonate-containing phospholipids makes it difficult to determine which of these lose arachidonate during cell activation. As previously discussed, 1-ether-linked phospholipids contain the major pools of arachidonate in a number of inflammatory cells including the neutrophil. Studies in several cell types indicate that labeled arachidonic acid is lost from both 1-acyl-2-arachidonoyl-GPC and 1-alkyl-2-arachidonoyl-GPC during cell activation (23, 48–54). By mass analysis, we have recently found that 1-alk-1′-enyl-2-arachidonoyl-GPE (glycerophosphoethanolamine) and 1-alkyl-2-arachidonoyl-GPC (23) are the major phospholipid subclasses which lose arachidonate during neutrophil activation (Fig. 5). In experiments where we have measured the mass loss of arachidonate, released LTB_4 and 20-OH LTB_4 account for only 10–35% of the arachidonate lost from phospholipids of the neutrophil during cell activation (23). Because released leukotrienes represent, by mass, such a small proportion of the total arachidonate lost from all phospholipids with ionophore stimulation, data measuring arachidonate loss from phospholipids does not allow one to determine which, if any, of the potential phospholipid subclasses is playing a dominant role in providing arachidonate for leukotriene biosynthesis. In order to get a better idea of which subclasses contribute arachidonate to the leukotrienes, we labeled the neutrophil so that the 6 major arachidonate-containing subclasses were at different radiospecific activities (55). The cells were then activated and the radiospecific activities of the phospholipid subclasses, as well as newly synthesized leukotrienes, were measured. Data from these studies indicated that of the 6 major arachidonate-containing phospholipid subclasses in the neutrophil, only the radiospecific activity of 1-alkyl-2-arachidonoyl-GPC matches that of LTB_4 and 20-OH LTB_4 (Fig. 6). However, it is still possible in these experiments that there are multiple phospholipids subclasses that contribute to the leukotrienes, and the average specific activity is reflected in the specific activity of the leukotrienes. In any event, 1-ether-linked phospholipids must contribute a large proportion of the arachidonate which forms the leukotrienes in the neutrophil since the radiospecific activities of the leukotrienes are well below that of 1-acyl-linked phospholipids. In a similar set of experiments in the platelet, Colard and colleagues (52) have found that the radiospecific activity of released arachidonic acid correlated closely with the specific activity of two phospholipids, 1-alkyl-2-acyl-GPC and 1,2-diacyl-GPE. Both experiments in the neutrophil and platelet provide evidence that 1-ether-linked phospholipids and, in particular, 1-alkyl-2-arachidonoyl-GPC may be an important source of arachidonate for eicosanoid biosynthesis.

COMMON REGULATORY MECHANISM FOR PAF AND ARACHIDONIC ACID

Further evidence for the coupling of PAF and leukotriene B_4 biosynthesis in the neutrophil has come from a study by McIntyre and co-workers (56) which demonstrates that activators of protein kinase C such as PMA (phorbol myristate acetate) enhance A23187-induced PAF and leukotriene B_4 biosynthesis. Furthermore, inhibitors of protein kinase C inhibit ionophore-induced synthesis of PAF and leukotriene B_4. This

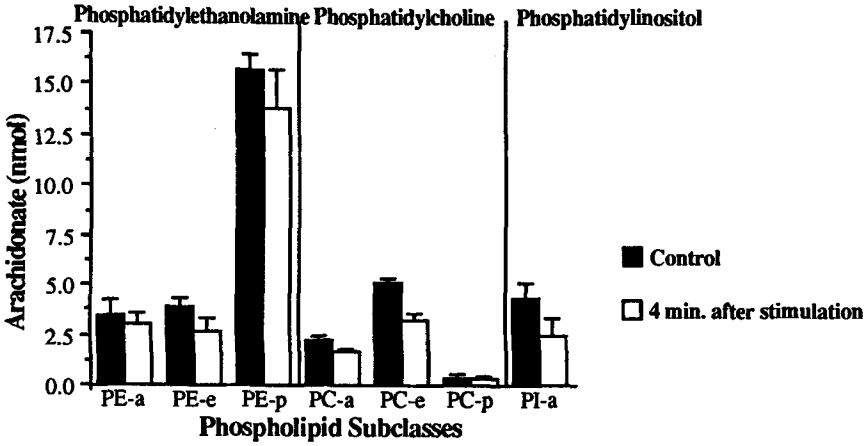

FIG. 5. Loss of endogenous arachidonate from phospholipid subclasses upon challenge with ionophore A23187. Neutrophils were incubated for 4 min with ionophore A23187 (2 μM) or no stimulus. Lipids were extracted from the cell pellet, and glycerolipid classes were separated by normal-phase HPLC. PE and PC were further separated by TLC as diradylglycerols into 1-acyl, 1-alkyl, and 1-alk-1′-enyl subclasses. The nanomole quantities of arachidonate in 1-acyl (a), 1-alkyl (e), and 1-alk-1′-enyl (p) subclasses were determined by gas chromatography/mass spectrometry. Quantity of arachidonate in an individual subclass after a 4 min incubation with no stimulus ■; quantity of arachidonate in an individual subclass after incubation with ionophore A23187 for 4 min □. The data are the mean ± SEM of four experiments (Chilton, F.H., *Biochem. J. 258*, 327, 1989).

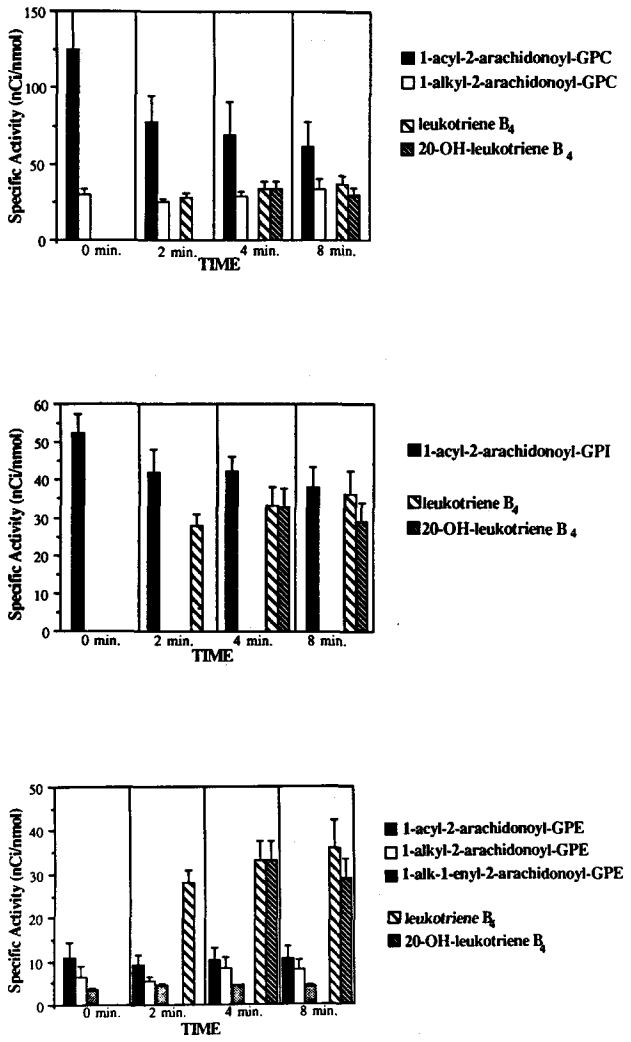

FIG. 6. Specific radioactivities of [^{3}H]arachidonic acid in the three major subclasses of cell-associated PC, PI and PE during cell activation. Neutrophils were labelled with [^{3}H]arachidonic acid as described (Chilton, F.H., *Biochem. J. 258*, 327, 1989) so that all the major arachidonate-containing subclasses had different specific radioactivities. The specific radioactivities of arachidonate in 1-acyl, 1-alkyl and 1-alk-1′-enyl-2-arachidonoyl-GPC, GPI, GPE as well as LTB_4 and 20-OH-LTB_4 were determined at various periods of time after ionophore stimulation. ■, □ and ▨ represent the specific radioactivity of arachidonate in 1-acyl-, 1-alkyl- and 1-alk-1′-enyl-2-arachidonoyl-GPC, GPI, and GPE respectively. ▧ and ▩ represent the specific radioactivity of LTB_4 and 20-OH-LTB_4 respectively. There is no value for the specific radioactivity of 20-OH-LTB_4 at 2 min owing to the fact that only small quantities of this leukotriene were produced at this time point. (Chilton, F.H., *Biochem. J. 258*, 327, 1989).

inhibition could be reversed for both PAF and leukotriene B_4 with the addition of the protein kinase C activator PMA. This study suggests that protein kinase C may regulate a step common to both mediators such as phospholipase A_2. Alternatively, activators of protein kinase C have recently been shown to inhibit the acylation of arachidonic acid into phospholipids (57). This mechanism could enhance both the production of PAF and eicosanoids by allowing for greater availability of lyso PAF and arachidonic acid during cell activation.

We have recently found that raising intracellular cyclic AMP in the mast cell will inhibit both PAF and leukotriene biosynthesis (58). In addition, this inhibition appears to occur at a mechanism independent of that which underlies cyclic AMP (adenosine 5′-monophosphate)-mediated inhibition of the rise in cytosolic calcium or histamine release. Similarly, we have found that agents which increase cyclic AMP in the neutrophil inhibit PAF biosynthesis in response to ionophore A23187 stimulation (unpublished observations). It was also found that the two nonenzymatic hydrolysis products of LTA_4 as well as LTB_4 were inhibited. All of these effects occurred in the absence of measurable effects on the ionophore-induced rises in cytosolic calcium. Given that ionophore-induced synthesis of these diverse lipid mediators—PAF, 6-*trans* LTB_4 and LTB_4—shares one common enzymatic step, namely phospholipase A_2, both results in the mast cell and neutrophil suggest that cyclic AMP regulates lipid biosynthesis at this step. Conversely, Nieto and colleagues (59) have demonstrated that acetyl transferase can be enhanced by the catalytic subunit of cyclic AMP-dependent protein kinase in the presence of magnesium ions and ATP (adenosine 5′-triphosphate). Studies with the neutrophil and mast cell implicate that regulation of C kinase and A kinase activities may influence a common step in the synthesis of both PAF and leukotrienes. However, further experiments will be needed to determine whether this step is a phospholipase A_2 reaction with specificity for 1-alkyl-2-arachidonoyl-GPC.

SUMMARY AND FUTURE DIRECTIONS

Studies in the last 5 yr from several laboratories suggest that PAF and arachidonic acid share common pathways in a number of inflammatory cells. For example, PAF is catabolized in cells by first removing the acetate moiety of the molecule by a cytosolic acetyl hydrolase, and replacing it with arachidonate. The acylation of 1-alkyl-2-lyso-GPC appears to take place via a CoA-independent transacylation reaction. In this reaction, it is thought that arachidonate is transferred from 1-acyl-2-arachidonoyl-GPC to 1-alkyl-2-lyso-GPC. In the biosynthesis portion of the pathway, 1-alkyl-2-lyso-GPC and free arachidonic acid are mobilized from 1-alkyl-2-arachidonoyl-GPC upon Ca^{++} activation. Both 1-alkyl-2-lyso-GPC and arachidonic acid may serve as precursors for PAF and eicosanoids, respectively. While a number of studies have now provided a plethora of direct and indirect evidence to support these pathways, many important questions still remain. For example, it has not been unequivocally established that 1-alkyl-2-arachidonoyl-GPC is the major precursor of PAF. The 1-alkyl-2-acyl-GPC with other fatty acid at the *sn*-2 position may work equally well. Although a few studies now suggest that the arachidonic acid released from 1-alkyl-2-arachidonoyl-GPC plays a role in eicosanoid formation, it is still not clear how tightly this arachidonic acid is coupled to eicosanoid production. In addition, recent studies suggest that some

cells make other 2-acetylated phospholipids such as 1-acyl-2-acetyl-GPC and 1-alk-1′-enyl-2-acetyl-GPE (60). It is not clear what role arachidonate plays in the biosynthesis of these molecules. Finally, several studies now indicate that 1-alkyl-2-arachidonoyl-GPC may undergo other reactions (phospholipase C and phospholipase D) during cell activation. These findings suggest that new avenues may be added to this pathway. Further studies in these directions should continue to provide valuable insight into the biochemistry of PAF and arachidonic acid.

REVIEW

Inositol Phospholipid Turnover in PAF Transmembrane Signalling[1]

Shivendra D. Shukla
Department of Pharmacology, School of Medicine, University of Missouri, Columbia, MO 65212

In a variety of cells and tissues, platelet activating factor (PAF) stimulates phospholipase C catalyzed breakdown of phosphoinositides. This results in the generation of the second messengers, inositol trisphosphate and diglyceride. This process occurs independently of extracellular Ca^{2+}. A number of PAF structural analogues, receptor antagonists and drugs have been utilized to pharmacologically probe the activation of phospholipase C. PAF stimulation of the phosphoinositide turnover was shown to be sensitive to pertussis toxin in some systems, but not in others. The involvement of guanine nucleotide binding protein(s) and tyrosine kinase(s) in this process have also been postulated. These developments give new insights into PAF-receptor function at the molecular level, and also provide leads towards a better understanding of the cellular responses to PAF.
***Lipids 26,* 1028–1033 (1991).**

A number of developments led to the discovery and the biochemical characterization of platelet-activating factor (PAF) as a unique biological mediator (1–7). After the elucidation of the structure of PAF as 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (AGEPC) in 1979 (8–10), one of the important facets of PAF research has been the identification of the molecular mechanism(s) of PAF action in cells. Ligand binding studies and various antagonists led to the pharmacological recognition of PAF receptors (7). Next, PAF receptor-associated transmembrane signalling mechanism, mediated *via* phosphoinositide (PPI) turnover, has been shown to be active in many systems. Since its discovery by Hokin (11), followed by the historical proposals by Michell (12) and Berridge and Irvine (13), it is now established that in response to many agonists inositol phospholipids [the primary one being phosphatidylinositol-4,5-*bis*phosphate (PIP_2)] are broken down by phosphoinositide specific phospholipase C (PLC). The generated products, inositol trisphosphate (IP_3) and diglyceride (DG), serve as second messengers and play a role in intracellular Ca^{2+} mobilization and in the activation of protein kinase C, respectively (13,14). It appears that this mechanism, mediated by PLC, is operative in several systems which respond to PAF (Table 1). It has further been documented that PAF action can also be mediated by phospholipase A_2 in some cells. However, a discussion of the PLA_2 pathway is not within the scope of this article. The present review summarizes recent developments which specifically relate to PAF stimulated PLC mediated phosphoinositide turnover and emphasizes the importance of this mechanism in PAF action.

[1]Based on a paper presented at the Third International Conference on Platelet-Activating Factor and Structurally Related Alkyl Ether Lipids, Tokyo, Japan, May 1989.

Abbreviations: AGEPC, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; DG, diglyceride; IP_2, inositol diphosphate; IP_3, inositol trisphosphate; IP_4, inositol tetraphosphate; IP_5, inositol pentaphosphate; IP_6, inositol hexaphosphate; PA, phosphatidic acid; PAF, platelet activating factor; PMA, phorbol myristate acetate; PI, phosphatidylinositol; PIP, phosphatidylinositol-4-phosphate; PIP_2, phosphatidylinositol-4,5-bisphosphate; PKC, protein kinase C; PLA_2, phospholipase A_2; PLC, phospholipase C; and PPI, phosphoinositides.

PAF STIMULATED PHOSPHOINOSITIDE TURNOVER

Three biochemical indicators, namely production of inositol polyphosphates (primarily IP_3), diglyceride (DG) and phosphatidic acid (PA) have been followed as criteria in PPI turnover studies (14). In the case of PA, this metabolite may also be generated by a phospholipase D action (45) in some systems. However, this issue has not been addressed in studies involving PAF, and therefore remains open at this stage.

In the initial studies with rabbit platelets, it was demonstrated that PAF enhanced the incorporation of ^{32}P into platelet phosphoinositides (PI, PIP and PIP_2), indicating an increased turnover of these lipids (15). The level of PA also increased as monitored by both its mass and ^{32}P radioactivity. Subsequently, utilizing [^{3}H]inositol labeled (16) and ^{32}P-labeled platelets (17), it was observed that PAF caused a rapid (within 5 seconds) and transient decrease in radioactive PIP_2. Thus the earliest response to PAF was a decrease in PIP_2. This decrease was apparently mediated through the PLC pathway because the level of IP_3 increased within the same time frame (18).

Investigations with human and horse platelets have further focussed on this mechanism. Addition of PAF to ^{32}P-labeled horse platelets induced rapid formation of [^{32}P]PA. When platelets were labeled with [^{14}C]arachidonic acid, PAF caused production of [^{14}C]PA (26). It was further shown that PAF caused a transient decrease in [^{32}P]PIP_2 in horse platelets (27). When ^{32}P-labeled human platelets were exposed to PAF, the level of [^{32}P]PA increased. A decrease in [^{3}H]PI was observed when [^{3}H]arachidonate labeled human platelets were treated with PAF (19). Several other investigators have subsequently confirmed PAF stimulated PPI turnover in human platelets (21–25). LysoPAF (1-*O*-alkyl-glycero-3-phosphocholine) was without effect on phosphoinositide metabolism in platelets.

In a number of other cells and tissues, PAF has been shown to stimulate inositol lipid turnover (Table 1). In guinea pig pancreatic lobule (an exocrine secretory gland), PAF exhibited effects similar to those of carbamylcholine. It enhanced the incorporation of [^{32}P]orthophosphate into PA, PI and polyphosphoinositides and stimulated the formation of diglyceride (40). Interestingly, addition of PAF caused a transient increase (within 10–15 seconds) in [^{3}H]PI, [^{3}H]PIP, and to a lesser extent in [^{3}H]PIP_2. This was followed by a decrease within 60–120 seconds

in all three lipids. In these experiments, the level of $[^3H]IP_3$ and $[^3H]IP_2$ increased within 10–20 seconds and then returned to basal levels. The level of [^{3}H]IP continued to increase over the 2 min period studied (40). Experiments with rat hepatocytes also showed that PAF caused a transient decrease in $[^{32}P]PIP_2$ (42), which recently was reported to be due to a PLA_2 mediated lipid breakdown (46).

Exposure of cultured renal mesangial cells to PAF also rapidly increased free arachidonate, diglyceride and IP_3 within 2 min (38). In normal bone marrow derived macrophages, addition of PAF to cells prelabeled with [^{3}H]inositol caused a marked increase in $[^3H]IP_3$ levels within 15 seconds (32). Human monocytic leukemic U-937 cells express PAF receptors when differentiated with dimethylsulfoxide to a macrophage-like state. In these cells, PAF causes rapid, but transient, increases in intracellular Ca^{2+} (47) which can be blocked by PAF receptor antagonists (48). In the differentiated U-937 cells, PAF induced hydrolysis of phosphoinositides and production of inositol phosphates within 5–15 seconds (34). Multiple forms of IP_3, including inositol 1,3,4-trisphosphate and inositol 1,4,5-trisphosphate were generated by PAF in U-937 cells (34) and in peritoneal macrophages (33). It is of interest to note that in rabbit platelets (49), U-937 cells (34) and peritoneal macrophages (33), a small increase in IP_4 and in bone marrow derived macrophages an increase in $IP_4 + IP_5$ (32) by PAF were also observed. Although the physiological significance of IP_4, IP_5 and IP_6 remains to be fully established, it is worth noting that a role for IP_4 in Ca^{2+} influx (50,52), and for IP_5 and IP_6 as neurotransmitters in blood pressure regulation (51), have been proposed (50,52). The role of IP_4 and IP_5 in PAF action remains unknown.

Thus, in the last few years, PAF has been reported to stimulate the metabolism of phosphoinositides in a wide spectrum of cells originating from blood, kidney, lung, liver, epithelium, intestine, etc. (Table 1). PLC catalyzed PIP_2 breakdown was noted to be one of the earliest events in the PAF response, and points toward a common mechanism underlying the PAF receptor signal transduction pathway in physiologically different cell systems.

PHARMACOLOGICAL MANIPULATIONS

Several agents, including PAF receptor antagonists, activators of adenylate cyclase and PKC, Ca^{2+} channel blockers and various inhibitors have been utilized to manipulate PAF stimulated phosphoinositide turnover (Table 2). PAF receptor antagonists CV-3988 (18,34), CV-6209, SRI 63-441, SRI 63-675 (59) and BN-52021 (20) have been shown to inhibit the PAF stimulated increases in IP_3 (18,34,59) and PA (20). It was also established

that both [^{3}H]PAF binding and [^{3}H]IP_3 production induced by PAF in rabbit platelets were inhibited by the antagonists and that PAF receptor occupancy correlated with PLC stimulation (59). It was proposed that low levels of receptor occupancy triggered a substantial activation of PLC, and it was speculated that a high affinity PAF receptor binding component is involved in the process (59). It has also been reported that full receptor occupancy may not be required for a maximal platelet aggregation response (60).

Activators of adenylate cyclase, which elevate cellular cyclicAMP, *e.g.*, forskolin or PGI_2, caused inhibition of PAF stimulated PPI turnover (18,41) and Ca^{2+} rise in the cells (61). Interestingly, PAF also has an inhibitory effect on adenylate cyclase activity (62). Activation of protein kinase C, *e.g.*, by phorbol myristate acetate (PMA), inhibits PPI turnover (32,54) and is negatively coupled to the stimulation of PLC. The specific mechanism for this remains to be explained. In neutrophils, activated PKC downregulates the high affinity PAF receptors which correlates with a decrease in Ca^{2+} transients (63). This issue has been further examined through the use of staurosporine, a putative inhibitor of PKC. This agent inhibited PAF→→PKC mediated protein phosphorylation and potentiated PAF stimulation of [^{3}H]IP_3 production (54). This led to the suggestion that the basal level of PKC activity in the cells imparts constraints on the activation of PLC (54). Further, the cyclooxygenase inhibitor indomethacin had little effect on PAF response, indicating that PLC activation is not secondary to production of a cyclooxygenase metabolite (18,26).

The turnover of phosphoinositides by PAF appears to be independent of extracellular Ca^{2+} because neither EGTA nor EDTA affected it (18,34). This is in accord with the PPI turnover observed in response to several other agonists (14). In the presence of 1 mM external Ca^{2+}, PAF caused an increase in platelet cytoplasmic Ca^{2+} ranging from 0.5–1.0 μM within 5 seconds (64). In the absence of external Ca^{2+}, this increase is about 25% of that seen in the presence of Ca^{2+} (34,64,65) and would represent Ca^{2+} released from internal stores by IP_3 (13, 14). Thus, increase in cytoplasmic Ca^{2+} from stored sites may initiate several biochemical reactions in the cell (14), but is inadequate to elicit the full PAF response. This points toward the importance of Ca^{2+} influx in PAF response (67). It should be noted that in one study Ca^{2+}

channel blockers, *e.g.*, verapamil, inhibited the PAF induced increase in Ca^{2+} (37), while in another study these blockers had no effect (34). An explanation for these differences remains to be sought. It is relevant to note that PAF is postulated to open, in some manner, Ca^{2+} channels in the plasma membrane (68,69). The relationship between such a Ca^{2+} channel and PPI turnover, if any, has yet to be explored. In platelets a correlation between PAF stimulated PA production (a metabolite of PPI turnover) and Ca^{2+} influx has been demonstrated (67,70).

Several other agents have also been investigated for their influence on lipid turnover (Table 2). Aminoglycosides, *e.g.*, neomycin, which bind to inositol lipids, inhibited PAF activated PPI turnover (24). In U-937 cells, manoalide, a purported inhibitor of PLC, also inhibited PAF stimulated PPI turnover (34). In the future, discovery of specific PLC inhibitors will be of great use to target this enzyme. In a new development, genistein, a putative tyrosine kinase inhibitor (71), inhibited PAF stimulated aggregation and PPI turnover (55,56). This may provide a new insight into the mechanism(s) of PAF action as outlined in the following section.

MECHANISM OF PHOSPHOLIPASE C ACTIVATION BY PAF

In a variety of systems in which hormonal activation of PPI-PLC has been observed, the involvement of guanine nucleotide binding proteins (G-proteins) has been proposed. Such a mechanism has also been considered for the PAF activation of PLC. It is of interest to note that GTPγS has been shown to activate PLC in several permeabilized systems, *e.g.*, platelets and neutrophils (72), in which PAF is known to stimulate PPI turnover. One of the arguments in this regard is that Gi or Ni (the inhibitory G protein of adenylate cyclase) itself is involved in control of PLC activity. In other studies, the possibility of a different G protein, termed Gp, in stimulation of PLC has also been raised (73). Both Gs and Gi have oligomeric structures consisting of α, β and γ subunits. Upon receptor activation, GTP binds to α subunit and dissociates it from β and γ subunits, and the dissociated α subunit becomes functional. Next, the intrinsic GTPase activity in the α subunit cleaves GTP favoring a reassociation of the three subunits. Pertussis toxin ADP-ribosylates the α subunit of Gi and renders it inactive, for example, in activating PLC. Several studies involving PAF have employed pertussis toxin to probe this question. The results are inconclusive. For example, in studies involving platelets, PAF stimulated PPI turnover was reported to be both sensitive (22) and insensitive (56,57) to pertussis toxin treatment. In macrophages (32) and neutrophils (28), the turnover was sensitive to the toxin while U-937 cells (34) were insensitive to this treatment. In neutrophils, pertussis toxin does block functional changes induced by PAF (31) but does not block Ca^{2+} elevation (28). Other agonists which are considered coupled to G protein and activate PLC also stimulate GTPase. PAF stimulates GTPase in human (74,75) and rabbit platelets (76) and in neutrophil membranes (74). The PAF stimulated GTPase activity in human platelet membranes was insensitive to pertussis toxin (74,22) while it was sensitive in neutrophil membranes. This has led to the suggestion that there may be multiple forms of PAF receptors in various cells and their interactions with G proteins could also vary. Existence of a family of G proteins is well recognized in this respect. The role and nature of G protein(s) in PAF stimulation of PLC therefore warrants further investigation.

Another approach to the mechanism of PAF stimulation of PLC has focused on the involvement of tyrosine kinases. Certain growth factors cause PPI turnover and the tyrosine kinase(s) have been implicated in the mechanism of PLC activation (77). In fact, certain forms of PPI-PLC are claimed as a substrate for the tyrosine kinase (78), although the exact nature of the PLC activation has yet to be defined. It has been reported that genistein is a putative inhibitor of tyrosine-specific protein kinases (71). Studies with genistein have indicated that this compound inhibited PAF stimulated IP_3 production in rabbit platelets (55,56). Interestingly, PAF was shown to phosphorylate two proteins of apparent molecular weight 50 K and 60 K which reacted with a monoclonal antibody (mAb) to phosphotyrosine. Genistein blocked the PAF stimulated reactivity of these two proteins to mAb. Further, phosphoamino acid analysis indicated that PAF increased the [^{32}P]phosphotyrosine residues in these two proteins (56). Of considerable interest is a recent report that the binding sites of PAF receptor in rabbit platelets resides in the polypeptide of Mr 52 K (79). Platelets have high levels of tyrosine kinase activity even though they are not a proliferating cell. It is therefore likely that tyrosine kinase is involved in signalling processes in this cell. The question whether PAF receptor is a tyrosine kinase or a substrate for tyrosine kinase will be worthy of investigation. Further, the role of tyrosine kinase in PLC activation and the consequential responses remain to be established.

SIGNIFICANCE OF PPI TURNOVER IN PAF RESPONSES

It is obvious from the preceding sections that changes in phosphoinositide turnover are among the earliest responses to PAF in many cells and tissues. IP_3 and DG generated by this pathway are involved in Ca^{2+} mobilization and in activation of PKC mediated protein phosphorylation, respectively (13,14,83). In addition to the above role, the significance of this phenomenon has also been explored towards the desensitization of cells to PAF. Prior exposure of platelets to PAF renders these cells desensitized (refractory) to any further PAF response, *e.g.*, aggregation (80). In a series of experiments it was observed that the PAF receptor coupled activation of PLC is desensitized under these conditions (49), and so is the protein phosphorylation (66). Thus, the PAF stimulation of PLC, the initial biochemical event after receptor occupancy, could well be the underlying mechanism for PAF desensitization. It is noteworthy that platelets desensitized to PAF still exhibited PPI turnover caused by thrombin (49). This observation has provided evidence that the activation of PLC and its regulation by PAF and thrombin may be distinct. The molecular mechanism of desensitization is poorly understood. In one study, the affinity of [^{3}H]PAF binding was altered in desensitized platelets (81), while in another study the characteristics of [^{3}H]PAF binding sites were reported to be unaltered in desensitized platelets (76). The possibility that PKC is involved in this mechanism appears

unlikely since inhibition of PKC by staurosporine failed to prevent the desensitization of PLC by PAF (54).

The relationship between a pathophysiological state and PAF stimulated PPI turnover has yet to be established. In a study involving platelets from asthmatics it was reported that these platelets had higher basal values of $[Ca^{2+}]i$ and IP_3 and showed a higher stimulation of both components by PAF. Thus, platelets of asthmatics showed increased PPI turnover in response to PAF (82). PAF stimulated PPI turnover has also been studied in diabetic human platelets. Compared to normal (control) human platelets, diabetic human platelets exhibited hypersensitivity (increased sensitivity) to PAF as monitored by the aggregation response and production of phosphatidic acid (Shukla, S.D., Paul, A., and Klachko, D.M., unpublished). Thus, the altered sensitivity of cells or tissues to PAF may result from alterations in the signal transduction pathway involving PPI turnover. The significance of PAF receptor coupled phosphoinositide turnover in pathophysiological conditions must await future investigations.

CONCLUDING REMARKS

In conclusion, studies with different cells and tissues have provided evidence that stimulation of PPI-PLC by PAF is a receptor dependent, extracellular Ca^{2+}-independent phenomenon. This pathway generates at least two second messengers, IP_3 and DG, which play roles in Ca^{2+}-homeostasis, protein phosphorylation and in other biochemical events of the cell. Elevation of cellular cAMP or activation of PKC negatively influences PLC activation. Although the mechanism for PLC activation by PAF is poorly defined, the involvement of G protein(s) and tyrosine kinase(s) have been suggested as depicted in Figure 1. In the future, it should be possible to probe this PAF transmembrane signalling pathway in depth and to relate its significance in PAF receptor mediated mechanisms and in the cellular response to PAF.

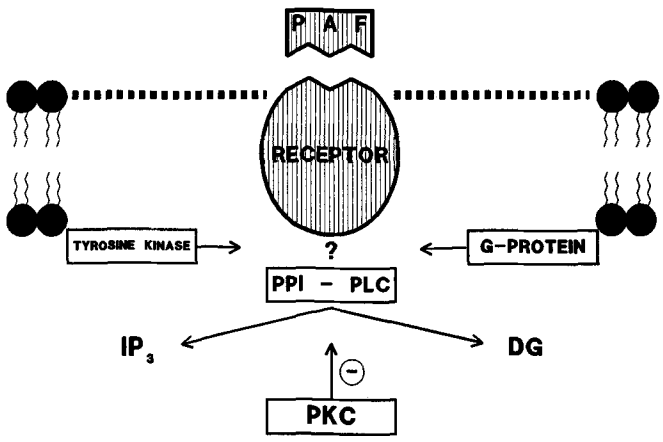

FIG. 1. A hypothetical model of PAF receptor coupled phosphoinositide specific phospholipase C. The model is simplified to depict the possible role of G-protein and/or tyrosine kinase in PAF receptor coupled stimulation of phosphoinositide specific phospholipase C (PPI-PLC). The question mark indicates that the nature of interaction(s) among these components is unknown. IP_3, inositol trisphosphate; PKC, protein kinase C; DG, diglyceride; and G-protein, guanine nucleotide binding protein.

ACKNOWLEDGMENTS

The author is grateful to Drs. Steve Halenda, Animesh Dhar and Anjan Paul for their critical suggestions. Thanks are also due to Mr. Lance Antle for technical help and to Ms. Kris Nelson for expert word processing. The work in the author's laboratory was supported by grants R01-DK35170 and K04-DK-01782 (Research Career Development Award) from the National Institutes of Diabetes, Digestive and Kidney Diseases.

Transmembrane Signalling and Paf-Acether Biosynthesis[1]

Ewa Ninio* and **Francine Joly**
Institut National de la Santé et de la Recherche Médical U200, 92140 Clamart, France

Expression of lyso paf-acether (lyso paf):acetyl-CoA acetyltransferase and its activation above basal levels by specific agonists controls the rate of paf biosynthesis in proinflammatory cells. Acetyltransferase activation in these cells is due to the rapid postranslational modification of an inactive precursor by phosphorylation, most probably catalyzed by a cAMP-dependent kinase. However, the possibility exists that a calcium/calmodulin-dependent kinase can be implicated as well. Unlike murine cultured mast cells, human neutrophils form paf when stimulated with phorbol myristate acetate (PMA) or diacylglycerol. In both cell types, acetyltransferase is activated by PMA. Controversy exists as to whether PMA activates the remodeling pathway, *i.e.* the activation of phospholipase A_2 and acetyltransferase, or the *de novo* route through CDPcholine cholinephosphotransferase action on alkylacetylglycerol. There is some indication that PKC might regulate paf biosynthesis. The implication of a GTP-regulated protein has also been postulated in signal transduction leading to paf formation in endothelial cells, neutrophils, and mast cells. The topography of paf formation is discussed in light of the subcellular distribution of acetyltransferase in neutrophils and Krebs II cells. ***Lipids 26,*** **1034–1037 (1991).**

Studies on various cell types have revealed the importance of expression of lyso paf-acether (lyso paf):acetyl-CoA acetyltransferase (EC 2.3.1.67) and its activation above basal levels by specific agonists in controlling paf biosynthesis (1). When activation of acetyltransferase is suppressed by pharmacological means, paf is not formed. We have shown this using antigenically stimulated mouse bone marrow-derived mast cells treated with ketotifen (an anti-allergic drug from Sandoz, Basel, Switzerland) (2). A similar conclusion was drawn from studies in which dexamethasone was shown to reduce by 50% both acetyltransferase activation and paf formation in the same cell model (3). The action of ketotifen was mainly due to the inhibition of Ca^{2+} influx into the cells during antigen challenge. Dexamethasone treatment of mast cells decreased by 50% the number of IgE receptors on the cell surface available for sensitization, suggesting that the occupancy of all receptors is required to exhibit maximal response to antigen.

Acetyltransferase activation in proinflammatory cells is due to the rapid posttranslational modification of an inactive precursor (4), with the level of the enzyme being rate-limiting in paf biosynthesis (5). The acetyltransferase proenzyme is modified by phosphorylation in murine spleen microsomes (6,7), exocrine glands (8), and mast cells (9). The enzyme responsible for phosphorylation(s) is most probably the cAMP-dependent protein kinase (PKA). This is suggested by direct incorporation of phosphate into acetyltransferase purified from rat spleen (7); however, the possibility exists that calcium/calmodulin-dependent protein kinase could be involved as well (8).

TRANSMEMBRANE SIGNALLING AND ACETYLTRANSFERASE ACTIVATION

In contrast to earlier studies on murine macrophages (10) and human neutrophils (11), which were not performed under optimized conditions with respect to phorbol myristate acetate (PMA) concentration and the length of incubation, our more recent experiments have indicated that acetyltransferase is stimulated in intact mast cells (9) or in human neutrophils (12) by treatment with phorbol esters or synthetic diacylglycerol. In human neutrophils, this stimulation was accompanied by lyso paf and paf formation (Fig. 1). Phorbol didecanoate, an analog of PMA that cannot activate PKC, is also incapable of stimulating acetyltransferase in neutrophils and in mast cells. All reactions leading to paf formation in human neutrophils induced by PMA or opsonized zymosan were inhibited as much as 40 to 50% by a 15-min treatment with 25 μM sphingosine (12), a relatively specific protein kinase C (PKC) inhibitor (13). Thus PKC may be involved in both lyso paf and paf formation and acetyltransferase activation in neutrophils stimulated with phagocytable particles. This study also showed that the molecular species of paf formed during the opsonized zymosan- or PMA-induced stimulation were similar, with C_{16} alkyl species representing 84.3 ± 5% and 80.7 ± 3.5% (mean ± S.E., n = 3), respectively, and the balance being C_{18}paf (12). This suggests that similar precursors may be involved. The role for PKC in phospholipase A_2 (PLA_2) activation was also suggested by McIntyre *et al.* (14) who showed that, while activation of PKC was not sufficient to induce paf and leukotriene B_4 synthesis, its action was required to couple the rise in intracellular Ca^{2+} to their synthesis. Failure to detect paf secreted by PMA-stimulated neutrophils could be due to the use of labeled acetate to quantitate paf instead of the much more sensitive bioassay based on aggregation of washed rabbit platelets (15). Nieto *et al.* (16) suggested that paf formed by PMA-activated neutrophils could be sythesized *via* the *de novo* pathway implicating CDPcholine cholinephosphotransferase. This observation was based on labeling studies showing that in PMA-stimulated cells, while [^{3}H]acetate was not incorporated into paf, [^{3}H]choline was incorporated. In contrast, the opsonized zymosan- or the ionophore

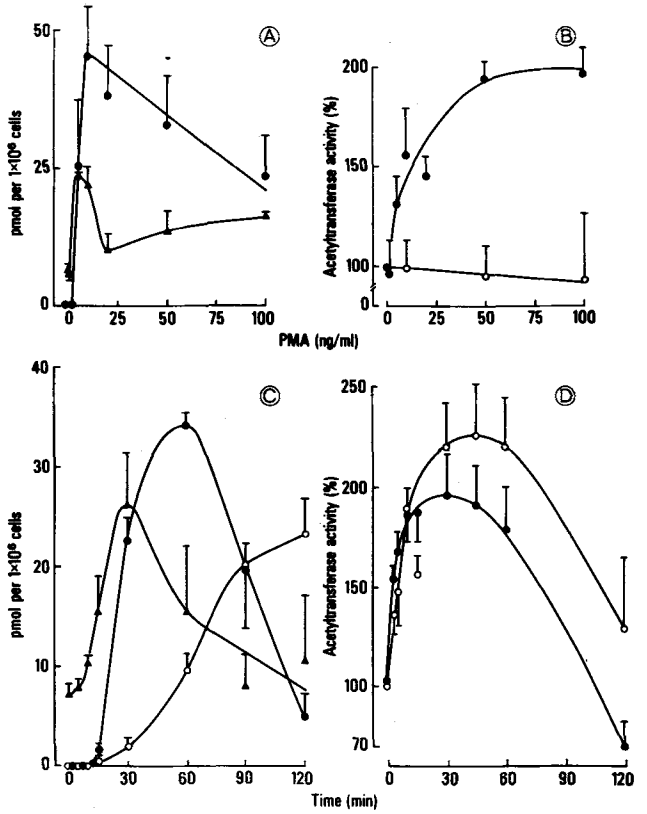

FIG. 1. Dose-dependency (A and B) and time-course (C and D) of paf, lyso paf biosynthesis, and acetyltransferase activation in human neutrophils stimulated with phorbol myristate acetate (PMA) or phorbol didecanoate (PDD). A: 1×10^6 cells/mL were stimulated for 60 min at 37°C. Amounts of total lyso paf (▲) and total paf (●). B: 1×10^6 cells/mL were simulated for 10 min at 37°C with PMA (●) or PDD (○). C: Cells were stimulated with 10 ng/mL of PMA. Amounts of released paf (○), cell-associated paf (●) and cell-associated lyso paf (▲). D: 2×10^6 cells/mL were stimulated with PMA 10 ng/mL (○) or 50 ng/mL (●). Results are the means ± SEM of four to five experiments. (Reproduced from Leyravaud *et al.* (1989) *J. Immunol. 143,* 245-249; with permission of The American Association of Immunologists)

A23187-stimulated neutrophils formed paf that was only labeled with [^{3}H]acetate. However, in the latter study (16) the major difficulty was to distinguish between the *de novo* incorporation of labeled choline into paf from the choline incorporated by the exchange reaction catalyzed by phospholipase D, which is activated by phorbol esters (17). The question also arose why paf formed in PMA-stimulated neutrophils was not labeled by [^{3}H]acetate. This finding is inconsistent with the involvement of an alkylglycerol:acetyl-CoA acetyltransferase that would be responsible for *de novo* formation of alkylacetylglycerol (18). From our more recent data using 2×10^7 neutrophils per incubation (19), it appears that both ionophore and PMA induce incorporation of labeled acetate into paf. In addition the specific activities (dpm [^{14}C]acetate incorporated into paf/paf mass quantified by bioassay) of paf formed were similar irregardless of the stimulus. When cells were prelabeled with [^{3}H]choline, the paf formed was weakly labeled for both stimuli, but only PMA stimulation triggered a several-fold increase in lyso paf and alkylacyl-GPC labeling.

In contrast to human neutrophils, mouse mast cells do not form paf when stimulated with phorbol esters in spite of substantial but delayed stimulation of acetyltransferase (20). This observation may be linked to the inability of PMA to induce lyso paf formation. However, short pretreatment of mast cells with PMA at a concentration that did not stimulate acetyltransferase, prior to the antigen challenge, increased by about 30% both acetyltransferase stimulation and paf formation, again without changing the level of lyso paf. Overnight treatment of mast cells with PMA (200 ng/mL) caused depletion of PKC in both cytosol and membranes. When such cells were stimulated further with antigen, acetyltransferase activation and paf formation were only partially decreased. In contrast, the PKC inhibitors chlorpromazine and staurosporine inhibited to a significant extent paf biosynthesis. We concluded that PKC-dependent mechanisms contribute only in part to paf biosynthesis in cultured mast cells. The PKC-dependent signal directly generated by PMA or diacylglycerol is not sufficient to trigger the full cell response, which is obtained only through receptor-mediated antigen challenge.

The receptor-mediated stimulation of PKC requires the coupling of receptors and phospholipase C (PLC) *via* the GTP-regulated proteins (G protein(s)). Diacylglycerol, inositol 1,4,5-triphosphate (IP_3) and inositol 1,3,4,5 tetraphosphate (IP_4) derived from phosphatidylinositol-4,5-*bis*-phosphate contribute directly or indirectly to the anchoring of PKC in the plasma membrane and the subsequent phosphorylation of various proteins (reviewed in ref. 21). In human neutrophils, the calmodulin-binding protein MARCKS is phosphorylated by PKC (22) and subsequently displaced from the plasma membrane into the cytosol (23). It thus participates in the propagation of transmembrane signalling within the cell and may cause displacement of bound calmodulin, possibly leading to the activation of Ca^{2+}-calmodulin-dependent processes (22). Adenylate cyclase was also shown to be among the proteins that are activated by phosphorylation due to PKC (24), suggesting that "crosstalk" takes place between the two corresponding transmembrane signalling pathways. The rise in cAMP level, in turn, promotes the increase of activity of PKA which might phosphorylate the acetyltransferase. Indeed, one of the earliest events being triggered by antigen bridging of adjacent IgE on murine peritoneal mast cell surfaces is a transient increase in intracellular cAMP level (25). However, controversies remain (reviewed in ref. 26) and, unlike cultured mast cells (9,20), the peritoneal counterparts (27) do not form paf.

A long-lasting stimulation of adenylate cyclase or inhibition of phosphodiesterase decreased paf formation in neutrophils (28) as well as in mast cells (29) and is a consequence of inhibition of PLA_2-like activity that generates lyso paf and arachidonate (29,30). In rat mast cells both type-I and type-II PKA are present in the cytoplasm and are activated after IgE-mediated cell triggering (reviewed in ref. 26). However, increased intracellular cAMP following addition of prostaglandin D_2 or theophylline does not activate the protein kinases (31). The latter finding might explain the apparently conflicting results concerning the role of cAMP in activating and inhibiting paf synthesis. Similarly, when rat basophilic leukemia cells were treated with cholera toxin, the level of inositol phosphate increased in concert with antigen-

stimulated $^{45}Ca^{2+}$ influx, cAMP level, and degranulation suggesting that cholera toxin-sensitive G protein might be an integral component of the mechanism responsible for the antigen-stimulated calcium influx (32). However, the effects of cholera toxin on calcium influx and secretion do not appear to be mediated *via* cAMP as a variety of agents capable of elevating cellular cAMP levels to a similar extent do not potentiate the antigen-stimulated calcium influx, and they partially inhibit stimulated secretion (32). Influx of Ca^{2+} is an obligatory step in stimulus-receptor coupling leading to paf biosynthesis (1,2,9,33,34). Paf biosynthesis can be activated solely by rise in Ca^{2+} level, as it was shown using the calcium ionophore A23187 (reviewed in ref. 1). When neutrophils are stimulated with PMA or diacylglycerol, paf is formed without a detectable rise in Ca^{2+} concentration (unpublished observation from our laboratory).

G proteins couple hormone-receptor binding to opening of membrane Ca^{2+} channels in endothelial cells, leading to paf synthesis (34). The formation of paf initiated by phagocytosis or formylmethionyl-leucylalanine in neutrophils was inhibited by pertussis toxin, suggesting that pertussis toxin-sensitive G protein might be involved (33). In murine cultured mast cells, acetyltransferase activation and paf biosynthesis are triggered by direct activators of G proteins (presented at the Third International Conference on Platelet-Activating Factor and Structurally Related Alkyl Ether Lipids, Tokyo, Japan, May 1989).

MECHANISM OF LYSO PAF FORMATION

The phospholipases A_2 are a family of enzymes which hydrolyze the ester bond at the glycerol *sn*-2 position of various phospholipids and thus participate in fatty acid release and lysophospholipid formation. The preferential release of arachidonic acid as compared to other fatty acids was observed in stimulated proinflammatory cells (35). Moreover, a close relationship between this release and paf synthesis was demonstrated (36,37). Consistent with this, in stimulated human HL-60 granulocytes only alkylarachidonoyl-GPC was hydrolyzed to an appreciable extent (38). In mammalian cells, two different types of PLA_2 have been purified and cloned: (i) a low molecular weight PLA_2 (13.5–14 kD), that was also found in inflammatory fluids, is active in the presence of Ca^{2+} at mM concentrations and is unspecific for fatty acids (39); (ii) a high molecular weight PLA_2 (105–110 kD) of cytosolic origin that is translocated into membranes and is active at Ca^{2+} μM concentrations, and exhibits high specificity for arachidonate containing phospholipids (40,41). The latter PLA_2 could be thus implicated in arachidonate release and lyso paf formation. However, the CoA-independent transacylases, which are specific for polyunsaturated fatty acids (42–45), might also be involved, as was suggested recently by Wykle's group (46,47), who demonstrated that lyso paf formation is induced by arachidonate transfer from alkyl-arachidonoyl-GPC to added lysophosphatidylethanolamine. In this context, PLA_2 might generate a lyso compound and thus indirectly participate in the deacylation of paf precursor.

G protein(s) can be implicated in the coupling of external receptors with intracellular responses, which leads to activation of certain types of PLA_2 (reviewed in ref. 48). The question arises as to whether the PLA_2 which participates in the generation of lyso paf is directly coupled to G protein(s), or whether its activation is not rather related to the increase in Ca^{2+} concentration due to IP_3 and IP_4 formation *via* the phospholipase C (PLC) route. The latter course appears more plausible given that acetylation of lyso paf through the specific acetyltransferase occurs in the non-plasma membranes, at least in human neutrophils (49), as was confirmed by Mollinedo *et al.* (50). The intracellular location of acetyltransferase would argue in favor of a similar topography for lyso paf formation as suggested by Record *et al.* (51). In addition, the endoplasmic reticulum is the biosynthetic site for alkylacyl-GPC which is formed from alkylacylglycerol *via* CDPcholine cholinephosphotransferase (52,53). If lyso paf formation depended on the plasma membrane PLA_2 directly coupled to G protein(s), it would be necessary to shuttle this newly formed lyso paf into the endoplasmic reticulum. In Krebs II cells, high levels of alkylacyl-GPC are found in the inner leaflet of the plasma membrane. By contrast, the acetyltransferase is located in the internal membranes, which served to explain impaired paf formation by Krebs II cells (51). Thus we believe that lyso paf is formed in the proximity of the acetyltransferase. The question still remains as to how PMA activates lyso paf formation. Late release of arachidonate (within 30 to 120 min) has been described in PMA-challenged Madin-Darby canine kidney cells (54) and neutrophils (19). This late release of arachidonate is compatible with delayed paf formation induced by PMA in human neutrophils (12) and might be linked to the PKC-dependent activation of PLA_2 (55). Another explanation for PMA-induced activation of PLA_2 might be derived from the results of Leslie and Channon (56) who showed that anionic phospholipids and diacylglycerol dramatically decreased the calcium concentration (from mM to nM range) required for full activity of partially purified PLA_2 acting on alkylarachidonoyl-GPC. Changes in the packing characteristics of the substrates induced by diacylglycerol correlate with increase in PLA_2 activity (57). A part of phorbol ester action on lyso paf accumulation (12) might also be attributed to the modulation of a CoA-independent transacylase which either competes with acetyltransferase for their common substrate or (19) generates lyso paf by itself (47). Indeed, in the ionophore A23187-stimulated neutrophils only a portion of generated lyso paf was acetylated to form paf, the balance being reacylated by various fatty acids to form phosphatidylcholine (58).

We believe that research on the regulation of paf biosynthesis will allow a better understanding of the role of paf in human health and desease. It should also stimulate the search for new drugs with anti-acetyltransferase properties. These drugs might become valuable tools for evaluating the roles of paf and other mediators such as leukotrienes or histamine, that are released from inflammatory cells during pathological processes.

ACKNOWLEDGMENT

We thank Dr. O. Colard for suggestions and critical reading of our manuscript.

PAF Effects on Transmembrane Signaling Pathways in Rat Kupffer Cells[1]

Chandrashekhar R. Gandhi and **Merle S. Olson***
Department of Biochemistry, University of Texas Health Science Center at San Antonio, San Antonio, Texas 78284

Platelet activating factor (PAF) was found to stimulate the metabolism of inositol phospholipids via deacylation and phospholipase C in Kupffer cells, the resident macrophages in liver. PAF-induced phosphoinositide metabolism occurred in two phases. Within seconds after stimulation, in the absence of extracellular Ca^{++}, platelet activating factor caused the phosphodiester hydrolysis of phosphatidylinositol 4,5-bisphosphate and phosphatidylinositol 4-phosphate with the release of inositol 1,4,5-trisphosphate and inositol 1,4-bisphosphate. This was followed by an extracellular Ca^{++}-dependent release of glycerophosphoinositol, inositol monophosphates and inositol bisphosphates. Various Ca^{++}-mobilizing agonists failed to evoke hydrolysis of phosphoinositides. Platelet activating factor also stimulated the synthesis and release of prostaglandins from these cells. Platelet activating factor-stimulated phosphodiester metabolism of phosphoinositides and prostaglandin synthesis was inhibited by treatment with pertussis toxin and cholera toxin. Pertussis toxin also inhibited platelet activating factor-induced glycerophosphoinositol release. Cholera toxin, in contrast, stimulated platelet activating factor-induced glycerophosphoinositol release and prostaglandin synthesis and synergistically stimulated the effect of platelet activating factor on these processes. The results suggest that platelet activating factor-induced metabolism in the Kupffer cells occurs via specific receptors and may be mediated through the activation of different G-proteins.
***Lipids 26,* 1038–1043 (1991).**

Hepatic responses of platelet activating factor (PAF; 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) present several intriguing questions concerning both intra- and intercellular signaling mechanisms. This agonist stimulates glucose production in the perfused rat liver *in situ* but fails to evoke such a response in isolated hepatocytes. PAF-induced glycogenolysis is accompanied by rapid, transient increases in portal pressure and alterations in oxygen consumption (1). Unlike various classical Ca^{++}-mobilizing agents such as phenylephrine, vasopressin and bradykinin, which stimulate glycogenolysis in perfused liver and isolated hepatocytes (2), PAF-induced hydrolysis of phosphoinositides occurs through the activation of phospholipase A_2 and not via the classical phosphodiester pathway in the isolated parenchymal cells (3).

Several hormones, neurotransmitters and secretagogues exert their effects on the target cell through the stimulation of a phosphatidylyinositol 4,5-bisphosphate (PIP_2)-specific phosphoplipase C, and many of these signal-transduction events are coupled through the activation of a G-protein. PIP_2 is hydrolyzed to two intracellular second messengers: inositol 1,4,5-trisphosphate (Ins 1,4,5-P_3), which is released into the cytosol and causes the mobilization of Ca^{++} from an intracellular non-mitochondrial pool and diacylglycerol (DAG), which remains in the plasma membrane and stimulates a Ca^{++}– and phospholipid-dependent protein kinase C (4–6). The increased concentration of intracellular Ca^{++} stimulates phosphodiester hydrolysis of phosphatidylinositol 4-phosphate (PIP) and phosphatidlyinositol (PI) to inositol 1,4-bisphosphate (Ins 1,4-P_2) and inositol 1-phosphate (Ins 1-P), respectively, and DAG. Ins 1,4,5-P_3 may be hydrolyzed sequentially to Ins 1,4-P_2, a conversion sensitive to 2,3-diphosphoglyceriate (7), Ins 1- and/or Ins 4-P and then to free inositol. Dephosphorylation of Ins 1,4-P_2 and Ins-P is known to be sensitive to Li^+ ions (8–13). Inositol is reutilized for the synthesis of PI. Alternatively, Ins 1,4,5-P_3 may be phosphorylated to inositol 1,3,4,5-tetrakisphosphate (Ins 1,3,4,5-P_4), which has been implicated as causal for the influx of Ca^{++} (14) and for Ca^{++} sequestration into intracellular organelles (15). Ins 1,3,4,5-P_4 may be hydrolyzed to Ins 1,3,4-P_3, the physiological function of which is not clear. DAG can be acted upon by specific lipases (16) resulting in the release of arachidonic acid or can be phosphorylated to phosphatidic acid in a kinase reaction. Phosphatidic acid may be converted to PI via CDP-DAG to complete the cycle.

Differential effects of PAF on hepatic and hepatocytic glycogenolysis in the perfused liver and in isolated hepatocytes suggest a somewhat indirect mechanism of action. On the basis of an extensive series of experiments, we have concluded that PAF exerts its hemodynamic and subsequent glycogenolytic effects on the liver independent of its ability to stimulate arachidonic acid release and metabolism to prostaglandins (17). There is little question that PAF stimulation of the intact liver or isolated hepatic Kupffer cells causes an increase in production of prostaglandins D_2 and E_2 and thromboxane B_2; this enhanced production of arachidonic acid metabolites seems to have little effect on the ability of PAF to evoke its hemodynamic and glycogenolytic responses in the isolated liver. Additionally, several recent reports illustrate the glycogenolytic action of eicosanoids, the lipoxygenase- and cycloxygenase-derived metabolites of arachidonic acid (18–23). Eicosanoids are synthesized by Kupffer and endothelial cells, but not hepatocytes, although the latter can metabolize these compounds (24). The precise role of the primary hepatic eicosanoids following their production during Kupffer cell stimulation is a subject for additional experimental

inquiry. Moreover, information regarding the second messenger signaling pathway in Kupffer cells is inadequate. Hence the present contribution concerns PAF-induced phosphoinositide metabolism and prostaglandin synthesis in the primary cultures of Kupffer cells.

MATERIALS AND METHODS

Materials. Collagenase (Type IV from Clostridium histolyticum), protease (Type XIV, from Streptomyces griseus), bovine serum albumin (fraction V), nifedipine, ethylene glycol *bis*-(β aminoethyl ether)*N,N,N',N'*-tetraacetic acid (EGTA), and heat-inactivated fetal bovine serum were purchased from Sigma Chemical Co. (St. Louis, MO). Metrizamide, which is 2-(3-acetamido-5-N-methylacetamido-2,4,6-triiodobenzamido)-2-deoxy-D-glucose, was from Nyegaard and Co. (Oslo, Norway), William's medium E from Gibco Labs (New York, NY). [2-^{3}H]-*myo*-Inositol (20 Ci/mmol) was purchased from Amersham (New York, NY) and [5,6,8,9,11,12,14,15-^{3}H(N)]-arachidonic acid (100 Ci/mmole) from DuPont (Boston, MA). Methyl formate was purchased from Eastman Kodak (Rochester, NY). All other chemicals and reagents purchased locally were of highest purity available.

Isolation and culture of Kupffer cells. Kupffer cells were isolated from livers of male Sprague-Dawley rats (200–250 g) using a modification of the centrifugal elutriation procedure of Knook and Sleyster (25). Briefly, livers were first perfused aseptically at 37°C through the portal vein and inferior vena cava with calcium- and magnesium-free Krebs-Henseleit buffer containing 0.2% glucose and 0.2% bovine serum albumin gassed with 95% O_2/5%CO_2 at a rate of 30 mL/min. This was followed by recirculating perfusion with the above buffer containing 0.03% collagenase and 0.02% protease in the presence of 2 mM Ca^{++}. The digestion was continued for 5 min, after which the perfusion was stopped, the liver capsule opened and the cells were dispersed in Krebs-Henseleit buffer. The cell suspension was filtered through two layers of nylon mesh and the filtrate was centrifuged at 525 × *g* for 45 seconds, followed by the centrifugation of the supernatant at 830 × *g* for 6 min. The pellet was suspended in Gey's balanced salt solution (GBSS) without NaCl containing 17.5% metrizamide. One mL of GBSS was layered over 6 mL of the above cell suspension and after centrifugation for 20 min at 1400 × *g*, nonparenchymal cells which collected at the interphase were aspirated and washed with Krebs-Henseleit buffer. Kupffer and endothelial cells were separated by centrifugal elutriation (25).

Isolation of hepatocytes. Hepatocytes were prepared by collagenase perfusion of the rat livers exactly as described by Berry and Fried (26).

Primary culture of Kupffer cells, endothelial cells and hepatocytes. Kupffer cells, endothelial cells and hepatocytes were suspended in William's medium E supplemented with 2 mM L-glutamine, 10% heat-inactivated fetal calf serum, 5000 U/mL penicillin and 5000 μg/mL streptomycin at 2 × 10^6, 2.5 × 10^6 and 1 × 10^6 cells/mL, respectively. Two-mL portions of this cell suspension were plated in 35 mm tissue culture dishes and placed in an incubator at 37°C in an atmosphere of 95%O_2/5%CO_2. Cells were allowed to attach for 2–3 hr and were washed with the incubation medium. After an overnight incubation, the attached cells were washed twice and placed in fresh medium containing 2% fetal calf serum and [^{3}H]-arachidonic acid [for prostaglandins (PG) determinations] or [^{3}H]inositol (for determination of inositol phosphates). Following incubation for 24 hr, cells were washed twice with nonradioactive medium and incubated. After 30 min in the incubator, cells were stimulated with agonists and the reaction was terminated with the addition of ethanol for the PG determinations (27), or with 5% ice-cold trichloroacetic acid (TCA) following rapid aspiration of the medium for the analysis of inositol phosphates.

Extraction of prostaglandins. Prostaglandins were extracted essentially as described by Powell (27). Cells were scraped from the culture plates and both the medium and cells were quantitatively transferred to tubes. The plates were washed with an additional 1 mL ethanol and water was added to the combined extracts to bring the final concentration of ethanol to 15%. The extract was centrifuged and the pellet was washed with 3–4 mL 15% ethanol. The combined supernatants were acidified to pH 3.5 with 1 M HCl, applied to SEP-PAK columns (C18 cartridges from Waters Associates, Milford, MA), washed with 15% ethanol and, finally, prostaglandins were eluted with methyl formate.

Analysis of prostaglandins. Methyl formate was evaporated under N_2, the residue was dissolved in 140 μL 36% acetic acid (0.1%, v/v) in acetonitrile and was filtered (0.45 μM Millipore Type HV filter). The filtrate (80–90 μL) was used for the analysis of prostaglandins by high performance liquid chromatography (HPLC). The analysis of prostaglandins was performed essentially as described by Peters *et al.* (28) using a Varian HPLC (Varian Associates, Palo Alto, CA) with an Ultrasphere ODS column (4.6 mm × 25 cm) and a pre-column. The solvent system used was 0.1% (v/v) aqueous acetic acid (pH 3.7) and acetonitrile with a flow rate of 1.5 mL/min. Half-minute fractions were collected and quantified by liquid scintillation spectroscopy. Scintillation counting was performed using a Beckman 5801 counter linked to a Beckman Data Transfer Module (Beckman Instruments, Fullerton, CA). The data was transferred directly to an IBM PC XT-type computer for analysis. Various prostaglandins were identified by spiking the cell extracts with a mixture of [^{3}H]PG standards.

Extraction and identification of [^{3}H]inositol phosphates. Cells were scraped from culture plates and the plates were washed with an additional 0.5 mL TCA. The combined extracts were centrifuged and the supernatant was washed with water-saturated diethyl ether, lyophilized and stored at −70°C. [^{3}H]Inositol phosphates were analyzed by HPLC essentially as described by Dean and Moyer (29). The identities of Ins 1-P, Ins 4-P, Ins 1,4-P_2 and Ins 1,4,5-P_3 were confirmed by spiking cell extracts with a mixture of [^{3}H]inositol phosphate standards. Other peaks observed were glycerophosphoinositol (GPI) which eluted between inositol and Ins 1,P, Ins 1,3,4-P_3 and Ins 1,3-P_2.

Analysis. Lyophilized extracts were dissolved in 250 μL of distilled water and filtered (0.45 μm Millipore Type HV filter). Samples of the extract (200 μL) were analyzed by HPLC essentially as described by Dean and Moyer (29). Buffers were made using HPLC grade ammonium phosphate (Fisher Scientific, Fair Lawn, NJ) and water purified with a Milli-Q* system (Millipore Corporation, Bedford, MA). Buffers were filtered (0.45 μM Millipore

TABLE 1

Effect of PAF on the Inositol Phospholipid Metabolism of Kupffer Cells, Endothelial Cells and Hepatocytes[a]

Cell type	GPI	IP	IP_2
Hepatocytes	118 ± 6 (235 ± 18)	103 ± 9 (199 ± 12)	100 ± 3 (45 ± 3)
Endothelial cells	135 ± 12 (141 ± 11)	237 ± 32 (212 ± 8)	284 ± 48 (58 ± 9)
Kupffer cells	204 ± 22 (241 ± 15)	527 ± 34 (278 ± 18)	418 ± 31 (79 ± 5)

[a]Hepatocytes, Kupffer cells and endothelial cells were prepared and cultured, as described in Materials and Methods at a cell density of 1×10^6 cells/mL (hepatocytes), 2×10^6 cells/mL (Kupffer cells) or 2.5×10^6 cells/mL (endothelial cells) (2 mL/dish). The cells were labeled with [^{3}H]inositol (2.5 μCi/mL), stimulated with 20 nM PAF, the reaction was terminated and the inositol phosphates were analyzed as described in Materials and Methods. The results are expressed as the percentage of the unstimulated control values ± S.E.M. of triplicate determinations from representative experiments. The values in parentheses represent radioactivity (DPM) in the inositol phosphates of the nonstimulated control samples.

Type HA filter) and degassed prior to use. A Waters HPLC system was used in conjunction with a 25 cm × 0.4 cm Partisil 10 SAX column (Phenomenex, Rancho Palos Verdes, CA). The A_{254} of the HPLC effluent was measured, and 30 second fractions were collected and quantified by scintillation spectroscopy.

RESULTS AND DISCUSSION

Table 1 shows the effect of PAF on the metabolism of [^{3}H]inositol-labeled lipids from hepatocytes, Kupffer cells and endothelial cells in primary culture. PAF treatment stimulated phosphoinositide hydrolysis in Kupffer and endothelial cells via deacylation and phospholipase C action, the Kupffer cells being more responsive to such stimulation. Consistent with the previous observations (3,30), hepatocytes did not respond to PAF, although a slight increase in their GPI content was observed. High affinity receptors for PAF have been reported on the liver plasma membranes (31) and these receptors may be coupled to phospholipase A_2. Interestingly, coupling of phospholipase A_2 to specific G-proteins has been shown (32–34).

Figure 1 illustrates the PAF-stimulated metabolism of phosphoinositides at 5 seconds and at 20 min in the cultured Kupffer cells. At 5 seconds, a sharp increase occurred in the Ins 1,4,5-P_3 and Ins 1,4-P_2 levels without a significant change in the inositol monophosphates or GPI, suggesting an early hydrolysis of PIP_2 and PIP. At 20 min, increases in the levels of Ins 1-P, Ins 4-P, Ins 1,4-P_2 and GPI were observed in the PAF-stimulated cells. At this time point the Ins 1,4,5-P_3 peak returned to the basal level with the appearance of Ins 1,3,4-P_3 and Ins 1,3-P_2, suggesting that Ins 1,4,5-P_3 was metabolized to these species via Ins 1,3,4,5-P_4. No significant change in the Ins 1,3,4,5-P_4 moiety was observed at any time during the stimulation of Kupffer cells with PAF (results not shown), indicating rapid metabolism of this species. EGTA inhibited phosphodiester metabolism as

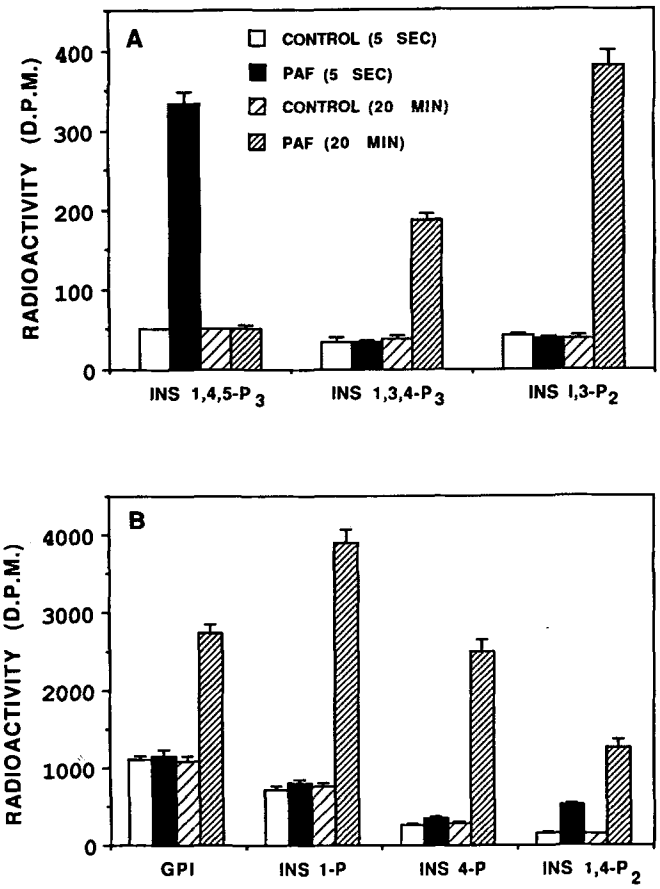

FIG. 1. Effect of PAF on the metabolism of phosphoinositides in Kupffer cells. Kupffer cells were isolated, cultured and labeled with 10 μCi/mL [^{3}H]inositol as described in the legend for Table 1. Cells were washed twice and stimulated with 20 nM PAF in the presence of 10 mM LiCl. Reaction was terminated at 5 seconds (A) and 20 min (B), and the inositol phosphates were extracted and analyzed essentially as described in Materials and Methods. The results are expressed as the means of triplicate determinations from a representative experiment ± S.E.M.

well as deacylation of phosphoinositides at 20 min, but not at 5 seconds (results not shown). The results indicate that PAF-induced metabolism of phosphoinositides in Kupffer cells involve distinct mechanisms. These assumptions were confirmed by thin-layer chromatography of [^{3}H]inositol-labeled lipids after PAF-stimulation of Kupffer cells for 5 seconds and 20 min as shown in Figure 2. Thus, at 5 seconds there was a decrease in PIP_2 and PIP but not in PI, indicating an extracellular Ca^{++}-independent hydrolysis of polyphosphoinositides. With continual stimulation, PIP hydrolysis progressed and PI hydrolysis also occurred to a large extent (Fig. 2). Since EGTA inhibited the release of inositol phosphates at the longer time interval, this metabolic activity was probably dependent on the extracellular Ca^{++}. Furthermore, these results suggest that two separate phospholipase C activities or two forms of the same enzyme (Ca^{++}-dependent and Ca^{++}-independent) must be present in the Kupffer cell membrane. A small but significant increase in lysophosphatidylinositol occurred at this time (results not shown). In another experiment, Kupffer cells were labeled with [^{3}H]glycerol and then stimulated with

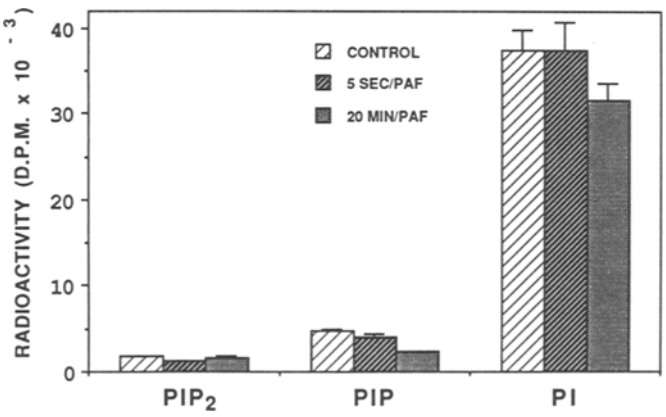

FIG. 2. Effect of PAF on [^{3}H]inositol-labeled phospholipids in Kupffer cells. Kupffer cells were isolated, cultured and labeled with [^{3}H]inositol (5 μCi/mL) for 24 hr. After washing, cells were stimulated with 20 nM PAF for indicated times. The reaction was terminated with the addition of TCA as described in the legend for Figure 1. Lipids from the TCA pellet were extracted with chloroform/methanol (2:1, v/v). Following addition of 2.4 M HCl and vortexing, phases were separated by low-speed centrifugation. Organic phase was dried under nitrogen and lipids were dissolved in chloroform/methanol/1M HCl (75:25:2, v/v/v). Phospholipids were separated by thin-layer chromatography on silica gel HL plates (Analtech) using the solvent system (chloroform/methanol/20% methylamine, 65:36:10, v/v/v). Authentic standards (Sigma Chemical Co., St. Louis, MO) were used to identify inositol phospholipid fractions which were scraped from the plates. Radioactivity was determined by liquid scintillation spectroscopy. The results are means of duplicate determinations ± S.E.M. from a representative experiment.

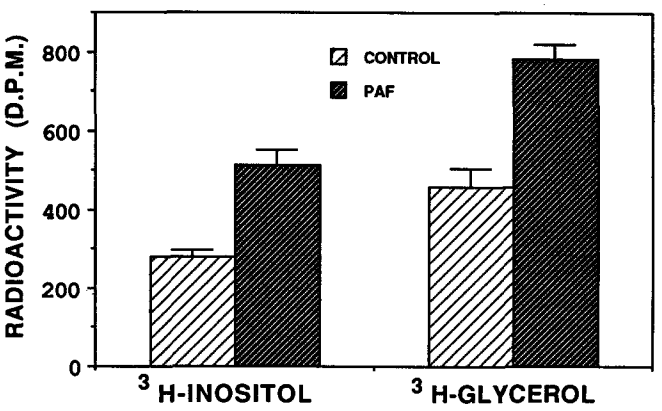

FIG. 3. Effect of PAF on the release of glycerophosphoinositol from [^{3}H]inositol- and [^{3}H]glycerol-labeled Kupffer cells. Kupffer cells were labeled with 2.5 μCi/mL [^{3}H]inositol or 5 μCi/mL [^{3}H]glycerol. Cells were stimulated with 20 nM PAF for 20 min. The reaction was terminated with TCA and GPI was analyzed in diethyl ether-washed extract by HPLC. For details, see legend for Figure 1 and Materials and Methods. The results are means of triplicate determination ± S.E.M. from one experiment.

PAF to evaluate the precursor of GPI. The results of this experiment are depicted in Figure 3. The extent of stimulation of GPI release was identical when the cells labeled with both radioactive inositol or glycerol were stimulated with PAF (Fig. 3). Glycerophosphoinositolphosphate (GPIP) or glycerophosphoinositolbisphosphate ($GPIP_2$) peaks (from cells labeled with radioactive inositol or glycerol) were not observed on the HPLC profiles,

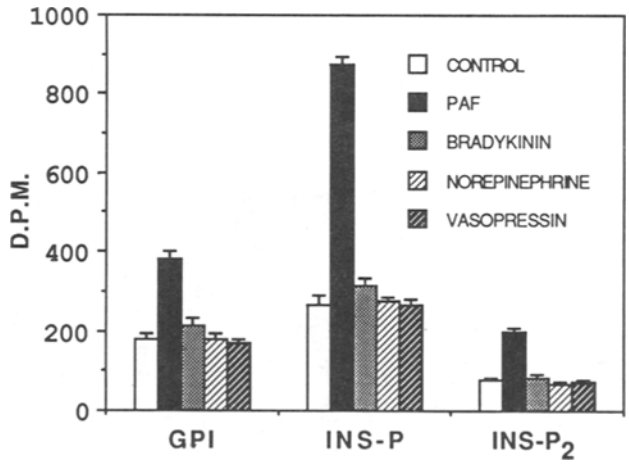

FIG. 4. Effect of Ca^{++}-mobilizing hormones on the metabolism of phosphoinositides in Kupffer cells. Kupffer cells were prepared and labeled with [^{3}H]inositol (2.5 μCi/mL) as described in Materials and Methods. Cells were then stimulated with PAF (20 nM), bradykinin (2 μM), norepinephrine (10 μM) and vasopressin (1 μM). Reaction was terminated at 20 min and the inositol phosphates were extracted and analyzed as described. The results are expressed as the means of triplicate determinations from a representative experiment ± S.E.M.

suggesting that deacylation of PIP or PIP_2 did not occur upon stimulation of Kupffer cells with PAF, or that GPIP and $GPIP_2$ were very rapidly converted to GPI.

Figure 4 illustrats a comparison of Ca^{++}-mobilizing hormones with PAF-stimulated phosphoinositide metabolism in Kupffer cells. These glycogenolytic hormones (vasopressin, norepinephrine and bradykinin) have been shown to induce phospholipase C-mediated metabolism of inositol lipids in hepatocytes (4,35). None of these hormones except bradykinin had an appreciable effect on Kupffer cell phosphoinositide turnover and the extent of the bradykinin effect was much less than observed for PAF.

Many receptor-mediated transmembrane signaling events occur through the activation of G-proteins. Pertussis toxin and cholera toxin alter such processes by causing ADP-ribosylation of the GTP-binding proteins (36). Table 2 shows the effect of pertussis toxin and cholera toxin on PAF-stimulated metabolism of phosphoinositides in the Kupffer cells. Pertussis toxin strongly inhibited both PAF-stimulated release of GPI and inositol phosphates suggesting the involvement of G-proteins in this transmembrane signaling process. In contrast, cholera toxin and PAF synergistically stimulated GPI release and cholera toxin inhibited the phospholipase C-mediated response induced by PAF. Consistent with these observations, cholera toxin and PAF had an additive effect on prostaglandin synthesis in Kupffer cells when the toxin was present in the cellular incubations throughout the duration of the experiment (C. R. Gandhi and M. S. Olson, unpublished observation).

On stimulation of [^{3}H]arachidonic acid-labeled Kupffer cells with PAF, a release of radioactivity (40 ± 8 over basal) in the medium occurred. However, only 1–3% of this released radioactivity was actually converted into prostaglandins (unpublished observation). Since arachidonic acid is attached at the *sn*-2 position in the

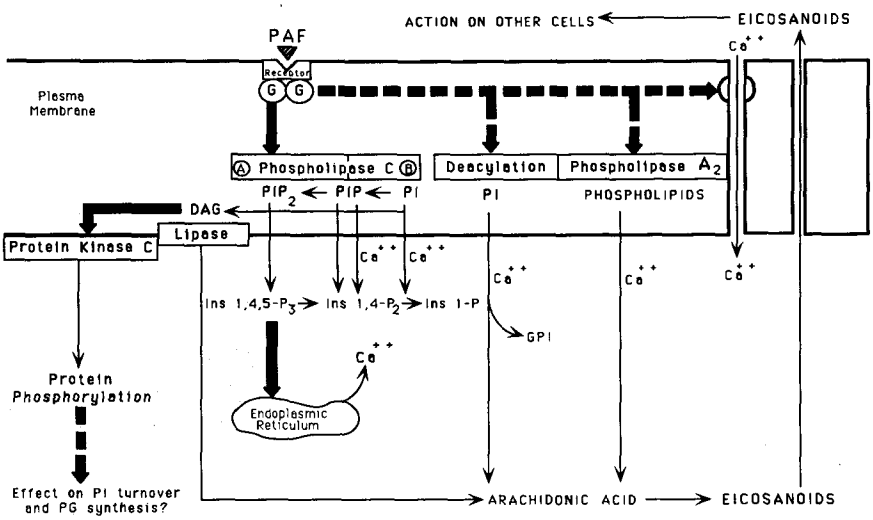

FIG. 5. A general scheme of the possible events occurring in Kupffer cells following stimulation with PAF.

TABLE 2

Effect of Pertussis Toxin and Cholera Toxin on PAF-induced Phosphoinositide Metabolism in the Kupffer Cells[a]

Treatment	GPI	IP	IP_2
Control	198 ± 12	221 ± 17	59 ± 3
PAF	360 ± 23	876 ± 34	178 ± 9
PTX	187 ± 8	241 ± 21	51 ± 5
PTX/PAF	204 ± 18	468 ± 29	89 ± 8
CTX	273 ± 15	199 ± 12	49 ± 2
CTX/PAF	423 ± 28	428 ± 36	45 ± 3

Kupffer cells were prepared and labeled with [^{3}H]inositol (2.5 μCi/mL) as described in the Materials and Methods. After washing, the cells were incubated in the medium containing 2 μg/mL cholera toxin or 100 ng/mL pertussis toxin for 3 hr. The cells were then stimulated with 20 nM PAF in the presence of LiCl. Other details of the procedure were described in the legend for Table 1. The results are expressed in DPM as means of duplicate determinations ± S.E.M. from a representative experiment of four experiments performed.

TABLE 3

Effect of EGTA and Nifedipine on PAF-Induced Prostaglandin Synthesis in Kupffer Cells[a]

Treatment	PGE_2	PGD_2
Control	277 ± 13	198 ± 15
PAF	798 ± 29	1162 ± 53
EGTA/PAF	246 ± 8	211 ± 17
Nifedipine/PAF	299 ± 19	257 ± 22

[a]Kupffer cells in primary culture were labeled with 0.5 μCi/mL [^{3}H]-arachidonic acid described in Materials and Methods. EGTA (5 mM) and nifedipine (100 μM) were added 5 min prior to the stimulation with PAF (20 nM). Reactions were terminated with the addition of ethanol and the prostaglandins were extracted and analyzed by HPLC as described. The results are expressed in DPM as mean values of triplicate determinations ± S.E.M. from a representative experiment of three experiments performed.

phospholipids, its release with PAF suggests stimulation of phospholipase A_2 activity. Phosphoinositides are rich in arachidonic acid and metabolically very active. Apart from the phospholipase A_2 pathway, arachidonic acid is released from DAG by a specific lipase. Alternatively, DAG is converted to phosphatidic acid and then may be hydrolyzed by phospholipase A_2 to release arachidonic acid. Thus, both deacylation and phospholipase C-mediated hydrolysis of phosphoinositides seem to be important for the PAF-stimulated prostaglandin synthesis in Kupffer cells. Table 3 illustrates the effect of the Ca^{++} ion chelator, EGTA, and the plasma membrane Ca^{++} channel antagonist, nifedipine, on the PAF-stimulated synthesis of prostaglandins in Kupffer cells. PAF-stimulated prostaglandin synthesis was completely inhibited by EGTA and nifedipine indicating the requirement of extracellular Ca^{++} for this process and suggesting that plasma membrane Ca^{++} channels may be regulated by PAF. The intracellular concentration of free arachidonic acid, which is the precursor of eicosanoids, is low (37). Therefore, in stimulated cells arachidonic acid is generated from the deacylation of membrane phospholipids by phospholipase A_2. This process has been reported to be receptor-mediated and modulated by G-proteins in certain cells (33,34). The intracellular concentration of Ca^{++} is increased through its mobilization from the cellular stores by Ins 1,4,5-P_3 and/or through an activation of plasma membrane Ca^{++} channels. Inhibition of PAF-stimulated synthesis of prostaglandins in Kupffer cells by EGTA and nifedipine (Table 3) implicates a requirement of extracellular Ca^{++} for this process and an activation of a membrane Ca^{++} channel by PAF. Involvement of Ca^{++} mobilized by Ins 1,4,5-P_3 in PAF-induced prostaglandin synthesis may be ruled out since EGTA was found not to inhibit early (5 second) PAF-stimulated hydrolysis of phosphoinositides, but strongly inhibited this process at later (20 min) times (results not shown). Although inositol lipids form a relatively minor pool of phospholipids, PAF-induced metabolism of these lipids may be important for prostaglandin synthesis and release since the phosphoinositides are rich

in arachidonic acid and are metabolically very active.

The results described in this study are outlined in the cartoon shown in Figure 5. PAF stimulates the early (5 seconds) hydrolysis of PIP_2 and PIP to Ins 1,4,5-P_3 and Ins 1,4-P_2, respectively, a process independent of extracellular Ca^{++} and mediated via the activation of a G-protein. PAF also induces Ca^{++} influx into the cells, which stimulates phosphodiester hydrolysis of PIP and PI, deacylation of PI (20 min), and the synthesis of prostaglandins. Inhibition of these processes by treatment with pertussis toxin suggests an involvement of G-protein(s). At this point it is not clear whether plasma membrane Ca^{++} influx, phospholipase A_2 activation, prostaglandin synthesis, or all of these processes involve G-protein(s). Also, it is not clear whether the same or different G-proteins are operating the above-mentioned processes. Stimulation of prostaglandin synthesis and GPI release by cholera toxin and the additive effect of cholera toxin and PAF on these processes suggest a possible involvement of cAMP. However, in separate experiments (data not shown) treatment of cells with dibutyryl cyclic AMP failed to stimulate GPI release or eicosanoid synthesis in Kupffer cells, suggesting an alternative mechanism of action of cholera toxin in these cells. Furthermore, in view of the recent reports concerning the involvement of protein kinase C in receptor-mediated events (38–44), such a mechanism of action in the PAF-induced Kupffer cell metabolism may not be ruled out.

Platelet-Activating Factor May Participate in Signal Transduction Processes in Rabbit Leukocytes[1]

Alastair G. Stewart* and **Trudi Harris**
Department of Physiology, University of Melbourne, Victoria, Australia

The bacterial chemotactic peptide, formyl-methionyl-leucyl-phenylalanine (fMLP), induces the generation of platelet-activating factor (PAF), the mobilization of arachidonic acid and generation of superoxide anion (O_2^-) in rabbit polymorphonuclear leukocytes (PMNs). The PAF receptor antagonists, WEB 2086 (10–100 μM) and CV 6209 (1–10 μM), reduced the mobilization of arachidonic acid and the O_2^- generation in response to fMLP but not that in response to A23187. Pretreatment of PMNs with the phospholipase A_2 inhibitor, chloroquine, or the serine protease inhibitor, tosyl-phenylalanine chloromethyl ketone, reduced the fMLP-stimulated generation of PAF and also reduced the generation of O_2^-. The respiratory burst induced by a submaximal concentration of phorbol myristate acetate was not affected by these compounds. These data are consistent with the suggestion that endogenous PAF may contribute to the signal transduction cascade initiated by fMLP. ***Lipids 26,*** **1044–1049 (1991).**

Membrane-derived mediators such as cyclooxygenase and lipoxygenase arachidonic acid metabolites and platelet-activating factor (PAF) are considered to play a key role in a variety of inflammatory conditions involving macrophages and polymorphonuclear leukocytes (PMNs). In addition to their extracellular actions, it has been proposed that lipoxygenase products may contribute to cellular transduction processes (1–3).

Several features of the biology of PAF suggest that it may have a role within the cell in addition to its suggested role as an extracellular mediator of inflammation. Although it is now well-established that pathophysiological stimuli elicit the synthesis of PAF in a range of cell types including endothelium, macrophages and PMNs (4), the release of PAF into the extracellular medium varies considerably in magnitude. Furthermore, once released, PAF may be rapidly inactivated by plasma acetylhydrolase (5) or its actions may be prevented by the presence of endogenous PAF inhibitors (4). The potency of PAF in causing platelet aggregation is considerably higher in washed platelets than in platelet rich plasma (6) suggesting that physiological concentrations of serum albumin greatly reduce the potency of PAF by binding it in a less active form. These characteristics of PAF may diminish its importance as a mediator of inflammation.

We have recently reported that PAF receptor antagonists reduce prostacyclin (PGI_2) generation in adherent macrophages (7–9). These unstimulated adherent macrophages had no detectable PAF in the supernatants, but PAF was readily detectable in cellular extracts. Thus, we put forward the hypothesis that, under certain conditions, PAF may be acting as part of the intracellular transduction mechanism for eicosanoid and superoxide anion (O_2^-) generation rather than, or in addition to, its role as an extracellular mediator (7–10). In this study, we have examined further the possible intracellular role of PAF using the phospholipase A_2 inhibitor, chloroquine (11) and the serine protease inhibitor tosyl-phenylalanine chloromethyl ketone (TPCK), since these compounds have been reported to inhibit PAF synthesis (12,13). Furthermore, we have investigated the effects of the cyclooxygenase inhibitor indomethacin and the 5-lipoxygenase inhibitor CGS 8515 (14) on O_2^- generation by rabbit PMNs.

MATERIALS AND METHODS

Chemicals. All reagents and solvents were of analytical or higher grade. Chemicals were obtained from the following sources: A23187; BSA, grade 5, essentially fatty acid free; cytochrome C (horse heart type III); dextran, clinical grade C: formyl-methionyl-leucyl-phenylalanine (fMLP); indomethacin; superoxide dismutase (Sigma Chemical Co., St. Louis, MO); hexadecyl platelet-activating factor (PAF, Bachen, Bubendorf, Switzerland); [1-^{14}C]arachidonic acid, 58.3 mCi/mmol (Amersham International, Amersham, U.K.); 1-*O*-[1,2-^{3}H]hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine, 59.5 Ci/mmol; [14,15-^{3}H]leukotriene B_4,32 Ci/mmol (New England Nuclear, Boston, MA); leukotriene B_4 antiserum (Dr. J. Salmon, Wellcome Research Laboratories, Beckenham, U.K.); leukotriene B_4 (Dr. J. Rokach, Merck, Frosst Laboratories, Montreal, Canada); HEPES (*N*-2-hydroxyethylpiperazine-*N*-2-ethanesulfonic acid, BDH Chemicals, Melbourne, Australia); heparin (Fisons Pty. Ltd., Melbourne, Australia); CV 6209 (Takeda Chemical Industries Ltd., Osaka, Japan); WEB 2086 (Boehringer Ingelheim, Ingelheim, West Germany).

Isolation of platelets and polymorphonuclear leukocytes. Rabbits of either sex (2–4 kg) were anaesthetized using propanidid and exsanguinated *via* a sterile cannula placed in the carotid artery. The blood was anticoagulated with citrate (0.38% w/v, final concentration), platelet-rich plasma was obtained by centrifugation (100 × *g*, 20 min, 20°C), and washed platelets were prepared as described previously (7,15). Polymorphonuclear leukocytes (PMNs) were prepared by centrifugation through Ficoll-Paque or Lymphoprep (endotoxin-tested) as described (7,9) and finally resuspended in HEPES (5mM)-buffered Tyrode solution (0.25% bovine serum albumin); composition (mM): 137, NaCl; 11, D(+)-glucose; 11.9, $NaHCO_3$; 2.7, KCl; 0.26, $MgCl_2$; 0.4, NaH_2PO_4; 1.8, $CaCl_2$.

Superoxide anion generation. The generation of O_2^-

Abbreviations: ANOVA, analysis of variance; fMLP, formyl-methionyl-leucyl-phenylalanine; HEPES, *N*-(2-hydroxyethyl) piperazine-*N*'-2-ethanesulfonic acid; HPLC, high-performance liquid chromatography; LTB_4, leukotriene B_4; NADPH, reduced nicotinamide adenine dinucleotide phosphate; PAF, platelet-activating factor; PGI_2, prostacyclin; PMA, phorbol myristate acetate; PMNs, polymorphonuclear leukocytes; SOD, superoxide dismutase; TPCK, tosyl-phenylalanine chloromethyl ketone.

was measured by the superoxide dismutase (SOD)-inhibitable reduction of cytochrome C (9,16). PMNs were suspended at 2–3 × 10^6/mL in Tyrode solution containing 80 μM cytochrome C and were pre-incubated with antagonists and inhibitors for 15 min at 37° before stimulation with fMLP (0.1–1000 nM) or phorbol myristate acetate (PMA, 0.1–1000 nM) for 15 min. The response to fMLP was complete within 5 min and the O_2^- generation by PMA-treated PMNs was stopped by the addition of 10 μg/mL SOD. The absorbance (550 nm) of the supernatants was determined in a Pye Unicam or Hitachi U2000 spectrophotometer. The data for O_2^- in response to fMLP (1 μM) and PMA (1 μM) in nmol/10^6 cells was 4.55 ± 0.75, n = 16 and 61.0 ± 9.4, n = 13, respectively and the basal value was 1.07 ± 0.40, n = 16.

Bioassay of PAF. Rabbit-washed platelets were suspended in Tyrode buffer containing indomethacin (2.8 μM) at 2 × 10^8/mL and a concentration-response curve for synthetic hexadecyl PAF (2–200 fmol)-induced aggregation (Chronolog 540 aggregometer) was constructed. PAF was assayed in supernatants without further purification and in cell extracts as previously described in detail (8–10,17). PAF was extracted into 80% ethanol and the identity of the extracted PAF was assessed by sensitivity of platelet aggregation induced by the extracted material to inhibition by the specific PAF receptor antagonist WEB 2086 (1 μM) and by the co-migration of this material with authentic PAF on a thin-layer chromatogram (chloroform/methanol/water/acetic acid, 65:35:6:0.1, by vol; Whatman LKD silica gel).

Radioimmunoassay of leukotriene B_4. The release of leukotriene B_4 into the supernatants of fMLP-stimulated PMNs was measured by radioimmunoassay of non-extracted PMN supernatants using previously described anti-serum and methods (9,18). None of the compounds used interfered with the radioimmunoassay. The limit of detection was 0.025 pmol (corresponding to 0.005–0.01 pmol/10^6 PMNs). The inter-assay co-efficient of variation was 11.5% and the intra-assay co-efficient of variation was 7% (n=7 assays).

Prelabelling of PMNs with [^{14}C]arachidonic acid. PMNs (10^7/mL) were incubated with 0.2 μCi/mL [^{14}C]arachidonic acid for 120 min during which time 20.4 ± 3.9% (n=5) of the label was taken up into phospholipid stores. At the end of this incubation period, the non-incorporated [^{14}C]arachidonic acid was removed by centrifuging the cells (1,000 × *g*, 5 min, ambient temperature) and decanting the supernatant. Residual non-incorporated [^{14}C]arachidonic acid was removed by resuspending the cells in Tyrode buffer and centrifuging to remove the supernatant as before. Finally the cells were resuspended in Tyrode buffer at a concentration of 2–3 × 10^6/mL and stimulated as described in the Results section. At the end of the stimulation period, the cells were pelleted by centrifugation and the ^{14}C-content of the supernatants was determined by liquid scintillation spectrometry (Packard). In some experiments the composition of the released radioactivity was examined by passing the supernatants through C^{18} Sep-paks to isolate the arachidonic acid and metabolites which were subsequently separated on reverse-phase high-performance liquid chromatography (HPLC) using a Nova-pak C^{18} column in a radial compression module and an initial mobile phase of methanol/water/acetic acid (65:35:0.1, v/v/v; pH 5.4) for the first 16 min followed by a 5-min linear gradient to 99% methanol containing 1% acetic acid for a further 20 min at a constant flow rate of 1 mL/min. Fractions were collected and counted for ^{14}C and products were identified by comparing their elution times with those of authentic ^{3}H standards. The released ^{14}C comprised [^{14}C]arachidonic acid (55%, elution time 29 min) and its metabolites (LTB_4; 6%, 9.5 min), an unidentified peak (12%) that eluted at 4 min but was distinguishable from leukotriene C_4 and 5-Hydroxy-eicosatetraenoic acid (10%, 26 min).

Statistical analyses. Concentration-response curves were analyzed by analysis of variance (ANOVA) with repeated measures. Single comparisons were made using Student's t-test. Differences were considered to be significant when $P<0.05$. There was considerable variability between rabbits in the amount of O_2^- generated and the release of [^{14}C]arachidonic acid. Therefore, these data have been normalized by expressing formation or release as a percentage of that observed in control incubations (no pretreatments) for individual experiments.

RESULTS

The bacterial chemotactic peptide fMLP concentration-dependently stimulated the generation of O_2^- (Fig. 1). PAF generation was also stimulated by fMLP (10 nM) (Table 1). To examine whether the PAF generated in fMLP-stimulated PMNs contributed to activation of O_2^- generation, PMNs were pretreated for 15 min before stimulation with the PAF receptor antagonists, WEB 2086 (10 μM) and CV 6209 (1 μM). The PAF receptor antagonists reduced fMLP (10 nM)-induced O_2^- generation, whereas only CV 6209 reduced the basal O_2^- (Table 2).

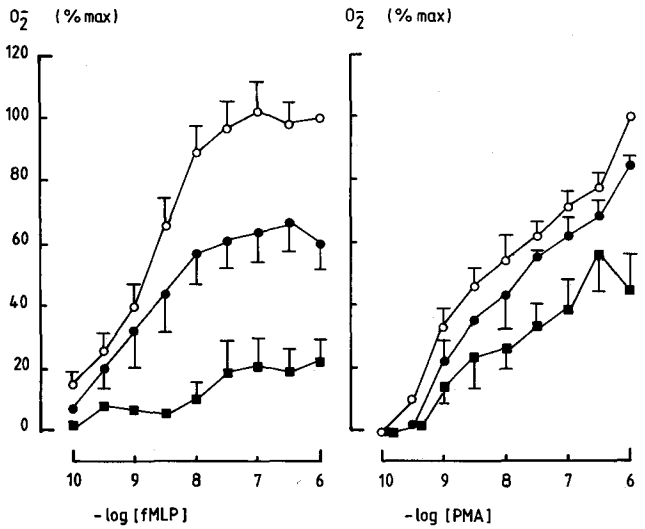

FIG. 1. fMLP and PMA (open circles)-induced O_2^- generation in a concentration-dependent manner. In cells which were pre-incubated in chloroquine (10 μM, filled circles; 100 μM, filled squares) the stimulation of O_2 generation by fMLP was significantly reduced. Responses to PMA were reduced only by the higher concentration of chloroquine. The data are expressed as percentages of the respective maximum control (no chloroquine) responses to 1 μM of the stimulus (fMLP or PMA) and are presented as the means and standard errors of the means (n = 4–11).

TABLE 1

Effects of PAF Antagonists on O_2^- Generation

[c]NT, not tested.

We examined the inhibitory effects of the PAF antagonists on ionophore A23187-induced O_2^- generation to check the specificity of these compounds. A23187 is considered to circumvent early steps in the signal transduction pathway by directly elevating intracellular Ca^{2+} and subsequently protein kinase C activity (19). In contrast to inhibition of fMLP responses, A23187-induced O_2^- generation was unaffected by the PAF receptor antagonists (Table 1).

Following 5 min of exposure to fMLP (10 nM), PAF was detected in cell extracts (0.024 ± 0.013 pmol/10^6 cells) and in supernatants (0.021 ± 0.012 pmol/10^6 cells). Thus, it was possible that PAF released during stimulation of PMNs by fMLP could augment the O_2^- response to fMLP. However, PAF (0.1 μM) alone elicited a barely detectable increase in O_2^- generation (0.26 ± 0.08 nmol/10^6 cells, n = 7) which was completely prevented by WEB 2086 (10 μM) or CV6209 (1 μM). Furthermore, we examined the possibility that PAF release early in the fMLP response could enhance the subsequent fMLP stimulation of O_2^- generation. However, PAF (0.1-1,000 nM) pretreatment of PMNs for 5 min before exposure to fMLP failed to augment the ensuing O_2^- response (n = 2, data not shown).

The activity of phospholipase A_2 appears to be rate-limiting for the formation of PAF. Thus, we used the inhibitor of phospholipase A_2, chloroquine, to reduce PAF formation induced by fMLP and then examined the generation of O_2^-. Chloroquine (10 and 100 μM) pretreatment produced a significant ($P<0.05$, ANOVA) inhibition of the O_2^- generation in response to fMLP, whereas only the higher concentration (100 μM) inhibited the response to PMA (Fig. 1). Parallel experiments confirmed that chloroquine inhibited the generation of PAF by fMLP (10 nM)-stimulated PMNs (% inhibition 10 μM, 58 ± 24; 100 μM, 95 ± 5). Recent studies indicate that serine proteases contribute to the regulation of enzymes involved in PAF synthesis. Pretreatment of PMNs with an inhibitor of serine proteases, TPCK (10 μM), caused the expected reduction in the generation of PAF in response to fMLP (Table 2). In addition, fMLP-induced O_2^- generation was inhibited by TPCK (Table 2), whereas the response to the activator of protein kinase C, phorbol myristate acetate (PMA, 0.3 nM), was unaffected (Table 2).

Chloroquine reduces PAF generation by inhibition of phospholipase A_2, probably by interacting with the substrate (11). Thus, this compound would be expected to reduce both the fMLP-induced mobilization of arachidonic acid from membrane phospholipids and its subsequent oxygenation to products implicated in PMN signal transduction processes (1-3). We confirmed that chloroquine reduced the release of [^{14}C]arachidonic acid (Table 3). It is interesting to note that chloroquine pretreatment gave only a marginal inhibition of A23187-induced [^{14}C]arachidonic acid release from PMNs (Table 3).

The possible importance of cyclooxygenase or 5-lipoxygenase products in the fMLP-stimulated O_2^- generation

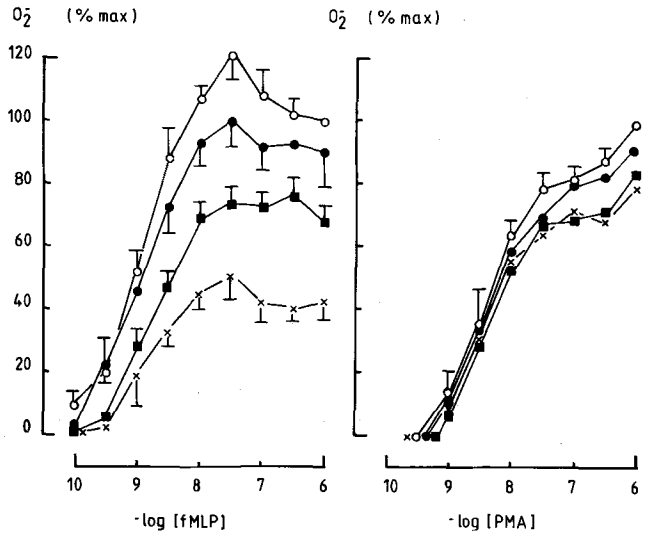

FIG. 2. The effects of pre-incubation of the cells with indomethacin (2.8 μM, filled squares), CGS 8515 (1 μM, filled circles) or their combination (crosses) on O_2^- generation induced by fMLP and PMA (control responses, open circles) have been assessed. Data are expressed as percentages of the respective maximum control (non-pretreated cells) responses to 1 μM of the stimulus (fMLP or PMA). Standard error bars for PMA experiments have been omitted for the sake of clarity (n = 5–7).

was investigated using pretreatment with either indomethacin (2.8 μM), CGS 8515 (1 μM) or their combination (Fig. 2). The 5-lipoxygenase inhibitor, CGS 8515, had no significant effects on O_2^- generation stimulated by either fMLP or PMA. On the other hand, the cyclooxygenase inhibitor, indomethacin, reduced fMLP and, to a lesser extent, PMA-induced O_2^- generation. Furthermore, the combination of these inhibitors produced greater inhibition of fMLP responses than indomethacin alone. Effective inhibition of 5-lipoxygenase by CGS 8515 was confirmed by examining its effect on immunoreactive LTB_4 generation by fMLP-stimulated PMNs (control 22.2 ± 5.2 pmol/10^6 cells, n = 6; CGS 8515 1 μM, 1.4 ± 0.9 pmol/10^6 cells, n = 6; P<0.05, paired Student's t-test).

Our previous studies in guinea-pig peritoneal macrophages suggested that endogenous PAF may have a role in the mobilization of arachidonic acid in response to receptor-operated stimuli (7–9). To examine whether PAF may play a similar role in PMNs, the PAF receptor antagonists, WEB 2086 and CV 6209, were incubated with PMNs for 15 min before stimulation with fMLP. The fMLP-induced mobilization of pre-incorporated [^{14}C]arachidonic acid was inhibited by WEB 2086 or CV 6209 as was [^{14}C]arachidonic acid release induced by PAF (Table 3). In contrast, A23187-induced mobilization of [^{14}C]arachidonic acid was not inhibited by these compounds indicating that phospholipase A_2 was not non-specifically inhibited.

DISCUSSION

Our findings suggest that PAF may contribute to the signal transduction cascade initiated by fMLP in rabbit PMNs. Several independent lines of evidence support this proposal. Firstly, the structurally distinct PAF receptor antagonists, WEB 2086 and CV 6209, reduced both arachidonic acid mobilization and O_2^- generation in response to fMLP. Secondly, we observed a reduction in O_2^- generation following pretreatment with the serine protease inhibitor, TPCK (12), and the phospholipase A_2 inhibitor, chloroquine (11), which concomitantly reduced the generation of PAF by fMLP-stimulated PMNs. Finally, in our previous studies, fMLP stimulated PMNs to generate PAF with a time course parallel to that of arachidonic acid mobilization and leukotriene B_4 (LTB_4) generation (9).

The specificity of the PAF antagonists has been established in detailed studies of platelet aggregation (20,21). In this study, evidence for a specific action is suggested by the differential inhibition of both PAF and fMLP-induced responses compared with those induced by the ionophore A23187. Inhibition of A23187-induced

O_2^- generation and arachidonic acid mobilization by PAF receptor antagonists could have been expected since A23187 is an effective stimulus for PAF generation (9,12,13,22). However, A23187 induces a large and persistent increase in cytosolic Ca^{2+} (23) and may activate protein kinase C (19). These combined actions appear to be sufficient stimuli for mobilization of arachidonic acid and generation of O_2^-, irrespective of the concomitant generation of PAF. The failure of the PAF receptor antagonists to reduce either arachidonic acid mobilization or O_2^- generation in response to A23187 indicates that these compounds do not inhibit non-specifically phospholipase A_2 or reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, or act as free radical scavengers (9).

Investigation of the role of PAF, particularly that of intracellular PAF, has been hampered by a lack of specific PAF synthesis inhibitors. Nevertheless, several compounds which reduce PAF generation have been described (11,24). PAF synthesis by PMNs is considered to involve activation of phopholipase A_2 and acetyl transferase (22) although non-physiological stimuli such as A23187 and the phorbol ester PMA may also activate the cholinephosphotransferase pathway (19,24). In our study, inhibition of phopholipase A_2 using chloroquine reduced both PAF synthesis and the mobilization of arachidonic acid. Furthermore, chloroquine concentration-dependently reduced O_2^- generation induced by fMLP, but inhibited responses to PMA to a lesser extent. The serine protease inhibitor, TPCK (12), reduced both PAF synthesis and O_2^- generation induced by fMLP, supporting our suggestion that PAF may be an important component of the signal transduction cascade.

The interpretation of the actions of chloroquine does not exclude a role of arachidonic acid itself, or its oxygenated products, both of which have received some consideration as second messengers (1–3). We examined a possible contribution of 5-lipoxygenase products in the activation of O_2^- generation using the selective inhibitor, CGS 8515 (14). An effective concentration of this compound had little effect on O_2^- generation stimulated by either fMLP or PMA, but it appeared to enhance the small inhibitory effect of indomethacin. These data do not support an important role for 5-lipoxygenase products in rabbit PMN signal transduction. It has been suggested that the actions of indomethacin on PMN function, including inhibition of aggregation and NADPH oxidase (25), may be unrelated to cyclooxygenase inhibition.

An involvement of arachidonic acid in the signal transduction cascade does not preclude a role for endogenous PAF, since PAF appears to be involved in arachidonic acid mobilization (7–10) and may therefore represent an earlier component of the transduction process.

We have previously proposed that PAF acts intracellularly to initiate mobilization of arachidonic acid in endothelial cells (10) and macrophages (8). These cells retain PAF intracellularly following activation by stimuli such as fMLP and bradykinin. However, in this and other studies (26), PMNs released a significant proportion of the PAF generated in response to fMLP. In contrast, Lynch and Henson (27) reported that rabbit PMNs release PAF only following pretreatment with cytochalasin B. This difference may be explained by the relatively insensitive assay ([^{3}H]serotonin release) used in the latter study. An effect of the released PAF in the generation of O_2^- seems unlikely, since even high concentrations of exogenous PAF (up to 0.1 μM) produced only 10% of the response to fMLP. Furthermore, although low concentrations of PAF are reported to prime human PMNs for enhanced O_2^- generation (28), we were unable to detect a similar enhancement of responses in rabbit PMNs. In parallel experiments, the possibility that the PMNs had already been primed by exposure to reagents containing endotoxin was excluded since low concentrations of added endotoxin (1–10 ng/mL) were able to prime PMNs (Stewart and Harris, unpublished observations). Thus, our findings support an intracellular rather than an extracellular site of action for PAF in rabbit PMNs.

Previous speculations on the role of intracelluar PAF include a possible receptor-independent regulation of membrane fluidity and expression of receptors (27). Our data with PAF receptor antagonists suggest that intracellular PAF may act by receptor stimulation. However, the possibility that PAF receptor antagonists inhibit PAF formation cannot be excluded. Indeed, recent evidence suggests that PAF stimulates its own synthesis in human PMNs, and PAF receptor antagonists inhibit this autogeneration (29). The possibility that PAF formed in response to unrelated stimuli such as fMLP could elicit autogeneration has yet to be explored.

In an early study, PAF release was shown to occur later than either degranulation or O_2^- generation in response to PMN activation, and the amount of PAF released did not correlate with either functional response (30) suggesting to these authors that PAF was not causally related to these responses. However, it is now clear that a significant proportion of the PAF synthesized by PMNs is retained and its formation precedes release (27). More recently, the synthesis of intracellular PAF has been temporally linked to the increase in PMN adhesion induced by A23187 and fMLP (26). Nevertheless, the lack of PAF synthesis in response to a number of stimuli known to increase adhesion (PMA, LTB_4, endotoxin, tumor necrosis factor α, platelet-derived growth factor) led these authors to suggest that PAF was not important for adhesion responses. This interpretation does not allow for the possibility that there are several signal transduction processes which may operate independently. Furthermore, we have confirmed the observation by Nieto *et al.* (24) that PMA is a potent stimulus for PAF formation in human PMNs (Stewart and Harris, unpublished observations). Both endotoxin (28) and tumor necrosis factor α (13) also elicit generation of measurable levels of PAF as detected by the platelet aggregation assay for PAF. Thus, the detection limit of the [^{3}H]acetate labelling assay may be too insensitive to detect PAF formed by these stimuli. Alternatively, the latter stimuli may use the cholinephosphotransferase pathway which may not be readily detected by [^{3}H]acetate labelling. Irrespective of the reason for these discrepancies, there is no unequivocal evidence to suggest that these stimuli for increased PMN adhesion do not produce PAF.

In conclusion, the data from these studies support a role for endogenous PAF in the mobilization of arachidonic acid and the generation of O_2^- by fMLP-stimulated rabbit neutrophils. The mechanism of action of endogenous

PAF is not clear, but appears to involve intra- rather than extracellular effects.

ACKNOWLEDGMENTS

We thank Dr. J. Rokach (Merck Frosst, Canada) and Dr. J. Salmon (Wellcome Research Laboratories, U.K.) for generous gifts of synthetic leukotriene B_4 and leukotriene B_4 anti-serum, respectively. We also thank Ms. A. Christov for expert technical assistance. This study was supported by the National Health and Medical Research Council of Australia.

[Received July 31, 1989; Revision accepted August 25, 1990]

Inhibition by the PAF Antagonist WEB 2086 of PAF Induced Inositol-1,4,5-trisphosphate Production in Human Platelets[1]

F.W. Birke* and **H.A. Ensinger**
Boehringer Ingelheim KG, Department of Biochemistry, D-6507 Ingelheim, Germany

Platelet-activating factor (PAF) activates human platelets by binding to a putative PAF receptor which evokes the rapid formation of inositol-1,4,5-trisphosphate (IP_3) by phospholipase C mediated phosphatidylinositol-4,5-bisphosphate (PIP_2) hydrolysis. Stimulation of [^{3}H]inositol-labeled human platelets by PAF (1 nM–1μM) resulted in a concentration-dependent increase of intracellular IP_3, IP_2 and inositolmonophosphate (IP_1). IP_1 levels increased up to three-fold upon maximum stimulation by 100 nM PAF. The EC_{50} concentration for PAF was 1.2 ± 0.3 nM. Addition of the hetrazepinoic PAF antagonist, WEB 2086, inhibited PAF stimulated hydrolysis of PIP_2 in a dose-dependent manner. WEB 2086 (100 μM) blocked inositol-1,4,5-trisphosphate formation down to baseline levels (IC_{50}=33 ± 12 μM WEB 2086). In thrombin and ADP stimulated platelets, inositol phosphate (IP) generation was not influenced by WEB 2086. It is concluded that WEB 2086 selectively antagonizes PAF-induced increases in IP and does not interfere directly with intracellular signal transduction. Instead, WEB 2086, which has been shown to bind specifically and with high affinity (K_i 15 nM) to human platelets, acts as a competitive antagonist at the PAF receptor level.
***Lipids 26*, 1050–1053 (1991).**

Platelet activating factor (PAF, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) is a potent phospholipid mediator which is synthesized by various cells and which is able to promote a number of biological effects including platelet activation, bronchoconstriction and hypotension (1). Induction of platelet activation by PAF is mediated by specific binding to a PAF receptor (2). PAF binding seems to exert its effects through guanine nucleotide binding (G) proteins. PAF induced effects on platelet adenylate cyclase are reported to be mediated by G_i (3). However, Houslay *et al.* (4) found that platelet GTPase activity associated with PAF stimulation was only slightly altered by treatment with pertussis toxin. They concluded that no G_i, but a different G protein named G_p, may be the predominant guanine nucleotide binding protein mediating the PAF signal. PAF binding was shown to be closely associated with the rapid cleavage of phosphodiester bonds in inositol phospholipids, especially phosphatidylinositol-4,5-bisphosphate (PIP_2) (5). The reaction, which involves phospholipase C cleavage, is thought to be mediated by G_p proteins and leads to the release of inositol-1,4,5-trisphosphate (IP_3). This second messenger IP_3 was shown to mobilize Ca^{2+} from intracellular stores of numerous cells, including platelets (6).

Two other platelet activators, thrombin and adenosine diphosphate (ADP), served as controls for PAF stimulation. ADP triggers platelet aggregation and is involved in amplifying the platelet response to other agonists such as thrombin or PAF (7).

Activation of platelets by thrombin and ADP has been shown to be mediated by activation of phospholipase C as is PAF stimulation, and unlike epinephrine activation, which involves the adenylate cyclase system. This process is independent of and dissociated from arachidonic acid metabolism (8). Furthermore, PAF and thrombin use the same pool of phosphatidylinositol-4,5-bisphosphate in rabbit platelets (9). Thrombin pretreatment evokes the phenomenon of desensitization both for thrombin and PAF stimulation (10). Therefore, thrombin and ADP stimulation seem to be relevant controls for PAF stimulation of human platelets.

WEB 2086 is a well characterized PAF antagonist with a hetrazepinoic structure. WEB 2086 was demonstrated to inhibit PAF induced effects *in vitro* and *in vivo* with high potency and specificity (11,12). WEB 2086 was shown to inhibit PAF binding to the PAF receptor in a competitive and specific manner in human platelets (13,14), neutrophils (15) and in eosinophils (16).

In the present study we examined whether WEB 2086, in addition to its PAF receptor antagonistic properties, has direct effects on the G protein/phospholipase C complex.

MATERIALS AND METHODS

Platelet activating factor (PAF, AGEPC, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) was supplied as C_{16}PAF by Serva (Heidelberg, Germany). Human thrombin with 30 IU/mL activity was from Behring (Marburg, Germany). Myo-[2-^{3}H]inositol (spec. act. 3.3 TBq/mmol) was purchased from Amersham Buchler (Braunschweig, Germany). Dowex resins (1-X8, 200–400 mesh, pa.) and prostacyclin were obtained from Serva. All other chemicals and solvents used were supplied by Merck (Darmstadt, Germany) in the highest analytical grade available. WEB 2086, which is 3-[4-(-2-chlorophenyl)-9-methyl-6H-thieno[3,2-f][1,2,4]triazolo[4,3-a][1,4]diazepine-2-yl]-1-(4-morpholinyl)-1-propanone, was synthesized in the Department of Chemistry at Boehringer Ingelheim.

Isolation of human platelets. Blood was freshly drawn from healthy volunteers. Citrated blood (200 mL) was centrifuged at room temperature for 15 min at 160 × *g* for preparation of platelet rich plasma. Then the platelets were centrifuged at 800 × *g* for 10 min.

[^{3}H]Inositol labeling of platelets. The pellet of a 800 × *g*/10 min centrifugation, containing about 2 × 10^{10} platelets, was resuspended in 5 mL labeling buffer, pH 7.4 (20 mM Hepes, 137 mM NaCl, 2.68 mM KCl, 1 mM $MgCl_2$, 1 mM EGTA, 11.9 mM $NaHCO_3$, 0.42 mM NaH_2PO_4, and 5.55 mM glucose). [^{3}H]Inositol (18.5 MBq) was added and the mixture was incubated for 2 hr

Abbreviations: ADP, adenosine diphosphate; DAG, diacylglycerol; IP_3, inositol-1,4,5-trisphosphate; IP, inositol phosphates; PAF, platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; PIP_2, phosphatidylinositol-4,5-bisphosphate; PKC, protein kinase C; PLC, phospholipase C.

at 37°C. The labeled platelets were washed twice by centrifugation (800 × *g*, 10 min) in labeling buffer supplemented with myoinositol (5 mmol/L), heparin (5000 U/L) and PGI_2 (0.25 nM).

Stimulation of labeled platelets. The resulting pellet was resuspended in assay buffer [labeling buffer supplemented with 0.1 mM $CaCl_2$ and 0.1% bovine serum albumin (BSA)] and used immediately for platelet stimulation. Platelets (10^9) were incubated in 1 mL final volume. The mixture contained PAF (concentrations as indicated), or thrombin (0.05 U/assay) or ADP (1 μM), and, additionally, the PAF antagonist WEB 2086 in inhibition experiments. Viability of labeled platelets was tested by monitoring thrombin and PAF induced aggregation.

LiCl (10 mM) was added 5 min before the start of incubations. WEB 2086 (100 μL), dissolved in ethanol/water (1:1, v/v) was added 10 min before the start of incubation (10 min, 37°C) by adding the agonist. After stimulation, the tubes were sealed and shaken vigorously.

Analysis of IP-species was performed according to Berridge *et al.* (17) with some modifications. The incubation was stopped by adding 2 mL of methanol/chloroform (1:1, v/v). For better separation of the layers, an additional 700 μL of both H_2O and $CHCl_3$ was added, followed by centrifugation for 15 min at 3500 rpm. The aqueous layer was removed for anion exchange chromatography on columns filled with Dowex 1-X8 slurry (1:1, v/v, with H_2O; 1 mL Dowex slurry per column). Two mL of aqueous phase was loaded on one column and washed once with 2 mL H_2O and twice with 1.0 mL of 5 mM Na tetraborate in 60 mM ammonium formate. Inositol phosphate (IP) species were eluted in three steps. The first step used 1 mL followed by twice 0.5 mL of 5 mM Na tetraborate in 150 mM ammonium formate. The second step used 2 mL of 0.1 mM formic acid in 400 mM ammonium formate; and the final step used 2 mL of 0.1 M formic acid in 1 M ammonium formate. Ten mL of scintillation fluid (Quickszint 2000, Zinsser, Frankfurt, Germany) per 0.5 mL eluent were added and radioactivity was quantified in a liquid scintillation counter.

Data are presented as mean ± S.E. of individual experiments from different blood donors as indicated. Statistical significance was calculated by paired Student's *t*-test.

RESULTS

Stimulation of human platelets by PAF resulted in a concentration dependent increase of intracellular concentrations of IP_3, IP_2 and IP_1.

In Figure 1, a typical experiment of PAF (0.3–100 nM) induced IP_1 production is shown. PAF at 1 μM did not increase IP_1 production further. The line was calculated by means of an iterative program of "coupled mass equilibria" using a one-compartment model (18). The effective PAF concentration for half the maximum IP_1 production was EC_{50} 1.2 ± 0.3 nM (mean of 4 experiments ± SEM), with a maximum IP_1 production of up to 2.5 fold the IP_1 basal levels.

Figure 2 shows the relative increases in the IP species IP_3, IP_2 and IP_1 10 min after 100 nM PAF stimulation. Due to the inhibition of IP_1 metabolism by 10 mM lithium and the incubation time of 10 min, IP_1 was predominantly formed. Therefore, IP_1 levels were used as an indicator of IP_3 production throughout the results reported. PAF (100 nM) stimulated IP_1 concentration to 167 ± 47% of control (mean of 9 experiments ± SEM).

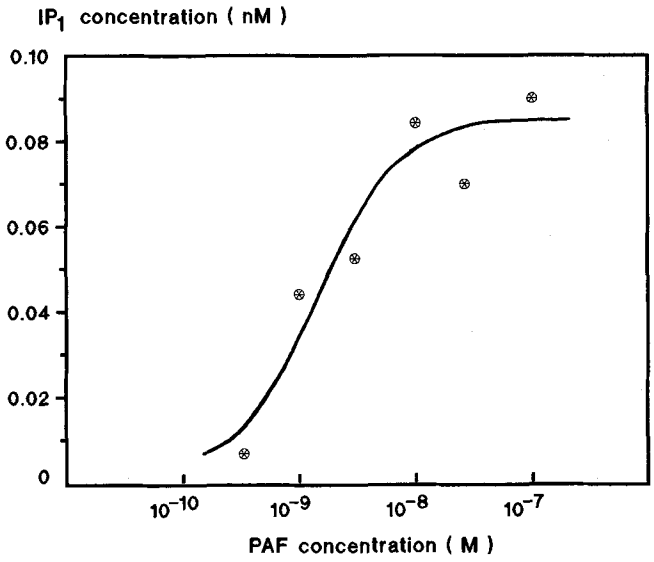

FIG. 1. Stimulation of IP_1 generation by PAF in human platelets. [^{3}H]Inositol-labeled human platelets (10^9/mL) were stimulated with increasing concentrations of PAF (0.3–100 mM). Inositol phosphates were extracted and fractionated by Dowex 1-X8 ion exchange chromatography. IP_1 concentration was calculated from the radioactivity of the IP_1 peak. Each point represents the mean of duplicate determinations in a typical experiment. The line was calculated by the program "coupled mass equilibria".

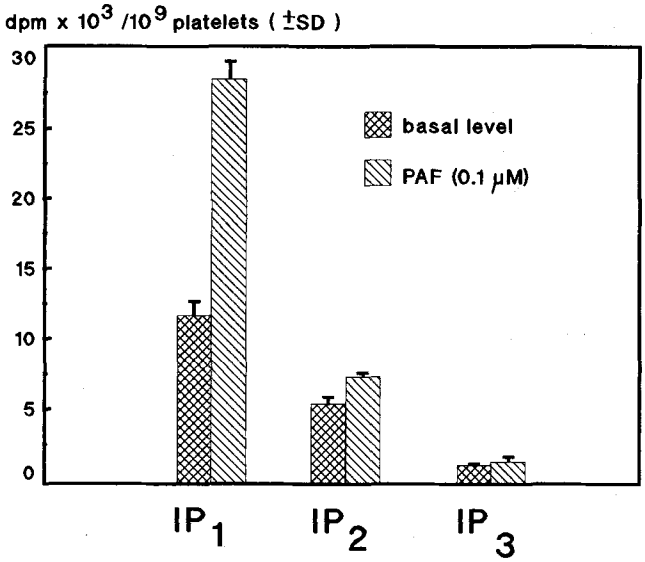

FIG. 2. Levels of the inositolphosphates IP_1, IP_2 and IP_3 induced by PAF in human platelets. Increase in inositol-1-phosphate (IP_1), inositol-1,4-bisphosphate (IP_2) and inositol-1,4,5-trisphosphate (IP_3) determined 10 min after 0.1 μM PAF stimulation in the presence of Li^+. The bars represent the mean of duplicate determinations ± S.E. in a typical experiment.

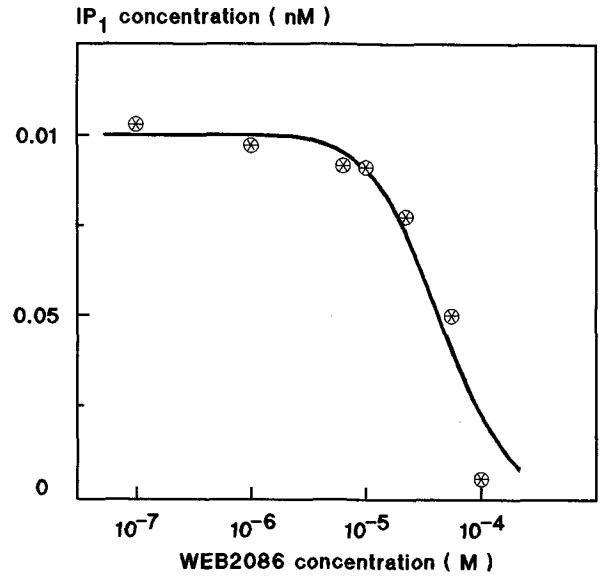

FIG. 3. Inhibition of PAF stimulated IP_1 production by WEB 2086 (0.1-100 μM). Each point of the WEB 2086 inhibition curve of 100 nM PAF stimulated IP_1 production represents the mean of triplicate determinations with SD less than 15%. WEB 2086 (100 μM) suppressed IP_1 generation to control levels. The line was fitted by the program "coupled mass equilibria". Considering the EC_{50} of 1.2 nM for PAF in a one-compartment model, a K_i value of 620 nM for WEB 2086 inhibition was calculated.

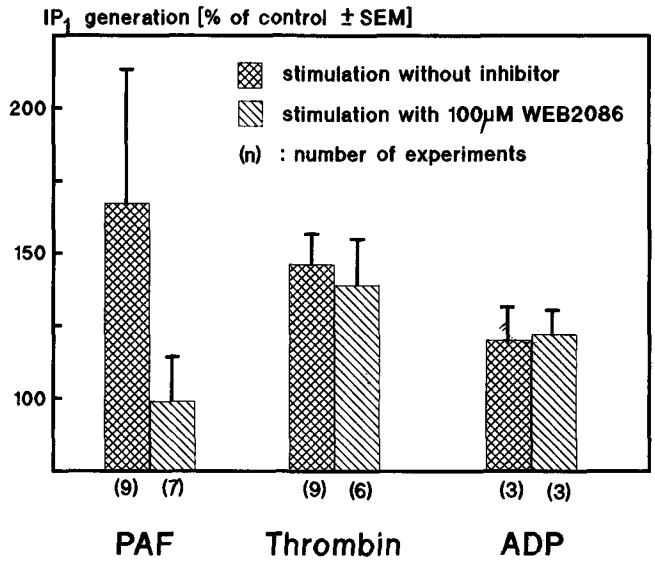

FIG. 4. Selectivity of WEB 2086 for PAF induced IP_1 generation in human platelets. WEB 2086 significantly inhibits PAF (100 nM) stimulated IP_1 generation ($p<0.01$), while thrombin stimulation (0.05 IU/mL) and ADP stimulation (1 μM) are not influenced. Baseline IP_1 levels (control) were set at 100% of IP_1 production.

Addition of the hetrazepinoic PAF antagonist WEB 2086 inhibited PAF induced IP_1 generation in a dose-dependent manner. WEB 2086 (100 μM) significantly blocked PAF mediated PIP_2 turnover of PLC, lowering IP_1 to the basal 100% level of controls (99 ± 16% of control, n=7, $p<0.05$).

In Figure 3, the inhibition of IP_1 production by increasing concentrations of WEB 2086 (1 μM-100 μM) is demonstrated in a typical experiment. Each point represents the mean of three independent determinations. The line was calculated by iterative fitting of data with a one-compartment model ("coupled mass equilibria" program). The concentration of WEB 2086 for half the maximum inhibition (IC_{50}) of IP_1 formation was 32 ± 12 μM (mean ± SEM, n=3). This corresponds to a calculated K_i value of 0.62 ± 0.23 μM for WEB 2086 inhibition, taking into consideration the intrinsic activity of PAF (EC_{50} 1.2 nM) in this system.

If WEB 2086 acts by binding selectively to the PAF receptor, platelet activation as measured by IP_3 production should not be influenced through mediators other than PAF using the same signaling pathway. Therefore, platelets were activated by thrombin and ADP (see Fig. 4). Using 1 μM ADP, only minor responses in IP_1 production were found in about half of the experiments (120 ± 11% of control, n=3). WEB 2086 (100 μM) did not influence this weak ADP stimulation (122 ± 9% of control, n=3).

In contrast to ADP, thrombin (0.05 IU/mL) consistently activated human platelet IP_1 production (146 ± 11% of control, n=9) to a degree comparable to 100 nM PAF stimulation. However, in contrast to PAF stimulation, thrombin stimulation of IP_1 generation was not changed by 100 μM WEB 2086 (139 ± 16% of control, n=6).

DISCUSSION

The results presented here confirm previous reports (for a review, see ref. 19) demonstrating the increase in intracellular inositol phosphate species (IP_1, IP_2, IP_3) after PAF stimulation of human platelets. IP generation reflects the activation of phospholipase C triggered by PAF binding to the PAF receptor and does not seem to be mediated by additional mediators (8).

The inositol-1,4,5-trisphosphate (IP_3) releasing effect of PAF was dose-dependently inhibited by WEB 2086. The relatively low potency of WEB 2086 (IC_{50} 32 μM) found for inhibition of PAF induced IP_1 generation, when compared with the K_i = 15 nM for [^{3}H]PAF displacement from the PAF receptor, may be due to the relatively high concentration of PAF (100 nM) used to assure maximum IP stimulation. Considering the high activity of PAF (EC_{50} 1.2 nM), however, a K_i value of 620 nM was calculated for WEB 2086 inhibition, which is only one order of magnitude higher than the inhibition constant derived from binding data. This difference is also found for the agonistic PAF comparing the EC_{50} 1.2 nM from platelet activation with K_D 0.07 nM from binding experiments (13). This may reflect the efficacy of coupling of receptor occupation with second messenger, *i.e.*, IP_3 production *via* G proteins. The inhibitory effect of WEB 2086 seems to be specific for PAF, since WEB 2086 did not influence thrombin or ADP stimulated IP production. Thrombin has been reported to use a similar transmembrane signalling pathway like PAF, as demonstrated by the heterologous desensitization of PAF stimulation by thrombin pretreatment (20). Additionally, thrombin seems

to use the same pool of PIP_2 as does PAF (9). Thus, when PAF and thrombin are using the same second messenger pathway, WEB 2086 specificity must be attributed to its specific interaction with the PAF receptor.

Further support for the specificity of WEB 2086 for PAF induced platelet activation is provided by *in vitro* platelet aggregation, where aggregation induced by thrombin, ADP, collagen or serotonin was not inhibited by WEB 2086 (11). Thus, we conclude that WEB 2086 inhibits PAF action at the level of the PAF receptor. This view is strongly supported by the direct binding experiments with [^{3}H]WEB 2086 (13,14) demonstrating high affinity (K_i 15 nM) and competitive binding of [^{3}H]WEB 2086 to PAF receptor sites on human platelets.

Additional support is provided by the report of Shukla (21), demonstrating the specific effects of the PAF antagonist CV 3988 on PAF induced IP_1, IP_2 and IP_3 generation in rabbit platelets. Simon *et al.* (22) reported similar effects of the PAF antagonist BN 52021 in human platelets. They, however, measured phosphatidic acid production by ^{32}P-labeling instead of IP generation. Phosphatidic acid is formed from diacylglycerol (DAG), which (like IP_3) is the product of PLC action on PIP_2. DAG is thought to activate protein kinase C(PKC) (23). A large proportion of diacylglycerol formed upon PLC action is immediately converted to phosphatidic acid. However, unwanted incorporation of ^{32}P into ATP and then into phosphatidic acid during the labeling procedure as described by Simon *et al.* (22) seems possible. These processes may produce [^{32}P]phosphatidic acid in addition to phosphorylation of the DAG arising from hydrolysis of phosphoinositides. There may also be competing fates of diacylglycerol disturbing its correlation to PLC activity.

Recent observations reported by Uhing *et al.* (24), using murine peritoneal macrophages, suggest that PAF can stimulate the accumulation of DAG derived from sources other than phosphatidylinositol and that this occurs subsequently to the activation of protein kinase C. This additional effect of PAF further complicates the interpretation of phosphatidic acid levels as a measure of PLC activation described by Simon *et al.* (22).

Thus, WEB 2086 is the first PAF antagonist reported to inhibit human platelet IP production as monitored by direct measurement of IP levels after PAF challenge.

In a recent paper by Barzaghi *et al.* (25), PAF induced production of phosphoinositols in U937 cells was shown to be inhibited by the PAF receptor antagonist CV 3988. This demonstrates that CV 3988, like WEB 2086, interacts with a PAF receptor in an example of a nucleated human cell.

The possible clinical relevance of PAF receptor blockage on human platelets is high-lighted by results obtained by Block *et al.* (26) which demonstrated increased PAF sensitivity in platelets of asthmatic patients as measured by a pronounced increase in phosphatidylinositol turnover in response to PAF. This finding, among others (for a review, see ref. 27) suggests that PAF plays a role in asthma and that PAF antagonists (like WEB 2086) may be useful in the therapy of this and other PAF dependent diseases.

In conclusion, it appears that WEB 2086 selectively inhibits the signal transduction evoked by PAF stimulation as measured at the level of phospholipase C. This inhibition of PAF stimulated PIP_2hydrolysis, but not thrombin- and ADP-stimulated PIP_2hydrolysis, supports PAF receptor antagonism as the mechanism of action of WEB 2086. WEB 2086 does not directly interfere with the G protein/phospholipase C mediated signaling pathway of platelet activation. WEB 2086 thus promises to represent a useful tool for investigating the role of PAF in physiology and pathophysiology.

Phorbol Ester Stimulates PAF Synthesis *via* the Activation of Protein Kinase C in Rat Leukocytes[1]

Masahiko Hayashi, Yohsuke Imai and Sachiko Oh-ishi*
Department of Pharmacology, School of Pharmaceutical Sciences, Kitasato University, Tokyo 108, Japan

When rat pleural mononuclear leukocytes were stimulated with 1 μM phorbol myristate acetate (PMA), platelet-activating factor (PAF)-like activity was detected in the supernatant and the cellular fractions of the incubation mixture, as measured by rabbit platelet aggregation. C_{16}PAF activity peaked at 30 min in both fractions. Acetyltransferase activity in the microsomal fraction of the stimulated cells also increased rapidly and showed a peak at 10 min. A protein kinase C inhibitor, staurosporine, and an inhibitor of phospholipase A_2, *p*-bromophenacylbromide, inhibited stimulated PAF formation in both fractions. Staurosporine also inhibited PMA induced acetyltransferase activity. The data suggest that PMA stimulates PAF synthesis by the remodeling pathway in rat pleural cells through activation of both phospholipase A_2 and acetyltransferase, and that the acetyltransferase, in turn, may be activated through activation of protein kinase C.
***Lipids 26,* 1054–1059 (1991).**

Platelet-activating factor (PAF), chemically identified as 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (1–3), was shown to be secreted from antigen-stimulated, IgE-sensitized basophils (4). PAF is also formed by various tissues, and by inflammatory cells such as polymorphonuclear neutrophils and monocytes (for reviews, see refs. 5,6). PAF exerts a variety of biological effects, including increased vascular permeability (7), hypotension (3), bronchoconstriction (8), platelet aggregation (4) and leukocyte activation (6,9). These activities are closely related to inflammatory and allergic reactions.

In a previous study (10) on rat pleurisy induced by phorbol myristate acetate (PMA), we found that a specific PAF antagonist, CV-3988, suppressed pleural exudation. In addition, PAF-like activity was observed in the exudate. Both these observations suggested that PAF may be involved in this type of rat pleurisy.

In the present study, the activation of PAF synthesizing enzymes in intact cells, which were stimulated with tumor-promoting phorbol ester, was examined. We found that stimulation of PAF formation by PMA occurs through the activation of acetyltransferase and that this change in activity most likely results from the phosphorylation of the enzyme by protein kinase C.

MATERIALS AND METHODS

Animals. Male Sprague-Dawley rats (7–8 weeks-old, Japan SLC, Hamamatsu, Japan) were used for the isolation of pleural cells, and male Japanese white rabbits (Doken, Ibaragi, Japan) were used for the preparation of washed platelets for PAF assay.

Agents. 1-*O*-Hexadecyl/octadecyl-2-acetyl-*sn*-glycero-3-phosphocholine (C_{16}/C_{18}PAF, Bachem Feinchemikalien, Bubendorf, Switzerland) were gifts from Funakoshi Pharmaceutical Co. (Tokyo, Japan). CV-3988 (*rac*-3-(*N*-octadecylcarbamoyloxy)-2-methoxypropyl-2-thiazolioethyl phosphate) and AA-861 (2-(12-hydroxydodeca-5,10-diynyl)-3,5,6-trimethyl-1,4-benzoquinone) were kindly supplied by Takeda Chemical Industries. Ltd. (Osaka, Japan). Diltiazem, (3-(acetyloxy)-5-[2-(dimethylamino)-ethyl]-2,3-dihydro-2-(4-methoxyphenyl)-1,5-benzothiazepin-4(5H)-one hydrochloride) was a gift from Tanabe Pharmaceutical Co. (Osaka, Japan). Staurosporine was a gift from Dr. S. Ōmura, Kitasato Institute, Tokyo, Japan. Indomethacin, phorbol myristate acetate (PMA), phorbol-12,13-didecanoate (PDD), acetyl-CoA, adenosinetriphosphate (ATP), diolein (DG), alkaline phosphatase (from *E. coli.*, Type III-S), C_{16}lysoPAF and phospholipase A_2 (*Naja naja* venom) were purchased from Sigma Chemical Co. (St. Louis, MO). Phosphatidylcholine (PC), lysophosphatidylcholine (LPC) and sphingomyelin (SM) (Serdary Laboratories, London, Ontario, Canada) were from Funakoshi Pharmaceutical Co., and W-7 and H-7 from Seikagaku Industries (Tokyo, Japan). [^{3}H]C_{16}PAF (40 Ci/mmol) and [^{3}H]acetyl-CoA (3.7 Ci/mmol) were from New England Nuclear (Boston, MA) and Amersham Japan (Tokyo, Japan), respectively. *p*-Bromophenacylbromide (BPB) and the lactate dehydrogenase (LDH) ultraviolet (UV) test kit were from Tokyo Kasei (Tokyo, Japan) and Boehringer-Mannheim (Mannheim, Germany), respectively.

Preparation of pleural mononuclear cells. Rats under light ether anesthesia were killed by exsanguination, and pleural cells were collected by washing the pleural cavity twice, each time with 7 mL of Ca^{2+}/Mg^{2+}-free Hanks balanced salt solution (HBSS(−)). Collected cells were pooled, and washed twice with HBSS (−). The cell suspension (4 mL) was applied onto a Ficoll-Paque gradient (Pharmacia, Uppsala, Sweden) (2 mL of 90% Ficoll-Paque diluted with saline and 2 mL of Ficoll-Paque). After centrifugation at 450 × *g* for 25 min at 22°C, the mononuclear cell fraction was found at the 90–100% Ficoll-Paque interface. This fraction contained more than 90% mononuclear cells with better than 95% viability as judged by trypan blue exclusion. The cells were washed twice and resuspended in HBSS (−).

Stimulation of mononuclear cells. Mononuclear cells (1×10^7/0.7 mL HBSS (−)) were initially incubated at 37°C for 10 min in the presence or absence of inhibitors and then Ca^{2+} (final 1.3 mM) was added to the medium.

Abbreviations: ATP, adenosinetriphosphate; BPB, *p*-bromophenacylbromide; DG, diolein; DTT, dithiothreitol; HBSS, Hanks balanced salt solution; HPLC, high-performance liquid chromatography; LDH, lactate dehydrogenase; LPC, lysophosphatidylcholine; lysoPAF, 1-*O*-alkyl-*sn*-glycero-3-phosphocholine; PAF, platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; PC, phosphatidylcholine; PDD, phorbol-12,13-didecanoate; PMA, phorbol myristate acetate; PMN, polymorphonuclear leukocyte; PS, phosphatidylserine; SM, sphingomyelin; TLC, thin-layer chromatography; UV, ultraviolet.

After 10 min, PMA at various concentrations was added to the medium, and the mixture was incubated for 30 min. The reaction was stopped by the addition of ice-cold HBSS (−) (2 vol) followed by centrifugation at 1600 × *g* for 10 min at 4°C. PAF activities in the supernatant and pellet were extracted separately by the method of Bligh and Dyer (11), and the PAF assay was carried out as previously described (10). The viability of the cells throughout the experiment was monitored by measuring LDH release.

Preparation of microsomal fraction. Mononuclear cells (not treated with PMA) were suspended in 20 mM Tris-HCl (pH 7.4) buffer containing 0.25 M sucrose and 1 mM DTT and were sonicated three times for 20 sec in an ice bath. The homogenate was centrifuged at 500 × *g* for 10 min at 4°C. The resulting supernatant was centrifuged at 15,000 × *g* for 15 min at 4°C. The supernatant was centrifuged at 105,000 × *g* for 60 min at 4°C. The 105,000 × *g* pellet (microsomal fraction) was resuspended in 20 mM Tris-HCl buffer containing 0.25 M sucrose and 1 mM dithiothreitol (DTT) (pH 7.4), and was used as the enzyme source of acetyltransferase. The cytosol fraction was used as the source of calcium/phospholipid dependent protein kinase (protein kinase C). Protein was quantitated by the method of Lowry *et al.* (12).

In other experiment, PMA stimulated cells were homogenized by sonication with 2 mL of 0.25 M sucrose, 20 mM Tris-HCl, 10 mM EGTA, 5 mM mercaptoethanol and 50 mM NaF (pH 7.4), according to the method of Lenihan and Lee (13). The homogenate was fractionated by the three centrifugation steps noted above. The microsomal fraction was used as the enzyme source of acetyltransferase.

Experiments with microsomal fractions. The microsomal fractions were incubated as described below and the incubation mixture was centrifuged at 105,000 × *g* to obtain the microsomal fraction for the acetyltransferase assay.

Phosphorylation/dephosphorylation of acetyltransferase was examined by the modified method of Lenihan and Lee (13). The stimulated microsomal fraction was resuspended in 20 mM Tris-HCl buffer containing 0.25 M sucrose and 1 mM DTT (pH 7.4). An aliquot of the cell suspension (100–120 μg protein) was incubated for 10 min at 25°C in the presence or absence of alkaline phosphatase (*E. coli.*, 10 units) in 100 mM Tris-HCl (pH 8.5, final volume 300 μL). The treated microsomal fraction was collected by centrifugation and resuspended as described above to assess acetyltransferase activity.

Assay of acetyltransferase activity. Microsomes obtained from leukocytes after various treatments were assayed for acetyltransferase as described by Wykle *et al.* (14) and Ninio *et al.* (15). Microsomes (50–100 μg/mg protein) and C_{16}lysoPAF (final 40 μM) were preincubated in an aliquot of 100 mM Tris-HCl buffer (pH 6.9) for 5 min at 37°C. The reaction was started by the addition of acetyl-CoA (final 200 μM) containing 0.5 μCi [^{3}H]acetyl-CoA and was continued for 10 min at 37°C in a final volume of 0.2 mL. Samples without lysoPAF served as blanks. The reaction was stopped by the addition of 1.25 mL of methanol containing 2% acetic acid and [^{14}C]PAF (3000 cpm, to assess recovery), and the mixture was extracted. The residue was dissolved in 30 μL of chloroform/methanol (1:1, v/v) containing authentic PAF and lysoPAF (5 μg each) as carrier and then applied onto a silica gel thin-layer plate (Kieselgel 60, Merck, Darmstadt, Germany). The plate was developed with chloroform/methanol/water (65:40:8, v/v/v). The zones corresponding to the authentic PAF and lysoPAF standards were scraped off and extracted according to Bligh and Dyer (11). The radioactivity was counted in a liquid scintillation counter. Characterization of ^{3}H-labeled products as PAF was by washed platelet aggregation assay as described below. The amount of ^{3}H-labeled PAF produced is expressed as nmole/min/mg protein and is corrected for recovery and after subtraction of blanks.

Extraction and measurement of PAF. PAF from media and cells was extracted and separated as previously reported (10). Briefly, [^{3}H]C_{16}PAF (about 4000 cpm) was added as internal standard to assess recovery, and PAF was extracted with chloroform containing 2% acetic acid by a modified Bligh and Dyer method (11). The combined chloroform layer was loaded onto a Sep-Pak silica cartridge (Waters, Milford, MA). The PAF fraction was eluted with 11.4 mL of chloroform/methanol/water (1:2:0.8, v/v/v) and reextracted according to Bligh and Dyer (11).

The final residue was dissolved in 50 μL of hexane/isopropanol (1:2, v/v) for high performance liquid chromatography (HPLC) using a Shimadzu LC-3A model system (Kyoto, Japan) fitted with a μ Bondasphere silica column (3.9 × 150 mm, Waters). The column was eluted with hexane/isopropanol/water (100:110:20, v/v/v) at a rate of 0.4 mL/min and the eluent was monitored at 206 nm. The fractions corresponding to authentic PAF were collected.

PAF activity was measured by aggregation of washed rabbit platelets as described previously (10), according to the method by Benveniste *et al.* (4). The amount of PAF was corrected for recovery.

Statistics. Statistical evaluation was performed by Student's t-test for unpaired values. Differences with $p<0.05$ were considered significant.

RESULTS

The molecular species of PAF synthesized by rat mononuclear leukocytes were analyzed by HPLC. As shown in Figure 1A, hexadecyl and octadecyl PAF migrated between SM and LPC, and all the fractions were separated from each other. Platelet-aggregating activity was found in the fraction corresponding to authentic C_{16}PAF, but not in the C_{18}PAF fraction, or other fractions, when the leukocyte sample was processed on HPLC (Fig. 1B). The results indicate that essentially the only molecular PAF species synthesized by rat pleural mononuclear cells was C_{16}PAF. Therefore, in the following experiments PAF content in the samples was expressed as ng of C_{16}PAF equivalent/10^7 cells.

The time course of PAF production and release in response to PMA was also examined. As shown in Table 1, PAF contents in both the medium and in cellular fractions increased with time and reached a maximum after 30 min.

Activation of intracellular acetyltransferase by PMA was examined in rat mononuclear cells. Acetyltransferase activity increased with time and reached a peak at 10 min when the cells were incubated with PMA (1 μM). The peak activity (1.74 ± 0.28 nmol/min/mg protein) was about 3 times the resting activity (Fig. 2A). A close correlation

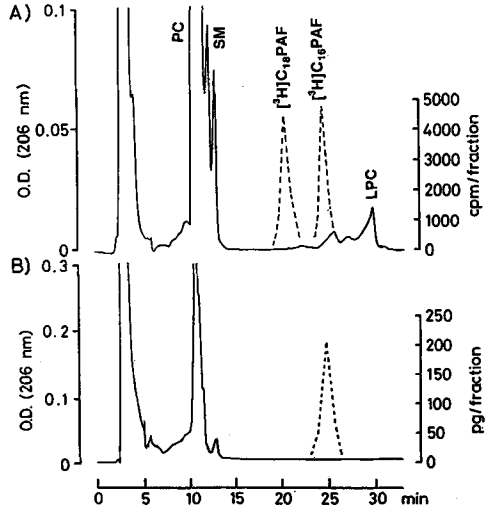

FIG. 1. HPLC profiles of authentic phospholipids, PAF (A) and extracted samples (B). (A) Authentic materials, 5 μg of phosphatidylcholine (PC), 20 μg of sphingomyelin (SM), 150 μg of lysophosphatidylcholine (LPC) and [^{3}H]labeled C_{16}/C_{18}PAF (5000 cpm, respectively) were subjected to HPLC. (B) A typical elution pattern of a sample from the cells stimulated by PMA (1 μM). Broken line shows platelet-aggregating activity.

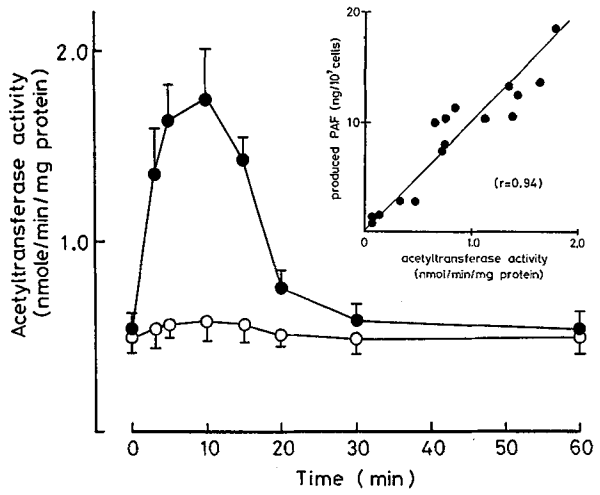

FIG. 2. Time course of induced acetyltransferase activity and its relationship with PAF production in PMA stimulated mononuclear cells of rat. Mononuclear cells were incubated with (●) or without (○) 1 μM PMA. At the times indicated, the cells were sonicated, and the acetyltransferase activities were assayed as described in the text. Inset: Relationship between PAF production and acetyltransferase activity in the cells stimulated with PMA (1 μM).

TABLE 1

Time Course of PAF Production and Release Resulting from PMA Stimulation by Pleural Mononuclear Cells[a]

Time (min)	n	ng/10^7 cells (C_{16}PAF equivalent)			
		Control		PMA (1 μM)	
		Medium	Cellular	Medium	Cellular
0	4	0.31 ± 0.19	1.05 ± 0.36	0.47 ± 0.18	0.96 ± 0.36
5	4	0.97 ± 0.48	1.76 ± 0.05	0.31 ± 0.04	1.96 ± 0.40
15	4	0.63 ± 0.02	1.93 ± 0.23	0.82 ± 0.07	4.93 ± 0.41
30	9	0.82 ± 0.17	2.93 ± 0.38	2.36 ± 0.31	10.24 ± 0.81
60	4	0.95 ± 0.52	2.29 ± 0.29	1.66 ± 0.09	3.89 ± 0.64
120	4	0.89 ± 0.46	1.19 ± 0.34	1.79 ± 0.40	2.84 ± 0.20

[a]Mononuclear cells (10^7 cells/mL) were incubated at 37°C with or without 1 μM PMA. At the times indicated, the reaction was terminated by centrifugation at 4°C, and PAF was immediately extracted from the supernatant (medium) and cellular fraction (cellular), respectively, as described in the text. Each value represents the mean ± SEM.

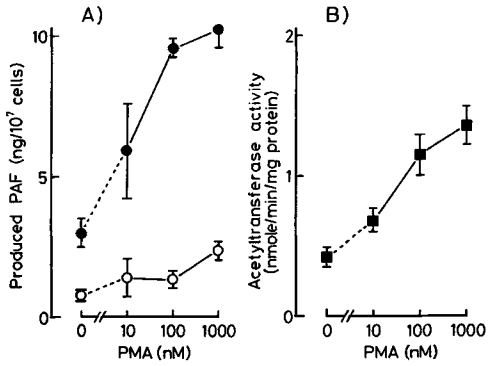

FIG. 3. Effect of PMA on PAF production (A) and acetyltransferase activity (B) in rat mononuclear leukocytes. After 10-min preincubation with Ca^{2+} (final 1.3 mM), the mononuclear cells were incubated with various concentration of PMA for 30 min to determine PAF production (A) or for 10 min for assay of acetyltransferase activity (B). PAF contents in the cellular fraction (●), PAF contents in the medium (○), and acetyltransferase activity (■) are the mean ± SEM from 4–9 experiments.

(r = 0.94) between PAF formation and acetyltransferase activity was observed in response to PMA (10–1000 nM) (Fig. 2B). In contrast, CDP choline cholinephosphotransferase activity, the *de novo* PAF synthesizing enzyme, was not changed by PMA stimulation (data not shown).

PAF production and acetyltransferase activation were dose dependent as shown in Figure 3. When incubated with PMA at concentrations from 10–1000 nM, rat mononuclear cells produced PAF dose-dependently; significant PAF release was observed at 1000 nM PMA (Fig. 3A). The acetyltransferase activity was also dose-dependently increased in response to PMA (Fig. 3B). However PAF induced, increased activity of acetyltransferase was not seen when PDD was used instead of PMA (data not shown).

The effects of some inhibitors on PMA-induced PAF production were examined in hope to shed light on the mechanism of PAF production (Table 2). Pretreatment of mononuclear cells with *p*-bromophenacylbromide (BPB) (50 μM) completely suppressed the increase in both production and release of PAF in response to PMA. Indomethacin, a cyclooxygenase inhibitor, and AA-861, a 5-lipoxygenase inhibitor, did not affect intracellular PAF production, and partially, but not significantly, reduced the release of PMA into the medium. These data suggest that PMA-induced PAF production may occur through the activation of phospholipase A_2 but that prostaglandins and leukotrienes are not involved in the formation of PAF in this cell system. Diltiazem, a Ca^{2+} channel blocker, and W-7, Ca^{2+}/calmodulin inhibitor, did not affect the production and release of PAF induced by PMA.

TABLE 2

Effects of Various Inhibitors on PAF Production and Release by Mononuclear Cells with PMA[a]

Treatment		n	ng/10^7 cells (C_{16}PAF equivalent) Medium	Cellular
PMA (1 μM)		5	2.42 ± 0.41	10.03 ± 0.67
+ BPB	50 μM	4	0.04 ± 0.04	0.57 ± 0.24[b]
+ indomethacin	50 μM	4	1.53 ± 0.26	9.00 ± 0.96
+ AA-861	10 μM	4	1.38 ± 0.31	9.62 ± 1.55
+ diltiazem	100 μM	4	1.80 ± 0.32	8.75 ± 0.50
+ W-7	10 μM	5	1.03 ± 0.36	8.76 ± 0.49
+ staurosporine	1 μM	5	0.89 ± 0.37[c]	1.62 ± 0.46[b]

[a]Inhibitors were added to the medium 20 min before the PMA stimulation. The reaction was terminated by centrifugation (1200 × *g*, 5 min, 4°C) at 30 min after PMA addition. PAF was extracted and assayed as described in the text. Each value represents the mean ± SEM.

[b,c]Statistically significant differences ($p<0.05$, $p<0.01$, respectively) from control value (PMA 1 μM).

In contrast, staurosporine, a potent protein kinase C inhibitor, caused a significant reduction of both PAF production and release. As shown in Figure 4A, increased production of PAF in mononuclear cells upon stimulation by PMA was dose-dependently inhibited by staurosporine (10–1000 nM). Increased activity of acetyltransferase was also dose-dependently inhibited by staurosporine (Fig. 4B). These data suggest that protein kinase C is involved in PMA induced PAF formation in rat mononuclear cells.

The effect of PMA on PAF production was further studied by examining the microsomal preparation from unstimulated cells (Table 3). The microsomal fraction (105,000 × *g* pellet) showed the highest acetyltransferase activity as compared to the cytosolic fraction (105,000 × *g* supernatant) or the mitochondrial fraction (15,000 × *g* pellet). When only PMA was added to the microsomal

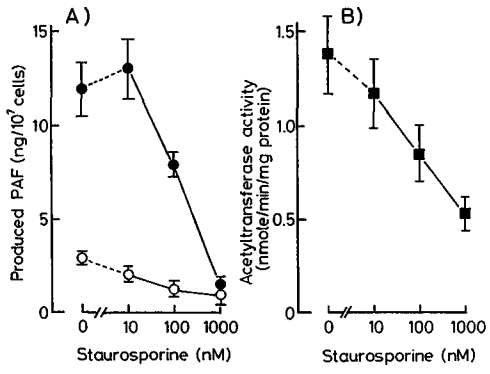

FIG. 4. Inhibitory effect of staurosporine on PMA stimulated PAF production and acetyltransferase activity. Mononuclear cells (10^7/mL) were incubated for 20 min in the presence or absence of staurosporine (final 10–1000 nM) and then incubated with PMA (1 μM) for 30 min for determination of PAF (A) or for 10 min for assay of acetyltransferase activity (B). Open circles (○) or closed circles (●) indicate released PAF or cellular PAF, respectively and closed squares (■) indicate acetyltransferase activity. Each point represents the mean ± SEM from 4–9 experiments.

TABLE 3

Effect of PMA on Acetyltransferase Activity in the Microsomal Fraction from Normal Cells[a]

Treatment	Acetyltransferase activity (nmol/min/mg protein)
105,000 × *g* ppt (microsome)	0.392 ± 0.024
105,000 × *g* sup (cytosol)	0.082 ± 0.008
Microsome + PMA (1 μM)	0.444 ± 0.031
Microsome + 105,000 × *g* sup	0.452 ± 0.102

[a]The microsomal fraction (105,000 × *g* pellet, 50–60 μg protein) or the cytosolic fraction (105,000 × *g* supernatant, 200–300 μg protein) was incubated in the presence of PMA (1 μM). Each value represents the mean ± SEM (n = 4).

fraction, no increase in acetyltransferase activity was observed, which suggests that PMA does not directly activate this enzyme. The data indicate that most of the enzyme activity is found in the microsomal fraction, and suggest that the activation of acetyltransferase takes place through the action of protein kinase C upon stimulation with PMA.

As shown in Table 4, acetyltransferase activity increased in the incubation mixture of the microsomal fraction with Ca^{2+} and/or PS, PMA or diolein in the presence of the cytosolic fraction, magnesium acetate (Mg^{2+}) and ATP. However, a more pronounced enhancement of the activity was observed when the mixture of Ca^{2+}, phosphatidylserine (PS) and diolein or Ca^{2+}, PS and PMA was incubated. The cytosolic fraction was used as the source of protein kinase C.

The effect of alkaline phosphatase treatment on acetyltransferase stimulation was also examined (Fig. 5). We found that the acetyltransferase activity induced by PMA or diolein was significantly reduced by treatment with 10 units of alkaline phosphatase. The data suggests that phosphorylation of the enzyme is necessary for activation of the acetyltransferase.

The effect of various inhibitors on microsomal acetyltransferase was then examined (Table 5). BPB inhibited the stimulation of acetyltransferase activity, while indomethacin (30 μM), AA-861 (10 μM), diltiazem (30 μM)

TABLE 4

Induction of Acetyltransferase Activity in the Microsomal Fraction from Normal Cells[a]

Treatment	Acetyltransferase activity (nmol/min/mg protein)
Ca^{2+}	0.526 ± 0.111
Ca^{2+} + PMA (100 nM)	0.892 ± 0.226
Ca^{2+} + DG (0.8 μg)	0.954 ± 0.194
Ca^{2+} + PS (5 μg)	1.056 ± 0.133
Ca^{2+} + PS + PMA	1.782 ± 0.266
Ca^{2+} + PS + DG	1.801 ± 0.234

[a]The microsomal fraction (50–60 μg) and the cytosol fraction (200 μg), plus magnesium acetate (10 mM) and ATP (5 mM) were mixed in a reaction tube at 0°C. After 10 min incubation at 25°C in the presence of the components indicated, acetyltransferase activity in the microsomal fraction was assayed as described in the text. Each value represents the mean ± SEM (n = 4).

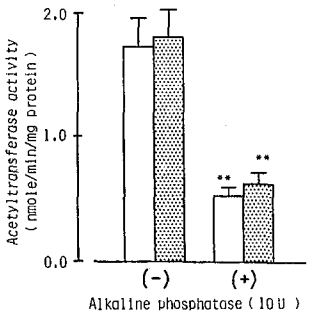

FIG. 5. Effect of treatment of alkaline phosphatase on the increased activity of acetyltransferase induced by PMA or diolein (DG). After incubation with Ca^{2+}, PS, and PMA (100 nM, open column) or with Ca^{2+}, PS, and DG (0.8 μg, dotted column) in the presence of other factors, microsomes were collected by centrifugation at 105,000 × *g* for 60 min at 4°C. The microsomal fraction was incubated for 10 min with or without alkaline phosphatase (10 units). After centrifugation at 105,000 × *g* for 60 min, acetyltransferase activity in the microsomal fraction was assayed as described in the text (n = 4–5). ** indicates statistically significant differences (p<0.01) relative to untreated groups (—).

TABLE 5

Effects of Various Inhibitors on PMA Induced Acetyltransferase Activity[a]

Treatment		Acetyltransferase activity (nmol/min/mg protein)
PMA (100 nM)		1.373 ± 0.161
+ indomethacin	30 μM	1.380 ± 0.206
+ AA-861	10 μM	1.195 ± 0.192
+ BPB	10 μM	0.512 ± 0.094[b]
+ W-7	10 μM	0.745 ± 0.139
+ diltiazem	30 μM	1.377 ± 0.112
+ H-7	10 μM	0.468 ± 0.064[b]
+ staurosporine	1 nM	1.328 ± 0.146
+ staurosporine	10 nM	0.783 ± 0.105
+ staurosporine	100 nM	0.283 ± 0.061[b]

[a]The microsomal fraction (50 μg protein) was incubated together with cytosolic fraction (200 μg protein), plus ATP (5 mM), magnesium acetate (10 mM), calcium chloride (2.5 mM), PS (5 μg) and PMA (100 nM) in the presence or absence of the indicated inhibitors. After 10 min incubation at 25°C, the reaction was terminated at 0°C. After centrifugation of 105,000 × *g* for 60 min, acetyltransferase activity in the microsomal fraction was assayed as described in the text.

[b]Indicates statistically significant difference (p<0.01) from control value (PMA 100 nM). Each value represents the mean ± SEM (n = 4–5).

and W-7 (10 μM) did not change the activity of the enzyme. In contrast, the protein kinase C inhibitors, staurosporine and H-7, significantly reduced enhanced activity of the enzyme. These data suggest the involvement of protein kinase C in the activation of acetyltransferase upon PMA stimulation in this cell free system.

DISCUSSION

As previously reported (10), rat mononuclear cells produce PAF in response to PMA stimulation. The major molecular PAF species produced in rat leukocytes in the present study was identified as C_{16}PAF, using HPLC (Fig. 1). This result is consistent with other reports that C_{16}PAF is predominantly synthesized in various types of rabbit and human cells (16,17).

As shown in Table 1, peak levels of PAF in the incubation medium and in various cellular fractions were reached 30 min after PMA stimulation, while peak activity of acetyltransferase was reached at 10 min (Fig. 2). The time lag between acetyltransferase activity and PAF levels would represent the time needed for the accumulation of PAF in the cells. Similar time lags were reported by other authors (18,19). However, acetyltransferase activity and PAF production may vary markedly between various cell types and stimuli used. The precise mechanism of this will need to be clarified in future study.

The pathways of PAF biosynthesis in various cells have been extensively studied. Two different pathways have been recognized: the *de novo* pathway through cholinephosphotransferase (20), and the remodeling pathway *via* phospholipase A_2 and acetyltransferase. In the remodeling pathway, PAF is formed by a two-stage process in which 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholine is enzymatically degraded by phospholipase A_2 to form lyso-PAF which is then acetylated by a specific lysoPAF:acetyl-CoA acetyltransferase (14,15,21,22).

The results we obtained on rat mononuclear cells suggest that PAF synthesis in response to PMA takes place mainly through the remodeling pathway. A controversy still exists concerning the *de novo* pathway in PMA-induced PAF synthesis in human polymorphonuclear leukocyte (PMN) (23). However, we have not been able to pinpoint an involvement of the *de novo* pathway in rat monocytes in response to PMA, since CDP choline cholinephosphotransferase activity was not changed when rat monocytes were incubated with PMA (data not shown). Moreover, our results suggest an involvement of phospholipase A_2 and of acetyltransferase in this system. Acetyltransferase activity in the cells increased prior to PAF levels in response to PMA. In addition, both PAF levels and acetyltransferase activity were lowered by staurosporine pretreatment, suggesting that the acetyltransferase plays a major role in PAF production. The close relationship between PAF levels and acetyltransferase activity (r = 0.94) also indicates that PMA stimulation acts on this pathway.

The microsomal acetyltransferase preparation was activated by PMA or diolein provided sufficient amounts of cofactors were present (Table 4). Acetyltransferase activity was suppressed by staurosporine, a known and potent inhibitor of protein kinase C (24,25). Protein kinase C can be directly activated by diacylglycerol which can, in turn, be produced by signal-induced inositol phospholipid turnover (26); PMA can substitute for diacylglycerol to activate protein kinase C (27). Thus, protein phosphorylation induced by this kinase might be necessary for the activation of acetyltransferase in response to PMA. The phosphorylation of acetyltransferase from rat spleen (28), parotid gland (29) and human polymorphonuclear leukocytes (30) has been reported, and was ascribed to cyclic AMP- or calmodulin-dependent protein kinase, rather than protein kinase C. The reason of this discrepancy is presently not known, but may be due in part to the different enzyme sources studied.

As for the activation of phospholipase A_2 by PMA, we previously showed that prostaglandin production in rat

pleural cells occurs in response to PMA (31). Levine and Ohuchi (32) reported that phorbol esters stimulate prostaglandin synthesis through the activation of phospholipase A_2 in an MDCK cell line. In the present work we found that BPB reduced PAF production (Table 2), even though BPB may not be a specific inhibitor for phospholipase A_2. The results suggest that phospholipase A_2 is also activated by PMA in rat monocytes.

Recent reports showing that protein kinase C is involved in the production of PAF, leukotrienes and prostaglandins upon stimulation with PMA or ionophore A23187 (19,33, 34) are in line with our data. We therefore conclude that the stimulatory effect of PMA on PAF production involves stimulation of protein kinase C which induces activation of phospholipase A_2 as well as of acetyltransferase.

ACKNOWLEDGMENTS

The authors are grateful to Takeda Co. Ltd. for providing AA-861 and CV-3988, to Tanabe Co. Ltd. for diltiazem, and to Funakoshi Co. Ltd. for PAF. The authors are also grateful to Dr. S. Ōmura from the Kitasato Institute for the generous gift of staurosporine.

Tumor Necrosis Factor Release by Human Monocytes Stimulated with Platelet-Activating Factor[1]

N.M. Ruis, J.K. Rose and F.H. Valone*
Department of Medicine, Veterans Administration Medical Center, San Francisco, California 94121

Platelet-activating factor (PAF) is a low molecular weight phospholipid which enhances human monocyte cytotoxicity for tumor cells. In the current studies, the capacity of PAF to stimulate release of tumor necrosis factor α (TNFα) by human monocytes was assessed. PAF induced maximal TNFα synthesis 2–3 hr after monocyte stimulation as assessed by dot blotting of cell-associated TNFα using polyclonal anti-TNF antibody. Maximal net release of TNFα occurred 5–16 hr after monocyte stimulation, as assessed by a specific ELISA. Dose-response studies revealed that a maximal two- to three-fold increase in release of TNFα occurs at 10–100 pM PAF. LysoPAF and the optical isomer of PAF did not stimulate release of TNFα, suggesting that stimulation is mediated by specific PAF receptors. Scatchard analysis of [^{3}H]PAF binding to monocyte membranes revealed 651 ± 495 binding sites/monocyte with a Kd of 4.7 ± 4.2 × 10^{-10}M. PAF is a structurally unique activator of monocytes whose interactions with TNFα and other cytokines may be critical to host defense against tumors.
***Lipids 26,* 1060–1064 (1991).**

Platelet-activating factor (1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; PAF) is a novel phospholipid which is a potent mediator of allergic and inflammatory diseases (1,2). PAF is synthesized and released after immunological activation of numerous cells including endothelial cells, neutrophils, monocytes and large granular lymphocytes (3–9). The name "platelet-activating factor" is clearly a misnomer as PAF activates numerous cells including monocytes, lymphocytes and neutrophils (3, 10–14). PAF stimulates several monocyte/macrophage functions which may be critical to host immunity against tumors, including adherence or aggregation (10), chemotaxis (11), release of reactive oxygen products (10,15) and release of the immunomodulatory cytokine IL-1β (16,17). PAF also directly enhances monocyte cytotoxicity (18). Pretreatment of human monocytes with 1 pM–1 nM PAF for 18 hr increases monocyte killing of tumor target cells. Several observations suggest that PAF increases monocyte cytotoxicity primarily by increasing release of tumor necrosis factor α (TNFα): PAF only stimulates monocyte killing of TNF-sensitive target cells and cell killing by PAF-treated monocytes is inhibited by specific antisera to TNFα. The experiments presented in this communication directly demonstrate that PAF stimulates human monocytes to release TNFα.

[1]Based on a paper presented at the Third International Conference on Platelet-Activating Factor and Structurally Related Alkyl Ether Lipids, Tokyo, Japan, May 1989.

Abbreviations: BSA, bovine serum albumin; enantioPAF, 3-*O*-hexadecyl-2-acetyl-*sn*-glycero-1-phosphocholine; IFNγ, γ Interferon; lysoPAF, 1-*O*-hexadecyl-*sn*-glycero-3-phosphocholine; PGE_2, prostaglandin E_2; MTT [3-(4,5-dimethylthiazol)2-yl)-2,5-diphenyltetrazolium bromide]; PAF, platelet-activating factor, 1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine; and TNFα, tumor necrosis factor α.

MATERIALS AND METHODS

PAF, lysoPAF and enantioPAF (Bachem, Torrance, CA), recombinant human TNFα and IFNγ (Genzyme Corp., Boston, MA), rabbit antisera to recombinant human TNFα (10^5 neutralizing units/mL; Genzyme Corp.), [^{3}H]PAF (1-*O*-[1′,2′-^{3}H]alkyl-; 51 Ci/mmol) (New England Nuclear, Boston, MA), radioimmunoassay kit for PGE_2 (Advanced Magnetics, Cambridge, MA), WEHI 164.13 cells (gift of Dr. Lois Epstein, University of California, San Francisco, CA) and cell culture media (University of California Cell Culture Facility, San Francisco, CA) were obtained as noted. All other chemicals were obtained from Sigma Chemical Co. (St. Louis, MO).

Quantitation of TNFα release. Monocytes were prepared from normal human donors and suspended at 1 × 10^6/mL in RPMI 1640 containing 0.25% (w/v) endotoxin-free bovine serum albumin (BSA) as described (3,18). One mL of cells was mixed with buffer, PAF, IFNγ or PAF analogs. After incubation for 30 min at 37°C in an atmosphere of 5% CO_2 and 95% air, 0.1 mL of low endotoxin fetal calf serum (Hyclone Laboratories, Logan, UT) was added to each tube. Serum was added after the 30 min to allow monocytes adequate exposure to PAF before PAF was degraded by serum acylhydrolases. The incubation was then continued for 30 min to 18 hr. TNFα release into culture supernates was quantified by cytotoxicity assay using WEHI 164 clone 13 cells (19). Serial two-fold dilutions of culture supernates or recombinant human TNFα were made in 96-well microtiter plates. WEHI 164.13 cells were pretreated with 1 μg actinomycin D/mL for 2 hr at 37°C in RPMI 1640 containing 7% fetal bovine serum. Twenty thousand cells were then added to each well in a final volume of 0.1 mL and incubated 18 hr at 37°C in an atmosphere of 5% CO_2 and 95% air. Viable cell number was determined by uptake of the dye MTT (20). One unit of TNFα was defined as the quantity of material which decreased cell number by 50%. In some cases TNFα released into culture fluids was quantified by a commercial ELISA (T-Cell Science, Cambridge, MA). The ELISA is specific for bioactive human TNFα and is not affected by denatured TNFα, lymphotoxin (TNFβ), Interleukin 1 or Interleukin 2.

Cell-associated TNFα protein (precursor and biologically active product) were quantified by dot blotting using specific rabbit antisera to recombinant human TNFα. Monocytes were treated with buffer or PAF, sedimented by centrifugation and resuspended at 1 × 10^6/mL in lysis buffer containing 1 μM pepstatin, 100 μM phenylmethylsulfonylfluoride, 10 mM EDTA, and 1 μM leupeptin in phosphate buffered saline. Aliquots of 5 × 10^5, 2.5 × 10^5, 1.25 × 10^5 and 0.625 × 10^5 cells were dotted onto nitrocellulose paper (BioRad, Richmond, CA) using a BioRad dot apparatus. The paper was blocked by incubation overnight in 5% non-fat dry milk in phosphate buffered saline and then incubated with rabbit anti-recombinant human TNFα at 1/200 dilution for 3 hr. Biotinylated goat anti-rabbit antibodies (Zymed, South

San Francisco, CA) at 1/2000 dilution was incubated with the paper for 2 hr, followed by washing and incubation with 10 microCi [^{125}I]strepavidin (Amersham, Arlington Heights, IL) for 2 hr. Bound radioactivity was quantified by autoradiography. Between each step, the nitrocellulose paper was washed extensively with 5% non-fat dry milk in phosphate buffered saline. Controls which were dotted on each paper were unstimulated cells and 10-1000 units recombinant, human TNFα.

PAF binding to monocyte membranes. Monocytes were treated with 5 mM diisopropylfluorophosphate and disrupted by nitrogen cavitation (21). After removing nuclei and large debris by sedimentation at 500 × *g* for 15 min the membranes were recovered by centrifugation at 30,000 × *g* for 30 min and resuspended at 10^7 cell equivalents/mL in RPMI 1640 containing 0.25 g/dl bovine albumin. Membrane protein recovery was 5.2 ± 3.3 mg/10^7 monocytes (mean ± SD, n = 3). One mL of membranes was incubated with one pmol [^{3}H]PAF (50,000 CPM) without or with inhibitors of PAF binding for 2 hr at 4°C. The membranes were sedimented by centrifugation at 30,000 × *g* for 15 min, after which unbound PAF in the supernates and bound PAF in the pellets was quantified by liquid scintillation counting. Specific binding was calculated as [^{3}H]PAF bound in the absence of inhibitors minus [^{3}H]PAF binding in the presence of a 10,000-fold molar excess of unlabeled PAF. Binding was subjected to Scatchard analysis as described (22).

RESULTS

Release of TNFα. In dose-response studies, PAF induced TNFα release by human monocytes with a peak effect at 10-100 pM PAF (Table 1). Maximal PAF-induced TNFα release was two- to three-fold greater than spontaneous TNFα release by monocytes incubated with buffer alone. Spontaneous TNFα release varied from 47 to nearly 300 units/10^6 monocytes. This wide variation resulted in wide standard errors in mean release of TNFα by the nine donors. Net TNFα release by PAF was comparable to net release by IFNγ, which was 232 ± 147 and 305 ± 241 units/10^6 monocytes for 10 and 100 units/mL, respectively (mean ± SD, n = 4).

Specific antibodies to TNFα were used to confirm that the cytotoxic factor present in monocyte supernates was TNFα. Aliquots of eight monocyte supernates containing 1-361 units TNF activity were incubated with non-specific antisera or 1,000 neutralizing units of antisera to recombinant human TNFα for 2 hr at 4°C, after which cytotoxic activity was assessed. In each case, the antibodies completely eliminated cytotoxic activity of the monocyte supernates (Table 2).

In order to confirm that enhanced release of TNFα is a specific effect of PAF, mediated by a PAF receptor, the capacity of the inactive PAF analog, lysoPAF, and PAF's unnatural optical isomer, enantioPAF, to stimulate TNFα release was examined. Neither lysoPAF (n = 4) nor entantioPAF (n = 2) stimulated release of TNFα above spontaneous release by unstimulated monocytes (Table 1).

The time course of TNFα synthesis and release induced by PAF was determined. Monocytes were incubated with 10 pM PAF or vehicle control for 1, 2, 3, 5 or 16 hr and sedimented by centrifugation. The quantity of TNFα released into culture media was determined by ELISA, and the quantity of cell-associated TNFα was determined by dot blotting. In two experiments, mean net TNFα release was 0 at 1 hr, 166 pg/10^6 cells at 3 hr, 206 pg/10^6 cells at 5 hr, and 200 pg/10^6 cells at 16 hr. Dot blotting revealed rapid appearance of cell-associated TNFα protein (Fig. 1). Negligible quantities of TNFα were detected in unstimulated cells; maximal cell-associated TNFα occurred 2-3 hr after cell stimulation, and minimal TNFα was detectable 5-16 hr after cell stimulation.

PGE_2 inhibits cytokine release by monocytes (23). As PAF stimulates PGE_2 release by monocytes under some circumstances (12), it was of interest to determine if PGE_2 release accounted for the failure of high concentrations of PAF to stimulate TNFα release. PGE_2 was quantified in culture supernatants from two of the experiments shown in Table 1. PGE_2 release by control monocytes exposed to buffer for 18 hr was 98 and 74 pg/mL in the two experiments. Incubation with 10 fM to 1 μM PAF for 18 hr did not increase PGE_2 release above control levels.

TABLE 1

Stimulation of TNF Release by PAF, LysoPAF and EnantioPAF

Stimulus concentration[a]	Net tumor necrosis factor release		
	PAF	LysoPAF	EnantioPAF
10^{-15}M	12 ± 82[b]		
10^{-13}M	93 ± 126[c]		
10^{-12}M	137 ± 142[d]	36 ± 161	0
10^{-11}M	235 ± 188[d]	46 ± 120	0
10^{-10}M	214 ± 316	−16 ± 61	28
10^{-9}M	126 ± 237	−52 ± 243	68
10^{-8}M	83 ± 179[c]	26 ± 159	68

[a]One × 10^6 monocytes/mL were incubated with buffer or the indicated stimulus for 18 hr, after which TNFα release into the supernatants was quantified.

[b]Mean (± SD) net TNFα release; n = 9 (PAF), n = 4 (lysoPAF), n = 2 (enantioPAF). Spontaneous release of TNFα by monocytes incubated with buffer was 158 ± 124 units/10^6 monocytes (mean ± SD, n = 9).

[c,d]Compared to buffer-stimulated monocytes $P < 0.05$ (c) or $P < 0.02$ (d) (paired t-test). PAF also increased release of TNFα significantly within each experiment at the 100 fM-10 pM concentrations ($p < 0.05$), log rank test.

TABLE 2

Inhibition of Cytotoxic Activity by Specific Antisera to TNFα

Stimulus[a]		TNF (Units/10^6 Monocytes) Anti − TNF − Antibody	
		−	+
Buffer		67	0
PAF	10^{-12}M	81	0
	10^{-11}M	361	0
	10^{-10}M	280	0
	10^{-9}M	227	0

[a]Monocytes were incubated with buffer or PAF for 18 hr. The supernatants were harvested, treated with non-specific antisera or antisera to human TNFα and then tested for TNF activity. This experiment is representative of two experiments performed using supernatants from monocytes from different donors.

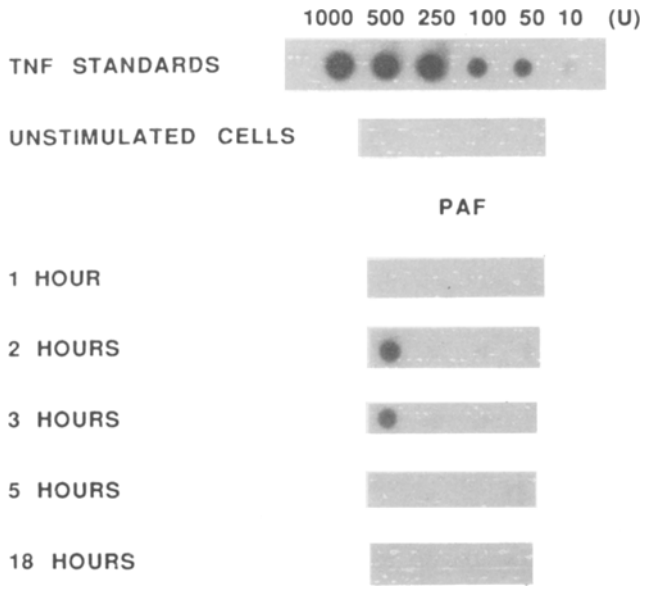

FIG. 1. Dot blot of monocyte-associated TNFα. Each time point shows blots of 1/2, 1/4, 1/8 or 1/16 dilutions of 1×10^6 monocytes treated with buffer or 10 pM PAF for the indicated times.

TABLE 3

Specificity of PAF Binding by Human Monocyte Membranes

Binding inhibitor[a]		% Inhibition of specific [^{3}H]PAF binding
Buffer		0
PAF	10^{-9}M	69 ± 22[b]
PAF	10^{-8}M	87 ± 20
PAF	10^{-7}M	100 ± 0
LysoPAF	10^{-7}M	29 ± 21
LysoPAF	10^{-6}M	45 ± 24
LysoPAF	10^{-5}M	65 ± 21
EnantioPAF	10^{-5}M	35 ± 13
Kadsurenone	10^{-6}M	21 ± 29
Kadsurenone	10^{-5}M	70 ± 23
Kadsurenone	10^{-4}M	85 ± 25
BN52021	10^{-4}M	98 ± 3

[a]Membranes from 10^7 human monocytes were incubated with 1 pmole [^{3}H]PAF (approximately 50,000 CPM) without or with the indicated binding inhibitor. After 2 hr, [^{3}H]PAF binding was quantified.

[b]Mean (± SD) percent inhibition of specific [^{3}H]PAF binding (n = 3–10). Total [^{3}H]PAF binding in the absence of inhibitors was 2825 ± 1476 CPM (6.1 ± 2.6%) (mean ± SD, n = 10). Specific [^{3}H]PAF binding (total binding minus [^{3}H]PAF binding in the presence of 10,000 pmoles unlabeled PAF) was 899 ± 651 CPM (1.6 ± 0.7%).

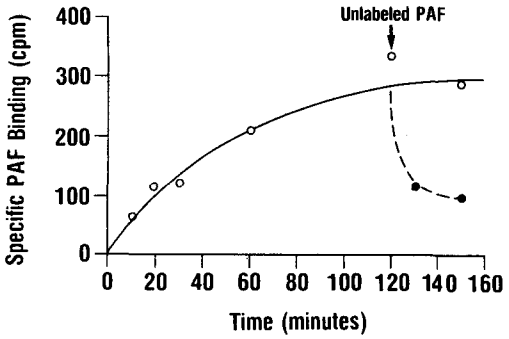

FIG. 2. Kinetics of [^{3}H]PAF binding association and dissociation from human monocyte membranes. Each point is the mean of three determinations using monocyte membranes from three donors.

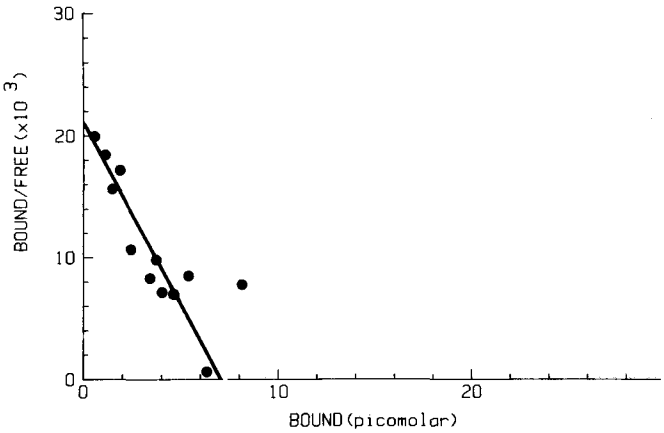

FIG. 3. Scatchard plot of PAF binding to monocyte membranes. The plot is representative of six plots prepared from binding studies with membranes from six donors. The binding data were fit to models composed of one or two specific binding sites plus a non-specific binding component. The plot for the one receptor model is shown.

Characterization of monocyte receptors for PAF. The observation that optimal TNFα release occurred at very low PAF concentrations (10–100 pM) suggested that human monocytes have unusually high affinity receptors for PAF which mediate TNFα release. So, PAF binding to monocyte membranes was examined. Analysis of the rate of binding revealed that specific PAF binding was maximal within 2 hr of incubation (Fig. 2). Specific binding was fully reversible, as shown by addition of a 1,000-fold molar excess of unlabeled PAF, which completely dissociated [^{3}H]PAF previously bond to the monocyte membranes. To examine the structural specificity of binding the capacity of PAF analogs and PAF binding antagonists to inhibit [^{3}H]PAF binding to monocyte membranes was determined (Table 3). The relatively inactive PAF analogs lysoPAF and enantioPAF were 10,000-fold less potent than unlabeled PAF for inhibiting [^{3}H]PAF binding. The capacity of the specific antagonists of PAF binding, BN52021 and kadsurenone, to inhibit PAF binding to monocyte membranes was tested. Both antagonists inhibited [^{3}H]PAF binding at concentrations which inhibit PAF binding to receptors on other cells.

PAF receptor number and binding affinity were determined by quantifying binding of 0.1–3 picomoles [^{3}H]PAF both alone and in the presence of 1 picomole to 1 nanomole unlabeled PAF. The binding data was subjected to Scatchard analysis using a computer program which uses the least squares method to fit the data to binding models composed of either one or two specific receptors plus a non-specific binding component (22,24).

The single receptor model fit the binding data best and revealed 651 ± 495 binding sites/monocyte with a dissociation constant of 4.7 ± 4.2 × 10^{-10}M (mean ± SD, n = 6) (Fig. 3). The binding data was also consistent with two PAF receptors: Receptor #1, 95 ± 80 sites/monocyte, Kd = 1.1 ± 1.4 × 10^{-10}M; receptor #2, 1035 ± 563 sites/monocyte, Kd = 1.9 ± 1.6 × 10^{-9}M. The second receptor model does not fit the binding data as well as the first receptor model, but the difference was not statistically significant.

DISCUSSION

Previous studies demonstrated that PAF enhances human monocyte cytotoxicity for tumor target cells (18). Indirect evidence suggested that PAF increases monocyte cytotoxicity by inducing release of TNFα. The current experiments directly demonstrated that PAF stimulates human monocytes to release TNFα with peak release at 10-100 pM PAF (Table 1). These concentrations of PAF are within the range of PAF concentrations detected *in vivo* during immunological reactions, so these *in vitro* observations are likely to be relevant to *in vivo* processes (25,26). It is likely that PAF stimulates TNFα synthesis rather than stimulating release of pre-existing TNFα in the monocyte preparations. Dot blotting of cell-associated TNFα did not demonstrate pre-existing TNFα, whereas PAF induced the appearance of TNFα 2-3 hr after monocyte activation (Fig. 1). PAF induced a two- to three-fold increase in TNFα release as compared to control monocytes incubated with buffer. TNFα release by 10 pM PAF is comparable to TNFα release by 10 U IFNγ/mL. Higher concentrations of IFNγ induce more TNFα release, whereas higher concentrations of PAF induce less TNFα release. High dose inhibition is frequently observed with PAF and the mechanisms are unknown. Our data indicate that high dose inhibition does not result from release of PGE_2 by the monocytes.

Bonavida *et al.* (27) reported recently that PAF stimulates release of TNFα by human monocytes. Compared to our study, those investigators found that smaller quantities of TNF were released and much higher concentrations of PAF were required to stimulate release. Methodological differences may account for the different results. Those investigators exposed the monocytes to PAF in media containing serum, so it is probable that much of the PAF was rapidly metabolized by serum acetylhydrolases. Higher PAF concentrations would be required to stimulate TNFα synthesis under those conditions than in the serum-free system used initially by us. Spontaneous and stimulated release of TNFα is higher in our study. This may result from contamination of our monocyte preparations by endotoxin concentrations or forms which are not detected by the Limulus assay (28). This possibility is supported by the recent observation that combinations of PAF and endotoxin stimulate release of TNFα by alveolar macrophages, whereas PAF alone was minimally effective (29).

Analysis of PAF binding to monocyte membranes reveals that models of binding consisting of either one or two specific receptors both fit the data. The high affinity PAF receptor in either model could account for TNFα release by 10 pM PAF. This high affinity receptor resembles other PAF receptors in that it neither binds (Table 3) nor is activated (Table 1) by lysoPAF and enantioPAF (24). There is no functional evidence for a second PAF receptor in monocytes and the one receptor model fits the binding data better than the two receptor model. Thus, current data indicate that monocytes have only one receptor for PAF.

PAF is a phospholipid and thus represents a novel class of monocyte activators which are structurally distinct from protein cytokines. However, there are complex, incompletely defined interactions between PAF and the cytokines TNFα, IL-1β and IFNγ in the regulation of human monocyte function and the immune response. PAF stimulates monocytes to release TNFα (Table 1) and IL-1β (16,17). In turn, TNFα, IL-1β and IFNγ stimulate monocytes to synthesize and release PAF in quantities sufficient to stimulate monocytes (3). These observations reveal a positive feedback loop in PAF and cytokine synthesis by monocytes which may be important to amplification of the immune response. PAF and TNFα have similar toxicities after administration *in vivo* (1,2,30). Thus, uncontrolled release of these toxic products because of the positive feedback loop could result in severe tissue damage. In this regard, it is noteworthy that specific PAF antagonists decrease bowel necrosis induced by intravenous administration of TNFα to rats (31). Further studies are required to fully elucidate the interactions among PAF, TNFα and IL-1β and to determine if these interactions can be manipulated to improve host immunity to tumors or to diminish the toxicity of immunotherapy.

We have previously reported that platelet-activating factor (PAF) induces proliferation and microbicidal activity of guinea pig bone marrow cells. In the present study, we have found that the conditioned medium of PAF- or nonmetabolizable PAF agonist-treated guinea pig bone marrow cells augmented DNA synthesis and induced microbicial activity of bone marrow cells. A PAF specific antagonist, CV-6209, inhibited generation of the active conditioned medium by PAF. Addition of the PAF antagonist only partially suppressed the augmentative effect of the active conditioned medium on DNA synthesis; this is consistent with the fact that, because of the rapid breakdown, no appreciable amount of PAF remained in the conditioned medium of PAF-treated cells. Although mouse bone marrow cells did not respond to PAF unlike guinea pig cells, their DNA synthesis was significantly enhanced by the conditioned medium of PAF-treated guinea pig bone marrow cells. Thus, some newly generated factor(s) distinct from the originally inoculated PAF seemed to modulate the bioactions of PAF on bone marrow cells. An appreciable amount of PAF was produced by calcium ionophore-treated guinea pig bone marrow cells. These findings indicate that PAF synthesized in guinea pig bone marrow cells induces generation in the cells of some factor(s) which affects proliferation or microbicidal activity.

***Lipids 26,* 1065–1070 (1991).**

Platelet-activating factor (PAF) is considered a potent mediator in various pathological and physiological reactions (1). Evidence has also been accumulating that PAF is involved in the regulation of cellular immune response (2). For instance, large granular lymphocytes were shown to release PAF on activation (3). Varying results concerning the effect of exogenous PAF on lymphocyte proliferation have been presented. Thus, Rola-Pleszczynski *et al.* (4) reported that PAF inhibited the proliferation of human peripheral blood lymphocytes. Patrignani *et al.* (5) reported that PAF caused a dose-dependent increase of prostaglandin E_2 and leukotriene B_4 synthesis in peripheral blood mononuclear cells. It was also shown that PAF partially down-regulated expression of the CD2 and CD3 antigens on human peripheral T cells (6).

The role of PAF in proliferation and induction of differentiation of immature leukocytes, however, has not been fully elucidated. Berdel *et al.* (7) showed that intravenous injection of bone marrow macrophages pretreated with ET18-OMe (1-*O*-octadecyl-2-*O*-methyl-*rac*-glycero-3-phosphocholine), a weak PAF agonist, inhibited the development of metastasis of 3-Lewis lung carcinoma in C57B1/6mice. ET18-OMe and related compounds were shown to induce cell differentiation *in vitro* of human and mouse myeloid cells (8), although the mechanism did not seem to involve PAF-specific binding sites. We suggested that the antitumor activity of synthetic alkyl ether lipid analogs might be mediated, at least in part, through *in vivo* activation of bone marrow macrophages (9). We also found PAF-specific binding sites on bone marrow cells of guinea pigs (10). Since it was widely accepted that PAF-responsive cells are activated through binding of PAF to specific PAF binding sites, we searched for functional alteration in PAF-treated bone marrow cells. We have found that PAF induces a microbicidal activity against *Candida parapsilosis* (10) and augments cell proliferation (11). The conditioned medium of bone marrow cells incubated in the presence of PAF was also shown to enhance DNA synthesis in another culture of bone marrow cells (11). In the studies mentioned below, evidence was obtained that PAF-induced proliferation and microbicidal activity are mediated by some newly generated factor(s), distinct from PAF itself, in bone marrow.

MATERIALS AND METHODS

Chemicals. Fetal calf serum (FCS) was obtained from HyClone Laboratories (Logan, UT) and used after heat inactivation. RPMI-1640 medium was from MA Bioproducts (Walkersville, MD). [*Methyl*-1′,2′-^{3}H]thymidine (specific activity, 112.7 Ci/mmol) was from the Radiochemical Centre, Amersham, UK; essentially fatty acid-free bovine serum albumin (BSA) was obtained from Sigma Chemical Co. (St. Louis, MO). PAF, 1-*O*-octadecyl-2-dimethylcarbamoyl-*sn*-glycero-3-phosphocholine (Compound I) (12), and CV-6209 (13) were provided by Takeda Chemical Industries, Ltd. (Osaka, Japan). FR900452 (14) was kindly provided by Fujisawa Pharmaceutical Co. Ltd. (Osaka, Japan).

Animals and preparation of bone marrow cells. Female Hartley guinea pigs (body weight 250–500 g), Japanese white rabbits, and ICR mice were obtained from the Japan Bio-supply (Tokyo, Japan). Bone morrow cells were prepared from femurs of guinea pigs as described previously (10).

Abbreviations: BSA, bovine serum albumin; FCS, fetal calf serum; PAF, platelet-activating factor.

Preparation of conditioned medium. The conditioned medium was obtained by centrifugation after cultivation of bone marrow cells (2×10^6 cells/ml) in RPMI1640 medium containing 10% FCS in the presnce of PAF for indicated periods. After repeated dialysis (four times) against RPMI 1640 medium containing 0.1% BSA, the medium was sterilized by filtration using a cellulose acetate membrane filter (pore size, 0.20 μm, Corning).

Assay for [^3H]thymidine incorporation. Bone marrow cells (5×10^4 cells) were seeded in flat-bottomed, 96-well plates with 100 μl of RPMI 1640 medium containing 20% FCS. After one day of incubation at 37°C under a 5% CO_2 atmosphere, conditioned medium (50 μl) was added. Eight hours before completion of the incubation, 0.5 μCi of radioactive thymidine was added. Radioactivity of the acid-insoluble fractions of cells was counted (15). Activation index, representing a relative potency to induce DNA synthesis, was calculated as described previously (11).

Assay for microbicidal activity. Microbicidal activity of bone marrow cells was determined by the methods described previously (10). *Candida parapsilosis* were used as target cells. In brief, bone marrow cells (1×10^5 cells) were seeded in flat-bottomed, 96-well plates with 0.2 ml of the RPMI 1640 medium with 10% FCS. After one day of incubation at 37°C under a 5% CO_2 atmosphere, cells were treated with PAF or the conditioned medium, and then infected with 10 μl of two-fold serially diluted *Candida parapsilosis* suspensions. After incubation for 48 hr at 37°C under a 5% CO_2 atmosphere, outgrowth of *Candida parapsilosis* cells in each well was determined under a microscope. Microbicidal activity of bone marrow cells (the maximum number of microbes killed, MNMK) was evaluated as the maximum number of microbes added to a well where the growth was completely suppressed.

RESULTS

Generation of conditioned medium affecting DNA synthesis. The conditioned medium of guinea pig bone marrow cells was prepared after incubation of cells in the presence of 10^{-5} M PAF and added to another culture of bone marrow cells. The conditioned medium appreciably enhanced DNA synthesis of the second culture of bone marrow cells (Table 1, exp. 1). The conditioned medium of the control culture did not have any significant effect (data not shown). The augmentative activity of the conditioned medium was not dialyzable and the effect was dose-dependent (Fig. 1A). In an experiment, 15 nmole of PAF was added to 1.5 ml of a culture of bone marrow cells in the medium containing 20% FCS, and the degradation of PAF during incubation was examined by bioassay using rabbit platelets (12). Only 2.2 nmole of PAF was recovered just after the start of incubation, and no appreciable amount of PAF was detected in the conditioned medium after incubation for 2 hr or longer, indicating that exogenously-added PAF was rapidly degraded, most probably by serum (16) or cellular (17) PAF acetylhydrolase.

A strong PAF agonist, Compound I, showed more potent activity in the generation of active conditioned medium than PAF itself; the conditioned medium prepared from cells cultivated in medium containing 10^{-10} M Compound I exhibited an augmentative activity comparable to that with 10^{-5} M PAF (Table 1, exp. 2). When guinea pig bone marrow cells were incubated with a PAF-specific antagonist, CV-6209 and subsequently treated with PAF, no augmentative activity was found in the conditioned medium (Table 1, exp. 3).

TABLE 1

Enhancement of DNA Synthesis by Conditioned Medium[a]

	Conditioned medium from bone marrow cells treated with		Acid-insoluble radioactivity (dpm)[b]
Exp. 1	Control		1,203 (1.0)[e]
	PAF	10^{-6} M	981 (0.8)
		10^{-5} M	4,712 (3.9)
Exp. 2	Control		455 (1.0)
	PAF	10^{-5} M	2,275 (5.0)
	Compound I	10^{-11} M	4,065 (8.9)
		10^{-10} M[c]	4,161 (9.1)
Exp. 3	Control		1,491 (1.0)
	PAF	10^{-5} M	6,084 (4.1)
	CV-6209 10^{-7} M[d] + PAF	10^{-5} M	2,263 (1.4)

[a] The conditioned medium was obtained by centrifugation and dialysis after cultivation of guinea pig bone marrow cells (2×10^6 cells/ml) in the presence of the indicated dose of PAF or Compound I for 15 hr. Bone marrow cells from another guinea pig were incubated in the presence of the conditioned medium for 56 hr. DNA synthesis of the bone marrow cells was examined as described in Materials and Methods.

[b] Results are mean values from triplicate cultures.

[c] After extensive dialysis, approximately 1/100 of the originally inoculated Compound I was detected in the conditioned medium (data not shown), indicating that the potent effect observed is due to newly generated factors.

[d] Thirty minutes prior to treatment with PAF, a PAF antagonist, CV-6209, was added to the culture.

[e] Numbers in parentheses represent values of activation index.

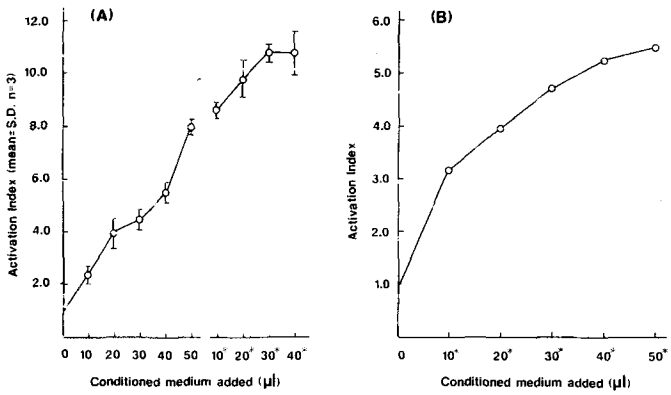

FIG. 1. Dose-dependent enhancement of DNA synthesis by conditioned medium. The conditioned medium was obtained by centrifugation and dialysis after cultivation of guinea pig bone marrow cells (2×10^6 cells/ml) in the presence of 10^{-5} M PAF for 15 hr. The various doses of conditioned medium or concentrated conditioned medium (*, one-fifth of the volume) were added to another culture of bone marrow cells of guinea pig (A), or mouse (B) for 72 hr. DNA synthesis was examined as described in Materials and Methods.

TABLE 2

Effect of Heat Treatment on the Conditioned Medium[a]

	Acid-insoluble radioactivity (dpm)[b]		
	Before heat treatment	After heat treatment	Control medium
Exp. 1	28,467 ± 4,439 (4.9)[c]	11,965 ± 759 (2.1)	5,790 ± 59 (1.0)
Exp. 2	5,937 ± 453 (5.3)	3,694 ± 178 (3.3)	1,112 ± 17 (1.0)
Exp. 3	17,961 ± 3,321 (4.1)	12,743 ± 1,246 (2.9)	4,337 ± 788 (1.0)

[a]The conditioned medium was prepared by centrifugation and dialysis after cultivation of guinea pig bone marrow cells in the presence of 10^{-5}M PAF for 8 hr (Exps. 1 and 2) or 15 hr (Exp. 3). The conditioned medium was then heated at 80°C for 15 min. The augmentative effect on DNA synthesis was then examined as described in Materials and Methods.

[b]Results are mean values ± S.D. from triplicate cultures.

[c]Numbers in parentheses represent values of activation index.

TABLE 3

Augmentation of DNA Synthesis in Bone Marrow Cells from Various Species by PAF or the Conditioned Medium[a]

		Acid-insoluble radioactivity (dpm)[b] of bone marrow cells treated with

	Exp. 2	14,305 ± 1,555 (2.13)	34,548 ± 2,396 (5.16)	N.D.	6,695 ± 484 (1.0)
Guinea pig	Exp. 1	31,927 ± 2,864 (5.76)	N.D.	23,194 ± 1,569 (4.18)	5,544 ± 465 (1.0)

[a]The conditioned medium was prepared by centrifugation and dialysis after cultivation of guinea pig bone marrow cells were cultivated in the presence of 10^{-5}M PAF for 5 hr. Bone marrow cells (2×10^6 cells/ml) from various species were treated with PAF, Compound I or the conditioned medium for 72 hr. DNA synthesis was examined as described in Materials and Methods.

[b]Results are mean values ± S.D. from triplicate cultures.

[c]Numbers in parentheses represent values of activation index.

[d]N.D. = not determined.

The augmentative effect of PAF on DNA synthesis of guinea pig bone marrow cells was inhibited by PAF-specific antagonists, CV-6209 or FR900452, in a dose-dependent manner, as reported previously (11). We found that the treatment of bone marrow cells with PAF-specific antagonists suppressed the augmentative effect of the conditioned medium, although the inhibitory effects were much weaker than those observed in the case of directly PAF-induced effects (Fig. 2). The activity decreased by approximately 30-60% when the conditioned medium was treated at 80°C for 15 min (Table 2).

Effect on bone marrow cells from various species. As in the case of guinea pig, cell proliferation was observed when rabbit bone marrow cells were cultured in medium containing PAF (Table 3). A similar augmentative effect was observed using a strong PAF agonist, Compound I. On the other hand, bone marrow cells prepared from ICR mouse did not respond to PAF or Compound I (Table 3). Other mouse strains (C3H/HeN, CDF1) were tested, but no significant effect of PAF has been observed so far (data not shown). In spite of the nonresponsiveness, mouse bone marrow cells carried specific binding sites for PAF (Fig. 3). The Kd value (6.1×10^{-10} M) and number of binding sites (4950) per cell were almost identical with those of guinea pig bone marrow cells (10).

The conditioned medium generated from PAF-treated guinea pig bone marrow cells was able to augment DNA synthesis in rabbit and mouse bone marrow cells as well (Table 3). The conditioned medium enhanced DNA synthesis of mouse bone marrow cells in a dose-dependent manner (Fig. 1B).

Induction of microbicidal action. The conditioned medium was prepared and added to another bone marrow cell culture. After three days of incubation, cells were

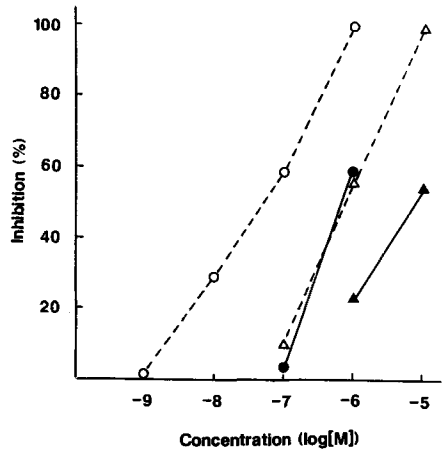

FIG. 2. Inhibition of augmentation of DNA synthesis by PAF antagonists. The conditioned medium was obtained from cultures of PAF-treated bone marrow cells. CV-6209 (○,●) or FR900452 (△,▲) was added to bone marrow cell culture 30 min prior to treatment with 10^{-5} M PAF (○,△) or 50 μl of conditioned medium (●,▲) for 72 hr. The DNA synthesis was examined as described in Materials and Methods.

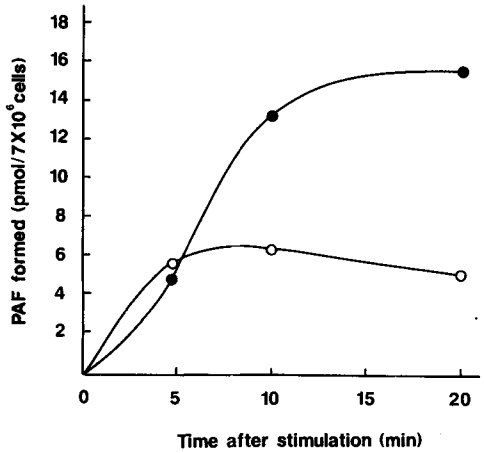

FIG. 4. Production of PAF by A23187-stimulated guinea pig bone marrow cells. Guinea pig bone marrow cells (7×10^6 cells/mL) were treated with (●) or without (○) phenylmethanesulfonyl fluoride (1 mM) for 10 min. After washing, cells were stimulated with A23187 (5 μg/ml) for the indicated periods. PAF was isolated by thin-layer chromatography and quantified by bioassay using rabbit platelets (12).

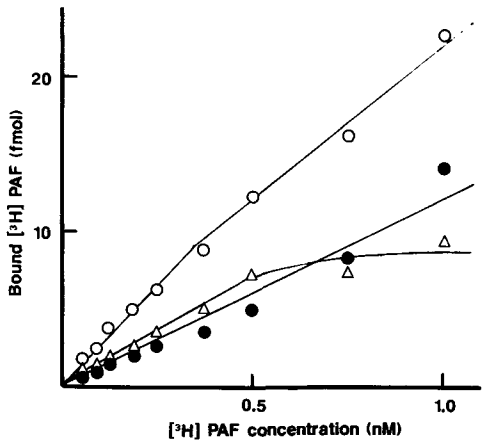

FIG. 3. Binding of PAF to murine bone marrow cells. [^{3}H]PAF binding to bone marrow cells was measured by the method described previously (10). Total binding, ○; nonspecific binding, ●; specific binding, △.

TABLE 4

Microbicidal Activity of Guinea Pig Bone Marrow Cells Treated with Conditioned Medium

Addition	Maximum number of microbes killed[a]		
	Exp. 1	Exp. 2	Exp. 2
Conditioned medium[b]			
Nontreated cells	74	10	10[d]
PAF(10^{-5}M)-treated cells	1,184	1,316 (82)[c]	1,316[d]
PAF(10^{-6}M)-treated cells	590	N.D.[e]	N.D.
PAF(10^{-6}M)	1,184	2,632	82[d]
BSA(0.25%) solution	37	82	82[d]

[a] Candidacidal activities of guinea pig bone marrow cells were determined as described in Materials and Methods.

[b] The conditioned medium was prepared after cultivation of guinea pig bone marrow cells for 20 hr in the absence or presence of PAF (10^{-5} M or 10^{-6} M).

[c] Conditioned medium heated at 80°C for 15 min.

[d] Bone marrow cells were treated with PAF antagonist, CV-6209 (10^{-6}M) 30 min prior to addition of the conditioned medium or PAF solution. Candidacidal activities were then determined.

[e] N.D. = not determined.

infected with *Candida parapsilosis* at various doses. After further incubation for two days, viable microbes present in each culture well were monitored. When bone marrow cells were cultivated in medium containing the conditioned medium, microbes were killed more effectively than in the control culture (Table 4, exp. 1). The effect was abolished when the conditioned medium was preincubated at 80°C for 15 min (Table 4, exp. 2). The PAF antagonist did not affect the microbicidal activity induced by the conditioned medium while, as reported previously (10), it inhibited that induced by PAF itself (Table 4, exp. 2).

Production of PAF in calcium ionophore-treated bone marrow cells. Stimulation of guinea pig bone marrow cells by addition of 2.5 μM calcium ionophore (A23187) led to the formation of a PAF-like substance when evaluated by bioassay using rabbit platelets (Fig. 4). The following results supported the idea that this substance is actually PAF: i) Treatment of cells with phenylmethanesulfonyl fluoride, a known inhibitor of PAF acetylhydrolase (18), prior to calcium ionophore stimulation increased the amount of PAF synthesized (Fig. 4); ii) a specific PAF antagonist, CV-6209, inhibited platelet activation (data not shown); and iii) treatment with porcine pancreatic phospholipase A_2 (19) diminished the activity (data not shown).

DISCUSSION

The conditioned medium of PAF-treated guinea pig bone marrow cells augmented the DNA synthesis of another culture of guinea pig bone marrow cells. We have

previously shown that PAF affects the proliferation of one or more classes of guinea pig bone marrow cells (11). PAF-specific antagonists inhibited the PAF-induced augmentation of DNA synthesis, as well as the induction of active conditioned medium. However, the proliferative activity detected in the conditioned medium did not appear to be due to exogenously added PAF, since after incubation for a short period at 37°C, no appreciable amount of PAF remained in the conditioned medium. The exogenously added PAF was most probably degraded to inactive lysoPAF during incubation by serum PAF acetylhydrolase, which is present in the culture medium. Thus, the augmentative effect of PAF on DNA synthesis seemed to be mediated through some factor(s) newly generated in the conditioned medium by PAF-treated bone marrow cells. The active conditioned medium appears to be produced through a specific mechanism via binding of PAF to receptors presnt on some cell population of bone marrow cells.

The augmentative effect of PAF on DNA synthesis in bone marrow cells was not always observed when various experimental animals were used. Cells from guinea pig or rabbit respond to PAF, while cells from mouse do not. Murine platelets do not respond to PAF because of the lack of binding sites on the cell surface (20). The nonresponsiveness to PAF of murine bone marrow cells, however, must have another reason, since specific and saturable binding sites were observed. The fact that the conditioned medium of PAF-treated guinea pig bone marrow cells augmented DNA synthesis of murine bone marrow cells further supported the hypothesis that an active factor(s) is generated.

In addition to the augmentative effect on DNA synthesis, the conditioned medium of PAF-treated guinea pig bone marrow cells induced the microbicidal action of cells against *Candida parapsilosis*, indicating that the active conditioned medium induces a functional alteration in bone marrow cells. It is noteworthy that a simple treatment of bone marrow cells with a recombinant human G-CSF did not cause any functional alteration (data not shown). We have observed slightly different characteristics of the two bioactions of the conditioned medium. The induction of microbicidal activity was not affected by a PAF-specific antagonist, though the antagonist did partially inhibit the augmentation of DNA synthesis. Heat treatment of the active conditioned medium totally abolished the activity to induce the microbicidal action. On the other hand, heat-treated conditioned medium still caused an augmentation of DNA synthesis, although the effect was rather weak. These differences would indicate an involvement of different factors in these two reactions. More than one factor might be produced.

One of the most important questions is to identify the active factor(s) present in the conditioned medium. Several groups have reported the production of cytokines by monocytes on stimulation with PAF (21). However, no information concerning the production of cytokines by bone marrow cells is available so far. We have observed several unique characteristics of the conditioned medium, such as a partial resistance to heat treatment and cross reactivity between species. In our preliminary experiments, a tumor necrosis factor-like activity and an interferon-like activity were detected in the conditioned medium of PAF-treated guinea pig bone marrow cells. However, in a preliminary experiment, recombinant mouse tumor necrosis factor or γ interferon failed to show an appreciable effect on bone marrow cells (data not shown). It therefore seems unlikely that the proliferative and induced microbicidal activities of PAF are wholly dependent upon these well-characterized cytokines.

It should be noted that the concentration of PAF (10^{-5} M) used in this experiment was high as compared to the expected level of PAF *in vivo* (22). Even so, we venture to emphasize the importance of the present observations for the following reasons. First, poor activity of PAF toward bone marrow cells could be due to the rapid degradation to inactive lysoPAF catalyzed by serum acetylhydrolase (17). Compound I, which is resistant to such metabolic inactivation, showed a relatively high activity. The activity of Compound I to induce functional alterations in bone marrow cells was similar to the relative potency to activate peritoneal macrophages or platelets (12). Second, on stimulation of bone marrow cells with calcium ionophore, an appreciable amount of PAF was produced. *In vivo*, PAF may modulate the fate and functions of bone marrow cells under conditions where it is produced and is delivered without degradation to the target cells. The relevance of the present study to the physiological and/or pathological roles of PAF *in vivo* needs to be further clarified.

The effect of platelet-activating factor (PAF) and of two specific PAF antagonists on tumor necrosis factor (TNF) induced superoxide production by human polymorphonuclear neutrophils (PMN) was examined. PAF alone (0.1 pM to 0.1 nM) failed to evoke superoxide production; however, when PAF was added for 10 min to cells upon prior incubation with 10 ng/mL TNF for 50 min, superoxide production was significantly enhanced as compared to that induced by TNF alone. Maximum amplification (+30%) was obtained with 10 pM PAF; however, the effect was completely abolished by two structurally unrelated PAF antagonists, BN 52021 and BN 52111. The antagonists also decreased by 25% the superoxide production elicited solely by TNF, implicating the involvement of endogenous PAF in this process. Pretreatment of the PMN with either pertussis or cholera toxin attenuated the PAF amplified superoxide production in TNF stimulated cells, suggesting that G proteins sensitive to these toxins may be involved in the mechanisms controlling amplification.
Lipids 26, 1071-1075 (1991).

The normal bactericidal response of human polymorphonuclear neutrophils (PMN) involves cell stimulation, followed by a respiratory burst which results from the activation of NADPH oxidase. This multicomponent electron transport chain transfers electrons from intracellular NADPH to extracellular oxygen, reducing molecular oxygen to superoxide. The latter product is rapidly converted to hydrogen peroxide and toxic free radicals (1). Activated PMN also release lysosomal proteases and adhere to the surface of endothelial cells leading to microvascular injury characteristic of pathologies such as shock, asthma, ischemia and graft rejection. All these processes may be partially mediated by dysregulation of PMN function.

Among the various agonistic mediators released into the inflammatory microenvironment, which are capable of modulating PMN activity, are platelet-activating factor (PAF) and tumor necrosis factor (TNF). PAF, structurally characterized as 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine, is a potent autacoid implicated in a diverse range of human pathological conditions (2). This alkyl phospholipid is now known to be produced by, and to act on, a variety of cell types including eosinophils, monocytes, macrophages, platelets, endothelial cells and PMN. PAF is a potent chemotactic agent for neutrophils, inducing superoxide release, aggregation and degranulation of these cells. *In vivo*, the mediator evokes pulmonary sequestration of neutrophils, hypotension, bronchoconstriction, increased vascular permeability, and plasma extravasation (2).

TNF is a polypeptide cytokine produced primarily by monocytes and macrophages in response to endotoxin and other immune and inflammatory stimuli (3). Large doses of TNF mimic the symptoms of endotoxic shock, such as circulatory collapse, hemorrhage and end-organ failure in a variety of species, and can lead to death (4). Similarly to PAF, TNF induces superoxide production by PMN and causes adherence of this cell type to the endothelium (5).

Although it is well established that endothelial cells produce PAF when stimulated with agonists such as thrombin, Camussi *et al.* (6) have shown that TNF *in vitro* can induce endothelial cells to synthesize PAF, the majority of which remains associated with the cells. Furthermore, Bonavida *et al.* (7) have reported that PAF can activate peripheral blood derived monocytes to produce and secrete TNF. In addition to eliciting the production of each other from cell types intimately involved in inflammatory reactions, at very low concentrations both PAF and TNF can also "prime" PMN to respond in an enhanced manner to subsequent agonistic stimuli. Following PAF (8) or TNF (9) priming, amplified PMN responses, including aggregation, adhesiveness, superoxide production and elastase release, have been observed using formyl-methionyl-leucyl-phenylalanine (FMLP) as inducing agonist.

The mechanisms involved in PAF and cytokine priming and amplification processes remain unclear. However, interaction of PAF with an undefined receptor protein may result in transmembrane signalling *via* the activation of a pertussis toxin sensitive guanyl nucleotide regulatory protein, Gi, involving GTP hydrolysis (9-11). Phospholipase C may then be stimulated, and phosphodiesterase-mediated cleavage of inositol phospholipids may induce Ca^{2+} mobilization from internal pools. Thus, activation of the Gi subunit by PAF or cytokines may lead to both inhibition of the catalytic unit of adenylate cyclase and activation of the phosphatidylinositol cycle (reviewed in ref. 12).

A positive self-generating feedback process may become operative between TNF and PAF, and PAF associated to the endothelium may prime or amplify PMN responses elicited by TNF and other agonists. The present study was therefore undertaken to examine the effect of PAF on TNF induced superoxide production by human PMN, and to define whether or not structurally unrelated specific PAF antagonists could modulate superoxide release elicited by these two mediators. The effect of bacterial toxins from

Vibrio cholerae and *Bordetella pertussis* on PAF modulation of TNF induced superoxide release was studied as well.

MATERIALS AND METHODS

Materials. PAF, FMLP, cytochrome C, phosphate buffered saline (PBS) and sodium chloride were obtained from Sigma Chemical Co. (St. Louis, MO). Ficoll Paque was purchased from Pharmacia (Uppsala, Sweden). Tumor necrosis factor was supplied by Genentech (San Francisco, CA). The PAF antagonists, BN 52021 (ginkgolide B), a 20-carbon cage terpene, and BN 52111, which is 2-heptadecyl-2-methyl-4-[5-(pyridinium-pentylcarbonyloxymethyl)]-1,3-dioxolane bromide, were produced by IHB Research Labs (Le Plessis-Robinson, France). Cholera and pertussis toxins were obtained from Institute Merieux (Chabonnieres les Bains, France).

Preparation of PMN. Blood was centrifuged at 1000 × *g* for 25 min. The platelet-rich plasma was discarded, and the PMN fraction was obtained following 6% dextran-500 sedimentation, centrifugation over Ficoll Paque, and ammonium chloride (160 mM) plus Tris (170 mM) treatment. PMN were then resuspended in a Ca^{2+}-free standard phosphate-buffered medium (PBS) containing (mM): Na^+, 146; K^+, 4; Cl^-, 142; HPO_4^{2-}, 2.5; $H_2PO_4^-$, 0.5; Mg^{2+}, 1; glucose, 10; (pH 7.4; determined osmolarity N 284 mOsM). Some experiments were performed in the same PBS containing 1mM Ca^{2+} to determine the effect of external Ca^{2+} on TNF induced superoxide generation. PMN were counted electronically using a Coulter Counter. The final preparation contained less than 5% lymphocytes and 15% platelets. Trypan blue staining revealed 95–99% viable cells.

TNF/PAF amplification and priming experiments. Priming and amplification are defined as follows: In a given cell system, for two effectors, A and B, inducing, respectively, the effects E_A and E_B, priming is the process when A added by itself at a subthreshold concentration at a given time induces no effect (E_A=0); however, when A is given prior to B the final effect is greater than E_B. Amplification is a process when A added alone at a given time prior to B applied at a subthreshold concentration (*i.e.*, B=0) results in a final effect greater than E_A.

TNF was freshly diluted with 1% bovine serum albumin (BSA), and the reaction was carried out in a Ca^{2+}-free phosphate-buffered saline (PBS). Cytochrome C (75 μM) was added to 2 × 10^6 cells/mL at 37°C. TNF was then added to the medium either at a concentration of 10 ng/mL (amplifcation experiments) or at very low concentrations (priming experiments), and the cells were incubated for 1 hr. After the incubation, superoxide production was determined as described below. PAF (10^{-16} to 10^{-8} M) was added 10 min before the end of the reaction to examine its potential amplifying effect. The 1-hr incubation was terminated by centrifugation for 7 min at 4°C. The supernatant was removed for measurement of cytochrome C reduction. When PAF antagonists, or pertussis or cholera toxins were used, they were added at a concentration of 10^{-6} M simultanuously with TNF at the start of the incubation period.

Results are expressed in nanomoles of superoxide anion following the equation:

$$\text{Concentration of } O_2^{\cdot-} = \frac{\text{Absorbance}}{21.1} \times 1000 \text{ nM} O_2^{\cdot-} = O_2^{\cdot-}/2 \times 10^6 \text{ cells/hr,}$$

where 21.1 μM^{-1} cm^{-1} = the absorption molecular coefficient (Σ).

Results are expressed as mean ± standard error of the mean (SEM), and differences from controls were statistically analyzed by the unpaired Student's *t*-test.

RESULTS

TNF induced superoxide production. In Ca^{2+}-free buffer, PMN (2 × 10^6 cells/mL) were incubated for 1 hr at TNF concentrations ranging from 0.01 ng/mL to 1000 ng/mL. A dose-response relationship was observed between TNF concentration and superoxide generation. The maximum response was obtained with 10 ng/mL TNF where the $O_2^{\cdot-}$ production was 4.45 ± 0.67 nmoles $O_2^{\cdot-}/2 \times 10^6$ cells/mL/hr. Thus, this concentration of TNF was selected for further studies on PMN with PAF. The presence of Ca^{2+} in the buffer significantly enhanced the superoxide production induced by TNF. At the lowest concentration (0.01 ng/mL) the free radical production became significant, and at 10 ng/mL the maximum $O_2^{\cdot-}$ production of 15.10 ± 1.36 nmoles $O_2^{\cdot-}/2 \times 10^6$ cells/mL/hr was obtained. Superoxide production was also dependent on cell number. As already shown, with 2 × 10^6 cells/mL, the TNF (10 ng/mL) induced superoxide generation was 4.45 ± 0.67 nmoles/hr, which was considered adequate to detect any modulatory effect of PAF on superoxide production. Doubling the cell number increased the superoxide release only by 35%.

To determine the time-course of TNF induced superoxide generation in the Ca^{2+}-free buffer, we measured the difference between the basal PMN $O_2^{\cdot-}$ production (control, cells not stimulated with TNF) and that obtained after stimulation of PMN with 10 ng/mL TNF for 3 hr at 37°C. Superoxide generation by TNF stimulated cells increased after 15 min, reached a maximum value at 90 min, and then gradually declined. An incubation period of 1 hr was selected for studies on the effect of PAF, as this marked the onset of a relatively stable period of maximal superoxide production in the presence of TNF.

PAF induced superoxide production. In Ca^{2+}-free buffer, PMN were incubated at various concentrations of PAF (10^{-16} M to 10^{-8} M) for periods of between 5 min to 3 hr. No significant superoxide production was elicited by PAF at any of the concentrations examined, except for 10^{-8} M PAF, which elicited the release of a marginally detectable amount (less than 1 nmole/hr) of superoxide (Fig. 1). PAF alone did not affect superoxide production regardless of incubation time or the cell number used.

PAF amplification of TNF induced superoxide production. As shown in Figure 1, when PAF (10^{-16} to 10^{-8} M) was incubated for 10 min with neutrophils which had been previously exposed to 10 ng/mL TNF for 1 hr in Ca^{2+}-free buffer, $O_2^{\cdot-}$ production was significantly amplified. Maximum amplification of TNF induced $O_2^{\cdot-}$ production was elicited by 10^{-12} M PAF, which increased superoxide release by 25–30% relative to that induced by TNF alone after 1 hr. In this system, when PAF was added before TNF at the start of the PMN incubation, no amplification was observed. Furthermore, the amplification effect required the intact PAF molecule because its biologically

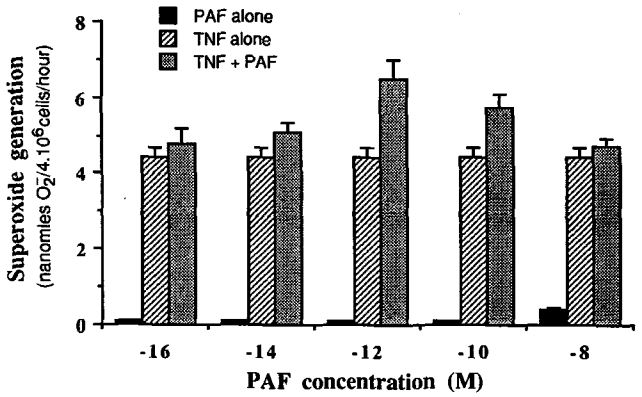

FIG. 1. PAF amplification of TNF induced superoxide generation in human neutrophils. A concentration of 10 ng/mL TNF was used and superoxide production was recorded after an incubation time of 1 hr. When PAF and TNF were used in combination, PAF was introduced 10 min before the 1 hr incubation with TNF. Values are means ± SEM, n=10. Amplification by PAF of TNF induced responses were statistically significant ($p < 0.05$) at 10^{-12} and 10^{-10} M PAF.

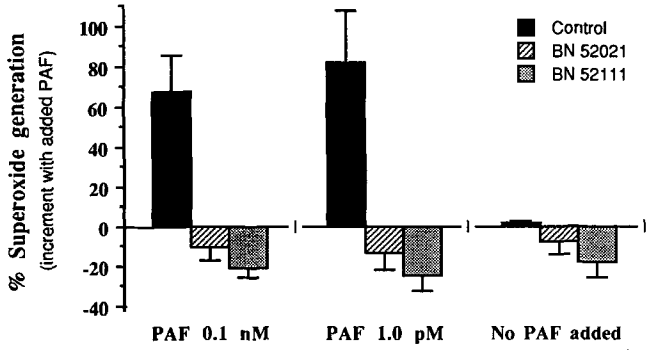

FIG. 2. Effect of two chemically unrelated PAF antagonists on PAF amplified TNF (10 ng/mL) induced superoxide production in human neutrophils. Results show means ± SEM, n=5; both PAF antagonists were used at 10^{-6} M and induced a statistically significant inhibition of PAF amplification of TNF induced superoxide production ($p < 0.05$).

inactive precursor and metabolite, lysoPAF, had no effect on TNF induced $O_2^{\cdot-}$ production. Cells in some experiments were washed twice with Ca^{2+}-free buffer to remove excess TNF before addition of PAF to determine whether the amplifying effect of the phospholipid mediator on superoxide release was dependent on the continuous presence of exogenous TNF during the incubation with PAF. PAF still amplified superoxide release when TNF was removed. In addition, the effect of PAF was found to result from an enhanced rate of superoxide release rather than from a prolongation of a relatively short oxidative response induced by PAF.

Inhibition of PAF amplification by PAF antagonists. The effects of two structurally unrelated specific antagonists on PAF amplification of TNF induced superoxide production were examined, namely, ginkgolide B (BN 52021) (10) and BN 52111 (13). These two antagonists inhibit [^{3}H]PAF binding to its rabbit platelet membrane receptor with IC_{50} values of 0.25 μM and 35 nM, respectively. As shown in Figure 2, both PAF antagonists added at a concentration of 1 μM concomitantly with TNF to the PMN at the beginning of the incubation in Ca^{2+}-free buffer completely inhibited the amplification of superoxide production induced by subsequent addition of 10^{-10} M PAF (left-hand graph) or 10^{-12} M PAF (middle graph). The inhibition of superoxide release was greater than the amplification effect of PAF indicating that the antagonists partially inhibited the superoxide production induced by TNF alone. This was confirmed by examining the effect of the two antagonists on TNF induced superoxide production in PMN which received no exogenous PAF. Figure 2 (right-hand graph) clearly shows that BN 52021 and BN 52111 inhibited TNF induced superoxide release by 8-25%. BN 52111 was the more potent antagonist.

Effect of pertussis and cholera toxin on PAF amplification of TNF induced superoxide production. The individual effects of pertussis and cholera toxin on PAF amplification of TNF induced superoxide production were examined. In addition, the effect of PAF on neutrophils preincubated in Ca^{2+}-free medium with the toxins and TNF was studied. The effect of incubation with PAF (10^{-10}, 10^{-12} M) for 10 min on neutrophils which had been previously incubated with pertussis toxin (1 μg/mL) and TNF (10 ng/mL) for 50 min is shown in Figure 3. Pertussis toxin alone released superoxide anion and significantly increased the effect of TNF. However, when PAF was added to neutrophils preincubated with pertussis toxin and TNF, no amplification of superoxide generation was observed. Instead, superoxide production decreased concentration-dependently by addition of PAF with 10^{-12} M, causing the greatest reduction (Fig. 3).

As shown in Figure 4, cholera toxin alone (0.1 or 1 μg/mL) was not capable of eliciting $O_2^{\cdot-}$ generation. When neutrophils were treated concomitantly with this toxin and TNF, there was a slight decline in the generation of

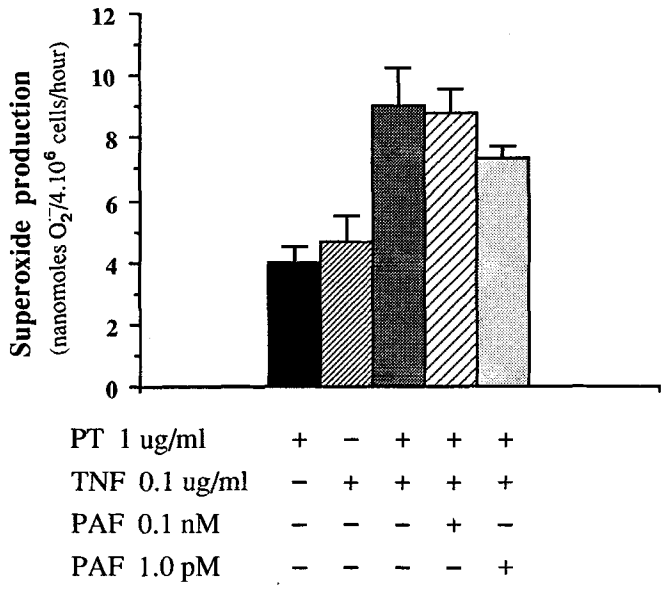

FIG. 3. Effect of pertussis toxin (PT) on PAF amplification of TNF induced superoxide production. PAF was introduced for 10 min before the end of 1 hr incubation with TNF. Pertussis toxin was added to the cells at the beginning of incubation with TNF, and significantly reduced superoxide production induced by 0.1 μg/mL TNF plus 1.0 pM PAF ($p < 0.05$).

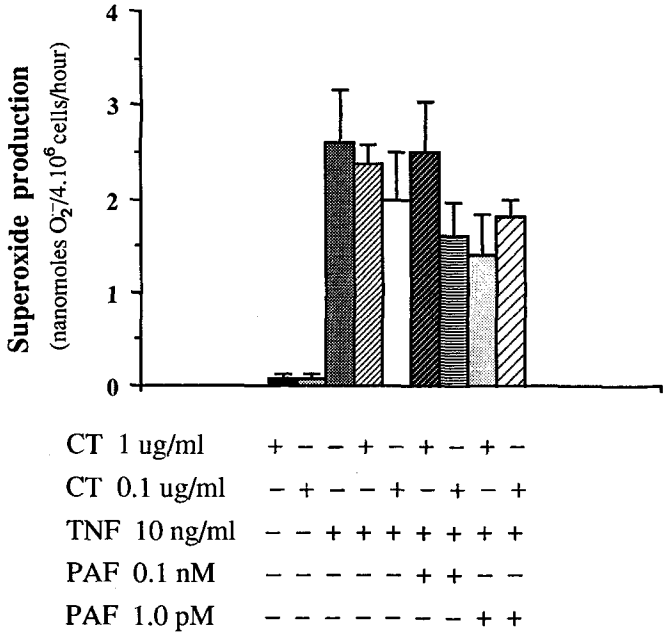

FIG. 4. Effect of cholera toxin (CT) on PAF amplication of TNF induced superoxide production. PAF was introduced 10 min before the end of the 1 hr incubation with TNF. Cholera toxin was added to the cells at the beginning of the incubation with TNF and showed a tendency to reduce superoxide generation induced by TNF and PAF.

superoxide as compared to that induced by TNF alone. When PAF (10^{-10} or 10^{-12} M) was added to the neutrophils one hr after initiation of the incubation with cholera toxin and TNF, alterations in superoxide generation depended on both the concentration of the mediator and the toxin. However, in all cases except for 10^{-10} M PAF and 1 μg/mL cholera toxin, $O_2^{\cdot-}$ production decreased when compared to that induced by cholera toxin and TNF. Thus, the amplication of TNF induced superoxide production induced by PAF was inhibited in the presence of cholera toxin, although, in contrast to pertussis toxin, cholera toxin itself was unable to elicit superoxide release and partially suppressed that induced by TNF.

TNF priming of PAF induced superoxide production. When neutrophils were incubated in Ca^{2+}-free medium for 1 hr with 0.01 and 0.1 ng/mL of TNF which were unable to elicit any detectable superoxide release by itself, the higher of these two concentrations was capable of priming the cells for $O_2^{\cdot-}$ release induced by addition of 10^{-10} M PAF for 10 min, while the other concentrations of PAF tested were ineffective. Similar to the result obtained for PAF amplification of the TNF induced response, even marginal superoxide production induced by a low concentration of TNF (1 ng/mL) was amplified when PAF was added 10 min before the end of the incubation.

DISCUSSION

Stimulation of PMN with various agonists leads to a respiratory burst which results in superoxide release, degranulation, and cell adhesion. Both TNF and PAF are modulators of the activity of PMN and play a crucial role in inflammation and host defense. In our system, TNF induced a time- and dose-dependent production of superoxide from normal human PMN. PAF alone (10^{-16} M to 10^{-8} M) caused no significant release of superoxide from the cells, regardless of cell number or incubation time. However, when PAF was added 10 min prior to the end of the 1 hr incubation period with TNF, the superoxide production of the cells was significantly enhanced in comparison with that found in cells incubated with TNF alone. Maximum amplification of superoxide production was observed at a concentration of 10^{-12} M PAF.

Several other investigators have reported PAF and TNF interactions *in vitro*. Valone and Epstein (14) have recently demonstrated that PMN stimulated with TNF are able to produce PAF in a biphasic fashion. The autacoid represented in the early peak (1–2 hr) is largely retained intracellularly, whereas the majority of PAF in the late peak (6–8 hr) is released into the medium. Studies by Rola-Pleszczynski (15) also have shown that priming of human PMN for 18 hr at various concentrations of PAF (0.1 fM to 1 μM) markedly enhanced subsequent TNF production in response to interleukin I. Maximum priming activity was observed at 1 pM to 1 nM PAF, which resulted in a 2–3-fold increase in TNF production.

In the present study, PAF had no effect on $O_2^{\cdot-}$ release when it was added to the cells before TNF at the start of the incubation period, and had only a relatively small amplifying effect when it was added before 40 min or after 2 hr (data not shown). The fact that PAF could not influence superoxide production alone and that its more pronounced amplifying effect occurred within the period when TNF induced $O_2^{\cdot-}$ release was maximal indicates that PAF augments TNF dependent $O_2^{\cdot-}$ generation even when TNF produces maximal superoxide output. Although the mechanism remains undefined, $O_2^{\cdot-}$ generation elicited solely by TNF may involve the production and release of endogenous PAF.

The results obtained with PAF antagonists support this hypothesis. The two structurally unrelated antagonists, BN 52021 and BN 52111, not only completely abolished the amplifying effect of PAF, but also partially inhibited the superoxide production evoked by TNF alone. The degree of this inhibition was related to the potency of the compound in antagonizing [^{3}H]PAF binding. The extremely potent PAF related dioxolane-derived antagonist, BN 52111 (IC_{50} 35 nM), reduced TNF induced $O_2^{\cdot-}$ release by 20%, while the less potent ginkgolide PAF antagonist, BN 52021 (IC_{50} 0.25 μM), reduced superoxide production by only 8%. This strongly suggests that TNF elicits PAF production in PMN and that this *de novo* synthesized PAF contributes to the TNF induced $O_2^{\cdot-}$ production *via* a receptor mediated process. Interestingly, a recent study by Sun and Hsueh (16) has also shown that a PAF antagonist inhibits TNF induced effects. These authors found that *in vivo*, the PAF antagonist, SRI 63-119, prevents TNF induced bowel necrosis in the rat.

PAF may have no amplifying effect when added before TNF and only a small effect when added before or after the period of maximum TNF induced $O_2^{\cdot-}$ release, because the phospholipid mediator has a short half-life in the cells. Neutrophils rapidly metabolize PAF to lysoPAF by means of an acetylhydrolase (17), although the precise half-life of PAF in our system remains to be determined. Other *in vivo* studies have found that PAF does not induce amplification when administered before TNF. Heuer *et al.* (18) have shown that pretreatment of mice with

either *S. typhosa* endotoxin or TNF significantly enhanced the mortality induced by PAF. Mortality occurred at doses of PAF, endotoxin or TNF which, given alone, did not significantly affect survival rate; however, the enhancing effect was not observed when PAF was given prior to TNF.

Our results suggest that pertussis toxin-sensitive G proteins are involved in superoxide production. Pretreatment of PMN with the toxin inhibited the amplification of TNF induced superoxide production by low doses of PAF. Recently, TNF has been shown to modulate the activity of guanylate cyclase and adenylate cyclase in human PMN, and to induce an increase in GTP binding and GTPase activity in HL-60 promyelocytic leukemic cells. GTP binding and GTPase activity are sensitive to pertussis toxin (19). The toxin also inhibits TNF induced cytotoxicity in mouse L296 fibroblasts, suggesting the involvement of a GTP binding protein in the TNF induced signalling process. In regard to the increased formation of cAMP in human neutrophil responses (20), one may speculate that the inhibition could at least in part be due to PAF induced amplification. Cholera toxin which induces cAMP production *via* activation of a G_s regulatory subunit, or phosphodiesterase inhibitors such as isobutyl methyl xanthine, antagonize the enhancement by PAF of TNF induced $O_2^{\cdot-}$ production. In addition, incubation of human PMN with TNF inhibits the alkalinization response to PAF, while preincubation with TNF results in an increase in the magnitude of the calcium transients that follow stimulation of the cells with PAF (unpublished observations). Such a phenomenon has already been observed in similar experiments using granulocyte monocyte colony stimulating factor as priming agent (21–23).

The mechanism of the amplification (and priming for low doses of TNF) may involve a modification of the functional state of certain subtypes of G protein, and/or a modulation of intracytosolic cAMP levels related to a decrease in calcium signal threshold. Finally, a similar priming phenomenon has also been found with endotoxin (24), which has been shown to prime PMN for enhanced production of superoxide upon subsequent stimulation, and that endotoxin priming induces a small but significant increase in intracellular PAF. Further stimulation of the primed PMN also produces a marked increase in cell-associated PAF as compared to controls (24). These data are consistent with results obtained in the present study, indicating that endogenous PAF production is an essential component of TNF induced superoxide generation, and suggests a role for the autacoid in the mediation of various agonist-induced cell responses.

In conclusion, an interaction between PAF and TNF is suggested to be involved in the modulation of neutrophil responses and consecutive inflammatory disorders. Although the biochemical mechanisms of priming and amplification remain to be defined, the present study shows that PAF plays an integral role in TNF induced superoxide production and suggests that this process involves several subtypes of G proteins. Furthermore, PAF antagonists may have some therapeutic value in treating conditions where this response is excessive and detrimental.

Protein Kinase C is not Involved in the Desensitization of Platelet Activating Factor Receptor in Rabbit Platelets[1]

Lee-Young Chau
Institute of Biomedical Sciences, Academia Sinica, Nankang, Taipei 11529, Taiwan, Republic of China

Rabbit platelets pretreated with platelet activating factor (PAF) became refractory to further stimulation by PAF. The effect was specific for PAF. In this study, the alteration in the specific agonist binding to PAF receptor in platelets following desensitization was investigated. As revealed by the Scatchard analysis of radioligand binding data, the affinity for specific PAF binding to desensitized platelet membranes was substantially lowered as compared with that to control platelet membranes. Guanine nucleotide triphosphate, which was shown to decrease the affinity of specific PAF binding to platelet membranes, had less effect on the PAF binding affinity to the desensitized preparation. In platelets pretreated with phorbol 12-myristate-13-acetate, the binding affinity of PAF receptor remained unaltered. Pretreatment of platelets with 1-(5-isoquinolinesulphonyl)-2-methylpiperazine, a protein kinase C inhibitor, or neomycin, an inhibitor of the polyphosphoinositide breakdown, failed to prevent the reduction of specific PAF binding affinity following subsequent exposure to PAF. These results suggest that the agonist-induced desensitization of PAF receptor in rabbit platelets is independent of activation of protein kinase C.
Lipids 26, **1076–1079 (1991).**

Platelet activating factor (PAF) is a potent lipid mediator implicated in a variety of pathophysiological states (1). The biological effects of this agent on target cells and tissues are believed to be receptor-mediated. Specific high affinity binding sites for PAF have been identified on various cells and in membrane preparations (2–8). It has been observed that prolonged exposure of cells or tissues to PAF results in the loss of responsiveness to further stimulation by PAF (9–13), which was recognized as a "desensitization" phenomenon. In rabbit platelets, the PAF-induced desensitization was characterized as "homologous" since the desensitized platelets retained the ability to respond normally to other aggregatory agents (9,11,13). The underlying biochemical mechanism for this specific desensitization remains unclear. Recently accumulating evidence has suggested a role for protein kinase C in the down regulation of receptors which are coupled to the phosphatidylinositol signaling pathway (14–16), presumably through phosphorylation of the receptor proteins. Since in platelets pretreated with protein kinase C activator, such as PMA, the inositol phospholipid breakdown and other responses induced by PAF, thrombin and collagen were attenuated markedly (17–22), we asked whether protein kinase C could serve as feed-back regulator in the PAF-induced desensitization of platelets.

In the present study, we demonstrated the conversion of a high affinity state of specific PAF binding to a low affinity state in rabbit platelets following desensitization. Direct activation of protein kinase C by pretreating platelets with phorbol 12-myristate-13-acetate (PMA) did not significantly affect the specific PAF binding sites. Pretreatment of platelets with a potent protein kinase C inhibitor 1-(5-isoquinolinesulfonyl)-2-methylpiperazine (H7) (23), again did not prevent the conversion of the high affinity PAF binding sites to the low affinity binding sites following the prolonged incubation with PAF. Likewise, neomycin, which blocks the turnover of polyphosphoinositides (24), was shown to block the accumulation of inositolphosphates in PAF-activated platelets without affecting the desensitization of PAF receptor. These results indicate that protein kinase C is not implicated in the specific agonist-induced desensitization of PAF receptor in rabbit platelets.

MATERIALS AND METHODS

Materials. [^{3}H]PAF, 1-*O*-[^{3}H]alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (specific activity, 179 Ci/mmol), myo-[^{3}H]inositol (specific activity, 19 Ci/mmol) and [^{3}H]inositolphosphate standards were purchased from Amersham International (Buckinghamshire, England). Unlabeled 1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine (C_{16} PAF), neomycin sulfate, H7 and guanine nucleotide triphosphate (GTP) were obtained from Sigma Chemical Co. (St. Louis, MO). Phorbol 12-myristate-13-acetate (PMA) was from Calbiochem (San Diego, CA).

Preparation of platelet membranes. Rabbit blood was drawn from an ear vein directly into 1/7 volume citrate-dextrose anticoagulant solution and centrifuged at 400 × *g* for 10 min. The platelet-rich plasma was removed and centrifuged at 900 × *g* for 20 min. The sedimented platelets were washed twice with Tyrode's buffer, pH 6.5, containing 0.1 mM EGTA [ethylene glycol *bis*(aminoethyl ether)*N,N,N',N'*-tetraacetic acid] and were finally resuspended in Tyrode's buffer, pH 7.2, at concentration of 1 × 10^9 platelets/mL. Unless otherwise stated, desensitization of platelets was conducted by adding 1 nM PAF into the platelet suspension and incubating at 37°C for 15 min. Bovine serum albumin (BSA) was then added to the platelet suspension at final concentration of 0.5% and the incubation was continued for an additional 2 min. Platelets were pelleted by centrifugation at 900 × *g* for 15 min and washed once with Tyrode's, pH 7.2, containing 0.1 mM EGTA. The control platelets were treated according to the same procedure except that PAF was omitted from the incubation. Platelets were finally resuspended in ice-cold 25 mM Tris-HCl, pH 7.4, containing

[1]Based on a paper presented at the Third International Conference on Platelet-Activating Factor and Structurally Related Alkyl Ether Lipids, Tokyo, Japan, May 1989.

Abbreviations: B_{max}, maximal binding site density; BSA, bovine serum albumin; EDTA, ethylenediaminetetraacetic acid; EGTA, ethylene glycol *bis*(aminoethyl ether)*N,N,N',N'*-tetraacetic acid; GTP, guanine nucleotide triphosphate; H7, 1-(5-isoquinoline sulfonyl)-2-methylpiperazine; HPLC, high performance liquid chromatography; IP_1, inositolmonophosphate; IP_2, inositolbisphosphate; IP_3, inositoltrisphosphate; K_d, dissociation constant; PAF, platelet activating factor; PMA, phorbol 12-myristate-13-acetate; PMSF, phenylmethylsulfonyl fluoride.

5 mM EDTA (ethylenediaminetetraacetic acid) and 0.1 mM phenylmethylsulfonyl fluoride (PMSF) at a concentration of 2×10^9 platelets/mL. Platelet membranes were prepared as described previously (25).

[^{3}H]PAF binding to platelet membranes. Platelet membrane proteins (15–20 μg) were incubated with [^{3}H]-PAF (50 fmol) and various amounts of unlabeled PAF (0–5000 fmol) in 0.5 mL of 25 mM Tris-HCl, pH 7.4, containing 0.1% BSA, 0.1M KCl and 10 mM $MgCl_2$ at room temperature for an hour. At the end of the incubation, membrane-bound [^{3}H]PAF was separated from free radioligand by vacuum filtration on glass fiber filters (Whatman GF/C) followed by rapid washing of the filters with 10 mL of ice-cold binding buffer. The radioactivity remaining on the filters was determined by liquid scintillation spectrometry. All assays were carried out in duplicate tubes. Specific binding was defined as the difference between the total binding and the non-specific binding which was obtained in the presence of 5000 fmol unlabeled PAF. When the incubation was carried out in the presence of [^{3}H]PAF alone, the specific binding activity accounted for 80% of the total binding activity. Analysis of both the filtrate and membrane-associated radiolabeled products by high performance liquid chromatography (HPLC) (25) indicated no degradation of [^{3}H]PAF under the conditions of the binding assay.

Preparation of [^{3}H]inositol-labeled platelets. [^{3}H]Inositol-labeled platelets were prepared according to the method of Morrison and Shukla (26). Prelabeled platelets were incubated with buffer alone, 10 mM neomycin, or 0.2 μM PMA, respectively, at 37°C for 15 min and then stimulated with 1 nM PAF at 37°C for 15 seconds. The reaction was terminated and inositolphosphates were extracted (26) and analyzed by HPLC (27). The extracts were injected onto a nucleosil SB-10 column (25 × 4.6 cm) equilibrated with water. The eluent was increased linearly to 0.7 M ammonium formate (adjusted to pH 3.7 with H_3PO_4) over 10 min. This concentration was held for an additional 2 min and then increased over 11 min to 1.1 M ammonium formate/H_3PO_4. The flow rate was 1.25 mL/min [^{3}H]IP_1, [^{3}H]IP_2 and [^{3}H]IP_3 standards were eluted at 10, 13, and 17 min, respectively (IP_1, inositolmonophosphate; IP_2, inositolbisphosphate; IP_3, inositoltrisphosphate).

RESULTS AND DISCUSSION

Rabbit platelets preincubated with 1 nM PAF at 37°C for 15 min became refractory to further stimulation with the same concentration of PAF (data not shown). The effect of desensitization on specific PAF binding to platelets was investigated. In this study, all the binding experiments were conducted with membrane preparations to avoid the complication of internalization of PAF by intact platelets (28). As shown in Figure 1, Scatchard analysis of the competition binding data revealed two PAF binding sites in rabbit platelets. As noted in previous observations (2,28,29), one of the binding sites is high affinity with low capacity, presumably representing the specific receptor binding for PAF; another type of binding site is low affinity with infinite capacity and is generally considered to be non-specific. Prolonged exposure of rabbit platelets to PAF resulted in a marked decrease in the affinity of the specific PAF binding sites from K_d = 0.78 nM to K_d = 2.73 nM (Fig. 1 and Table 1).

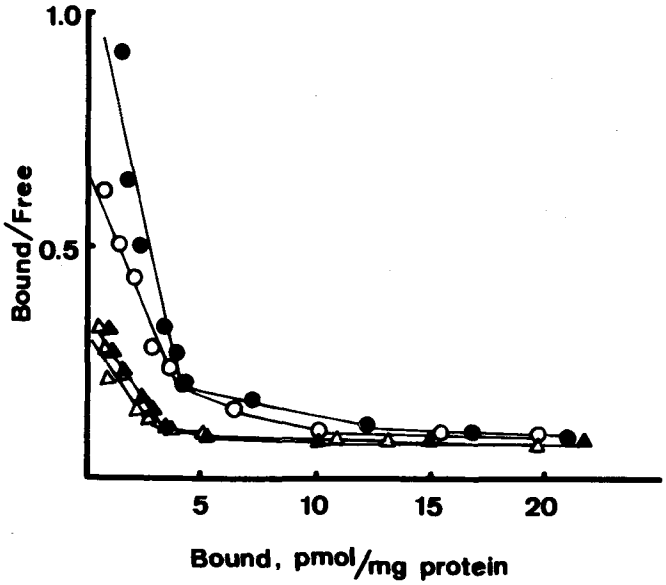

FIG. 1. Scatchard analysis of [^{3}H]PAF binding to control (circles) and desensitized (triangles) platelet membranes in the absence (•,▲) and presence (○,△) of GTP. Specific binding activity of high affinity binding sites was calculated by subtracting the nonspecific binding activity from the total binding.

The receptor density (B_{max}; B_{max} = maximal binding site density), however, was not significantly affected ($p > 0.05$). The observation of decreased agonist binding affinity to PAF-desensitized rabbit platelets was comparable to previous study on desensitized human platelets (11), and indicated the conversion of a high affinity state of the receptor to a low affinity state following agonist-induced desensitization. Recently, several lines of evidence supported the coupling of the PAF receptor to a regulatory GTP-binding protein (G-protein) which, in turn, mediated the PAF-induced polyphosphoinositide hydrolysis and inhibition of adenylate cyclase in platelets (30–32). A PAF-activated GTPase activity was demonstrated in platelet membranes (30–32). Furthermore, the specific PAF binding to rabbit platelet membranes was specifically regulated by guanine nucleotide triphosphate (GTP) (33). As illustrated in Figure 1, when the binding assay was carried out in the presence of 0.1 mM GTP, the binding affinity of the specific PAF binding to the control membranes was substantially reduced. The K_d was shifted to a value which was comparable to that of the desensitized membranes (Table 1). Although the affinity of the desensitized PAF binding sites was also further decreased by GTP, the effect was not statistically significant ($p > 0.05$). In accordance with the previous reports on the decreased PAF-induced GTPase activity in desensitized platelets (31,33), the reduced sensitivity of specific PAF binding to the modulation by GTP suggested the impairment of coupling of PAF receptor to a G-protein after desensitization.

To test whether protein kinase C—which is presumably activated following the hydrolysis of polyphosphoinositides—might be involved in the down regulation of PAF receptor, the effects of protein kinase C activator (PMA) and inhibitor (H7) on the specific PAF binding activity to platelet membranes were examined. As shown in Table 2, activation of rabbit platelets with 1 nM PAF resulted in a rapid accumulation of inositolphosphates.

TABLE 1

Effect of GTP[a] on Binding Parameters of PAF Receptor in Rabbit Platelet Membranes Before and After PAF-Induced Desensitization

	Control membranes		Desensitized membranes	
	−GTP	+GTP	−GTP	+GTP
K_d (nM)	0.78 ± 0.05[b]	2.60 ± 0.43[c]	2.73 ± 0.36[c]	3.77 ± 0.60
B_{max} (pmol/mg protein)	1.90 ± 0.08	1.93 ± 0.09	1.57 ± 0.33	1.46 ± 0.09

[a] [^{3}H]PAF binding assays were performed in the absence or presence of 0.1 mM GTP at room temperature for 1 hr as described in Materials and Methods.

[b] Data presented are the mean ± S.D. of three separate experiments. Significance was determined by paired Student's *t*-test.

[c] $P < 0.025$ for difference from value of control membranes (−GTP).

Effects of PMA and Neomycin on PAF-Induced Formation of Inositolphosphates in Rabbit Platelets

Treatment[a]	[^{3}H]inositolphosphates/cpm (IP_1 + IP_2 + IP_3)
None	2430[b]
PAF	4515
PMA/PAF	2681
Neomycin/PAF	2491

[a] [^{3}H]Inositol-labeled rabbit platelets were pretreated with buffer alone, 0.2 μM PMA or 10 mM neomycin, respectively, at 37°C for 15 min and then stimulated with 1 nM PAF at 37°C for 15 seconds.

[b] Data shown is the representative of two separate experiments with similar results.

TABLE 3

Effects of H7, PMA and Neomycin on PAF-Induced Desensitization of PAF Receptor in Rabbit Platelet Membranes

Pretreatment	K_d (nM)	B_{max} (pmol/mg protein)
None	0.80 ± 0.24[c] (n=3)	1.87 ± 0.34 (n=3)
PAF	2.64 ± 0.32[d] (n=3)	1.73 ± 0.25 (n=3)
H7[a]	1.05 ± 0.19 (n=3)	1.70 ± 0.14 (n=3)
H7 + PAF	3.17 ± 0.5[d] (n=3)	1.62 ± 0.19 (n=3)
PMA[b] 0.25 μM	1.14 ± 0.26 (n=2)	2.05 ± 0.35 (n=2)
1.0 μM	1.13 ± 0.35 (n=2)	1.83 ± 0.12 (n=2)
Neomycin[a]	0.87 ± 0.28 (n=5)	1.60 ± 0.28 (n=5)
Neomycin + PAF	2.66 ± 1.0[d] (n=5)	1.92 ± 0.46 (n=5)

[a] Rabbit platelets were preincubated with 200 μM H7 or 10 mM neomycin at 37°C for 15 min prior to the desensitization with buffer alone or 1 nM PAF as described in Materials and Methods.

[b] Rabbit platelets were pretreated with 0.2 μM PMA or 1 μM PMA at 37°C for 15 min. Platelet membranes were then prepared and the [^{3}H]PAF binding activity was determined as described in Materials and Methods.

[c] Data presented are the mean ± S.D. of numbers of experiments indicated in parentheses.

[d] $P < 0.025$ by paired Student's *t*-test for difference from values of PAF-untreated membranes.

It was conceivable that the formation of the other product, diacylglycerol, would lead to the activation of the protein kinase C which, in turn, phosphorylated several platelet proteins and contributed in part to the aggregation of platelets. When rabbit platelets were preincubated with 200 μM H7 at 37°C for 15 min, the aggregation induced by 1 nM PAF was completely abolished (data not shown). Nonetheless, pretreatment of platelets with H7 followed by the prolonged incubation with the same concentration of PAF did not prevent the conversion of the high affinity PAF binding sites to the low affinity binding sites (Table 3), suggesting that protein kinase C is unlikely to be participating in the desensitization of PAF receptor. This was further confirmed by the experiment with PMA. When platelets were pretreated with PMA (0.2 μM) at 37°C for 15 min, the accumulation of inositolphosphates following PAF activation was inhibited (Table 2), indicating uncoupling of PAF receptor from the phospholipase C pathway by PMA treatment. However, the specific PAF binding to the PMA-pretreated membranes was not significantly altered as compared with that to control membranes (Table 3), again suggesting that the PAF receptor is not the site of inhibitory action of protein kinase C. Pretreatment of rabbit platelets with higher concentrations of PMA (1 μM) which would induce the aggregation of platelets to some extent still had no effect on PAF binding acativity to the platelet membranes (Table 3). In an attempt to further explore the relationship between the phosphoinositide turnover and the desensitization of PAF receptor following the activation of platelets by PAF, neomycin, which was known to inhibit the breakdown of polyphosphoinositides by binding to the phospholipid substrates (24), was also employed in present study. As revealed in Table 2, preincubation of platelets with 10 mM neomycin completely blocked the hydrolysis of the polyphosphoinositides in response to PAF stimulation. When neomycin-treated platelets were incubated subsequently with 1 nM PAF at 37°C for 15 min, the decrease in the affinity of specific PAF binding sites was still observed (Table 3), indicating that the desensitization of the PAF receptor is an event distinct from inositol phospholipid turnover.

Taken together, these results clearly demonstrated that protein kinase C is not involved in the agonist-induced desensitization of PAF receptor in rabbit platelets. Since pretreatment of platelet with PMA also resulted in the attenuation of the subsequent cellular events induced by

other aggregatory agents (17-22), it was conceivable that protein kinase C might alter the function of a common target coupling to various receptors. Nevertheless, it would then be puzzling that the protein kinase C activated in PAF-treated platelets did not cause the heterologous desensitization of platelets activated by other agents. More recently, a study (34) has demonstrated that PAF-induced desensitization of platelets also resulted in the decrease in the phosphorylation of several proteins, including a 40K protein which was known to be the target of protein kinase C in activated platelets (35). Whether the protein kinase C also became desensitized in PAF-pretreated platelets is an intriguing question to be answered. Although a recent study with human neutrophils demonstrated that the inhibition of PAF-induced Ca^{2+} transients, as well as degranulation, by a protein kinase C activator was correlated with the down regulation of high affinity PAF receptor (36), it is apparent that the actions of protein kinase C in various cell types are quite different. Previously, a distinct β-adrenergic receptor kinase was shown to be responsible for the homologous desensitization of β-adrenergic receptor (37). Whether a similar mechanism is involved in the agonist-induced desensitization of PAF receptor in rabbit platelets remains to be clarified.

[Received July 27, 1989; Revision accepted June 5, 1990]

A Unique Pool of Free Arachidonate Serves as Substrate for both Cyclooxygenase and Lipoxygenase in Platelets[1]

Françoise Chevy, Claude Wolf and Odile Colard*
URA CNRS 1283, Département de Biochimie, Université Paris VI, 75571 Paris, France

Stimulation of platelets induces a rapid release of arachidonate from specific phospholipids and subsequent remodeling of arachidonate-containing phospholipids. This process is accompanied by transformation of released arachidonate by cyclooxygenase and lipoxygenase enzymes. We addressed the question of whether the cyclooxygenase and the lipoxygenase products originated from the same arachidonate-containing phospholipids. [^{14}C]Arachidonate prelabeled platelets were stimulated by thrombin or by ionophore A 23187. We monitored the cyclooxygenase pathway by following 12-hydroxy-5,8,10-heptadecatrienoic acid [12(S)-HHT] formation and the lipoxygenase pathway by following 12-hydroxy-5,8,10,14-eicosatetraenoic acid [12(S)-HETE] formation and compared specific activities. The data showed that the same pool of released arachidonate can be utilized by either cyclooxygenase or by lipoxygenase. Indeed, the specific activity of both products was identical when both enzymes were acting. Since cyclooxygenase was rapidly deactivated while lipoxygenase continued to be active, the specific activity of 12(S)-HETE became lower than the specific activity of 12(S)-HHT when large amounts of 12(S)-HETE were synthesized. Based on comparison of specific activity between phospholipids and oxygenated products, the pools of arachidonate-containing phospholipids involved in the synthesis of oxygenated products are dependent on the amount of arachidonate released.
***Lipids* 26, 1080–1085 (1991).**

When platelets are stimulated by thrombin or calcium ionophore A 23187, they release eicosanoids which are formed from arachidonate (AA) by initial action of cyclooxygenase and 12-lipoxygenase enzymes. Arachidonate is transformed by cyclooxygenase, *via* cyclic endoperoxides, primarily into thromboxane A_2 and 12-hydroxy-5,8,10-heptadecatrienoic acid [12(S)-HHT] (1–3), and by lipoxygenase into 12-hydroxy-5,8,10,14-eicosatetraenoic acid [12(S)-HETE] (4,5). The first step of the biosynthetic pathway of eicosanoids involves the release of arachidonate from membrane phospholipids (6,7).

The mechanisms involved in the stimulation of platelets by thrombin and by A 23187 are different. Thrombin stimulates polyphosphoinositide hydrolysis leading to intracellular calcium mobilization and protein kinase C activation (reviewed in refs. 8 and 9) whereas A 23187 stimulates the influx of extracellular calcium (10). The lipid changes induced by the two agonists are also different in platelets (11,12).

We have recently compared the specific activity of non-oxygenated arachidonate released from arachidonate radiolabeled platelets stimulated by thrombin to the specific activities of the different classes of phospholipids (13). In the present study, the specific activities of the products of the cyclooxygenase and lipoxygenase pathways released in response to stimulation by thrombin or by A 23187 were examined to determine whether cyclooxygenase and lipoxygenase derivatives originate from the same arachidonate-containing phospholipids. A similar arachidonate labeling strategy was used in both studies and consisted of short labeling periods to obtain a wide range of different specific activities in the phospholipid precursor pools.

MATERIALS AND METHODS

Materials. [1-^{14}C]Arachidonic acid (58 mCi/mmol) and calcium ionophore A 23187 were purchased from CEA (Paris, France) and Boehringer (Mannheim, Germany), respectively. Bovine serum albumin, bovine thrombin, 12-hydroxy-5,8,10-heptadecatrienoic acid [12(S)-HHT], arachidonic acid, phenacyl bromide and triethylamine were purchased from Sigma (St. Louis, MO). BW 755C was obtained from Wellcome Research Laboratories (Beckenham, Kent, U.K.). Gelatin used in Tyrode buffers was purchased from Merck (Darmstadt, Germany). All solvents were high-performance liquid chromatography (HPLC) grade (BDH Chemicals Ltd., Poole, U.K.). 12-Hydroxy-5,8,10,14-eicosatetraenoic acid [12(S)-HETE] was synthesized from arachidonic acid as described by Boynaems *et al.* (14), separated from other hydroxylated products, and repurified by HPLC. The 12(S)-HETE was identified by mass spectrometry. The two standards were quantified from their molar absorption coefficient at 235 nm in ethanol: E = 33400 cm^{-1} for 12(S)-HHT and E = 30500 cm^{-1} for 12(S)-HETE (15).

Methods. Rat platelets were isolated and washed as previously described (12). Washed platelets suspended in Tyrode buffer, pH 6.5, were labeled with arachidonate by incubating them for 30 min with [^{14}C]arachidonate (0.8 μCi/mL of platelets) bound to serum albumin. The labeled platelets were washed twice, resuspended in Tyrode buffer, pH 7.4, and allowed to stand for 20 min at 37°C before stimulation. Platelets were stimulated with 1 unit/mL of thrombin or with 1 μM Ca^{2+} ionophore A 23187. Reactions were stopped by addition of solvents.

Thin-layer chromatography (TLC) analysis of arachidonate derivatives. Chloroform/methanol (1:2, v/v) was added to the platelet suspension and lipids were extracted by the method of Bligh and Dyer (16) after acidification to pH 3.0 with acetic acid. The chloroform layer was dried under N_2, and the residue was spotted

Abbreviations: AA, arachidonate; GPC, *sn*-glycero-3-phosphocholine; GPE, *sn*-glycero-3-phosphoethanolamine; 12(S)-HHT, 12-hydroxy-5,8,10-heptadecatrienoic acid; 12(S)-HETE, 12-hydroxy-5,8,10,14-eicosatetraenoic acid; HPLC, high-performance liquid chromatography; TLC, thin-layer chromatography.

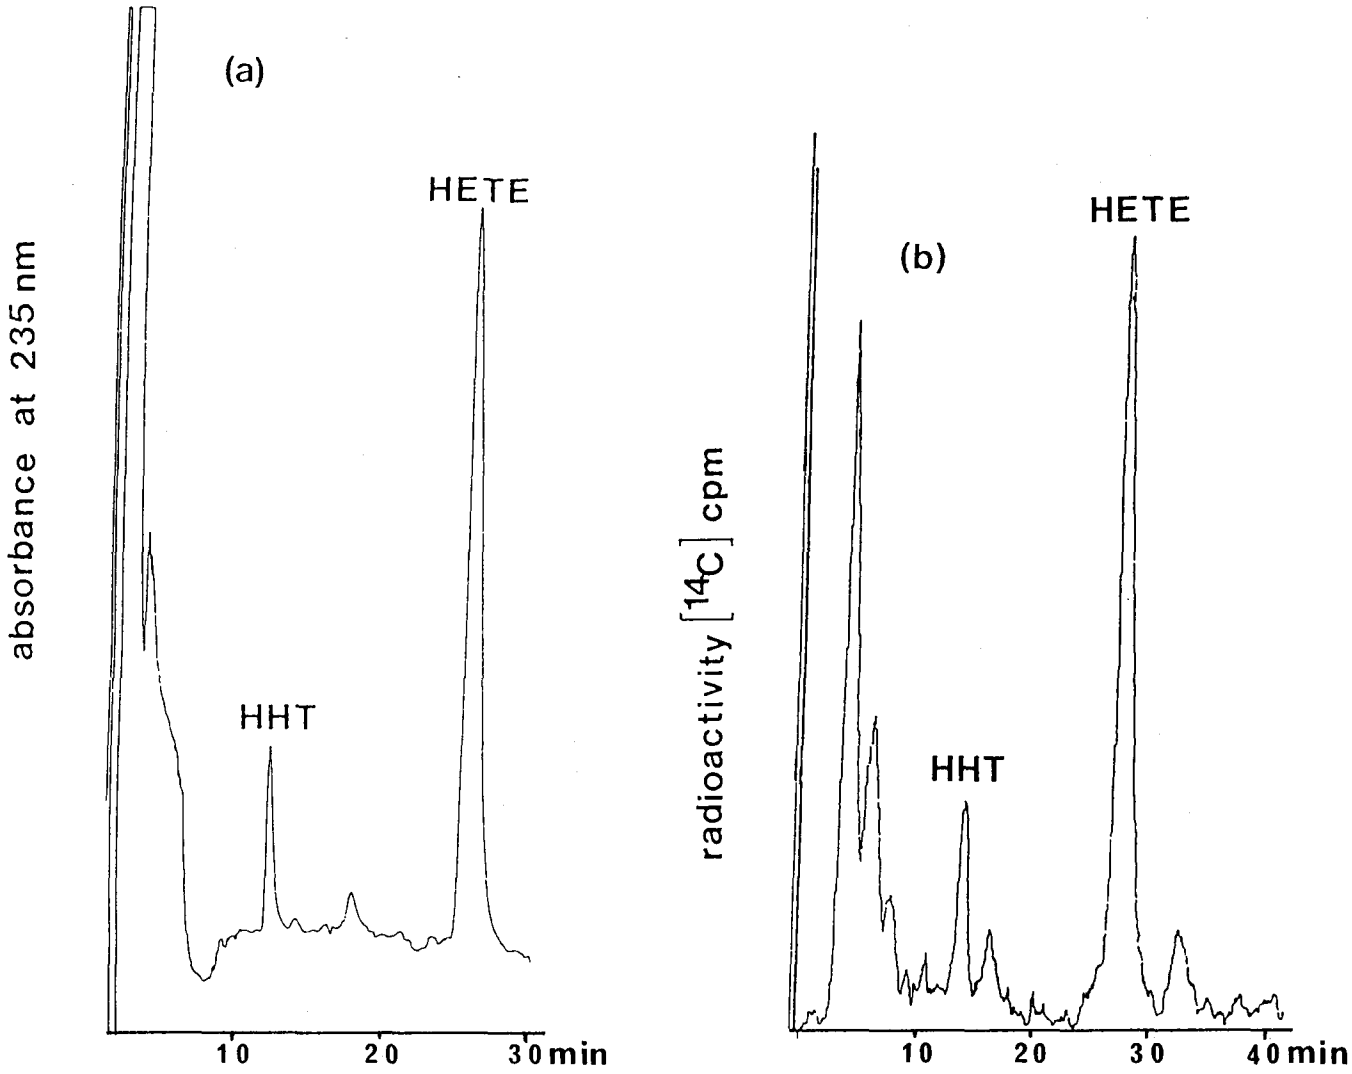

FIG. 1. HPLC analysis of 12(S)-HHT and 12(S)-HETE produced upon rat platelet stimulation. [1-^{14}C]Arachidonate prelabeled platelets (1 mL) were stimulated with A 23187 for 5 min. The reaction was stopped by adding 0.5 mL of methanol, and the mixture was centrifuged. The supernatant, acidified with acetic acid to pH 3.0, was directly injected onto a reverse phase C-18 column and analyzed by isocratic elution (1.2 mL/min) with methanol/water/acetic acid (74:26:1, v/v/v). Absorbance at 235 nm is shown in (a) and radioactivity counted on line is shown in (b).

onto silica gel thin-layer plates, and the plates were developed according to Croset *et al.* (17). A first elution with hexane/diethyl ether/acetic acid (60:40:1, v/v/v) separated arachidonate from 12(S)-HETE and 12(S)-HHT; prostaglandins and thromboxanes remained at the origin together with the phospholipids. A second elution with diethyl ether/methanol/acetic acid (90:1:2, v/v/v) separated thromboxane B_2 from the other compounds.

HPLC analysis of 12(S)-HHT and 12(S)-HETE. Arachidonate derivatives were separated by a slight modification of the method of Borgeat (18). Methanol (0.5 mL) was added to the prelabeled platelet suspension (1 mL). The mixture was allowed to stand for 30 min over ice and was centrifuged at 1600 × *g* for 15 min. The supernatant, which was acidified to pH 3.0 with 5 μL acetic acid, was directly injected into a reverse phase C-18 column (250 × 4 mm, 10 μm particles, Merck). The compounds were eluted with methanol/water, (74:26, v/v; pH 3.0) at a flow rate of 1.2 mL/min. The column was then washed with methanol and re-equilibrated with the elution mixture for 15 min before the next injection. 12(S)-HHT and 12(S)-HETE were quantified by measuring UV absorbance at 235 nm after calibration with standards. The radioactivity corresponding to 12(S)-HHT and 12(S)-HETE was counted on line following HPLC separation, as shown in Figure 1. Alternatively, fractions corresponding to 12(S)-HHT and 12(S)-HETE were collected, and the radioactivity was counted in a scintillation counter. The specific activities of the two hydroxylated compounds were expressed as dpm/nmol.

RESULTS

Preliminary experiments were carried out to determine the different eicosanoids synthesized by rat platelets, and their amounts were compared to total arachidonate re-

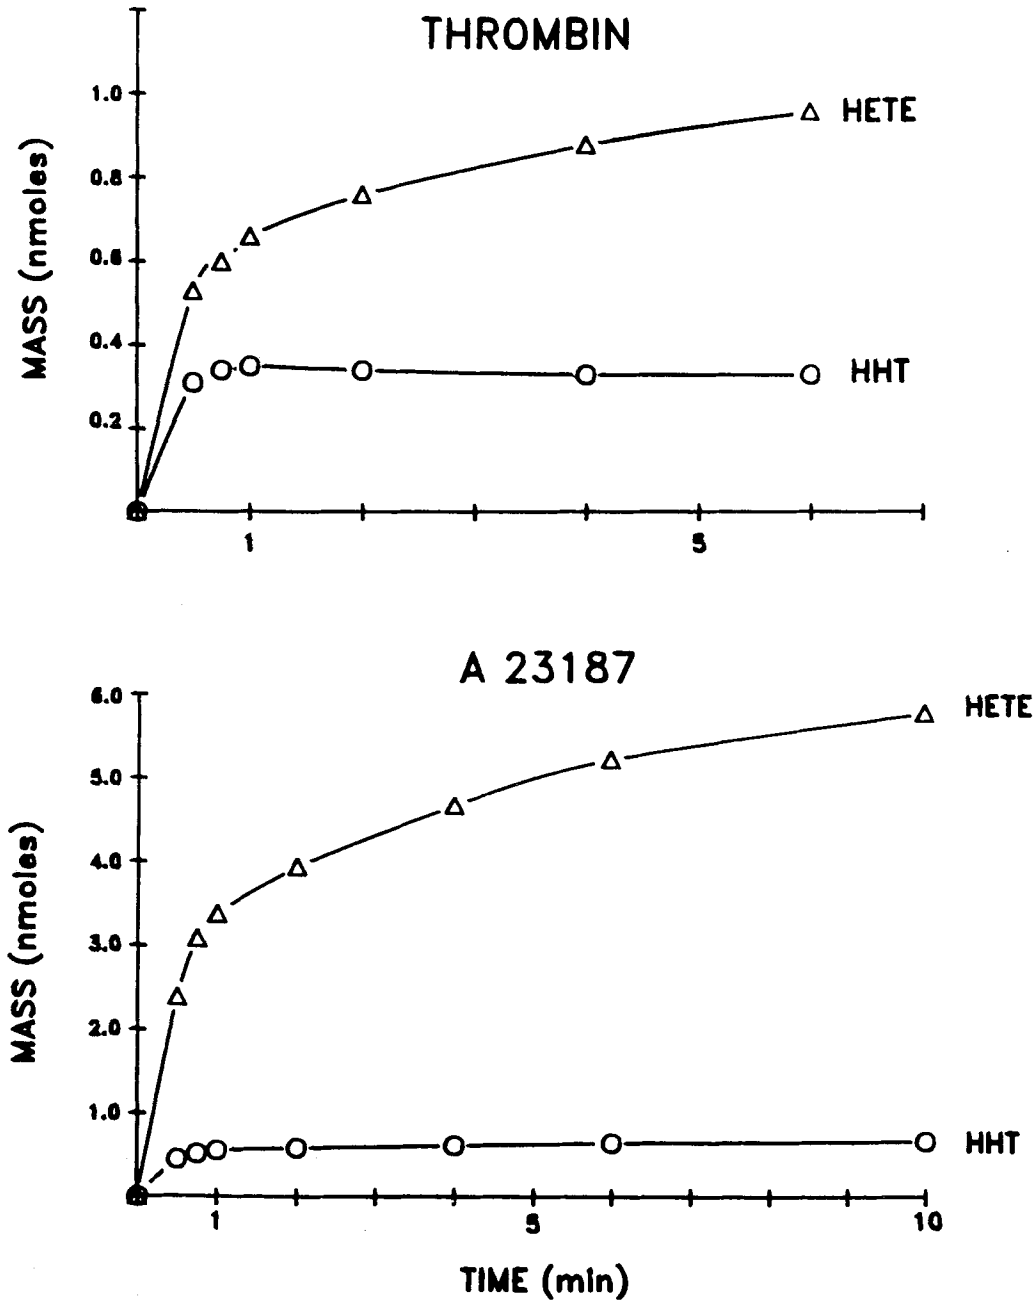

FIG. 2. Time dependence of 12(S)-HHT and 12(S)-HETE synthesis following platelet stimulation. The platelet suspension was challenged with 1 unit/mL of thrombin or with 1 μM A 23187 as described in Materials and Methods. 12(S)-HHT and 12(S)-HETE, separated by HPLC as in Figure 1, were quantified based on their absorbance at 235 nm. The data are from one platelet preparation and are representative of three other experiments.

leased from phospholipids. [^{14}C]Arachidonate prelabeled platelets were stimulated with thrombin or with Ca^{2+} ionophore A 23187; then the lipids were extracted, and the arachidonate derivatives were separated from arachidonate and from phospholipids by TLC. In the solvent system used four main radioactive fractions were detected whose R_f values corresponded to those of 12(S)-HHT, arachidonic acid, 12(S)-HETE and thromboxane B_2 (19). The non-oxygenated [^{14}C]arachidonate represented only 10.3 ± 2.9% of the total radioactively labeled arachidonate released from the phospholipids, whether the platelets were stimulated with thrombin or with A 23187. Therefore, most of the arachidonate released from phospholipids was transformed by the cyclooxygenase pathway leading to thromboxane B_2 and 12(S)-HHT, or by the lipoxygenase pathway leading to 12(S)-HETE.

The specific activities of 12(S)-HETE and of 12(S)-HHT were compared to determine whether biosynthesis of cy-

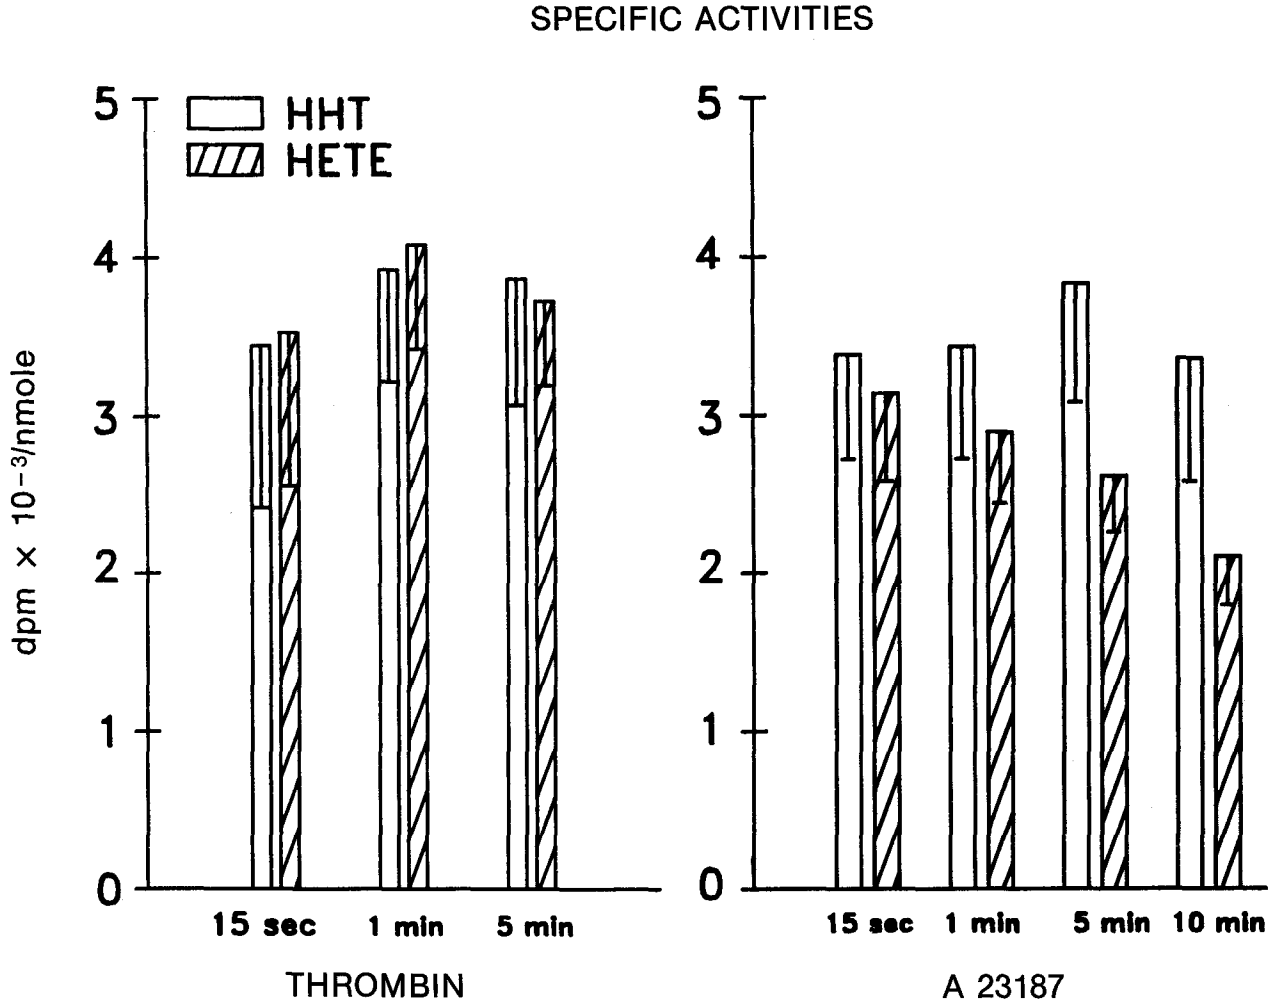

FIG. 3. Specific activities of 12(S)-HHT and 12(S)-HETE as a function of stimulation time. Prelabeled platelets were treated as in Figure 2. The fractions corresponding to 12(S)-HHT and 12(S)-HETE were collected and counted. The data are the mean ± SE of four different experiments.

clooxygenase and lipoxygenase products was linked to specific phospholipid pools. Figure 1 shows a typical HPLC separation of 12(S)-HHT and 12(S)HETE derived from the acidified supernatant of stimulated platelets; radioactivity and absorbance patterns are shown in a and b, respectively.

The kinetics of 12(S)-HHT and 12(S)-HETE synthesis upon stimulation are shown in Figure 2. The production of 12(S)-HHT almost reached the maximum as early as 30 seconds after stimulation with thrombin or with A 23187. In contrast, 12(S)-HETE synthesis increased rapidly until 1 min, and then at a slower rate up to 10 min. The amounts of the two compounds formed upon stimulation of platelets with A 23187 were always higher than upon stimulation with thrombin. In addition, the ratios between 12(S)-HHT and 12(S)-HETE differed depending on the stimulus. The amount of 12(S)-HETE was two-fold the amount of 12(S)-HHT following 5 min of platelet stimulation by thrombin; and six-fold the amount upon stimulation by A 23187.

The specific activities of 12(S)-HHT produced following stimulation with thrombin and A 23187 were not significantly different and did not vary until 10 min (Fig. 3). The specific activities of 12(S)-HETE and 12(S)-HHT were identical after thrombin stimulation and after 15 seconds of A 23187 stimulation. In contrast, the specific activity of 12(S)-HETE was significantly lower than that of 12(S)-HHT after 1 min of A 23187 stimulation, and continued to decrease until 10 min.

The decrease in the specific activity of 12(S)-HETE appeared to be correlated with massive formation of 12(S)-HETE as shown in Figure 4. When the amount of 12(S)-HETE produced was lower than 2 nmol/10^9 platelets, its specific activity was not significantly different from 12(S)-HHT, and this is consistent with the relatively low amount of 12(S)-HETE synthesized when platelets were

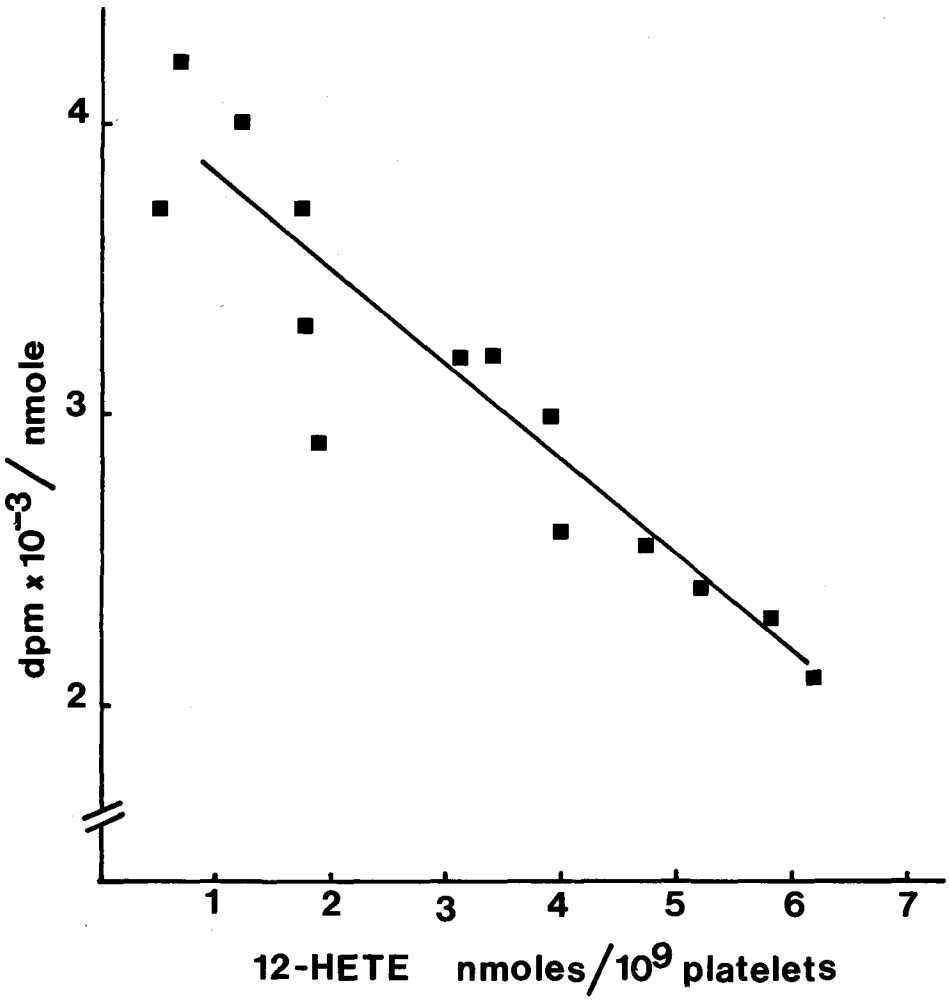

FIG. 4. Correlation between the amount of 12(S)-HETE synthesized and its specific activity. The specific activity of 12(S)-HETE, following stimulation with thrombin or A 23187, is reported as a function of the mass production of 12(S)-HETE. The values are from one experiment.

stimulated with thrombin. The amount of 12(S)-HETE produced upon A 23187 stimulation was higher than 3 nmol/10^9 platelets. Thus, the specific activities of 12(S)HHT and 12(S)-HETE produced after 1 min of stimulation with the ionophore differed.

DISCUSSION

We had previously observed that the specific activity of total arachidonate released by rat platelets stimulated with thrombin remained unchanged for 5 min (13). The total arachidonate was measured in the presence of BW 755C, an inhibitor of both cyclooxygenase and lipoxygenase in platelets. In the present work, the specific activities of 12(S)-HHT and of 12(S)-HETE were compared to determine whether the arachidonic acid available for the cyclooxygenase or for the lipoxygenase originated from the same pool of arachidonate-containing phospholipids. 12(S)-HHT is a side product of the cyclooxygenase reaction and absorbs in the UV range. Its release has been shown to parallel the release of thromboxane B_2 in human platelets (20). 12(S)-HETE is the major product of the lipoxygenase pathway in platelets and also absorbs in the UV range. The specific activities of the two compounds can be determined after HPLC separation from the same sample.

Our data show that the same pool of arachidonate released from platelet phospholipids appears to be available for the synthesis of both compounds. There was no significant difference between the specific activities of 12(S)-HHT and 12(S)-HETE when platelets were stimulated with thrombin for 5 min or with ionophore A 23187 up to 30 seconds. This greatly favors the hypothesis that the cyclooxygenase and lipoxygenase pathways are not preferentially linked to a particular pool of arachidonate-containing phospholipids, although cyclooxygenase activity is found in the intracellular membrane system (21,22), while lipoxygenase activity is mainly located in the cytosol (23,24). In addition, the hypothesis of a unique pool of arachidonate available for cyclo-

oxygenase and lipoxygenase is consistent with the increased synthesis of lipoxygenase derivatives when inhibitors of the cyclooxygenase pathway are used (25).

In accordance with the self-deactivation of cyclooxygenase observed by others (26), the maximum biosynthesis of 12(S)-HHT was reached rapidly, whereas 12(S)-HETE biosynthesis increased more steadily. 12(S)-HETE biosynthesis proceeded at a higher rate following A 23187 stimulation than following thrombin stimulation. The specific activity of 12(S)-HETE decreased and was significantly lower than the specific activity of 12(S)-HHT 1 min after platelets were challenged with ionophore A 23187. Then, a decrease in the specific activity of 12(S)-HETE was observed when cyclooxygenase was no longer active and when 12(S)-HETE was synthesized by lipoxygenase in large amounts. Moreover, the decrease in the specific activity of 12(S)-HETE correlated with the amount of 12(S)-HETE released. This may very well be related to the recruitment of phospholipid pools with slower and slower turnovers.

We have previously shown that the specific activity of total arachidonic acid released when platelets were stimulated with thrombin corresponded to the specific activity of alkyl-arachidonoyl-GPC (13). In contrast with other cells where only a fraction of the released arachidonate is transformed (27-29), most of the arachidonate released from rat platelets, as well as from human platelets (20), was transformed into oxygenated derivatives. Moreover, under conditions where a small amount of arachidonate was released (stimulation by thrombin or a short challenge by A 23187), 12(S)-HHT and 12(S)-HETE had identical specific activities. Therefore, the specific activity should correspond to the specific activity of alkyl-arachidonoyl-GPC. Chilton (29) also observed such a correlation between the specific activity of alkyl-acyl-GPC and leukotriene B_4 in human neutrophils in which only 10-30% of the arachidonate released after challenge by A 23187 was converted to leukotrienes. However, alkyl-arachidonoyl-GPC cannot account for the total amount of the arachidonate released after thrombin stimulation; diacyl-GPE, following arachidonate transfer from diacyl-GPC, is probably also involved in supplying the arachidonate available for the synthesis of oxygenated derivatives (13). Moreover, the present results suggest that hydrolysis of pools of arachidonate-containing phospholipids with a lower specific activity, such as alkenyl-acyl-GPE, has to occur and does account for the decrease in the specific activity of 12(S)-HETE when large amounts of arachidonate were released. This is in accordance with the hydrolysis of diacyl-GPE and alkenyl-acyl-GPE observed upon A 23187 stimulation of endothelial cells labeled at equilibrium with arachidonate (27).

In summary, depending on the stimulus used and the amount of arachidonate released, different pools of arachidonate-containing phospholipids may be mobilized. The arachidonate originating from the initial pool can be oxygenated by both cyclooxygenase and lipoxygenase. Further pools with a lower specific activity are mobilized after cyclooxygenase is self-deactivated but lipoxygenase continues to synthesize 12(S)-HETE.

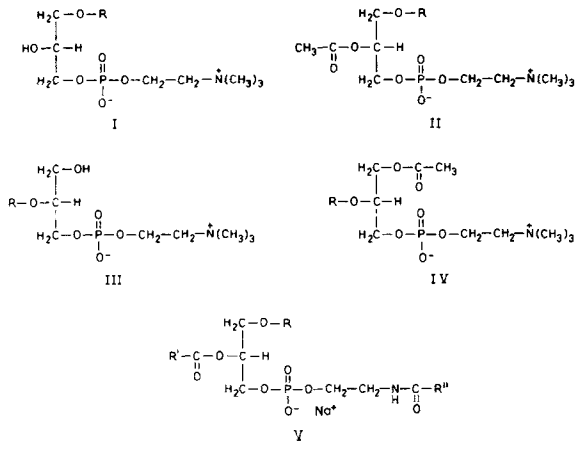
REVIEW

Biotransformation of Alkylglycerols in Plant Cell Cultures: Production of Platelet Activating Factor and Other Biologically Active Ether Lipids[1,2]

Helmut K. Mangold, Shashank S. Apte[3] and Nikolaus Weber*
Federal Center for Lipid Research, Institute for Biochemistry and Technology, H.P. Kaufmann-Institute, D-4400 Münster, Germany

Plant cells in culture are capable of incorporating exogenous 1-*O*-alkyl-*sn*-glycerols into various neutral and ionic ether lipids. 1-*O*-Alkyl-2-acyl-*sn*-glycero-3-phosphocholines, the major class of compounds thus formed, are used for the preparation of platelet activating factor (PAF) in high yields. Similarly, the prochiral 2-*O*-alkyl-*sn*-glycerols are transformed to chiral 2-*O*-alkyl glycerophospholipids from which compounds can be obtained that exhibit antiviral activity in plant and animal cells. Reaction of 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholines with phospholipase D in the presence of ethanolamine leads to 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphoethanolamines, which serve as starting material for the preparation of 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phospho-(*N*-acyl)ethanolamines, compounds known to have antitumor activity.
***Lipids* 26, 1086–1092 (1991).**

Plant cells in suspension culture rapidly absorb lipophilic compounds from the medium and incorporate them into lipid constituents of various organelles. This forms the basis for the use of plant cell cultures in the biotechnological production of fairly complex lipids from simple precursors.



Ether lipids that do not occur in plants can be prepared by biotransformation of synthetic alkylglycerols in cell suspension cultures of rape (*Brassica napus*), soya (*Glycine max*) and other plants. 1-*O*-Alkyl-2-acyl-*sn*-glycero-3-phosphocholines, the major lipids formed by incubating *rac*-1(3)-*O*-alkylglycerols with such cell suspension cultures, serve as starting materials for the semisynthesis of some ether lipids of great current interest and high value. A few "unnatural" ether lipids that are biologically active can be prepared similarly from 2-*O*-alkyl-1-acyl-*sn*-glycero-3-phosphocholines, compounds formed by incubating 2-*O*-alkyl-*sn*-glycerols with cell suspension cultures of higher plants.

The present review summarizes our recent studies which have led to the production of a series of biologically active ether lipids whose structures are shown in Scheme 1. In addition, this article includes some pertinent experimental procedures.

The isolation of ionic ether lipids from plant cell cultures can be a rather tedious task as these substances occur predominantly in the cell membranes. Thus, the amounts of biologically active ether lipids that can be obtained by semisynthesis following this technique are typically small. Plant cell cultures are nevertheless of great value, especially if radioactively labelled chiral compounds are to be prepared. We venture to predict that in the future, immobilized plant cells as well as isolated enzymes will be found useful in the preparation of ether lipids in larger amounts.

PLANT CELL CULTURES

The techniques used in work on plant cell cultures resemble those employed in microbiology (1,2), they are easy to learn (3,4). Cells or sterile sections of plant tissue are incubated on a sterile solid medium contain-

SCHEME 1. Chemical structures of classes of ether phospholipids that were prepared using photomixotrophic cell suspension cultures of rape. Abbreviations: EDTA, ethylenediaminetetraacetic acid; lysoPAF, 1-*O*-alkyl-*sn*-glycero-3-phosphocholines; PAF, platelet activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholines; PNAE, plasmanyl-(*N*-acyl)ethanolamines, 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phospho-(*N*-acyl)ethanolamines; TLC, thin-layer chromatography.

ing agar, sucrose as the major source of 'organic carbon', small proportions of auxins plus a number of inorganic salts as sources of nitrogen and phosphorus as well as trace elements (5,6).

Plant cells grown on a solid medium form a callus which is divided every four to six weeks, and each of the resulting parts is placed on fresh medium. Alternatively, aliquots of such callus cultures can be transferred into liquid media in which they grow as cell suspension cultures under continuous shaking. Aliquots of these cultures are transferred to fresh medium every two to three weeks.

Heterotrophic callus cultures and cell suspension cultures use organic compounds such as sucrose as sources of carbon; they are grown in the dark, the latter under shaking. Photomixotrophic callus cultures and cell suspension cultures use both organic compounds and carbon dioxide as sources of carbon; they require light, and the suspension cultures must be shaken. Photoautotrophic cell suspension cultures use carbon dioxide as the sole source of carbon; they require light and continuous shaking.

LIPIDS IN PLANT CELL CULTURES

The lipid contents, the proportions of lipid classes as well as their fatty acid patterns depend predominantly on the mode of carbon supply, the light conditions, and the age of the cultures (7–9).

Heterotrophic cell suspension cultures contain lipids in amounts between 15 and 50 mg/g dry weight. Photosynthetically active cultures have much larger amounts of lipids than heterotrophic ones. Thus, photoautotrophic cell suspension cultures contain lipids in amounts between 50 and 120 mg/g dry weight.

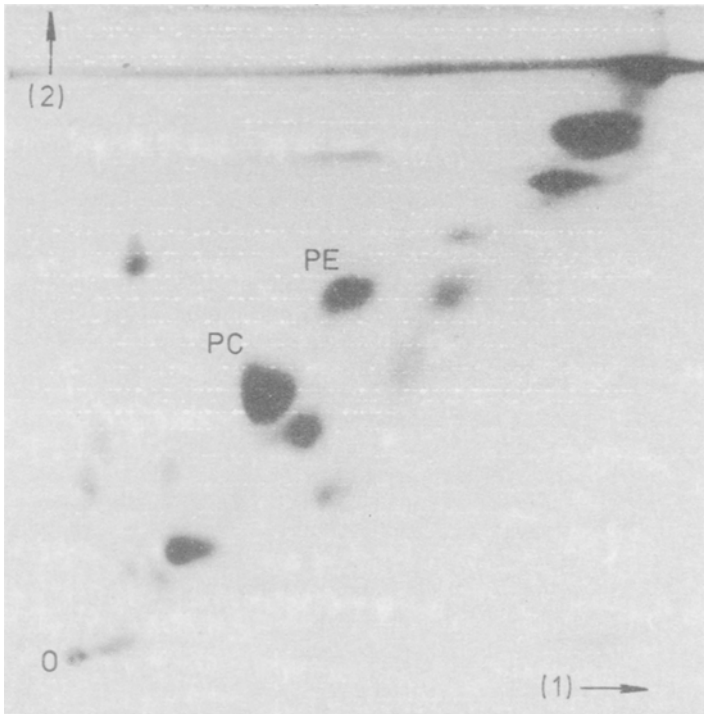
The lipid classes found in plant cell cultures are the same as those occurring in various parts of intact plants. In the exponential phase of growth, the total lipids of heterotrophic cell suspension cultures consist predominantly of phospholipids. After one week, diacylglycerophosphocholines, diacylglycerophosphoethanolamines, and diacylglycerophosphoglycerols occur at levels of about 3, 1.5 and 0.1 mg/g dry weight. Glycolipids are found in even smaller amounts. In the stationary phase, i.e., after two to four weeks of growth, sterols and complex lipids containing sterols predominate. In the exponential phase of growth, the total lipids of photosynthetically active cell suspension cultures produce much larger amounts of phospholipids and glycolipids than those of heterotrophic ones. After one week, photoautotrophic cell suspension cultures contain diacylglycerophosphocholines, diacylglycerophosphoethanolamines, and diacylglycerophosphoglycerols at levels of about 8, 4, and 2 mg/g dry weight. Glycolipids are found in even larger amounts. In the stationary phase, i.e., after two to four weeks of growth, sterols and complex lipids containing sterols predominate.

The major constituent fatty acid of the various acyl lipids in heterotrophic cell suspension cultures is linoleic acid, whereas in photomixotrophic and photoautotrophic cultures linolenic acid predominates.

BIOTRANSFORMATION OF ALKYLGLYCEROLS IN PLANT CELL CULTURES

Cell suspension cultures of different plants are capable of incorporating exogenous 1-*O*-alkyl-*sn*-glycerols as well as 2-*O*-alkyl-*sn*-glycerols into more complex compounds, especially phospholipids, although ether lipids do not occur in cells of higher plants. The proportions of complex lipids in the cultures is not markedly influenced by incubating them with such precursors. The proportions of various lipid classes also remain about the same as shown in Figure 1. Yet, most classes of glycerolipids isolated from cells that had been incubated with alkylglycerols consist of two subclasses, the endogenous neutral and ionic 1,2-diacylglycerolipids and the corresponding 1-*O*-alkyl-2-acyl- or 2-*O*-alkyl-1-acylglycerolipids, respectively.

The major neutral ether lipids formed by incubating cell suspension cultures with 1-*O*-alkyl-*sn*-glycerols (11–14) or 2-*O*-alkyl-*sn*-glycerols (14,15) are the various alkylacylglycerols, whereas alkyldiacylglycerols are found in trace amounts. The predominant components are ionic lipids, however, especially the 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholines and 2-*O*-alkyl-1-acyl-*sn*-glycero-3-phosphocholines, respectively (Scheme 2). Alkylacylglycerophosphoethanolamines and other ether phospholipids are formed in much smaller proportions.



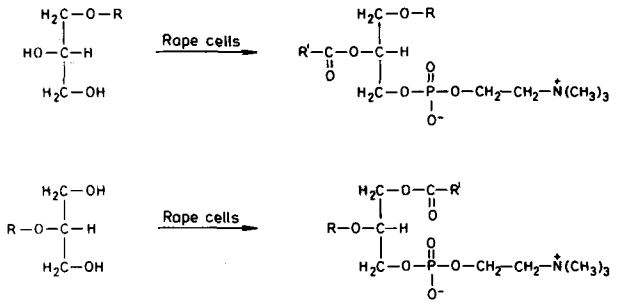


FIG. 1. Thin-layer chromatogram of the total lipids extracted from a photomixotrophic cell suspension culture of rape that had been incubated with *rac*-1(3)-*O*-hexadecylglycerol for three days. Adsorbent: Silica gel H (Merck). Solvents: Chloroform/methanol/conc. ammonia (13:7:1, v/v/v) (1st direction); acetone/ethanol/acetic acid/water (5:2:1:1, v/v/v/v) (2nd direction) (10). Fractions were detected by charring after spraying the plate with chromic-sulfuric acid solution. The cell suspension culture was 10 days old, its chlorophyll content was 1.0 mg/g dry weight. PC, diradylglycerophosphocholines; PE, diradylglycerophosphoethanolamines.

SCHEME 2. Preparation of starting material for the semisynthesis of biologically active ether lipids: Biotransformation of *rac*-1(3)-*O*-alkylglycerols to 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholines and of 2-*O*-alkyl-*sn*-glycerols to 2-*O*-alkyl-1-acyl-*sn*-glycero-3-phosphocholines using photomixotrophic cell suspension cultures of rape (R = alkyl; R'-CO-O- = acyl).

When cell suspension cultures are incubated with various *rac*-1(3)-*O*-alkylglycerols, the cells specifically utilize the "natural" 1-*O*-alkyl-*sn*-glycerols from such racemic mixtures for the formation of phospholipids—though at different rates—whereas the "unnatural" 3-*O*-alkyl-*sn*-glycerols are not incorporated (12,14). It is remarkable that plant cells in suspension culture can even transform a 2-*O*-alkyl-*sn*-glycerol, i.e., a prochiral compound, into optically active 2-*O*-alkyl glyceroether lipids (14,15), as illustrated in Scheme 2.

In work aimed at the isolation of biologically active ether lipids, photomixotrophic cell suspension cultures are preferred over heterotrophic ones mainly because of their much higher lipid contents, and they are preferred over photoautotrophic as well as heterotrophic cultures because they grow much faster than the latter two. Data on the incorporation of alkylglycerols into alkylacylglycerols, the major neutral ether lipids, and alkylacylglycerophosphocholines, by far the predominant ionic ether lipids of photomixotrophic cell suspension cultures of rape, *B. napus*, are presented in Table 1.

The extent of biotransformation of 1-*O*-alkyl-*sn*-glycerols to more complex ether lipids is obviously dependent on both chain length and degree of unsaturation of their alkyl chains (14:0 ~ 18:1 > 16:0 > 18:0) (14,16) (Fig. 2). The rates of incorporation of individual 1-*O*-alkyl-*sn*-glycerols from an equimolar mixture of four saturated *rac*-1(3)-*O*-alkylglycerols reflect the substate specificities of enzymes involved in the biosynthesis of various classes of ether lipids (13).

The results of quantitative determination of 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholines and the stereospecific distribution of acyl moieties in these lipid classes of rape cell cultures reveal that 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholines can replace the corresponding natural membrane lipids (i.e., 1,2-diacyl-*sn*-glycero-3-phosphocholines) to an appreciable extent (16,17).

In photomixotrophic rape cells, complex ether lipids are remarkably stable; dehydrogenation of alkyl moieties to 1-alkenyl moieties does not occur and enzymatic cleavage of the ether bond, which leads to the formation of fatty acids, is insignificant (14,16).

Rape cells in suspension culture incorporate up to 3 mg alkylglycerol/g wet weight under the experimental conditions specified in the following procedure.

Incorporation of alkylglycerols into the lipids of rape cells in suspension culture. Procedure (14). Photomixotrophic cell suspension cultures of rape (*B. napus*) are propagated in modified MS-medium (6) containing 1×10^{-6} M 2,4-dichlorophenoxyacetic acid, 1×10^{-6} M 6-benzylaminopurine and 1×10^{-6} M gibberellic acid. The cultures are shaken under continuous illumination at 25°C. After 10 to 14 days, rape cells are collected on sintered glass funnels and washed briefly with distilled water. An aliquot of the cells is used for the determination of dry weight. After drying at 110°C for 3 hr, 10 g wet cells yield about 0.9 g of dry material.

A solution of 25 mg 1-*O*-alkyl-*sn*-glycerol (or 50 mg of *rac*-1(3)-*O*-alkylglycerol or 2-*O*-alkyl-*sn*-glycerol) in 0.125–0.25 mL ethanol is added to about 50 g photomixotrophic rape cells (wet weight) in 150 mL MS-

TABLE 1

Alkylacylglycerols and Alkylacylglycerophosphocholines Isolated from Photomixotrophic Rape Cells Grown in Suspension Culture After Three Days Incubation with Various *rac*-1(3)-*O*-Alkylglycerols or a 2-*O*-Alkyl-*sn*-Glycerol (14)

	Ether lipids isolated[a] (mg/kg wet weight)		
Alkyl chains	Alkylacylglycerols	Alkylacylglycero-phosphocholines[b]	Yield[c] %
1-*O*-Tetradecyl	82	190	8
1-*O*-Hexadecyl	86	96	6
1-*O*-Octadecyl	43	80	4
1-*O*-[(Z)-9'-Octadecenyl]	64	233	9
2-*O*-Hexadecyl	73	95	5

[a]In addition, small amounts of 1-*O*-alkyl-2,3-diacyl-*sn*-glycerols, 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphoethanolamines and 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphoglycerols were isolated.

[b]Calculated from the content of 1-*O*-alkyl-*sn*-glycero-3-phosphocholines or 2-*O*-alkyl-*sn*-glycero-3-phosphocholines derived by alkaline hydrolysis from total diradylglycerophosphocholines of rape cells after incubation with *rac*-1(3)-*O*-alkylglycerols or a 2-*O*-alkyl-*sn*-glycerol, respectively.

[c]On the basis of the amount of *sn*-1 or *sn*-2 isomer in the substrate added. Chiral 1-*O*-alkyl-*sn*-glycerols are incorporated in substantially higher yields.

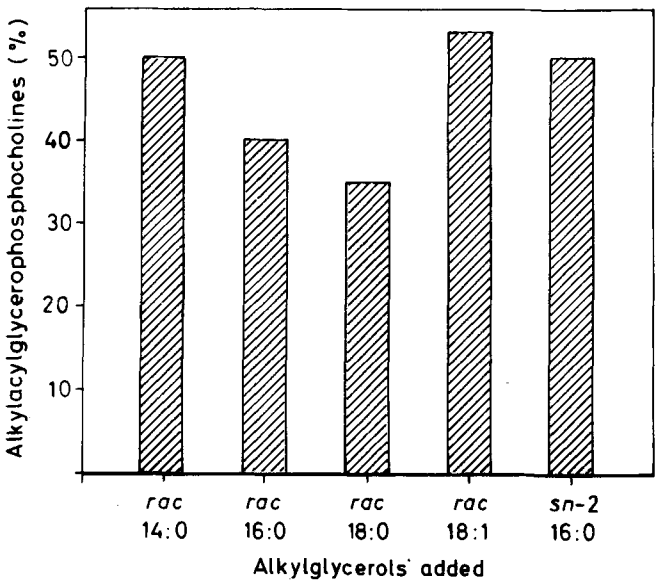

FIG. 2. Proportions of alkylacylglycerophosphocholines in the total diradylglycerophosphocholines of photomixotrophic rape cells grown in suspension culture after three days incubation with various *rac*-1(3)-*O*-alkylglycerols or a 2-*O*-alkyl-*sn*-glycerol (16).

medium on days 7, 8, and 9 (each) of growth. On day 10 the cells are collected by suction on a sintered glass funnel and washed briefly with distilled water. The lipids are extracted with hot isopropanol and chloroform/methanol following an established procedure (18).

The total lipids, about 0.4 g/100 g wet cells, are fractionated by TLC on silica gel H with chloroform/methanol/water (65:25:4, v/v/v). The neutral lipids and the diradylglycerophosphocholines are each eluted with chloroform/methanol/water (5:10:4, v/v/v) (19) and purified by repeated chromatography under the previously described experimental conditions. Chiral purity of the final product is best checked by enzymatic hydrolysis with phospholipase A_2 in combination with TLC analysis (20); yields are given in Table 1.

SEMISYNTHESIS OF ALKYLGLYCEROPHOSPHOCHOLINES (I,III) AND ALKYLACETYLGLYCEROPHOSPHOCHOLINES (II,IV)

The biotransformation of synthetic *rac*-1(3)-*O*-alkylglycerols in cell suspension cultures of rape yields stereochemically pure 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholines having a defined alkyl chain. These substances are eminently suitable as starting materials for the preparation of 1-*O*-alkyl-*sn*-glycero-3-phosphocholines (lysoPAF) (I) and 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholines (PAF) (II). Similarly, the biotransformation of synthetic 2-*O*-alkyl-*sn*-glycerols in cell suspension cultures of rape yields stereochemically pure 2-*O*-alkyl-1-acyl-*sn*-glycero-3-phosphocholines having a defined alkyl chain. These substances are suitable as starting materials for the preparation of 2-*O*-alkyl-*sn*-glycero-3-phosphocholines (III) and 2-*O*-alkyl-1-acetyl-*sn*-glycero-3-phosphocholines (IV). The specific optical rotations of various lysoPAF and PAF prepared by semisynthesis from ether lipids of rape cell cultures are given in Table 2.

TABLE 2

Specific Optical Rotations[a] of Ether Lipids Isolated from Rape Cell Suspension Cultures and Subsequently Derived by Alkaline Hydrolysis or Hydrolysis Followed by Acetylation (14)

1-*O*-[(*Z*)-9′-Octadecenyl]	− 1.1
2-*O*-Hexadecyl	+13.5

[a]Optical rotations of alkylglycerophosphocholines were determined in chloroform/methanol (1:1, v/v), those of alkylacetylglycerophosphocholines in chloroform (c = 1).

The use of cell suspension cultures of higher plants is particularly rewarding in the preparation of chiral ether lipids labelled with an isotope. 1-*O*-[1′-^{14}C]Hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine, for example, can be obtained in an overall yield of 50–60%, based on [1-^{14}C]palmitic acid used as starting material for the synthesis of 1-*O*-[1′-^{14}C]hexadecyl-*sn*-glycerol (21). The specific activity of this precursor is not diminished during its biotransformation in cell suspension cultures of rape because the cells do not contain ether lipids that would lead to isotope dilution. Similar results are obtained in the preparation of 2-*O*-[1′-^{14}C]hexadecyl-1-acetyl-*sn*-glycero-3-phosphocholine (15). Radioactively labelled alkylacylglycerols isolated as by-products can be used for the preparation of additional alkylacylglycerophosphocholines.

The simple procedure described below leads in excellent yields to chemically pure and biologically highly active compounds.

Preparation of lysoPAF (I) and PAF (II). Procedure (14). Diradylglycerophosphocholines, 160 mg (~0.2 mmol) isolated from photomixotrophic rape cells that had been incubated with an alkylglycerol are dissolved in 10 mL of chloroform/methanol (2:1, v/v) and deacylated by alkaline hydrolysis with 5 mL of 0.33 N methanolic potassium hydroxide solution for 1 hr at room temperature. The reaction mixture is neutralized by addition of 3 mL of ethyl formate, stirred for 15 min at room temperature, and diluted with 8 mL of chloroform/methanol (2:3, v/v). After the addition of 6 mL of water, the chloroform phase is collected, the aqueous-alcoholic phase is extracted with two portions of 10 mL chloroform each, and the chloroform solutions are

SCHEME 3. Preparation of 1-*O*-alkyl-2-palmitoyl-*sn*-glycero-3-phospho-(*N*-palmitoyl)ethanolamines (PNAE) by incubating photomixotrophic cell suspension cultures of rape with *rac*-1(3)-*O*-alkylglycerols followed by enzymatic and chemical reactions. R = Tetradecyl, hexadecyl or (*Z*)-9-octadecenyl; PNAE containing a 1-*O*-octadecyl moiety is obtained by catalytic hydrogenation of the corresponding unsaturated compound; R'-CO-O- = acyl; $C_{15}H_{31}$ CO-O- = palmitoyl.

combined. The chloroform is distilled off in a rotary evaporator and traces of water are removed by repeated distillation with chloroform/methanol (2:1, v/v) and chloroform. The residue, dissolved in chloroform/methanol (2:1, v/v) is fractionated by TLC on silica gel H with chloroform/methanol/water (10:5:1, v/v/v). The fraction of lysophospholipids ($R_f \sim 0.2$) is eluted from the adsorbent with chloroform/methanol/water (1:2:0.8, v/v/v); yield of alkylglycerophosphocholine ~ 95%.

After evaporation of the solvents in a rotary evaporator, an aliquot of 50 mg alkylglycerophosphocholine is acetylated by reaction with 2 mL of acetic anhydride/dichloromethane (1:10, v/v) containing 10 mg of 4-(*N',N'*-dimethylamino)pyridine for 1 hr at room temperature. The resulting alkylacetylglycerophosphocholine is purified by TLC on silica gel H with chloroform/methanol/acetic acid/water (14:7:1:1, v/v/v/v). The desired fraction ($R_f \sim 0.2$) is eluted with chloroform/methanol/water (1:2:0.8, v/v/v); yield of alkylacetylglycerophosphocholine (PAF) ~ 95%. The biological activities, defined as 50% of the maximum aggregation of rabbit platelets, were found to be: 1-*O*-tetradecyl PAF, $6.6 \cdot 10^{-11}$ M; 1-*O*-hexadecyl PAF, $2.2 \cdot 10^{-11}$ M; 1-*O*-octadecyl PAF, $5.7 \cdot 10^{-11}$ M; 1-*O*-[(*Z*)-9'-octadecenyl] PAF, $2.6 \cdot 10^{-11}$ M.

SEMISYNTHESIS OF ALKYLACYLGLYCEROPHOSPHO-(*N*-ACYL)ETHANOLAMINES (V)

Stereochemically pure 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholines having a defined alkyl chain are suitable as starting material for the preparation of 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phospho-(*N*-acyl)ethanolamines (V). The sequence of reactions leading from *rac*-1(3)-*O*-alkylglycerols to the desired compounds is shown in Scheme 3.

The biotransformation of *rac*-1(3)-*O*-alkylglycerols in photomixotrophic cell suspension cultures of rape under the previously described experimental conditions yields 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholines. The latter substances are converted to 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphoethanolamines by means of phospholipase D from *Streptomyces chromofuscus* in presence of ethanolamine (22,23). Mild alkaline hydrolysis of the ethanolamine phospholipids thus obtained and the fraction isolated from the total lipids of rape cells followed by acylation of the intermediate lyso compounds, e.g., with palmitic anhydride, yields 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phospho-(*N*-acyl)ethanolamines in which both the *O*-acyl and the *N*-acyl moieties consist of palmitoyl groups.

The procedure described below leads to chemically pure and biologically highly active compounds.

Preparation of PNAE (V). Procedure (24). Diradylglycerophosphocholines, 40 mg (~ 0.05 mmol), isolated from photomixotrophic rape cells that had been incubated with an alkylglycerol are dissolved in 1 mL of chloroform. This solution is combined with a solution of ethanolamine, 150 mg (~ 2.4 mmol) in 3 mL of 0.1 M Tris-HCl buffer, pH 8.0, containing 40 mmol calcium chloride. A solution of 100 U of phospholipase D of *S. chromofuscus* (Boehringer Mannheim, Mannheim, Federal Republic of Germany) in 1 mL of Tris-HCl buffer is added; the two-phase system is shaken vigorously in a Vortex mixer for 30 seconds and then magnetically stirred in a water bath at 35°C. After 2 hr, the base exchange reaction is stopped by the addition of 2 mL 0.1 M Na_2EDTA, the mixture is diluted with 10 mL of chloroform and 7 mL of methanol, and after shaking the chloroform layer is taken off. The aqueous layer is washed twice with 10 mL of chloroform (each) the chloroform layers are combined, and the solvents distilled off in a rotary evaporator. The residue is dissolved in chloroform/methanol (2:1, v/v), and the mixture of diradylglycerophosphoethanolamines and unchanged diradylglycerophosphocholines is resolved by TLC on silica gel H with chloroform/methanol/water (65:25:4, v/v/v). The two fractions are recovered, each, by elution from the adsorbent with chloroform/methanol/water (1:2:0.8, v/v/v). The unreacted diradylglycerophosphocholines of several batches are combined and subjected to the enzymatic reaction once more. Overall yields of diradylglycerophosphoethanolamines range from 65–80%.

The diradylglycerophosphoethanolamines are deacylated by alkaline hydrolysis with 0.33 N methanolic

potassium hydroxide solution and isolated as described in the previous procedure.

About 5 mg (~ 10 μmol) of alkylglycerophosphoethanolamine thus obtained is dissolved in 2 mL of dry chloroform, and 75 mg (0.15 mmol) of palmitic anhydride plus 5 mg of 4-(*N'*,*N'*-dimethylamino)pyridine are added. The solution is shaken in a water bath at 50°C for 8 hr. After evaporation of the chloroform in a rotary evaporator, the desired PNAE (V) is purified by TLC on silica gel H with chloroform/methanol/conc. aqueous ammonia (40:10:1, v/v/v) and eluted from the adsorbent with chloroform/methanol/water (1:2:0.8, v/v/v); yields range from 50–60%. Specific optical rotations of the ammonium salts were determined in chloroform/methanol (1:1, v/v; c = 1):1-*O*-tetradecyl-2-palmitoyl PNAE, $[\alpha]_D^{20}$ + 1.8°; 1-*O*-hexadecyl-2-palmitoyl PNAE, $[\alpha]_D^{20}$ + 1.7°; 1-*O*-octadecyl-2-palmitoyl PNAE, $[\alpha]_D^{20}$ + 1.5°; 1-*O*-[(*Z*)-9'-octadecenyl]-2-palmitoyl PNAE, $[\alpha]_D^{20}$ + 1.5°. 1-*O*-Octadecyl-2-palmitoyl PNAE was prepared by hydrogenation of 1-*O*-[(*Z*)-9'-octadecenyl]-2-palmitoyl PNAE in methanol using a PtO_2 catalyst.

DISCUSSION

Past efforts to produce specific lipids by means of plant cell cultures have not been very successful. Evidently, cell cultures do not contain all the constituents of various parts of a plant from which they are derived. They are capable, however, of transforming certain exogenous precursors to more complex compounds. Thus, as we have shown, plant cells in culture stereospecifically incorporate alkylglycerols into both neutral and ionic ether lipids even though such compounds do not occur in cultured plant cells.

The stereochemically pure alkylacylglycerophosphocholines and -ethanolamines that can be isolated from cell suspension cultures of various plants after incubation with alkylglycerols constitute ideal starting materials for the semisynthesis of various biologically active ether lipids, some of which are difficult to prepare by total synthesis (25). The ether lipids derived from such alkylacylglycerophospholipids by deacylation and reacylation or acetylation are individual compounds. In contrast, ether lipids obtained by semisynthesis from lipid constituents of microorganisms and animal tissues are mixtures of compounds differing in chain length and degree of unsaturation of their alkyl moieties.

Identity and purity of the compounds we obtained using plant cell suspension cultures for the preparation of the chiral starting materials were established by their rates of migration in a number of chromatographic systems, their IR spectra and specific optical rotations as well as chemical and enzymatic reactions (26). The biological effects of these compounds were tested in cooperation with other laboratories.

The activity of PAF obtained by our fairly simple procedure is as high as that of synthetic preparations, or even higher (21). To the best of our knowledge, PAF is the first lipid that could be produced economically using plant cell cultures; this applies particularly to radioactively labelled species. The same is true for ionic ether lipids having the alkyl chain in position 2 of the glycerol backbone. Some of the latter compounds are of interest as antiviral agents (27,28). PNAE, a class of ether lipids exhibiting antineoplastic activity *in vitro* and *in vivo*, has been isolated from degenerating chick embryonal tissues (29). A set of compounds we prepared includes PNAE having a 1-*O*-tetradecyl, 1-*O*-hexadecyl, 1-*O*-octadecyl, or 1-*O*-[(*Z*)-9'-octadecenyl] chain in position 1, an *O*-palmitoyl moiety in position 2 and an *N*-palmitoyl moiety at the polar head group. All of these substances exhibit selective cytolytic effects in human tumor cells (J. Kára, *et al.*, unpublished data).

We found that photomixotrophic cell suspension cultures of rape incorporate exogenous 1-*O*-(1'-alkenyl)-*sn*-glycerols into various classes of 1-*O*-(1'-alkenyl)-2-acyl-*sn*-glycerophospholipids, but yields are low (14). Thus far, we neither succeeded in using cell suspension cultures to effect the biotransformation of *rac*-1(3)-*O*-alkyl-2-*O*-methylglycerols to the corresponding diradylglycerophosphocholines—antineoplastic agents of great current interest (30,31)—nor were we able to incorporate *rac*-1(3)-*S*-alkylglycerols or *rac*-1(3)-*S*-alkyl-2-*O*-methylglycerols into photomixotrophic rape cells.

Algae grow much faster and contain considerably larger proportions of lipids than cell cultures of higher plants. Therefore, we investigated whether *Chlorella fusca*, a green alga, can be used to effect the biotransformation of alkylglycerols to alkylacylglycerophospholipids (32). We found that *C. fusca* is indeed able to utilize synthetic *rac*-1(3)-*O*-alkylglycerols as precursors of neutral and ionic ether lipids, yet the rates of incorporation of alkylglycerols into the algal cells—as observed in tissue slices of higher plants as well (33)—are much lower than in cell suspension cultures of rape and soya.

Paf is a phospholipid mediator present in human skin which induces inflammatory events, such as neutrophil infiltration and increased vascular permeability. Recent data suggest that cutaneous cells, such as fibroblasts and keratinocytes, produce paf and that paf is released during allergic cutaneous reactions. It is tempting to speculate that paf may contribute to the development of various skin disorders with acute and chronic skin inflammation. Paf antagonists may help in bringing answers to this hypothesis and may offer new prospects for the treatment of cutaneous inflammatory diseases.
***Lipids 26*, 1093-1094 (1991).**

Inflammatory reactions commonly observed in human skin have largely been attributed to the action of lipid and peptide mediators, including arachidonic acid metabolites and paf-acether. Paf-acether (paf) first described as platelet-activating factor (1) and later identified as 1-*O*-alkyl-2-*O*-acetyl-*sn*-glycero-3-phosphocholine (2-4) is one of the most potent mediators of acute allergic and inflammatory reactions (5,6). Paf is synthesized by a wide variety of human inflammatory cells including neutrophils, monocytes, macrophages, platelets, eosinophils, and vascular endothelial cells (7).

Paf may also play an important role in the development and maintenance of cutaneous inflammation and in the pathogenesis of inflammatory dermatoses as it produces inflammatory responses in the skin and has been identified in lesional tissue (8,9). For instance, paf has been found in psoriatic scales (10) and has been shown to be associated with primary acquired cold urticaria (11). In human skin, paf is a potent *in vivo* agonist capable of inducing inflammatory events. When locally applied onto human dermis, it increases vascular permeability and neutrophil infiltration (9). When injected intracutaneously, paf elicits a wheal-and-flare response with a perivascular neutrophil infiltrate in normal individuals (8), whereas in allergic patients, a typical hypersensitivity cutaneous reaction occurs associated with an intense eosinophil infiltration (12). Such paf-induced eosinophil recruitment is similar to that induced by antigen in atopic individuals.

By using a skin chamber technique *in vivo*, we recently showed that prolonged contact of allergen with the dermis of atopic volunteers induces appearance of paf and intense eosinophil recruitment (13,14). We also observed that, in response to antigen, paf precursors are released in skin chamber fluids from pollen-sensitive patients. In such patients, paf and its precursors appeared during the late phase of the reaction and persisted for at least 18 hr after the allergen had been removed. The cellular origin of paf is not clear. Inflammatory cells, such as eosinophils, migrating to the inflammatory site in response to the allergen, may produce paf (12,15). Resident cutaneous cells may also synthesize paf. We recently demonstrated that at least two populations of cutaneous cells, one the fibroblasts in the dermis (16), and the other the keratinocytes in the epidermis (17), produce paf in response to calcium ionophore. Addition of lyso paf-acether (lyso paf) to fibroblast cultures enhanced paf synthesis two-fold. By contrast, addition of lyso paf to cultured keratinocytes did not modify paf production. However, acetyl-coenzyme A (acetyl-CoA) did enhance epidermal paf production five-fold. During inflammatory reactions, platelets or neutrophils may carry exogenous lyso paf and/or acetate donors to fibroblasts or epidermal cells, thus increasing the production of paf by these cells.

At the present time, the physiologic signals that induce fibroblasts or epidermal cells to produce paf are unknown. One possibility is that paf production is induced by cytokines present in the skin such as interleukin 1 (IL1). Epidermal cells secrete IL1 in large amounts (18), and IL1 induces paf synthesis in endothelial cells (19) and monocytes (20).

CONCLUSION

The ability of human epidermal cells and human dermal fibroblasts to generate paf provides additional evidence that paf is a mediator of diverse cellular origin including cells not classically designed as proinflammatory. Paf production by skin may contribute to the development of acute inflammation, to the late allergic response, and to the pathophysiology of various inflammatory dermatoses including psoriasis and cold urticaria.

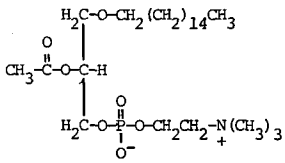
Chemical Synthesis and Physiological Activity of Sulfonium Analogues of Platelet Activating Factor[1]

Morris Kates[a,*], George A. Adams[b], Merle L. Blank[c] and Fred Snyder[c]

[a]Department of Biochemistry, University of Ottawa, Ottawa, Ontario K1N 9B4, [b]University of Ottawa Heart Institute, Ottawa Civic Hospital, Ottawa, Ontario K1Y 4E9, Canada and [c]Medical and Health Sciences Division, Oak Ridge Associated Universities, Oak Ridge, Tennessee 37831

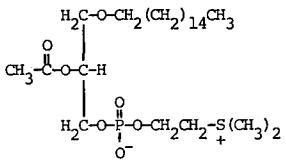
Phosphatidylsulfocholine (PSC), the sulfonium analogue of phosphatidylcholine (PC), occurs naturally in some diatoms. The replacement of the $-\overset{+}{N}(CH_3)_3$ group by a $-\overset{+}{S}(CH_3)_2$ results in an increase in the polar head group size in PSC relative to that of PC, consistent with the observed increase in permeability of PSC bilayers towards urea. It was of interest to see whether replacement of the $-\overset{+}{N}(CH_3)_3$ group in platelet activating factor (PAF) by an $-\overset{+}{S}(CH_3)_2$ group leads to any change in platelet aggregation or other physiological activity. Synthesis of the sulfonium analogue of PAF was carried out by suitable modifications of known procedures. The PAF-sulfonium analogue was found to have almost the same platelet aggregating activity as PAF itself, in the concentration range 1–20 μM, but a much lower activity in the range 0.01–1 μM. The analogue had little or no effect on the platelet aggregation activity of PAF when added in the concentration range 0.01–1 μM and had about half the hypotensive activity of PAF towards hypertensive CDF male rats. The sulfonium analogue, however, was much more cytotoxic to HL-60 cells than PAF itself, in the concentration range 0–15 μM; replacement of the acetate group by a benzyl group increased the cytotoxicity to the level of that of the methoxy analogue of PAF. Thus, replacement of the $-\overset{+}{N}(CH_3)_3$ group by a $-\overset{+}{S}(CH_3)_2$ group in the polar head group region of PAF results in a relatively small change in its platelet aggregation activity and a decrease in its hypotensive activity, but greatly increases its antitumor activity.

Lipids 26, 1095–1101 (1991).



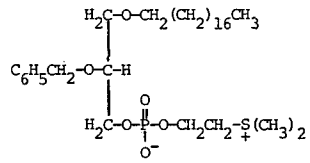
Since the discovery and structure elucidation of platelet activating factor (1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; PAF) considerable information has become available concerning the structure-function relationships of this potent bioactive phospholipid (1,2). The structural features of the PAF molecule shown to be essential for its biological activity (see reviews, refs. 1 and 2) are: i) an ether-linked alkyl group (usually 16:0 or 18:0) at the *sn*-1 position; ii) an acetyl or propionyl group at the *sn*-2 position; and iii) a phosphocholine or phosphoquaternary base group at the *sn*-3 position of the glycerol moiety (Fig. 1).

The effect on PAF activity of replacing the trimethyl ammonium $[-\overset{+}{N}(CH_3)_3]$ group by a dimethyl sulfonium $[-\overset{+}{S}(CH_3)_2]$ group (see Fig. 1) has not previously been studied. When such a replacement is performed on phosphatidylcholine (PC) to form phosphatidylsulfocholine (SC) (3), liposomes of the latter show only minor changes in thermal properties as compared to PC liposomes (4), but the PSC liposomes have appreciably higher permeabilities than PC liposomes in the presence or absence of cholesterol (5,6). Such an effect may be due to the larger volume and lower surface charge density of the sulfocholine group compared to the choline group.



We have therefore synthesized the sulfonium as well as the 2-*O*-benzyl sulfonium analogues of PAF (Fig. 1) by the procedure shown in Scheme 1 and examined the effect of these changes on platelet aggregation, hypotensive activity and cytotoxicity to tumor cells.

MATERIALS AND METHODS



Materials. 1-*O*-Hexadecyl-*sn*-glycerol, 1-*O*-octadecyl-*sn*-glycerol and their racemates were purchased from Sigma Chemical Co. (St. Louis, MO). *Bis*(trichloroethyl)chlorophosphate and triisopropylbenzenesulfonylchloride (TPS) were obtained from Aldrich Chemical Co. (Milwaukee, WI). Sulfocholine tosylate or iodide were synthesized as described elsewhere (3). Authentic PAF (synthetic 1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine) was purchased from Sigma Chemical Co., or from Serdary Research Labs Inc. (London, Ontario, Canada, beef heart preparation). All solvents were glass distilled before use. Pyridine was dried over fresh KOH pellets and used without distillation.

FIG. 1. Chemical structures of PAF (1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine), and PAF sulfonium analogues, 7 (1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphosulfocholine), and 12 (1-*O*-octadecyl-2-*O*-benzyl-*sn*-glycero-3-phosphosulfocholine).

[1]Based on a paper presented at the Third International Conference on Platelet-Activating Factor and Structurally Related Alkyl Ether Lipids, Tokyo, Japan, May 8–12, 1989.

*To whom correspondence should be addressed.

Abbreviations: FAB-MS, fast-atom bombardment mass-spectrometry; GPC, glycerophosphocholine; GPSC, glycerophosphosulfocholine; NMR, nuclear magnetic resonance; PC, phosphatidylcholine; PSC, phosphatidylsulfocholine; TLC, thin-layer chromatography; TMS, tetramethylsilane; TPS, triisopropylbenzenesulfonyl chloride; trityl, triphenylmethyl.

SCHEME 1. Procedures for chemical synthesis of PAF sulfonium analogues.

Chromatography. Thin-layer chromatography (TLC) was carried out on silica gel G precoated plates (Whatman, 20 × 20 cm; 0.25 mm thick for analytical and 0.75 mm thick for preparative use). Solvent systems used were: A, chloroform/methanol/28% NH_4OH (65:35:5, v/v/v); B, chloroform/methanol/water (65:25:4, v/v/v); C, petroleum ether/diethyl ether (70:30, v/v); and D, chloroform/methanol (45:5, v/v).

Physical measurements. ^1H NMR (nuclear magnetic resonance) spectra of $CDCl_3$ solutions of the compounds were measured on a Bruker CXP-300 spectrometer, and chemical shift values (δ) are given as ppm relative to tetramethylsilane (TMS). Positive fast atom bombardment (FAB) and chemical ionization (CI, in source, diethyl ether) mass spectra were obtained on a VG-7070E mass spectrometer.

PAF activity measurement. Platelet aggregating activity was measured in an aggregometer (Payton Instruments, Toronto, Canada) on platelet rich plasma or washed platelets (7) diluted in autologous plasma at a cell concentration of 3×10^8 cells/mL; maximum extent of aggregation during 4 min was measured. Solutions of PAF or PAF analogs in 0.9% sodium chloride were tested against a blank of 0.9% sodium chloride alone over the concentration range 0.001 to 100 μM, and compared with aggregation produced by a standard 0.005% collagen solution.

Hypotensive activity waas measured by recording changes in arterial blood pressure in an 11-month-old CDF male rat after intravenous injection of 10 pmole of PAF or PAF analogs, as described elsewhere (8).

Cytotoxicity of PAF or PAF analogs was assayed as described previously (9), using cultured HL-60 cells grown in serum-free RPMI 1540 medium (9) and measuring cell viability by trypan blue exclusion (10).

Chemical synthesis of PAF analogues (see Scheme 1) *1-O-Hexadecyl-2-acetyl-sn-glycero-3-phosphate* (6). 1-*O*-Hexadecyl-*sn*-glycerol (1; R = 16:0) was tritylated with trityl chloride in anhydrous pyridine as described previously (11), and the product was freed from most of the contaminating tritanol by trituration with low-boiling petroleum ether to yield the 1-*O*-hexadecyl-3-trityl derivative (2, R = 16:0); TLC (solvent C) R_f = 0.57 (still contaminated with some tritanol, tritane and ditrityl ether). The crude trityl derivative 2, without further purification, was acetylated (12) with a ten-fold excess of acetic

anhydride/anhydrous pyridine (1:2, v/v) at 50°C for 2 hr to yield the 1-*O*-hexadecyl-2-acetyl-3-trityl-*sn*-glycerol (3, Rf = 0.88 in solvent C). The latter was then detritylated by passage of its solution in petroleum ether through a silicic acid/boric acid (10:1, w/w) column and elution with petroleum ether/diethyl ether (3:1, v/v), according to the method of Buchnea (13). The resulting product, 1-*O*-hexadecyl-2-acetyl-*sn*-glycerol (4), gave a single spot on TLC (petroleum ether/diethyl ether, 3:2, v/v; R_f = 0.20), corresponding to a 1,2-diacylglycerol standard; only low amounts of the faster-moving (R_f = 0.23) 1,3-isomer could be detected; yield, 70–80% from 3. ^{1}H NMR ($CDCl_3$): 0.86 (terminal CH_3, 3H), 1.24 (alkyl CH_2, ω-1 to C-3, 26H), 1.56 (alkyl C-2, 2H), 2.08 (minor), 2.10 (major) (acetyl CH_3, 3H); 2.48 (C-O$\underline{H}$); 3.42 (O-C$\underline{H}_2$ alkyl, 2H); 3.50 (C$\underline{H}_2$-O, *sn*-1 glycerol, 2H), 3.60 (C$\underline{H}_2$-OH, *sn*-3 glycerol, 2H), 4.95 (C$\underline{H}$-O, *sn*-2 glycerol, 1H) ppm. CI-MS: 359 (M + 1), 341 (M + 1 − H_2O); calcd. for $C_{21}H_{72}O_4$, M = 358.

Compound 4 (R = 18:0) was synthesized in the same way starting from 1 (R = 18:0); yields, TLC mobilities, and NMR spectra were essentially identical to 4 (R = 16:0); CI-MS: 387 (M + 1), 369 (M + 1 − H_2O); calcd. for $C_{23}H_{46}O_4$, M = 386.

Compound 4 (0.17 g, 0.49 mmol) was then reacted with *bis* (trichloroethyl)chlorophosphate (0.2 g, 0.5 mmole) in anhydrous pyridine (2.6 mL) at room temperature, by the procedure described previously (14) and the blocked phosphorylated product (5) was isolated by acidic Bligh-Dyer extraction (12,14); yield of crude 5, 0.46 mmole (95%); TLC (solvent D) R_f = 0.89 (contaminated with some tritylated material). The crude product 5 (0.46 mmole) was then deblocked by reaction with Zn powder (0.27 g) in a mixture of chloroform (2.5 mL) and glacial acetic acid (4 mL) at room temperature for 1 hr, as described elsewhere (14). The product, 1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphate (6), was isolated by acidic Bligh-Dyer extraction and purified by repeated acetone precipitation of the ammonium salt (12,14); yield, 0.15 g (0.32 mmole, 70%); TLC (solvent A) R_f = 0.08 (P-positive) (12). ^{1}H NMR ($CDCl_3$): 0.86 (terminal CH_3, 3 H), 1.23 (alkyl CH_2, ω-1 to C-3, 26 H), 1.50 (alkyl C-2, 2H), 2.08 (acetyl CH_3, 3 H), 3.39 (O-CH_2 alkyl, 2 H), 3.54 (CH_2-, *sn*-1 glycerol, 2 H), 3.90 (CH_2-O-P, *sn*-3 glycerol, 2 H), 5.13 (CH-O, *sn*-2 glycerol, 1 H) ppm. Anal. Calcd. for monoammonium salt monohydrate $C_{21}H_{46}O_7NP{\cdot}H_2O$ (MW 473.59): C, 53.26; H, 10.22; N, 2.96; Found: C, 52.36; H, 10.03; N, 3.17. Negative FAB-MS (mass spectrometry): 437 $(M - NH_3)^-$, 395 (M − NH_3 − acetyl)$^-$; calcd. for $C_{21}H_{46}O_7NP$, M=455. The racemic form of compound 6 (R = 16:0) was synthesized by the same route as for the enantiomeric form (Scheme 1), but starting from *rac*-1-hexadecylglycerol (1, R = 16:0).

The enantiomeric and racemic forms of compound 6 (R = 18:0) were also synthesized by the same route (Scheme 1), but starting from 1-*O*-octadecyl-*sn*-glycerol or *rac*-1-octadecylglycerol (1, R = 18:0), respectively. Yields, TLC mobilities and NMR spectra were identical or very similar to those of 6 (R = 16:0).

*1-O-Hexadecyl-2-acetyl-*sn*-glycero-3-phosphosulfocholine (7; R = 16:0). Compound* 6 (77 mg, 0.16 mmole) was converted to the free acid form by acid Bligh-Dyer extraction (12), mixed with sulfocholine tosylate (0.45 g, 1.6 mmole) and dried overnight *in vacuo* over phosphorus pentoxide; anhydrous pyridine (10 mL) was added and the mixture was stirred at 50°C until clear (1 hr). Trichloracetonitrile (3 mL) was added and stirring was continued at 50°C for 48 hr, following the procedure of Ali and Bittman (15). The clear, dark-colored reaction mixture was brought to dryness under reduced pressure and the residual dark brown oil was partitioned by the acidic Bligh-Dyer procedure (12) to remove pyridine and other water-soluble material. The chloroform phase was concentrated to dryness under reduced pressure and the residual oil was dissolved in methanol/water (95:5, v/v; 2 mL) and passed through a column of mixed-bed ion-exchange resin (Bio-Rad AG 501-X8(D), Bio-Rad Laboratories, Richmond, CA; 9 g], equilibrated in the same solvent. The column was washed with a total of 10 mL of methanol/water (95:5, v/v). Alternatively, treatment with the ion-exchange resin can be done batchwise with filtration and washing of the resin on a sintered glass filter. The combined column washings were diluted with appropriate amounts of chloroform and water to form a two phased mixture (chloroform/methanol/water, 1:1:0.9, v/v/v), and the chloroform phase was diluted with benzene and brought to dryness under reduced pressure; yield 13.3 mg of crude product 7; TLC (solvent A) R_f = 0.18; contains unidentified fast-moving contaminants (R_f = 0.8), but is free of starting material 6.

Further purification was achieved by chromatography of crude 7 (13 mg) on a column of silicic acid (Bio-Sil A, 100–200 mesh; 2.5 g) eluted in succession with 10 column volumes each of chloroform, chloroform/methanol (9:1), chloroform/methanol (1:1) and methanol. The PAF analogue 7 appeared in the chloroform/methanol (1:1) and methanol eluates together with some unidentified contaminants. Pure compound 7 was finally obtained by preparative TLC in solvent A and elution from the silica with chloroform/methanol/water (1:2:0.8, v/v/v), followed by Bligh-Dyer partition (12); yield, 3.4 mg (4%); TLC (solvent A) R_f 0.18 (P-positive) (12); ^{1}H NMR ($CDCl_3$) (Fig. 2), 0.86 (terminal CH_3, 3H), 1.22 (alkyl CH_2-, ω-1 to C-3, 26 H), 1.50 (alkyl C-2, 2 H), 1.78 (H_2O), 2.05 (acetyl CH_3, singlet, 3 H), 3.15 (-$\overset{+}{S}(CH_3)_2$, singlet, 6 H), 3.39 (alkyl CH_2O-, 2 H), 3.55 (CH_2 *sn*-1 glycerol, 2 H), 3.67 (CH_2S, 2 H), 3.94 (CH_2-O-P,*sn*-3 glycerol, 2 H), 4.30 (CH_2-O-P-,sulfocholine, 2 H), 5.12 (-C$\underline{H}$-O-acetyl, 1 H) ppm. Positive FAB-MS: 527 $(M + 1)^+$, 485 $(M + 2 - CH_3CO)^+$; 341 (M + 2 − phosphosulfocholine)$^+$; (calcd. for $C_{25}H_{51}O_7PS$, M = 526).

The 18:0 homologue of compound 7 (R = 18:0) was synthesized by the same procedures as for the 16:0 homologue, but starting from compound 6 (R = 18:0); yields, TLC mobilities and NMR spectra were essentially the same as for 7 (R = 16:0). Positive FAB/MS: 555 $(M+1)^+$, 513 $(M+2-CH_3CO)^+$; 369 (M+2−phosphosulfocholine)$^+$; (calcd. for $C_{27}H_{55}O_7PS$, M = 554).

*1-O-Octadecyl-3-benzyl-*sn*-glycero-3-phosphate* (11). 1-*O*-Octadecyl-*sn*-glycerol (1, R= 18:0) was tritylated as described previously (11) and the crude product, 1-*O*-octadecyl-3-trityl-*sn*-glycerol (2, R = 18:0) was isolated as described above for (2, R = 16:0); TLC (solvent C) R_f = 0.59. Without further purification, the crude trityl derivative was converted to the 1-*O*-octadecyl-2-benzyl-3-trityl-*sn*-glycerol (8) by reaction with benzyl chloride in dry benzene in presence of powdered KOH, as described elsewhere (16); TLC (petroleum ether/diethyl ether, 3:2,

v/v) R_f = 0.67 (crude **8** contains some tritanol and dibenzyl octadecylglycerol). The crude product (**8**) was detritylated by hydrolysis in methanol/water/conc. HCl (18:1:1, v/v/v) and the 1-*O*-octadecyl-2-benzyl-*sn*-glycerol (**9**) was isolated and purified by chromatography on a column of silicic acid as described previously (16); TLC (petroleum ether/diethyl ether, 3:2, v/v) R_f = 0.35. ^{1}H NMR ($CDCl_3$): 0.86 (terminal CH_3, 3H), 1.22 (alkyl CH_2, ω-1 to C-3,30H), 1.52 (alkyl C-2, 2H), 2.15 (C-OH); 3.42 (O-CH_2 alkyl, 2H), 354 (CH_2, *sn*-1 glycerol, 2H), 3.64 (CH_2OH, *sn*-3 glycerol, 2H), 3.75 (CH-O, *sn*-2 glycerol, 1H) 4.65 (benzyl CH_2, 2H), 7.30 (aryl H, 5H) ppm. CI-MS: 435 (M+1), 417 (M+1−H_2O); 343 (M−benzyl); calcd. for $C_{28}H_{50}O_3$, M = 434.

Compound **9** (0.38 g, 0.87 mmole) was phosphorylated with *bis*(trichloroethyl)chlorophosphate (0.36 g, 0.95 mmole) in dry pyridine (3.5 mL), as described elsewhere (14), and the blocked phosphorylated product (**10**) was isolated by acidic Bligh-Dyer extraction (12,14); yield of crude **10**, 0.52 g (77%); TLC (solvent D) R_f =0.80 (P-positive) (12). The crude product **10**, without further purification, was dissolved in chloroform (3.5 mL) diluted with glacial acetic acid (6 mL) and deblocked by treatment with Zn powder (0.4 g) with stirring for 1 hr at room temperature (14). The product 1-*O*-octadecyl-2-benzyl-*sn*-glycero-3-phosphate (**11**) was isolated by acidic Bligh-Dyer extraction and purified by repeated acetone precipitation of the ammonium salt (12,14); yield 92 mg (25%); TLC (solvent A) R_f =0.05 (P-positive) (12). ^{1}H NMR ($CDCl_3$): 0.86 (terminal CH_3, 3 H), 1.22 (alkyl CH_2, ω-1 to C-3, 30 H), 1.50 (alkyl C-2, 2H), 3.36 (alkyl CH_2-O-, 2 H), 3.52 (CH_2-, *sn*-1 glycerol, 2 H), 3.74 (H_2O), 3.96 (CH_2-O-P, *sn*-3 glycerol, 2 H), 4.65 (benzyl CH_2, 2 H), 7.30 (aryl H, 5 H) ppm. ^{13}C NMR ($CDCl_3$): 14.0 (terminal CH_3) 22.6 (ω-1 CH_2), 26.0 (alkyl C-2), 29.6 (alkyl CH_2-, ω-3 to C-3), 32.0 (ω-2 CH_2), 65.0 (CH_2-O-P), 70.5, 71.5 (CH_2-O-CH_2), 77.0 (CH-O-), 128 (phenyl C) ppm. Negative FAB-MS: 513 (M−2NH_4+1)$^-$; 423 (M−2NH_3−benzyl)$^-$; calcd. for $C_{28}H_{57}O_6N_2P$, M = 548.

*1-O-Octadecyl-2-benzyl-*sn*-glycero-3-phosphosulfocholine* (**12**). Compound **11** (73.6 mg, 0.14 mmole) was converted to the free acid form (**12**) which was reacted with anhydrous sulfocholine iodide (61.2 mg, 0.17 mmole) and TPS (45 mg, 0.15 mmole) in anhydrous pyridine (27 mL) with stirring at room temperature for 48 hr. After addition of water (2.5 mL) to hydrolyze any unreacted TPS, the reaction mixture was diluted with benzene and brought to dryness under reduced pressure, and the residue was partitioned by the acidic Bligh-Dyer procedure (12) to remove water-soluble material. The chloroform phase was concentrated *in vacuo* and the residual oil was dissolved in 5 mL of methanol/water, 95:5 (plus 0.1 mL of chloroform) and passed through a column of mixed-bed ion exchange resin [Bio-Rad AG 501-X8 (D), 10 g], followed by elution with 25 mL of methanol/water/chloroform (95:5:5, v/v/v) to remove final traces of starting material **11**, the treatment with ion exchange resin was repeated. The combined eluates were then diluted with appropriate amounts of chloroform and water to form a two-phased mixture and the chloroform phase was diluted with benzene and brought to dryness *in vacuo*. The product **12** (13 mg), now free of compound **11** but still contaminated with fast-moving impurities, was finally purified by repeated acetone precipitation from chloroform solution (0.2–0.3 mL) with 3.5 mL of acetone in the cold. The precipitate of compound **12** now gave only a single spot (P-positive) (12) on TLC; yield, 6.3 mg (7.5%); TLC (solvent A) R_f = 0.25 (standard PAF had R_f = 0.18). ^{1}H NMR ($CDCl_3$): 0.86 (terminal CH_3, 3H), 1.23 (alkyl CH_2, 30 H), 1.55 (alkyl C-2, 2 H), 2.44 (H_2O), 3.06 (−$S(CH_3)_2$, 6 H), 3.42 (alkyl CH_2-O-, 2 H), 3.54 (*sn*-1 glycerol CH_2, 2 H), 3.78 (CH_2S, 2 H), 3.93 (CH_2-O-P, *sn*-3 glycerol, 2 H), 4.19 (CH_2-O-P, sulfocholine, 2 H), 4.68 (Ph-CH_2, 2 H), 7.30–7.34 (aryl H, 5 H) ppm. Positive FAB-MS: 603 (M+1)$^+$; 513 (M+2−$CH_2C_6H_5$); Negative FAB-MS: 587 (M−CH_3)$^-$; 539 [M−$S(CH_3)_2$−1]$^-$; 513 [M+1−$CH_2CH_2S(CH_3)_2$]$^-$; calcd. for $C_{32}H_{59}O_6PS$, M = 602.

RESULTS AND DISCUSSION

Chemical synthesis. Synthesis of the sulfonium analogue of PAF (**7**) was carried out by the following steps (see Scheme 1): i) Tritylation of *rac*- or *sn*-1-*O*-hexadecyl (or octadecyl) glycerol (**1**) to form the respective 3-trityl derivative (**2**), as described previously (11); ii) acetylation of compound **2**, as described elsewhere (12), to form the respective 1-alkyl-2-acetyl-3-trityl-glycerol; iii) detritylation of compound **3** on a column of boric acid/silicic acid by the procedure of Buchnea (13) to form the 1-alkyl-2-acetyl-glycerol (**4**) with little contamination from the isomeric 1-alkyl-3-acetyl-glycerol; iv) Phosphorylation of compound **4** with *bis*(trichloroethyl)chlorophosphate, as described previously (14), to give the 1-alkyl-2-acetyl-glycerol-3-*bis*(trichloroethyl)phosphate (**5**), followed by removal of the trichloroethyl groups by treatment with Zn in chloroform/glacial acetic acid (14) to give the 1-alkyl-2-acetyl-glycero-3-phosphate (**6**)—the latter compound was isolated as the ammonium salt in TLC- and isomerically-pure form, as confirmed by NMR and FAB-MS; v) reaction of **6** with sulfocholine-*p*-toluenesulfonate in dry pyridine in presence of trichloracetonitrile by the procedure of Ali and Bittman (15) or in the presence of TPS (3), to give the expected PAF sulfonium analogue, 1-alkyl-2-acetyl-glycero-3-sulfocholine (**7**).

The 2-*O*-benzyl sulfonium analogue (**12**) was synthesized by essentially the same route, but starting from 1-alkyl-2-benzylglycerol (**9**), which was prepared by benzylation of 1-alkyl-3-tritylglycerol (**2**) followed by detritylation of compound **8**, as described previously (16).

The sulfonium analogues **7** and **12** were obtained in rather low yields (4% and 8%, respectively), due mostly to the poor yield of the sulfocholine condensation reaction (see Scheme 1) and the large losses incurred in isolation and purification of the final products **7** and **12**. Much higher yields have been reported for the synthesis of bulky head group analogues of phosphatidylcholine using trichloracetonitrile as condensing agent (15) and for synthesis of sulfonium analogues of phosphatidylcholine using TPS as condensing agent (3). The low yields with the PAF analogues **7** and **12** may perhaps be attributed to unexplained low reactivity of the 1-alkyl-2-acetyl- or benzyl-glycerophosphates. It is of interest that Bittman *et al.* (17) reported high yields of PAF analogues by carrying out the phosphorylation and base condensation steps in one step, using $POCl_3$ and choline *p*-toluenesulfonate. It might be worthwhile to apply such a strategy to the synthesis of sulfonium analogues of PAF.

However, both PAF analogues 7 and 12 were obtained in TLC- and isomerically-pure form and were shown by NMR (Fig. 2) and mass spectrometry to have the respective PAF sulfonium structure. The ^1H NMR spectrum of 7 (Fig. 2B) showed signals for the 1-*O*-alkylglycerol group (δ, 0.86, 1.22, 1.50, 3.39 and 3.55 ppm), the glycero-3-phosphate group (δ 3.94 ppm), the dimethylsulfonium group [δ 3.15 ppm singlet; cf. the $N(CH_3)_3$ signal in PAF at δ 3.4 ppm; Fig. 2A], the phosphosulfocholine group (δ 4.30 and 3.67) and the 2-acetylglycerol group (δ 2.05 ppm, singlet, and 5.12 ppm), consistent with the structure 1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphosulfocholine (7). The positive FAB-MS spectrum showed a mass peak $(M+1)^+$ at *m/z* 527 (calcd. M = 526) and peaks at *m/z* 485 and 341 attributed to the loss of the acetyl group $(M-acetyl)^+$, and the phosphosulfocholine group, respectively, as expected for compound 7.

The ^1H NMR spectrum of compound 12 (Fig. 2C) showed the same signals as for compound 7, except for the replacement of the acetyl signal by signals attributed to the benzyl group (δ 4.6 and 7.3 ppm), consistent with the structure 1-*O*-octadecyl-2-benzyl-*sn*-glycero-3-phosphosulfocholine. The positive FAB-MS spectrum showed a mass peak $(M+1)^+$ with *m/z* 603 (calcd. M = 602) and a peak with *m/z* 513 $(M+2-benzyl)^+$, as expected for compound 12; negative FAB-MS showed a peak for $(M-CH_3)^-$ at *m/z* 587, and peaks at *m/z* 539 and 513 due to the loss of $S(CH_3)_2$ and $CH_2CH_2S(CH_3)_2$, respectively.

Platelet aggregating activity. The effect of the sulfonium analogue of PAF (7) on platelet agregation using either washed platelets or platelet-rich plasma, compared with the effect of PAF, is shown in Figure 3 and Table 1. The sulfonium analogue 7 had essentially the same platelet aggregating activity as PAF itself, in the concentration range 1 to 20 μM, with either platelet preparation, but with washed platelets, analogue 7 had a much lower activity than PAF in the concentration range 0.1 to 1 μM. No activity was observed either with PAF or the analogue 7 below 0.01 μM. Analogue 7 also had little or no inhibiting effect, in the concentration range 0.001 to 1 μM, on the platelet aggregating activity of PAF (Table 1).

Hypotensive activity. Intravenous injection of 10 pmole of PAF into an eleven-month-old CDF rat lowered the mean arterial blood pressure (99 mm Hg) an average of 45%; normal pressure was restored after 2.1 min. By comparison, the PAF sulfonium analogue 7, under the same conditions, lowered the blood pressure to the extent of 35% and returned to normal in 1.5 min (56% of the hypotensive activity of PAF) (Table 2). In contrast, the benzyl sulfonium analogue 12 had no effect at all on the mean arterial pressure, up to a dose of 1 nmole injected intravenously.

Cytotoxicity to HL-60 tumor cells. The sulfonium analogue 7 of *sn*-3 PAF showed a moderate cytotoxic effect (LD_{50} = 11 μM) towards HL-60 cells in the concentration range 0–20 μM (Fig. 4). In the same concentration range and under the same conditions, *sn*-3 PAF itself showed little or no cytotoxicity, as reported previously (9). In contrast, the 2-*O*-benzyl sulfonium analogue (12) was highly toxic to HL-60 cells in the concentration range 0–10 μM (LD_{50} = 4.5 μM), almost as toxic as the 2-*O*-methoxy PAF analogue (LD_{50} = 3.5 μM) (Fig. 4); the high cytotoxicity of the latter has been reported previously (9,18,19).

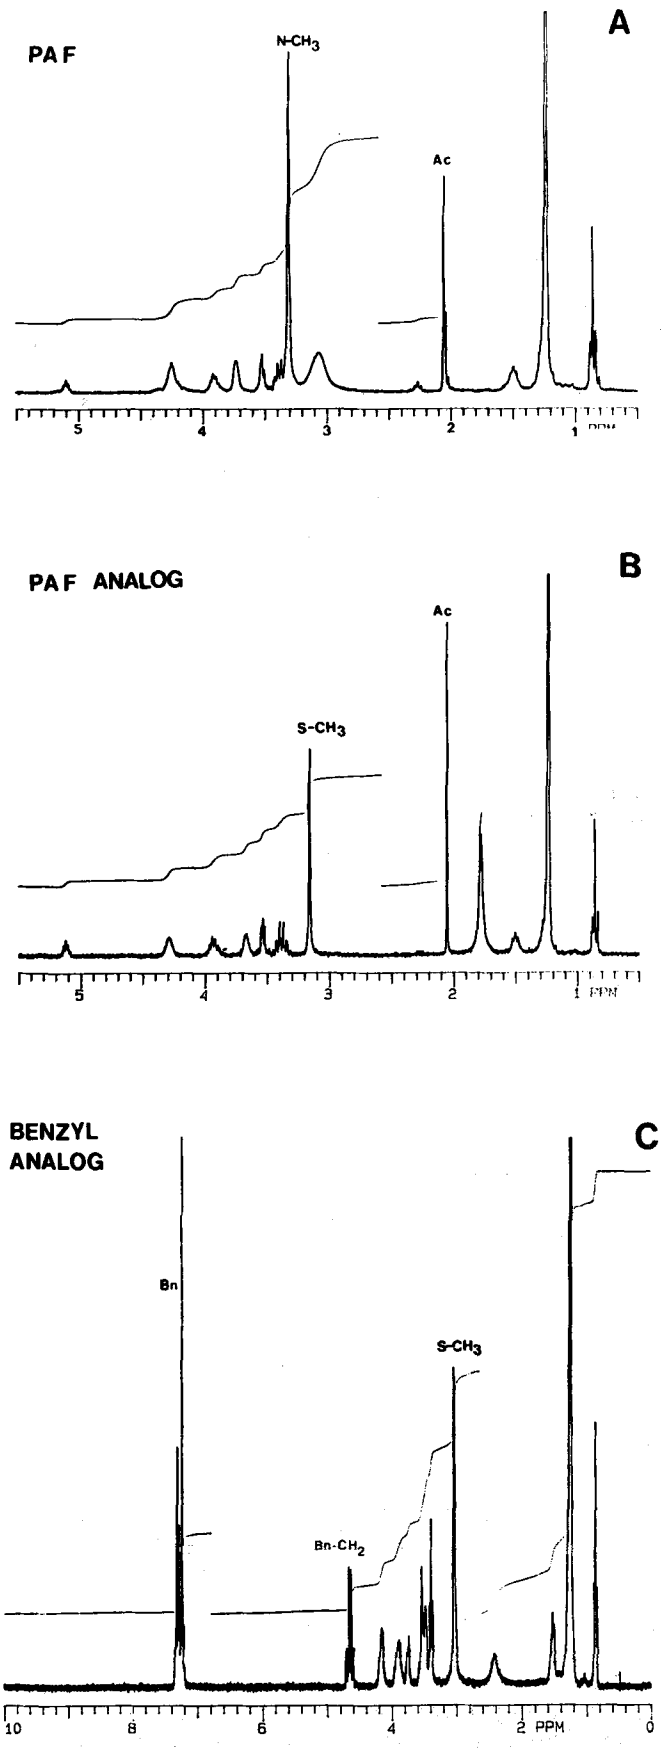

FIG. 2. ^1H NMR spectra in $CDCl_3$ of: A, authentic PAF (Serdary); B, PAF sulfonium analogue 7; and C, PAF sulfonium analogue 12.

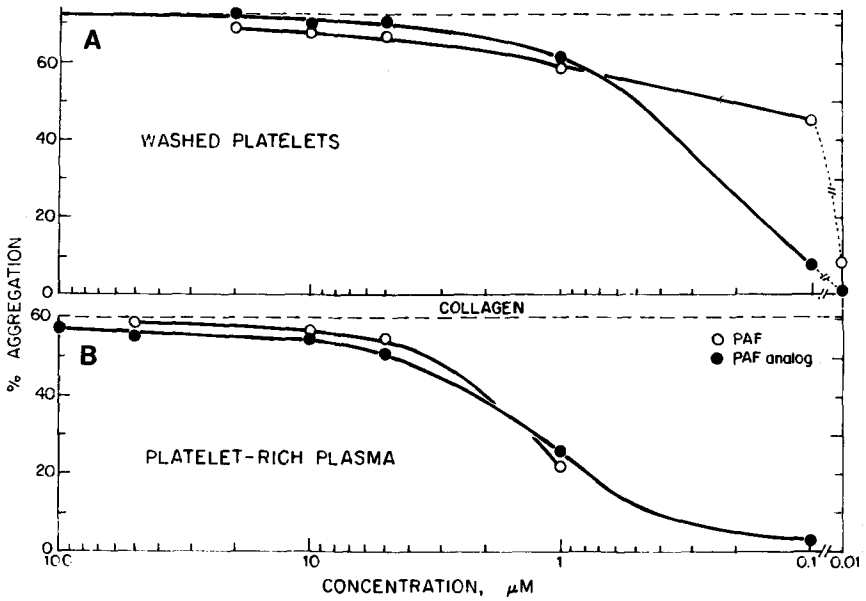

FIG. 3. Platelet aggregating activity of PAF (Sigma) and PAF sulfonium analogue 7 towards: A, washed human platelets; and B, human platelet-rich plasma.

TABLE 1

Effect of Sulfonium Analogue of PAF on Platelet Aggregating Activity of PAF[a]

Substance tested	Concentration PAF μM	Concentration PAF analogue μM	Platelet aggregation %
PAF (Sigma)	20	0	77
	1	0	73
PAF sulfonium analogue **7**	0	20	79
	0	2	75
	0	1	73
	0	0.1	24
	0	0.01	0
	0	0.001	0
PAF plus sulfonium analogue **7**	1	1	68
	1	0.1	69
	1	0.01	68
	1	0.001	75

[a]Platelet aggregation was measured as described in the text under Materials and Methods; 0.9% NaCl blanks gave zero % aggregation and a 0.005% collagen control gave 80% aggregation. The data in this table are independent of those in Figure 3.

TABLE 2

Hypotensive Activities of PAF and PAF Analogues[a]

Phospholipid tested	Amount injected pmole	Hypotensive activity
PAF: 1-hexadecyl-2-acetyl-*sn*-GPC	10	95 ± 13 (n=3)
PAF analogue **7**: 1-hexadecyl-2-acetyl-*sn*-GPSC	10	53 ± 8 (n=6)
PAF analogue **12**: 1-octadecyl-2-benzyl-*sn*-GPSC	1000	0 (n=4)

[a]Samples were injected into an 11-month-old normotensive CDF male rat (normal control mean blood pressure, 99 mm Hg). Hypotensive activity, defined as maximum % decrease in pressure × time (min) for blood pressure to return to normal, was measured as described elsewhere (8). Values reported are averages ± S.D. based on three or more determinations.

The results presented show that replacement of the quaternary $\overset{+}{N}(CH_3)_3$ group in the polar head group of PAF by a sulfonium $\overset{+}{S}(CH_3)_2$ group has little effect on the platelet aggregating activity of PAF and does not impart any detectable antagonistic activity towards the platelet aggregating activity of PAF (Fig. 3, Table 1). This finding would suggest that replacing the choline group of PAF by a sulfocholine group, which has a larger volume and resulting lower surface charge density than the choline group (4-6), does not significantly influence the binding of PAF to the appropriate receptor sites involved in the platelet aggregating process. Such a replacement appears to have an effect on platelet aggregating activity equivalent to changing the trimethyl ammonium group of PAF to a diethyl amino group (1,2); it is noteworthy that an increase in the bulkiness of the quaternary ammonium group to a diethyl methyl ammonium group doubles the platelet aggregating activity of PAF, but that a further increase to a triethyl ammonium group abolishes this activity (1,2).

However, replacement of the choline group of PAF by a sulfocholine group does have a lowering effect on the hypotensive action of PAF, by a factor of 2 (Table 2); replacement of the 2-acetyl group in sulfonium PAF by a benzyl group abolished the hypotensive action (Table 2), as similar replacement in PAF itself also results in no detectable hypotensive activity (8).

Of great interest was the fact that the sulfonium analogue **7** was much more cytotoxic to HL-60 cells than PAF itself, and that the 2-*O*-benzyl sulfonium analogue

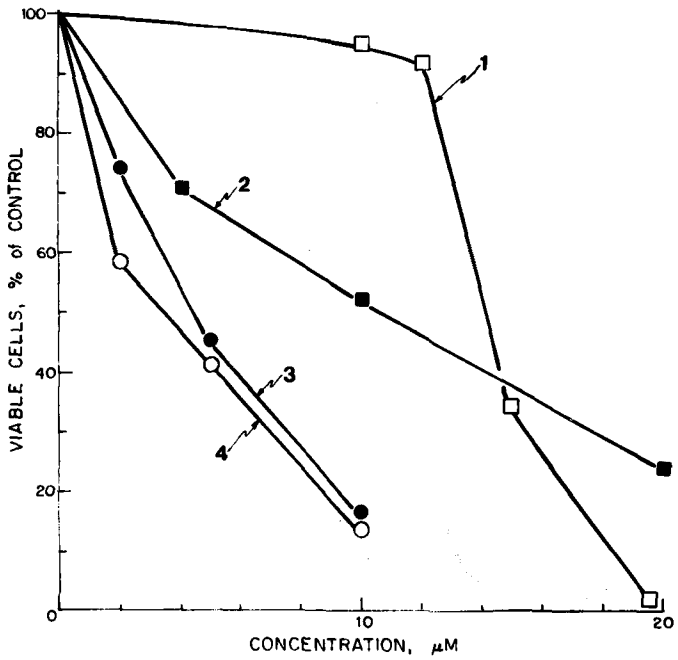

FIG. 4. Cytotoxic activity of PAF (Sigma) and PAF analogues towards HL-60 cells. 1, *sn*-3 PAF; 2, PAF sulfonium analogue 7; 3, PAF 2-*O*-benzyl sulfonium analogue 12; 4, 2-*O*-methyl analogue of PAF. Data for *sn*-3 PAF are taken from reference 9. Values plotted are means of quadruplicate measurements with mean deviations of 1-7%.

12 was much more toxic than analogue 7 (Fig. 4), but comparable to that of the 2-methoxy analogue of PAF (9,18,19). The increased cytotoxic effect of analogue 7 may be attributable to the presence of the sulfonium group, which has been shown previously to impart cytotoxicity to the sulfonium analogues of phosphatidylcholine (20,21). The further increase in cytotoxicity imparted by replacing the 2-acetyl group by a 2-benzyl group cannot be explained by the present data; further studies along the lines used for the 2-methoxy and 2-acetamide analogues (9,18,19) are necessary to establish structure-cytotoxicity relationships for the 2-benzyl analogue 12.

The sulfonium analogues of PAF thus have some interesting physiological properties that may be useful in the design of drugs for various pharmaceutical purposes. Further study of the properties of sulfonium analogues of PAF should be of interest.

ACKNOWLEDGMENTS

This work was supported by a grant from the Medical Research Council of Canada. The technical assistance of C. Hallee with the platelet aggregation studies, E. A. Cress with the blood pressure measurements, Z. Smith with the cytotoxic assays, and R. Chin, S. De Silva and J. W. Lee with the syntheses is gratefully acknowledged. One of us (M.K.) is indebted to Dr. Bruce Holub for pointing out the potential use of the sulfonium analogues as PAF substitutes.

We investigated the effect of platelet-activating factor (PAF) and of the PAF specific antagonist CV-6209 on plasma lipid metabolism, and particularly on post-heparin plasma lipolytic activity in male Wistar rats. Lipoprotein lipase (LPL) activity was enhanced by intravenous injection of PAF before intravenous injection of heparin when the PAF dose was low (0.2 μg/kg). PAF activated hepatic triacylglycerol lipase (HTGL) activity dose-dependently. Plasma triacylglycerols (TG) significantly decreased with the activation of LPL and/or HTGL. Plasma total cholesterol (TC) and phospholipid (PL) levels decreased at a low dose of PAF (0.2 μg/kg), but increased when higher doses were used. The PAF antagonist CV-6209 partially reversed the PAF induced effects on HTGL, TC and PL. ***Lipids 26,*** **1102–1107 (1991).**

Platelet-activating factor (PAF), a biologically active phospholipid (PL), induces a variety of effects, including platelet activation (1), hypotension (2), vasopermeability (3), and increased intestinal movement (4). PAF's involvement in a variety of physiological or pathologic processes has attracted much attention. PAF appears to play a role in differentiation and proliferation of undifferentiated cells of bone marrow (5,6) as well as in such processes as implantation of fertilized ovum (7), parturition (8), and maturation of fetal lung (9). In addition, PAF has been shown to elicit pathologic changes including inflammation (10), bronchial asthma (11), nephropathy (12), collagen diseases (13), anaphylactic shock (14), and ulceration (15). Involvement of PAF in energy metabolism is little understood, and it has only been reported that PAF accelerates glycogenolysis in the liver (16). The effect of PAF on lipid metabolism has also remained unclear.

In the present study, we investigated the effects of PAF and of a PAF antagonist on plasma lipid metabolism, and particularly on post-heparin plasma lipolytic activity *in vivo.*

MATERIALS AND METHODS

PAF (1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine, purity 98%, Sigma Chemical Co., St. Louis, MO) and a PAF antagonist, CV-6209 (17) (provided by Takeda Chemical Industry, Osaka, Japan) were dissolved in isotonic saline containing 0.25% defatted bovine serum albumin (Fraction V, Sigma). Male Wistar rats, each weighing 300 g, were separated into 5 groups (A–E) after 12-hr fasting, anesthetized with sodium pentobarbitol (50 mg/kg body wt i.p.), and blood samples were taken (Fig. 1). In group A, heparin, 100 units/kg, (Novo Industries, Copenhagen, Denmark) was administered intravenously, followed by blood sampling 10 min after heparin administration (n = 5). In group B, heparin (100 units/kg) was administered intravenously, then PAF (1 μg/kg) was administered intravenously 5 min after heparin administration, followed by blood sampling 5 min later (n = 4). In Group C, PAF (0.2 μg/kg) was administered intravenously to 4 animals, 0.5 μg/kg to 4 animals, 1.0 μg/kg to 5 animals, and 1.5 μg/kg to one animal. Five min later, heparin, 100 units/kg, was intravenously administered to all subgroups, followed by blood sampling 10 min later. In Group D, PAF, (1 μg/kg), was administered intravenously and blood samples were drawn 15 min later (n = 5). In Group E, CV-6209 at 0.001, 0.01, and 0.1 mg/kg was administered intravenously to 1, 3, and 2 animals, respectively, and PAF (1 μg/kg) was administered intravenously 5 min later. Heparin (100 units/kg) was administered intravenously 5 min after PAF administration, and 10 min later blood samples were taken. Plasma of the latter blood samples from each group was used to determine post-heparin plasma lipolytic activity, consisting of lipoprotein lipase (LPL) and hepatic triacylglycerol lipase (HTGL) activities, following the method of Hernell *et al.* (18). LPL activity was obtained by subtraction of HTGL activity from total post-heparin plasma lipolytic activity. Levels of total protein, albumin, total cholesterol (TC), triacylglycerols (TG), PL, free fatty acids (FFA), high density

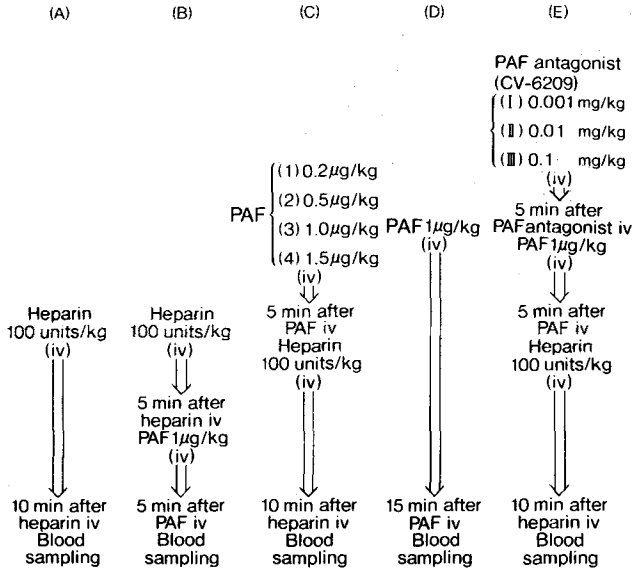

FIG. 1. Experimental design. After 12-hr fasting, blood samples were taken and the protocol shown was followed.

[1]Based on a paper presented at the Third International Conference on Platelet-Activating Factor and Structurally Related Alkyl Ether Lipids, Tokyo, Japan, May 1989.

Abbreviations: FFA, free fatty acids; HTGL, hepatic triacylglycerol lipase; LDL, low density lipoprotein; LPL, lipoprotein lipase; MDA, malondialdehyde; PAF, platelet-activating factor; PL, phospholipid; TC, total cholesterol; TG, triacylglycerols; VLDL, very low density lipoprotein.

lipoprotein (HDL) cholesterol, blood urea nitrogen (BUN), and malondialdehyde (MDA) (MDA with Lipoperoxide Test Kit, Wako Chemical Industry, Osaka, Japan) (19) were measured in all blood samples. We then compared the results from each group.

Statistical analysis. Student's t-test for unpaired values was used to compare different groups. Student's t-test for paired values was used in experiments comparing the changes before and after each treatment. Differences were considered significant at $p \leq 0.05$. Each value is reported as mean ± SD.

RESULTS

Post-heparin plasma lipolytic activity was 17.3 ± 0.7 and 17.8 ± 2.5 μmol FFA/mL/hr in Groups A and B, respectively, with no significant difference between both groups. In group C, post-heparin plasma lipolytic activity was 26.4 ± 0.3 in those animals given PAF at 0.2 μg/kg, 22.6 ± 1.1 in those given 0.5 μg/kg, 23.4 ± 1.3 in those given 1.0 μg/kg, and 24.0 in one animal given 1.5 μg PAF/kg. The respective subgroups which had received 0.2, 0.5 and 1.0 μg PAF/kg showed a significant increase in post-heparin plasma lipolytic activity compared to Group A. The post-heparin plasma lipolytic activity increased by 53, 31 and 35%, respectively. The subgroup given the lowest dose of PAF (0.2 μg/kg) showed the highest post-heparin plasma lipolytic activity. In Group D, no appreciable post-heparin plasma lipolytic activity (1.1 ± 0.4) was observed as no heparin was administered. In Group E, the post-heparin plasma lipolytic activity was 24.6 in one animal given CV-6209 at 0.001 mg/kg, 24.2 ± 3.5 in three given 0.01 mg/kg, and 20.0 ± 2.3 in two given 0.1 mg/kg. As compared to the subgroup of Group C, given PAF at 1.0 μg/kg, no appreciable difference in post-heparin plasma lipolytic activity was noted in two subgroups of Group E given CV-6209 at 0.001 and 0.01 mg/kg; a significantly smaller decrease of 15.6% was seen in a subgroup given CV-6209 at 0.1 mg/kg (Fig. 2).

LPL activity was 6.1 ± 2.6 μmol FFA/mL/hr in Group A and 3.9 ± 1.5 in Group B. Group B had a lower LPL activity than did Group A, but the difference was not significant. In group C, LPL activity was 11.7 ± 1.2 in those animals treated with PAF at 0.2 μg/kg, 7.3 ± 1.7 in those treated with 0.5 μg/kg, 7.8 ± 1.2 in those treated with 1.0 μg/kg, and 9.1 in one animal treated with 1.5 μg/kg. Only a subgroup given the lowest dose of PAF (0.2 μg/kg) had a significant increase in LPL activity (91.8%) compared to Group A. In Group D, no appreciable LPL activity (0.6 ± 0.5) was observed. In Group E, LPL activity was 8.2 in one animal given CV-6209 at 0.001 mg/kg, 10.4 ± 3.1 in three given 0.01 mg/kg, and 7.4 ± 1.4 in two given 0.1 mg/kg. As compared to the subgroup of Group C, given 1.0 μg PAF/kg, no appreciable difference in LPL activity was noted in the three subgroups of Group E (Fig. 3).

HTGL activity was 11.2 ± 2.1 μmol FFA/mL/hr in group A and 13.9 ± 1.6 in Group B. Group B had a higher HTGL activity than did Group A, but the difference was not significant. In Group C, HTGL activity was 14.7 ±

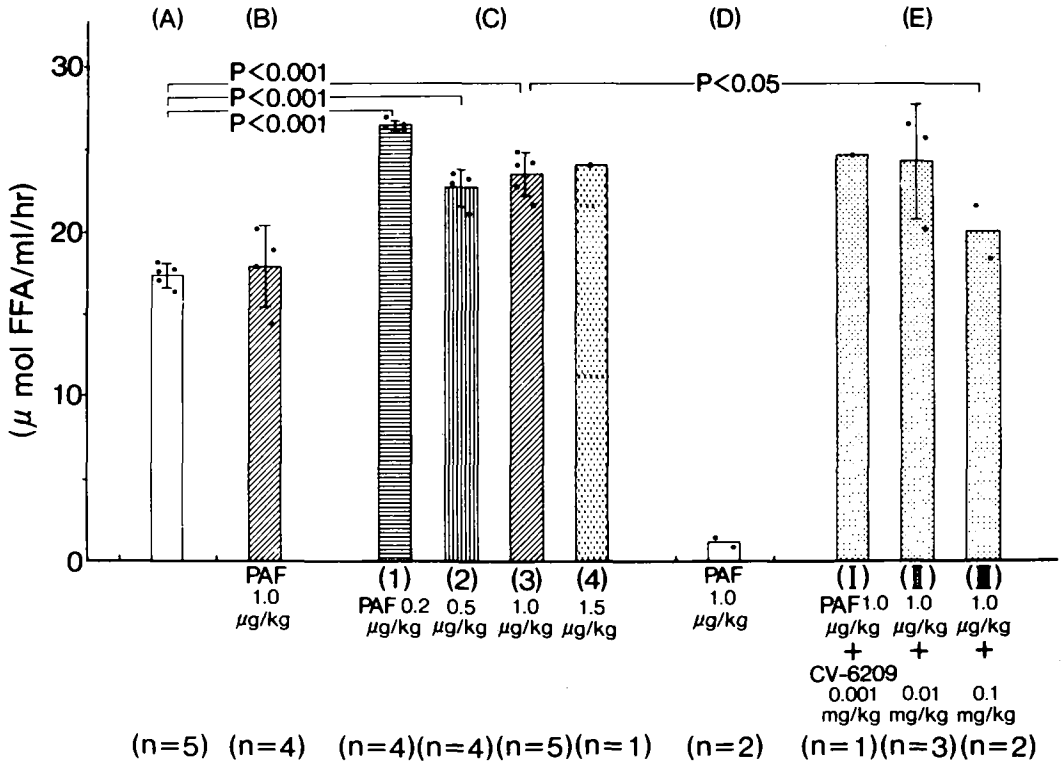

FIG. 2. Effect of PAF and PAF antagonist CV-6209 on post-heparin plasma lipolytic activity. Post-heparin plasma lipolytic activity was determined after each treatment, as shown in Figure 1. Each value represents the mean ± SD.

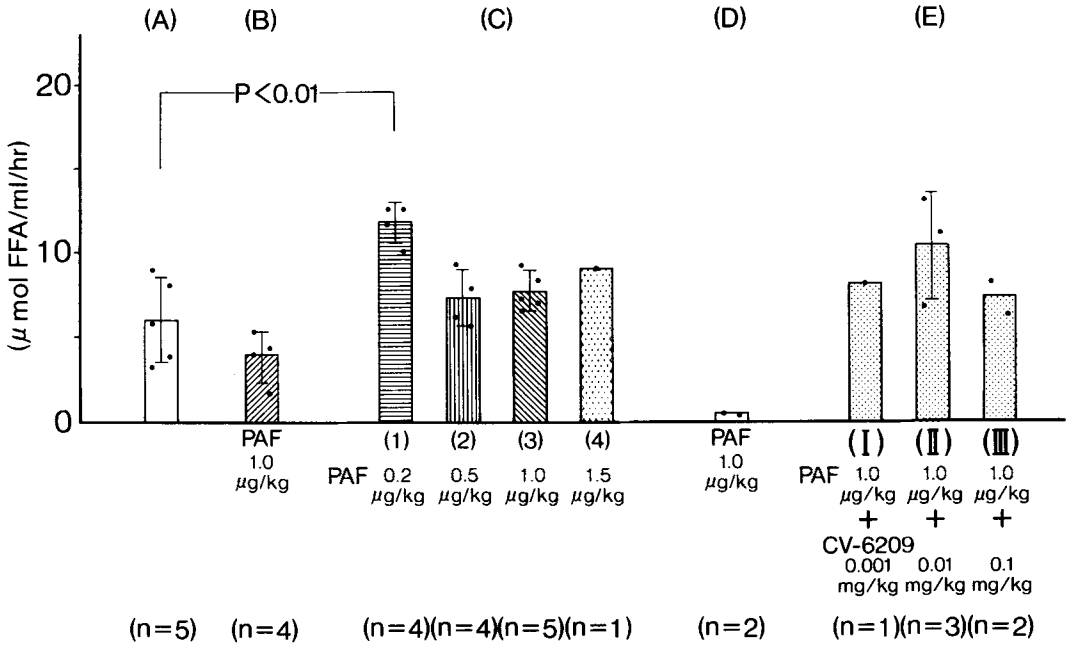

FIG. 3. Effect of PAF and PAF antagonist CV-6209 on plasma LPL activity. LPL activity was determined after each treatment, as shown in Figure 1. Each value represents the mean ± SD.

1.2 in the animals treated with 0.2 μg PAF/kg, 15.3 ± 1.1 in those treated with 0.5 μg/kg, 15.6 ± 1.2 in those treated with 1.0 μg/kg, and 14.9 in one animal treated with PAF at 1.5 μg/kg. Three subgroups treated with PAF at 0.2, 0.5, or 1.0 μg/kg had a significant increase in HTGL activity compared to Group A, with the activity being increased by 31, 37 and 39%, respectively. A dose-dependent increase was noted in these subgroups. In Group D, as in post-heparin plasma lipolytic activity, HTGL activity (0.6 ± 0.5) was barely observed. In Group E, HTGL activity was 16.4 in one animal treated with CV-6209 at 0.001 mg/kg, 13.8 ± 0.8 in three treated with 0.01 mg/kg, and 12.6 ± 0.9 in two treated with 0.1 mg/kg. Compared to a subgroup of Group C treated with 1.0 μg PAF/kg, a subgroup of Group E treated with CV-6209 at 0.1 mg/kg showed a 19.2% decrease (Fig. 4).

Group A showed a significant decrease in the plasma levels of TG, TC and PL after treatment. In Group B, the TG level was significantly decreased, while the TC level was significantly increased, and the PL level was higher. In Group C, there was a significant decrease in TG level. The TC level decreased in the subgroup treated with PAF at 0.2 μg/kg, while the other subgroups showed increased levels. A tendency toward a decrease in PL levels was noted only in a subgroup treated with 0.2 μg PAF/kg. In Group D, the TG level was significantly decreased, while TC and PL levels increased. In Group E, the TG, TC and PL levels significantly decreased (Figs. 5–7). FFA increased in all groups. HDL cholesterol increased in all groups other than Group D, with a significant increase being offered in Group E. There were no appreciable changes in MDA and other parameters tested (data not shown).

DISCUSSION

We have demonstrated that LPL activity is enhanced by intravenous injection of PAF, but only when the dose is low, 0.2 μg/kg. The fact that the activation of LPL was noted only at the time of PAF injection and before heparin injection could imply that PAF may induce some changes in LPL that exists on the surface of capillary endothelial cells and thus may stimulate its activation. It is generally thought that LPL on the surface of vascular endothelial cells originates from parenchymal cells, such as fat and cardiac muscle cells (20). Recently, a high level of LPL activity in arteriosclerotic lesions has also been reported (21,22) and attention has been focused on the release of LPL in macrophages (23). LPL may also be of importance in foam cell formation (24). However, there appear to be no receptors for PAF on rat macrophages (25); hence increased LPL is not likely to be of macrophage origin.

Several factors that affect LPL activity have been reported. Feeding and insulin increase LPL activity in adipose tissue (20,26,27). In contrast, fasting and glucagon increase LPL in the heart muscle (26,28). In macrophages, endotoxin (lipopolysaccharide) (29) and dexamethason (30) inhibit LPL secretion, while inflammation (31) and very low density lipoprotein (VLDL) (24) increase LPL secretion. However, the mediators and hormones which increase LPL secretion of macrophages are not known. It would be of interest to examine whether PAF enhances the activity of LPL in macrophages of animals which have PAF receptors on macrophages, such as human, rabbit and guinea pig.

In the present study, a marked increase in post-heparin lipolytic activity, especially LPL activity, was noted in a

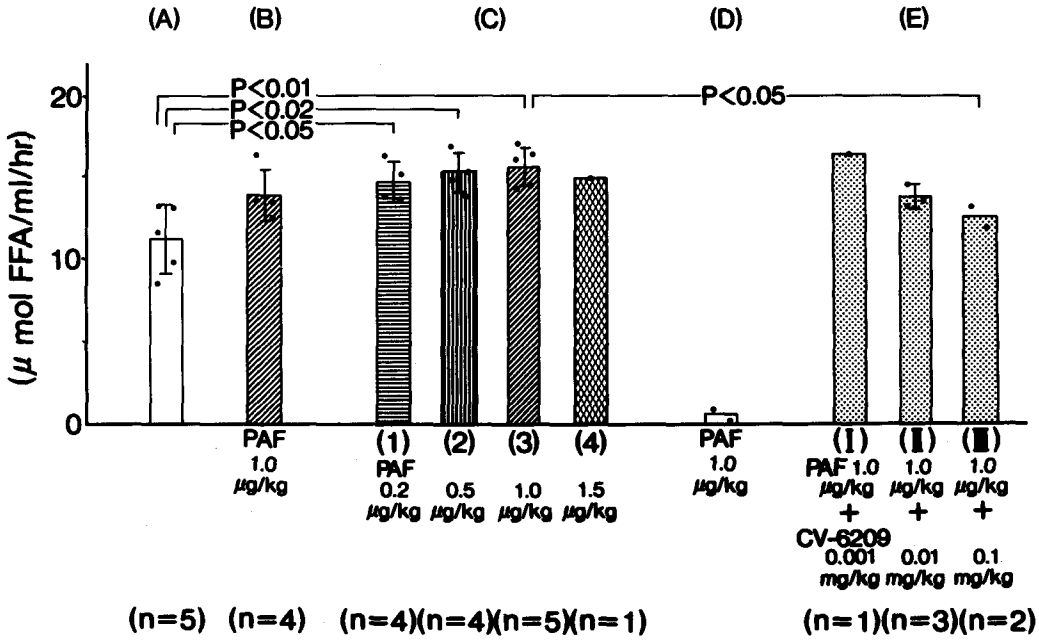

FIG. 4. Effect of PAF and PAF antagonist CV-6209 on plasma HTGL activity. HTGL activity was determined after each treatment, as shown in Figure 1. Each value represents the mean ± SD.

subgroup of Group C which had been treated with the lowest dose of PAF (0.2 μg/kg). In this subgroup, plasma levels of TC and PL tended to decrease, in contrast to those of other subgroups treated with higher doses of PAF. The decreases seem to be associated with accelerated transport of lipids to cells. In this subgroup, PAF could thus be involved in regulating the supply of energy. In the other subgroups, the levels of HTGL and plasma TC were increased, while the PL level remained unchanged, suggesting that lipid transport was impaired.

PAF may also play a pathological role in respect to arteriosclerosis, as recent *in vitro* studies have demonstrated that low density lipoprotein (LDL) modified by LPL or HTGL is taken up by macrophages more readily than is native LDL (32).

PAF activates HTGL activity dose-dependently. Thus, PAF may be able to affect the energy metabolism in the liver by modulating HTGL. It has been reported that hepatic cells have PAF receptors (33). Because HTGL activity was partially inhibited by CV-6209, which is

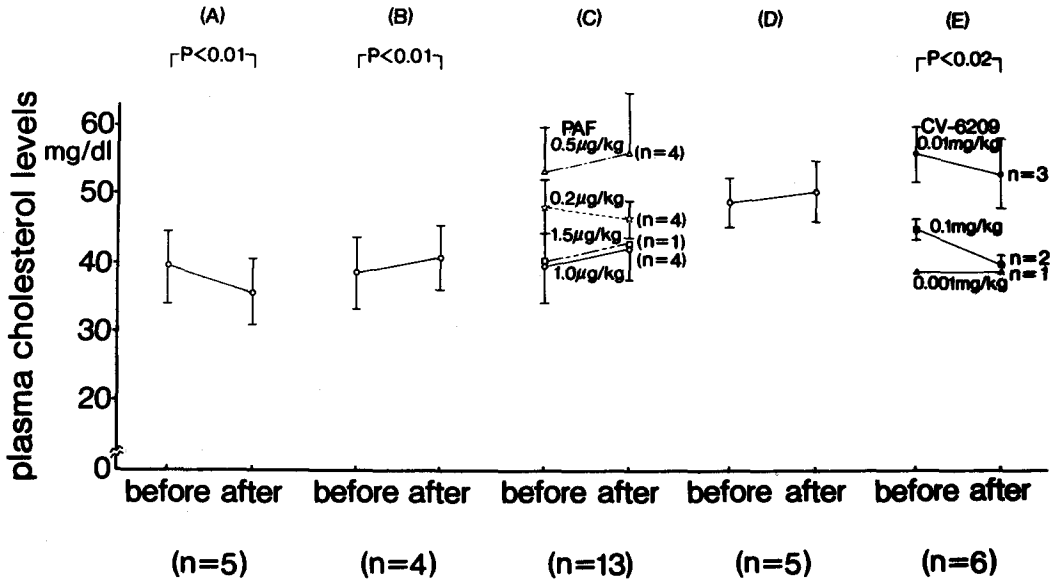

FIG. 6. Effect of PAF and PAF antagonist CV-6209 on plasma cholesterol levels. Plasma cholesterol levels were measured before and after each treatment, as shown in Figure 1. Each value represents the mean ± SD.

a specific PAF receptor antagonist, the observed activation of HTGL may indeed be mediated *via* PAF receptor.

Increased levels of TC and PL were noted after pretreatment with higher doses of PAF. These increases were significantly inhibited after administration of the PAF antagonist, which again suggests that the effect is mediated by PAF. However, the definite mechanism involved remains unknown.

Administration of platelet-activating factor (PAF) to perfused adrenal increased cortisol and corticosterone secretion. With hexadecyl PAF (C_{16}PAF; 1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine), the increase was significant at 1 nM and maximal at 10 nM. The responses to 10 nM octadecyl PAF (C_{18}PAF; 1-*O*-octadecyl-2-acetyl-*sn*-glycero-3-phosphocholine) were one fourth of those to 10 nM C_{16}PAF. The addition of C_{16}PAF to dispersed adrenal cells significantly increased cortisol and corticosterone production at 0.1 nM and 10 nM, respectively. C_{16}PAF was about 1000 times more potent than histamine on a molar basis in respect to cortisol response in both perfused adrenal and dispersed adrenal cells. The results suggest that PAF induces cortisol release from dog adrenal.

***Lipids* 26, 1108–1111 (1991).**

Platelet-activating factor (PAF), which was discovered in 1972 (1), is a phospholipid mediator involved in anaphylaxis and inflammation. PAF is produced by a variety of cell types and causes platelet aggregation, neutrophil activation, increased vascular permeability, bronchoconstriction, decreased cardiac output, and anaphylactic hypotension (2–4).

Glucocorticoids are known to suppress various inflammatory and immune responses. This can mainly be attributed to the fact that glucocorticoids depress the effect of certain mediators and cytokines (5) and induce phospholipase A_2 inhibitory protein (lipocortin), which affects the arachidonic acid cascade and release of the PAF precursor, lysoPAF (6,7).

In the present study we found that PAF is a potent stimulator of adrenal cortex in dogs.

MATERIALS AND METHODS

Materials. Collagenase (CLSPA), trypsin (TRL) and lima bean trypsin inhibitor were obtained from Cooper/Worthington (Freehold, NJ). Deoxyribonuclease and bovine serum albumin (BSA, fraction V) were purchased from Sigma (St. Louis, MO). 1-*O*-Hexadecyl- and 1-*O*-octadecyl-2-acetyl-*sn*-glycero-3-phosphocholine (C_{16}PAF, C_{18}PAF) and 1-*O*-hexadecyl-*sn*-glycero-3-phosphocholine (C_{16}lyso-PAF) were purchased from Bachem (Bubendorf, Switzerland). Synthetic adrenocorticotropic hormone 1-24 (ACTH, Cortrosyn) was obtained from Organon (Boxtel, Holland). Krebs-Ringer bicarbonate glucose solution (KRBG) contained (in mM): 121 NaCl, 2.37 KCl, 1.19 $MgSO_4 \cdot 7H_2O$, 1.19 KH_2PO_4, 2.54 $CaCl_2 \cdot 2H_2O$, 25 $NaHCO_3$, and 10 glucose.

Perfusion procedure. Adult male mongrel dogs (7.8–13.6 kg) were used. The left adrenal of hypophysectomized-nephrectomized dogs was perfused *in situ* with KRBG containing 0.2% BSA as described earlier (8,9). Briefly, perfusion medium was introduced, through the right renal artery, into an isolated segment of the aorta, from which the left adrenal arteries arise, and was collected from the cannula in the left lumboadrenal vein after passing through the adrenal gland. The perfusion started 4 hr after the end of hypophysectomy and nephrectomy. The right renal artery was cannulated, and the cannula was connected to the long arm of a silicon T-tube (Phicon No. 5, Fuji Systems, Tokyo, Japan), which was covered with a water jacket maintained at 39°C by circulating water from a constant temperature bath by means of a Perista mini-pump (SJ-1211, Atto, Tokyo, Japan). One short arm of the T-tube was connected to a large beaker and the other short arm was attached to a small beaker. Both beakers were placed in a water bath maintained at 39°C. KRBG in the beakers was gassed with 95% O_2/5% CO_2. PAF dissolved in saline containing 0.2% BSA was added to the small beaker. The aorta just below the celiac trunk was clamped with a hemostatic forceps to stop the blood flow after the KRBG began to flow from the large beaker to the left adrenal. The silk thread that had been passed around the left lumboadrenal vein was ligated to direct the adrenal venous flow toward the exterior. Approximately 40 min after the perfusion started, PAF was administered over a 10-min period. The perfusate was collected, for 1 min, at 5 min before, and 2.5, 5, 10, 15 and 20 min after the start of PAF infusion. Constant flow was maintained by changing pump speed during the experiment. Outflow after 10 or 100 nM C_{16}PAF infusion did not change by increasing inflow rate by +15%. The weight of 22 left adrenals infused with various amounts of C_{16}PAF was 599 ± 26 mg (means ± S.E.). Adrenal flow rates at 5 min before, and 5 and 20 min after the start of C_{16}PAF infusion were 503 ± 27, 484 ± 29, and 505 ± 29 μL/100 mg adrenal weight/min (means ± S.E., n=22), respectively. Completeness of hypophysectomy was checked by inspection of the brain at the end of the experiment and by the cortisol level at 35 min after the start of the perfusion.

Dispersed adrenal cells. Dispersed cells were prepared by the method of Hirose *et al.* (10) with some modification. The adrenal glands were cut into small pieces. The minced tissue was incubated in 2.5 mL KRBG containing collagenase (150 U/mL), 0.005% deoxyribonuclease and 4% BSA for 30 min at 38°C under an atmosphere of 95% O_2/5% CO_2 with stirring. The supernatant was

[1]Based on a paper presented at the Third International Conference on Platelet-Activating Factor and Structurally Related Alkyl Ether Lipids, Tokyo, Japan, May 1989. The present data were also reported at the VIIth International Congress on Hormonal Steroids, Madrid, Spain, September, 1986 (*J. Steroid Biochem.* 25, 76S, 1986, Abstract).

Abbreviations: ACTH, adrenocorticotropic hormone; BSA, bovine serum albumin; C_{16}lysoPAF, 1-*O*-hexadecyl-*sn*-glycero-3-phosphocholine; C_{16}PAF, 1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine; C_{18}PAF, 1-*O*-octadecyl-2-acetyl-*sn*-glycero-3-phosphocholine; KRBG, Krebs-Ringer bicarbonate glucose solution; lysoPAF, 1-*O*-alkyl-*sn*-glycero-3-phosphocholine; PAF, platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine.

discarded and the tissue fragments were rinsed with KRBG containing 4% BSA. The tissue fragments were incubated with collagenase for 1 hr in the same manner as described above. After rinsing with KRBG, 3 mL KRBG containing 0.01% trypsin was added. The mixture was incubated with stirring for 10 min at 38°C under an atmosphere of 95% O_2/5% CO_2, and the supernatant was separated. Trypsin treatment was repeated eight times. Pooled supernatants were filtered through siliconized gauze and centrifuged at 100 × *g* for 30 min at 4°C. The sedimented cells were resuspended in KRBG containing 0.5% BSA, 0.1% lima bean trypsin inhibitor and 7.65 mM calcium, and the concentration of cells was adjusted to approximately 3 × 10^5 cells/mL. Incubations were carried out with shaking for 2 hr at 38°C under an atmosphere of 95% O_2/5% CO_2. Both media and cells were extracted with methylene chloride.

In each preparation, viability of adrenal cells was >88% as assayed by trypan blue exclusion. Cortisol and corticosterone production upon stimulation with 10 nM C_{16}PAF or 10 ACTH (ng/mL), for 2 hr was twice that after 1 hr.

Biochemical analysis. The perfusate was centrifuged and the supernatant was extracted with methylene chloride. Cortisol and corticosterone in the extracts were analyzed by fluorometric assay subsequent to thin-layer chromatography (11), and secretory rates were calculated by multiplying steroid concentration (ng/mL) and adrenal flow (mL/100 mg adrenal weight/min). Steroid production by the adrenal cells was expressed as ng/10^5 cells.

Histamine was measured by single isotope enzymatic assay (12) following column chromatography. Half a milliliter of perfusate was deproteinized with 1 mL of 1 M $HClO_4$ and centrifuged. The supernatant was neutralized and was applied to a Dowex 50 × 4 column (H^+ form, buffered with 0.1 M sodium phosphate buffer, pH 6.5, 8 × 15 mm). Impurities were washed off with 3 mL of 0.1 M sodium phosphate buffer, 3 mL of distilled water, and 3 mL of 1 M HCl. Finally, histamine was eluted with 3 mL of 4 M HCl. The frozen eluate was lyophilized and dissolved in 50 μL of 0.002 M HCl. For the assay of histamine, 10 μL *S*-adenosyl-L-methionine:histamine *N*-methyltransferase (EC 2.1.1.8) was incubated at 37°C for 90 min with 20 μL of the sample or the histamine standard (3–50 pmol), 0.25 μCi *S*-adenosyl-L-[*methyl*-^{3}H]methionine (500 Ci/mmol, NEN, Boston, MA) and a sufficient amount of 0.1 M sodium phosphate buffer, pH 7.9, to make a final volume of 40 μL. The reaction was terminated by the addition of 20 μL of 0.8 M $HClO_4$ containing 1-methylhistamine (5 μg/20 μL). After the addition of 2 N NaOH saturated with NaCl, the radiolabeled methylhistamine was extracted with 5 mL of chloroform. The extract was washed with 2 mL of 2 N NaOH, transferred to counting vials, evaporated to dryness, and assayed for radioactivity.

Statistical analyses were by paired and unpaired Student's *t*-test.

RESULTS AND DISCUSSION

In the present studies we found that PAF acts directly on adrenocortical cells, and facilitates synthesis and release of glucocorticoids. PAF has been shown to cause platelet aggregation at subnanomolar concentrations in several species (2,13). In the present study, the effective dose of C_{16}PAF for cortisol response in the perfused adrenal and isolated cells were 1 nM and 0.1 nM, respectively (Fig. 1, Table 1). We previously reported that the effective doses of histamine for cortisol response in the perfused adrenal and isolated cells were 1 μM and 0.1 μM, respectively (9,14). C_{16}PAF was about 1000 times more potent than histamine on a molar basis in regard to cortisol response in the dog. The increment of the cortisol secretion rate at 5 min after the onset of continuous infusion of 10 nM C_{16}PAF was 5 times that of 10 μM histamine (9) and about half that of 100 pg/mL ACTH (data not shown). The results suggest that PAF is a potent stimulator of the adrenal cortex and that the induction of cortisol release may be one of pathophysiological actions of PAF in the dog.

TABLE 1

Effect of C_{16}PAF on Cortisol and Corticosterone Production by Dog Adrenal Cells[a]

	Cortisol	Corticosterone
Vehicle	23.3 ± 1.2	8.1 ± 0.7
C_{16}PAF		
0.1 nM	32.4 ± 2.9[c]	9.9 ± 1.3
1 nM	36.6 ± 2.8[d]	10.7 ± 1.5
10 nM	38.1 ± 4.0[c]	13.1 ± 1.7[b]
100 nM	38.0 ± 2.8[d]	15.1 ± 2.0[c]
1000 nM	37.6 ± 3.9[c]	14.6 ± 1.8[c]
ACTH 10 ng/mL	170.4 ± 15.8[d]	76.5 ± 9.4[d]

[a]Data shown are means ± S.E. (ng/10^5 cells/2 hr; n=10).

[b]$P < 0.05$, [c]$P < 0.01$, [d]$P < 0.001$, significantly different when compared to vehicle by unpaired *t*-test.

The secretory responses of cortisol and corticosterone to 10 nM C_{18}PAF were one fourth of those to 10 nM C_{16}PAF (Fig. 1). Infusion of 10 nM C_{16}lysoPAF into the perfused adrenal did not induce any change in steroid response. This suggests that the acetyl moiety in the 2 position and the length of alkyl side chain in the 1 position affect the induction of cortisol response as they affect platelet activation in rabbits (15).

Recently, we found that the infusion of histamine into the canine adrenal perfused with artificial medium induced marked increases in the secretory rates of aldosterone, cortisol and corticosterone (9), and that the infusion of 200 μg/mL of compound 48/80 caused a marked release of histamine from mast cells in the adrenal cortex, followed by steroid release (data not shown). Therefore, the histamine concentration of the perfusate was measured before and after the infusion of 10 nM C_{16}PAF over a 10-min period. Histamine values were 82 ± 34 at 5 min before, 48 ± 12 at 0 min, 45 ± 12 at 1 min, 43 ± 16 at 2.5 min, 45 ± 13 at 5 min, 39 ± 10 at 10 min, 42 ± 10 at 15 min, and 40 ± 11 pmol/mL (means ± S.E., n=3) at 20 min after the start of PAF infusion, respectively. Administration of 10 nM C_{16}PAF to the perfused adrenal did not induce any change in histamine levels. The addition of 200 μg/mL of compound 48/80 to the isolated cells had no effect on cortisol and corticosterone production (data not shown). It appears likely that the action of PAF on the perfused adrenal and on isolated cells is independent of histamine release.

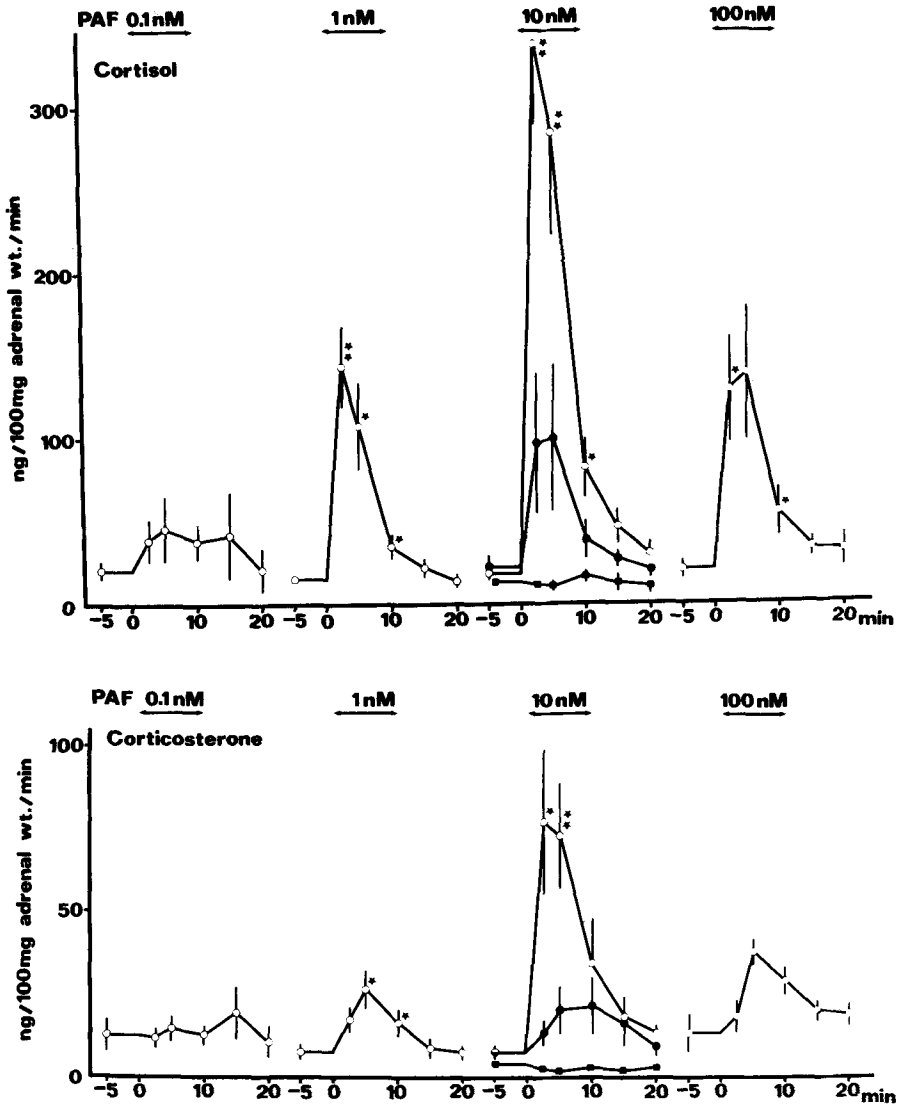

FIG. 1. Secretory responses of cortisol and corticosterone to increasing amounts of C_{16}PAF. The response to 10 nM C_{16}PAF (open circle) were compared to the responses to 10 nM C_{18}PAF (closed circle) and 10 nM C_{16}lysoPAF (closed square). The infusion of agents over 10 min started 40 min after the onset of perfusion. Values are means ± S.E. (0.1, 1 and 10 nM C_{16}PAF, n=6; 100 nM C_{16}PAF, n=4; 10 nM C_{18}PAF and 10 nM C_{16}lysoPAF, n=5). *, $p<0.05$; **, $p<0.01$; significantly different when compared to control values at 5 min before PAF infusion by paired *t*-test.

Cortisol and corticosterone response of the perfused adrenal to 10 nM C_{16}PAF was much higher than that to 10 μM histamine (9), while cortisol and corticosterone production by dispersed cells in response to 10 nM C_{16}PAF was comparable to that to 10 μM histamine (14). The response of the perfused adrenal to 100 nM C_{16}PAF was less pronounced than that to 10 nM. Conversely, steroid production of the cells in response to C_{16}PAF reached a plateau at 10 nM and 100 nM for cortisol and corticosterone, respectively. Infusion of 10 nM or 100 nM C_{16}PAF into the perfused adrenal evoked a slight decrease in outflow. PAF at high concentration may cause increased vascular permeability and vasoconstriction in the adrenal. The possibility cannot be excluded that the marked response to 10 nM C_{16}PAF and sub-maximal response to 100 nM C_{16}PAF in the perfused adrenal are modified by the action of PAF on various cells other than adrenocortical cells.

PAF, a phospholipid mediator of inflammation and allergy, is produced by a variety of cell types such as neutrophils, basophils, eosinophils, monocytes, macrophages, mast cells, mesangial cells, endothelial cells and platelets. It still remains to be determined whether or not the PAF which is released from various cell types at inflammatory or allergic loci into the systemic circulation and/or the PAF locally released from the cells of the adrenal cortex cause the glucocorticoid release. Glucocorticoids are known to suppress various inflammatory and immune responses. Glucocorticoids depress the actions of certain chemical mediators and cytokines (5) and inhibit

vascular permeability induced by PAF, histamine and leukotriene C_4 (16). In addition, glucocorticoids induce phospholipase A_2 inhibitory protein (lipocortin), which affects the arachidonic acid cascade and the release of the PAF precursor, lysoPAF (6,7). Hence, glucocortoid release induced by PAF may result in the inhibition of the action and in the generation of chemical mediators, including PAF itself, in inflammatory or allergic loci.

Tandem Mass Spectrometry of Negative Ions from Choline Phospholipid Molecular Species Related to Platelet Activating Factor[1]

J.A. Zirrolli, K.L. Clay and **R.C. Murphy***
Department of Pediatrics, National Jewish Center for Immunology and Respiratory Medicine, Denver, Colorado 80206

Fast atom bombardment mass spectrometry of choline phospholipids produces negative ions characteristic of the intact molecule and tandem mass spectrometry of collision-induced decomposition of M-15 anions characterizes both the identity and substituent position of radyl groups. Certain choline phospholipid molecular species which may be of special interest in the generation of platelet activating factor contain a highly unsaturated fatty acyl substituent at *sn*-2 and an ether radyl group at *sn*-1; other choline phospholipid molecular species which contain esterified arachidonic acid are of interest as potential sources of arachidonate for eicosanoid biosynthesis. Collisional activated decomposition of 1-hexadecanoyl-2-arachidonoyl-*sn*-glycerophosphocholine produce abundant carboxylate anions at *m/z* 303 (arachidonate) and *m/z* 255 (hexadecanoate) in a ratio of 3:1, diagnostic for the *sn*-2 arachidonoyl position. The ether analog, 1-*O*-hexadecyl-2-arachidonoyl glycerophosphocholine, produces only one collision-induced dissociation ion at *m/z* 303 and no product ions corresponding to the ether substituent at *sn*-1. Molecular weight information from the M-15 ion combined with the CID generated carboxylate anions completely characterize these important phospholipids.

Precursor ion studies of M-15 anions from glycerophosphocholine lipids indicate that this ion is derived directly from a unique adduct ion formed by attachment of the molecular species to a matrix alkoxide ion, neutralizing the positive charge of the quaternary choline nitrogen. Decomposition of this adduct ion yields a methylated matrix molecule and the nominal M-15 ion.
***Lipids 26,* 1112–1116 (1991).**

Considerable advances have been made in understanding the complex roles that phospholipids play in cell biology. The recognition of platelet activating factor as an important mediator of numerous intra- and intercellular events has significantly altered the view that phospholipids are inert or inactive constituents of cellular membranes. Therefore, the need to characterize not only phospholipid classes present in cellular membranes, but also molecular species within each class has emerged as an important analytical requirement.

A wide variety of analytical techniques is available for the characterization of phospholipid molecular species. The most traditional approach has involved isolation and purification of classes followed by enzymatic or chemical degradation in order to identify radyl substituents at *sn*-1 and *sn*-2 (1). It is difficult to precisely assign substituents at *sn*-1 and *sn*-2 with a chemical degradative strategy and, therefore, the use of rather specific enzymes, e.g. phospholipase A_2, have been required to ascertain radyl group substituent position (2). Another approach has involved diglyceride analysis following phospholipase C hydrolysis (3), and molecular species information has been reported in several systems (4). Choline phospholipids have been studied by position ion electron ionization mass spectrometry; however, determination of the radyl position has been rather difficult (5). Field desorption mass spectrometry enabled characterization of the intact molecular weight, but lacked specific information concerning the substituents at *sn*-1 or *sn*-2 (6). Chemical ionization mass spectrometry has been useful in providing molecular species information (7); however, numerous abundant ions not related to radyl group position are produced in the isobutane (8) and ammonia (7) chemical ionization mass spectra of phosphatidylcholine species. These ions make mixture analysis somewhat difficult and only a few classes of phospholipids are amenable to such analyses. The most successful technique has been fast atom bombardment mass spectrometry (9) which has been applied to the study of intact choline phospholipids with investigation of both positive (10) and negative ions (11).

Tandem mass spectrometry has been shown to be a useful technique for the structure elucidation of phosphatidylserine and phosphatidylcholine molecular species through analysis of negative ions generated by fast atom bombardment (FAB) (11). The position ion tandem mass spectrometric behavior of PAF has recently been reported (12) and is substantially different than that described in this report. Phosphatidylcholines do not produce negative ions characteristic of the intact molecule; however, three abundant ions are observed at high mass corresponding to $[M\text{-}CH_3]^-$, $[M\text{-}HN^+(CH_3)_3]^-$ and $[M\text{-}CH{=}CH\text{-}HN^+(CH_3)_3$ corresponding to the loss of 15, 60, and 86 atomic mass units from the molecualr weight of the phosphocholine. Five different molecular species of phosphatidylcholines have been studied and each one of these produced a characteristic pattern by tandem mass spectrometry, notably the decomposition of the precursor $[M\text{-}CH_3]^-$ ion yielding a product carboxylate anion corresponding to each ester at *sn*-1 and *sn*-2. More interestingly, a substantial difference in the abundance of the carboxylate anions was reported for the radyl group de-

Abbreviations: B/E, product ion linked scans where the mass spectrometer magnet is scanned while holding the ratio of the magnet field (B) to electric sector voltage (E) constant; B^2/E; precusor ion linked scans where the mass spectrometer magnet is scanned while holding the ratio of the square of the magnetic field (B) to electric sector voltage (E) constant; CID, collision-induced decomposition; FAB, fast atom bombardment; GPCho, glycerophosphocholine.

pending upon its substitution position (11). The group at *sn*-1 was two to three times less abundant than the carboxylate anion corresponding to the radyl group from *sn*-2. Analysis of choline phospholipid molecular species containing highly unsaturated fatty acyl substituents have not been reported by this technique, nor species with ether radyl groups at *sn*-1. Since these molecular species are of substantial interest in the generation of platelet activating factor, these compounds were the subject of the present study.

EXPERIMENTAL PROCEDURES

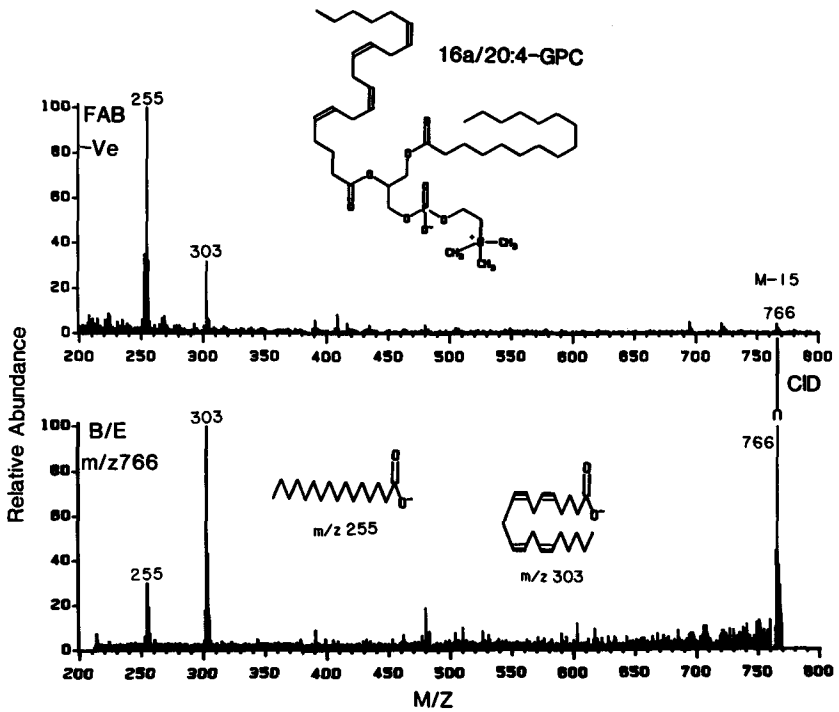
All fast atom bombardment mass spectra and collision-induced decomposition (CID) spectra were obtained on a VG7070E double focusing mass spectrometer (VG Instruments, Altrincham, U.K.) equipped with a commercial FAB probe. The capability for linked scan, B/E [product ion linked scans where the mass spectrometer magnet is scanned while holding the ratio of the magnet field (B) to electric sector voltage (E) constant] and B^2/E [precursor ion linked scans where the mass spectrometer magnet is scanned while holding the ratio of the square of the magnetic field (B) to electric sector voltage (E) constant] for product ion and precursor ion experiments, was possible with this instrumentation. The instrument was equipped with a standard VG FAB source (VG Instruments) and Ion Tech saddle field ion gun (Ion Tech, Teddington, U.K.). The ion gun was operated at 6–8 KV using xenon as the particle source. The instrument was operated at 6 KV accelerating voltage in the negative ion mode and the sample was placed in the matrix which was ether glycerol or 3-nitrobenzyl alcohol.

Collision-induced decomposition spectra were obtained in the first field region by adjusting the pressure of the collision gas (helium) until a 50% reduction of the abundance of the selected ion was observed. Product ions formed in this process were detected by B/E scanning and 5–20 scans were typically signal averaged for each spectrum. Signal averaging was accomplished with a Teknivent (Teknivent, St. Louis, MO) data system. Precursor ions were studied by focusing the production of interest with the collision gas pressure set as for product ion formation (*vide supra*) and scanning the instrument in a B^2/E mode.

Materials. 1-*O*-Hexadecanoyl-2-arachidonoyl-*sn*-glycero-3-phosphocholine was obtained from Avanti Polar Lipids (Birmingham, AL) and 1-*O*-hexadecyl-2-arachidonoyl-*sn*-glycero-3-phosphocholine was obtained from Biomol Laboratories (Philadelphia, PA).

RESULTS AND DISCUSSION

Carboxylate Anions. The negative ions obtained by fast atom bombardment mass spectrometry of 1-hexadecanoyl-2-arachidonoyl-*sn*-glycero-3-phosphocholine are shown in Figure 1A. As previously described by Jensen, Tomer and Gross (11), there is no molecular anion observed at *m/z* 781, but rather ions at M-15 (*m/z* 766, loss of methyl), M-60 [*m/z* 721, loss of $HN^+(CH_3)_3$), and M-86 [*m/z* 695, loss of CH=CH-



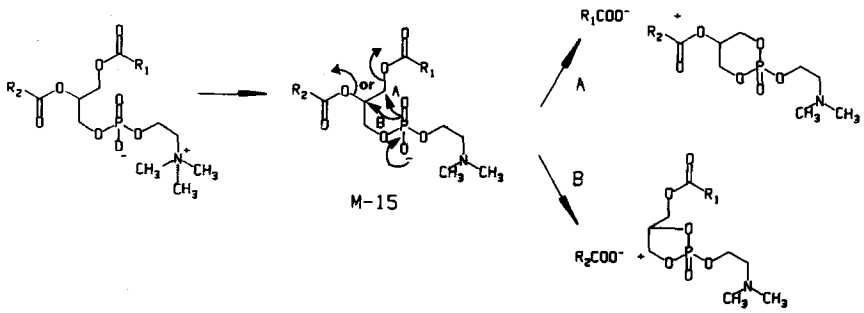


FIG. 1. A, fast atom bombardment mass spectrum of 1-hexadecanoyl-2-arachidonoyl-*sn*-glycero-3-phosphocholine using glycerol as matrix; B, collision-induced decomposition of the M-15 ion at *m/z* 766 and linked scan (B/E) analysis.

$N^+(CH_3)_3$]. Also present were two abundant carboxylate anions at *m/z* 255 and 303, corresponding to the hexadecanoyl and arachidonoyl carboxylate anions, respectively. Figure 1 does not indicate other ions present above *m/z* 800 which were less than 1% abundant on the scale indicated. These source-formed FAB ions were subjected to collision-induced decompositions in the first field free region, and the products derived from *m/z* 766 are shown in Figure 1B. Two abundant ions were observed, again the carboxylate anions at *m/z* 255 (hexadecanoyl carboxylate anion) and *m/z* 303 (arachidonoyl carboxylate anion).

The ratio of the abundances of the ions at *sn*-2/*sn*-1 was approximately three (Fig. 1B), which was previously observed for other diacyl species of phosphatidylserine and phosphatidylcholine analyzed by tandem mass spectrometry (11). This work extends the analysis of diacyl molecular species of phosphatidylcholine and further confirms the ability to assign the acyl groups at *sn*-1 and *sn*-2 based upon the relative abundance of the carboxylate anions. It is of interest to note a reversal of the abundances of carboxylate anions observed in direct FAB analysis (source ions) where the ions corresponding to the radyl group at *sn*-1 were more abundant than those ions arising from the radyl group at *sn*-2 (arachidonate). A possible explanation for the reversed ion ratio for these carboxylate anions following collision-induced decomposition

SCHEME 1

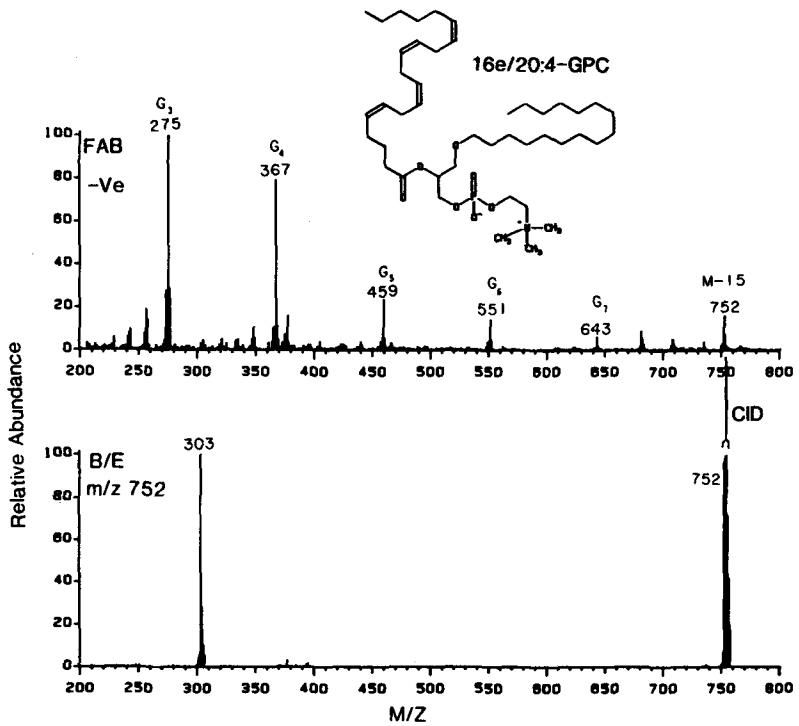

FIG. 2. A, fast atom bombardment mass spectrum of 1-*O*-hexadecyl-2-arachidonoyl-*sn*-glycero-3-phosphocholine using glycerol as matrix, B, collision-induced decomposition of the M-15 ion at *m/z* 752 and linked scan (B/E) analysis.

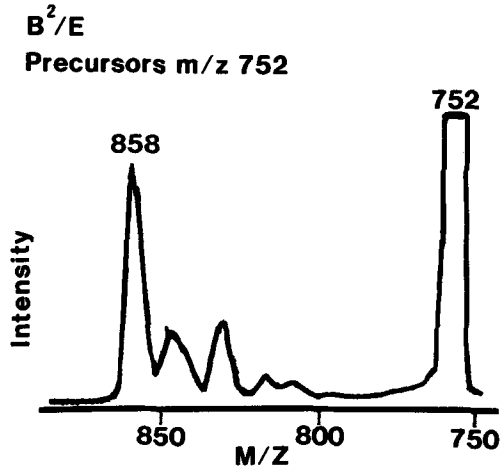
might be related to the mechanism of ion formation. As shown in Scheme 1, the formation of the M-15 ion would most likely have the site of charge localization on the phosphate moiety. This anionic site can attack the carbon atoms either at *sn*-1 or *sn*-2 by pathways A and B through a six- or five-membered ring transition state, respectively. In the gas phase it would appear that the transition state for the attack of the phosphate anion (formation of a cyclic phosphate ester and liberation of the carboxylate anion) appears to be more favored in a five-membered ring case as compared to the six-membered ring. It would appear that both the stability of the cyclic phosphate ester as well as the stability of the carboxylate anions are quite important in the competitive generation of these abundant anions. It has also been suggested that steric hindrance in the transition state plays an important role (13).

As shown in Figure 2A, the negative ions derived from the 1-*O*-alkyl choline phospholipid species are somewhat different. Fast atom bombardment of 1-*O*-hexadecyl-2-arachidonoyl-*sn*-glycero-3-phosphocholine yields abundant ions in the high molecular weight region at M-15, M-60, and M-86, characteristic of choline phospholipids. However, for this mass spectrum substantially less phospholipid was placed in the glycerol matrix, and the most abundant ions at lower masses arose from the glycerol cluster ions (*m/z* 275, 367, 459,



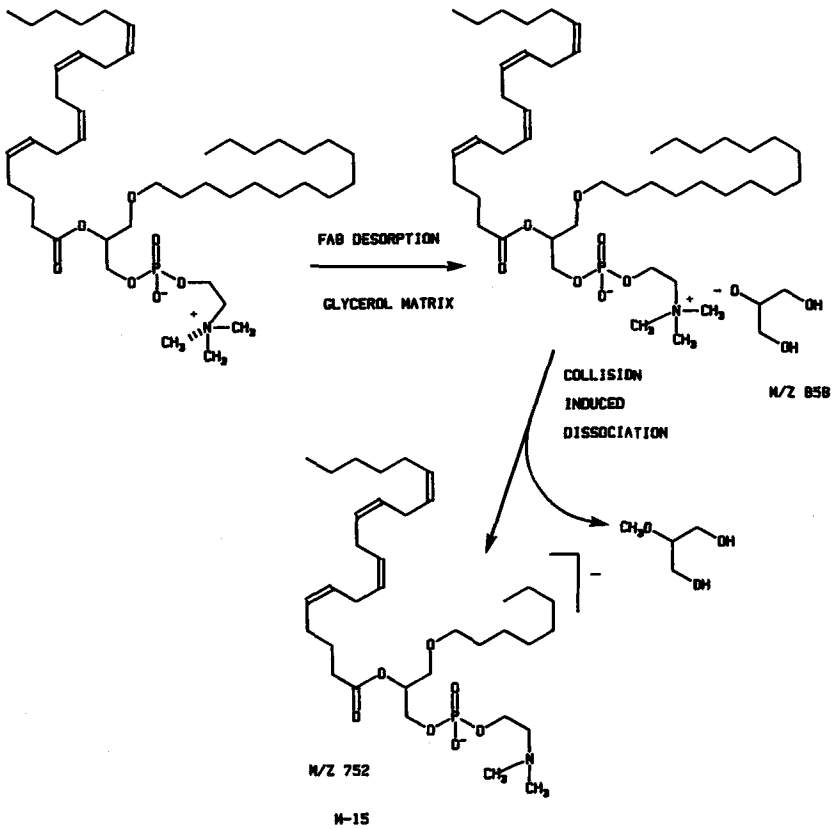


FIG. 3. B²/E linked scan experiment of *m/z* 752 (M-15) formed in the fast atom bombardment mass spectrometry of 1-*O*-hexadecyl-2-arachidonoyl-*sn*-glycero-3-phosphocholine. The observed precursor ions at *m/z* 858 suggest formation of the glycerol alkoxide adduct ion with the intact choline phospholipid.

SCHEME 2

551, and 643). Again, ions of less than a 1% abundance above *m/z* 800 are not indicated. The appearance of the abundant ions illustrates a fundamental problem with source-generated ions present in the direct fast atom bombardment mass spectrum. Ions could originate from substances other than the lipid, e.g., the matrix or impurities present in a phospholipid mixture. Collision-induced decomposition of the M-15 at *m/z* 752 (Fig. 2B) yielded essentially one ion, *m/z* 303 (the arachidonoyl carboxylate anion). No negative ions were observed resulting from charge retention on the alkyl ether substituent present at the *sn*-1 group. This is in keeping with the mechanism of formation of the ions illustrated in Scheme 1, where the stability of the carboxylate anion is an important facet in the collisional activation process and formation of carboxylate anions. Thus, alkyl ether choline phospholipids yield one carboxylate anion in accordance with only one ester moiety present and its position is at *sn*-2.

Origin of the M-15 ion. As shown in Scheme 1, the formation of these important carboxylate anions in the collision-induced decomposition of choline phospholipids relies on the generation of a N,N-dimethylamino moiety from the quarternary ammonium group in choline. Little is known concerning the mechanism by which such M-15 ions are formed. Linked scans were carried out to search for any precursor ion species for the M-15 ion in the gas phase. It is possible that the M-15 ion originated during the FAB process in the glycerol matrix, and thus demethylation would have taken place in the condensed phase. However, the B^2/E experiments revealed that there was a precursor ion for the M-15 ion for both the 1-*O*-hexadecyl-2-arachidonoyl molecular species and the diacyl molecular species as well. This ion from the 1-*O*-hexadecyl-2-arachidonoyl-*sn*-glycerophosphocholine appeared at *m/z* 858, corresponding to an attachment of a glycerol alkoxide anion to the choline phospholipid molecular species $[M + 91]^-$ (Fig. 3). When 3-nitrobenzyl alcohol was used for the fast atom bombardment matrix, an adduct ion was observed 152 daltons above the molecular weight of the choline phospholipid supporting formation of the alkoxide attachment ion from this matrix as well. Linked scans (B/E) for these adduct ions from each matrix revealed decomposition to the M-15 ions, suggesting that the demethylation process most likely involved simultaneous formation of the methyl ether of the matrix alcohol and a demethylated choline phosphate anion (M-15; Scheme 2). Since these adduct ions were observed in the B^2/E experiment, they were source-formed ions; however, it is possible that the demethylation process occurred to some extent in the condensed phase.

In summary, the tandem mass spectrometry of choline phospholipids which contain highly unsaturated acyl groups, such as arachidonic acid at the *sn*-2 group, provides useful information as to the radyl groups at *sn*- and *sn*-2. In the case of the 1-*O*-alkyl-2-acyl-glycerophosphocholines, a single acyl carboxylate anion is observed in the decomposition of the M-15 ion. The observation of this single carboxylate anion combined with the molecular weight of the molecule (deduced from the ions at M-15, M-60, and M-86), allows one to construct the radyl groups at *sn*-1 (an alkyl group) as well as *sn*-2 (the acyl group). Correspondingly for diacyl glycerophosphocholines, decomposition of the M-15 ion results in two carboxylate anions and from the ratio of these two products one can assign the fatty acyl substituents at *sn*-1 and *sn*-2. The formation of the carboxylate anion from the *sn*-2 group is preferred, most likely due to the stability of the five-membered ring cyclic phosphate ester as compared to the six-membered cyclic ester product. It is of interest that the formation of the M-15 ion—which is quite useful for molecular species analysis/arises from a demethylation reaction of a desorbed attachment ion of the phosphocholine with an ionized matrix molecule. This alkoxide ion from the matrix neutralizes the permanent positive charge on the quaternary nitrogen of the choline species, leaving a phosphate anion to direct acceleration into the mass spectrometer. Identical decomposition reactions were observed in a triple quadrupole mass spectrometer for these glycerophosphocholines which supports the charge-driven mechanisms outlined in Schemes 1 and 2 as being low energy processes.

Determination of Platelet-Activating Factor by a Chemiluminescence Method and Its Application to Stimulated Guinea Pig Neutrophils[1]

Yukio Hasegawa*, Eiko Kunow, Junko Shindou and Hidetaka Yuki
Department of Clinical Chemistry, School of Pharmaceutical Sciences, Toho University, Chiba 274, Japan

A simple, rapid and sensitive chemiluminescence method has been developed to measure platelet-activating factor (PAF). Hydrogen peroxide generated from PAF, upon phospholipase D cleavage, by choline oxidase is determined as chemiluminescence by a luminol-microperoxidase system. The detection limit of PAF by this method is 5 pmol/tube. The method is reproducible with a 5.5% coefficient of variation at 10 pmol of PAF (n = 5). Lipids were extracted from guinea pig neutrophils after stimulation with cytochalasin B and *N*-formyl-methionyl-leucyl-phenylalanine, and PAF was isolated by high-performance liquid chromatography and determined by chemiluminescence measurements. The amount of PAF detected was 96.1 ± 39.7 (mean ± SD, n = 7) pmol/10^8 cells. This highly sensitive method could be useful for the determination of PAF generated under pathophysiological conditions.
***Lipids* 26,** 1117–1121 (1991).

Platelet-activating factor (PAF, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) is an important mediator of allergic and inflammatory reactions (1). A wide variety of cell types produce PAF in very low concentrations upon stimulation (2). Few structural characteristics of PAF exist which can be detected easily; thus a simple and sensitive method for the measurement of PAF is needed.

PAF is usually determined by bioassay of platelet aggregation, the release of 5-hydroxytryptamine (3), or by gas chromatography/mass spectrometry (GC/MS)(4,5). The bioassay is a very sensitive method that can detect even picogram quantities of PAF, but its accuracy is limited because the platelet-activating activity of PAF varies with the chain length of the alkyl ether moiety of the molecule, and by other variables. By comparison, GC/MS is specific, sensitive and accurate. However, it requires expensive equipment and multistep sample preparation procedures which are time-consuming.

Various chemiluminescent reactions have been used for the quantitative analysis of a variety of biological substances (6,7). In our present study, a simple, rapid, and sensitive chemiluminescence method has been utilized to determine choline-containing phospholipids. The method was applied to the measurement of PAF produced in stimulated guinea pig neutrophils. The method is based on the detection of choline liberated from PAF. Takayama *et al.* (8) have measured choline-containing phospholipids by an enzymatic method; however, this method is not sensitive enough to determine trace amounts of PAF. We applied chemiluminescence detection to the enzymatic assay by using chemiluminescent reagents instead of colorimetry. As seen in the sequence of reactions shown in Figure 1, PAF is hydrolyzed by phospholipase D (PLD), and the choline liberated is subsequently oxidized by choline oxidase (CO). The hydrogen peroxide produced is then determined as chemiluminescence by the luminol-microperoxidase (mPOD) system.

$$\text{PAF} + H_2O \xrightarrow{\text{PLD}} \text{1-}O\text{-alkyl-2-acetyl-}sn\text{-glycerophosphate} + \text{choline}$$

$$\text{choline} + 2O_2 + H_2O \xrightarrow{\text{CO}} \text{betaine} + 2H_2O_2$$

$$\text{luminol} + 2H_2O_2 + 2OH \xrightarrow{\text{mPOD}} \text{aminophthalate} + N_2 + 4H_2O + \text{light}$$

FIG. 1. The sequence of enzymatic and chemiluminescent reactions for determination of PAF.

MATERIALS AND METHODS

Chemicals. 1-*O*-Hexadecyl- and 1-*O*-octadecyl-2-acetyl-*sn*-glycero-3-phosphocholine (C_{16}PAF and C_{18}PAF) and 1-*O*-hexadecyl-*sn*-glycero-3-phosphocholine (LPAF) were products of Novabiochem (Laufelfingen, Switzerland). Phosphatidylcholine (PC), phosphatidylethanolamine (PE), and phosphatidylglycerol (PG), all from egg yolk; phosphatidylinositol (PI) from soybeans; and sphingomyelin from bovine brain were obtained from Sigma Chemical Co. (St. Louis, MO). Palmitoyl and stearoyl lysophosphatidylcholine (LPC), phospholipase D (PLD) from *Streptomyces chromofuscus,* choline oxidase (CO) from *Alcaligenes,* microperoxidase (mPOD, MP-11), *N*-formyl-methionyl-leucyl-phenylalanine (FMLP), cytochalasin B, and bovine serum albumin (BSA; essentially fatty acid-free) were purchased from Sigma. Luminol and Triton X-100 were obtained from Wako Pure Chemical Industries (Osaka, Japan). All other reagents used were reagent grade.

Chemiluminescence determination. Enzymatic reactions by PLD and CO were carried out according to a modification of the method of Takayama *et al.* (8). PAF, LPAF, PC or LPC (0.025–2.5 μM) was dissolved in 10 mM Tris-HCl buffer (pH 8.0) containing 1 mM $CaCl_2$ and Triton X-100 (0.1–2 g/L). The above solution (200 μL) was transferred to a microtube (5 × 50 mm), and 10 μL each of PLD (50 U/mL) and CO (30 U/mL) was added. The mixture was then incubated for 15 min at room temperature. Tris-HCl buffer (pH 8.0) used for dissolving the choline-containing lipids was also incubated with PLD and CO to serve as blank. After incubation, the hydrogen

peroxide generated in the reaction mixture was determined as chemiluminescence. A calibration curve was prepared for each choline phospholipid.

The chemiluminescence reaction was carried out according to a modification of the method of Schroeder *et al.* (9). Luminol was dissolved in 0.1–1.0 M sodium carbonate-sodium bicarbonate buffer (pH 8.6–12). Stock solution of 100 μM mPOD was prepared in 10 mM Tris-HCl buffer (pH 7.4) and diluted to 20 μM in the carbonate buffer just before use. The chemiluminescence reaction was initiated by adding 50 μL each of 0.1 mM luminol and 20 μM mPOD to the microtube in which hydrogen peroxide was generated by CO upon PLD cleavage. Upon vortexing for 3 sec, the microtube was immediately inserted into a cell holder cavity of the reaction chamber mounted on top of a photometer NU-620 with an integrated timer (Nition, Tokyo, Japan), and chemiluminescence (350–550 nm) was measured at room temperature. The chemiluminescence time course was simultaneously recorded. The chemiluminescence intensity was expressed as the amount of chemiluminescence integrated over 1 min.

Preparation of guinea pig neutrophils. Neutrophils were prepared from guinea pig (Hartley, 300–350 g, female) peritoneal exudates by intraperitoneal injection of 30–35 mL of 2% sodium caseinate solution 14–16 hr before peritoneal lavage, as described previously (10). The exudates were collected by washing the peritoneal cavity with 60 mL of phosphate buffered saline (pH 7.4) containing heparin (1 unit/mL). Cells were then centrifuged (400 × *g*, 5 min) and washed with the same buffer. Contaminated erythrocytes were eliminated by suspending the cells in 0.2% NaCl for 30 sec at 4°C, and by then returning the osmolarity to normal by addition of an equal volume of 1.6% NaCl. Cells were sedimented by centrifugation (400 × *g*, 5 min) and then suspended in phosphate buffered saline before use.

Production of PAF. Guinea pig neutrophils were adjusted to a concentration of 1×10^7 cells/mL in Hanks' balanced saline buffer (pH 7.4) containing 0.25% gelatin and 0.25% bovine serum albumin as described (11). Neutrophils (10^8 cells) were prewarmed for 5 min at 37°C, incubated with cytochalasin B (1 μg/mL) for 5 min at 37°C, and then challenged with 1 μM FMLP for 3 or 10 min. Phosphate buffered saline, the vehicle of FMLP and cytochalasin B, were added to another sample as control. After incubation, the cell suspensions were centrifuged and the pellets were used for lipid extraction.

Lipid extraction and purification of PAF. Lipids were extracted from the cell pellets by the method of Bligh and Dyer (12). The extracted lipids were dissolved in 200 μL of chloroform/methanol (1:1, v/v), and 100 μL of the solution was analyzed by high-performance liquid chromatography (HPLC) on a Senshu-pak silica 1151-N column (4.6 × 150 mm) fitted with a Shimadzu LC-3A pump (Osaka, Japan). The solvent(100 μL) used for dissolving the lipids was also applied to HPLC as blank. The column was eluted with chloroform/methanol/water (240:220:11, v/v/v) at a flow rate of 1 mL/min (elution system I) as described before (13). PAF was further purified by HPLC using a Wakosil (Osaka, Japan) 5 SIL column (4.5 × 150 mm), a Tosoh ultraviolet (UV)-8000 detector (Tokyo, Japan), a Tosoh CCPM dual pump, and a linear solvent gradient of n-hexane/isopropanol/water from 100:100:12 (v/v/v) to 100:100:18 (v/v/v) over 20 min at a flow rate of 1 mL/min (elution system II), as described before (14). One mL of eluate was collected per fraction, and then dried with a centrifugal evaporator (Taitec VC-360, Taiyo Scientific Industrial, Tokyo, Japan). The PAF residue from each fraction was dissolved in 400 μL of 10 mM Tris-HCl buffer (pH 8.0) containing 1 mM $CaCl_2$ and Triton X-100 (2 g/L), and an aliquot of above solution (200 μL) was transferred to a microtube (5 × 50 mm) for chemiluminescence measurements. The chemiluminescence intensity of blanks for each fraction was also determined. The intensities of the blanks were almost identical for all fractions and corresponded to about 10 pmol of C_{16}PAF. The chemiluminescence intensity attributed to PAF was obtained by subtracting the intensity of the corresponding blank. The amount of PAF per fraction was calculated from the calibration curve established for the C_{16}PAF standard. The total amount of PAF present was the sum of the values obtained for the individual fractions.

Recovery of PAF. C_{16}PAF standard (1 nmol) was added to the neutrophil (without stimulation) suspension just before lipid extraction. PAF was isolated by HPLC using elution systems I and II as described above, and determined by the chemiluminescence method. The neutrophil suspension with no addition of PAF was used as a control. The recovery of PAF was calculated from the chemiluminescence intensity obtained by subtracting the intensity of the control. The PAF standard (100 pmol) was also directly applied to HPLC using elution systems I and II, and the recovery of PAF by HPLC was determined.

RESULTS AND DISCUSSION

The chemiluminescence intensity of PAF by the luminol-mPOD system is a function of pH and concentration of the carbonate buffer, and of the concentrations of luminol and mPOD. Each of these variables was examined individually. The chemiluminescence intensity rose sharply with an increase in the pH of the carbonate buffer, and reached a plateau above pH 10.5. At pH 10.5, 95% of the chemiluminescence reaction was completed within one minute. Chemiluminescence intensity also increased with an increase of the concentration of the buffer; the maximum intensity was obtained at the final concentration of 330 mM. Optimal concentrations of luminol and mPOD added to the reaction mixture were 0.1 mM and 20 μM, respectively. Under optimized conditions, a linear relationship was obtained between chemiluminescence intensity and the amount of hydrogen peroxide produced. The intensity was linear with hydrogen peroxide concentrations in the range of 4 to 500 pmol of hydrogen peroxide (coefficient of variation, 2.8% at 12 pmol H_2O_2, n = 3).

To save incubation time, the hydrolysis of PAF by PLD and the oxidation by CO were initiated by the simultaneous addition of both enzymes to the reaction mixture. The reaction was virtually complete within 15 min, the time span that was chosen as the incubation time. The optimal concentrations of PLD and CO were 50 U/mL and 30 U/mL, respectively. The enzymatic reactions of PLD and CO were not affected by 0.1–2.0 g/L Triton X-100 or by the addition of other lipids such as PE, PG, PI or cardiolipin (CL) to the reaction mixture. The reaction mixture without PAF was used as the blank. The blank itself gave a comparatively high background, which corresponded to about 10 pmol of C_{16}PAF standard. This background is

likely to be due to contaminations in the enzyme preparations. The yield of hydrogen peroxide from PAF by PLD and CO was 92.9 ± 4.4% (mean ± SD, n = 4), based on the chemiluminescence intensity due to hydrogen peroxide theoretically generated from PAF. The yield of conversion of choline to hydrogen peroxide by CO was about 98.2 ± 3.7% (n = 3), based on the chemiluminescence intensity produced by a hydrogen peroxide standard.

Figure 2 shows the relationship between the chemiluminescence intensity and the increasing concentrations of PAF on a double log plot under the optimized conditions specified above for both the enzymatic and the chemiluminescent reactions. The chemiluminescence intensity increased in direct proportion to the amount of PAF present, within the range of 5 to 500 pmol. The coefficient of variation was 5.5% at 10 pmol of PAF (n = 5) indicating good reproducibility.

Determination of PAF by the present method is as sensitive as is GC/MS (4). In the chemiluminescence method, the impurities in both enzyme preparations affect chemiluminescence intensity as the reactions are performed in the same tube. Purification of the enzymes would be necessary to decrease background noise and to achieve lower PAF detection limits. Alternatively, utilizing a flow injection system equipped with columns of immobilized PLD and CO would eliminate the effects of impurities in the enzyme preparations and should provide a higher sensitivity for the determination of PAF. We have previously demonstrated the effectiveness of a flow system with immobilized enzymes which minimize the background of chemiluminescence for the determination of inorganic phosphate (15). The chemiluminescence intensities of PC, LPC and LPAF determined by this method were almost the same as those of equimolar PAF. The results suggest that the chemiluminescence method is a sensitive detection system for choline phospholipids, including PAF.

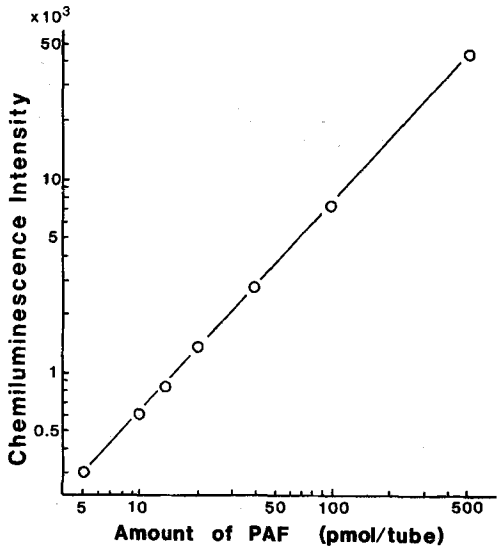

FIG. 2. Calibration curve for C_{16}PAF by the chemiluminescence method. C_{16}PAF (0.025–2.5 μM) was dissolved in 10 mM Tris-HCl buffer (pH 8.0) containing 1 mM $CaCl_2$ and Triton X-100 (2 g/L). Ten μL each of PLD (50 U/mL) and CO (30 U/mL) was added to 200 μL of the PAF solution. After incubation for 15 min, the chemiluminescence intensity was measured as described in Materials and Methods. Each point represents the mean of three experiments.

To investigate the applicability of the chemiluminescence method to biological samples, guinea pig peritoneal neutrophils were stimulated with FMLP and cytochalasin B, and the PAF produced was determined. PAF was separated from other choline phospholipids by HPLC using first the elution system I and then elution system II. Figure 3 shows the HPLC separation of choline phospholipid standards using elution system I. PAF was well separated from other choline phospholipids. C_{16}PAF and C_{18}-PAF were eluted in fraction 30–32 and fraction 32–34, respectively, between sphingomyelin and LPC. HPLC of the extracted lipids from the stimulated neutrophils was done as described above. PAF was not completely separated from the pronounced tailing of the sphingomyelin peak (Fig. 4); therefore, PAF was further purified

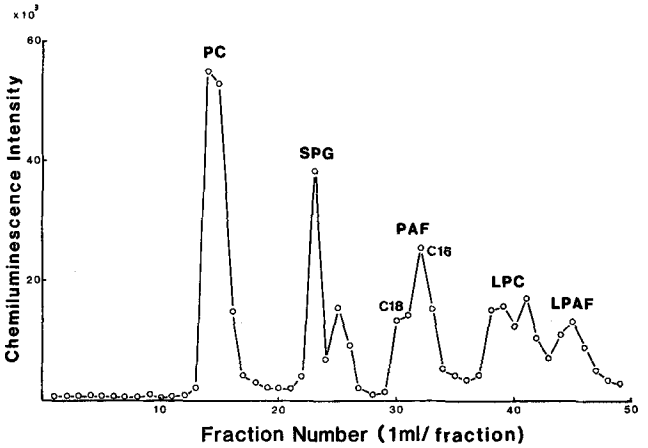

FIG. 3. HPLC separation of choline-containing phospholipid standards using elution system I. PC (2 nmol), sphingomyelin (1 nmol), C_{16}PAF (700 pmol), C_{18}PAF (300 pmol), palmitoyl LPC (500 pmol), stearoyl LPC (500 pmol) and LPAF (500 pmol) were dissolved in 100 μL of chloroform/methanol (1:1,v/v) and analyzed by HPLC with a Senshu-pak silica 1151-N column (4.6 × 150 mm). HPLC conditions were as described in Methods and Materials. One mL of eluate was collected in each fraction and dried. The dried lipids in each fraction were dissolved in 400 μL of 10 mM Tris-HCl buffer (pH 8.0) containing 1 mM $CaCl_2$ and Triton X-100(2 g/L), and 200 μL of the solution was used for measurement of the chemiluminescence intensity as described in Materials and Methods.

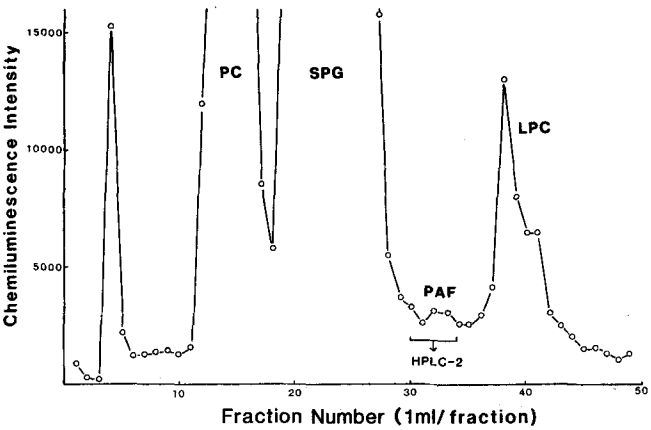

FIG. 4. HPLC separation of lipids extracted from stimulated guinea pig neutrophils using elution system I. Conditions for HPLC and for chemiluminescence measurements are the same as those shown in Figure 3. PAF contained in fraction 30–34 was further purified by HPLC using elution system II.

by HPLC using elution system II. Figure 5 shows the HPLC separation of the phospholipid standards using elution system II. PAF and sphingomyelin in HPLC fractions 30–34, using elution system I, were eluted separately (Fig. 6). Most of the PAF was eluted in the same fractions (fraction 25–27) as the C_{16}PAF standard. The amount of PAF produced upon stimulation by FMLP and cytochalasin B for 3 or 10 min was 41.8 ± 12.5 (mean ± SD, n = 3) or 96.1 ± 39.7 (n = 7) pmol/10^8 cells, respectively. The amounts of PAF in the control group, which was incubated for 3 or 10 min without stimulation, were 21.4 ± 8.1 and 40 ± 19.2 pmol/10^8 cells (n = 3), respectively. Relatively high levels of PAF were detected in the guinea pig neutrophils without stimulation. Approximately 65% of the PAF standard added to the neutrophils was recovered in the course of the isolation (n = 3). The recovery of PAF by HPLC, using elution system I, was 89.3 ± 6.1% (n = 3). Using elution system II, the recovery of PAF by HPLC was 76.8 ± 9.7% (n = 3). Ramesha and Pickett (16) reported that PAF determined by GC/MS in guinea pig peritoneal neutrophils stimulated with ionophore A23187 was 8.4 ng (about 15 pmol)/10^7 cells. A very high amount of PAF (5.2 ng/10^7 cells) was also detected in guinea pig neutrophils without stimulation. The major molecular species of PAF detected by GC/MS were C_{16}PAF and C_{17}PAF. The value of PAF determined by the chemiluminescence method in the neutrophils, stimulated with FMLP and cytochalasin B, was a little lower than that obtained by GC/MS in guinea pig neutrophils stimulated with ionophore A23187. Lynch and Henson (17) found that the quantity of PAF generated upon FMLP stimulation was less than that obtained upon stimulation with ionophore A 23187. Direct comparisons between the PAF amounts determined by the chemiluminescence method and those determined by GC/MS will be needed. PAF determined by GC/MS (18) and bioassay (19) in human neutrophils stimulated by ionophore A 23187 were 80 and 1000 pmol/10^7 cells. The reason for this large discrepancy between the values obtained by two methods is unknown. The levels of PAF detected in human neutrophils were somewhat higher than those determined by GC/MS or with the chemiluminescence method in stimulated guinea pig neutrophils. PAF detected by GC/MS in rabbit peripheral neutrophils stimulated with ionophore A 23187 was 40 ± 15 pmol/10^7 cells (20). The results suggested that only low levels of PAF occur in stimulated guinea pig peritoneal neutrophils, the reasons for which are not clear.

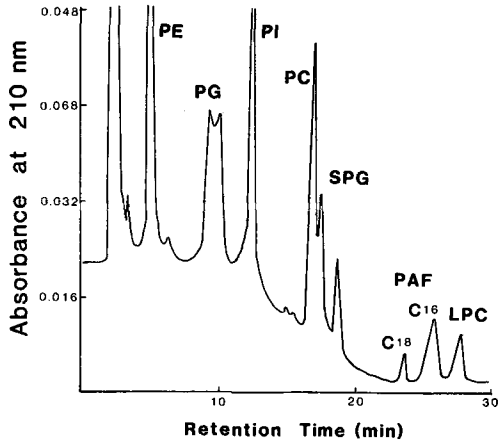

FIG. 5. HPLC separation of the phospholipid standards using elution system II. PE (25 μg), PG (11 μg), PI (25 μg), PC (25 μg), C_{18}PAF (100 nmol), C_{16}PAF (300 nmol) and palmitoyl LPC (250 nmol) were dissolved in 100 μL of n-hexane/isopropanol/water (100:100:12, v/v/v), and separated by HPLC using a Wakosil 5 SIL column (4.6 × 150 mm) and UV detection at 210 nm. HPLC conditions are those described in Materials and Methods.

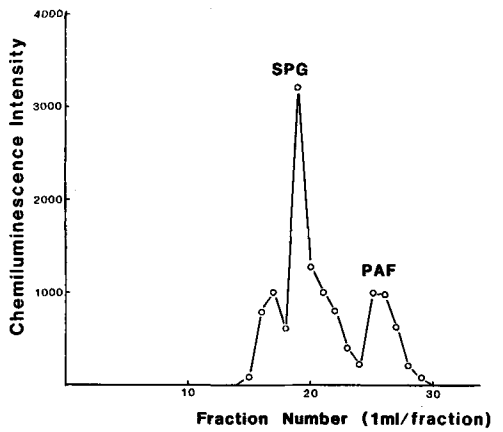

FIG. 6. HPLC separation of PAF and sphingomyelin using elution system II. PAF contained in HPLC fraction 30–34 using elution system I (Fig. 4) was dissolved in 100 μL of n-hexane/isopropanol/water (100:100:12, v/v/v) and separated from sphingomyelin by HPLC using elution system II. Conditions are the same as those shown in Figure 5, except for the chemiluminescence detection. The chemiluminescence measurements were carried out as described in Materials and Methods.

Many studies have shown the presence of different molecular species of PAF in various types of cells (20,21). Although in the present study we did not determine the molecular species of PAF, the retention time in HPLC suggests that most of the PAF produced in guinea pig neutrophils was C_{16}PAF. More accurate determination of the molecular species may be possible by reverse phase HPLC.

The proposed chemiluminescence method is simple, sensitive, and rapid, and does not require expensive instrumentation for the determination of choline-containing phospholipids. Our method is applicable to the determination of PAF produced in stimulated neutrophils, and may also be useful for studies of other choline phospholipids, including LPC and LPAF. The determination of PAF by flow injection analysis using immobilized PLD and CO columns is presently being investigated.

Specific Binding of Antibodies to Platelet-Activating Factor (PAF) as Demonstrated by Thin-Layer Chromatography/Immunostaining[1]

Ken Karasawa, Noriko Satoh, Toshio Hongo, Yasuhito Nakagawa, Morio Setaka and Shoshichi Nojima*

Department of Membrane Biology, Faculty of Pharmaceutical Science, Teikyo University, Sagamiko, Kanagawa 199-01, Japan

The specificity of rabbit antibodies produced by injection of 1-*O*-(15'-carboxypentadecyl)-2-*N,N*-dimethylcarbamoyl-*sn*-glycero-3-phosphocholine bovine serum albumin (BSA) conjugates was examined by a thin-layer chromatography (TLC)/immunostaining method. Phosphatidylcholine (PC), lysophosphatidylcholine (lysoPC), lyso platelet-activating factor (lysoPAF), phosphatidylethanolamine (PE), phosphatidylglycerol (PG), phosphatidylserine (PS), sphingomyelin (SM), phosphatidylinositol (PI), phosphatidic acid (PA) and cardiolipin (CL) were not immunostained. Among several synthetic PAF-related compounds, the antibodies only bound to PAF agonists which have the activity to induce washed rabbit platelet aggregation. The results suggest that the binding sites of the antibodies on the PAF molecule are the acetyl group at the *sn*-2 position and the choline moiety at the *sn*-3 position of glycerol, both of which are essential for exerting the biological function of PAF and for binding to the PAF receptors located on cellular membranes.
***Lipids 26,* 1122–1125 (1991).**

1-*O*-Alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (PAF) is a potent biologically active phospholipid that plays a major role in inflammatory reactions (1). We have recently reported the successful production of rabbit polyclonal antibodies to PAF by injection of a nonhydrolyzable synthetic PAF analogue conjugated to BSA with Freund's complete adjuvant (2). High specificity is required for the application of antibodies, e.g., as reagents for immunoassay or immunohistochemistry, or as tools for study of the receptor. A sensitive enzyme-immunochemical staining method has been used for detection of glycosphingolipids on silica gel thin-layer chromatography (TLC) (3). In this study we examined the specificity of rabbit antibodies to PAF by the TLC/immunostaining method and identified the binding sites for the antibodies on the PAF molecule.

MATERIALS AND METHODS

Materials. 1-*O*-Hexadecyl PAF, 1-*O*-octadecyl PAF and 1-*O*-hexadecyl lysoPAF were obtained from Bachem (Bubendorf, Switzerland). Dipalmitoyl phosphatidylcholine and rabbit γ-globulin, bovine serum albumin (BSA), polyvinylpyrrolidone (PVP) and 4-chloro-1-naphthol were from Sigma Chemical Co. (St. Louis, MO). Freund's complete adjuvant was from Difco Laboratories (Detroit, MI). Phosphatidylinositol (PI) (from yeast), phosphatidic acid (PA) (from egg yolk), sphingomyelin (from bovine brain) and 1-palmitoyl-*sn*-glycero-3-phosphocholine were a gift from Dr. M. Umeda (Univ. of Tokyo, Japan). Biotinylated goat anti rabbit-IgG (Ig, immunoglobulin) and avidin-biotinylated horseradish peroxidase complex were from Vector Laboratories Inc. (Burlingame, CA). Phosphatidylethanolamine (PE), phosphatidylglycerol (PG) and cardiolipin (CL) were prepared from *Escherichia coli* (4). Enantio-PAF (3-*O*-hexadecyl-2-acetyl-*sn*-glycero-1-phosphocholine) was from Nova Biochem (Laufelfingen, Switzerland). Polyisobutylmethacrylate was from Aldrich (Milwaukee, WI). Protein A-Sepharose CL-6B was from Pharmacia Fine Chemicals (Uppsala, Sweden).

Preparation of antibodies. 1-*O*-(15'-Carboxypentadecyl-2-*N,N*-dimethylcarbamoyl-*sn*-glycero-3-phosphocholine BSA conjugates were injected into rabbits according to the method described in our previous report (2). At one week after the booster injection, blood was drawn from the ear vein of the rabbit which had the highest titer of antibody activity. The IgG fraction was separated from antisera by protein A-Sepharose CL-6B column chromatography.

TLC/immunostaining. TLC/immunostaining was performed according Higashi *et al.*, with slight modifications (3). In brief, phospholipids were applied to a plastic-backed TLC plate (Polygram Sil G, Macherey-Nagel, W. Germany). The spotted TLC plate was dried and dipped into a hexane solution containing 0.4% polyisobutylmethacrylate for several seconds. After drying, the plate was soaked in PBS containing 1% ovalbumin and 1% PVP for 2 hr. After washing of the TLC plate with PBS, IgG from rabbit antiserum diluted with PBS containing 1% PVP (46.8 μg protein/ml) was applied to the TLC plate and incubated for 1 hr. After washing of the TLC plate with PBS, biotinylated goat anti-rabbit IgG diluted at 1:200 with PBS containing 1% PVP was applied to the plate and incubated for 30 min. The plate was again washed with PBS, and an aliquot of the avidin-biotinylated horseradish peroxidase complex diluted at 1:200 with PBS was applied. After incubation for 30 min, the TLC plate was washed thoroughly with PBS and then exposed for 15 min at room temperature, to 4-chloro-1-naphthol/hydrogen peroxide solution, which was freshly prepared before use by the method of Hawkes *et al.* (5). The enzyme reaction was stopped by washing the TLC plate with water/methanol (5:1, v/v). The immunostained TLC plate was allowed to dry and was scanned with a dual-wave-

Abbreviations: BSA, bovine serum albumin; CL, cardiolipin; Ig, immunoglobulin; PA, phosphatidic acid; PAF, platelet-activating factor; PBS, phosphate-buffered saline; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; PI, phosphatidylinositol; PS, phosphatidylserine; SM, sphingomyelin; TLC, thin-layer chromatography.

length TLC scanner, CS-910 (Shimadzu Co., Kyoto, Japan). The absorbance at 578 nm was measured in the transmittance mode. Peak areas were measured with a Chromatopack CR-1B integrator (Shimadzu Co., Kyoto, Japan).

Platelet aggregation. Washed rabbit platelets were prepared according to the method described by Pinckard *et al.* (6). Test compounds were solubilized in 0.15 M NaCl containing 2.5 mg/ml BSA. Platelet aggregation was monitored using an aggregometer (RAM-11, Rikadenki Kogyo, Co., Tokyo, Japan).

RESULTS

We were successful in applying the TLC/immunostaining method to the detection of very small amounts of PAF on a TLC plate, by introducing a fixation step with polyisobutylmethacrylate. Otherwise, PAF spotted on a TLC plate is easily lost from the plate during conventional TLC/immunostaining. This fixing method has previously been used in the TLC/immunostaining of glycosphingolipids (7). Figure 1 shows the results of TLC/immunostaining of PAF and other phospholipids. Both PAF and 1-*O*-hexadecyl-2-*N*,*N*-dimethylcarbamoyl-*sn*-glycero-3-phosphocholine were immunostained as blue-purple spots, but were not immunostained at all by IgG separated from preimmune rabbit serum. The antibodies did not bind to other naturally occurring phospholipids such as PC, PE, PG, CL, PA, sphingomyelin (SM), lysoPC and lysoPAF. The effect of fixation by polyisobutylmethacrylate on the lipid fractions on TLC plates was examined. Figure 2 shows that PAF, lysoPAF and DPPC are well fixed and stained with phosphomolybdic acid reagent, but only PAF was immunostained. Similar results were obtained with mouse liver lipids and mouse brain lipids. Also, in these cases, the lipids were not lost, but were well retained on TLC plates even after treatment with a polyisobutylmethacrylate solution, but only PAF was immunostained (data not shown).

Various amounts of PAF were applied onto a TLC plate and immunostained, and the plate was scanned with a densitometer (Fig. 3). As little as 1 pmol of PAF could be detected with a good signal-to-noise ratio (S/N > 2). An acceptable densitometric response was observed up to 125 pmol of PAF, although it deviated somewhat from linearity.

We studied the structure-immunoreactivity relationship of PAF and its analogues by the TLC/immunostaining method (Table 1). In regard to modification of the 1-*O*-alkyl group, no significant difference in immunoreactivity was recognized between C_{18}PAF (II) and C_{16}PAF (I). The acyl analogue of PAF [1-palmitoyl-2-acetyl-*sn*-glycero-3-phosphocholine (III)] reacted weakly as compared to PAF. This result showed that a change from the alkyl ether bond ($-CH_2-O-CH_2CH_2-$) to the acyl ester one ($-CH_2-OCO-CH_2-$) markedly decreased the cross-reactivity with the antibodies. The acetyl group at *sn*-2 was required for the binding of PAF to the antibodies, as lysoPAF (V) did not show any cross-reactivity. PAF analogues with substituents such as $(CH_3)_2NCOO-$ (VIII), CH_3CONH- (IX), CH_3COCH_2COO- (X) and $CH_3OCONH-$ (XI), in place of the acetyl group at *sn*-2 of the glycerol backbone,

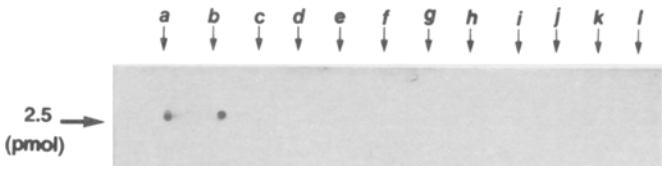

FIG. 1. TLC/immunostaining of PAF and other phospholipids. In this case, 2.5 pmol of each phospholipid was spotted on the TLC plate and immunostained as described in Materials and Methods. (a) 1-*O*-Hexadecyl PAF, (b) synthetic hapten (1-*O*-(15'-carboxypentadecyl)-2-*N*,*N*-dimethylcarbamoyl-*sn*-glycero-3-phosphocholine), (c) phosphatidylcholine, (d) lysophosphatidylcholine, (e) lysoPAF, (f) phosphatidylethanolamine, (g) phosphatidylserine, (h) phosphatidylglycerol, (i) phosphatidylinositol, (j) cardiolipin, (k) phosphatidic acid, and (l) sphingomyelin.

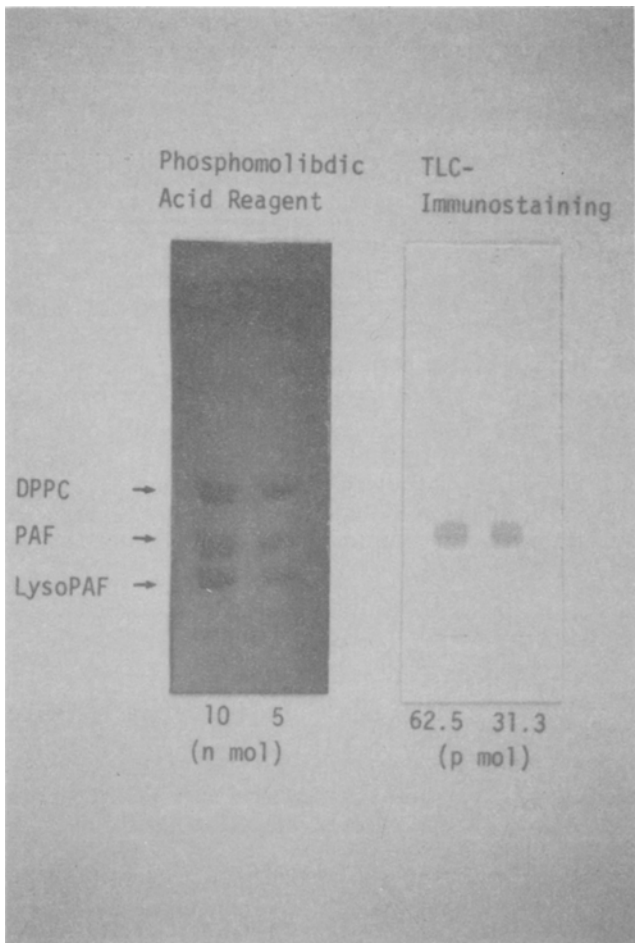

FIG. 2. Effect of fixation with polyisobutylmethacrylate on thin-layer chromatograms of DPPC, PAF and lysoPAF. Left panel: DPPC, 1-*O*-hexadecyl PAF and lysoPAF (10 or 5 nmol, respectively) were spotted on a plate and developed in $CHCl_3/CH_3OH$/water (65:35:6, v/v/v). After drying, the plate was treated with polyisobutylmethacrylate. The treated plate was dipped in phosphomolybdic acid reagent (10%, w/v, phosphomolybdic acid in ethanol) for a few seconds and heated at 120°C on a hot plate. Right panel: After DPPC, 1-*O*-hexadecyl PAF and lysoPAF (62.5 or 31.3 pmol, respectively) were spotted and developed in the same manner as described above (left panel), the plate was treated for immunostaining as described in Materials and Methods.

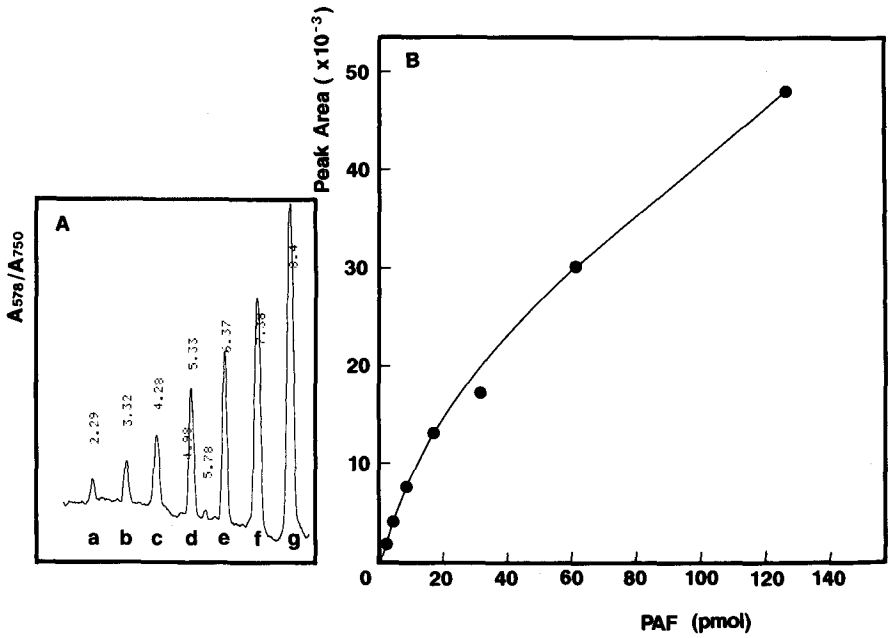

FIG. 3. TLC/immunostaining of PAF and densitometric scanning of the enzyme-immunostained spots on the chromatogram. A series of 1-*O*-hexadecyl PAF samples [(a) 0.98, (b) 1.95, (c) 3.90, (d) 7.81, (e) 15.6, (f) 31.3 and (g) 62.5 pmol] were spotted onto a TLC plate, immunostained, and the plate was scanned with a densitometer (see Materials and Methods). The integral densitometric response was plotted vs PAF concentration.

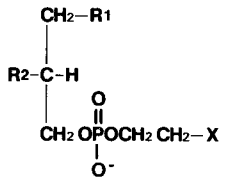
were immunostained to various extents. The D-isomer of PAF, the inactive enantiomer of natural PAF (IV), was not stained. A compound containing a morpholino group at *sn*-3 (XII) in place of the choline moiety was immunostained. All of the immunostained compounds had the activity to induce rabbit platelet aggregation, while the other compounds were neither immunostained nor had PAF agonist activity.

DISCUSSION

It has been reported already that antibodies to some phospholipids, such as CL (8), PI (9), polyphosphoinositides (10,11) and PS (12) are produced in rabbits and mice. The haptenic activity was enhanced by the addition of cholesterol and lecithin with an appropriate carrier protein such as methylated BSA. However, antibodies to PAF could not be produced by the injection of a mixture of PAF, lecithin, cholesterol and methylated BSA. We considered that this might be because PAF is easily removed from the lipid micelles, since serum proteins such as albumin have a high affinity for PAF (13,14). Further, PAF is rapidly degraded in plasma and tissues; $T_{1/2}$ of PAF in rabbit plasma is only 10 min (15). Therefore, we attempted to produce antibodies to PAF by injection of a nonhydrolyzable PAF analogue covalently attached to a carrier protein. Since 1-*O*-hexadecyl-2-*N*,*N*-dimethylcarbamoyl-*sn*-glycero-3-phosphocholine has almost the same activity as PAF and is resistant to acetylhydrolase (16), we synthesized a hapten bearing a carboxy group at the ω-position of the C-1 alkyl chain of this derivative and used the conjugate composed of this PAF analogue covalently attached to BSA as an immunogen. The antibodies to this immunogen showed high specificity for PAF.



We also showed that the acetyl group at C-2 of PAF was distinctly recognized by the antibodies. In addition, we observed that rabbit antibodies to the antigen in which a monobutylcarbamoyl group was present at the *sn*-2 position of glycerol, in place of the dimethylcarbamoyl group, have higher affinity for the monobutylcarbamoyl derivative of PAF than for PAF (Karasawa, K., *et al*, unpublished data). We are now attempting to produce rabbit antibodies to immunogenic conjugates composed of synthetic haptens having acyl groups with different chain lengths or being deacylated at the *sn*-2 position of glycerol. A series of antibodies with different specificities for the acyl chain length at the *sn*-2 position of glycerol might be useful for analysis of each of these phospholipids in biological materials.

A unique feature of the antibodies is the recognition of the chirality of the *sn*-2 position of PAF. These antibodies had negligible cross-reactivity with D-PAF in TLC/immunostaining and radioimmunoassay (less than 0.047 %) (17). To our knowledge, this is the first report of an antibody that recognizes the stereospecificity at C-2 of phospholipids, although Umeda *et al.* (12) reported the stereospecific recognition of the polar head group in PS by mouse monoclonal antibodies.

Among the PAF-related compounds, only PAF agonists showed cross-reactivity with the antibodies. These results suggest that the binding sites of the antibodies on PAF involve at least part of the structure which is necessary for binding to PAF receptors. The existence

TABLE 1

Cross-Reactivity and Platelet Aggregating Activity of PAF-Related Phospholipids

[a]Twenty-five pmol of each compound was spotted on the TLC plate and immunostained as described in Materials and Methods. Positive (+) compounds were detectable as blue-purple spots.

[b]Positive (+) compounds caused aggregation of washed rabbit platelets at 5×10^{-7} M (over 50% change was recorded in light transmission).

[c]Weakly positive in TLC/immunostaining.

of PAF receptors has been demonstrated in platelets (18), neutrophils (19) and other cells.

In the present study we showed that PAF can be quantitatively detected by the TLC/immunostaining method. This method has already successfully been employed to detect and estimate glycosphingolipid (e.g., tumor-associated Hanganuitziu-Deicher antigen) (20). We are now interested in the application of our PAF antibodies to biological samples. We developed the TLC/immunostaining method for measurement of PAF using C_{16}PAF as authentic standard, since C_{16}PAF is a predominant component in a number of biological materials (21). However, PAF in biological materials consist of various molecules species, such as C_{18}PAF, $C_{18:1}$PAF and others. In this respect, caution is required when the amount of PAF in biological samples is estimated by the TLC/immunostaining method, because C_{18}PAF is also cross-reacting with these antibodies.

In the previous report we described the substantial cross-reactivity between lysoPAF and PAF antibodies by ELISA inhibition assay (2). On the other hand, we have shown in this paper [and in an accompanying one (17)] that no cross-reactivity of lysoPAF with PAF antibodies could be found by either TLC/immunostaining and or radioimmunoassay (less than 0.025%). We cannot explain this discrepancy at the present time, but the inconsistent results may be due, in part, to the different immunochemical assay systems used. Anyway, antibodies which we used here for the present study do not cross-react at all with lysoPAF up to the amount of 125 pmol tested (unpublished results).

ACKNOWLEDGMENTS

We thank Dr. Y. Suzuki, School of Pharmaceutical Science, University of Shizuoka, Shizuoka-Shi, Japan, for his valuable advice on TLC/immunostaining techniques. This work was supported by Grants-in-Aid (Nos. 01771991 and 63870099) for Scientific Research from the Ministry of Education, Science and Culture of Japan.

Radioimmunoassay for Platelet-Activating Factor[1]

Ken Karasawa, Noriko Satoh, Toshio Hongo, Yasuhito Nakagawa, Morio Setaka and Shoshichi Nojima*
Department of Membrane Biology, Faculty of Pharmaceutical Science, Teikyo University, Sagamiko, Kanagawa 199-01, Japan

A radioimmunoassay (RIA) for measurement of platelet-activating factor (PAF) was developed. At a final antiserum dilution of 1:640, the lowest detection limit of PAF was 0.1 pmol (50 pg). The standard curve obtained was suitable for measurement of PAF in amounts ranging from 0.1 pmol to 30 pmol. The antiserum showed high specificity. Cross-reaction for lysoPAF, lysophosphatidylcholine and long-chain phosphatidylcholines was very low (less than 0.025%). 1-Palmitoyl-2-acetyl-*sn*-glycero-3-phosphocholine cross-reacted slightly (6.25%). PAF exogenously added to macrophage suspensions was quantitatively determined by RIA after solvent extraction and high-performance liquid chromatographic separation. RIA was also used to estimate PAF formation after stimulation of rabbit alveolar macrophages in suspension with calcium ionophore A23187.
***Lipids 26,* 1126–1129 (1991).**

Platelet-activating factor [PAF; 1-*O*-hexadecyl (or octadecyl)-2-acetyl-*sn*-glycero-3-phosphocholine] is a potent lipid mediator of various inflammatory and allergic reactions (1). PAF administered *in vivo* elicits pathophysiological responses at low doses, and PAF antagonists are effective in several pathological animal models. Although quantitative estimation of PAF levels in various disease states is necessary for evaluation of its pathological role, very little information has been obtained about the amounts of PAF present in biological samples. The most commonly employed methods for measurement of PAF are the bioassay, based on aggregation or secretion of washed rabbit platelets (2), and gas chromatography-mass spectrometry (GC-MS) (3). The former is sensitive, but not sufficiently accurate, because the conditions used for platelet preparation affect reproducibility. The latter method yields structural information, but requires relatively large samples. Radioimmunoassay (RIA) is specific, sensitive and practical for routine measurements. The RIA method has been widely used for the quantitation of lipid mediators, such as prostaglandins and leukotrienes. Therefore, we have attempted to establish a RIA for PAF. We have already reported the preparation of rabbit antibodies by injection of a non-hydrolyzable synthetic PAF analogue conjugated to bovine serum albumin (BSA) with Freund's complete adjuvant (4). In the present study we developed a sensitive (0.1 pmol) and specific RIA for PAF using these antibodies.

MATERIALS AND METHODS

Materials. 1-*O*-Hexadecyl PAF and 1-*O*-hexadecyl lysoPAF were obtained from Bachem (Bubendorf, Switzerland). Dipalmitoyl phosphatidylcholine, rabbit γ-globulin, BSA and ionophore A23187 were from Sigma Chemical Co. (St. Louis, MO). Freund's complete adjuvant was from Difco Laboratories (Detroit, MI). Phosphatidylinositol (PI) (from yeast), phosphatidic acid (PA) (from egg yolk), sphingomyelin (SM) (from bovine brain) and 1-palmitoyl-*sn*-glycero-3-phosphocholine were a gift from Dr. M. Umeda (University of Tokyo, Japan). Phosphatidylethanolamine (PE), phosphatidylglycerol (PG), and cardiolipin (CL) were prepared from *Escherichia coli* (5). Enantio-PAF (3-*O*-hexadecyl-2-acetyl-*sn*-glycero-1-phosphocholine) was from Nova Biochem (Laufelfingen, Switzerland). 1-*O*-[^{3}H]Octad ecyl PAF (132 Ci/mmol) and ACS scintillation fluid were from Amersham International (Amersham, Buck, U.K.). Polyethylene glycol (#6000) was from Nakarai Chemicals (Kyoto, Japan). 1-Palmitoyl-2-acetyl-*sn*-glycero-3-phosphocholine was prepared by acetylation of 1-palmitoyl-*sn*-glycero-3-phosphocholine in pyridine and purified by thin-layer chromatography.

Preparation of Antibodies. 1-*O*-(15′-Carboxypentadecyl)-2-*N,N*-dimethylcarbamoyl-*sn*-glycero-3-phosphocholine/BSA conjugates were injected into a rabbit according to the method described in our previous report (4). At one week after the booster injection, blood was drawn from the ear vein of a rabbit which had a high titer of antibody activity. Antiserum was inactivated at 56°C for 30 min.

RIA. RIA with polyethylene glycol 6000 was performed by a slight modification of the method by Schiller *et al.* (6). Antiserum, radiolabelled PAF, standard PAF and other reagents were all prepared in phosphate-buffered saline (PBS) containing 0.05% Tween 20. The addition of Tween 20 to the assay buffer decreased both the non-specific binding of labelled PAF to γ-globulin and adsorption to the plastic test tubes. The non-specific binding of labelled PAF was less than 3% for the γ-globulin precipitation. 1-*O*-[^{3}H]Octadecyl PAF (0.1 mL, 30,000 dpm), and standard PAF (0.1 mL, 0–100 pmol) were added to plastic, micro test tubes (Eppendorf, Hamburg, FRG) with antiserum (0.25 mL) diluted to 1:320 (final concentration, 1:640). Then, 1% rabbit γ-globulin (0.05 mL) was added. The tubes were vortexed and incubated for 16 hr at 4°C. At equilibrium, the antibody-bound radiolabelled PAF and the free PAF were separated by precipitation of γ-globulin with 0.5 mL of a chilled (4°C) aqueous solution of 25%

Abbreviations: BSA, bovine serum albumin; CL, cardiolipin; GC-MS, gas chromatography-mass spectrometry; GPC, glycerophosphocholine; HPLC, high performance liquid chromatography; PA, phosphatidic acid; PAF, platelet-activating factor; PBS, phosphate-buffered saline; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; PI, phosphatidylinositol; PS, phosphatidylserine; RIA, radioimmunoassay; SM, sphingomyelin.

w/v polyethylene glycol, incubation for 1 hr at 4°C and centrifugation at 4°C for 10 min at 9,000 × *g* to compact the γ-globulin pellet. The supernatant was aspirated and discarded. The γ-globulin pellet was reconstituted in 0.5 mL of 0.5 N NaOH, and the sample was transferred to a scintillation vial. ACS scintillation fluid (10 mL) was added and the amount of antibody-bound [^{3}H]PAF was determined with an Aloka LSC-900 liquid scintillation counter.

Extraction and chromatography of samples. Alveolar macrophages were harvested from the lungs of New Zealand White rabbits (male, 3 kg weight) according to the method of Myrvik *et al.* (7). Macrophages (5 × 10^6) were suspended in 1 mL of MEM medium (Nissui Pharmaceutical Co., Tokyo, Japan) with 20 mM Hepes buffer (pH 7.3). A trace of [^{3}H]PAF (3,000 dpm) was added to the samples for calculating recoveries. Lipids were extracted from macrophage suspensions by the method of Bligh and Dyer (8). The chloroform layer was evaporated to dryness. These samples were separated by high performance liquid chromatography (HPLC) according to the method of Hayashi *et al.* (9). Briefly, the above residue was dissolved in 60 μL of hexane/isopropanol (1:2, v/v). HPLC was performed using a Shimadzu LC-6A system (Shimadzu, Kyoto, Japan), which was connected to a UV detector. PAF was separated from other phospholipids by a 3.9 × 150-mm μ Bondasphere silica column (Waters Associates Inc., Milford, MA) eluted with isopropanol/hexane/water (110:100:20, v/v/v), and the fraction corresponding to PAF was collected. After evaporation of the PAF fraction to dryness under nitrogen, 0.5 mL of PBS containing Tween 20 (0.05%, w/v) was added. An aliquot (0.2 mL) was removed to determine percentage recovery and the remainder was used for PAF determination by RIA, as described above.

Accuracy of RIA. The accuracy of the assay was assessed by analyzing the content of PAF in (i) a standard buffer solution of PAF; and (ii) macrophage suspensions (5 × 10^6 cells) with known amounts of added PAF. These samples were extracted and chromatographed as described above prior to RIA.

Cell incubation. Macrophage suspensions preincubated at 37°C for 1 min were incubated with ionophore A23187 (1 μg/mL) for 20 min. The incubation was stopped by addition of 1 mL of ice-cold methanol, followed by extraction and chromatography of samples prior to RIA.

RESULTS

Specificity and sensitivity of RIA. Figure 1 shows the elevation of the antiserum titer after injection of the immunogens into rabbit. The titer of the antiserum increased by repeated injections of the immunogen. For the radioimmunoassay, we used the antiserum collected after the fourth injection (19 weeks). Fifty percent binding of [^{3}H]PAF was observed at an antiserum dilution of 1:200 (final concentration).

The standard curve for PAF was obtained using the antibody at 1:640 dilution, which bound 25% of the labelled PAF in the absence of standard PAF. As shown in Figure 2, increasing amounts of PAF inhibited the binding of labelled PAF to antibody in a competitive

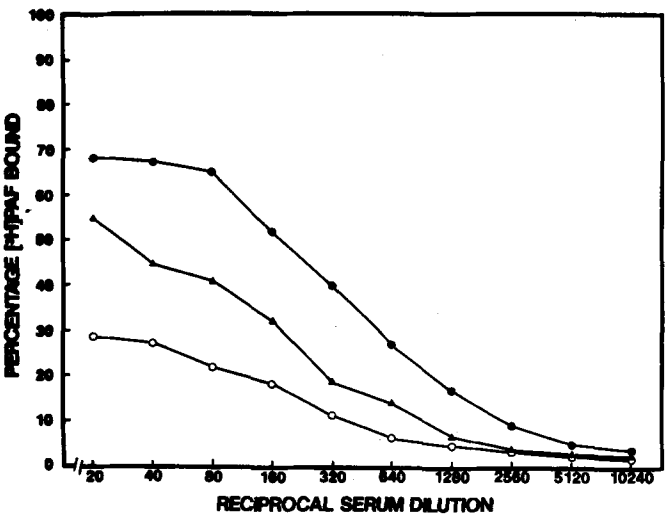

FIG. 1. Binding activity of rabbit antisera. Percentage of [^{3}H]PAF bound was measured 10 weeks (○), 13 weeks (▲) and 19 weeks (●) after the beginning of antigen injection. RIA was carried out as described in Materials and Methods.

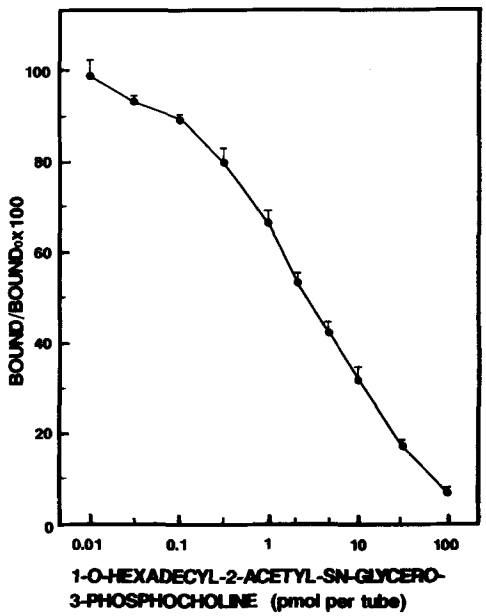

FIG. 2. Calibration curve for the quantitation of PAF. Each reaction mixture contained standard PAF (0.1 mL, 0–100 pmol), radioactive PAF (0.1 mL, 30,000 dpm, 2.03 pmol), antiserum (0.1 mL, 1:320, 0.25 mL), and 1% γ-globulin (0.05 mL). Other procedures were carried out as described in Materials and Methods. B/B_0 (%) indicates radioactivity bound to the precipitate in the presence of standard PAF over the radioactivity bound in the absence of PAF. Points represent the mean S.D. (n=3) using polyethylene glycol precipitation of antibody-bound radiolabelled PAF.

manner. The sensitivity of the standard curve, i.e., the lowest amount that could be significantly (± 2 S.D.) distinguished from zero, was 0.1 pmol (50 pg)/tube. The standard curve obtained was suitable for measurement of PAF ranging from 0.1–30 pmol. The specificity of the PAF antibody was examined in cross-reactivity studies with other phospholipids (Table 1). The antibody bound to a synthetic hapten (1-*O*-hexadecyl-2-*N,N,*-dimethylcarbamoyl-*sn*-glycero-3-phosphocholine) with higher affinity than PAF itself. Choline containing phospholipids (lysoPAF, lysoPC and PC) demonstrated little or no effect on the binding of radiolabelled PAF to antibodies. However, slight cross-reactivity (6.25%) was observed for 1-palmitoyl-2-acetyl-*sn*-glycero-3-phosphocholine. All other natural phospholipids tested (PE, SM, PI, PG and CL) showed less than 0.01% cross-reactivity. The cross-reaction of the D-isomer of PAF was only 0.047%.

Accuracy of RIA. To test the validity of the RIA, a series of known amounts of PAF (0–50 pmol/tube) were added to 1-mL aliquots of rabbit alveolar macrophage suspensions (5×10^6). The recovery of [^{3}H]PAF after Bligh and Dyer extraction followed by HPLC was 64.2%. There was a good correlation between the amount of added PAF and that measured by RIA (Table 2). A background level of 1.71 pmol PAF/mL (0.34 pmol/10^6 cells) was detected.

Determination of PAF in activated rabbit alveolar macrophages by calcium ionophore A23187. The amount of PAF produced by rabbit alveolar macrophage suspensions stimulated with ionophore A23187 was determined by RIA. Ionophore A23187 (1 μg/mL) increased the amount of PAF from a background level of 0.34 pmol/10^6 cells to 4.50 pmol/10^6 cells.

DISCUSSION

We have described here the development of a sensitive and specific RIA for PAF. The PAF antiserum showed a relatively high degree of sensitivity with a minimum detection limit for PAF of 0.1 pmol (50 pg) at a final antiserum dilution of 1:640 with 1-*O*-[^{3}H]octadecyl PAF (132 Ci/mmol, 30,000 dpm) as a tracer. If a PAF tracer with higher specific activity (e.g., ^{125}I-labelled tracer) were to be used, the detection limit would be lowered further. Cross-reactivity studies of the antiserum revealed a high specificity for PAF. Choline-containing phospholipids such as lysoPAF, lecithin or lysoPC did not cross-react with PAF antiserum (Table 1). This result is in good agreement with that obtained by the thin-layer chromatography/enzyme immunostaining method (10). Specificity studies of the antibody showed that the binding sites are against both the acetyl group at *sn*-2 and the phosphocholine moiety at *sn*-3. The PAF antiserum showed slight cross-reactivity with 1-palmitoyl-2-acetyl-*sn*-3-GPC (6.25%). This result shows that the antibody recognizes, in part, the alkyl ether bond (-CH_2-O-CH_2CH_2-) at the *sn*-1 position. The presence of a significant amount of the acyl analogue of PAF has been demonstrated in some tissues, such as bovine brain (11). Removal of the acyl analogue of PAF by hydrolysis using lipase may be required prior to RIA in a sample containing this analogue.

Recently, Baldo and his collaborators reported the production of rabbit polyclonal antibodies to PAF (12). They used a synthetic PAF analogue coupled to a protein carrier at the terminus of the alkyl chain. However, their immunogens were different from ours in two respects. First, the acetyl group at *sn*-2 was left intact. Second, the alkyl chain at *sn*-1 was very short (C_6 or C_{12}). In contrast, the immunogen we used was a non-hydrolyzable analogue of PAF containing a *N,N*-dimethylcarbamoyl group in place of the acetyl group at *sn*-2 and a hexadecyl chain at sn-1. Although the free form of PAF was rapidly degraded by serum acetylhydrolase, it is uncertain whether the acetyl group of the immunogen covalently attached to the carrier protein is hydrolyzed by serum acetylhydrolase. Serum acetylhydrolase may not have access to substrate covalently attached to a protein by steric hindrance or may not hydrolyze a substrate containing a short alkyl chain at *sn*-1, since human acetylhydrolase shows lower activity with the short alkyl chain-containing PAF derivative (13). Smal *et al.* (12) showed that a

TABLE 1

Specificity of Rabbit Polyclonal Antibody to PAF

Compound	Mass required to displace 50% bound [^{3}H]PAF (pmol)	Relative cross-reactivity[a]
1-*O*-Hexadecyl-2-acetyl-*sn*-3-GPC	2.5	100
1-*O*-Hexadecyl-2-*N,N,*-dimethylcarbamoyl-*sn*-3-GPC	1.33	188
1-*O*-Octadecyl-2-acetyl-*sn*-3-GPC	3.8	65.8
1-Palmitoyl-2-acetyl-*sn*-3-GPC	40.0	6.25
3-*O*-Hexadecyl-2-acetyl-*sn*-1-GPC (enantio-PAF)	530	0.047
1-*O*-Hexadecyl-*sn*-3-GPC (lysoPAF)	>10,000	<0.025
1-Palmitoyl-*sn*-3-GPC (lysoPC)	>10,000	<0.025
1,2-Dipalmitoyl-*sn*-3-GPC (PC)	>10,000	<0.025

[a]Relative cross-reactivity is expressed as the relative potency of each compound compared to PAF in displacing 50% of bound radioactive PAF. RIA was performed as described in Materials and Methods.

TABLE 2

Recovery of Added PAF from Macrophage Suspensions[a]

PAF added pmol/mL	Amount of PAF measured by RIA pmol/mL From buffer	From macrophage suspensions	Recovery[b] %
0	0	1.71	
5	5.22	6.37	94.9
10	10.8	12.0	102
20	18.8	22.9	105
30	28.2	29.7	93.7
50	49.7	49.5	95.7

[a]Various amounts of PAF were added to 1-mL aliquots of rabbit macrophage suspension (5×10^6). Each sample was immediately mixed with 1 mL ice-cold methanol and stored at −20°C. A trace of [^{3}H]PAF (3,000 dpm) was added to each sample for calculating recoveries. After extraction and HPLC separation, as described in Materials and Methods, an aliquot (0.2 mL) was removed for determining percentage recovery, and the remainder was analyzed for PAF content by RIA as described in Materials and Methods. Each value is the mean of two samples.

[b]Recovery was determined as: Amount of PAF measured/Amount of PAF added + background PAF × 100.

large amount of PAF, 2.5-250 ng per tube (approximately 5-500 pmol) was required for the displacement of antibody-bound labelled ligand. The detection limit of PAF was about 50 times larger than that calculated by RIA using our antiserum (0.1 pmol, Fig. 2). Possible effects of structural differences in the antigen on the sensitivity of RIA are unclear. We obtained the present antibody to PAF by injection of an immunogen, in which 1-*O*-(15′-carboxypentadecyl)-2-*N,N,*-dimethylcarbamoyl-*sn*-glycero-3-phosphocholine was covalently bound to BSA. The affinity of the antibody for the dimethylcarbamoyl derivative of PAF was higher than that for PAF. In cross-reactivity studies, the amount of the PAF dimethylcarbamoyl derivative necessary for 50% inhibition was approximately half that of PAF itself (Table 1). This result suggests that the antibody strictly recognizes the substituent at the *sn*-2 position of glycerol.

PAF is produced by a variety of inflammatory cells (basophils, neutrophils, endothelial cells, monocytes). Since the majority of newly synthesized PAF remains intracellular and is not released into the extracellular environment (14), extraction of PAF from the cells is necessary. In an RIA for PAF, however, there is a problem because of insolubility of the Bligh and Dyer extracts from samples in the assay buffer, which makes it impossible to separate antibody-bound [^{3}H]PAF from free [^{3}H]PAF. In the present study, therefore, the sample extract was subjected to HPLC for removal of insoluble materials. The fraction corresponding to the authentic PAF was soluble in the assay buffer. In the present study, addition of A23187 to rabbit alveolar macrophages increased the level of immunoreactive PAF from a background level of 0.34 pmol/10^6 cells to 4.50 pmol/10^6 cells. It has been demonstrated that alveolar macrophages produce PAF upon ionophore stimulation (15,16). Arnoux *et al.* (16) detected PAF released from human, monkey and rat alveolar macrophages by bioassay in the presence of 1-5 μg/mL ionophore A23187 (2.5 pmol of PAF from 2.5×10^5 cells). This value is of the same order as that obtained in our present experiment using rabbit alveolar macrophages. Work is in progress to determine the amount of PAF in cells and tissues in various pathological states. RIA for PAF will undoubtedly prove to be a useful tool for detailed studies on the pathological role of PAF.

Platelet activating factor (PAF), a naturally occurring phospholipid with many potent physiological and pharmacological activities, is implicated as a mediator of many diseases. An immunoassay for PAF would greatly improve quantitation, and hence PAF-specific antibodies were required. Chemically-reactive analogs of PAF, containing an aldehyde group at the end of the 1-*O*-alkyl chain (hexyl or dodecyl), were synthesized from readily available materials. During the multi-step synthetic procedure, the aldehyde group was protected as an acetal, which was converted by mild acidic hydrolysis to the aldehyde immediately prior to protein coupling. These analogs were coupled to methylated bovine serum albumin and the resultant conjugates were injected into rabbits. Antibodies to PAF were detected using a solid phase radioimmunoassay based on Protein A-Sepharose. The dodecyl PAF conjugate proved to be the more immunogenic conjugate with more than half of the rabbits producing significant levels of antibodies (at least a 10-fold increase in radioactive uptake over pre-immune levels). Results from solid phase immunoassays employing nitrocellulose discs impregnated with PAF, lysoPAF, lecithin, lysolecithin and 2-*O*-methyl-lysoPAF indicated that the antibodies recognized only PAF. PAF-specific antibodies were isolated by affinity chromatography using a column of PAF-poly(lysine) conjugated to carboxy-activated polyacrylamide. The antibodies may be employed in a sensitive and specific immunoassay for PAF and for many other studies involving PAF.
***Lipids* 26, 1130–1135 (1991).**

Platelet activating factor (PAF) is a naturally occurring phospholipid with potent biological activities, such as the promotion of hypotension, bronchoconstriction, anaphylaxis and chemotaxis (1,2). It was originally described as a substance released from rabbit basophils during IgE-antibody mediated anaphylaxis (3) and was subsequently identified as 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (4). Numerous cell types, especially those involved in inflammation, have been shown to produce and release PAF under appropriate stimulation (5,6).

Because of its potent inflammatory activity, PAF has been implicated in many disease states, such as asthma (7,8), allergic diseases (9), anaphylaxis (10), endotoxic shock (11) and kidney disease (12). Elucidation of the role of PAF in disease and also in normal physiological processes is dependent upon accurately quantitating PAF in biological tissues and fluids. Currently, PAF is measured by aggregation or secretion bioassays employing rabbit platelets (13,14). Although these methods are sensitive to 10^{-10} M, they are often difficult to standardize and are unreliable because other substances can induce aggregation or inhibit the response of platelets to PAF (13).

Measurement of PAF by immunoassay would have distinct advantages, such as specificity, wide applicability and high sample through-put. It would also be independent of the ambiguous relationship between occupancy of the PAF-receptor on the platelet and functional response. To develop an immunoassay, a specific antibody to PAF was needed. In this paper we report the synthesis of a PAF-immunogen and the production of PAF-specific antibodies.

MATERIALS AND METHODS

Chemicals. Solvents were reagent grade or better and were purchased from Ajax Chemicals (Sydney, Australia). Cyclododecanone and sodium hydride were from Fluka AG (Buchs, Switzerland); C_{16}- and C_{18}PAF were from Bachem Feinchemikalien (Bubendorf, Switzerland). Biogel P-100 and nitrocellulose (NC) membrane (0.45 μm) were from Bio-Rad (Richmond, CA) and Protein A-Sepharose was from Pharmacia (Uppsala, Sweden). Complete Freund's adjuvant and the Coomassie blue protein assay reagent were from Difco Laboratories (Detroit, MI) and Pierce Chemical Company (Rockford, IL), respectively. [^{125}I]Donkey anti-rabbit F(ab')$_2$ with a specific activity of 9 μCi/μg was from Amersham (Buckinghamshire, U.K.) and 1-*O*[^{125}I]alkyl-2-acetyl-*sn*-glycero-3-phosphocholine ([^{125}I]PAF) was a generous gift from Dr. J. Czarnecki, Silenus Laboratories (Melbourne, Australia). All other chemicals and biochemicals were purchased from Sigma Chemical Company (St. Louis, MO). Cord serum (CS) solution used in immunoassays was prepared by acidifying human fetal cord serum to pH 2.5 and, after 15 min, adding phosphate buffered saline (PBS) containing 0.1% Tween 20 (7 vols).

Abbreviations: Ac, acetyl; BSA, bovine serum albumin; C_nPAF, PAF where the 1-*O*-alkyl chain is *n* carbons long; CS, human cord serum; DMOC$_6$PAF, 1-*O*-(6',6'-dimethoxyhexyl)-2-acetyl-*sn*-glycero-3-phosphocholine; DMOC$_{12}$PAF, 1-*O*-(12',12'-dimethoxydodecyl)-2-acetyl-*sn*-glycero-3-phosphocholine; Ig, immunoglobulin; [^{125}I]PAF, 1-*O*-[^{125}I]alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; lysoPAF, 1-*O*-alkyl-*sn*-glycero-3-phosphocholine; MBSA, methylated bovine serum albumin; 2-*O*-methyl-lysoPAF, 1-*O*-octadecyl-2-*O*-methyl-*sn*-glycero-3-phosphocholine; NC, nitrocellulose; PA, polyacrylamide; PAF, platelet activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; PAF-PL-PA, PAF-poly(lysine)-polyacrylamide; PBS, phosphate (50 mM) buffered saline pH 7.2; PL-PA, poly(lysine)-PA.

Synthesis of 1-O-(ω,ω-dimethoxyalkyl)-2-acetyl-sn-glycero-3-phosphocholines. *(R)*-1-(Benzyloxy)-2, 3-epoxypropane was prepared from (+)1,2-*O*-isopropylidene-*sn*-glycerol as described by Hirth and Barner (15). Choline *p*-toluenesulfonate was prepared from dimethylethanolamine and methyl *p*-toluenesulfonate, as previously reported (16). 6,6-Dimethoxy-hexan-1-ol and 12,12-dimethoxydodecan-1-ol, prepared from cyclohexanone and cyclododecanone, respectively, by the method described by Schmidt and Grafen (17), were condensed with the epoxypropane in the presence of sodium hydride; the product was acetylated, hydrogenolyzed and phosphorylated as recently described by Smal *et al.* (18) to produce 1-*O*-(6′,6′-dimethoxyhexyl)-2-acetyl-*sn*-glycero-3-phosphocholine ($DMOC_6PAF$) and 1-*O*-(12′,12′-dimethoxydodecyl)-2-acetyl-*sn*-glycero-3-phosphocholine ($DMOC_{12}PAF$) in 27% and 14% overall yields, respectively.

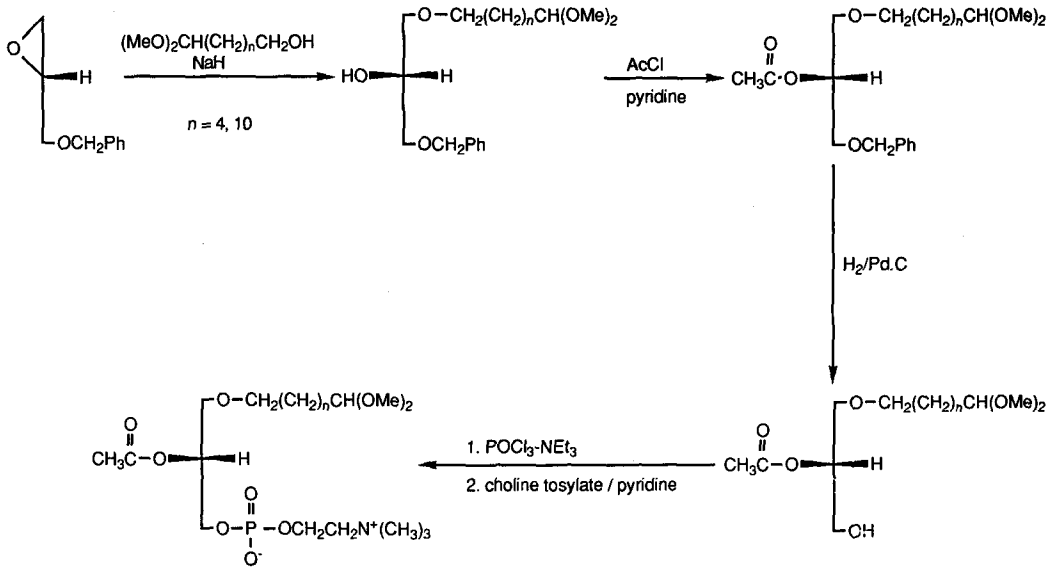
Deprotection and coupling to protein. The dimethoxy PAF analogs were deprotected by acidic hydrolysis to yield the free aldehydes, as described (18). Briefly, the PAF analog (130 mg) was suspended in ethyl acetate and trifluoroacetic acid/water (9:1,v/v) (170 μL) was added. The reaction was kept at room temperature until complete, and the pH was carefully adjusted to 5–6 with 1 M $NaHCO_3$. The mixture was evaporated and the residue redissolved in methanol/water (2:3, v/v). A Purpald spot test (19) indicated the presence of free aldehyde. The aldehyde-PAF analogs were coupled to either methylated bovine serum albumin (MBSA) or poly(Lys) (mol. wt 90,000) by the following method. The analogs (25–50 mg) in methanol/water were added to a methanolic solution of the protein (300 mg) and, after 0.5 hr, $NaCNBH_3$ (100 mg) was added. The pH of the solution was adjusted to 5 with 1N HCl. After 16 hr, the solution was evaporated and the residue dispersed in water. The suspension was dialyzed against water for 6 hr, and then lyophilized. The resultant material was analyzed for phosphorus (20).

Platelet aggregation. Washed rabbit platelets were prepared as described by Coeffier *et al.* (21) and platelet aggregation carried out as reported by Huo *et al.* (22). Ethanolic stock solutions of the dimethoxy-PAF analogs were diluted in PBS containing 0.25% bovine serum albumin (BSA), and these solutions (20 μL) were added to the platelet suspensions (18). Changes in optical density were monitored with a Payton dual-channel aggregometer.

Antibody production. Six-month-old New Zealand white rabbits were injected intramuscularly with either C_6PAF or $C_{12}PAF$ conjugated to MBSA (5–10 mg, 0.5-1.5 μmol PAF), emulsified with saline (0.5 mL) and complete Freund's adjuvant (0.5 mL) (18). The rabbits were boosted three weeks later with a subcutaneous injection of the same dose of conjugate in saline and were maintained on this alternating injection schedule. The rabbits were bled seven days after the boosts and the blood was allowed to clot. The serum was removed and stored at −20°C.

Determination of anti-PAF antibody titer. Serum was diluted 1 in 10 in 0.1% Tween/PBS, and 25 μL was incubated with 9 μL of swollen Protein A-Sepharose beads. After 3 hr, the beads were washed once with 0.05% Tween/PBS (3 mL), and then incubated with 40,000 cpm of [^{125}I]PAF (diluted in 0.1% Tween/PBS)(50 μL). After 16 hr, the beads were washed twice and counted. Results are expressed as a percentage of the total counts added.

Preparation of PAF-NC discs. Five-mm discs were cut from NC membrane and soaked in a solution of $C_{18}PAF$ (5 mg) in 70% ethanol (0.5 mL) plus 0.07% Tween/PBS (1.5 mL) for 16 hr. The discs were removed and blotted dry. Discs impregnated with 1-*O*-alkyl-*sn*-glycero-3-phosphocholine (lysoPAF), lecithin, lysolecithin, 1-0-octadecyl-2-*0*-methyl-*sn*-glycero-3-phosphocholine (2-*0*-methyl-lysoPAF) and 0.07% Tween alone were prepared in a similar manner, as described previously (18).



Preparation of PAF-poly(Lys)-polyacrylamide (PAF-PL-PA) and PAF-AcPL-PA. Plastic labware was used for all operations involving polyacrylamide (PA) beads. Succinylhydrazide PA was prepared from Bio-gel P100 (4 g) as previously reported (23), and $C_{12}PAF$-poly(Lys) (190 mg, approx 30 μmol PAF) was coupled to the beads in the presence of 1-ethyl-3(3-dimethylaminopropyl)carbodiimide (3.47 g) at pH 5, as described previously (18). The beads were washed extensively with water, saline, PBS and 0.1 M acetate buffer, pH 4.0. The beads (60 mL bed volume) were resuspended in water to a total volume of 120 mL. For the acetylation procedure, the bead suspension (6 mL) was mixed with PBS (5× concentrate) (6 mL) and cooled to 0°C. While gently stirring, acetic anhydride (250 μL) was added, followed by 2.5 M NaOH to maintain the pH at 6–7. The addition of acetic anhydride and NaOH was repeated, and then the beads were washed and resuspended in water to a total volume of 6 mL. For the immunoassays, the bead suspension was diluted with two parts of water.

Affinity purification of anti-PAF antibodies. The immunoglobulin (Ig) fraction of antiserum was isolated by chromatography on Protein A-Sepharose as previously reported (24), except that 0.1 M citrate (pH 3.0) and 0.1 M glycine (pH 3.0) were used for elution. The Ig fraction (4 mg protein) was loaded onto a 20-mL column of PAF-PL-PA beads equilibrated in 0.1% Tween/saline. After the non-binding material had been eluted, the elution buffer was changed to 4.5 M $MgCl_2$ in saline containing 0.1% Tween to elute the PAF-binding antibodies. The desired fractions were pooled and concentrated; protein concentrations were determined by the Bradford method (25).

Binding of anti-PAF antibodies to PAF-solid phases. Rabbit serum or purified Ig was diluted in 0.1% Tween/PBS or CS solution, respectively, and 50 μL of these solutions were incubated with a PAF-NC disc (or control disc) for 3 hr. The disc was washed three times with 0.05% Tween/PBS and then incubated with [^{125}I]donkey anti-rabbit $F(ab')_2$ (diluted in 0.005% Tween/PBS)(50 μL). After 16 hr, the disc was washed again and counted. In binding studies with PA beads, the NC disc was replaced by 50 μL of bead suspension, and the tracer was diluted in 0.1% BSA/PBS.

RESULTS

Synthesis and biological activity of protected PAF analogs. Protected PAF analogs with either a 6- or a 12-carbon chain in position 1 were prepared in moderate yields (14–27%) following the sequence of reactions

SCHEME 1. Synthesis of protected PAF analogs.

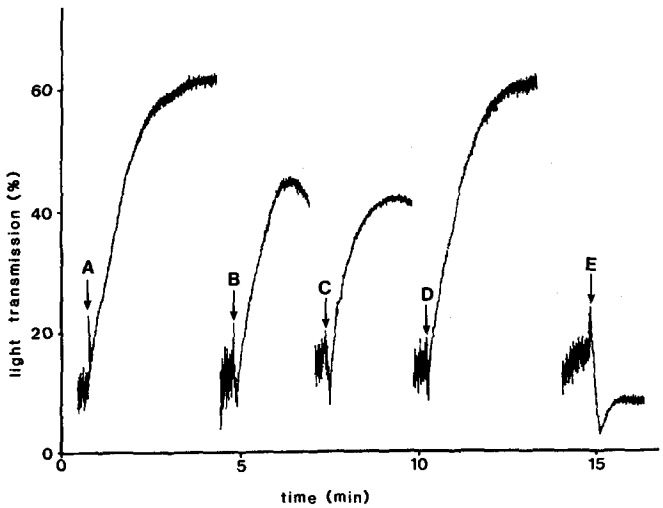
shown in Scheme 1. It was important that acidic conditions be avoided during these steps in order to preserve the acetal protecting group. The ability of these analogs to induce aggregation was tested with washed rabbit platelets (Fig. 1). Protected C_6PAF did not induce aggregation at a final concentration of 8.3 μM, whereas the protected C_{12}PAF had approximately 1% of the activity of C_{16}PAF.

Coupling of the PAF analogs to protein. Conversion of the dimethyl acetal protecting group to the free aldehyde was achieved with trifluoroacetic acid, and the PAF analog was condensed with the protein, as outlined in Scheme 2. The deprotection reaction was relatively free of by-products, and spectral analysis, as well as a Purpald test of the product, showed conversion to an aldehyde. The acetyl group was preserved during this procedure. Results of the phosphorus assay for the PAF-protein conjugates indicated a 50-70% coupling efficiency.

Antibody production. The anti-PAF antibody titer of rabbit sera was checked by the Protein A-Sepharose-based assay, and the production of antibodies over an extended time period in five rabbits is summarized in Figure 2. Of the three rabbits immunized with the C_6PAF-MBSA conjugate, only one produced significant levels of antibody. However, five out of the eight rabbits immunized with the C_{12} analog produced antibodies to PAF.

Specificity of antibodies. The specificity of antibodies was tested using NC discs to which selected analogs of PAF had been adsorbed. Both whole antiserum and the Ig fraction obtained by Protein A-Sepharose chromatography were tested (Table 1). The only significant binding occurred when PAF discs were used with antiserum or the corresponding Ig fraction. The antibodies did not react with the lysoPAF-, lecithin-, lysolecithin- or 2-*O*-methyl-lysoPAF-NC discs.

Affinity purification of anti-PAF antibodies. The PAF-poly(Lys) conjugate was immobilized onto PA beads *via* a spacer arm of succinylhydrazide. Polyacrylamide



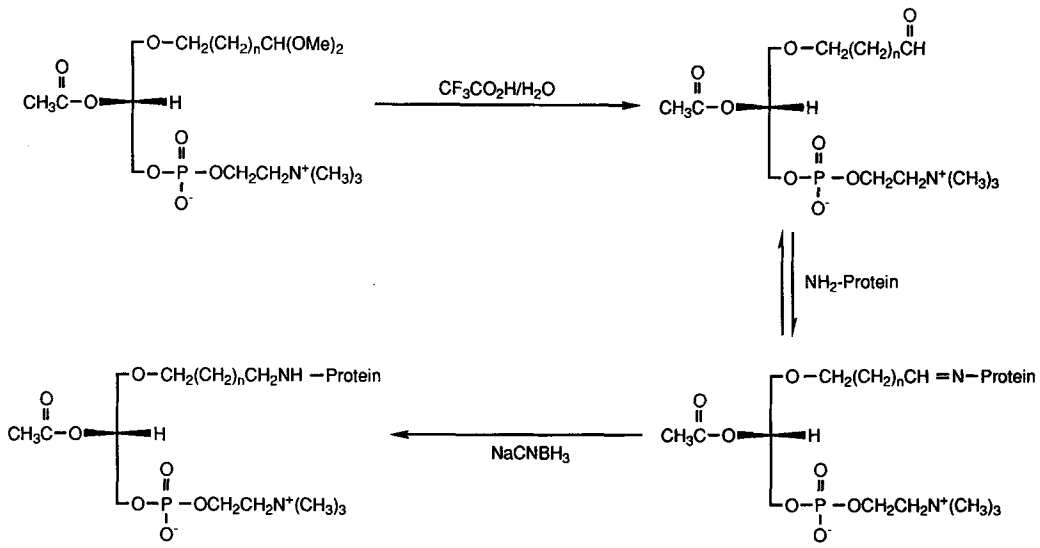


FIG. 1. Response of washed rabbit platelets to PAF and the dimethoxy PAF analogs: A, C_{16}PAF 4 nM (final concentration); B, C_{16}PAF 0.4 nM; C, DMOC_{12}PAF 30 nM; D, DMOC_{12}PAF 300 nM; and E, DMOC_6PAF 12.6 μ M.

was chosen because it gave the lowest non-specific binding of the commonly available chromatography media. Whole antisera was initially fractionated on Protein A-Sepharose to obtain the Ig fraction and remove the enzyme PAF-acetylhydrolase, which converts PAF to lysoPAF (26). When the Ig fraction was applied to a PAF-PL-PA column and the non-binding material eluted, a sharp peak representing the PAF-binding Igs was recovered with 4.5 M $MgCl_2$ (Fig. 3). Affinity purified Igs were compared with the corresponding whole Ig fraction and normal Ig for binding to various PAF solid phases (Fig. 4). By the NC assay, affinity purification did not enhance binding, but there was a slight increase in specificity, as seen by a lower binding to lecithin-NC. Affinity purifica-

Tween	1.3	2.7	—	—
Lecithin	—	—	0.5	0.9
Lysolecithin	—	—	0.9	1.1
2-*O*-Methyl-lysoPAF	—	—	0.7	1.1

[a]Diluted serum or Ig (50 μL) was incubated with a PAF or other NC disc for 3 hr. The disc was washed, incubated with [^{125}I]donkey anti-rabbit F(ab')$_2$(40,000 cpm) for 16 hr and washed again. The disc was counted to determine the bound radioactivity (% of total activity).

[b]Serum from unimmunized rabbit, diluted 1:1000 in 0.1% Tween/PBS.

[c]Serum from rabbit 7 immunized with C_6PAF-MBSA, diluted 1:1000 in 0.1% Tween/PBS.

[d]Ig fraction from normal serum, diluted to 0.23 μg Ig/mL in CS solution.

[e]Ig fraction from immune serum, diluted to 0.21 μg Ig/mL in CS solution.

tion markedly enhanced binding to PAF-PL-PA beads. However, binding to the control support, poly(lysine)-PA (PL-PA), was also significant—this binding could be abolished by acetylation of the lysine residues on the PL-PA beads without affecting the PAF-specific binding. Affinity purification was attempted with PAF-AcPL-PA, but did not yield any substantial improvement.

DISCUSSION

Since PAF has a molecular weight of only approximately 500, it is too small a molecule to elicit an immune response and must, therefore, be coupled to a high molecular weight "carrier". It was reported that antibodies to PAF were produced using an incompletely defined antigen complex of PAF, lecithin and cholesterol; however, these antibodies also recognized lysoPAF (27). In the only other report of anti-PAF antibodies, the immunogen used was a PAF analog, containing a *N,N*-dimethylcarbamate group and not an acetyl group at carbon 2, and was coupled to BSA through the end of the alkyl chain (28). These antibodies were also cross-reactive with lysoPAF.

In the present study, the acetyl group at carbon 2 was deliberately retained since it is a unique and essential feature of the PAF molecule, and PAF-specific antibodies would have to recognize this group. The most suitable site for coupling the PAF molecule to a protein is the end of the alkyl chain, and an aldehyde group was chosen as the functional group through which coupling

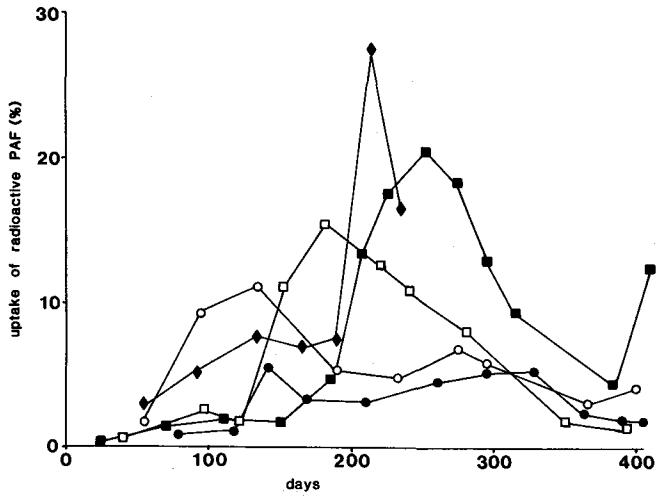

FIG. 2. Production of anti-PAF antibodies in rabbits over time. Rabbit 7 (●) was immunized with C_6PAF-MBSA, and rabbits 9 (■), 11 (○), 12(♦) and 14 (□) were immunized with C_{12}PAF-MBSA. Titer was determined by incubating diluted serum (1:10 in 0.1% Tween/PBS) with Protein A-Sepharose beads for 3 hr. The washed beads were incubated with [^{125}I]PAF for 16 hr, and then washed. The beads were counted to determine the bound radioactivity (% of total activity).

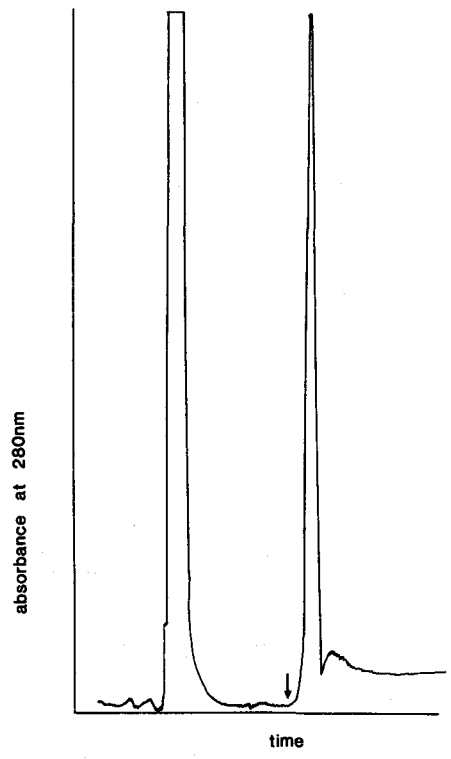

FIG. 3. Elution profile for the purification of anti-PAF antibodies by affinity chromatography. The Protein A purified Igs were applied to a PAF-PL-PA column and, after the non-binding Igs were eluted, elution of the anti-PAF antibodies was commenced with 4.5 M $MgCl_2$ (indicated by the arrow)(from ref. 18).

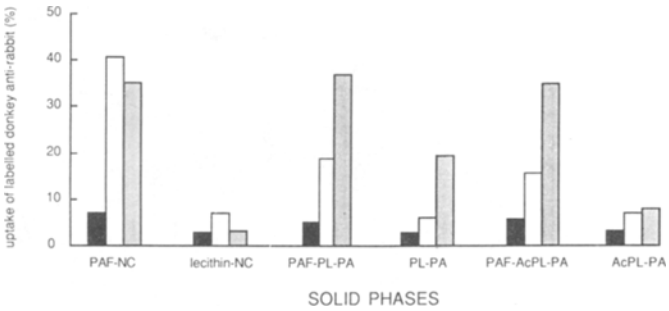

FIG. 4. The binding of Ig from unimmunized rabbits (solid bars), immune Ig from rabbit 7 (open bars) and affinity-purified immune Ig (hatched bars) to PAF- and lecithin-NC discs, and PAF-PL-PA, PL-PA, PAF-AcPL-PA and AcPL-PA beads. Binding was determined by incubating Ig (5 μg/mL diluted in CS solution; 50 μL) with either discs or bead suspension for 3 hr. These were then washed, incubated with [^{125}I] donkey anti-rabbit F(ab')$_2$(40,000 cpm) for 16 hr, washed again, and counted. The bound radioactivity is expressed as % of the total activity (data from ref. 18).

to the amino residues of the protein carrier could occur. In order to synthesize such analogs, the aldehyde group had to be protected as a dimethyl acetal during the many steps of the synthetic procedure. Two aldehyde analogs of PAF, with alkyl chain lengths of 6 and 12 carbons, were synthesized and coupled with 50–75% efficiency to MBSA. The protected C_6PAF had no activity towards platelets, but the protected C_{12}PAF had a reduced activity towards platelets as compared with C_{16}PAF. Antibodies were raised in rabbits immunized with either the C_6PAF-MBSA or C_{12}PAF-MBSA conjugates, although the latter appeared to be more immunogenic. Attempts were made to raise murine monoclonal antibodies with these antigens, but no response was observed. The NC-disc assay showed that the antibodies did not recognize lysoPAF, suggesting that the PAF immunogens were not hydrolyzed *in vivo*. The antibodies also did not recognize 2-*O*-methyl-lysoPAF nor lecithin, indicating that the antibody combining site recognizes, at least in part, a short chain acyl group at carbon 2 of the glycerol backbone. The specificity of these antibodies recently has been fully characterized (29).

The aldehyde analogs of PAF were also used to prepare a stable PAF-affinity column PAF-PL-PA for the purification of anti-PAF antibodies. A PAF-affinity column had been previously described in which PAF was bound non-covalently to albumin-Sepharose; however, under these conditions, PAF was slowly lost from the column (30). Anti-PAF antibodies, purified on the PAF-PL-PA column, showed increased binding to PAF-PL-PA beads, but no significant change in the binding to PAF-NC discs. There was also significant binding of the antibodies to poly(Lys) bound to PA beads, indicating a population of antibodies directed against lysine or PAF-lysine. This is not surprising, because the immunogen contained lysine residues, some of which were bound to PAF. Binding to lysine could be abolished by *N*-acetylation of the poly-(Lys)-PA beads.

The antibodies produced in this study are specific for PAF and the methodology outlined here has been ap-

plied to the development of a sensitive and specific radioimmunoassay for PAF (31). The antibodies have also been employed in localization studies using immunocytochemical methods (32), and have potential application in studies on the PAF receptor and various *in vitro* and *in vivo* investigations of the pharmacological, physiological and biochemical effects of PAF. The PAF-affinity column is also likely to have applications for purification of the PAF-receptor and other PAF-binding proteins.

[Received July 20, 1989, and in revised form August 5, 1991; Revision accepted August 12, 1991]

A Specific, Sensitive and High-Capacity Immunoassay for PAF[1]

Brian A. Baldo[a,b,*], Mary A. Smal[a] and Alistair C. McCaskill[c]

[a]Kolling Institute of Medical Research, Royal North Shore Hospital of Sydney, St. Leonards, N.S.W., 2065, [b]Department of Medicine, University of Sydney, Sydney, 2006 and [c]Silenus Laboratories, Victoria, 3122, Australia

A specific radioimmunoassay for platelet-activating factor (PAF) sensitive in the range 10–1000 pg (0.02–2 pmoles) has been developed. Detailed quantitative hapten inhibition studies showed specificity for the acetyl group at C-2 of PAF, a requirement for the ether linkage at C-1 and some tolerance for substituents on the choline nitrogen. No significant cross-reactivity was found with phosphatidylcholine and lysophosphatidylcholine or with lysoPAF.

***Lipids* 26, 1136–1139 (1991).**

The involvement and importance of platelet-activating factor (PAF) in a variety of normal and disease states make its quantitation in biological fluids an important priority. Because of its potency, detection and measurement of PAF must take place at very low concentrations. Currently, this is usually achieved by employing assays based on aggregation of human or rabbit platelets. Although these methods are sensitive, they are not usually simple or straightforward and have the drawback of the inherent variability associated with biological assays.

Application of the radioimmunoassay, which we have developed, to the measurement of PAF in some biological fluids and comparisons with results obtained by platelet aggregation has revealed that the latter method is frequently affected by the presence of inhibitors of PAF-induced aggregation. The net effect of this inhibition is that levels of PAF determined by platelet aggregation are frequently underestimated. The immunoassay is not subject to this serious drawback. The accurate determination of PAF levels in fluids from subjects with asthma, shock and allergic reactions, and a variety of other conditions, may increase our understanding of the role of PAF in these conditions.

Accurate measurement of very small amounts of PAF in normal and pathological fluids and extracts is a prerequisite for studying and understanding the role of PAF in health and disease. At present, the methods most commonly used for the quantitation of PAF rely on the interaction of PAF with platelets (1). These methods are not strictly quantitative, lack specificity, are difficult to standardize and reproduce, and do not have a high capacity. Mass spectrometric techniques (2–4) are sensitive and specific, but the cost and specialized nature of the equipment required, and the difficulty of rapidly assessing large numbers of samples side-by-side, preclude the widespread and routine use of this technique.

Introduction of a simple, specific, sensitive and high-capacity immunoassay for PAF has overcome these problems associated with the measurement of PAF, and it is now possible to routinely and accurately quantitate PAF in large numbers of samples.

MATERIALS AND METHODS

Materials. C_{16}, C_{18} and $C_{18:1}$PAF were from Bachem Feinchemikalien, Bubendorf, Switzerland. All other lipids were from Sigma Chemical Co., St. Louis, MO. [^{125}I]PAF and donkey anti-sheep immunoglobulin (Ig) fractions were supplied by Silenus Laboratories, Hawthorn, Victoria, Australia. Chloroform and methanol were supplied by Ajax Chemicals (Sydney, Australia) and polyethylene glycol MW 6000 by BDH Chemicals (Kilsyth, Victoria, Australia).

Antigen and antisera. C_{12}PAF-methylated bovine serum albumin conjugates were prepared as previously described (5) and were emulsified in Freund's complete adjuvant and injected intramuscularly into sheep (1 mg/sheep). Animals were boosted 1 mon and 4 mon later with 1-mg doses of the antigen in Freund's incomplete adjuvant before being bled eleven days after the third injection.

PAF-acetylhydrolase activity in the antiserum was destroyed by incubating the serum with an equal volume of 1 M acetic acid for 6 hr before diluting with 0.2 M phosphate buffer pH 7.2.

Radioimmunoassay (RIA). Assays were carried out in disposable polystyrene tubes (Disposable Products, Adelaide, Australia). To each tube was added 100 μL of the sample to be tested or the PAF standard solution (equal parts C_{16}PAF and C_{18}PAF in aqueous ethanol), 100 μL of diluted anti-PAF (1–8,000 in 0.05 M sodium acetate buffer pH 6 containing 0.1% Tween 20 and 0.1% sodium azide), 100 μL anti-sheep Ig (1–250 in the above buffer containing 6% glycol) and [^{125}I]PAF (40,000 cpm per tube) and tubes were incubated at room temperature for 16 hr. After the addition of 4 mL of acetate buffer, the tubes were centrifuged at 1900 × *g* for 25 min, decanted and the remaining radioactivity measured. The percent of tracer bound to the precipitate in the tubes (% B/B_0) was calculated from the formula $(B\text{-}NSB)/(B_0\text{—}NSB) \times 100$ where B_0 represents the counts from tubes containing no PAF and NSB the non-specific binding tubes which contain only the second antibody, tracer and buffer. PAF in the test samples was determined from the standard curve obtained by plotting PAF concentrations against $\%B/B_0$.

RESULTS AND DISCUSSION

Procedure, sensitivity and specificity. A diagrammatic representation of the RIA procedure is summarized in Figure 1 and a resulting typical standard curve is shown in Figure 2. Since PAF in most biological samples is a mixture of alkyl homologs with C_{16}PAF and C_{18}PAF predominating, the standard chosen at present for the RIA is an equimolar mixture of the two.

The standard curve permits accurate quantitation of PAF in the range of 10–1000 pg (0.02–2 pmol) per tube.

Quantitative hapten inhibition studies with selected PAF analogs revealed that C_{16}PAF and $C_{18:1}$PAF were better inhibitors than C_{18}PAF, 1-acyl analogs were inactive and 2-propionyl-C_{18}lysoPAF and 2-butyryl-C_{18}lysoPAF were weak inhibitors. These, and other results summarized in Table 1, led us to conclude that the best inhibitors have an acetyl group at position 2 and an ether linkage at position 1 of the glycerol backbone, whereas variations at position 3 are less critical. The latter conclusion is consistent with the finding that acetyl-C_{18} GPDME was a good inhibitor and some activity was retained by acetyl-C_{18} GPE despite the absence of the three methyls of the PAF choline group. Importantly, lysoPAF was without inhibitory activity at concentrations of 100 ng/mL and was very weakly inhibitory in the μg/mL range. No inhibition was seen with the commonly occurring lipids cholesterol, cholesteryl oleate, lysophosphatidylcholine, lysophosphatidylethanolamine, oleic acid, phosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol, phosphatidylserine, sphingomyelin and triolein at concentrations up to 20 μg/mL.

Application of the RIA to the measurement of PAF in biological fluids. The RIA has so far been used to determine PAF levels in human saliva (6), sputum, serum (7) and in supernatants from embryo cultures (8) and antigen-challenged human lung (Baldo, B.A., Smal, M.A., and

[a]LysoPAF produced 50% inhibition at a concentration of 13,300 pmoles, a reactivity of 34,000 relative to C_{16}PAF.

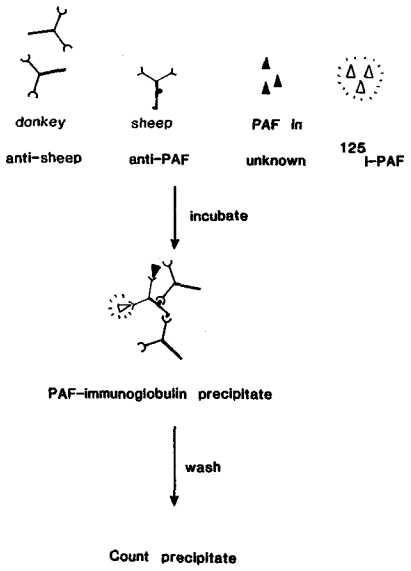

FIG. 1. Diagrammatic representation of the RIA for PAF.

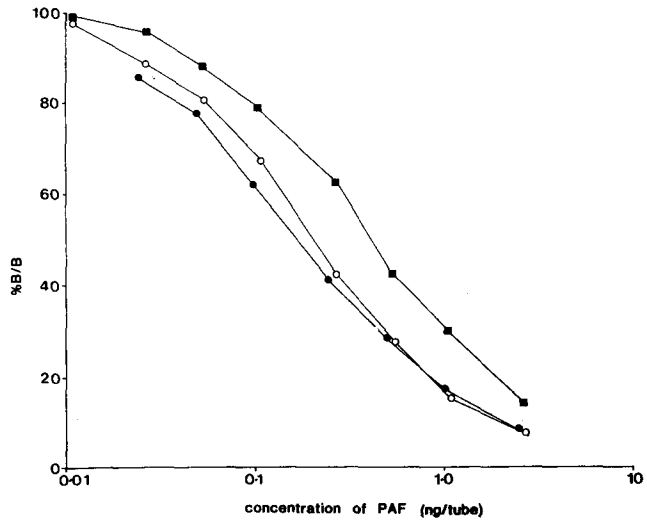

FIG. 2. Typical standard curves obtained with the RIA for PAF. (○) C_{16}PAF; (●) an equimolar mixture of C_{16}PAF and C_{18}PAF; (■) C_{18}PAF.

Cooney, S.J., unpublished). A research priority is now to establish "normal" levels of PAF in body fluids and tissues before employing the assay for the study of various disease states. As with saliva (6) and serum, it is anticipated that extraction of tissues and fluids with chloroform/methanol/water (9) will be a necessary step in preparing samples for examination by RIA.

Comparison of assays for the quantitation of PAF. A comparison of PAF levels detected in human salivas by RIA and platelet aggregation showed that figures obtained by the aggregation assay are much lower (6,10). Apart from the fact that losses are often likely to be greater during the sample preparation for platelet aggregation methods, interfering substances are clearly a problem with platelet-based assays (11–14). The presence of a substance(s) in saliva that inhibits PAF-induced platelet aggregation (14) but which does not affect the RIA highlights an important advantage of the latter method.

TABLE 2

Comparison of the Available Assays for the Routine Measurement[a] of PAF

Assay	Principle	Working range (pg/tube)	Potential problems
Radioimmunoassay	Interaction of PAF with specific antibody	10–1000	
Platelet aggregation (1)	Interaction of PAF with platelets	10–1000	—Preparation of platelet suspension —Interfering substances —Difficult to standardize —Low capacity; 1 sample at a time
Platelet degranulation (1)	Interaction of PAF with platelets and release of [^{3}H] serotonin	50–300	—As above —Labelling of platelets
Radioreceptor assay (15,16)	Binding of PAF to membrane receptor(s)	10–1000	—Preparation of membranes —Standardization of membrane batches —High non-specific binding

[a]Mass spectrometric methods are not considered because of the cost and specialized nature of the equipment required, lack of access by many medical laboratories and, in particular, the low rate of through-put of samples.

Table 2 lists the methods most commonly used to measure PAF and summarizes what we see as the main problems and disadvantages of the methods when compared to the newly developed RIA described here.

Application of the RIA should, in the near future, lead to a clearer understanding of the role of PAF in health and disease.

Quantitation by Radioimmunoassay of PAF in Human Saliva[1]

Sue J. Cooney[a], Mary A. Smal[a] and Brian A. Baldo[a,b,*]
[a]Kolling Institute of Medical Research, Royal North Shore Hospital, St. Leonards, N.S.W. 2065 and [b]Department of Medicine, University of Sydney, N.S.W. 2006, Australia

Approximately 75% of the PAF present in saliva is recovered on extraction of whole saliva (0.8 vol) with chloroform/methanol/water (2:2:1, v/v/v). PAF levels, determined by our recently developed radioimmunoassay, in saliva extracts ranged from 0.5–21 ng/mL with 59% between 2–6 ng/mL. These figures, for apparently healthy subjects, are higher than previously reported levels obtained by platelet assays. The validity of our radioimmunoassay results was checked by isolating and quantitating the PAF fraction from whole saliva. In addition, when we examined our saliva samples by platelet aggregation, low levels of PAF, comparable with the values found in the literature, were detected. Investigations revealed the presence of a substance(s) which inhibited PAF-induced platelet aggregation but which did not affect the radioimmunoassay.
Lipids 26, 1140–1143 (1991).

The biologically active phospholipid platelet activating factor (PAF) (1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) (1) is synthesized and released by various cell types upon stimulation (2). The variety of physiological effects exhibited by PAF (3) suggests that it may be involved in a number of diseases including asthma (4), anaphylactic shock (5), gastric ulceration (6) and other allergic reactions (7).

Determination of the significance of PAF in diseased states depends, to a large degree, on the precise quantitation of PAF in biological systems. Using techniques which rely on the interaction of mediator with platelets, Cox *et al.* (8) and Janero *et al.* (9) demonstrated the presence of PAF in human saliva. However, these assays are not simple to perform and would be unsuitable for the measurement of PAF in the large numbers of samples required to determine "normal" levels and hence demonstrate deviations from normal due to any particular disease.

Recently, a specific radioimmunoassay (RIA) for PAF has been developed and extensively characterized (10,11). In this paper, we present results which validate the use of the PAF RIA for the routine measurement of PAF in saliva.

MATERIALS AND METHODS

Materials. 1-*O*-Hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine (C_{16}PAF) and 1-*O*-octadecyl-2-acetyl-*sn*-glycero-3-phosphocholine (C_{18}PAF) were purchased from Bachem Feinchemikalien (Bubendorf, Switzerland). Anti-PAF serum, donkey anti-sheep immunoglobulin (Ig) and [^{125}I]-PAF were from Silenus Laboratories Pty. Ltd. (Melbourne, Australia). [^{3}H-*alkyl*]PAF (1-*O*-[^{3}H]alkyl-2-acetyl-*sn*-glycero-3-phosphocholine, a mixture of C_{16} and C_{18} alkyl ethers, 81 Ci/mmol) was from Amersham (Buckinghamshire, U.K.) and [^{3}H-*acetyl*]PAF (1-*O*-alkyl-2-[^{3}H]acetyl-*sn*-glycero-3-phosphocholine, 10 Ci/mmol) was from DuPont NEN (Boston, MA). Polyethylene glycol MW 6000 and organic solvents were from BDH Chemicals (Kilsyth, Vic, Australia) and Ajax Chemicals (Sydney, Australia), respectively. Phospholipase A_2 attached to agarose beads was from the Sigma Chemical Company (St. Louis, MO) and silica gel 60 was purchased from E. Merck (Darmstadt, Germany). All other chemicals and reagents were from Sigma.

Saliva samples. Mixed, unstimulated human saliva samples were collected from healthy volunteers and stored at 4°C for up to 30 min. All salivas were extracted by the method of Bligh and Dyer (12) and reconstituted in the appropriate assay buffer.

PAF RIA procedure. Samples to be tested for PAF content were reconstituted in 0.05 M acetate buffer pH 6.0 containing 0.05% Tween 20 (AcT). Anti-PAF serum was diluted 1/100 in AcT buffer. The second antibody, anti-sheep Ig, was diluted 1/250 in AcT buffer containing 6% polyethylene glycol and [^{125}I]PAF was added to give 40,000 cpm per 100 μL. In the assay, each tube contained 100 μL sample to be tested, 100 μL anti-PAF serum and 100 μL anti-sheep Ig/tracer. The B_0 tubes (zero binding) contained no sample and the NSB (non-specific binding) tubes contained only anti-sheep/tracer. After the tubes were incubated for 16 hr at room temperature, 4 mL of AcT was added and the tubes centrifuged at 1900 × *g* for 25 min. Supernatants were removed and the radioactivity remaining was determined. The percent of tracer bound to the precipitate (%B/B_0) was calculated from the formula (B-NSB)/(B_0-NSB) × 100. The amount of PAF present was interpolated from a standard curve constructed using serial dilutions of a 1:1 C_{16}/C_{18}PAF stock solution (0.1 mg/mL).

Platelet aggregation. Washed rabbit platelets were prepared as previously described (13) and aliquots (50 μL) of the platelet suspension were preincubated with Tyrodes-Ca^{2+} (450 μL) (14) before stimulation. Samples to be tested were reconstituted in phosphate buffered saline (PBS) pH 7.2 containing 0.25% BSA and these solutions (20 μL) were added to the platelet suspensions. Changes in the optical transmission were monitored by a Payton dual-channel aggregometer. For quantitation of PAF a standard curve was constructed using serial dilutions of 0.1 mg/mL C_{16}/C_{18}PAF (1:1).

Phospholipase A_2 treatment. Samples were reconstituted in 10 mM Tris buffer (pH 8.0) containing 0.1% BSA. Each incubation tube contained 600 μL buffer, 100 μL reconstituted saliva sample and 100 μL phospholipase A_2 suspension or buffer. Incubations were carried out at 37°C for 4 hr with mixing to prevent settling of the enzyme

suspension. Reactions were stopped by centrifugation to remove the phospholipase A_2 bound to the agarose beads. Supernatants were re-extracted using the Bligh-Dyer method (12) and the PAF content was determined by RIA.

Silica gel chromatography. To the total lipid extract from 5 mL of saliva, [^{3}H-*alkyl*]PAF (38,500 cpm) was added and the mixture reconstituted in 400 μL chloroform. The solution was loaded onto a silica gel column (0.5 g), which had been packed in chloroform, and the lipids were eluted sequentially with 5 mL chloroform, 5 mL chloroform/methanol (3:2, v/v), 5 mL chloroform/methanol (1:3, v/v) and 5 mL chloroform/methanol/water (2:3:1, v/v/v). Each fraction collected (1 mL) was evaporated, reconstituted in ethanol, and assayed for radioactivity and PAF content.

RESULTS AND DISCUSSION

Initially, experiments using [^{3}H-*acetyl*]PAF incubated with whole, fresh saliva showed that very little PAF was degraded to lysoPAF. This suggested that there was little PAF-acetylhydrolase activity in saliva and therefore, discrepancies in the measurement of PAF levels would not occur as a result of specific PAF hydrolysis. However, when PAF was added to whole saliva and centrifuged, the PAF was adsorbed to the precipitated sediment. In order to make accurate, quantitative PAF measurements, saliva (0.8 vol) was therefore extracted with chloroform/methanol/water (2:2:1, v/v/v) and the reconstituted lipid extracts assayed. Using [^{3}H]PAF, this method produced recoveries of greater than 75%.

RIA and PAF in saliva. The specificity of the PAF RIA has been demonstrated using a large range of naturally occurring lipids and synthetic PAF analogs (10,11). Authenticity of the PAF levels measured in saliva was confirmed by three further experiments: i) Saliva extracts were assayed at different dilutions in the presence and absence of a known amount of synthetic PAF (Table 1). Dilution of the extracts produced the desired decrease in PAF levels as determined by RIA. ii) Each fraction collected from silica gel chromatographic separation, of a pooled saliva extract spiked with [^{3}H-*alkyl*]PAF, was tested for PAF activity by platelet aggregation and RIA, the recovery of [^{3}H]PAF tracer was also determined (Table 2). Only the fractions exhibiting PAF activity (chloroform/methanol/water, 2:3:1, v/v/v, fractions) also contained [^{3}H]PAF radioactivity. When compared to the total unfractionated activity (determined by both platelet aggregation and RIA), the percentage recovery of radioactivity corresponded to the percentage recovery of PAF activity. iii) Phospholipase A_2 (PLA_2) degrades PAF to the inactive lysoPAF which is not detected by the RIA (10,11). Extracted saliva samples were incubated with PLA_2 followed by RIA to determine the levels of PAF remaining (Fig. 1). After treatment with PLA_2 all samples, including a stock solution of synthetic PAF, showed less than 1 ng/mL PAF remained. The results of these experiments and the known specificity of PLA_2 and the RIA leads to the conclusion that the PAF-like activity detected in the saliva was indeed due to PAF.

RIA vs platelet aggregation. One interesting result of this work was the observation that PAF levels determined by platelet aggregation were consistently lower than the values obtained by RIA (Table 3). PAF induces aggregation of platelets at concentrations as low as 0.1 nM (15) and results obtained by RIA showed levels of PAF in saliva within the range 4–25 nM. However, with some of these saliva extracts, stimulation of platelets did not result in aggregation. Furthermore, platelets treated with these extracts did not respond to the subsequent addition of synthetic PAF. Results of these studies with sample 3 (Table 3) are shown in Figure 2 and are compared with the response of platelets to the same amount of synthetic PAF, in the absence of saliva extract.

[b]Tested as a ×2.5 concentrate relative to saliva.

[c]Tested as a ×10 concentrate relative to saliva.

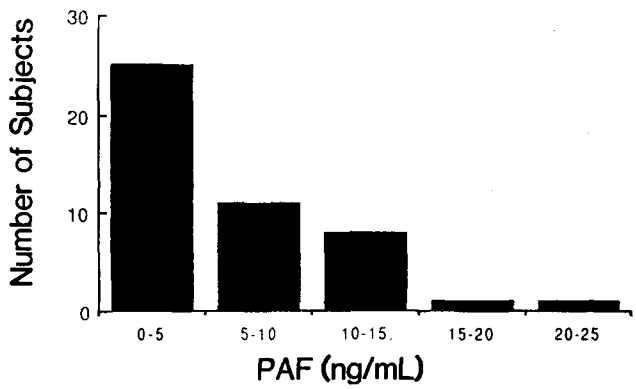

FIG. 3. Levels of PAF in human saliva. Samples of saliva were collected from 46 healthy volunteers. PAF was extracted by the method of Bligh and Dyer (12) within 15 min of sample collection. PAF levels were determined by RIA.

These observations suggest the presence in saliva of an endogenous inhibitor(s) which interferes with the determination of PAF levels using the biological assay, but does not affect the RIA. Experiments to determine the identity of these inhibitors are currently in progress (16).

PAF levels in normal human saliva. To date, only two groups have reported PAF levels in human saliva. The first study (8) employed a bioassay based on platelet degranulation and the second (9) utilized radioligand competitive binding methodology with intact canine platelets. These assay procedures may be influenced by antagonists/agonists of PAF activity in biological fluid (17). Indeed, we have shown (Fig. 2) that inhibitor(s) of platelet aggregation are present in saliva extracts and will therefore affect results using this method (16).

Having determined that the RIA is specific for PAF, is free of interfering factors and that chromatographic separation of samples is not necessary prior to RIA, the procedure was used to quantitate PAF in human saliva. Unstimulated human salivas from 46 healthy volunteers were examined (Fig. 3). The levels of PAF, not corrected for percent recovery, ranged from 0.46–21 ng/mL, with over 50% between 2–6 ng/mL, which is significantly greater than the values of 0.3–1.2 ng/mL previously reported (8,9) for apparently healthy subjects. These results are not surprising, as the latter values were obtained

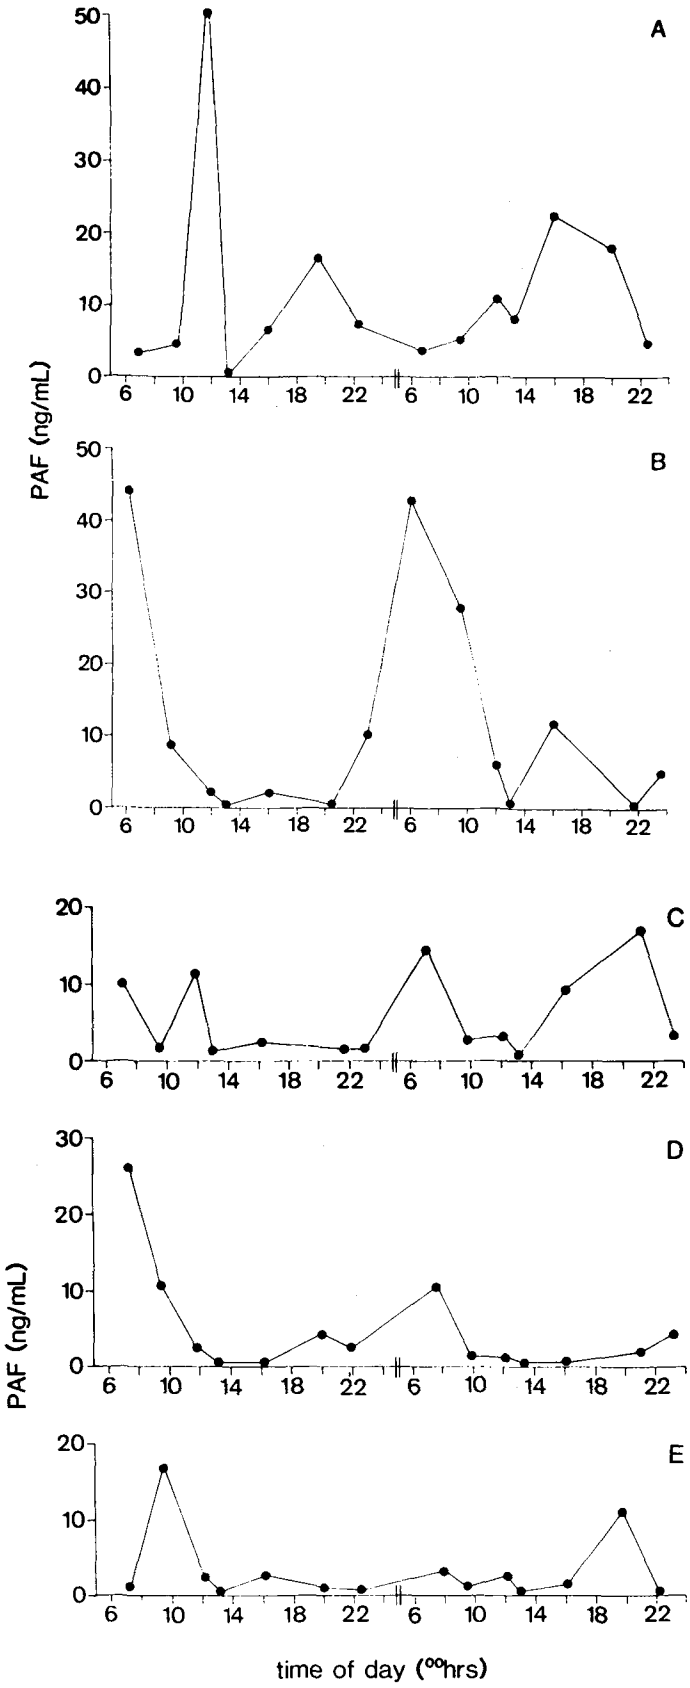

FIG. 4. Variation of PAF levels in human saliva over 48 hr. Saliva samples were collected from five volunteers at various times over a 48-hr period. Samples were stored at −20°C. After thawing samples, lipids were extracted by the Bligh and Dyer method (12). Levels of PAF were determined by RIA.

using platelet based assays. The response of platelets to endogenous PAF is diminished due to the presence of inhibitors which have now been demonstrated in rat liver (18), rat uterus (19) and, more recently, in human saliva (16). In our sample of 46, a wide range of PAF levels was observed, and therefore, the levels of PAF in the saliva from five healthy volunteers was monitored over a 48-hr period (Fig. 4). Significant variation can be seen in each individual with, in general, a peak in the morning followed by decreasing levels in the middle of the day which are lower than those at night. It is possible that these variations are due to the levels of hydration of the subject at the time of donation although further experiments are required before any firm conclusions can be reached. One clear feature of these results is the important role that standardization, not only of assay procedure but also of sample collection, will play in any future investigations on the levels of PAF in both normal and diseased states.

In summary, the RIA appears to be a suitable and reliable method for measuring PAF levels, with the added advantage of high sample capacity. Further investigations should reveal whether or not PAF levels in saliva reflect a relationship between PAF and disease.

Inhibitor(s) of Platelet-Activating Factor (PAF) in Human Saliva[1]

Mary A. Smal[a] and **Brian A. Baldo**[a,b,*]

[a]Kolling Institute of Medical Research, Royal North Shore Hospital, St. Leonards, N.S.W. 2065, and [b]Department of Medicine, University of Sydney, N.S.W. 2006, Australia

Quantitation of platelet-activating factor (PAF) in human saliva samples by radioimmunoassay indicated there was, at times, sufficient PAF present to aggregate platelets. However, in certain samples, we observed little or no aggregation, and furthermore, these samples were found to inhibit aggregation induced by PAF (200 pg). Chromatographic fractionation of pooled saliva increased the PAF activity 4-fold, and the observed inhibitory activity was found to co-migrate with the fatty acids. The inhibitory fraction was found to be active against platelet aggregation induced by arachidonic acid (3.4 nmole) as well as PAF (25 pg), but not thrombin (20 mU). These results indicate the existence of a PAF inhibitor in saliva, which may explain why potentially toxic levels of PAF can occur in the saliva of normal, healthy individuals. These findings also highlight an important advantage of the radioimmunoassay over platelet aggregation for the quantitation of PAF in, at least, some biological fluids. *Lipids 26*, 1144–1147 (1991).

Platelet-activating factor (PAF), 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine, is a naturally occurring phospholipid with many potent biological activities (1,2). Amongst the bioactions, the capacity to induce aggregation of human and rabbit platelets at concentrations of 0.1nM is unique (3). Predictably, PAF has been implicated as a mediator of many diseased states, including asthma (4), other allergic diseases (5), septic shock (6), kidney disease (7) and gastric ulceration (8). The proposed role of PAF in these diseases and in normal physiological processes may be clarified by the quantitation of PAF in the relevant tissues or fluids.

The development of a specific and sensitive radioimmunoassay (RIA) for PAF (9) allows PAF to be accurately and routinely measured in various biological samples. Using the RIA, we quantitated PAF levels in numerous samples of mixed human saliva and found the levels to range from 0.5 to 21 ng/mL (10). These levels were higher than the previously reported data determined by bioassay (11,12) and higher than our results based on platelet aggregation measurements (10).

The most likely explanation for these observations seemed to be the presence of an inhibitor of PAF activity in the saliva extract. In this communication we report the isolation and preliminary examination of an inhibitory fraction from human saliva.

MATERIALS AND METHODS

Materials. Solvents were reagent grade or better and were obtained from Ajax Chemicals (Sydney, Australia). C_{16}PAF and C_{18}PAF were purchased from Bachem Feinchemikalien (Bubendorf, Switzerland) and an equimolar mixture of these two PAF homologs was used for all studies. Silica gel 60 for column chromatography (70–230 mesh), aluminum-backed thin-layer chromatography (TLC) plates (silica gel 60, 0.2 mm thick) and glass-backed preparative TLC plates (silica gel 60, 0.25 mm thick, 20 cm × 20 cm) were purchased from E. Merck (Darmstadt, Germany) and these were activated before use by heating to 100°C. All other chemicals and reagents were obtained from the Sigma Chemical Company (St. Louis, MO). Analytical TLC plates were developed in the standard solvents for lipid separation (13) and visualized by charring with sulfuric acid.

Extraction of saliva. Unstimulated mixed salivas (0.8 vol) were extracted with chloroform/methanol/water (2:2:1, v/v/v) by the method of Bligh and Dyer (14). The organic layer was evaporated under nitrogen, and the residue stored at −20°C. For platelet aggregation, the residue was reconstituted in phosphate-buffered saline (PBS) containing 0.25% bovine serum albumin (BSA).

Platelet aggregation. Washed rabbit platelets were prepared as previously described (15) and platelet aggregation carried out in duplicate as described by Huo *et al.* (16). PAF and arachidonic acid (AA) were diluted in 0.25% BSA/PBS and thrombin in saline. A standard dose-response curve was obtained by stimulating platelets with synthetic PAF, and this curve was used to quantitate PAF-activity in unknowns. For inhibition studies, the platelets were incubated with the saliva extracts or fractions for 1 min before addition of PAF. For the control response, platelets were pre-treated with the vehicle only before stimulation. Inhibition (%) (average) was calculated comparing the maximum height of the aggregation curve to that of the control.

Column chromatography. An extract of pooled saliva (72 mL) in chloroform (0.6 mL) was loaded onto a silica gel column (2 g) packed in chloroform. The column was eluted sequentially with 5 mL of each of the following: chloroform, chloroform/methanol (3:2, v/v), chloroform/methanol (1:3, v/v), methanol, chloroform/methanol/water (2:3:1, v/v/v) (2 lots). One-mL fractions were collected and each was analyzed by TLC. An aliquot of each fraction was evaporated, reconstituted in 0.25% BSA/PBS, and tested by platelet aggregation assay.

Preparative TLC. Extract of saliva (89 mL) in chloroform was applied to a preparative TLC plate and the plate developed in chloroform/methanol (19:1, v/v). The plate was divided into 1-cm bands, and these were scraped into glass centrifuge tubes. The silica was extracted 4 times with chloroform/methanol (2:1, v/v) (4 × 4 mL) and the combined extracts evaporated. Each

fraction was analyzed for lipids present and inhibitory activity.

RESULTS

Effect of whole saliva extract on platelet aggregation. Figure 1 shows the changes in light transmission when platelets were preincubated with several saliva extracts followed by the addition of PAF. Thirty different saliva extracts were studied; with each of the extracts, the response to PAF was diminished and with some extracts, completely abrogated. A representative selection is shown in Figure 1. Platelets aggregated when stimulated with some saliva extracts, but the response was weak (saliva B in Fig. 1). It has also been noted several times that the observed level of PAF in some saliva extracts, as determined by platelet aggregation, apparently increased as the sample was diluted.

Separation of salivary PAF activity from inhibitory activity. A sample of pooled saliva extract was fractioned by column chromatography and the fractions were analyzed for PAF and inhibitory activities (Table 1). PAF activity was observed in fractions corresponding to the more polar phospholipids (phosphatidylcholine and sphingomyelin) and this activity increased approximately 4-fold over the activity observed in the whole extract. Furthermore, PAF inhibitory activity was observed in the fractions corresponding to the neutral lipids, cholesterol and fatty acids. It is possible that there are inhibitors that co-migrate with PAF. These may be difficult to detect since the endogenous PAF would desensitize the platelets (17) and hence, it would be unclear which compounds were responsible for the observed inhibition.

A purer fraction containing the above inhibitory activity was isolated by subjecting the whole saliva extract to preparative TLC (Table 2). The only significant inhibitory activity was confined to fractions 11 and 12; analytical TLC indicated that the major component of these fractions co-migrated with the fatty acids.

Specificity of inhibitory activity. The PAF inhibitory fractions (11 and 12 from the TLC separation) were tested for their capacities to block platelet aggregation induced by AA and thrombin. The results for fraction 12 are shown in Figure 2; similar results were obtained for fraction 11.

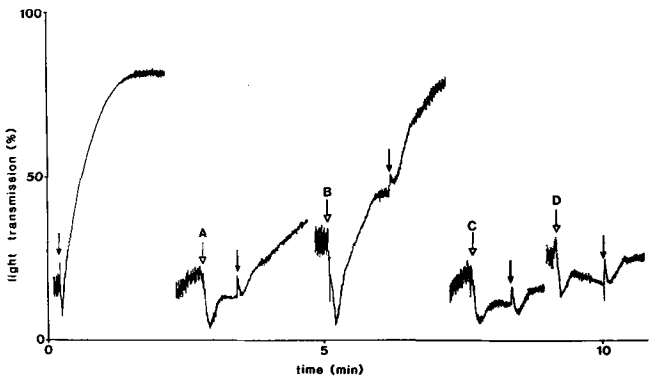

FIG. 1. The response of washed rabbit platelets (0.5 mL) following addition of lipid extracts of salivas A, B, C and D (equivalent to 0.2 mL saliva) (open arrow) and stimulation with PAF (200 pg) (closed arrow).

[a]The lipid extract of pooled saliva was separated by preparative TLC as described in Materials and Methods.

[b]On silica gel plates run in methanol/chloroform (1:19, v/v).

[c]Platelets (0.5 mL) were incubated with an aliquot of each fraction (equivalent to 2 mL saliva) and followed stimulation with PAF (100 pg).

[d]Uncorrected for the turbidity of the lipid sample; the true inhibitory potencies of these fractions were lower than observed.

[e]MG, monoglycerides.

[f]U, unknown.

[g]PL, phospholipids.

PAF- and AA- induced aggregation were completely blocked, whereas thrombin-induced aggregation was unaffected by the same dose of inhibitor. Dose-dependent inhibition was observed for PAF-induced aggregation. Studies with other aggregating agents are in progress.

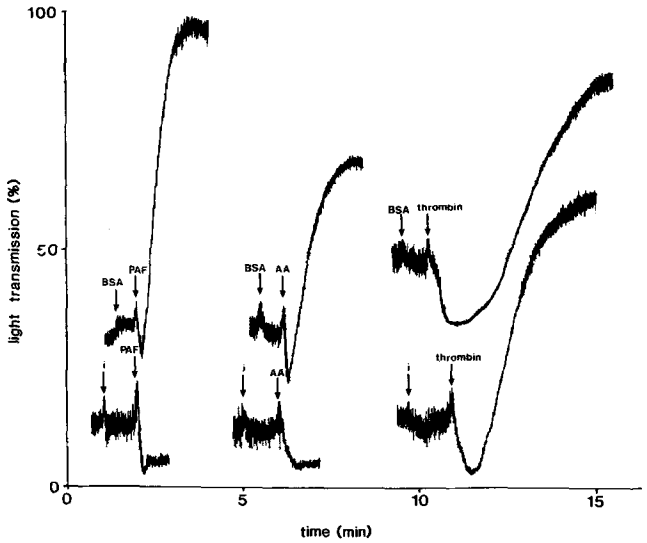

FIG. 2. The response of washed rabbit platelets (0.5 mL) following incubation with saliva fraction (i) number 12 from preparative TLC and equivalent to 2 mL saliva, followed by stimulation with either PAF (25 pg), AA (3.4 nmol) or thrombin (20 mU). The vehicle (0.25% BSA/PBS) was used for the control response.

DISCUSSION

In our previous study (10), PAF levels in whole saliva extracts were quantitated by RIA, and results indicated that there was sufficient PAF present in saliva to aggregate platelets. However, when measured by platelet aggregation, little PAF activity was found. One possible explanation for these results was that the extracts contained lipids which interfered with the functional response of platelets to the endogenous PAF.

In this study, we examined this possibility by incubating platelets with various saliva extracts before stimulation with PAF, and the diminished platelet response we observed (Fig. 1) supported this hypothesis. Upon chromatographic fractionation of whole saliva extract, the PAF activity increased 4-fold, indicating that an inhibitory factor had been removed. Indeed, inhibitory activity was observed in fractions that co-migrated with the more polar neutral lipids.

The inhibitory fraction studied here was further purified by preparative TLC, and found to co-migrate with the fatty acids. The inhibitor is suspected to be a fatty acid, and additional supportive evidence may be obtained by carrying out preparative TLC in a different solvent system. A variety of naturally-occurring fatty acids are currently being tested for PAF inhibitory activity.

The specificity of the inhibitor(s) was also investigated. AA-induced aggregation was also blocked, whereas thrombin-induced aggregation was not. This suggests that the inhibitor(s) does not act through the PAF receptor, but may affect a biochemical reaction which is common to both PAF- and AA-induced platelet aggregation. The effect of the inhibitor(s) on other cells and tissues that are sensitive to PAF has not yet been studied.

Recently, three reports have appeared in the literature on the existence of lipid-like inhibitors of PAF in mammalian tissues. Nakayama *et al.* (18) isolated two inhibitory fractions from rat uterus, and identified them to be mixtures of firstly, 1-acyl-*sn*-glycero-3-phosphocholines and 1-alkyl-*sn*-glycero-3-phosphocholines, and secondly, *N*-acyl sphing-4-enylphosphocholines. These substances were specific inhibitors of PAF-induced platelet aggregation. Masugi *et al.* (19) reported the existence of a non-specific inhibitor in renal venous blood from patients with renovascular hypertension; this inhibitor had an R_f similar to PAF and was thought to be a polar phospholipid. Miwa *et al.* (20) reported the existence of an endogenous inhibitor in rat liver that had the chromatographic properties of a non-polar lipid. This inhibitor may be similar to the salivary inhibitor(s) described here.

The existence of an endogenous inhibitor(s) in saliva extracts serves to highlight the unreliability of the platelet bioassays for quantitating PAF (3). Since the RIA is only dependent on the binding of PAF to an antibody, which is highly specific for PAF (9), the PAF levels obtained by this method are more likely to reflect the true levels. This would also explain why higher levels of PAF were observed using the RIA (10) compared to those previously reported using platelet bioassays (11,12).

The existence of a PAF inhibitor in saliva may be incidental or it may have some functional role. Since the levels of PAF in saliva appear to be sufficient to elicit biological responses, this inhibitor may serve to protect oral tissues from the inflammatory effects of PAF.

L-659,989: A Useful Probe in the Detection of Multiple Conformational States of PAF Receptors[1]

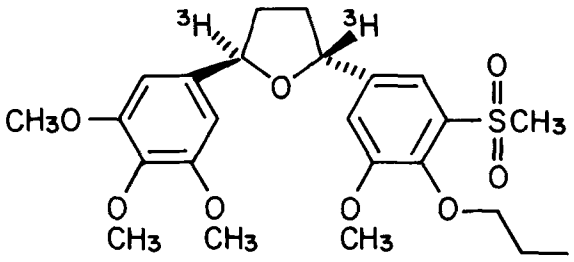
San-Bao Hwang* and **My-Hanh Lam**
Merck Sharp & Dohme Research Laboratories, Department of Biochemical Regulation, Rahway, New Jersey 07065-0900

L-659,989 is a potent, specific and competitive platelet-activating factor (PAF) receptor antagonist. The 2,5-tritium labeled L-659,989, similar to [^{3}H]PAF, specifically binds to rabbit platelet membranes with an equilibrium dissociation constant (K_D) of 1.60 (±0.20) nM in 10 mM $MgCl_2$. However, guanosine 5′-triphosphate (GTP) and several cations affect the specific binding of [^{3}H]PAF and of [^{3}H]L-659,989 to rabbit platelet membranes in different ways. K^+, Mg^{2+}, Ca^{2+} and Mn^{2+} potentiate the specific binding of both ligands. Na^+ and Li^+ inhibit the specific [^{3}H]PAF binding, but enhance the binding of [^{3}H]L-659,989; GTP reduces the [^{3}H]PAF binding but has no effect on the binding of [^{3}H]-L-659,989. Ni^{2+} inhibits the [^{3}H]L-659-989 binding, but has no effect on the binding of [^{3}H]PAF. In the presence of 150 mM NaCl, [^{3}H]L-659,989 exhibits identical K_D and detectable binding sites (B_{max}) values as those in the presence of 10 mM $MgCl_2$, while K_D And B_{max} values of [^{3}H]PAF are dramatically reduced in the presence of 150 mM NaCl compared to those in 10 mM $MgCl_2$. These results suggest the existence of multiple conformational states of the PAF specific receptor and that PAF and L-659,989 bind differently to those states. In the presence of 150 mM NaCl and 1 mM GTP, receptors appear to exist in a single conformational state with an equilibrium dissociation constant (K_B) of 0.93 μM for PAF as derived from the Schild plot. In isolated rabbit platelets pretreated with 10 μM ETH 227, a Na^+-specific ionophore, the detectable [^{3}H]PAF binding sites drop from 260 to 100 binding sites per platelet, but the binding sites for [^{3}H]L-659,989 remain roughly the same. The Na^+ binding sites which modulate the conformation of PAF receptors are therefore protected from extracellular Na^+ until ionophore is added, and are probably located on the cytoplasmic side of the plasma membrane.
***Lipids 26,* 1148–1153 (1991).**

Platelet-activating factor (PAF) is a potent phospholipid mediator with a wide variety of biological activities, which include aggregation and degranulation of platelets and leukocytes, bronchoconstriction, vascular permeability and hypotension (1). A cell surface receptor that specifically binds PAF is generally believed to mediate cellular responses to PAF. Indeed, specific receptors for PAF have been reported in a variety of cell membranes, including those from human (2–4) and rabbit platelets (5,6), human polymorphonuclear leukocytes (PMNs) (7–9) and membranes from several types of tissues (10–12).

Working with isolated membranes, we have previously shown that a single type of PAF-specific receptor exists in human (4) and rabbit (5) platelets, human PMNs (9), human lung tissue (10), rat liver tissue (11), and rat peritoneal PMNs (9). In each case, we detected a single equilibrium dissociation constant of about 0.5 nM for [^{3}H]-C_{16}-PAF under identical ionic conditions. O'Flaherty *et al.* (8) have reported both high and low affinity binding sites for PAF in human PMNs (K_D = 0.2 and 500 nM, respectively). These could result from the existence of multiple conformational states of the receptor which could be detected under different ionic or other experimental conditions. Indeed, with the help of 2,5-tritium labeled L-659,989 (*trans*-2-(3-methoxy-5-methylsulfonyl-4-propoxyphenyl)-5-(3,4,5-trimethoxyphenyl)tetrahydrofuran, (Scheme 1), we could detect multiple conformational states of a single type of PAF receptors (13). This review summarizes these studies and extends the work with the sodium specific ionophore, ETH 227, to demonstrate that the Na^+ binding sites are probably located on the cytoplasmic side of the plasma membrane.

L-659,989 is a potent specific and competitive receptor antagonist of PAF. L-659,989 is an orally active and extremely potent, selective and competitive PAF receptor antagonist (14). It potently inhibits the [^{3}H]C_{16}-PAF (1-*O*-hexadecyl-2-*O*-acetyl-*sn*-glycero-3-phosphocholine) binding to either rabbit platelet or rabbit PMN membranes with an equilibrium constant (K_I of 1.1 nM) but is about 10 times less potent with a K_I of 14.3 nM in human platelet (Table 1), PMN, and lung membranes. This difference is consistent with the species difference in PAF receptor between human and rabbit platelets (4).



L-659,989 is one of the most potent PAF receptor antagonists reported in the literature. As shown in Table 1, it is about 10 times more potent than L-652,731 (4) and almost 100 times more potent than kadsurenone (4) in rabbit platelet membranes. L-659,989 is about 5- to 6-fold more potent than WEB2086 and about 70-fold more potent than FR72112 in human platelet membranes.

L-659,989 shares a common binding site with PAF. The specific binding of 2,5-tritium-labeled L-659,989 to rabbit platelet membranes is saturable with a single type of high affinity binding site detectable in Scatchard plots. The equilibrium dissociation constant (K_D) is 1.60 ± 0.20 nM (n = 6) in 10 mM $MgCl_2$ (13). This value is almost identical to the equilibrium inhibition constant (K_I), 1.10 ± 0.19 nM (n = 4) (Table 1) in inhibiting the

TABLE 1

Equilibrium Inhibition Constants (K_I) for the Inhibition by PAF Receptor Antagonists of [^{3}H]C_{16}-PAF Binding to Rabbit and Human Platelet Membranes

Compound	K_I[a]	
	Rabbit platelet membranes	Human platelet membranes
L-659,989	1.10 (± 0.19) × 10^{-9}	1.43 (± 0.49) × 10^{-8}
L-652,731	9.83 (± 2.92) × 10^{-9}	
Kadsurenone	8.81 (± 1.4) × 10^{-8}	
WEB 2086	7.93 (± 0.50) × 10^{-8}	
FR72112		9.51 (± 1.74) × 10^{-7}

[a]Data are expressed as mean (± S.D.) of four to five experiments.

specific [^{3}H]C_{16}-PAF binding to those membranes. The specific binding of [^{3}H]L-659,989 can be fully displaced by PAF and PAF analogs and also by several selected PAF receptor antagonists of different chemical structures (13). The K_I values of these PAF analogs, PAF receptor antagonists, and PAF against [^{3}H]L-659,989 binding are about the same as their K_I values against [^{3}H]C_{16}-PAF binding. An excellent correlation ($\gamma = 0.997$, slope = 0.94) exists between the potencies of the compounds in displacing [^{3}H]C_{16}-PAF from its binding sites and in inhibiting the specific [^{3}H]-659,989 binding (13).

The specificity of [^{3}H]L-659,989 is similar to that of [^{3}H]C_{16}-PAF and [^{3}H]dihydrokadsurenone binding (13,15). Several selected pharmacologically defined drugs or agents show no significant inhibition of [^{3}H]L-659,989 binding. The competitive nature of the antagonism was demonstrated by the inhibition of [^{3}H]C_{16}-PAF binding to rabbit platelet membranes and by the inhibition of PAF-induced gel-filtered rabbit platelet aggregation (14). These results strongly indicate that L-659,989 shares with PAF a common binding site in the PAF receptor.

PAF induces a conformational change of the PAF receptor. Although L-659,989 is a competitive inhibitor of [^{3}H]PAF binding (see above), the reverse is not true. L-659,989 alters the apparent dissociation constant (K_D') of specific [^{3}H]C_{16}-PAF binding to rabbit platelet membranes, but not the number of detectable binding sites (B_{max}) as shown by Scatchard plots (Fig. 1A). However, C_{16}-PAF alters not only the K_D' of [^{3}H]L-659,989 binding to the receptors in rabbit platelet membranes but also the B_{max} (Fig. 1B). In the presence of 30 nM C_{16}-PAF, the B_{max} drops from 3.84 ± 0.08 pmol/mg protein (n = 3) to 2.05 ± 0.23 pmol/mg protein (n = 3, mean ± S.D.), nearly 50% lower than that in the absence of C_{16}-PAF (13). Since L-659,989 is a competitive PAF receptor antagonist, the most likely explanation is that PAF but not the antagonist induces a conformational change in the PAF receptor from a high-affinity state for L-659,989 to a low-affinity state. This change could also account for the difference in the detectable receptor number between [^{3}H]C_{16}-PAF and [^{3}H]L-659,989. The B_{max} for [^{3}H]L-659,989 (4.27 ± 0.34 pmol/mg protein, n = 6) is about 25% higher than the B_{max} of [^{3}H]C_{16}-PAF binding sites (3.19 ± 0.39 pmol/mg protein, n = 3) assayed in the same membranes under identical ionic conditions (13). Therefore, PAF could also convert the PAF receptor from a high-affinity state to a low-affinity state for binding of PAF itself. However, we cannot rule out the possibility that the detection of the lower B_{max} value for [^{3}H]PAF is due to the difference in the dissociation rate constants between the two ligands.

Modulation by ions and GTP of the binding of [^{3}H]C_{16}-PAF and [^{3}H]L-659,989 to rabbit platelet membranes. Na^+ and Li^+ inhibit, but K^+, Mn^{2+}, Ca^{2+}, and Mg^{2+} potentiate the specific [^{3}H]C_{16}-PAF binding to rabbit (16) and human (9) platelet membranes. The Na^+ inhibitory effect is apparently due to an increase in the equilibrium dissociation constant of the PAF binding, but not in the number of receptor sites. However, the increase in the specific [^{3}H]C_{16}-PAF binding by divalent cations is mainly due to an increase in the total number of the detectable binding sites (16). On the other hand, the specific [^{3}H]L-659,989 binding to rabbit platelet membranes is potentiated not only by K^+, Mg^{2+}, Ca^{2+} and Mn^{2+} but also equally by Na^+ and Li^+ (13). A detailed Scatchard analysis of the specific [^{3}H]L-659,989 binding shows that the potentiation effects of Na^+ and Mg^{2+} are apparently due to the increase in B_{max} with a minimal alteration in the K_D. In the presence of either 150 mM NaCl or 10 mM $MgCl_2$, the PAF receptors show identical affinity and similar detectable binding sites for L-659,989. Ni^{2+} inhibits the specific [^{3}H]L-659,989 binding, even though it shows no effect on the specific [^{3}H]C_{16}-PAF binding to rabbit platelet membranes (17). GTP specifically inhibits the [^{3}H]PAF binding (16) but

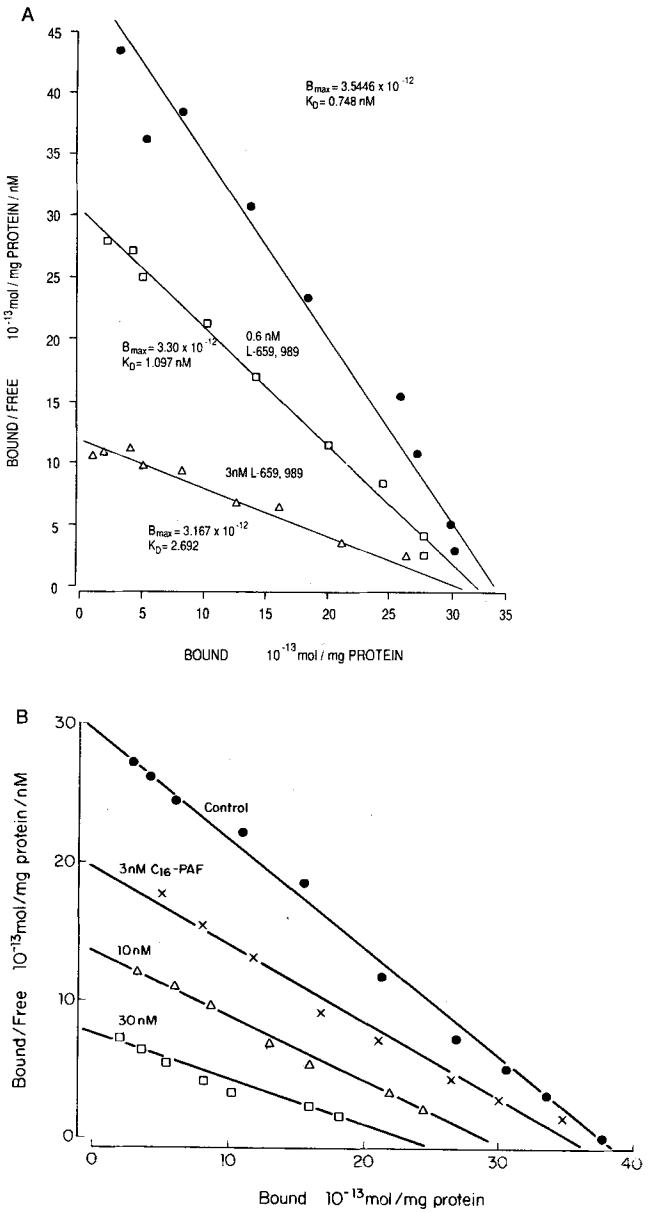

FIG. 1A: Scatchard plots of [^{3}H]C_{16}-PAF binding to rabbit platelet membranes without (●) and with L-659,989 at a concentration of 0.6 nM (□) and 3 nM (△). The assay medium was 10 mM $MgCl_2$, 10 mM Tris and 0.25% BSA at pH 7.0. Lines were plotted by linear regression. The data points are the mean of duplicate determinations. B: Scatchard plots of the specific [^{3}H]L-659,989 binding to rabbit platelet membranes in the absence (●) and in the presence of unlabeled PAF at 3 nM (X), 10 nM (△) and 30 nM (□) (13).

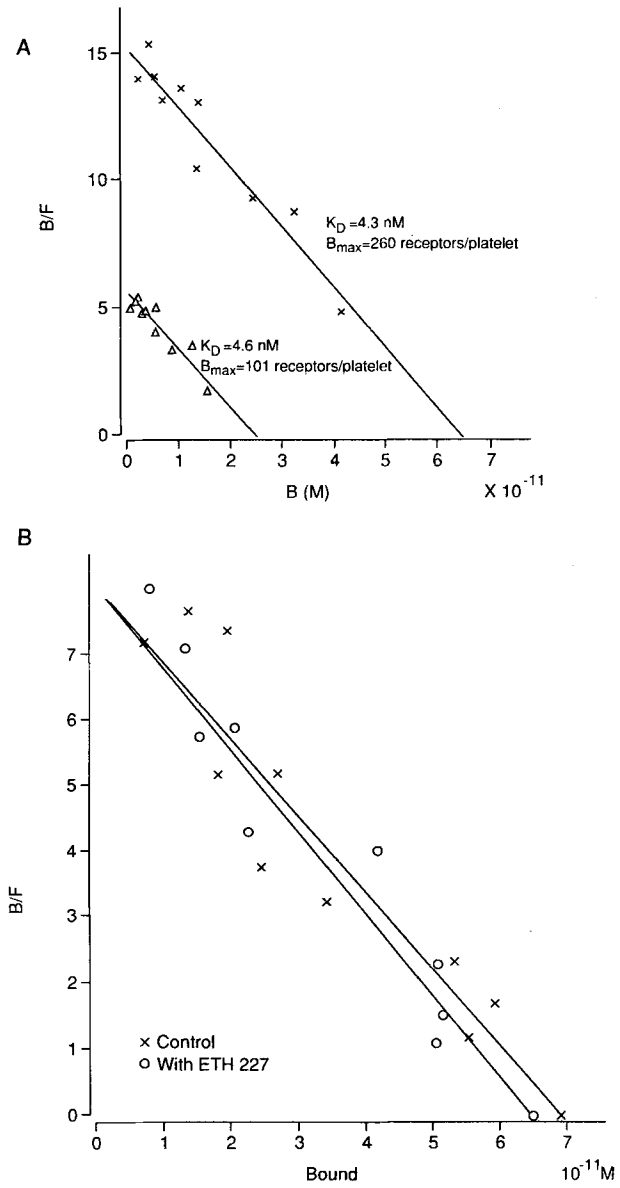

FIG. 2. Scatchard plots of the binding of [^{3}H]C_{18}-PAF (2A) and [^{3}H]L-659,989 (2B) to gel-filtered rabbit platelets with or without 10 μM ETH 227. Platelets were prepared as previously described (5) and incubated (3 × 10^8 platelets/mL) at 37°C for 2 min either with or without 20 μM ETH 227. ETH 227 (4 mM) was dissolved in dimethylsulfoxide (DMSO). DMSO (5 μL) was added as control. Cells (250 μL) incubated either with or without ETH 227 in column buffer were added to Microwell tube strips (Skatron, Inc., Stirling, VA) which contained 250 μL of 0.1 to 6 nM [^{3}HC_{18}-PAF (Fig. 2A) or [^{3}H]L-659,989 (Fig. 2B) such that the final cell number was 1.5 × 10^8 platelets per mL and the concentration of ETH 227 was 0 or 10 μM. Nonspecific binding was measured in the presence of 1,000-fold excess of unlabeled C_{18}-PAF or L-659,989. After 2 hr incubation at 0°C, bound and unbound radioligands were separated through filtermat with a 12 well cell harvester (Skatron, Inc.) and radioactivity was counted.

shows no effect on the binding of [^{3}H]L-659,989 (13). Differences in the modulation by ions and GTP of the binding of [^{3}H]C_{16}-PAF and [^{3}H]L-659,989 to rabbit platelet membranes seem to be clear. Such a clear change in the binding of agonist and antagonist caused by ionic conditions strongly suggests that the variation in the maximal number of binding sites under different ionic conditions results from a direct receptor effect rather than from altered membrane structure and that these ions and GTP could modulate the conformation of the PAF receptor. Thus, multiple conformational states could exist in a possible single type of PAF receptor.

The Na^+ binding site is located at the cytoplasmic side of plasma membranes. As discussed above, Na^+ and Li^+ inhibit, but K^+ and divalent cations such as Mn^{2+}, Ca^{2+} and Mg^{2+} potentiate the specific [^{3}H]PAF binding (16). In the presence of 10 mM $MgCl_2$, the detectable

TABLE 2

Specific Binding of [^{3}H]C_{18}-PAF of [^{3}H]L-659,989 to Intact Gel-Filtered Rabbit Platelets Without and With Na^+-Ionophore Treatment

Ligand	ETH 227	K_D (nM)	B_{max} (receptors/platelet)
[^{3}H]C_{18}-PAF	0	3.62 (± 1.23)	259 ± 7 (n = 3)
[^{3}H]C_{18}-PAF	10 μM	3.14 (± 1.62)	110 ± 9 (n = 3)
[^{3}H]L-659-989	0	1.75 (± 0.79)	267 ± 16 (n = 4)
[^{3}H]L-659,989	10 μM	1.44 (± 0.35)	251 ± 9 (n = 4)

receptor number of [^{3}H]PAF in rabbit platelet membranes is about twice of that found in the presence of 150 mM NaCl (16). The decrease in the detectable receptor number in the presence of Na^+ is apparently due to the presence of the reduced affinity of the receptor for [^{3}H]PAF since binding with a K_D value in the μM range cannot be detected in Scatchard plots of experiments with the radioligand in the nanomolar concentration range (13). On the other hand, the specific binding of [^{3}H]L-659,989 is potentiated not only by K^+, Mg^{2+}, Ca^{2+} and Mn^{2+}, but also equally potentiated by Na^+ and Li^+. Therefore, in intact gel-filtered rabbit platelets, if the Na^+ binding sites which modulate the specific binding of [^{3}H]PAF are located in the cytoplasmic side of the plasma membranes, we suspect that induction of Na^+ inward movement will decrease the detectable binding sites of [^{3}H]PAF but not those of [^{3}H]L-659,989. Indeed, Na^+ influx induced by a Na^+ specific ionophore, ETH 227 [*N,N',N''*-triheptyl-*N,N',N''*-trimethyl-4,4',4''-prophylidyne-*tris*(3-oxabutyramide)] (Scheme 1) (10 μM), decreases the [^{3}H]PAF binding sites by half with no significant change of [^{3}H]L-659,989 binding sites as demonstrated by the experiments described below.

The tritium-labeled C_{18}-PAF (1-*O*-[9',10'-^{3}H]octadecyl-2-*O*-acetyl-*sn*-glycero-3-phosphocholine) specifically binds to isolated rabbit platelet membranes with K_D of 1.99 ± 0.09 nM (mean ± S.D., n = 3) in an assay medium of 10 mM $MgCl_2$ 10 mM Tris, and 0.25% bovine serum albumin (BSA) at pH 7.0. However, it binds to gel-filtered rabbit platelets with a K_D of 3.62 (±1.23) nM (mean ± S.D., n = 3) in a sodium-containing buffer (126 mM NaCl, 14.5 mM Tris, 0.1% glucose, 5.4 mM KCl, 10 mM $MgCl_2$, 0.05 mM $CaCl_2$ and 0.25% BSA at pH 7.6). A sodium specific ionophore, ETH 227, (18,19) was used to determine whether a Na^+-sensitive site might be shielded from extracellular Na^+ in the intact platelets. The specific binding of [^{3}H]C_{18}-PAF to intact rabbit platelets in the presence of 10 μM ETH 227 was reduced to about half of the binding in the control experiments. Scatchard plots indicated that the reduction in the specific binding of [^{3}H]C_{18}-PAF is due to a decrease in the B_{max} without a significant alteration in the K_D. The detectable PAF binding sites decreased from 260 to 110 receptors per platelet in the presence of 10 μM ETH 227 (Fig. 2A and Table 2). In contrast, ETH 227 showed no significant effect on either the K_D or B_{max} of [^{3}H]-L-659,989 binding (Fig. 2B and Table 2). A single class of binding sites was observed for [^{3}H]L-659,989 binding to intact rabbit platelets with a K_D value close to 1.5 nM, which is the K_D value also found in the isolated rabbit platelet membranes (13). The B_{max} of [^{3}H]L-659,989 either with or without ETH 227 treatment was similar to the B_{max} value for [^{3}H]C_{18}-PAF in the control experiments. These results indicate that in platelets the Na^+ binding sites which modulate the affinity of PAF for specific PAF receptors are inaccessible to extracellular Na^+ and are probably located in the cytoplasmic side of the plasma membranes. Similar conclusions have been reached in the α_2-adrenergic receptor system of human platelets (20). Our data do not distinguish whether the Na^+ binding site is on the PAF receptor itself or on a regulatory protein. Also, since the receptors which cannot be detected by [^{3}H]C_{18}-PAF in the ETH 227-treated rabbit platelets are still detectable by [^{3}H]L-659,989, the reduction in [^{3}H]PAF binding is not due to the receptors being either embedded into the membrane or translocated into the inner membrane surface, but is due to the interaction of receptors with the ionophore-carried sodium such that the receptors' affinity is reduced. This lower-affinity binding cannot be detected in conventional Scatchard plots with radioligand in the nM range concentration. The identity of B_{max} for [^{3}H]C_{18}-PAF and [^{3}H]L-659,989 in the untreated rabbit platelets support the conclusion that L-659,989 is a specific PAF receptor antagonist and that both L-659,989 and PAF bind to the same receptor and share a common binding site in the receptor.

Multiple conformational states of a single type of PAF receptor. As discussed above, the K_D of [^{3}H]L-659,989 binding to rabbit platelet membranes is the same in 10 mM $MgCl_2$ and in 150 mM NaCl and is not altered by GTP. On the other hand, Na^+ and GTP do greatly affect the binding of [^{3}H]L-659,989 binding. In the presence of 10 mM $MgCl_2$, the effective dose, 50% (ED_{50}) of C_{16}-PAF to inhibit the specific [H]L-659,989 binding is 1.4 nM, whereas in the presence of 150 mM NaCl, the ED_{50} value is shifted to about 1 μM, almost 1,000-fold higher than that in 10 mM $MgCl_2$ (Fig. 3). GTP at 1 mM also significantly shifts the C_{16}-PAF competition curves to the right, from an ED_{50} value of 1.4 nM to 10 nM in the presence of 10 mM $MgCl_2$ and from 1 μM to 2 μM in the presence of 150 mM NaCl. The competition curves of C_{16}-PAF in the presence of either 10 mM $MgCl_2$ or 10 mM $MgCl_2$ and 1 mM GTP belong to a "shallow" competition curve, with a cooperativity index, R_s, value >81, indicating that multiple orders of binding sites of C_{16}-PAF are occurring in the competition binding (see Ref. 21 for the definition of R_s value). Two straight lines with slope equal to −1 and −0.5 in the indirect Hill plots better fit the data of C_{16}-PAF in the presence of either 10 mM $MgCl_2$ or 10 mM $MgCl_2$ and 1 mM GTP (13). Indeed, the competitive binding data under the assay conditions of 10 mM $MgCl_2$, 10 mM $MgCl_2$ and 1 mM GTP,

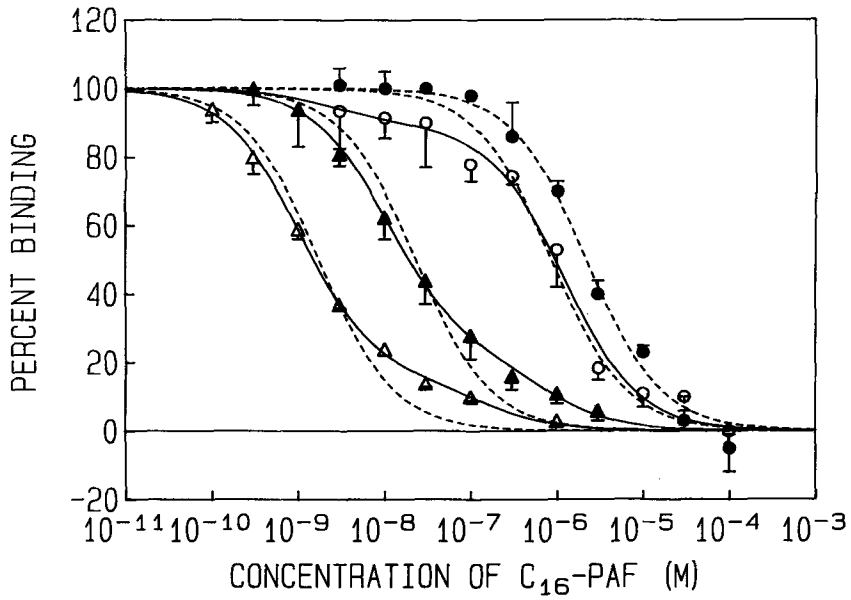

FIG. 3. Inhibition of [^{3}H]L-659,989 binding to rabbit platelet membranes by C_{16}-PAF. Membrane protein (100 μg) and 1 nM [^{3}H]L-659,989 were used in each tube in the assay medium containing 10 mM Tris and 0.25% BSA at pH 7.0 with 10 mM $MgCl_2$ (△), 10 mM $MgCl_2$ and 1 mM GTP (▲), 150 mM NaCl (○), and 150 mM NaCl and 1 mM GTP (●). Data points and error bars are mean and standard deviation of two or three experiments (13). Solid lines were plotted by fitting the competitive binding data with two components by a nonlinear regression computer software, GraphPAD, version 2.0 (GraphPAD Software, San Diego, CA). Dashed lines were plotted by fitting competitive binding data with one site by the same computer software.

or 150 mM NaCl can be better fitted with two sites (solid lines in Fig. 3) than with one site (dashed lines in Fig. 3). However, in the presence of 150 mM NaCl and 1 mM GTP, the competitive binding data can be best fitted with one component (Fig. 3). A normal steepness competition with a pseudo-Hill coefficient equal to −1 was observed in the indirect-Hill plot (13). A simple competitive antagonism of C_{16}-PAF on the specific binding of [^{3}H]-L-659,989 is therefore expected under this experimental condition. In fact, in the Scatchard plots of the saturation binding isotherms of [^{3}H]L-659,989 in the presence of 150 mM NaCl and 1 mM GTP, C_{16}-PAF alters the apparent dissociation constant (K_D') of [^{3}H]L-659,989 to its receptor but not the intercept at the x-axis or the maximal number of receptor sites (B_{max}). The equilibrium dissociation constant (K_B) of the unlabeled C_{16}-PAF could thus be determined indirectly from the Schild plot and is found to be 0.93 μM in the presence of 150 mM NaCl and 1 mM GTP (13), which is more than 1,000-fold higher than the K_D value (0.53 nM) obtained directly from the C_{16}-PAF binding isotherms in 10 mM $MgCl_2$ (16).

We conclude that PAF receptors exist in several distinct conformational forms with different affinity either to PAF or to a PAF receptor antagonist, L-659,989. Figure 4 shows a schematic representation. R_o is the state of the receptor with no addition of ions which shows low affinity for both [^{3}H]PAF and [^{3}H]L-659,989. Mg^{2+} and possibly other divalent cations, such as Ca^{2+} and Mg^{2+}, convert the receptor from R_o to $R_{Mg^{2+}}$ state, possibly through the interaction between PAF receptor and guanine nucleotide-binding protein, which is unrelated to the calmodulin system (17). $R_{Mg^{2+}}$ is the state with a high affinity for both PAF and L-659,989 (K_D = 0.53 nM and 1.60 nM, respectively). GTP in the presence of Mg^{2+} converts $R_{Mg^{2+}}$ into $R_{Mg^{2+}\cdot GTP}$, which has a lower affinity for PAF but not for L-659,989. Na^+ and

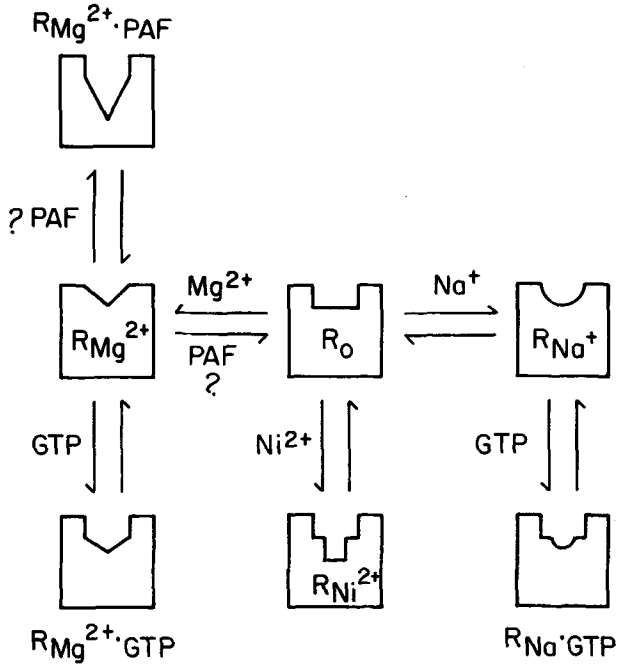

FIG. 4. Possible conformational states of PAF receptors in rabbit platelet membranes (13).

possibly Li^+ bind to the cytoplasmic side of plasma membrane and convert R_o into R_{Na^+}, which shows low affinity for PAF (K_D in the submicromolar range) but high affinity for L-659,989 (K_D = 1.5 nM). GTP can similarly transform R_{Na^+} into $R_{Na^+ \cdot GTP}$, possibly the lowest affinity state for PAF (K_D = 0.93 μM). L-659,989 shows similar affinity for receptor states in the forms of $R_{Mg^{2+}}$, $R_{Mg^{2+} \cdot GTP}$, R_{Na^+}, and $R_{Na^+ \cdot GTP}$ but shows low affinity for R_o. PAF could induce a conformational change of the receptor, possibly through the interaction between the receptor and guanine nucleotide-binding protein, resulting in a transition from $R_{Mg^{2+}}$ to either R_o or $R_{Mg^{2+} \cdot PAF}$, another conformation state of the receptor, which shows low affinity for L-659,989. Ni^{2+} could possibly induce another conformation of the receptor $R_{Ni^{2+}}$.

O'Flaherty *et al.* (22) recently reported that phorbol myristate acetate (PMA) reduced the availability of high affinity receptors for PAF in PMNs. Also, depletion of high affinity receptors for PAF paralleled inhibition of PAF-induced increase in cytosolic calcium. Losses in high affinity receptors may therefore be responsible for reducing the calcium mobilization response (12), and multiple conformational states of receptors may regulate the function of PAF.

CONCLUSIONS

L-659,989 is a potent, specific and competitive receptor antagonist. With the combined use of [^{3}H]PAF and [^{3}H]-L-659,989, we have demonstrated that PAF itself can induce a conformational change of its receptor and that the PAF receptor can exist in multiple conformational states which could possibly regulate and mediate the function of PAF.

ACKNOWLEDGMENTS

We wish to thank Dr. James C. Robbins for helpful discussion and Mrs. Joan Kiliyanski for typing the manuscript.

REVIEW

Chemical and Biochemical Characterization of Lignan Analogs as Novel PAF Receptor Antagonists[1]

T.Y. Shen
Department of Chemistry, University of Virginia, Charlottesville, Virginia 22901

Various derivatives and isosteres of neolignans of the 2,5-diaryl tetrahydrofuran type have been synthesized as antagonists of platelet-activating factor (PAF). A detailed analysis of their structure-activity relationship (SAR) has revealed a clear preference for an asymmetrical molecular configuration with a high degree of stereo and chiral specificity associated with greater potency. The *trans*-2S,5S enantiomers are generally 10–200 times more potent *in vitro* than their corresponding *cis* or *trans*-2R,5R isomers. A similar stereochemical preference is indicated by the recently reported PAF antagonist MK-287 which has undergone clinical evaluation. An azido derivative L-662,025 has been characterized as a photolabile irreversible antagonist of PAF for the investigation of solubilized and partially purified PAF binding proteins from cell membranes. The biological justification for concomitant inhibition of both PAF receptor and 5-lipoxygenase in inflammation is well recognized. The feasibility of developing such dual-functional agents has been demonstrated by a group of dithiolane analogs of neolignans and several derivatives of futoenone.
***Lipids* 26, 1154–1156 (1991).**

With therapeutic applications of platelet-activating factor (PAF) antagonists closer to reality, increasing attention is being given to further improvement of the antagonists' potency, pharmacodynamics and, possibly, tissue selectivity. Following the initial discovery of CV-3988 and kadsurenone, and the subsequent identification of L-652,731, ginkgolide B (BN 52021) and 48,740 R.P. as moderately active, specific receptor antagonists (1,2), a wide variety of chemical structures have been found to possess similar properties, several of which are active *in vitro* at nM concentrations and are undergoing clinical evaluations (3). In conjunction with a better understanding of the cellular biology of PAF (for reviews, see refs. 4,5), classification of PAF receptors and antagonists into subtypes may now be possible according to specific criteria, such as the relative receptor affinity for PAF and antagonists, the influence of metal ions on ligand binding to the receptor, and the differential effects of various inhibitors of the signal transduction mechanism on receptor function (6,7). Irreversible PAF antagonists have now been developed as biochemical probes for the characterization of PAF receptors. Based on the structure-activity relationship of PAF antagonists of the lignan type, some progress has also been made toward the development of dual-functional inhibitors of both PAF and 5-lipoxygenase (5-LO) as potentially more effective anti-inflammatory and anti-allergic agents.

STRUCTURE-ACTIVITY RELATIONSHIP OF LIGNAN ANALOGS

The structure-activity relationship (SAR) of receptor agonists and specific antagonists may reflect the topography of the receptor binding domain. In a detailed SAR analysis of the lignan-type PAF antagonists, we have previously noted that there is a high degree of stereospecificity in receptor blockade. For both kadsurenone (8) and 2,5-diaryl-tetrahydrofuran analogs (9), the *trans* isomers are generally more potent than the corresponding *cis* isomers. Similar correlations have since been extended to other isosteres of lignans with terahydrothiophene, cyclopentane, dioxolane and dithiolane ring systems (Fig. 1).

The asymmetrical configuration of the more potent antagonists, which is presumably complementary to a high affinity receptor binding site, is clearly indicated by two lignan derivatives, L-659,989 (10) in Figure 2 and its β-hydroxyethylsulfonyl analog L-680,573 (MK-287) (11), which are 10 times more potent than the symmetrical prototype L-652,731. The chirality of the molecule is also important. In a comparison of several pairs of optical isomers, which were obtained either by resolution of the racemic mixture on a chirapack column in high-performance liquid chromatography (HPLC) or through stereospecific synthesis using newly developed chiral reducing reagents (12,13), the 2S,5S-enantiomers are more active than their mirror images, *i.e.*, the 2R,5R-enantiomers. The potency ratio of S,S- over R,R-enantiomer is higher for antagonists with greater potency. For example, the K_i value of the (−) 2S,5S-isomer of

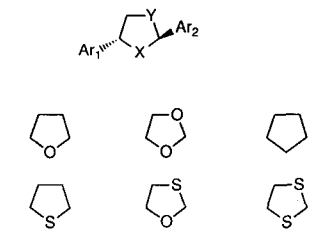

FIG. 1. Isosteres of 3,5-diaryl-tetrahydrofuran lignans possessing PAF antagonistic activities. The X and Y in the center ring may be oxygen (tetrahydrofuran, dioxolane), carbon (cyclopentane) and sulfur (tetrahydrothiophene, oxathiolane, dithiolane) as shown from left to right. Ar_1 and Ar_2 are substituted phenyl groups.

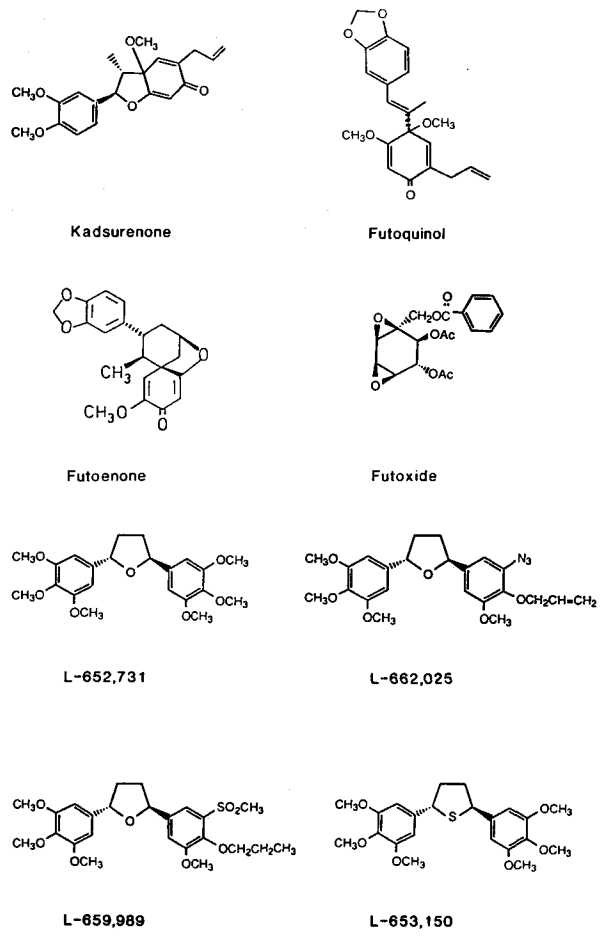

FIG. 2. Chemical formulae of neolignans and synthetic analogs which are PAF antagonists.

L-659,989 (1 nM) is 20–30 times lower than that of the (+) 2R,5R-isomer (14). The geometry of the binding domain near the tetrahydrofuran ring oxygen was clarified by a recent report (15) on a series of highly potent cyclopentane analogs of L-659-989 (Fig. 3). The IC_{50} value of two derivatives with R being α-allyloxy and α-propargyloxy analogs in the human platelet aggregation assay are in the range of 4 nM, nearly 10 times more potent than L-659,989. Based on X-ray crystallographic studies, the compound with an α-propargyloxy substituent in the center of the cyclopentane ring is 15 times more active than its β-isomer. The analog with a smaller α-methoxy substituent is less active, but it is still more potent than L-659,989 which has the ether group in the ring. It appears that at this position there is a deep hydrophobic trough that is asymmetrically oriented and thus can discriminate against the β-isomer.

Obviously, for this series of lignan-type PAF antagonists, especially for those with greater affinity for the receptor, the hypothetical "receptor contour" is highly stereospecific and significantly different from the symmetrical "ear-muffs" model described recently (16), which seems to accommodate some general features of kadsurenone, BN 52021 and other less active ginkgolides better.

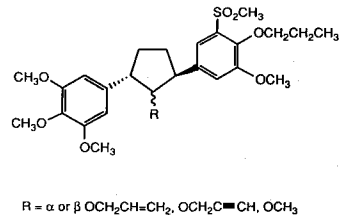

FIG. 3. Potent cyclopentane analogs of neolignans.

SOLUBILIZATION AND PARTIAL PURIFICATION OF PAF BINDING PROTEINS

In an attempt to elucidate the structural features of the binding domain of the PAF receptor more definitely, we have solubilized the PAF binding proteins of human platelet and bovine lung with 1% w/v digitonin and significantly increased their specific binding to [^{3}H]PAF through partial purification by ion exchange and affinity chromatography. Similar solubilization and purification conditions have been reported (17,18). Further chemical and biochemical characterization of purified binding proteins may help to clarify the subtype diversity of PAF receptors and antagonists.

As a research probe of PAF receptor and a specific marker in the identification of PAF binding proteins, an azido analog (L-662,025) of the antagonist L-659,989 was recently characterized as a photo-activatable, irreversible PAF antagonist (19). Upon irradiation at 260–320 nm for 15 min, L-662,025 selectively and irreversibly inactivates the PAF receptor on human platelets or in solubilized membrane preparations from bovine lung. As the PAF receptor from the guinea pig lung was cloned and expressed most recently (20), it would be interesting to identify the binding domains of PAF and its antagonists, and shed further light on the molecular interactions involved.

PAF ANTAGONISTS WITH DUAL ACTIONS

The synergism and potentiation of PAF with other inflammatory mediators are well recognized. To achieve greater therapeutic efficacy in clinical disorders such as asthma, which is mediated by both PAF as well as leukotrienes, there are ample biological justification and experimental data to support the use of a mixture of two agents (21), or preferably a single compound, which can inhibit the synthesis or function of PAF and leukotrienes. The search for such dual-function inhibitors of two inflammatory mediators is reminiscent of the recent study of dual inhibitors of both cyclooxygenase and 5-lipoxygenase as new antiarthritic agents.

We have previously shown that it is feasible to achieve both PAF antagonism and 5-lipoxygenase inhibition with one chemical structure. The tetrahydrothiophene analog L-653,150 (Fig. 2) was an early example (1). Recently, we have found that the 1,3-dithiolane analog of L-653,150 possesses even greater potency in blocking PAF-induced

aggregation of human platelets and the biosynthesis of LTB_4 by calcium ionophore-stimulated human monocytes at micromolar concentrations (22). In addition, three other constituents of the Chinese herbal plant *piper futokadsura*, futoxide, futoenone and futoquinol (Fig. 2) have recently been found to be effective PAF antagonists. The latter two are also useful as intermediates in the synthesis of dual PAF and 5-lipoxygenase inhibitors (23).

In summary, some progress has been made in the synthesis of lignan analogs as potent PAF antagonists, photoactivatable receptor probe, and dual functional inhibitors. Encouraged by the recent structure elucidation of a PAF receptor protein (20), further chemical and biological studies may facilitate the discovery of second generation PAF antagonists with greater potency, dual actions and possibly tissue selectivity.

REVIEW

Thieno-triazolo-1,4-diazepines as Antagonists of Platelet-Activating Factor: Present Status[1]

Jorge Casals-Stenzel*
Boehringer Ingelheim KG, 6507 Ingelheim am Rhein, Germany

The platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine, (PAF) antagonistic activity of thienotriazolodiazepines has recently been described. The lead compound in this series was brotizolam, which also exhibits sedative and hypnotic effects. By combination of brotizolam with the benzodiazepine receptor antagonist RO 15-1788, PAF antagonistic and central nervous system (CNS) activities could be segregated. Systematic structure variation has led to potent and selective PAF antagonists without CNS effects. WEB 2086 and its analogues WEB 2170 and STY 2108 are representative examples of this structural type and have shown a high potency and selectivity in PAF-induced and PAF-dependent *in vitro* tests and in experimental models. Studies in healthy volunteers have demonstrated potent pharmacological activity and good safety and tolerance of oral, intravenous or inhaled WEB 2086 in man. These agents should therefore prove useful for the further elucidation of the pathophysiological role of PAF and provide an opportunity for therapeutic applications in diseases in which the involvement of PAF has been implicated.
Lipids 26, 1157–1161 (1991).

Platelet-activating factor (PAF, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) was first described by Benveniste *et al.* in 1972 (1). In the following decade, a variety of physiological and pharmacological responses *in vitro* and *in vivo* have been attributed to PAF (2,3). However, the pathophysiological role of PAF remained poorly understood. Thus, a search for specific PAF antagonists became essential for the further elucidation of the functional significance of PAF.

Basically three types of compounds of different origin and structure have been shown to act as PAF antagonists: (i) PAF analogues (*e.g.* CV-3988); (ii) natural products (*e.g.* kadsurenone, and BN 52 021); and (iii) other synthetic compounds with a chemical structure different from that of PAF (*e.g.* the thieno-triazolo-1,4-diazepines, such as brotizolam and WEB 2086) (4).

The thieno-triazolo-1,4-diazepines were already known as powerful sedative and hypnotic agents for some 15 years (5). In 1983, the PAF antagonistic activity of this type of substances, benzo- as well as thieno-triazolo-1,4-diazepines, was first observed in the laboratories of Boehringer Ingelheim (Ingelheim, Germany). Using the PAF-induced human platelet aggregation assay and by screening about 200 carefully selected compounds with different structures and pharmacological properties, it was possible to select certain substances, such as calcium antagonists and benzodiazepines, which showed PAF antagonism (6–8). Among the benzodiazepines, the most powerful compounds were those containing an annelated triazolo ring (9). Triazolam and alprazolam, two *benzo*-triazolo-1,4-diazepines, and particularly brotizolam, a *thieno*-triazolo-1,4-diazepine, which was synthetized by Weber *et al.* (10) at Boehringer Ingelheim some years earlier, showed pronounced and specific PAF antagonistic activities in these first *in vitro* tests (9). These observations were the key to the development of the thieno-triazolo-1,4-diazepines as PAF antagonists. At approximately the same time, Kornecki *et al.* (11) described the triazolobenzodiazepines which also acted as antagonists to PAF.

A major problem with the diazepine derivatives with specific PAF antagonistic activity *in vitro* was their potent sedative and hypnotic activity. In the first experiments that were carried out to demonstrate anti-PAF activity *in vivo*, the animals died due to apnoea induced by the relatively high triazolam or brotizolam doses needed in addition to urethane anaesthesia (9). The question arose whether the effect on the central nervous system (CNS) and the PAF antagonistic activity of these compounds would be associated with the same structural features of the compounds. Clarification of this question was the first step toward the development and the successful application of the thieno-triazolo-1,4-diazepines as PAF antagonists.

DISSOCIATION OF CNS AND ANTI-PAF ACTIVITY

Central and peripheral type benzodiazepine (BDZ) receptors, as well as PAF binding sites in human and animal tissues, were already known before the anti-PAF activity of BDZ was described (12–14). The possibility that the PAF antagonistic effects of the *thieno*- and *benzo*-triazolo-1,4-diazepines would be mediated by a central or peripheral type BDZ receptor was examined using the specific BDZ receptor ligands RO 15-1788 (central antagonist) and RO 5-4864 (peripheral ligand) in combination with brotizolam and triazolam. It was expected that the BDZ antagonist would counteract the typical BDZ and CNS activities of these drugs.

In vitro, RO 15-1788 inhibited the platelet aggregatory activity of PAF at relatively high concentrations. When RO 15-1788 at a concentration of 10–1000 μM was combined with brotizolam (1 μM) or triazolam (20 μM), the PAF antagonistic activity of either compound was not only not inhibited, but was in fact increased (15). These findings were confirmed by *in vivo* experiments in guinea pigs. The PAF antagonistic activity of brotizolam (10 mg/kg p.o.) and triazolam (200 mg/kg p.o.) was not affected but actually (numerically) enhanced when either compound was used in combination with RO 15-1788 (20–100

or 400 mg/kg p.o., respectively) in a ratio of 1:2 or 1:10 (agonist/antagonist). By comparison, the BDZ antagonist, RO 15-1788, clearly blocked the motor depressant and hypnotic effect of these triazolodiazepines in guinea pigs. RO 15-1788 itself, given at high doses (100 mg/kg p.o. or 10 mg/kg i.v.), did not prevent the lethal effect of PAF.

The relationship between the peripheral-type BDZ receptors, RO 5-4864, and the activity of PAF on platelets was also studied *in vitro*. RO 5-4864 had virtually no effect on PAF-induced human platelet aggregation and did not inhibit the PAF antagonistic activity of brotizolam (15). Consequently, these studies showed that the PAF antagonistic activity of triazolo-diazepines in general, and thieno-triazolo-1,4-diazepines in particular, is independent of their activity on the central or peripheral BDZ binding sites. This clear segregation of PAF-antagonistic activity and CNS activity allowed the development of new thieno-triazolo-1,4-diazepine derivatives with potent PAF antagonistic properties.

SYNTHESIS OF NEW COMPOUNDS: WEB 2086

Brotizolam (1) (inhibitory concentration 50% (IC_{50}) 0.54 μM) and its alkyl analog etizolam (2) (IC_{50} 0.5 μM) (16) served as lead compounds for the search and synthesis of PAF antagonists without CNS effects (Fig. 1). After systematic structural variations, a series of new compounds were found which proved to be highly potent PAF antagonists (Table 1).

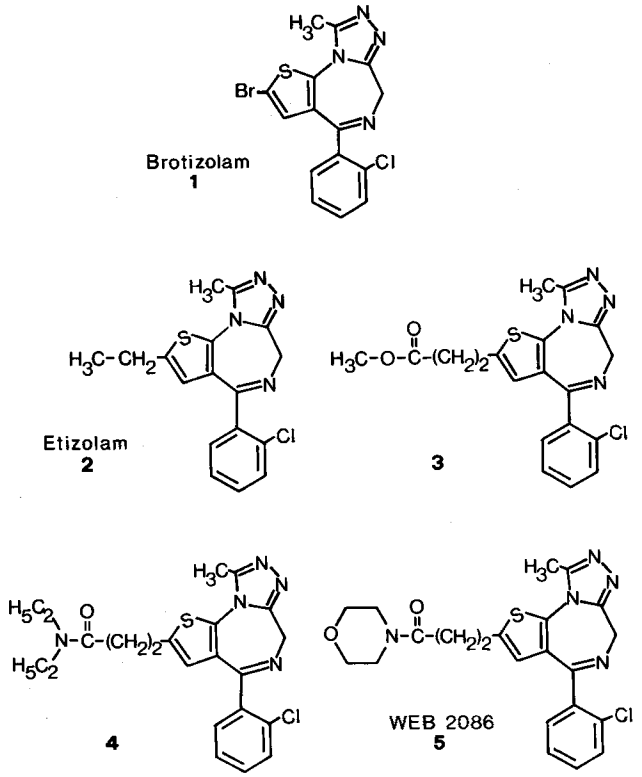

FIG. 1. Brotizolam (1) and etizolam (2) served as lead compounds for the synthesis of WEB 2086 (5). Compounds 3 and 4 are conceptual steps between 1 and 5.

[a]Inhibition of PAF (5×10^{-8}M)-induced human platelet aggregation.

The replacement of the ethyl side chain at position-2 of etizolam (2) by an alkoxycarbonyl or ester function led to compound (3) which had encouraging anti-PAF activity *in vitro* (IC_{50} 0.21 μM). Unfortunately, compound (3) was completely ineffective *in vivo*. This was explained by hydrolitic cleavage of the ester side chain *in vivo*. A corresponding analog with a free propionic acid side chain at position-2 was inactive in the *in vitro* test.

The ester function was replaced by a carboxamide alkyl function which resulted in the water soluble derivative (4) (IC_{50} 0.72 μM). Because of its high selectivity and potency *in vitro* and *in vivo*, it became the first candidate for further pharmacological characterization. The side chain at position-2 not only increased water solubility of the compound but was also responsible for its lack of CNS side effects. Several potent amides were synthesized and characterized pharmacologically (17). Among them, WEB 2086 (5) became the final candidate for drug development (18). The introduction of this compound in PAF research set new standards in this field (19), and stimulated broad interest in the synthesis of closely related structures.

At Boehringer Ingelheim, a second series of very active compounds was obtained by ring closure (6) between the side chain at position-2 and the thiophene ring. The resulting new tetracyclic compounds (Sty 2108 (7), WEB 2170 (8) and WEB 2347 (9)) show lower BDZ receptor affinity than the tricyclic thieno-triazolo-1,4-diazepines (Fig. 2) (20,21). These tetracyclic compounds possess a chiral center in the new ring and were prepared in racemic form. In WEB 2170, the chiral carboxamide side chain has a high degree of stereospecificity: the S (−) optical enantiomer (K_i 14 nM) proved much more active than the R (+) isomer (K_i 660 nM) (22).

Other substituents at position-2 have recently been introduced. An aralkyl moiety (isobutyl-phenyl-ethyl, Y-24180) (10) also improved PAF activity and reduced CNS effects (23). In addition, side chains consisting of aryl or bi- and tricyclic heterocyclic moieties bound to the

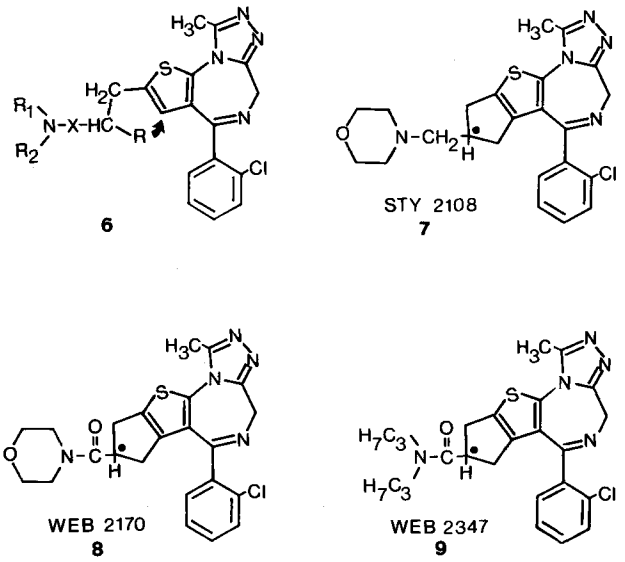

FIG. 2. Tetracyclic thieno-triazolo-1,4-diazepines: Structure 6 represents schematically the ring closure between the side chain and the thiophene ring. Compounds 7 to 9 are new tetracyclic PAF antagonists.

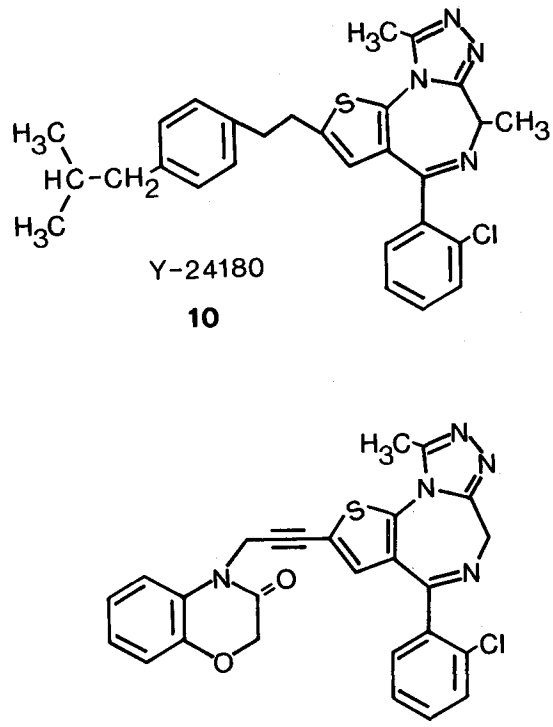

FIG. 3. Other thieno-triazolo-1,4-diazepines with different substituents at position-2.

2-position of the thiophene ring by a propynyl bridge (11) led to powerful PAF-antagonists (24) (Fig. 3).

Other compounds of this family are likely to emerge in the future.

STRUCTURE ACTIVITY RELATIONSHIP

Some important and basic findings in regard to the structure-activity relationship of thieno-triazolo-1,4-diazepines as PAF antagonists are summarized in Figure 4. The abbreviated scheme describes a simplified situation, but it focuses on the possibility of producing potent PAF antagonists without CNS effects.

It is apparent that changes at the 1,4-diazepine and chlorophenyl moiety are very poorly tolerated in respect to the PAF antagonistic effect. For example the substitution of the chlorine in triazolam (IC_{50} 7.6 μM) by a hydrogen (alprazolam, IC_{50} 13.7 μM) reduces anti-PAF activity (9). By contrast, the introduction of a methyl group in position-6 at the diazepine ring can increase anti-PAF potency. But in general, major changes in these structures will reduce or completely abolish the activity.

The 1,2,4-triazolo or an imidazole ring is essential for anti-PAF activity, *i.e.* for affinity to the PAF-receptor. Diazepines without such rings have little or no effect against PAF (8,9,21). Moreover, the substituent at 9-position (R_1 in Fig. 4) drastically influences the affinity to the PAF receptor, and in consequence the PAF antagonistic activity depends on the bulkiness of the substituent (25). Small substituents such as methyl, bromo, ethyl and cyclo-propyl groups appear optimal; the hydrogen analogues possess a lower affinity in comparison to the methyl-substituted compounds (19,21).

The thiophene ring itself is not essential for anti-PAF activity, but it improves it. This feature is well illustrated by comparing triazolam with brotizolam. Compounds with a benzene ring at this position are up to 20 times less active than the thieno derivatives (9).

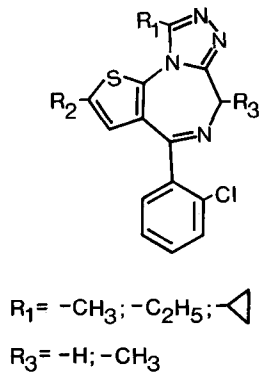

FIG. 4. Structure/activity relationship of thieno-triazolo-1,4-diazepines as PAF antagonists: R_1 is essential for affinity to the PAF receptor but not to the BDZ receptor. Optimal substituents are shown above. R_2 is important for dissociation of CNS and anti-PAF activity, for the increase of anti-PAF potency and water solubility. Changes at R_3 generally cause loss of activity. Optimal substituents are shown in the figure.

The substituent at position-2 of the thiophene ring (R_2 in Fig. 4) is essential for several reasons. It is responsible for the dissociation of PAF antagonistic from CNS activity which is achieved by a complete lack of, or by a low affinity to, the central type BDZ receptor (17,26), causing a corresponding decrease or abolition of the CNS side effects. Furthermore, the water solubility of the thieno-triazolo-1,4-diazepine molecule can be improved, and its lipophilicity can be reduced resulting in low partition coefficients (log D for brotizolam 2.44, WEB 2086 0.8 and

WEB 2170 1.0). Reduced lipophilicity is important to minimize penetration of this type of compounds through the blood-brain barrier. The search for the optimal and most potent substituent at position-2 of the thiophene ring continues. It was evident from the beginning that in principle various types of substitution at the 2-position of the thiophene ring would result in potent PAF antagonists with more or less dissociated CNS effects (17,26). Although there are numerous possibilities for the synthesis of PAF antagonists with a thieno-triazolo-1,4-diazepine structure, one would not expect that upcoming new compounds will add superior insights to the basic findings described (17,21).

SELECTIVITY FOR THE PAF RECEPTOR

Thieno-triazolo-1,4-diazepines generally show a high affinity for the central type BDZ receptor. By introduction of bulky substituents in position-2 of the thiophene ring, it is possible to separate PAF-receptor binding from BDZ-receptor binding in ratios up to 1:5000, *e.g.* in the tetracyclic compound WEB 2347 (20). In general the tetracyclic compounds have lower BDZ receptor affinity than the tricyclic thieno-triazolo-1,4-diazepines. A simple elongation of the side chain further increases the affinity for this receptor (17,26).

It has been shown that the PAF antagonistic activity of WEB 2086 is specific and competitive (27). In PAF-induced human platelet or neutrophil aggregation experiments *in vitro*, the thieno-triazolo-1,4-diazepines (brotizolam, WEB 2086, etc.) and the benzo derivatives (triazolam, alprazolam) had little or no effect on the cellular responses to other aggregating agents, such as ADP, arachidonic acid, epinephrine, and collagen in the platelet aggregation experiments and Concanavalin A (Con A), *N*-formyl-L-methionyl-L-leucyl-L-phenylalanine (FMLP), and leukotriene B_4 (LTB_4), in the neutrophil aggregation tests.

The competitive character of this antagonism has been shown in platelet aggregation and binding studies. In PAF-induced human platelet aggregation *in vitro*, concentration/response curves of WEB 2086 were shifted to the right in a parallel manner by increasing concentrations of PAF (28,29). In binding studies performed on human and rabbit platelets, specific binding and competitive displacement of WEB 2086 from the PAF receptor was shown. WEB 2086 inhibits [^{3}H]PAF binding at the PAF receptor while [^{3}H]WEB 2086 is displaced by PAF and WEB 2086 (27,28,30).

The specific interaction of WEB 2086 with the PAF receptor has also been shown in other cell types (eosinophils, endothelial cells, lung, etc.) (31–33).

PHARMACOLOGY IN ANIMALS AND MAN

The pharmacological properties of the thieno-triazolo-1,4-diazepines in respect to their PAF antagonism have been described in detail (9,18,34–36). The *in vitro* and *in vivo* pharmacologies of the PAF antagonists known so far, regardless of their source or structure, are very similar, particularly in experiments where exogenous PAF is used as inducer.

Nevertheless, there are three features which distinguish these compounds from other antagonists. First, the potency of this group is generally very high; *in vitro*, the concentrations needed are in the nM range (Table 1). *In vivo* the very low doses reach the μg range per kg body weight (18,19). Secondly, these compounds have a long duration of action with biological half-lives ($t_{1/2}$) of up to 15 hr depending on the route of administration (19). Thirdly, the thieno-triazolo-1,4-diazepines are active orally, intravenously and after inhalation (9,18,19). In guinea pigs, the oral dose-range is about 10 times higher than the intravenous one. The bioavailability of WEB 2086 is very good, independently of the route of administration. Bronchoconstriction induced by intravenous PAF in guinea pigs can be blocked by inhaled WEB 2086 and *vice versa* (18). Oral WEB 2086 antagonizes both intravenously administered and inhaled PAF.

Thieno-triazolo-1,4-diazepines are essentially non-toxic. The lethal dose 50% (LD_{50}) values of WEB 2086 in mice were very high (4600 mg/kg p.o. and 540 mg/kg i.v.) (18). In chronic toxicity studies, WEB 2086 did not cause any problems which would argue against clinical trials with this compound. In man, some double-blind and placebo controlled tolerance studies have been performed with WEB 2086 (37–39). Healthy volunteers received WEB 2086 either orally (1.25–400 mg), intravenously (0.5–50 mg) or by inhalation (0.5 and 1 mg) in several doses. During the following 24 hr, inhibition of PAF-induced platelet aggregation *ex vivo* was recorded as an index of pharmacological action. The PAF-antagonistic activity *ex vivo* was dose-dependent and maximal at doses of 20 mg p.o., 10 mg i.v., and 1 mg inhaled. No side effects, particularly on the central nervous system, were observed, thus confirming the dissociation of anti-PAF and CNS effects in man. Therefore, in man as well, WEB 2086 shows a high potency, good tolerance and is safety independent of the route of administration.

CONCLUSION

The synthesis and production of thieno-triazolo-1,4-diazepines with potent anti-PAF activity, but free from CNS side effects, can now be carried out without difficulty. PAF antagonists of this family, such as the well known WEB 2086 or the newer compounds WEB 2170 and WEB 2374, are very potent, highly specific, long acting, non-toxic and, as known to date, well-tolerated substances in animal and man. Hence, potential drugs with almost ideal features are available. Results from animal experiments suggest that PAF antagonists have a beneficial effect in diseases such as endotoxic shock and anaphylaxis (34,35).

For biochemical and pharmacological purposes there appears to be no need for further compounds of this type. Hence, all efforts should be concentrated on well-conducted clinical studies which can prove the utility of these compounds in man.

ACKNOWLEDGMENT

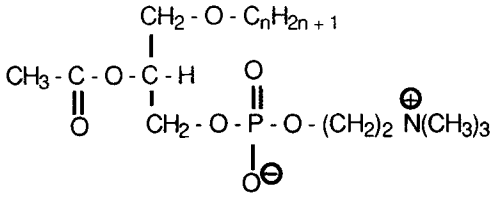
REVIEW

PAF Receptor Structure: A Hypothesis[1]

J.-J. Godfroid[a,*], G. Dive[b], J. Lamotte-Brasseur[b], J.-P. Batt[a] and F. Heymans[a]



[a]Laboratoire de Pharmacochimie Moléculaire, Université Paris 7, Paris, France and [b]Centre d'Ingéniérie des Protéines, Institut de Chimie, Liège-Sart-Tilman, Belgium

Different hypotheses of the structure of platelet-activating factor (PAF) receptor based on structure-activity relationships of agonists and antagonists are reviewed. For an agonistic effect, strong hydrophobic interactions and an ether function are required in position-1 of the glycerol backbone; chain length limitations and steric hindrance demand a small group in position-2. The unusual structural properties of non-PAF-like antagonists required 3-D electrostatic potential calculations. This method applied to seven potent antagonists suggests a strong "Cache-oreilles" (ear-muff) effect, *i.e.*, two strong electronegative wells (isocontour at −10 Kcal/mole) are located at 180° to each other and at a relatively constant distance. Initial consideration of the "Cache-oreilles" effect implied the structure of a bipolarized cylinder of 10–12 Å diameter for the receptor. However, very recent results on studies with agonists and antagonists structurally similar to PAF suggest that the receptor may in fact be a multi-polarized cylinder.
***Lipids 26*, 1162–1166 (1991).**

The diverse structural properties of platelet-activating factor (PAF) antagonists (reviewed in refs. 1–4) and the existence of specific high affinity binding sites for the mediator (reviewed in ref. 5) invite a comparison of the common electronic features of non-PAF-like molecules. In this review we will examine the structural requirements for potent agonistic activity (2,6) and the 3-D electrostatic potential maps of non-PAF-like high potency antagonists selected for their diversity in chemical structure (7). We will also present a simplified model of the PAF receptor.

PAF RECEPTOR AGONISTS

A wide variety of PAF analogs have been synthesized to establish the structural requirements for potent PAF-like activity (reviewed in refs. 2, 3, 6 and 8) and to distinguish antagonist from agonistic activities. The existence of specific binding sites is consistent with the enantiospecificity of platelet stimulation. Synthetic PAF in its natural R configuration (n = 16 and 18) is 1000 times more potent than its S enantiomer (9–12).

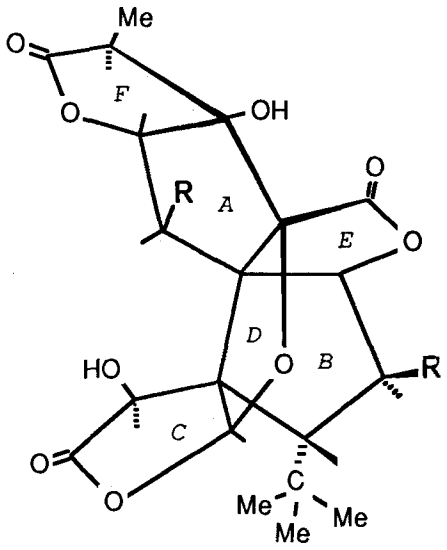
The effects of modifying the PAF structure at the three positions of the glycerol backbone have been investigated. The hydrophobicity of the ether chain in position-1 is one of the key factors that permits interaction of PAF with its receptor (13; reviewed in ref. 6). Godfroid and coworkers (13,14; reviewed in ref. 8) have demonstrated by quantitative structure activity relationship (QSAR) calculations that regression analyses performed with data for 15 PAF analogs are significant with respect to a parabolic correlation between lipophilicity of the chain and platelet stimulation. This result is characteristic of a hydrophobic interaction between the agonist and the PAF receptor. Maximum activity corresponds to the lipophilicity of a C_{16}–C_{18} linear chain. The interaction energy is estimated to be 11–13 Kcal/mole. The ether function in position-1 is an absolute requirement for platelet stimulating potency (13), and changes in the steric effect around the glycerol skeleton decrease or nullify agonistic activity (reviewed in ref. 8).

In position-2, steric hindrance limits chain length to small groups (reviewed in refs. 2, 3, 6 and 8), such as *N*-methylcarbamate, propionate or ethoxy. For example, the butanoyl analog shows only residual aggregating activity amounting to 10% of that of PAF (11; reviewed in ref. 8).

In position-3, replacement of the phosphate group by a phosphonate, carboxylate or ether group decreases or abolishes platelet stimulation (reviewed in ref. 1–4, 6, 8 and 15). Agonistic activity rapidly decreases with the number of methylenes inserted between the phosphate group and the ammonium function, while antagonistic activity appears and becomes maximal with six methylenes inserted (16 and 17; reviewed in ref. 8). The latter features are observed in some (18), but not in all (19), series of PAF analogs. Replacement of trimethylammonium of PAF by triethylammonium, methylpiperidinium, methylpyrrolidinium or other bulky or hydrophobic groups enhances the stimulatory effect on platelets above that of PAF itself (20–22; reviewed in refs. 6 and 8).

3-D ELECTROSTATIC MAPS OF SELECTED PAF ANTAGONISTS: THE "CACHE-OREILLES" EFFECT

Godfroid and Braquet (6) and Braquet and Godfroid (2) initially presented a model of interaction at the binding site which suggested a probable role of the oxygen doublets of the ether group of PAF (agonist) as a site of protonation *vs.* those present in antagonists, such as kadsurenone, gingkolides and neolignan derivatives, which



[1]Based on a paper presented at the Third International Conference on Platelet-Activating Factor and Structurally Related Alkyl Ether Lipids, Tokyo, Japan, May 1989.

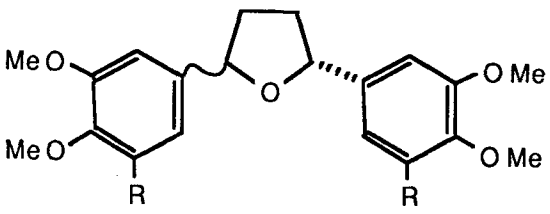
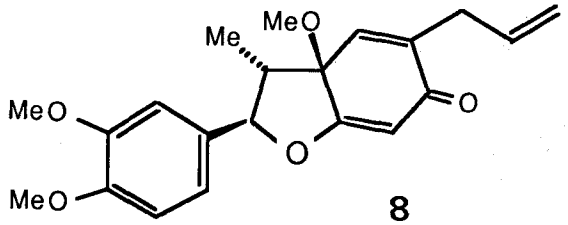
Abbreviations: 3-D, three-dimensional (electrostatic potential map); PAF, platelet-activating factor; QSAR, quantitative structure activity relationship.



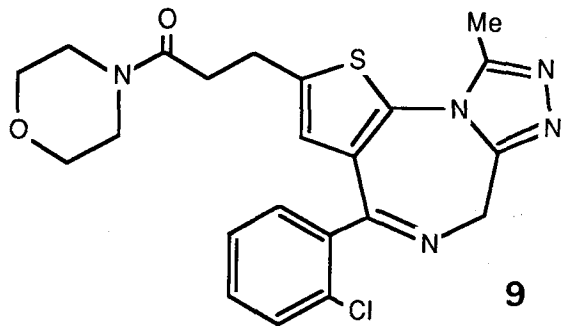
possess a tetrahydrofuran ring. These oxygens were postulated to function as key anchor points for the interaction with the receptor. The structural diversity of synthetic and natural PAF antagonists, including examples without oxygenated rings, which have since appeared in the literature (reviewed in refs. 3 and 4), required a new approach to account for more subtle structural similarities.

The 3-D electrostatic potential map is the best "fingerprint" of a molecule, and takes into account volume, conformation and electronic properties. In a recent paper (7), the 3-D electrostatic potential maps of non-PAF-like high potency antagonists selected for their diversity in chemical structure and for their structural difference from PAF (absence of fatty chain and charged moieties) were calculated. These are the gingkolides A, B and C (*i.e.*, compounds 1, 2, and 3, which are BN 52020, 52021 and 52022, respectively),



1 : R = R' = H BN 52020
2 : R = OH ; R' = H BN 52021
3 : R = R' = OH BN 52022

the synthetic furanoid neolignan L-652,731 (compound 5),



4 : R = OMe; *trans*
5 : R = OMe; *cis*
6 : R = H; *trans*
7 : R = H; *cis*

the neolignan kadsurenone 8,

and the triazolothienobenzodiazepin WEB 2086 (compound 9).

The magnitude of the contour level significantly determines the shape of the electrostatic potential cloud. Three-dimensional maps were contoured at −10 Kcal/mole, as the electrostatic clouds were defined best at this level. The negative isocontours revealed the existence of the so-called "Cache-oreilles" ("ear-muffs"), which comprise two electronegative wells located at 180° to each other.

In the gingkolides, the lactone rings are the functional groups generating the negative wells. For instance, in BN 52021 (compound 3), two distinct areas appear on the left (Fig. 1) and a third well is generated on the right by the

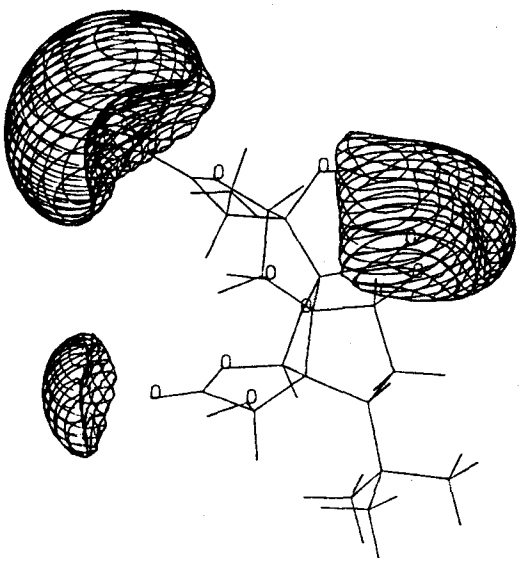


FIG. 1. 3-D electrostatic map (isocontours drawn at −10 Kcal/mole) calculated for BN 52021 (2). For details, see ref. 7.

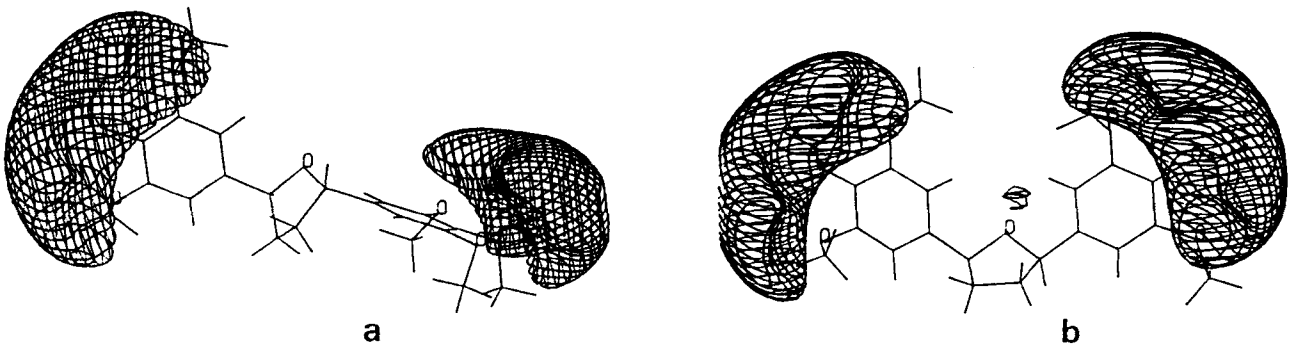

FIG. 2. 3-D electrostatic maps calculated for the 2,5-diaryltetrahydrofurans; a) *trans*-2,5-*bis*-(3,4,5-trimethoxyphenyl)tetrahydrofuran 4, L-652,731; b) the *cis*-isomer of 4 (5).

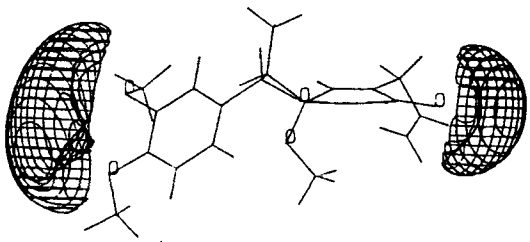

FIG. 3. 3-D electrostatic map calculated for kadsurenone 8.

other lactone group. The *tert*-butyl group may function as the hydrophobic binding site. For the three gingkolides 1, 2 and 3, no significant negative potential is generated around the oxygen of the innermost tetrahydrofuran ring, a feature which is inconsistent with the earlier hypothesis.

The latter observation was also made for *trans*-2,5-*bis*-(3′,4′,5′-trimethoxyphenyl)tetrahydrofuran 4, for which the "cache-oreilles" are generated by the trimethoxy groups. This compound does not bear a hydrophobic moiety (Fig. 2). When the distance between the atoms generating the negative clouds was shortened in *cis*-isomer 5, a negative capsule occurs around the oxygen of the tetrahydrofuran ring. The binding of this isomer to rabbit platelets was 1000 times less pronounced than that of the *trans* isomer 4. The negative capsule was also observed with *cis*- and *trans*-2,5-*bis*-(3′,4′-dimethoxyphenyl)tetrahydrofuran (6,7), and both were less potent than L 652,731 (4).

In extended conformations, the more the substituents become negatively charged, the less significant is the electronic contribution of the bearing skeleton. Dispersion of negative charges decreases biological activity, which is inconsistent with the earlier hypothesis which emphasized the likely importance of oxygen doublets.

Kadsurenone also represents a "cache-oreilles" system that is generated by the dimethoxy substituents and by the carbonyl oxygen of the quinone ring (Fig. 3). Once again, no weak negative cloud was observed around the tetrahydrofuran oxygen. The alkyl group may be a moderately hydrophobic tail.

In WEB 2086, the negative wells are generated by the triazolo ring and the carbonyl oxygen of the amide group bearing the morpholino ring. The orthochlorophenyl group may serve as hydrophobic binding site (Fig. 4).

Suggested requirements for potent agonistic activity include a site at position-1 for strong hydrophobic interaction with the receptor and conformational restrictions imposed by the acetyl group in position-2 of the glycerol backbone. In a recent publication (23), after examining the electronic and conformational properties of 14 PAF analogs (agonists and antagonists), we concluded that the folded conformation of the substituent in position-2 induces agonistic activity. In contrast, an extended conformation in position-2 induces antagonistic activity. 3-D electrostatic potential maps of the PAF analogs show a strong electronegative effect generated by the phosphate and acetate groups. The positive contour mainly is located close to the zwitterionic system and N-substitution enhances the volume of the positive cloud. Consequently, we re-examined the activity of several PAF analogs. For example, the 2-butanoyl PAF derivative is described in the literature as only a very weak agonist. We therefore concluded that this derivative exists in an extended conformation. We found that the 2-butanoyl PAF analog inhibited rabbit platelet aggregation at 10^{-7} M (23).

The results in regard to the selected non-PAF-like antagonists suggest a major electronic effect which induces interaction with subcomponents of the PAF receptor. The distances between atoms generating the "cache-oreilles", and the maximum distances between the envelopes of both isocontours (22–27 Å) are remarkably constant, with the gingkolides showing the shortest distances. Except for the synthetic neolignan L 652,731 (4), all antagonists have a moderately hydrophobic tail.

CONCLUSION

A first step towards constructing a mirror image of the PAF receptor of platelets is to compare common electronic features of molecules belonging to the heterogeneous series. Dive *et al.* (7) concluded that as a first approximation the features resemble interaction with a polarized cylinder of 10–12 Å diameter (Fig. 4).

Except for the tetrahydrofuran derivatives, well-defined hydrophobic sites may interact with a third site located inside the receptor. The hydrophobic tail may better position the electronegative clouds and does not make a

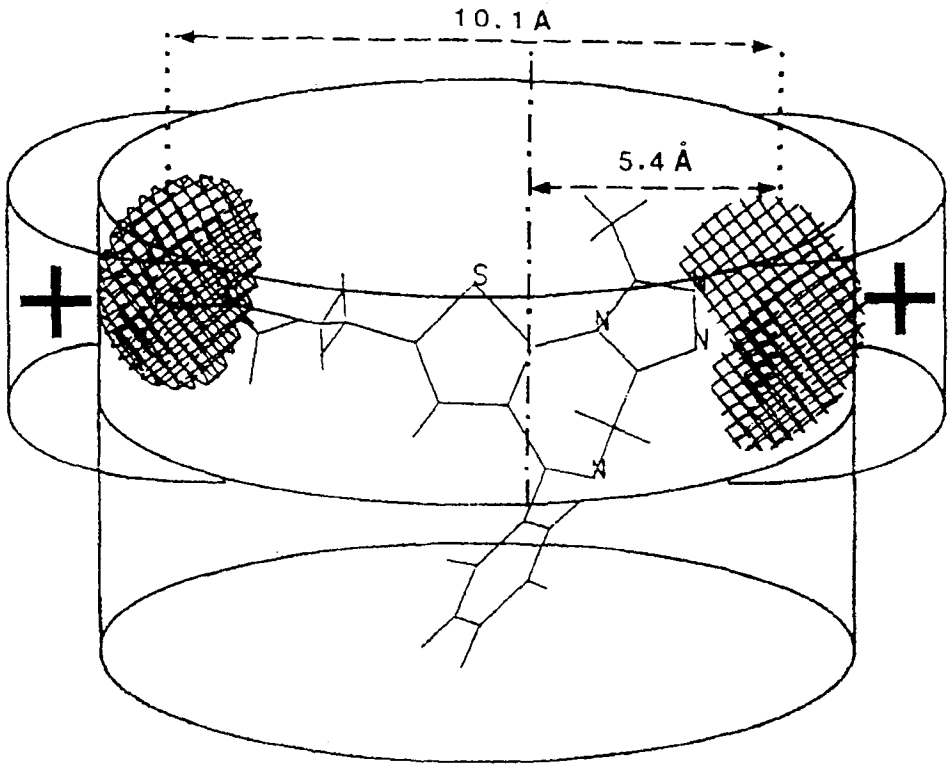

FIG. 4. 3-D electrostatic map calculated for WEB 2086 included in the simplified model of the "polarized cylinder" (see text); (+) represents the positive counterpart at this site of the receptor. Note the hydrophobic pocket inside the receptor. For details, see ref. 7.

"cache-oreilles" effect mandatory, as is observed with the tetrahydrofuran compounds.

The significant information that is provided by the negative electrostatic potential isocontours raises questions about molecules bearing only one strong electronegative cloud together with a weak negative well and a moderately hydrophobic tail. An extensive theoretical study of PAF and its analogs has been published (23) which updates the simple original model. The "cylinder," it appears, is probably multipolar, alternatively electronegative and electropositive, with at least two hydrophobic zones (24).

Nine simple and structurally flexible PAF antagonists were synthesized and their inhibitory effects on PAF induced platelet aggregation were measured. Compounds with PAF antagonistic activity exhibited a negative electrostatic potential generated by two trimethoxyphenyl groups (isocontour at −10 Kcal/mole) at various distances between the negative clouds. The optimal distance between the atoms generating the "cache-oreilles" system for exhibiting potent PAF antagonistic activity is estimated to be 11–13 Å. In the flexible molecules studied, the dispersion of the electronic distribution is not necessarily favorable for anti-PAF activity. The data support the simple bipolarized model for the PAF receptor that has been proposed by the authors.
***Lipids 26*, 1167–1171 (1991).**

In our attempt to test the "Cache-oreilles" model for the platelet-activating factor (PAF) receptor (1) based on 3-D electrostatic potential maps of several PAF antagonists, a series of simple compounds of the general formula 1 were synthesized. The two 3,4,5-trimethoxyphenyl groups that generate the negative wells were linked by a flexible straight or branched chain Z.

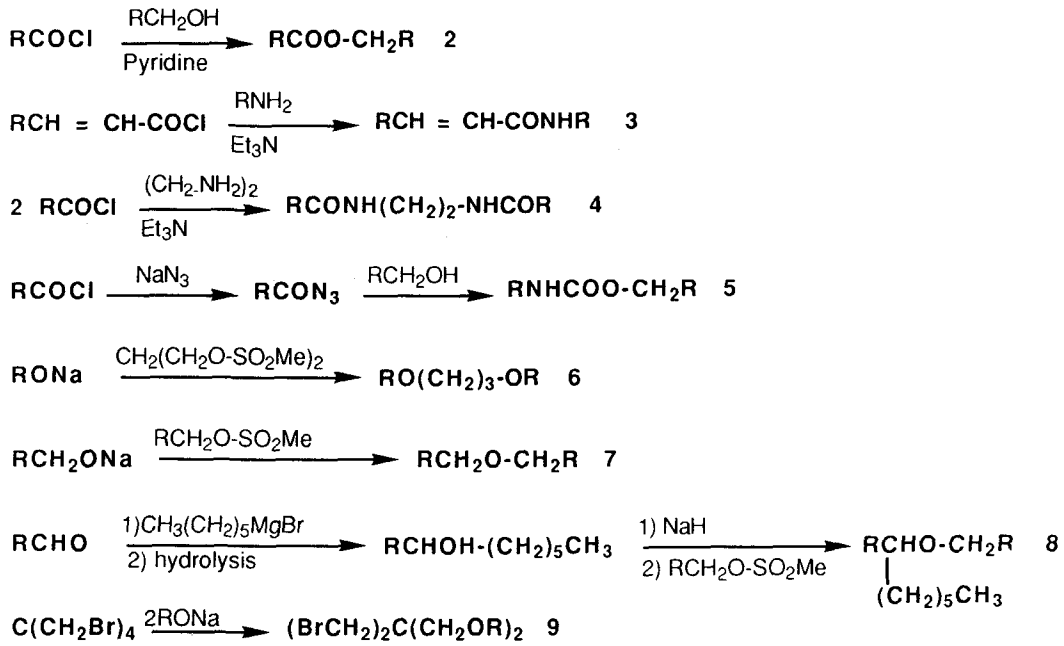
1

We have previously suggested (1) that the structure of the PAF receptor appears to be cylindrical, having a diameter of 10–12 Å (for a review, see ref. 2). In the present study, two factors in molecular design have been taken into consideration—the distance between the atoms generating the "Cache-oreilles" system, and the general location of these negative clouds within the molecular skeleton of 1. These two characteristics seem critical when we want to test whether our simple model of the PAF receptor is correct.

In the present study we have attempted: (i) to estimate the ideal distance (d) between the atoms that generate the negative wells that is required to attain maximum antagonistic activity; and (ii) to assess the effect of the dispersion of the negative electrostatic potential (isocontour at −10 Kcal/mole) on antagonistic activity. The studies were carried out on flexible molecules with moderate antagonistic activity as a first step towards studies on more rigid and complex structures.

MATERIALS AND METHODS

Chemical synthesis. All compounds of the general formula 1 were prepared in one or two synthetic steps following standard methods. The syntheses are outlined in Scheme 1 (R = 3,4,5-trimethoxyphenyl).



The 3′,4′,5′-trimethoxybenzyl 3,4,5-trimethoxybenzoate 2 was obtained by reaction of 3,4,5-trimethoxybenzylalcohol with an adequate amount of the acyl chloride. Treatment of 3,4,5-trimethoxyaniline with the corresponding cinnamoyl chloride led to *N*-(3′,4′,5′-trimethoxyphenyl) 3,4,5-trimethoxycinnamamide 3. *N,N′*-Di-3,4,5-trimethoxybenzoylethylenediamine 4 was prepared starting from ethylenediamine and the corresponding acyl chloride. The action of 3,4,5-trimethoxybenzoyl azide prepared following the method of Munch-Peterson (3) on 3,4,5-trimethoxybenzyl alcohol in boiling benzene afforded the *N*-(3′,4′,5′-trimethoxyphenyl)carbamoyloxymethyl 3,4,5-trimethoxybenzene 5. Ethers were synthesized by reacting sodium alcoholates with methanesulfonates. The reaction between sodium 3,4,5-trimethoxyphenoxide and 1,3-dimethylsulfonyloxypropane yielded the 1,3-di-3′,4′,5′-trimethoxyphenoxypropane 6, while sodium 3,4,5-trimethoxybenzyloxide with 3,4,5-trimethoxybenzyl methanesulfonate formed the di-(3,4,5-trimethoxybenzyl) ether 7. When 3,4,5-trimethoxybenzyl methanesulfonate was reacted with the sodium salt of 1-(3′,4′,5′-trimethoxyphenyl)hexan-1-ol prepared by Grignard reaction, it yielded the 1-(3,4,5-trimethoxyphenyl) 1-(3′,4′,5′-trimethoxybenzyloxy) hexane 8. Pentaerythrityl tetrabromide was used to prepare the 1,3-di-(3′,4′,5′-trimethoxyphenoxy) 2,2-dibromomethyl propane 9 by reaction with sodium 3,4,5-trimethoxyphenoxide and to obtain the 1,3-di-(3′,4′,5′-trimethoxyphenoxy) 2-*o*-chlorophenoxymethyl-2-bromomethyl propane 10 by successive reaction with sodium *o*-chlorophenoxide and sodium 3,4,5-trimethoxyphenoxide.

Materials. Solvents were all reagent grade. The purity of each product was checked by thin-layer chromatography (TLC) on silica gel plates (Merck, Darmstadt, Germany; Kieselgel 60 F_{254}, thickness 0.2 mm). Column chromatography was carried out on silica gel (Merck, particle size 0.063–0.200 mm) without any special treatment. Melting points were determined on a digital melting point apparatus (Electrothermal) using capillary tubes. The structures of all compounds were confirmed by infrared (IR) (SP_3-200, Pye-Unicam Ltd., Cambridge, England) and ^1H nuclear magnetic resonance (NMR) spectroscopy

SCHEME 1

(WP 80 Bruker, Wissembourg, France) in $CDCl_3$ with hexamethyldisiloxane (HMDS) as internal standard. Elemental analyses were consistent with the proposed structures.

3',4',5'-Trimethoxybenzyl 3,4,5-trimethoxybenzoate (2). A solution of 2.3 g (10 mmoles) of 3,4,5-trimethoxybenzoyl chloride in benzene (20 mL) was added dropwise to a stirred solution of 1.98 g (10 mmoles) of 3,4,5-trimethoxybenzyl alcohol in dry benzene (20 mL) and pyridine (5 mL) at room temperature. The mixture was stirred for 1 hr and then evaporated *in vacuo*, leading to a residue which was diluted with H_2O and extracted with $CHCl_3$. The organic layer was washed twice with H_2O and dried ($MgSO_4$); the solvent was evaporated. The crude compound 2 was then chromatographed on a silica gel column using diethyl ether/petroleum hydrocarbon (50:50, v/v) as eluent to give 1.6 g (40%) of pure 2 as white crystals; mp 113°C. IR (film in nujol): 1705 (C=O), 1590 (aromatic C=C), 1130 (C-O) cm^{-1}. ^1H NMR δ: 7.42 (*s*, 2H, benzyl aromatic H), 6.77 (*s*, 2H, benzoyl aromatic H), 5.35 (*s*, 2H, CH_2), 3.92 (*s*, 18H, CH_3O).

N-(3',4',5'-Trimethoxyphenyl) 3,4,5-trimethoxycinnamamide (3). A solution of 2.6 g (10 mmoles) of 3,4,5-trimethoxycinnamoyl chloride in 10 mL of benzene was added dropwise to a stirred solution of 1.83 g (10 mmoles) of 3,4,5-trimethoxyaniline in dry benzene (20 mL) and triethylamine (5 mL) at room temperature. After stirring for one more hour, the solvent was evaporated, and the residue, after extraction as described for 2 above, was chromatographed on a silica gel column using $CHCl_3$/MeOH (99:1, v/v) as eluent. Compound 3 was recovered (3.1 g, 77%) as yellow crystals; mp 162°C. IR (film in nujol): 3270 (N-H), 1650 (C=O), 1600 (C=C) and 1580 (aromatic C=C) cm^{-1}. ^1H NMR δ: 8.40 (*s*, 1H, NH), 7.67 (*d*, J = 15 Hz, 1H, Ar-CH=), 7.02 (*s*, 2H, anilide aromatic H), 6.72 (*s*, 2H, aromatic H), 6.61 (*d*, J = 15 Hz, 1H, =CH-CO), 3.80 (*s*, 18H, CH_3O).

N,N'-Di-3,4,5-trimethoxybenzoylethylenediamine (4). A solution of 7.65 g (33.2 mmoles) of 3,4,5-trimethoxybenzoyl chloride in benzene (20 mL) was added dropwise to a stirred solution of 1 g (16.6 mmoles) of ethylenediamine in benzene (20 mL) and triethylamine (5 mL) at room temperature. After stirring for one more hour, the white precipitate was filtered and washed with H_2O. The precipitate was subsequently washed with a 5% $NaHCO_3$ solution, then with MeOH, and finally dried *in vacuo*. The very insoluble compound 4 (7.4 g, yield 100%) was obtained as white crystals; mp 255°C. IR (film in nujol): 3310 (N-H), 1645 (C=O), 1585 (aromatic C=C) cm^{-1}. ^1H NMR δ: 7.25 (*s*, 2H, NH), 7.05 (*s*, 4H, aromatic H), 3.87 (*s*, 18H, CH_3O), 3.70 (*t*, 4H, CH_2).

N-(3',4',5'-Trimethoxyphenyl)carbamoyloxymethyl 3,4,5-trimethoxybenzene (5). A solution of 23 g (100 mmoles) of 3,4,5-trimethoxybenzoyl chloride in 30 mL of acetone was added dropwise to a stirred solution of 7.8 g (120 mmoles) of NaN_3 in water (50 mL) maintained at 20-25°C. After stirring for 30 min, the white precipitate of 3,4,5-trimethoxybenzoyl azide was filtered, washed with H_2O, and dried *in vacuo* (100% yield) for use in the next step without further purification. 3,4,5-Trimethoxybenzyl alcohol (1 g, 5 mmoles) and the azide (1.15 g, 6 mmoles) were then refluxed in dry benzene (15 mL) for 2 hr. After cooling, the solvent was evaporated, and the residue was chromatographed on a silica gel column using $CHCl_3$/MeOH (99:1, v/v) as eluent to recover 2 g (98%) of 5 as white crystals; mp 108°C. IR (film in nujol): 3300 (N-H), 1730 (C=O), 1600 (aromatic C=C) cm^{-1}. ^1H NMR δ: 6.87 (*s*, 1H, NH), 6.67 (*s*, 2H, anilide aromatic H), 6.60 (*s*, 2H, benzyl aromatic H), 5.10 (*s*, 2H, CH_2), 3.82 (*s*, 18H, CH_3O).

1,3-Di-(3',4',5'-trimethoxyphenoxy)propane (6). One g (25 mmoles) of NaH (60% dispersion in mineral oil) was added carefully in small portions to a stirred solution of 3 g (16.3 mmoles) of 3,4,5-trimethoxyphenol in 30 mL of dry dimethylformamide (DMF). The suspension was heated (50°C, oil bath) for 30 min, cooled, and added dropwise to a solution of freshly prepared 1,3-dimethylsulfonyloxypropane (1.89 g, 8.15 moles). The mixture was stirred overnight at room temperature, and excess NaH was destroyed by adding 5 mL of MeOH dropwise while cooling. After evaporation of DMF, the residue was taken up in water and extracted with $CHCl_3$. The organic layer was washed with water to pH 7, dried ($MgSO_4$), and evaporated. Silica gel column chromatography using diethyl ether/petroleum hydrocarbon (50:50, v/v) as eluent yielded 2.4 g (72%) of **6** as white crystals; mp 107°C. IR (film in nujol): 1590 (aromatic C=C), 1130 (C-O) cm^{-1}. ^1H NMR δ: 6.13 (*s*, 4H, aromatic H), 4.06 (*t*, 4H, CH_2O), 3.75 (*s*, 18H, CH_3O), 2.15 (*quintet*, 2H, CH_2).

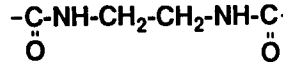
Di-(3,4,5-trimethoxybenzyl) ether (7). 3,4,5-Trimethoxybenzyl methanesulfonate was freshly prepared from 3,4,5-trimethoxybenzyl alcohol and methanesulfonylchloride in dry benzene in the presence of Et_3N in 74% yield. An aliquot of the methanesulfonate (2.9 g, 10.5 mmoles) was added to a stirred suspension of sodium 3,4,5-trimethoxybenzyloxide (1.9 g, 8.7 mmoles) prepared as described above in 50 mL of dry DMF. The mixture was heated (80°C) and stirred for 2 hr, then cooled and excess NaH was destroyed as above. After extraction and purification as described for **6**, compound **7** was recovered (2.5 g, 76%) as white crystals; mp 88°C. IR (film in nujol): 1595 (aromatic C=C), 1130 (C-O) cm^{-1}. ^1H NMR δ: 6.61 (*s*, 4H, aromatic H), 4.50 (*s*, 4H, CH_2), 3.86 (*s*, 18H, CH_3O).

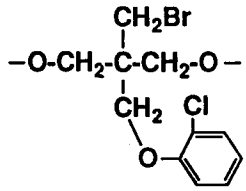
1-(3',4',5'-Trimethoxybenzyloxy) 1-(3,4,5-trimethoxyphenyl) hexane (8). n-Hexyl bromide (24.7 g, 150 mmoles) in 100 mL of diethyl ether was added dropwise to a stirred suspension of Mg turnings in 10 mL of dry diethyl ether (3.6 g, 150 mmoles) at 0°C (ice bath). The mixture was stirred at room temperature for 1 hr. A solution of 19.6 g (100 mmoles) of 3,4,5-trimethoxybenzaldehyde in 70 mL of dry benzene was then added dropwise, while the solution was cooled (0°C) and stirred. After two more hours of stirring at room temperature, the mixture was cooled again (0°C) and hydrolyzed by dropwise addition of 10 mL of acetic acid in 100 mL of water. After stirring for 30 min, the solution was filtered. The organic layer was washed with water until pH 7, dried ($MgSO_4$), and evaporated to give 29 g of crude 1-(3',4',5'-trimethoxyphenyl)hexan-1-ol as a liquid which was characterized spectroscopically and used without purification in the next step. An aliquot (2.8 g, 10 mmoles) of the alcohol was diluted with dry DMF (30 mL), and NaH (0.6 g, 15 mmoles) was added in small portions. After stirring for 1 hr at 60°C, a solution of 3.31 g (12 mmoles) of 3,4,5-trimethoxybenzyl methanesulfonate in 10 mL of DMF was added, the mixture was heated at 80°C and stirred for 2 hr. After cooling, excess NaH was destroyed and compound **8** was obtained as a syrup, following the same extraction and purification procedures as for **6**, in 65% yield. IR (film in nujol): 3000 (aromatic C-H), 2940, 2860 (C-H), 1595 (aromatic C=C), 1130 (C-O) cm^{-1}. ^1H NMR δ: 6.52 (*s*, 4H, aromatic H), 4.55-4.07 (*m*, 3H, CH-O-CH_2), 3.80 (*s*, 18H, CH_3O), 1.65 (*m*, 2H, CH_2-C-O), 1.25 (*s*, 8H, $(CH_2)_4$), 0.81 (*t*, 3H, CH_3).

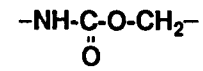
1,3-Di-(3',4',5'-trimethoxyphenoxy) 2,2-di-bromomethyl propane (9). A suspension of sodium 3,4,5-trimethoxyphenoxide prepared as described above from 5.71 g (31 mmoles) of 3,4,5-trimethoxyphenol and 2 g (50 mmoles) of NaH in 100 mL of DMF was added dropwise to a stirred solution of 12 g (31 mmoles) of pentaerythrityl tetrabromide in 60 mL of DMF. The mixture was heated (80°C) and stirred for 2 hr. After the same treatment as described for **6**, column chromatography using first diethyl ether/petroleum hydrocarbon (50:50, v/v), then $CHCl_3$/MeOH (99:1, v/v), eluted successively 2.72 g of monosubstituted derivative and 3.19 g 34.6%) of compound **9** as white crystals; mp 152°C. IR (film in nujol): 1600 (aromatic C=C), 1130 (C-O) cm^{-1}. ^1H NMR δ: 6.11 (*s*, 4H, aromatic H), 4.02 (*s*, 4H, CH_2O), 3.77 (*s*, 18H, CH_3O), 3.72 (*s*, 4H, CH_2Br).

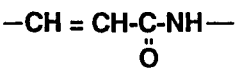
1,3-Di-(3',4',5'-trimethoxyphenoxy) 2-o-chlorophenoxymethyl-2-bromomethyl propane (10). 1-*o*-Chlorophenoxy-3-bromo-2,2-dibromomethyl propane was obtained from pentaerythrityl tetrabromide and sodium *o*-chlorophenoxide following the procedure described above. Its reaction with two equivalents of sodium 3,4,5-trimethoxyphenoxide under conditions as for **9** yielded compound **10** (50%) as white crystals; mp 140°C. IR: 1600 (aromatic C=C), 1130 (C-O) cm^{-1}. ^1H NMR δ: 7.42-6.76 (*m*, 4H, *o*-chlorophenyl H), 6.17 (*s*, 4H, aromatic H), 4.26 (*s*, 5H, CH_2 and *o*-chlorophenyl O-CH), 3.91 (*s*, 1H, *o*-chlorophenyl O-CH), 3.78 (*s*, 18H, CH_3O), 3.75 (*s*, 2H, CH_2Br).

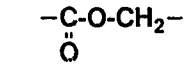
Geometry calculations. Molecular geometrics were obtained by the energy minimization method of the MM2 program (Molecular Mechanics, 1987, Force Field; Quantum Chemistry Program Exchange, Dept. of Chemistry, Indiana University, Bloomington, IN) (4). The quality of the generated conformations was evaluated by the semi-empirical MNDO (modified neglect of differential overlap) method applied to the full optimization of compound **5**.

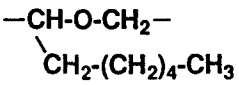


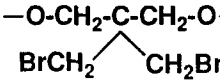












Electrostatic potential calculations. The electrostatic potential was calculated within a complete CNDO (complete neglect of differential orbitals) scheme (5,6), excluding the off-diagonal matrix elements. The nuclear attraction integrals were approximated by substracting the repulsion integrals between S orbitals (7). A regular 3-D grid was calculated around each molecule. The dimensions of the box were defined as the dimensions of the molecules increased by 5 Å in each direction. From these data sets, contouring algorithm (Jorgensen W.I., program PS177, Purdue University, West Lafayette QCPE 340) was applied joining the points at the level of −10 Kcal/mole.

Electrostatic potentials could not be calculated for compounds **9** and **10** as no nuclear attraction integral calculation was available for the bromide atom. The choice of CNDO electrostatic potential calculation at the MNDO geometry was guided by the consistency and the quality of the results derived by this method (8). The electrostatic repulsion between the trimethoxyphenyls, within the same negative environment, generates an extended conformation of the skeleton which was confirmed by the MNDO conformational analysis.

The MM2 minimizations were conducted on a Gould NP1 at the Paris 6 computer center (ccr-p6) and on an Apple MacIntosh using the Chem-3D-Plus program. The

[b]See text for details.

other computer calculations were performed in the Centre d'Ingéniérie des Protéines (Institut de Chimie, Université de Liège) with a FPS164 processor linked to a VAX 11/780. The program PS177 was interfaced with the DI3000 library implemented on a Data General MV7800 (1).

Platelet aggregation assay. Inhibition of platelet aggregation was measured using platelet-rich plasma (PRP) of New Zealand rabbits following the method of Cazenave *et al.* (9). Blood samples were collected from the auricular artery into citrate buffer (3.8%; pH 7.4) and PRP was obtained by centrifugation for 15 min at 1200 rpm. The antagonists were solubilized in DMSO at concentrations from 10^{-2} to 10^{-7} M and added to the incubated and stirred PRP for 1 min before PAF (2.5 nM) challenge. Platelet aggregation induced by PAF in the presence of the antagonist was monitored by continuous recording of light transmission in a dual-channel recorder (Cronolog Coultronics Apparatus) and was compared to a control aggregation induced by PAF alone. The drug concentration required to produce 50% inhibition (IC_{50}) was calculated from dose-response curves.

RESULTS AND DISCUSSION

The compounds we synthesized were tested for their inhibitory effect (IC_{50}) on PAF induced rabbit platelet aggregation and classified from least to most active (Table 1). For several of the compounds we observed that the electrostatic repulsion between the trimethoxyphenyls generates an extended conformation of the skeleton (Fig. 1). In addition, these molecules exhibit large negative electrostatic potential clouds (at −10 Kcal/mole) which are located as a "Cache-oreilles" system (compounds 6–8) at various distances (d) between the respective parathoxy substituents. Conversely, compounds 2, 4 and 5 generate

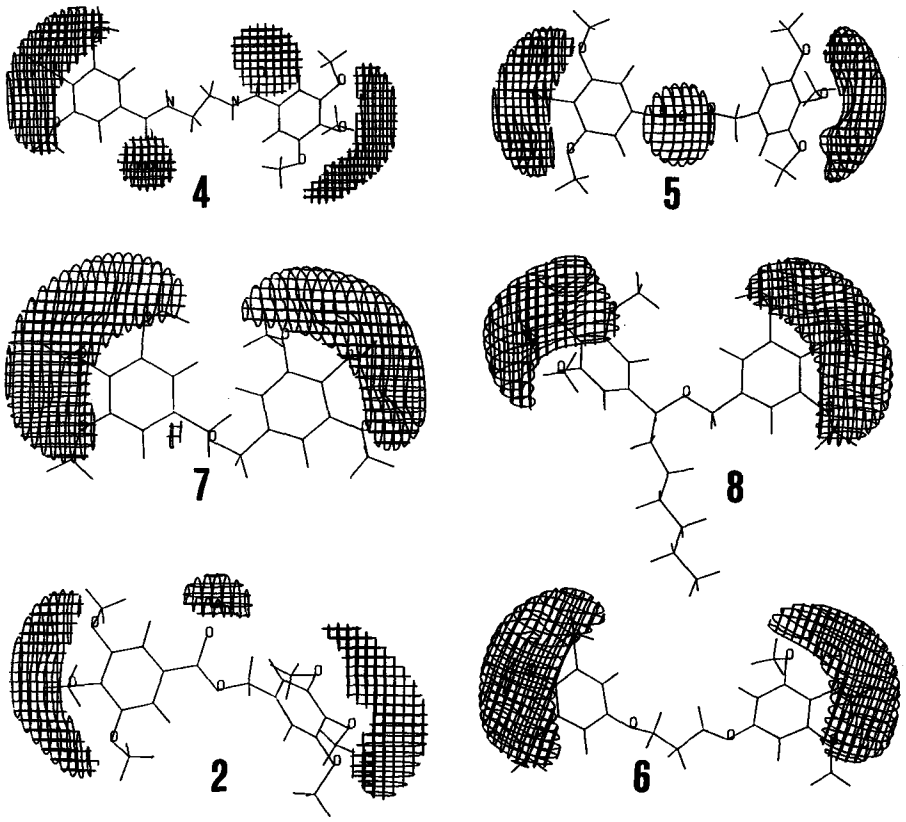

FIG. 1. 3-D electrostatic map calculated for selected compounds.

secondary negative wells around the ester, amide and carbamate groups. Compound **9** exhibits the highest antagonistic activity (d = 13 Å). In comparison with compound **6**, *bis*-bromomethylene substitution enhances the inhibition of PAF induced platelet aggregation; the distance of d = 13 Å is consistent with our PAF receptor hypothesis. Compounds **7** and **8** represent ideal "Cache-oreilles" structures consistent with our model and they also exhibit considerable antagonistic activity; however, the hydrophobic tail in compound **9** does not increase the antagonistic activity of this compound. The activity of the other compounds is weaker. This is probably due to the greater distance (d) in the case of compound **4** (16.5 Å) and dispersion of the electronic distribution in compounds **2**, **4** and **5**.

In conclusion, the flexibility of the molecules selected makes it difficult to assess whether the extended conformation is always the arrangement preferred by the receptor. However, the strong electrostatic repulsion of the trimethoxy groups may be sufficient to assume that the extended conformation is the likely one to interact at the receptor level. Several of these flexible molecules synthesized for the present study exhibit interesting PAF antagonistic activities and their molecular conformation is in accordance with our simple PAF receptor model. In a follow-up study, we have recently synthesized several semi-rigid compounds with a distance (d) of 11–13 Å between the atoms that generate the clouds of negative potential. These compounds exhibit more potent PAF antagonistic activity (10), adding further support to the "Cache-oreilles" hypothesis for the conformation of the PAF receptor. PAF antagonists, such as the ginkgolides, which possess a shorter distance (d, 7–8 Å), (10) can also be accommodated within the hypothesis if the structure of the receptor is considered a multi-polarized cylinder, rather than a bi-polarized structure.

ACKNOWLEDGMENT

From a series of amide analogs of the histamine H_1 antagonist, azatadine, a potent, orally active, dual platelet-activating factor (PAF) and histamine antagonist, Sch 37370, namely 1-acetyl-4-(8-chloro-5,6-dihydro-11*H*-benzo-[5,6]cyclohepta[1,2-b]pyridin-11-ylidine)piperidine, was discovered. Sch 37370 selectively inhibits PAF-induced aggregation of human platelets *in vitro* (IC_{50} = 0.6 μM), and *in vivo* inhibits PAF- and histamine-induced bronchospasm in guinea pigs with ED_{50} values of 6.0 and 2.4 mg/kg p.o., respectively. Sch 37370 is expected to be more efficacious than single mediator antagonists in allergic diseases, such as asthma.

Lipids 26, 1172-1174 (1991).

Allergic diseases such as asthma are thought to be due to immediate hypersensitivity reactions mediated by IgE (1,2). In this scenario, the interaction of antigen with IgE-primed mast cells causes the release of preformed mediators, *e.g.* histamine, and turns on the synthesis of others, *e.g.* leukotrienes, platelet-activating factor (PAF), and thromboxane A_2. These mediators elicit the physiological effects that characterize the disease. These include smooth muscle contraction, influx of inflammatory cells and edema (3). The importance of the contribution that any one of these mediators makes to clinical asthma is largely unknown. H_1 histamine antagonists have not been very effective in treating asthma (4), although one of the very potent compounds, ketotifen, is reported to have antiallergic activity in man (5). The newer non-sedating antihistamines such as terfenadine and cetirizine are also being tested clinically in asthma (6). Selective antagonists of other mediators, leukotriene D_4, PAF and thromboxane A_2, have been developed (7-9) and are also currently being evaluated in clinical trials in asthma.

The approach in our laboratories has been to search for compounds that inhibit more than one of these mediators (10), with the expectation that they would be clinically more effective than single mediator antagonists. Here we report the discovery of the first dual antagonist of PAF and histamine, Sch 37370.

The physiological effects of histamine (11,12) and PAF (13) are mainly smooth muscle contraction (bronchospasm) and edema formation. However, for histamine, these are of rapid onset and short duration, whereas, for PAF, they are of slow onset and long duration. Therefore, inhibition of both mediators should be complementary. Furthermore, histamine causes the release of PAF from cultured endothelial cells (14) and the H_1 antihistamines, ketotifen and terfenadine, largely block the cutaneous response to PAF in man (15,16). Lastly, we have a great deal of experience testing histamine antagonists clinically. With a dual PAF/histamine antagonist we can define the safety profile and bioavailability using antihistamine activity, and then investigate the therapeutic consequences of additional PAF blockade.

MATERIALS AND METHODS

Sch 37370 and the analogs reported here were synthesized as described (17). Other compounds that were used in this work were obtained as follows: PAF (Calbiochem; Los Angeles, CA); azatadine, loratadine, L-652,731, CV-3988 (Schering-Plough Research, Bloomfield, NJ); WEB 2086 (Boehringer Ingelheim; Elmsford, NY); ketotifen fumarate (Sandoz; East Hanover, NJ); terfenadine (Merrell-Dow, Cincinnati, OH); astemizole (Janssen, Beerse, Belgium); alprazolam (Upjohn, Kalamazoo, MI).

Platelet aggregation assay. Human blood (50 mL) was collected from healthy male donors in an anticoagulant solution (5 mL) containing sodium citrate (3.8%) and dextrose (2%). Blood was centrifuged at 110 × *g* for 15 min to obtain platelet-rich plasma. The aggregation assays were performed using a dual-channel aggregometer (Model 440, Chrono-Log Corp., Haverton, PA). Solutions of the test compounds or vehicle were added to the platelet-rich plasma, and, after incubation for 2 min, 10-15 μL aliquots of the PAF solution were added to achieve a final concentration of 1-5 × 10^{-8}M. In different experiments the aggregatory response was kept within a set limit by varying the concentration of PAF. Incubations were continued until the increase in light transmission reached a maximum (usually 2 min). Values for inhibition were calculated by comparing the rate of aggregation obtained in the absence and in the presence of the compound. For each experiment, alprazolam, a benzodiazepine with anti-PAF activity, was used as a positive control.

Spasmogen-induced bronchospasm in guinea pigs. Male Hartley guinea pigs (450-550 g) were obtained from Charles River Breeding Labs. (Wilmington, MA). The animals were fasted overnight and were anesthetized the following day with 0.9 mL/kg of dialurethane i.p. (containing 0.1 g/mL diallylbarbituric acid, 0.4 g/mL ethylurea and 0.4 g/mL urethane). The left jugular vein was cannulated for the administration of the compounds. The trachea was cannulated and the animals were ventilated by a rodent respirator at 55 strokes/min with a stroke volume of 4 mL. A side arm to the tracheal cannula was connected to a pressure transducer to obtain a continuous measure of inflation pressure. Bronchoconstriction was measured as the percent increase in inflation pressure that peaked within 5 min after the challenge with spasmogen. The animals

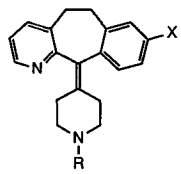
were challenged intraveneously with either PAF (0.4 μg/kg in isotonic saline containing 0.25% bovine serum albumin —BSA), histamine (10 μg/kg) or methacholine (10 μg/kg).



RESULTS AND DISCUSSION

Sch 37370 **6** is structurally related to two clinically used H_1 antihistamines, azatadine **1** (18) and loratadine **2** (19) (Fig. 1). However, these potent antihistamines have no significant PAF antagonist activity. The main structural difference between these compounds and Sch 37370 **6** is the group attached to the piperidine nitrogen atom. In Sch 37370, this group is an acetamide. We have attached a great variety of groups to the piperidine nitrogen and found that only compounds that contain an amide or, to a lesser extent, a thioamide group have good PAF antagonist activity. Some of these compounds are listed in Figure 1 with their *in vitro* biological activity listed in Table 1. Thus, the acetamide **6** is much more potent than the thioacetamide **5**, which in turn is more potent than the methylamine **3** and the methylsulfonamide **4**. The size of the alkyl moiety of the amide derivative is important for high PAF antagonist potency, and we found the methyl group, as in Sch 37370, to be optimal. We also investigated the effect on *in vitro* PAF antagonist potency of changing the C-8 substituent in this series (Table 1). The fluoro **8** and bromo **9** analogs are both equipotent to Sch 37370 **6**, which is somewhat more potent than the unsubstituted compound **7**. However, *in vivo*, the chloro derivative, Sch 37370, had the most desirable profile.

In PAF-induced platelet aggregation assays, Sch 37370 caused a concentration-dependent shift of the PAF dose response curve to the right, indicating competitive inhibition (20). When compared to other PAF antagonists (13,21) in this assay, Sch 37370 was approximately equipotent to L-652,731, more potent than CV-3988 and alprazolam, and less potent than WEB-2086 (Table 2).

In vivo, Sch 37370 was active against PAF- and histamine-induced responses in guinea pigs. It caused dose-dependent inhibitions of both PAF- and histamine-induced bronchospasms when given intravenously or orally (Table 3). After i.v. administration, Sch 37370, with an ED_{50} of 0.7 mg/kg against PAF, was equipotent to L-652,731 and more potent than alprazolam, while WEB 2086 was more potent than Sch 37370. WEB 2086 also showed greater oral potency than Sch 37370, which had an ED_{50} of 6 mg/kg, while L-652,731 and alprazolam were inactive at 30 mg/kg. Several standard antihistamines showed little or no inhibition of PAF-induced bronchospasms except at doses that greatly exceeded their antihistamine dose. Sch 37370 also inhibited histamine-induced bronchospasms with ED_{50} values of 0.6 mg/kg i.v. and 2.4 mg/kg p.o. The specificity for the PAF and histamine receptors was indicated by the much weaker inhibition of the methacholine-induced bronchospasm (20).

In summary, Sch 37370 is a dual antagonist of PAF and histamine *in vitro* and *in vivo*. It is active in anti-PAF and antihistamine assays both upon intravenous and oral administration. While it is neither the most potent PAF antagonist nor the most potent antihistamine, it is the first agent that embodies the unique combination of anti-PAF and antihistamine activities in the same molecule. This combination of activities warrants future testing of Sch 37370 in man.

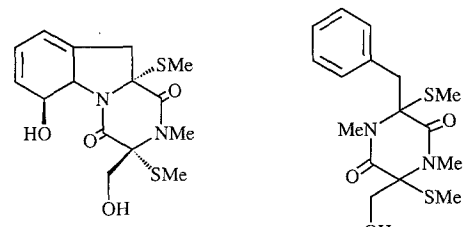
PAF Inhibitory Activity of Diketopiperazines: Structure-Activity Relationships[1]

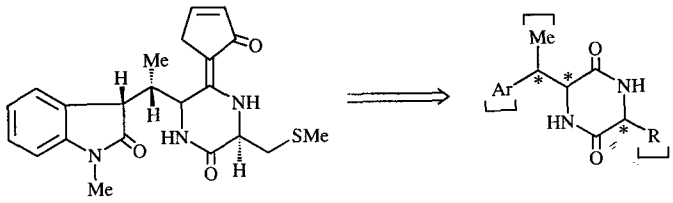
Norihiko Shimazaki, Ichiro Shima, Masanori Okamoto, Keizo Yoshida, Keiji Hemmi* and Masashi Hashimoto



Exploratory Research Laboratories, Fujisawa Pharmaceutical Co., Ltd., Tsukuba, Ibaraki, Japan

FR900452, a natural product isolated from the culture broth of *Streptomyces phaeofaciens* No. 7739, was found to inhibit PAF-induced rabbit platelet aggregation with an IC_{50} of 3.7×10^{-7}M. FR900452, 1-methyl-3-[1-[5-methylthiomethyl-6-oxo-3-(2-oxo-3-cyclopenten-1-ylidene)-2-piperazinyl]ethyl]-2-indoline, has an oxocyclopentylidene group incorporated as a vinylogous amide in a diketopiperazine skeleton. This unique structure led us to synthesize diketopiperazine derivatives, 3-arylalkyl-6-substituted-piperazine-2,5-diones. Their observed PAF inhibitory activity suggest that the D-D configuration of diketopiperazine is an important factor for anti-PAF activity and that the hydrophobic aromatic portion may play a specific role in the binding of the diketopiperazine to the PAF receptor.

***Lipids* 26, 1175-1178 (1991).**



Platelet-activating factor (PAF), an endogenous phospholipid, has been suggested to act as a potent mediator in pathological processes such as anaphylaxis and inflammation (1-3). Our interest in the pathophysiological function of PAF led to the search for PAF inhibitors of microbial origin. For this purpose, a wide range of fermentation broths were tested for their inhibitory effect against PAF-induced rabbit platelet aggregation. Two natural products, designated FR49175 and FR106969 (Scheme 1), were isolated from the culture filtrate of *Penicillium terlikowskii* No. 5348 and *Penicillium citrinum* No. 2973, respectively (4-6). Both compounds have a diketopiperazine skeleton and a *bis*(methylthio) function as common structural units.

Recently, a new compound, designated FR900452, was isolated from the culture broth of *Streptomyces phaeofaciens* No. 7739 and identified as 1-methyl-3-[1-[5-methylthiomethyl-6-oxo-3-(2-oxo-3-cyclopenten-1-ylidene)-2-piperazinyl]ethyl]-2-indolinone (Scheme 2) (7,8). The compound showed high inhibitory potency against PAF-induced rabbit platelet aggregation with an IC_{50} of 3.7×10^{-7} M. The structure of this compound is unique as the oxocyclopentylidene group is incorporated as a vinylogous amide into the diketopiperazine skeleton. Moreover, structurally simpler analogues with diketopiperazine skeleton were prepared to examine whether the vinylogous diketopiperazine moiety contributes to the ability of the molecule to bind to the PAF receptor site.

FR49175 FR106969

SCHEME 1

FR900452

SCHEME 2

In the synthesis of the derivatives, we focused on: i) the stereochemistry of the diketopiperazine; ii) the modification of the oxindole moiety; iii) the modification of the *S*-methylcysteine part; and iv) the effect of the β-methyl group (Scheme 2).

In the present study, the relationship between the structure of diketopiperazine derivatives and the ability of the derivatives to inhibit PAF was examined. Our results suggest that the stereochemistry of the diketopiperazine moiety is an important factor in the inhibition of PAF activity and that the hydrophobic aromatic portion plays an important role in the binding of the diketopiperazine to the PAF receptor.

MATERIALS AND METHODS

Synthesis. Diketopiperazine derivatives were synthesized by peptide coupling using the dicyclohexylcarbodiimide method, followed by removal of the *N*-protecting group with hydrogen chloride in ethyl acetate and subsequent cyclization in alcoholic ammonia (9). Derivatives prepared from *dl-erythro* and *dl-threo-N*-Boc-1, β-dimethyltryptophans and *S*-methylcysteine have already been reported (10). Optically active (αR, βR)-1,β-dimethyltryptophans were prepared by reaction of aziridine-2-carboxylate and *N*-alkylindoles in the presence of boron trifluoride etherate (11). Purities and structures of the diketopiperazines were confirmed by thin-layer

[1]Based on a paper presented at the Third International Conference on Platelet-Activating Factor and Structurally Related Ether Lipids Tokyo, Japan, May 1989.

Abbreviations: IC_{50}, concentration required to inhibit the platelet aggregation response by 50%; PAF, platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; PRP, platelet-rich plasma.

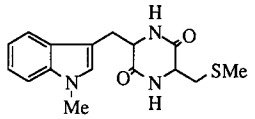
chromatography, nuclear magnetic resonance spectroscopy, and elemental analysis.

Inhibition of platelet aggregation. Platelet aggregation was measured using a Sienco (Morrison, CO) dual-sample aggregometor (DP-247E). Blood was collected in 3.8% sodium citrate (1 mL for 9 mL of blood) from the carotide arteries of male Japanese white rabbits (2.5–3 kg body weight). Blood was then centrifuged at 150 × *g* for 10 min at 10°C to prepare platelet-rich plasma (PRP). The remaining blood was further centrifuged at 1000 × *g* to obtain platelet-poor plasma for adjusting the concentration of platelets to 4.0×10^5 platelets/mL. PRP (0.3 mL) was incubated with drugs or vehicle for 2 min before PAF (1×10^{-8} M) was added. Activity of inhibition was expressed as IC_{50} value, *i.e.*, the concentration required to inhibit the platelet aggregation response by 50%.

RESULTS

Stereochemistry of the diketopiperazine. The four stereoisomers with L-L, D-L, L-D, and D-D configuration were prepared starting from *N*-Boc-1-methyl-L- and D-tryptophan and *S*-methyl-L- and D-cysteine ethyl ester to examine which stereochemistry of the diketopiperazine is preferable to express optimal inhibitory activity. The inhibitory activities of the compounds are listed in Table 1. Of the four stereoisomers, compound 1 with D-D configuration was the most effective inhibitor of PAF; the other diastereoisomers were less potent or essentially inactive. The derivative 5 prepared from D-tryptophan and D-methionine also showed potent inhibitory activity.

Modification of the oxindole moiety. The inhibitory activities of the derivatives modified at the oxindole moiety are given in Table 2. The naphthyl derivative 8 was more potent than the phenyl derivatives 6 and 7. The 1-methylindole derivative 5 was more potent than the indole derivative 10. The activity of the naphthyl derivative 8 was almost the same as that of the 1-methylindole derivative 5. The pyridyl derivative 9 showed very weak activity.



Modification of the S-methylcysteine moiety. The inhibitory activities of the derivatives modified at the *S*-methylcysteine moiety are listed in Table 3. The most potent analogue was the n-butyl derivative 11. The long-chain analogue 12 showed only weak activity. The benzyl derivative 13 was as potent as the methylthioethyl derivative 5. The α-picolyl derivative 16 showed more potent activity than the β-picolyl 17 and γ-picolyl derivative 18. The hydrophilic derivatives 19 and 20 exhibited only weak activities, and the corresponding ester derivatives 14 and 15 showed relatively high potencies.

Effect of the β-methyl group. The inhibitory activities of the four stereoisomers which have a β-methyl group in the tryptophan residue are shown in Table 4. Compound 21 with (7R)-β-methyl and D-D diketopiperazine configuration was the most active. The inhibitory activity of the (7S)-methyl counterpart 22 was about five-fold less than that of compound 21. Compounds 23 and 24 with L-D diketopiperazine configuration were essentially inactive.

Effect of substituents on the indole moiety of tryptophan. Compound 16 was modified to examine the effect of substituents on the indole moiety. The inhibitory activities of these derivatives are shown in Table 5. The inhibitory activities of the *N*-ethyl (26) and the *N*-propyl (27) derivatives were approximately three-fold higher than that of the *N*-methyl derivative 25. Compounds 30 and 31, with the hydrophobic chloro and methyl substituents at the 5-position of the indole, respectively, showed about a three-fold increase in potency compared to the inhibitory

DISCUSSION

Four stereoisomers of diketopiperazines from *N*-methyltryptophan and *S*-methylcysteine were synthesized to determine which diketopiperazine stereochemistry was most desirable for inhibitory activity (Table 1). The most active compound had D-D configuration and the compounds prepared from L-N-methyltryptophan showed only weak activities. Thus the D-D configuration is necessary for potent inhibitory activity in this diketopiperazine series. Next, the effect of modification of the oxindole moiety on inhibitory activity was examined (Table 2). The hydrophobic α-naphthyl and *N*-methylindole derivatives showed high inhibitory activity, whereas the hydrophilic pyridyl derivative showed very weak activity. These results suggest that the hydrophobic aromatic moiety is important in the inhibition of PAF. Hydrophobic, moderately hydrophobic, and hydrophilic derivatives were synthesized to examine the effect of the modification of the *N*-methylcysteine part (Table 3). The hydrophobic derivatives 5, 11, and 13 showed high potency. The hydrophilic derivatives 19 and 20 showed only weak activities, whereas the corresponding esters 14 and 15, which were more hydrophobic, showed moderate potency. These results suggest that a hydrophobic side chain is preferable in inhibiting PAF activity. The long chain derivative 12, which is the most hydrophobic compound prepared in this study, showed relatively weak activity, probably due to steric hindrance. The difference in activities between the three picolyl isomers suggests that there may be an ionic and/or hydrogen bonding interaction in addition to a hydrophobic interaction between the inhibitors and the receptor. The effect of the β-methyl group in the tryptophan residue was examined to see whether the methyl group is necessary for inhibitory activity (Table 4). The inhibitory activity of the derivative with (7R)-methyl and D-D diketopiperazine configuration was about three times higher than that of the corresponding desmethyl derivative. The activity of the (7S)-methyl counterpart was almost the same as that of the desmethyl derivative. These results suggest that the configuration of the β-methyl group affects the inhibitory activities of diketopiperazines.

Finally, the effect of substituents on the indole ring were examined (Table 5). Compounds having the hydrophobic group showed potent inhibitory activities. This result is similar to that observed when the oxindole part was modified. Compound **32**, a regioisomer of compound **31**, showed less than one-tenth of the activity of compound **31**. This suggests that a steric limitation may exist at the receptor site which interacts with the aromatic portion of diketopiperazines.

In summary, our results suggest the stereochemistry of the diketopiperazine, *i.e.*, the D-D configuration, is an important factor in the inhibition of PAF. In addition, the hydrophobic aromatic portion and hydrophobic side chain play important roles in the binding of the diketopiperazine to the PAF receptor.

Pharmacological Properties of YM461, a New Orally Active Platelet-Activating Factor Antagonist[1]

Toshimitsu Yamada, Munetoshi Saito, Toshiyasu Mase, Hiromu Hara, Hitoshi Nagaoka, Kiyoshi Murase and Kenichi Tomioka*

Medicinal Research Laboratories, Yamanouchi Pharmaceutical Co., Ltd., Tsukuba, Ibaraki 305, Japan

The antagonistic effect of YM461 [1-(3-phenylpropyl)-4-[2-(3-pyridyl)thiazolidin-4-ylcarbonyl]piperazine fumarate] against platelet-activating factor (PAF) was examined in several *in vitro* and *in vivo* systems. We found that YM461 inhibited [^{3}H]PAF binding to rabbit platelet membranes with a pK_i value of 8.90. YM461 inhibited PAF induced rabbit and human platelet aggregation with pA_2 values of 7.52 and 7.29, respectively; the slopes of the Schild plots were 1.07 and 1.01, respectively. However, YM461 at 10^{-4}M did not affect rabbit and human platelet aggregation induced by ADP, collagen, arachidonic acid or epinephrine. YM461 inhibited PAF induced death in mice with an ED_{50} (50% effective dose) value of 0.35 mg/kg *p.o.* YM461 at doses above 0.3 mg/kg *i.v.* inhibited PAF induced hypotension in rats. YM461 showed a dose-dependent inhibition of PAF induced hemoconcentration in rats with ED_{50} values of 0.15 and 0.21 mg/kg *p.o.*, respectively, at 0.5 and 1 hr after oral administration. The anti-PAF effect of YM461 persisted more than 6 hr after 3 mg/kg *p.o.* in rats. YM461 inhibited the bronchoconstriction induced by PAF with an ED_{50} value of 1.2 mg/kg *p.o.* in anesthetized guinea pigs. Furthermore, the compound at doses above 3 mg/kg *p.o.* significantly inhibited antigen-induced anaphylactic asthma in conscious guinea pigs pretreated with mepyramine and propranolol. These results indicate that YM461 is a selective, potent and orally active PAF antagonist.
***Lipids* 26, 1179–1183 (1991).**

Platelet-activating factor (PAF) is a phospholipid (1,2) that is synthesized by various cells including neutrophils (3), eosinophils (4), basophils (1), macrophages (5), platelets (6) and endothelial cells (7). PAF exerts various biological effects such as platelet aggregation (8), neutrophil degranulation (9), cardiac and renal dysfunction (10), hypotension (11), bronchoconstriction (12) and enhancement of vascular permeability (13). Because of its various potent activities, PAF has been implicated to possibly play an important role in asthma, shock, glomerulonephritis and other diseases. Therefore, inhibitors of the formation and the action of PAF are thought to be of therapeutic value in the treatment of these diseases. In fact, beneficial effects of PAF antagonists in several animal models and in human diseases have been reported. For example, WEB 2086, a thienotriazolodiazepine derivative, inhibits antigen-induced bronchoconstriction in guinea pigs (14). BN52063, an extract of the Ginkgo biloba, improves symptoms in asthmatic patients (15). CV-3988, a structural analogue of PAF, inhibits endotoxin-induced shock in rats (16). L-652,731, a trimethoxyphenyl tetrahydrofuran derivative, protects the rat from renal injury in nephrotoxic glomerulonephritis (17).

We have synthesized several thiazolidin derivatives, tested their anti-PAF effects, and found several orally active PAF antagonists. In the present study, we describe the pharmacological properties of 1-(3-phenylpropyl)-4-[2-(3-pyridyl)thiazolidin-4-ylcarbonyl]piperazine fumarate (YM461, Fig. 1), one of the orally active PAF antagonists, in several *in vitro* and *in vivo* test systems.

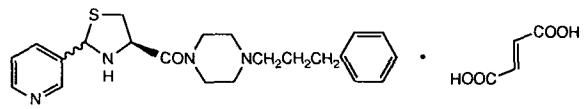

FIG. 1. Chemical structure of YM461. YM461 is a mixture of *cis* and *trans* isomers; the *cis/trans* ratio reaches equilibrium (*cis/trans*, 3:2) in aqueous solution within 2 min.

MATERIALS AND METHODS

Chemicals. Tritium-labeled PAF ([^{3}H]PAF) was purchased from Amersham (Buckinghamshire, England). PAF was obtained from Funakoshi Pharmaceuticals (Tokyo, Japan) and kept at −80°C in a stock solution of saline containing 0.25% bovine serum albumin (BSA, Sigma, St. Louis, MO). Dilutions were made with 0.25% or 0.1% (for platelet aggregation) BSA-saline on a daily basis as needed. Mepyramine, DL-propranolol hydrochloride and arachidonic acid were purchased from Sigma, ADP from Boehringer Mannheim (Mannheim, Germany), collagen from Niko Bioscience (Tokyo, Japan), and epinephrine from Daiichi (Tokyo, Japan). YM461 and WEB 2086 were synthesized in our labolatories.

Animals. Male, Japanese, white strain rabbits were obtained from the Clean experimental animal center (Saitama, Japan). Male ICR mice and Wistar rats were obtained from Japan SLC (Hamamatsu, Japan). Male Hartley guinea pigs were from Hitachi Animal Medical Research Institute (Ibaraki, Japan).

[^{3}H]PAF binding to rabbit platelet membranes. [^{3}H]-PAF binding to rabbit platelet membranes was determined by the method of Hwang *et al.* (18). Briefly, platelets from male, Japanese, white strain rabbits, weighing about 3 kg, were separated by centrifugation and the platelet membranes were obtained by repeated freezing and thawing. The incubation mixture contained 1.5 nM [^{3}H]PAF (222 dpm/fmol), 0.25% BSA in the presence or absence of unlabeled PAF or test compound, and rabbit platelet membrane protein (75 μg) in 0.5 mL of incubation buffer containing 5 mM $MgCl_2$, 2 mM EDTA and 10 mM Tris-HCl (pH 7.0). Incubations were performed at 0°C for

Abbreviations: BSA, bovine serum albumin; EC_{50}, 50% effective concentration; ED_{50}, 50% effective dose; IC_{50}, 50% inhibitory concentration; PAF, platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; PPP, platelet-poor plasma; PRP, platelet-rich plasma.

120 min and the mixtures were rapidly filtered. The radioactivity on the filter was counted in a Packard liquid scintillation counter linked to an HP-85 computer (Hewlett Packard, San Diego, CA). The radioligand competition activity (K_i) of each compound was calculated from the equation: $K_i = IC_{50}/(1 + [[^3H]PAF]/K_d)$ where IC_{50} is the concentration required to inhibit specific binding by 50%, and K_d is the equilibrium dissociation constant for [^{3}H]PAF binding to specific binding sites on the rabbit platelet membrane. The pK_i values were calculated from the negative logarithm of the K_i values.

Platelet aggregation. Rabbit and human blood were collected in plastic syringes with 1 volume of 3.8% sodium citrate. The blood was centrifuged at 270 × *g* for 10 min. The upper platelet-rich plasma (PRP) was removed carefully. The pellet was further centrifuged and the supernatant was used as platelet-poor plasma (PPP). The platelet concentrations were adjusted with PPP to 5×10^8 cells/mL for rabbit and 3×10^8 cells/mL for human. Platelet aggregation was measured by the method of Born (19) using a Hema Tracer IV (Niko Bioscience, Tokyo, Japan). Test compounds at various concentrations were added to PRP 2 min prior to the aggregant.

PAF-induced death in mice. Six-week-old male ICR mice were injected with 75 μg/kg PAF through the tail vein, and the mortality of animals was estimated at 24 hr after PAF injection. Test compounds were administered orally 1 hr prior to PAF.

PAF-induced hypotension. Wistar rats weighing 295 to 330 g were anesthetized with sodium pentobarbital (50 mg/kg *i.p.*). Blood pressure was monitored from the right carotid artery. The test compound was injected into the right femoral vein 5 min prior to bolus injection of PAF (0.5 μg/kg *i.v.*).

PAF-induced hemoconcentration. Wistar rats weighing 250 to 315 g were anesthetized with sodium pentobarbital (50 mg/kg *i.p.*) and cannulated in the right carotid artery for blood sampling. Hemoconcentration was determined by measuring the changes of hematocrit between before and 10 min after *i.v.* injection of 1.65 μg/kg PAF. The test compound was administered orally 0.5, 1, 2, 3, 4 or 6 hr before injection of PAF.

PAF-induced bronchoconstriction. Airway resistance was determined according to the method of Konzett and Rössler (20). Guinea pigs, weighing 500 to 690 g, were anesthetized with 1.2 g/kg *i.p.* urethane, and intratracheal cannula and catheter were inserted into the jugular vein for drug administration. Animals were then ventilated with a respirator (Shinano, Tokyo, Japan) at 60 strokes/min with a volume of 1 mL/100 g body weight/cycle; gallamine (1 mg/kg *i.v.*) was injected to suppress spontaneous breathing. Intrapulmonary pressure was measured with a bronchospasm transducer (Ugo Basile, Comerio, Italy) connected to AD-611G (Nihon Kohden, Tokyo, Japan) and bronchoconstriction was expressed as percentage of maximal response obtained by clamping the trachea. The test compound was administered orally 1 hr prior to bolus injection of 50 ng/kg PAF.

Anaphylactic asthma in conscious guinea pigs. Hartley guinea pigs, weighing 370 to 430 g, were passively sensitized by intravenous injection of 1 mL/kg of rabbit anti-BSA serum (passive hemagglutination titer, 20480) (21, 22). Twenty-four hr after sensitization, the animals were pretreated with mepyramine (2 mg/kg *i.v.*) and propranolol (0.3 mg/kg *i.v.*) 5 min prior to antigen challenge. The animals were placed in an 11-L chamber connected to a glass nebulizer (KG-20, Kinoshita, Tokyo, Japan), and 1% solution of BSA was sprayed into the chamber for 30 sec. The animals were exposed to the antigen aerosol for 2 min and observed for 20 min after antigen challenge. The time from the start of inhalation to the onset of coughing and the mortality of animals were recorded. The test compound was administered orally 1 hr before antigen challenge.

Statistics. The IC_{50}, EC_{50} and ED_{50} values were calculated by the Probit method (23). The pA_2 values for the antagonists were obtained from Schild plots of the log of the molar concentration of the antagonist against the log of (concentration ratio −1) as described by Arunlakshana and Schild (24). Statistical significance of the data was estimated using Dunnett's multiple comparison test or Student's *t*-test.

RESULTS

[^{3}H]PAF binding to rabbit platelet membranes. K_d and B_{max} for [^{3}H]PAF binding to rabbit platelet membranes were 1.8 nM and 0.53 nmole/mg protein, respectively. YM461, PAF and WEB 2086 inhibited [^{3}H]PAF binding to rabbit platelet membranes in a dose-dependent manner, and their pK_i values were 8.90 (8.80–9.00), 8.48 (8.36–8.62) and 7.74 (7.64–7.82), respectively (Fig. 2).

Platelet aggregation in rabbit and human platelet-rich plasma. PAF produced a dose-dependent aggregation of rabbit platelets with EC_{50} value of 1.7×10^{-9} M (Fig. 3). YM461 shifted the PAF dose-response curve to the right in a parallel manner without reduction of the maximal response (Fig. 3). The pA_2 value for YM461 was 7.52 and the slope of the regression line of the Schild plot was 1.07. WEB 2086 also showed a dose-dependent inhibition of rabbit platelet aggregation with a pA_2 value of 7.31 (data not shown). This pA_2 value was similar to that reported by O'Donnell and Barnet (25).

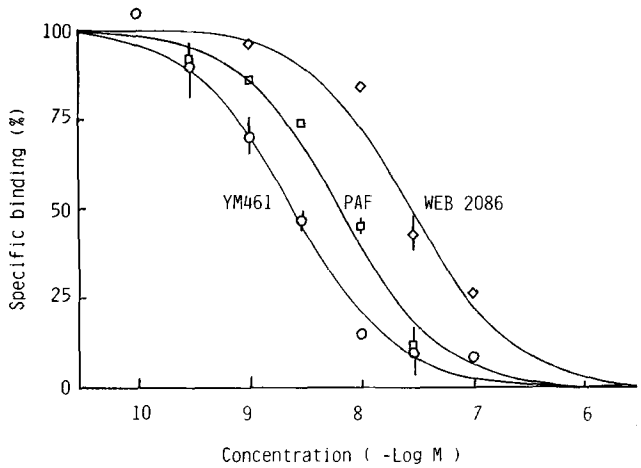

FIG. 2. Effects of YM461, PAF and WEB 2086 on [^{3}H]PAF binding to rabbit platelet membranes. Various concentrations of test compounds, 75 μg membrane protein and 1.5 nM [^{3}H]PAF were added to the medium containing 5 mM $MgCl_2$, 2 mM EDTA and 0.25% BSA and 10 mM Tris-HCl (pH 7.0). Each point represents the mean ± SEM of six experiments.

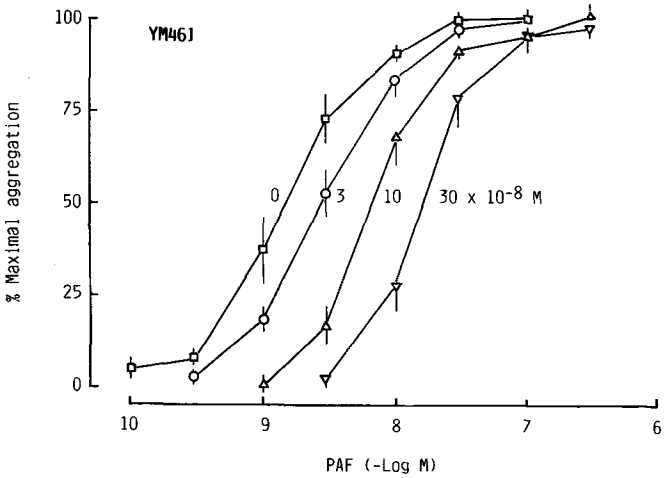

FIG. 3. Inhibition of PAF induced rabbit platelet aggregation by YM461. The % aggregation is relative to the maximal response (100%) obtained with 10^{-7} M PAF in corresponding control (0 M) platelets. Each point represents the mean ± SEM of seven experiments.

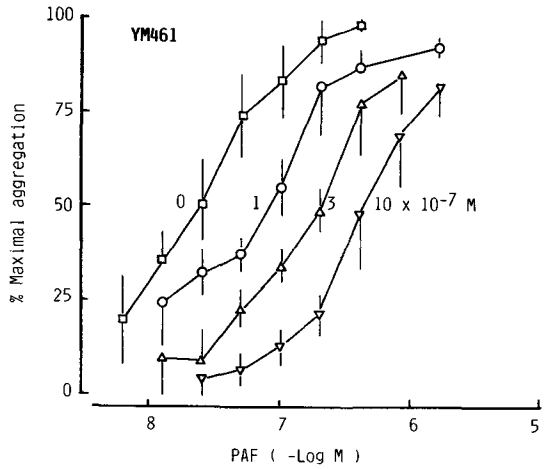

FIG. 4. Inhibition of PAF induced human platelet aggregation by YM461. The % aggregation is relative to the maximal response (100%) obtained with 4×10^{-7} M PAF in corresponding control (0 M) platelets. Each point represents the mean ± SEM of four experiments.

The effect of YM461 on PAF induced human platelet aggregation is shown in Figure 4. PAF induced dose-dependent aggregation of human platelets with an EC_{50} value of 2.8×10^{-8} M. As with rabbit platelets, YM461 showed a parallel shift of the PAF dose-response curve to the right without altering the maximal response. The pA_2 value for YM461 and its slope were 7.29 and 1.01, respectively.

As shown above, YM461 dose-dependently inhibited PAF induced rabbit and human platelet aggregation. However, there is a possibility that YM461 exerts non-specific inhibitory effect on platelets. Therefore, we determined next the effect of YM461 on rabbit and human platelet aggregation induced by PAF, ADP, collagen, arachidonic acid or epinephrine. As shown in Table 1, YM461 inhibited PAF induced rabbit and human platelet aggregation with IC_{50} values of 7.1×10^{-8} and 2.2×10^{-7} M, respectively. However, YM461 at 10^{-4}M did not show any significant inhibitory effect on platelet aggregation induced by ADP, collagen, arachidonic acid or epineprine.

TABLE 1

Effect of YM461 on Platelet Aggregation Induced by PAF, ADP, Collagen, Arachidonic Acid or Epinephrine in Rabbit and Human Platelet Rich Plasma[a]

Agonist	Concentration of agonist (μm)	IC_{50} (μM) Rabbit	Human
PAF	0.01,[b] 0.1∼0.4[c]	0.22	0.071

Epinephrine	1∼5	—	> 100

[a]Concentrations of platelets were adjusted to 5×10^8 and 3×10^8 cells/mL, respectively, for rabbit and human. IC_{50} values were calculated by the Probit method (23) (N=3∼9).
[b]Rabbit. [c]Human. [d]μg/mL. [e]NT, not tested.

TABLE 2

Protective Effects of YM461 and WEB 2086 on PAF Induced Death in Mice

Drug[a]	Dose (mg/kg *p.o.*)	Mortality (death/tested)	Inhibition (%)	ED_{50} (mg/kg *p.o.*)
Control	—	10/10	—	
YM461	0.03	10/10	0	
	0.1	8/11	27	0.35
	0.3	7/10	30	(0.17-0.73)[b]
	1.0	2/10	80	
	3.0	0/10	100	
Control	—	9/10	—	
WEB 2086	0.1	8/10	11	0.57
	0.3	6/10	33	(0.33-0.98)[b]
	1.0	4/10	56	
	3.0	0/10	100	

[a]Drugs were administered orally 1 hr prior to PAF (75 μg/kg *i.v.*).
[b]95% Confidence limit of ED_{50} value calculated by Probit method (23).

Effect on PAF induced death in mice. As shown in Table 2, the mortality in control mice was 90 to 100% at 24 hr after PAF injection. YM461 and WEB 2086 dose-dependently inhibited PAF induced death in mice; the 50% protective dose of these compounds were 0.35 and 0.57 mg/kg *p.o.*, respectively.

Effect on PAF induced hypotension in anesthetized rats. Bolus injection of PAF produced a marked hypotension and reached a peak effect (36% decrease in blood pressure) at 2 min after injection. YM461 dose-dependently inhibited PAF induced hypotension; complete inhibition was observed at 0.3 mg/kg YM461 (Fig. 5).

PAF induced hemoconcentration in rats. In 35 control rats, the hematocrit value increased by 43 ± 1% at 10 min after PAF injection. YM461 dose-dependently inhibited PAF induced hemoconcentration (Fig. 6). When the anti-PAF effect of YM461 was plotted as a function of time, the peak effect was observed between 0.5 and 1 hr after oral administration, and ED_{50} values were 0.15 and

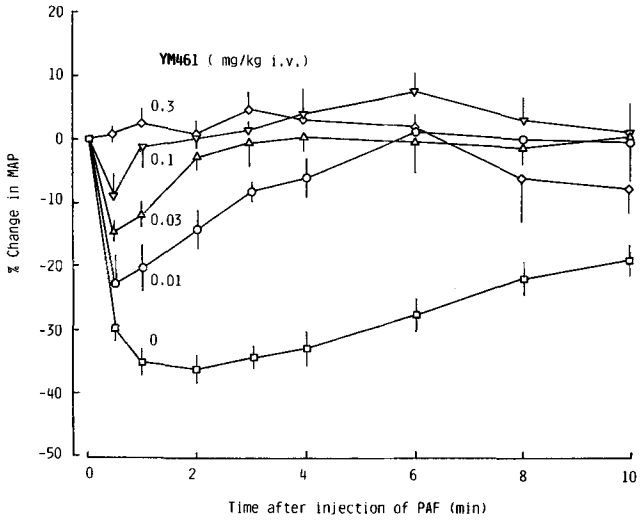

FIG. 5. Effect of YM461 on PAF induced hypotension in anesthetized rats. YM461 was administered intravenously 5 min prior to bolus injection of 0.5 μg/kg PAF. Each point represents the mean ± SEM of 4 to 16 rats.

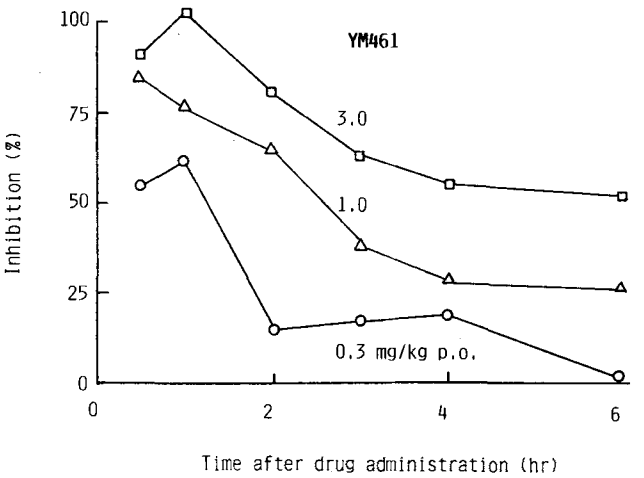

FIG. 6. Inhibitory effect of YM461 on PAF induced hemoconcentration in rats. YM461 was administered orally 0.5 to 6 hr before PAF (1.65 μg/kg *i.v.*). Each point represents the mean ± SEM of 3 to 13 rats.

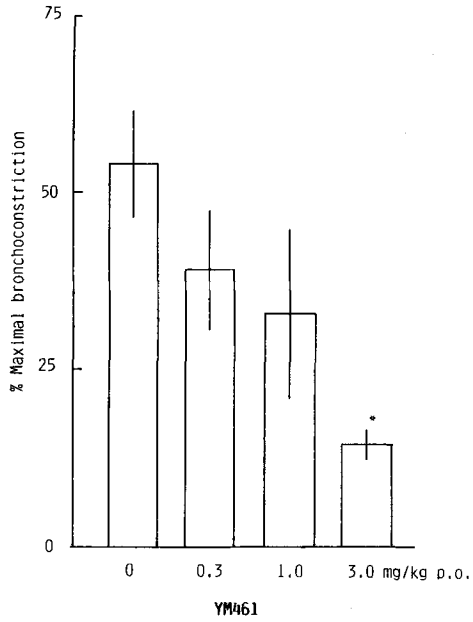

FIG. 7. Effect of YM461 on PAF induced bronchoconstriction in anesthetized guinea pigs. PAF (50 ng/kg) was injected in the jugular vein. YM461 was administered orally 1 hr before PAF. Bronchoconstriction is expressed as a percentage of the maximal response obtained by clamping the trachea. The data represent the mean ± SEM of 4 to 12 guinea pigs. *Significantly different from the value of control group at $p<0.05$ by Dunnett's multiple comparison test.

Control	—	8	433 ± 53	3/8
WEB 2086	10	8	562 ± 26[d]	1/8

[a] Guinea pigs were passively sensitized with rabbit anti-BSA serum one day before antigen challenge, and pretreated with mepyramine (2 mg/kg *i.v.*) and propranolol (0.3 mg/kg *i.v.*) 5 min prior to antigen challenge.

[b] Test compounds were administered orally 1 hr prior to inhalation of 1% BSA solution.

[c] When animals did not cough over 10 min after challenge, time was calculated as 600 sec.

[d] Significantly different from the value of control group at $p<0.05$ by Student's *t*-test.

0.21 mg/kg *p.o.*, respectively. The anti-PAF effect of YM461 at 0.1 and 0.3 mg/kg *p.o.* returned to near control levels at 3 hr, but at 1 and 3 mg/kg *p.o.* the compound showed 25 and 58% inhibition, respectively, 6 hr after treatment.

PAF induced bronchoconstriction in guinea pigs. As shown in Figure 7, bolus injection of PAF produced 54% bronchoconstriction of maximal response in control group. YM461 at 0.3, 1 and 3 mg/kg *p.o.* dose-dependently inhibited PAF induced bronchoconstriction; the ED_{50} value was 1.2 mg/kg *p.o.*

Antigen-induced anaphylactic asthma in conscious guinea pigs. The guinea pigs in the control group exhibited cough within an average of 361 to 454 sec following inhalation of antigen; 1/8 to 1/2 of the animals died within 20 min. YM461 at 3 and 10 mg/kg *p.o.* significantly prolonged the time till onset of cough and tended to reduce the mortality of animals. WEB2086 at 10 mg/kg also prolonged the time interval by onset of cough (Table 3).

DISCUSSION

YM461 was shown to possess the activity profile of a PAF antagonist in several *in vitro* and *in vivo* test systems. YM461, PAF and WEB 2086 inhibited [^{3}H]PAF binding to rabbit platelet membranes with pK_i values of 8.90, 8.48 and 7.74, respectively (Fig. 4). The affinity of YM461 to PAF receptors on platelet membranes was 2.6, and 14 times higher than those of PAF and WEB 2086. Furthermore, YM461 inhibited PAF induced rabbit and human platelet aggregation with pA_2 values of 7.52 (Fig. 3) and 7.29 (Fig. 4), respectively. Competitive antagonism of YM461 against PAF induced rabbit and human platelet aggregation was confirmed by the slope of unity of the Schild plot. YM461 at 10^{-4} M did not show any inhibitory effect on rabbit and human platelet aggregation induced by ADP, collagen, arachidonic acid or epinephrine (Table 1). These results indicate that YM461 is a selective and competitive PAF antagonist.

Next, we examined the anti-PAF effect of YM461 using five *in vivo* models. Intravenous injection of PAF into ICR mice produced a lethal shock which resembled anaphylactic action (26). Several mediators, especially lipoxygenase products, may contribute to this reaction, because different types of drugs, including steroids, β-adrenoceptor agonists, lipoxygenase inhibitors and PAF antagonists, protect mice from PAF induced death (27).

YM461 dose-dependently protected the mice from PAF induced death with ED_{50} value of 0.35 mg/kg *p.o.* (Table 2). YM461 is not a steroid and has no β-agonistic action because the compound inhibits anaphylactic asthma in the presence of propranolol (Table 3). Furthermore, YM461 does not act as a leukotriene antagonist or a 5-lipoxygenase inhibitor, because the compound at 10^{-5} or 10^{-4} M inhibits neither LTD_4 (10^{-8} M) induced contraction of guinea pig ileum nor 5-lipoxygenase from mastocytoma P-815 cells (unpublished data). These results indicate that YM461 inhibits PAF induced death in mice *via* its anti-PAF effect.

Intravenous PAF injection induced marked hypotension and hemoconcentration in rats. YM461 at doses above 0.01 mg/kg *i.v.* and 0.1 mg/kg *p.o.* dose-dependently inhibited PAF induced hypotension and hemoconcentration. The compound at 3 mg/kg *p.o.* inhibited hemoconcentration by 58% even at 6 hr after oral administration, indicating YM461 has a relatively long duration of action. PAF induced reactions in rats are brought about through platelet-independent mechanisms because rat platelets are insensitive to PAF (28). Accordingly, YM461 can block PAF actions both in platelet-dependent and platelet-independent systems.

YM461 at doses of 0.3 to 3.0 mg/kg *p.o.* dose-dependently inhibited PAF induced bronchoconstriction in guinea pigs (Fig. 7). YM461 at doses above 3 mg/kg *p.o.* also inhibited antigen-induced anaphylactic asthma in passively sensitized guinea pigs (Table 3). Furthermore, YM461 inhibited antigen-induced late airway responses and associated airway hyperresponsiveness in allergic sheep (29). These results indicate that oral YM461 is able to inhibit the actions induced not only by exogenously administered PAF but also by endogenously liberated PAF.

In summary, our results indicate that YM461 is a selective, potent and orally active PAF antagonist. YM461 may therefore be useful in the treatment of pathological conditions associated with excessive PAF production.

ACKNOWLEDGMENTS

The authors wish to thank Mr. M. Terai and Mr. K. Hidaka for carrying out PAF binding assays and Miss T. Hanazato and Mrs. K. Teramura for excellent technical assistance.

REVIEW

Bioactions of 5-Hydroxyicosatetraenoate and its Interaction with Platelet-Activating Factor[1]

Adriano G. Rossi* and **Joseph T. O'Flaherty**
Department of Medicine, Section of Infectious Diseases, Wake Forest University Medical Center, Winston-Salem, NC 27103

In a variety of stimulated cells, platelet-activating factor (PAF) and numerous arachidonate derivatives are co-products that form as a consequence of receptor-mediated phospholipid mobilization. These lipid co-products produce a plethora of biological effects in a wide variety of cell systems. Furthermore, they often have a fascinating, although less widely appreciated, interaction. 5-HETE, at submicromolar concentrations, exerts relatively few direct bioactions. It does, however, potently (16–160 nM) raise cytosolic free calcium $[Ca^{2+}]_i$ and augment PAF-induced responses in human polymorphonuclear neutrophils (PMN) by as much as 100- to 1000-fold. 5-HETE acts on PMN by a structurally specific, stereospecific and pertussis toxin-inhibitable mechanism. In addition, PMN exposed to 5-HETE exhibit homologous but not heterologous desensitization. These findings suggest that 5-HETE, like PAF, may bind to its own specific plasmalemmal receptors to exert its unique set of bioactions. However, further investigation is required to demonstrate any putative 5-HETE receptors. Other potential mechanisms of 5-HETE-induced bioactions together with the possible effects of 5-HETE on PAF transduction mechanisms are also discussed.
Lipids 26, 1184–1188 (1991).

Many stimuli (S) elicit function by inducing target cells to convert their resident phospholipids into a series of signalling molecules (Fig. 1) (1,2). They generally achieve this by binding with specific plasmalemmal receptors (R) that operate through guanine nucleotide-binding proteins (G-proteins) to activate phospholipase(s) C (PLC). The activated phospholipase(s) cleaves phosphatidylinositol 4,5-bisphosphate (PIP_2) into two critical secondary messengers—inositol 1,4,5-triphosphate (IP_3) and diacylglycerol (DAG). IP_3 mobilizes storage calcium to elevate cytosolic free Ca^{2+}($[Ca^{2+}]_i$), whereas DAG activates protein kinase C (PKC) by a Ca^{2+}-enhanced interaction (3–9). Concurrently with these events, the stimuli also cause target cells to attack their phospholipids by a second route involving a calcium-dependent phospholipase(s) A_2 (PLA_2). The enzymes principally release

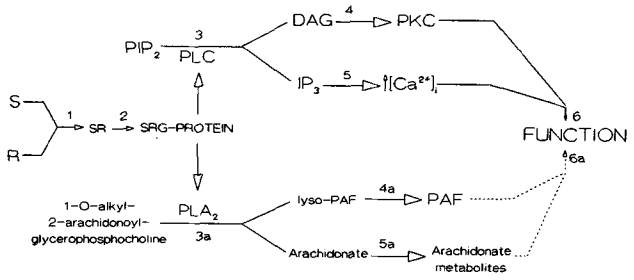

FIG. 1. Simplified schematic representation of stimulus-response coupling. See text for details.

arachidonate from the *sn*-2 position of phospholipids. When the substrate phospholipid is 1-*O*-alkyl-2-acyl-glycerophosphocholine, 1-*O*-alkyl-2-lyso-glycerophosphocholine is formed. Acetyltransferase converts this lyso intermediate into platelet-activating factor (PAF) (10–12). Finally, cyclooxygenase and various lipoxygenases oxygenate the arachidonate released by the phospholipase(s)-mediated cleavage reaction. Products of these oxygenations include prostaglandins (PGs), thromboxanes (TXs), hydroxyicosatetraenoates (HETEs), leukotrienes (LTs), and lipoxins (LXs) (13–20). Many of the above phospholipid derived products interact to influence cellular responsiveness. This review article focuses on some of these intriguing interactions.

PAF BIOSYNTHESIS, METABOLISM, AND MECHANISMS OF ACTION

As already indicated, cells commonly form PAF during stimulation by deacylating their resident 1-*O*-alkyl-2-acyl-glycerophosphocholine and then acetylating the lyso intermediate (10–12). In addition to the deacylation/acetylation pathways, cells form PAF by a *de novo* pathway involving the formation of 1-alkyl-2-acetyl-glycerophosphates and ultimate conversion of 1-alkyl-2-acetyl glycerol to PAF by a cholinephosphotransferase (12).

Cells also rapidly and quantitatively inactivate PAF. The principal pathway of cellular PAF metabolism uses an acetylhydrolase to convert PAF to its bioinactive derivative, 1-*O*-alkyl-2-lyso-glycerophosphocholine. The product is then rapidly acylated (commonly with arachidonate) by acyltransferase. 1-*O*-alkyl-2-acyl-glycerophosphocholine is stored but available for reconversion to PAF by the deacylation/acetylation pathway during cell stimulation (10–12). Minor pathways of PAF degradation (e.g., cleavage at *sn*-3) have also been reported (21–24).

PAF possesses a broad range of bioactions upon diverse cell types. Many, if not all, the bioactions of PAF proceed through a classical transduction mechanism (Fig. 1). That is, PAF binds with specific plasma membrane receptors

Abbreviations: $[Ca^{2+}]_i$, cytosolic free calcium ions; DAG, diacylglycerol; G-proteins, guanine nucleotide-binding proteins; HETE, hydroxyicosatetraenoate; HPETE, hydroperoxyicosatetraenoate; IP_3, inositol 1,4,5-triphosphate; LT, leukotriene; PAF, platelet-activating factor; PG, prostaglandin; PIP_2, phosphatidylinositol 4,5-bisphosphate; PKC, protein kinase C; PL, phospholipase; PMN, polymorphonuclear neutrophils; R, receptor; S, stimulus; TX, thromboxane.

that couple to G-proteins resulting in the activation of phospholipases C and A_2. Hence, PAF-challenged cells form DAG and IP_3, mobilize storage Ca^{2+} and PKC, and synthesize various arachidonate metabolites (11,12, 25–34). Three unique aspects of the PAF transduction cascade merit emphasis. First, G-proteins linked to PAF receptors may have somewhat different sensitivities to pertussis and cholera toxins than G-proteins linked with other receptor elements (35–39). Second, PAF receptors may couple with plasmalemmal calcium channels (36,37,40). Third, PAF, in utilizing the standard transduction cascade, stimulates its own synthesis (41,42). It should also be noted that PAF stimulates 5-HETE synthesis in target cells capable of forming this arachidonate metabolite (33,34).

5-HETE BIOSYNTHESIS, METABOLISM, AND STRUCTURAL CONSIDERATIONS

As indicated earlier, stimulated cells release arachidonate from phospholipids. Depending on the arachidonate pools utilized and the active enzymatic machinery available within a particular cell type, liberated arachidonate is converted to a variety of bioactive compounds. In leukocytes and mast cells, for example, arachidonate is predominantly attacked by the calcium- and ATP-dependent 5-lipoxygenase. This enzyme attaches molecular oxygen to carbon 5 of the fatty acid. The product may abstract a proton to form 5-hydroperoxyicosatetraenoate (HPETE), which is rapidly reduced to 5-HETE, or, alternatively, form the 5,6-epoxide, LTA_4. This unstable epoxide is metabolized enzymatically to the dihydroxy derivative, LTB_4, or converted non-enzymatically into isomers of LTB_4 (13–18,43,44). LTB_4, but not its isomers, is an extremely potent leukocyte (45,46) and smooth muscle (46–49) stimulus. It operates by binding to specific plasmalemmal receptors (50–53). While LTB_4 is a 5,12-diHETE, and therefore contains a 5-hydroxy residue, it should be noted that LTB_4 differs from 5-HETE in double bound positions and geometry. LTB_4 is a 5(S),12(R)-dihydroxy-6-*cis*, 8-*trans*,10-*trans*,14-*cis*-eicosatetraenoate, whereas 5-HETE is a 5(S)-hydroxy-6-*trans*-8-*cis*,11-*cis*, 13-*cis*-eicosatetraenoate. The two compounds have remarkably different spacial configurations and thus may not be structural analogs with similar bioactions. On the other hand, two other endogenously formed diHETEs, 5,15-diHETE and 5,20-diHETE, are 5(S),15(R)-dihydroxy-6-*trans*, 8-*cis*,11-*cis*,13-*trans*- and 5(S),20-dihydroxy-6-*trans*, 8-*cis*,11-*cis*,13-*cis*-eicosatetraenoates. These compounds more closely resemble 5-HETE and therefore might have biological analogies to 5-HETE.

After producing 5-HETE, cells may release the product extracellularly or metabolize it further by one of two alternate routes. First, many cells incorporate 5-HETE into glycerolipids, principally triglycerides but also various species of phospholipids. This pathway proceeds rapidly but is readily saturated (54–57). The second pathway slowly converts 5-HETE to its C-20 hydroxy derivative, 5,20-diHETE. This C-20 hydroxylation may be catalyzed by the same C-20 hydroxylase that converts LTB_4 to 20-OH-LTB_4 (57,58). Note that 5,20-diHETE and 20-OH-LTB_4 are 10–100-fold less potent than their respective parent compounds (57,59–62). The potency of certain PGs also appears to be reduced by C-20 hydroxylation (63). Thus, C-20 hydroxylation generally results in the inactivation of diverse bioactive arachidonate metabolites.

BIOACTIONS OF 5-HETE

Agonist activity. In many assays, 5-HETE by itself exerts relatively weak, but nevertheless definite, bioactions (17). For example, at concentrations ≥ 1 μM, it activates leukocytes (64–73), contracts smooth muscle-containing tissues [e.g., guinea pig lung strip and human isolated bronchial muscle (74)] and releases insulin from isolated rat pancreatic cells (75), luteinizing hormone from cultured rat pituitary cells (76), mucus from human airways (77), amylase from isolated guinea pig pancreatic acini (78), and intestinal secretions from rabbit colonic mucosa (79). In most of the above studies, various other mono-HETEs were shown to be comparably inactive. Given the concentration of 5-HETE required, the physiological relevancy of these bioactions remains uncertain. On the other hand, 5-HETE exhibits one of its most potent effects in raising $[Ca^{2+}]_i$—it mobilizes calcium in human PMN at ≥ 16 nM (80–83).

5-HETE interaction with PAF. In addition to its direct actions, 5-HETE has strikingly prominent influences on certain PAF-induced responses. For example, it increases the potency of PAF in stimulating PMN degranulation and oxidative metabolism by as much as 1000-fold (84,85). Under the same assay conditions, 5-HETE by itself fails to induce function. Thus, 5-HETE potentiates PAF bioactions. 5-HETE also potentiates the PMN stimulating actions of DAG and, to a much lesser extent, LTB_4 (86). However, it has no influence on functional responses to chemotactic peptides or ionophoretic stimuli. Thus, the potentiating actions of 5-HETE are stimulus-selective and, intriguingly, restricted to those stimuli that are generated in activated cells. Other arachidonate metabolites have 5-HETE-like bioactions. For example, 5-HPETE is as potent as 5-HETE at inducing many of the above responses. In addition, 5,15-diHETE and 5,20-diHETE also potentiate the PMN degranulating actions of PAF: these compounds are ~30 and ~100-fold, respectively, less potent than 5-HETE. Various other analogs, such as 8-HETE, 11-HETE, 12-HETE, 8,15-diHETE, and LTB_4 do not promote the actions of PAF (84–88).

More recent studies reveal that 5-HETE increases the bioactions of PAF at a very fundamental level—in PMN, it potentiates the ability of PAF to activate PKC (89–92) and mobilize phospholipids (42,93,94). These activities have mechanistic implications which are discussed below.

5-HETE interaction with other stimuli. 5-HETE potentiates antigen-stimulated histamine release from human basophilic leukocytes (95,96), IgE-stimulated histamine release from rat mast cells (97), FMLP-stimulated arachidonate release from dimethylsulfoxide differentiated HL60 granulocytes (98), LTD_4-induced contractions of isolated guinea pig trachea (99) and histamine-induced contractions of isolated human bronchial muscle (74). Unfortunately, the mechanisms and consequences of these effects have not been reported.

MECHANISMS OF ACTION

It seems quite unlikely that any single mechanism will successfully explain the many diverse bioactions of 5-HETE. We suggest that 5-HETE has a multiplicity of effects, any one of which may be pertinent to a particular

response, stimulus, or assay condition. The proposed mechanisms of 5-HETE's bioactions fall into five areas.

Membrane perturbation. As noted above, PMN incorporate 5-HETE into cellular triglycerides and phospholipids (54–57). Stenson and Parker (54) have suggested that this alters membrane physiochemistry to promote function. This mechanism, however, fails to explain the agonist-selectiveness of 5-HETE. The arachidonate metabolite does not promote degranulation per se, but rather enhances the degranulation and other bioactions of a restricted few types of stimuli.

Antimetabolic action. PMN convert 5-HETE and LTB_4 to C-20 oxidized derivatives (57–61). It is likely that this oxidation is achieved by a common C-20 hydrolase. Thus 5-HETE might compete for the hydrolase to prolong the metabolic half-life and bioavailability of LTB_4. This effect could potentiate the stimulatory actions of the leukotriene. Indeed, we have observed that 5-HETE approximately doubles the half-life of LTB_4 in PMN under the same conditions in which it increases LTB_4 potency (unpublished observations). However, we find that 5-HETE does not inhibit PAF metabolism. The antimetabolic hypothesis, then, is unlikely to explain the actions of 5-HETE on PAF, the actions of 5-HETE on direct PKC activators (e.g., DAG and phorbol myristate acetate) or the ability of 5-HETE to stimulate responses by itself. However, if a significant part of the response induced by PAF or PKC activators is mediated by LTB_4, the antimetabolic hypothesis may have broader application to the potentiating actions of 5-HETE. Further investigation is required to clarify this possibility.

5-HETE receptors. The bioactions of 5-HETE resemble those of other receptor-mediated agonists in several respects. First, 5-HETE mobilizes Ca^{2+} and potentiates PAF at nanomolar concentrations. Therefore, these effects might require the amplification produced by receptors. In contrast, other actions of 5-HETE (e.g., potentiation of LTB_4) occur only in the near micromolar range—it is not certain that these findings are of more than a pharmacological interest. Second, 5-HETE bioactions are structurally-specific, as well as stereospecific. Thus, the unnatural enantiomer of 5-HETE, 5(R)-HETE is 20 to 100-fold less potent than the natural 5-HETE in raising PMN $[Ca^{2+}]_i$ and potentiating PAF. Since this unnatural 5-HETE preparation likely contained 1–3% natural 5-HETE enantiomer, the potency difference may be even more pronounced (83). In any event, these structural effects support the receptor hypothesis. Third, in PMN, 5-HETE rapidly desensitizes to itself in assays of Ca^{2+} mobilization (82) and PAF potentiation (84,88). Furthermore, PMN desensitized to 5-HETE raise $[Ca^{2+}]_i$ almost normally in response to LTB_4 or PAF (82). This stimulus-selective desensitization seems best explained as resulting from receptor down-regulation. Finally, the bioactions of 5-HETE are blocked by agents that interfere with G-protein/receptor interactions like pertussis and cholera toxins (100).

We have attempted to define PMN receptors for 5-HETE using [^{3}H]-labeled analogs. Unfortunately, the cells (as well as their isolated membrane preparations) quantitatively metabolized [^{3}H] 5-HETE as well as [^{3}H] 5-HETE methyl ester even at 4°C. This has interferred with our ability to assay these receptors. Nevertheless, the four findings listed above support further efforts to demonstrate 5-HETE receptors. Studies have demonstrated 15-HETE receptors in selected cell types (101,102).

Ca^{2+} mobilization. As discussed previously, 5-HETE potently mobilizes storage Ca^{2+} in PMN. Such mobilization raises $[Ca^{2+}]_i$ and appears responsible for increasing the PKC-activating potency of DAG as well as other direct PKC activators (81,103). It cannot explain other potentiating effects of 5-HETE. For example, 5-HETE does not enhance LTB_4-induced PKC mobilization (81). Furthermore, although 5-HETE potentiates PAF-induced PKC mobilization, studies discussed below suggest that this effect may result from a more fundamental interaction between PAF and 5-HETE.

Effects of 5-HETE on other receptors. 5-HETE exhibits little or no ability to cross-desensitize PMN to LTB_4 and PAF, or to interfere directly with the binding of these two latter ligands to their receptor sites (82). Nevertheless, 5-HETE may have a less direct actions on PAF receptors. This possibility is revealed by analyzing how PAF activates PMN. As indicated by the diagram, PAF operates in at least six discrete steps: step 1, PAF-receptor (R) binding; step 2, formation of a ternary complex with G-protein; step 3, activation of phospholipase C to cleave PIP_2; step 4, DAG mediated activation of PKC; and step 5, release of Ca^{2+} by IP_3. Concurrently, PAF also triggers a parallel pathway involving *sn*-2-cleavage of 1-*O*-alkyl-2-arachidonoyl-glycerophosphocholine (step 3a) and further metabolism of the cleavage products (step 4a and 5a). Following these steps, a complex set of poorly understood events (here termed steps 6 and 6a) produce function. Initial studies on the effects of 5-HETE in potentiating PAF-induced function indicated a site of action at or before step 6. More recent studies, however, show that 5-HETE enhances PAF-induced PKC mobilization (step 4) (81), Ca^{2+} transients (step 5) (unpublished observations) and PAF synthesis (step 4a) (42). Thus, 5-HETE appears to influence the actions of PAF at a very early stage, i.e., possibly at the PAF receptor or the receptor linked G-proteins. It therefore seems likely that 5-HETE will have a fundamental effect on the PAF transduction mechanism: the arachidonate metabolite may up-regulate PAF receptors and/or enhance these receptors' interactions with G-proteins.

CONCLUSION

5-HETE, one of many phospholipid derived products of activated cells, exerts unique bioactions and potently enhances specific agonist-induced responses. Its effects are structurally specific, stereospecific, and pertussis toxin sensitive. Furthermore, cells exposed to 5-HETE are desensitized to a second 5-HETE challenge but not to other receptor-mediated agonists. These observations suggest that 5-HETE operates through a specific receptor mechanism. However, the presence of putative 5-HETE receptors has not been demonstrated and therefore awaits documentation. In any event, the influences of 5-HETE on the bioactions of other agonists seem to reflect various mechanisms. Some of these may be "5-HETE-receptor" independent. Thus, 5-HETE may promote the bioactions of LTB_4 as well as LTB_4-dependent stimuli by directly interferring with LTB_4 metabolic inactivation. On the other hand, 5-HETE may potentiate direct PKC

activators by raising $[C_a^{2+}]_i$ through a receptor-dependent route. Finally, 5-HETE/PAF interactions could reflect 5-HETE-induced up-regulation of PAF receptors. The many other effects of 5-HETE on diverse agonists in other systems have yet to be explored. These studies will not only help decipher novel mechanisms involved in stimulus-response coupling, but also give insight into the role of multiple mediators in various biological processes.

[Received August 28, 1989; Revision accepted December 29, 1989]

Platelet-Activating Factor (PAF) Receptor Antagonists Inhibit Arachidonic Acid Induced Platelet Aggregation in Rabbit Whole Blood[1]

Alaina Jean Ammit and Chris O'Neill*
Human Reproduction Unit, Royal North Shore Hospital of Sydney, St. Leonards, 2065, N.S.W., Australia

The potency of several platelet-activating factor (PAF) receptor antagonists was measured by observing their inhibitory effects against PAF induced platelet aggregation. Their selectivity was assessed by monitoring their effect on platelet aggregation induced by arachidonic acid (AA) and adenosine diphosphate (ADP). The antagonists inhibited platelet aggregation induced at the PAF EC_{50} (0.023 μM) with the following rank order of potency: WEB 2086> WEB 2170> SRI 64-412> SRI 63-675> BN 52021> kadsurenone> SRI 63-441> alprazolam. While the antagonists had no inhibitory effect at the EC_{50} for ADP (10 μM), they did inhibit platelet aggregation induced at the EC_{50} for AA (55 μM). However, there was considerable variability in the slope of the inhibitory response and the relative potency of each antagonist against PAF induced platelet aggregation as compared to AA induced platelet aggregation. The antagonist IC_{50} (μM) against PAF and AA were as follows, with those that showed significantly different ($p < 0.01$) slopes indicated by an asterisk: SRI 63-441* (3.8, 15.1); SRI 63-675 (1.4, 36.2); SRI 64-412 (0.5, 10.5); BN 52021* (2.4, 58.9); kadsurenone* (2.8, 28.3); alprazolam* (10, 25); WEB 2086 (0.055, 0.220), and WEB 2170 (0.107, 0.534). Therefore, in rabbit whole blood the antagonists were potent, although not completely selective, inhibitors of PAF induced platelet aggregation. These results suggest that the mode of action of PAF and AA induced platelet aggregation may share some common features. However, since the slope of the inhibitory response against PAF and AA for some antagonists differed, mechanistic differences in their action appear to exist.

Lipids 26, 1189-1192 (1991).

Platelet-activating factor (PAF) induces platelet aggregation *via* receptor-mediated mechanisms. Using a rapid *in vitro* bioassay for the quantification of platelet aggregation (1), our aim was to measure the potency and selectivity of several PAF receptor antagonists in rabbit whole blood. The antagonists examined were either synthesized compounds based on the PAF structure, such as SRI 63-441, SRI 63-675 and SRI 64-412; natural products, such as the terpene, BN 52021 and the neolignan, kadsurenone; or pharmacological agents such as the triazolobenzodiazepine alprazolam and the thienotriazolobenzodiazepines, WEB 2086 and WEB 2170. Antagonist potency was measured by observing their inhibitory effects at PAF EC_{50} (*i.e.*, the effective concentration required to induce 50% platelet aggregation), and was expressed as the IC_{50} (*i.e.*, the lowest concentration required to totally inhibit the EC_{50}). Antagonist selectivity was assessed by monitoring their effect on the platelet aggregation induced at the EC_{50} for arachidonic acid (AA) and adenosine diphosphate (ADP).

MATERIALS AND METHODS

Whole blood (0.8 volumes) was collected, using 20G teflon catheters (Surflo, Terumo, Tokyo, Japan), from the marginal ear vein of male New Zealand White rabbits into 0.2 volumes of citrate 3.2% (w/v) (trisodium salt-dihydrate, Sigma Chemicals Co., St. Louis, MO). The citrated rabbit whole blood was added, in 50 μL aliquots, to each of the eight wells of a teflon micromixing device, followed by 25 μL of antagonist/vehicle. After a 30-sec temperature equilibration period, 25 μL of the agonist EC_{50}/vehicle was added. A 10 μL sample was taken immediately and after 15 min incubation at 37°C for counting of the single, non-aggregated platelets (3–24 μm^3) using the Baker Instruments Series 810 Platelet Analyzer (Baker Instruments, Allentown, PA). The results were expressed as the platelet aggregation index, *i.e.*, $1\text{-}P_{15}/P_0$, where P_{15} and P_0 are the platelet count at 15 and 0 min, respectively. Therefore, an index of 0 signifies no platelet aggregation and, conversely, 1 is total platelet aggregation. The platelet count for male New Zealand White rabbits was approximately $250 \times 10^3/\mu L$, and there was minimal variation between experimental animals. The bioassay was performed immediately after blood collection.

PAF receptor antagonists examined were: SRI 63-441 (*cis*-(±)-1-[2-[hydroxy[[tetrahydro-5-[(octadecylaminocarbonyl)oxy]methyl]furan-2-yl]methoxy-phosphinyloxy]-ethyl]quinolinium hydroxide, inner salt; Sandoz Research Institute, East Hanover, NJ) dissolved in calcium/magnesium-free phosphate buffered saline (PBS) (140 mM NaCl, 2.6 mM KCl, 8.1 mM Na_2HPO_4, 1.5 mM KH_2PO_4; Sigma); SRI 63-675 (*cis*-(±)-1-[2-[hydroxy[[tetrahydro-2, 5-dimethyl-5-[(octadecylaminocarbonyl)oxy]methyl]furan-2-yl]methoxy-phosphinyloxy]ethyl]quinolinium hydroxide, inner salt; Sandoz) dissolved in PBS; SRI 64-412 (5-[4'-(3,4,5-trimethoxy phenylethyl)phenyl]-2,3-dihydroimidazo[2,1-a]isoquinoline hydrochloride; Sandoz) dissolved in 2% (v/v) acetic acid (AR grade; BDH Chemicals, Melbourne, Vic., Australia) in distilled water; BN 52021 (9H-1,7a-(epoxymethano)-1H,6a-H-cyclopenta-[c]-furo[2,3-b]furo[3',2':3,4]cyclopenta[1,2-d]furan-5,9,12-(4H)-trione,3-*tert*-butylhexahydro-4,7b-11-hydroxy-8-methyl; IHB-IPSEN, Le Plessis Robinson, France) dissolved in methanol (AR grade; BDH); kadsurenone (2-(3,4-dimethoxyphenyl)-2,3-dihydro-3a-methoxy-3-methyl-5-(allyl)-6-2H-oxobenzofuran; Merck, Sharp and Dohme Research Laboratories, Rahway, NJ) dissolved in ethanol (AR grade; BDH); alprazolam(8-chloro-1-methyl-6-phenyl-4H-2-tri-

azolo[4,3-a][1,4]benzodiazepine; Upjohn, Kalamazoo, MI) dissolved in ethanol; WEB 2086 (3-[4-(2-chlorophenyl)-9-methyl-6H-thieno[3,2-f][1,2,4]triazolo-[4,3-a][1,4]diazepin-2-yl]-1-(4-morpholinyl)-1-propanone; Boehringer Ingelheim KG, Ingelheim am Rhein, Germany) dissolved in PBS; and WEB 2170 (6-(2-chloro-phenyl)-8,9-dihydro-1-methyl-8-(4-morpholinyl-carbonyl)-4H,7H-cyclopenta[4,5]-thieno[3,2-f][1,2,4]triazolo-[4,3-a][1,4]diazepine; Boehringer Ingelheim) dissolved in PBS. All dilutions were in PBS.

Activators used were: PAF (1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; Sigma) dissolved in chloroform (AR grade; BDH), solvent was evaporated with N_2 and the sample was resuspended and diluted in PBS containing 0.25% (w/v) bovine serum albumin (CSL, Melbourne, Vic., Australia); AA (from porcine liver; Sigma) dissolved in ethanol, solvent was evaporated with N_2 and the sample was resuspended in 10 mM Na_2CO_3 (Sigma) and diluted in 0.9% (w/v) NaCl (Sigma); and ADP (sodium salt, grade I, from equine muscle; Sigma) dissolved and diluted in 0.9% NaCl. The concentrations of activators used were the EC_{50} as determined in a previous study (1).

Statistical analysis was performed by estimating regression models for the linear section of the inhibition dose-response curve (after correcting for differences in antagonist concentration), and by examining equality of slopes by analysis of covariance.

RESULTS

PAF receptor antagonists inhibited platelet aggregation induced by PAF at the EC_{50} (0.023 μm) in rabbit whole blood with the following rank order of potency: WEB 2086> WEB 2170> SRI 64-412> SRI 63-675> BN 52021> kadsurenone> SRI 63-441> alprazolam.

While the antagonists had no inhibitory effect at the EC_{50} for ADP (10 μM), they did inhibit platelet aggregation induced at the EC_{50} for AA (55 μM). The IC_{50} of the antagonist, the slope of the inhibitory response, and the relative potency of each antagonist against PAF and AA induced platelet aggregation are given in Table 1. Half of the antagonists examined showed significantly different ($p < 0.01$) slopes for the inhibition of PAF induced platelet aggregation as compared to AA induced platelet aggregation. Also, the relative potency of each PAF receptor antagonist ranged widely, *i.e.*, from 2.5 to 25.8. Based on these differences, the antagonists can be categorized into four groups: i) Those with parallel slopes and small differences in relative potency, *i.e.*, WEB 2086 and WEB 2170; ii) those with different slopes and small differences in relative potency, *i.e.*, SRI 63-441 and alprazolam; iii) those with parallel slopes and large differences in relative potency, *i.e.*, SRI 63-675 and SRI 64-412; and iv) those with different slopes and large differences in relative potency, *i.e.*, BN 52021 and kadsurenone. The inhibitory responses for antagonists that are representative of each group are shown in Figure 1 (a-d).

TABLE 1

Effect of PAF Receptor Antagonists on PAF Induced and Arachidonic Acid Induced Platelet Aggregation in Rabbit Whole Blood[a]

Antagonist	PAF		AA		Relative potency
	IC_{50} (μM)	Slope	IC_{50} (μM)	Slope	
SRI 63-441[b]	3.8	−0.10	15.1	−0.02	4.0
SRI 63-675	1.4	−0.28	36.2	−0.28	25.8
SRI 64-412	0.5	−0.79	10.5	−0.78	21.0
BN 52021[b]	2.4	−0.18	58.9	−0.06	24.5
Kadsurenone[b]	2.8	−0.15	28.3	−0.04	10.1
Alprazolam[b]	10.0	−0.03	25.0	−0.09	2.5
WEB 2086	0.055	−6.15	0.220	−6.12	4.0
WEB 2170	0.107	−3.64	0.534	−2.96	5.0

[a]The IC_{50} (μM), the slope of the inhibitory response and the relative potency of each PAF receptor antagonist against platelet aggregation induced at the EC_{50} for PAF (0.023 μM) and AA (55 μM) after 15 min incubation were determined with citrated rabbit whole blood.

[b]Significantly different slopes at $p < 0.01$.

To investigate whether the antagonists affected any of the whole blood cellular constituents or were acting as partial agonists, high concentrations of antagonists alone were incubated with rabbit whole blood and examined for blood smear abnormalities or platelet aggregation by phase contrast microscopy. WEB 2086 and WEB 2170 had no effect on the morphology of any of the whole blood cells when tested up to 55 μM, while SRI 63-441 and SRI 63-675 caused platelet and erythrocyte lysis at 150 μM and 362 μM, respectively. None of these antagonists acted as partial agonists. There was difficulty, however, in performing the same examinations with antagonists dissolved in non-aqueous solvents, since the solvent alone can cause non-specific effects. The solvent for SRI 64-412 was 2% acetic acid in distilled water. At a concentration of 25000 ppm in citrated rabbit whole blood this solvent caused platelet and erythrocyte lysis (unpublished data). The solvent for BN 52021 was methanol, while kadsurenone and alprazolam were dissolved in ethanol. Methanol and ethanol at 100000 and 25000 ppm, respectively, completely blocked the ability of platelets to respond to an activating signal, since they non-specifically inhibited platelet aggregation induced by ADP, AA and PAF (unpublished data). Therefore, due to the properties of the solvent, the highest antagonist concentrations that could be tested were 21, 118, 28 and 25 μM for SRI 64-412, BN 52021, kadsurenone and alprazolam, respectively. At these concentrations the antagonists did not affect the morphology of the whole blood cellular constituents or induce platelet aggregation. Therefore, we can exclude the possibility that the results obtained in this study were due to the PAF-receptor antagonists acting as partial agonists or causing haemolysis of platelets or erythrocytes.

DISCUSSION

In rabbit whole blood, PAF receptor antagonists were potent inhibitors of PAF induced platelet aggregation. The slope of the inhibition response was correlated with antagonist potency, and reflects the differing affinities of the antagonists for the platelet PAF receptor (2). Comparative studies on the potency of PAF receptor antagonists are rare, and this is the first which performs the examination on whole blood. Since various experimental conditions can affect PAF-induced platelet aggregation, antagonist potency obtained from separate experiments cannot be strictly compared. Therefore, it is difficult to relate our

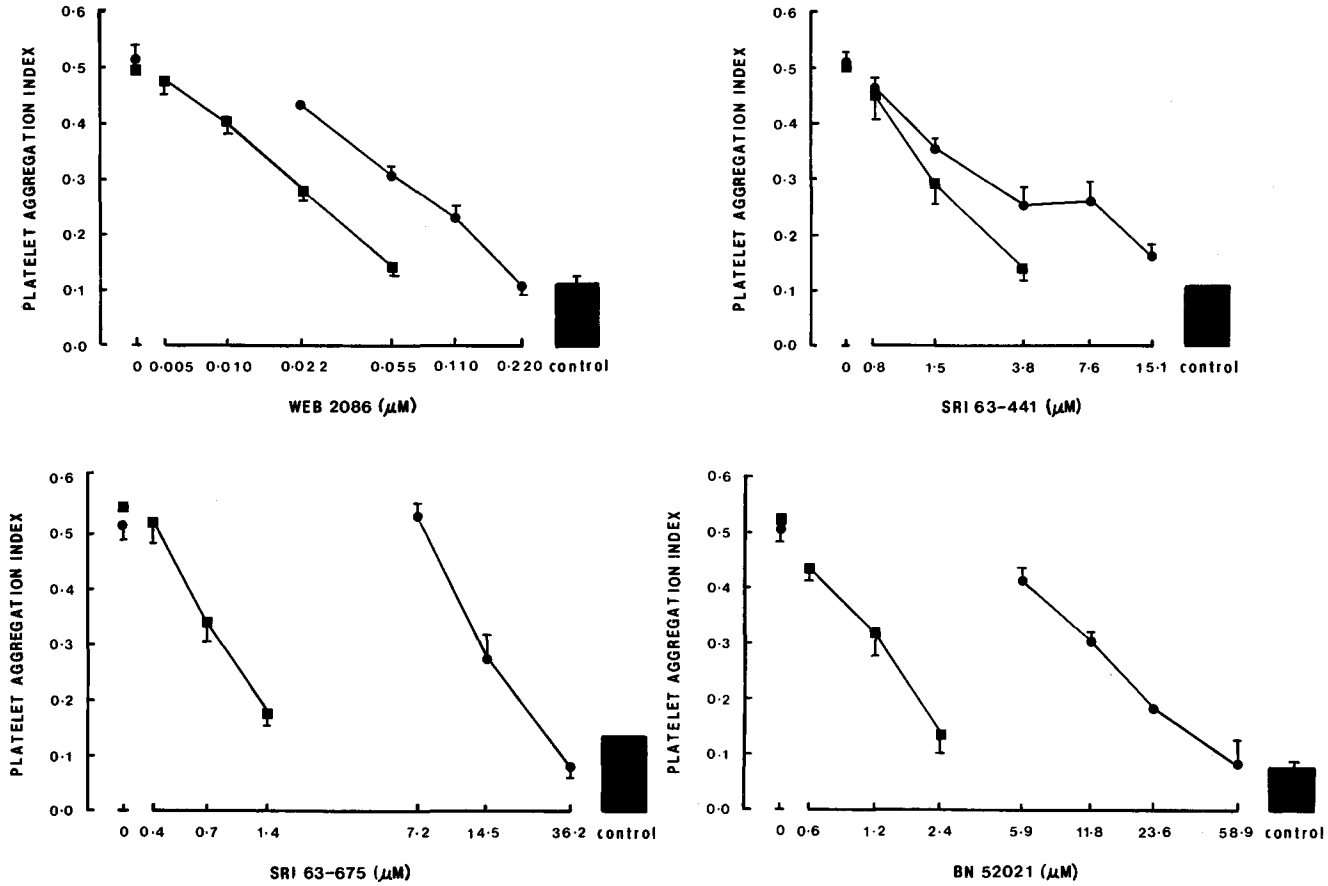

FIG. 1. Effect of increasing concentrations of PAF receptor antagonists on platelet aggregation induced at the EC_{50} for PAF (0.023 μM; ■) and AA (55 μM; ●), after 15 min incubation with citrated rabbit whole blood. Each point represents the mean ± SEM of ⩾ 3 replicates. The effect of vehicle alone is represented by the histogram (control), which is the mean ± SEM of ⩾ 11 replicates.

results to published values. However, some of the antagonists used in this study were examined in a comparative study with human platelet-rich plasma using turbidometric aggregometry (3). These authors obtained a similar rank order of potency, WEB 2086> BN 52021> kadsurenone> alprazolam.

The PAF receptor antagonists were not completely selective for PAF since, at concentrations that were 2.5- to 25.8-fold higher than required for the inhibition of PAF, they also inhibited platelet aggregation induced by AA. For four of the eight PAF receptor antagonists studied, *i.e.*, SRI 63-675, SRI 64-412, BN 52021 and kadsurenone, the antagonist concentration required to inhibit AA induced platelet aggregation were 10-fold higher than those required for PAF. Although this may be considered reasonably selective by pharmacological standards, these results are in contrast to previous reports where PAF receptor antagonists were shown to have either no effect on AA induced platelet aggregation (4,5), or only minimal effects requiring concentrations that were 200- to 1100-fold higher than those required for inhibition of PAF (6,7). These studies were performed using isolated human platelets.

There are a number of possible explanations for the inhibition of AA induced platelet aggregation by PAF receptor antagonists, although we are not able to define the actual mechanism from this study. The effect could be due to either inhibition of the (membrane-associated) enzymes responsible for the conversion of AA to its activator products, prostaglandin G_2, prostaglandin H_2 and thromboxane A_2; or *via* direct competitive inhibition of the platelet receptor for these AA metabolites. Currently there is no literature supporting these suggestions. A more likely explanation, given the mixed population of cells in whole blood and the increasing evidence supporting the involvement of AA in PAF induced platelet aggregation (8,9), is that PAF may be involved in AA induced platelet aggregation. This could be either autocrine (*i.e.*, AA induces platelets to produce PAF) or paracrine (*i.e.*, generation of PAF by other cells in the whole blood, *e.g.*, neutrophils). Although there was a general trend for the slope of the inhibitory response against AA induced platelet aggregation to be similar to that against PAF in magnitude, half of the antagonists showed significant differences. This, together with the wide range of relative potency observed, suggests that the inhibitory effect of the antagonists on AA induced platelet aggregation is not solely *via* a direct competitive inhibition of the platelet PAF receptor. Therefore, the PAF receptor antagonists may be demonstrating intrinsic pharmacological selectivity for the PAF receptor, as previously demonstrated in defined systems which examined isolated cell types, but

the results are a reflection of the mixed population of cells in whole blood and the poorly understood complex interplay understood complex interplay between PAF and AA metabolites.

Therefore, in an *in vitro* bioassay which uses whole blood to closely mimic the *in vivo* situation, PAF receptor antagonists were potent, although not completely selective inhibitors of PAF induced platelet aggregation. To clarify the nature of the inhibition of AA induced platelet aggregation by PAF antagonists, and to allow a better comparison with previous data, it would be of interest to perform these experiments with rabbit platelets prepared as platelet-rich plasma and/or washed platelets, and to examine human platelet responses as well. Our results would appear to be relevant to *in vivo* studies using PAF receptor antagonists and indicate that whole blood seems more appropriate for the *in vitro* assessment of antagonist selectivity.

ACKNOWLEDGMENTS

The authors would like to thank Michael P. Jones for his assistance with the statistical analysis, and the following companies for their generous gifts of PAF receptor antagonists: Sandoz Research Institute; IHB-IPSEN; Merck, Sharp and Dohme Research Laboratories; Upjohn; and Boehringer Ingelheim.

We investigated the effects of platelet-activating factor (PAF) on guinea pig peritoneal macrophages. Specific and high-affinity binding sites for PAF were detected on guinea pig peritoneal macrophages. Scatchard analysis of PAF binding revealed high affinity binding sites (7.9×10^4/cell) with a dissociation constant of 2.3×10^{-10} M. When treated with 10^{-9}–10^{-5} M PAF, guinea pig peritoneal macrophages released hydrogen peroxide into the medium in a time-dependent manner. The release reaction upon stimulation with 10^{-5} M PAF reached a plateau within 30 min and the extent of release was twice as high as that when stimulated by *N*-formyl-L-methionyl-leucyl-L-phenylalanine (fMLP; 2 μM)-treated cells. Neither lysoPAF nor the PAF enantiomer was effective. PAF-induced H_2O_2 release was inhibited specifically by PAF antagonists, suggesting that PAF activated macrophages through binding to specific sites. Lysosomal enzyme (*N*-acetyl-β-D-glucosaminidase) was released from guinea pig peritoneal macrophages upon treatment with 10^{-5} M PAF for 60 min. Guinea pig peritoneal macrophages were treated with PAF for 8 hr and the conditioned medium was examined for cytokines. The medium exhibited cytocidal activity against mouse fibroblast L929 cells [tumor necrosis factor (TNF) activity], and this activity was comparable to that detected after treatment of cells with the bacterial lipopolysaccharide (LPS). Furthermore, the same conditioned medium also showed colony-stimulating factor (CSF) activity. Generation of these cytokines was stereospecific. Our findings suggest that PAF is a unique macrophage activator that potentiates both respiratory burst/lysosomal enzyme release (early-phase response) and monokine production/glucose consumption (late-phase response).

***Lipids* 26, 1193-1199 (1991).**

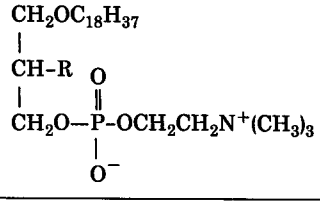
Since its discovery, platelet-activating factor (PAF) has been widely viewed as an inflammatory mediator of various physiological and pathological reactions. In addition, recent evidence suggests that PAF is a potent modulator of cellular immune response (1). Cells of the macrophage/monocyte lineage produce PAF upon stimulation. It has also been shown that macrophages or related cells respond to PAF when activated under certain conditions. We have previously reported that PAF stimulated glucose consumption of guinea pig peritoneal macrophages through its binding to specific sites on the cells (2). Hartung (3) showed that PAF stimulated oxidative burst in macrophages. Production of monokines such as tumor necrosis factor (TNF) or interleukin-1 (IL-1) by human monocytes in response to PAF has also been observed (4,5). Recently, specific binding sites for PAF on human peripheral monocytes were detected (6).

In the present study, we examined the effect of PAF on macrophages. The possible role of PAF in the regulation of macrophage function under physiological and pathological conditions will be discussed.

MATERIALS AND METHODS

Chemicals. Fetal bovine serum (FBS) and RPMI1640 medium were obtained from Hy Clone Laboratories (Logan, UT) and MA Bioproducts (Walkerville, MD), respectively. Eagle's minimum essential medium (EMEM) and Hank's balanced salt solution (HBSS) were obtained from Nissui Pharmaceutical Co. Ltd. (Tokyo, Japan). LPS (lipopolysaccharide W, *E. coli* 0127:B8) and Freund's complete adjuvant were obtained from Difco Laboratories (Detroit, MI). 5-Hydroxy-6,8,11,14-eicosatetraenoic acid (5-HETE) and leukotriene B_4 (LTB_4) were purchased from Cayman Chemical Co. (Ann Arbor, MI). Other chemicals were obtained from Sigma Chemical Co. (St. Louis, MO).

PAF, PAF agonists and PAF antagonists. PAF, racemic 1-*O*-octadecyl-2-*O*-(*N*,*N*-dimethylcarbamoyl)-glycero-3-phosphocholine (dimethylcarbamoyl-OGPC), racemic 1-*O*-octadecyl-2-acetamido-2-deoxyglycero-3-phosphocholine (acetamido-OGPC), 1-*O*-ocdadecyl-2-*O*-methyl-*sn*-glycero-3-phosphocholine [methyl-OGPC(*sn*-3)], 3-*O*-octadecyl-2-*O*-methyl-*sn*-glycero-1-phosphocholine [methyl-OGPC(*sn*-1)] (2) and the PAF antagonists, CV6209 (7) and NT176, were provided by Takeda Chemical Industries (Osaka, Japan). Respective structures of PAF and its analogs are listed in Scheme 1. FR900452 (8) was kindly provided by Fujisawa Pharmaceutical Co. (Osaka, Japan). [^{3}H]Octadecyl PAF (80 Ci/mmol) was obtained from Amersham (Buckinghamshire, U.K.).



Animals and macrophage preparation. Female Hartley guinea pigs (body weight 300–500 g) and fe-

male Japanese white rabbits (body weight 1.5–2.5 kg) were obtained from Japan Biosupply (Tokyo, Japan). Specific pathogen-free female ICR mice (7–10-wk-old) were purchased from Japan SLC, Inc. (Hamamatsu, Japan). Guinea pig peritoneal exudate cells (PEC) were prepared as described previously (2). Murine PEC were prepared by induction with casein, as described previously (9,10). Rabbit alveolar macrophages were prepared from pulmonary lavage fluid of rabbits injected intravenously with 1 mL Freund's complete adjuvant 3 wk before the animals were killed.

Measurement of H_2O_2 release from macrophages. Release of H_2O_2 from macrophages was measured by a modification of the procedure described by Cohen *et al.* (9). PEC (2.5×10^6 cells/mL) suspended in RPMI 1640/10% FBS were cultured in wells of 24-well multiplates (25820, Corning, NY) at 37°C for 150 min in an atmosphere of 5% CO_2 in air. After culture, the plates were rinsed twice with warm HBSS and then incubated in 1.0 mL HBSS (without phenol red) containing 10 μM scopoletin, 1 mM NaN_3 and 5 U/mL horseradish peroxidase. After 60 min of incubation, the cells were quickly chilled on ice and centrifuged at 500 $\times g$ for 5 min. Then 0.2-mL aliquots of the cell culture were transferred to wells of 96-well multiplates (Imuron 2, flat bottom), and the fluorescence at 450 nm upon activation by 365-nm light was measured using a microplate reader (MTP-32, Corona, Ibaraki, Japan). The difference in fluorescence between preparations incubated with and without peroxidase was converted to the concentration of H_2O_2 released from the cells.

Lysosomal enzyme secretion. The activity of secreted *N*-acetyl-β-D-glucosaminidase was determined by the method of Homma *et al.* (11). Guinea pig peritoneal macrophage monolayers (3×10^5 cells/mL) prepared in the wells of 96-well multiplates (flat bottom) were preincubated in 1.0 mL of HBSS (without phenol red) containing 5 μg/mL cytochalasin B for 10 min at 37°C, and cultured with PAF and its analogs (10^{-5} M) for 60 min at 37°C in an atmosphere of 5% CO_2 in air. The cells were quickly chilled on ice and centrifuged at 500 $\times g$ for 10 min at 37°C. Fifty microliters of supernatant was incubated with 4 mM *p*-nitrophenyl-*N*-acetyl-β-D-glucosaminide in 0.05 M sodium citrate buffer (pH 4.5) in a total volume of 500 μL for 30 min at 37°C. The reaction was terminated by the addition of 0.4 M glycine/NaOH buffer (pH 10.5). The nitrophenol released was measured at 410 nm. Total enzyme activity within macrophages (100% activity) was determined by addition of 0.1% Triton X-100.

Preparation of culture medium of guinea pig peritoneal macrophages and TNF assay. PEC at 5×10^6 cells per 2 mL were placed in one well of a 6-well culture plate (25810, Corning) and incubated for 150 min at 37°C in a 5% CO_2 incubator. Non-adherent cells were removed by washing with warmed HBSS 3 times. EMEM/10% FBS-containing stimulants were then added. After a predetermined incubation period, culture supernatants were harvested and centrifuged at 500 $\times$ *g* for 5 min. Cell-free supernatants were dialyzed against RPMI 1640 medium containing 0.1% bovine serum albumin (BSA). The supernatants were then filtered with a disposable syringe filter (21053 FCA, Corning). The activity of TNF was determined by the L929 fibroblast cell lytic assay according to Tamatani *et al.* (12). Fifty μL of an appropriate dilution of culture medium and 50 μL of a L929 cell suspension (2.5×10^4 cells) in the presence of actinomycin D (1 μg/mL) were added to flat-bottomed, 96-well tissue culture plates. After 18-hr culture, the plates were washed and the degree of cell lysis was determined by staining the plates with 0.1% crystal violet in methanol/water (1:4, v/v). The dye-stained cells were solubilized with 0.1 mL of 1% SDS and absorbance at 550 nm was measured by a microplate reader (MTP-32, Corona). One unit of TNF activity was defined as the reciprocal of the sample dilution that lysed 50% of the test cells.

Quantitation of PAF binding. [^{3}H]PAF binding to macrophages was measured by a modification of the procedure decribed previously (13). Guinea pig peritoneal macrophages were prepared by the method of Kumagai *et al.* (14). [^{3}H]PAF solution (50 μL) with or without a 1000-fold molar excess of unlabeled PAF was added to 200 μL of macrophage suspension (2.5×10^6 cells per mL) in Ca^{2+}, Mg^{2+}-free HBSS with 0.1% BSA (binding buffer) in an Eppendorf tube (1.5 mL). After incubation at 24°C for 10 min, 200 μL of the cell suspension was filtered through a glass fiber filter (GF/C, Whatman, Maidstone, England) using a vacuum apparatus (SM16547, Sartorius, Goettingen, Germany) attached to an aspirator. Each filter was rapidly washed four times with 5 mL of ice-cold binding buffer and dried. Radioactivity bound to filter was then measured.

RESULTS

Specific binding of PAF to macrophages. Guinea pig peritoneal macrophages were examined for specific binding sites for PAF. At 24°C, PAF binding reached plateau saturation within 10 min, and minimal PAF metabolism was observed at the time when binding saturation was achieved (data not shown). The total amount of radioactive PAF bound to the cells increased when more radioactive PAF was added to the cell suspension. Non-specific binding, the binding of radioactive PAF in the presence of a 1000-fold molar excess of non-labeled PAF was not saturable, whereas specific binding (total binding minus non-specific binding) was saturable (Fig. 1A). Two dis-

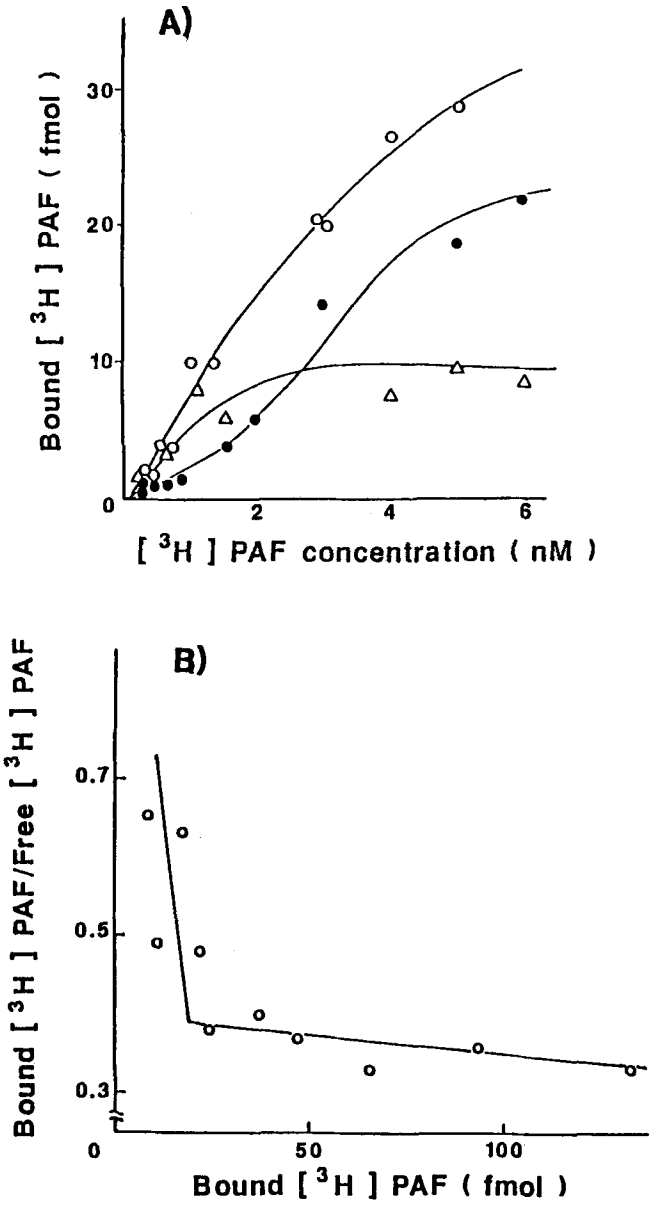

FIG. 1. (A) Binding of PAF to guinea pig peritoneal macrophages. Experiments were performed as described in Materials and Methods. Total binding, ○; non-specific binding, ●; specific binding, △. Each point is the mean of triplicate determinations; standard deviation is less than 10% of the count. (B) Scatchard plot of [^{3}H]PAF binding data.

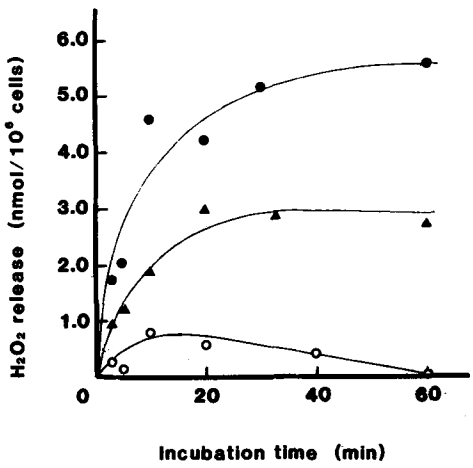

FIG. 2. Kinetics of H_2O_2 release from guinea pig peritoneal macrophages. Macrophages were treated with 10^{-6} M PAF or 2×10^{-6} M fMLP in HBSS containing 10 μM scopoletin, 1 mM NaN_3, and 5 U/mL horseradish peroxidase at the indicated times. Generation of H_2O_2 was determined as described in Materials and Methods. PAF, ●; fMLP, ○; control, △.

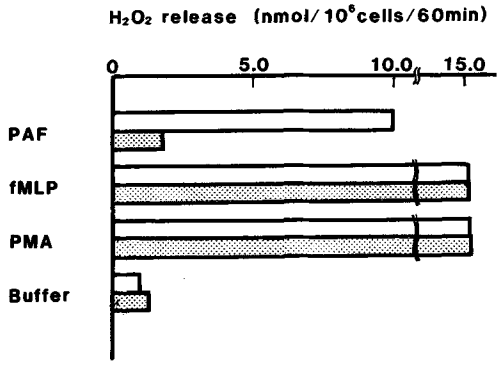

FIG. 3. Desensitization of H_2O_2 release from guinea pig peritoneal macrophages by PAF. Macrophages were incubated with (grey bars) or without (open bars) 10^{-8} M PAF for 10 min, washed, and then stimulated with PAF (10^{-5} M), fMLP (2×10^{-6} M) or PMA (6×10^{-7} M) for 60 min.

tinct binding sites for PAF were tentatively determined by Scatchard plot analysis. One of the sites exhibited high affinity of Kd = 2.3×10^{-10} M and a capacity of 7.9×10^4 binding sites per macrophage (mean, n = 3). The other site, with a substantially lower affinity and greater binding capacity, probably corresponds to nonreceptor-related uptake of PAF into the membrane.

Generation of H_2O_2 from macrophages by PAF. Generation of active oxygen was induced in guinea pig peritoneal macrophages upon incubation with 10^{-5} M of PAF. The H_2O_2 generation reached a plateau within 30 min (Fig. 2). The chemotactic peptide, fMLP (2 μM), also released H_2O_2 from the macrophages with the same time course as did PAF. PAF and dimethylcarbamoyl-OGPC were the most active in releasing H_2O_2, followed by acetamido-OGPC (Table 1), whereas no appreciable release was observed with methyl-OGPC (*sn*-3), the PAF enantiomer, or lysoPAF. The effects of a series of PAF agonists on macrophages roughly parallelled their relative potencies in inducing platelet activation, as determined by serotonin release from washed guinea pig platelets, except for methyl-OGPC (Table 1). These findings indicated that PAF induced the release of H_2O_2 through a recognition mechanism similar to that of platelets.

We performed desensitization experiments to clarify whether H_2O_2 release by PAF was induced through a specific recognition mechanism. Macrophages were preincubated in the presence of PAF at a low dose (10^{-8} M) with 5 mM ethyleneglycol *bis*(β-aminoethyl-ether)*N*, *N*, *N'*, *N'*-tetraacetic acid (EGTA) for 10 min at 37°C.

TABLE 1

Effects of PAF and Its Agonists on Guinea Pig Macrophages and Platelets[a]

	H_2O_2 release from macrophages (ED_{50}; M)	Serotonin release from platelets (ED_{50}; M)
PAF	5.0×10^{-9}	2.9×10^{-10}
Dimethylcarbamoyl-OGPC	5.8×10^{-9}	5.5×10^{-10}
Acetamido-OGPC	1.6×10^{-7}	3.4×10^{-8}
Methyl-OGPC (*sn*-3)	$> 10^{-6}$	1.4×10^{-6}

[a]H_2O_2 release from guinea pig peritoneal macrophages was measured as described in Figure 2. [^{14}C]Serotonin release from guinea pig platelets was measured as described previously (2). Effective doses of PAF or its agonists required for 50% maximum activation were determined.

TABLE 2

Effects of PAF Antagonists on H_2O_2 Release from PAF-Induced Guinea Pig Peritoneal Macrophages[a]

		H_2O_2 release nmol/10^6 cells/60 min (% of control)

PMA	6×10^{-7} M	15.24 (99.7)	15.26 (99.8)	15.29 (100)
Control		1.88 (119.0)	1.74 (110.1)	1.58 (100)

[a]Macrophages were pretreated with PAF antagonists, NT176 (10^{-6} M) or FR900452 (10^{-6} M), for 10 min before stimulation.

TABLE 3

H_2O_2 Release from Macrophages of Various Animal Species[a]

		H_2O_2 release (nmol/10^6 cells/60 min)		
Stimulants		Guinea pig peritoneal macrophages	Rabbit alveolar macrophages	Mouse peritoneal macrophages
PAF	10^{-6} M	6.43	7.02	1.25
	10^{-8} M	6.41	n.d.	1.95
PMA	6×10^{-7} M	8.36	7.22	5.26
Control		1.03	5.65	2.02

[a]H_2O_2 release from guinea pig peritoneal macrophages, rabbit alveolar macrophages and caseinate-induced murine peritoneal macrophages were determined as described in Figure 2; n.d., not determined.

Under these conditions, no appreciable induction of H_2O_2 was detected. After washing the cells, H_2O_2 release by 10^{-5} M PAF was suppressed almost to the basal state (88% suppression) (Fig. 3). This was also observed after addition of low amounts of the PAF agonist, dimethylcarbamoyl-OGPC (data not shown). By comparison, fMLP or phorbol myristate acetate (PMA) induced H_2O_2 release from the PAF-desensitized macrophages in the same manner as non-treated macrophages. These results suggested that desensitization by PAF was stimulus-dependent. Moreover, the PAF antagonists, NT176 and FR900452, specifically inhibited the generation of H_2O_2 by PAF, but they did not inhibit the reaction induced by PMA (0.6 μM) (Table 2).

Species differences in H_2O_2 release from macrophages. Table 3 shows the release of H_2O_2 from macrophages of various species. Treatment of rabbit alveolar macrophages with PAF or its agonist, dimethylcarbamoyl-OGPC, caused a similar amount of H_2O_2 release as PMA. Unlike guinea pig and rabbit macrophages, casein-induced or resident murine peritoneal macrophages failed to demonstrate enhanced H_2O_2 release in response to either PAF or dimethylcarbamoyl-OGPC, whereas PMA (0.6 μM) stimulated the release of H_2O_2 from the murine macrophages. One possible explanation for the non-responsiveness to PAF may be a lack of specific binding of PAF to cells; we therefore carried out PAF binding assays on rabbit and mouse macrophages. Rabbit alveolar macrophages carried saturable specific binding sites for PAF (Kd = 9.4×10^{-10} M, 8.1×10^4 sites/cell). By contrast, we couldn't detect the specific binding of PAF to murine peritoneal macrophages

TABLE 4

Effect of EGTA on H_2O_2 Release from Guinea Pig Peritoneal Macrophages[a]

Stimulants		H_2O_2 release nmol/10^6 cells/60 min (% of control)	
		Control	EGTA 5 mM
PAF	10^{-5} M	7.06 (100)	3.05 (43.2)
	10^{-8} M	4.40 (100)	0.68 (15.5)
fMLP	2×10^{-6} M	8.41 (100)	0.13 (1.5)
Control		0.07	0

[a]5 mM EGTA was added 10 min prior to PAF or fMLP treatment.

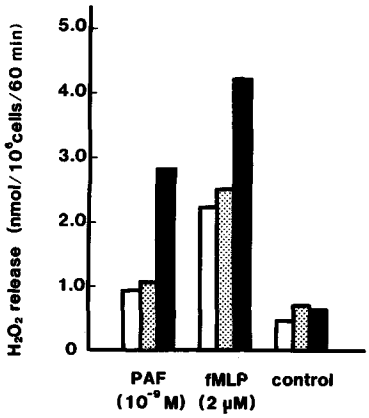

FIG. 4. Effect of 5-HETE on H_2O_2 release from macrophages treated with PAF. Macrophages were incubated with PAF (10^{-9} M) or fMLP (2 μM) in the absence (open bars) or presence of 5-HETE (50 nM, grey bars; 500 nM, solid bars).

in this study (data not shown). Casein-induced rat peritoneal macrophages had no appreciable, specific binding sites for PAF (data not shown).

Mode of action of PAF in H_2O_2 release. The presence of EGTA in the medium suppressed the PAF-induced generation of H_2O_2 by macrophages (Table 4). An antagonist of calmodulin [*N*-(6-aminohexyl)5-chloro-1-naphthalene sulfonamide; W-7] at 10^{-4} M and an intracellular Ca^{2+} chelator [8-(*N*,*N*-diethylamino)octyl-3,4,5-trimethoxybenzoate; TMB-8] at 10^{-3} M inhibited the PAF-induced generation of H_2O_2 appreciably (49% and 74%, respectively). PAF-induced H_2O_2 release was effectively inhibited by nordihydroguaiaretic acid (NDGA); addition of 1, 3, 10, or 30 μM NDGA to the incubation mixture suppressed the H_2O_2 generation to 81, 44, 16, or 3.5% of the control, respectively. This observation strongly suggested that the response was mediated by some lipoxygenase product(s). A low dose (10^{-9} M) of PAF induced no appreciable release from the cells. In the presence of 500 nM 5-HETE, however, stimulation of H_2O_2 release by PAF was observed (Fig. 4). 5-HETE alone failed to induce any H_2O_2 release at this concentration, suggesting that 5-HETE stimulates the PAF-induced reaction synergistically. Another lipoxygenase product, LTB_4, had no effect up to a concentration of 1 mM.

TABLE 5

Effects of PAF or Its Analogs on *N*-acetyl-β-D-glucosaminidase Secretion from Guinea Pig Peritoneal Macrophages[a]

PAF analogs	Control (%)
PAF	24.6 ± 1.3
Dimethylcarbamoyl-OGPC	26.4 ± 1.3
Acetamido-OGPC	29.1 ± 3.3
Methyl-OGPC (*sn*-3)	19.4 ± 4.6
LysoPAF	8.4 ± 2.1
Enantio-PAF (*sn*-1)	4.9 ± 2.3

[a]Experiments were performed as described in Materials and Methods. Results are expressed as percentage of total activity within macrophages (cells lysed with 0.1% TritonX-100).

(10^{-8} M)		25.5	
Control		11.2	

[a]Macrophages were treated with stimulants for the indicated times, and the culture supernatants were collected. The TNF activity in culture supernatants was measured as described in Materials and Methods.

TABLE 7

CSF Activity Released from Guinea Pig Peritoneal Macrophages[a]

Stimulants		Number of colonies (colonies/plate)
PAF	(10^{-5} M)	258
Methyl-OGPC (*sn*-3)	(10^{-5} M)	271
Methyl-OGPC (*sn*-1)	(10^{-5} M)	31
LPS	(1.0 μg/mL)	178
Control		1

[a]Conditioned medium of guinea pig peritoneal macrophages treated with 10^{-5} M PAF, methyl-OGPC or 1 μg/mL LPS for 6 hr was examined for ability to induce colonies of guinea pig bone marrow cells in the semisolid medium. After 7 days of culture, the numbers of colonies formed were counted.

Indomethacin, a cyclooxygenase inhibitor, had no effect or only a slightly stimulatory effect on H_2O_2 release (data not shown).

Release of lysosomal enzyme. The macrophages were incubated in the presence of cytochalasin B, together with PAF or its analogs, for 60 min. Release of *N*-acetyl-β-D-glucosaminidase was induced by PAF or its agonists (dimethylcarbamoyl- and acetamido-OGPC) (Table 5). No appreciable release of lactate dehydrogenase, a marker enzyme of cytosol, was observed under the same experimental conditions. Both lysoPAF and an enantiomer of PAF failed to produce any appreciable release of lysosomal enzyme. These findings indicate that PAF induces the release of lysosomal enzymes through a specific mechanism.

Release of monokines. When guinea pig peritoneal macrophages were treated with 10^{-5} M PAF, cytotoxic activity against murine fibroblast L929 cells was detected in the culture medium, suggesting that macrophages in the presence of PAF produce TNF activity and release it into the medium. This activity reached a maximum 8 hr after the addition of PAF (Table 6). LPS also induced the release of TNF activity from cells. Significant activity was detected in the medium of PAF-treated cells after 1.5 hr of incubation, whereas no appreciable activity was observed after 1.5 hr of incubation with LPS.

One of the potent PAF agonists, dimethylcarbamoyl-OGPC, which is resistant to metabolic inactivation, possessed a marked ability to release TNF activity (Table 6). LysoPAF, a major metabolite of PAF, showed no activity even at 10^{-5} M (data not shown). Another PAF agonist, methyl-OGPC, with an *sn*-3 configuration, induced TNF production, whereas its enantiomer (the *sn*-1 isomer) possessed no activity at all (Table 6). Pretreatment of macrophages with a specific PAF antagonist, CV6209 (10^{-6} M), abolished the stimulatory effect of PAF on release of activity (from 43 units/mL to 10 units/mL).

We detected colony-stimulating factor (CSF) activity in the culture medium of macrophages stimulated by PAF or methyl-OGPC (*sn*-3) (Table 7).

DISCUSSION

We demonstrated specific binding sites for PAF on guinea pig peritoneal macrophages. In the H_2O_2 release experiment, preincubation of the cells with a sub-stimulatory dose of PAF (10^{-8} M) caused desensitization against subsequent PAF stimulation. In addition, a PAF-specific antagonist inhibited PAF-induced H_2O_2 release, suggesting that this reaction was mediated through the binding of PAF to the specific binding site.

Since both EGTA and TMB-8 inhibited the stimulatory effect of PAF on H_2O_2 release, extracellular Ca^{2+} uptake and intracellular Ca^{2+} mobilization in the macrophages may be a necessary part of the process leading to macrophage activation. This idea is further supported by the experiment showing PAF-induced uptake of $^{45}CaCl_2$ by macrophages (data not shown). Moreover, Maudsley and Morris (15) and Ward and Westwick (16) had previously shown a rapid but transient increase in the intracellular free Ca^{2+} concentration in a human monocyte/macrophage-like cell line, U937.

Macrophage activation by PAF was inhibited by the lipoxygenase inhibitor, nordihydroguaiaretic acid (NDGA), but not by the cyclooxygenase inhibitor, indomethacin. One of the lipoxygenase products, 5-HETE, activated macrophages with PAF synergistically. These findings suggest that, similar to the activation of neutrophils (17,18), the activation of macrophages by PAF may be mediated through the products of the lipoxygenase pathway.

PAF-induced generation of H_2O_2 was observed not only with guinea pig macrophages but also with rabbit alveolar macrophages. We detected specific binding sites for PAF on rabbit alveolar macrophages; however, no appreciable reactivity was observed with mouse peritoneal macrophages under the same conditions. In preliminary experiments, we also found that rat peritoneal macrophages failed to respond to PAF. No specific binding of PAF was observed either with rat or mouse macrophages, indicating that peripheral macrophages in these animals have few receptors for PAF, and do not respond to it. These findings are in agreement with the fact that no specific PAF receptor binding has been found on the rat alveolar macrophage membrane (19). No effects were elicited on the platelets of either rat or mouse, although platelets from human, rabbit and guinea pig were highly sensitive to PAF (20). Platelets from rat or mouse that are insensitive to PAF also lack specific binding (21, 22). Prepic *et al.* (23) reported the presence of specific receptors for PAF on purified membranes derived from murine peritoneal macrophages. They showed that PAF induced the generation of breakdown products of polyphosphoinositides and elevated the intracellular level of Ca^{2+}. We have no explanation for this discrepancy at present.

We showed that PAF induced the production of TNF activity by guinea pig peritoneal macrophages. This reaction was stereospecific and inhibited by a PAF-specific antagonist, suggesting that it was also mediated through a specific mechanism. In our preliminary experiment, antibody to recombinant murine TNF neutralized the cytotoxic activity against L929 cells, indicating that this factor may be guinea pig TNF. Since TNF, IL-1 and γ-interferon (INF-γ) are known to stimulate PAF synthesis in macrophages (24), activation of monocyte/macrophage lineage cells by PAF may be further stimulated through this positive feedback mechanism. Valone *et al.* (5) reported that PAF enhanced the cytotoxicity of human monocytes for WEHI 164 cells mediated by TNF production. However, we were unable to detect any TNF production by murine macrophages treated with PAF or its agonists (data not shown).

Trinchieri *et al.* (25) showed that TNF induced the monocytic differentiation of a human myeloid leukemic cell line into macrophage-like cells. Highly purified guinea pig TNF also induced differentiation of a mouse myeloid leukemic cell line, M1, into macrophage-like cells in the presence of IL-1 (12). We recently reported that PAF affected the proliferation of one or more classes of guinea pig bone marrow cells through release of soluble factor(s) (26) and induced their candidacidal activity (13). These results indicate that the CSF activity observed in the present study and the effect of PAF on bone marrow cells observed previously is mediated by this TNF-like factor.

Macrophage activation can be classified into two types: (i) the activation detected when cells are incubated with reagents for a rather short period (5 min

to several hr); and (ii) the activation that is detected only when cells are incubated for a longer period (several hours). A complement degradation product (C5a), PMA, fMLP, opsonized zymosan or Ca^{2+} ionophore (A23187) induces early responses in macrophages (release of lysosomal enzymes and respiratory burst), which are detectable within a short incubation period. Lipopolysaccharides (LPS), γ-interferon (INF-γ), muramyldipeptide (MDP), CSF or A23187 induces late responses in macrophages (TNF release, stimulation of glucose consumption, expression of microbicidal and tumoricidal activity), which are detected after a long incubation time. However, none of these factors can induce both early and late responses in macrophages except for ionophore A23187.

PAF is a unique macrophage activator present in nature, which acts both as a short-term and a long-term activator of macrophages. The long-term activation requires a much higher amount of PAF than the short-term activation. PAF may manifest its activity on macrophages *in vivo* under conditions where it is produced continuously by the macrophages themselves or by some other cells such as neutrophils or endothelial cells, located near the target macrophages. The majority of newly synthesized PAF appears to be retained within these PAF-producing cells and not released (27). We previously reported that PAF incorporated into liposomes increased glucose consumption by macrophages (long-term culture; 2–3 days) about 400-times more effectively than did PAF in its free form (28). In addition to the increased resistance to metabolic inactivation of PAF incorporated in liposomes, the marked activity of liposomal PAF on macrophages may be explained by a more efficient mechanism of PAF transfer.

[Received October 7, 1989, and in revised form August 15, 1991; Revision accepted August 16, 1991]

Production of Platelet-Activating Factor by Human Normodense and Hypodense Eosinophils[1]

Ayako Ojima-Uchiyama[a], Yasuo Masuzawa[a], Takayuki Sugiura[a,*], Keizo Waku[a], Takeshi Fukuda[b,2] and Sohei Makino[b,2]

Normodense eosinophils and neutrophils from normal donors produced considerable amounts of platelet-activating factor (PAF) when stimulated with ionophore A23187. PAF produced by eosinophils appeared to be degraded more rapidly than PAF formed by neutrophils, suggesting a higher activity of PAF-degrading enzyme in eosinophils. Substantial proportions of PAF newly formed by both eosinophils and neutrophils were shown to be cell-associated. By comparison, hypodense eosinophils obtained from a patient with idiopathic hypereosinophilic syndrome produced an extremely large amount of PAF and released much of it into the incubation medium. The accelerated formation of PAF in hypodense eosinophils may be related to various cardiovascular complications associated with hypereosinophilic syndrome.
Lipids 26, 1200–1203 (1991).

It is generally accepted that eosinophils play an important role in various allergic reactions. For instance, the role of eosinophils in active bronchial asthma and in parasitic infections have been documented in recent years (1–5). The granular proteins of eosinophils have been found at the sites of epithelial damage and denudation in asthma (6), and in skin tissues of patients with atopic dermatitis (7,8). These toxic proteins have been assumed to induce various pathological changes in airways and in skin.

Eosinophils are also known to produce potent lipid mediators such as platelet-activating factor (PAF) (9) and leukotriene C_4 (LTC_4) (10–12) upon exposure to various stimuli. These lipid mediators have also been suggested to participate in the pathogenesis of various allergic reactions. In particular PAF is currently receiving much attention, because it has been reported that the administration of PAF results in changes that mimic the pathology of asthma (13–15) and of anaphylactic shock (16). Thus, in order to better understand allergic processes, it is important to investigate in detail the production of PAF by various inflammatory cells, including eosinophils, as well as the effects of PAF on eosinophil function.

In a previous communication, we reported that an unusually large amount of the stored PAF precursor, alkylacylglycerophosphocholine (alkylacyl-GPC), is present in human eosinophils (75.5% in choline glycerophospholipids) (17). In this communication, we compare the production of PAF in A23187-stimulated human eosinophils with that in stimulated human neutrophils. We also describe the production of PAF by hypodense and normodense eosinophils from a patient with idiopathic hypereosinophilic syndrome (HES), because the two types of eosinophils are known to be considerably different from each other in several biological properties (18–25). We found that a substantially higher amount of PAF was produced in hypodense eosinophils than was in normodense eosinophils.

MATERIALS AND METHODS

Chemicals. All chemicals were of reagent grade. 1-*O*-Hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine (16:0-PAF) was purchased from Bachem (Bubendorf, Switzerland). 1-*O*-[^{3}H]Octadecyl-2-acetyl-*sn*-glycero-3-phosphocholine (92 Ci/mmol, [^{3}H]PAF) was obtained from Amersham (Amersham, United Kingdom). A23187 was from Calbiochem (La Jolla, CA). CV3988, a PAF-antagonist, was a generous gift from Dr. Tsushima, Takeda Chemical Industries (Osaka, Japan). Pre-coated silica gel plates (layer thickness 0.25 mm) were from Merck (Darmstadt, Germany).

Cells. Human eosinophils and neutrophils were separated from peripheral blood of normal healthy donors and a patient with idiopathic hypereosinophilic syndrome (HES), using a Percoll discontinuous density gradient (26) as described in a previous report (17). Eosinophils having a density lower than 1.082 are defined as "hypodense"; others as "normodense" (27). The peak density of "hypodense" eosinophils was 1.075–1.077, that of "normodense" was 1.085–1.090. More than 70% of the leukocytes of the HES patient were eosinophils, and most of them were "hypodense". The purity of the eosinophils from a HES patient was usually >95%. The purity of eosinophils from normal donors was usually 85–90% and that of neutrophils was 85–95%.

PAF production by eosinophils and neutrophils. Eosinophils or neutrophils (2.5×10^6 cells) in 0.5 mL of 5 mM Hepes-Hanks balanced salt solution (pH 7.4) containing 0.25% bovine serum albumin (BSA) were preincubated at 37°C. Fifteen minutes later, cells were stimulated by the addition of A23187 (final concentration, 1 μg/mL). After a further incubation (0–30 min), the reaction was stopped by adding chloroform/methanol (1:2, v/v), and [^{3}H]PAF (approximately 8000 dpm) was added as internal standard to monitor the recovery of PAF. Total lipids were extracted by the method of Bligh and Dyer (28). In some experiments, after incubation, cells were immediately spun down (2500 rpm for 5 min) at 4°C, and the lipids from the cells and from the supernatant were extracted as described above.

Abbreviations: BSA, bovine serum albumin; CGP, choline glycerophospholipids; EGP, ethanolamine glycerophospholipids; GLC, gas-liquid chromatography; GPC, *sn*-glycero-3-phosphocholine; Hepes, *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid; HES, hypereosinophilic syndrome; LTC_4, leukotriene C_4; PAF, platelet-activating factor; TLC, thin-layer chromatography.

Estimation of PAF production. Individual phospholipid classes were separated by thin-layer chromatography (TLC) using chloroform/methanol/water (65:35:6, v/v/v) as developing solvent. The area corresponding to authentic PAF was scraped off and extracted by the method of Bligh and Dyer (28). The chloroform layer was removed and evaporated to dryness. The residue was dissolved in chloroform/methanol (1:2, v/v), and an aliquot of the solution was placed into a scintillation vial to determine the extraction recovery of PAF. Another aliquot of solution was evaporated to dryness, and the residue was resuspended in Hepes-buffered Tyrode's solution (pH 7.4) containing 0.25% BSA. The amount of PAF was measured by estimating the aggregating activity toward washed rabbit platelets (29), using 16:0-PAF as a standard. The aggregation of rabbit platelets by the PAF fraction was completely inhibited by pretreatment of the cells with 10 μM CV3988.

Phospholipid and fatty acid analyses. Phospholipids and fatty acids were analyzed as described previously (17). Briefly, lipids were extracted by the method of Bligh and Dyer (28) and fractionated by TLC. Choline and ethanolamine glycerophospholipids (CGP and EGP) were extracted separately, and then fractionated into the alkenylacyl, alkylacyl and diacyl subclasses. Their fatty acids were analyzed as methyl esters by gas-liquid chromatography (GLC). The methyl esters were separated on a capillary column coated with SP-2330, using helium as the carrier gas. The amounts of the subclasses were estimated from their fatty acid contents, using methyl heptadecanoate as an internal standard.

RESULTS AND DISCUSSION

Production of PAF by neutrophils and eosinophils from a normal donor. The biosynthesis and release of PAF by neutrophils have been studied by several investigators (for a review, see ref. 30). However, no precise data comparing the production of PAF by neutrophils and by eosinophils are available so far.

Figure 1 shows the time course of PAF production by human neutrophils and eosinophils stimulated with A23187. The production of PAF by neutrophils reached a maximum at 5–15 min, and gradually decreased thereafter. Throughout the incubation, large proportions of newly formed PAF were found to be cell-associated. About 98% (2 min) and 90% (30 min) of PAF were retained in cells. These results are in good agreement with previous observations of others (31–33). The profiles of PAF production by eosinophils are considerably different from those of neutrophil-produced PAF. The amounts of total PAF reached a peak within 2 min after stimulation and then rapidly declined during prolonged incubation. Most of the PAF generated by eosinophils was shown to be cell-associated. However, the percentage of retained PAF was lower at 30 min (78%) than at 2 min (97%). These observations may be due to the rapid degradation of intracellular PAF in this type of cell. Lee *et al.* (34) had already demonstrated that the activity of PAF degrading enzyme, acetylhydrolase, was about four times higher in human eosinophils than in neutrophils.

Production of PAF by hypodense and normodense eosinophils. Recent studies with purified eosinophils from individuals with eosinophilia have demonstrated that

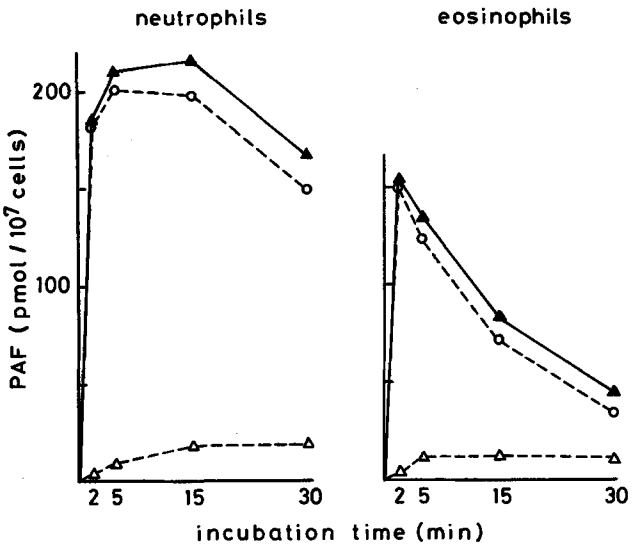

FIG. 1. PAF production by neutrophils (left) and eosinophils (right) from a normal donor as a function of time. After incubation, the cells were spun down. The amount of PAF in the external medium (△) and cell-associated PAF (○) were measured, and the sum of them is represented by closed triangles (▲). The number of the axis of ordinate in the right side of the figure is the same as that in the left side. The data represent means of two or three determinations.

TABLE 1

PAF Production by Hypodense and Normodense Eosinophils from a Patient with Hypereosinophilic Syndrome[a]

	PAF (pmol/10^7 cells/15 min)		
	Exp. 1	Exp. 2	Exp. 3
Hypodense	753.8 ± 80.6[b]	501.1 ± 24.7[d]	660.5 ± 143.2[d]
Normodense	213.9 ± 31.2[c]	252.6 ± 44.4[d]	193.0 ± 48.8[d]

[a]Eosinophils (2.5 × 10^6 cells/0.5 mL) from a patient with idiopathic hypereosinophilic syndrome were stimulated by A23187 (1 μg/mL) for 15 min. The total lipids were extracted. PAF was separated by TLC and assayed by measuring the aggregating activity toward washed rabbit platelets. The experiments were repeated with different preparations of eosinophils (Experiments 1–3). The data represent means ± S.D. from (b) seven, (c) eight and (d) three determinations. Exp., experiment.

eosinophils consist of cells with varying densities and with different biological activities (18–25,27). Eosinophils from blood of normal donors, used in the experiment of Figure 1, are usually normodense (d = 1.085–1.09). By contrast, eosinophils from bronchoalveolar lavages of subjects with asthma or blood of patients with hypereosinophilic syndrome (HES) are known to be mainly hypodense (d = 1.075–1.077) (18,20,22,27). These observations prompted us to investigate the production of PAF in two populations of eosinophils obtained from a patient with HES. Table 1 shows the amounts of PAF produced by hypodense and normodense eosinophils, both of which had been stimulated with A23187 for 15 min. The striking observation was that hypodense eosinophils produced 2–3

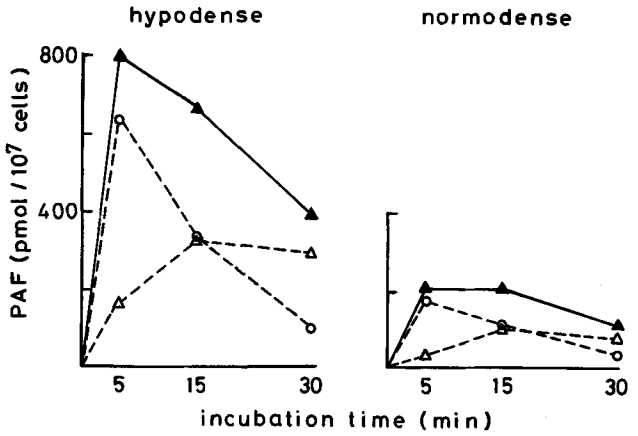

FIG. 2. PAF production by hypodense (left) and normodense (right) eosinophils from a patient with hypereosinophilic syndrome (HES) as a function of time. PAF produced by both types of cells was estimated as described in the legend to Figure 1. Symbols are the same as in Figure 1. The number of the axis of ordinate in the right side of the figure is the same as that in the left side. The data represent means of two or three determinations.

times more PAF than did normodense eosinophils. The amount of PAF synthesized by hypodense eosinophils was considerably higher than that synthesized by neutrophils from normal subjects (151.4 ± 40.9 pmole/10^7 cells/15 min, mean ± S.D., n = 6). Thus it appears that among human blood cells hypodense eosinophils are one of the most effective in generating PAF (30).

Figure 2 shows the time course of PAF production by hypodense and normodense eosinophils. The amounts of total PAF produced reached a maximum within 5 min after stimulation with A23187 and then decreased with time in both hypodense and normodense eosinophils. A similar decrease was observed for normodense eosinophils from normal donors (Fig. 1). However, the relative proportions of the released PAF were higher in both hypodense (49% at 15 min) and normodense (47% at 15 min) eosinophils than in normodense eosinophils obtained from normal subjects (23 ± 5% at 15 min, mean ± S.D., n = 4). The data suggest that, in HES patient, considerable amounts of PAF can be released into biological fluids if eosinophils are activated with appropriate stimuli. Small vessel and large vessel thrombotic occlusions are characteristic features of HES (35). Furthermore, exclusive cardiac ventricular intracavity thrombi can develop in some patients with HES (36). PAF released from hypodense eosinophils may therefore play a role in thromboembolic complications. It is furthermore possible that hypodense eosinophil-derived PAF is involved in the recruitment of eosinophils at tissue sites close to allergic and inflammatory lesions, as PAF is known to be a potent chemotactic agent to eosinophils (37). The question whether PAF actually mediates the symptoms of HES still needs to be answered.

The mechanism of accelerated PAF synthesis in hypodense eosinophils is presently not known. The levels of alkylacyl-GPC, a "storage form" of PAF precursor, were found to be relatively similar in hypodense and normodense eosinophils (64.2% and 75.6%, respectively). In addition, the fatty acid profiles of alkylacyl-GPC in hypodense and normodense eosinophils are quite similar (data not shown). Regulation of the activities of the enzymes involved in PAF biosynthesis, or the supply of the immediate PAF precursors (lysoPAF and acetyl-CoA) may, therefore, be quite different in these two types of cells. Alternatively, differences in the intracellular processing of PAF may affect the amounts of PAF produced.

Earlier studies had already demonstrated that a number of biological properties seem to differ between these two types of eosinophils. Hypodense eosinophils contain significantly smaller amounts of major basic proteins than normodense eosinophils (18). Furthermore, hypodense eosinophils have enhanced antibody-mediated cytotoxicity (19,20), increased consumption of oxygen and glucose (20–22) and enhanced expression of IgE-low affinity receptors (23) as compared to normodense eosinophils. Increased LTC_4 formation has also been demonstrated in hypodense eosinophils (24), although divergent results were reported in regard to the mode of LTC_4 formation (25). Further and more detailed studies on the synthesis and release of PAF, as well as LTC_4 by both hypodense and normodense eosinophils should contribute to a better understanding of the pathogenesis of various diseases in which eosinophils have been implicated.

The role of paf-acether (paf), a phospholipid cytokine, in the modulation of human B cell function was investigated. Paf, from 1×10^{-5} M to 10^{-6} M, decreased B cell proliferation induced by both phorbol myristate acetate (PMA) and anti-IgM antibodies (anti-IgM Ab). By contrast, 1×10^{-7} M to 1×10^{-9} M paf enhanced PMA triggered, but not anti-IgM triggered B cell proliferation. B cell proliferation was modulated between 24 and 72 hr of culture indicating that the effect of paf did not merely reflect a shift in proliferation kinetics. Interestingly, paf also enhanced the spontaneous proliferation of a Burkitt lymphoma-derived B cell line, Raji, which suggests that paf can directly act on B cells. The modulatory effect of paf on peripheral blood B cells was independent of PMA concentration, yet the effect on Raji cells was dependent upon cell density. The data suggest that paf is a potent modulator of B cell function, and may be involved in the control of humoral immune response.
***Lipids* 26, 1204–1208 (1991).**

At initiation of humoral immune response, mature B lymphocytes recognize specific antigen through interaction with their surface immunoglobulins (Ig), a signal which stimulates transition from the G0 to the G1 phase of the cell cycle (1). Once in G1, activated B cells can progress to the S/M phase and proliferate before final maturation to antibody-secreting cells. This differentiation process is dependent on regulatory signals generated by either cellular interactions or soluble factors (2). For instance, B cell proliferation has been shown to be controlled by proteic mediators such as interleukin 2 (IL-2), IL-4, and/or B cell growth factors (2,3). In some situations, as in those found in Epstein-Barr virus (EBV) infected B cell lines, homogenous populations of "activated-cycling" B cells are generated (4). Transmembrane signalling related to surface Ig cross-linking relies at least in part on protein kinase C (PKC) activation *via* membrane phosphoinositide breakdown, generation of diacylglycerol, and mobilization of intracytoplasmic Ca^{2+}. These biochemical events can be triggered *in vitro* by anti-IgM Ab (1,5–8). Alternatively, intracytoplasmic PKC can be directly stimulated by phorbol esters such as phorbol myristate acetate (PMA) (7). Although both reagents, anti-IgM Ab and PMA, are well defined as polyclonal B cell activators inducing the G1 entry of resting B cells, they have also been shown to act as B cell mitogens (9,10).

Paf-acether (1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine, paf) is a phospholipid originally characterized as platelet-activating factor released by IgE-sensitized basophils upon antigenic stimulation (11). Paf is involved in a wide variety of proinflammatory events *in vitro* and *in vivo*, and exerts an immunoregulatory function (12,13). For instance, in addition to its capacity to downregulate CD2 and CD3 expression (14), paf inhibits T cell activation induced by phytohemagglutinin (PHA) (15,16) or anti-CD3 mAb, and potentiates activation induced by anti-CD2 mAb (17). Moreover, paf upregulates IL-1, and tumor necrosis factor (TNF) α production by human monocytes, suggesting that paf may be involved in the control of monocyte/T cell interactions (18,19).

Although previous studies have demonstrated the release of paf-like material by long term B cell lines or leukemic B cells stimulated with Ca^{2+} ionophore (20,21), little is known about the interactions between paf and B lymphocytes. In the present study, we found that paf exerts a dual effect on peripheral blood B cell proliferation induced by PMA but inhibits only the effect induced by anti-IgM Ab. Further, addition of paf to the B cell line, Raji, derived from an EBV infected Burkitt lymphoma resulted in a substantial increase in DNA synthesis indicating that paf may directly act on B cells. The data suggest that paf interferes with the processes leading to B cell activation.

MATERIALS AND METHODS

Media and reagents. The final medium used for B cell cultures consisted of Iscove's modified medium (Gibco, Grand Island, NY) supplemented with 50 μg/mL human transferrin, 5 μg/mL bovin insulin, 2 μg/mL each of oleic, linoleic and palmitic acids (Sigma, St. Louis, MO), 1% L-glutamin, 1% antibiotics (Gibco), 0.25% human serum albumin (HSA, Bio Merieux, Lyon, France) (22) and 2% heat inactivated fetal calf serum (FCS, Gibco). Synthetic C_{18}paf (1-*O*-octadecyl-2-acetyl-*sn*-glycero-3-phosphocholine; Bachem, Bubendorf, Switzerland) was dissolved in ethanol (60% v/v) at a concentration of 10 mM. The solution was diluted in 0.9% NaCl containing 0.25% HSA at a concentration of 100 μM and stored at −20°C. In all further dilutions, the concentration of 0.25% HSA was maintained. The effect of NaCl/HSA (0.25%) used as vehicle was tested at the same final dilution as used in the paf-treated cultures.

B cells and B cell line. Mononuclear cells were isolated from blood of healthy volunteers using Ficoll-Hypaque (Pharmacia, Uppsala, Sweden) density gradient centrifugation. Monocytes and macrophages were removed

Abbreviations: anti-IgM Ab, anti-IgM antibodies; EBV, Epstein-Barr virus; FCS, fetal calf serum; HSA, human serum albumin; IL, interleukin; paf, paf-acether, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; PHA, phytohemagglutinin A; PKC, protein kinase C; PMA, phorbol myristate acetate; TNF, tumor necrosis factor.

by L-leucine methyl ester (Sigma) treatment (23). Monocyte-depleted mononuclear cells were incubated with sheep red blood cells treated with 2-aminoethyl-isothiouronium bromide hydrobromide (Sigma). The non-rosetting cell fractions that were recovered after two cycles of incubation were highly enriched B cell preparations containing 83 ± 3% $CD19^+$, 3 ± 1% $CD2^+$ and 6 ± 1% $CD11b^+$ cells.

The Burkitt lymphoma B cell line, Raji, was kindly provided by Dr. T. Tursz (CNRS UA 1156, Villejuif, France). The cell line was cultured in RPMI 1640 medium supplemented with 1% glutamine, 1% antibiotics, 1 mM sodium pyruvate and 10% heat inactivated fetal calf serum (Gibco), and was readjusted every 3 days to a density of 3×10^5 cells/mL. Before the assay, cells were subcultured for 24 hr and harvested in the log growth phase.

Proliferation assays. All culture experiments were carried out in triplicate in microtest tissue culture dishes (Falcon, Oxnard, CA) kept in a humidified atmosphere containing 7% CO_2 in air at 37°C. Peripheral blood B cells (1×10^5/well) were cultured for different periods of time (24 to 72 hr) in 200 μL final medium in the presence of either paf (1×10^{-5} to 10^{-11} M) or vehicle. Stimuli included PMA (Sigma; 1 to 10 ng/mL) or goat anti-IgM Ab coupled to sepharose beads (Biorad, Richmond, CA; 7 μg/mL).

Raji cells were cultured (1 to 20 × 10^3/well) in 200 μL final medium without addition of fetal calf serum, for 24 to 72 hr in the presence of either paf (1×10^{-5} to 10^{-11} M) or vehicle. During the last 12 hr of culture, peripheral blood B cells or Raji cells were pulsed with 0.5 μCi/well (18.5 KBq/well) of [^{3}H]thymidine (CEA, Saclay, France) and then harvested using a skatron cell apparatus. Incorporation of [^{3}H]thymidine was measured by liquid scintillation counting. Results are expressed as mean counts per min (cpm) ± SEM of triplicate samples rounded to the nearest hundred. Cell counts and viability tests (by trypan blue exclusion) were performed on all cell cultures at the time of the assay.

Statistical analysis. Mean of results obtained from at least three independent experiments were compared using the paired Student t-test.

RESULTS

The effect of paf on mitogen-induced B cell proliferation was investigated. Highly purified peripheral blood B cells (1×10^5/well) were stimulated with PMA or anti-IgM Ab in the presence of different concentrations of paf or vehicle. [^{3}H]Thymidine incorporation was assessed after 72 hr of culture. As shown in a representative experiment (Fig. 1), stimulation of human B lymphocytes with anti-IgM Ab or PMA was sufficient to trigger B cell proliferation. When B cells were stimulated with anti-IgM Ab (7 μg/mL), 1×10^{-5} and 1×10^{-6} M paf inhibited the proliferative response; 1×10^{-5} M paf decreased cell proliferation by 44.9 ± 6.4% (mean ± SEM, n = 22). By contrast, when B cells were stimulated with PMA, a biphasic effect was observed. Paf, at 1×10^{-5} and 1×10^{-6} M inhibited PMA-induced B cell proliferation, whereas 1×10^{-7} to 1×10^{-9} M paf potentiated it. Upregulation (paf 1×10^{-8} M) and downregulation (paf 1×10^{-5} M) were 34.5 ± 9.5% and 39.5 ± 6.2% (mean ± SEM, n = 22), respectively. Although the magnitude of the modulation

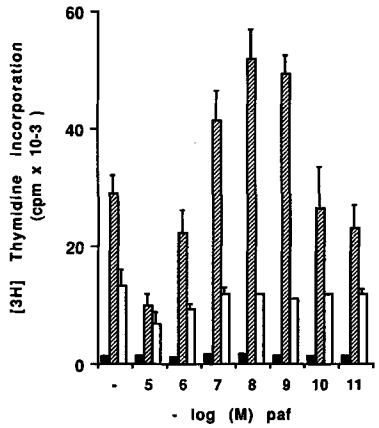

FIG. 1. Effect of paf on mitogen-induced B cell proliferation. B cells (1×10^5/well) were cultured with medium (solid bar), PMA at 5 ng/mL (hatched bar) or anti-IgM Ab (open bar) in the presence of paf (1×10^{-5} to 10^{-11} M) or vehicle (v). After 72 hr of culture, B cell proliferation was assessed by determining [^{3}H]thymidine incorporation. Results of one representative experiment are shown and expressed as mean cpm × 10^{-3} ± SEM of triplicate cultures. When error bar is absent, SEM is within the symbol.

was quite variable among different individuals tested, the effects of paf were statistically significant ($p<0.001$). In the absence of stimuli, paf alone did not modulate the background B cell proliferative response. Furthermore, no cytotoxic effect of paf was observed at all concentrations tested, as judged by cell counts and trypan blue exclusion. The results suggest that paf up- or downregulates B cell proliferation induced by PMA, but only inhibits proliferation induced by anti-IgM Ab.

In the following experiments, we focused on the dual effect of paf (at 1×10^{-5} and 10^{-8} M) on PMA-induced B cell proliferative response. B cells were incubated with varying concentrations of PMA in the presence of paf or vehicle for 72 hr to investigate whether the changes induced by paf were dependent upon the level of PMA-induced B cell proliferative response. As shown in Table 1, 1×10^{-5} and 1×10^{-8} M paf, respectively, down- and upregulated [^{3}H]thymidine incorporation at all PMA concentration tested. The data suggest that both effects of paf are not dependent on PMA concentration and occur at suboptimal as well as optimal cell stimulation. In the next set of experiments, the kinetics of PMA-induced B cell proliferation in the presence of paf (1×10^{-5} and 10^{-8} M) were investigated. As depicted in Figure 2, paf-induced downregulation and upregulation of B cell proliferation were detectable as early as 24 hr after initiation of the culture, increased by 48 and 72 hr, and plateaued thereafter (96 to 120 hr, data not shown). Upregulation (1×10^{-8} M paf) was 30.1 ± 4.2% (n = 5) and 34.5 ± 9.5% (n = 22) at 48 and 72 hr, respectively. Downregulation (1×10^{-5} M paf) was 37.2 ± 6.6% (n = 5) and 39.5 ± 6.2% (n = 22) at 48 and 72 hr, respectively. These results indicate that paf does not merely modify the kinetics of PMA-induced B cell proliferation.

Highly enriched B cell populations were not totally devoid of residual T cells and/or monocytes, and the possibility remained that the primary targets of paf were not B cells, but rather T cells or monocytes. Therefore, the

TABLE 1

Modulation by Paf of PMA-Induced B Cell Proliferation[a,b]

PMA (ng/mL)	Vehicle	Paf 1×10^{-5} M	Paf 1×10^{-8} M
0	1.8 ± 0.5	1.3 ± 0.3	2.0 ± 0.5
	1.3 ± 0.5	1.1 ± 0.1	1.7 ± 0.4
1	3.1 ± 0.4	1.4 ± 0.2	3.7 ± 0.3

	15.2 ± 1.2	8.5 ± 0.9	27.1 ± 2.7

[a] B cells (1×10^5/well) were incubated with different concentrations of PMA in the presence of paf or vehicle. After 72 hr of culture, B cell proliferation was assessed by determining [^{3}H]thymidine incorporation. Results are expressed as mean (cpm $\times 10^{-3}$) ± SEM of triplicate cultures.

[b] Upper line at each PMA concentration refers to experiment 1, lower line refers to experiment 2.

[c] Not tested.

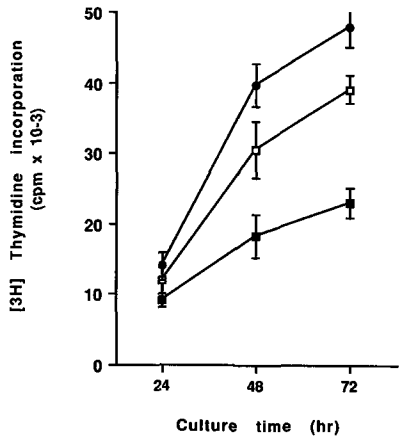

FIG. 2. Kinetics of paf effect on PMA-induced B cell proliferation. B cells (1×10^5/well) were stimulated with PMA (5 ng/mL) in the presence of 1×10^{-5} M paf (black square), 1×10^{-8} M paf (black circle), or vehicle (open square). B cell proliferation after 24, 48 or 72 hr of culture was assessed by determining [^{3}H]thymidine incorporation. Results of one representative experiment are shown and expressed as mean $\times 10^{-3}$ ± 1 SEM of triplicate cultures.

effect of paf on the proliferation of a homogeneous population of autoproliferating cells, the Burkitt lymphoma-derived B cell line Raji was investigated. Raji cells (10^4 cells/well) were grown in a chemically defined, serum-free medium in the presence of various concentrations of paf or vehicle. Within 72 hr after addition of 1×10^{-6} M paf, spontaneous proliferation of Raji cells increased by 167 ± 33% (mean ± SEM, n = 8, $p<0.005$). Paf from 1×10^{-7} to 1×10^{-11} M did not affect the proliferation (data not shown). As expected, addition of higher concentrations of paf (1×10^{-5} M) produced cytotoxic effects because in serum-free medium, paf is not hydrolyzed by serum acetyl hydrolase (24).

As the autonomous growth of Raji cells depends on cell density, the effect of paf at various cell concentrations was tested. As shown in Figure 3, the potentiating effect of paf at 1×10^{-6} M was observed at all cell concentrations that can sustain autonomous growth. This latter result suggests that paf may act as a cofactor in the spontaneous proliferation of Raji cells. The two-log difference in the upregulating concentration of paf between peripheral blood and Raji B cells, could be the difference between normal and malignant cell types, the latter being able to take up and/or to metabolize paf more efficiently. Kinetic analysis of paf-induced modulation of Raji cell proliferation revealed that the increase in [^{3}H]thymidine incorporation by Raji cells in the presence of 1×10^{-6} M paf occurred at 24 as well as at 48 and 72 hr after initiation of the culture (Table 2). The latter data suggest that paf does not delay the Raji cell cycle but facilitates Raji cell growth at each time point of the culture. Furthermore, upregulation of DNA synthesis was directly related to cell proliferation as determined by the increase in cell counts at 24, 48 and 72 hr of culture (data not shown). The results

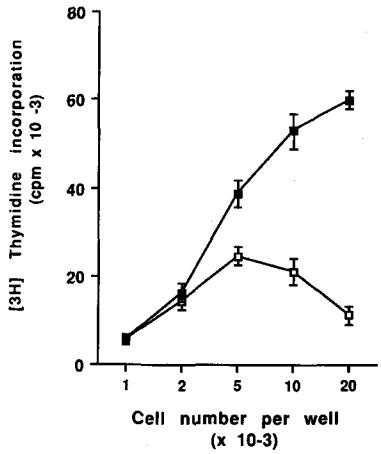

FIG. 3. Paf-induced modulation of Raji cell proliferation. Raji cells were cultured from 1×10^3 to 2×10^4 cells/well in the presence of 1×10^{-6} M paf (black square) or vehicle (open square). After 72 hr of culture, B cell proliferation was assessed by determining [^{3}H]thymidine incorporation. Results of one representative experiment out of 8 are shown and expressed as mean cpm $\times 10^{-3}$ ± 1 SEM of triplicate cultures.

TABLE 2

Kinetics of Paf Effect on Spontaneous Raji Cell Proliferation[a,b]

Length of culture (hr)	Vehicle	Paf 1×10^{-6} M
24	26.4 ± 2.2	70.7 ± 5.0
48	47.8 ± 3.1	97.3 ± 2.1
72	40.4 ± 2.7	95.3 ± 6.4

[a] Raji cells (1×10^4/well) were cultured for the times indicated in the presence of paf (1×10^{-6} M) or vehicle.

[b] Raji cell proliferation was assessed by determining [^{3}H]thymidine incorporation. Results are expressed as mean cpm $\times 10^{-3}$ ± SEM of triplicate cultures. Results of one representative experiment out of three are shown.

obtained on pure B cell populations would indicate that B lymphocytes are potential targets for the immunoregulatory action of paf, and specifically in their proliferative stage.

DISCUSSION

In this study, we have shown that paf, a naturally occurring phospholipid, has potent *in vitro* effects on B cell function. In particular, paf could exert dual biological activities depending on its concentration and on the B cell stimulus. At 1×10^{-5} and 1×10^{-6} M, paf downregulated PMA induced as well as anti-IgM induced B cell proliferation, whereas from 1×10^{-7} to 1×10^{-9} M paf upregulated proliferation induced by PMA, irrespective of the magnitude of the proliferative response. The magnitude of the paf effect was quite variable between different individuals tested and did not reflect differences in the activation and differentiation status of the responsive B cells. No inherent differences in the ability of B cells from either peripheral blood or tonsils to respond to paf were found (data not shown), although the latter can be considered as potentially *in vivo* activated (25). Thus, the variability of the paf effects may be due to differences in contaminating T cells and monocytes generating soluble factors that in turn regulate B cell function (26,27). In this regard, paf has been shown to increase monocyte production of IL-1 or TNF-α (18,19). Irrespective of which of these interpretations is correct, the fact that paf can act directly on B cells is clear because 1×10^{-6} M paf upregulated the spontaneous proliferation of the Burkitt lymphoma B cell line, Raji.

The inhibitory effect of paf was not merely due to a shift in proliferation kinetics, nor to cytotoxicity. It could be argued that at 1×10^{-5} M paf, cells could be affected by this phospholipid concentration even if no lytic effect was apparent. However, lysophosphatidylcholine, a phospholipid about as lytic to cell membranes as paf, did not affect B cell proliferation (Vivier, E., unpublished observation). Paf at 1×10^{-5} M may act during the early steps of B cell activation, limiting the pool of cells entering into the G1 phase of the cell cycle. Alternatively, paf may suppress the proliferation of activated B cells, *i.e.* their progression in the cell cycle. We favor the latter interpretation since paf at 1×10^{-5} M was also shown to downregulate high affinity IL-2 receptors on T cells, a mechanism which may explain the inhibition of mitogen-induced T cell proliferation (15,28). By analogy, a similar concentration of phospholipid may diminish the density of functional growth factor binding sites on B cell membranes. In this regard, a preliminary report seems to indicate that paf inhibits activated B cell proliferative response to IL-2 and to a low molecular weight B cell growth factor (29).

It is intriguing that paf-induced upregulation of peripheral blood B cell proliferation was dependent upon the stimuli used, since no potentiation of anti-IgM proliferative response was observed. First, it is possible that paf from 1×10^{-7} to 1×10^{-9} M synergizes with biochemical events triggered by PMA and not by anti-IgM Ab. The quantitative difference between both reagents and their capacity to stimulate, either directly or indirectly, intracytoplasmic PKC may be important (1). Further, PKC activation, either by paf alone or in synergy with PMA, has been previously reported in human neutrophils (30-32). Second, paf may differentially regulate the proliferation of distinct functional B cell subsets responsive to PMA or anti-IgM Ab stimulation. Both hypothesis are not mutually exclusive.

Finally, the precise mechanisms whereby paf could directly enhance the proliferation of human peripheral blood B cells or Raji cells have not been delineated. One possibility is that paf enhances B cell production of factors such as IL-1, TNF α and IL-6 which are known to modulate B cell function (33-37). Alternatively, since paf seems to enhance CD23 expression on B cells (38), its enhancing activity could be due to an increased production of soluble CD23 which in turn acts as a B cell growth factor (39). This seems unlikely since preliminary results suggest that paf also modulates proliferation of Rjcl3, a mutant cell line from Raji that displayed a HLA-DR$^-$ CD23$^-$ cell surface phenotype (data not shown).

According to our data, paf modulates human B cell function producing a singular or dual effect, *i.e.* down- and upregulating B cell proliferation, depending on the first signal applied. The mechanism underlying such a dual effect may involve interactions with high and low affinity paf binding sites coupled to different signaling pathways. Two classes of paf receptors have been previously described in human neutrophils (40). Further studies on B cells using the cDNA probe to the paf receptor will clarify this issue (41). Finally, paf may be an important immunoregulatory factor regulating human B cell function either directly or indirectly through its functional interactions with T cell or monocyte derived cytokines.

Intracellular Ca^{2+} Concentration and H_2O_2 Production in Mouse Peritoneal Macrophages Are Stimulated by Platelet Activating Factor[1]

Masayuki Sasaki, Kazutaka Maeyama* and Takehiko Watanabe
Department of Pharmacology I, Tohoku University School of Medicine, Sendai 980, Miyagi, Japan

The intracellular calcium concentration ($[Ca^{2+}]i$) in mouse peritoneal macrophages cultured on a coverglass was measured in the superfusion system using fura-2 as a fluorescent calcium probe and platelet activating factor (PAF) as a stimulant. In the presence of extracellular Ca^{2+}, 10^{-7} M PAF sharply increased $[Ca^{2+}]i$ from a basal level of 90 nM to 340 nM. Thereafter, the $[Ca^{2+}]i$ level gradually decreased in two phases, in an initial rapid phase and a subsequent slow phase of decrease. The calcium response was dependent on the PAF concentration. In the absence of extracellular Ca^{2+}, a single sharp peak was observed, suggesting two different modes of Ca^{2+} movement, one from intracellular stores and the other from the extracellular medium. A simple, sensitive fluorometric assay system was developed for measuring H_2O_2 in the superfusate of macrophages after stimulation by use of immobilized peroxidase and 3-(*p*-hydroxyphenyl)propionic acid as a fluorogenic substrate. With this system, as little as 2 pmol of H_2O_2 could be measured. PAF (1 μM) increased H_2O_2 production in peritoneal macrophages in the presence of extracellular Ca^{2+}, but H_2O_2 production was not observed in the absence of extracellular Ca^{2+}.

Lipids 26, 1209–1213 (1991).

Mouse macrophages bear various kinds of surface receptors specific for various ligands, such as immunoglobulins and chemical mediators, and are stimulated by the binding of these ligands. The stimulations are transmitted by a second messenger system such as cyclic adenosinemonophosphate (AMP), inositol phosphates and calcium resulting in various cell responses, e.g., phagocytosis, respiratory burst and secretion of lysosomal enzymes (1–3). Platelet activating factor (PAF), 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine, is a phospholipid mediator released from a variety of inflammatory cells, including macrophages (4). PAF induces various physiological and pathological responses, such as platelet aggregation, degranulation of neutrophils, hypotension and bronchoconstriction (5,6). It is also a potent stimulant of macrophages and causes release of prostanoids (7,8), glucose consumption in guinea pig macrophages (9), production of active oxygen species and aggregation in human monocytes (10,11). Meanwhile, $[Ca^{2+}]i$ has been measured in the murine macrophage cell line J774 and mouse peritoneal macrophages stimulated with immunocomplexes (12). Recently, a new fluorescent calcium probe, fura-2-, which is generally thought to be superior to quin2, has been widely used for measurement for intracellular concentration of Ca^{2+} ($[Ca^{2+}]i$) in cell suspensions, monolayered cells and single cells (13–15). We developed a new system for measurement of $[Ca^{2+}]i$ in which cell monolayers on coverslips are superfused and $[Ca^{2+}]i$ is calculated with a microcomputer from the ratio of fura-2 fluorescences excited at two wavelengths (16). Using this system, we previously measured $[Ca^{2+}]i$ in J774.2 cells and suggested that there are two sources of $[Ca^{2+}]i$, the intracellular sources and Ca^{2+} derived from the medium by influx across the plasma membrane (16). Unfortunately, J774.2 cells showed no secondary cell response to a calcium signal, such as H_2O_2 production and release of lysosomal enzymes, and we could not study the coupling of the increase in $[Ca^{2+}]i$ and the cellular response. In the present work, using mouse peritoneal macrophages, we confirmed the above hypothesis of two locations for mobilization of Ca^{2+}, and also measured H_2O_2 production. For H_2O_2 measurement we developed a new fluorometric system using immobilized peroxidase, which condenses 3-(*p*-hydroxyphenyl)propionic acid (HPPA) with H_2O_2 (17).

MATERIALS AND METHODS

Cell preparation. Mouse macrophages were obtained from the peritoneal cavity of male ddY mice (25–30 g, Shizuoka Laboratory Animal Center, Shizuoka, Japan) after i.p. injection of 0.5 mL liquid paraffin. Ten days later, peritoneal exudate cells were collected in Hanks' balanced salt solution (HBSS) containing 10 U/mL heparin. The cells were washed twice with HBSS and layered on a coverslip (0.9 × 2.2 cm) in RPMI 1640 medium containing 15% fetal calf serum and antibiotics (100 U/mL penicillin, 100 μg/mL streptomycin and 0.25 μg/mL Fungizone), and cultured at 37°C in an atmosphere of 5% CO_2 and 95% air.

Measurement of $[Ca^{2+}]i$ in peritoneal macrophages. The intracellular concentration of Ca^{2+}, $[Ca^{2+}]i$, was measured by the method described by Sasaki *et al.* (16). Details of the method will be reported elsewhere. Briefly, macrophages on a coverslip were loaded with 5 μM fura-2 acetoxymethylester (fura-2/AM) for 30 min at 37°C in (PIPES) buffer (PIPES, 25 mM; NaCl, 119 mM; KCl, 5 mM; glucose, 5.6 mM; $MgCl_2$, 0.4 mM; $CaCl_2$, 1.0 mM; and NaOH, 40 mM; pH 7.2). After 30-min incubation to allow hydrolysis of fura-2/AM to

[1]Based on a paper presented at the Third International Conference on Platelet-Activating Factor and Structurally Related Alkyl Ether Lipids, Tokyo, Japan, May 1989.

AMP, adenosine monophosphate; $[Ca^{2+}]i$, intracellular concentration of Ca^{2+}, EGTA, ethyleneglycol *bis*-β(aminoethyl ether)*N,N,N',N'*-tetraacetic acid; fMLP, formyl Met-Leu-Phe; fura-2/AM, fura-2 acetoxymethylester; HBSS, Hanks' balanced salt solution; HPPA, 3-(*p*-hydroxyphenyl)propionic acid, PAF, platelet activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; PIPES, piperazine-*N,N'-bis*(2-ethane sulfonic acid).

fura-2 by esterase in the cells, the coverslip was inserted into a quartz cuvette (1 cm × 4 cm, 0.2 cm width) with a tube at its bottom. The cuvette was placed diagonally to the light path in a holder of a fluoromonitor (Fi-4000, Hitachi, Tokyo, Japan), and capped with silicon rubber with an outlet tube. The cells were superfused upwards with PIPES buffer containing stimuli such as PAF and formyl Met-Leu-Phe (fMLP) using a peristaltic pump (ATTO, Tokyo, Japan) and a flow rate of 1 mL/min. Fractions were collected every minute for measurement of H_2O_2 as described below. The cuvette and medium were kept at 37°C. The fluorescences of fura-2 were monitored with a Hitachi fluoromonitor (F-4000) at an emission wavelength of 505 nm with excitations at 340 nm and 380 nm, which were changed automatically. $[Ca^{2+}]i$ was calculated with a microcomputer from the ratio of the fluorescence intensities obtained with excitations at 340 and 380 nm by the methods described by Grynkiewicz *et al.* (13) and Scanlon *et al.* (18).

Measurement of H_2O_2 in the superfusates of peritoneal macrophages stimulated by PAF. H_2O_2 was measured by the method described by Zaitsu and Ohkura (17) in combination with immobilized peroxidase using a flow system. As shown in Figure 1, a sample was injected via an injector in 25 mM PIPES buffer, pH 7.2, delivered by Pump 1 into a column of Affi-Prep 10 with fixed peroxidase. Pump 2 delivered a reagent, HPPA, and an fluorescence enhancer, 1 M NaOH-0.05 M boric acid, and the resulting fluorescence was measured by a fluoromonitor (Hitachi F-1100) with excitation and emission wavelengths of 340 nm and 404 nm, respectively. H_2O_2 levels in fractions were measured by this method. Alternatively, the superfusion system was directly connected to the immobilized peroxidase so that the relationship between calcium response and H_2O_2 production were directly compared.

Chemicals. Fura-2/AM and HPPA were purchased from Dojindo Laboratories (Kumamoto, Japan). PAF (1-*O*-octadecyl-2-acetyl-*sn*-glycero-3-phosphocholine) was obtained from Bachem Feinchemilkalien AG (Bubendorf, Switzerland) and ionomycin was from Calbiochem Corp. (La Jolla, CA). Formyl-methionyl-leucyl-phenylalanine (fMLP) and peroxidase (horseradish) were from Sigma Chemical Co. (St. Louis, MO) and RPMI1640 powder was from Gibco Laboratories (Grand Island, NY). Fetal calf serum, penicillin, streptomycin and Fungison were from Whittaker M.A. Bioproducts (Wakersville, MD). Affi-Prep 10 was purchased from Bio-Rad Laboratories (Richmond, CA). Other chemicals were analytical grade reagents from Wako Pure Chemical Industries (Osaka, Japan).

RESULTS

Measurement of $[Ca^{2+}]i$ in mouse peritoneal macrophages stimulated by PAF or fMLP. $[Ca^{2+}]i$ in peritoneal macrophages was measured using fura-2 as a fluorescent probe. The two thin lines in Figure 2 show typical fluorescences at 505 nm excited at 340 and 380 nm in mouse macrophages loaded with fura-2 and stimulated by PAF. After addition of 10^{-7} M PAF, the two fluorescences changed inversely—the fluorescence excited at 340 nm (upper line) increased with a corresponding decrease of the fluorescence excited at 380 nm (lower line). For calibration of Ca^{2+} concentrations in the course of each experiment, the fluorescence intensities at the maximal and zero Ca^{2+} levels and the spontaneous fluorescence were obtained by addition of 1 μM ionomycin, 1 mM ethyleneglycol *bis*-β(aminoethyl ether) *N,N,N',N'*-tetraacetic acid (EGTA) and 5 mM $MnCl_2$, respectively. Using these parameters, $[Ca^{2+}]i$ was calculated as described by Sasaki *et al.* (16). As shown by the bold line in Figure 2, after stimulation with 10^{-7} M PAF in medium containing 1 mM Ca^{2+}, $[Ca^{2+}]i$ increased rapidly, reaching a peak (340

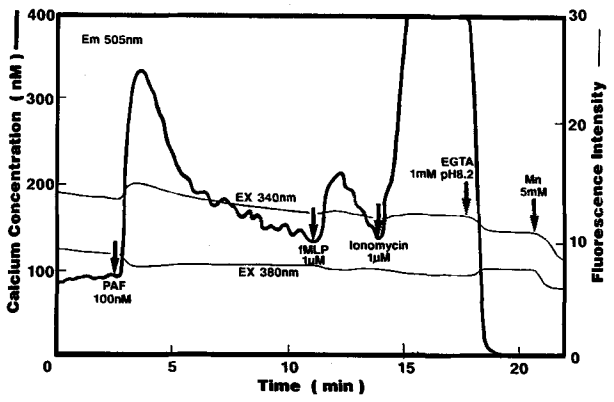

FIG. 1. Flow diagram of H_2O_2 analysis. The sample is injected via the injector in 25 mM PIPES, pH 7.2 (in A), delivered by Pump 1 to a column of Affi-Prep 10 with fixed peroxidase. Pump 2 delivers HPPA (in B) and an alkaline enhancer, 1 M NaOH-0.05 M boric acid (in C), and the resulting fluorescence is measured in a fluoromonitor at excitation and emission wavelengths of 340 nm and 404 nm, respectively.

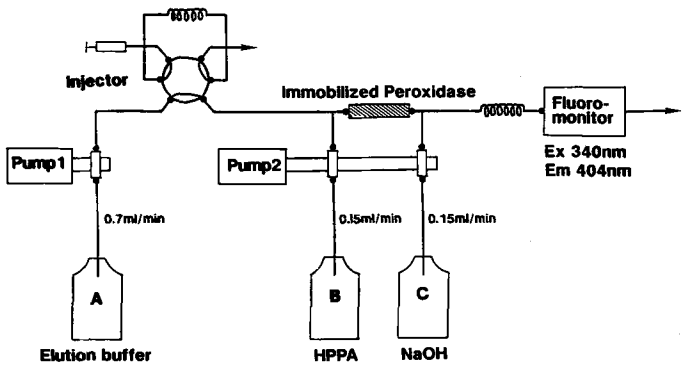

FIG. 2. Increase in $[Ca^{2+}]i$ in peritoneal macrophages stimulated by PAF or fMLP. Peritoneal macrophages were stimulated with 100 nM PAF or 1 μM fMLP, and $[Ca^{2+}]i$ was measured with fura-2 as a fluorescent probe as described in Materials and Methods. After the experiments, for calibration of Ca^{2+} concentrations, 1 μM ionomycin, 1 mM EGTA and 5 mM $MnCl_2$ were added to obtain the values for maximum and minimum fluorescences and autofluorescence, respectively.

nM) at 1 min, and then decreased, first rapidly, and from 3 min more slowly, to the basal level (90 nM). A chemotactic peptide, fMLP, increased $[Ca^{2+}]i$ (220 nM) even after the calcium response was induced by PAF. The dose dependence of the increase of $[Ca^{2+}]i$ by PAF is shown in Figure 3. The response was observed at a PAF concentration as low as 10^{-9} M and reached a plateau at 10^{-7} M PAF—in this concentration range of PAF, the calcium response increased dose-dependently. PAF is labile and metabolized rapidly during incubation with cells. Since macrophages were superfused with PAF, the dose response curve as shown in Figure 3 is quite similar to that obtained by stimulation with liposome-incorporated PAF (19).

Upon removal of extracellular Ca^{2+} with 0.2 mM EGTA, 10^{-7} M PAF caused a sharp increase in $[Ca^{2+}]i$, followed by a rapid decrease to a level lower than the base after 2 min (Fig. 4b). Addition of 1 mM Ca^{2+} resulted in rapid increase of $[Ca^{2+}]i$ to more than 500 nM (Fig. 4b). For comparison, the calcium signal in the presence of 1 mM Ca^{2+} in the medium is shown in Figure 4a.

Measurement of H_2O_2 production in peritoneal macrophages stimulated by PAF. As described in Materials and Methods, we developed a new method for measurement of H_2O_2 by combining immobilized peroxidase with the fluorometric assay described by Zaitsu and Ohkura (17). Figure 1 shows the flow diagram of the method. A sample containing H_2O_2 is delivered to a column of Affi-Prep 10 with fixed horseradish peroxidase, which oxidizes HPPA giving rise to a fluorophore. The fluorescence is then measured on line with a fluoromonitor. Figure 5 shows typical measurements, demonstrating that 1 pmol H_2O_2 gives a two-fold higher peak than buffer. The linear standard curve with 1–20 pmol of H_2O_2 is shown in the Figure 5 insert. Upon addition of catalase to the samples, no peaks were seen (data not shown).

Using the new method for assay of H_2O_2 described here, we measured H_2O_2 production in the superfusate of peritoneal macrophages stimulated by PAF. Immediately after addition of 1 μM PAF to the medium, the rate of H_2O_2 production (Fig. 6, closed circles) increased sharply and reached a maximum within 5 min. H_2O_2 production then remained at this level while PAF was present. Upon removal of PAF from the medium, the rate of H_2O_2 production began to decrease. Total H_2O_2 production reached 2 nmol/10^6 cells/10 min; this was calculated by summation of the production rates and is in good agreement with values reported by others (20,21). The effect of calcium-free superfusion medium

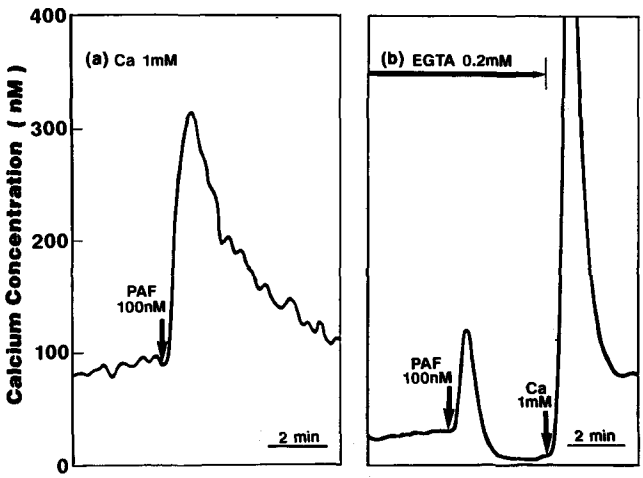

FIG. 4. Effect of extracellular calcium on increase in $[Ca^{2+}]i$ in peritoneal macrophages stimulated by PAF. The calcium signal in macrophages stimulated by 10^{-7} M PAF was measured in the presence of 1 mM Ca^{2+} (a) and in the absence of Ca^{2+} (b) in the extracellular medium. In (b), 1 mM Ca^{2+} was added to the superfusion medium at the time points indicated by arrows.

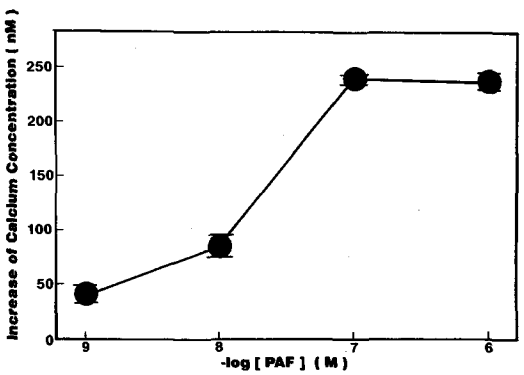

FIG. 3. Dose response curve of increase in $[Ca^{2+}]i$ by PAF. $[Ca^{2+}]i$ in peritoneal macrophages stimulated by PAF at various concentrations was measured as described in Materials and Methods. Values are means ± S.E.M. of three determinations.

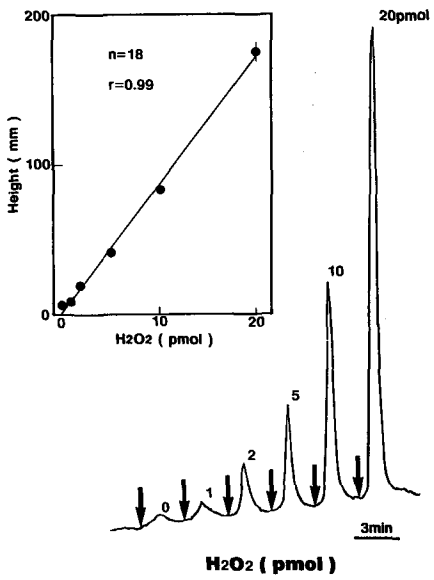

FIG. 5. Measurement of H_2O_2 by the immobilized peroxidase-fluorescence method. Typical measurements of H_2O_2 by the present method and a standard curve (insert) are shown.

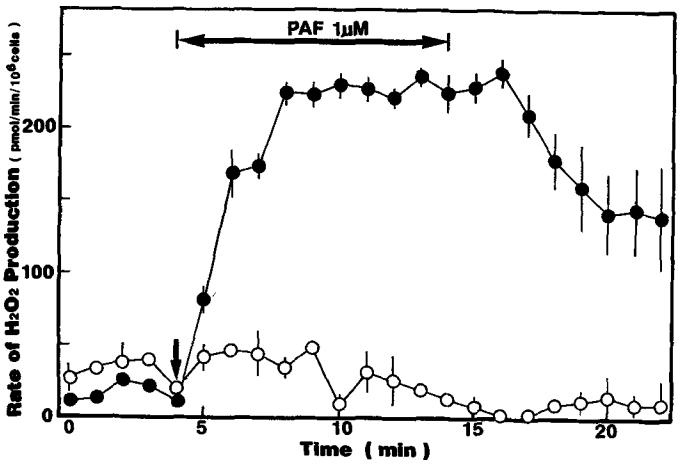

FIG. 6. Effect of extracellular calcium on H_2O_2 production in peritoneal macrophages stimulated by PAF. H_2O_2 production in macrophages stimulated by 1 μM PAF was measured in the absence (-o-) or presence (-●-) of 1 mM extracellular Ca^{2+} as described in Materials and Methods. Values are means ± S.E.M. of three determinations.

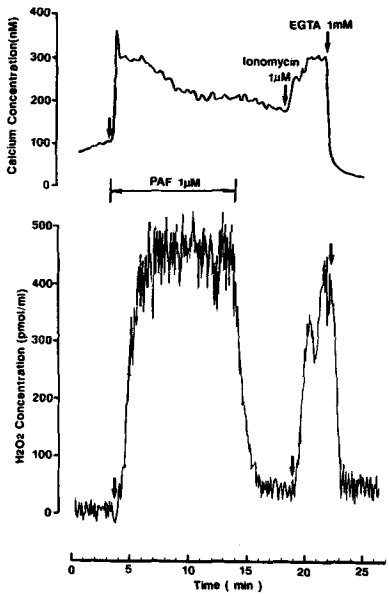

FIG. 7. Simultaneous determination of the calcium signal and H_2O_2 production in peritoneal macrophages. In the presence of external Ca^{2+}, the calcium signal and the rate of H_2O_2 production were directly compared after stimulation with 1 μM PAF and 1 μM ionomycin.

on H_2O_2 production in macrophages is also shown in Figure 6 (open circles). Upon addition of 1 μM PAF, the rate of H_2O_2 production did not increase in the absence of extracellular Ca^{2+}.

Direct comparison of $[Ca^{2+}]i$ and the rate of H_2O_2 production. For this purpose, the superfusates were directly delivered into the immobilized peroxidase column (Fig. 7).

After stimulation with 1 μM PAF, $[Ca^{2+}]i$ increased quickly and reached a peak (350 nM) within 1 min, and then decreased slowly, in a fashion similar to that shown in Figure 2. The rate of H_2O_2 production increased more slowly than the calcium signal and reached a peak within 3 min. Removal of PAF from a superfusion solution decreased H_2O_2 production to the basal level before $[Ca^{2+}]i$ reached the basal level. After stimulation with ionomycin, both $[Ca^{2+}]i$ and H_2O_2 production increased (Fig. 7).

DISCUSSION

The stimulation of cell surface receptors by various specific ligands elicits cellular responses mediated by a second messenger system (22). Macrophages have more than fifty types of receptors, and PAF is a representative stimulant. PAF increases $[Ca^{2+}]i$ in mouse peritoneal macrophages activated by thioglycollate as has been shown with quin2 as a probe (23). In the present study using fura-2, we demonstrated a similar increase in $[Ca^{2+}]i$ in peritoneal macrophages stimulated by PAF. However, the patterns of decrease of $[Ca^{2+}]i$ differed when quin2 and fura-2 were cited as fluorescent probes—with fura-2, $[Ca^{2+}]i$ showed a biphasic decrease, i.e., an initial rapid phase and a subsequent slow one (Fig. 2). On the other hand, with quin2, only a single phase of decrease occurred (12,23). This difference may be due to the lower concentration of fura-2 than of quin2 required in the cells for measuring $[Ca^{2+}]i$ and the higher K_d value of fura-2 than of quin2 for calcium binding (13).

As described above, in the absence of extracellular Ca^{2+}, only one symmetrical sharp peak was seen and a second slow phase of increase in $[Ca^{2+}]i$ was not observed (Fig. 4b). The addition of Ca^{2+} restored the second phase of $[Ca^{2+}]$ increase, suggesting that once PAF receptors are stimulated by PAF, Ca^{2+} movement across the plasma membrane occurs by some unknown mechanism. Thus, we assume that the increase in $[Ca^{2+}]i$ originates from two different sources—the first sharp peak of increase is due to movement of Ca^{2+} from intracellular stores and the second to influx of Ca^{2+} from extracellular medium across the plasma membrane. The idea of two modes of calcium movement in macrophages is consistent with previous observations on a murine macrophage cell line, J774.2 cells (16). In macrophages, the voltage-dependent calcium channel is not observed as it is in other leukocytes (24), and the mechanism of calcium influx remains unknown. One possibility is that extracellular Ca^{2+} enters via non-selective cation channels as has been observed in human neutrophils (25).

It should be also noted that the chemotactic peptide, fMLP, increase $[Ca^{2+}]i$ in peritoneal macrophages (Fig. 2), but not in J774.2 cells (16). We speculate that macrophages consist of multiple populations of cells at different stages of differentiation and that expressions of various receptors occur at different time periods after activation with paraffin, thioglycollate and other stimuli.

It is generally thought that neutrophil activation occurs by increase in $[Ca^{2+}]i$, which is followed by a respiratory burst, and by superoxide and H_2O_2 production (26). As one of the responses of activated macrophages, we measured the production of H_2O_2 using a new assay system in which immobilized peroxidase is used in the fluorometric assay described by Zaitsu and Ohkura (17). Results obtained by this assay using *p*-hydroxyphenylacetate were shown to correspond well to those obtained by the chemiluminescence method (27,28). HPPA was a more sensitive fluorogenic substrate of horseradish peroxidase than was *p*-hydroxyphenylacetate (17). The method is simple, highly reproducible, and can be applied to measure H_2O_2 in fractions. For a more time-resolved assay, the superfusion system was directly connected to an on-line system. PAF stimulation induced a prompt increase in the rate of H_2O_2 production reached a plateau within 5 min after PAF stimulation, and then decreased to the original level upon removal of PAF. Ionomycin also caused H_2O_2 production. This response, a result of the respiratory burst, required the presence of Ca^{2+} in the extracellular medium. This Ca^{2+} dependency of H_2O_2 production has also been observed in polymorphonuclear leukocytes (27,29). We suggest that PAF stimulation first causes the Ca^{2+} response, which is followed by H_2O_2 production in mouse peritoneal macrophages.

In the superfusion system, we were able to measure changes in $[Ca^{2+}]i$ and production of H_2O_2 simultaneously. This system will be useful for measuring H_2O_2 or lysosomal enzymes in superfusates to establish potential relationships between signal transduction and cell response.

Platelet-Activating Factor Stimulates Receptor-Mediated Formation of Reactive Oxygen Intermediates in Human Monocytes[1]

M.G. Pustynnikov*, N.V. Porodenko, O.V. Makarova, A.V. Kozyukov, E.Yu. Moskaleva, A.A. Sokolovsky and E.S. Severin

Stimulation of production of reactive oxygen intermediates (ROI) was examined in human peripheral blood monocytes by luminol-dependent chemiluminescence. The dose-response curve characterizing the dependence of ROI production on the concentration of platelet-activating factor (PAF) showed that stimulation occurred within a concentration range of 2×10^{-9}M to 5×10^{-6}M. Transformation of the dose-response curve to an Eadie-Hofstee plot indicated that the process is characterized by two K_m values. The K_m value corresponding to the high-affinity branch of the curve is 1.3 ± 0.14 nM. In the same cells, the dissociation constant for the [^{3}H]PAF/receptor complex was determined. The K_d value was 0.8 ± 0.1 nM, which agreed quite well with the high-affinity K_m value obtained in the Eadie-Hofstee plot. The data indicate that stimulation of ROI generation is mediated through PAF binding at specific receptor sites at nanomolar PAF concentrations. Along with the specific receptor-mediated ROI generation, a nonspecific effect of PAF at a high concentration was demonstrated.
***Lipids* 26, 1214–1217 (1991).**

Platelet-activating factor (PAF) is a phospholipid mediator that activates many of the inflammatory cells including eosinophils, neutrophils, platelets, and macrophages (1–4). Among the products that are formed during the activation of these cells, reactive oxygen intermediates (ROI), namely superoxide anion (O_2^-) and hydrogen peroxide (H_2O_2), are particularly important. Active forms of oxygen are involved in the destruction of microbes (5). Convincing evidence also suggests that blood cells respond by the release of O_2^- and H_2O_2, which can be induced by several agonists (6–8). NADPH-oxidase, an enzyme located in plasma membranes, catalyzes singlet electron reduction of O_2 to O_2^-, as well as O_2^- release in macrophages (9).

The ability of PAF to stimulate the formation of ROI in human peripheral blood macrophages has only been demonstrated quite recently (4,10) and it is still not regarded as an established fact. However, such stimulation has not been observed in alveolar macrophages (11). In the present study we evaluated the effect of PAF on the induction of ROI by human monocytes in comparison with similar effects observed in experiments with tetradecanoylphorbol acetate (TPA), a well known stimulator of intracellular oxidative burst.

MATERIALS AND METHODS

Chemicals. Sodium chloride, potassium chloride, disodium phosphate, and potassium dihydrophosphate were obtained from Fluka (Buchs, Switzerland), ethylenediaminetetraacetic acid (EDTA) from Merck (Darmstadt, Germany), Ficoll-Paque from Pharmacia (Uppsala, Sweden), trypan blue, PAF, and TPA from Serva (Heidelberg, Germany), [^{3}H]PAF (a mixture of [^{3}H]C_{16}PAF and [^{3}H]C_{18}-PAF), from Amersham (Little Chalfont, England), and superoxide dismutase (SOD) from Boehringer (Mannheim, Germany).

Cell isolation. Monocytes were obtained from donor blood containing citrate anticoagulant (0.38% aqueous solution of sodium citrate). The blood was placed on a Ficoll-Paque gradient (density 1.077 g/mL), and the mixture was centrifuged for 40 min at $400 \times g$. The monocyte-containing cell fraction from the interface was collected and washed twice in phosphate buffer (137 mM NaCl, 2.7 mM KCl, 8.1 mM Na_2HPO_4 and 1.5 mM KH_2PO_4, pH 7.4) and centrifuged for 15 min at $400 \times g$. The above procedures were performed twice. The monocytes were further purified by attaching them onto the surface of plastic culture dishes. The attached macrophages were washed in phosphate buffer and removed from the surface by intensive shaking in 0.2% EDTA. The viability of the cells was determined using trypan blue (12). The suspended cells were counted by the nonspecific esterase test (13).

Determination of reactive oxygen intermediates. The active oxygen forms were measured by chemiluminescence of luminol (5-amino-2,3-dihydro-1,4-phthalasinedion) (14), which reacts with these radicals during the oxidative burst of phagocytizing cells. Emission was measured with an LKB 1250 luminometer at 37°C (sensitivity of 1mV/cm). Cells (1.4×10^6) were placed into a cuvette at a luminol concentration of $1\text{–}2 \times 10^{-5}$M.

Quantitative characteristics of PAF binding. The dissociation constant (K_d) of the [^{3}H]PAF complex with the receptor was estimated by the radioreceptor method using a Scatchard plot. The reaction mixture containing the cell suspension (1×10^6 cells) and labeled PAF at a concentration range of 0.2 nM to 50 nM were incubated in phosphate-buffered saline (PBS) for 30 min at 37°C. The bound and the free ligands were separated by centrifugation ($3000 \times g$ for 3 min) followed by rinsing. Nonspecific binding was obtained as binding in the presence of 1 μM unlabeled PAF. For competition experiments, the conditions of incubation were the same; the reaction mixture contained [^{3}H]PAF at a concentration of 0.5 nM and unlabeled PAF at a concentration range of 0.5 nM to 1 μM.

Abbreviations: lysoPAF, lyso platelet-activating factor, 1-*O*-hexadecyl-*sn*-glycero-3-phosphocholine; PAF, platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; ROI, reactive oxygen intermediates; SOD, superoxide dismutase; TPA, tetradecanoylphorbol acetate.

RESULTS

PAF stimulated rapid formation of ROI in macrophages which were assessed by luminol-dependent chemiluminescence (Fig. 1). A maximum level of ROI formation was observed approximately after 1 min. Dose dependence was observed in the PAF concentration range from 2×10^{-9}M to 5×10^{-6}M (Fig. 2), with a maximum effect at 2×10^{-6}M PAF. Figure 3 depicts Eadie-Hofstee transformation of the ROI stimulation curve (its hyperbolic part). The dependence was strikingly non-linear, with K_m being equal to 1.3 nM and 94 nM for the "high" and "low" affinity branches, respectively.

The data on displacement of ^{3}H-labeled PAF, bound to human peripheral blood monocytes, are represented in a semilogarithmic plot in Figure 4. The data are consistent with PAF interaction at one binding site.

The dissociation constant (K_d) for the [^{3}H]PAF/receptor complex on monocytes (K_d) was 0.8 ± 0.1 nM. This K_d value agreed rather well with the high-affinity K_m value obtained in the Eadie-Hofstee plot (Fig. 3). The low-affinity branch may reflect less specific processes occurring in cells which bear no relation to specific PAF receptor binding at corresponding binding sites. Addition of lysoPAF at concentrations of up to 1 μM had no effect.

To determine the origin of the product formed by monocytes in response to PAF treatment, the sample was supplemented with 350 U of superoxide dismutase (SOD). As seen in Figure 1b, no ROI formation was observed that would be indicative of PAF stimulated release of superoxide anion. O_2^- induction can be activated by the soluble stimulus TPA. The corresponding curve is shown in Figure 5. As in the case of PAF, chemiluminescence ceased after the addition of SOD (Fig. 5b), indicating O_2^- release.

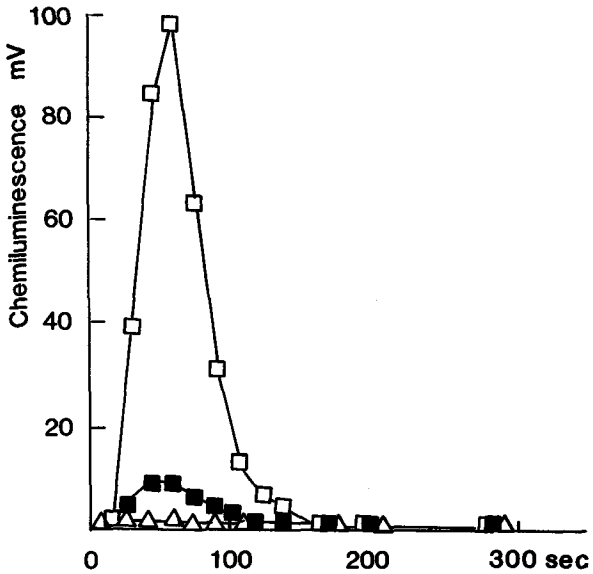

FIG. 1. Effect of PAF and SOD on ROI production in human monocytes. Experiments were performed as described in Materials and Methods; —□— in the presence of PAF (2×10^{-6}M); —■— in the presence of PAF (2×10^{-6}M) and SOD (350 units); —△— in the presence of 1 μM lysoPAF. The results are shown as the means of triplicate determinations from one of three similar experiments.

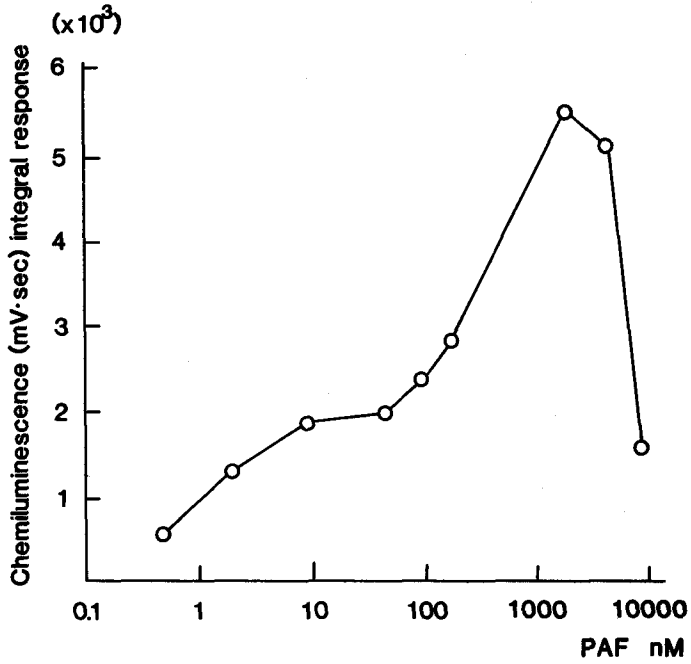

FIG. 2. Effect of increasing dose of PAF on ROI production. The results shown are the means of duplicate determinations from one of three similar experiments.

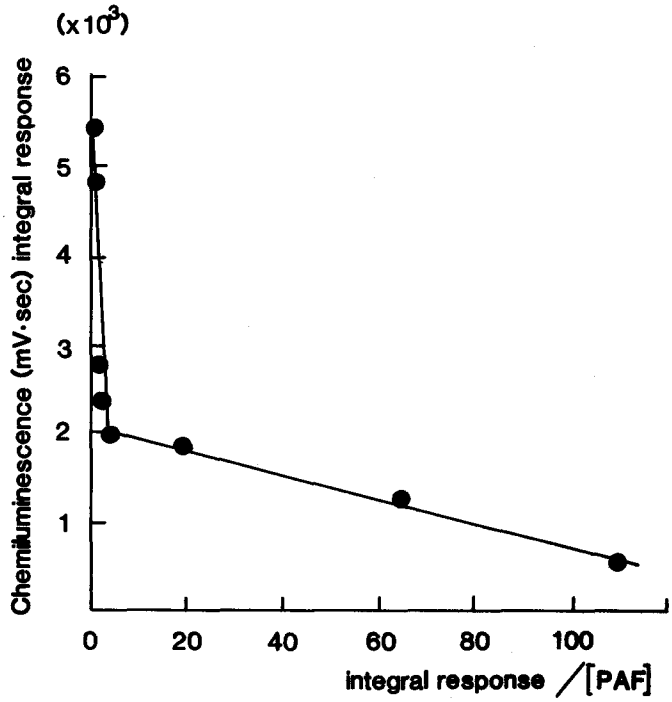

FIG. 3. Dependence of ROI production on PAF concentration in the Eadie-Hofstee plot. Data are the means of duplicate determinations from three separate experiments.

A comparison of the data in Figure 1 and Figure 5 shows that TPA appears to be a more efficient activator of respiratory burst in monocytes (Fig. 6); the kinetic parameters of O_2^- release under the action of PAF and TPA were significantly different.

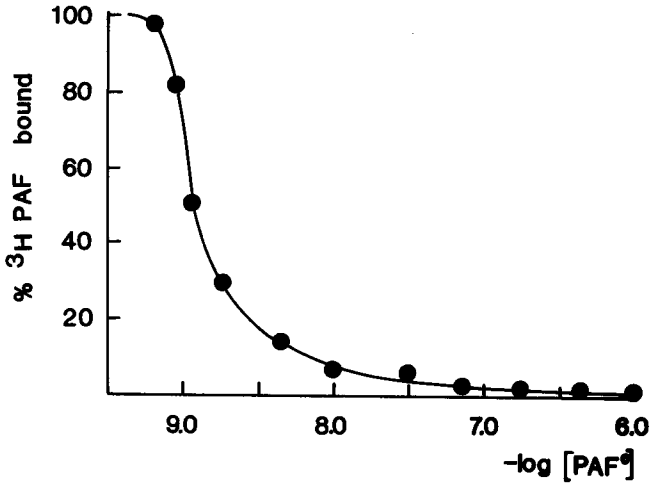

FIG. 4. Competitive displacement of [^{3}H]PAF by nonlabeled PAF. PAF°, nonlabeled PAF. Experiments were performed as described in Materials and Methods. Data are the means of triplicate determinations.

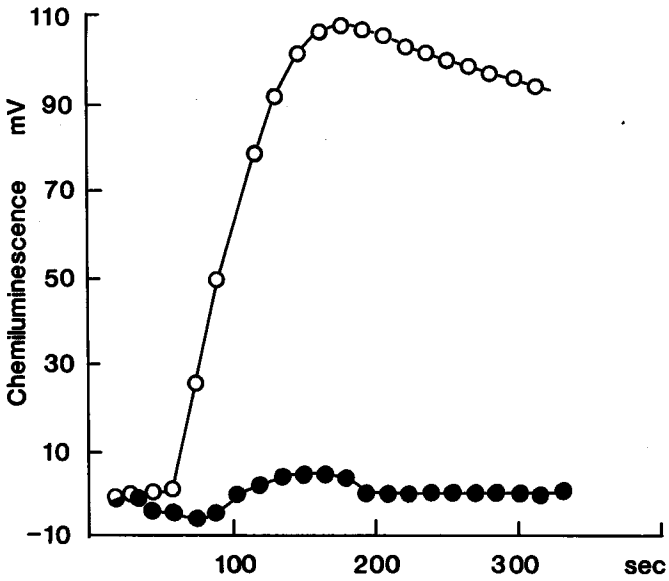

FIG. 5. Effect of TPA and SOD on ROI production in human monocytes; —○— in the presence of TPA (1×10^{-7}M); —●— in the presence of TPA (1×10^{-7}M) and SOD (350 units). The results shown are the means of triplicate determinations from one of three similar experiments.

DISCUSSION

ROI production, being one of the key functions of macrophages, is known to be induced by intracellular stimuli (15). Although these stimuli can be quite diverse, the metabolic pathways of their action within the cell are quite similar. A noticeable stimulation of ROI production, once the macrophages are exposed to TPA treatment, indicates the involvement of protein kinase C in this process (16,17).

Our results have shown that TPA stimulates ROI production more actively than does PAF. This is probably due to a lesser activation of protein kinase C by diacylglycerol than that observed with TPA.

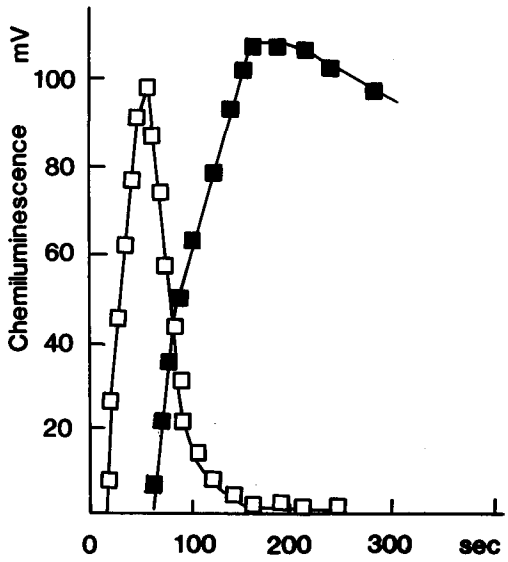

FIG. 6. Stimulation of ROI production in response to PAF and TPA; —□— in the presence of PAF (2×10^{-6}M); —■— in the presence of TPA (1×10^{-7}M). Experiments were performed as described in Materials and Methods.

The estimated PAF concentration generating a half-maximal response of monocytes (1.3×10^{-9}M) correlates rather well with the K_d value obtained for PAF interaction with the specific receptor on the monocytes. This concentration of PAF is substantially lower than indicated by the binding constant in (4) (5×10^{-6}M). We found that chemiluminescence decreases when the PAF concentration exceeds 3×10^{-6}M (Fig. 2).

Our data are consistent with the postulated role of PAF as a stimulator of ROI generation by monocytes which is mediated through PAF receptor binding at specific sites at nanomolar PAF concentrations.

Calcium Channel Blockade Inhibits Platelet Activating Factor Production by Human Umbilical Vein Endothelial Cells[1]

J.P. Tolins*, A. Melemed, D. Sulciner, K.S. Gustafson and G.M. Vercellotti
University of Minnesota School of Medicine and Veterans Administration Medical Center, Minneapolis, Minnesota 55417

An increase in intracellular calcium level is an important signal in the regulation of cellular responses under normal and pathological conditions. Because two key enzymes in the synthetic pathway of platelet activating factor (PAF), phospholipase A_2 and acetyltransferase, are calcium dependent, we hypothesized that calcium channel blockade may inhibit agonist-induced PAF synthesis. Primary cultures of human umbilical vein endothelial cells (EC), pre-incubated with [^{3}H]acetate, were exposed to thrombin (5 U/mL) and PAF production was quantitated by incorporation of radiolabel into the EC lipid fraction co-migrating with exogenous PAF in thin-layer chromatography. The effect of pre-incubation with calcium channel blockers (verapamil, diltiazem, 10^{-4} M) or buffer was determined. Results (triplicate experiments, * $P<0.05$ vs buffer, † $P<0.05$ vs thrombin) demonstate that pre-incubation with calcium channel blocker markedly inhibits thrombin-induced PAF production (verapamil:buffer 273 ± 122, thrombin 10,735 ± 1524*, thrombin + verapamil 178 ± 91 † cpm/plate; diltiazem:buffer 1097 ± 581, thrombin 15,283 ± 2661*, thrombin + diltiazem 280 ± 56 † cpm/plate). The effect of diltiazem was dose-dependent (% inhibition: 10^{-7} M, 46%; 10^{-5} M, 60%; 10^{-4} M, 98%). Diltiazem also inhibited bradykinin (10^{-8} M) induced PAF synthesis. In calcium-free medium or in the presence of $LaCl_3$ (10^{-3} M), the PAF response of EC to thrombin was blunted (buffer 582 ± 360, thrombin 5394 ± 1069, thrombin + calcium free medium 1055 ± 571, thrombin + $LaCl_3$ 1271 ± 58 cpm/plate). We conclude that calcium channel blockers prevent agonist-induced PAF synthesis, possibly by preventing cellular calcium influx and activation of PAF synthetic enzymes. We speculate that this mechanism may underlie, at least in part, the beneficial effect of calcium channel blockade under various pathological conditions.
***Lipids 26,* 1218–1222 (1991).**

An increase in intracellular calcium concentration has been postulated to be pathogenetically important in diverse forms of cellular injury, such as ischemia, by virtue of calcium-dependent activation of membrane-associated phospholipases, subsequent degradation of the cell membrane, and eventual loss of the barrier properties essential to cell function (1,2). Less severe forms of cellular injury and cellular activation by various endogenous mediators are also associated with increases in intracellular calcium levels and activation of phospholipases (3). In this setting the phospholipids of the cell membrane serve as a storage depot for precursors of a variety of lipid-derived, biologically active mediators, such as arachidonic acid and lysophospholipids, which can be rapidly converted into sets of highly active compounds including eicosanoids, leukotrienes and platelet activating factor (4,5). Thus, an increase in intracellular calcium, either through influx of extracellular calcium or mobilization of intracellular storage pools, links cellular activation with the generation of lipid mediators of inflammation that may play a role in various pathological conditions.

Platelet activating factor (PAF†) has been identified as 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (6). It is synthesized by various activated cell types, including vascular endothelial cells (7), and has a broad spectrum of inflammatory and hemodynamic actions that may be important in disease states (6,8). Based on *in vitro* studies, it is clear that the synthesis of PAF is dependent on the presence of extracellular calcium (9), and that transmembrane calcium flux is the signal that initiates PAF synthesis (10). This most likely reflects the calcium-dependence of two key enzymes in the PAF synthetic pathway, phospholipase A_2 and acetyltransferase (9,11).

Calcium channel blockers, such as verapamil and diltiazem, are in widespread clinical use for the treatment of hypertension and atherosclerotic cardiovascular disease (12). While they have been demonstrated to block calcium entry via voltage-dependent calcium channels, particularly in vascular smooth muscle cells, the effect of these agents on receptor-operated calcium channels is not as well defined (13). Block and coworkers (14) recently reported that calcium channel blockade inhibited the mitogenic effect of platelet-derived growth factor (PDGF) on vascular smooth muscle cells, in association with a decrease in intracellular calcium accumulation. Furthermore, they suggested that this effect could be due to modulation of the PDGF receptor itself or the receptor-linked calcium channel. Shultz and Raij (15) also recently reported that three different calcium channel antagonists inhibited human mesangial cell proliferation in response to either PDGF or thrombin. They suggested that the calcium antagonists blocked receptor mediated calcium influx in this cell type. We therefore hypothesized that by interfering with receptor-mediated cellular calcium influx, calcium channel blockade might prevent agonist-induced synthesis of platelet activating factor.

Thrombin has a number of biological effects that are mediated by a high affinity cell-surface receptor, rather than its enzymatic action (16). Included in this category is the induction of PAF synthesis by vascular endothelial cells (7,17). This effect is associated with an increase in intracellular calcium concentration that

†Abbreviations: BSA, bovine serum albumin; HBSS, Hank's balanced salt solution; EC, human umbilical vein endothelial cells: PAF, platelet activating factor; PDGF, platelet derived growth factor, PGI2, prostacyclin.

is dependent on the presence of extracellular calcium (18). In the current study, we evaluated the effect of calcium channel blockade on thrombin-induced stimulation of PAF synthesis in human umbilical vein endothelial cells (EC) in culture.

MATERIALS AND METHODS

Materials. PAF, bovine serum albumin (BSA), lanthanum chloride ($LaCl_3$), bradykinin and human thrombin were purchased from Sigma Chemical Co. (St. Louis, MO). Hank's balanced salt solution (HBSS) was obtained from Gibco (Grand Island, NY). [^{3}H]Acetate was from New England Nuclear (Boston, MA). Verapamil was purchased from Searle Pharmaceuticals (Chicago, IL). Diltiazem was the generous gift of Marion Laboratories (Kansas City, MO). All materials were endotoxin-free as tested by the Limulus amoebocyte assay (19).

Endothelial cell cultures. EC were harvested from umbilical cords by collagenase digestion as previously described (20). EC plated in 60 × 15 mm tissue culture dishes (Becton-Dickinson Labware, Oxnard, CA) were grown to confluent monolayers (2.5×10^6 cells/plate) and used as primary cultures.

PAF assay. Plates were preincubated with either buffer (HBSS/0.5% BSA) or buffer containing appropriate concentration of calcium channel blocker for 20 min at 37°C. EC were then exposed to [^{3}H]acetate (55 μCi/dish) with or without calcium blocker, either in the presence or absence of thrombin (5.0 U/mL) for 5 min at 37°C. PAF production was then quantified by determining [^{3}H]acetate incorporation into EC PAF. Cells were scraped from the plate and a lipid extraction performed on the 2 mL cell suspension by the method of Bligh and Dyer (21). The suspension was transferred to the extraction solvents, chloroform (2.5 mL) and methanol (5.0 mL), and 25 μg of cold carrier PAF added. The single phase mixture was vortexed for 2 min and broken by the addition of 2.5 mL chloroform and water, with vortexing after each addition. The mixture was filtered (Whatman #2) and the chloroform layer removed. The remaining aqueous layer was washed with 5.0 mL chloroform and the combined chloroform layers dried under nitrogen. The separation and purification of PAF by thin layer-chromatography was accomplished using the method of Pinckard *et al.* (22). Plates precoated with silica gel H were dried for at least 3 hr at 105°C. Following application of the samples, the plates were returned to the oven for an additional 3–5 min and then developed in a solvent tank containing chloroform/methanol/water (65:35:6, v/v/v). Subsequently, plates were air dried and exposed to iodine vapors to locate the standard lipids. The specific position of PAF was identified using exogenous unlabeled PAF standard ($R_f = 0.21$). This area was scraped and radioactivity determined by liquid scintillation counting (Beckman LS230, Beckman Instruments, Inc., Palo Alto, CA). In control studies using [^{3}H]PAF, 87% recovery of label was obtained using this technique. The authenticity of PAF isolated by this technique was documented by sensitivity of the recovered material to PLA_2, and ability to aggregate rabbit platelets, as previously described (23).

Measurement of intracellular calcium concentration in EC monolayers: Effect of calcium channel blockade on thrombin-induced calcium flux. We measured intracellular calcium concentration in intact monolayers of EC, grown on coverslips, with the fluorescent calcium-sensitive probe, fura 2, by the technique previously described by our laboratory (18). EC were preincubated with either diluent or calcium channel blocker (diltizem or varapamil, 100 μg/mL final concentration) for 10 min, and then exposed to thrombin (0.5 U/mL). Intracellular calcium concentration was monitored for five additional minutes. Experimental conditions were performed in duplicate.

Effect of calcium channel blockade on thrombin-induced prostacyclin synthesis. EC were harvested as previously described (20) and plated in 2 cm^2 24-well Costar plates (Costar, Cambridge, MA). EC were grown to confluent monolayers and used as primary cultures. Experiments were performed in triplicate. All wells were rinsed with buffer (HBSS, 25 mM Hepes, 0.05% human serum albumin) and incubated with either verapamil (10^{-4} M) or buffer for 15 min. All wells were then incubated with thrombin (1.0 U/mL) for 10 min. Supernatants were removed and transferred to cold 12 × 75 mm polypropylene tubes containing 10 μg/mL indomethacin, vortexed and frozen at −70°C until assayed. Samples were assayed for the stable prostacyclin metabolite, 6-keto-prostaglandin-F1-α(PGF1-α), with a commercial radioimmunoassay kit (Dupont NEN, Boston, MA).

Statistical analysis. Data are presented as mean ± standard error. Differences between groups were analyzed by one-way analysis of variance and subsequent Scheffe's test. Differences were considered significant for $P<0.05$.

RESULTS

The effect of calcium channel blockade with either verapamil or diltiazem (10^{-4} M) on thrombin-induced PAF generation by EC is shown in Figure 1. Values represent triplicate experiments performed on different days. Thrombin exposure induced marked radiolabel incorporation into EC PAF compared to control cells exposed to buffer alone, reflecting marked stimulation of PAF synthesis. As can be seen, pre-incubation with either verapamil or diltiazem completely inhibited thrombin-induced PAF synthesis. In separate experiments, incubation of EC with this concentration of calcium antagonist (10^{-4} M) did not effect EC viability as assessed by trypan blue exclusion. Exposure of EC to the structurally distinct agonist, bradykinin (10^{-8} M) also induced PAF synthesis, although to a lesser extent than thrombin. This effect was also inhibited by pre-incubation with diltiazem (10^{-4} M), as shown in Figure 2. Inhibition of thrombin-induced PAF synthesis by diltiazem was dose-dependent (Fig. 3), with 50% inhibition occuring between 10^{-7} M and 10^{-6} M. As shown in Figure 4, exposure of EC to thrombin in the absence of calcium in the medium, or with standard buffer in the presence of $LaCl_3$ (10^{-3} M), resulted in significant blunting of the PAF synthetic response. Thus, thrombin-induced PAF synthesis by EC was dependent on the presence of extracellular calcium and

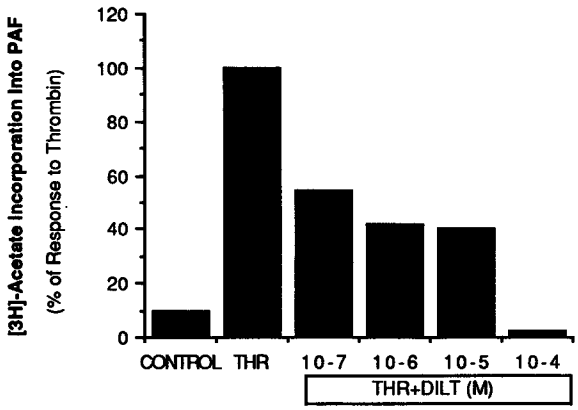

FIG. 3. Effect of calcium channel blockade with diltiazem (DILT) on stimulation of PAF synthesis by thrombin (THR, 5.0 U/mL) in endothelial cells. Diltiazem inhibits thrombin-induced PAF synthesis in a dose-dependent manner. Mean of duplicate experiments.

inhibitable by calcium channel blockade with either the non-specific calcium entry blocker, lanthanum chloride, or the pharmacologic calcium channel blockers, verapamil or diltiazem. The inhibitory effect of diltiazem occurred in a dose-dependent fashion, and this agent also inhibited the PAF synthetic response to a distinct agonist, bradykinin.

As shown in Figure 5, stimulation of EC with thrombin resulted in a rapid rise in intracellular calcium that peaked at 2 min and slowly returned toward baseline over the next 4–5 min, consistent with previous reports from this laboratory (18). Preincubation of the EC with either verapamil or diltiazem markedly blunted this response. Thus, calcium channel blockers, at a concentration that prevented thrombin-induced PAF synthesis, also blunted thrombin-induced increases in intracellular calcium concentration.

If calcium channel blockers prevent thrombin-induced activation of PLA_2 by blunting increases in intracellular calcium concentration, then it would be predicted that synthesis of eicosanoids, in addition to PAF, would also be inhibited by these agents. Consistent with this prediction, preincubation of EC with verapamil markedly inhibited release of prostacyclin into the supernatant after stimulation with thrombin (thrombin vs thrombin + verapamil, 2717 ± 247 vs 968 ± 32 pg PGF1-α/well, P<0.05).

DISCUSSION

The calcium channel blockers are in widespread clinical use in the treatment of hypertension and cardiovascular disease (12). Much attention has focused on the systemic and renal hemodynamic effects of these agents (13,24) and the relationship of these effects to therapeutic benefits. However, given the central role of calcium as a signal in the regulation of diverse aspects of cellular metabolism and, in particular, phospholipid metabolism (3,4), it is not surprising that the importance of the metabolic effects of these agents has become increasingly apparent. The calcium channel blockers have been demonstrated to have protective effects in models of ischemic (25), toxic (26,27) and chronic

hypertensive renal injury (28,29). Although the mechanism of these protective effects is unclear, prevention of abnormal cellular calcium accumulation, as well as decreased cellular metabolic demands, have been suggested to be important (28,30). An increase in intracellular calcium results in activation of phospholipase A_2 which catalyzes the hydrolysis of the fatty acid ester linkage at position 2 of the phospholipid molecule, generating arachidonic acid and lysoPAF (4). Eicosanoids can be synthesized from arachidonic acid and, furthermore, through action of another calcium dependent enzyme, acetyltransferase, lysoPAF can be converted to PAF (9), with resultant inflammatory and hemodynamic effects that may be important in disease processes (5). By preventing calcium influx in response to biologically relevant mediators, the calcium channel blockers may prevent generation of these inflammatory mediators and thus provide protection from tissue injury in various pathological conditions. Although it has been previously demonstrated that calcium channel blockade blunts agonist-induced prostaglandin synthesis (31,32), the effect of these agents on PAF synthesis has not previously been studied.

In the current study we have demonstrated that pre-incubation with either verapamil or diltiazem markedly inhibits thrombin-induced [^{3}H]acetate incorporation into the EC lipid fraction comigrating with PAF. The effect of diltiazem occurred in a dose-dependent fashion, and this agent also blocked the PAF synthetic response to bradykinin. Removal of calcium from the medium or non-specific blockade of calcium entry with lanthanum chloride also inhibited thrombin-induced PAF synthesis. Furthermore, we have demonstrated that verapamil inhibits EC prostacyclin release after thrombin stimulation. Calcium antagonists, at concentrations that inhibited synthesis of PAF and prostacyclin, also markedly blunted the rise in intracellular calcium concentration observed after stimulation of EC with thrombin. Thus, it is likely that the effect of calcium channel blockade on PAF synthesis is due to the prevention of agonist-induced calcium entry. However, the mechanism whereby the calcium channel blockers exert their inhibitory effect on PAF synthesis cannot be determined with certainty from this study. These agents have been thought to inhibit calcium entry via voltage-dependent calcium channels. Recent evidence suggests that they can interfere with calcium entry due to the binding of agonists to cell receptors, as well. Block *et al.* (14) demonstrated that calcium antagonists inhibited the mitogenic effect of PDGF in vascular smooth muscle cells, and postulated that the calcium channel blockers could modulate the agonist-receptor interaction or interfere with coupling between receptor activation and calcium entry. Similarly, Schultz and Raij (15) demonstrated that calcium channel blockers inhibited glomerular mesangial cell mitogenesis in response to thrombin or PDGF. Calcium channel blockers have also been demonstrated to have PAF-receptor blocking activity on platelets (33). Thus, it is clear that the calcium antagonists can interfere with cellular responses that depend on receptor-mediated calcium fluxes, although the exact mechanism of this effect is unknown.

In summary, calcium channel blockade inhibited thrombin-induced PAF synthesis by endothelial cells, *in vitro*. This suggests an additional, novel mechanism by which calcium antagonists may exert a protective effect in pathological conditions. The exact mechanism of this effect and relevance to clinical use of these agents awaits further study.

[Received June 22, 1989; Revision accepted April 13, 1990]

The Effect of Eicosapentaenoic Acid Consumption on Human Neutrophil Chemiluminescence[1]

Philip J. Thompson*[a], Neil L.A. Misso[a], Marion Passarelli[a] and Martin J. Phillips[b]
[a]Department of Medicine, University of Western Australia and [b]Department of Respiratory Medicine, Sir Charles Gairdner Hospital, Nedlands, W.A. 6009, Australia

The effect of eicosapentaenoic acid (EPA) on the inflammatory potential of neutrophils was investigated by supplementing the diets of 12 subjects with 2.16 g of EPA or 12 g of olive oil per day for 4 weeks in a double blind crossover study. Neutrophil function as assessed by luminol enhanced chemiluminescence responses to platelet-activating factor (PAF) and formyl-methionyl-leucyl-phenylalanine (FMLP) was significantly reduced after EPA but not after olive oil consumption in the subjects who consumed EPA first. In contrast, EPA had no significant effect on neutrophil chemiluminescence in the subjects who consumed olive oil first. Dietary supplementation with EPA inhibits neutrophil responses to inflammatory mediators such as PAF while other fatty acids appear to modify the effects of EPA.
Lipids 26, 1223–1226 (1991).

Populations such as the Greenland Eskimos and Japanese have a high dietary intake of fish oil compared to most Western diets and are noted to have a much lower prevalence of coronary artery disease (1) and chronic inflammatory diseases such as asthma, rheumatoid arthritis and psoriasis (2).

These epidemiological observations have led to the hypothesis that the eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) in oily cold-water fish may offer protection against these diseases. EPA inhibits the uptake of arachidonic acid (AA) into cell membrane phospholipids and competes with AA for metabolism by the cyclooxygenase and lipoxygenase pathways. DHA is an inhibitor of these pathways (3). Metabolites of AA (thromboxane A_2, prostaglandins and leukotrienes) are thought to contribute to the inflammatory process in asthma by recruiting and activating neutrophils, eosinophils and macrophages (4). Platelet-activating factor (PAF), another likely mediator of inflammation in asthma, is derived from 1-*O*-alkyl-2-arachidonoyl-*sn*-glycero-3-phosphocholine, and its formation is closely linked with AA metabolism in neutrophils (5). Dietary supplementation with fish oil increases the proportion of EPA to AA in cell membrane phospholipids (6) and thus could result in a decreased production of PAF and inflammatory eicosanoids as well as the production of less potent analogues such as thromboxane A_3 and LTB_5 (leukotriene B) (3,7).

An important function of stimulated neutrophils is the production of reactive oxygen metabolites (8), a process which can be monitored by the technique of luminol-enhanced chemiluminescence (CL) (9). In this study the effect of dietary supplementation with EPA on the inflammatory potential of neutrophils was assessed by measuring neutrophil CL responses to *in vitro* stimulation with PAF and formyl-methionyl-leucyl-phenylalanine (FMLP) and comparing this with the effect of a placebo in the form of olive oil.

MATERIALS AND METHODS

Twelve healthy volunteers were entered into a double blind balanced crossover study comparing the effects of EPA and olive oil (placebo) on neutrophil chemiluminescence. They were asked to avoid all medication for two weeks prior to entry, and to maintain their normal diets prior to and during the study. The study was of sixteen weeks' duration and divided into 4 four-week intervals. Six subjects (Group 1, 3 males, 3 females aged 24–40 years with a mean age of 33 years) consumed MaxEPA capsules (Lipitac, Reckitt & Colman Products Pty. Ltd., West Ryde, NSW, Australia) in the first four weeks while the other six subjects (Group 2, 3 males, 3 females aged 23–38 years with a mean age of 29.5 years) consumed identical capsules containing olive oil. The dosage was 12 capsules daily, which provided 2.16 g of EPA per day or in the case of olive oil 12 g per day. After 4 weeks all subjects entered a four-week wash-out period when no capsules were taken. In the third four-week period, subjects were crossed over to the alternate capsules, and the study concluded with a four-week wash-out period. At the commencement of the study and after each four-week period (day 0, 28, 56, 85, and 112 of the study), blood was taken for neutrophil isolation.

Neutrophils were isolated by centrifugation of heparin anticoagulated whole blood on discontinuous Percoll (Pharmacia LKB, Uppsala, Sweden) gradients (10). Neutrophils were washed in phosphate buffered saline, counted in a haemocytometer and resuspended in Hanks balanced salt solution buffered with *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid (HBSS-HEPES) at 1.8×10^6 cells/mL.

A 5 mM stock solution of luminol (Boehringer Mannheim, Mannheim, W. Germany) in dimethylsulfoxide (DMSO) was diluted in HBSS to give a 0.5 mM working solution. PAF (1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine, Sigma Chemical Co., St. Louis, MO) was stored as a 1 mM solution in ethanol at −20°. On the day of use, 0.1 mL of the stock solution was evaporated under N_2 and resuspended in 1 mL of HBSS containing 0.25% human serum albumin to give a 10^{-4} M solution which was further diluted with HBSS to give working solutions of the required concentration. FMLP (Sigma) was stored as a 10^{-2} M solution in 50 μL aliquots of DMSO at

[1]Based on a paper presented at the Third International Conference on Platelet-Activating Factor and Structurally Related Alkyl Ether Lipids, Tokyo, Japan, May 1989.

Abbreviations: AA, arachidonic acid; CL, chemiluminescence; DHA, docosahexaenoic acid; DMSO, dimethylsulfoxide; EPA, eicosapentaenoic acid; FMLP, formyl-methionyl-leucyl-phenylalanine; HBSS-HEPES, Hanks balanced salt solution buffered with *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid; 5-HETE, 5-hydroxyeicosatetraenoic acid; LTB, leukotriene B; PAF, platelet-activating factor.

−70°. Dilutions to give working solutions of the required concentration were made with HBSS.

Chemiluminescence was measured in a LKB 1250 luminometer. The reaction mixture (total vol 0.5 mL) contained 7.5×10^5 neutrophils and 25 μM luminol. The reaction was started by the addition of 50 μL of PAF or FMLP to give the required final concentration. The CL response was monitored for 10–15 min on a digital display/printer unit and chart recorder.

CL responses were measured as the maximum amplitude in mV, and the data were analyzed by calculating mean values (± standard error of mean). Students t-test for paired data with a significance level of $p < 0.05$ was used when comparing data from the same group of subjects on different days.

RESULTS

The luminol-enhanced CL response of neutrophils to PAF and FMLP was biphasic. An initial rapid burst of chemiluminescence which peaked at 1–2 min after the addition of the stimulus was followed by a more gradual rise in CL which reached a maximum at 8–10 min. In this study the maximum amplitude of the initial peak which is associated with the production of extracellular reactive oxygen metabolites (11) was used as a measure of neutrophil CL responses to PAF and FMLP.

Neutrophil CL dose response curves to PAF and FMLP representing the mean responses of the 12 subjects at the commencement of the study are shown in Figure 1. The mean maximum response to PAF was observed at a concentration of 5×10^{-6} M. The mean FMLP response was maximum at 10^{-5} M and was higher than the mean PAF response (14.2 ± 7.3 vs 10.6 ± 2.4 mV). Similar PAF and FMLP concentrations have been used previously in the measurement of neutrophil CL responses and have not been shown to affect cellular integrity (12,13). The FMLP response was more variable at 10^{-5} M than at 10^{-6} M, and for this reason the latter concentration was used when comparing the mean responses on different days.

At the PAF concentration which produced a maximum response, neutrophils from Group 1 subjects who consumed EPA from day 0 to day 28 showed a significant decrease in the mean CL response on day 28 compared to day 0 (4.9 ± 2.9 vs 10.9 ± 4.6 mV, $p < 0.005$) (Fig. 2A). At the end of the first wash-out period (day 56), the CL response had increased to 8.3 ± 3.4 mV which was not significantly different to day 0. There were no significant changes in the CL responses measured after consumption of placebo in the form of olive oil (day 85) or at the end of the study (day 112) (Fig. 2A).

In the Group 2 subjects who consumed placebo capsules from day 0 to day 28, the mean CL response to a maximum PAF concentration was not significantly different on day 28 (6.4 ± 1.3 mV) compared to day 0 (10.3 ± 4.3 mV) (Fig. 2B). However the mean responses on day 85 (8.8 ± 2.0 mV) after EPA consumption and on day 112 (6.3 ± 2.0 mV) were also not significantly different to the response on day 0 or on day 56 (6.9 ± 1.6 mV) prior to EPA consumption.

In response to 10^{-5} and 10^{-6} M PAF, similar trends were observed with a reduction in CL at day 28 in the Group 1 subjects. With 10^{-7} M PAF, the CL responses were so low that meaningful variations with time could not be discerned. For the Group 2 subjects, mean CL responses to PAF concentrations of 10^{-5}, 10^{-6} and 10^{-7} M did not change significantly during the course of the study.

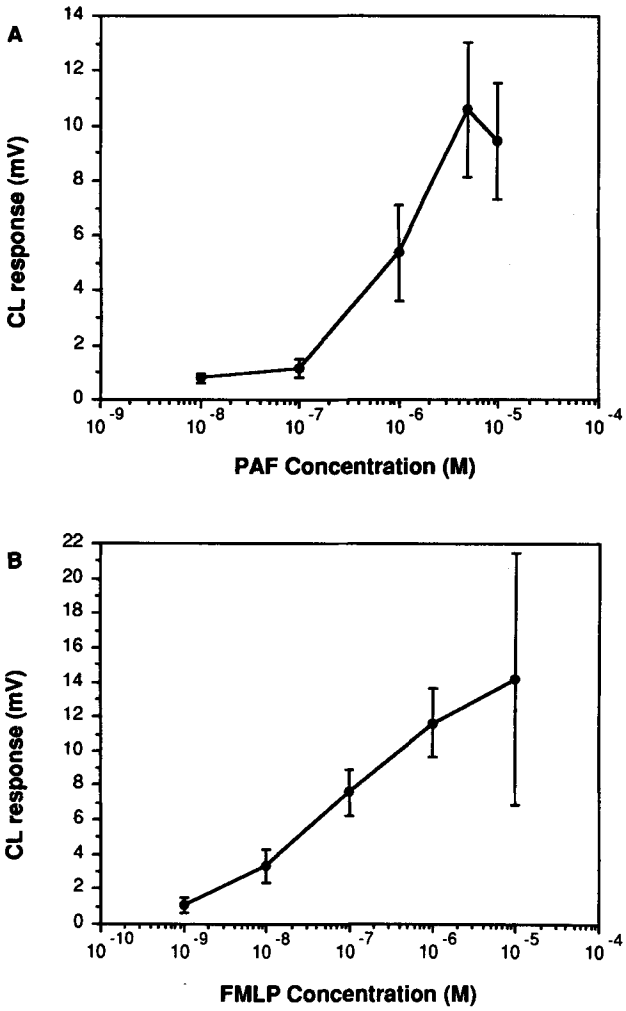

FIG. 1. Dose responses of neutrophil chemiluminescence to PAF (A) and FMLP (B). Each point represents the mean (±SEM) CL response for all 12 subjects on day 0. For each test, PAF or FMLP was added to 7.5×10^5 neutrophils with 25 μM luminol, and the maximum amplitude of the CL response was measured in mV.

Comparisons of the mean CL responses to 10^{-6} M FMLP were used to assess the effect of EPA consumption on neutrophil response to this stimulus (Fig. 3A). In Group 1 subjects, the CL response to 10^{-6} M FMLP was 13.8 ± 2.5 mV on day 0. After EPA consumption this decreased to 7.6 ± 3.3 mV on day 28 and decreased further to 5.7 ± 1.5 mV at the end of the first wash-out on day 56 which was significantly less than day 0 ($p < 0.05$). After subsequent placebo (olive oil) consumption, the mean CL response returned to 12.0 ± 3.6 mV on day 85 and to 13.4 ± 5.2 mV at the end of the study.

Neutrophils from Group 2 subjects who consumed olive oil first gave a mean CL response to 10^{-6} M FMLP of 9.4 ± 3.0 mV on day 0 (Fig. 3B). This did not change significantly after placebo consumption (11.8 ± 5.3 mV on day 28, 11.5 ± 3.9 mV on day 56) and although there was a decrease in the response after EPA consumption

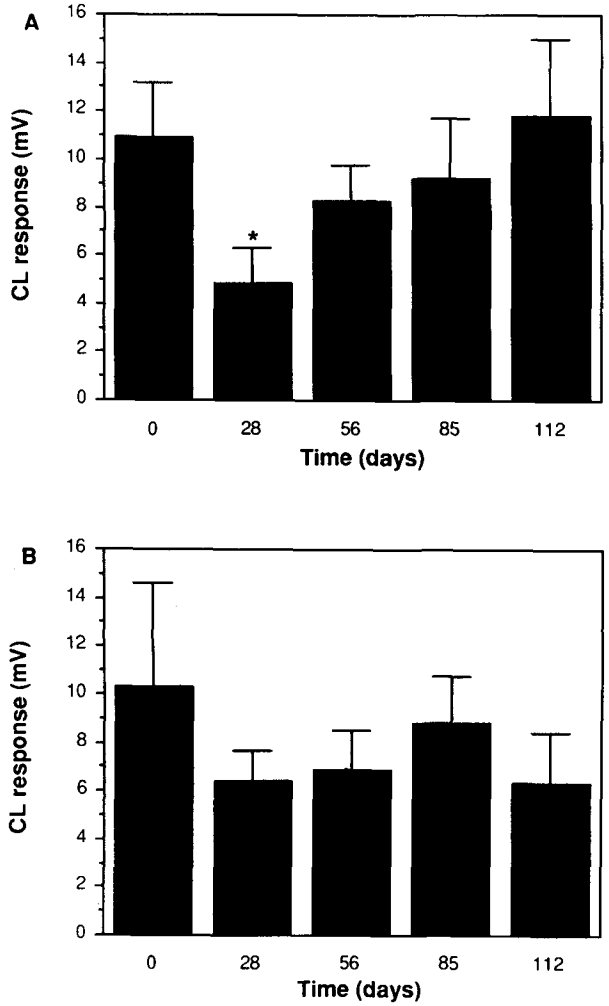

FIG. 2. Mean (±SEM) neutrophil chemiluminescence responses to PAF (5×10^{-6} M) in Group 1 subjects who consumed EPA from day 0 to day 28 (A) and in Group 2 subjects who consumed olive oil capsules from day 0 to day 28 (B). * = $p < 0.005$ compared to day 0 by paired t-test.

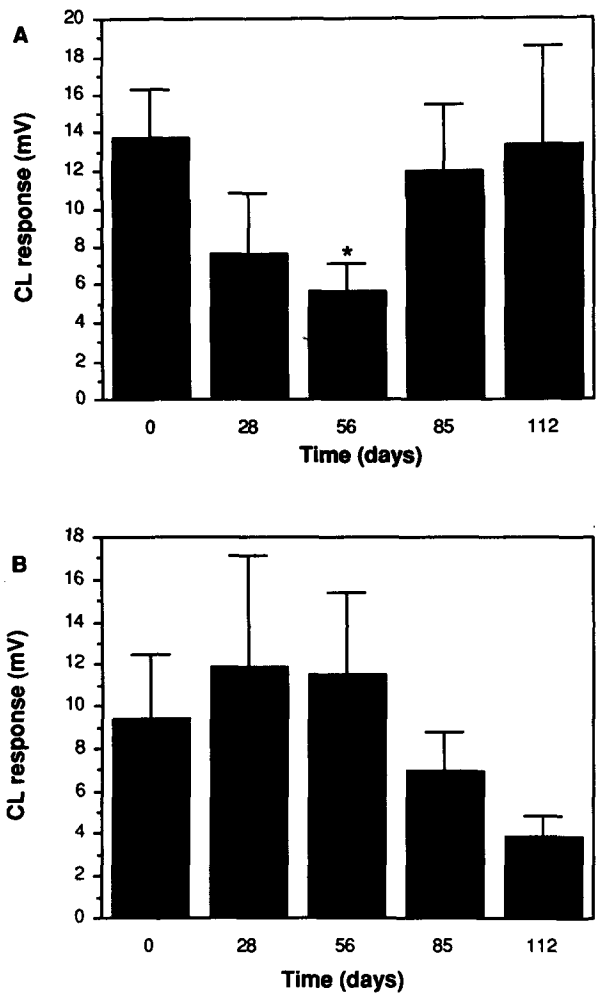

FIG. 3. Mean (±SEM) neutrophil chemiluminescence responses to FMLP (10^{-6} M) in Group 1 subjects who consumed EPA from day 0 to day 28 (A) and in Group 2 subjects who consumed olive oil capsules from day 0 to day 28 (B). * = $p < 0.05$ compared to day 0 by paired t-test.

(7.0 ± 1.8 mV on day 85, 3.9 ± 1.0 mV on day 112), this did not reach statistical significance.

In the Group 1 subjects, CL responses to 10^{-5} and 10^{-8} M FMLP showed similar trends to those described for 10^{-6} M FMLP with CL being reduced on day 56 compared to day 0. With 10^{-7} M FMLP, the trend for a reduction in CL could not be discerned. For the Group 2 subjects, the CL responses to 10^{-5}, 10^{-7} and 10^{-8} M FMLP did not change significantly with time.

DISCUSSION

In the group of six subjects who consumed EPA capsules from day 0 to day 28, there was a significant reduction in the neutrophil CL responses to PAF and FMLP immediately after the consumption of EPA. Consumption of placebo capsules containing olive oil from day 56 to day 85 had no significant effect on neutrophil CL responses to PAF or FMLP in this group. In the other group of six subjects, olive oil consumption from day 0 to day 28 did not produce significant changes in CL response. After EPA consumption from day 56 to 85, the CL response to FMLP, but not to PAF, declined although the change was not statistically significant. Thus the results from the Group 2 subjects have to be regarded as inconclusive although there is some suggestion that olive oil may inhibit EPA suppression of neutrophil chemiluminescence.

Three previous studies have examined the effects of dietary supplementation with EPA and DHA on human neutrophil chemotaxis and LTB_4 production (14-16). Higher doses (3.2-4.0 g) and longer durations (6-10 weeks) were used compared to this study. Neutrophil chemotaxis was reduced by up to 70% (14) and LTB_4 production was decreased, with an increase in LTB_5 production (15,16). In one of these studies, neutrophil function was not altered by consumption of placebo capsules containing olive oil (16). These studies have all assessed neutrophil function by measuring chemotactic responses to various stimuli (LTB_4, FMLP, C5a). The chemiluminescence response investigated in this study monitors the release of reactive oxidant species, an important function of stimulated neutrophils. The chemotactic and chemiluminescence responses may be modified differently by dietary supplementation with EPA. Furthermore the

effect of EPA on PAF-induced neutrophil responses had not been investigated prior to this study. EPA consumption may have differential effects on neutrophil responses to PAF and other stimuli such as FMLP, LTB_4 and C5a.

The normal product of lipoxygenase activity in stimulated neutrophils, LTB_4, may amplify the chemotactic and chemiluminescence responses to other stimuli such as PAF and FMLP. PAF has been shown to stimulate the production of LTB_4 in neutrophils (17,18), and in support of this data the lipoxygenase inhibitor, nordihydroguaiaretic acid, inhibits the neutrophil CL response to PAF (12). CL responses to FMLP have also been linked to lipoxygenase activity (12). Other workers have shown that consumption of 3.2 g of EPA per day for 3 weeks (total dose 67.2 g) resulted in a 500% increase in the content of EPA in neutrophil phospholipids (14). It seems likely that in our study in which the total dose was 60.5 g of EPA (2.16 g per day for 4 weeks) a similar incorporation of EPA into neutrophil phospholipids would have occurred and that this would have caused decreased LTB_4 production, and increased LTB_5 production. Consequently, reduced CL responses to PAF and FMLP as observed in this study would be expected to occur. Incorporation of EPA into the phospholipids of neutrophil membranes may alter the structure and/or fluidity of the membrane such that function of surface receptors, such as those for PAF and FMLP, may be altered. However, in one previous study, evidence for a change in neutrophil membrane fluidity after dietary supplementation with EPA was lacking (14).

In this crossover study, there was some indication that the effect of EPA persisted for up to four weeks after dietary supplementation ceased. Thus, in Group 1 subjects, the mean CL response to FMLP was less on day 56 than on day 28, and in Group 2 subjects the mean FMLP response was less on day 112 than on day 85. This effect was not observed in the mean responses to PAF. In the design of this study, the duration of the wash-out period was determined on the basis that neutrophils are turned over rapidly, with a blood clearance half-time of approximately 7 hr. The fact that the effects of EPA on FMLP-induced CL responses persisted at the end of a four-week wash-out period suggests that the EPA was turned over and reincorporated into maturing cells or possibly incorporated into stem cells during dietary supplementation.

Consumption of placebo capsules which contained olive oil did not alter neutrophil CL in this study, and is in agreement with the lack of effect on chemotaxis as reported previously (16). However prior consumption of olive oil appeared to reduce the effectiveness of EPA in inhibiting neutrophil CL. Oleic acid, the major fatty acid constituent of olive oil (approximately 75%), can be metabolized to eicosatrienoic acid which may be converted to LTB_3 by the lipoxygenase pathway (7). Recent studies (7,19) have suggested that LTB_3 may be as potent as LTB_4 as an inflammatory stimulus. Olive oil also contains linoleic acid (5%) which can be metabolized to AA. Thus consumption of placebo capsules by the Group 2 subjects may have increased the amounts of pro-inflammatory eicosatrienoic acid and AA in their neutrophil membranes thereby reducing the subsequent effectiveness of the fixed dose of EPA. Other fatty acids may also be capable of influencing the effects of EPA, and it has been suggested (20) that the low prevalence of coronary artery disease and inflammatory disorders in Eskimos is due to the combined effects of high dietary EPA and genetically determined high plasma concentrations of dihomo-gamma-linolenic acid.

Olive oil is probably not an ideal placebo because, as this study has shown, it may be metabolized by similar biochemical pathways to those which metabolize EPA. Indeed the question of whether olive oil affects neutrophil function is worthy of investigation. The only ideal placebo for the study of the effects of EPA would be a marine lipid concentrate from which all the EPA is removed, but this is expensive and difficult to produce.

Although the dose (2.16 g) and duration (4 weeks) of EPA supplementation were reduced in this study in comparison with others (3-4 g of EPA for 6-10 weeks) (14-16), the results are in agreement that dietary supplementation with EPA suppresses neutrophil function *in vitro*, and suggest lower doses may be effective. Although several studies have shown EPA has no effect on clinical symptoms when administered to asthmatic subjects (16,21,22), this may reflect clinical trial design. Alternatively, neutrophils may not play the major role in the inflammatory processes of asthma, and the concentration and duration of EPA supplementation needed to influence other inflammatory cell types and mediators involved in the pathogenesis of asthma (4) have yet to be elucidated.

First Department of Medicine, Kyoto Prefectural University of Medicine, Kyoto 602, Japan

The effect of platelet-activating factor (PAF) in superoxide production by human polymorphonuclear leukocytes (PMN) was studied. Cypridina luciferin analog (CLA) dependent chemiluminescence was used to detect superoxide anion radicals. PAF induced superoxide generation in human PMN in a dose-dependent manner. Preincubation with a small amount of PAF (5×10^{-9} M) enhanced PMN superoxide release induced by various stimuli, such as phorbol myristate acetate (PMA), opsonized zymosan (OZ), calcium ionophore (A23187) and *N*-formyl-methionyl-leucyl-phenylalanine (FMLP). The PAF antagonist, CV-6209, inhibited superoxide production induced by PAF, but not that induced by other stimuli. These findings would indicate that PAF may play an important role at inflammatory reaction sites and that CV-6209 may inhibit excessive inflammatory reaction.

Lipids 26, 1227-1230 (1991).

Platelet-activating factor (PAF, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) was initially discovered by its ability to aggregate and degranulate platelets *in vitro* (1). PAF, an endogenous phospholipid, which is released from a number of activated cells, including polymorphonuclear leukocytes (PMN), macrophages, monocytes and endothelial cells (2-5), also shows a variety of other biological activities (6). For example, PAF induces hypotension and bronchoconstriction, and it increases vascular permeability. Recently, it has been suggested that PAF stimulates PMN as well as platelets, and causes aggregation, chemotactic motility, superoxide production, and enzyme release (7-9). It has also become apparent that oxygen-derived free radicals, such as superoxide and hydroxyl radicals, play an important role in the pathogenesis of many diseases (10,11).

In the present study, we investigated the role of PAF on superoxide generation from human PMN by means of chemiluminescence using the Cypridina luciferin analog, 2-methyl-6-phenyl-3,7-dihydroimidazo[1,2-a]pyrazin-3-one (CLA) which is highly specific for and sensitive to superoxide anion radicals (12-14).

MATERIALS AND METHODS

Reagents. The following reagents were purchased from Sigma Chemical Co. (St. Louis, MO): phorbol myristate acetate (PMA), zymosan A, *N*-formyl-methionyl-leucyl-phenylalanine (FMLP), calcium ionophore A23187, and diethylenetriaminepentaacetic acid (DETAPAC). Other reagents used were: Ficoll-Paque (Pharmacia AB., Uppsala, Sweden), PAF (Sandoz Pharmaceuticals Ltd., Basee, Switzerland), dimethylsulfoxide (DMSO, Wako Pure Chemical Industry, Osaka, Japan), and PAF antagonist 2-[*N*-acetyl-*N*-(2-methoxy-3-octadecyl-carbamoyloxy-proxycarbonyl)aminomethyl]-1-ethylpyridinum chloride (CV-6209, Takeda Chemical Industry, Osaka, Japan). PAF and CV-6209 were each dissolved in physiological saline at the required concentration and diluted in assay buffer. PMA, FMLP and A23187 dissolved in DMSO, respectively, at 20 μg/mL, 10^{-2} M and 10^{-3} M, were stored at −70°C until use, and diluted with distilled water to the required concentration, and then diluted in assay buffer.

Preparation of human PMN. PMN were isolated from the peripheral blood of normal volunteers by dextran sedimentation followed by Ficoll-Paque separation and hypotonic lysis of contaminating erythrocytes. PMN, 4×10^5 cells/mL, were suspended in Hanks' balanced salt solution (HBSS) at pH 7.4 and kept at 0°C until use. Cell viability was assessed by trypan blue exclusion and exceeded 96%. We examined the influence of preincubation of PMN with PAF or CV-6209 for 10 min on cell viability by this method.

Opsonized zymosan (OZ). Zymosan A in physiological saline (4 mg/mL) was boiled for 1 hr and centrifuged at $1600 \times g$ for 10 min. Sediments were washed twice with HBSS, suspended in fresh human serum (40 mg/mL), and incubated at 37°C for 30 min. The resultant opsonized zymosan pellet was washed twice with HBSS, resuspended in the same solution at a concentration of 30 mg/mL, and stored frozen at −70°C until use.

Measurement of superoxide. A Luminescence Reader (Aloka, Co., Ltd., Tokyo, Japan) was used for the assay of CLA dependent chemiluminescence. The standard reaction mixtures contained 4×10^5 PMN/mL, 1 μM CLA, 0.1 mM DETAPAC, plus stimulus in a total volume of 2 mL HBSS. PMN in HBSS were preincubated at 37°C for 3 min; the reaction was initiated by the addition of PAF as stimulus at a final concentration of 5×10^{-9} M to 5×10^{-4} M. The amount of superoxide produced was determined using the maximal increase of light intensity. In some experiments, after incubation of PMN for 3 min at a low concentration of PAF, which induced production of only a small amount of superoxide, a stimulus was added, and the measured maximal intensity was compared with that produced in the absence of PAF in order to assess the priming effect of PAF. PMA, OZ, FMLP, or A23187 were used as the PMN stimuli at a final concentration of 2 ng/mL, 1 mg/mL, 1×10^{-5} M, or 1×10^{-6} M, respectively. In other experiments, CV-6209 was added to test its effect on superoxide production by stimulated PMN.

Data are given as mean ± SE. Significances between groups were assessed by Student's t-test.

Abbreviations: CLA, Cypridina luciferin analog; DETAPAC, diethylenetriaminepentaacetic acid; FMLP, *N*-formyl-methionyl-leucyl-phenylalanine; HBSS, Hanks' balanced salt solution; OZ, opsonized zymosan; PAF, platelet-activating factor; PMA, phorbol myristate acetate; PMN, polymorphonuclear leukocytes.

RESULTS

Human PMN stimulated by PAF produced superoxide anion radicals in a dose-dependent manner (Fig. 1). The greatest effect was seen at a PAF concentration of 5×10^{-5} M, whereas there was only a slight effect at a concentration of 5×10^{-9} M. This dose-dependency was observed in all cases examined. The superoxide production by PMN stimulated by PMA, OZ, A23187 or FMLP was enhanced in PMN preincubated with 5×10^{-9} M PAF (Figs. 2 and 3). This enhancement by PAF was much more than the increase that would be induced by 5×10^{-9} M PAF alone. This enhancement was also not seen when the PMN were exposed to PAF (5×10^{-9} M) simultaneously with the second stimulus (data not shown); *i.e.*, PAF needs to be preincubated with PMN prior to the second stimulation to prime the PMN. PAF priming was not dose-dependent (Table 1).

When PMN were first preincubated for 3 min with the PAF antagonist, CV-6209 and then stimulated by PAF, PMN superoxide production induced by PAF was inhibited dose-dependently (Fig. 4). However, CV-6209 did not inhibit superoxide production induced by PMA or A23187 (Table 2), nor by OZ or FMLP (data not shown). CV-6209 at a concentration of 5×10^{-6} M completely abolished superoxide generation by stimulated PMN (Table 2). Viability of PMN exceeded 95% when PMN were preincubated for 10 min with up to 5×10^{-5} M PAF or with up to 5×10^{-7} M CV-6209 (Fig. 5). However, 5×10^{-4} M PAF, or 5×10^{-6} M CV-6209, caused loss of cellular viability (Fig. 5).

DISCUSSION

During the inflammatory process, respiratory burst can be induced in PMN exposed to a variety of biological stimuli. The resultant oxygen-derived free radicals can act as microbicidal agents or, if produced in excess, as initiators or amplifiers of inflammation (15). Among these bioactive substances are soluble stimuli such as PMA, FMLP, or A23187, and particulate stimuli such as OZ. PAF is a mediator of allergic and inflammatory processes (16) and stimulates PMN degranulation, aggregation, oxidative metabolism, and chemotaxis. PAF is also produced by various cells and tissues at inflammatory reaction sites (17). Several studies have demonstrated now the induction of respiratory burst in human PMN by PAF (8,18) and PAF priming of superoxide production by PMN.

In the present study, we also examined the role of PAF in superoxide production by PMN, but used a newly designed chemiluminescence probe, CLA (12-14). We observed that PAF alone induced a dose-dependent burst of superoxide production by human PMN. Preincubation of PMN with small amounts of PAF furthermore enhanced superoxide production when PMN were subsequently exposed to soluble or particulate stimuli. These results, which are mostly consistent with those of previous reports (7-9), suggest that PAF may play an important role in the inflammatory process by enhancing PMN superoxide generation. However, there are some differences between our reults and those of others; *i.e.*, a lack of a dose-dependency of PAF priming, and a lack of an instantaneous priming effect. We speculate that PMN, when incubated with PAF at higher than 5×10^{-9} M concentra-

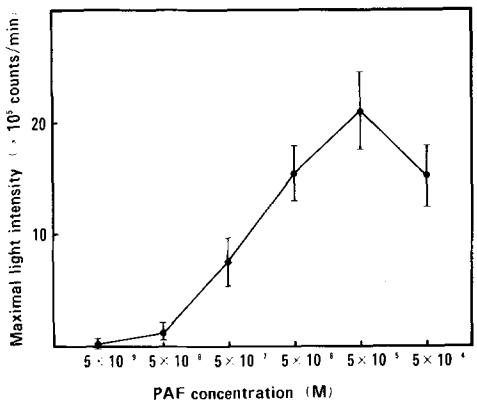

FIG. 1. CLA-dependent chemiluminescence of 4×10^5 PMN stimulated by PAF at various concentrations. Each point represents the mean ± SE of 6 experiments.

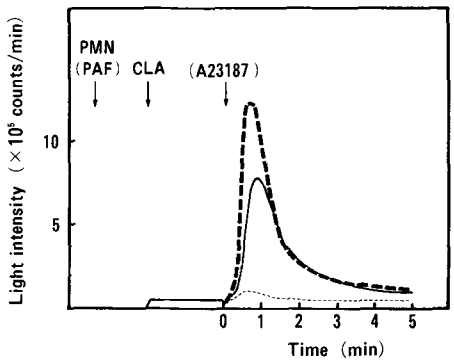

FIG. 2. Effect of PAF on superoxide production by PMN monitored continuously. PMN were preincubated with PAF (5×10^{-9} M) or physiological saline 3 min before the addition of A23187 (1×10^{-6} M). The tracings are reproduced from actual recordings and are representative of the results for four experiments. PAF addition 3 min before A23187, ---- ; A23187, ——— ; PAF, ------ .

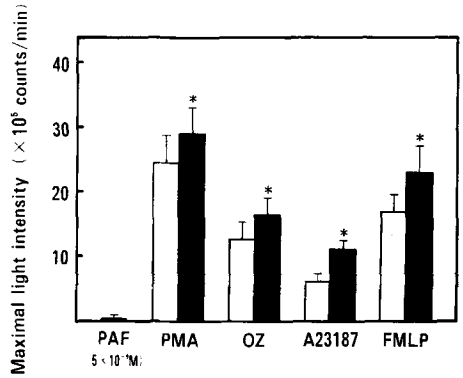

FIG. 3. Effect of PAF on superoxide production by PMN. PMN were incubated with PAF (5×10^{-9} M) or physiological saline (control group) for 3 min at 37°C and stimulated with PMA, OZ, A23187, or FMLP, and maximal light intensity representative of the amount of superoxide production was measured by CLA-dependent chemiluminescence. Each value indicates the mean ± SE of 4 experiments. Open bars represent the control group, and shaded bars represent preincubation with PAF. *$p<0.05$ when compared with the control group.

TABLE 1

Effect of PAF at Varying Concentrations on Superoxide Production by A 23187 Stimulated PMN[a]

PAF concentration (M)	Maximal light intensity (10^5 counts/min)
0	6.8 ± 2.1
5×10^{-9}	12.1 ± 3.8[b]
5×10^{-8}	14.3 ± 4.1[b]
5×10^{-7}	13.0 ± 3.0[b]
5×10^{-6}	8.6 ± 3.3
5×10^{-5}	2.5 ± 2.1[b]
5×10^{-4}	0.8 ± 0.7[b]

[a]PMN were incubated with PAF at varying concentrations for 3 min at 37°C and stimulated with A23187, and maximal light intensity was measured. Each value indicates the mean ± SE of 4 experiments. PAF, platelet-activating factor; PMN, polymorphonuclear leukocytes.

[b]$p<0.05$ when compared with the value in the absence of PAF.

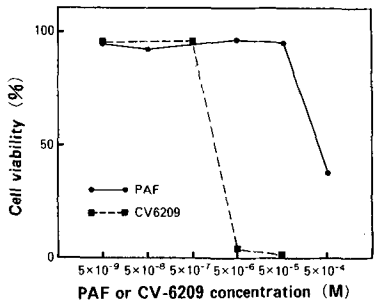

FIG. 5. Effect of PAF or CV-6209 on cell viability examined by trypan blue exclusion. PMN were incubated with PAF or CV-6209 at varying concentrations at 37°C for 10 min, and then trypan blue was added.

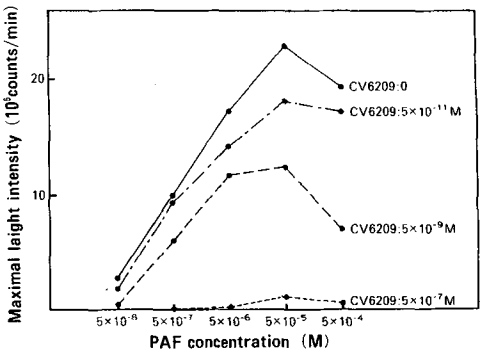

FIG. 4. Effect of CV-6209 on superoxide production by PMN. PMN were incubated with CV-6209 at varying concentration for 3 min at 37°C, stimulated with PAF at varying concentration, and superoxide production was measured. Results shown are representative of four separate experiments.

TABLE 2

Effect of CV-6209 on Superoxide Production by PMA or A23187 Stimulated PMN[a]

CV-6209 concentration (M)	Maximal light intensity (10^5 counts/min)	
	PMA stimulation	A23187 stimulation
0	23.5 ± 5.6	6.6 ± 2.4
5×10^{-11}	21.9 ± 4.9	6.4 ± 1.9
5×10^{-9}	20.8 ± 6.0	6.7 ± 2.3
5×10^{-7}	21.1 ± 5.1	6.8 ± 3.0
5×10^{-6}	0	0

[a]PMN were incubated with CV-6209 at varying concentrations for 3 min at 37°C and stimulated with PMA or A23187, and maximal light intensity was measured. Each value indicates the mean ± SE of 4 experiments. PMA, phorbol myristate acetate; PMN, polymorphonuclear leukocytes; CV-6209, a specific PAF antagonist.

tion, produce a fair amount of superoxide during preincubation. Thus superoxide production induced by a second stimulus may diminish, resulting in a lack of dose-dependency of the priming event. The differences and lack of instantaneous priming may also be explained in part by differences in assay conditions, including the superoxide assay used, preincubation time, or the stimulus concentration chosen. Further studies will be needed to pinpoint the detailed mechanism of priming.

It appears that PAF promotes the oxygen-dependent microbicidal activity of PMN (18) by enhancing superoxide production. However, at excessive levels, PAF may induce superoxide production by PMN in excess of that required, leading to exacerbation of inflammation. In the present study, at concentrations lower than that of PAF, CV-6209, a specific PAF receptor antagonist, dose-dependently inhibited PMN superoxide production induced by PAF. The inhibitory effects of CV-6209 were shown to be specific for PAF (19). So CV-6209 blocked PAF priming, but did not inhibit superoxide production induced in PMN by other stimuli. The PAF antagonist had little effect on the enzymes of the arachidonic acid cascade, on α-adrenergic receptors or calcium channels (19). Cell viability was lost at 5×10^{-6} M CV-6209, but CV-6209 exerted its anti-PAF effect at much lower concentrations that did not affect cell viability. It appears likely that CV-6209 would reduce tissue injury caused by excess PAF.

Our data suggest that PAF plays an important role at inflammatory reaction sites and that CV-6209 should be able to inhibit excessive inflammatory reaction.

IgA Immune Aggregates Stimulate Platelet-Activating Factor and Superoxide Anion Production by Human Neutrophils. A Comparison with IgG Aggregates[1]

Paloma Hernando, Jesus Egido*, Rosario de Nicolas and Eva Gonzalez
Department of Nephrology, Fundación Jiménez Diaz, Universidad Autonoma-CSIC, Madrid, Spain

We have examined the possibility that human polymorphonuclear cells exposed to IgA immune complexes can mediate the production of platelet-activating factor (PAF) and oxygen radicals. We found that human IgA and IgG immune aggregates stimulated, to a similar extent, PAF and O_2^- production by human polymorphonuclear cells (PMN) in a concentration and time dependent manner. The PAF, that was largely associated with cells, was shown to be identical to synthetic PAF, as determined by physicochemical, chromatographic and enzymatic assay. Furthermore, *de novo* synthesis of PAF by PMN was shown to occur by incorporation of radioactive precursors, such as [^{3}H]acetate. The addition of normal human serum to PMN incubated with IgG aggregates resulted in a significant amount of PAF formation which was not observed with IgA aggregates. By contrast, no change was seen in PMN O_2^- with either aggregates. The preincubation of PMN with cytochalasin B, an inhibitor of phagocytosis, did not affect PAF and O_2^- production by both aggregates. The results suggest that the interaction of PMN with the IgA complexes in blood vessel walls of different tissues can result in the release of lipid mediators, such as PAF and oxygen radicals that could contribute to the inflammatory response.
Lipids 26, 1231–1235 (1991).

Immune complex (IC) deposition in vessel walls generates products of complement activation that increase vascular permeability and recruit polymorphonuclear cells (PMN) from the blood. In addition, it has been suggested that IC can stimulate PMN to release lysosomal proteases and to generate oxygen metabolites (reviewed in ref. 1). It is already well established that IgG-IC deposition in different organs, such as in kidney and lung, can cause tissue injury. Much less information exists in regard to the mechanisms of IgA-mediated tissue injury (reviewed in ref. 2).

IgA seems to play a key role in various human diseases, such as IgA nephropathy, Henoch-Schölein purpura, systemic *lupus erythematosus* and *dermatitis herpetiformis* (reviewed in ref. 3). A model of acute lung injury in rat caused by IgA-IC has been described (4). Recent studies have also shown that IgA-IC, or IgA-opsonized *Stafilococcus aureus,* can stimulate oxygen radical production by various cells (5). This is not surprising since the presence of Fcα membrane receptors (FcαR) in most blood cells has been reported (6).

Platelet-activating factor (PAF: 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) is a potent biologically active phospholipid that plays a major role in inflammatory reactions. This lipid is synthesized and released by several inflammatory cell types including platelets, neutrophils, macrophages, monocytes, mast cells, eosinophils, and endothelial and mesangial cells (7,8). Although a variety of stimuli, including IgG-IC, opsonized zymosan, calcium ionophore A23187, and C5a, are capable of inducing PAF production, there is no evidence that IgA-IC may also play such a role.

The aim of the present study was to explore the possibility that human PMN exposed to IgA immune aggregates (akin to immune complexes) can mediate the production of PAF and of oxygen radicals. For comparison, we have also tested IgG immune aggregates of the same molecular weight.

MATERIAL AND METHODS

Isolation of proteins. Human IgA and IgG were isolated from the sera of patients with myeloma, as previously described (9). Both the IgA and IgG preparations were found to be free of other immunoglobulins as judged by immunoelectrophoresis and double-immunodiffusion analysis. F(ab')$_2$ fragments of IgG were prepared by pepsin digestion and gel filtration as described by Stanworth and Turner (10). The F(ab')$_2$ preparation was free of intact heavy chain when analyzed by sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE) following the method of Laemmli (11).

Preparation of soluble aggregates. Aggregation was brought about by heating 10 mg/mL of IgA or IgG at 63°C in 0.15M Tris-buffered saline (TBS) for 150 or 30 min, respectively. Soluble aggregates of IgA or IgG of 1–2 × 10^6 mol wt were separated from non-aggregates by column chromatography on Ultrogel AcA 22 (LKB Instruments Ltd., Bromma, Sweden) with TBS, pH 7.4, containing 0.5% bovine serum albumin (BSA) to prevent aggregation (12).

Isolation of neutrophils. Human peripheral blood polymorphonuclear leukocytes (PMN) were isolated from the blood of healthy donors using a Ficoll/Hypaque gradient, gelatin sedimentation, and hypotonic lysis of red cells following standard techniques. The cell suspension contained 95 ± 1% PMN without contamination from platelets or erythrocytes.

Measurement of neutrophil PAF production. In most experiments, PAF was determined by bioassay by measuring the release of [^{3}H]serotonin from rabbit platelets as described by Henson (13) with some modifications (14).

Abbreviations: BSA, bovine serum albumin; IC, immune complexes; IgA-A, IgA immune aggregates; IgG-A, IgG immune aggregates; O_2^-, superoxide anion; PAF, platelet-activating factor; PMA, phorbol myristate acetate; PMN, polymorphonuclear cells; SDS-PAGE, sodium dodecylsulfate polyacrylamide gel electrophoresis; TBS, Tris-buffered saline; TLC, thin-layer chromatography.

Briefly, 5×10^6 PMN were incubated with various concentrations of immune aggregates, or 10 μM calcium ionophore A23187 (Sigma Chemical Co., St. Louis, MO), in a final volume of 1 mL of HEPES containing BSA 0.25%. After stimulation, the samples were centrifuged at 2000 rpm at 4°C for 10 min. The supernatants were decanted into 1 mL of methanol. The cell pellets were resuspended in 1 mL of methanol, and vortexed. Each sample was extracted twice by the method of Bligh and Dyer (15) and the chloroform phase was dried under a nitrogen stream.

Samples were purified by thin-layer chromatography (TLC) on silica gel plates (Merck, Darmstadt, Germany) using chloroform/methanol/water (1:1:0.9, v/v/v) as solvent. Fractions were scrapped off the plates as narrow zones corresponding to the migration rate of authentic PAF (Sigma), the samples were extracted by two consecutive elutions with methanol, and the extracts were pooled and dried under a stream of nitrogen. Each sample was then dissolved in 0.1 mL of HEPES containing 0.25% of BSA.

PAF was quantified by measuring the release of [^{3}H]-serotonin from labeled rabbit platelets (13). The percentage of release effected by each sample was then compared with a standard curve of the release elicited by known amounts of synthetic PAF (hexadecyl PAF, Sigma). The amount of PAF in each sample was expressed as nanogram equivalents of the synthetic PAF.

In some experiments the production of PAF by stimulated PMN was measured by [^{3}H]acetate (sodium salt) incorporation into PAF (16). In these experiments, the same stimulation protocol was followed, except that the PMN were preincubated with 25 μCi of [^{3}H]acetate (3.6 Ci/mmol, Dupont, Boston, MA) for 10 min before agonist stimulation. The reaction was stopped by placing the cell suspension into glass tubes containing chloroform and 50 mM acetic acid in methanol. Lipids were extracted from stimulated PMN as previously described (15) and the radioactivity associated with the PAF band in TLC was quantitated by liquid scintillation counting (see above). In two experiments, a portion of the purified sample of neutrophil-derived PAF was treated with phospholipase A_2 (from *Crotalus adamanteus,* Sigma) before determining biological activity (17).

Measurement of O_2^- generation. PMN (5×10^6 cells) were incubated in duplicate samples with phorbol myristate acetate (PMA, Sigma) or immune aggregates at various concentrations in the presence of 75 μM ferricytochrome C, type III (Sigma) with or without 10 μg/mL of superoxide dismutase (2700 U/mg) (Sigma) in 1 mL of KRP solution, pH 7.4, for various periods of time up to 30 min (18). Incubations were terminated by placing the tubes in ice, after which they were centrifuged at 4°C for 10 min at 2000 rpm. Cell-free supernatants were decanted and the amount of reduced cytochrome C generated during the incubation was measured at 550 nm in a Spectronic 601 spectrophotometer (Bausch-Lomb, München, Germany). The total amount of cytochrome C present was calculated using an absorbance coefficient of 21.1 $mM^{-1} \times cm^{-1}$ at 550 nm. O_2^- generation is expressed as nanomoles cytochrome C reduced per 5×10^6 PMN.

In some experiments PMN were preincubated for 10 min with 5 μg/mL of cytochalasin B (Sigma) before the addition of immune aggregates.

Statistical analysis. Values are expressed as mean ± standard error of the mean. The Wilcoxon test was employed in all comparisons. Differences were considered significant for $p<0.05$.

RESULTS

Effect of IgA immune aggregates on the synthesis of PAF by neutrophils. Both IgA and IgG aggregates stimulated PAF production by PMN in a dose and time dependent manner (Fig. 1). Although maximal production of PAF was obtained when PMN were incubated with IgG aggregates, the differences were not significant as compared to the levels obtained with IgA aggregates (Fig. 1, top). Maximal accumulation of PAF, with both aggregates ocurred at 60 min (Fig. 1, bottom). The total amount of PAF produced by cells stimulated with aggregates was significantly greater than with nonstimulated cells, and much less than that observed in response to calcium ionophore A23187 (not shown).

The PAF produced in this manner was largely associated with cells and not secreted into the medium. Cell-associated material constituted 70% of the total PAF seen after stimulation.

The bioactive material was confirmed as PAF by use of the structurally unrelated PAF receptor antagonists BN 52021 (Institut Henri Beaufour, Les Plessis Robinson, France) and WEB 2086 (Boehringer Ingelheim, Germany). The release of [^{3}H]serotonin from platelets, induced by synthetic PAF or the "PAF-like material" obtained from stimulated cells, was inhibited when the platelets were preincubated with BN 52021 (10^{-5} M) or WEB 2086 (10^{-6} M). The activity of the "PAF-like material" was also lost after phospholipase A_2 treatment (not shown). In some experiments, the PMN were preincubated with [^{3}H]acetate before the addition of immune aggregates. PMN incorporated [^{3}H]acetate into a polar lipid that co-migrated with authentic PAF in TLC. In these experiments, the maximal incorporation of [^{3}H]acetate was obtained when PMN were incubated with IgG aggregates. For the same dose of protein (150 μg/mL) the percentage increase in relation to basal levels was 128 ± 14 for IgG *vs.* 87 ± 32 for IgA (not significant) (Fig. 2).

In other experiments, we examined PAF production by PMN incubated with IgA or IgG immune aggregates (100 μg/mL) in the presence of normal human serum (100 μL). The addition of human serum to PMN incubated with IgG immune aggregates resulted in a significant amount of PAF production (an increase of 227% in relation to the aggregates alone). This incremental increase was not observed when PMN were incubated with IgA aggregates in the presence of serum (an increase of 22% in relation to the aggregates alone) (not shown).

The preincubation of PMN with cytochalasin B (5 μg/mL), before the addition of immune aggregates, did not affect the total production of PAF from PMN stimulated with both immune aggregates (Table 1).

In other experiments, PMN (5×10^6) were incubated with $F(ab')_2$ of IgG and IgG aggregates for 60 min. At the same dose of protein (100 μg), the $F(ab')_2$ fragments of IgG released a significantly lesser amount of PAF than did the IgG aggregates (67.6 ± 11 pg/5×10^6 cells for $F(ab')_2$ *vs.* 254 ± 49 pg/5×10^6 cells for IgG aggregates) ($p<0.001$). A representative case is shown in Figure 3.

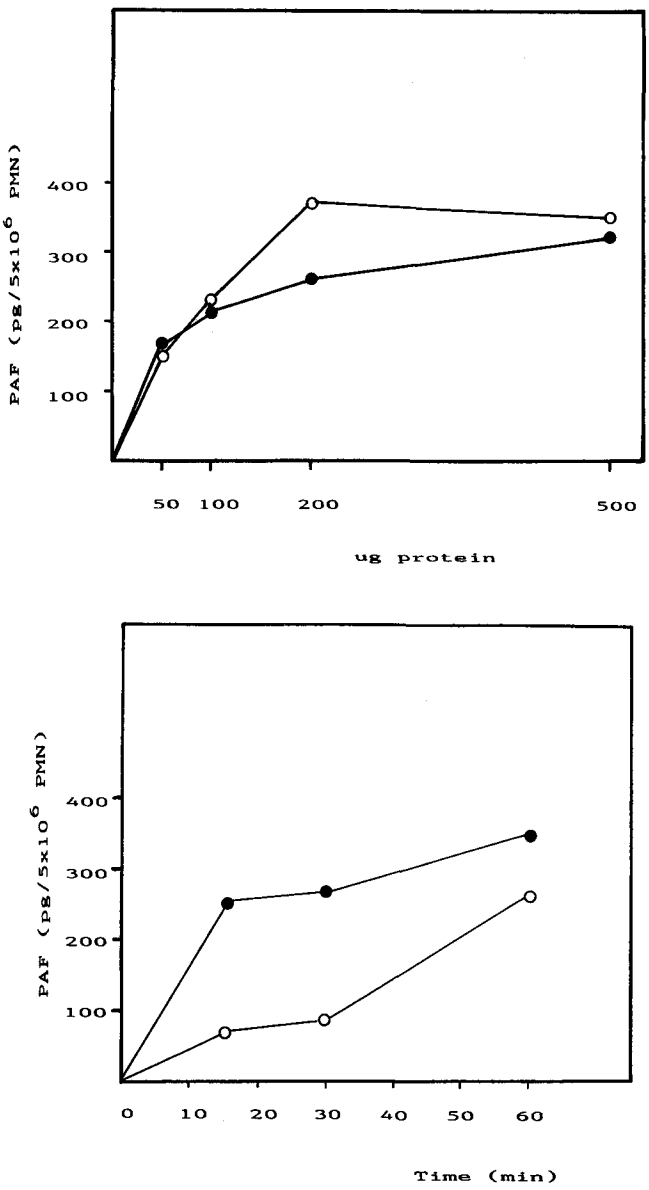

FIG. 1. Production of PAF by human PMN stimulated with IgG (○) or IgA (●) aggregates. Top: Production of PAF by PMN incubated with varying concentrations of IgG or IgA aggregates for 60 min. Total PAF was determined by bioassay, as described in Materials and Methods. Bottom: Time course of PAF production obtained upon IgA or IgG aggregate stimulation. PMN were incubated with 100 μg/mL of IgA or IgG aggregates. Results represent the mean of 6–10 experiments. No differences were found between either aggregate.

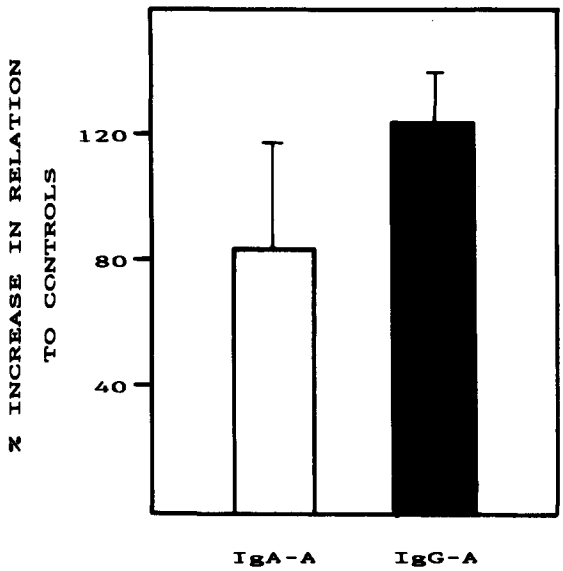

FIG. 2. Production of PAF by human PMN stimulated with IgG or IgA aggregates. PMN were preincubated with 25 μCi of [^{3}H]acetate for 10 min before addition of aggregates. The reaction was terminated as described in Materials and Methods. The data are expressed in percentage increase in relation to that obtained in PMN without aggregates. Mean ± S.D. (n=4), not significant.

TABLE 1

Effect of Cytochalasin B on PAF and O_2^- Production by Neutrophils Stimulated with IgG and IgG Aggregates[a]

Stimulus	PAF (pg/5 × 10^6 cells)	O_2^- (nmol/5 × 10^6 cells)
None	89 ± 65	0.9 ± 0.1
A-IgG[b]	254 ± 49	4.7 ± 0.4
A-IgG + cyto B	200 ± 40	4.3 ± 0.7
A-IgA[c]	216 ± 72	5.2 ± 0.9
A-IgA + cyto B	195 ± 77	5.1 ± 0.7
PMA	ND[d]	24.5 ± 7.0

[a]The doses of both IgG and IgA aggregates were 100 μg/mL and 300 μg/mL for PAF and O_2^- production, respectively. PAF was determined at 60 min of incubation and O_2^- at 30 min (each study was done in separate experiments). Results represent the mean of 6–14 experiments in duplicate.

[b]$p < 0.0025$. [c]$p < 0.0125$. [d]Not detected.

To determine the effect of cell adhesion on PAF production, further experiments were carried out. The PAF production by IgG aggregates was similar in both adherent and suspended cells, except that PAF production was delayed and decreased in adherent PMN. These results are in agreement with those published by Sisson *et al.* (16).

PMN O_2^- generation. In order to determine the ability of IgA and IgG immune aggregates to stimulate O_2^- generation in PMN, the cells were incubated with various concentrations (100–500 μg/mL) of both immune aggregates for different time periods (5,15 and 30 min), and the O_2^- release into the supernatant was measured.

PMN stimulated with immune aggregates produced a significantly higher amount of O_2^- compared to the non-stimulated cells (Table 1). PMA stimulation of PMN produced significantly greater O_2^- generation than did immune aggregates (Table 1). Both IgA and IgG immune aggregates enhanced O_2^- release in a dose and time dependent manner (Fig. 4). Although maximal O_2^- generation was observed when PMN were incubated with IgA aggregates, the differences were not significant (Fig. 4). Stimulation of PMN (5 × 10^6) with F(ab')$_2$ of IgG for 30 min resulted in a significant decrease in O_2^- generation compared with O_2^- production in cells stimulated with identical doses of aggregates [for the same dose of protein, 100 μg/mL, 1.73 ± 0.54 nmol O_2^-/5 × 10^6 cells for F(ab')$_2$ *vs.* 3.0 ± 0.79 nmol O_2^-/5 × 10^6 cells for IgG

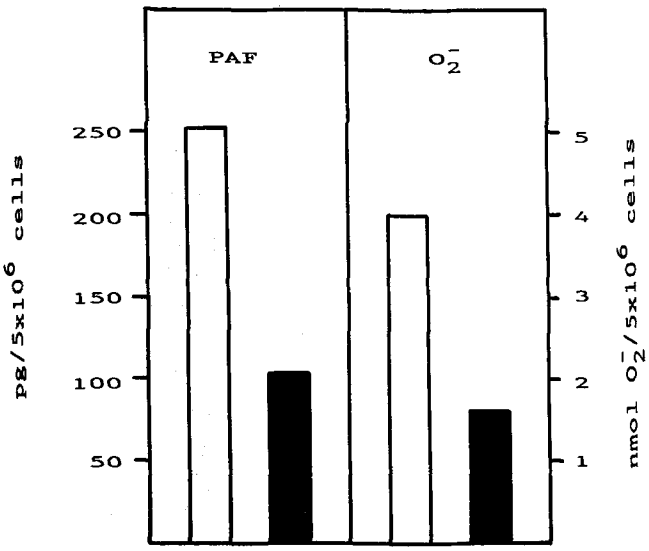

FIG. 3. Production of PAF and O_2^- by PMN stimulated with 100 μg/mL F(ab')$_2$ fragments of IgG (closed columns), obtained as described in Materials and Methods, or (100 μg/mL) IgG aggregates (open columns). A representative case of four different experiments is shown.

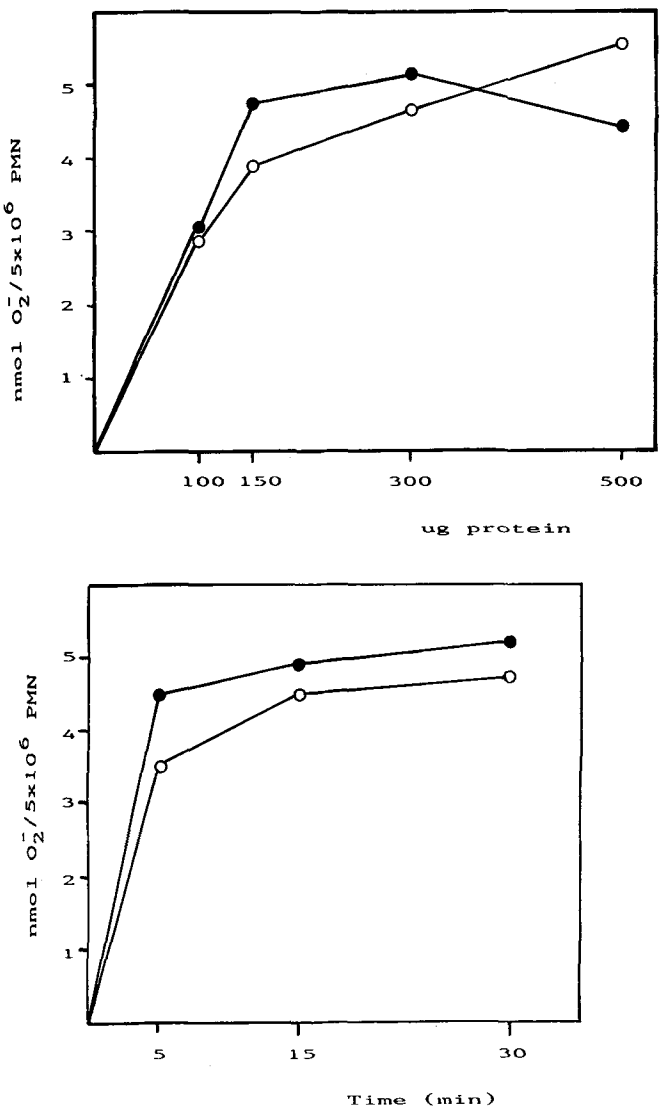

FIG. 4. Effect of IgA (●) and IgG (○) aggregates on O_2^- production by human PMN. Top: Release of O_2^- by PMN incubated with various concentrations of IgA or IgG aggregates for 30 min at 37°C. Bottom: Time course of O_2^- release. PMN were incubated with 300 μg/mL of IgA or IgG aggregates. Each point represents the mean of 10–14 experiments. No differences were found between the two aggregates.

aggregates, $p<0.05$]. A representative case is shown in Figure 3.

The cytochrome C reduction induced by IgG and IgG aggregates was almost completely inhibited by 10 μg/mL superoxide dismutase (never exceeding 0.72 nmol/5 × 10^6 PMN per 30 min) which suggests that the reduction was O_2^- mediated.

In other experiments, we also examined O_2^- generation by PMN incubated with IgA or IgG immune aggregates (100 μg/mL) in the presence of normal human sera. The addition of human sera to PMN did not increase O_2^- generation induced by both immune aggregates (not shown).

Treatment of PMN with cytochalasin B is known to induce a variety of PMN responses. In this study, we found that the release of O_2^- from PMN stimulated with immune aggregates was not increased by pretreatment of PMN with cytochalasin B (5 μg/mL) (Table 1).

DISCUSSION

Our results show that IgA and IgG immune aggregates induce PAF and O_2^- production by human PMN in a dose and time dependent manner. The presence of PAF was determined by bioassay, and in selected experiments by the incorporation of [^{3}H]acetate. Characterization of the labeled and non-labeled lipid obtained under various conditions (see Results) indicated that it was in fact PAF. Furthermore, it was shown that incorporation of [^{3}H]-acetate is an accurate measure of PAF synthesis, as determined by gas chromatography and mass spectrometry (19). Our data suggest that not only IgG, but also IgA, immune complexes can contribute to inflammatory reactions by stimulating PMN to produce PAF and O_2^-. Presumably, the stimulation of PMN by these immune aggregates takes place through the Fc receptor. This conclusion is supported by our studies in which immune aggregates containing the F(ab')$_2$ portion were ineffective in causing PMN activation as defined as production of O_2^- and PAF. Although we have not done the same type of study for IgA, the presence of receptors for IgA (FcαR) has recently been demonstrated on phagocytes from different species (6). In contrast to our results in humans, rat neutrophils exhibited O_2^- production and lysosomal enzyme secretion in response to IgG immune complexes, but not in response to IgA complexes. Interestingly, alveolar macrophages did respond to IgA complexes (20). We do not have a good explanation for this discrepancy, but it is clear that species differences do exist.

PMN treatment with cytochalasin B is known to cause a variety of PMN activation responses (21,22). In the present study, cytochalasin B had no effect on PAF and O_2^- production by PMN stimulated with IgA or IgG immune aggregates. These data suggest that phagocytosis by PMN is not required for immune complexes to stimulate

PAF and O_2^- synthesis, as it is for particulates such as zymosan (1).

Most of the PAF produced by PMN upon stimulation with both classes of immune aggregates remained cell associated quite independently of the time of incubation and the total amount of PAF synthesized. This feature is reminiscent of the processing of PAF by activated human PMN under a variety of conditions, and by other human cells including endothelial cells (23,24).

The addition of normal fresh sera as a source of complement potentiated PAF production by PMN upon stimulation with IgG immune aggregates more significantly than by PMN upon stimulation with IgA immune aggregates. This is not unexpected. Although it has recently been shown that IgA immune complexes activate the alternative pathway of complement, their capacity of triggering C5 cleavage to C5a and C5b is less striking than that of IgG immune complexes (25,26).

Although this is the first observation of PAF production induced by IgA complexes, previous studies have shown the activation of arachidonate metabolism in PMN by aggregated IgA (27). Therefore, the interaction of PMN with IgA immune complexes deposited in blood vessel walls in Henoch-Schölein purpura, or in organs such as lung and kidney, may result in the release of a series of lipid mediators including PAF and arachidonic acid metabolites, as well as oxygen free radicals, that could contribute to the inflammatory response.
