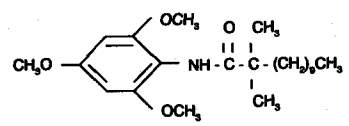
Inhibition of Acylcoenzyme A:Cholesterol Acyltransferase Activity by PD128042: Effect on Cholesterol Metabolism and Secretion in CaCo-2 Cells

F. Jeffrey Field*, Ella Albright and Satya Mathur
Department of Internal Medicine, University of Iowa, Iowa City, Iowa 52242

The regulation of cholesterol uptake and secretion by acylcoenzyme A:cholesterol acyltransferase (ACAT) was investigated in the human intestinal cell line, CaCo-2. A new ACAT inhibitor, PD128042 (CI-976), was first characterized. The addition of the fatty acid anilide to membranes prepared from CaCo-2 cells inhibited ACAT activity without altering the activities of HMG-CoA reductase, fatty acid Co-A hydrolase, or triglyceride synthetase. PD128042 was a competitive inhibitor of ACAT with 50% inhibition occurring at a concentration of 0.2 μg/mL. When added to the medium of CaCo-2 cells at a concentration of 5 μg/mL, PD128042 inhibited oleate incorporation into cholesteryl oleate by 92% and increased oleate incorporation into triglycerides and phospholipids by 51% and 38%, respectively. After incubating CaCo-2 cells with the ACAT inhibitor, the rate of newly synthesized cholesterol decreased by 75% and membranes prepared from these cells contained significantly less HMG-CoA reductase activity. PD128042 significantly decreased the basolateral secretion of newly synthesized cholesteryl esters without affecting the secretion of newly synthesized triglycerides or phospholipids. The inhibitor decreased the esterification of labeled exogenous cholesterol which was taken up by the cell from bile salt micelles. Moreover, after 16 hr of ACAT inhibition, less labeled unesterified micellar cholesterol was associated with the cell. The esterification of cholesterol in CaCo-2 cells plays an integral role in the uptake of cholesterol through the apical membrane and its eventual secretion at the basolateral membrane.
Lipids 26, 1-8 (1991).

The esterification of cholesterol by the small intestinal absorptive cell is believed to be an important step in the transport of cholesterol from the lumen to its eventual secretion into the lymphatics as part of a triglyceride-rich lipoprotein particle (1). The intracellular enzyme which catalyzes this reaction is acylcoenzyme A:cholesterol acyltransferase (ACAT) (2). This enzyme has been found in the intestines of many animal models, including humans (3-6). It is an enzyme which is regulated by a variety of factors including dietary cholesterol and fats, bile salts, hormones, such as progesterone and thyroxine, oxygenated sterols, and changes in membrane fatty acid saturation (3,4,7-10).



Previous studies have demonstrated a decrease in cholesterol absorption after inhibiting ACAT activity in the small intestine. Bennett-Clark and Tercyak (11) used Sandoz compound 58-035 and demonstrated that less cholesteryl esters were secreted into the lymph of lymph-fistula rats, an observation which is consistent with the inhibition of ACAT activity. Heider, Pickens, and Kelly (12) showed in cholesterol-fed rabbits that cholesterol absorption could be inhibited by 46% utilizing a related ACAT inhibitor, 57-118. Another ACAT inhibitor, DL-melinamide, was used by Fukushima *et al.* (13) and Natori *et al.* (14). These investigators observed a significant decrease in the transport of cholesterol and particularly cholesteryl esters into the lymph of lymph-fistula rats following the administration of DL-melinamide. The data suggest that intestinal ACAT has a regulatory role in the absorption of cholesterol.

The present study was undertaken to investigate the effect of ACAT inhibition on the regulation of cholesteryl ester transport in CaCo-2 cells. A new ACAT inhibitor, PD128042 (CI-976, Parke-Davis Pharmaceutical Research Division, Warner-Lambert Co., Ann Arbor, MI), a fatty acid trimethoxyanilide (see Scheme 1), whose synthesis has been recently described (15), was used in this study. The present results suggest that the secretion of newly synthesized cholesteryl esters is decreased following the inhibition of ACAT. Moreover, after chronic inhibition of ACAT activity, less unesterified cholesterol is taken up from bile salt micelles at the apical membrane.

MATERIALS AND METHODS

Materials. [9,10-^{3}H]Oleic acid, [2-^{14}C]acetate, [4-^{14}C]cholesterol, [1-^{14}C]oleoyl Coenzyme A, [5-^{3}H]mevalonic acid, 3-hydroxy-3-methyl [3-^{14}C]glutaryl Coenzyme A, and [1,2-^{3}H]cholesterol were purchased from New England Nuclear (Boston, MA). Oleic acid, oleoyl coenzyme A, glucose-6-phosphate, glucose-6-phosphate dehydrogenase and nucleotide adenine diphosphate were purchased from Sigma (St. Louis, MO). HMG-CoA was from P-L Biochemicals, Inc. (Milwaukee, WI). PD128042 was a generous gift from Brian Krause, Parke-Davis Pharmaceutical Research Division, Warner-Lambert Co. All other chemicals were reagent grade.

Cell culture. Cells were grown in T-75 plastic flasks

Abbreviations: ACAT, acylcoenzyme A:cholesterol acyltransferase; DMEM, Dulbecco's modified Eagle minimum essential medium.

(Corning Glassworks, Corning, NY) in Dulbecco's modified Eagle minimum essential medium (DMEM, Gibco, Grand Island, NY) containing 4.5 g/L glucose and 1% nonessential amino acids, supplemented with 20% fetal calf serum (Hyclone Laboratories, Inc., Logan, UT), 4 mM glutamine, 10 μg/mL insulin, 50 μg/mL penicillin, and 50 μg/mL streptomycin. Prior to confluency, the cells were split according to the method of Mohrmann *et al.* (16). Monolayers were grown on 60 mm plastic Petri dishes in 5 mL of supplemented DMEM. Fresh medium was added every 2 days. Cultures were used only after dome formation, usually 11–13 days after plating. Experiments were performed in medium-199/Earle's (Gibco) containing 1 mM HEPES, pH 7.4. Since the amount of cellular protein per dish did not vary, 5.50 ± 0.03 mg/dish, n=12, the data are expressed as per dish. For experiments performed on micropore filters, CaCo-2 cells were aliquoted on fibronectin-treated micropore polycarbonate filters (Transwells-3412; 0.4 μm pore size; Costar, Cambridge, MA) separating an upper and lower well. Medium in the upper (1.5 mL) and lower (2.6 mL) wells was changed every other day. The cells were used 10 or 11 days after plating and by this time had formed tight monolayers as assessed by electron microscopy. Tight junctions were also present as demonstrated by freeze fracture studies. To estimate monolayer "tightness," transport of albumin from the top well to the bottom well was measured as described by Shasby and Shasby (17). The cells were not used if more than 2.0% of the albumin was found in the lower well after 60 min. Cell viability was monitored by trypan blue exclusion, cell protein, and light microscopy. PD128042 had no significant effect on CaCo-2 cell viability at any of the concentrations tested.

Measurement of lipid synthesis. The rates of cholesteryl ester, triglyceride, and phospholipid synthesis were estimated by oleic acid incorporation into the respective lipid class as previously described (10). Cholesterol synthesis was measured by [^{14}C]acetate incorporation into unesterified and esterified cholesterol as described (18).

In experiments using the transwells, medium containing fetal bovine serum was removed from the bottom well and was replaced with M199 containing 10 mM HEPES, without fetal bovine serum, pH 7.4. The medium from the top well was also removed and the cells were washed five times with 1 mL of M199 buffer. PD128042, at the concentrations indicated, was added to 1.5 mL of M199 in 0.01 mL of dimethylsulfoxide. After incubation with the ACAT inhibitor, the medium was removed and replaced by M199 containing 1 mM taurocholate, 50 μM cholesterol, and 25 μM [^{3}H]oleic acid (spec act, 30,000 dpm/nmol). After six hr, media from the upper and lower wells were removed and centrifuged at 2,000 rpm for 15 min to remove any intact cells or debris. The supernatants from the media were extracted with chloroform/methanol (2:1, v/v). The chloroform phase was taken to dryness under a stream of nitrogen. The residue was taken up in 0.125 mL of chloroform and applied to Silica Gel G thin-layer plates. The plates were developed with hexane/diethyl ether/methanol/acetic acid (70:30:1:1, by vol) and the lipids were visualized with iodine vapor. The bands corresponding to cholesteryl ester, triglycerides, and phospholipids were scraped into 4 mL of liquid scintillation fluid and counted as described previously (10). The cells on the micropore filter were washed three times with 1.0 mL of ice-cold phosphate-buffer saline. The cells were scraped carefully from the filters in 1.0 mL of 0.2 N NaOH. After neutralizing the alkali with HCl, lipids were extracted from the cell digests and separated as described above.

Cholesterol uptake and esterification. Cells were cultured on plastic dishes and micropore filters as described above. After a preincubation with or without PD128042, 50 μM [^{14}C]cholesterol (spec act, 5,000 dpm/nmol), solubilized in M199 containing 1 mM taurocholate and 30 μM monoolein was added to the apical medium. At the end of six hr, cells were analyzed as described above except that bands corresponding to unesterified and esterified cholesterol were scraped from the plates and counted.

Enzyme assays. Acylcoenzyme A:cholesterol acyltransferase activity was measured in a total volume of 0.2 mL containing 0.100–0.150 mg of membrane protein, 0.5 mg of fatty acid-poor bovine serum albumin, and 8.6 nmol of [^{14}C]oleoylCoA (spec act, 23,000 dpm/nmol). The assay mixture was incubated at 37°C for 5 min before the addition of the substrate to start the reaction. The reaction was stopped after 5 min with the addition of chloroform/methanol (2:1, v/v). [^{3}H]Cholesteryl oleate was added as an internal standard and the samples were processed as previously described (19). In one experiment, cholesterol, solubilized in egg phosphatidylcholine (2:1, mol/mol) was added to the assays prior to determining ACAT activity (9). 3-Hydroxy-3-methylglutaryl coenzyme A reductase activity was measured in a total volume of 0.170 mL containing 0.100–0.150 mg of protein, 25 mM glucose-6-phosphate, 3 mM NADP, 70 mM NaCl, 0.174 units of glucose-6-phosphate dehydrogenase, and 15 mM dithiothreitol. The remaining volume was made up by buffer containing 0.04 M KH_2PO_4, 0.05 M KCl, 0.25 M sucrose, and 0.03 M EDTA, pH 7.2. The mixture was incubated for 10 min before starting the assay with 15 nmol of [^{14}C]HMG-CoA (spec act, 22,500 dpm/nmol). Assays were stopped after 20 min by the addition of 0.025 mL of concentrated HCl. D,L-[5-^{3}H]mevalonic acid (20,000 dpm) was added as an internal standard and the assays were processed as previously described (20). Fatty acylcoenzyme A hydrolase and triglyceride synthetase activity were determined as described for the ACAT assay except bands corresponding to free fatty acids and triglycerides were scraped from the plates and counted. Activities were measured in total membranes which were prepared by centrifuging the cellular whole homogenates at 100,000 × *g* for 1 hr. The resulting membrane pellets were resuspended in the sucrose buffer described above and recentrifuged at 100,000 × *g*. The total membrane pellets were diluted with buffer and used immediately for the assays (21).

Chemical and statistical analysis. Protein was determined according to the method of Lowry *et al.* (22), and the unpaired Student's *t*-test was used to determine significance.

RESULTS

Effect of PD128042 on the activities of HMG-CoA reductase, fatty acyl-CoA hydrolase, triglyceride synthetase, and ACAT in CaCo-2 cell membranes. To determine the specificity of PD128042, total membranes were prepared from CaCo-2 cells and incubated with increasing concentrations of the inhibitor solubilized in dimethylsulfoxide. Control assays contained the same amount of dimethylsulfoxide but without the inhibitor. After 15 min, the respective assays were performed as described in Materials and Methods. The activities which were determined in control assays represented 100% and were as follows: HMG-CoA reductase, 1.31 nmol/mg/30 min; fatty acyl Co-A hydrolase, 6.17 nmol/mg/5 min; triglyceride synthetase, 1.70 nmol/mg/5 min; and ACAT, 139 pmol/mg/5 min.

As shown in Figure 1, PD128042 inhibited the activity of ACAT only. Its effect was dose-dependent with 50% of the activity remaining at a concentration of 0.2 μg/mL of PD128042. Maximal inhibition occurred between 2 and 5 μg/mL. Activities of HMG-CoA reductase, triglyceride synthetase, and fatty acyl CoA-hydrolase were not affected by PD128042 even at the highest concentration used (10 μg/mL).

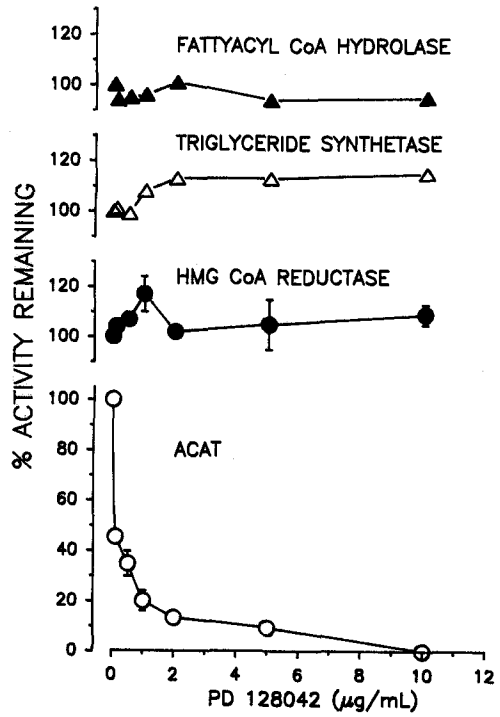

FIG. 1. Effect of PD128042 on the activities of HMG-CoA reductase, fatty acyl Co-A hydrolase, triglyceride synthetase, and ACAT. Total membranes were prepared from CaCo-2 cells as described in Materials and Methods. The membranes, 100-150 μg protein, were incubated for 15 min with PD128042 solubilized in 0.01 mL of dimethylsulfoxide at the concentrations shown. Control assays contained the same amount of dimethylsulfoxide but without the inhibitor. The assays were initiated by adding the respective labeled substrates. Control assays were designated as 100% and the values are given in the text. The points represent the mean ± SE of three to six assays performed at each concentration of PD128042.

Effect of PD128042 on ACAT activity: Competition by fatty acyl-CoA and cholesterol. To determine if the inhibition of ACAT activity by PD128042 was competitive, the inhibitor was added to CaCo-2 cell membranes at a concentration of 0.2 μg/mL. ACAT activity was then measured at increasing concentrations of its fatty acyl-CoA substrate. In each assay, the ratio of oleoyl coenzyme A to bovine serum albumin was kept constant. Figure 2 shows these results. In this experiment, 0.2 μg/mL of PD128042 inhibited ACAT activity more than what was observed in the previous experiment. In the insert, the double reciprocal plot of the data is shown. The results of this experiment suggest that PD128042 is a competitive inhibitor of ACAT activity.

To investigate the effects of cholesterol on the inhibition of ACAT activity by PD128042, CaCo-2 cell membranes were incubated for 1 hr with liposomes containing egg phosphatidylcholine and increasing concentrations of cholesterol (cholesterol/phospholipid ratio of 2:1, mol/mol). PD128042, 0.2 μg/mL, was added and the mixture was incubated for a further 30 min. ACAT activity was then measured by adding labeled oleoyl CoA. The results in Figure 3 show that in control membranes without PD128042, ACAT activity progressively increased as more exogenous cholesterol was added to the assay. At 100 μM cholesterol, ACAT activity increased by 66%. In contrast, in membranes incubated with PD128042, ACAT activity did not increase with the addition of increasing concentrations of exogenous cholesterol.

Effect of PD128042 on the incorporation of [^{3}H]*oleate into cellular lipids.* CaCo-2 cells were preincubated for 2 hr with increasing concentrations of PD128042. At the end of this time, the medium containing the in-

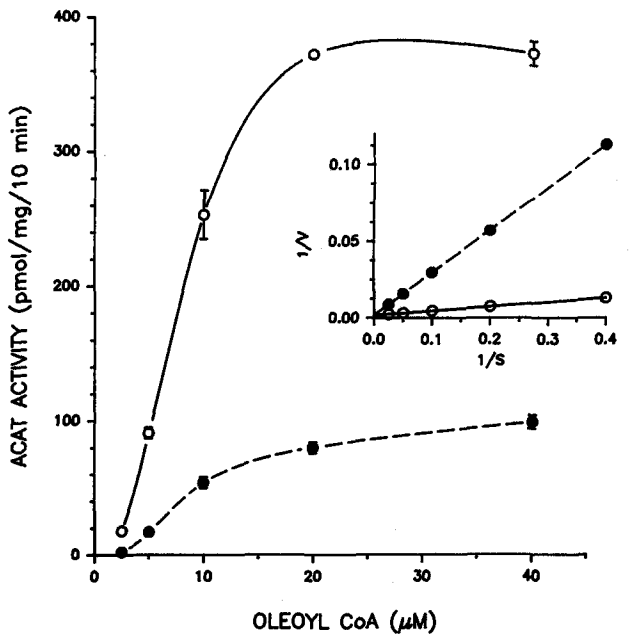

FIG. 2. Effect of PD128042 on membrane ACAT activity. The membranes were incubated for 15 min with or without 0.2 μg/mL of PD128042. The reaction was started by adding labeled oleoyl CoA at the concentrations shown. The albumin to substrate ratio was kept constant. The points represent the mean of duplicate or triplicate assays at each concentration. ○, Control; ●, PD128042.

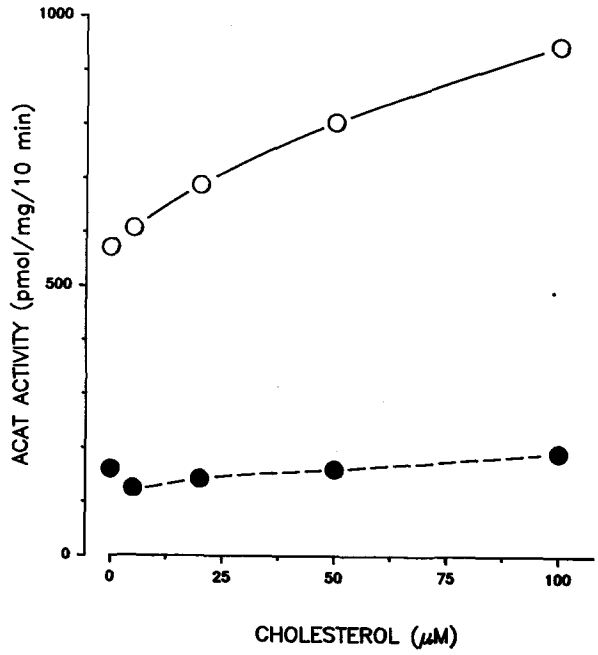

FIG. 3. Effect of PD128042 on membrane ACAT activity. CaCo-2 cell membranes were incubated for 1 hr with liposomes containing egg phosphatidylcholine and increasing concentrations of cholesterol (cholesterol/PC, 2:1, mol/mol). PD128042, 0.2 μg/mL, was added and 30 min later ACAT activity was determined. The points represent the mean ± SE of triplicate assays. ○, Control; ●, PD128042.

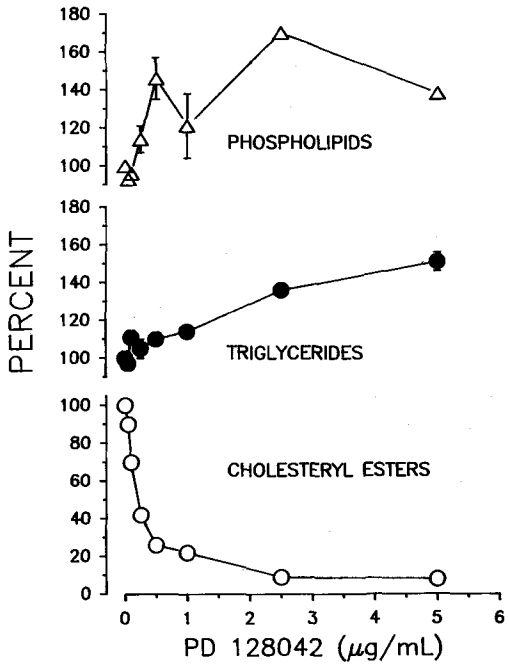

FIG. 4. Effect of PD128042 on [^{3}H]oleate incorporation into cellular lipids. PD128042 was added in dimethylsulfoxide (0.01 mL) to CaCo-2 cells cultured on plastic dishes at the concentrations shown. Control dishes received the vehicle alone. After 2 hr, the medium containing the inhibitor was removed and labeled oleate, 50 μM (spec act, 13,500 dpm/nmol), attached to albumin (3:1, mol/mol) was added for 30 min. The cells were washed with M199 and scraped from the dishes. Lipids were extracted and separated as described in Materials and Methods. Control values were designated as 100% and are given in the text. The values represent the mean ± SE of three dishes at each concentration.

hibitor was removed and the monolayer was washed three times with 1 mL of M199. Labeled oleate attached to albumin, 50 μM, was added and thirty min later, the lipids were extracted from the cell digests and separated (Fig. 4). Control cells, which were incubated with the vehicle alone, incorporated [^{3}H]oleate into cholesteryl esters, triglycerides, and phospholipids at rates of 74 pmol/30 min, 3.40 nmol/30 min, and 2.55 nmol/30 min, respectively. The effect of PD128042 on the incorporation of oleate into cholesteryl oleate was dramatic, reaching maximal inhibition between 1.0 and 2.5 μg/mL. The rate of oleate incorporation into triglycerides was stimulated, particularly so at the higher concentrations of PD128042. The estimated rate of phospholipid synthesis was unaffected until concentrations of the ACAT inhibitor reached 0.5 μg/mL. At this concentration and above, the incorporation of oleate into phospholipids was increased.

Effect of PD128042 on cholesterol synthesis. The results shown in Figure 1 suggested that when PD128042 was added to membranes, it had no affect on HMG-CoA reductase activity. Decreasing the cells ability to esterify cholesterol by PD128042, however, might lead to an expansion of a pool of unesterified cholesterol, which, in turn, could regulate intracellular cholesterol synthesis. To investigate if PD128042 could have a secondary effect on cholesterol synthesis, CaCo-2 cells were incubated for 4 hr in the presence or absence of increasing concentrations of PD128042. Labeled acetate was added during the last hour and the incorporation of acetate into cholesterol was determined (Fig. 5A). In the presence of the ACAT inhibitor, there was a concentration-dependent decrease in the rate of acetate incorporation into unesterified cholesterol. Results shown in Figure 5B also demonstrate that the effect of PD128042 on the rate of newly synthesized cholesterol was time-dependent. Acetate incorporation into total lipids was not reduced by PD128042.

A substantial decrease in the synthesis of new cholesterol by PD128042 was unexpected. To further support this observation, CaCo-2 cells were incubated for 4 hr in the presence or absence of 10 μg/mL of PD128042. The monolayers were washed and total membranes were prepared. In membranes prepared from cells incubated with PD128042, HMG-CoA reductase activity was 298 pmol/mg/30 min as compared to 628 pmol/mg/30 min in membranes prepared from control cells (Fig. 6). The inhibition of ACAT activity by PD128042 in intact cells, therefore, resulted in the inhibition of HMG-CoA reductase activity. In these same membranes, the activities of ACAT were 20 pmol/mg/5 min *vs* 263 pmol/mg/5 min in cells incubated with or without the inhibitor, respectively (Fig. 6).

Effect of PD128042 on the basolateral secretion of lipids by CaCo-2 cells. To investigate the effect of

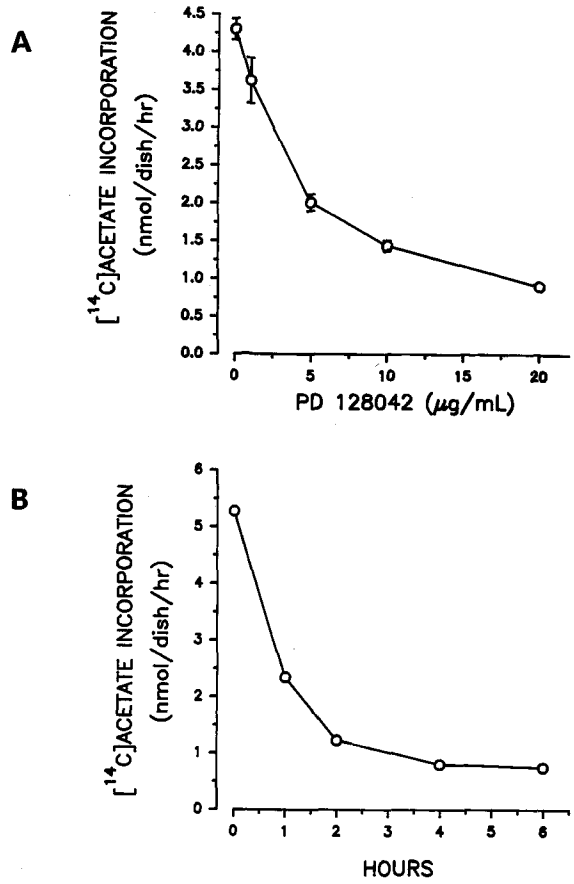

FIG. 5. Effect of PD128042 on [^{14}C]acetate incorporation into cholesterol. A: CaCo-2 cells were incubated for 4 hr with increasing concentrations of PD128042. During the final hour, [^{14}C]acetate, 5 mM (spec act, 100 dpm/nmol), was added. The monolayer was washed and scraped from the plates. Lipids were extracted and separated by thin-layer chromatography as described in Materials and Methods. B: At the indicated time, PD128042, 20 μg/mL, was added to the medium of CaCo-2 cells. During the last hour of incubation, [^{14}C]acetate incorporation into cholesterol was determined as described above. The data points represent the mean ± SE of 3-6 dishes.

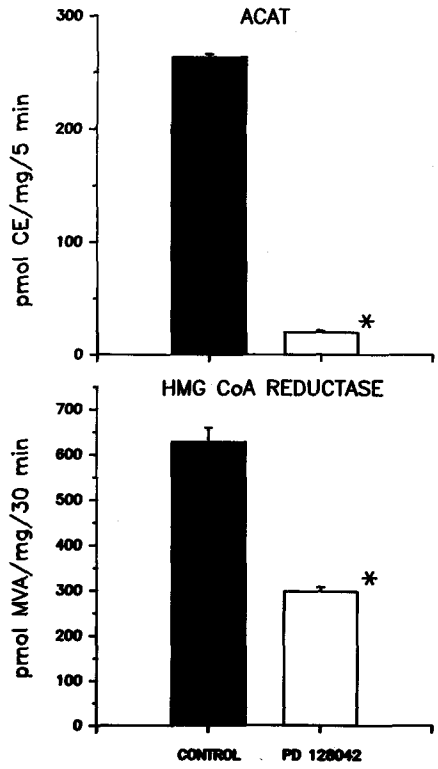

FIG. 6. Effect of PD128042 on membrane ACAT and HMG-CoA reductase activities. CaCo-2 cells were incubated for 4 hr with 10 μg/mL of PD128042. Following the incubation, the cells were washed and total membranes were prepared. The activities of HMG-CoA reductase and ACAT were determined. The data represent the mean and SE from two experiments with assays performed in triplicate, *, $p<0.001$ *vs* control.

PD128042 on the secretion of newly synthesized lipids, CaCo-2 cells were grown on polycarbonate filters separating an upper and lower well. PD128042 or its vehicle was added for 30 min. Following the preincubation, the medium containing the inhibitor was removed and 25 μM of labeled oleate solubilized in a solution containing 1 mM taurocholate and 50 μM of cholesterol was added to the apical medium. After 3 and 6 hr, the incorporation of labeled oleate into cellular lipids and lipids secreted into the apical medium and basal wells was determined. Figure 7 shows the data from the 6 hr time point. The results of the 3 hr time point were similar except the values were 50% of those at 6 hr. As expected, in cells incubated with the ACAT inhibitor, the incorporation of oleate into cellular cholesteryl oleate was dramatically decreased. Because of the decrease in newly synthesized cholesteryl esters, there was a significant decrease in the amount of labeled cholesteryl esters found in the basal well. In contrast, PD128042 did not alter the incorporation of labeled oleate into cellular triglycerides or phospholipids or the amount of these labeled lipids found in the basal well. The secretion of labeled cholesteryl esters and triglycerides was basally oriented. For reasons which are not clear, phospholipid secretion was not polarized as similar amounts of labeled phospholipids were observed in both the apical and basal wells.

Effect of PD128042 on cholesterol uptake and esterification by CaCo-2 cells. Results from previous studies have suggested that cholesterol absorption is decreased after inhibiting cholesterol esterification in the gut (11,12). To investigate the effect of PD128042 on cholesterol absorption and esterification, CaCo-2 cells were preincubated for 30 min with PD128042. After removing the medium containing the inhibitor, 50 μM of labeled cholesterol solubilized in a solution containing 1 mM taurocholate and 30 μM monoolein was added to the apical surface. At 1, 2, and 4 hr, the amount of labeled free and esterified cholesterol within cells was determined. As shown in Figure 8, the amount of labeled unesterified cholesterol within cells was not altered by the ACAT inhibitor. No detectable esterification of the absorbed cholesterol was observed in CaCo-2 cells preincubated with PD128042. At 1, 2, and 4 hr, the amount of labeled unesterified cholesterol secreted into the basal well was similar. The amount of labeled cholesteryl esters secreted into the basal well in both

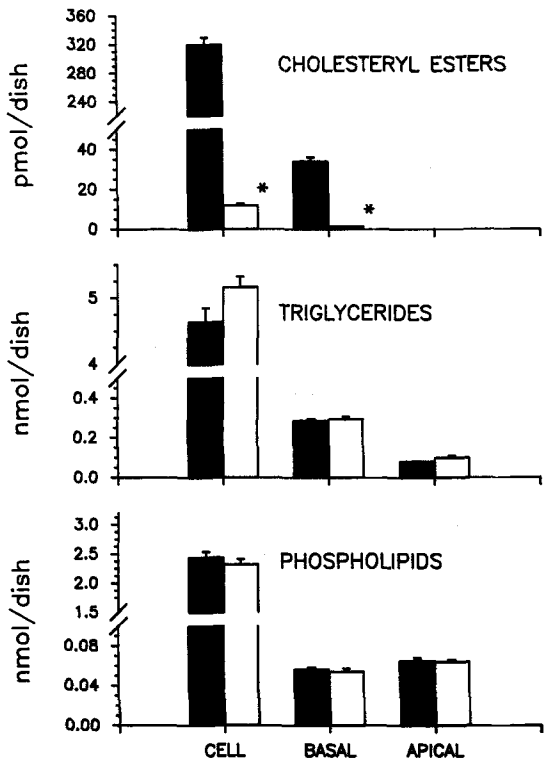

FIG. 7. Effect of PD128042 on the incorporation of [^{3}H]oleate into lipids released at the basolateral membrane. CaCo-2 cells were cultured on micropore polycarbonate filters. After washing the monolayer, M199 containing 5 μg/mL of PD128042 was added to the apical surface for 30 min. The medium containing the inhibitor was removed and a solution containing 1 mM taurocholate, 50 μM cholesterol, and 25 μM [^{3}H]oleic acid (spec act, 30,000 dpm/nmol), was added to the upper well. After six hr, lipids were extracted from the upper and lower wells and separated as described in Materials and Methods. The cells were washed three times with 1 mL of M199 and scraped from the filters. Cellular lipids were extracted and separated. The results are the mean ± SE of four control and 20 experimental wells. Lower well, basal; upper well, apical. ■, Control; □, PD128042.

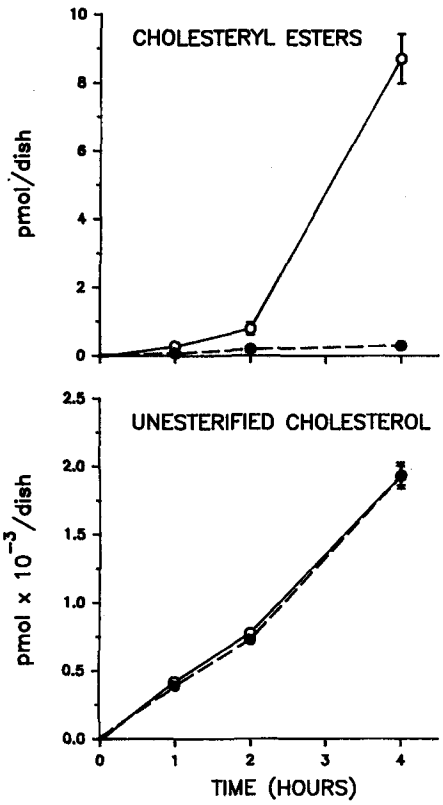

FIG. 8. Acute effect of PD128042 on the uptake and esterification of [^{14}C]cholesterol. Cells were cultured and ACAT activity inhibited as described in Figure 7. [^{14}C]Cholesterol, 50 μM (spec act 5,000 dpm/nmol), was added to the apical medium in a solution containing 1 mM taurocholate and 30 μM monoolein. After 6 hr, the lipids from the lower and upper wells were extracted and separated. The cells were washed and scraped from the filters. Lipids were extracted and separated. The results are the mean of four control and eight experimental wells. ○, Control; ●, PD128042.

control and ACAT-inhibited cells was too low for detection (data not shown).

If CaCo-2 cells were preincubated overnight with the ACAT inhibitor, there was a consistent decrease in the amount of labeled unesterified cholesterol associated with the cell following a 1, 3, and 6 hr incubation with labeled micellar cholesterol (Fig. 9). In control cells, the cholesterol which was taken up was esterified. By contrast, no detectable esterification occurred in cells incubated overnight with PD128042. Labeled cholesteryl esters secreted into the basal wells were too low for detection (data not shown).

DISCUSSION

PD128042 is a potent inhibitor of human intestinal ACAT activity with an IC_{50} of approximately 0.2 μg/mL. PD128042 had no direct effect on HMG-CoA reductase, triglyceride synthetase, or fatty acyl CoA hydrolase activities when added to CaCo-2 cell membranes. PD128042 is a fatty acid anilide and competes for ACAT with the fatty acyl-CoA substrate much like the fatty acylamides 57-118 and 58-035 (12). It is clear from the present data, however, that the inhibition of ACAT activity by PD128042 is not affected by increased amounts of exogenously added cholesterol. The inhibitory effect of PD128042 on ACAT activity, therefore, will not be minimized by an increase in cholesterol flux through the intestine.

Inhibition of ACAT activity by PD128042 in CaCo-2 cells resulted in a significant decrease in the rate of newly synthesized cholesterol and a corresponding decrease in HMG-CoA reductase activity. A decrease in cellular reductase activity occurs when there is excess unesterified cholesterol available to the cell, either from newly synthesized or lipoprotein cholesterol (23,24). The present data suggest, therefore, that in intestinal cells in which ACAT activity is inhibited by PD128042, unesterified cholesterol, which would otherwise be esterified, enters other intracellular pools of cholesterol which may, in turn, regulate *de novo* cholesterol synthesis.

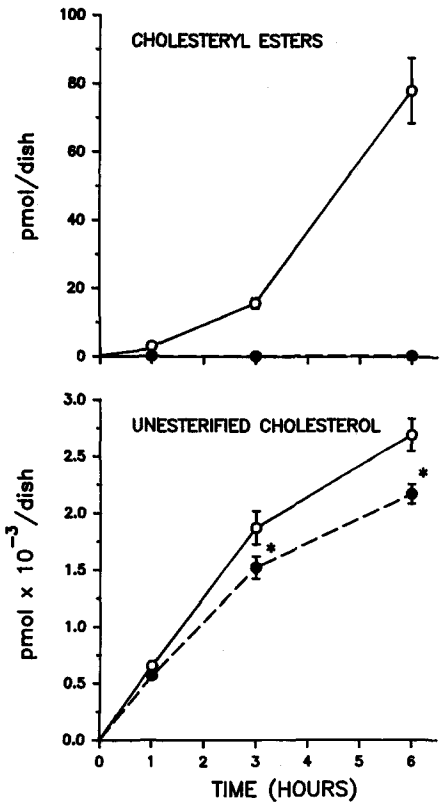

FIG. 9. Chronic effect of PD128042 on the uptake and esterification of [^{14}C]cholesterol. CaCo-2 cells were incubated overnight with 5 μg/mL of PD128042. The next morning [^{14}C]cholesterol, solubilized in a solution containing 1 mM taurocholate and 30 μM monoolein, was added as described in Figure 8. After 6 hr, the lipids from the cells and both lower and upper wells were extracted and separated. The results are the mean ± SE of four control and four experimental wells. ○, Control; ●, PD128042; *, $p<0.05$ *vs* control.

Long-term effects of inhibiting both cholesterol synthesis and esterification in the intestine may be beneficial. Cholesterol synthesized in the intestine contributes directly to the plasma cholesterol compartment (25). Since the rates of cholesterol synthesis in the intestine are second only to the rates observed in the liver (26), a decrease in the contribution made by the intestine could lead to a reduction in plasma cholesterol levels. In the liver, newly synthesized cholesterol has been shown to be important for the assembly and secretion of triglyceride-rich lipoproteins (27). Chronic ACAT inhibition in the intestine could result in the depletion of both surface and core components of the triglyceride-rich lipoprotein by inhibiting the synthesis of unesterified and esterified cholesterol, respectively. Thus, normal lipoprotein assembly may be altered, resulting in a decrease in lipoprotein secretion. It has been previously demonstrated that the composition of triglyceride-rich lipoproteins secreted by CaCo-2 cells can be modified by ACAT inhibition (28). The regulation of cholesterol synthesis by PD128042 occurred in the absence of gross changes in intracellular cholesterol mass. Unesterified and esterified cholesterol contents were similar in cells incubated for 4 hr with the inhibitor. It is not surprising that small changes occurring in intracellular cholesterol pools, which are sufficient to cause changes in HMG-CoA reductase activity, would not be detected by gross measurements of cellular cholesterol mass after 4 hr of ACAT inhibition.

The data also demonstrate that ACAT is responsible for the esterification of cholesterol, which is absorbed from micelles at the apical membrane as PD128042 significantly inhibited this process. As evidenced by the significant decrease in the basolateral secretion of newly synthesized cholesteryl esters (Fig. 7), PD128042 will likely cause a decrease in the transport of cholesteryl esters by the intestine. This supports previous data in lymph fistula rats which demonstrated a significant decrease in the amount of cholesteryl esters transported in lymph chylomicrons following the inhibition of ACAT activity (11).

In a previous study in CaCo-2 cells, the inhibition of ACAT by progesterone resulted in a decrease in the uptake of unesterified cholesterol (10). In the acute situation, despite a significant inhibition of cholesterol esterification by PD128042, the amount of labeled unesterified cholesterol taken up by CaCo-2 cells was similar as compared to the amount taken up by control cells with normal ACAT activity. In a more chronic situation, however, after ACAT activity had been inhibited for 16 hr, there was a modest decrease in the uptake of unesterified cholesterol. Perhaps an expansion of an unesterified cholesterol pool within the intestinal cell is necessary to disrupt the cholesterol gradient across the cell impairing the uptake of the sterol. Further studies will obviously be necessary to define a mechanism for this effect.

[Received June 19, 1990; Revision accepted October 30, 1990]

Lipid and Fatty Acid Composition is Altered in Plaque Tissue from Multiple Sclerosis Brain Compared with Normal Brain White Matter

Robert Wilson[a,*] and **Douglas R. Tocher**[b]

[a]Department of Biological and Molecular Sciences and [b]NERC Unit of Aquatic Biochemistry, School of Natural Sciences, University of Stirling, Stirling FK9 4LA, Scotland, U.K.

Plaques and white matter from brains of multiple sclerosis (MS) patients were analyzed for lipid content, class composition, and fatty acid composition of total lipid, together with the fatty acid composition of plaque glycerophospholipids, and the results were compared with white matter from normal brain. Plaques contained less than 30% of the lipid present in normal white matter. Plaque lipid was characterized by significantly increased proportions of glycerophospholipids and decreased cerebrosides and sulfatides. In addition, a subacute plaque contained approximately 10 times the proportion of steryl esters observed in chronic plaques or normal white matter. Total lipid from all the MS plaques showed significantly increased percentages of saturated fatty acids, n-6, n-3 and total polyunsaturated fatty acids and decreased percentages of monoenes and alk-1-enyl ethers in comparison with normal brains. These results were consistent with increased cellularity and astrogliosis associated with MS plaques. However, analysis of plaque glycerophospholipids showed that the fatty acid changes observed in total lipid were not simply due to the increased proportion of glycerophospholipids and decreased myelin lipids, but that the fatty acid composition of the individual glycerophospholipids was different. *Lipids 26,* **9–15 (1991).**

Multiple sclerosis (MS) is a disease of the central nervous system which is characterized by areas of demyelination. Despite considerable effort, the pathogenesis of the disease is unknown. However, it has been recognized that both cell mediated and humoral immunological responses occur (1) although the search for a common infectious (viral) agent has been unsuccessful (2). During the course of demyelination, both myelin and oligodendrocytes are destroyed. This process results in the formation of disseminated plaques characterized by infiltration of fibrous type-2 astrocytes (1,3).

It has long been suggested that there is a relationship between dietary fat and MS (4,5). As a result of the early findings (4), much of the subsequent research into the primary defect in MS was centered on changes in the lipid and fatty acid compositions of macroscopically normal-appearing white matter or myelin from brains of MS patients *post-mortem.* There is contradictory evidence of changes in lipid composition of MS brain (see ref. 6). In general, there is a decrease in cerebrosides, sulfatides and myelin phospholipid, particularly ethanolamine alk-1-enyl phospholipid, and often an increase in cholesteryl ester levels (6–9). The latter has been related to a reduction in myelin cholesterol esterase activity (10). Although there is a lower yield of myelin from MS brain there is little change in the lipid composition of the myelin (7,11). However, changes in the lipid class composition, similar to those in normal-appearing white matter from MS brain, have been noted in a few studies of MS plaques (6,7).

Consistent patterns of change in the fatty acid composition of normal-appearing white matter in MS have been difficult to obtain. There are reports of changes in the fatty acid composition of total lipid (8,9,11) and individual lipid classes (6,8,9,12) from normal-appearing white matter (8,9,11) and myelin (8,11) in MS. Overall, there appears to be increased levels of saturated fatty acids, and decreased levels of monounsaturated fatty acids and polyunsaturated fatty acids (PUFA) in normal-appearing white matter (13). However, other studies have noted fatty acid profiles in MS similar to those of control brain (7,14). In contrast, MS plaques were commonly thought to be not as useful as white matter in elucidating the pathogenesis of MS, and so the fatty acid compositions of plaque lipids have not been thoroughly studied. However, histochemical and immunochemical studies have shown that plaques are active in both demyelination and remyelination (1,15). Furthermore, serial magnetic resonance imaging studies have shown both the appearance and disappearance of MS lesions (16). These studies suggest plaques are in a biochemically dynamic situation and may provide pathogenetic information.

In the present study, we have investigated the lipid and fatty acid composition of MS plaque and white matter in comparison with normal brain white matter in order to determine the major differences between these tissues. Of particular interest was the occurrence and extent of changes in the PUFA composition of plaque tissue.

MATERIALS AND METHODS

Tissue samples. Samples of tissues from MS and normal brains were obtained from The Multiple Sclerosis Society Brain Bank, Institute of Neurology, London. Chronic MS plaques were dissected from associated white matter from the parietal (2 samples) and occipital (1 sample) ventricle regions from different patients (see ref. 17). A subacute plaque was dissected from the occipital ventricle region. Macroscopically normal white matter was obtained from the MS brains from regions adjacent to the chronic plaques. Normal brain white matter from the region of the parietal ventricle was obtained from patients of similar age who died from cardiac failure. All samples were collected and frozen at −70°C within 10 to 44 hr after death of the patient.

Lipid extraction and quantification. Total lipid was extracted from 200–250 mg of brain tissue according to the method of Folch *et al.* (18). After homogenization in approximately 10 volumes of ice-cold chloroform/methanol (2:1, v/v), the homogenates were filtered and 0.25 vol of

*To whom correspondence should be addressed.

Abbreviations: BHT, butylated hydroxytoluene; Cer, cerebroside; CerOH, hydroxycerebroside; CL, cardiolipin; DMA, dimethylacetal; FFA, free fatty acids; MS, multiple sclerosis; PA, phosphatidic acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; PUFA, polyunsaturated fatty acid; SE, steryl ester; SM, sphingomyelin; Sulf, sulfatide; SulfOH, hydroxysulfatide; TAG, triacylglycerol; VLCFA, very long chain fatty acid.

0.88% KCl added and the solutions mixed. After separation, the chloroform layer was removed and refiltered, and the solvent removed under nitrogen. The lipid was dried in a vacuum desiccator before weighing. The weighed lipid extracts were redissolved in chloroform/methanol (2:1, v/v) at a final concentration of 10 mg lipid/mL and were stored at −20°C between procedures. All solvents contained 0.01% butylated hydroxytoluene (BHT) as an antioxidant. Protein content was determined in the residue after lipid extraction by sodium hydroxide/sodium dodecylsulfate solubilization, essentially according to Lowry *et al.* (19).

Lipid class analysis. Lipid classes were separated by a one-dimentional double development HPTLC method (20). Approximately 5–20 μg of total lipid was spotted on HPTLC plates that had been pre-run in hexane/diethyl ether (1:1, v/v) and activated at 110°C for 30 min. The plates were developed for 6 cm in methyl acetate/isopropanol/chloroform/methanol/0.25% aqueous KCl (25:25:25:10:9, by vol) to separate phospholipid classes, sulfatides and cerebrosides, with neutral lipids running at the solvent front (21). After drying, the plates were developed fully in hexane/diethyl ether/acetic acid (80:20:2, v/v/v) to separate the neutral lipids and cholesterol. Lipids were stained by charring at 160°C for 20 min after spraying with 3% copper acetate/8% phosphoric acid and identified by comparison with pure, commercial standards. Lipid classes were quantified by calibrated densitometry as described by Olsen and Henderson (20) using a Shimadzu CS-9000 (Shimadzu, Columbia, MD) dual wavelength flying-spot TLC scanner and DR-13 recording integrator.

Separation of lipid classes. Total neutral lipids were separated from total polar lipids by TLC on 20 × 20 cm plates using hexane/diethyl ether/acetic acid (80:20:2, v/v/v) as developing solvent essentially as described previously (22). Individual phospholipid classes, sulfatides and cerebrosides were separated by TLC as above using methyl acetate/isopropanol/chloroform/methanol/0.25% aqueous KCl (25:25:25:10:9, by vol) as developing solvent. The lipids were visualized by spraying with 2′,7′-dichlorofluorescein. The separated phospholipid bands were scraped off and eluted with chloroform/methanol/water (10:10:1, v/v/v). Solvent was removed from the samples as detailed above, with the purified phospholipids redissolved in chloroform/methanol (2:1, v/v) and stored at −20°C between procedures. All solvents were supplemented with 0.01% BHT.

Fatty acid analyses. Fatty acid methyl esters were prepared from samples by acid-catalyzed transmethylation overnight at 50°C, according to Christie (23). Aldehydes released from alk-1-enyl phospholipids formed dimethyl acetal derivatives (DMA) during transmethylation (23). After extraction, the methyl esters and DMA were purified by TLC using hexane/diethyl ether/acetic acid (90:10:1, v/v/v) as solvent. The methyl esters and DMA were redissolved in hexane containing 0.01% BHT and analyzed in a Packard 436 gas chromatograph equipped with either CP Wax 52CB or CP Sil5CB chemically bonded fused silica capillary columns (both 50 m × 0.34 mm i.d.) (Chrompack U.K., Ltd.), on-column injection and using H_2 as carrier gas with a thermal gradient from 50°C to 225°C (CP Wax) or 260°C (CP Sil). Individual methyl esters and DMA were identified by comparison with known standards and a well-characterized fish oil and also by reference to published data (24–26). The identities of all fatty acid methyl esters and DMA were confirmed by GLC/mass spectrometry courtesy of Dr. W. W. Christie, The Hannah Institute, Ayr, Scotland, U.K. Quantification was performed using a Shimadzu CR-3A recording integrator.

Statistical analysis. The four MS plaques, three MS white matter and three normal brain white matter samples were analyzed separately and not pooled. For the lipid class composition and total lipid fatty acid composition each sample was analyzed in triplicate and the results are the means ± SD of each respective group. However, for the fatty acid compositions of individual glycerophospholipid classes, each sample was analyzed once with the data expressed as the means of the three normal brain and four MS plaque samples ± SD. Significance of differences between MS tissues and normal white matter was determined by the Student's *t*-test.

Materials. BHT and pure lipid class standards were from Sigma Chemical Co. Ltd. (Poole, U.K.). HPTLC plates (10 × 10 cm × 0.15 mm) and TLC plates (20 × 20 cm × 0.25 mm) precoated with silica gel 60 (without fluorescent indicator) were obtained from Merck. All solvents were HPLC grade and were obtained from Rathburn Chemicals (Walkerburn, U.K.).

RESULTS

There was no difference between the protein contents of the MS tissue (average 63 mg/g wet wt.) and those of normal brain tissue (average 64 mg/g wet wt.) (Table 1). However, the mean total lipid content of all MS tissue samples was considerably lower than that of normal brain tissue. This resulted in lipid/protein ratios being two-fold, 3.3-fold and 4.3-fold lower for MS white matter, chronic plaques and the subacute plaque, respectively, as compared to normal white matter (Table 1).

The one-dimensional double-development HPTLC system effectively separated all the major lipid classes with the exception of PA and CL (Fig. 1). However, the presence of CL in all MS tissue was confirmed by two-dimensional HPTLC. Other than the quantitatively minor components CL and FFA, there were no significant differences between MS white matter and normal white matter (Table 2). There is a significant loss of cerebrosides ($p<0.01$) and sulfatides ($p<0.05$), together with a significant increase in PE ($p<0.01$), PI ($p<0.02$) and CL ($p<0.002$)

TABLE 1

Lipid and Protein Contents of Multiple Sclerosis White Matter, Multiple Sclerosis Plaque and White Matter from Normal Brain[a]

		Multiple sclerosis

Chol	27.1 ± 2.8	27.4 ± 2.5	25.7 ± 2.6	24.8 ± 2.1
FFA	0.1 ± 0.1	1.2 ± 0.6*	0.6 ± 0.3	0.4 ± 0.2
TAG	1.9 ± 2.4	0.8 ± 0.5	0.7 ± 0.4	1.7 ± 1.2
SE	1.4 ± 0.4	1.6 ± 0.3	1.6 ± 0.4	14.9 ± 4.0**#

[a]Values are means ± S.D. for triplicate analysis and of three samples/group, except for the single subacute plaque. Where indicated (*), values are significantly different to normal brain white matter *($p<0.05$), **$p<0.02$). Where indicated (#), values for the subacute plaque are significantly different to chronic plaques #($p<0.05$). PL, phospholipid; and WM, white matter.

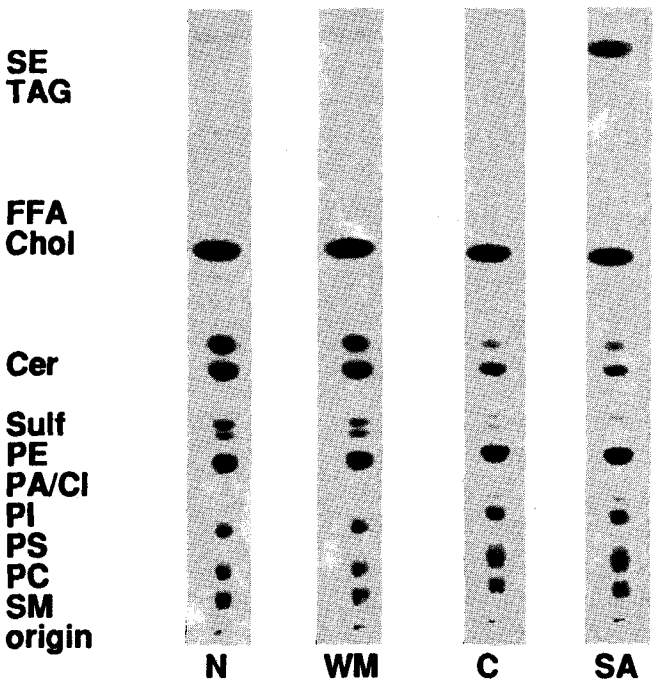

FIG. 1. Separation of lipid classes by one dimensional double development HPTLC (20). Samples are total lipid from N, normal brain white matter; WM, MS, white matter; C, MS chronic plaque; SA, MS subacute plaque. The cerebrosides and sulfatides were resolved into two components with the hydroxy-derivative having the lesser R_f value. Cer, cerebrosides; Chol, cholesterol; CL, cardiolipin; FFA, free fatty acid; PA, phosphatidic acid, PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; SE, steryl ester; SM, sphingomyelin; Sulf, sulfatide; and TAG, triacylglycerol.

in both chronic and subacute plaques (Table 2). The percentage of cholesterol was generally lower and FFA was increased in MS plaques, but the differences were not significant.

There were some significant differences between the subacute plaque and the chronic plaques. In the subacute plaque both hydroxycerebrosides and hydroxysulfatides were decreased 2.9-fold, whereas in chronic plaques the decreases were larger in the non-hydroxylated classes (Table 2). Furthermore, the subacute plaque contained almost 15% SE.

The total lipid from the subacute and chronic plaques showed significantly increased percentages of total saturated fatty acids ($p<0.01$ or less), n-6 PUFA ($p<0.05$ or less), n-3 PUFA ($p<0.05$ or less) and total PUFA ($p<0.01$ or less) and decreased percentages of total monoenes ($p<0.002$ or less) and DMA ($p<0.01$ or less) in comparison with normal white matter (Table 3). The increased levels of saturated fatty acids were primarily due to increased 16:0 and, to a lesser extent, 18:0. The decrease in monoenes was more general, including 18:1 and 20:1 isomers and 24:1. The overall decrease in DMA was primarily due to decreased 18:1 DMA. Increases in 20:4n-6 and 22:6n-3 were primarily responsible for the increased PUFA in MS plaques, and n-3 PUFA increased proportionaly more as evinced by the increased n-3/n-6 ratios in the MS plaques (Table 3). MS white matter displayed the same trends as described for plaque tissues but, with the exception of total n-6 PUFA, the differences between MS white matter and normal white matter were non-significant (Table 3).

The presence of very long chain fatty acids (VLCFA, C_{24} and greater) was investigated using a CP Sil5CB

column. This showed that 25:0/26:0 totalled 0.6% and 0.2%, on average, and 25:1/26:1 totalled 1.8% and 0.8%, on average, in total lipid from normal white matter and MS plaques, respectively (Table 3). The major very long chain PUFA was 24:4n-6 present at 0.8% and 0.6% of the total lipid fatty acids in normal white matter and MS plaques, respectively (Table 3). The 25:0, 25:1, 26:0 and 26:1 were confined mainly to cerebrosides, sulfatides and sphingomyelin with 0.1% 26:0 and 0.6% 26:1 in PC. However, 24:4n-6 was found predominantly in PE and PS (data not shown).

The glycerophospholipids showed the characteristic distribution of fatty acids associated with neural tissues (see ref. 27). PC had high 16:0 and relatively low PUFA levels and PE had low saturated fatty acids and relatively high PUFA levels (Table 4). PS had high 18:0 and a high C_{22}/C_{18}–C_{20} PUFA ratio, whereas PI had high 18:0 and 20:4n-6 (Table 5). This distribution was maintained in MS plaques.

The changes in fatty acid composition observed with total lipid were also reflected in the individual glycerophospholipids (Tables 4 and 5). Therefore, the

glycerophospholipids in MS plaques had significantly increased percentages of saturated fatty acids, n-6, n-3 and total PUFA and decreased percentages of monoenes superimposed on the distributions described above. The major increase in 16:0 in MS plaque was in PC, and increased 18:0 was primarily in PE and PI. As with total lipid, the decreased monoenes in MS plaque was more evenly spread, but 18:1n-9 accounted for the largest decrease in all glycerophospholipids. The largest increases in 22:6n-3 were observed in PE and PS, whereas 20:4n-6 increased to the greatest extent in PI in MS plaque. The decreased percentages of DMA derived from MS plaque was primarily due to decreased 18:1 DMA from PE (Table 4).

DISCUSSION

The lower lipid contents and lower lipid/protein ratios and the reduced percentages of cerebrosides, sulfatides and ethanolamine plasmalogens in the MS plaques are all classical indicators of demyelination that had occurred or was occurring in the plaques (28). It is difficult to compare the lipid class composition data with much of the earlier work due to the many different ways of expressing the data that have been used. Where comparison is possible there is generally good agreement between the data for normal brain white matter and MS white matter and plaques obtained in the present study and data from earlier studies (7,28). However, the percentages of

PC are lower in the present study when compared with those in earlier studies.

It was noteworthy that our results also showed a significant increase in the proportion of total glycerophospholipids in chronic plaques with significant increases in PE, PI and PA/CL. The significant increases in the proportions of total glycerophospholipids and CL would be consistent with increased cellularity in the plaques. Overall, the qualitative changes in the lipid class composition of the plaques were similar to those previously reported for normal-appearing white matter in MS (6–9). The lipid class compositional changes in normal-appearing white matter in MS are probably an indication of the presence of micro-plaques not observed on macroscopic examination.

The increased saturated fatty acid and decreased monounsaturated fatty acid percentages are consistent with the loss of monoenoic-rich myelin lipids (13). However, whereas increased saturated fatty acids and decreased monoenes are features consistently reported for white matter and myelin in MS, the changes in PUFA levels have been variable. For instance, 18:2n-6 and 20:4n-6 have been reported as decreased in PC in apparently normal white matter in MS (11,29) and myelin (11,30), although other studies have found little difference in PUFA levels (6,14). However, the data presented here for MS plaques were very consistent between samples from different patients, different brain regions and different stages and clearly show a general increase in the proportion of total PUFA. Therefore, the present data are an important new observation in MS, but are consistent with increased cellularity in the plaques, especially chronic plaques (1,3).

The increased PUFA in total lipid in plaques was almost entirely due to an approximate doubling of 20:4n-6 and a three-fold increase in 22:6n-3. All the other PUFA, including 22:4n-6, are far less affected. Therefore, astrogliosis not only increased the total PUFA levels but also altered the PUFA balance and, consequently, the eicosanoid status in the plaques. Furthermore, the increased PUFA was not simply the result of an effective exchange of relatively monoene-rich myelin lipid for relatively PUFA-rich cellular lipids. This was confirmed by the analysis of the glycerophospholipids, which showed that their composition was also different with predominantly increased proportions of 20:4n-6 and 22:6n-3 in the MS plaques. This suggests that the glycerophospholipids of the proliferating and invading astrocytes have a higher PUFA content than glycerophospholipids from tissue

composed predominadntly of myelin. However, it is not clear if these alterations in PUFA balance play any role in the progression of the plaques. It may be that these changes are entirely secondary, but it is also possible that eicosanoids are involved in the disease process (31).

Several other studies reported low levels of certain PUFA, especially 18:2n-6, in serum, platelets and erythrocytes in MS (32,33). Some later studies have confirmed this (34,35), but others have failed to find reduced serum PUFA (36-38). Overall, these studies modified the early idea that an excess consumption of saturated fatty acids was a causal factor in MS (4) to one of a relative deficiency in essential fatty acids (33,39). This hypothesis has resulted in several clinical trials (5,40), with some mild improvement observed with both n-6 and n-3 dietary supplementation (40). However, the mechanisms underlying the effects of essential fatty acids in MS are unclear and probably complex (40). The present results show an alteration in PUFA balance in plaques that may be involved in plaque development.

It is noteworthy that VLCFA were not found in the MS plaques or MS white matter in significant amounts. Indeed, levels were slightly lower than in normal brain white matter. Saturated VLCFA are increased due to impaired peroxisomal β-oxidation and thought to play a major role in the pathology of adrenoleukodystrophy, a disease also characterized by demyelination (41). Although it is not fully understood how VLCFA influence demyelination in adrenoleukodystrophy it is clear from our results that they are not involved in the pathology of MS.

Some differences in the lipid composition between a subacute plaque and chronic plaques were apparent from the data, although it should be noted that only one subacute plaque was analyzed. The subacute plaque had a lower lipid content (40 mg/g tissue wet wt.) than on average for the chronic plaques (53 mg/g tissue wet wt.) and also the lowest lipid/protein ratio. The percentages of cerebrosides, sulfatides and especially their hydroxylated derivatives were also lower in the subacute plaque. These results were perhaps unexpected as myelin lipid loss should be greatest in the chronic plaques and so may indicate some remyelination in the chronic plaques. However, sterol esters were ten-fold higher in the subacute plaque, as would be expected for an actively demyelinating sample. In contrast to class composition, there were no significant differences in the fatty acid composition of total lipid between the subacute and chronic plaques.

This study has provided important data on the lipid and, especially, the fatty acid composition of MS plaque tissue. The consistently increased PUFA in the plaques, due to increased proportions of 20:4n-6 and 22:6n-3, and the low levels of VLCFA were of particular interest. The results were generally consistent with increased cellularity, probably due to astrogliosis, known to be associated with MS plaques. However, the increased proportion of PUFA in the plaques was not simply the result of an increased proportion of glycerophospholipids as the percentages of PUFA in the individual glycerophospholipids was also increased in the plaques.

ACKNOWLEDGMENTS

We are grateful to Dr. J. Newcombe, The Multiple Sclerosis Society Laboratory, Department of Neurochemistry, Institute of Neurology, London, U.K., for the provision of the samples of MS brain tissue. We thank Dr. W. W. Christie for performing and interpreting the GLC/mass spectrometral analyses and Dr. Peter J. Brophy for critical reading of the manuscript. Dr. R. Wilson is supported by a research project grant from Croda Universal Ltd., Hull, England.

[Received May 24, 1990; Revision accepted September 29, 1990]

Regulation of Polyunsaturated Fatty Acid Metabolism in Tissue Phospholipids of Obese (fa/fa) and Lean (Fa/−) Zucker Rats. 1. Effect of Dietary Lipids on Cardiac Tissue

Klaus W.J. Wahle*, Lesley Milne and **Gwen McIntosh**
Rowett Research Institute, Bucksburn, Aberdeen AB2 9SB, Scotland, U.K.

The present investigation addressed three questions: (i) Does the obese syndrome alter the fatty acid composition of cardiac tissue and membrane phospholipids in obese (fa/fa) rats? (ii) Are changes, if they occur, similar to those reported for tissues of the genetically obese (ob/ob) mouse? (iii) Can cardiac tissue phospholipids and their component fatty acids be modified by dietary lipids and if so does this occur to the same extent in both fa/fa and lean (Fa/−) rats? Proportions of polyunsaturated fatty acids (PUFA) in cardiac total phospholipids of fa/fa rats differed significantly from those of Fa/− rats and from those reported for ob/ob mice. Increased 18:2n-6 and decreased 20:4n-6 and 22:6n-3 in fa/fa rats indicated impaired PUFA metabolism, possibly reduced Δ6 and/or Δ5 desaturase activity, compared with Fa/− rats. No differences in hepatic Δ6 and Δ5 desaturase activity between fa/fa and Fa/− were found but enhanced activity of Δ9 desaturase activity in fa/fa as compared to Fa/− was evident. Inclusion of sunflower oil (SO) or triolein (TO) at 5% and 20% by weight in the diet elicited marked changes in the fatty acyl composition of cardiac phospholipids in both fa/fa and Fa/− rats when compared with animals fed the control Oxoid diet alone. Supplementation with triolein was most effective, reducing 18:2n-6 and increasing 20:4n-6 proportions in fa/fa rats so that they resembled those in Fa/− rats fed the control Oxoid diet. The type of fat rather than the amount of its dietary intake appears to be the main determinant of the observed changes in phospholipid composition. Pair feeding hyperphagic fa/fa rats to the lower intakes of Fa/− rats did not abolish the characteristic differences in the proportions of PUFA in cardiac phospholipids between the two phenotypes. The effect of triolein on cardiac phospholipid fatty acid composition in the present studies is intriguing and may be relevant in understanding the beneficial role of dietary olive oil in ameliorating cardiovascular disease in man.
Lipids 26, 16-22 (1991).

Genetically obese Zucker rats (fa/fa) are characterized by a variety of endocrine and metabolic abnormalities when compared to lean rats (Fa/−) of the same strain. In particular hyperinsulinaemia, hyperphagia, increased energetic efficiency and elevated lipogenesis result in excessive accretion of triacylglycerols in adipose tissue giving the obese (fa/fa) rats their characteristic corpulent appearance (1-8). Increased lipogenesis in fa/fa rats occurs mainly in the liver which also exhibits enhanced Δ9 desaturase activity (9). Low proportions of polyunsaturated fatty acids (PUFA) in tissue lipids of fa/fa compared with Fa/− rats (4-9) are probably a reflection of increased synthesis *de novo* of saturated and monounsaturated fatty acids in these animals. The extent to which these abnormalities in fatty acid metabolism in fa/fa rats are also reflected in the fatty acid composition, particularly the essential PUFA, of their tissue and membrane phospholipids is not known.

Changes in the availability of essential fatty acids (EFA) in membrane phospholipids of cells and tissues are potentially of major physiological significance. EFA are important determinants of both the physicochemical and functional properties of cell membranes. They have a structural role as components of phospholipids in membrane bilayers and, more importantly, they are the precursors of the eicosanoids which are involved in the regulation of cellular and tissue metabolism (8-14). Many membrane-bound enzymes, receptors, ion gates and transport proteins exhibit a requirement for specific phospholipid or PUFA (15-18). Decreased proportions of EFA in tissue phospholipids, resulting from endocrine abnormalities and/or dietary deficiencies, could conceivably impair tissue metabolism and consequently reduce tissue function (10,12-14). This is emphasized by the observations that differences in the fatty acid composition of membrane phospholipids from various tissues of genetically obese mice (ob/ob), when compared to lean phenotypes, correlate with adverse changes in physicochemical and functional properties (5,19-22). Defects in membrane function similar to those found in ob/ob mice also occur in tissues of fa/fa rats, particularly in interscapular brown adipose tissue (IBAT) (5,19). This suggests that similar changes in membrane phospholipids to those observed in ob/ob mice may occur in fa/fa rats. However, sufficient physiological differences exist between ob/ob and fa/fa animals (23) to suggest that obesity may not have the same etiology in these animals and may consequently not elicit the same lipid compositional and functional changes in membranes and tissues from both phenotypes.

The present investigation addressed three questions: (i) Does the obese syndrome in fa/fa rats, apart from eliciting excessive triacylglycerol accretion in adipose tissue, also result in changes in phospholipid fatty acid composition of cardiac tissue and membranes when compared with those from Fa/− rats)? (ii) If differences in phospholipid fatty acid composition occur between rat phenotypes, are they similar to those reported for ob/ob and lean mice? (iii) Can the fatty acid composition of tissue/membrane phospholipids in fa/fa and Fa/− rats be modified by dietary lipids and, if so, does this occur to the same extent in both phenotypes.

Abbreviations: BHT, butylated hydroxytoluene; EFA, essential fatty acids; Fa/−, lean; fa/fa, obese; GLC, gas-liquid chromatography; HSO, high sunflower oil; HTO, high triolein; IBAT, interscapular brown adipose tissue; LSO, low sunflower oil; LTO, low triolein; ob/ob, genetically obese; PBS, phosphate buffered saline; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; PUFA, polyunsaturated fatty acids; SO, sunflower oil; TLC, thin-layer chromatography; TO, triolein; WCOT, wall-coated open tubular.

The present studies comprise part of a program of research which seeks to determine the extent to which membrane phospholipids in different organs and tissues of obese and lean Zucker rats can be modified by dietary and endocrine manipulations and whether such modifications are deleterious or beneficial to organ and tissue function. Changes in cardiac phospholipid fatty acid composition due to obesity *per se* and/or dietary and/or endocrine manipulations may also help to elucidate the interaction of these factors in the etiology of cardiovascular disease in man. Although not prone to atherosclerosis, rats will exhibit cardiac arrhythmias with certain dietary fats (12).

Preliminary findings have been published in abstract form (24,25).

MATERIALS AND METHODS

Chemicals were purchased from B.D.H. or Sigma Chemicals Co. (both at Poole, Dorset, U.K.). All organic solvents were ANALAR grade with 0.005% butylated hydroxytoluene (BHT) added as antioxidant. Radiolabelled [1-^{14}C]stearic (18:0), [1-^{14}C]linoleic (18:2n-6) and [1-^{14}C]-dihomo-γ-linolenic (20:3n-6) acid were purchased from Amersham (Amersham, U.K.). High performance silica gel thin-layer chromatography (TLC) plates (LK5) were purchased from Whatman (Maidstone, U.K.). Capillary columns were purchased from Chrompack U.K. Ltd. (London, U.K.).

Animals, diets and tissue sampling. Cardiac tissues were obtained from groups of 35–40-day-old lean (Fa/−) and obese (fa/fa) Zucker rats taken from the Rowett Research Institute's colony (Bucksburn, Aberdeen, Scotland, U.K.). Unless otherwise stated, the rats were fed to appetite for 14–16 days from weaning with free access to water. Animals were individually housed in plastic cages with stainless-steel grid flooring in rooms with a 12-hr light/dark cycle and controlled temperature of 22°C.

The control diet consisted of the standard pelleted laboratory diet (Oxoid, Herbert C. Styles, Bewdley, Worcs, U.K.). Experimental diets were based on the Oxoid diet with 5% and 20% (w/w) supplementation of sunflower oil (SO), low sunflower oil (LSO) and high sunflower oil (HSO), respectively, or triolein (TO), low triolein (LTO) and high triolein (HTO), respectively. Energy content, fat content and fatty acid composition (wt %) of the diets are given in Table 1. The commercial diet also contained 17.3% digestible crude protein, 1.2% digestible fiber, 46.7% digestible carbohydrate, adequate minerals, and vitamins.

During pair-feeding, fa/fa rats (4) were housed individually and fed the amount of control diet that age and sex matched Fa/− rats (4) had consumed the previous day. A group of 3 fa/fa rats fed to appetite were included as a comparison. Desaturase assays were carried out on liver microsomal preparations from age and sex matched fa/fa and Fa/− rats which had been fed to appetite on the control Oxoid diet. The proportions of phospholipid species in cardiac tissues were investigated in age and sex matched fa/fa and Fa/− rats fed to appetite in groups of 3 on the control diet, HTO or LTO diets. Animals were killed by stunning and bleeding. Tissues were excised, washed in ice-cold phosphate buffered saline (PBS), placed in snap-seal polythene bags, frozen in liquid nitrogen and stored at −20°C until analyzed (usually within 2–3 wk).

TABLE 1

Energy Content and Fatty Acid Composition of Rat Diets*

Diet	Energy (k cal/g)	% Fat (w/w)	Fatty acid composition (wt%) 16:0	16:1n-7	18:0	18:1n-9	18:2n-6
HSO[a]	4.4	20	7.4	tr	4.4	19.7	69.4
LSO[b]	3.9	5	8.8	tr	5.2	23.6	59.7

HTO[e]	4.7	20	6.1	7.4	1.4	69.4	10.4

[a]20% sunflower oil; [b]5% sunflower oil; [c]control diet, non-supplemented; [d]5% triolein; [e]20% triolein. Only traces of 18:3n-3, 20:4n-6, 20:n-3, 22:5n-3 and 22:6n-3 detected in experimental diets: Oxoid diet contained 1.2, 1.0 and 1.9 (wt%) of 20:4n-6, 22:5n-3 and 22:6n-3, respectively. Mean of two determinations given.

Analytical methods. Tissue lipids were extracted according to the method of Bligh and Dyer (26), separated into neutral and phospholipids on silica cartridges under vacuum (27). Separation of total phospholipids into individual phospholipid classes was achieved by one-dimensional (28) or two-dimensional (29) thin-layer chromatography (TLC). Phospholipid content was determined by phosphorus estimation according to the method of Bartlett (30). Methyl esters of phospholipid fatty acids were formed by a standard transmethylation procedure with methanolic-HCl (31) and analyzed by gas-liquid chromatography (GLC) on 25 M wall-coated open tubular (WCOT) glass capillary columns containing SIL5 or SIL88 (Chrompack U.K., Ltd., Millharbour, London, U.K.) as the liquid phase in a PU4500 Chromatograph (Pye Unicam Ltd., Cambridge, U.K.) at 195°C and 1.5 kg/cm^2 helium pressure. Peaks were plotted and analyzed on an SP4270 plotter/integrator (Spectra-Physics, San Jose, CA) and identified from retention times of authentic standards on the polar and nonpolar liquid phases.

Microsomal and mitochondrial preparations were obtained by homogenization and ultracentrifugation, and their purity checked by methods essentially as described by Hübscher *et al.* (32). The method for determining Δ9 desaturase activity has been described in detail elsewhere (33). The activity of Δ6 and Δ5 desaturase was assayed according to the method of de Gomez-Dumm *et al.* (34) using [1-^{14}C]labelled 18:2n-6 and 20:3n-6 acids (0.1 μCi/μmole) as the respective substrates. Methyl esters of fatty acids were separated and identified using silica gel G plates impregnated with 10% $AgNO_3$ (35) rather than radio-gas chromatography. Radioactivity determinations were done as described previously (33).

Statics. Significant differences between means of the experimental diets and the control diet were assessed by analysis of variance and Student's t-test. Results are expressed as means ± S.D.

RESULTS

Heart weights and lipid content. Weights and lipid content of hearts from rats fed the control, sunflower oil and triolein diets are given in Table 2. No marked effect of diet on heart weights, total lipid, phospholipid or neutral

TABLE 2

Total Lipid, Phospholipid and Neutral Lipid Content of Hearts from Obese and Lean Zucker Rats Fed on Oxoid, 5% Triolein (LTO), 5% Sunflower oil (LSO), 20% Triolein (HTO) or 20% Sunflower oil (HSO)[a]

[a]Means ± SD are given with the number of animals used in parenthesis. Differences between control and experimental diets within each phenotype are denoted by superscript b = P<0.05 or lesser. Differences between phenotypes fed the same diet, including the control diet, are denoted by superscript d = P<0.05 or lesser. Differences between high and low (H,L) diets denoted by superscript c = P<0.05 or lesser. More precise P values given in text.

lipid was evident within the obese phenotype (fa/fa). Both sunflower oil and triolein diets significantly reduced the neutral lipid content of the lean (Fa/−) rats but did not influence any other parameters studied when compared with the control diet.

Cardiac phospholipids from fa/fa animals fed on the control diet had significantly higher (P<0.001) proportions of 18:2n-6 and lower (P<0.001) proportions of both 20:4n-6 and 22:6n-3 than those from Fa/− rats fed this diet (Table 3). The fatty acid analyses showed a significantly greater proportion of 18:2n-6 (P<0.001) than 20:4n-6 in fa/fa rats and a lower proportion of 18:2n-6 (P<0.01) than 20:4n-6 in Fa/− rats. This pattern of PUFA content is reflected in the greater ratio of 18:2n-6/20:4n-6 in fa/fa compared with Fa/− rats.

Triolein diets significantly reduced 18:2n-6 and increased 20:4n-6 in fa/fa and Fa/− rats (P<0.001 or P<0.01) when compared with the control group. The changes elicited by triolein diets were such that the pattern of 18:2n-6 to 20:4n-6 in fa/fa resembled that of Fa/− rats fed on the control diet; this was reflected in reduced 18:2n-6/20:4n-6 ratios in fa/fa rats. Proportions of 22:6n-3 increased significantly in fa/fa fed HTO (P<0.001) but decreased in Fa/− rats fed either of the triolein diets (P<0.001 and P<0.01 for LTO and HTO, respectively) when compared with rats of each phenotype fed the control diet. Triolein diets, as expected, increased the 18:1n-9 content of cardiac phospholipids in both phenotypes.

Sunflower oil diets also reduced 22:6n-3 in fa/fa (P<0.001 for HSO) and in Fa/− rats (P<0.001 for LSO and HSO). These diets also increased 20:4n-6 proportions by a significant but to a lesser extent than triolein diets in fa/fa (P<0.01 and P<0.05 for LSO and HSO, respectively). Neither the pattern of 18:2n-6 relative to 20:4n-6 nor the 18:2n-6/20:4n-6 ratio was altered toward that observed in Fa/− rats fed on the control diet when fa/fa rats were fed on the sunflower oil diets. This contrasts with the marked changes in these parameters elicited when fa/fa rats were fed on the triolein diets. There appeared to be an inverse relationship between dietary 18:2n-6 concentration and cardiac phospholipid 22:6n-3 proportions. Sunflower oil diets elicited a reduction in the 18:1n-9 proportions of cardiac phospholipids (P<0.001 for LSO and HSO, respectively) in fa/fa rats but LSO produced an increase in 18:1n-9 in the Fa/− phenotypes (P<0.05).

Cardiac subcellular preparations. The characteristic differences in the pattern of PUFA in cardiac phospholipids between fa/fa and Fa/− rats were also found in cardiac microsomal and mitochondrial preparations derived from cardiac tissue of the two phenotypes which had been fed the control diet (Fig. 1). The characteristically lower 22:6n-3 in cardiac phospholipids from fa/fa compared with those from Fa/− was also observed in microsomal but not mitochondrial preparations.

Cardiac phospholipid classes. The effect of the HTO diet on the proportions of the major PUFA in phosphatidylcholine (PC) and phosphatidylethanolamine (PE) of cardiac tissue from the two phenotypes is shown in Figure 2. The distinctive differences in the fatty acid pattern of cardiac total phospholipids between phenotypes fed the control diet were more accentuated, particularly in the PC fraction of fa/fa rats. This was again reflected in the 18:2n-6/20:4n-6 ratios (3.7 and 0.6 for fa/fa and FA/−, respectively). In the cardiac PE fractions from rats fed the control diet, the proportion of 18:2n-6 was significantly higher (P<0.001) in fa/fa compared to Fa/− rats, although the proportion of 20:4n-6 was similar; this was again reflected in a higher 18:2n-6 to 20:4n-6 ratio in fa/fa than Fa/− rats (0.9 and 0.4, respectively). The

[a]Means ±SD are given with the number of animals used in parenthesis. Differences between control and experimental diets within each phenotype are denoted by superscript b = P<0.05 or lesser. Differences between phenotypes fed the same diet, including the control diet, are denoted by superscript d = P<0.05 or lesser. Differences between high (H) and low (L) diets within phenotypes are denoted by c = P<0.05 or lesser. Ratios derived from mean values. More precise P values given in text.

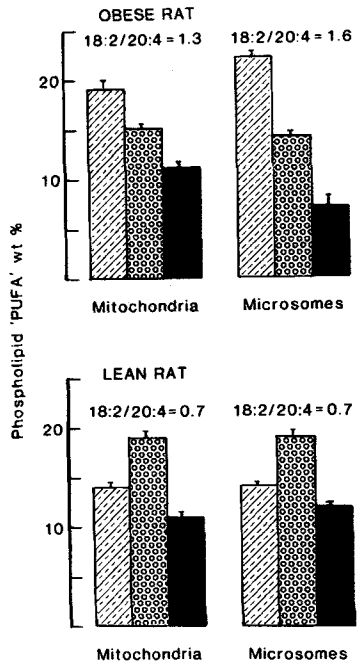

FIG. 1. Proportions of the major PUFA (wt%) in total phospholipids of cardiac mitochondrial and microsomal membranes from fa/fa and Fa/— rats fed on Oxoid diet. Diagonal, stipled hatching, 18:2n-6; circled hatching, 20:4n-6; closed hatching, 22:6n-3. Means and ranges of 2 experiments given. 18:2n-6/20:4n-6 ratios given.

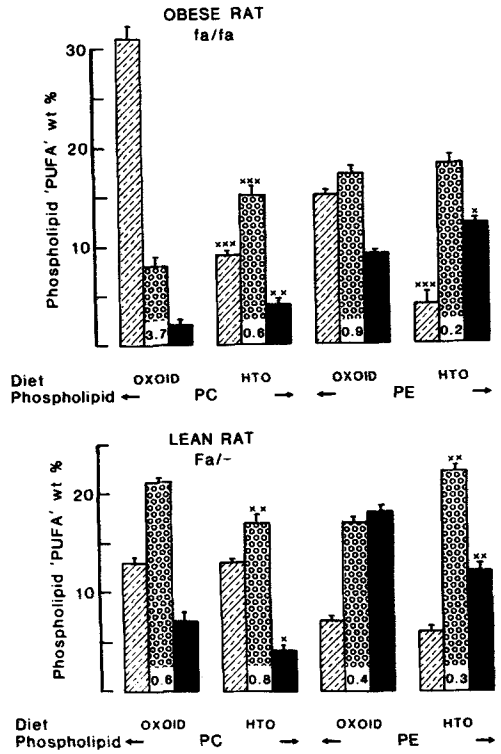

FIG. 2. Proportion of the major PUFA (wt%) in the main phospholipid classes (PC and PE) of cardiac tissue from fa/fa and Fa/— rats fed the control (Oxoid) or triolein (HTO) diets. Diagonal, stipled hatching, 18:2n-6; circled hatching, 20:4n-6; closed hatching, 22:6n-3. Means ± S.D. of 3–5 animals/group are given. P values * = <0.05; ** = <0.01, *** = <0.001 when compared with control diet. Ratios of 18:2n-6/20:4n-6 given in brackets in the 20:4n-6 column.

proportion of 22:6n-3 was significantly lower (P<0.001) in the PE fractions from fa/fa as compared to Fa/− rats on the control diets.

The HTO diet altered the pattern of PUFA in the PC fraction from fa/fa rats to resemble that of the PC fraction from Fa/− rats fed the control diet; this is reflected in the identical 18:2n-6/20:4n-6 ratios (0.6 for both fa/fa − HTO and Fa/− control groups). The altered pattern of PUFA in cardiac PC from fa/fa rats on the HTO diet was due to decreased 18:2n-6 (P<0.001) and increased 20:4n-6 (P<0.001) proportions when compared with fa/fa fed the control diet. HTO also increased the proportion of 22:6n-3 (P<0.01) in PC from fa/fa rats. In Fa/− rats, however, 18:2n-6 proportions in cardiac PC remained unchanged with HTO diet and both 20:4n-6 and 22:6n-6 proportions were reduced (P<0.01 and P<0.05, respectively). The effect of HTO diet on the PC composition was greatly attenuated in Fa/− rats when compared to fa/fa rats.

In cardiac PE fractions the HTO diet reduced 18:2n-6 (P<0.001) and increased 22:6n-3 (P<0.05) in fa/fa rats and increased 20:4n-6 (P<0.01) but decreased 22:6n-3 (P<0.01) in Fa/− rats when compared with values found in the respective phenotypes fed the control diet.

The LTO and HTO diets also altered the proportions of individual phospholipid classes in cardiac tissue from both phenotypes (Table 4). HTO significantly increased PC (P<0.01) and decreased PE (P<0.01) in fa/fa rats. HTO also decreased PE (P<0.01) without affecting PC and decreased PI (P<0.05) in Fa/− rat tissue. LTO diets decreased phosphatidylserine (PS) (P<0.02) and phosphatidylinositol (PI) (P<0.02) in cardiac tissue of fa/fa rats. Unfortunately, the effect of LTO on Fa/− rat cardiac tissue was not determined.

Food intake, phospholipid fatty acids and desaturases. Reducing the food intake of the normally hyperphagic fa/fa rats by feeding them the same amount of food as age and sex matched Fa/− rats (pair-feeding) did not alter the pattern or proportions of fatty acids in their cardiac total phospholipids (data not shown).

No differences in hepatic Δ6 and Δ5 desaturase activity were found between fa/fa and Fa/− rats fed the control diet (data not shown). The Δ9 desaturase activity of hepatic microsomal preparations was significantly greater in fa/fa (15.0±2.1 nmol/30min/mg protein) as compared to Fa/− rats (4.0±1.2 nmol/30min/mg protein) (P<0.001).

DISCUSSION

The significant reductions in the neutral lipid content of hearts from Fa/− rats fed on the sunflower oil and triolein diets were surprising and no simple explanation is apparent. Whether these high fat diets induce a greater rate of mobilization and/or oxidation of fat in cardiac tissue or a reduction in its uptake into the tissue is not clear and would require further investigation.

The characteristic differences observed between phenotypes in the pattern of PUFA in their cardiac total phospholipids, namely increased 18:2n-6 and decreased 20:4n-6 proportions in fa/fa, indicated an impairment in essential PUFA metabolism in the fa/fa compared with Fa/− rats. This was highlighted by the marked differences in 18:2n-6/20:4n-6 ratios between phenotypes on the Oxoid diet which, although not definitive, are considered as indicators of the activity of the Δ6 and Δ5 desaturase enzymes responsible for PUFA metabolism *in situ.* The proportions and ratios of 18:0 and 18:1 indicated enhanced conversion of 18:0 to 18:1 in fa/fa cardiac tissue which is a characteristic feature of fatty acid metabolism in fa/fa animals (9). The findings that the characteristic pattern of PUFA for the two phenotypes persisted in both mitochondrial and microsomal membrane preparations and to a greater or lesser extent in the two major phospholipid classes of cardiac membranes are indicative of their fundamental nature and presumably a reflection of the metabolic and endocrine abnormalities in the fa/fa rats *(vide supra).* In contrast, only minor PUFA compositional changes were observed in the phospholipid classes of hepatic (21) and adipocyte (20) plasma membranes from lean and ob/ob mice. This suggests that the aetiology of obesity *per se* may vary between species and that it does not influence membrane phospholipid composition in a uniform manner in all species. This is not surprising considering the differences that exist between ob/ob and fa/fa animals in certain endocrine and metabolic abnormalities (5). Alternatively, membrane phospholipids from different tissues within an individual animal from a certain species and phenotype may be affected differently by the endocrine and metabolic changes characteristic of a particular form of obesity. Unfortunately, information on the fatty acid composition of cardiac membrane phospholipids in other forms of obesity, particularly in the ob/ob mouse, is

TABLE 4

Effect of Diet on the Proportions of Phospholipid Classes in Cardiac Tissues of Obese and Lean Zucker Rats[a]

Diet	Phenotype	PS	PA	PI	PC	PE	CL	PE/PC
Control	Obese	6.7 ± 0.3	2.4 ± 0.6	6.5 ± 0.8	40.2 ± 1.4	36.0 ± 1.2	5.6 ± 0.8	0.90 ± 0.03

[a]Values are means ± SD of 3 animals/group. Values significantly different from control/diet are indicated by superscript b = P<0.05 or less. Differences between HTO and LTO diets in obese rats denoted by superscript c = P<0.05 or less. Control diet is standard Oxoid laboratory diet; LTO, low triolein diet (5%); HTO, high triolein diet (20%); n.d., not determined; PS, phosphatidylserine; PA, phosphatidic acid; PI, phosphatidylinositol; PC, phosphatidylcholine; PE, phosphatidylethanolamine; CL, cardiolipin.

lacking. Unpublished observations from our laboratory support the view that membrane phospholipids from various tissues in the fa/fa rat, not surprisingly, differ in composition but they also respond differently, in both magnitude and extent, to dietary and endocrine manipulations. Despite the similarity in membrane phospholipid fatty acid composition of the same tissues from lean and ob/ob mice, marked differences in composition of hepatic and adipocyte membranes from ob/ob mice have also been observed (20,22).

The effect of the triolein diets on the proportions and pattern of the major PUFA in cardiac total phospholipids of fa/fa rats was quite dramatic. They elicited what might be described as a 'normalizing' effect with a marked decrease in 18:2n-6 and increases in 20:4n-6 and/or 22:6n-3 so that the fa/fa pattern resembled that of the Oxoid-fed Fa/− 'control' rats in both total phospholipid and in the individual PC and PE fractions. These effects of triolein diets could be interpreted as an induction of the Δ6/Δ5 desaturase pathway, which is supported by marked changes in 18:2n-6/20:4n-6 ratios so that they resembled those found in Oxoid-fed Fa/− rats. An induction of Δ5 desaturase by diets high in oleic acid has been reported (33) but this was attributed to a general deficiency of 18:2n-6 and other essential PUFA since increased proportions of 20:3n-9, a fatty acid which is considered to be a good indicator of such a deficiency, were found (32). No such increases in 20:3n-9 were observed while feeding the present diets (data not given) suggesting that essential PUFA levels in the triolein diets were adequate but low. The precise mechanism by which low or deficient dietary 18:2n-6 levels regulate Δ6/Δ5 desaturase activity has not been elucidated and warrants further investigation. A simple substrate inhibition of enzyme activity seems an unlikely explanation since the LSO and HSO diets in the present investigations gave no indication of such a mechanism as judged by the increased 20:4n-6 proportions in cardiac phospholipids from both fa/fa and Fa/− rats fed these diets.

That fa/fa rats may have impaired PUFA metabolism when compared with Fa/− rats is suggested by the marked differences in the proportions of PUFA in their tissues, namely high 18:2n-6 relative to 20:4n-6 in the fa/fa (9,10,24,33). In this respect, fa/fa rats resemble primates and man (12,36). Although the hepatic activity of the Δ6 and Δ5 desaturases did not differ between fa/fa and Fa/− rats, and this is considered the major quantitative site for PUFA metabolism in rats, cardiac activity of these enzymes, which was not determined, may be sufficiently impaired in fa/fa rats to account for the observed differences in PUFA profiles between phenotypes. This point requires further elucidation.

The response of total phospholipids and individual phospholipid classes of Fa/− rat heart to dietary lipid was less pronounced than those of fa/fa rats. This may be indicative of a greater responsiveness of 'abnormal' fa/fa tissues to modification of their lipid composition by dietary means. This point was illustrated by the marked effect of the HTO diet on cardiac phosphatidylcholine composition in fa/fa compared with Fa/− rats. The phospholipid class distribution in tissues and membranes is generally not amenable to dietary modulation (37–39). However, the present studies show significant changes in PS, PI, PC and PE content of cardiac tissues from fa/fa and Fa/− rats fed the triolein as compared with the control Oxoid diet. Dietary modulations of PE/PC ratios have been observed in cardiac mitochondria, brain and intestine of rats (40–42). The significant decrease in PE and increase in PC observed in cardiac phospholipids of fa/fa rats fed the HTO as compared with the control diet could be indicative of an enhanced methylation of PE to PC elicited by dietary triolein in these animals. This requires verification. Methylation of PE to PC has been postulated as an endocrine-signal transduction mechanism in cell membranes (43) but not without question (44). Increasing the proportion of PC relative to PE in cell membranes can lead to increased membrane viscosity (decreased fluidity) similar to that observed when the saturation index of the phospholipid acyl chains is increased (10,11). Changes in the physicochemical characteristics of cell membranes due to modifications of phospholipid polar head groups or fatty acyl composition have been shown to alter membrane-bound functional proteins in such cells and tissues (10–12). The decrease in the proportion of PI in fa/fa and Fa/− rats fed triolein diets could also have functional implications since PI plays a major role in endocrine signal transductions across cell membranes (45). Investigation of certain functional changes in relation to membrane lipid modification will be determined in future studies.

The observed changes in phospholipid PUFA composition of cardiac tissues elicited by dietary lipid reflect the importance of the type of fatty acid in the lipid rather than the amount of lipid. This is supported by the pair-feeding experiments where fa/fa rats were given the same amount of feed as Fa/− rats, *i.e.* a food restriction regime, without any changes in the fatty acid composition of cardiac phospholipids being evident.

Clearly, the type of dietary fats, in this case particularly triolein diets, can significantly alter the proportions of phospholipids and their fatty acyl constituents in cardiac tissues of fa/fa and to a lesser extent Fa/− rats. The precise relevance of the observed changes in tissue phospholipids to the physiological function of the tissue is not clear at present and requires further investigation. Similarly, the mechanism(s) by which the triolein diets exert their influence on tissue phospholipid PUFA composition, whether by a direct effect on desaturase enzymes or through modification of endocrine stimulation, is not clear and warrants further study.

Ascertaining the relevance of these observations to the understanding of the role of dietary lipids in cardiac function and dysfunction in man would be speculative. However, it is interesting to note the apparent beneficial effect of dietary olive oil with its high content of oleic acid on the incidence of heart disease in Mediterranean populations (46).

ACKNOWLEDGMENT

We are grateful to Mr. D. Grubb for assistance with the statistics.

The Presence of Oxidative Polymeric Materials in Encapsulated Fish Oils

Vijai K.S. Shukla[a] and **Edward G. Perkins**[b,*]

[a]Karlshams Research and Development Center, P.O. Box 68, DK8520, Lystrup, Denmark and [b]Department of Food Science, University of Illinois, Burnsides Research Laboratory, Urbana, Illinois 61801

Encapsulated health food oils such as fish oils are readily available in health food stores, pharmacies, and supermarkets. They are popular in the United States as well as in the European countries. However, such oils, because of their high degree of unsaturation, are easily oxidized and form complex mixtures of high molecular weight oxidation products. The present work reports the application of high-performance size exclusion chromatography to the determination of these materials in encapsulated fish oils. Of the six samples studied, five showed from 1–10% of dimeric triacylglycerols and one contained 6.3% trimeric triacylglycerols and 3.1% oligomeric triacylglycerols. Further investigation of this sample with silicic acid chromatography indicated that it contained a total of 36.3% polar material.

Lipids 26, 23–26 (1991).

Fish oils have been extensively studied in recent years due to their antiatherosclerotic (1–3) and hypotriglyceridemic effects (4). Recent reports have discussed the oxidative deterioration of fish oils and have suggested that ingestion of unstabilized fish oils entails a risk of exposure to potentially toxic products of n-3 fatty acid peroxidation. The resultant oxidation products may play a role in carcinogenesis (5,6), inhibit prostacyclin production (7) and may exert other adverse biological effects (8).

Unless extreme care is taken, fish oils, which contain a high percentage of long-chain polyunsaturated fatty acids such as eicosapentaenoic and docosahexaenoic acids in triacylglycerol form, are very susceptible to autoxidation (9,10). Such autoxidation will initially form hydroperoxy free radicals which become stabilized by addition of hydrogen to hydroperoxides or by reaction with triacylglycerols to form dimeric and trimeric triacylglycerols linked *via* peroxidic-type bonds (10).

Encapsulated fish oils are now readily available for purchase. It would be useful to ascertain the presence or absence of such oxidation products and high molecular weight materials in such oils. The technique of high-performance size exclusion chromatography (HPSEC) is well established and has been employed repeatedly to separate triacylglycerols from higher molecular weight oxidation products such as the dimeric, trimeric, and oligomeric materials formed as a result of lipid oxidation (10–20).

It was the purpose of this work to examine several different brands of encapsulated fish oils in order to ascertain the presence or absence of higher molecular weight oxidation products.

Abbreviations: DG, diacylglycerol; FFA, free fatty acids; HPLC, high-performance liquid chromatography; HPSEC, high-performance size exclusion chromatography; MG, monoacylglycerol; TG, triacylglycerol; THF, tetrahydrofuran.

EXPERIMENTAL

Various brands of encapsulated fish oils were purchased locally. Three capsules of fish oil from each of different bottles from different batches were opened. The oil from each capsule was individually taken up into tetrahydrofuran (THF) to make a 20% solution by weight of oil. This solution was injected directly into each of the high-performance liquid chromatography (HPLC) column systems described below. Two different sets of columns were used as follows: Set one was a series of connected polystyrene-divinyl benzene polymer packed columns, in the order 500 Å, 100 Å, and 100 Å. Each column was 30 cm × 4.7 mm stainless steel (PL Laboratories, Shropshire, England) and the packing was 5 microns in diameter. Column set two was a series connected G 2000, to a G 1000 column, prepared with the same general type of polymeric packing as above, 5 microns diameter, 30 cm × 7 mm diameter (Supelco Inc., Bellefonte, PA). Detectors used were the Waters Model 410 differential refractometer and a Du Pont infrared detector set at 1735 cm^{-1} to monitor the ester carbonyl absorption. The remainder of the HPLC system and data handling system was as previously described (21). In both column systems, tetrahydrofuran (THF) was used as the eluting solvent at a flow rate of 1 mL/min. The THF used as mobile phase was kept under an atmosphere of nitrogen gas, and contained 0.027% butylated hydroxytoluene to minimize peroxide formation. This did not interfere with the HPSEC since it eluted in the low molecular weight exclusion volume peak at the end of the run. Polymeric standards as well as lipid standards were obtained from Supelco Inc.

Fractionation of oils into polar and nonpolar components was carried out according to the International Union of Pure and Applied Chemistry (IUPAC) method for the determination of polar components in fats using silicic acid column chromatography (22). The determination of peroxide, iodine, and anisidine values was carried out according to the IUPAC methods (21). Each sample was analyzed in triplicate and the range of values obtained reported. The fatty acid composition of the fish oils was determined according to the procedure of Ackman *et al.* (23). Tocopherols were determined according to the method described by Shukla (24).

RESULTS AND DISCUSSION

Data for six encapsulated oil samples which were analyzed are shown in Table 1. A considerable range of quality is shown as evidenced by the peroxide value and anisidine value. The range of peroxide values found as well as the anisidine values, which are a measure of aldehyde content of a fat, indicate that both hydroperoxides and other types of peroxide linkages as well as their decomposition products are present in these oils. The fatty acid composition of the encapsulated material is given in

[i]Ethyl esters; the sample is a concentrate of fatty acid ethyl esters.

Table 2. The values appear to be typical of those obtained from fresh oils (23).

Further analysis of each of the encapsulated oils by high-performance size exclusion chromatography (HPSEC) with two different column systems and comparison with standard mixtures of lipids (Fig. 1) indicated that all of the samples contained varying percentages of mono- and diacylglycerols as well as dimeric and higher molecular weight triacylglycerols (Table 3). The appearance of free fatty acids, mono- and diacylglycerols may be a result of enzyme action on the oils prior to encapsulation. As an example of the separation obtained, a chromatogram of sample F obtained from one of the chromatographic systems is shown in Figure 2. High molecular weight thermal and oxidative products may have been formed as a result of thermal treatment of the oil such as in deodorization or as a result of autooxidation prior to encapsulation. High molecular weight oxidation products may have also been formed in the oils after encapsulation. It has been shown previously that soft gelatin capsules are somewhat permeable to oxygen and that this is dependent upon the plasticizer content as well as storage conditions (25). Therefore a certain amount of autooxidation may have taken place within the capsule, at a more increased rate considering the increased susceptibility of fish oils toward oxidation as indicated by Cho *et al.* (26). These authors indicated that the oxygen uptake of eicosapentaenoic and docosahexaenoic acid was 5.2 and 8.5 times faster, respectively, than of ethyl linolenate.

The oils examined in the present study contained from 164 to 7,965 ppm of tocopherols (Table 4), presumably added to stabilize the oils toward oxidation. However, tocopherols are known to be rather poor antioxidants

TABLE 4

Tocopherol Composition of Encapsulated Fish Oils

Product	Tocopherols (total) ppm	Alpha T[a] ppm	Gamma T[b] ppm	Delta T[c] ppm	Alpha TT[d] ppm	Gamma TT[e] ppm

[a]Alpha tocopherol. [b]Gamma tocopherol. [c]Delta tocopherol. [d]Alpha tocotrienol. [e]Gamma tocotrienol.

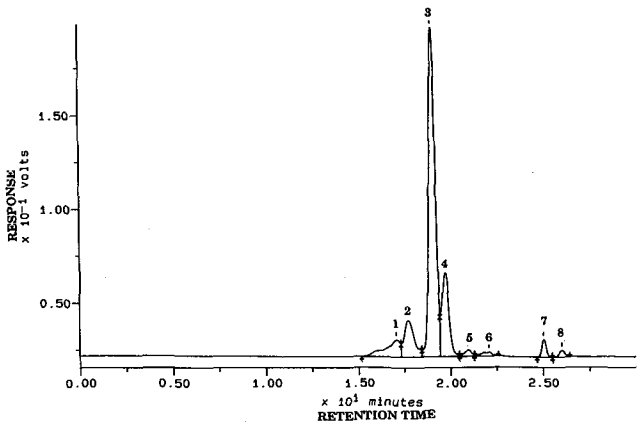

FIG. 2. High-performance size exclusion chromatogram of encapsulated oil (sample F). 1, Triacylglycerol trimer and oligomers; 2, triacylglycerol dimer. Peaks 3–6 are identified in Figure 1. Peaks 7 and 8 are residual solvent and short-chain materials of mol wt *ca.* 100, at the low mol wt exclusion limit of the columns.

when used in edible oils. They are even less efficient when used with oils containing polyunsaturated fatty acids (27). Furthermore, depending upon their level in an oil, tocopherols can exhibit prooxidant effects. In soybean oil containing 1,500 ppm of mixed tocopherols, optimum stability was found when the tocopherol levels were reduced to 400–600 ppm (27). The products examined in this work contained, with the exception of one sample, high levels of tocopherols (Table 4). In view of the prooxidant effects of high levels of tocopherols, and the known permeability of gelatin capsules toward oxygen (25), autooxidation may be expected to continue within an encapsulated oil.

In order to determine the general types of materials found as dimeric, trimeric and oligomeric triacylglycerols, further chromatography was carried out. Oils can contain materials resulting from both thermal and oxidative stress. Thermal stress, occurring in the absence of oxygen produces a variety of high molecular weight materials which elute from HPSEC columns with the same elution volumes as those materials shown in Figures 1 and 2. These materials, because of their elution volumes, can also be described as dimers, trimers and oligomers of triacylglycerols. Ratnayake *et al.* (13) have recently indicated that there were significant levels of materials defined as "polymers" in 10 of 16 samples of encapsulated fish oils they examined. However these authors did not further define the composition of the "polymeric" material. Furthermore the same types of materials may

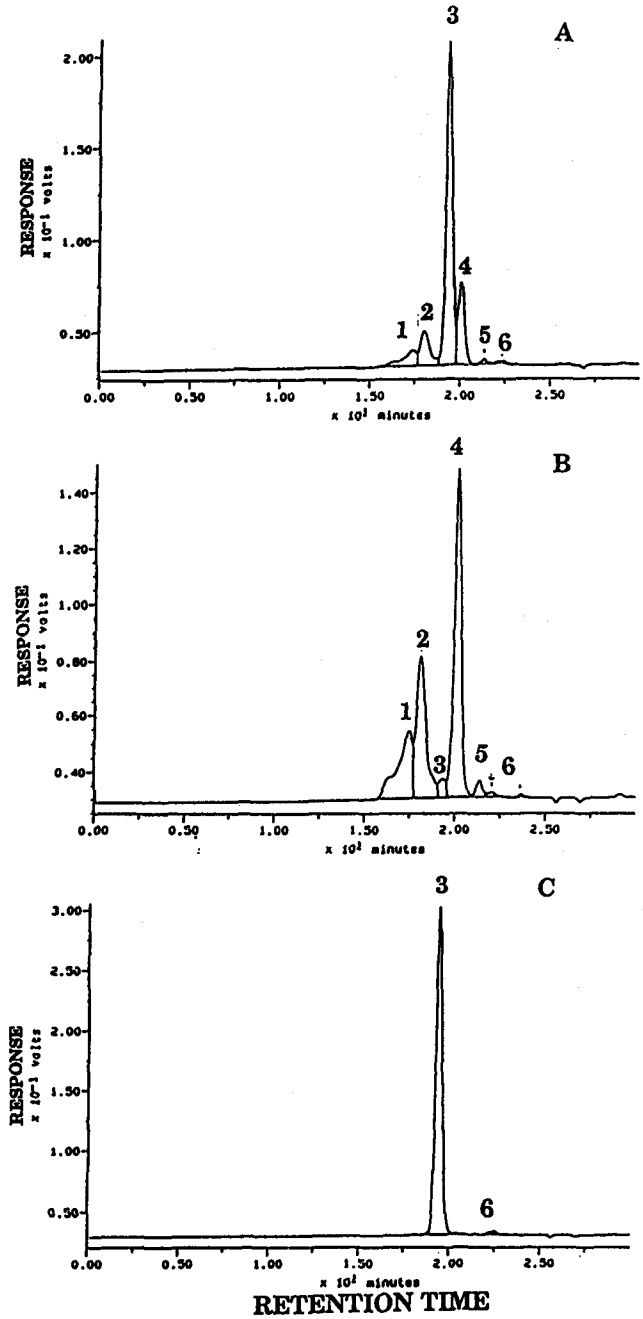

FIG. 3. High-performance size exclusion chromatogram of the polar (B) and nonpolar (C) fractions resulting from silicic acid chromatography of encapsulated oil sample F (A). Peak identity as in Figures 1 and 2.

be formed as a result of oxidative stress and usually contain peroxide linked triglyceride moieties. These materials also exhibit the same elution volumes on the HPSEC columns since their resolution is such that high molecular weight materials differing in molecular weight by one or more extra oxygen atoms cannot be separated. However, it is possible to separate oils which may contain high molecular weight compounds with the aid of adsorption chromatography on silicic acid. The oils can be easily separated into a fraction containing the nonpolar components of the oil and another containing polar and polymeric material (22). Separation of the oil sample F into its nonpolar and polar fraction with the aid of a silica column using the method specified in the IUPAC manual (22) indicated that it contained 36.3 wt % of polar material (by gravimetric determination of the eluted fractions from the IUPAC method). Subsequent HPSEC analysis of both the nonpolar and polar fractions is shown in Figure 3. HPSEC indicated that the polar fraction consisted of materials corresponding to the molecular weights and agreeing with the elution volumes of dimeric and higher polymeric materials, mono- and diacylglycerols and free fatty acids. The nonpolar fraction appeared to contain only triacylglycerol. The data indicated that the higher molecular weight material present is likely to be composed of triacylglycerol bonded *via* peroxy bridges. Heating this oil will lead to the destruction of the peroxidic linkages and the formation of both volatile and nonvolatile degradation products.

Further research on the chemical structure of the products formed in these oils as well as on their nutritional and physiological effects is currently under way in our laboratories.

It appears that because of the unknown health effects of the oxidative polymeric materials, and their high level in some encapsulated oils, caution may be advised when ingesting fish oil capsules on a regular basis.

[a]Laboratory of Nutrition Chemistry, Kyushu University School of Agriculture 46-09, Higashi-ku, Fukuoka 812, [b]Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606 and [c]Laboratory of Microbial Science, Institute for Fundamental Research, Suntory Ltd., Shimamoto, Osaka 618, Japan

The effects of perfused oleic (18:1n-9), arachidonic (20:4n-6) and 5,8,11,14-nonadecatetraenoic (19:4n-5) acids on triglyceride and cholesterol secretion and ketone body production were studied in isolated rat liver. As compared to oleic and 19:4n-5 acids, both ketone body production and triglyceride secretion were significantly lowered when arachidonic acid was perfused. The concentration of triglyceride in the post-perfused liver was lower upon perfusion with arachidonic acid than upon perfusion with oleic acid or 19:4n-5 acid. Cholesterol secretion in the liver perfused with arachidonic acid or 19:4n-5 acid was significantly higher than with oleic acid. The concentration of cholesterol in the post-perfused liver was slightly but significantly higher with 19:4n-5 acid than with the other fatty acids. The results suggest that 19:4n-5 acid when compared with arachidonic acid affects lipid metabolism in liver differently.
Lipids 26, 27-30 (1991).

Polyunsaturated n-6 fatty acids (PUFAs) and particularly linoleic acid exert a hypocholesterolemic effect in experimental animals and humans (1,2). Although several mechanisms have been proposed for this cholesterol-lowering effect (2), the precise mechanism has not been elucidated as yet. Fatty acids are secreted from the liver to varying degrees in very low density lipoprotein (VLDL) and are subsequently metabolized in the blood stream to form intermediate and low density lipoproteins. A decrease in VLDL secretion may thus result in a reduction of serum cholesterol concentration. Beynen and Katan (3) suggested that PUFAs, when compared to saturated fatty acids, are more readily oxidized to ketone bodies in the liver rather than secreted as VLDL-triglyceride.

Studies *in vitro* showed that the rate of oxidation of individual PUFAs depends on the number of double bond and chain length of the PUFA (4-6). In order to gain insights into the effect of various fatty acids on lipid metabolism, it is, therefore, important to study the effect of PUFAs on the secretion of lipids and the production of ketone bodies in the liver. Although arachidonic acid has been shown to have a more pronounced hypocholesterolemic effect than linoleic acid (7), only limited information is available on the metabolic fate of 20:4n-6 in the liver.

In the present study, the effect of infused arachidonic acid on lipid metabolism was compared with that of oleic acid in isolated perfused rat liver. The metabolic effect of 5,8,11,14-nonadecatetraenoic (19:4n-5) acid was also examined because it is of interest to establish structure-function relationships of PUFAs as regulators of lipid metabolism.

Abbreviations: 19:4n-5, 5,8,11,14-nonadecatetraenoic acid; 5-HETE, 5-hydroxyeicosatetraenoic acid; 5,12-HETE, 5,12-dihydroxyeicosatetraenoic acid; PUFAs, polyunsaturated fatty acids; VLDL, very low density lipoprotein.

MATERIALS AND METHODS

Materials. Oleic acid (99% purity) was purchased from Nacalai Tesque, Inc. (Kyoto, Japan). Arachidonic acid (99% purity) and 5,8,11,14-nonadecatetraenoic acid (99% purity) were microbial products (8). Bovine serum albumin fraction V and 3-hydroxybutyrate dehydrogenase were obtained from Boehringer Mannheim GmbH (Germany).

Animals and diets. Male Sprague-Dawley rats (Seiwa Experimental Animals, Fukuoka, Japan) weighing 300 g-330 g were housed in a temperature-controlled room and fed commercial rat chow (type CRF-1, Japan Charles River, Kanagawa, Japan) *ad libitum.* Liver was isolated under sodium pentobarbital anesthesia and perfused with recirculating 120 mL Krebs-Henseleit buffer (pH 7.4) containing 0.1% glucose, 1.5% bovine serum albumin and 25% washed bovine erythrocytes at a rate of 20 mL/min at 37°C. The procedure was described in detail previously (9). At the beginning of circulation, 5 mL of 20 mM fatty acid sodium salt (100 μmole) was added and the solution was continuously infused at the rate of 5 mL/hr (100 μmole/hr). At 1-hr intervals, 15 mL perfusate was removed for analysis of ketone bodies and lipids. The perfusion was continued for 4 hr.

Analysis of ketone body. Acetoacetate and β-hydroxybutyrate were measured enzymatically in a deproteinized sample of the perfusate as described previously (9).

Analysis of lipids. Lipids in perfusate and post-perfused liver were extracted and purified by the method of Folch *et al.* (10). Triglycerides (11) and cholesterol (12) were analyzed by procedures described elsewhere. Triglyceride in the perfusate and liver was separated by silica gel G thin-layer chromatography (petroleum ether/diethyl ether/acetic acid, 82:18:1, v/v/v). The triglyceride fraction was visualized with fluorescein, scraped off the plate, and treated with 14% boron trifluoride/methanol (1:1, v/v) (13). Fatty acid methyl esters were extracted with hexane and analyzed by gas-liquid chromatography on a 10% SILAR 10C column (13).

Statistical analysis. Data were analyzed by one-way analysis of variance followed by Duncan's new multiple range test to evaluate the significant difference between a pair of means (14).

RESULTS

Ketone body production in perfused rat liver. Ketone body production in liver perfused with arachidonic acid was significantly lower than in liver perfused with either oleic

acid or 19:4n-5 acid (Fig. 1). Infusion of 19:4n-5 acid slightly decreased ketone body production compared to oleic acid infusion, although the difference was not significant.

Secretion of lipids by perfused rat liver. As in ketone body production, secretion of triglycerides by liver perfused with arachidonic acid was significantly lower than by liver perfused with either oleic acid or 19:4n-5 acid (Fig. 2). Triglyceride secretion was the same in the latter two fatty acids. As shown in Figure 3, liver perfused with 19:4n-5 acid, when compared to oleic acid, secreted two times more cholesterol. Infusion of arachidonic acid resulted in a slight decrease in secretion of cholesterol compared to 19:4n-5 acid infusion, but was significantly higher than in oleic acid infusion at 3 and 4 hr.

Lipid concentration in post-perfused liver. The concentration of cholesterol and triglyceride in post-perfused rat liver is shown in Table 1. The concentration of liver triglyceride was lowest in arachidonic acid infusion, highest in 19:4n-5 acid infusion, and intermediate in oleic acid infusion. The difference between arachidonic acid and 19:4n-5 acid was significant. The concentration of liver cholesterol was slightly but significantly higher with infusion of 19:4n-5 acid than with oleic acid or arachidonic acid.

Fatty acid composition of perfusate and liver triglyceride. The fatty acid composition of triglyceride in perfusate and post-perfused rat liver is shown in Tables 2 and 3, respectively. In each instance, triglyceride in perfusate was enriched with the infused fatty acids. The proportion of the elongated metabolites of 19:4n-5 acid and arachidonic acid also increased in the perfusate triglyceride upon infusion of these PUFAs. When 19:4n-5 acid was perfused, the proportion of the fatty acids tentatively identified as arachidonic acid and 21:4n-5 increased significantly. In post-perfused liver, the proportion of each fatty acid perfused was also increased, but the extent of the increase was moderate compared to that in the perfusate. The extent of the enrichment in liver triglyceride of respective fatty acids infused was relatively higher in arachidonic acid than in 19:4n-5 acid and oleic acid.

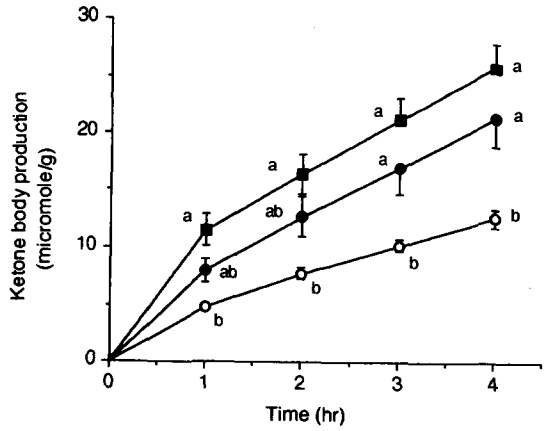

FIG. 1. Ketone body production in perfused rat liver. Rat liver was perfused in the presence of oleic acid (■), arachidonic acid (○) or 19:4n-5 acid (●) for 4 hr. Each point represents the mean ± SE of 6 rats. [a,b] Means not sharing a common superscript letter are significantly different at P<0.05.

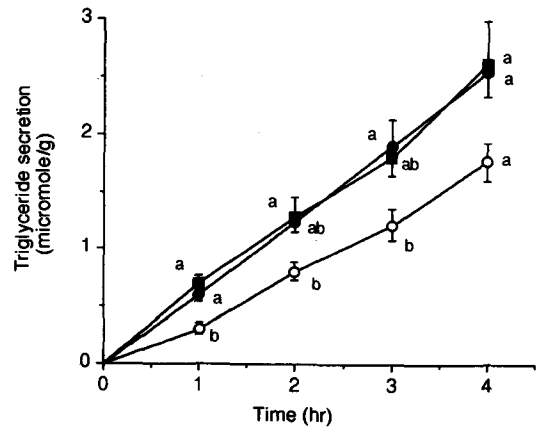

FIG. 2. Triglyceride secretion in perfused rat liver. Rat liver was perfused in the presence of oleic acid (■), arachidonic acid (○) or 19:4n-5 acid (●) for 4 hr. DISCUSSION

The present results indicate that arachidonic acid when infused into liver influences lipid metabolism differently than does oleic acid as evidenced by the decrease in triglyceride secretion and the production of ketone bodies by the liver as well as by the decrease in hepatic triglyceride concentration. Consistent with our observations, Wong *et al.* (15) observed a depression of production and secretion of triglyceride in rat hepatocytes incubated with arachidonic acid as compared to oleic acid.

It is known that fatty acids infused into liver stimulate synthesis and secretion of VLDL (16–21). Kohout *et al.* (21) showed that the output of triglyceride from perfused liver was proportional to the number of carbon atoms when infusion of caproic, caprylic, lauric, palmitic and stearic acids was compared. When fatty acids containing 18 carbon atoms were infused, the output of triglyceride decreased as the number of double bonds in the fatty acids increased. However, only a small difference was observed in the rate of ketone body production among the various fatty acids infused. Wilcox *et al.* (18) also observed that unsaturated fatty acids (palmitoleic, oleic and linoleic acids) stimulated the secretion by perfused liver of VLDL-triglyceride more than did saturated fatty acids (myristic, palmitic and stearic acids), whereas the effects of the unsaturated fatty acids on VLDL secretion was comparable. On the other hand, when hepatocytes were incubated with oleic, linolenic, arachidonic, eicosapentaenoic or docosahexaenoic acid, synthesis and secretion of triglycerides progressively decreased with increasing fatty acid chain length and unsaturation (15). Therefore, triglyceride synthesis and secretion by the liver appear to decrease with infusion of saturated or highly polyunsaturated fatty acids (13,16,19). However, with 19:4n-5 acid the rate of triglyceride secretion did not decrease when compared to oleic acid infusion.

Salem *et al.* (20) showed that increased secretion of VLDL-triglyceride stimulated by infusion of oleic acid resulted in a simultaneous increase in cholesterol secretion and in the activity of hepatic cholesterol synthesizing enzymes. Thus, requirement of cholesterol as a component of VLDL may be increased when VLDL secretion is stimulated (20). This does not fit the observation we made with arachidonic acid in this study. Arachidonic acid, compared to oleic acid, stimulated cholesterol secretion, whereas it decreased triglyceride secretion. The results showed that the lipid composition of the VLDL fraction, a major lipoprotein in the perfusate, may be changed by infusion of arachidonic acid as compared to oleic acid. Although the results do not necessarily explain the cholesterol-lowering activity of n-6 PUFAs, there is a possibility that the change in the lipid composition of VLDL secreted from the liver may influence subsequent metabolism and thus plasma cholesterol levels (9). It is of interest in this context that Wilcox *et al.* (18) reported that VLDL secreted by the liver after infusion of unsaturated fatty acids (palmitoleic, oleic and linoleic acids) is composed of large particles with less phospholipid and cholesterol relative to triglyceride than VLDL produced after infusion of saturated fatty acids (myristic, palmitic and stearic acids).

In contrast to arachidonic acid, the effects of 19:4n-5 acid on ketone body production and triglyceride secretion as well as hepatic triglyceride concentration were similar to those observed with oleic acid. However, 19:4n-5 acid stimulated cholesterol secretion to the same extent as arachidonic acid. In addition, 19:4n-5 acid caused an increase in cholesterol concentration in post-perfused liver which was larger than that caused by arachidonic acid or oleic acid. The results suggest that 19:4n-5 acid, in comparison with oleic acid and arachidonic acid, stimulates cholesterol synthesis and/or inhibits bile acid synthesis in the liver. The effect of 19:4n-5 acid on liver lipid metabolism appears to be quite different from that of

arachidonic acid. This odd-numbered PUFA, in contrast to arachidonic acid which mainly altered triglyceride metabolism, influenced mainly cholesterol metabolism.

The triglyceride concentration in post-perfused liver was higher upon oleic and 19:4n-5 acid infusion than upon arachidonic acid infusion, although all stimulated triglyceride secretion from the liver. On the other hand, the cholesterol concentration in post-perfused liver was not correlated to the secretion of cholesterol from the liver. Interpretation of these reciprocal changes of the lipid concentration and secretion in liver is difficult at present. It was reported that there was no correlation between liver triglyceride output and liver triglyceride concentration when various fatty acids were infused (21).

When 19:4n-5 acid was perfused, the proportion of fatty acid which was tentatively identified as arachidonic acid on a SILAR 10C column increased in triglyceride of the perfusate and post-perfused liver. Further analysis of the fatty acid composition by CP-Sil 88 WCOT fused silica capillary column (50m × 0.25mm) (Chrompack International, Middelburg, Holland) also supported the view that a portion of 19:4n-5 acid might be converted to arachidonic acid. However, since it is difficult to explain the metabolic pathway leading 19:4n-5 acid to arachidonic acid in mammals, more detailed analyses will be required before definite conclusions are drawn. Jakschik *et al.* (22) reported that 19:4n-5 acid was converted to compounds that comigrated with 5-hydroxyeicosatetraenoic (5-HETE) and 5,12-dihydroxyeicosatetraenoic acids (5,12-HETE) in rat basophilic leukemia cells. Thus, 19:4n-5 acid might be elongated to arachidonic acid. Alternatively, it would be possible that 19:4n-5 acid replaces arachidonic acid in membrane lipids with the liberated arachidonic acid being subsequently incorporated into triglycerides. As the levels of 22:4n-6 in the perfusate and post-perfused liver triglyceride tended to decrease after perfusion with 19:4n-5 acid, it would also be possible that increased arachidonic acid levels might result from 22:4n-6 by retroconversion.

The present study shows characteristic differences in the effects of oleic, arachidonic and 19:4n-5 acids on lipid metabolism in isolated perfused rat liver. The possibility exists that these PUFAs also influence the concentration of plasma lipids differently when they are given *per os.*

[Received February 26, 1990; Revision accepted October 16, 1990]

Cholesterol Ester Hydrolase Activity in Mammary Tissue of the Lactating Rat

D.W. West* and **J.H. Shand**
Hannah Research Institute, Ayr, Scotland, KA6 5HL

Cholesterol ester hydrolase activity has been studied in mammary glands of rats. Subcellular fractionation of the glands obtained in mid-lactation indicated that around 80% of the recovered activity was associated with particulate fractions. Two distinct cholesterol ester hydrolase activities were identified, one with an optimum pH of 7.5–9.0 and the second (approximately 5% of the total activity) with a more acidic pH optimum. Although the neutral cholesterol ester hydrolase had some properties in common with the lipoprotein lipase in mammary tissue, it was shown to be a separate entity by several criteria. Its activity could be increased following treatment with Mg-ATP and cAMP-dependent protein kinase, suggesting identity with the hormone sensitive lipase of adipose tissue. The cholesterol ester hydrolase activity in mammary glands just after parturition was greater than in glands obtained either from late-pregnant or mid-lactating animals. The subcellular distribution of the neutral cholesterol ester hydrolase suggested that it may have a different function to the neutral cholesterol ester hydrolase of adrenals and other tissues. Nevertheless the fact that the activity of the enzyme can be modulated by cAMP-dependent protein kinase suggests the possibility that hormonal control of this enzyme may be involved in the regulation of cholesterol metabolism in the mammary gland.
Lipids 26, 31–36 (1991).

A number of hormone-sensitive tissues contain cholesterol ester hydrolase (CEH) activity with neutral pH optima (1,2). Such enzymes have been reported to be localized in both soluble and particulate fractions of cell homogenates (3–5), although those occurring in the soluble fraction have been investigated most (6–8). One of the best characterized of these is the CEH of the bovine adrenal cortex (9). This enzyme catalyzes an important rate-limiting step in steroidogenesis (10) and its activity is regulated by the action of adrenocorticotrophic hormone acting *via* an increase in cAMP levels and consequent activation of protein kinase A (11). The increase in activity on phosphorylation by cAMP-dependent protein kinase resembles the activation seen with hormone-sensitive lipase from adipose tissue (12,13), and the two enzymes have recently been shown to be the same entity by immunological techniques (8). The mammary gland is also a hormone-sensitive tissue and during lactation requires a considerable throughput of cholesterol to support milk production (14). In the rat it has been calculated that between 60% and 80% of the milk cholesterol is derived in this way (15,16). Labelled cholesterol was rapidly taken up by the gland when it was infused into plasma but its subsequent appearance in the milk was surprisingly slow and the radiolabel required about 20 hr to attain its maximum activity in the milk (17,18). It was suggested that this time lag was due to the incorporation of the labelled cholesterol into tissue membranes from which it was only slowly released (17). The mammary gland has been reported to contain acyl-CoA: cholesterol acyltransferase activity (19) and these two results considered together would suggest that esterification of cholesterol, prior to storage in a cholesterol ester pool in the gland, had occurred. Evidence for the presence of cholesterol esters in the mammary gland has been presented (20). In spite of this, very little esterified cholesterol is secreted into milk (21). This suggests that active metabolism of this cholesterol ester pool occurs and there is some evidence in the literature supporting a rapid turnover of cholesterol esters in the mammary gland (22,23). Active turnover of cholesterol esters implies the presence of CEH activity and although the LPL activity of the mammary gland has been studied (24), no attempt appears to have been made to investigate or characterize its CEH activity.

In the study reported here, the lactating mammary gland is shown to contain both acid and neutral CEH activities which are mainly associated with the particulate cell fractions. The activity of the neutral CEH can be increased by cAMP-dependent protein kinase, suggesting that hormonal modulation of the activity of this enzyme may be involved in the control of cholesterol metabolism in the gland.

MATERIALS AND METHODS

Cholesteryl [1-^{14}C]oleate (52 mCi/mmol), [9,10(n)-^{3}H]oleic acid (5 Ci/mmol), glycerol tri-[9,10(n)-^{3}H]oleate (1 Ci/mmol), and uridine diphospho-D-[U-^{14}C]galactose (231 mCi/mmol) were purchased from Amersham International (Amersham, Bucks, U.K.). All biochemicals were purchased from Sigma Chemical Co. (Poole, Dorset, U.K.) or from BCL (Lewes, Sussex, U.K.).

Bovine serum was prepared as described by Clegg (24), but was inactivated by heating at 56°C for 10 min before final centrifugation and storage at −20°C. Lipids were removed from the heat-inactivated serum by preparation of an acetone/ether powder (25). The resultant preparation was redissolved to give the same protein concentration as the original serum.

Preparation of mammary microsomes and acini. Female Wistar rats were kept on a constant light cycle (lights on 08.00–20.00) and were used at 14.30. They were anaesthetized (pentobarbital; 80 mg/Kg), and the abdominal mammary glands dissected free from the skin and abdominal wall before being rapidly freeze-clamped with tongs pre-cooled in liquid nitrogen. Approximately 2 g of gland was homogenized (Polytron; PMA20N probe, 17000 rpm, 30 seconds) in 5 volumes of an ice-cold medium consisting of 250 mM sucrose, 100 mM KF, 1 mM EDTA, and 50 mM MES-50 mM Tris/HCl buffer pH 7.1. The homogenate was centrifuged (10,000 × *g*,

*To whom correspondence should be addressed.

Abbreviations: CEH, cholesterol ester hydrolase; HSL, hormone sensitive lipase; IBMX, isobutylmethyl xanthine; LPL, lipoprotein lipase; MES, 2-(*N*-morpholino)ethanesulfonic acid.

10 min), the pellet discarded and the supernatant recentrifuged for 30 min at 100,000 × *g*. The resultant pellet was resuspended in 50 mM MES-50 mM Tris/HCl buffer pH 7.1 containing 100 mM KCl and again centrifuged at 100,000 × *g* for 30 min. The pellet was then resuspended in the same medium at a concentration of 7 mg/mL, and stored at −80°C before use. Microsomes were similarly prepared in homogenization medium to which 0.5 M KCl had been added (salt-washed microsomes). Acini were prepared from lactating mammary tissue by collagenase digestion (26).

Subcellular fractionation of mammary tissue and of mammary acini. Subcellular fractionation was carried out after homogenization in a "high" ionic strength buffer containing 250 mM sucrose, 1 mM EDTA, 100 mM KCl, and 10 mM Tris/HCl pH 7.4 as described by Clegg (24). Four fractions were obtained, P1, nuclear/debris pellet (1000 × *g*); P2, mitochondrial pellet (3000 × *g*); P3, microsomal pellet (105,000 × *g*); and S3, the post-microsomal supernatant. Assays for marker enzyme activities were as follows: 5′-Nucleotidase (EC 3.1.3.5) was according to Michell and Hawthorn (27). Phosphodiesterase-1 (EC 3.1.4.1), NADPH-cytochrome C oxidoreductase (EC 1.6.2.4), acid phosphatase (EC 3.1.3.2), and cytochrome C oxidase (EC 1.9.3.1) were assayed as described by Brown *et al.* (28). Galactosyl transferase (EC 2.4.1.22) was assayed using UDP-D[U-^{14}C]galactose by a modification of the method of Morré *et al.* (29). LPL was determined according to Nilsson-Ehle and Schotz (30), as modified by Clegg (24), using bovine serum prepared as above to activate the substrate. Lactate dehydrogenase (EC 1.1.1.27) was measured using a standard photometric assay. A slightly cruder subcellular fractionation was also carried out after homogenization of the mammary gland in a "low" ionic strength buffer containing 250 mM sucrose, 1 mM EDTA, and 10 mM Tris/HCl pH 7.4. Three fractions were obtained P1+P2, a combined nuclear/mitochondrial pellet (3000 × *g*), P3, a microsomal pellet (105,000 × *g*) and S3, the post-microsomal supernatant, all of which were assayed for CEH activity. Acini were homogenized in the KCl-containing buffer and fractionated by differential centrifugation giving two pellet fractions (10,000 × *g* and 105,000 × *g*) and a post-microsomal supernatant fraction which were assayed for CEH activity.

Protein and DNA measurements. The protein concentrations were determined by the dye-binding technique of Bradford (31), and the DNA contents of mammary tissue and acini were assayed as described by Labarca and Paigen (32).

Treatment with heparin. Microsomes (0.4 mg) were mixed with heparin (50, 100 or 200 μg/mL) in 50 mM MES-50 mM Tris/HCl pH 7.1 containing 100 mM KCl. After standing for 30 min in ice, the mixture was centrifuged at 15,000 × *g* for 30 min at 4°C. The supernatant was collected and the pellet resuspended in the same volume of fresh buffer. CEH activity was measured in both.

Treatment with Triton X-114. Microsomes (1.8 mg) were mixed with Triton X-114 (final conc. 0.16% w/v) in 50 mM MES-50 mM Tris/HCl pH 7.1 containing 100 mM KCl. After standing for 60 min in ice, the mixture was incubated for 10 min at 30°C, to precipitate Triton X-114, before being centrifuged (15,000 × *g*, 5 min, 30°C). CEH activity was measured in the detergent-free supernatant.

Activation with Mg-ATP. Microsomes (0.04–0.1 mg) were preincubated for 10 min at 37°C with $MgCl_2$ (3 mM), ATP (5 mM), cAMP (0.01 mM), and IBMX (2.5 mM) in 25 mM MES-25 mM Tris/HCL buffer pH 7.1 with and without protein kinase A (0.26 mg/mL) before assaying for neutral CEH activity. Where present, protein kinase inhibitory peptide was at a concentration of 0.01 mg/mL. Enzyme protein, released into the detergent-free supernatant following treatment with Triton-X-114, was also incubated under the same conditions.

Assay of CEH. Activity was measured in terms of the release of [1-^{14}C]oleic acid from cholesteryl [1-^{14}C]oleate (33). The microsomal fraction (40 μg) and an ethanolic solution of the substrate (20 nmol, 10 μL, 100,000 dpm) were incubated at 37°C for 40 min in 50 mM MES-50 mM Tris-HCl pH 7.1 containing 0.7 mM $MgCl_2$, 25 mM KCl, and bovine serum albumin (1%, w/v), in both the presence and absence of 1M NaCl (total volume of 200 μL). In the presence of 1M NaCl, a three-fold higher specific activity substrate was used. The reaction was initiated by the addition of substrate and terminated by the addition of a chloroform/heptane/methanol (1.25:1:1.41, v/v/v) mixture followed by 0.45 mL of K_2CO_3/boric acid buffer pH 10.5. In each assay, appropriate controls without microsomes were incubated concurrently in order to correct for background. After the addition of [9,10(n)-^{3}H]oleic acid (2.1 μmole, 6000 dpm) and agitation on a vortex mixer, the mixture was separated by centrifugation and an aliquot of the upper aqueous layer was counted to determine the amount of fatty acid released. Corrections for recovery were applied by reference to the added oleic acid. The presence of 1 M NaCl invariably led to a lower recovery of the released fatty acid.

RESULTS

Optimization of assay conditions. The rate of hydrolysis of cholesteryl oleate (typically 300–700 pmol per min/mg of protein) was highest when the substrate was presented as an ethanolic solution. Activity was optimal at 100 μM cholesteryl oleate and was a linear function of time (to 40 min) and microsomal protein concentration (10 μg to 200 μg). In the absence of bovine serum albumin, a marked reduction in the hydrolytic rate was observed. The standard assay conditions were incubation at 37°C for 40 min in 50 mM MES-50 mM Tris/HCl pH 7.1 buffer containing bovine serum albumin (1%, w/v), 40 μg microsomal protein and 100 μM cholesteryl oleate (total volume 200 μL). The assay was carried out in the presence and absence of 1 M NaCl.

Subcellular fractionation. Regardless of the ionic strength of the buffer used in the homogenization, an average of just over 70% of the CEH activity of the homogenate was recovered during the subcellular fractionation, which compared favorably with the general recovery of the marker enzyme activities. The subcellular distribution of CEH activity in the mammary gland homogenized in the "high" ionic strength buffer is presented in the form of DeDuve plots (34) (Fig. 1) and is compared with that determined for various marker enzyme activities in lactating rat mammary tissue during a single representative experiment. Approximataely 21% of the recovered CEH activity was found in the S3 faction, but the bulk of the activity was present in membrane

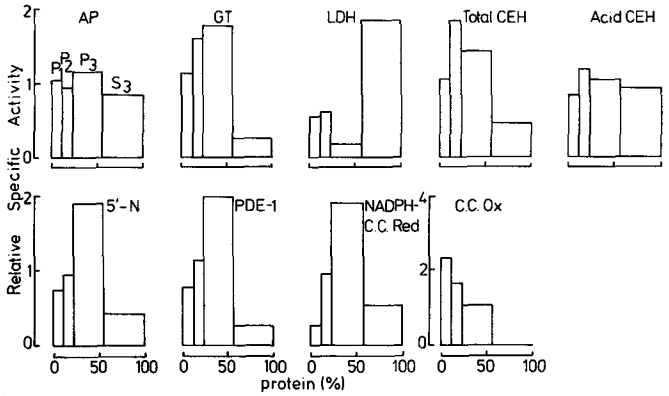

FIG. 1. Subcellular distribution of some enzyme activities in lactating mammary tissue. The tissue was homogenized in "high-ionic" strength buffer (see text). The results are presented in the form of DeDuve plots (34), where the width of any one histogram bar is proportional to the percentage of the total recovered protein in the fraction to which that bar relates. The relative specific activity is calculated by dividing the percentage of the total recovered activity in the fraction by the percentage of the total protein in that fraction. AP, acid phosphatase (lysosomes); GT, galactosyl transferase (Golgi); LDH, lactate dehydrogenase (cytosol); total CEH, total cholesterol ester hydrolase; acid CEH, salt-resistant cholesterol ester hydrolase; 5′-N, 5′-nucleotidase (plasma membrane), PDE-1, phosphodiesterase-1 (plasma membrane); NADPH-C.C.Red, NADPH-dependent cytochrome C oxidoreductase (endoplasmic reticulum); C.C.Ox, cytochrome C oxidase (mitochondria).

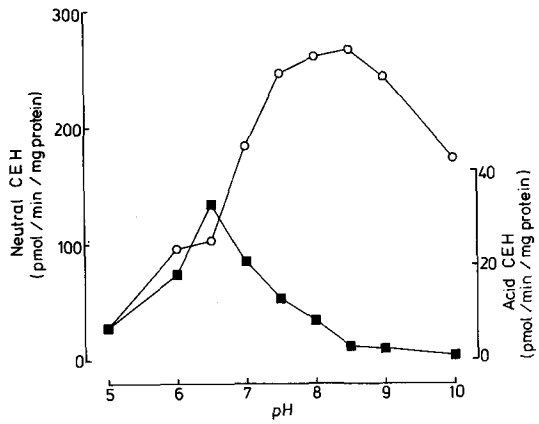

FIG. 2. Variation of CEH activity with pH. CEH activity was measured in the presence and absence of 1 M NaCl as described in the Materials and Methods section using 50 mM Tris-50 mM MES-50 mM glycylglycine adjusted to the correct pH with NaOH or HCl as required, as buffer throughout. The difference in the two readings at each pH value was plotted as the neutral esterase activity (○—○). The acid esterase activity was that measured in the presence of the high salt (■—■). Results are expressed as pmol cholesteryl oleate hydrolyzed per min/mg protein.

TABLE 1

The Distribution of Enzyme Activities Between the Particulate and the Soluble Fractions of Mammary Gland Homogenates[a]

Enzyme	Ionic strength of homogenizing buffer	Particulate (P1+P2+P3)	Soluble (S3)
NADPH-cyto C oxidoreductase	High	78.4	23.0
	Low	79.8	20.1
5′-Nucleotidase	High	81.3	18.7
	Low	67.9	32.1
Total cholesterol ester hydrolase	High	79.2	20.9
	Low	49.0	51.0

[a]The mammary glands were homogenized in both "low" and "high" ionic strength buffers (see text) and the amount of each enzyme activity present in each fraction expressed as percentage of the total recovered activity.

fractions. The distribution of specific CEH activity among these membrane fragments was broadly similar to those of NADPH-cytochrome C oxidoreductase (endoplasmic reticulum marker), 5′-nucleotidase and phosphodiesterase-1 (plasma membrane markers) and galactosyl transferase (Golgi marker). Homogenization in the "low" ionic strength buffer altered the distribution of the enzyme activities with a greater proportion of the CEH being recovered in the cytosolic fraction (Table 1). This was nevertheless mirrored by the plasma membrane marker 5′-nucleotidase, which exhibited a similar redistribution into the soluble fraction. In contrast, the endoplasmic reticulum marker NADPH-cytochrome C oxidoreductase showed no such change in its distribution between these subcellular fractions.

The CEH activity was strongly inhibited by 1 M NaCl with its activity being reduced to around 5% of the original. The salt-resistant hydrolase activity was a small but consistent portion of the total CEH activity associated with each of the subcellular fractions, but its distribution was slightly different to that observed for the total activity (Fig. 1) and resembled the pattern shown by acid phosphatase, a lysosomal marker. The salt-resistant ester hydrolase had an optimum activity at pH 6.5 (Fig. 2) rather higher than that normally associated (35,36) with the lysosomal enzyme. In contrast, the salt-inhibited hydrolase activity (total minus the salt-resistant activity) had a broad optimum over the range pH 7.5–9.0, similar to that shown by LPL and the neutral CEH activity reported in a number of other tissues (1–7). The microsomal pellet P3 was subjected to further fractionation on a discontinuous sucrose gradient similar to that used by Clegg (24) and the distribution of both CEH activities and various marker enzymes again compared (Table 2). The neutral CEH was relatively more concentrated at the 0.9/32% interface when compared with the other fractions. This distribution resembled that of the two plasma membrane markers 5′-nucleotidase and phosphodiesterase-1 and was unchanged by homogenization and fractionation in "low" ionic strength buffer.

The distribution was unlike that shown by NADPH-cytochrome C oxidoreductase and galactosyl transferase suggesting that the neutral CEH was preferentially associated with plasma membrane fragments rather than with endoplasmic reticulum or Golgi membranes. At "high" ionic strength the partition of the acid CEH between the gradient fractions resembled that of the neutral hydrolase, but at "low" ionic strength a significant proportion was shifted into the heavier fractions and in this characteristic it resembled the redistribution shown by acid phosphatase.

When acini were similarly homogenized and fractionated, 73% of the original CEH was recovered in the fractions obtained and again 75% of the recovered activity

TABLE 2

Density Gradient Purification of Rat Mammary Microsomal (P3) Fraction[a]

Enzyme	Ionic strength of homogenizing buffer	% of total activity recovered in fraction			
		F1	F2	F3	F4
NADPH-cytochrome C oxidoreductase	High	29.2	25.0	30.4	15.4
	Low	18.1	31.4	36.1	14.4
Galactosyl transferase	High	26.3	60.6	6.5	6.6
5′-Nucleotidase	High	50.9	25.7	18.5	4.9
	Low	56.2	32.1	9.5	2.2
Phosphodiesterase-1	High	53.4	19.3	17.0	10.3
	Low	47.0	31.2	16.5	5.3
Salt-inhibited (neutral) cholesterol ester hydrolase	High	41.6	21.2	24.0	13.2
	Low	39.5	17.8	22.5	20.2
Acid phosphatase	High	25.0	25.2	36.8	13.0
	Low	18.6	28.9	34.4	18.1
Salt-resistant (acid) cholesterol ester hydrolase	High	43.8	17.7	25.3	13.2
	Low	30.6	36.8	27.3	5.3
Lipoprotein lipase	Low	27.7	28.0	29.2	15.1

[a]Fraction P3 (47 mg protein) was layered onto a sucrose gradient consisting of 6 mL each 40%, 36%, and 32% (w/w) sucrose and carefully overlayered with 0.9% sucrose. All sucrose solutions were made up in 20 mM Tris-HCl pH 7.4. After centrifugation (105,000 × *g*, 90 min) membrane material was collected from the interfaces between the 0.9% and 32% layers (F1), the 32% and 36% layers (F2) and the 36% and 40% layers (F3). These three fractions, together with the pellet fraction (F4), were diluted with 20 mM Tris-HCl pH 7.4 and sedimentable material collected by centrifugation (105,000 × *g*, 45 min). The resultant pellets were suspended in the Tris buffer and assayed for enzyme activities as described in the Materials and Methods section. The salt-resistant hydrolase was taken as that activity measured in the presence of 1 M NaCl and having an acid pH optimum. The salt-inhibited hydrolase, showing a more neutral pH optimum, was the difference between the activities measured in the presence and absence of NaCl. The results are given as the percentage of the activity recovered in each interface fraction for the microsomal pellets obtained from the homogenization in both "high" and "low" ionic strength buffers.

TABLE 3

Solubilization of CEH Activity[a]

Condition	Neutral hydrolase	Acid hydrolase
Control	100	100
0.5 M KCl treated microsomes	21.5	28.4
Detergent-free supernatant	79.4 ± 3.6(7)	16.4
Resuspended Triton pellet	6.1	0
Heparin treatment		
50 μg/mL		
Supernatant	6.8 ± 2.9(2)	n.d.[b]
Pellet	93.3 ± 2.9(2)	n.d.
100 μg/mL		
Supernatant	7.5 ± 4.6(2)	n.d.
Pellet	92.5 ± 4.6(2)	n.d.
200 μg/mL		
Supernatant	17.4 ± 1.6(2)	n.d.
Pellet	82.6 ± 1.6(2)	n.d.

[a]Microsomes were either prepared in the presence of 0.5 M KCl or treated with Triton X-114 or heparin as detailed in the Materials and Methods section. Results are expressed as percentages of controls ± SEM with the number of animals in parenthesis. Control values were 523.0 and 11.0 pmol cholesteryl oleate hydrolyzed per min/mg of protein for the neutral and acid hydrolases, respectively.

[b]n.d. = not determined.

was associated with the particulate material (results not shown). Moreover, when the CEH activity was compared in homogenates of whole mammary glands and in acini prepared from the same glands, the hydrolase activity in the acini (5473 pmol per min/mg of DNA) averaged (for two preparations) 82.9% of the value determined for the whole tissue. Together these results, obtained on a cellular preparation free of adipose tissue, confirmed that the bulk of the CEH activity was definitely associated with the mammary epithelial cells.

The inhibition by high salt and the broad pH optimum indicated a similarity of the neutral CEH activity with the LPL associated with this tissue (24). However, only 11.6% of the neutral hydrolase and 19.8% of the acid hydrolase activity were retained following acetone/diethyl ether treatment (25) of the microsomal pellet; and the inclusion of heat-inactivated serum, at a concentration of serum protein reported to stimulate LPL activity (24), gave greater than 85% inhibition of the neutral hydrolase and a total loss of the acid hydrolase activity. Extraction of the serum with acetone/diethyl ether to remove lipids did not affect its inhibition of CEH. The results of these two tests taken together with the results obtained from the gradient fractionation (Table 2) indicate that the neutral CEH activity present in the microsomal fraction obtained from the mammary gland was distinct from the LPL activity previously identified to be in this fraction (24).

Solubilization of esterase activity. Following treatment of the microsomes with Triton X-114, 50.3 ± 3.9% (n=10) of the neutral hydrolase activity was released into the soluble fraction together with 70.3 ± 4.9% (n=10) of the protein. The specific activity of the enzyme was reduced relative to that in the microsomes (Table 3) but was reduced even further if the detergent was not removed from the solution (37). The acid hydrolase was inhibited by this detergent treatment. Around 80% of the activity was lost when the microsomes were washed with 0.5 M KCl, but heparin (200 μg/mL) released only 17% of the neutral hydrolase into the soluble fraction (Table 3).

Inhibition and activation of CEH. Taurocholate and cholate (1 mM) both significantly ($P<0.025$) enhanced the activity of the neutral CEH (Table 4). Increasing the cholate concentration to 20 mM caused inhibition. The acid hydrolase activity was also activated by 1 mM cholate and inhibited by the higher concentration of this bile salt. Potassium fluoride (10 mM) and sodium pyrophosphate (10 mM) were inhibitory and both CEH activities were essentially abolished by phenylmethyl sulfonyl fluoride. Phenyl boronic acid also greatly inhibited both hydrolases, but they were less susceptible to its butyl analogue. The inclusion of phosphate or vanadate had no significant effect, although performing

TABLE 4

Influence of Various Materials on the CEH Activities in Microsomes Prepared from Rat Lactating Mammary Gland[a]

Addition	Neutral hydrolase	Acid hydrolase
None (control)	100	100
Potassium fluoride (10 mM)	73.6 ± 4.8	64.6 ± 8.0
Potassium phosphate (25 mM)	91.7	129.3
Sodium vanadate (0.2 mM)	106.4 ± 2.7	113.5 ± 8.7
Sodium pyrophosphate (10 mM)	64.5 ± 3.0	48.2 ± 9.3
Sodium taurocholate (1.0 mM)	122.0 ± 2.94	n.d.[b]
Sodium cholate (1 mM)	120.0 ± 4.9	115.2 ± 6.0
Sodium cholate (20 mM)	0.9 ± 0.7	0.4 ± 0.4
Phenylmethylsulfonyl fluoride (1 mM)	0.0	15.6 ± 12.0
Phenyl boronic acid (0.4 mM)	3.6 ± 1.6	17.6 ± 14.31
Butyl boronic acid (1 mM)	52.0 ± 6.2	30.7 ± 23.2

[a]The assay for CEH activity was carried out as detailed in the Materials and Methods section with additions included at the final concentrations shown. The results are expressed as percentages of controls ± SEM for four animals. Control values wre 652.0 and 28.5 pmol cholesteryl oleate hydrolyzed per min/mg of protein for the neutral and acid hydrolases, respectively.

[b]n.d. = not determined.

TABLE 5

Activation of Neutral CEH[a]

Additions	Relative activity	
	Microsomes	Solubilized enzyme
None (control)	100.00	100.00
ATP	102.9 ± 0.4(3)	134.6 ± 3.9(3)
ATP + protein kinase A	105.8 ± 7.1(7)	156.5 ± 8.5(6)
ATP + protein kinase A + inhibitory peptide	n.d.[b]	108.3 ± 2.5(3)

[a]Microsomes or Triton-X114 solubilized enzyme protein (see Materials and Methods) (40–100 μg) were assayed for CEH activity in the presence of $MgCl_2$ (3 mM), cAMP (0.01 mM), and IBMX (2.5 mM), with and without ATP (5 mM). Where indicated, protein kinase A was present at a concentration of 0.25 mg/mL and the inhibitory peptide at 10 μg/mL. The substrate concentration for the CEH assay was reduced from 100 μM to 30 μM. Results are expressed as percentages of the controls ± SEM with the number of animals in parenthesis. The control values wre 276.5 and 208.0 pmol cholesteryl oleate hydrolyzed per min/mg of protein for the microsomes and solubilized enzyme, respectively.

[b]n.d. = not determined.

TABLE 6

CEH Activities in Microsomes Isolated from the Mammary Glands of Pregnant, Early- and Mid-Lactating Rats[a]

Animals	Neutral hydrolase	Acid hydrolase
Pregnant	119.7 ± 12.7 (6)	20.2 ± 2.2 (7)
Early-lactating	239.9 ± 46.5* (3)	10.4 ± 1.6** (4)
Mid-lactating	114.0 ± 40.6 (4)	6.3 ± 2.1***(4)

[a]The microsomes were prepared in the standard manner from the mammary glands of rats on day 18–19 of pregnancy and 2 days and 10–12 days after parturition and assayed for CEH activity as described in Materials and Methods. Results are expressed as pmol cholesteryl oleate hydrolyzed per min/mg of DNA ± SEM with the number of animals in parenthesis. Statistically significant differences between lactating and pregnant glands are indicated by *P<0.05, **P<0.01, and ***P<0.005.

the assay in phosphate buffer rather than MES-Tris/HCl led to a lowering of activity (from 254 to 92 pmol cholesteryl oleate hydrolyzed per min/mg of protein).

Activation by Mg-ATP. Incubation of microsomes with Mg-ATP, cAMP, cAMP-dependent protein kinase and IBMX caused only a small and very variable activation of the neutral hydrolase activity (Table 5). If the enzyme was first solubilized with Triton X-114 and the detergent subsequently removed, greater stimulation of enzyme activity was observed following incubation with this mixture. Inclusion of the cAMP-dependent protein kinase made little difference to the extent of activation of the solubilized enzyme, but the presence of the peptide inhibitor of the cAMP-dependent kinase (38) markedly inhibited the activation caused by Mg-ATP.

Influence of pregnancy and lactation. Microsomes obtained from the glands of animals early in lactation had a higher activity of the neutral CEH than glands from either the late pregnant or mid-lactating animals (Table 6), whereas the microsomes obtained from the pregnant glands had a significantly higher level of the acid CEH than either of the lactating groups.

DISCUSSION

Our data demonstrate that both a neutral and an acid CEH exist in the microsomal fraction of the lactating mammary gland. The resemblance of these activities in the mammary gland to those existing in other tissues is an obviously important point to consider. A number of tissues contain CEH activities, apparently all identical, that are activated by high concentrations of bile salts (39). Although low levels of such materials activated the neutral CEH present, in mammary tissue higher levels were markedly inhibitory, making it unlikely that the mammary enzyme was the same entity. The neutral CEH was inhibited by high salt concentrations, a property that it shares with LPL. Nevertheless, it was distinct from the LPL previously demonstrated to be present in this fraction since its partition on the sucrose gradient was different and it was destroyed by preparation of an acetone/diethyl ether powder, a procedure generally used to prepare LPL, and was inhibited by delipidized serum. In this, and in a number of other properties, it resembled the HSL and neutral CEH present in adipose tissue and in the adrenal cortex, respectively. The neutral CEH activities of adipose tissue, adrenal, and liver can all be activated by incubation with cAMP-dependent protein kinase and Mg-ATP suggesting that activation resulted

from phosphorylation of the enzyme. Slight activation of the neutral CEH in the microsomes from the mammary gland by Mg-ATP could also be demonstrated but was more readily observed when it had been first solubilized by detergent treatment. The extent of activation of between 30–84% was similar to that reported for HSL from rat adipose tissue (40), but was considerably less than that obtainable with the enzyme from chicken adipose tissue. Stimulation of enzyme activity by ATP could be almost completely inhibited by the presence of the inhibitor of protein kinase A. Thus, like HSL, the modulation of activity was most probably due to phosphorylation by the cAMP-dependent protein kinase indicating that the activity of the enzyme would be altered by changes in the cAMP content of the epithelial cell in response to hormonal signals. The inability to demonstrate reasonable activation of the unsolubilized enzyme by Mg-ATP could be due to a number of factors including limited access of the enzyme to the kinase or the presence of an active phosphatase which we have previously shown to exist in this microsomal fraction (41). Attempts to remove this phosphatase by a high salt wash of the microsomes, prior to treatment with Mg-ATP, led to a loss of activity in the preparation. Similarly, the presence of the normally used phosphatase inhibitors KF and pyrophosphate led to inhibition of the ester hydrolase activity, so it proved difficult to nullify easily this putative phosphatase activity.

Although the neutral CEH had many similarities to HSL, the distribution of the mammary enzyme indicated that it had a predominantly membrane location rather than the cytosolic location of the adrenal and adipose tissue enzymes, suggesting that it may function in a different manner to the latter enzymes. Nevertheless, the fact that the mammary enzyme can be regulated by a mechanism involving phosphorylation-dephosphorylation by cAMP-dependent protein kinase suggests the possibility that hormonal control of the activity of this enzyme has a role in manipulating the cholesterol metabolism of the mammary gland and in the secretion of cholesterol into milk.

The cholesterol ester levels in samples of prepartum milk have been shown to be higher than that of milk obtained after parturition (42,43) suggesting that the glands of pregnant animals contain a higher amount of cholesterol ester. Recent work in our laboratory has shown that the cholesterol ester content of microsomes from pregnant glands is about twice that found in early lactators. The doubling of the neutral CEH activiaties between late pregnancy and day two of lactation is therefore consistent with an inverse correlation between the hydrolase and the cholesterol ester content of the gland at these two stages of development.

ACKNOWLEDGMENT

We thank Ms. S. Tawil for technical assistance.

A cross-fostering design was used to examine the effects on brain and behavioral development in mice of pre- and/or postnatal dietary supplementation with n-3 fatty acids. Pregnant mice were fed either of two liquid diets, control (con) or experimental (exp). Each diet provided 3% of the calories in the form of n-6 fatty acids; the experimental diet was supplemented with an additional 1.5% from long chain n-3 fatty acids derived from fish oil. There were four treatment groups, with all pups fostered at birth. These groups were (prenatal diet/postnatal diet): Group 1, exp/exp; Group 2, exp/con; Group 3, con/exp; Group 4, con/con; a fifth control group (unfostered) was fed lab chow (LC) throughout the study. Animals from the exp/exp and con/con groups were weaned onto lab chow for later behavioral assessment. Prenatal n-3 supplementation resulted in a small acceleration of behavioral development. The adult animals did not differ on visual discrimination learning nor did they differ in visual acuity. During development the fatty acid composition of the brain membrane phospholipids reflected closely that of the pre- and postnatal dietary conditions. Levels of 22:5n-3 and 22:6n-3 increased in the n-3 supplemented groups, accompanied by a decrease in levels of 22:4n-6 and 22:5n-6; the net effect of these changes was to increase the total levels of C_{22} fatty acids. While these results support considerable plasticity of the fatty acid composition of the developing brain with respect to the immediate dietary availability of n-3 compounds, they do not support long term effects on learning capacity of n-3 supplementation during the developmental period.

***Lipids 26,* 37-45 (1991).**

This paper addresses the putative functional role played by polyunsaturated fatty acids (PUFA) of the n-3 series in mammalian brain and behavioral development. The structural lipids of the grey matter of the mammalian nervous system are unique from others of the body in terms of their high proportion of PUFA, particularly arachidonic acid (AA, 20:4n-6) and docosahexaenoic acid (DHA, 22:6n-3) (1). In the brain, concentrations of DHA differ between subcellular fractions, with high levels in the microsomes and synaptosomes, particularly in the *sn*-2 position of phosphatidylethanolamine and phosphatidylserine (2,3). Similarly high concentrations have been reported in the retina (4). The fatty acid precursors of both the n-6 and n-3 series (LA, linoleic acid, 18:2n-6, and LN, α-linolenic acid, 18:3n-3) cannot be synthesized *de novo* by mammals, and are therefore considered essential dietary nutrients. LA and LN are desaturated and elongated by the same enzymes to form the longer carbon chain derivatives (5). Changes in membrane fatty acid composition have been associated with alterations in the activity of various membrane-bound enzymes (6,7). It has been suggested that such functional changes may underlie reported associations between dietary lipid composition and behavior in mature animals (8).

Because these long chain PUFA accrue rapidly in the brain during the prenatal and suckling periods (9-11), the question arises as to whether specific dietary deficiencies during gestation and lactation may have enduring consequences on brain lipid composition and function. Of the studies on the effects of essential fatty acid (EFA) deficiency on brain phospholipid composition, some have shown decreases in levels of 20:4n-6 and 22:6n-3, with most showing increases in 20:3n-9, 22:3n-9, and in 22:5n-6 (12-18). Studies which specifically address n-3 deficiency, while showing minimal effects on levels of 20:4n-6, show a consistent decrease in levels of 22:6n-3, accompanied by a corresponding increase in levels of 22:5n-6 (19-23). Nutritional rehabilitation of such animals results in a decrease in levels of 22:5n-6 with an increase in levels of 22:6n-3 (24-26). Together with these biochemical differences, studies in the rhesus monkey have reported effects of n-3 on the physiological responsiveness of the retina, as well as on behavioral measures of visual acuity—the retinal changes appear to be independent of later nutritional rehabilitation (23,27). Changes in retinal function associated with decreased levels of 22:6n-3 have also been reported in the rat (28), although another study finds no such effects in either the rat or the guinea pig (29). Studies conducted on rodents have compared the effects of dietary n-3 *vs* n-6 fatty acids on learning ability, and report improved associative capacities as a result of the provision of n-3 during development (30-34). However, much of this work does not dissociate possible effects on sensory thresholds from those on cognitive function. Moreover, in these studies, the animals were maintained on the dietary treatment until they were tested as adults, and they therefore do not provide information on the importance of specific developmental periods. These issues were addressed in the present study. Recent work from our laboratory (35,36), in which pregnant mice consuming ethanol received n-3 dietary supplementation, while showing no effect of n-3 on spatial reversal learning in a water maze, did show a modest effect in accelerating indices of sensory development in the pups, particularly eye-opening. Therefore, in this study, a cross-fostering design was used to ascertain whether there was a critical period, either pre- or postnatal, during which the provision of n-3 fatty acids in the maternal diet would affect behavioral development in the offspring. The study also examined whether supplementation of n-3 fatty acids throughout the prenatal and preweaning developmental period would have an effect on

Abbreviations: AA, arachidonic acid; ANOVA, analysis of variance; BHT, butylated hydroxytoluene; DHA, docosahexaenoic acid; EFA, essential fatty acids; GLC, gas-liquid chromatography; GLM, general linear model; LA, linoleic acid; LC, lab chow; LN, α-linolenic acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PUFA, polyunsaturated fatty acids; SAS, Statistical Analysis Systems; TLC, thin-layer chromatography.

later learning ability. This was accomplished by assessing the learning capacity of adult animals which had been fed either n-6 supplemented with n-3 or n-6 fatty acids only throughout gestation and lactation and then weaned onto a chow diet containing both n-3 and n-6 fatty acids. A visual discrimination learning task was used and the procedure incorporated a behavioral measure of visual acuity in order to separate effects on learning ability from those on sensory capacity. The fatty acid composition of the brain glycerophospholipids was measured during development and in the adult animals.

METHODS

Subjects. Parents were 10–12-week-old B6D2 F_1 hybrid mice purchased from Charles River Breeding Laboratories (St. Constant, P.Q., Canada). They were maintained under a reversed 12 hr light:12 hr dark schedule at 22 ± 1°C, with tap water and lab chow (Purina # 5001) available *ad libitum.* The animals were group-housed in standard plastic cages containing Beta-Chip hardwood bedding and toilet tissue for nesting material. Breeding commenced at about 20 weeks of age.

Experimental design and materials. Maternal animals were fed one of two liquid diets, each of which provided 20% of the calories from oil. The control diet (con) provided 3% of the calories as n-6 fatty acids (FA). The experimental diet (exp) similarly contained 3% n-6 FA and was supplemented with an additional 1.5% of long-chain n-3 FA derived from fish oil. The liquid diets were the sole source of food and fluid. They were the same as those used previously (35), formulated by BioServ (Frenchtown, NJ); 20% of the calories were provided as protein (fat-free casein, < 0.5% fat) and 60% as carbohydrate (maltose-dextrin), together with minerals and vitamins; a typical analysis indicates 56 i.u. of α-tocopherol per liter. In the control diet the oil was constituted from a mixture of safflower and olive oil, with the proportions of each based on prior analysis and calculated to yield 3.0% of the dietary calories as n-6 fatty acids. Similarly, in the experimental diet, the oil contained a mixture of safflower oil, olive oil, and Polepa (a fish oil concentrate, provided by Efamol Research Institute, Kentville, Nova Scotia, Canada), such that the contribution to the dietary calories was 3.0% n-6 and 1.5% n-3. The n-3 content of the Polepa was: 18:3, 2.1%; 20:5, 12.9%; 22:5, 1.7%; 22:6, 7.5%. The oil mixtures were also analyzed and a representative analysis of the EFA composition of each is shown in Table 1. There were four treatment groups in the study, which were constituted by cross-fostering all pups at birth, either to a dam receiving the same diet as their prenatal dam, or to one receiving the diet opposite to that of their prenatal dam. Thus the groups were (prenatal diet/postnatal diet): Group 1, exp/exp; Group 2, exp/con; Group 3, con/exp; and Group 4, con/con. A fifth untreated group was included [Group 5, lab chow (LC)], in which pregnant and lactating mice were allowed free access to lab chow (containing 22.3% 18:2n-6, 2.3% 18:3n-3, 1.3% 20:5n-3 and 1.1% 22:6n-3) and tap water throughout the course of the experiment. There is one point which should be addressed here with respect to the design of this study. The diets were formulated to provide *equivalent* amounts of n-6 fatty acids, with *additional* n-3 being added to constitute the n-3 group. Although the design might also be described as one which addresses n-3 *deficiency,* with the control group being the deficient group, the experimental dietary manipulation is better described as providing n-3 *supplementation.* The reason for this is that, regardless of levels of essential fatty acids in the maternal diet, these compounds may nevertheless remain available to the developing offspring through the presence of maternal stores. In order to obtain a true deficiency in the supply of n-3 fatty acids to the offspring, it may be necessary to deplete the maternal diet for successive generations (18) or gestations (37).

TABLE 1

Selected Fatty Acid Composition of Dietary Oils[a]

	Experimental[b]	Control[c]
18:2n-6	14.2	13.3
18:3n-3	0.8	<0.2
20:4n-6	0.3	—
20:5n-3	3.3	—
22:5n-3	0.4	—
22:6n-3	1.9	—

[a] Representative GLC analysis of oil mixtures, where value represents % of total fatty acids. Note that levels of n-6 fatty acids are similar in each group, with the experimental oil supplemented with n-3 fatty acids derived from fish oil concentrate.

[b] Experimental = olive/safflower/polepa, 100 g:27.5 g:72.5 g.

[c] Control = olive/safflower, 9 g:1 g.

Procedure. Animals were mated daily, starting at the beginning of the dark phase, and were checked for the presence of copulatory plugs about 7 hr later. The day on which a vaginal plug was detected was considered day 0 of gestation. All pregnant dams were weighed and then randomly assigned to the exp, con or lab chow condition in the ratio 2:2:1, respectively. Dams in the liquid dietary groups were fed 0.75 mL × body wt. (g) daily until day 20. The animals were weighed on days 1, 5, and every two days thereafter, and the amount of food adjusted accordingly. Birth occurred on day 19 or 20 and all dams and litters were weighed on day 20. At this time, litters were culled to six (three of each sex), and these pups were placed with their appropriate foster mother (groups 1–4 —dietary treatments) or returned to their natural mother (group 5—lab chow). From day 20 until day 32 (post-conception), when the pups were tested on behavioral development, lactating mothers were fed the appropriate liquid diet *ad libitum* at 1.5 × strength. Daily food intake was monitored throughout the feeding period.

Day 32 behavioral development. On day 32 post-conception litters were coded by an independent observer so that the experimenter was blind to their experimental condition. Then all pups were weighed, and two pups of each sex were selected randomly from each litter, and subjected to a battery of 12 tests to measure behavioral development. These tests are identified as follows: i) Righting reflex; ii) cliff aversion; iii) forelimb and hindlimb grasp reflex iv) vibrissae-placing reflex; v) level screen test; vi) vertical screen test; vii) screen climbing test; viii) pole grasp; ix) forelimb and hindlimb stick grasp; x) eye opening; xi) visual placing reflex; and xii) auditory startle response. The pup was assigned a score on each test, using standardized criteria, and these scores ranged from 1 to 10. The scores were then averaged over all the

tests to yield a mean behavioral test score. By substituting the mean score of each pup into a previously derived quadratic equation predicting chronological age from behavioral test score, it was possible to obtain a measure of "B6D2F$_2$-equivalent behavioral age" for each mouse. (See references 38 and 39 for a full description of these procedures.) Previous studies have employed this technique to investigate the effects of nutritional availability (40) and interactions between dietary fatty acids and prenatal ethanol exposure (35,41,42) on behavioral development in the mouse. Following testing on day 32, one animal of each sex was selected randomly, anaesthetized with halothane and then decapitated. The brains of these animals were extracted and trimmed by removal of the olfactory bulbs anteriorly and 2 mm below the medulla posteriorly. Within two min the brains were then weighed to the nearest 0.1 mg, and frozen at −80°C to await biochemical analysis. All remaining pups were discarded, except those in Groups 1 (exp/exp) and 4 (con/con), which were left with the dam until weaning at day 46 post-conception. Dams were fed the appropriate liquid diet up to day 35. Thereafter feeding reverted to lab chow and tap water *ad libitum*.

Water maze testing. Twenty animals (10 males and 10 females) from each of the exp/exp and con/con groups were tested in a water maze at 90 ± 12 days of age. The apparatus consisted of a stainless steel "T"-shaped container; the dimensions have been described in detail previously (35). The container was filled to a depth of 15 cm with 22°C tap water to which was added enough milk powder to ensure opacity. An escape platform was available in either the right or the left arm; the presence of this platform was indicated by striped stimulus cards which were placed inside plexiglass holders which lined the walls of the appropriate arm. These striped cards were generated by computer and had alternating vertical black and white stripes of width 0.6 cm, such that 50% of the area was black and 50% white. The arm of the maze which did not contain the platform also had computer-generated cards, with the same percentage of black and white as the striped card, but comprised of black dots on a white background, such that they appeared a uniform grey. It is customary in vision research to express the intensity of a striped stimulus grating in terms of "cycles per degree," which describes the relationship, at a constant distance, between the spatial frequency of the grating and the visual angle subtended by the animal's eye (43). The closer together the cycles, the smaller the visual angle between cycles, therefore the more cycles per degree of visual angle. Assuming that the behavioral choice occurred when the animal had reached the border of the T junction, and was facing the stripes on the back wall, the intensity of the striped stimulus can be expressed as 0.095 cycles per degree. Following two days of acclimation, which was comprised of a two min exposure to the maze with the striped stimulus cards and escape platform in each arm, each animal was tested on a block of six trials twice daily for five consecutive days. During testing the sequence of sides on which the platform was placed was randomized, with the constraint that there always be three presentations on each side in any one block. Following placement of the animal in the stem of the T, the number of seconds for it to reach the platform was recorded, as was the number of wrong turns it made. A wrong turn was defined as the animal's whole body (tip of nose to base of tail) pointing down an arm of the maze which did not contain the platform. The animal was allowed to rest on the platform for 20 seconds before being placed in a warmed, paper towel-lined cage, on top of a domestic heating pad, for a 30 second inter-trial interval. An animal was considered to have learned the task when only two wrong turns were made during two consecutive blocks (10/12 correct). When an animal reached this criterion, its next block of trials consisted of five trials, in which there was one presentation of the original stripe width, and one of each of four decreasing stripe widths, 0.6 cm, 0.3 cm, 0.15 cm, 0.075 cm and 0.0375 cm (*i.e.*, increasing cycles per degree, 0.095, 0.19, 0.38, 0.75 and 1.5). The order of presentation was randomized, as was the side of the "T" on which the stimulus cards were placed (left or right, relative to the grey cards). The objective of this last block of trials was to assess the limits of the animal's visual acuity, the rationale being that as the stripe width decreased, the animal would eventually be confronted by a stimulus which it would be unable to distinguish from grey, and would therefore have difficulty locating the platform.

Brain lipids. All tissue was coded such that the biochemical analysis was conducted independently of prior knowledge of the treatment conditions. The homogenized brains were extracted using a modified Bligh and Dyer method (44), utilizing chloroform/methanol (1:1, v/v), with 0.02% BHT (w/v). After separation and drying under nitrogen, the total lipids were fractionated by one-dimensional thin-layer chromatography (TLC), using silica gel plates (Analtech GF, Newark, DE) and a chloroform/methanol/acetic acid/water (50:30:4:2, by vol) solvent system. The fatty acids in the resulting phospholipid fractions were transesterified with 14% boron trifluoride in methanol, and analyzed on a gas chromatograph (Perkin-Elmer 8420, Norwalk, CT) equipped with a flame ionization detector and a 15 m × 0.32 m (i.d.) capillary column (Supelco Wax 10, Bellefonte, PA). The temperature program for the GLC run consisted of 2 min at 160°C, followed by a 2°/min increase to 190°C. After 10 min at 190°C the temperature was increased 5°/min to 220°C, followed by 2 min at 220°C.

Statistical analyses. The data were analyzed using the general linear model (GLM) provided by the Statistical Analysis System (SAS) to do analysis of variance (ANOVA), with the α level set at 0.05. The litter mean score, collapsed across sex, was used as the unit of analysis for the pup data, except for those measures obtained in the water maze, where one pup from each litter was tested. As the fatty acid determinations were conducted on the pooled brains from a litter, the litter also represents the unit of analysis for these measures. The sample sizes are shown in the respective tables, with an average of 15 litters per group. The few instances of missing data are due to experimenter oversight or technical problems. The experimental hypotheses were addressed by the pre-planned linear comparisons outlined here: i) Prenatal n-3 supplementation: exp/exp + exp/con *vs* con/exp + con/con; ii) postnatal n-3 supplementation: exp/exp + con/exp *vs* exp/con + con/con; iii) prenatal × postnatal interaction: exp/exp + con/con *vs* exp/con + con/exp; and iv) nutritional effects: exp/exp *vs* LC, con/con *vs* LC.

TABLE 2

Maternal and Pup Variables as a Function of Pre- and Postnatal Dietary Supplementation with n-3 Fatty Acids[a]

Prenatal diet	Exp	Con	LC	Effects[b]
Maternal wt. day 0 (g)	24.0 ± 0.2 (32)	24.2 ± 0.2 (36)	24.1 ± 0.3 (17)	
Maternal wt. gain to day 17 (g)	15.3 ± 0.7 (15)	15.6 ± 0.7 (15)	16.5 ± 0.6 (17)

[d]$p < 0.01$.

RESULTS

Maternal and pup weight. These data are presented in Table 2. Our previous work had shown no differences between groups in maternal diet consumption, and this was confirmed in the present study by analysis of the data for only half the dams (randomly chosen). There were no differences among groups in the average weight of the mothers at the beginning of the experiment, nor in the amount of weight gained during pregnancy. At birth, the exp and con pups were similar in weight, but weighed less than the LC pups, $F(1,81) = 9.85$, $p < 0.01$). There were no differences in litter size (data not shown). On day 32 postconception the pups of the dams fed liquid diets did not differ in weight, but were heavier than those of mothers fed lab chow, $F(4,79) = 4.20$, $p < 0.01$. There were no significant differences among the groups on day 32 for brain weight.

Behavioral development. As is seen in Figure 1, the overall development of the pups of dams which received the n-3 supplemented diet prenatally was advanced in comparison with those which received the control diet prenatally, $F(1,79) = 5.22$, $p < 0.025$. There was also a nutritional effect, in which the pups in the LC group were developmentally advanced when compared both with those in the exp/exp group and in the con/con group, $F(1,79) = 4.97$, $p < 0.05$ and $F(1,79) = 11.46$, $p < 0.01$, respectively. Table 3 shows the scores obtained on each of the individual tests, together with the outcome of the respective statistical analyses. It can be seen from the general pattern of these results that the major effect (other than the nutritional effects) was due to prenatal n-3 supplementation. In the single case for which there was a postnatal n-3 effect, the level screen test, the performance of the con/exp group was much worse than those of the other groups.

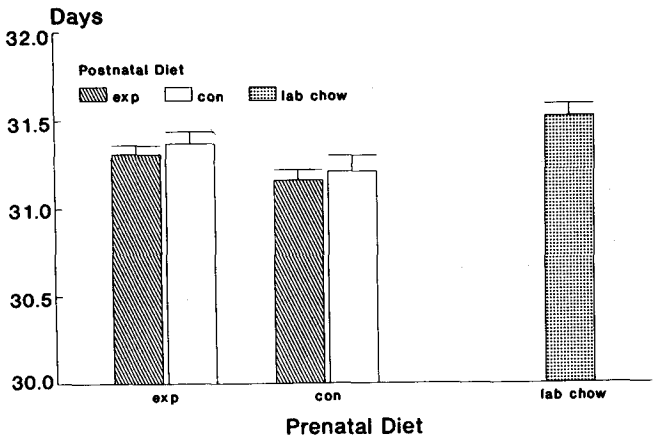

FIG. 1. Effect of pre- and postnatal dietary supplementation with n-3 fatty acids on behavioral development, expressed as "days postconception" in B6D2F$_2$ mice tested on day 32 postconception (exp = n-3 supplemented diet; con = control diet).

Water maze learning. There was no difference between the exp/exp and con/con groups with respect to the number of trials to reach criterion (exp Mean = 51.6 ± 3.0 SEM; con Mean = 51.9 ± 2.8 SEM). As shown in Figure 2 and supported by a repeated measures analysis, there was a clear effect of decreasing stripe width in increasing the time taken to escape to the platform, $F(4,25) = 7.87$, $p < 0.001$. This reflected the significant increase in the number of errors made by the animals as the stripe width decreased (data not shown). Neither escape time nor

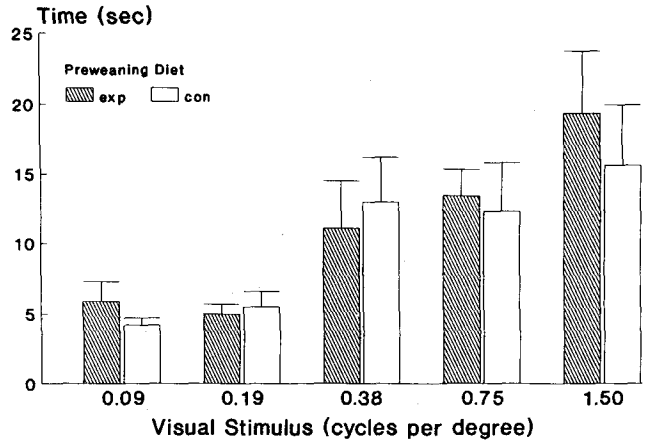

FIG. 2. Effect of stimulus intensity (*i.e.*, decreasing stripe width, expressed as increasing "cycles per degree") on visual discrimination in adult B6D2F$_2$ mice (exp = n-3 supplemented diet; con = control diet; preweaning = includes prenatal period and postnatal period prior to weaning).

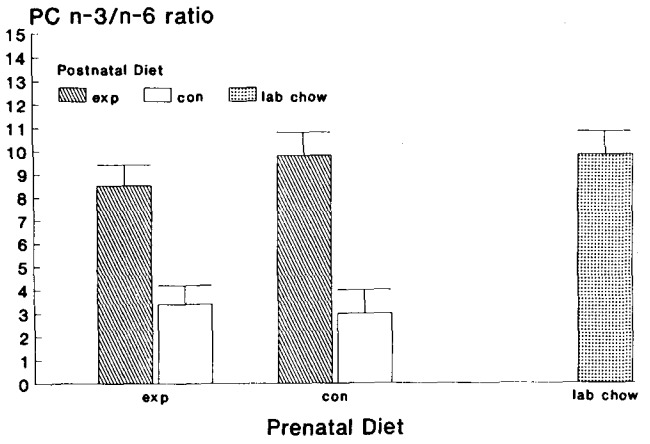

FIG. 3. Effect of pre- and postnatal dietary supplementation with n-3 fatty acids on long chain n-3:n-6 Ratio [(22:5n-3 + 22:6n-3)/(22:4n-6 + 22:5n-6)] of brain phosphatidylcholines in B6D2F$_2$ mouse pups on day 32 postconception (exp = n-3 supplemented diet; con = control diet).

number of errors showed a significant difference between the two dietary groups.

Brain phospholipid analysis. The fatty acid compositions of the brain phosphatidylcholine (PC) and phosphatidylethanolamine (PE) fractions from day 32 animals are shown in Tables 4 and 5; these include a detailed description of the significant results. At both ages, in both the PC and PE fractions, 20:4n-6 (AA) and 22:6n-3 (DHA) were the predominant long chain n-6 and n-3 fatty acids, respectively. At day 32, the PUFA composition of the brain reflected that of the pre- and postnatal dietary n-3 conditions. Dietary supplementation with n-3 compounds increased levels of n-3 fatty acids, particularly 22:5n-3 and 22:6n-3, with a concomitant decrease in levels of 22:4n-6 and 22:5n-6 in the groups which received the n-3 diet postnatally. This can be summarized by the long chain n-3/n-6 ratio, [(22:5n-3 + 22:6n-3)/(22:4n-6 + 22:5n-6)], which is shown in Figures 3 and 4. In the PC fraction this was increased by postnatal n-3, $F(1,73) = 46.98$, $p <$

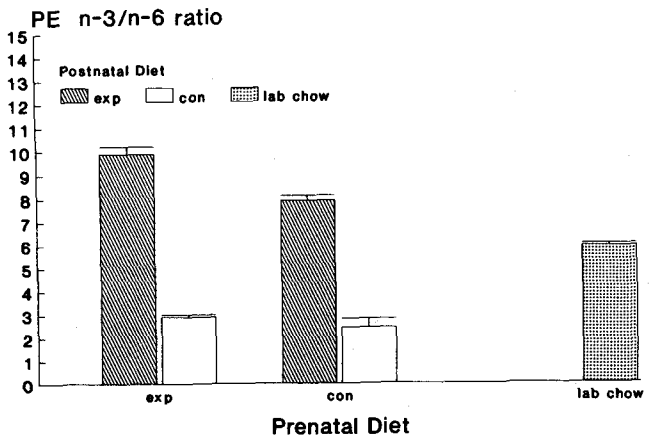

FIG. 4. Effect of pre- and postnatal dietary supplementation with n-3 fatty acids on long chain n-3:n-6 ratio [(22:5n-3 + 22:6n-3)/(22:4n-6 + 22:5n-6)] of brain phosphatidylethanolamines in B6D2F$_2$ mouse pups on day 32 postconception (exp = n-3 supplemented diet; con = control diet).

0.0001. The PE fraction showed significant effects of both pre-, F (1,72) = 25.91, $p < 0.0001$, and postnatal supplementation, F (1,72) = 616.63, $p < 0.0001$, with an interaction between the pre- and postnatal treatments, F (1,72) = 8.46, $p < 0.01$, due to a slightly larger postnatal effect in the exp/exp group. When compared with the group fed lab chow, in the PE fraction the ratio in the exp/exp group was greater, and in both the PE and PC fractions this value was lower in the con/con group. The total percentages of the C_{22} fatty acids are shown in Figures 5 and 6. In the PC fraction there was a significant prenatal effect, F (1,75) = 19.40, $p < 0.0001$, and a marginal postnatal effect, F (1,75) = 3.04, $0.1 > p > 0.05$, with n-3 supplementation increasing the amount of these long chain compounds. The PE fraction, while showing pre-, F (1,72) = 10.67, $p < 0.01$, and large postnatal effects, F (1,72) = 31.22, $p < 0.0001$, also showed a significant interaction, F (1,72) = 4.57, $p < 0.05$, due to a large increase due to postnatal supplementation in the con/exp group. In both fractions, the total C_{22} fatty acids in the exp/exp group exceeded that of the lab chow control. With respect to the individual fatty acids, it is worth noting that in the PE fraction levels of 22:6n-3 in the con/exp group were equivalent to those found in the exp/exp group, Interaction F (1,72) = 5.3, $p < 0.05$. There were also decreases in levels of 20:4n-6 due to postnatal n-3 supplementation, F (1,72) = 127.11, $p < 0.0001$. In both the PC and PE fractions the levels of 20:3n-6 were increased by prenatal [PC: F (1,75) = 17.15, $p < 0.0001$; PE: F (1,72) = 16.27. $p < 0.001$] and postnatal n-3 supplementation, [PC: F (1,75) = 69.51, $p < 0.0001$; PE: F (1,72) = 91.24, $p < 0.0001$]. This reflects the inhibition of the activity of Δ5 desaturase by long chain n-3 compounds, and is consistent with our previous findings (36,42). The analysis of the adult brains from the exp/exp and con/con dietary groups (which were subsequently weaned onto lab chow)

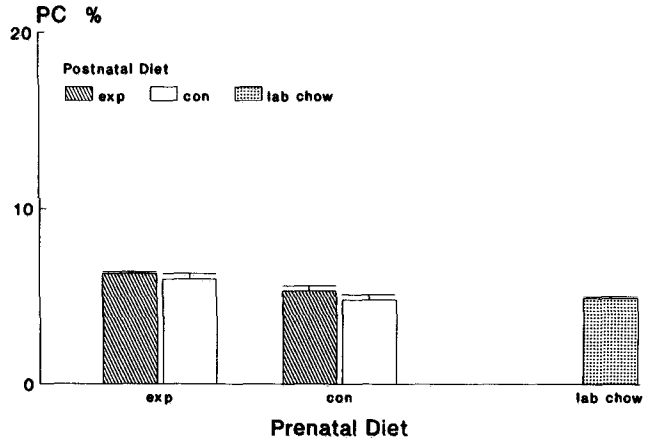

FIG. 5. Effect of pre- and postnatal dietary supplementation with n-3 fatty acids on total percentage of C_{22} polyunsaturated fatty acids [(22:5n-3 + 22:6n-3 + 22:4n-6 + 22:5n-6)] of brain phosphatidylcholines in B6D2F$_2$ mouse pups on day 32 postconception (exp = n-3 supplemented diet; con = control diet).

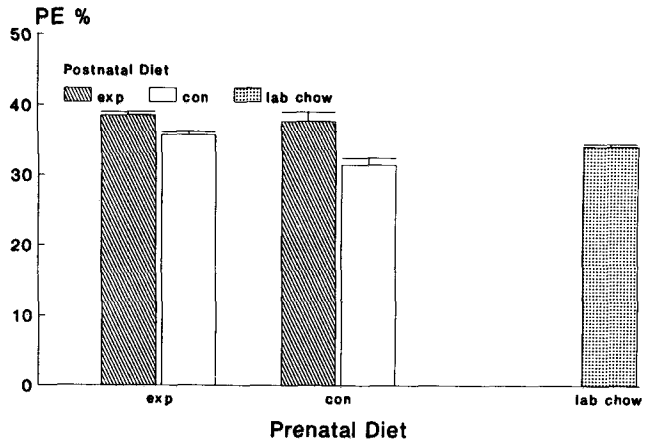

FIG. 6. Effect of pre- and postnatal dietary supplementatiuon with n-3 fatty acids on total percentage of C_{22} polyunsaturated fatty acids [(22:5n-3 + 22:6n-3 + 22:4n-6 + 22:5n-6)] of brain phosphatidylethanolamines in B6D2F$_2$ mouse pups on day 32 postconception (exp = n-3 supplemented diet; con = control diet).

are shown in Table 6. The only notable differences were in the PE fraction and included increases in 18:2n-6, 18:3n-6 and 22:5n-6 in the con/con group.

Dependent variable correlations. Pearson product-moment correlation coefficients were calculated within groups for the litter-mean scores obtained on the overall developmental score, eye opening, and PC and PE levels of 22:6n-3. As expected, there were consistent positive correlations between the overall score and eye-opening, but neither of these scores correlated with the DHA levels (data not shown).

DISCUSSION

The hypothesis of this study was that supplementation of the maternal diet with n-3 fatty acids during the pre- and/or postnatal periods would accelerate indices of sensorimotor development in the pups, and would also contribute to differences in discrimination learning ability

and visual acuity in these animals as adults. The design of the study incorporated methodological controls which are important in interpreting effects of n-3 supplementation during development. First, cross-fostering procedures are necessary to separate pre- from postnatal effects on development. Similarly, in order to establish that the provision of n-3 compounds during prenatal and preweaning development is indeed critical with respect to adult behavior, all pups which are tested as adults should be weaned onto a control diet. This is because considerable plasticity has been demonstrated in the brains of postweaning and adult animals with respect to dietary fatty acid content, particularly the n-3 compounds, with the observed changes occurring within days to a few weeks (17-19,45-48). Second, before differences on a learning task can be attributed unequivocally to differences in ability to make the required association, it is necessary to exclude possible effects on sensory thresholds. Finally, in conducting developmental studies in a species where multiple births are the norm, the litter, and not the individual pup, should be used as the independent unit of analysis; failure to do this may inflate artificially the power of the design (49).

The results on behavioral development support our previous work in showing an effect of n-3 supplementation, and identify the prenatal period as critical. In the present study both sensory and motor categories were affected and again there was a strong effect on the eye-opening score. This replication of the n-3 effects occurred despite the fact that in this study the differences in maternal weight gain observed previously were not there (35,42), and by day 32 postconception the pups in both liquid diet groups were slightly heavier than the lab chow controls. This confirms that the effects on behavioral development were not related to differences in caloric availability or utilization. However, these effects were very modest in size, with the statistical significance reflecting the power provided by the large number of litters tested. There were no significant differences between

adult animals from the exp/exp and con/con groups when they were tested on visual discrimination learning ability. Neither did they appear to differ in visual acuity, with a similar increase in the number of errors with decreasing stimulus width. These results are at variance with those cited previously (31-34). However, this may be explained by differences among the studies related to the methodological issues discussed above, particularly with respect to the learning behavior, where in the previous work the animals were tested while still undergoing dietary treatment.

The analyses of the fatty acid content of the PC and PE fractions from the pup brains on day 32 postconception show that the long chain PUFA composition reflects both the pre- and postnatal dietary treatments, with an increase in 22:5n-3 and 22:6n-3 in the n-3 supplemented group, with a concomitant decrease in 22:5n-6 and 22:4n-6. Previous work has shown that the fatty acid composition of the newborn brain reflects that of the maternal diet during gestation (20,35,42), and the present results indicate considerable plasticity of these measures with respect to the composition of the maternal diet during lactation as well. Noteworthy in this respect is the large effect of the postnatal supplementation in the PE fraction, where the total amount of 22:6n-3 was as high in the con/exp group, which received the n-3 supplementation only during the 12 day postnatal period, as in the exp/exp group which was supplemented during gestation and lactation. Thus, these results show that the n-3/n-6 ratio of the long chain PUFA in the brain of the developing offspring can be altered within days through manipulation of the n-3 content of the maternal diet during lactation. Another potentially important finding of this work is that of the increase in the C_{22} fatty acids by the long chain n-3 supplementation. However, it should be noted that while our analysis shows a proportional increase, in the absence of absolute values it is not possible to determine whether there were changes in the actual lipid pool sizes. Nevertheless, these data are consistent with reports of the preferential uptake by the developing brain of preformed, longer chain, more unsaturated fatty acids (50,51). It is possible that, as has been shown in adult animals, the developing brain is not protected against an excess of very long chain PUFA (48). Previous work has shown that rats supplemented with n-3 during development maintain higher levels of 22:6n-3, even following a further two months on a n-3 deficient diet (52). Because of the possible functional consequences of such changes, and the increasing commercial availability of highly purified fatty acids, future work should address this question in the context of a dose-response relationship. The fact that the adult animals in the con/con group had similar n-3 levels to those of the exp/exp group shows an ability to regain normal composition by incorporating dietary n-3 after weaning. The lingering increase in 22:5n-6 seen in the adult animals of the con/con group is consistent with some previous work on EFA deficiency during early development (53).

In summary, these results show that the long chain n-3 fatty acid content of developing mouse brain, when measured in the preweaning period, very readily reflects the n-3 content of the pre- and postnatal maternal diet; most of these effects are reversible by the postweaning diet. Despite a small acceleration of indices of sensorimotor development, particularly eye-opening, by prenatal n-3 dietary supplementation, there is no enduring effect of n-3 supplementation during both the prenatal and preweaning periods on functional abilities related to visual learning capacity.

ACKNOWLEDGMENTS

Financial assistance for this work was provided by research grants from the Natural Sciences and Engineering Council of Canada to P. Wainwright and D. Mills. The authors are indebted to R. Ward and B. Parker for technical assistance in analysis of the dietary oils and brain lipids, respectively, L. Giglia and D. Winfield for help in feeding the animals, C. Campbell for computer programming, and D. Sutherland for secretarial assistance.

To investigate the effect of *trans* fatty acids on plasma lipid levels and systolic blood pressure, hydrogenated corn oil was fed to SHRSP (stroke-prone spontaneously hypertensive rats) and WKY (Wistar-Kyoto) rats for 30 days. Significantly lower systolic blood pressure and plasma total cholesterol were observed in SHRSP rats fed *trans* fatty acids when compared with rats fed *cis* fatty acids from olive oil. In addition, higher HDL cholesterol and lower VLDL plus chylomicron cholesterol levels were found in SHRSP rats fed *trans* fatty acids. Although no significant changes of systolic blood pressure and plasma total cholesterol levels were observed in WKY rats after *trans* fatty acids treatment, WKY rats fed *trans* fatty acids had lower plasma LDL cholesterol and higher HDL cholesterol levels. In addition, platelet aggregation induced by collagen was decreased in WKY rats fed *trans* fatty acids. It is interesting that *trans* fatty acids increased the activity of plasma lecithin:cholesterol acyltransferase (LCAT) in both SHRSP and WKY rats. The observed influence of *trans* fatty acids on plasma lipid levels, systolic blood pressure and platelet aggregation suggests that *trans* fatty acids might prevent thrombotic disorders in SHRSP rats.

***Lipids* 26, 46–52 (1991).**

The unsaturated fatty acids of vegetable and animal fats possess the *cis* configuration almost exclusively. In the 18:1 and 18:2 fatty acids, the double bonds are typically located at the ω9 and ω6 positions. Hydrogenated vegetable oil used as cooking oils, shortenings and margarines contains *trans* unsaturated fatty acids, which can amount to more than one-third of the total fatty acids present (1–4).

Dietary *trans* fatty acids have been shown to be incorporated into various tissues of rat (5–7). Autopsy and biopsy studies have revealed that they are also found in human tissues, with highest concentrations in liver and adipose tissues (8). In addition, *trans* fatty acids have also been identified in human milk (9). Although the amount of *trans* fatty acids that can be deposited in tissues has been shown to be related to the amount of *trans* fatty acids in the diet (10), Adlof and Emken (8) demonstrated that no *trans* 18:3 isomers were detected in human tissues and that *trans* 18:2 isomers would not be expected to have a significant physiological impact. The studies on the biological effects of *trans* fatty acids were typically focused on elaidic acid (*trans*-9-octadecenoate), because *trans* monoenoic acids (*t*-18:1) are quantitatively important components of our diet (11).

Although the effects of *trans* fatty acids on serum lipid levels and on the development of atherosclerosis have been studied in both animals and human (12–15), results have been inconclusive. Sugano *et al.* (16) reported that *trans* fatty acids are hypercholesterolemic in some cases and normocholesterolemic in others. A major reason for this discrepancy seems to be the difference not only in the types and amounts of *trans* fatty acids ingested, but also in the amount of dietary linoleic acid present in the experiments. It is, therefore, of considerable importance to examine the metabolism and biological properties of *trans* 18:1 fatty acids.

In the present study, the effect of *trans* fatty acids on plasma lipids and platelet function was studied using SHRSP (stroke-prone spontaneously hypertensive rats) and WKY (Wistar-Kyoto) rats given 1% NaCl water for four weeks.

MATERIALS AND METHODS

Eight-week-old SHRSP rats were used as experimental models and WKY rats of the same age were chosen as controls. Each of the two groups was divided into two subgroups (*cis*-FA and *trans*-FA) of equal body weight and systolic blood pressure. They were housed in individual stainless steel cages in a room kept at 23 ± 1°C. Fresh diets and 1% NaCl drinking water were available *ad libitum* for 30 days. The composition of the basal diet is shown in Table 1 and the fat composition of each diet is shown in Table 2 (17).

TABLE 1

Composition of Experimental Diet

Casein	20%
Mineral mixture[a]	4
Vitamin mixture (water souble)	1
Vitamin mixture (fat souble)[b]	1
Cholesterol	0.5
Cholic acid	0.3
cis or *trans* Fat[c]	10
Corn starch	up to 100

[a]Harper's salt mixture.

[b]100 Grams of vitamin mixture contain: Vitamin A, 150,000 IU; vitamin E, 2 gram; *p*-aminobenzoic acid, 1 gram; and choline chloride, 15 gram.

[c]*cis* Fat: 86% olive oil + 14% tristearin; *trans* fat: 94% + hydrogenated corn oil + 6% safflower oil; 500 gram of fats contain 10,000 IU vitamin D.

20:0	0.4	0.2
22:0	0.1	0.6

[a] Fatty acid compositions were determined by gas liquid chromatography (17).

[b] C: *cis*-isomers; T: *trans*-isomers.

Determination of blood pressure. The arterial blood pressure of unaesthetized rats was measured by the indirect method using the caudal artery (18).

Fatty acid analysis. Analysis of fatty acyl groups of total lipids was done by gas-liquid chromatography of the corresponding methyl esters (19). Fatty acid esters were analyzed using a quadrex fused silica capillary column (20) (Silar 10C, 0.25 mm I.D. × 25 m × 0.25 μ film; oven temperature, 160°C to 170°C at 0.5°C/min) and a 15% DEGS column. Methyl esters of 18:2 (*tc* + *ct*) used as standards were generously supplied by the Japan Institute of Oils & Fats, Other Foods Inspection Foundation (Tokyo, Japan) (17); other fatty acid ester standards were purchased from Funakoshi Pharmaceutical Co. (Tokyo, Japan).

Determination of plasma lipids and lipid peroxides. Total cholesterol, phospholipids, triacylglycerols and free cholesterol in plasma were determined by enzymatic methods (20) using kits purchased from Wako Pure Chemical Company (Osaka, Japan). High density lipoprotein (HDL), low density lipoprotein (LDL), and very low density lipoprotein (VLDL) plus chylomicrons in plasma were determined by ultracentrifugation (21). The thiobarbituric acid (TBA) value of rat plasma was determined by the method of Yagi *et al.* (22).

Platelet aggregation induced by collagen. The platelet count of platelet rich plasma (PRP) was adjusted to a concentration of 6 × 10^6 cells/μL with autologous platelet poor plasma (PPP) (23). PRP was incubated with 60 μg/mL of collagen (Hormon-Chemie, Munich, Germany) in a Lumi-Aggregometer (Chrono-Log Corporation, Broomall, PA). The change in light transmission after the addition of aggregants was recorded.

Determination of prostaglandins (PG) and thromboxanes (TX). Rat kidney and platelet PG and TX were determined by the method of Kiyomiya *et al.* (24). The arachidonate metabolites were extracted by the method of Powell (25) using a Sep-pak C18 cartridge (26). The resultant fraction containing PG and TX was allowed to react with 9-anthryldiazomethane (ADAM). After removing contaminants and degraded reagent by silica gel Sep-pak, samples were applied to reverse phase high-performance liquid chromatography on octadecylsilyl silica gel (Cosmosil 5 C18, 4.6 mm I.D. × 150 mm; Nacalai; Tesque Inc., Kyoto, Japan) and monitored by a fluorescent detector. PGE_2, $PGF_{2\alpha}$, 6-keto-$PGF_{2\alpha}$ and TXB_2 were generously supplied by Ono Pharmaceutical Co. (Osaka, Japan). ADAM was purchased from Funakoshi Pharmaceutical Co. Silica gel Sep-pak and C18 Sep-pak were purchased from Waters Associates (Milford, MA).

Measurement of urine volume. Rats were moved into metabolic cages on day 28. The volume of urine for a 24-hr period was recorded at 3:00 p.m. The room temperature was kept at 23 ± 1°C.

Determination of LCAT activity. LCAT activity was measured by the method of Strokke and Norum (27) and was expressed as percentage of labeled cholesterol acylated per hour.

RESULTS

No significant difference in body weights was observed between the *cis* fat group and the *trans* fat group of SHRSP rats (range, 210–230 g) or WKY rats (range, 255–270 g) at the end of the fourth week.

Systolic blood pressure. The systolic blood pressure of the rats fed the experimental diets is shown in Figure 1. SHRSP rats fed *trans* fat showed a significant reduction in systolic blood pressure at the end of the experimental period. However, no significant influence on systolic blood pressure was observed in WKY rats fed the experimental diets.

Plasma lipids. Statistical analysis of plasma total cholesterol and lipoprotein cholesterol levels revealed a significant difference between animals fed *trans* fat and those fed *cis* fat. SHRSP rats fed hydrogenated corn oil showed significantly increased HDL cholesterol and decreased total cholesterol levels (Table 3). In addition, a significant decrease in the plasma lipoprotein cholesterol levels associated with LDL and VLDL plus chylomicrons was also observed in SHRSP rats fed *trans*

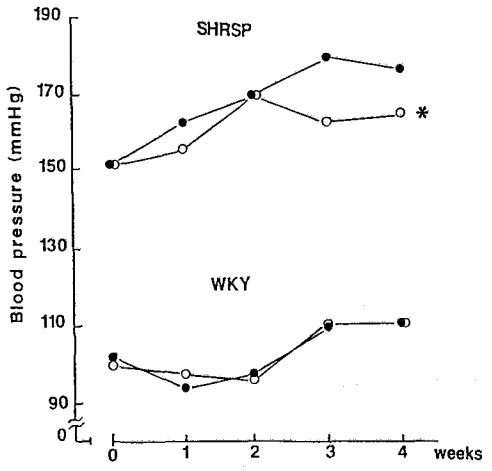

FIG. 1. Effect of *trans* fatty acids on systolic blood pressure in rats. Each point represents the average value from eight rats. *cis* Fat group, —●—; *trans* fat group, —○—. *Significant difference from the *cis* fat group at $p < 0.05$.

TABLE 3

Effect of Dietary *trans* Fatty Acids on Plasma Total Cholesterol and Cholesterol Associated with HDL, LDL, and VLDL plus Chylomicrons[a]

Exp. group	Diet	Cholesterol (mg/100 mL)							
				HDL		LDL		VLDL + Chylomicrons	
		Total	Free	Total	Free	Total	Free	Total	Free
SHRSP	*cis*-FA	83 ± 13[a]	20 ± 3[b]	24 ± 2[c]	6 ± 2	15 ± 3[d]	4 ± 1	32 ± 5[e]	9 ± 3
	trans-FA	50 ± 10[a]	10 ± 2[b]	31 ± 1[c]	5 ± 2	8 ± 3[d]	2 ± 1	16 ± 4[e]	5 ± 2
WKY	*cis*-FA	68 ± 12	16 ± 4	24 ± 3[f]	5 ± 2	21 ± 3[g]	6 ± 1	19 ± 2	7 ± 1
	trans-FA	58 ± 7	12 ± 3	38 ± 4[f]	7 ± 1	12 ± 2[g]	4 ± 2	14 ± 2	4 ± 1

[a]Results are expressed as mean ± SD for 8 rats per each dietary group. Values in the same column of each experiment with the same superscript letter are significantly different ($p < 0.05$).

TABLE 4

Effect of Dietary *trans* Fatty Acids on Plasma Triacylglycerols and Phospholipids[a]

Exp. group	Diet	Triacylglycerols (mg/100 mL)	Phospholipids (mg/100 mL)
SHRSP	*cis*-FA	91 ± 8	112 ± 3[a]
	trans-FA	100 ± 12	140 ± 16[a]
WKY	*cis*-FA	62 ± 15	98 ± 6
	trans-FA	70 ± 11	110 ± 7

[a]Results are expressed as mean ± SD for eight rats per each dietary group. Values in the same column of each experiment with the same superscript letter are significantly different ($p < 0.05$).

fat. Although there was no significant change in plasma total cholesterol in WKY rats fed the experimental diets, higher HDL cholesterol was found in the rats fed *trans* fat. The results for plasma phospholipids and triacylglycerols are given in Table 4. A significant increase in plasma phospholipid levels was observed in SHRSP rats fed *trans* fat, but no significant change was found in WKY rats fed the experimental diets. No significant difference in triacylglycerol values was observed between rats on the *cis* fat diet and on the *trans* fat diet. It is interesting to note that the ratio of plasma total cholesterol to phospholipids in rats fed *trans* fat were significantly ($p < 0.05$) decreased not only in SHRSP rats (mean ± SD; 0.7 ± 0.0 for *cis* fat group and 0.4 ± 0.1 for *trans* fat group), but also in WKY rats (mean ± SD; 0.6 ± 0.0 for *cis* fat group and 0.5 ± 0.0 for *trans* fat group).

Platelet aggregation. As shown in Figure 2, platelet aggregation induced by 60 μg/mL collagen was markedly reduced in WKY rats fed *trans* fat. Because of the hypoaggregability in SHRSP rats (28), there was no significant difference between the SHRSP groups.

Prostaglandins production of kidney. Figures 3 and 4 show the levels of PGE_2 and $PGF_{2\alpha}$ in kidney from rats fed experimental diets for four weeks. Although *trans* fat significantly decreased the level of $PGF_{2\alpha}$ production in kidney of SHRSP rats, the amount of PGE_2 formed in rats fed *trans* fat was only slightly decreased, which resulted in an increase of the ratio of $PGF_2/PGF_{2\alpha}$ in kidney of SHRSP rats. Both the levels of PGE_2 and $PGF_{2\alpha}$ in kidney from WKY rats fed the *trans* fat were significantly decreased, but no significant difference was found in $PGE_2/PGF_{2\alpha}$ ratios of the two dietary groups (Fig. 5).

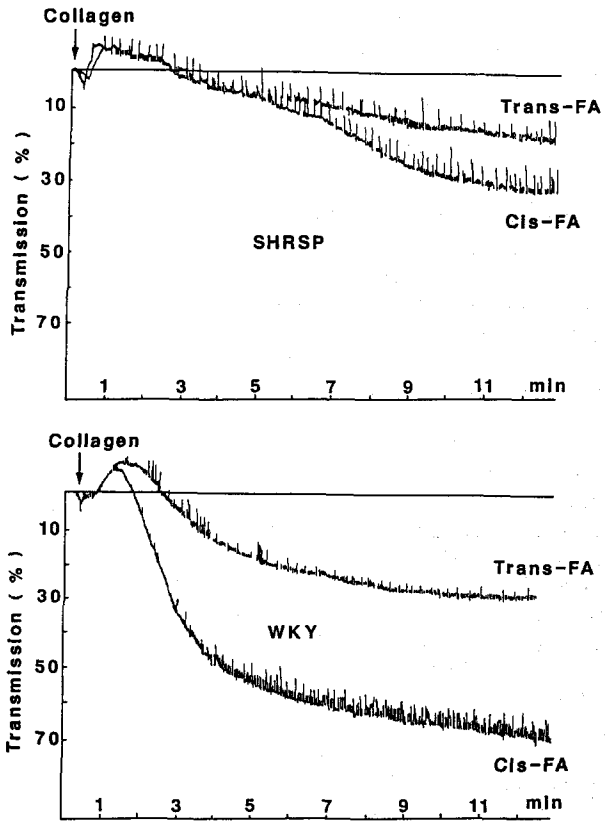

FIG. 2. Effect of *trans* fatty acids on platelet aggregation in SHRSP and WKY rats. Citrate PRP was preincubated for 2 min at 37°C, then the platelet response to collagen (60 μg/mL) was tested.

Urine excretion. The volume of urine excreted is shown in Figure 6. SHRSP rats fed *trans* fat showed a decrease in urine excretion, which reflected the diuretic effect of *trans* fatty acids induced by the higher ratio of $PGF_2/PGF_{2\alpha}$ in kidney when compared to that of rats fed *cis* fat. In WKY rats fed *cis* fat and *trans* fat, there was no significant difference in the ratio of $PGE_2/PGF_{2\alpha}$ in kidney, and there was no significant change in urine excretion volume.

Plasma lipids peroxide. The plasma thiobarbituric acid (TBA) values for SHRSP rats (4.0 ± 0.5 nmole MDA/mL)

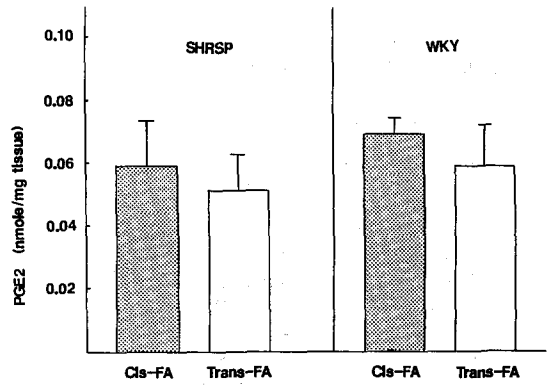

FIG. 3. Effect of dietary *trans* fatty acids on PGE_2 level in kidney of rats. Results are expressed as mean ± SD for eight rats in each dietary group.

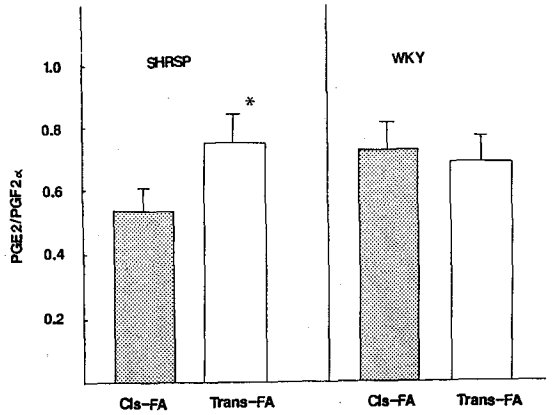

FIG. 5. Effect of dietary *trans* fatty acids on $PGE_2/PGF_{2\alpha}$ in kidney of rats. Results are expressed as mean ± SD for eight rats in each dietary group. *Significant difference from the *cis* fat group at $p < 0.05$.

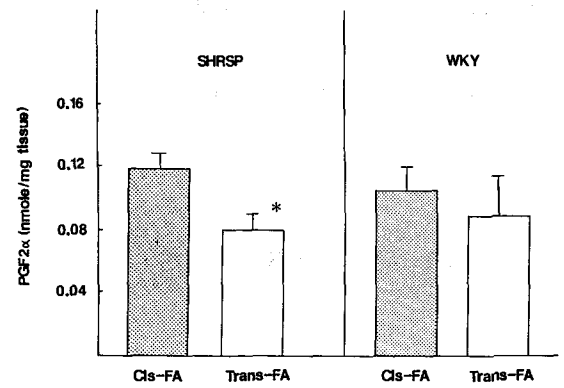

FIG. 4. Effect of dietary *trans* fatty acids on $PGF_{2\alpha}$ level in kidney of rats. Results are expressed as mean ± SD for eight rats in each dietary group. *Significant difference from the *cis* fat group at $p < 0.05$.

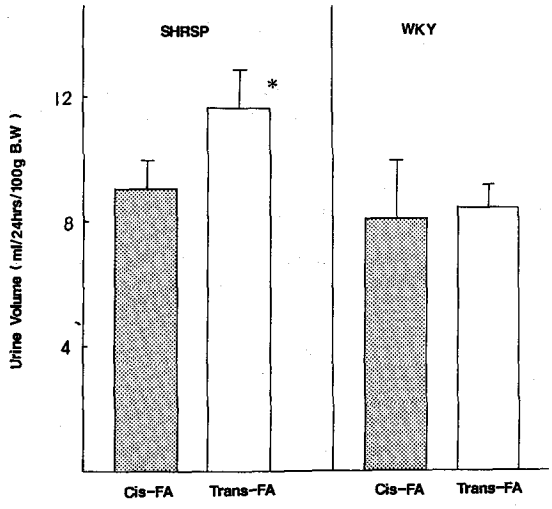

FIG. 6. Effect of dietary *trans* fatty acids on urine excretion for 24 hr in rats. Results are expressed as mean ± SD for eight rats in each dietary group. *Significant difference from the *cis* fat group at $p < 0.05$.

and WKY rats (5.3 ± 0.5 nmole MDA/mL) on the *trans* fat diet were significantly decreased ($p < 0.05$) when compared to animals that received the *cis* fat diet (2.8 ± 0.2 nmole MDA/mL in SHRSP rats, and 4.0 ± 0.5 nmole MDA/mL in WKY rats) for 30 days.

Fatty acid composition of the tissues. In platelets, *trans* 18:1 fatty acid was found in total lipids in both SHRSP and WKY rats. Although there was no significant change of the level of 20:4n-6 in total lipids of platelets from rats fed the experimental diets, the ratio of 20:4/18:2 decreased with dietary *trans* fatty acids. In addition, linoleic acid (18:2) levels in platelets of animals fed the *trans* fat were higher than in platelets of animals fed the *cis* fat, as shown in Table 5. On the other hand, the changes of fatty acid composition in kidney appeared to be similar to those of platelets in animals fed the experimental diets (Table 6).

LCAT activity. Significant ($p < 0.05$) increases in plasma LCAT activity were found in rats fed the *trans* fat for 30 days. The LCAT activities in plasma of animals of the *cis* fat group and the *trans* fat group were 5.8 ± 2.1 and 10.9 ± 1.5% cholesterol esterified/hr in SHRSP rats and 7.8 ± 0.9 and 10.3 ± 1.2% cholesterol esterified/hr in WKY rats.

DISCUSSION

Various studies have indicated a relationship between dietary intake, particularly of dietary fat, and cardiovascular disease in different populations (29). It has been shown that the degree of atherosclerosis can depend on the type of dietary fat and that it closely correlates with increased blood lipid concentrations (15,30-32).

Hydrogenation of vegetable oil causes positional and geometrical isomerization of the natural *cis* double bonds in fatty acids. These isomeric fats, which can constitute 5-8% of the fatty acids in human diets, are readily absorbed and deposited in tissues. Deposition of *trans* fatty acids in tissues appears to be selective. *trans* Octadecenoate is primarily incorporated into phospholipids and triacylglycerols of plasma, liver, heart, adipose, kidney, and red blood cells (33-35). Adipose tissue and liver generally contain higher levels than do other tissues (8). Minimum deposition of *trans* fatty acids occurs in the brain (36). Higher levels of 16:1 and 18:2 in platelets and

[c]Values in the same column of each experiment with the same superscript letter are significantly different ($p < 0.05$).

kidney of rats fed *trans* fat were observed when compared with rats fed *cis* fat diet. This could indicate that elaidic acid (*t*-18:1n-9) may inhibit the conversion of 18:2n-6 to 20:4n-6 by acting as a competitive inhibitor of desaturases (*e.g.*, Δ6 desaturase) (37). Other studies have shown that *trans* fatty acids have no adverse effects if rats are also fed adequate amounts of essential fatty acids (38,39); this is similar to what we found in the present study.

Many investigators have focused on the effect of *trans* fatty acids on eicosanoid metabolism, because there is evidence that dietary *trans* fatty acids may regulate prostaglandin (PG) synthesis by affecting the enzymes of PG metabolism (37). Zevenbergen and Haddeman (11) found that high amounts of *trans* fatty acids in hydrogenated vegetable oil do not interfere with the cyclooxygenase or lipooxygenase pathways. Our results, however, indicate

that *trans* fatty acids may possibly influence eicosanoid metabolism by affecting tissues phospholipase A_2 activities in both SHRSP and WKY rats.

Douglas *et al.* (40) reported that vitamin E inhibited phospholipase A_2 *in vivo* and *in vitro* in a dose-dependent manner. It is also well known that higher TBA values typically correlate with lower vitamin E concentrations in tissues. Results of the present study indicate that *trans* fatty acids may reduce the consumption of vitamin E in plasma, which may result in lower phospholipase A_2 activity and in a reduction in platelet aggregability.

On the other hand, studies on the relationship between cholesterol levels and platelet aggregation by Shattil *et al.* (41) showed that cholesterol acquired by platelets may exert its effect by modifying the platelet membrane. Wörner and Patscheke (42) reported that increases in the cholesterol/phospholipid ratios of platelets resulted in increased aggregation and liberation of arachidonate. In addition, more recent studies demonstrated that in cholesterol-enriched platelets (pre-labelled with [^{14}C]arachidonic acid), thrombin stimulation led to the release of more arachidonic acid from pre-labelled platelet phospholipids (43). It is possible that cholesterol induces an increase in platelet membrane microviscosity, thereby affecting the activity of phospholipase A_2, which can be responsible for the release of arachidonic acid. Therefore, lower platelet aggregability is possibly related to lower cholesterol-to-phospholipid ratios in blood.

Furthermore, studies on the acute effects of lipoproteins on platelet function showed that VLDL, as well as LDL, increased platelet aggregation (28). Brook *et al.* (44) found that the platelet [^{14}C]serotonin release and platelet aggregation paralleled changes in LDL levels. It is thus suggested that lower platelet aggregability in rats fed *trans* fatty acids might be due to the lower cholesterol-to-phospholipid ratios and the lower levels of LDL and VLDL cholesterol.

SHRSP rats fed *trans* fatty acids having a decreased systolic blood pressure might show a lower risk of thrombosis, since the incidence of stroke in SHRSP rats is dramatically diminished if the blood pressure in controlled (45). The hypotensive effect of *trans* fatty acids in SHRSP rats may be due to the high ratio of PGE_2-to-$PGF_{2\alpha}$ in kidney.

The two principal prostaglandins, PGE_2 and $PGF_{2\alpha}$, have opposing effects—PGE_2 is a vasodilator which increases blood flow and participates in the regulation of water and salt excretion; $PGF_{2\alpha}$ is a vasoconstrictor. Although lower phospholipase A_2 (PLA_2) activity in rats fed *trans* fatty acids could decrease the synthesis of PGE_2 and $PGF_{2\alpha}$, SHRSP rats require adequate amounts of PGE_2 to facilitate excretion of excess sodium, since SHR rats have a high preference for NaCl (46). Results of the present study showed that slightly decreased PGE_2 levels and significantly decreased $PGF_{2\alpha}$ levels caused the higher ratios of PGE_2-to-$PGF_{2\alpha}$ that occurred in SHRSP rats fed the *trans* fatty diet. Higher $PGE_2/PGF_{2\alpha}$ ratios in the kidney might thus play an important role in protecting against the development of hypertension and be beneficial in the prevention of thrombosis in SHRSP rats. We therefore suggest that dietary *trans* fatty acid may influence the type of prostaglandins produced in the kidney that exert the hypotensive effect in SHRSP rats.

LCAT is thought to prevent the accumulation in plasma of unesterified cholesterol derived from the surface of chylomicrons and VLDL. In addition, LCAT may play a role in the transport of unesterified cholesterol from peripheral tissues to the liver (47). Because some cholesteryl ester could arise from LCAT activity in that the cholesteryl esters of the HDL exchange with those of LDL and VLDL plus chylomicrons (48), the appearance of the ester in serum LDL and VLDL might serve as an indicator of the extent of the exchange reaction (49), as no cholesteryl eicosatrienoate appears to be produced in liver. It is thus suggested that the lower level of plasma VLDL plus chylomicron cholesterol in rats fed *trans* fat possibly resulted from the higher plasma LCAT activity.

Moore *et al.* (20) has reported that plasma LCAT activity generally decreased when *trans* fatty acids were fed to rats, and the decreased esterification of cholesterol might be related to a reduced amount of free cholesterol in serum. However, other investigators showed that there was no or an inverse correlation between LCAT activity and serum cholesterol levels (50,51). Takatori *et al.* (49) demonstrated that an initial increase in LCAT activity was observed in rats fed a concentration of elaidic and linoelaidic acids. In the present study, higher HDL cholesterol and lower total cholesterol levels were found in rats fed *trans* fat.

Several earlier studies had shown that *trans* fatty acids have a plasma cholesterol-elevating effect (52–54). Other investigators found that there was no significant increase of plasma cholesterol levels due to *trans* fatty acids (13,20). Although data are available on the effect of dietary *trans* fatty acids, they are often inconclusive because of poor experimental design, lack of appropriate controls, and because of poorly defined diets. Recent studies showed that *trans* monoenoic acids have either no effect or a lowering effect on plasma cholesterol levels (16,17). Several hypotheses have been advanced to explain why blood cholesterol levels are lowered by these fatty acids, including a possible reduction of cholesterol absorption together with a lower rate of fat absorption and modulation of intestinal cells to process cholesterol (16). According to the results of the present study, it is possible that the low level of the total plasma cholesterol may be explained on the basis of impaired secretion of cholesterol and cholesteryl ester of *trans* fatty acids from liver, together with an increase in plasma LCAT activity.

Thus, it appears that selectively hydrogenated vegetable oils, as they are used in margarine manufacture, and which contain positional and geometrical isomers of the unsaturated fatty acids, not only are digestible as determined by long-term studies (38), but also appear to offer a prophylactic approach to the prevention of thrombotic disorders as shown in SHRSP rats.

Possible Essentiality of Docosahexaenoic Acid in Japanese Monkey Neonates: Occurrence in Colostrum and Low Biosynthetic Capacity in Neonate Brains

The importance of mother's milk as a source of docosahexaenoic acid (DHA) in Japanese monkey neonates was investigated. The DHA content in monkey colostrum total lipids was 2.2%, similar to or slightly higher than in humans. A comparison of the biosynthetic capacity of brain microsomes from monkeys of different age (up to 10 years) showed that chain elongation/desaturation of linolenic acid and eicosapentaenoic acid in neonates was significantly less pronounced than in adults. In particular, the formation of DHA, which is the product of Δ4 desaturase, was negligible. These results suggest that milk is an important source of DHA in Japanese monkey neonates.
Lipids 26, 53–57 (1991).

Long-chain polyunsaturated fatty acids (PUFA), which are major fatty acid components at the 2-position of glycerophospholipids in membranes, are thought to be essential for maintaining fluidity and physiological activity. Docosahexaenoic acid (DHA, 22:6n-3) is particularly abundant in phosphatidylethanolamine of brain grey matter (1) and retina (2). In these tissues, most of the n-3 PUFA is DHA, not eicosapentaenoic acid or linolenic acid. DHA is known to be selectively incorporated into the developing brain (3,4). Holman *et al.* (5) reported a neurological disturbance in a 6-year-old girl who was maintained on parenteral nutrition that lacked n-3 PUFA. Neuringer *et al.* (6,7) found that dietary n-3 fatty acid deprivation caused subnormal visual acuity in rhesus monkeys. Feeding of n-3 PUFA-deficient oils to rats was shown to decrease DHA level in brain phospholipids (8–10) and be associated with inferior learning capacity (8,9), whereas supplementation with DHA partially restored learning ability (11). These findings suggest that DHA might be essential in maintaining nervous system function.

In animals, long-chain PUFA such as 20:4n-6, 22:4n-6 and 22:6n-3 are synthesized from dietary C_{18} precursors, 18:2n-6 and 18:3n-3, which are synthesized *de novo* in plants. Animal studies have suggested that the capacity for chain elongation and desaturation is species and age dependent. Indirect evidence indicated that newborn human infants cannot produce sufficient quantities of long-chain PUFA from C_{18} precursors and, hence, depend on maternal supply (12,13). This would explain why DHA is present in human milk, although its content is variable and partially dependent on dietary fat intake (14). However, even the milk from vegetarians contains a considerable amount of DHA (15). The milk from various animals (16), including rats (17–21), rabbits (22), guinea pigs (22) and pigs (23), contains only trace or negligible amounts of DHA, whereas fish-eating marine animals have high DHA levels (16). Human milk provides DHA for neonates, whose DHA biosynthetic activity may be low at the time the human brain develops (12,13).

In the present study, Japanese monkeys were used as experimental models to investigate the effects of age on the biosynthetic capacity of long-chain PUFA in brain. First, the fatty acid composition of colostrum lipids was analyzed for comparison with that of humans. Then, the ability of brain microsomes to produce long-chain PUFA from their precursors was determined *in vitro* for animals of different age.

To test whether there is any relationship between the local PUFA content and the local synthetic activity of PUFA in cerebral cortex, three major regions of cerebral cortex were compared in respect to both long-chain PUFA content and synthetic capacity to produce long-chain PUFA.

MATERIALS AND METHODS

Materials. [1-^{14}C]Linolenic acid (2.07 GBq/mmole) and [1-^{14}C]eicosapentaenoic acid (2.17 GBq/mmole) were purchased from Amersham Japan (Tokyo, Japan). Radioactive purities were checked by high performance liquid chromatography (HPLC) and liquid scintillation counting as described below. Non-radioactive linolenic and eicosapentaenoic acids were obtained from Sigma Chemical Co. (St. Louis, MO). Octadecatetraenoic (n-3), eicosatetraenoic (n-3) and docosapentaenoic (n-3) acids used as standards were provided by Nippon Suisan Kaisha (Tokyo, Japan). Arachidonic and octadecatetraenoic acids (n-3) were provided by Idemitsu Petrochemical Co. (Tokyo, Japan). Coenzymes were purchased from Oriental Yeast Co. (Tokyo, Japan).

Animals. Cerebral cortices of Japanese monkeys [*Macaca fuscata fuscata;* two newborns, (a male and a female), a male 2 years of age, a male 6.5 years of age, and a male 10 years of age] were obtained from the Primate Research Institute, Kyoto University, Inuyama, Japan. Animals were fasted for 24 hr prior to killing. Tissues were frozen and kept at −80°C until use. The frontal lobe from a 6.5-year-old animal and the occipital lobes from a 2-, a 6.5- and a 10-year-old animal were used for the preparation of microsomes. The specific origin of the samples from the two neonatal brains was unknown.

The colostrum was obtained from a 10-year-old female animal four days after delivery. All animals had been fed a commercial monkey diet, Oriental APF (Oriental Yeast Co.).

Abbreviations: DHA, docosahexaenoic acid; GLC, gas-liquid chromatography; GSH, glutathione (reduced form); HPLC, high performance liquid chromatography; PUFA, polyunsaturated fatty acids.

Isolation of microsomes. The cerebral cortex was homogenized using a Potter-Elvehem homogenizer in 5 vol of a solution containing 0.25 M sucrose, 0.15 M KCl, 5 mM $MgCl_2$, 1.5 mM glutathione (reduced form) (GSH) and 50 mM K_2HPO_6 at pH 7.0. The homogenate was centrifuged at 800 × *g* for 10 min to remove cell debris, and then the supernatant was centrifuged at 10,000 × *g* for 20 min. The supernatant at 10,000 × *g* was further centrifuged at 100,000 × *g* for 1 hr to obtain the microsomal fraction. The microsomal pellet was suspended in a buffer containing 0.15 M KCl, 5 mM $MgCl_2$, 0.15 mM GSH and 50 mM K_2HPO_4 at pH 7.0. The entire isolation procedure was carried out at 0–4°C. The protein content of the microsomal solution was measured using the method of Lowry *et al.* (24).

Assay of PUFA chain elongation-desaturation. The assay conditions were basically those of the procedure described by Purvis *et al.* (25). Typically, reaction mixtures contained 100 mM fatty acids, 150 mM $MgCl_2$, 1.5 mM GSH, 5 mM ATP, 1.25 mM NADH, 1.25 mM NADPH, 0.3 mM CoA, 0.3 mM malonyl CoA and 50 mM K_2HPO_6 at pH 7.0 in a final volume of 0.5 mL. The fatty acids were a mixture of labeled and unlabeled 18:3 or 20:5 and were used in experiments after conversion to ammonium salt and suspension in 1% aqueous solution of Triton WR1339 containing fatty acid-free bovine serum albumin (Sigma Chemical Co., St. Louis, MO) at a molar ratio of 4:1. The radioactivities in reaction mixtures were in the range of 5.0 to 8.3 × 10^3 Bq. Incubation was initiated by adding 0.5 to 1.0 mg of microsomal protein to the reaction mixture and carried out at 37°C for 20 min. Assays were terminated by addition of 0.5 mL of 20% KOH containing 1 mg BHT. The mixtures were saponified at 80°C for 30 min, acidified with 0.5 mL of 5 M HCl, and the fatty acids were extracted with chloroform/methanol (2:1, v/v). After evaporation to dryness, the mixture was methylated with 13% (w/v) BF_3/methanol at 80°C for 5 min (26). Reaction mixtures without microsomes were used for control experiments. Recovery of radioactivity in the control experiment was 72.6%.

Separation of fatty acids and liquid scintillation counting. Fatty acid methyl esters were separated by HPLC essentially as described by Hirata *et al.* (27) using a Hitachi chromatograph model 635A (Hitachi, Tokyo) fitted with two Lichrosorb RP-18 columns (5 μm particle size, 4 × 250 mm connected with 7 μm particle size, 4 × 250 mm; Kanto Chemical Co., Tokyo) in series. The methyl esters were eluted stepwise with aqueous methanol (14%, 10% and 6%) at a flow rate of 0.6 mL/min. Fractions were detected with a UV monitor set at 210 nm and identified by comparison of their retention times with those of standards.

The radioactivities of the methyl esters were determined by counting fractions collected at 1-min intervals in scintillation vials containing 6 mL of NT scintillation fluid (28) using an Aloka liquid scintillation system, LSC-903 (Aloka, Tokyo).

Lipid analysis. Colostrum lipids were extracted by the Bligh-Dyer method (29). The lipid classes were separated by silicic acid and Florisil column chromatography (30). The lipids of the diet and tissues were extracted by the Folch method (31). Tissue lipids were fractionated into lipid classes on a Sep-Pak Cartridge Silica (Waters Associates, Milford, MA) (32). Lipids were transmethylated with sodium methylate. Microsomal lipids were saponified, extracted with chloroform/methanol (2:1, v/v), and then methylated with 13% BF_3/methanol as described above. Fatty acid methyl esters were analyzed by gas-liquid chromatography (GLC) on a JEOL JGC-20K apparatus (JEOL, Tokyo) equipped with a glass column (2.0 mm × 2 m) containing 10% Silar 10C on Chromosorb W (60/80 mesh). Column temperature was programmed from 170–220°C at 1°C/min. Duplicate determinations were carried out. Fatty acid methyl esters were identified by comparison of their retention times with those of standards.

RESULTS

Fatty acid compositions of diet and colostrum. The diet for monkeys contained 10.3% total lipids (w/w), of which the major fatty acids were as follows: 37.3% linoleic acid, 36.4% oleic acid, 13.8% palmitic acid, 2.7% linolenic acid and 2.6% stearic acid. Percentages of n-6 and n-3 PUFA in the total lipids were 41.7% and 3.6%, respectively.

Fatty acid compositions of the colostrum from *Macaca fuscata fuscata*, together with the cited data for human samples, are presented in Figure 1. The fatty acid profile in the monkey is similar to that in humans, although the linoleate content is a little higher in the monkey while palmitate is lower than in human colostrum. The total n-3 fatty acid levels in the monkey were similar to those in humans (33). The n-6/n-3 ratio in monkey was 5.9 and slightly higher than in humans. The DHA content in monkey was 2.2% and essentially identical to that in humans (33,34).

Synthesis of chain elongation-desaturation products by brain microsomes. Synthesis of chain elongation-desaturation products from linolenate was substantially influenced by age in the monkeys tested (Fig. 2). Judging from the total amount of metabolites produced, the activity in newborns was lower than in older monkeys. The synthesis of 22:6 was highly variable, *i.e.*, the greatest activity was found in a 6.5-year-old, while the activity in newborns was negligible. Similar results were obtained

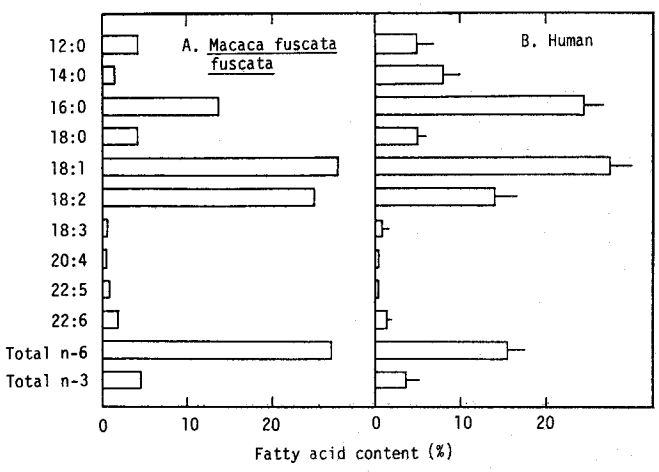

FIG. 1. Fatty acid composition of breast milk. Comparison between colostrum of *Macaca fuscata fuscata* and human (29). The monkey colostrum was collected from a 10-year-old female four days after delivery.

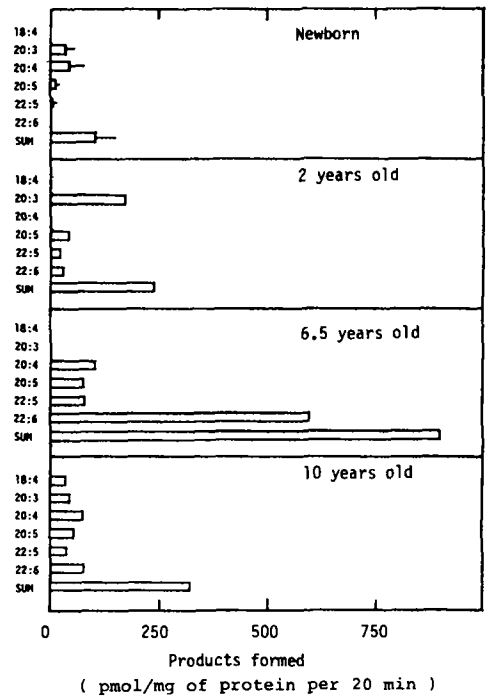

FIG. 2. Metabolites from 18:3n-3 by brain microsomes from *Macaca fuscata fuscata* of different ages. Sizes of brains are given in parentheses (longitudinal axis × bilateral axis, cm). A female and a male newborn (6.2 × 5.1), a 2-year-old male (6.8 × 5.5), a 6.5-year-old male (7.5 × 6.1) and a 10-year-old male (7.0 × 6.1) were tested.

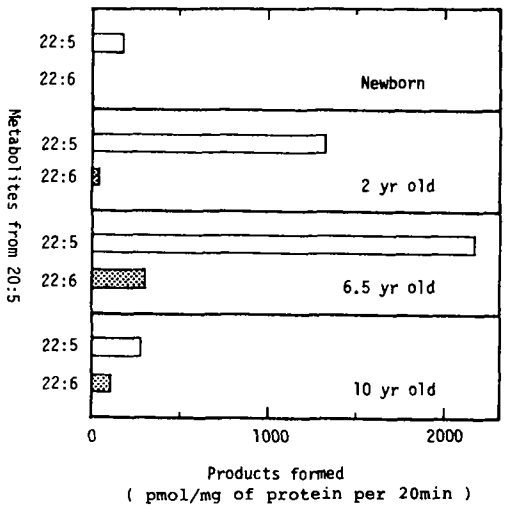

FIG. 3. Metabolites from 20:5n-3 by brain microsomes from *Macaca fuscata fuscata* of different ages. A female newborn, a 2-year-old male, a 6.5-year-old male, and a 10-year-old male were tested.

for the metabolism of 20:5 which was elongated and desaturated most extensively in a 6.5-year-old monkey, while the formation of 22:6 in the newborn again was negligible (Fig. 3).

Regional fatty acid composition and synthesis of long-chain PUFA in cerebral cortex. The DHA content of total lipids varied considerably between cerebral regions. DHA was found in decreasing abundance in occipital, in temporal and in frontal lobes (Table 1). The reverse was observed for n-6 PUFA, such as 20:4 and 22:4. A similar pattern of PUFA distribution was found in microsomal lipids (Table 2) with DHA being most abundant in the occipital lobe. On the other hand, brain microsomes prepared from frontal and occipital lobes showed almost the same activity for producing DHA from linolenic acid (Fig. 4). Thus, no direct relationship was apparent between long-chain PUFA synthetic activity and PUFA content of the cerebral cortex.

TABLE 1

Regional Variation in Fatty Acid Composition of Grey Matter Lipids of a 10-Year-Old Male *Macaca fuscata fuscata*

	Frontal	Temporal	Occipital
16:0	19.4%	20.7%	21.9%
18:0	22.8	21.7	20.3
18:1n-9	19.9	21.6	19.1
18:2n-6	2.7	2.8	3.7
18:3n-3	tr	tr	tr
20:4n-6	6.8	5.8	4.1
20:5n-3	tr	tr	tr

DISCUSSION

Although the fatty acid composition of milk of a wide variety of animals has been reported (16–23), the occurrence of DHA in milk was only noted in marine animals which live on a fish diet rich in DHA (16). This does not necessarily rule out the occurrence of trace amounts of DHA in animal milk, because in many of the studies no special attention appears to have been paid to the possible occurrence of small amounts of DHA. In human milk, DHA is always present, although its content varies with dietary habits. It also must be emphasized here that the DHA content in colostrum is highest and that it decreases somewhat in mature milk (33,35,36). This has been used as an argument for the maternal origin of long-chain PUFA needed by human newborns. Because the composition of lipids and fatty acids in the Japanese monkey's colostrum is similar to that in humans, it appears that *Macaca fuscata fuscata* would be a superior model to elucidate PUFA metabolism in neonates relevant to humans.

In the present study, the biosynthetic activity of n-3 long-chain PUFA in monkey brain was assessed using microsomes *in vitro*. Kinetic studies on the metabolic conversion of PUFA have shown that the rate of activation of a fatty acid to its CoA thioester in rat liver microsomes is greater than either elongation or desaturation of the acyl CoA ester (37–39). The incorporation of the metabolic products into lipids is also not rate limiting—the rate of acylation has been found to be of the same order or greater than the rate of activation in rat liver (37). Therefore, the ease of conversion of short-chain PUFA is commonly examined. Our data suggest that, in monkey brain, desaturation steps and not chain-elongation steps are rate-limiting in converting 18:3n-3 to DHA, because among the intermediates of this reaction (Fig. 2), the substrates for the desaturation (20:3, 20:4 and 22:5) were more abundant than the substrates for the chain-elongation (18:4 and 20:5). The ratios of the two were 6.6 for newborns, 4.6 for 2-year-olds, 2.5 for 6.5-year-olds and 2.3 for ten-year-olds.

In the case of rats, Strouvé-Vallet and Pascaud (40) reported that the brain microsomal activity for elongation and desaturation of linoleic acid was high in the first four days after birth, but decreased rapidly thereafter. Studies by Cook (41,42) also confirmed that the highest Δ6 desaturase activity is associated with neonatal rat brain. In liver, desaturase activity is stable up to 30 days (40) or increases slightly after weaning (41,42).

In the case of perinatal piglets, the brain enzyme activity was also greatest in the neonatal period, while the liver enzyme activity was higher in the postnatal period. Δ5 Desaturase activity, in particular, was very low during the neonatal period (25,43).

The importance of the liver in supplying DHA for the nervous system has recently been reported in rat (44). In our study, however, we could not assess the metabolizing activity of liver, because monkeys had been fasted for 24 hr. Under this condition, Δ6 desaturase activity is known to be very low (45,46). In contrast, the activity in brain is quite independent of diet (data not shown).

In the present study, the capacity of the brain for elongation/desaturation was found to be lower in newborn monkeys than in older animals. In particular, Δ4 desaturation and formation of DHA in newborns was negligible (Figs. 3 and 4). The lower chain elongation/desaturation activity in monkey neonates observed in the present study is quite different from the results previously reported for rats (see above). The cause for this is unknown, but differences in the developmental stage of brain neural cells at parturition may be responsible for that, as primates are born at the end of the cell-stretching stage, while rat neonates are at the end of the cell-multiplication stage (47). Therefore, from the point of brain neural cell development, monkey neonates correspond to the stage of rats 10 days after birth, when Δ6 desaturase activity is decreased to very low levels (40). It appears reasonable to assume that the occurrence of DHA in primate colostrum compensates for the low biosynthetic activity in the neonate brain.

Besides the low desaturase activity, another factor responsible for the low capacity of long-chain PUFA biosynthesis may be the competitive compartmentalization of linolenate and its intermediate metabolites between acylation to form glycerophospholipids and desaturation. In Macaque monkey, all neurons have completed cell division during the 120 days of gestation, and after birth only the multiplication of glia can be observed (48). Furthermore, the size of the brain and the number of synapses reach almost steady levels after three years (49). The brain of a 6.5-year-old monkey used in the present study is thought to be mature. In neonatal monkeys, a marked increase of glia cells would occur. Therefore, the accelerated incorporation of PUFA into microsomal membranes of glia cells might result in a low rate of desaturation. However, the lipid analyses of astrocytes and oligodendrocytes in rats showed a very low content of n-3 PUFA other than DHA, similar to neurons (50). This observation again supports the idea of a specific affinity of DHA to neural tissues. Judging from these results, the compartmentalization of 18:3, or intermediate n-3 PUFA, in membrane phospholipids may not be the principal cause for the poor desaturation activity in monkey neonates.

Lowered capacity for long-chain PUFA synthesis in rhesus monkey neonates was also suggested by the observation that the plasma DHA level drastically decreased after birth (6,51). It has been suggested that Δ4-desaturase in humans (52–54) and monkeys (55) is much less predominant than Δ5 and Δ6 desaturase activities, because administration of linolenic acid or 20:5 resulted in accumulation of 22:5n-3 rather than DHA. Although the number of monkeys used in the present studies was quite limited, the data suggest the possibility that Δ4 desaturase activity in primate newborns is too low to produce sufficient DHA for brain development and that a large portion of the long-chain polyunsaturated fatty acids required may depend on maternal supply and/or the metabolites of the liver as source.

ACKNOWLEDGMENTS

We thank Dr. J. Beare-Rogers for critical reading of the manuscript. The work was supported in part by the Food Science Institute Foundation (Ryoshoku Kenkyukai, Japan). Nippon Suisan Kaisha and Idemitsu Petrochemical Co. provided standard polyunsaturated fatty acids for HPLC and GLC.

Vitamin E and the Susceptibility of Erythrocytes and Reconstituted Liposomes to Oxidative Stress in Aged Diabetics

[a]Tokyo Metropolitan Institute of Gerontology and [b]Tokyo Metropolitan Geriatric Hospital, Itabashi-ku, Tokyo 173, Japan

A remarkable increase in the permeability of erythrocyte ghosts and liposomal membranes composed of erythrocyte lipids from aged diabetics was revealed by measuring [^{14}C]glucose leakage. There were no significant differences in the contents of free cholesterol or phospholipids, or in the cholesterol/phospholipid ratio between diabetic and normal erythrocyte membranes, but significantly higher amounts of unsaturated fatty acids, arachidonic acid and docosahexaenoic acid were observed in the erythrocyte membranes of diabetics. Reconstituted liposomes prepared from aged diabetic erythrocyte lipids were highly susceptible to superoxide-induced oxidative stress. Vitamin E was highly effective in suppressing the peroxidative lysis of liposomes composed of diabetic erythrocyte lipids. The effect of superoxide dismutase (SOD) on the inhibition of peroxidation of unsaturated lipids within liposomal membranes was less than that of vitamin E.

Lipids 26, 58-61 (1991).

It is well recognized that one of the serious problems facing aged diabetic patients is the high prevalence of thrombotic disorders (1). However, the pathogenesis of these disorders is not well understood. One possible factor contributing to this morbid state is thought to be due to hemorheologic changes in diabetics, since abnormalities in the physical properties of erythrocytes from diabetic patients have been reported. These abnormalities include increased whole-blood and plasma viscosity, reduced erythrocyte deformability, and an increased adhesion of erythrocytes to endothelial cells (2-6).

In general, membrane phospholipids appear to play an important role in such physicochemical properties of erythrocyte membranes (7). In fact, there is substantial evidence to suggest that dietary supplementation with polyunsaturated fatty acids induces changes in membrane-associated cell functions and physical properties such as fluidity (8-11). However, the direct relationship between the physicochemical properties and membrane fatty acid composition of erythrocytes from diabetic patients has not yet been examined.

Polyunsaturated lipids, which influence membrane properties, are abundant in biological membranes, and their peroxidation is thought to constitute a serious threat to membrane integrity. Once peroxides are produced, the physicochemical properties of membranes are believed to be affected, and hence, membrane function could be altered (12). In order to clarify the question whether the abnormalities in erythrocytes from aged diabetics arise from differences in their polyunsaturated lipid content, and whether vitamin E protects erythrocyte membranes against peroxidation, the permeability of erythrocyte ghosts and reconstituted liposomes prepared from erythrocyte membrane lipids was investigated. Also the susceptibility of erythrocyte lipids from aged diabetics to superoxide and the inhibitory effect of vitamin E on lipid peroxidation in erythrocytes from aged diabetics were examined.

Abbreviations: MDA, malondialdehyde; PBS, phosphate buffered saline; SOD, superoxide dismutase; TBARS, thiobarbituric acid reactive substance.

MATERIALS AND METHODS

Materials. Erythrocytes were obtained from 70- to 80-year-old diabetic patients and normal age-matched subjects. Patients with diabetes were receiving insulin therapy. All subjects took an almost identical restricted diet (amount of dietary lipids, 40 g/day). The studies were performed after informed consent was obtained from all subjects. Fresh, heparinized blood was centrifuged at 1,500 × *g* for 10 min, and the erythrocytes were washed three times with phosphate buffered saline (PBS, pH 7.4). Erythrocyte ghosts were obtained by the method of Steck (13). Xanthine, xanthine oxidase, superoxide dismutase (SOD), and cytochrome c were purchased from Sigma Chemical Co. (St. Louis, MO). D-[U-^{14}C]glucose was obtained from Amersham International PLC (Buckinghamshire, UK); α-tocopherol (vitamin E) was from E. Merck (Darmstadt, FRG). All other chemicals were of the highest grade available.

Preparation of liposomes. The erythrocyte ghosts were extracted with a mixture of chloroform and methanol (2:1, v/v) following a previously reported procedure (14). Briefly, the extracted lipids (3.12 mg), dicetyl phosphate (0.24 mg) and α-tocopherol (if necessary, 0.3 molar ratio to lecithin) were dissolved in 1 mL of a mixture of chloroform and methanol (2:1, v/v). After rotary evaporation under N_2, 0.2 mL of [^{14}C]glucose solution in PBS (pH 7.4) was added to the dried lipids (under N_2). The mixture was shaken vigorously on a vortex mixer to obtain a suspension. The suspension was allowed to swell for 2 hr at room temperature and was then applied to a 20-cm column of Sephadex G-200. The column was eluted with PBS to yield a liposome suspension.

Measurement of the permeability of erythrocyte ghosts and liposomes to [^{14}C]glucose. Erythrocyte ghosts (1 mL of suspension) were mixed with [^{14}C]glucose and 0.1 mM $MgSO_4$ in 0.5 mM sodium phosphate and incubated at 4°C for 15 hr. The radioactive marker was sealed inside by the shear stress through a No. 27 gauge hypodermic needle as previously reported (15). The vesicles were then washed twice, suspended in cold 50 mM sodium phosphate (pH 7.8), and incubated at 25°C. The vesicle suspensions were centrifuged at 15,000 × *g* for 20 min at various intervals up to 7 hr. The radioactivity of each supernatant was measured using a scintillation counter.

Triplicate 0.2-ml aliquots of liposome suspension were placed into dialysis bags (0.8 cm diameter) containing appropriate reagents (xanthine and xanthine oxidase, and

if necessary, SOD) in 1 mL of PBS and were dialyzed at 22°C against 4 mL of PBS with constant mixing by rotation. At various intervals up to 24 hr, the dialysis bags were removed and placed in 4 mL of fresh PBS at each time point. [^{14}C]Glucose leakage was determined by measuring the radioactivity of the dialysate using a scintillation counter. Results were expressed as percent of total glucose released from erythrocyte ghosts or liposomes in suspensions to which the detergent, Triton X-100 (1% v/v), had been added.

Superoxide generating system. The complete system consisted of xanthine (2.5 μmol) and xanthine oxidase (0.2 U). The generation of superoxide (O_2^-) by this system was measured as previously reported (16). The inhibitory effect of α-tocopherol (0.3 molar ratio relative to lecithin) or SOD (30 μg) on the peroxidation of membranes was assessed by the inhibition of the O_2^--induced increase in membrane permeability to [^{14}C]glucose.

Analysis of erythrocyte membrane lipids. Erythrocyte membrane lipids were extracted with a mixture of chloroform and methanol (2:1, v/v) as described previously (13). Aliquots were applied to a silica gel plate and developed with chloroform/methanol/acetic acid/formic acid/water (37.5:12.5:6:3:1, by vol) as the first solvent, and hexane/isopropyl ether/acetic acid (3:95:2, v/v/v) as the second solvent. The fractions were analyzed using a density chromatoscanner (Shimadzu, CS-910). In order to analyze the fatty acid composition of the extracted lipids, portions of the lipids were mixed with butylated hydroxytoluene and heated at 100°C for 2 hr with 5% HCl solution in methanol. The reaction mixture was extracted with hexane and washed with water. The hexane solution was evaporated under nitrogen gas and lipids were taken up to 200 μL of hexane. The esterified fatty acids were analyzed by gas chromatography on an EGSS-X column. For analysis of vitamin E content in erythrocyte membranes, portions of the lipids extracted were re-extracted with ethyl acetate, and the ethyl acetate extract was injected on the guard column of the HPLC (Wakogel LC-5H, Wako Pure Chemical Co., Osaka, Japan). The experimental conditions of HPLC used for analysis were identical to those described earlier (17).

RESULTS AND DISCUSSIONS

Erythrocyte membranes from aged diabetics were significantly more permeable to [^{14}C]glucose than those from normal subjects as shown in Figure 1 ($p<0.05$). One of the contributing factors to changes in the permeability of membranes is thought to be due to variation in the proportion of unsaturated lipids. It seems that the erythrocyte membrane lipids of aged diabetics are less saturated than those of normal aged subjects. We therefore analyzed the phospholipid, cholesterol, vitamin E and fatty acid contents of various erythrocyte membranes. Table 1 shows a comparison of the content of vitamin E and the compositions of erythrocyte ghost lipids between aged diabetics and normal subjects. There were no significant differences in the content of vitamin E, free cholesterol or phospholipids, or in the cholesterol/phospholipid ratios between diabetic and normal erythrocyte membranes. On the other hand, as shown in Table 2, we found that diabetic erythrocyte membranes contain a significantly higher proportion of arachidonic acid (20:4, 16.5%) and

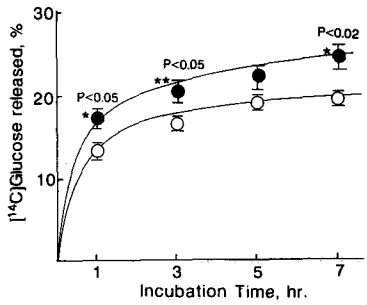

FIG. 1. Comparison of the permeability of erythrocytes to [^{14}C]-glucose. The PBS suspensions of diabetic (●) and normal (○) erythrocyte ghosts resealed with radioactive glucose were incubated at 25°C. Released glucose was measured by scintillation counting as described under Materials and Methods. Percent release of glucose at each time point is expressed in accumulated counts of radioactivity released.

docosahexaenoic acid (22:6, 11.1%) as compared to normal erythrocyte membranes. Considering high arachidonic acid contents in either erythrocyte membrane in young diabetic women or in platelets of aged diabetics (18,19), the results suggest that there exists a difference in the lipid content of erythrocyte membranes between aged diabetics and normal subjects that can largely be ascribed to differences in the levels of unsaturated fatty acids. In the present study, both groups had essentially

the same dietary lipid intake. It is therefore suggested that the abnormal lipid content of erythrocyte membranes in aged diabetics could be due to disease-induced changes rather than diet-induced ones, although this mechanism can presently not be verified.

In order to investigate whether the increase in the level of unsaturated fatty acids in erythrocyte membranes of aged diabetics induces the increased permeability of the membranes to [^{14}C]glucose, the permeability of reconstituted liposomes prepared from lipids extracted from diabetic erythrocyte ghosts was investigated.

Although the permeability of liposomes composed of diabetic erythrocyte lipids to [^{14}C]glucose was greater than that of liposomes composed of normal erythrocyte lipids, the difference was not statistically significant in the early stage of incubation (Fig. 2). After 18 hr, however, the rate of glucose leakage from liposomes composed of diabetic erythrocyte membrane lipids was significantly higher. As shown in Figure 2, the peroxidation of the diabetic and normal lipids (thiobarbituric acid reactive substances—TBARS value) was progressive after 18 hr. These results suggest that as the degree of unsaturation of the lipids in erythrocyte membranes becomes higher, the leakage of glucose increases, and that the large difference in glucose leakage between diabetic and normal erythrocytes arises from differences in their susceptibility to peroxidation. Previously it has been shown that the oxidation of xanthine by xanthine oxidase caused lysis of erythrocyte membranes and liposomes, and that their permeability to glucose or chromate ions was significantly increased (15,16). Consequently, in order to clarify the susceptibility of liposomes to oxidative stress, liposomes were exposed to superoxide (O_2^-) generated by the xanthine-xanthine oxidase system (16). Figure 3 shows the kinetics of liposome damage caused by exposure to O_2^-. In this experiment, the oxidation of lipids in both types of liposomes progressed with incubation time. Although glucose leakage from liposomes composed of either diabetic or normal erythrocyte lipids was enhanced by the addition of O_2^-, the leakage from the diabetic liposomes increased more markedly than that from normal liposomes. From these results, it would seem that diabetic erythrocyte membranes are more readily oxidizable probably due to their greater unsaturated fatty acid, especially arachidonic acid and docosahexaenoic acid, contents.

It is recognized that aerobic organs and cells are protected from oxygen toxicity by an array of defense systems, including preventive antioxidants, such as vitamin E, and antioxidative enzymes, such as superoxide dismutase (SOD) (20-22). In order to verify the inhibitory effects of vitamin E and SOD on the oxidative damage of diabetic erythrocyte membranes by O_2^-, we examined the protection of liposomes against oxidation by vitamin E inside the membranes or SOD outside the membranes. As shown in Figure 4B, the inhibitory effect of vitamin E on the oxidative damage of normal liposomes was similar to the effect of SOD. In contrast, Figure 4A shows that vitamin E was much more effective than SOD in suppressing the oxidative damage to diabetic liposomes. In this experiment, no significant inhibitory effect of vitamin E against lipid peroxidation was observed by the use of physiological vitamin E content in liposomes, probably because of the nonphysiologically high

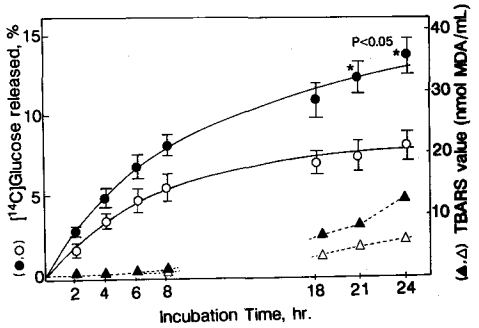

FIG. 2. Kinetics of [^{14}C]glucose leakage from reconstituted liposomes upon lipid peroxidation. Suspensions of liposomes, sealed with radioactive glucose, composed of lipids from diabetic erythrocyte membranes (●) or from normal erythrocyte membranes (○) were incubated at 22°C for 24 hr. At various intervals up to 24 hr, glucose leakage into the outside PBS solution of the dialysis bag was measured by scintillation counting. Lipid peroxides in diabetic (▲) and normal (△) liposomes were measured by the thiobarbituric acid method (27). Results are expressed as quantities of malondialdehyde (MDA) formed.

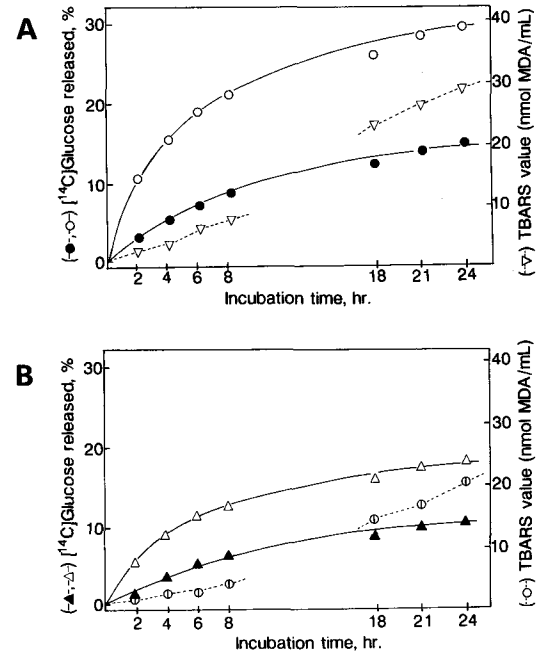

FIG. 3. Comparison of liposome damage caused by exposure to superoxide (O_2^-) and O_2^--induced lipid peroxidation. (A) ●, diabetic liposomes, no O_2^- or ○, diabetic liposomes with O_2^- exposure; (B) ▲, normal liposomes, no O_2^- or △, normal liposomes with O_2^- exposure was incubated at 25°C for 24 hr. The incubation system consisted of 2.5μM xanthine and 0.2 unit xanthine oxidase in 1 mL of PBS (pH 7.4). Vitamin E contents in diabetic and normal liposomes were 0.3 μg and 0.4 μg/mg lipids. TBARS values in diabetic (▽) and normal (⊖) liposomes upon O_2^- exposure were measured at each time point as previously described (27).

amount of O^-_2 used. Consequently, we also used a relatively high amount of vitamin E (0.3 molar ratio to lecithin). Although the physical properties of the membranes could be altered under these conditions, it is reasonable to assume that the membranes are stabilized by the addition of vitamin E (23,24), and that the inhibitory effect of vitamin E in both types of liposomes,

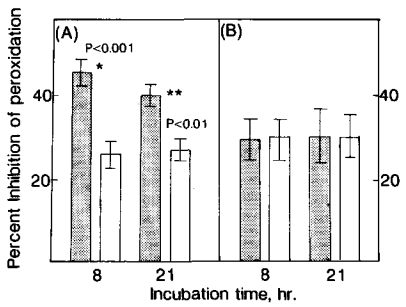

FIG. 4. Inhibitory effects of vitamin E and SOD on oxidative damage to liposomes. Liposomes prepared from diabetic (A) or normal (B) erythrocyte lipids were incubated with the xanthine-xanthine oxidase system in the presence of vitamin E (0.3 molar ratio to lipids, closed columns) or SOD (30 μg, open columns) at 22°C as described under Materials and Methods. Percent inhibition was expressed as the percentage decrease of glucose leakage from liposomes.

which include the same amount of vitamin E, can be compared under these conditions.

As it has been proven that O_2^- generated outside the membrane can freely diffuse across the membrane (25), it seems that O_2^- or other oxygen radicals derived from O_2^- (for example, $^{\bullet}O_2H$, H_2O_2 and $^{\bullet}OH$) induce oxidative chain reactions within membranes. In the diabetic erythrocyte membrane, this chain oxidation may propagate more readily, because diabetic erythrocyte lipids are more unsaturated than the lipids of normal erythrocytes. Vitamin E is known to act as a chain-breaking antioxidant rather than a deactivator of oxygen radical species in membranes. Consequently, the effect of vitamin E on oxidative damage to liposomes made from diabetic erythrocyte membrane lipids is greater than the effect on damage to normal erythrocyte lipid liposomes. On the other hand, SOD directly scavenges only O_2^- outside the membrane, while other active oxygen species derived from O_2^- may not be scavenged there and may diffuse across the membrane thus inducing oxidative chain reactions. Consequently, the inhibitory effect of SOD in diabetic liposomes would be less than that of vitamin E (Fig. 4).

In conclusion, erythrocyte membranes from aged diabetics are significantly more permeable to glucose than erythrocyte membranes from normal aged subjects. The content of unsaturated fatty acids is higher in diabetic erythrocyte membranes, making them more susceptible than normal erythrocytes to oxidative stress. Furthermore, vitamin E is highly effective in suppressing peroxidation within diabetic erythrocyte membranes in accordance with its excellent chain-breaking activity. Although it is impossible at present to verify the mechanism of the increased leakage of glucose from diabetic erythrocyte membranes, it appears reasonable to suggest that the abnormal lipid environment in these membranes and their high susceptibility to oxidative stress would affect glucose transporter activity and thus glucose flux from erythrocytes (26).

[Received April 12, 1990; Revision accepted October 24, 1990]

Phospholipid Synthesis by Chick Retinal Microsomes: Fatty Acid Preference and Effect of Fatty Acid Binding Protein

Peggy A. Sellner[a,b,*] and **Ariana R. Phillips**[a]
Departments of [a]Anatomy and Cell Biology and [b]Ophthalmology, University of Kansas Medical Center, Kansas City, Kansas 66103

The acylation of 1-palmitoyl-*sn*-glycerophosphocholine (1-16:0-GPC) or 1-palmitoyl-*sn*-glycerophosphoethanolamine (1-16:0-GPE) was measured using the microsomal fraction prepared from retinas of 14–15-day-old chick embryos. Rates of incorporation of exogenously supplied fatty acids into diacyl-GPC were generally 5–7 times greater than into diacyl-GPE. Substrate preferences for incorporation into diacyl-GPC and diacyl-GPE were, respectively, 18:2 > 18:3 = 20:5 > 20:4 > 18:1 > 22:6 = 18:0 and 18:2 > 22:6 ≥ 18:3 = 18:0 ≥ 20:4 = 18:1 > 20:5. The apparent selectivities were not consistent with the reported fatty acid compositions of these lipid classes. The addition of partially purified fatty acid binding protein (FABP) to the reaction had no effect either on overall rates of incorporation or on the substrate preference. When fatty acyl-CoA substrates were used, rates of incorporation of the 18:0 derivative were much higher than with the fatty acid, while rates with other fatty acyl-CoA were similar to those with the respective fatty acid. Substrate preferences for CoA derivatives incorporated into diacyl-GPC were: 18:0 > 20:4 > 18:2 ≥ 22:6, and into diacyl-GPE: 20:4 = 22:6 > 18:0 > 18:2. Polyunsaturated fatty acyl CoA (PUFA-CoA) were thus favored for incorporation into diacyl-GPE, and to a lesser extent into diacyl-GPC, a result that is consistent with composition data. When purified FABP was added to the reactions, there was an increase in the incorporation of 18:0-CoA and a decrease or no change in the incorporation of PUFA-CoA. The deacylation/reacylation cycle thus appears to play a role in the modification of phospholipid composition. The data are not consistent, however, with a role for FABP in directing PUFA toward membrane lipid synthesis.
Lipids 26, 62–67 (1991).

The fatty acid composition of retinas, like other neural tissue, is remarkably high in polyunsaturated fatty acids (PUFA), particularly of the n-3 family (1,2). Within the retina, the concentration of n-3 fatty acids is highest in the photoreceptor outer segments, where 22:6n-3 alone may constitute over 50% of fatty acids present in a given phospholipid class (1,3). Within the major phospholipid classes, PUFA are more prevalent among diacyl-GPE than among diacyl-GPC. For example, in adult chicken retina, PUFA constitute 48.5% of fatty acids in diacyl-GPE, but only 4.5% in diacyl-GPC (4).

The incorporation of PUFA into phospholipids first requires the activation of the fatty acid to its coenzyme A (CoA) derivative *via* the enzyme long-chain acyl-CoA synthetase. Two forms of the enzyme are generally recognized, one that is non-specific and one that is selective for arachidonic acid. The non-specific form is present in microsomes, mitochondria, and peroxisomes of liver (5,6). The cDNA for this protein has recently been shown to be expressed in liver and heart, and to a much lesser extent in brain (7). The arachidonic acid-specific form of acyl-CoA synthetase has been described in blood vessel endothelium (8), brain (9) and retina (10). In the latter two tissues, activation of docosahexaenoic acid was also demonstrated with a K_m similar to that for arachidonic acid (11,12). Thus, this 20:4-selective CoA synthetase may play an important role in the incorporation of these two PUFA into phospholipids.

The fatty acyl-CoA can then serve as a substrate for acyl-CoA:1-acyl-GP acyltransferase for *de novo* synthesis of phosphatidic acid, or for acyl-CoA:1-acyl-GPC (or -GPE) acyltransferase, involved in the tailoring of existing diacyl-GPC (or -GPE). The specificity of these acyltransferase enzymes for particular fatty acids could influence the composition of a particular membrane. For example, retinal microsomes can incorporate [^{3}H]22:6 into phosphatidic acid (13,14) suggesting the introduction of long-chain PUFA during *de novo* synthesis. In other tissues the deacylation/reacylation cycle is involved in the restructuring of *de novo* synthesized phospholipids (15). Lands *et al.* (16) have shown that the reacylation of 1-acyl-GPC in rat liver preferentially incorporates PUFA. That this latter pathway also exists in the photoreceptor is consistent with the detection of phospholipase A_2 activity in photoreceptor outer segments (17–19), thus providing a means of generating the lysophospholipids used in the acyltransferase reaction. Differences in turnover rates of individual molecular species of phospholipids in the retina (20) also imply active replacement of part or all of the membrane lipid molecules.

The above reactions involve the intracellular trafficking of fatty acids between cytoplasmic and/or membrane compartments; this movement may involve one or more binding proteins as intracellular carriers. Fatty acid binding protein (FABP) is a 12–14,000 dalton protein found in the cytosol of many tissues (for reviews, see refs. 21–24) including retina (25). This protein has been reported to have a binding preference for unsaturated fatty acids or their CoA esters (22), and has been suggested to play a role in directing these substrates to various metabolic pathways such as oxidation or esterification. For example, FABP stimulates the activities of acyl-CoA:glycerol-3-phosphate acyltransferase (26–28) and acetyl-CoA carboxylase (29). Peeters *et al.* (30) have demonstrated the ability of liver and heart FABP to mediate the accelerated transfer of fatty acids between mitochondria and lipid vesicles. While functional studies with retinal FABP have not been performed, this protein could be an important mechanism for channelling PUFA into the phospholipids of outer segment membranes.

We investigated the reacylation reaction in embryonic

Abbreviations: ATP, adenosine triphosphate; CoA, Coenzyme A; DTT, dithiothreitol; FABP, fatty acid binding protein; GPC, glycerophosphocholine; GPE, glycerophosphoethanolamine; GP, glycerophosphate; PMSF, phenylmethylsulfonyl fluoride; PUFA, polyunsaturated fatty acids; ROS, rod outer segments; RPE, retinal pigment epithelium; fatty acids are listed as chain length:number of double bonds.

chick retinas using synthetic lysophospholipids and seven fatty acids as the substrates. 1-Acyl-GPC and 1-acyl-GPE acyltransferase activities were measured using the microsomal fraction prepared from these retinas. FABP was partially purified from the retina cytosol, and its effect on the reaction was measured. Under these conditions, rates of incorporation of fatty acid did not correlate well with composition data, and FABP did not significantly influence either the reaction rate or the inherent substrate preference of the reactions. However, when CoA esters of four fatty acids were prepared and tested, there was greater incorporation of PUFA into diacyl-GPE and, to a lesser extent, into diacyl-GPC. The addition of purified FABP to this reaction increased the incorporation of the saturated fatty acid and decreased the incorporation of PUFA.

MATERIALS AND METHODS

Fertilized chicken eggs were obtained from a local supplier and were incubated for 14–15 days. Embryos were sacrificed by decapitation. The anterior segment of the eye was cut away and the vitreous was lifted out. A few drops of 0.1 M Tris-HCl, pH 7.8 (containing the following protease inhibitors in μg/mL: phenylmethylsulfonyl fluoride (PMSF), 2; pepstatin, 3.4; aprotinin, 5; leupeptin, 2.4; and chymostatin, 5) were added to facilitate peeling away of the retina with fine forceps. At the region of the pecten, the retina was loosened by stroking with the tip of the forceps. At this stage of embryonic development, the retinal pigment epithelium does not adhere to the retina, which can thus be isolated cleanly.

Retinas were kept on ice in a small volume of Tris-HCl plus protease inhibitors and were homogenized in a glass Potter-Elvehjem homogenizer. The homogenate was centrifuged at 12,000 × *g* for 20 min to remove cell debris. The supernatant was then centrifuged at 100,000 × *g* to pellet the microsomal fraction, which was resuspended in 0.1 M Tris-HCl, pH 7.8 plus 5 mM dithiothreitol (DTT).

The high-speed supernatant was layered onto a Sephadex G-100 column and eluted with 0.1 M Tris-HCl buffer, pH 7.8, containing 0.2% sodium azide. The elution volume of FABP was determined in initial preparations by mixing an aliquot of supernatant with a trace amount of [1-^{14}C]oleic acid and counting 200 μL from each of the eluted fractions. In subsequent preparations, non-labelled fractions containing FABP were pooled and concentrated using an Amicon ultrafiltration cell. This concentrated "FABP fraction" was used in most of the enzyme assays. FABP was not purified further for these experiments; this allowed for the use of microsomes and FABP from the same preparation. All of the above procedures were carried out at 0–4°C.

In the experiments with fatty acyl-CoA derivatives, FABP was further purified (Sellner, P.A., and Phillips, A.R., manuscript in preparation). Briefly, the "FABP fraction" prepared as described above was separated by native polyacrylamide gel electrophoresis. After staining one of the lanes with Coomassie Blue to locate the FABP band, the corresponding regions from the remaining gel were cut. FABP was then eluted from the gel using the BioRad Electroeluter and concentrated by lyophilization.

In most experiments, all embryos (7 dozen) were sacrificed on the same day, and microsomes were kept refrigerated overnight to be used the following day after the FABP fraction had been prepared. Acyltransferase activity was lost or greatly compromised if the microsomes were stored at −20°C or if they were kept refrigerated for 2 days.

Preparation of fatty acyl-CoA. Derivatives of [1-^{14}C]-18:0, 18:2, 20:4, and 22:6 were prepared according to the method of Schmidt and Burns (31). We used 200 nmol of unlabelled fatty acid with 2 μCi labelled fatty acid in the synthesis to achieve a final concentration in our assays of 100 μM fatty acyl-CoA.

Acyltransferase assays. Each assay contained the following in a total volume of 0.1 mL: 0.1 mM 1-16:0-GPC or -GPE (pipetted in chloroform/methanol solution onto the bottom of the vial, solvent was evaporated with a stream of nitrogen), 0.1 M Tris-HCl, pH 7.8 plus 5 mM dithiothreitol (DTT), 1 mM adenosine triphosphate (ATP), 10 mM $MgCl_2$, 0.1 mM CoA, and 100 μM (0.1 μCi) [1-^{14}C]fatty acid (18:0, 18:1n-9, 18:2n-6, 18:3n-3, 20:4n-6, 20:5n-3, or 22:6n-3), added in 5 μL of propylene glycol. The fatty acyl-CoA (18:0, 18:2, 20:4, or 22:6) was added in 40 μL of aqueous suspension. The solution was vigorously vortexed after the addition of each constituent. Following a 5-min preincubation, 0.1–0.2 mg microsomal protein in 10 μL was added, and the reaction was allowed to proceed at 37°C for 6 min. For those assays containing FABP fraction, the protein was added (10–20 μg in 10 μL) after the preincubation. Another 5-min incubation was allowed prior to the addition of microsomes. The reaction was stopped by the addition of 0.9 mL of $CHCl_3$/MeOH (2:1, v/v). Lipids were extracted by the method of Folch *et al.* (32), and separated by thin-layer chromatography on 0.25 mm Silica Gel H plates (Analtech, Newark, DE) containing 7.5% magnesium acetate. The plate was developed twice in $CHCl_3$/MeOH/H_2O (60:30:5, v/v/v), each time one-third the way up; then in hexane/diethyl ether/formic acid (80:20:2, v/v/v), developed to within 1 cm from the top (33). Standard lanes were sprayed with 2′,7′-dichlorofluorescein and spots were visualized under ultraviolet light. The phospholipid and free fatty acid spots were scraped directly into scintillation vials and counted. Counts were converted to nmol after determining the specific activity from a 1 μL aliquot of the fatty acid-propylene glycol mixture. The data are expressed as nmol diacyl-GPC or -GPE formed/mg protein/6 min.

Protein was determined by the method of Lowry *et al.* (34). Non-radiolabelled fatty acids were obtained from Sigma Chemical Company (St. Louis, MO); radiolabelled fatty acids were from Dupont/New England Nuclear (Wilmington, DE). All other chemicals were of reagent grade.

RESULTS

The elution profile of retina cytosolic fraction (high-speed supernatant) mixed with [1-^{14}C]18:1 from a Sephadex G-100 column is shown in Figure 1. FABP elutes between 130–160 mL; the peak corresponds to a molecular weight of around 12,000 daltons. When an aliquot of this fraction with a trace amount of [1-^{14}C]18:1 methyl ester is electrophoresed on a native polyacrylamide gel, only one band (FABP) contains radioactivity, though several bands are present upon staining with Coomassie Blue (data not shown). Thus, we reasoned that any effect of

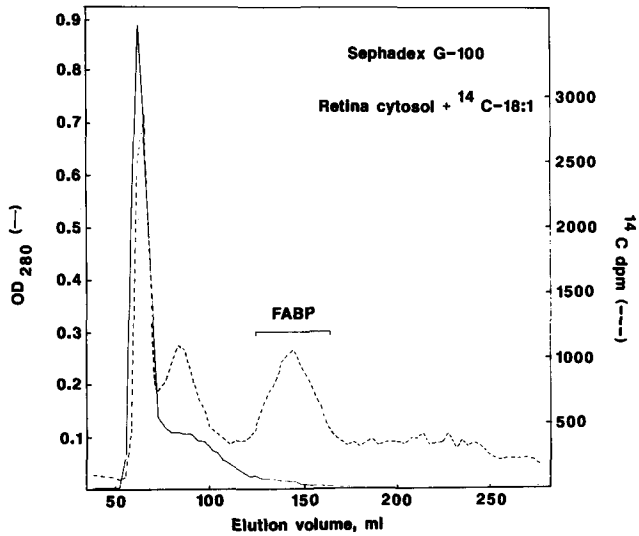

FIG. 1. Elution of FABP fraction in retina cytosol. An aliquot of retina cytosolic fraction was mixed with a trace amount (0.5 μCi) of [^{14}C]18:1. The labelled cytosol was eluted from a column of Sephadex G-100 as described in Materials and Methods. The solid line represents protein (OD_{280}); the dashed line represents fatty acid bound to protein (cpm). In subsequent runs without added fatty acid, the fractions marked "FABP" were pooled, concentrated, and used without further purification.

[a]Acyltransferase activities were measured as described in Materials and Methods, using 1-palmitoyl-*sn*-GPC and the indicated [^{14}C]labelled fatty acid as substrates. Where indicated, FABP fraction (20 μg total protein) was added prior to addition of microsomes. Values represent means ± SEM for the number of experiments indicated in parentheses

the addition of this fraction on the reaction was attributable to FABP.

The incorporation of fatty acid into diacyl-GPC and the effect of FABP is shown in Table 1. While the absolute reaction rates varied considerably between experiments, within a given experiment, some general trends could be observed. For 1-16:0-GPC, the maximum rates of incorporation were with 18:2 as the substrate, followed by 18:3 = 20:5 > 20:4 > 18:1 > 22:6 = 18:0. The incorporation of 18:0 was low, as would be expected for acylation of the 2-position of the phospholipid, but rates for the incorporation of 20:4 and 22:6 were also lower than would be expected from the composition data (4).

TABLE 2

Incorporation of Fatty Acids into Diacyl-GPE and the Effect of FABP[a]

Fatty acid	nmol GPE formed/mg protein/6 min	
	no FABP	+ FABP
18:0	0.34 ± 0.18 (4)	0.28 ± 0.11 (4)
18:1n-9	0.24 ± 0.10 (5)	0.26 ± 0.07 (4)
18:2n-6	0.60 ± 0.23 (5)	0.68 ± 0.39 (3)
18:3n-3	0.36 ± 0.13 (3)	0.92 ± 0.56 (4)
20:4n-6	0.27 ± 0.16 (3)	0.26 ± 0.14 (4)
20:5n-3	0.17 ± 0.05 (5)	0.26 ± 0.04 (3)
22:6n-3	0.40 ± 0.15 (3)	0.20 ± 0.03 (2)

[a]Acyltransferase activities were measured as described in Materials and Methods, using 1-palmitoyl-*sn*-GPE and the indicated [^{14}C]-labelled fatty acids as substrates. Other information is as for Table 1.

The addition of 20 μg of FABP fraction caused a decrease (not statistically significant) in the incorporation of 18:1, 18:3, and 20:4, and a slight increase in rates with 18:0, 18:2, 20:5, and 22:6. In conjunction with these minor effects on absolute reaction rates, the effect of FABP on the overall substrate preference was minimal. Thus, for diacyl-GPC, 18:2 was again the substrate with maximal rates of incorporation, followed by 20:5 > 18:3 > 18:1 = 20:4 > 18:0 = 22:6. This represents a trend toward increasing the incorporation of 20:5 over 18:3 and decreasing the incorporation of 20:4 relative to 18:1 in the absence of FABP.

Rates of incorporation of fatty acids into diacyl-GPE and the effects of FABP are given in Table 2. Again, 18:2 was the substrate with the highest rates of incorporation, followed by 22:6 ⩾ 18:3 = 18:0 ⩾ 20:4 = 18:1 > 20:5.

In the presence of FABP, the incorporation of 18:3 was increased substantially; most of this increase is due to the result of one experiment in which an unusually large amount of this fatty acid was incorporated. Smaller increases were seen with 18:1, 18:2, and 20:5, while the reaction rates with 18:0, 20:4, and 22:6 declined. The substrate preference was changed to 18:3 > 18:2 > 18:0 = 18:1 = 20:5 = 20:4 ⩾ 22:6. There was a greater similarity of reaction rates among many of the fatty acids, and a trend, surprisingly, toward decreasing the incorporation of 22:6 into this phospholipid.

Incorporation rates with 1-16:0-GPE were generally 5-7-fold lower than for 1-16:0-GPC. Interesting exceptions were the rates of 18:0 and 22:6 incorporation, which were nearly equal in the two phospholipids, and 20:5, which had rates of incorporation into diacyl-GPC that were 15-fold greater than into diacyl-GPE. In neither phospholipid was the pattern of substrate preference consistent with the composition of PUFA in these membrane lipids.

To bypass the CoA activation step and thus eliminate any selectivity the acyl-CoA synthetase might have on the incorporation, we performed an experiment using synthesized fatty acyl-CoA derivatives (Table 3). Rates were generally similar to those obtained with the fatty acids, except for a 10-fold higher rate of incorporation of 18:0-CoA into diacyl-GPC. There were some differences in substrate preference: for diacyl-GPC, 18:0 showed the

TABLE 3

Incorporation of Fatty Acyl-CoA into Diacyl-GPC and Diacyl-GPE, and the Effect of FABP[a]

	nmol formed/mg protein/6 min			
	diacyl-GPC		diacyl-GPE	
Fatty acyl-CoA	no FABP	+ FABP	no FABP	+ FABP
18:0	5.39	6.04	1.65	3.21
18:2n-6	0.58	0.17	0.15	0.22
20:4n-6	1.87	1.46	2.32	1.04
22:6n-3	0.31	0.23	2.19	1.38

[a]CoA esters of [^{14}C]labelled fatty acids were prepared as described in Materials and Methods. Acyltransferase activities were measured as for Tables 1 and 2, except that 10 μg of purified FABP was added rather than FABP fraction. Values represent the means of duplicate determinations.

highest rates of incorporation, followed by 20:4, 18:2, and 22:6. For diacyl-GPE, 20:4 and 22:6 were equally effective, followed by 18:0 and 18:2. Interestingly, the effect of FABP was to increase the incorporation of 18:0, and to decrease or have no effect on the incorporation of the unsaturated fatty acids.

DISCUSSION

The purpose of the high n-3 fatty acid content of retina is unclear, but is not limited to providing a highly fluid environment for the visual pigment (35,36). The function of n-3 fatty acids may be related to other characteristics of the outer segment disk membrane, such as flexibility, permeability, or the high degree of membrane turnover in the photoreceptor outer segment. Clearly unique mechanisms exist within the photoreceptor or photoreceptor-retinal pigment epithelium (RPE) complex to create and maintain the unusual composition. One possibility is that the acyltransferase could prefer PUFA, as has been shown in other systems. Additionally, FABP could direct certain PUFA toward incorporation into lysophospholipids and away from oxidation or other routes, thus tailoring the composition of *de novo* synthesized molecular species.

In these studies, rates of incorporation of fatty acids into diacyl-GPC were much greater than into diacyl-GPE, despite the fact that these phospholipids are present in approximately the same molar concentrations in these membranes (4). Masuzawa *et al.* (37) also found that 1-acyl-GPC was the preferred acceptor over 1-acyl-GPE for the CoA- and ATP-dependent acylation. Similar results in retina were found by investigators using different experimental protocols. For example, when rat eyes were injected intravitreally with radiolabelled 20:5n-3, more label was recovered in the diacyl-GPC than diacyl-GPE fraction at all time points (38). Bovine retinas incubated *in vitro* with 20:4n-6, 20:5n-3, or 22:6n-3 labelled diacyl-GPC to a greater extent in all subcellular fractions than diacyl-GPE (39). This may suggest that *in vivo* the principal species synthesized is diacyl-GPC, and diacyl-GPE is prepared from this *via* base exchange or other conversion.

Louie *et al.* have found 10-fold greater specific activities among 22:6-containing species of diacyl-GPC than diacyl-GPE in frog rod outer segments (ROS) prepared from eyes injected with [^{3}H]glycerol. In addition, half-lives of all 22:6-containing species were longer in diacyl-GPE than in diacyl-GPC. Similarly, *in vitro* experiments with isolated bovine ROS incubated with [^{3}H]22:6 yielded specific activities of diacyl-GPC that were 10 times greater than those of diacyl-GPE or diacyl-glycerophosphoserine (40). Specific activities of 22:6-22:6 species were higher than any other 22:6-containing species for all phospholipids studied. Thus, while more diacyl-GPC is initially formed, it may also be rapidly turning over, a process which could not be estimated from our short incubations.

Low rates of incorporation of 18:0 would be expected for the 2-position of GPC and GPE, and our observed rates were therefore consistent with composition data. However, the rates of incorporation with 18:0-CoA were much higher. We have no explanation for this, even though disaturated species of GPC have been isolated (41). The greatest rates of incorporation of fatty acid in our studies were seen with 18:2, although when the CoA esters were used, 18:2 was the least utilized substrate. This suggests that in the assays with fatty acids, conditions were optimal for the activation and incorporation of 18:2 over other substrates. The acyltransferase, on the other hand, is not selective for this fatty acyl-CoA. Johnston and Hudson (4) report 0.1 mol% of 18:2 in whole retina diacyl-GPC and 7.8 mol% in diacyl-GPE. We have found very little (<1%) 18:2 in chick retina total phospholipids throughout development (Sellner, P.A., and Clough, J.A., submitted for publication). This difference from Johnston and Hudson's data (4) may reflect the influence of diet in the hen, an effect that can be significant (42), or the effect of developmental stage. Even if the 18:2 that we find in the retina phospholipid fraction is concentrated in the photoreceptors, our data would be consistent with a major role for the acyl-CoA synthetase in selectively activating this fatty acid for subsequent targeting, as the acyltransferase itself does not appear to select for this substrate (Table 3).

Johnston and Hudson (4) also report 11.4 mol% 20:4 and 19.3 mol% 22:6 in diacyl-GPE, figures that correspond with the rates of acyltransferase activity observed in this study with the fatty acyl-CoA derivatives, but not with the fatty acids. In general, the substrate preference using fatty acids was not consistent either with the final fatty acid composition or with the expected pattern of incorporating PUFA, particularly into diacyl-GPE. A similar conclusion was reached by Zimmerman and Keys (18) in their studies of acyltransferase in isolated bovine rod outer segments. In our studies using microsomes, however, the result apparently reflects the activity of the activation step rather than the acylation. The deacylation/reacylation cycle is contributing in part to the introduction of CoA derivatives of PUFA into these lipids. This path can work in conjunction with the incorporation of PUFA into phosphatidic acid *via* the Kennedy pathway, as Bazán and Bazán have shown (14).

Other mechanisms responsible for establishing a PUFA-rich composition, whether in retina or other tissues, have been suggested (35,43). In retina, there may be selective delivery of particular fatty acids to the photoreceptors *via* the blood and retinal pigment epithelium

(RPE) using special receptors and/or binding proteins. Evidence from Scott and Bazán (44) suggests that in the rat n-3 acids are delivered to the RPE in the form of long-chain PUFA (*e.g.*, 22:6) rather than as the precursor (18:3). In addition, rates of synthesis of long-chain PUFA may be greater for n-3 fatty acids than for other families. While there is no direct evidence for the capacity of the RPE or photoreceptors to synthesize long-chain PUFA from their 18-carbon precursors, synthesis of 22:6 from 22:5n-3 *in vitro* (45) or from 20:5n-3 following intravitreal injection (38,46) does occur, albeit at a low rate.

Restructuring of existing phospholipids may involve other subcellular fractions, as shown in bovine retina by Rotstein and Aveldaño (47). Their data indicate that the mitochondria are not only enriched in PUFA, but actively incorporate exogenous PUFA supplied *in vitro*. This is an especially intriguing possibility in light of the mitochondria-rich region of the photoreceptor adjacent to the outer segment. Other reactions such as CoA-dependent and CoA-independent transacylation may be important in modifying existing phospholipids. In brain microsomes, the latter reaction has been shown to be a significant path for the introduction of 22:6 and 20:4 (37). The transacylation of 16:0 in retina ROS was not significant (48), but similar measurements with PUFA have not been performed. Rates of incorporation can also be different depending on the presence of other fatty acids in the pool. This was pointed out by Lands *et al.* (16), who estimated the relative effectiveness of competing fatty acyl-CoA in the esterification of 20:4-CoA by rat liver microsomes. Such competition studies or determination of fatty acid or acyl-CoA pools would help clarify the mechanisms involved in phospholipid restructuring within a particular system.

The role of FABP has not been clearly established, though it is thought to play a role in intracellular trafficking of potentially toxic hydrophobic substances (22). FABP has been shown to affect several lipid-synthesizing enzymes, including glycerol-3-phosphate acyltransferase and acyl-CoA synthetase, though not always in a consistent manner. The lack of effect of FABP on the incorporation of fatty acid into diacyl-GPC and diacyl-GPE in this study suggests that FABP may be serving simply as a nondiscriminate carrier in the cell, or that its action is directed toward some other pathway of lipid metabolism, *e.g.*, oxidation. This conclusion is substantiated by the data from the experiments with acyl-CoA, in which incorporation of saturated fatty acid was increased and that of PUFA decreased or was unchanged. However, recent results of Bordewick *et al.* (49) using rat liver microsomes and FABP suggest that FABP greatly increases the incorporation of 16:0-CoA, 18:0-CoA, and 18:1-CoA into diacyl-GP and 1-acyl-GP. These authors did not use CoA derivatives of PUFA in their experiments, therefore the enhancement of PUFA incorporation into diacyl-GP during *de novo* phospholipid synthesis could not be assessed. Such a role for FABP in the retina could explain Bazán's result, *i.e.*, a high proportion of phosphatidic acid that contains 22:6, thus establishing a physiological function for this enigmatic protein.

Finally, both the substrate preference data and the effect of FABP may depend on the stage of development of the chick retina. At 14–15 days, the outer segments of the photoreceptors are not fully developed, thus there may not be the demand for long-chain PUFA as when disk membranes are being synthesized at a maximal rate. The data may reflect regulation of acyl-CoA pools *via* acyl-CoA synthetase or *via* the activities of PUFA synthesizing enzymes. Future studies will address this question at a later developmental stage, and will determine if there is a sudden appearance of PUFA when outer segments are being formed, that is, 18–19 days (50). We have found that the 22:6 content of retina phospholipids indeed increases from 4.5% on day 15 to 11.1% on day 21 (Sellner and Clough, submitted for publication). The fact that the chick retina is cone-dominant makes this an interesting and useful comparison with rod-dominant retinas, such as rat or bovine. The cone outer segment is not fully enclosed by a plasma membrane, as is the rod outer segment. Thus, while many lipid synthesizing activities have been described in the rod outer segment, the corresponding enzymes in the cone outer segment have not been studied and may not, in fact, be present. Hence, the mechanisms utilized by the immature retina for the synthesis of PUFA-containing phospholipids may persist in the adult retina.

[Received June 18, 1990; Revision accepted November 24, 1990]

Triolein-Phosphatidylcholine-Cholesterol Emulsions as Substrates for Lipoprotein and Hepatic Lipases

Susanne Bennett Clark* and **Henry L. Laboda**[1]
Departments of Biophysics, Medicine and Physiology, Boston University School of Medicine, Housman Medical Research Center, Boston, MA 02118-2394

Lipolysis of emulsified glycerol tri[9,10-^{3}H]oleate by lipoprotein lipase purified from bovine milk (E.C. 3.1.1.34) and by hepatic lipase purified from rat liver perfusate was studied as a function of the phosphatidylcholine molecular species and the cholesterol content of the emulsions. Overall, the activities of the two enzymes were similar on a molar basis. Lipoprotein lipase initial lipolysis rates also were comparable for emulsions made with egg phosphatidylcholine or with saturated (dimyristoyl, dipalmitoyl and distearoyl) phosphatidylcholines when cholesterol was low. Increasing the cholesterol content of the emulsion from 2–3 mole percent to 7–14 mole percent reduced triolein lipolysis by lipoprotein lipase in emulsions made with saturated phosphatidylcholines. Rat hepatic lipase was more sensitive to increased cholesterol in emulsions made with saturated phosphatidylcholines than was lipoprotein lipase. The ability to maintain triolein lipolysis during longer incubations differed strikingly among the emulsions and for the two enzymes. Lymph chylomicrons were better substrates for both enzymes than any of the emulsions.
***Lipids* 26, 68–73 (1991).**

Lipoprotein lipase(s) (LPL, E.C. 3.1.1.34) and hepatic lipase (HL) are important enzymes which contribute to the metabolism of lipoproteins (LP), particularly the triglyceride (TG)-rich LP, namely chylomicrons (CM), chylomicron remnants (CR) and very low density lipoproteins (VLDL). Both enzymes catalyze the hydrolysis of triacylglycerol (TG), releasing fatty acids (FA) which are ultimately metabolized. The enzymes differ in several respects. HL is confined to the liver whereas LPL, which may represent a group of proteins of differing molecular weights and specific activities (1), is found in many different tissues. LPL, but apparently not HL, requires a cofactor for maximal activity, namely apolipoprotein C-II (apoC-II) which is found in plasma associated mainly with CM, VLDL, and high density lipoproteins (HDL). LPL is also sensitive to high salt concentrations (1M NaCl), unlike HL.

Native substrates for HL have been reported to include HDL_1, HDL_2 (2), apoE containing intermediate density lipoprotein (IDL) (3) and chylomicron remnants (4). Native substrates for LPL are, mainly, VLDL and chylomicrons (5,6). Triglyceride-rich emulsions thus are reasonable models for many of the natural substrates of both enzymes.

Lipoprotein and emulsion surfaces are bounded by phospholipid monolayers, which contain up to 3 mol % TG (7,8) and whose compositions can vary greatly. Studies of LPL have shown that hydrolysis of TG incorporated into planar monolayers is critically dependent on how the substrate molecules are organized at the lipid-water interface; the enzyme activity varies with the surface pressure and the composition of the lipid film (see (5) for review). The lipolytic activity of HL on TG incorporated into monolayers is also influenced by the phospholipid (PL) composition, the unesterified cholesterol (UC) content and the physical state of the monolayer (9,10). Similarly, triolein emulsified in a variety of PL differs in reactivity to rat adipose tissue LPL (11). The present study examines the effect of phosphatidylcholine (PC) molecular species differences and UC content on the lipolysis, by LPL and HL, of a fluid TG (triolein) incorporated into well-characterized, chylomicron-sized emulsion particles of differing surface composition.

MATERIALS AND METHODS

LPL and HL were purified respectively from bovine milk and rat liver perfusate, essentially according to published methods (12,13). Both enzymes showed a single band on 10% SDS-PAGE with a mass of about 50 kD (14,15). Aliquots of a single, combined preparation of each enzyme were stored at −80°C in 50% aqueous glycerol and were used within minutes after thawing.

ApoC-II was isolated from human plasma VLDL (16–18), and its purity was established by IEF electrophoresis and amino acid analysis. Aliquots of an aqueous solution were stored at −80°C.

Emulsions were prepared by sonication above the respective PC chain melting temperatures (19). The final emulsions had surfaces that, at 37°C, were either very fluid, fluid but viscous, very viscous, just below the chain melting transition, or partly solid, depending on the PC composition and the cholesterol content (see Table 2). Aliquots of chloroform solutions of [9,10-^{3}H]trioleoylglycerol (40 mg; SA 0.5 μCi/μmol TG), cholesterol (0.75 or 4.0 mg), and either egg yolk lecithin (EYPC), dimyristoyl phosphatidylcholine (DMPC), dipalmitoyl phosphatidylcholine (DPPC) or distearoyl phosphatidylcholine (DSPC) (9.25 or 6.0 mg, respec-

Chylomicrons[c]	3.0	6.7	87.9	150	1960

[a]Computed from the phase analysis program developed by Miller and Small (23,24) and Spooner and Small (25).
[b]Mean (SEM) of 5–7 separate preparations.
[c]Single batch. Chylomicrons also contained cholesteryl esters (CE) (2.4 mol% total lipid) and protein (2.3 wt% total chylomicron mass).

tively) were pipetted into 10-mL glass vials. Solvent was blown off with a stream of N_2, and the vials were placed into a vacuum desiccator at 4°C for at least 18 hr. Saline (80 mM NaCl, pH 7.2) was added (10 mL) and the vials were heated or cooled to the appropriate temperature (0°C for EYPC, 25–30°C for DMPC, 45–50°C for DPPC and 60–65°C for DSPC). The mixtures were sonicated continuously at the respective temperatures for 11 min at approximately 30% of maximum power output (Branson Sonifier Model 350, 1 cm probe tip). The sonicated mixtures were then transferred, at room temperature, to ultracentrifuge tubes (SW41), overlayered with 1.5–2.0 mL distilled water and centrifuged for 11 min at 23,000 rpm at 25°C. The floated emulsion particles, of a narrow size range, were harvested by tube slicing and were used in enzyme assays within 15 min. Negative stain electron microscopy of representative preparations revealed that all of the emulsion types displayed unimodal populations of particles with round profiles and no fragmented particles.

Chylomicrons were isolated from rat mesenteric lymph which was collected, on ice, for 10 hr after a gastric dose of 0.5 mL triolein containing 100 μCi [9,10-^{3}H]trioleoylglycerol, during continuous gastric infusion of saline at 2 mL/hr. CM were washed and concentrated by ultracentrifugation through an overlay of 6 mL distilled water per tube, in a swinging bucket rotor (SW41; 30,000 rpm for 30 min at 12°C). The final specific activity was approximately 300,000 dpm/μmol TG.

Analytical. Emulsions (5–7 preparations of each emulsion type) and chylomicrons (single preparation) were chemically characterized by standard methods, as described (20). The compositions of the emulsions are shown in Table 1.

Enzyme assays. Both enzyme activities were monitored simultaneously, with each individual emulsion. Assays were performed in duplicate for each preparation in round-bottom glass tubes. Blank tubes contained all ingredients except enzyme. Single pools of apoC-II, albumin and heparin aqueous solutions were used throughout the entire series of experiments.

Lipoprotein lipase. The components were added at room temperature in the order NaCl, pH 7.4 potassium phosphate buffer (KPB), heparin, emulsion, apoC-II, FA-free bovine serum albumin (BSA). The final concentrations in the reaction mixture were NaCl 150 mM, heparin 2.65 μg/mL, apoC-II 16.7 μg/mL, emulsion TG 3.33 μmol/mL, BSA 15 mg/mL, 10 mM pH 7.4 KPB. Tubes were warmed to 37°C for 5 min after apoC-II was added and before adding BSA. The reaction was then initiated by the addition of LPL, freshly diluted in 10 mM pH 7.4 KPB, to yield an enzyme/substrate ratio of 100 ng protein/μmol TG.[2] The LPL and apoC-II concentrations used provided about 1 and 300 molecules per emulsion particle, respectively, giving an apoC-II/LPL ratio of 300. A ratio of 50 has been shown to produce maximal lipolysis in PC monolayers (21). Incubations were routinely performed for both 10 and 20 min and, in certain instances, for up to 1 hr (see Results) with continuous shaking at 1 vibration/sec. The reaction was stopped by addition of a mixture of chloroform/methanol/benzene (0.5:1.2:1.0,v/v/v), containing 0.1 mM oleic acid, and the released FA was partitioned (93%) into an aqueous phase with 0.3M NaOH, as described (20). Aliquots of the aqueous phase were taken for liquid scintillation spectrometry in Liquiscint (National Diagnostics, Manville, NJ).

Hepatic lipase. The reaction mixtures contained NaCl 100 mM, BSA 15 mg/mL and emulsion TG 3.33 μmol/mL in 10 mM pH 7.4 KPB. The reaction was initiated by the addition of HL freshly diluted in 10 mM pH 7.4 KPB, in a ratio of 100 ng protein to 1 μmol TG. Lipolysis was followed at 37°C, routinely for 10 and 20 min but occasionally (see Results) for up to 1 hr, and was stopped as described above for LPL.

[2]In a single series of assays using triolein (TO) emulsified with a non-hydrolyzable PC ether (1-*O*-hexadecyl-2-*O*-oleyl-glycerophosphocholine), the lipolysis rate (FA released/hr/mol TO/mg LPL) was constant over an enzyme/substrate range of 12.5–150 ng LPL/μmol TO (Laboda, unpublished data).

Materials. Nonradioactive lipids were used without further purification. All were >99% pure, as stated by the suppliers and confirmed by thin-layer chromatography (TLC) for lipid class purity and by gas-liquid chromatography (GLC) of FA methyl esters. Cholesterol, DMPC, DPPC, DSPC and EYPC were obtained from Sigma Chemical Co. (St. Louis, MO). Triolein was from Nu Chek Prep (Elysian, MN). Glycerol tri[9,10-^{3}H]oleate, from Research Products, Amersham Corp. (Arlington Heights, IL), was shown to be >99% pure by thin-layer chromatography of neutral lipid classes and liquid scintillation spectrometry. FA-free albumin (Fraction V) was from Sigma Chemical Co.

Statistical procedures. Data were analyzed by 2-way analysis of variance, Student's t-test or paired t-test, as appropriate.

RESULTS

Lipoprotein lipase. Lipolysis rates were essentially linear for at least 20 min for all 8 emulsion types (Fig. 1). Within the groups, the rates determined over 20 min were not significantly different from the rates determined over 10 min (paired t-test).

Overall, PC species significantly affected lipolytic rates ($p<0.05$). Saturated PC emulsions containing the lower cholesterol concentrations (2–3 mol % of the total emulsion) were hydrolyzed at rates similar to those of EYPC-LoC emulsions ($p=0.18$). When the cholesterol content was increased, TG lipolysis was reduced in saturated PC emulsions significantly more than in EYPC emulsions ($p<0.005$). In EYPC emulsions lipolysis was unaffected by an increase in the cholesterol content to above a UC/PC equimolar ratio ($p=0.89$).

When lipolysis was followed for 1 hr in duplicate experiments with each of the 8 emulsion types, further differences became apparent (Fig. 2, top). In emulsions made with EYPC, which contained either low (2.2) or high (14.0 mol%) cholesterol concentrations, and in the DMPC-LoC emulsion, lipolysis rates remained in excess of 80% of the initial rates after 1 hr. In contrast, lipolysis was negligible after 20–30 min in emulsions made with DPPC or DSPC. Lipolysis of the DMPC-HiC emulsion also slowed somewhat after about 30 min, and the overall rate was considerably slower than for the DMPC-LoC emulsion. Even for the most rapidly hydrolyzed emulsions, however, the maximum fraction of substrate triolein hydrolyzed during 1 hr was <8%. Less than 3% of TG was hydrolyzed when the emulsions were stabilized by DPPC or DSPC. Hence the reactions were essentially zero order, at least for 20 min.

The best substrates for LPL were the lymph chylomicrons, although EYPC-stabilized emulsions were almost as reactive.

Hepatic lipase. HL activities for the 8 types of emulsions are shown in Figure 3. As with LPL, the lipolytic rates obtained at 10 and 20 min were not significantly different within groups by paired t-test, although some appear slower at 20 min (Fig. 3). Emulsions made with saturated PCs did not differ significantly from one another, and all were significantly less effective substrates then EYPC stabilized emulsions

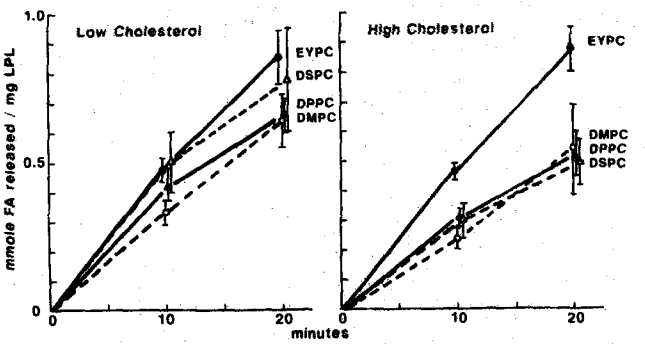

FIG. 1. Activity of purified bovine milk LPL on triolein emulsions with differing PC compositions and cholesterol contents, in the presence of apoC-II and albumin. Data are means and SEM from 5–7 separate preparations of each emulsion. Emulsion compositions are shown in Table 1. Conditions as described in Materials and Methods.

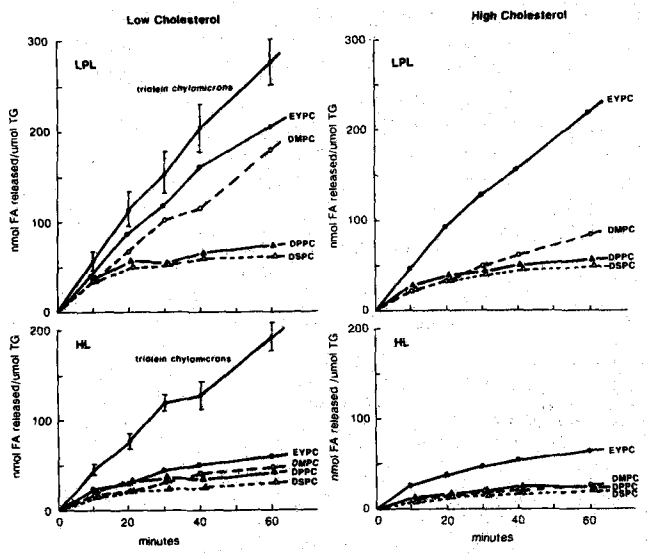

FIG. 2. LPL and HL activities on triolein emulsions and lymph chylomicrons over 1 hr. Assay conditions are described in Materials and Methods. Data points are means of duplicate emulsions, each assayed in duplicate. Chylomicrons ($\bar{X} \pm$ SEM, N=3) were obtained from a single pool of lymph from a triolein-fed rat, and duplicate assays were performed on each of 3 separate days.

($p<0.005$). Individual comparisons between EYPC and either DMPC, DPPC or DSPC all showed significant differences (p range 0.01 to 0.05 for 6 comparisons). Increasing the cholesterol concentration reduced HL activity overall ($p<0.005$); however, only for DPPC and DSPC were the individual comparisons (HiC *vs* LoC) significant ($p\leq0.05$). Thus, HL activity was more profoundly influenced by both the type of PC species and the cholesterol content of the emulsions than was LPL, although the overall trends were similar.

When the incubations were extended for 1 hr, TG lipolysis rates decreased with time for all the emul-

[d]Molecular weight of tetramer 200 KD by gel fractionation as reported by Twu *et al.* (14).

sions (Fig. 2, bottom). The decrease was most marked for emulsions made with saturated PCs and higher concentrations of cholesterol. In contrast to LPL, no emulsions were as effective HL substrates as were lymph chylomicrons. Although the absolute lipolysis rates obtained with HL were less than with LPL when the same weights of both enzymes were used in the assays (100 ng per μmol TG), comparison of the enzymes on a molar basis revealed that HL activity approached that of LPL and in some cases exceeded it (Table 2). Emulsions made with EYPC and particularly chylomicrons, which have a similar PC composition to EYPC, were more rapidly hydrolyzed by HL than by LPL.

DISCUSSION

The present experiments have established that the physical state and the chemical composition of an emulsion surface both influence the rate and particularly the extent to which emulsified triolein is hydrolyzed by a purified lipoprotein lipase isolated from bovine milk and by purified hepatic lipase isolated from rat livers. All the 8 emulsion types studied were quite effective substrates for both enzymes in these isolated *in vitro* systems. For LPL, the initial lipolysis rates were significantly reduced when saturated PCs replaced mixed chain PCs and when the cholesterol content was increased. Increasing the cholesterol raises the viscosity of fluid PC monolayers. However, since lipolysis was unaffected by even a surface-saturating cholesterol content when EYPC was used, it is clear that a condensed, viscous surface alone does not necessarily inhibit triolein lipolysis by LPL. Similarly, fluidity of the emulsion surface is not, of itself, a determinant for lipolysis by LPL because DPPC- and DSPC-stabilized emulsions were better substrates when their surfaces were partially solid (low cholesterol) than when they were very viscous fluids (high cholesterol). HL, however, clearly was inhibited by a high surface viscosity alone. The inhibition was most evident with saturated PCs, but also occurred when the cholesterol concentration was increased in the presence of the unsaturated, mixed chain EYPC (see Figs. 2 and 3). The difference between the two lipases could be explained if the HL molecules require closer association with the emulsion surface monolayer in order to catalyze lipolysis than do LPL molecules. HL may even penetrate into the monolayer. If so, a highly viscous surface may inhibit HL activity by preventing penetration. LPL is thought not to attach directly to monolayers, but instead attaches as an enzyme-cofactor complex (5) in an optimum orientation for TG lipolysis. The present results might thus imply that apoC-II binding is less affected by emulsion surface composition than is the binding of a larger, higher molecular weight protein such as HL.

Although the assay conditions chosen ensured an excess of total TG substrate (about 1–4% was hydrolyzed in 20 min), the results suggested that TG available to the enzymes might, nevertheless, have become rate-limiting in certain instances. Thus, in certain emulsions lipolysis began to slow down within 20 min, while in others lipolysis was sustained beyond 60 min (see Fig. 2). This decrease in lipolytic rate over time could not have been caused by an increase in the back reaction rate for the following reasons. For LPL, the most effective emulsion substrates, which sustained rapid lipolysis rates (EYPC-LoC and EYPC-HiC), released about 200 nmol FA per μmol TG in 1 hr. This equates to about 130 nmol FA per 200 μL assay medium at 1 hr and about 40 nmol FA at 20 min. Since the BSA concentration was about 50 nmol/200 μL, the total FA released even after 1 hr was sufficient to occupy only about 3 of the 7 albumin binding sites. Moreover, the

reaction remained nearly linear for at least 1 hr not only for the EYPC emulsions, but also for the even more rapidly hydrolyzed lymph chylomicrons. Thus, TG lipolysis in DPPC- and DSPC-stabilized emulsions is most unlikely to have ceased after 20 min because of accumulation of product in the medium. That transfer of FA molecules from their formation site on the emulsion surface to BSA in the medium failed for some of the emulsions is theoretically possible, but is unlikely at pH 7.4 (22). Differences in co-factor binding or activation of LPL may play a role, as mentioned previously. However, the relative suppression of lipolysis by omission of apoC-II was indistinguishable among the 8 emulsions[3], which tends to suggest that neither differential apoC-II binding to the original emulsions nor enzyme activation was a major contributing variable in these systems. Nevertheless, co-factor binding may have differed among the emulsions once their surfaces had been further modified by the presence of other lipolytic products released during initial lipolysis of TG—diglycerides (DG), monoglycerides (MG), FA. More work is underway to clarify this possibility.

The differences in the reactivities of the substrate emulsions may relate in part to the surface TG concentration (23-25). No data are currently available that bear directly on triolein concentrations in emulsion surfaces of differing PC composition. Data obtained in pure PC vesicles (8), however, suggest that triolein may be present to a maximum of about 3 mol% of the surface irrespective of PC species (EYPC or DPPC). The number of surface TG molecules per emulsion particle were therefore calculated (Table 1) with the assumption that increasing the cholesterol in the surface inhibited TG incorporation similarly for all four PCs. It can be seen that surface TG concentration *per se* is not a predictor of lipolytic rate (compare Table 1 with Figs. 1-3). However, the decrease in lipolysis rate after 20 min observed in the partially solid-surfaced DPPC and DSPC emulsions, in particular, may have been caused by a failure to replace surface triolein molecules from the core as those originally present were removed. To date, no mechanism has been described for such a hypothetical failure, however. In sum, although very high (saturating) surface concentrations of cholesterol do reduce the emulsion surface triglyceride concentration to as little as 0.1 mol% or less (25), neither a decreased surface triglyceride concentration *per se* nor a high surface viscosity *per se* could have been major determinants of the failure to sustain lipolysis, because EYPC-HiC emulsions continued to be hydrolyzed at close to initial rates for at least an hour. Lipolysis of DMPC-HiC emulsions also remained roughly constant for 1 hr, albeit at a slower rate than DMPC-LoC.

The use of well-defined, chylomicron-sized emulsions as substrates revealed further differences between HL and LPL. Although EYPC emulsions were the best model substrates for both enzymes, even these were much less effective substrates for HL than were lymph chylomicrons. Chylomicrons were hydrolyzed twice as fast by HL as by LPL (see Table 2). With HL, unlike with LPL, triolein lipolysis in all of the emulsion substrates, including those made with EYPC, slowed considerably after 10-20 min. Only chylomicron lipolysis proceeded linearly for a full hour. However, with HL as with LPL, the emulsions whose lipolysis slowed down most over time contained DPPC or DSPC with high cholesterol concentrations. Thus, some similar, as yet unidentified, constraints probably affected both assay systems.

The pools of emulsified TG accessible to HL and LPL lipolysis also appear to differ, because the effects of emulsion surface composition on TG lipolysis were significantly more dramatic for HL than for LPL. Comparing Figures 1 and 3, it is clear that HL activity is more affected by the type of surface PC species and by cholesterol content than is LPL.

[3]Duplicate tubes lacking apoC-II were routinely included in all 20 min LPL assays (Bennett Clark, unpublished data).

ACKNOWLEDGMENTS

Eva Belur provided expert technical assistance and Anne Plunkett prepared the manuscript. We appreciate the helpful discussions with Dr. D.M. Small on some aspects of this work.

METHODS

Separation and Quantitation of Phospholipids in Animal Tissues by Iatroscan TLC/FID

Remi De Schrijver* and **Daniel Vermeulen**
Catholic University of Leuven, Laboratory of Nutrition, B-3001 Leuven, Belgium

A procedure has been developed to separate and quantitate phospholipids, including phosphatidylinositol and phosphatidylserine, from animal tissues by means of the Iatroscan TLC/FID technique. The method is based on the use of 0.01 M oxalic acid impregnated Chromarods-SII and stepwise resolution of the phospholipids in the presence of 1,2-dipalmitoyl-*sn*-glycero-3-phospho (*N,N*-dimethylethanolamine) as internal standard. To remove the neutral lipids, the rods are initially developed in a non-polar solvent mixture followed by partial scanning. Next, the rods are impregnated with oxalic acid, developed twice in $CHCl_3/CH_3OH/CH_3COOH/HCOOH/H_2O$ (80:35:2:1:3, v/v/v/v/v) and partially scanned for measuring lysophosphatidylcholine, sphingomyelin and phosphatidylcholine. The subsequent step involves double development in $CHCl_3/CH_3OH/30\%$ NH_4OH (60:35:0.9, v/v/v) to resolve cardiolipin, internal standard, phosphatidylethanolamine, phosphatidylinositol, phosphatidylserine and phosphatidic acid. For each phospholipid a linear calibration curve with a highly significant correlation coefficient was obtained. However, the calibration lines extrapolated to negative intercepts on the ordinate, indicating declining sensitivity at low phospholipid loads. ***Lipids 26,*** **74–76 (1991).**

The Iatroscan TH-10 system combines thin-layer chromatography (TLC) and flame ionization detection (FID) and has been shown to be a useful tool in lipid analysis (1,2). However, the separation and quantitation of certain phospholipids still poses problems. Analysis of blood plasma phospholipids with the solvent system $CHCl_3$/MeOH/H_2O (80:35:3, v/v/v) resulted in poor separation of cardiolipin (CL), phosphatidylserine (PS) and phosphatidylglycerol (PG) (3). Phosphatidylinositol (PI) and PS from lymphocytes were not separated by $CHCl_3$/MeOH/H_2O (60:30:3.5, v/v/v) (4). The major phospholipids from heart mitochondria, including PS and PI, were resolved by development in $CHCl_3$/MeOH/H_2O (80:35:3, v/v/v) (5). In the latter solvent system, the water concentration was reported to be critical. However, using the same experimental conditions in our laboratory, or changing the volume ratios of $CHCl_3$/MeOH/H_2O, did not result in satisfactory resolution of PI and PS. Banerjee *et al.* (6) demonstrated that rod impregnation with 0.25M oxalic acid in acetonitrile gave better and more reproducible separations. Nevertheless, oxalic acid treatment did not prevent concomitant elution of PI and PS. Except for lysophosphatidylcholine (LPC), the major phospholipids from trout gill could be separated using the solvent system $CHCl_3$/MeOH/H_2O (80:35:3, v/v/v), but quantitation of PI by the Iatroscan method did not agree with the results obtained by classical TLC combined with phosphorus determination (7). Kramer *et al.* (8) developed the rods twice in $CHCl_3$/MeOH/H_2O (68.5:29:2.5, v/v/v) with air drying between developments, which enhanced the separation of PI and PS, but PI was not reproducibly resolved from PE. The use of internal standards was recommended to reduce the variation in results attributed to the inconsistent behavior of individual rods (9,10).

The present paper describes a modification of existing TLC/FID methods permitting better resolution of phospholipids from blood plasma and animal tissues.

MATERIALS AND METHODS

Chemicals. The phospholipid standards PE, PC, PI, PS, LPC, SPH, PA and CL were obtained from Serdary Research Laboratories (London, Ontario, Canada). The internal standard 1,2-dipalmitoyl-*sn*-glycero-3-phospho-(*N,N*-dimethylethanolamine) was purchased from Koch-Light Laboratories (Colnbrook, England). Control for purity of the individual phospholipid standards revealed a single peak on the chromatogram. All other chemicals and organic solvents were of analytical grade.

Instrumentation. The Iatroscan TH-10 Mark II was used in combination with Chromarods-SII having a precoated active silica thin layer (Iatron Laboratories Inc., Tokyo, Japan). Peak areas were calculated with a Shimadzu RIA-integrator (Shimadzu Corporation, Tokyo, Japan). Rods were scanned under the following conditions: hydrogen pressure, 0.8kg/cm^2; air flow, 1300 mL/min; scanning speed, 3.8 cm/sec. In order to allow sufficient time for peak area integration after each rod scan, we installed a push-button in the Iatroscan instrument, making it possible to stop the rod holder between successive scannings.

Lipid extraction. Total lipids were extracted from blood plasma and animal tissues (liver, heart) using successive solvent mixtures: $CHCl_3$/MeOH/30% aqueous NH_4OH (35:5:2, v/v/v), $CHCl_3$/MeOH (2:1, v/v) and $CHCl_3$/MeoH (1:2, v/v). Each solvent system contained 0.01% butylated hydroxytoluene as antioxidant. Tissue samples were homogenized in the solvents with an Ultra Turrax mixer (Janke & Kunkel, Staufen, Germany). The homogenates were centrifuged and the supernatants from each extraction step were combined. Subsequently, the total lipid extract was washed with 0.2% $CaCl_2$. The organic phase

Abbreviations: CL, cardiolipin; FID, flame ionization detector; LPC, lysophosphatidylcholine; PA, phosphatidic acid; PC, phosphatidylcholine; PDME, phosphatidyl-*N,N*-dimethylethanolamine, 1,2-dipalmitoyl-*sn*-glycero-3-phospho(*N,N*-dimethylethanolamine); PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; SPH, sphingomyelin; TLC, thin-layer chromatography.

was separated by centrifugation and solvents were almost completely removed in a rotary evaporator at 35°C. Finally, the lipid residue was evaporated to dryness under a stream of nitrogen at 35°C. Dried lipids were redissolved in chloroform containing the internal standard (4 mg/mL). The internal standard was intended to reduce the variability in FID response due to differences between rods as well as to the quantity applied to the rods (9,11).

Chromarod development and scanning. Chromarods-SII were routinely stored in 4.5M H_2SO_4. Prior to use, the rods were washed with distilled water, dried at 110°C for 15 min and activated by passing through the flame of the Iatroscan detector. One μL of total lipids, containing the internal standard, was spotted on each rod using a 10-μL Hamilton syringe. To separate total phospholipids from neutral lipids, rods were developed in hexane/diethyl ether/formic acid (70:30:1, v/v/v), dried at 70°C, followed by a partial burn, leaving the polar lipid fraction unpyrolyzed. Thus, scanning was stopped when the peak of free cholesterol reached baseline. The phospholipids were resolved in subsequent steps, starting with impregnating the rods with oxalic acid. For that purpose, the rods were placed upside down in a development chamber containing 0.01 M oxalic acid in acetone and allowed to develop over their full length in direction of the lipid spot. The reason for developing the rods in the upside down position was that oxalic acid impregnation appeared to diminish in the direction of the moving solvent and that higher impregnation levels facilitated the separation of PI and PS (see Results and Discussion). Acetone was chosen because phospholipids do not migrate in this solvent. Next, the rods were developed twice in $CHCl_3$/MeOH/CH_3COOH/HCOOH/H_2O (80:35:2:1:3, v/v/v/v/v) with drying at 70°C for 10 min before each development. The slower migrating components LPC, SPH and PC were very well resolved; the other phospholipids moved to 1 cm from the top of the rod and were poorly resolved, however well separated from PC. After drying (70°C, 10 min) and partial burning to quantitate LPC, SPH and PC, rods were developed twice in $CHCl_3$/MeOH/30% aqueous NH_4OH (60:35:0.9, v/v/v) with drying (70°C, 10 min) after each development. The remaining phospholipids CL, IS, PE, PI, PS and PA were then scanned.

Calibration curves. Regression equations were calculated between the phospholipid amounts (x) spotted on the rods and the area ratios (y) between phospholipid and internal standard. Data were used from analyses of eight different loads, each load being analyzed with 12 different Chromarods-SII. Phospholipids were applied in the 0.4–20 μg range, depending on the nature of the phospholipid (Table 1). Regression analyses was done for the following functions: $y = a + bx$, $y = a + bx + cx^2$ and $y = a.x^b$ (12).

RESULTS AND DISCUSSION

In the procedure given in the Materials and Methods section, only the optimal conditions for Chromarod development and scanning are reported. However, various oxalic acid concentrations, solvent systems, single *vs* multiple development procedures and different ways of partial burns were tested. Figure 1 shows a typical phospholipid chromatogram obtained from the lipid extract of chicken liver.

TABLE 1

Linear Regression Parameters for Phospholipid Calibration Curves

Phospholipid[a]	Range (μg)	Linear calibration curve[b] slope	Y-intercept	Correlation (R^2)
LPC	0.4-9.2	0.119	−0.026	0.986
SPH	1.0-9.4	0.185	−0.184	0.969
PC	1.9-20.0	0.302	−0.347	0.986
CL	1.2-10.0	0.193	−0.140	0.992
PE	1.2-20.0	0.415	−0.510	0.981
PI	1.5-10.0	0.133	−0.025	0.986
PS	1.5-10.0	0.225	−0.082	0.988
PA	1.7-10.0	0.220	−0.221	0.996

[a]For abbreviations, see footnote to title.

[b]According to the equation: area ratio between phospholipid and internal standard = slope.μg phospholipid + y-intercept.

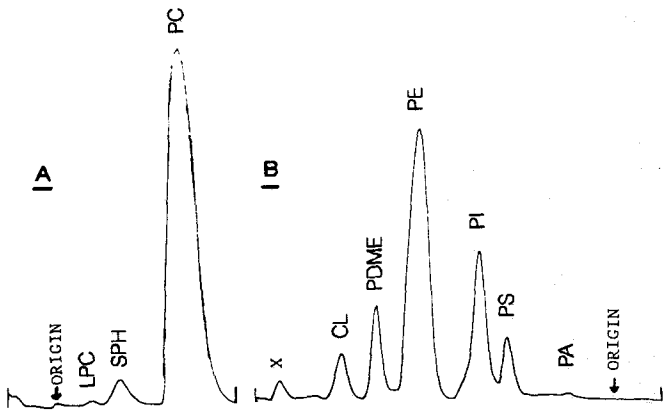

FIG. 1. TLC/FID separation of chicken liver phospholipids on Chromarods-SII impregnated with 0.01 M oxalic acid in acetone. A, first partial phospholipid scan after double development in $CHCl_3$/MeOH/CH_3COOH/HCOOH/H_2O (80:35:2:1:3, v/v/v/v/v). B, second partial phospholipid scan after double development in $CHCl_3$/MeOH/30% NH_4OH (60:35:0.9, v/v/v). For peak assignments, see abbreviations in footnote to title; X, probably monoglyceride. In A and B, scanning direction was from left to right.

Neutral lipids were eliminated from total lipid extract by rod development in hexane/diethyl ether/formic acid (70:30:1, v/v/v), followed by partial burning. The inclusion of hexane in the solvent system resulted in quick development and a greater difference in the retention times between free cholesterol and the polar lipid fraction, facilitating complete burning of the neutral lipids and leaving the phospholipids intact. However, this solvent mixture did not separate cholesteryl esters and triglycerides. Consequently, in case the neutral lipids are also to be determined, a less polar solvent system has to be used. Neutral lipids can be separated with the solvent system hexane/diethyl ether/formic acid (85:50:0.1, v/v/v).

Our experiments showed that oxalic acid impregnation of the rods improved peak shape, which is consistent with the observation of Banerjee *et al.* (6). However, we noted that the oxalic acid concentration in acetone is critical.

Concentrations lower than 0.01 M produced a non-symmetrical PS peak, while concentrations higher than 0.01 M gave rise to an additional spurious peak in front of CL. This extra peak was not a phospholipid, as demonstrated by spraying of the developed rod with molybdenum reagent (13), but had the same R_f value as a monoglyceride. Possibly, monoglycerides were not well separated from phospholipids in the first solvent system. The rods were impregnated upside down, with the remaining phospholipids on top, because impregnation in the other direction resulted in no baseline separation of PI and PS. The reason for this is not clear, but it may be due to the existence of an oxalic acid gradient along the rod. It was also necessary to perform oxalic acid impregnation just prior to the phospholipid separations. When the oxalic acid treatment was carried out after quantitation of LPC, SPH and PC, there was an insufficient separation between PE, PI and PS, while PDME and CL co-migrated. It has been suggested that oxalic acid may form a complex with the inorganic phospholipid moiety, improving phospholipid separation (6). If this were true, the formation of the complex may be pH-dependent, apparently being favored by acidic pH.

Satisfactory separations of phospholipids could not be achieved by using only one solvent system, even when the analyses were carried out with oxalic acid impregnated rods combined with repeated developments. This should not be surprising since also in ordinary TLC, two-dimensional procedures combined with two different solvent systems are the method of choice (13).

In general, neutral and acidic solvent mixtures gave satisfactory separations between LPC, SPH and PC, whereas the resolution of the remaining phospholipids was best achieved with basic solvent systems. The acidic solvent system was made rather polar in order to obtain baseline separation between LPC and SPH. In the composition of the basic solvent system the amount of NH_4OH was very critical. Using 0.5 instead of 0.9 volumes resulted in poor resolution of PS and PI. Both phospholipids remained separated up to 1.5 volumes of 30% NH_4OH, but then CL and the internal standard co-migrated. Increasing the NH_4OH content shifted the components towards the solvent front, except for PA.

Regression analysis revealed that for all phospholipids, linear as well as curvilinear calibration curves were obtained with excellent fits. For the linear regression lines, the coefficient of determination (R^2), the slope and y-intercept are presented in Table 1. The R^2 values for the curvilinear (data not tabulated) and the linear regressions were similar ($R^2>0.97$). The FID-response varied consistently among phospholipids, as indicated by the slope differences. In accordance with Hazel (7), the linear standard curves passed through the x-axis, the PE and PC curves showing the highest Y-intercept deviation. Thus the regression equations are not suitable for measurements of loads which are lower than the range studied. Consequently, the concentration of the lipid extract applied to the rods must be adjusted so that the quantity of each phospholipid is within the range for which its standard curve was calculated.

A drawback of the present procedure is that the Chromarods need to be impregnated each time before use. Also, the multiple developments are more time-consuming as compared to methods employing only a single developing solvent system. However, these disadvantages become less important in routine analyses, the more so since all phospholipids can be quantified by the present method.

A Procedure for the Simultaneous Determination of Lipid and Protein in Biomembranes and Other Biological Samples

Felipe Rodríguez-Vico*, Marina Martínez-Cayuela, M. Flor Zafra, Eduardo García-Peregrín and Hilario Ramírez

Department of Biochemistry and Molecular Biology, University of Granada, 18071 Granada, Spain

Very small sample sizes frequently become the limiting factor in biochemical and biomembrane studies in which routine quantification of protein and bulk lipids are required. The procedure described here allows the simultaneous determination of protein and lipid without initial, multiple aliquots. The method is based on the quantitative precipitation of proteins from a defined hexane/isopropanol mixture. The liquid phase resulting after decanting and concentrating to dryness can then be used to assay the lipid content directly. Quantitative assay of protein can be achieved after resuspension of the pelleted material by addition of sodium dodecyl sulfate (0.1%) and deoxycholate (1%). The method is also applicable to other types of lipid- and protein-containing samples with a broad range of protein/lipid ratios and lipid compositions, as they occur, for example, in serum lipoproteins.
***Lipids 26,* 77-80 (1991).**

The Lowry procedure is the most often used method for the routine assay of proteins (1). While the procedure was originally developed for working with soluble proteins, it is also extensively employed for the assay of hydrophobic proteins, such as those in membrane subcellular fractions.

When working with hydrophobic proteins, a number of difficulties can be encountered which can make it necessary to include a preliminary solubilization or delipidation step (1-3). Heat solubilization by holding samples at 37°C overnight, or at 100°C for 30 min, has been used by various investigators to dissolve protein from samples containing large amounts of lipid. Nevertheless, this treatment can give rise to significant errors due to lipid oxidation and subsequent reaction with the Folin-phenol reagent (4,5).

Delipidation methods based on acid precipitation and/or precipitation with organic solvents represent alternatives to achieve solubilization of protein from membrane preparations (3,6-8). These methods allow the removal of most lipids. Alternatively, the precipitation step involves protein concentration, which has been proven highly useful for very dilute samples (6-8). Lipid extraction with organic solvents can be used to determine proteins and lipids in the same sample aliquot simultaneously. The solvent mixture most frequently used to extract lipids is chloroform/methanol/water. However, this solvent system is not suited to precipitate proteins quantitatively prior to the Lowry assay (5,9,10).

The new procedure we describe in this communication lends itself very well to the determination of soluble as well as hydrophobic proteins and allows simultaneous extraction and determination of lipids on the same sample. The method is especially useful when very small volumes of membrane samples are to be analyzed for their protein and lipid contents.

Abbreviations: DTT, dithiothreitol; HDL, high density lipoprotein; IDL, intermediate density lipoprotein; LDL, low density lipoprotein; SDS, sodium dodecyl sulfate; TCA, trichloroacetate; VLDL, very low density lipoprotein.

MATERIALS AND METHODS

Chemicals. HEPES, imidazole, dithiothreitol (DTT), sodium dodecyl sulfate (SDS), phospholipids (phosphatidylcholine from egg yolk), deoxycholate and leupeptine were purchased from Sigma Chemical Co. (St. Louis, MO); trichloroacetic acid (TCA), isopropanol and hexane were from Merck (Darmstadt, Federal Republic of Germany); Folin-Ciocalteu reagent was from Analema (Vigo, Spain). All other reagents used were of analytical grade.

Isolation of microsomes from chicken liver. White Leghorn male chicks (14-day-old) were used. Livers were removed, weighed, minced and homogenized with a motor-driven, all-glass Potter-Elvejhem homogenizer in 3 vol of 10 mM HEPES buffer, pH 7.4, containing 0.25 M sucrose, 50 mM NaCl, 20 mM EDTA, 2 mM EGTA, 40 mM leupeptine and 5 mM DTT. The broken cell preparation was centrifuged at 17,000 × *g* for 20 min. The resulting supernatant fraction was centrifuged at 105,000 × *g* for 60 min. The pellet containing microsomes was resuspended with a motor-driven mechanical Potter-Elvejhem homogenizer in 50 mM imidazole buffer, pH 7.4, containing 250 mM NaCl, 1 mM EDTA, 2 mM EGTA, 40 mM leupeptine and 5 mM DTT. The resuspended suspension was then centrifuged at 105,000 × *g* for 60 min to obtain a very clean microsomal fraction. All operations were done at 4°C.

Isolation of lipoproteins from chick plasma. Plasma from three-week-old chicks was used. Chicks were fed a standard diet (Sanders A-00) *ad libitum* from 0 to 14 days of age, followed by the standard diet supplemented with 20% coconut oil for seven days. Samples of plasma were adjusted to a density of 1.21 with solid KBr as described by Redgrave *et al.* (11). Ultracentrifugation was done on a density gradient according to the procedure of Hermier *et al.* (12). On completion of the centrifugation, fractions of 0.5 mL instead of 0.4 mL were collected from the bottom by using a peristaltic pump. This fractionation did not affect the final 2 mL at the bottom of the tube, which contained proteins almost exclusively and lacked lipids (12).

Procedure. An aliquot (50 μL) of the appropriate aqueous microsomal or lipoprotein fraction was added to 5 mL of hexane/isopropanol (3:2, v/v). Samples were vortexed and centrifuged at 4000 × *g* for 15 min. The liquid phase was decanted and concentrated to dryness under a stream of N_2. Pelleted protein was also dried under a stream of N_2 and then solubilized by addition of 200 μL of SDS (0.1%) and deoxycholate (1%) in NaOH (0.5 M). The amount of protein present was determined in each case by the standard Lowry method using 2.5 mL of Biuret reagent and 0.25 mL of Folin-Ciocalteu reagent

(1). Lipid phosphorus was determined by the method of Bartlett (13). Cholesterol and triglycerides were determined by enzymic colorimetric methods using test kits from Boehringer Mannheim GmbH (Mannheim, Federal Republic of Germany) with samples being dissolved in isopropanol.

Precipitation with trichloroacetic acid. Unless otherwise specified, an aliquot (500 μL) of trichloroacetic acid (20%) was added to 500 μL of sample. Samples were vortexed and centrifuged at 15000 × *g* for 5 min, and the supernatant was removed. The protein pellet was resuspended in water and assayed for protein content by the standard Lowry method (1).

RESULTS AND DISCUSSION

Quantitative analysis of the protein and lipid content of biological materials frequently requires an extraction procedure suitable for separating lipids from protein. Folch *et al.* (9) developed a procedure for the extraction of lipids based on a chloroform/methanol/water biphasic solvent system which has been used by numerous investigators (*e.g.*, 6,14–16). This method, however, was not optimized for determining proteins, and protein recoveries are normally lower than 80% (5,10). Additional drawbacks are encountered when working with subcellular fractions because of the small sample sizes which make it impossible to extract proteins without loss. All biphasic solvent systems that are in use seem to have the same disadvantage (10,14,15). Because monophasic methods have been shown to be more efficient for lipid extraction (16,17), we decided to use a single-phase solvent system in the present study.

Our method is based upon a precipitation step with a hexane/isopropanol mixture which allows separation of lipids from proteins. The solvent mixture, which is similar to mixtures suggested by others, has successfully been adapted and used for microsomal, mitochondrial and liposomal samples (14,18,19). After protein precipitation the supernatant is decanted to determine the lipid content, whereas the protein pellet is solubilized with SDS (0.1%) and deoxycholate (1%) in NaOH (0.5M) for the Lowry assay. Use of this solubilization mixture does not interfere with the Lowry method. In fact, we observed that use of the mixture can partially counteract the increase in absorbance at 640 nm produced by Triton X-100 or phospholipids when these are added before addition of the Biuret solution.

The purpose of the present procedure is not only to determine protein, but also to quantitatively extract lipids for assay. We have studied the effective ranges in which the method remains operative with respect to volume as well as lipid and protein concentrations.

As shown in Table 1, the assay of neither protein, nor phospholipid nor cholesterol was appreciably affected by the sample volume in the entire range assayed (5–50 μL). Standard errors of the mean for the protein, phospholipid or cholesterol values obtained were lower than 10%. We measured phospholipids and cholesterol in the organic phase because these typically constitute the bulk of membrane lipids and commonly require assay in biochemical studies.

When different concentrations of protein, phospholipid or cholesterol were measured in the same volume of sample (50 μL), the estimated concentrations were approximately linear in all the ranges assayed (Fig. 1).

TABLE 1

Effect of Sample Volume on Protein, Phospholipid and Cholesterol Determinations[a]

Volume (μL)	Protein (μg)	Phospholipid (μg)	Cholesterol (μg)
5	30.56 ± 1.08	1.508 ± 0.256	4.651 ± 0.141
10	32.54 ± 1.43	1.251 ± 0.049	4.250 ± 0.041
25	32.38 ± 0.58	1.279 ± 0.111	4.912 ± 0.496
50	33.19 ± 0.66	1.216 ± 0.061	4.530 ± 0.095

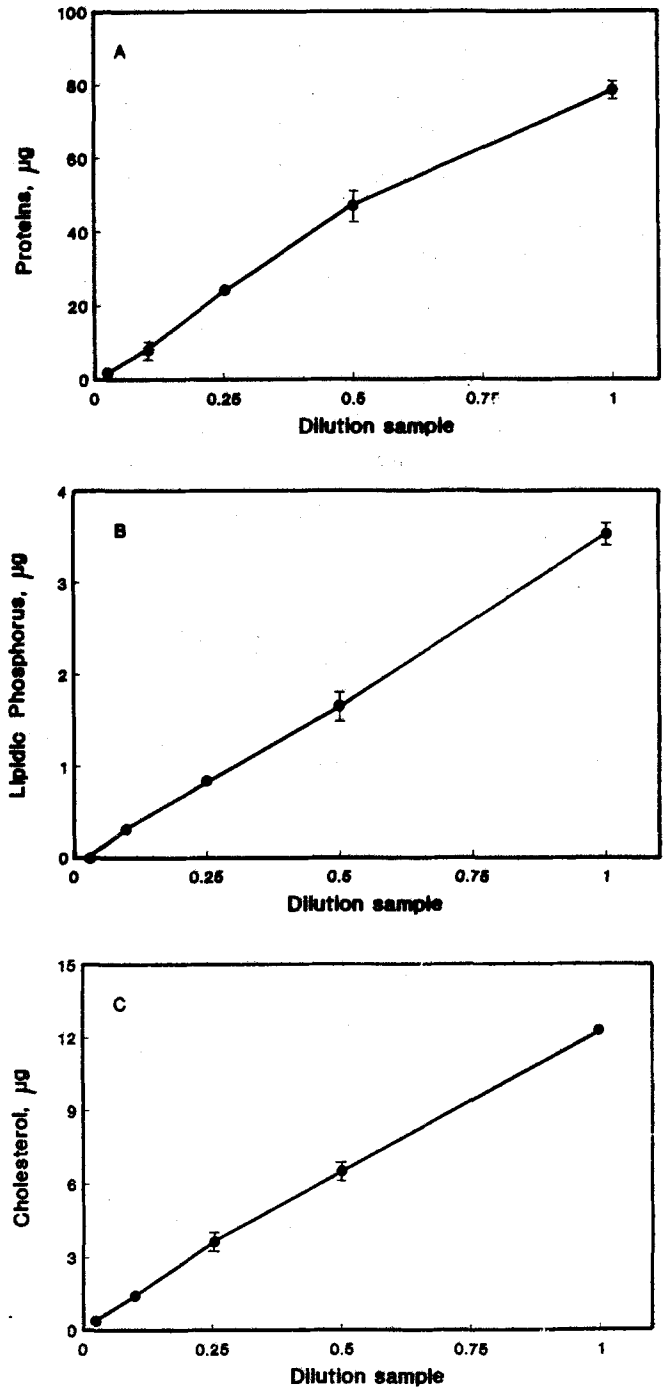
[a]Different volumes of samples ranging from 5 μL to 50 μL, but containing the same amount of microsomal protein, were assayed according to Lowry *et al.* (1) (28.22 μg). Phospholipid (1.32 μg) and cholesterol (3.64 μg) were measured after extraction by the Folch method (9) using the new procedure. Values are means ± SEM of five determinations.

Acidic precipitation is normally used on membrane preparations to eliminate multiple interferences and to separate proteins from lipids. This approach, however, does not guarantee quantitative recovery when used at protein levels lower than 5 μg (8). To demonstrate the higher efficiency of our procedure as opposed to the common acidic precipitation method, we have compared the operative ranges with regard to protein concentration and sample volume. With respect to the amount of protein, both methods showed an essentially linear relationship; nevertheless, values obtained by acidic precipitation were lower than those obtained by our new procedure (Fig. 2). Furthermore, the minimum amount of protein (1.88 μg) required was clearly higher for the acidic precipitation (5.51 μg) than for our procedure (1.64 μg). Likewise, values resulting from the acidic precipitation showed higher SEM at low protein concentrations, indicating a comparatively lower reproducibility. Standard deviations obtained for the new method were clearly lower.

Measurement of the same amount of protein at varying volumes of sample seemed to show poor efficiency of precipitation with trichloroacetic acid for volumes below 25 μL (Fig. 3). Precipitation with the hexane/isopropanol mixture was, by contrast, equally efficient over the entire range assayed.

In order to determine whether the method would also be applicable to the analysis of other types of lipid- and protein-containing samples within the range of protein/lipid ratios and for different lipid compositions in respect to phospholipids, cholesterol, cholesterol ester and triacylglycerol, chick lipoproteins were analyzed. Table 2 shows that the results obtained by direct measurement of each of the components (expected results) were quite similar to those obtained with our new method (measured results).

In summary, the new procedure reported here simplifies the assay of lipid and protein in membrane and other preparations, and permits their quantitative separation. The procedure allows the investigator to carry out the Lowry assay on the sedimented proteins, and to directly analyze the lipids present in the liquid phase. The method avoids the need for initial, multiple aliquots of the same sample for the separate measurement of proteins and lipids.



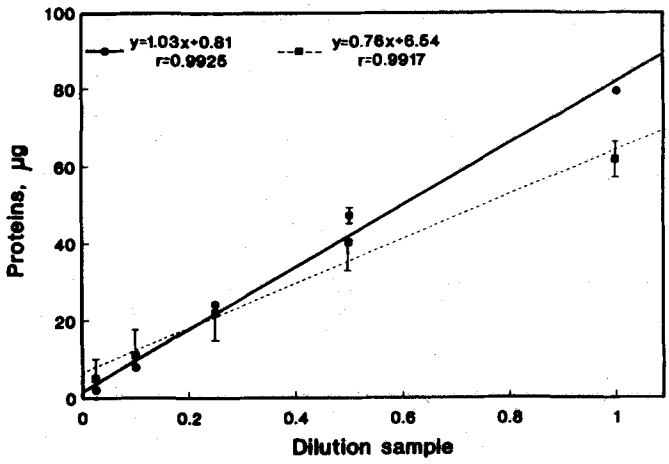


FIG. 1. Effect of the concentration of protein (A), phospholipid (B) and cholesterol (C) on the hexane/isopropanol precipitation method. A 50-µL sample containing different amounts of microsomal extract was assayed for protein, phospholipid and cholesterol using the new procedure. Values are means ± SEM of five determinations.

DIF. 2. Effect of protein concentration on the trichloroacetic acid and the hexane/isopropanol precipitation method for protein determination. A 50-µL sample containing different amounts of microsomal extract was assayed for protein using the new procedure (●), or the trichloroacetic acid precipitation method (■). Values are means ± SEM of five determinations.

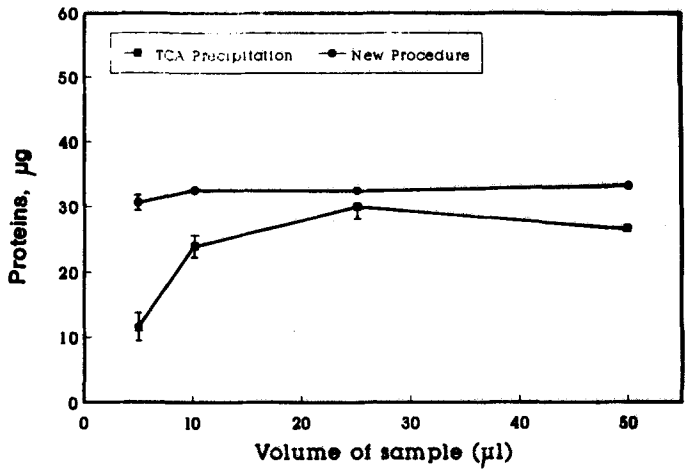

FIG. 3. Effect of volume of the sample on protein determination by the trichloroacetic acid and the hexane/isopropanol precipitation method. Different volumes of samples ranging from 5 µL to 50 µL but containing the same amount of microsomal extract, were assayed for protein using the new procedure (●), or the trichloroacetic acid precipitation method (■). Five hundred µL of 20% TCA were added to samples. Values are means ± SEM of five determinations.

TABLE 2

Plasma Lipoprotein Composition Determined by Different Procedures[a]

Component	Fraction	Expected (mg/mL plasma)	Measured (mg/mL plasma)
Cholesterol	HDL	1.579 ± 0.020	1.607 ± 0.028
	LDL	0.598 ± 0.015	0.580 ± 0.018
	IDL	0.055 ± 0.005	0.057 ± 0.005
	VLDL	0.111 ± 0.006	0.093 ± 0.005
Triglyceride	HDL	0.179 ± 0.010	0.185 ± 0.005
	LDL	0.108 ± 0.007	0.108 ± 0.006
	IDL	0.028 ± 0.004	0.025 ± 0.004
	VLDL	0.059 ± 0.004	0.055 ± 0.003
Phospholipid	HDL	2.498 ± 0.091	2.565 ± 0.096
	LDL	0.936 ± 0.010	0.781 ± 0.011
	IDL	0.090 ± 0.008	0.102 ± 0.012
	VLDL	0.059 ± 0.006	0.047 ± 0.009
Protein	HDL	2.186 ± 0.120	2.392 ± 0.111
	LDL	0.455 ± 0.021	0.365 ± 0.025
	IDL	0.033 ± 0.005	0.040 ± 0.006
	VLDL	0.093 ± 0.007	0.100 ± 0.010

[a]Different lipoprotein fractions were analyzed for cholesterol, triglyceride, phospholipid and protein contents by direct determination using the classical methods (expected results) or by the new procedure (measured results). Values are means ± SEM of three determinations.

Absence of Sterol Biosynthesis in Oyster Tissue Culture

Marcia J. Holden[1] and **Glenn W. Patterson***
Department of Botany, University of Maryland, College Park, Maryland 20742

An oyster heart tissue culture was used to investigate the ability of the American oyster (*Crassostrea virginica*) to synthesize sterols from [^{14}C]acetate. Lipids were extracted from cultured oyster heart cells and no label was found in the purified fatty acid fraction, 90% of which was located in the saturated and monounsaturated fractions. Although these results cannot rule out the possibility of sterol synthesis in other oyster tissues, this and previous evidence are in support of the hypothesis that the American oyster is unable to synthesize sterols.
Lipids 26, 81-82 (1991).

The oyster has long been one of the most difficult of the challenges to the sterol biochemist. Approximately forty sterols have been identified from the oyster, *Crassostrea virginica* (1-3). Since it appeared that many of the sterols identified must be of dietary origin, the ability of the oyster to incorporate injected radioactive acetate was studied (4). Of the forty sterols naturally occurring in the oyster, only four were labeled by injection of labeled acetate: cholesterol, desmosterol, 24-methylene-cholesterol, and fucosterol. Most animals synthesize sterols, but the sterols produced are usually of the C-27 series only. Perhaps it is coincidental that aquatic fungi frequently produce the same four sterols (5-8), that were labeled in the oyster study (4). It is not possible at present to grow oysters aseptically. However, some success has been attained with the development of an oyster tissue culture. It was the objective of this work to determine whether actively metabolizing oyster tissue culture cells can convert acetate into sterols.

MATERIALS AND METHODS

Oyster heart tissue culture. The procedure for oyster heart tissue culture was adopted from Dr. Frank Hetrick (personal communication). Hearts were dissected from the pericardial sac of oysters (*Crassostrea virginica*), minced and washed with an antibiotic solution (125 μg/mL gentamicin sulfate, 100 μg/mL polymixin B sulfate, 200 U/μL penicillin, 200 μg/mL streptomycin, 100 U/mL mycostatin, 1% glucose, 1% galactose in filtered sea water) for 2 hr. This was followed by rinses in 1% zephalin chloride to eliminate possible protozoan contamination and digestion of the tissue with 0.05% trypsin for 10 min. Between treatments the heart pieces were washed with 1/2 strength sea water (pH 7.0) containing 1% each glucose and galactose. All solutions and media were filter-sterilized (0.2 μm Millipore filter). Heart pieces were transferred to wells of a culture dish each containing 2.5 mL of medium. The medium consisted of 40% NCTC-135 medium (Grand Island Biologicals, Grand Island, NY), 10% fetal calf serum, 47% 1/2 strength sea water, 1 mg/mL glucose, 1 mg/mL galactose, 1 mg/mL trehalose, 50 U/mL penicillin-streptomycin, 100 mg/mL gentamicin, 0.0025% phenol red, and 10 mM piperazine-*N,N'-bis*(2-ethanesulfonic acid) (PIPES), pH 7.0. Cultures were incubated at 11°C and the medium was changed every 3-5 days. The cultures were labeled after 7 to 10 days, when a confluent layer of cells was observed to cover the bottom on the 24-well dish. A total of 8-10 μCi of [^{14}C]acetate was added to the culture medium in this dish and incubation continued for 65 hr.

Lipid extraction. Tissue pieces were scraped from culture wells, collected on filter paper and washed. A crude lipid fraction was prepared by saponifying the tissue followed by acidification and extraction, twice with diethyl ether and then chloroform. Unlabeled oyster sterols and myristic acid were added to the combined crude lipid extract which was then chromatographed, along with standards, on a silica gel 60 plate using a solvent system of hexane/diethyl ether/acetic acid (80:20:1, v/v/v). The plate was developed twice and components were visualized with 2,7-dichlorofluorescein. Fatty acids and sterols were separately eluted from the silica gel with diethyl ether.

Chromatographic separation of fatty acids and sterols. Sterols were rechromatographed as above. This was followed by chromatography on an alumina column and elution of sterols with diethyl ether (4). Sterols were subsequently acetylated using pyridine/acetic anhydride (1:1, v/v), and the product was applied to an alumina column and eluted with hexane/benzene (1:1, v/v). At each step, the sterol fraction was identified using a Varian 3700 Gas Chromatograph (3% SE-30 column, 246°C) by comparing the relative retention times of the major sterol components with those of standards (1-3,9). Radioactivity was determined by scintillation counting.

Fatty acids were converted to methyl esters with

10% boron trichloride/methanol. Fatty acid methyl esters were applied to an alumina column and eluted with hexane/benzene (1:1, v/v). Separation of the fatty acid methyl esters, based on type and number of double bonds, was accomplished by silver nitrate thin-layer chromatography (15 g $AgNO_3$/100 g silica gel 60) using 25% diethyl ether in hexane (v/v) as the developing solvent system. A known mixture of unlabelled fatty acids was added as carrier to the oyster fatty acids prior to chromatography to provide sufficient material for determining the double bond composition of the separated fractions. At each step, fatty acids were identified using a Varian 3700 gas chromatograph (15% Hi-EEF-1BP column, 160°C), and radioactivity was determined by scintillation counting as previously described (4).

RESULTS AND DISCUSSION

Previous results giving positive evidence of a low rate of synthesis of four oyster sterols were considered due to probable fungal contamination of wild oysters. An oyster tissue culture system, developed by Hetrick and co-workers (personal communication) was used to resolve the problem of contamination. While several oyster tissues have been cultured successfully, the heart tissue was chosen because it is initially free of microorganisms while enclosed in the pericardial sac. Heart tissue, exposed to potential contamination only during dissection, requires less drastic antibiotic and fungicidal treatment than other oyster tissues. The disadvantage of the oyster tissue culture is that the cells that form the confluent layer are mostly amoebocytes which migrate from the tissue pieces. The cultures can be maintained in a metabolically active state for up to a year, but show no real evidence of cell multiplication (Hetrick and co-workers, personal communication).

Between 3-4% of the total [^{14}C]acetate provided to the cultured cells was recovered in the crude lipid extract from the cells (Table 1), but only a very small fraction of that was left in the first sterol fraction. Acetylation of the sterol fraction, followed by chromatography on alumina, produced a sterol acetate fraction which was devoid of label. Analysis of the fatty acid components of the labeled crude lipid extract showed that 22% of the label in the total lipid was in the crude fatty acid fraction (Table 2). Subsequent separation of fatty acids, based on the number of double bonds, revealed that most of the label was in the saturated and monounsaturated fatty acids. Thus, oyster tissue culture is capable of synthesizing fatty acids which shows that biosynthetic activity is maintained in cell culture.

Previous work demonstrated the synthesis of sterols from acetate in intact oysters (4). The present results suggest that the incorporation of labeled acetate into four labelled sterols in intact oysters was likely due to contamination of the oysters by aquatic fungi which have been shown to contain the same series of sterols labelled in the intact oyster (5-8). Although the results of this study do not rule out the possibility of synthesis of sterols by other oyster tissues, it adds strength to previous data suggesting that the oyster cannot synthesize sterols from acetate.

ACKNOWLEDGMENTS

We thank Dr. Frank Hetrick and Kathleen Lutrell for the tissue culture methodology and their help in initiating the cultures. The work was supported by Maryland Sea Grant project No. NA79AA-D-00058. This is Scientific Article No. A6037, Contribution No. 8198 of the Maryland Agricultural Experiment Station.

Enhanced β-Oxidative Utilization of [1-^{14}C]Palmitate During Active Myelinogenesis in Developing Rat Brain Under Nutritional Stress

S. Padmini and **P. Srinivasa Rao***
National Institute of Nutrition, Indian Council of Medical Research, Jamai Osmania P.O., Hyderabad 500 007, India

Food restriction was found to impair the incorporation of [1-^{14}C]palmitate into myelin membrane lipids of developing rat brain. An attempt was made to determine whether this phenomenon is due to differences in the rate of utilization of the labelled precursor or to its enhanced degradation *via* β-oxidative pathways. Undernutrition in pups was imposed by food restriction during gestation and lactation. β-Oxidation by brain region homogenates using [1-^{14}C]palmitate was monitored at days 7, 14 and 21 of postnatal age. There was a significant increase in β-oxidation in the brain regions of undernourished pups, with the cerebrum and cerebellum being more affected than the brain stem. Because developing brain possesses the enzymic potential to utilize ketone bodies, the data may indicate increased usage of palmitate as an energy source in the developing brain of undernourished animals.
***Lipids 26,* 83–85 (1991).**

Myelinogenesis in the developing nervous system is affected by diet and responds to subnormal nutriture with certain dietary components (1,2). Protein caloric restrictions that are imposed during gestation and lactation were found to significantly impair incorporation of [1-^{14}C]palmitate-associated radioactivity into myelin membrane phospholipids and cerebrosides (3) in young rat pups. It is known that fatty acids can serve as fuel to meet the energy requirements of the brain in suckling rats (4,5). The studies of Spitzer (6) revealed that brains of adult dogs do not utilize free fatty acids *in vivo*, but that in the brains of starved puppies up to 25% of the oxygen consumption is accounted for by utilization of palmitate. We hypothesized that a greater proportion of palmitate produced *in situ* might be used as an energy source rather than for the biosynthesis of lipids, *viz.* phospholipids and cerebrosides, in undernourished, growing rat brains.

The present report describes the capacity of various regions of the developing rat brain to degrade palmitate by β-oxidation. The results affirm that under conditions of food restriction, the rapidly developing brain displays a significantly higher potential for routing fatty acids into energy-generating pathways.

MATERIALS AND METHODS

[1-^{14}C]Palmitate (sp. act. 20.5 mCi/mmol) and chemicals for scintillation counting were purchased from BARC (Bombay, India). Radiopurity as assessed by thin-layer chromatography (TLC) analysis and scintillation counting was 95–98%. Solvents used were of analytical grade. Substrates and cofactors for assays were obtained from Sigma Chemical Co. (St. Louis, MO).

Undernutrition was imposed by food restriction during gestation and lactation. Ten-day pregnant Wistar strain rats fed a 22% protein diet *ad libitum* (adequate with respect to all other essential nutrients, *i.e.*, fats, carbohydrates, vitamins, and minerals) were used as controls, while animals fed 50% of the diet consumed by controls (measured as 50% of the previous day's control intake) were treated as the experimental (undernourished) group. Pups nursed by these two groups of dams were considered controls and experimentals, respectively. Litters were culled to a size of 8 at birth. Pups were used at 7, 14 and 21 days of postnatal age, in order to bracket the period of myelinogenesis.

The rats were decapitated by guillotine, while care was taken not to damage nervous tissue. The surface of the brain was washed free of blood in saline and blotted on filter paper. The time from decapitation to homogenization was kept constant. Brain tissues from pups nursed by control and food-restricted dams were pooled. Each pooled sample had 8 whole brains at day 7, whereas 4 cerebra or 8 cerebella or 8 brain stems were pooled at day 14 and day 21 per sample. Six whole brains or regional tissue samples were homogenized in 20 vol of 25 mM (hydroxymethyl)aminomethane (Tris)-HCl/1 mM ethylenediaminetetraacetic acid (EDTA) 0.32 M sucrose (pH 7.4) buffer. The crude homogenates were centrifuged at 800 × *g* for 10 min at 4°C (after reserving an aliquot of the homogenate in chloroform/methanol, 2:1, v/v, for extraction of lipids).

β-Oxidation of [1-^{14}C]palmitate was monitored according to the method by Menon *et al.* (7) using the 800 × *g* supernatant. Lipids of aliquots of brain region homogenates were extracted (8), and the nonpolar lipids were resolved by TLC on silica gel G using the solvent system petroleum hydrocarbon (40–60°C bp)/diethyl ether/acetic acid (80:20:1, v/v/v). The bands corresponding to free fatty acids were visible under ultraviolet (UV) light after spraying with 2′,7′-dichlorofluorescein. Bands were scraped off, and fractions were eluted with chloroform containing 0.22% formic acid. The eluates were taken to dryness and methylated (9). The methyl esters were resolved using a Varian Model 3700 gas chromatograph equipped with a flame ionization detector (FID). The stainless-steel chromatographic column (3 m length × 2mm i.d.) packed with 10% Silar 10c on Chromosorb-W was kept at 190°C. Nitrogen was used as carrier gas at a flow rate of 20 mL/min. Weight percentages of methyl palmitate in total fatty acid methyl esters were computed, using

an electronic integrator, based on the peak areas of known amounts of standard fatty acid methyl esters. The data on the concentration of free palmitate pools are expressed as μmoles/g brain tissue.

RESULTS AND DISCUSSION

It has been shown (10) that protein deficiency influences lactation quantitatively, but not qualitatively. Although no attempt was made in this study to measure milk output of lactating dams, body weights in experimental pups were found to be significantly lower (62% and 40% of controls at 14 and 21 days, respectively). Brain and brain region weights were less affected with 80–90% of control weights being reached at both these ages.

Quantitation of the free palmitic acid pool in brain tissues of control and experimental pups showed no difference between the two groups when expressed as weight percentages of total free fatty acid methyl esters. However, experimental rats showed relatively higher concentrations of palmitate pools (in terms of μmols/g wet weight of brain tissue) especially in the three regions of the brain of experimental rats on day 14 (Table 1). The β-oxidative degradation profiles of [1-^{14}C]palmitate, as reflected by $^{14}CO_2$ liberation, however, showed large differences between control and feed-restricted animals (Fig. 1). The rate of β-oxidation of palmitate in whole brain from experimental animals at day 7 was 142% of that in controls. At day 14, β-oxidation of palmitate in experimental cerebra, cerebella and brain stems was 283%, 197% and 323% of that in corresponding control regions, while by day 21 β-oxidation in experimental cerebra and cerebella reached 334% and 289% of corresponding control values ($P<0.001$). On the other hand, the β-oxidative capacity in control cerebra and cerebella at day 21 was lower than at day 14, with 78% and 68% at 14 days. This age-related decrease was not observed in brain tissues from feed-restricted pups.

Growth and development during the suckling period appears to place an exceptional demand for appropriately constituted nutrient sources. Fat as a major carbon source in rat milk appears to be earmarked to contribute to energy needs next to providing building

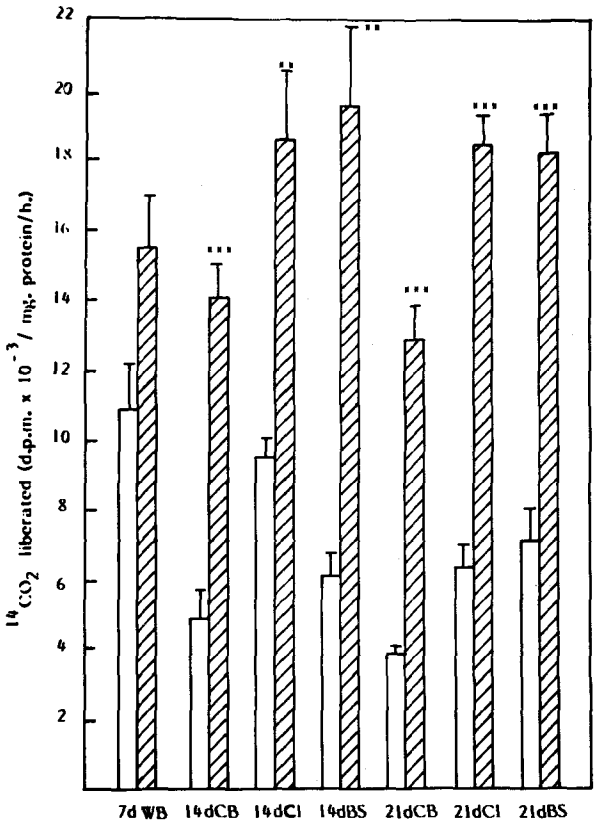

FIG. 1. β-Oxidation of [1-^{14}C]palmitate in developing brain regions from control *vs* feed-restricted animals. Open bars, control animals; hatched bars, undernourished animals. units for lipid metabolism. Acetoacetate and 3-hydroxybutyrate, which are transition metabolites in the conversion of fat into energy and serve as substrates for lipogenesis, are produced by ketogenesis in liver mitochondria by fatty acid oxidation. The liver produces ketone bodies for export of acetoacetate and 3-hydroxybutyrate, but does not use them for respiration as precursors of mitochondrial acetyl-CoA (11), while the developing brain possesses the enzymic potential to do so.

Under the conditions of feed insufficiency imposed on growing rat pups, it is reasonable to speculate that subnormal intake of milk in such animals would affect the supply of fat to hepatic tissue and thereby diminish the levels of circulating ketone bodies. By inference, this could diminish fatty acid synthesis in the developing brain, which in turn, could down-regulate complex myelin membrane lipid synthesis.

The distinctly higher β-oxidative capacity of the brains of undernourished animals is indicative of an attempt by the rapidly growing brain to compensate for the deficit in energy substrates (milk-derived fats), albeit at the expense of lipogenesis. Another interesting observation (12) is the ability of ketone bodies at high concentrations to impair the *de novo* pathway of pyrimidine biosynthesis. Thus, higher rates of β-oxidation could be expected to impair rates of fetal brain growth under conditions of nutritional stress.

The Effect of a Salmon Diet on Blood Clotting, Platelet Aggregation and Fatty Acids in Normal Adult Men

Gary J. Nelson[a,*], **Perla C. Schmidt**[a] and **Laurence Corash**[b]

[a]Western Human Nutrition Research Center, U.S. Department of Agriculture, ARS, Presidio of San Francisco, California 94129 and [b]Department of Laboratory Medicine, University of California School of Medicine, San Francisco, California 94143

This study was designed to measure the effect of dietary n-3 fatty acids (FA) on platelets and blood lipids. Healthy men (n=9), ages 31 to 65, were fed diets in which salmon was the source of n-3 fatty acids. They were confined in a nutrition suite at this Center for 100 days. Food intake and exercise levels were rigidly controlled. Initially they were placed on a stabilization diet for 20 days, then six men were fed the salmon diet for 40 days. The others remained on the stabilization diet. The two groups switched diets for the last 40 days of the study. Both diets were isocaloric [16% protein, 54% carbohydrate, and 30% fat by energy-% (En%)]. The salmon diet contained 7.5% of calories from n-6 FA and 2% from n-3 FA, primarily eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) in a 40:60 ratio, while the stabilization diet contained 7.5% of calories from n-6 FA and less than 0.3% n-3 FA, mainly 18:3n-3. The bleeding time was unaffected by the diets in this study. The prothrombin time was shortened (11.6 sec. *vs.* 12.6 sec., $p < 0.01$) for the subjects consuming the salmon diet as compared to that measured after 20 days of the stabilization diet. Mean platelet volume increased significantly during the period in which the volunteers consumed the salmon diet compared to the baseline diet ($p<0.01$), while the mean platelet levels decreased. Platelet aggregation (PA) was measured in platelet rich plasma before, during, and after the salmon diet using collagen, ADP, arachidonic acid (AA), and thrombin agonists. The PA threshold for ADP was significantly increased for the subjects on the salmon diet ($p < 0.05$). No change in the PA threshold was detected for collagen or thrombin. The PA threshold for AA was unchanged also, but the platelets in subjects consuming the salmon diet had a prolonged time to maximum aggregation ($p<0.01$) with this reagent compared to platelets from men on the stabilization diet. Plasma, red cell, and platelet total FA composition was determined by capillary GLC. While the men consumed the salmon diets, there were marked increases (3 to 10-fold) in the EPA and DHA levels in all blood components with concomitant decreases in linoleic acid and AA levels. Thus, a salmon diet, high in n-3 FA, did not influence the bleeding times, but it decreased the sensitivity of platelets to ADP and AA, increased the mean platelet size, decreased the platelet count, and changed the FA composition of the plasma, RBC and platelet membrane lipids.

Lipids 26, 87-96 (1991).

Epidemiological studies have suggested that populations consuming fish regularly tend to have a lower incidence of morbidity and mortality from heart disease (1-4). Purified fish oils, usually consumed as a supplement to an *ad libitum* diet, influenced human blood clotting parameters in several previous studies (5-8). The hypothesis accepted by most investigators is that the long-chain, polyunsaturated n-3 fatty acids found in the marine food chain are the beneficial nutrient in a diet containing large amounts of fish or other foods of marine origin. Few studies have been reported, however, in which fresh fish was the only source of dietary n-3 fatty acids, although van Houwelingen *et al.* (8) and Singer and associates (9) have used canned fish instead of fish oil supplements. Goodnight *et al.* (10) used fresh salmon combined with a salmon oil supplement in a study with free-living volunteers eating meals prepared in a dietetic kitchen.

The beneficial effects of a fish diet or fish oil supplement is still controversial (11-15), and the mechanism by which a fish diet or fish oil supplement provides its purported beneficial effect is unproven (16-19). The main supposition is that the n-3 fatty acids incorporated in the platelet membrane reduce the tendency for platelets to aggregate *in vivo* (20,21) perhaps through alteration in the production of pro-aggregating eicosanoids (22,23). Even if dietary fish or fish oil have beneficial health effects, it is not practical to recommend that the public take fish oil supplement. Consuming fresh fish is a reasonable alternative, if the fish have a reasonable oil content and are oceanic varieties, not aquacultured unless the aquacultured species are fed n-3 fatty acids.

In an attempt to determine if short-term feeding of a moderate amount of fresh fish to normal subjects would produce similar effects as reported when subjects consumed large amounts of pure fish oils, a carefully controlled dietary study was designed. The study was intended to find, among other items, the effects of a fish diet on *in vivo* and *in vitro* hemostatic parameters and to correlate those changes with corresponding changes in the fatty acid composition of the blood.

Results of this study are reported here and in the companion paper (24). We fed normal, healthy, male volunteers a diet containing approximately 500 g daily of fresh salmon for 40 days. The volunteers were confined to a Nutrition Suite for the entire period of the study (100 days) and consumed only food prepared in the metabolic kitchen. All exercise and activity was rigidly controlled. Hemostatic parameters, *in vitro* platelet aggregation and fatty acid composition of plasma, red cells and platelets were analyzed at regular intervals during the study.

MATERIALS AND METHODS

Materials. All natural foods were purchased at local food markets. The salmon (Pacific, chinook, *Oncorhynchus tshawytscha*) was purchased fresh from a seafood wholesale supply company as a large batch from a single boat.

*To whom correspondence should be addressed.

Abbreviations: AA, arachidonic acid; ADP, adenosine diphosphate; DHA, docosahexaenoic acid; DPA, docosapentaenoic acid; EPA, eicosapentaenoic acid; FA, fatty acid; GLC, gas-liquid chromatography; PA, platelet aggregation; PPP, platelet poor plasma; PRP, platelet rich plasma; RBC, red blood cells; RDA, recommended daily allowance.

It was frozen until used for the meal preparation during the study. Fatty acid standards were purchased from Nu-Chek-Prep (Elysian, MN). Aggregating agents [adenosine diphosphate (ADP), collagen, thrombin, arachidonic acid (AA)] were obtained from Chrono-log Corporation (Havertown, PA). Organic solvents were obtained from Baxter Scientific, Burdick and Jackson Brand (McGaw Park, IL).

Subjects. The volunteers were recruited from the West Coast, and consisted of men between the ages of 30 and 65. Table 1 gives the physical characteristics of the final nine volunteers who completed the study. Initially twelve volunteers were included in the study, but three were unable to complete the protocol. The volunteers were given complete physical examinations. Body weights had to be within −10 to +10% of ideal body weights using the Metropolitan Life Insurance Company tables (Medium frame values from the 1983 edition). Evidence of existing illness or chronic disease was an exclusion criterion. Mild hypertesion was not an exclusion criterion, but the group that was recruited tended to have blood pressures slightly below average for men in this age group. Smoking, excessive alcohol consumption or evidence of narcotic abuse were also exclusionary.

Experimental design. All the volunteers were confined to the Nutrition Research Suite of the Western Human Nutrition Research Center for the duration of the study. A diagram of the study design is given in Figure 1. A crossover design was used. The subjects were fed a stabilization diet, without 20-carbon, polyunsaturated n-3 fatty acids for 20 days. On day 21 of the study, they were divided into two groups. The first was designated group A and placed on the salmon diet for 40 days. The other group, designated Group B, remained on the stabilization diet. After forty days, day 61 of the study, the groups switched diets for the remaining 40 days of the study.

TABLE 1

Characteristics of the Subjects upon Entry into the Study (All Males)

Parameter	Values
Subjects completing study	9
Number in group A	6
Number in group B	3
Age, yrs (n=9) (mean ± S.D.)	52.0 ± 12.7
Weight, kg (n=9) (mean ± S.D.)	84.0 ± 12.5
Body mass index, Kg/m^2 (n=9) (mean ± S.D.)	24.79 ± 2.33
Blood pressure, systolic (n=9) (mean ± S.D.)	118.5 ± 10.3
Blood pressure, diastolic (n=9) (mean ± S.D.)	78.9 ± 5.4
Smokers	None

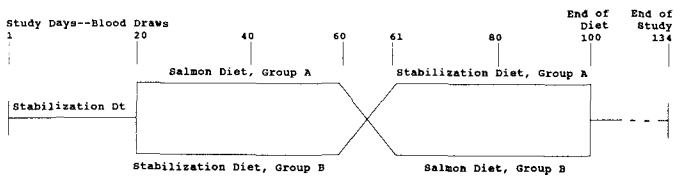

FIG. 1. A schematic presentation of the design of this dietary study showing the days on which blood samples wre drawn and the various dietary periods.

After 100 days, all the volunteers were discharged from the Nutrition Suite and returned to an *ad libitum* diet. They returned to the Center on day 134 of the study for a follow-up visit and final blood draw. During the confinement period of the study, there was a blood draw every 20 days. Statistical comparisons of the measured parameters were made using day 20 as the baseline values for each subject. Subjects served as their own controls.

Diets. The diets consisted of natural foods. No dietary supplements were given except α-tocopherol to bring the diet to 200% of the RDA for this vitamin. The macronutrient composition of the diets is given in Table 2. (A complete description of the diets, listing all the major and minor nutrients is available upon request.) There was a five-day menu cycle used throughout the study. The proximate analysis was made on five individual diet composite samples taken on each menu once during the study for both the stabilization diet and salmon diet diets. The results for the five composite samples were averaged to find the actual composition of the diets. No alcohol was included in these diets. The diets were designed around a prudent diet concept of 30:55:15 fat, carbohydrate, protein in energy percent (En%). The nutrient composition of the diet was calculated from a computerized nutrient data bank, and adjusted to provide at least the RDA for known essential nutrients.

Table 3 gives the measured fatty acid composition of both diets. The amount of saturated and n-6 fatty acids were held constant in these diets. The stabilization diet had less than 1% n-3 fatty acids as α-linolenic acid and approximately 50% monounsaturated fatty acids. The salmon diet had approximately 7.5% long chain polyunsaturated n-3 fatty acids and concomitant reduction in the level of monounsaturated fatty acids.

At the beginning of the study, each participant's caloric intake was estimated, and the caloric content of portions calculated to maintain current body weight. As the estimates were subject to error, the participants were weighed every day, and the caloric value of their meals adjusted daily, if necessary, to maintain their weight within the design limits of the study. Thus, the average weights of the participants did not vary significantly

TABLE 2

Composition of the Diets. Average Values from Diet Composite Samples (n=5)

	Stabilization diet (n-6)		Salmon diet (n-3)	
Dietary component	Calculated	Measured	Calculated	Measured
Protein[a]	16.41	18.83	16.02	18.53

22:6n-3	—	2.8
Sum of identified fatty acids[a]	97.0	96.6
Subtotals,		
Saturated	26.5	23.6
Monounsaturated	43.2	37.9
Polyunsaturated, n-6	21.4	23.6
Polyunsaturated, n-3	1.1	6.7
n-3/n-6 ratio	0.1	0.3

[a]The listed components will not add to this total as the diet samples contained many minor components that are not shown here, but their contributions to the total recovery are included in the totals given on this line.

during the 100 days of the study. If all the intakes for each volunteer were averaged during the entire study, the mean energy intake was approximately 2800 Kcal/day.

As no two subjects ate the same amount of salmon each day the amount of n-3 fatty acids is best expressed in terms of percent of calories per day rather than grams of n-3 fatty acids consumed per day. Individuals who take fish oil capsules usually consume a set number of capsules per day, and, thus, the dosage varies from individual to individual depending on their specific weight. In this study each volunteer received 2.1% of their calories from long chain, n-3 polyunsaturated fatty acids. If, for example, an individual in this study was receiving 3000 Kcal/day, he would have consumed about 2.1 g of 20:5n-3, 0.8 g of 22:5n-3 and 3.0 g of 22:6n-3. This amounts to a total of about 6 g/day of n-3 polyunsaturated fatty acids.

Measurements. Blood was drawn according to the schedule shown in Figure 1 between 7:00 and 8:00 a.m. after an overnight fast. It was drawn into vacutainers with appropriate anticoagulants using a Teflon catheter (Angiocath, Deseret Medical, Sandy, UT) for fatty acid analysis, or syringes containing 1 mL of citrate solution for platelet aggregation studies. Platelet rich plasma (PRP) was prepared by low speed centrifugation for 10 min at 100 × *g*. Platelet poor plasma (PPP) was prepared by respinning the blood after removal of the PRP for 15 min at 400 × *g*. Red cells for fatty acid analysis were prepared from the residue by resuspending the cells in 10 mL of PBS and recentrifuging the cells at 400 × *g* for 15 min three times. The supernate was discarded. The red cells were frozen at −70°C until their lipids could be extracted.

Blood for platelet sizing was drawn into plastic 20-mL syringes and then transferred to polyethylene tubes containing the final concentrations as follows: sodium citrate 13mM, EDTA 1mM, 1.1 μg/mL PGE-1, theophylline 5.4 mg/mL (25). The blood for the prothrombin and partial thromboplastin times were drawn into vacutainers containing 3.2% sodium citrate.

Platelet aggregation. Solutions of the aggregating agents were prepared as recommended by Chrono-log as follows: ADP, 1 μM/μL; collagen, 0.5 μg/mL, AA, 0.05 μM; thrombin, 10 units/mL. The *in vitro* aggregation characteristics of the subjects' platelets were measured in a Chrono-log Model 560 dual channel aggregometer. Briefly, 0.45 mL of PRP were added to an aggregation tube containing a Teflon coated stirring bar. The blank was 0.5 mL of the individuals PPP, unstirred. The instrument was zeroed to 10% transmission of the sample *vs* the blank. An appropriate amount of aggregating reagent was added to the PRP and aggregation was measured as the increase in transmission of light through the PRP. Generally the sample was monitored until the curve became flat or, with some reagents, notably ADP, disaggregation occurred. The threshold for aggregation was determined when the amount of a particular reagent produced at least 50% of maximum aggregation within 15 min of its addition to PRP. All aggregation tests were performed within 4 hr of the initial blood draw.

Platelets. Platelet counts were determined with an electronic particle counter, a Baker-Serono Model 9000 Differential Cell Counter (Baker-Serono, Inc., Allentown, PA) electronic particle counter and cytometer using the manufacturers recommended procedures (Operations Manual, System 9000 Differential Cell Counter, Baker-Serono, Manual No. DS-014A). Mean platelet volume was measured by the procedure described by Corash *et al.* (26). Briefly, sizing was performed using a Particle Data System (Particle Data, Chicago, IL) equipped with a 48 μ orifice and a logarithmic amplifier. Platelet volume was expressed as the median volume derived from a probability plot distribution of platelet volume.

Bleeding time. Bleeding times were measured on the left or right proximal forearm of each subject using a 1 mm deep by 1 cm long incision using a Simplate II bleeding time device (Organon Teknika, Durham, NC). A wipe of the incision was made every 15 sec. Time was measured with a hand-held stop watch.

Clotting factors. Prothrombin time and the partial thromboplastin times were measured by the methods described by Houghie (27). Briefly platelet poor plasma was prepared as described and the PT and PTT were measured using the Bio/Data Corporation Model MCA 110 instrument (Bio/Data Corp., Hatboro, PA) with Organon Teknika coagulation reagents.

Lipid extraction and fatty acid analysis. Tissues were extracted by the procedures described by Nelson (28, 29) using chloroform/methanol (2:1, v/v). Samples were then transmethylated with methanolic HCl (7%, w/w) by the procedures described elsewhere (30,31). When the total lipid extract was transmethylated, the impurities,

TABLE 4

Hemostatic Parameters in All Subjects (n=9), Stabilization and Salmon Diet

Parameter	Pre-diet	Stabilization diet mean ± S.D.	Salmon diet
Prothrombin time (sec)	10.6 ± 0.9	12.6 ± 0.4[a]	12.00 ± 0.4[a]
Partial thromboplastin time (sec)	29.5 ± 1.7	29.5 ± 1.5	29.4 ± 4.1
Mean platelet volume (femtoliters)	5.3 ± 0.5	6.1 ± 0.3[a]	6.8 ± 0.4[a]

[a]Values significantly different from each other at P<0.01, paired *t*-test.

extracted into the hexane phase after termination of the reaction, were removed by thin-layer chromatography as described by Nelson (29). Because the amount of material available from human platelets for fatty acid analysis was limited, fatty acid methyl esters were obtained by direct transmethylation of the intact tissue without prior solvent extraction as described in an earlier publication (32). The conditions for capillary gas-liquid chromatography (GLC) have been described previously (30). Briefly, the column was a 30 meter by 0.025 mm fused quartz column coated with SP-2340 purchased from Supelco, Inc. (Bellefonte, PA). The GLC data were processed with a Perkin-Elmer Corp. (Norwalk, CT) Model 7500 data station using Perkin-Elmer Chrom 3 software.

Statistical analysis. The clotting data and aggregation data were analyzed using the paired *t*-test with a n=9. Analysis of variance was used to determine if Group A and Group B data were comparable. The fatty acid data were analyzed with a single tailed *t*-test. All the statistical analyses were performed with an IBM PS/2 Model 60 using the PC SAS data system, version 6.03, obtained under license from the SAS Institute, PC-SAS, version 6.03 (SAS PC Manual, SAS Institute, Chapel Hill, NC).

RESULTS

There were no significant differences in the bleeding time between subjects on or off the salmon diet (stabilization n-6 diet, 4.2 ± 0.5 min; salmon n-3 diet, 4.1 ± 1.1 min). The bleeding time for subjects on the salmon diet was slightly shorter than for those on the stabilization diet.

In this study, the prothombin time was significantly shorter for the subjects while they were consuming the salmon diet than on the stabilization diet (Table 4). There was no difference in the partial thromboplastin time but the platelets from subjects on the salmon diet were significantly larger than while they were consuming the stabilization diet (Table 4). The platelet counts were reduced when subjects consumed the salmon diet (Table 5). In Group A, after being off the salmon diet for 40 days, the platelet count increased significantly.

The salmon diet did not influence the aggregation characteristics of the subjects' platelets in response to collagen or thrombin, but there was a marked decrease in the sensitivity of the subjects' platelets to ADP on the salmon diet (Table 6). Although there was no difference in the threshold amounts of arachidonic acid necessary to induce aggregation, the time to reach maximum aggregation was significantly longer while the subjects were consuming the salmon diet (Table 6).

TABLE 5

Platelet Counts in Subjects, Stabilization and Salmon Diet

Diet period	Cells × 10^9/L × 10^3 Stabilization diet mean ± S.D.	Salmon diet mean ± S.D.
All subjects, pre-diet (n=9)	316.2 ± 110.6	
All subjects (n=9)	288.1 ± 80.9[a]	250.7 ± 76.5[a]
Group A, day 60 (n=6)		238.2 ± 84.9[b]
Group A, day 100 (n=6)	278.3 ± 62.0[b]	
Group B, day 60 (n=3)	290.6 ± 62.0	
Group B, day 100 (n=3)		249.0 ± 67.8
All subjects, post-diet (n=9)	275.6 ± 78.1	

[a]Values significantly different at P<0.01, paired *t*-test.
[b]Values significantly different at P<0.05, paired *t*-test.

Stearate, oleate and arachidonate levels in the platelets of subjects after 40 days on the salmon diet were markedly reduced while the eicosapentaenoate and docosahexaenoate levels were significantly increased (Table 7). Palmitate and linoleate levels were unchanged by the salmon diet. The fatty acid composition of the platelets from Group A were analyzed after 100 days in the study and those for Group B after 60 days in the study (Table 8). Group A had been removed from the salmon diet and placed on the stabilization diet for 40 days (Table 8), and Group B had consumed only the stabilization diet for 60 days. The fatty acid composition of their platelets was similar except that Group A still retained a significant amount of DHA. EPA apparently had been washed out of the platelets in Group A after this fatty acid was eliminated from their diet for 40 days.

Plasma fatty acid composition of subjects before and after the salmon diets were similar to those observed in the subjects' platelets (Tables 9 and 10). Palmitate and linoleate levels were essentially unchanged, while oleate and arachidonate levels decreased. EPA and DHA levels increased significantly, as expected after the subjects had consumed the salmon diet for 40 days. After Group A had returned to the stabilization diet for forty days (Table 10) the plasma showed no significant carryover of the n-3 fatty acids as compared to Group B who had been eating the stabilization diet for 60 days.

After 40 days on the salmon diet there was a marked change in the fatty acid composition of the erythrocytes in the subjects (Tables 11 and 12). EPA, DPA and DHA all showed marked increases while the oleate and linoleate

content of the erythrocytes was reduced. The arachidonic acid content of the cells did not decrease significantly. After Group A was returned to the stabilization diet for 40 days, the fatty acid composition of their erythrocytes was still different from that observed in Group B after 60 days on the stabilization diet. Most of the EPA was eliminated from Group A's erythrocytes by study day 100, but the DHA content remained elevated. As erythrocytes have a 120-day half life in the circulation, neither *de novo* synthesis nor the removal of old cells could account for changes and disappearance of EPA from the erythrocytes of these subjects. Linoleate levels were unaffected by the diet, but arachidonic acid levels in the red cells were higher in the subjects consuming the stabilization diet for sixty days.

DISCUSSION

Most reports on the hematological effects of fish oils have indicated that these substances, when consumed as the purified oil, tend to prolong bleeding times in humans (10–12,21). In this study bleeding times were not prolonged after the volunteers consumed the salmon diet for 40 days. A possible explanation is that the amount of n-3 fatty acids present in the diet of these subjects was less than the amount necessary to elicit this response, or,

perhaps, the duration of the intervention period was not long enough. Volunteers consuming purified fish oil supplements can ingest as much as 50 g of oil containing up to 20 g of n-3 fatty acids such as EPA or DHA per day (33). Van Houwelingen *et al.* (8), using free-living volunteers fed a canned mackerel supplement, *ad libitum* diet, did report mild increases in bleeding times, but no changes in platelet aggregation responses. The amount of n-3 fatty acids consumed by the volunteers (1.7 g EPA and 3.0 g DHA) in the studies by Van Houwelingen *et al.* (8) was equal to or less than the amount fed to the volunteers in our study. The subjects in the study reported by Van Houwelingen *et al.* were consuming alcohol, but it is not known if this would influence the results.

In the present study the typical volunteer consumed approximately 2 g of 20:5n-3 and 3 g of 22:6n-3 daily. Still, it should be noted that the amount of n-3 fatty acids consumed by the volunteers in this study exceeded the amount consumed by most populations noted for consuming large amounts of fish in their diets. Japanese fishing villages have been reported to consume equivalent amounts of fish as the volunteers in this study (34). Only Eskimos routinely consume more fish oil than the volunteers in this study (4). Additionally, 40 days may be an insufficient period to manifest the prolongation of bleeding time noted by other investigators with this dietary level of n-3 fatty acids. Also, triglycerides containing n-3 fatty acids are hydrolyzed more slowly than other triglycerides without n-3 fatty acids (35,36). Thus, it is also possible that purified fish oils, when consumed as a bolus of oil, have pharmacological properties different from those manifested by n-3 fatty acids when they are consumed during a normal meal (37).

The threshold for platelet aggregation in response to ADP was significantly raised, confirming other investigator's reports (6-8,10). The anomalous response of the time to reach maximum aggregation when arachidonic acid was the agonist has not been reported previously. Until recently arachidonic acid was not used often as an aggregating agent in human platelet studies.

Houwelingen *et al.* (22) recently reported use of a mackerel paste (135 g/day) as a dietary supplement in a group of normal male volunteers. They measured platelet aggregation response to collagen and observed a small effect that was only apparent after sophisticated statistical analysis of the diets and was dependent on the amount of the supplement consumed. These observations are consistent with those reported here using a salmon diet, although the present experiment was not large enough to apply the same type of statistical analysis used by Houwelingen *et al.* (22).

A more consistent effect of the fish diet was observed on platelet size and count in the subjects consuming the salmon diet. Consumption of purified fish oil supplements does cause a decrease in platelet counts (6,8,11-12). The subjects in this study did have modest but statistically significant reductions in the platelet counts and a concomitant increase in platelet size. These observations suggest a decrease in the platelet life span in the circulation, although that parameter was not measured directly in this study.

Another anomalous result was that the prothrombin time in the subjects consuming the salmon diet decreased. (These data were statistically significant but may not be physiologically significant.). The prothrombin time does not correlate with the bleeding time *in vivo*, and the

prothrombin time is not related to platelet aggregation *per se,* so that a change in this parameter may have little relation to platelet function and thrombus formation *in vivo.*

Overall, the results of the coagulation tests and platelet aggregation studies in this investigation are consistent with earlier reports in the literature (8,9,21,38), in which larger amounts of fish oil were fed to human volunteers. It should be noted that the 2 g/day of 20:5n-3 fed on the average to the volunteers in our study was considerably less than the amount used in clinical trials, in which up to 20 MaxEPA capsules containing 3.6 g of 20:5n-3 were fed daily (12-14,21).

These data do not establish, however, that modest amounts of dietary n-3 fatty acids shift the thrombotic properties of the blood toward a less thrombotic condition. Still, epidemiological reports (3,39,40) have suggested that very modest amounts of fish, if consumed regularly over extended time periods, will reduce mortality and morbidity from cardiovascular disease. The role of the eicosanoids in this picture is currently unclear (18,23,40,41).

This study also found that the n-3 fatty acids from fish are rapidly incorporated into plasma, platelets and red cells, as reported by other investigators (7,10,17,18,38, 42-44). We found that equilibrium between the diet and the blood tissues was reached after 20 days for plasma and platelet (data not shown); red bloods cells (RBC) also equilibrated more rapidly than could be accounted for by *de novo* synthesis of new cells in the marrow. Without plasma exchange the presence of 20:5n-3 in RBC after 20 days on the salmon diet would be barely detectable, as only 15% of the red cells have been replaced in that period. Thus, exchange in the plasma must account for the initial equilibrium that was observed in this study. It also appeared that in erythrocytes arachidonic acid can be replaced by EPA and DHA. No conservation of n-3 fatty acids was detected in plasma in this study.

Dyerberg and Bang have reported the fatty acid composition of Eskimo platelets (5). It is interesting that the amount of n-3 fatty acids in the Eskimo platelets was not much higher than that found in the volunteers in this study after 20 days on the salmon diet. Presumedly the Eskimos had been eating their normal diet from childhood, yet their platelets contain about the same amounts of n-3 fatty acids as men who had consumed n-3 fatty acids in modest amounts for only 40 days. This would suggest that it is not simply the fatty acid composition of the platelet membrane that prolongs the bleeding time nor the primary cause of the purported protection against cardiovascular disease.

There was no significant persistence of the n-3 fatty acids in the plasma or platelet membranes after the volunteers stopped consuming the salmon diet. After 40 days of n-3 devoid diet, the subjects plasma and platelet fatty acid composition was similar to that found in the plasma and platelets of volunteers who had consumed a n-3 deficient diet for 60 days. There was some persistence of n-3 fatty acids in the erythrocytes of these volunteers, presumedly reflecting the 120-day life-span of red cells. It is noteworthy that the EPA content of the erythrocyte did decrease more than expected from red cell turnover. Hence, exchange processes in the circulation probably influence removal of EPA from red cells, just as they apparently increase its uptake when it is present in the diet. Holub has speculated that the lecithin:cholesterol acyltransferase is an important mediator of the exchange of platelet fatty acids when fish oil is consumed (44). It may be equally important in exchanging red cell fatty acids.

Generally, this study confirmed that eating a diet in which fresh fish is the only source of n-3 fatty acids does induce similar changes to those observed when people consume fish oil supplements. The fatty acid composition of the blood components shows rapid incorporation of the n-3 fatty acids. Platelet aggregation changes are small but in the direction of less aggregation. Yet the bleeding times in these volunteers did not change, an observation in sharp contrast to previous studies using fish oil supplements or mackerel paste (8,10-12). The subjects in the study conducted by van Houwelingen *et al.* (8) consumed roughly the same amount of n-3 polyunsaturated fatty acids as those in our study. No explanation for the difference observations between the two studies is readily apparent. Also, the prothrombin time was statistically shorter, but not beyond the normal, laboratory range, in the volunteers on the salmon diets. Platelet counts in the volunteers consuming the salmon diet did decrease, a phenomenon also observed when individuals consumed mackerel (8) or fish oil supplements (10). Finally, there was little persistence of the n-3 fatty acids in the blood 40 days after cessation of the salmon diet.

ACKNOWLEDGMENTS

The authors wish to express their appreciation to the Staff of the Jones Operation and Maintenance Company for preparations of the diets, and the care of the volunteers while domiciled at the Nutrition Suite at the Western Human Nutrition Center. We thank Manuel Tengonciang and Satinder Virk for technical assistance.

[Received August 2, 1990; Revision accepted November 29, 1990]

Effect of a Salmon Diet on the Distribution of Plasma Lipoproteins and Apolipoproteins in Normolipidemic Adult Men

Frank T. Lindgren[a,*], Gerald L. Adamson[a], Virgie G. Shore[b], Gary J. Nelson[c] and Perla C. Schmidt[c]

[a]Research Medicine and Radiation Biophysics Division, Lawrence Berkeley Laboratory, University of California, Berkeley, California 94720, [b]Biomedical Sciences Division, Lawrence Livermore National Laboratory, Livermore, California 94550 and [c]Western Human Nutrition Research Center, U.S. Department of Agriculture, ARS, Presidio of San Francisco, California 94129

The effects of n-3 fatty acids on plasma lipids, lipoproteins and apoproteins have usually been studied in humans after feeding of purified fish oil. This study describes the effect of a natural diet, containing salmon as the source of n-3 fatty acids, on these parameters as compared to a diet very low in n-3 fatty acids. The subjects were nine normolipidemic, healthy males who were confined to a nutrition suite for 100 days. During the first 20 days of the study the participants were given a stabilization diet consisting of 55% carbohydrates, 15% protein, and 30% fat. The n-3 content of this diet was less than 1%, and it contained no 20- or 22-carbon n-3 fatty acids. After the stabilization period the men were split into two groups, one group continued on the stabilization diet while the other received the salmon diet that contained approximately 2.1 energy percent (En%) of calories from 20- and 22-carbon n-3 fatty acids. Both diets contained equal amounts of n-6 fatty acids. This regime continued for 40 days, then the two groups switched diets for the remainder of the study. Plasma triglycerides were lowered significantly ($p<0.01$) and high density lipoprotein cholesterol (HDL-C) was significantly elevated ($p<0.01$) after the men consumed the salmon diet for 40 days. The very low density lipoproteins (VLDL) were lowered, but the trend did not reach statistical significance during the intervention period. The total plasma cholesterol, total low density lipoprotein (LDL) and the total high density lipoprotein (HDL) levels were not influenced by the salmon diet. Within the HDL fraction, however, the larger HDL_2 subfractions were significantly elevated ($p<0.002$), and the smaller, more dense HDL_3 was lowered ($p<0.002$) by the salmon diet. These significant changes were detected by analytic ultracentrifugation and confirmed by gradient gel electrophoresis. Analysis of the apolipoproteins (apo) AI, AII, B, and E, and Lp(a) indicated only significant lowering of apoAI, consistent with the increased HDL_2, which is higher in cholesterol but lower in the major HDL apolipoprotein, apoAI. Thus, the purported beneficial cardiovascular effects of consumption of n-3 fatty acids by humans may, in part, be attributable to changes in the HDL distribution, *i.e.*, the lowering of the more dense HDL_3 and the elevation of the larger, less dense HDL_2.

***Lipids 26,* 97-101 (1991).**

There is considerable evidence that fish oils containing a high content of n-3 polyunsaturated fatty acids lower plasma triglycerides and very low density lipoprotein (VLDL) (1-3). However, the effect of fish oil supplements high in n-3 fatty acids is not consistent with many reports of either lowering or raising both low density lipoprotein (LDL) cholesterol (LDL-C) and high density lipoprotein (HDL)-C. The recent comprehensive review by Harris (4) compares the results obtained with both normolipidemic and the major types of hyperlipidemic patients. Certainly, part of the discrepancies result from the different types of fish oil fed, the dosage, the subjects or patients used, and the design of the experiment. Also, whatever effects observed appear to be the result of the fish oils high in n-3 polyunsaturated fatty acids. Thus, early dietary studies of defatted fish showed no effects on cholesterol levels but the extracted fish oil did lower plasma cholesterol in rats (5). The early epidemiologic studies of Greenland Eskimos (5-7) indicated a very low incidence of ischemic heart disease, and these findings initiated interest in the potential beneficial effects of n-3 polyunsaturated fatty acids. However, these studies were of a normal population whose food consisted of chronic ingestion of marine foods rich in n-3 polyunsaturated fatty acids, estimated to be of the order of about 7 g/day of these specific marine n-3 polyunsaturated fatty acids.

Thus, while it is clear that pharmacological dosages of purified fish oil in man produce marked changes in blood lipid and lipoprotein levels, fatty acid distributions, and lipid metabolism (8-10), it is not clear whether similar changes, particularly in the distribution of lipoproteins and apolipoproteins, occur when whole fish are consumed as a significant part of the diet. This study, the protocol of which is described in more detail in the companion paper (11), fed healthy volunteers all natural diets where fresh salmon supplied 2.1 En% of calories as n-3 fatty acids. The results are compared to a diet containing little (<1 En% of calories) n-3 fatty acids but a similar amount of n-6 fatty acids in a totally controlled environment, at the nutrition suite at USDA's Western Human Nutrition Research Center (San Francisco, CA). This study using marine (salmon) and terrestrial polyunsaturated food seems appropriate and practical to help resolve some of the discrepancies in results of the lipid and lipoprotein effects of n-3 polyunsaturated fatty acids. Of particular interest is the quantitative change, or no change, in the subfractions of all major VLDL, LDL, and HDL lipoprotein classes.

METHODS

Materials. All natural foods were purchased at local food markets. The salmon was purchased fresh from a seafood wholesale supply company as a large batch from a single boat, and was frozen until used for meal preparation during the study.

Subjects. The volunteers were recruited from the West Coast and consisted of men between the ages of 30 and 65. The physical characteristics of the final nine

TABLE 1

Plasma Lipids in All Subjects (N = 9) on Stabilization and Salmon Diets

Lipid	Stabilization diet Mean ± S.D. (mg/dL)	Salmon diet Mean ± S.D. (mg/dL)
Total cholesterol	187.1 ± 37.7	192.8 ± 44.3
LDL-C	137.6 ± 34.7	140.6 ± 41.0
HDL-C	30.4 ± 10.0[a]	36.8 ± 8.7[a]
Triglycerides	94.2 ± 33.7[a]	77.2 ± 36.7[a]

[a]Values significantly different at $p < 0.01$, paired t-test.

volunteers who completed the study are given in Table 1 of the companion paper (11).

All volunteers were confined to the Nutrition Research Suite of the USDA Western Human Nutrition Research Center for the duration of the study. The study protocol is described in the companion paper (11). Statistical comparison of the measured parameters were made using day 20 as the baseline values for each subject. Subjects served as their own controls.

Diets. A complete description of the diets is given in the companion paper (11). The diets consisted of natural foods. No dietary supplements were given except α-tocopherol to bring the diet to 200% of the RDA for this vitamin. No alcohol was included in these diets. The diets were designed around a prudent diet concept of 30:55:15, fat/carbohydrate/protein En%.

The amount of saturated and n-6 polyunsaturated fatty acids (7.5 En%) were held constant in these diets. The stabilization diet had <1% n-3 fatty acids as α-linolenic acid and approximately 50% monounsaturated fatty acids (oleic acid). The salmon diet had approximately 2.1 En% long-chain polyunsaturated n-3 fatty acids and a concomitant reduction in the level of monounsaturated fatty acids.

Measurements. Blood was drawn between 7:00 a.m. and 8:00 a.m. after an overnight fast. It was drawn into vacutainers with EDTA as the anticoagulant using a Teflon catheter (Angiocath, Deseret Medical, Sandy, UT). Plasma was separated from the cellular components of the blood by centrifugation at 400 × *g* for 15 min. Plasma samples were drawn using EDTA, gentamicin sulfate, and ε-amino-n-caproic acid (12) at the end of each of the three diet periods, the 20-day stabilization diet, the 40-day n-3 salmon diet, and the 40-day n-6 diet. Plasma triglycerides, total cholesterol, LDL-C, and HDL-C were done on a Cobas-Fara centrifugal analyzer (Hoffman-La Roche, Nutley, NJ). Preparative isolation of the total low density fraction, $d < 1.063$ g/mL and the total lipoprotein fraction, $d < 1.21$ g/mL) were as described earlier (13). Also, analytical ultracentrifugation (AnUC) of both total LDL and HDL with complete computer analysis of the schlieren films were as described previously (13,14) using a sonic digitizer and a VAX Station 3200. HDL subfractions by AnUC, HDL_{2b}, HDL_{2a}, and HDL_3, were resolved as described elsewhere (15).

Nondenaturing quantitative gradient gel electrophoresis (GGE) was performed using Pharmacia 2-16% gels for total LDL and 4-30% gels for HDL as described by Nichols *et al.* (16). The LDL gels were stained with Coomassie Brilliant Blue R-250, and scanned at 555 nm using an RFT Transidyne grating densitometer (17). HDL gels were similarly scanned and HDL subfractions of HDL_{2b}, HDL_{2a}, HDL_{3a}, HDL_{3a}, and HDL_{3c}, were calculated as percent of total HDL area as described previously (16).

Plasma apolipoprotein concentrations. Plasma concentrations of apolipoproteins AI, AII, B and E and Lp(a) were measured in plasmas that had been stored at −70°C and thawed just before analysis. Samples from all the diet periods were analyzed simultaneously. Competitive ELISA tests (18) were used for all assays except apoAI, which was measured by RID (19) with commercially available plates (TAGO Inc., Burlingame, CA, and Kent Laboratories, Inc., Redmond, WA). Controls included purified apoAI, isolated HDL at several dilutions, pooled plasmas including five (frozen) from the Northwest Lipid Research Center and our freshly prepared pools. In the competitive ELISA tests, anti-apolipoprotein was immobilized in 96-well NUNC high-binding, flat-bottomed microtiter plates (Alameda Chemical and Scientific, Oakland, CA) by a capture antibody, anti IgG Fc (USB Immunochemicals, Cleveland, OH) that had been precoated, 1 μg/well, in carbonate buffer, pH 9. The apoB assay used a mixture of high-affinity monoclonal antibodies (MEDIX Biotech Inc., Foster City, CA) at a total concentration of 0.0045 μg/well; the apoAII assay used polyclonal goat antiserum (International Immunology Corp., Murrieta, CA), 0.045 μg IgG/well; the apoE assay used a mixture of monoclonal antibodies totaling 0.035 μg/well (Chemicon clones 16 and 17, Chemicon International Inc., El Segundo, CA); the Lp(a) assay used 100 μL of a 1/300 dilution of an Lp(a)-specific polyclonal rabbit antiserum (Calbiochem-Behring Corp., La Jolla, CA). Standards and samples were premixed with a fixed amount (antibody-saturating but not excess) of the appropriate biotinylated antigen in sample diluter containing 0.375% Tween 20, 1% bovine albumin (RIA grade), 1% casein acid hydrolysate, and 0.5 mM EDTA in phosphate-buffered saline, pH 7.2, with gentamicin sulfate (0.05 mg/mL) and 0.1 mM thimerosal as preservatives. Samples, 100 μg/well, at two different dilutions, each in triplicate, were incubated with antibody for 4 hr at room temperature. After washing the plates, bound labeled antigen was detected with streptavidin-horseradish peroxidase and *o*-phenylenediamine substrate (18). A standard curve of B/B° *vs* ng antigen/well was constructed, with B and B° the optical densities at 492 nm in the presence and absence, respectively, of competing, unlabeled antigen.

RESULTS

Table 1 shows the plasma lipid data for both the stabilization and salmon diets. No significant differences were observed in plasma cholesterol or LDL-C concentrations. However, HDL-C levels were significantly increased ($p<0.01$) and plasma triglycerides were decreased significantly ($p<0.01$) in subjects consuming the salmon diet as compared to those consuming the stabilization diet. Table 2 shows the AnUC concentrations of the major low density subfractions, total HDL, and HDL subfractions. The data show a lower VLDL level (not significant) in subjects on the salmon diet, but otherwise the

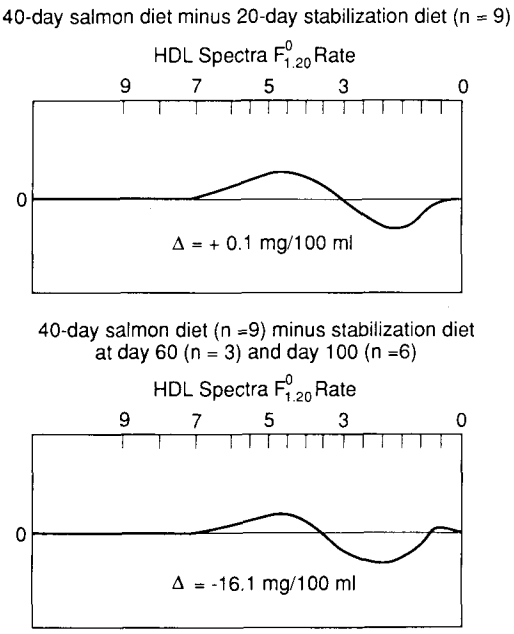

FIG. 2. Difference spectra for high density lipoprotein distribution profiles obtained by analytic ultracentrifugation.

levels of each major class are comparable for the initial stabilization diet, the salmon diet and the final stabilization diet periods. However, examination of the AnUC HDL subfractions HDL_{2b}, HDL_{2a}, and HDL_3, reveals differences in the subjects' patterns between the salmon and the stabilization diet periods, both on 40-day and 20-day duration, respectively. Plasma HDL_{2b} increased by 15.1 ± 2.9 mg/dL on the salmon diet, while HDL_{2a}, HDL_3 and total HDL decreased by 13.3 ± 8.0, 17.7 ± 8.5 and 16.1 ± 13.1 mg/dL, respectively. These decreases were not significant in paired t-tests; however, the HDL_{2b} increase was significant (P=0.0009). A more complete visual picture of the AnUC data are provided by mean Schlieren difference plots (Figs. 1 and 2). Plasma VLDL was consistently lower on the salmon diet (not significantly) while LDL and IDL varied, but neither systematically nor significantly. However, the HDL Schlieren difference plots for subjects on the 40-day salmon diet *vs* the stabilization diet at 20 and 60 days showed a consistent redistribution of HDL with an elevation of the

TABLE 3

Comparison of HDL Subfractions from Densitometric Scans of Gradient Gel Electrophoresis Patterns: Salmon Diet Minus Stabilization Diet[a] (Paired t-test, N = 9 each)

Subfraction	Δ% Area ± SEM	T	P
HDL_{2b}	9.1 ± 1.3	7.28	0.0001
HDL_{2a}	−0.7 ± 0.9	−0.71	(NS)
HDL_{3a}	−6.1 ± 0.9	−6.65	0.0002
HDL_{3b}	−2.4 ± 0.9	−2.82	0.023
HDL_{3c}	−0.4 ± 0.4	−1.18	(NS)

[a]The definition of the HDL Subfractions and the area measurements were done as described in detail in ref. 16.

TABLE 4

Plasma Concentrations (Average ± S.D. in mg/mL for Nine Subjects) of Apolipoproteins and Lp(a) After the Stabilization (20-day), Salmon (40-day), and Stabilization (40- or 60-day) Diet Periods

Diet	AI	AII	B	E	Lp(a)	AI/AII	AI/B
Stabilization	1.04 ± 0.07	0.28 ± 0.04	0.81 ± 0.20	0.086 ± 0.007	0.23 ± 0.14	3.84 ± 0.56	1.35 ± 0.31
Salmon	1.01 ± 0.05	0.26 ± 0.05	0.77 ± 0.23	0.087 ± 0.008	0.23 ± 0.14	3.90 ± 0.56	1.40 ± 0.37
Stabilization (40 or 60 day)	1.11 ± 0.05	0.31 ± 0.04	0.79 ± 0.22	0.088 ± 0.008	0.23 ± 0.15	3.59 ± 0.43	1.48 ± 0.37

$F^{o}_{1.20}$ 3.5-9 (HDL_2) and depression of the $F^{o}_{1.20}$ 0-3.5 (HDL_3) AnUC subclasses. Comparisons were significant at $p<0.002$, $p<0.002$, and $p<0.04$, $p<0.02$, respectively.

The percentage distribution of HDL in GGE confirmed the redistribution of smaller HDL_3 to larger HDL_2 subclasses noted in quantitative AnUC. Table 3 compares by paired t-test the five major subfractions obtained by GGE of HDL from the subjects on the salmon and the stabilization diets. Since resolution is higher with GGE and total HDL relatively constant, it is not unexpected that the elevation of HDL_{2b} and depression of the smaller HDL_{3a} and HDL_{3b} were highly significant.

The plasma concentrations of apolipoproteins AI, AII, B, and E and Lp(a) are given in Table 4. The ELISA Lp(a) measurements were independently confirmed by a quantitative GGE method (20) which yielded plasma concentrations in mg/mL of 0.246 ± 0.135 (salmon diet, r= 0.911), 0.237 ± 0.119 (20-day stabilization diet, r=0.957) and 0.242 ± 0.118 (40- or 60-day stabilization diet, r= 976). Comparison of ELISA and GGE values for Lp(a) yielded r=0.943 in all 27 cases. Table 5 gives the corresponding comparison by paired t-test of apolipoprotein levels in subjects as a function of diet. In all individuals, apoAI concentration was lower after the salmon diet than after the 40 or 60 day stabilization diet ($p=0.0004$). ApoAII was also lower in six subjects (those with salmon diet preceding the stabilization diet) and similar in two, for $p<0.053$ for all subjects. The ratio of apoAI to apoAII was higher by 24% on the average in the six subjects who ate the salmon diet before the stabilization diet, and approximately 20% lower in the other three subjects. ApoAI values, ranging from 0.95 to 1.18 mg/mL, were on average 15% lower than pooled male plasma values (approximately 1.20 mg/mL) obtained with the same ELISA reagents and conditions. Concentrations of apoB, apoE and Lp(a) were similar on average after all the diets. Individual changes, generally <10%, were uncorrelated with diet, total plasma cholesterol, or apolipoprotein concentration, which ranged from 0.59 to 1.25 mg/mL for apoB and 0.033 to 0.41 mg/mL for Lp(a). Even though apoAI was lower in all subjects, on the salmon diet, only five subjects had lower apoAI to apoB ratios. ApoE concentrations, 0.076 to 0.102 mg/mL, were somewhat higher than the average (0.066 ± 0.031 mg/mL) for a random group of 70 plasmas that were assayed under the same conditions. By chance, Lp(a) concentrations proved to be high in six of the nine subjects, so the average concentrations in Table 4 is twice that (0.115 ± 0.140 mg/mL) observed in the 70 control plasmas.

TABLE 5

Comparison of Apolipoprotein Data: Salmon Diet *vs.* Stabilization Diet (Paired t-test)

Apolipoprotein	n	Mean Δ mg/100 mL±SEM	T	P
AI	9	−9.7 ± 1.7	−5.74	0.0004
AII	9	4.8 ± 2.1	−2.27	0.053
B	9	1.9 ± 16	−1.24	(NS)
E	9	0.17 ± 0.24	−0.69	(NS)
Lp(a)(ELISA)	9	−0.6 ± 1.2	−0.48	(NS)
Lp(a)(GGE)	9	−0.5 ± 2.0	−0.25	(NS)

DISCUSSION

Although the dietary effects of marine (20 and 22 carbon) n-3 fatty acids in humans have been studied extensively, there are conflicting results with regard to LDL-C and HDL-C (4). However, in nearly all previous studies, plasma triglycerides and VLDL were lowered. In the normolipidemic human studies reported in the Harris review (4), there was essentially no change in total or LDL cholesterol, a slight rise (3%) in HDL-C, and a 25% decrease in plasma triglycerides. Our data and that of the previous paper (11) are consistent with these earlier studies, and also explain the nature of the increased HDL-C as a significant shift in particle size and density of the HDL subfractions. Other recent studies of three groups of volunteer normal males in the Netherlands and Norway by Van Houwelingen *et al.* (21) also showed significantly increased HDL-C after six weeks of long-chain n-3 polyunsaturated fatty acid consumption. Triglycerides were significantly lowered in these studies. Another recent six-week n-3 study of mildly hypercholesterolemic males by Abbey *et al.* (22) also observed a substantial fall in VLDL and triglycerides, an increase in LDL-C, and a slight fall in HDL-C. However, despite the decrease in HDL-C, there was a consistent increase in the HDL_2/HDL_3 ratio as measured by GGE. In our study, the larger, more lipid-rich HDL_2 were increased and the smaller, more protein-rich HDL_3 were significantly reduced, consistent with the results of Abbey *et al.* (22). Since the total HDL concentration was not significantly changed, this redistribution from small to large HDL would tend to raise the HDL-C and lower the major HDL apolipoproteins, AI and AII.

In the study of Abbey *et al.* (22), apoAI was lower by 10% on average in 11 mildly hypercholesterolemic men

after six weeks on a fish-oil-supplemented diet than after the preceding 3-week diet supplemented with safflower oil. ApoB and apoAII were also lower by 6% and 14%, respectively, and the apoAI/apoAII ratio was higher. In our study with normolipidemic men, significant differences in apoAI (lower with the salmon diet) were observed only after the maximum diet periods (40-day salmon diet *vs* 40- or 60-day stabilization diet); apoB did not change. Although our results on apoAII and apoAI/apoAII ratios did not reach the significance of changes in the study of Abbey *et al.* (22), our results tend to confirm theirs. Perhaps we needed more than nine subjects to establish this effect. In retrospect, 20 days on the stabilization diet may have been insufficient for equilibration of plasma apoAI concentration; increased values were observed in six subjects after 40 or 60 days on the diet.

Reductions in plasma apoE and/or Lp(a) concentrations could be anti-atherogenic. However, no changes during this study were observed, irrespective of whether the subject's plasma Lp(a) was high or low. The potentially anti-atherogenic effect of n-3 fatty acid consumption may include a profound redistribution of HDL with a selective increase in HDL_2. The larger, less dense HDL_2 appear to be the most variable and the anti-atherogenic subfraction in the HDL spectrum (23,24). Possibly this change in HDL profile is related to a reduction in plasma VLDL, which has been reported after fish-oil diets (22), but did not reach significance in this study. Offsetting this apparently beneficial effect on HDL, the salmon diet lowered plasma apoAI, and the apoAI/apoB ratio was reduced by 5% or more, up to 21%, in four subjects.

The above findings are more realistic in terms of human dietary modification because they included n-3 fatty acids fed as natural marine food as opposed to fish oil supplements. The 2.1 En% of n-3 fatty acids in our salmon diet compared quantitatively to the mean n-3 supplements cited in the Harris review (4). Recently Harris *et al.* (25) found similar results with a diet containing 4.5 g/day of n-3 fatty acids. While it is possible to consume large amounts of n-3 fatty acid-containing marine food over an extended period of time, it is more realistic to evaluate the chronic dietary effect in humans of a lower n-3 intake, *e.g.*, 1.5–3 g/day. This amount of n-3 fatty acid was effective when fed as fish oil supplements (4).

ACKNOWLEDGMENTS

We thank Joseph R. Orr for processing the AnUC data, Marie Laskaris for assistance in the immunoassays, Bonnie Miller for statistical analysis, and Mary Lou Kurtz for her help in preparing the manuscript. The research performed at Lawrence Berkeley Laboratory and at Lawrence Livermore National Laboratory was supported by NIH Program Project Grant HL 18574 from the National Heart, Lung, and Blood Institute of the National Institutes of Health and by a research grant funded by the National Dairy Research and Promotion Board. This study was conducted at the Western Human Nutrition Research Center, ARS, USDA, San Francisco, CA, and at Lawrence Berkeley Laboratory (Department of Energy contract DE-AC03-76SF00098 to the University of California), and the Lawrence Livermore National Laboratory (Department of Energy contract W7405-ENG48 to the University of California).

The Participation of Soluble Factors in the ω-Oxidation of Fatty Acids in the Liver of the Sheep

W. Robert Hare* and **Klaus W.J. Wahle**
Rowett Research Institute, Bucksburn, Aberdeen, AB2 9SB, United Kingdom

The removal of soluble components from an ovine hepatic microsomal preparation decreased the ω-hydroxylation of dodecanoic and hexadecanoic acids. The results suggest that one or more soluble components play a role in the microsomal ω-hydroxylation of fatty acids. The possible roles in the reaction of catalase (known to stimulate the microsomal desaturations of fatty acids and alkylglycerols) and superoxide dismutase were investigated. The addition of these enzymes to the complete (but not the washed) microsomal preparation stimulated both the initial ω-hydroxylation reaction and the subsequent dehydrogenation reactions of the ω-oxidation pathway. The similarity of the effects of catalase and superoxide dismutase and stimulation of two different steps of the ω-oxidation pathway suggest that these agents are acting indirectly by removing active oxygen species rather than directly on the enzymes of microsomal fatty acid ω-hydroxylation.
Lipids 26, 102–106 (1991).

Three separate reactions constitute the ω-oxidation of fatty acids in mammalian tissues: i) the hydroxylation[1] of the ω1- or ω2-carbons of a fatty acid (1,2); ii) the dehydrogenation of the resulting ω1- or ω2-hydroxyl group to produce an aldehyde or ketone group, respectively; and iii) the dehydrogenation of the aldehyde (but not the ketone) group to yield a carboxyl group (2–4). The pathway thus converts monocarboxylic into dicarboxylic acids. The complete β-oxidation of an even carbon number dicarboxylic acid produces succinate which can enter the tricarboxylic acid cycle (5). The ω-oxidation of fatty acids is, therefore, able to spare or allow the synthesis of glucose and to reduce ketosis (5). This could be of importance to domestic ruminants, particularly to high-yielding dairy cows and twin-bearing ewes, in which ketosis due to hypoglycemia causes economically significant losses.

The ω-hydroxylation reaction is catalyzed by cytochrome P-450 of the endoplasmic reticulum using electrons supplied by NADPH cytochrome P-450 reductase. Reconstitution of the ω-hydroxylation systems of the rat (6) and mini-pig (7) has been achieved using purified cytochrome P-450, the reductase and lipids. However, the reconstitution of a functional enzyme system from these components does not exclude the participation of other components in the reaction. In the intact microsomal system, cytochrome b_5 and, by implication, NADH cytochrome b_5 reductase have been shown to play a role in supplying electrons from NADH to cytochrome P-450 for fatty acid ω-hydroxylation (8).

Similar results have been obtained for the fatty acid desaturase systems of hepatic microsomes. There are several desaturase systems, each consisting of a desaturase enzyme which obtains electrons from NADH-cytochrome b_5 reductase. They may be reconstituted using only these two enzymic components and lipid (9). However, in microsomal desaturation systems *in vitro* the participation of soluble factors such as catalase and various fatty acid binding proteins including bovine serum albumin, ligandin and Z-protein (10,11), and an additional unidentified protein which appeared to act directly on the desaturase system (12), has been demonstrated. Catalase has also been shown to stimulate the microsomal desaturation of 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphoethanolamine in the synthesis of ethanolamine plasmalogen (13).

Here we report findings which support the participation of one or more soluble stimulatory factors in optimizing the ω-hydroxylation of fatty acids by sheep liver microsomes.

MATERIALS AND METHODS

Animals and preparation of tissue fractions. Samples of liver tissue from adult male and female sheep (Ovis aries) were obtained from a local abattoir. Animals were killed by captive bolt and immediately exsanguinated. Samples of liver tissue were quickly removed, placed in ice-cold homogenizing medium, and transported to the laboratory within 30 min. The homogenizing medium contained sucrose, 200 mM; *N*-2-hydroxyethylpiperazine-*N*-2-ethanesulfonic acid (HEPES), 40 mM; ethylenediaminetetraacetic acid (EDTA), 1 mM; and dithiothreitol, 1 mM, adjusted to pH 7.2. Tissue was coarsely chopped, washed, then homogenized (15% tissue w/v) at 0°C using a Potter-Elvehjem type homogenizer (Norlab Instruments, Dyce, Aberdeen, U.K.). Mitochondria, nuclei and cell debris were sedimented by centrifugation of the homogenate at 10,000 × *g* for 10 min at 4°C, and then the resulting supernatant was centrifuged at 140,000 × *g* for 60 min. The supernatant from the second centrifugation was termed the particle-free supernatant (PFS). The sediment from the second centrifugation was crude microsomes. Half of the crude microsomes were resuspended in homogenizing medium to a concentration of about 20 mg protein/mL (the non-washed or "complete" preparation). A "washed" microsomal fraction was prepared by gently resuspending the other half of the crude microsomal fraction in 15 mL of ice-cold homogenizing medium and recentrifuging (at 140,000 × *g* for 60 min). This washing step was repeated. During the washing procedures, the non-washed microsomal preparation was maintained at 0°C. Protein concentrations were measured by the method of Lowry *et al.* (14), using bovine serum albumin as the standard.

Incubations, and measurement of ω-oxidation activity. The microsomal activities of the ω-oxidation of dodecanoic and hexadecanoic acids were measured in a final volume of 1.0 mL of medium containing HEPES, 50 mM;

[1]The term ω-hydroxylation, without specification of position of hydroxylation, refers to ω1-hydroxylation plus ω2-hydroxylation.

Abbreviations: EDTA, ethylenediaminetetraacetic acid; HEPES, *N*-2-hydroxyethylpiperazine-*N*-2-ethanesulfonic acid; PFS, particle-free supernatant.

$MgCl_2$, 5 mM; $MnCl_2$, 5 nM; NAD, NADH, and NADPH all at 1 mM; glucose-6-phosphate dehydrogenase, 0.4 I.U./mL, pH 7.5. Radiolabeled substrate was added in propylene glycol; final concentrations were 300 μM (specific activity 0.33 mCi/mmol) for [1-^{14}C]dodecanoic acid and 100 μM (2.0 mCi/mmol) for [1-^{14}C]hexadecanoic acid in all incubations except the investigation of the time course, in which the final concentration of [1-^{14}C]dodecanoic acid was 500 μM (5.0 mCi/mmol). Unless otherwise indicated, the concentration of microsomal protein was 1 mg/mL in all incubations. If present, the concentration of PFS protein was 1 mg/mL; catalase (bovine liver, Boehringer Corporation Ltd., Lewes, U.K.), 8.000 ("low") or 80,000 ("high") I.U./mL; superoxide dismutase (bovine blood, type I, Sigma Chemical Co. Ltd., Poole, U.K.), 4 ("low") or 160 ("high") I.U./mL; sodium azide, 100 mM. Incubations were at 37°C and aerobic, and unless otherwise indicated, for 30 min. Incubations were stopped by the addition of 1 mL KOH in methanol (0.5 M), carrier fatty acids were added, the mixture saponified, and substrate and products extracted into diethyl ether, methylated, separated by thin-layer chromatography on silica gel G plates (15) and quantitated by liquid scintillation counting. The conversions of dodecanoic and hexadecanoic acids to products of ω-hydroxylation in the complete microsomal incubation system were typically about 10% and 2%, respectively, and recoveries of products typically greater than 97%. The identities of the products were confirmed by gas-liquid chromatography and mass spectrometry (15).

RESULTS AND DISCUSSION

Previous studies have shown that the microsomal fraction of sheep liver carries out the ω1- and ω2-hydroxylations of both medium- and long-chain fatty acids (15,16). The rate of the ω-hydroxylation of dodecanoic acid by a complete hepatic microsomal preparation was linear for more than 40 min (Fig. 1), and proportional to the concentration of microsomal protein up to 3 mg/mL (Fig. 2).

Washing procedure. Measurements of the protein present in the wash solutions showed that the washing procedures had removed 58% of the total protein of the crude microsomal preparation. The non-washed (complete) preparation was kept at the same temperature as the preparation being washed for the duration of the washing process. This was to limit, as far as possible, the differences between the preparations to those caused by the losses of soluble components. It should be noted that measurements of microsomal protein in the complete preparation represent both microsomal and soluble proteins; in contrast, those for the washed preparation represent microsomal protein with only traces of soluble protein.

Effect on ω-hydroxylation activity of removal of soluble material from the microsomal preparation. Figure 2 shows the relationships between the protein concentrations of the washed and the complete microsomal preparations and the rate of ω-hydroxylation of dodecanoic acid. At concentrations of microsomal protein of 1.0 mg/mL or less there were no significant differences in the specific activities of the ω-hydroxylation of dodecanoic acid. It follows that, because the washing process had removed about 60% of the protein present in the complete microsomal preparation, a loss of approximately 60% of the ω-hydroxylation activity originally present in the complete preparation had occurred. The dotted line shows the relation between specific activity and microsomal protein concentration which would have been obtained if no loss of activity had occurred on washing. Comparison of this relation with that for the washed preparation demonstrates the extent of the loss of activity.

The loss of activity became greater as the concentration of microsomal protein increased. At 3 mg microsomal protein/mL, the specific activity of the ω-hydroxylation of dodecanoic acid by the washed preparation was 58% of that of the complete preparation (Fig. 2). A similar variation in specific activity with microsomal protein concentration was observed for hexadecanoic acid. At a concentration of microsomal protein of 1.0 mg/mL, the specific activity of the ω-hydroxylation of hexadecanoic acid

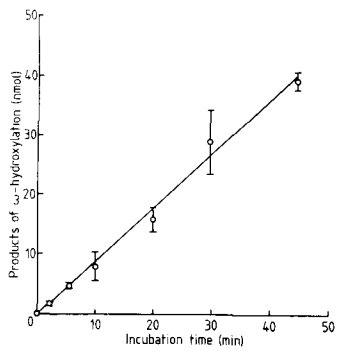

FIG. 1. Time course of the ω-oxidation of dodecanoic acid by an ovine hepatic microsomal preparation. The concentration of microsomal protein was 1 mg/mL, and of dodecanoic acid was 500 μM (specific activity 5.0 mCi/mmol). Values are the mean ± S.D. of three results.

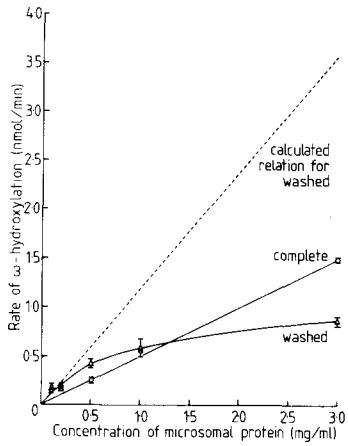

FIG. 2. Effect of washing an ovine hepatic microsomal preparation on the relation between the rate of ω-hydroxylation of dodecanoic acid and the concentration of microsomal protein. Results for the complete microsomal preparation are shown as circles, and for the washed preparation are shown as triangles. Values are the mean ± S.D. of three determinations, or mean ± range of two determinations (about half of the points for each preparation were from three determinations). The calculated relation between the expected activity after washing (based on the amount of protein removed during washing) and the concentration of microsomal protein is shown as a dotted line.

by the washed preparation was little different from that of the complete preparation (Fig. 3). At 3 mg microsomal protein/mL, the specific activity of the ω-hydroxylation of hexadecanoic acid was 54% of that of the complete preparation (Table 1). Thus, at the higher concentration of microsomal protein, the results for both dodecanoic and hexadecanoic acids suggest a loss due to washing of approximately 80% of ω-hydroxylation activity.

Figure 2 shows that the relationship between specific activity and microsomal protein concentration was linear for the complete preparation, but not for the washed preparation. This suggests that, at higher ratios of protein to the substrate fatty acid, the binding of the substrate to microsomal proteins reduces its access to the ω-hydroxylation system to a greater extent than does binding to soluble proteins (the latter may include specific fatty acid binding proteins). A limitation of reaction rate due to lack of the known participating agents such as NADPH or oxygen is improbable, since the total ω-hydroxylation activity in the incubations with the washed microsomal preparations was less than that with the complete preparations for both dodecanoic and hexadecanoic acids.

It is unlikely that an inherent instability of the ω-hydroxylation system could have caused the observed differences between the complete and washed microsomal preparations. Studies on the rat hepatic microsomal system have shown that it is quite stable. Okita *et al.* (17) found that storage for 24 hr at 4°C caused a loss of only 34% of ω-hydroxylation activity. In our studies, dithiothreitol (for protection of protein −SH groups) was present in the media for both microsomal preparations. Furthermore, the experimental design minimized differences caused by temperature and time in the enzyme activities of the washed and complete microsomal preparations. If the principal cause of the loss of activity was exposure to degradative (*e.g.*, lysosomal) enzymes, then the complete preparation would have been expected to show the largest decrease. Our results are consistent with the observed losses of activity being due to the removal by the washing process of one or more soluble components of the crude microsomal preparation.

Effect on dehydrogenation activity of removal of soluble material from the microsomal preparation. The conversion of the ω-hydroxy fatty acids to dicarboxylic acids occurs through the actions of alcohol and aldehyde dehydrogenases. Each of these enzymes is present in both the cytosol and in the microsomal membrane (18–20). Figure 4 shows that the removal, by washing, of the alcohol and aldehyde dehydrogenases present in the soluble fraction of a crude microsomal preparation did not significantly reduce the rate of production of dicarboxylic acid per mg microsomal protein. This suggests that approximately 60% of the total dehydrogenase activity of the crude microsomal preparation was present in the soluble fraction, and about 40% was associated with the microsomal membrane. The removal of the soluble dehydrogenases, together with around 60% of the total protein would result in little observable change in the dehydrogenase specific activity of the microsomal preparation.

TABLE 1

The Specific Activity of the ω-Hydroxylation of [1-^{14}C]Hexadecanoic Acid by Washed and Complete Preparations of Hepatic Microsomes[a]

Treatment	15- plus 16-hydroxy-hexadecanoic acids	Hexadecanedioic acid
Washed	26.7 ± 2.3	2.3 ± 0
Complete	44.0 ± 1.7	10.0 ± 9.3

[a]The concentration of microsomes was 3.0 mg/mL. The tabulated values represent the mean ± range of two determinations. The rates of formation of the different products are expressed as pmol/min/mg microsomal protein.

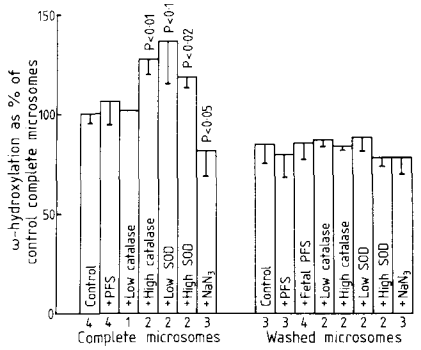

FIG. 3. The effects of adding 1 mg PFS, catalase at "low" (8,000 I.U./mL) or "high" (80,000 I.U./mL) concentrations, superoxide dismutase (SOD) at "low" (4 I.U./mL) or "high" (160 I.U./mL) concentrations or azide (100 mMol) to either the complete or washed ovine hepatic microsomal preparations on the ω-hydroxylation of hexadecanoic acid. Results were calculated as specific activities, and expressed as percentages in relation to the result for the control complete incubation. The values shown are means ± S.D. (three or more determinations) or means ± ranges (two determinations). The number of determinations is shown below each treatment. The significances of differences (by t-test) from the appropriate complete or washed control are shown. It should be noted that, if no activity had been lost on washing, the activity of the control washed microsomal preparation would have been about 240% of that of the control complete preparation.

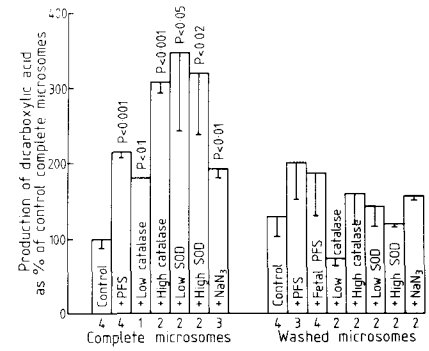

FIG. 4. The effects of the additions detailed for Figure 3 on the production of hexadecanedioic acid from hexadecanoic acid by complete or washed ovine hepatic microsomal preparations. Results were calculated as specific activities, and expressed as percentages in relation to the result for the control complete incubation. The values shown are means ± S.D. of three or more determinations or means ± ranges of two determinations. The number of determinations is shown below each treatment. The significances of differences from the appropriate complete or washed control are shown.

Effect on ω-hydroxylation activity of adding back a soluble fraction. No effect of the PFS on the ω-hydroxylation of hexadecanoic acid by either the washed or the complete microsomal preparations was observed (Fig. 3). This negative finding may simply reflect the large dilution of soluble components which occurred on homogenization and the further dilution occurring when the necessarily limited volume of PFS was added to the incubation system (overall dilution was about 250-fold). Alternatively, if the lowered activity was the result of the removal of a protective factor, then it would suggest that damage had occurred to either the enzyme system or its membrane environment, and was not reversible by replacement of the factor.

Effect on dehydrogenation activity of adding back a soluble fraction. For both the complete and the washed microsomal preparations, the addition of the soluble cytosolic fraction of liver (PFS) approximately doubled the rate of conversion of 16-hydroxy-hexadecanoic acid to dicarboxylic acid (Fig. 4). This is consistent with the presence in the PFS of soluble forms of the alcohol and aldehyde dehydrogenases which act in concert with the microsomal membrane bound dehydrogenases.

PFS from fetal liver was shown to have the same stimulatory effect on the dehydrogenation activity as the adult PFS (Fig. 4). This is of interest in the light of our previous observation that the ω-hydroxylation activity of fetal liver microsomes is negligible compared with that of adult preparations (15), consistent with findings on other fetal hydroxylation reactions (21). This suggests that dehydrogenases capable of acting on ω-hydroxy fatty acids develop earlier in ovine fetal life than the capacity to hydroxylate fatty acids.

Effects of catalase, superoxide dismutase and azide. The effects of two concentrations of catalase (8,000 = "low" and 80,000 I.U./mL="high") and superoxide dismutase (4 and 160 I.U./mL, "low" and "high") were investigated in incubations with both the washed and complete microsomal preparations. The concentrations of catalase were 10 ("low") and 100 times ("high") greater than the amount per mg microsomal protein found to give maximal stimulation of the alkylglycerol desaturation reaction (13). The concentrations of superoxide dismutase were similar to ("low") and about 50 times ("high") the concentration of this enzyme in mouse liver (22). The concentration of azide (100 mM) added to the incubations was sufficient to completely inhibit catalase activity, to inhibit 80% of superoxide dismutase activity and to quench singlet oxygen (23-25).

Both catalase and superoxide dismutase can interrupt the sequences of reactions which create "active oxygen" species. The latter are produced in large quantities by microsomal systems *in vitro* in the presence of NADPH (26). Since active oxygen species can damage both enzymes and membrane structures, they readily inhibit the functioning of enzyme systems. A well supported sequence of synthesis of active oxygen species begins with the production of the superoxide radical (27,28). This decomposes to give hydrogen peroxide, and the latter gives rise to the highly reactive hydroxyl radical (29). The hydroxyl radical can initiate fatty acid peroxidation which can produce singlet oxygen (30). Any of these active oxygen species could reduce ω-oxidation activity, either directly by reacting with the microsomal electron transport or cytosolic enzymes, or indirectly by attacking the lipid or protein of the membrane which contains the enzymes (31).

Catalase and superoxide dismutase both increased the rate of the ω-hydroxylation of hexadecanoic acid by the complete microsomal preparation (Fig. 3). Additionally, the proportion of products recovered as the dicarboxylic acid from the complete microsomal preparation in the presence of catalase or superoxide dismutase was about three times that found in the control incubation (Fig. 4). However, no effects of either catalase or superoxide dismutase were observed on the hydroxylation or dehydrogenation reactions carried out by the washed microsomal preparation (Figs. 3 and 4).

The dual stimulation of the electron-transporting enzymes of the microsomal membrane, and of the soluble and/or membrane bound dehydrogenases, strongly suggests that catalase and superoxide dismutase are acting non-specifically to increase the activity of these enzymes. Moreover, it is difficult to visualize a direct role for catalase or superoxide dismutase in the electron transport or dehydrogenation reactions of the ω-oxidation enzyme sequence. It seems likely, therefore, that the stimulatory effects of the additions of catalase and superoxide dismutase to the complete microsomal incubation system were due to the protection given to the microsomal and soluble enzymes from the damaging effects of active oxygen species produced by microsomes in the presnce of NADPH. In the cyclooxygenase enzyme system, self-destruction due to its associated peroxidase activity has been demonstrated by Lands and Byrnes (32), and may have some similarities to the effects we have described. Our results complement the previous findings that catalase stimulates the desaturations of fatty acids (10) and alkylglycerols (13).

The lack of effect of catalase and superoxide dismutase in the washed preparation could be explained by the production of much smaller quantities of active oxygen species by the washed microsomal preparation, or by the involvement of one or more soluble components in the complete preparation in the processes leading to membrane damage by active oxygen species.

Azide greatly stimulated the dehydrogenation reactions but inhibited the initial ω-hydroxylation reaction in the incubations with the complete microsomes. The stimulation may well reflect the ability of azide to quench singlet oxygen. The inhibitory effects may be exerted directly on the microsomal electron transporting enzymes or indirectly through inhibition of endogenous catalase and superoxide dismutase.

In conclusion, a large loss of fatty acid ω-hydroxylation activity is caused by the removal of the soluble components of a crude microsomal preparation. This suggests that one or more soluble factors may participate in or optimize the ω-hydroxylation of fatty acids by liver preparations from sheep. Possible identities of the soluble factor include: i) a fatty acid binding protein (or more than one) which functions, at least *in vitro,* as a carrier of substrate or products in the ω-hydroxylation reaction; ii) a component with direct stimulatory action on the ω-hydroxylase system; and iii) a factor (or more than one) which protects the ω-hydroxylase system from damage by oxygen radicals or other agents.

Both catalase and superoxide dismutase were able to

stimulate the ω-hydroxylation and dehydrogenation reactions carried out by crude microsomal plus soluble fractions *in vitro*. This finding implicates active oxygen species as agents which reduce the activity of the microsomal ω-hydroxylation system, either by acting directly on the enzymes, or by lipid peroxidation reactions which result in a disruption of the membrane environment of the ω-hydroxylation system.

The Effects of Dietary Protein on the Fatty Acid Composition and Δ6 Desaturase Activity of Rat Hepatic Microsomes

Marie Lindholm and **Anders Eklund***
Department of Medical and Physiological Chemistry, University of Uppsala, Uppsala, Sweden

Recently, significant differences between rats fed a casein diet and rats fed a soybean protein diet have been observed in hepatic phospholipid fatty acid patterns (Sjöblom, L., and Eklund, A., *Biochim. Biophys. Acta 1004,* 187–192, 1990). The influence of these two diets on the Δ6 desaturase activity was investigated in the present study because the hepatic desaturase system is a source of unsaturated fatty acids. The rats fed a casein diet showed higher desaturase activity than those fed soybean protein when using either linoleic acid ($P<0.005$) or oleic acid ($P<0.05$) as substrates. The phosphatidylcholine fraction of hepatic microsomes showed increases in oleic acid ($P<0.005$) and 20:3ω9 ($P<0.001$) levels as well as decreases in stearic acid ($P<0.001$), linoleic acid ($P<0.005$) and arachidonic acid ($P<0.005$) levels in rats which were fed casein rather than soybean protein. Similar differences between the two groups were also observed in the phosphatidylethanolamine and phosphatidylinositol fractions. These data indicate that the qualitative properties of the dietary protein source may influence the fatty acid pattern of rat hepatic microsomes by interfering with Δ6 desaturase activity.
***Lipids 26,* 107–110 (1991).**

Dietary protein exerts a profound influence on the level and composition of the different plasma lipid and lipoprotein fractions in various experimental animals (1–4). Recently, it has been shown that the source of protein also influences the fatty acid pattern in various lipids in the liver, aorta and plasma of rats fed cholesterol-containing and cholesterol-free diets (5–7).

Within the lipid fractions of casein-fed rats, reduced levels of linoleic (18:2ω6) and arachidonic (20:4ω6) acids and raised levels of oleic (18:1ω9) and vaccenic (18:1ω7) acids were found compared to rats fed soybean protein. When the dietary fat solely consisted of olive oil, casein-fed rats showed markedly increased hepatic levels of Mead acid (20:3ω9) compared to rats fed soybean protein (7).

A possible explanation for the changes in fatty acid patterns could be a stimulation or inhibition of fatty acid desaturase activities in the rat liver, induced by the source of dietary protein. Choi *et al.* (8) have recently demonstrated increased Δ6 desaturase activity in rats fed casein compared to rats fed soybean protein, when both proteins were administered in a cholesterol-free diet. These authors did not report Δ6 desaturase activity in rats fed cholesterol-containing diets, and the dietary fat source and amount used were different from those used in the present study; we therefore undertook these experiments to compare the Δ6 desaturase activities in liver microsomes from rats fed casein or soybean protein in combination with cholesterol and olive oil.

Abbreviations: BHA, butylated hydroxyanisole; CAS-rat, rat fed a casein diet; GLC, gas-liquid chromatography; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; SOY-rat, rat fed a soybean protein diet; TLC, thin-layer chromatography.

MATERIALS AND METHODS

Materials. [1-^{14}C]Linoleic acid (specific activity 59 mCi/mmol) and [1-^{14}C]oleic acid (specific activity 57 mCi/mmol) were purchased from DuPont (Boston, MA); unlabeled linoleic acid, oleic acid and fatty acid standards were from Nu-Chek-Prep (Elysian, MN). KF was obtained from Aldrich-Chemie (Steinheim, Germany). Butylated hydroxyanisole (BHA) was purchased from May & Baker LTD (Dagenham, England). Adenosine triphosphate (ATP), Coenzyme A (CoA), reduced nicotinamide adenine dinucleotide (NADH) and N-acetyl-L-cystein were obtained from Sigma (St. Louis, MO). Other chemicals and reagents were obtained from Merck (Darmstadt, Germany).

Preparation of microsomes. Male 70 g Sprague-Dawley strain rats (Alab, Sollentuna, Sweden) were fed either a casein or a soybean protein-based diet, containing 20% protein, 10% olive oil, 0.5% cholesterol, vitamins, minerals, cellulose and cornstarch for four weeks as previously described (2). The rats were housed in a temperature- and light-controlled room (22°C, lights on 0600–1800). Water and food were provided *ad libitum.* The animals were killed in pairs, one from each diet on each occasion, and the livers were immediately excised and rinsed in ice-cold physiological saline solution. The livers were homogenized in 0.25 M sucrose, 0.15 M KCl, 4.9 mM $MgCl_2$ and 1.4 mM N-acetyl-L-cysteine in 40 mM KH_2PO_4/K_2HPO_4, pH 7.2. The homogenate was layered above an equal volume of 0.34 M sucrose, 0.15 M KCl, 4.9 mM $MgCl_2$ and 1.4 mM N-acetyl-L-cysteine in 40 mM KH_2PO_4/K_2HPO_4, pH 7.2 and was centrifuged 10 min at 800 × *g*. The supernatant was collected and centrifugated for 10 min at 17,000 × *g* (RC2-B centrifuge, Sorvall, Newtown, CT). The supernatant obtained was collected and centrifugated for 1 hr at 100,000 × *g* (Prepspin 50 ultracentrifuge with a fixed angle rotor, cat. no. 43114-118, MSE, Crawley, England). The remaining pellet was resuspended in 2 × 750 μL of the homogenization buffer. This suspension is referred to as the microsomal fraction.

Protein content was determined by the Lowry method (9). NADPH-cytochrome C-reductase was assayed as a microsomal marker (10).

Δ6 Desaturase assay. The optimal concentration of microsomes was determined in a series of incubations with different amounts of microsomes to assure a non-saturating protein level. Microsomal suspensions (300 μL) were mixed with 500 μL of incubation medium to a final microsomal concentration of 5 mg protein/mL. The homogenization buffer with 63.5 mM KF, 2.08 mM ATP, 97.7 μM CoA and 1.39 mM NADH added was used as incubation medium. After the addition of 5 μL 5.5 mM

[1-^{14}C]linoleic acid with a final specific activity of 1.14 mCi/mmol, the samples were incubated for 15 min at 37°C. The experimental procedure was repeated with 5 μL [1-^{14}C]oleic acid (1.14 mCi/mmol, 5.5 mM). The incubations were terminated by addition of 650 μL of 10% KOH in ethanol. BHA was added to suppress oxidation (final concentration 0.005%). The sample was saponified for 20 min at 100°C, cooled to room temperature and neutralized with 650 μL 2 M H_2SO_4.

The fatty acids were extracted with 2 × 5 mL of n-hexane, dried under a stream of N_2, and methylated with 1 mL of H_2SO_4/dry methanol (0.5:20, v/v) for 1 hr at 67°C. After addition of 1.0 mL of distilled water, the fatty acid methyl esters were extracted with 3 × 1.5 mL of petroleum ether (boiling range 40–60°C), concentrated by evaporation, and purified by thin-layer chromatography (TLC) on a prewashed silica gel plate (20 × 20 cm, Merck DC-Fertigplatten, cat. no. 5721) which was developed with hexane/toluene (1:1, v/v). After extraction, the purified fatty acid methyl esters were separated according to the degree of unsaturation by TLC on a $AgNO_3$ impregnated plate developed with hexane/diethyl ether/acetic acid (80:20:1, v/v/v). For the purpose of identification, pure standard fatty acids were run in parallel. The plates were scanned for radioactivity using an LB 2842 Automatic TLC-linear analyzer (Berthold, Wildbad, Germany).

Fatty acid analysis. The amount of total lipid in the microsomes was determined by Folch-extraction, as previously used by us (11). Phosphatidylcholine (PC), phosphatidylethanolamine (PE) and phosphatidylinositol (PI) were isolated by TLC as described previously (7). The fatty acid composition of the phospholipid classes in the hepatocyte microsomes was determined by gas-liquid chromatography (GLC) (7).

Statistical data treatment was by Student's t-test with NADPH-cytochrome C-reductase and desaturase activity values grouped in pairs (12).

RESULTS AND DISCUSSION

Fatty acid composition. As shown in Figures 1 and 2, the fatty acid composition of the two predominant phospholipid classes present in hepatic microsomes differed significantly depending on the source of dietary protein consumed by the rats. Oleic acid ($P<0.005$), vaccenic acid ($P<0.005$), and 20:3ω9 (Mead acid, $P<0.001$) reached higher levels in the microsomal PC fraction of rats fed a casein diet (CAS-rats) than in the corresponding fraction from rats fed a soybean protein diet (SOY-rats)

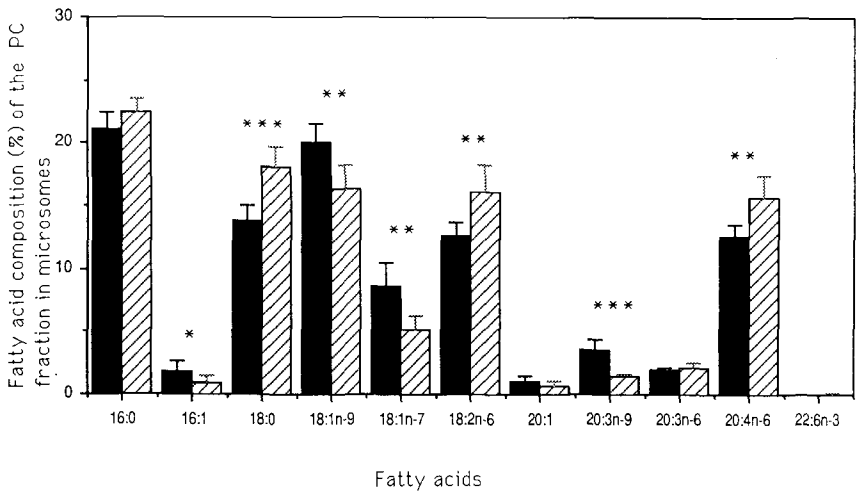

FIG. 1. Fatty acid composition of the PC fraction in hepatic microsomes from rats fed a casein- (solid bar) or a soybean protein- (hatched bar) based diet. Mean values ± SD. Significance levels: *P<0.05, **P<0.005, ***P<0.001.

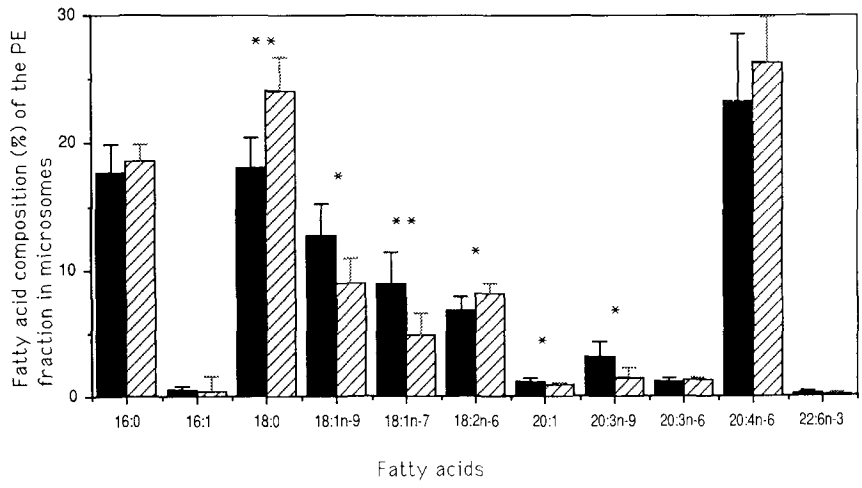

FIG. 2. Fatty acid composition of the PE fraction in hepatic microsomes from rats fed a casein- (solid bar) or a soybean protein- (hatched bar) based diet. Mean values ± SD. Significance levels: *P<0.05, **P<0.005, ***P<0.001.

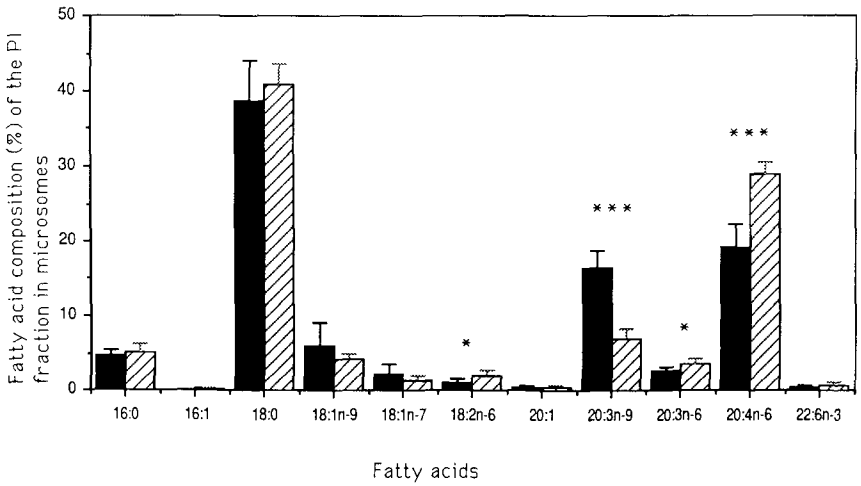

FIG. 3. Fatty acid composition of the PI fraction in hepatic microsomes from rats fed a casein- (solid bar) or a soybean protein- (hatched bar) based diet. Mean values ± SD. Significance levels: *P<0.05, **P<0.005, ***P<0.001.

TABLE 1

Effects of Diet on Δ6 Desaturase and NADPH-cytochrome C-Reductase Activities[a]

	Δ6 Desaturase activity of hepatic microsomes		
Dietary groups	Linoleic acid as substrate μmol/sec/mg protein	Oleic acid as substrate μmol/sec/mg protein	NADPH-cyt C-reductase activity μmol/sec/mg protein
Casein	4.14 ± 1.07	0.69 ± 0.24	30.6 ± 5.9
Soybean protein	2.90 ± 1.10	0.43 ± 0.15	39.4 ± 8.3
Significance level	P < 0.005	P < 0.05	P < 0.025

[a]The values represent mean values and SD of 10 rats (NADPH-cytochrome C-reductase and Δ6 desaturase with linoleic acid as substrate) or 7 rats (Δ6 desaturase with oleic acid as substrate). Three rats were not analyzed with oleic acid as substrate due to insufficient sample size.

(Fig. 1). In contrast, the levels of stearic (P<0.001), linoleic (P<0.005) and arachidonic (P<0.005) acids were reduced in the hepatic microsomal PC fraction of CAS-rats compared to SOY-rats. Thus CAS-rat hepatic microsomes contained increased levels of fatty acids of the ω9 series and decreased levels of ω6 series acids when compared to SOY-rat hepatic microsomes. The hepatic microsomal PE fraction displayed a similar pattern of differences in fatty acid composition between groups, as shown in Figure 2. The differences between CAS- and SOY-rats are similar to the patterns previously observed in whole livers (7).

Liver cells can produce oleic acid and a precursor of vaccenic acid by Δ9 desaturation of stearic and palmitic acid, respectively. Therefore, variations in fatty acid patterns observed between CAS-rats and SOY-rats could in part be explained by differences in Δ9 desaturase activity between groups. However, since the level of 20:3ω9 in the CAS-rat hepatic microsomal phospholipids was more than twice that in the SOY-rat microsomes, the fatty acid patterns show a difference in Δ6 desaturation of oleic acid as well.

In the present study, the PI fraction was also collected and analyzed, in addition to PC and PE, because in our previous work (7) the fatty acid patterns of the hepatic PI fractions were shown to differ significantly between rats fed casein and soybean protein diets. In CAS-rats, the level of 20:3ω9 in the PI fraction was more than twice as high as in the corresponding fraction of the SOY-rats (137% increase), while the level of arachidonic acid was reduced by 34% (Fig. 3). The results imply that casein feeding causes increased Δ6 desaturation of oleic acid, possibly due to reduced availability of linoleic acid (see below).

Δ6 Desaturase activity. As shown in Table 1, there was a significant difference in microsomal Δ6 desaturase activity between the two groups when either linoleic acid (P<0.005) or oleic acid (P<0.05) was used as substrate. With both substrates, the CAS-rats showed a higher activity than was observed in SOY-rats (43% higher with linoleic acid as substrate, 60% higher with oleic acid). In contrast, the activity of the microsomal NADPH-cytochrome C-reductase was on the average 29% higher in SOY-rats than in CAS-rats (P<0.025) which strengthens the significance of the difference in Δ6 desaturase activity between the two groups.

Provided the dietary supply of linoleic acid is limited, an increase in Δ6 desaturase activity could produce the changes in hepatic microsomal fatty acid pattern observed in the CAS-rats as compared to the SOY-rats by causing a depletion of the preferred substrate linoleic acid. In both experimental diets the linoleic acid content was approximately 2 energy percent (7). The recommended minimum level in rat diet is 1.3 energy percent (13). Although no visible signs of essential fatty acid deficiency became apparent in rats fed corresponding diets for 9 mon (Eklund, Anders, Sjöblom, Linnéa, and Lindholm, Marie,

unpublished observations), the present level of dietary linoleic acid may be insufficient provided that an increased metabolic need arises by increased Δ6 desaturase activity.

Thus, if a casein diet causes increased release and metabolism of arachidonic acid, this may accelerate the desaturation of linoleate to an extent that the hepatic linoleic acid pool becomes depleted. If so, the Δ6 desaturase system will use the normally less preferred substrate oleic acid and the level of 20:3ω9 will rise, as seen in the hepatic microsomes of the CAS-rats.

The mechanism behind the variable Δ6 desaturase activity is unknown. However, one possibility would be that the inability of CAS-rat hepatic microsomes to replace the metabolized arachidonic acid by Δ6 desaturation of linoleic acid, when the supply of the latter is inadequate, may cause a secondary increase in Δ6 desaturase activity.

Triacylglycerol Synthesis in the Oleaginous Yeast *Candida curvata* D

Jane E. Holdsworth[1] and **Colin Ratledge***
Department of Applied Biology, University of Hull, Hull HU6 7RX, United Kingdom

Low rates of triacylglycerol (TAG) biosynthesis were observed in cell-free extracts of *Candida curvata*, but rates were increased up to 10-fold by adding either α- or β-cyclodextrins. Spheroplasts, whole or gently disrupted, had higher rates of incorporation of both [*U*-^{14}C]glycerol 3-phosphate or [1-^{14}C]oleate into triacylglycerol and the intermediates of its biosynthesis: lysophosphatic acid, phosphatidic acid and diacylglycerol. Fatty acyl-CoA synthetase was highest with palmitate, oleate and linoleate but was some 6- to 8-fold lower with stearate. Stearate and stearoyl-CoA were poorly incorporated into lipids. Subcellular fractionation of the spheroplasts into mitochondrial, microsomal, lipid bodies and supernatant fractions diminished the rates of ^{14}C incorporation of oleate into triacylglycerol. By comparing the relative specific activities for each activity in each fraction, the fatty acyl-CoA synthetase activity appeared mainly in the lipid bodies, and that for phosphatidic acid formation was mainly in the mitochondrion; other activities were too weak and too dispersed for accurate assessment of their location. Recombining all the subcellular fractions restored triacylglycerol synthesizing activity. Omitting any single fraction from the mixture did not result in restoration of triacylglycerol synthesizing activity. Starvation of the yeast, which leads to utilization of the endogenous lipid reserves, stimulated fatty acyl-CoA synthetase activity, but diminished phosphatidic acid and triacylglycerol biosynthesis indicating probable induction of β-oxidation in the peroxisomes and repression of lipid biosynthesis.
Lipids 26, **111-118 (1991).**

The biosynthesis of lipids in oleaginous yeasts, species possessing adenosine triphosphate (ATP):citrate lyase activity and producing more than 25% of biomass as lipids, has been studied extensively in our laboratories (1,2). Previous work concentrated on the events surrounding the hyperproduction of acetyl-CoA in these organisms. The events involving the conversion of fatty acyl-CoA esters into triacylglycerol have only been studied in the non-oleaginous yeasts *Saccharomyces cerevisiae* and *Candida tropicalis* (3,4). The pathways in non-oleaginous yeasts are broadly similar to those in plant and mammalian systems where the steps involved are well-established and the endoplasmic reticulum is considered the site for triacylglycerol synthesis. The pathway to triacylglycerol formation may be summarized as follows:

glycerol 3-phosphate + RCO-CoA → lysophosphatidic acid [1]

lysophosphatidic acid + RCO-CoA → phosphatidic acid [2]

phosphatidic acid → diacylglycerol + P_i [3]

diacylglycerol + RCO-CoA → triacylglycerol [4]

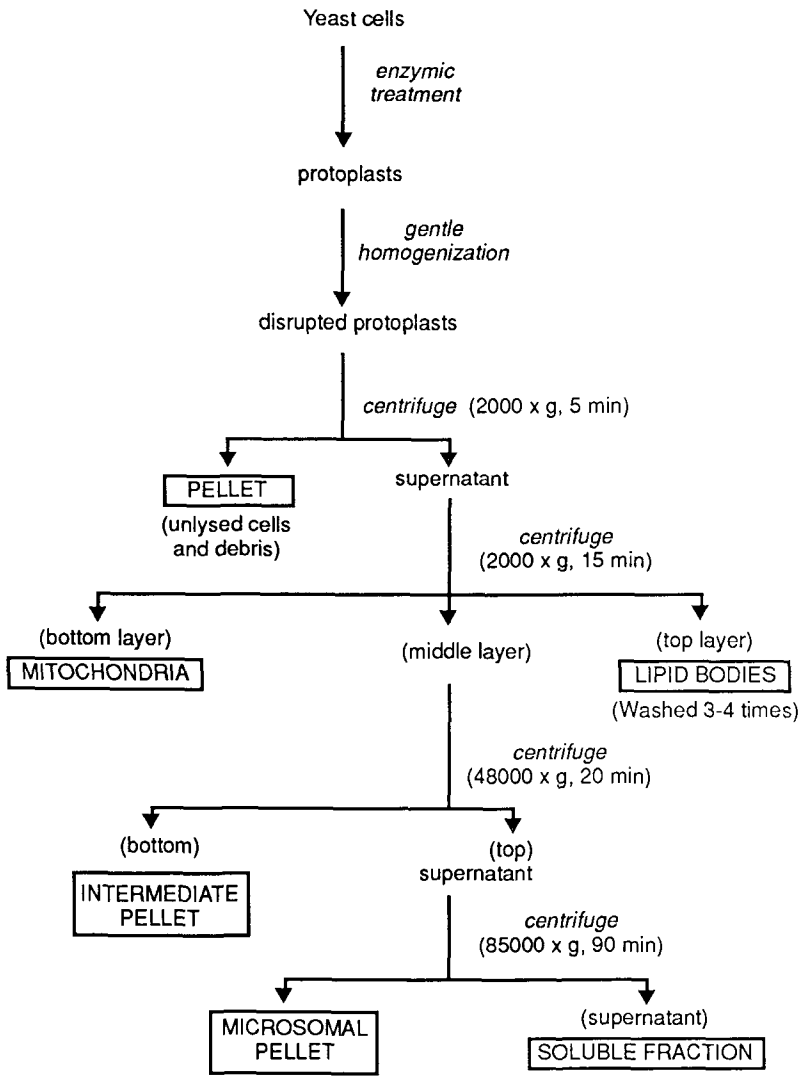
Using *S. cerevisiae,* Christiansen (5) reported that so-called "lipid particles" were associated with triacylglycerol-synthesizing enzymes in this yeast. Lipid particles are described as containing a mixture of triacylglycerols (45 to 50%) and may correspond to the larger, and more extensive, lipid droplets found as lipid storage bodies in oleaginous yeasts (6). The purpose of this study was to establish the pathway for triacylglycerol biosynthesis in *Candida curvata* and to identify the site of its synthesis.

MATERIALS AND METHODS

Media and growth of yeast. Candida curvata D (*Apiotrichum curvatum* ATCC 20599) was grown in batch culture at 30°C in 1-L, vortex-aerated bottles (7) containing 700 mL of nitrogen-limiting medium containing (g/L): glucose, 10; NH_4Cl, 0.5; KH_2PO_4, 7.0; Na_2HPO_4, 2.0; $MgSO_4 \cdot 7H_2O$, 1.5; yeast extract, 1.5; $CaCl_2 \cdot 2H_2O$, 0.1; $FeCl_3 \cdot 6H_2O$, 0.008; $ZnSO_4 \cdot 7H_2O$, 0.001; $CuSO_4 \cdot 5H_2O$, 0.0001; $Ca(NO_2)_2 \cdot 6H_2O$, 0.0001; $MnSO_4 \cdot 5H_2O$, 0.0005 with the pH adjusted to 5.5. Media were sterilized *in situ* by autoclaving at 121°C for 15 min.

Preparation of spheroplasts. Exponential phase cultures were harvested by centrifuging at 5000 × *g* for 10 min at 4°C. The cells were washed twice in citrate/phosphate buffer (0.01 M), pH 5.85, containing 0.6 M KCl and 5 mM dithiothreitol, resuspended in 20 mM MES buffer, pH 6.0, containing 2 M sorbitol and 2 mg Novozym 234 (Novo Industri, Bagsvaerd, Denmark) per mL, to give about 80 mg wet wt cells per mL. The cells were then incubated at 30°C for 45 min and spheroplast formation was followed by phase-contrast light microscopy. After complete conversion of whole cells to spheroplasts, the Novozym was removed by two washes of 20 mM MES buffer, pH 6.0, containing 2 M sorbitol.

Lysis of spheroplasts. Spheroplasts were lysed by diluting the sorbitol concentration of the suspending medium from 2 M to 0.25 M. The resultant suspension was centrifuged (2000 × *g* for 5 min) to remove whole cells and debris and the supernatant was used in the enzyme assays.



Subcellular fractionation of yeast cells (see Scheme 1). Complete rupture of the spheroplasts was accomplished using a Potter glass homogenizer. The resultant suspensions were centrifuged at 2000 × *g* for 5 min to remove any whole unlysed cells and debris. The supernatant was fractionated by centrifuging at 20,000 × *g* for 15 min to yield a crude mitochondrial pellet and a crude lipid fraction as top layer. The intermediate (middle) layer was centrifuged further at 48,000 × *g* for 20 min giving a pellet (termed the intermediate pellet) and a turbid supernatant which was re-centrifuged at 85,000 × *g* for 90 min to yield a microsomal pellet and a clear supernatant.

Purification of lipid globules. Lipid bodies or globules were purified by removing them from the top layer arising

from the 20,000 × *g* centrifugation and resuspending them in 20 mM MES buffer, pH 6.0, containing 1 M sorbitol and re-centrifuging at 7000 × *g* for 5 min at 4°C. This washing procedure was repeated three or four times until the final top layer consisted only of purified oil globules.

Radiochemical assay procedure for enzymes involved in triacylglycerol biosynthesis. Assay systems were as described by Christiansen (5). All assays were performed in triplicate on two different extracts. Results shown are average values. Soluble protein was estimated by the method of Bradford (8) with bovine serum albumin as standard. In some assays whole spheroplasts were used as protein source, in others spheroplasts were lysed prior to use. Assays were also performed using subcellular fractions. The basic incubation mixture for all assays contained the following constituents: Tris/HCl, pH 7.4, 100 mM; ATP, 15 mM; $MgCl_2$, 15 mM; β-mercaptoethanol, 8 mM; and oleic acid, 0.4 mM, bound to 1mg/L defatted bovine serum albumin (fraction V, Sigma Chemical Co., St. Louis, MO). When added, glycerol 3-phosphate was at 5 mM. The reactions were carried out in a shaking water-bath at 27°C and initiated by adding the appropriate cell fractions. The total assay volume was 1 mL and reactions were carried out for 1 hr unless otherwise stated.

Assay of acyl-CoA synthetase. The conversion of 0.4 μmol [1-^{14}C]oleate (sp. act. 0.64 Ci/mol) to [1-^{14}C]oleoyl-CoA was measured in a total reaction volume of 0.25 mL basic incubation mixture. The reaction was started by the addition of protein (10 to 40 μg), carried out for 4 min and stopped by adding 1 mL Dole reagent. (propan-2-ol/n-heptane/1 M H_2SO_4, 40:10:2, v/v/v), 0.35 mL H_2O and 0.6 mL n-heptane (see ref. 5). The specific activity of the enzyme was determined with two different concentrations of protein. The extraction and scintillation counting of the product, acyl-CoA, was carried out as described by Lloyd-Davies and Brindley (9). The tube contents were mixed and separated and the heptane layer removed. The lower phase was washed 3 times with 0.6 mL portions of n-heptane. The radioactivity, in a 0.5 mL sample of the lower phase, was measured by scintillation counting after

adding 0.1 mL H_2O and 5 mL Triton X100/xylene (1:2, v/v) containing 2,5-diphenyloxazole (5.5 g/L), and 1,4-*bis*(5-phenyloxazol-2-benzene) (0.1 g/L).

sn-*Glycerol 3-phosphate acylation assay.* The biosynthesis of triacylglycerol was determined by measuring the rate of incorporation of *sn*-[2-^{3}H]glycerol 3-phosphate (sp. act. 0.1 Ci/mol) or [*U*-^{14}C]glycerol 3-phosphate (sp. act. 0.2 Ci/mol) into lipids in a total reaction volume of 1 mL. The reaction was started by the addition of 0.1 to 0.3 mg protein and carried out for 60 min. The reaction was terminated by the addition of 1.5 mL n-butanol followed by 2 mL H_2O. After shaking, the mixture was centrifuged and the butanol phase pipetted off and washed once with 3 mL water saturated with butanol to remove unreacted glycerophosphate. The butanol extract was removed and the solvent evaporated under reduced pressure. The residual lipid was dissolved in a known amount of chloroform, samples of which were taken for counting total radioactivity and for chromatography. Neutral lipids were analyzed by thin-layer chromatography on silica gel plates (Silica Gel G, 250-μm) using petroleum hydrocarbon (b.p. 60–80°C)/diethyl ether/acetic acid (60:40:1, v/v/v). In this system triacylglycerol, free fatty acids, diacylglycerol and monoacylglycerols are separated from phospholipid and acyl-CoA esters which remain at the origin. Phospholipids were separated from the neutral acyl-CoA using chloroform/methanol/acetic acid/water (80:15:2:2, by vol). Lipid classes were detected by exposure to iodine vapor and their R_F values compared with those of standards (Sigma). After the iodine had evaporated, the spots were scraped from the plates and the radioactivity determined by counting in 7.5 mL of a scintillation mixture containing 0.3 g 1,4-*bis*(5-phenyloxazol-2-yl benzene), 7.0 g 2,5-diphenyloxazole, 100 g naphthalene, 200 mL of water and 1 L dioxan.

Oleate esterification with added glycerol 3-phosphate as acyl acceptor. Oleate esterification was measured by incubating 0.4 μmol [1-^{14}C]oleic acid (sp. act. 0.64 Ci/mol) with 5 μmol glycerol 3-phosphate in a total reaction volume of 1 mL of basic incubation mixture. The reaction was stopped by adding 20 mL chloroform/methanol (2:1, v/v). After standing for 15 min, precipitated protein was removed by filtering the extract through Whatman No. 1 filter paper. The test tube and the filter were rinsed with 15 mL chloroform/methanol (2:1, v/v), followed by 15 mL chloroform/methanol (1:2, v/v). The combined extracts (50 mL) were evaporated in a rotary evaporator. The residue was extracted with 0.5 mL chloroform and the insoluble remainder dissolved in 1 mL chloroform/methanol/water, (4:10:2, v/v/v). For determination of total radioactivity, equal volume percentages of the two solutions were placed in the same vial, the solvent removed under a stream of nitrogen and then counted as for the glycerol 3-phosphate studies. Lipids in the two solutions were separated by thin-layer chromatography by applying aliquots representing equal-volume percentages as a single spot to the chromatogram which was developed and counted as in the glycerol 3-phosphate studies.

Oleate esterification with endogenous acyl acceptor. [1-^{14}C]Oleate was incubated under exactly the same conditions as stated above, except that glycerol 3-phosphate was not added. The extraction of the incubation mixture and the radioactivity assay were also as above.

RESULTS

Lipid synthesizing activities in cell-free extracts and spheroplasts. Initial experiments for assaying oleoyl-CoA synthetase and for following incorporation of [1-^{14}C]-oleate into intermediates of triacylglycerol biosynthesis using various acceptor molecules used unfractionated cell-free extracts (Table 1). Activities were lower than could account for the calculated rate of lipid synthesis in growing cells (see ref. 10). Addition of pre-formed lipids (di- and triacylglycerols), protease inhibitors or alternative acyl acceptors to glycerol 3-phosphate all failed to increase these activities. Some stimulation of oleate esterification activity, particularly of the formation of oleoyl-CoA and of phosphatidic acid, occurred in the presence of α- and β-cyclodextrins which are thought to increase the hydrophilicity of the substrate (Table 1). Cyclodextrins were, however, not included in subsequent experiments. Similar rates of incorporation of oleate into lipids occurred at both pH 6.0 and 8.0 (results not shown); subsequent experiments always were done at pH 7.4.

When assays were carried out using whole spheroplast preparations as protein source, considerable stimulation (increases between 5- and 10-fold) occurred for all activities being measured (Table 1). As such preparations of spheroplasts would have been lysed in the assay mixtures due to osmotic shock, the observed enzyme activities did not depend upon the spheroplasts remaining intact. Spheroplasts deliberately lysed before assay showed similar activities to preparations not lysed before commencement of the assay (Fig. 1). Spheroplast preparations also showed substantially improved ability to catalyze the acylation of *sn*-[*U*-^{14}C]glycerol 3-phosphate compared to cell-free extracts (Table 1).

The rates of biosynthesis of the various lipid components with [1-^{14}C]oleate as substrate (Fig. 1) showed that formation of oleoyl-CoA and of phosphatidic acid was most rapid and would not limit the incorporation of ^{14}C into intermediates later in the pathway. Formation of both di- and triacylglycerols was essentially linear over the 45-min incubation period. A small but apparently constant amount of label was incorporated into lysophosphatidic acid. A comparison of the data given in Table 1 and Figure 1 indicates, within the limits of experimental

error, that the ratio of incorporation of [1-^{14}C]oleate and [*U*-^{14}C]glycerol 3-phosphate into the various lipids is stoichiometrically compatible. Similar rates of biosynthesis occurred at 25°C; subsequent assays always were at 27°C.

Although no significant difference was seen between the triacylglycerol (TAG) synthesizing activities in spheroplasts and lysed spheroplasts, low-speed centrifuging (2000 × *g* for 5 min) of the lysed protoplasts led to substantial loss of activity in the supernatant, but recombining the pellet and supernatant restored activity.

It thus appeared that intact spheroplasts were not essential to achieve biosynthesis, but subsequent work showed that mechanical disruption of the spheroplasts using a Potter homogenizer was very critical if active cell-free extracts were to be obtained. Disruption of spheroplasts in a Potter homogenizer with 20 strokes of the rotor led to virtually complete loss of di- and triacylglycerol synthesizing ability in the supernatant following low-speed centrifugation. Ten strokes of the Potter rotor disrupted the spheroplasts without loss of enzyme activity which remained in the supernatant. Thus lipid-synthesizing activity could be obtained in a cell-free extract devoid of any residual whole cells, spheroplasts or large organelles (*e.g.*, nuclei).

Such preparations of lysed spheroplasts readily formed fatty acyl-CoA esters with [1-^{14}C]-labelled linoleic, palmitic and oleic acids but less readily with stearic acid (Table 2). Incorporation of the former three fatty acids into triacylglycerol and intermediates was also rapid and that of stearic acid also slow (Table 2). When stearoyl-CoA and [*U*-^{14}C]glycerol 3-phosphate were used to follow lipid biosynthesis (instead of labelled stearate and unlabelled glycerol 3-phosphate), there was no significant increase in activity and, indeed, no incorporation into triacylglycerol could be detected.

Lipid synthesis in subcellular fractions. Subcellular fractionation of the spheroplasts from *C. curvata* was carried out as detailed in Materials and Methods (see Scheme 1). Each fraction was used immediately in assays for fatty acyl-CoA synthetase and for the enzymes of triacylglycerol biosynthesis. The latter were assayed by following the incorporation of either [1-^{14}C]oleate (oleate esterification) or [*U*-^{14}C]glycerol 3-phosphate (glycerol 3-phosphate acylation) into the intermediates of the phosphatidic acid pathway. The results are shown in Table 3. The highest rates of incorporation of ^{14}C into acyl-CoA and phosphatidic acid pathway intermediates were in the pellet fraction which would have contained whole spheroplasts and whole cells. However, the highest activity of fatty acyl-CoA synthetase was found in the lipid bodies but, judging from the relative specific activity values which indicate if an enzyme has become located in particular fraction by relating its activity to how much protein is recovered in that fraction, no obvious location could be identified for the remaining enzymes of the triacylglycerol pathway. Two marker enzymes were assayed simultaneously: citrate synthase, as a mitochondrial enzyme, was recovered at a very high relative specific activity in this fraction though reduced nicotinamide adenine dinucleotide phosphate (NADPH)-cytochrome *c* reductase, as a microsomal enzyme, was recovered slightly preferentially in this fraction but it also occurred in the final soluble fraction. NADPH-cytochrome *c* reductase has been previously used as a marker for the microsomal fraction of baker's yeast (11). The nonexclusive location of the enzyme within *C. curvata* is in keeping with results found for other yeasts (12,13). Thus it appears that triacylglycerol biosynthesis only occurs maximally in extracts containing all cell components. Recombining all six fractions in their original proportions (by protein content) after fractionation restored the

activity to the order seen with whole spheroplasts. Combining two or more of the fractions did not enhance the rate. Therefore it was concluded that all fractions were necessary for triacylglycerol biosynthesis to occur.

Assay for the enzyme of triacylglycerol biosynthesis in spheroplast preparations from C. curvata *grown under carbon starvation conditions. Candida curvata* was starved in a glucose-less medium (14) for 24 hr following growth on nitrogen-limited media prior to preparation of spheroplasts. Assays were carried out using the entire spheroplasts with and without added glycerol 3-phosphate as acyl acceptor and using [1-^{14}C]oleic acid esterification as a measure of activity. The results are shown in Table 4. The activity of fatty acid acyl-CoA synthetase was much higher in these starved spheroplasts than it had been in those undergoing accumulation. However, as expected, rates of incorporation of label into the intermediates of triacylglycerol biosynthesis were now much slower than those observed in preparations grown under nitrogen-limitation and hence accumulating lipid.

DISCUSSION

Previous studies on the location of the enzymes involved in lipid biosynthesis in yeasts have used almost exclusively *Saccharomyces cerevisiae* and have concentrated primarily upon the enzymes of phospholipid biosynthesis. These enzymes are associated with the membranes of the mitochondria and microsomes (15). Enzymes for triacylglycerol synthesis (see Introduction), of which the first two are the same as those involved with phospholipid biosynthesis, also seem to be membrane associated (16,17) though Christiansen's work (5,18) indicated the site of triacylglycerol biosynthesis to be the "lipid particles" of baker's yeast.

Saccharomyces cerevisiae is not a particularly good yeast for synthesizing triacylglycerols as these lipids usually do not constitute more than 5 or 6% of the cell's biomass (12) and only account for 50% of the lipids within the "lipid particles" (5). Oleaginous yeasts, such as *C. curvata* as used here, would seem more useful as they can readily accumulate over 50% of the entire biomass as triacylglycerol. In spite of the conceptual advantage of using an oleaginous yeast to study triacylglycerol biosynthesis, it has proved very difficult to elucidate the exact sites of synthesis principally because of the inherent instability of the enzyme systems.

Using whole spheroplasts, incorporation of both ^{14}C-labelled oleoyl-CoA and glycerol 3-phosphate into triacylglycerol and intermediates was achieved. The maximum rate of incorporation was about 100 to 110 nmol oleate/hr per mg protein. Previous work (10) indicated that a rate of about 250 nmol oleate should be incorporated per hr and mg protein to account for the observed rate of lipid biosynthesis in growing cells. Although the observed rate was less than it should have been it was considerably higher than previously reported by Christiansen (18) and is comparable to the rates reported for phospholipid biosynthesis in *S. cerevisiae* (15,19).

A linear rate of incorporation of label into diacylglycerol and triacylglycerol was observed over 30 min (Fig. 1). Incorporation of label into acyl-CoA and other intermediates of the pathway was not linear over this time but did not limit flow of carbon through the pathway. This finding was consistent with phosphatidic acid phosphatase being the rate-limiting step of lipid biosynthesis found in *S. cerevisiae* by Hosaka and Yamashita (16,17).

Assays using whole spheroplasts gave similar results to those using lysed spheroplasts but considerable activity was lost upon slow speed centrifugation (2000 × *g* for 5 min) of the lysed spheroplasts indicating that a subcellular component, necessary for biosynthetic activity, was being removed. Gentle homogenization (10 strokes of a homogenizer) could, however, be used to prepare

extracts from the spheroplasts which still retained triacylglycerol biosynthesizing activity. However great care had to be taken when using this technique as further homogenization (*e.g.*, 20 strokes) led to partial loss of activity. A possible explanation for this is that the lesser number of strokes led to gentle separation of the subcellular components and that the greater number led to actual disruption or dislocation of one or more subcellular components. Such a component, which may not be a protein, might be involved in the presentation of the substrate, oleoyl-CoA, to the appropriate enzyme. This speculation is supported by observing that triacylglycerol biosynthesis could be stimulated by adding α- and β-cyclodextrins to crude cell-free extracts. These molecules cyclohexa- and cyclohepta-amylose can bind lipids below their critical micelle concentration ($\sim$3 μM for oleoyl-CoA) and probably provide a more conducive (*i.e.*, hydrophilic) environment for the substrate to approach the enzyme's active site. By using whole or gently broken spheroplasts for triacylglycerol biosynthesis, the dependency upon cyclodextrins disappeared possibly indicating that correct orientation of the substrate was now being achieved *in situ*.

Subcellular fractionation of *C. curvata* resulted in six fractions including the first pellet. Mitochondrial and microsomal fractions were characterized by specific activities of marker enzymes. The highest relative specific activity of fatty acyl-CoA synthetase was in the pellet and lipid body fractions. That the lipid bodies could contain such activity possibly corresponds with the previous reports of Christiansen (5,18) for the location of triacylglycerol biosynthesis being in the "lipid particles" of baker's yeast. The final step(s) of triacylglycerol biosynthesis in the present yeast did not appear to be similarly located even though the lipid bodies of *C. curvata* would be composed primarily of triacylglycerol. However so much activity was lost during the preparation of the subcellular fractions, apart from the pellet which retained activity probably because of the presence of whole spheroplasts and unbroken cells, that it is not possible to ascribe with any certainty the possible location of the other enzymes for triacylglycerol biosynthesis. Nevertheless incorporation of both glycerol 3-phosphate and oleate into phosphatidic acid (*i.e.*, as a common precursor of both phospholipids and triacylglycerols) appeared to occur in the mitochondrial fraction with some activity being recovered in the intermediate fraction (for oleate incorporation) and microsomal fraction (for glycerol 3-phosphate incorporation). Such results would then be in agreement with the previous conclusions of Kuchler *et al.* (15).

Similar activities of fatty acyl-CoA synthetase(s) were observed with linoleic (18:2), oleic (18:1) and palmitic (16:0) acids in *C. curvata* though activity with stearic acid (18:0) was very low. (Such a difference was not seen when the specificity of the fatty acyl-CoA synthetase from another oleaginous yeast, *Lipomyces starkeyi* CBS 1809, was examined; ref. 20.) Rates of incorporation of linoleate, oleate and stearate into lipid intermediates using [*U*-^{14}C]-glycerol 3-phosphate were similar, but again little incorporation was seen using stearic acid. Although this was not surprising due to the low activities of stearoyl-CoA synthetase, very little improvement occurred when stearoyl-CoA itself was used as substrate. The reason for this is not clear as *C. curvata* has probably the highest content of stearic acid in its triacylglycerols of any yeast (1,21).

The most detailed knowledge of the long-chain fatty acyl-CoA synthetase of yeasts comes from work on *Yarrowia (Candida) lipolytica* (see ref. 22 for a review). These studies have indicated the presence of two long-chain fatty acyl-CoA synthetases, I and II. Synthetase I was present in cells grown on glucose and oleate, and was distributed between mitochondrial and microsomal fractions being responsible for the production of acyl-CoA in the synthesis of cellular lipids. Its activity toward stearic acid was half of that observed for palmitic, oleic or linoleic acids. Synthetase II, immunologically distinct from synthetase I, was induced by growing the yeast on oleic acid, and was located in peroxisomes, its main function being to produce acyl-CoA prior to degradation *via* β-oxidation. In the present study, the specific activity of fatty acyl-CoA synthetase for oleic acid increased 40-fold when *C. curvata* was starved, and thus was induced to consume its own intracellular storage lipid (6,14). This increase in activity then corresponds to the induction of synthetase II in the peroxisomes of *Y. lipolytica* as starvation of an oleaginous yeast also induces formation of peroxisomes (6). This, however, remains to be examined on some future occasion.

Simultaneously with this increase in fatty acyl-CoA synthetase activity in starved yeasts, enzymes for phospholipid and triacylglycerol biosynthesis were almost completely absent. This would again be in keeping with our previous observation that utilization of endogenous (or exogenous) lipid quickly leads to cessation of lipid biosynthesis (14). Thus the entire pathway of lipid biosynthesis, from citrate translocation across the mitochondrial membrane and cleavage of citrate by ATP:citrate lyase (see ref. 2) to the final steps of lipid synthesis, could be under strong regulatory control in oleaginous yeasts.

ACKNOWLEDGMENT

We are grateful to Cadbury-Schweppes plc for their support and cooperation of this research through an SERC-CASE award to JEH.

The Comparative Effects of Dietary α-Linolenic Acid and Fish Oil on 4- and 5-Series Leukotriene Formation *in Vivo*[1]

J. Whelan*, K.S. Broughton[2] and J.E. Kinsella[3]
Lipids Research Laboratory, Institute of Food Science, Cornell University, Ithaca, New York 14853

The comparative effects of dietary α-linolenic acid and fish oil on eicosanoid metabolism was studied *in vivo*. Resident murine peritoneal cells were stimulated *in vivo* with opsonized zymosan in animals maintained on diets containing increasing amounts of α-linolenic acid or fish oil concentrate with projected n-3/n-6 ratios of 0.2, 0.4 and 1.0. While fish oil feeding resulted in significant changes in eicosapentaenoate tissue levels, α-linolenic acid was preferentially metabolized to docosahexaenoate. High performance liquid chromatographic analysis revealed the formation of leukotriene E_5 (LTE_5) in all the fish oil groups (19.8 ± 3.5 ng/mouse to 83.3 ± 13 ng/mouse), but only in the highest linolenic acid group (6.0 ± 3.2 ng/mouse). Concomitantly, the 4-series sulfidopeptide leukotrienes and PGI_2 were significantly reduced in the two highest fish oil containing dietary groups. Similar reductions were observed in the highest linolenic acid group, but the changes were not statistically different from the control values. In summary, this paper reports the *de novo* synthesis of 5-series sulfidopeptide leukotrienes in animals consuming α-linolenic acid. It also reveals that dietary fish oil is 2.5 to 5 times more effective than α-linolenic acid in modulating eicosanoid metabolism and altering tissue phospholipid fatty acid composition.
***Lipids* 26, 119-126 (1991).**

The physiological significance of dietary polyunsaturated fatty acids (PUFA) in relation to lipid and eicosanoid metabolism is being elucidated (1-3). The role of n-3 PUFA, particularly those of marine origin, generate interest because they appear to possess distinct biological effects separate from the n-6 analogues. For example, n-6 unsaturated fatty acids of vegetable origin are effective in decreasing plasma cholesterol, while n-3 PUFA from fish oils can significantly depress plasma triglyceride levels (1,4). Additionally, n-3 long-chain PUFA have been shown to be involved in decreasing the pathology of diet-induced vascular lesions, parameters associated with carcinogenesis and modulate inflammatory indices (5-8). It has been postulated that while dietary n-6 unsaturated fatty acids are essential and beneficial, elevated intakes may contribute to pathologies associated with a number of chronic diseases, and it has been suggested that long-chain n-3 PUFA, *viz.*, eicosapentaenoic acid (20:5n-3), may ameliorate some of these effects by influencing eicosanoid metabolism (8,9).

While 20:5n-3 is exclusively derived from marine sources, α-linolenic acid (α-LNA, 18:3n-3), a precursor of 20:5n-3 and docosahexaenoic acid (22:6n-3), can be obtained from commonly consumed vegetable oils, such as soybean and canola oils. Dietary α-LNA can inhibit eicosanoid metabolism (10-13). Additionally *in vitro* studies have demonstrated that 20:5n-3 derived lipoxygenase and cycloxygenase products can be formed from α-LNA. Hwang *et al.* (14) observed 5-HEPE and 12-HEPE formation from lung homogenates, and TXB_3 and 12-HEPE from stimulated platelet preparations; however, these products were not quantified. Similarly, LTB_5 formation has been observed following stimulation of isolated leukocytes from rats maintained on a high α-LNA based diet (13).

These previous studies evaluated eicosanoid metabolism utilizing *in vitro* conditions. The present study investigates the effects of dietary α-LNA on eicosanoid synthesis *in vivo*, emphasizing sulfidopeptide leukotriene (SP-LT) formation. SP-LT are collectively known as the slow reacting substances of anaphylaxis and are involved in inflammatory response (15-18). At sites of inflammation, leukocytes such as neutrophils, lymphocytes and macrophages can produce significant quantitites of SP-LT upon stimulation. SP-LT have potent ionotropic properties, can increase postcapillary venule permeability, are potent stimulators of airway smooth muscle cells, and are mediators of pulmonary asthmas (19-22). Therefore, if long-chain n-3 PUFA possess beneficial properties, evaluating the effects of dietary α-LNA on tissue lipid composition and SP-LT formation *in vivo* is of great importance.

MATERIALS AND METHODS

Experimental design. Eighty-four CD-1 male mice (20 g) were randomly divided into seven dietary groups, 12 animals per group (each group contained two control animals) (Table 1). The control diet (group 1) contained 18:2n-6 as the sole dietary source of polyunsaturated fatty acids (PUFA). In addition to 18:2n-6, the experimental diets contained graded amounts of either α-LNA in the form of trilinolenin (NuChek Prep, Elysian, MN) or a fish oil concentrate as the sources of n-3 PUFA.

Diets. The mice were maintained on Prolab chow diet (Agway, RMF1000, Syracuse, NY) for 1 week, followed by a fat free diet (ICN Biochemicals, Clevelad, OH) for one week, at which time they were placed on their respective experimental or control diets for two weeks.

All diets (experimental and control) contained 10 wt% fat. The linoleic acid (18:2n-6) content of all the diets, as supplied by safflower oil (75%, 18:2n-6) was maintained at 1.5 wt%. The filler oils consisted of equal amounts of a high oleic safflower oil (73%, 18:1n-9) (SVO, Eastlake, OH) and tripalmitin (99%, 16:0) (Sigma, St. Louis, MO). Fish oil concentrate (NSK, Ltd., Japan) contained 20:5n-3 (27%), and docosahexaenoic acid (22:6n-3, 12%) as the major long-chain n-3 PUFA, with 18:2n-6 and 18:3n-3 comprising less than 1% of the total.

[a]g/kg Diet. [b]Less than 1 g/kg diet.

The purified trilinolenin contained 97% α-LNA. The experimental diets were designed to provide incremental levels of n-3 PUFA to generate n-3/n-6 ratios of 0.2, 0.4 and 1.0. The fatty acid composition of the diets are presented in Table 2.

The diets were prepared in bulk and prepackaged in separate Whirl-Pak bags (Nasco, Fort Atkinson, WI) and stored under nitrogen at 4°C. Water and food were provided *ad libitum* for two weeks. To minimize exposure to air prior to consumption, fresh diets were provided daily, with uneaten food being discarded. Gas chromatographic analysis demonstrated that storage of the diets did not alter their fatty acid composition.

In vivo generation and isolation of eicosanoids. Following two weeks on the control and experimental diets, opsonized zymosan (1 mg in 0.5 mL saline) was injected intraperitoneally to induce an inflammatory response (23–25). After 30 min, the animals were sacrificed by ether inhalation and the peritoneal cavity was washed with 3 mL saline (0.9%) containing 1 mM EDTA and 100 ng of prostaglandin B_1 (PGB_1) as internal standard, followed by a second wash of EDTA-saline (2 mL). The peritoneal washes were pooled and centrifuged (700 × *g* for 4 min at 25°C) to pellet the cells. The supernatant was made up to a final volume of 10 mL containing 10% methanol and 1.5 mM formic acid. One mL was used for 6-keto $PGF_{1\alpha}$ analysis and the remaining 9 mL for leukotriene analyses. The pelleted cells were analyzed for phospholipid fatty acid composition.

Leukotriene analysis. The leukotrienes were isolated by solid phase extraction using a C-18 cartridge (Burdick and Jackson, Muskegon, MI), sequentially washed with distilled water, then hexane, and eluted off the cartridge with methanol. Following evaporation, the residue was reconstituted in the HPLC solvent system of methanol/water (65:35, v/v), pH 5.6, containing 5 mM ammonium acetate and 1 mM EDTA. The leukotrienes were separated by reversed phase (RP)-HPLC on a Whatman (Hillsboro, OR) Partisphere C-18 column (6 mm × 12.5 cm) with a flow rate of 0.9 mL/min and quantified

[b] Σ (18:3n-3, 20:5n-3, 22:5n-3, 22:6n-3)/Σ (20:3n-6, 20:4n-6, 22:4n-6, 22:5n-6).

based on their molar extinction coefficients (26) using the internal standard PGB_1, with a Hewlett-Packard (Liverpool, NY) 1040A Diode Array scanning spectrophotometer, monitoring at 280 nm. All compounds were identified by their distinct ultraviolet (UV) absorption spectra and retention times were compared to known standards.

Prostaglandin analysis. The prostaglandins were extracted (three times) from the aliquot of the peritoneal wash with equal volumes of ethyl acetate. The pooled extracts were evaporated to dryness under nitrogen and the prostaglandins were resuspended in phosphate buffered saline (0.9%) containing 0.1% (w/v) gelatin. Each sample was then analyzed for 6-keto-$PGF_{1\alpha}$ by radioimmunoassay (Advanced Magnetics, Cambridge, MA) according to the manufacturer's instructions. The reported antiserum crossreactivities (at 50% B/B_0) for $PGF_{1\alpha}$, 6-keto-PGE_1, and $PGF_{2\alpha}$ are 7.8%, 6.8% and 2.2%, respectively.

Fatty acid analysis. Livers were perfused with saline (0.9%), removed, and quick frozen in liquid nitrogen. For fatty acid analysis, the livers were thawed and homogenized in saline (0.9%). The liver homogenates and pelleted peritoneal cells were resuspended in equal volumes of saline (0.9%) and chloroform/methanol (1:2, v/v), and the lipids were extracted sequentially with chloroform/saline (1:1, v/v) and chloroform (×2). The pooled organic extracts were evaporated to dryness under nitrogen and redissolved in chloroform. The macrophage phospholipids were separated by TLC, using a chloroform/methanol (8:1, v/v) solvent system, and visualized with 0.01% 8-hydroxy-1,3,6-pyrene-trisulfonic acid trisodium salt (Eastman Kodak Co., Rochester, NY) in anhydrous methanol. The phospholipids were recovered from the TLC plates by scraping the appropriate bands and resuspended in toluene. They were then saponified with 0.5 N KOH in ethanol for 8 min at 86°C. Following acidification with 0.7 N HCl, the free fatty acids were extracted with equal volumes of hexane (×2), evaporated under nitrogen and methylated with ethereal diazomethane. Following evaporation, the fatty acid methyl esters were resuspended in hexane and analyzed by gas chromatography on a DB23 capillary column (0.25 mm × 30 m) (J&W Chromatography, Folsom, CA) with hydrogen as the carrier gas. The fatty acids were quantified using pentadecanoic acid as an internal standard. Fatty acid composition of the diets were determined using the same methods described above, excluding the TLC step.

Statistical analysis. The data from all diets were analyzed by randomized block design. The results were statistically evaluated by Duncan's Protected Least Significant Difference. Significance was determined at $p < .05$.

RESULTS

Tissue phospholipid fatty acids. Liver and peritoneal cell phospholipids contained equivalent amounts of 18:2n-6, respectively, with the exception of the liver phospholipids from mice consuming the fish oil concentrate, where 18:2n-6 progressively declined with increasing dietary fish oil (Tables 3 and 4). The levels of 20:4n-6 in hepatic and peritoneal cell phospholipids progressively declined in animals consuming the experimental diets compared to the animals on the control diet. The diets containing fish oil were more effective than those containing α-LNA in depressing 20:4n-6.

The 20:5n-3, 22:5n-3 and 22:6n-3 levels progressively increased in hepatic and peritoneal cell phospholipids in animals on all experimental diets (Tables 3 and 4). However, alterations of n-3 PUFA levels in the tissue

[b] Σ (18:3n-3, 20:5n-3, 22:5n-3, 22:6n-3)/Σ (20:3n-6, 20:4n-6, 22:4n-6, 22:5n-6).

phospholipids were more dramatic in animals consuming the n-3 highly unsaturated fatty acids (HUFA) in fish oil than the animals consuming the α-LNA. The lowest fish oil diet (diet 5) was as effective in increasing tissue n-3/n-6 ratios as the highest α-LNA diet (diet 4) (Fig. 1).

Leukotrienes. Mice fed diets devoid of n-3 PUFA produced only LTC_4 and LTE_4, with LTE_4 being the major SP-LT formed (Fig. 2a). There was no evidence of LTD_4 formation. Upon introduction of fish oil to the diet, and to a lesser extent, α-LNA, LTE_5 was also formed following *in vivo* stimulation of peritoneal cells with opsonized zymosan (Fig. 2b and 2c). All of the SP-LT, 4- and 5-series, exhibited characteristic triplet UV absorption spectra indicative of conjugated triene formation, with absorption maxima at 280 nm (Fig. 3). LTE_5 formation was confirmed previously (27), based on i) co-chromatography with authentic standards; ii) equivalent elution profiles with previously published values (26,28,29); and iii) characteristic UV absorption spectra. The identity of LTE_5 was further confirmed enzymatically following conversion to LTF_5 *via* transpeptidation using γ-glutamyl transpeptidase (27). Previous studies indicated that LTE_5 was the major (80%) 5-series SP-LT formed (27,30).

In contrast to n-3 HUFA of fish oil, dietary α-LNA had very little effect on leukotriene formation even at the highest levels. No significant differences in 4-series SP-LT production were observed in any of the α-LNA dietary groups when compared to animals on the control diet (Fig. 4). While 4-series SP-LT production was depressed in the highest α-LNA group (diet 4), the decline was not statistically significant ($p < .05$).

Changes in leukotriene formation were much more responsive to fish oil feeding. Animals maintained on diets 6 and 7 produced approximately 50% less tetraenyl SP-LT than animals on the control diet. Additionally, as

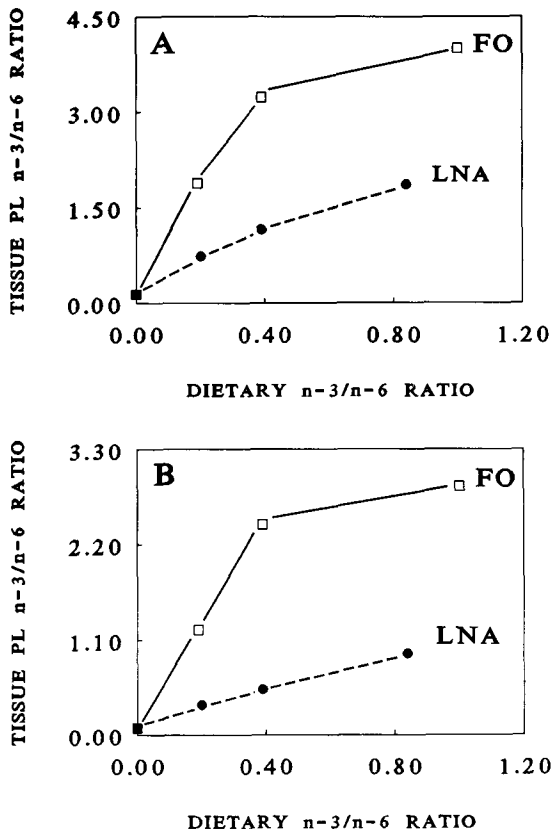

FIG. 1. Relationship between dietary n-3/n-6 ratio and the n-3/n-6 ratio of A) liver and B) peritoneal cell phospholipids. FO: fish oil (solid line); LNA: α-linolenic acid (broken line).

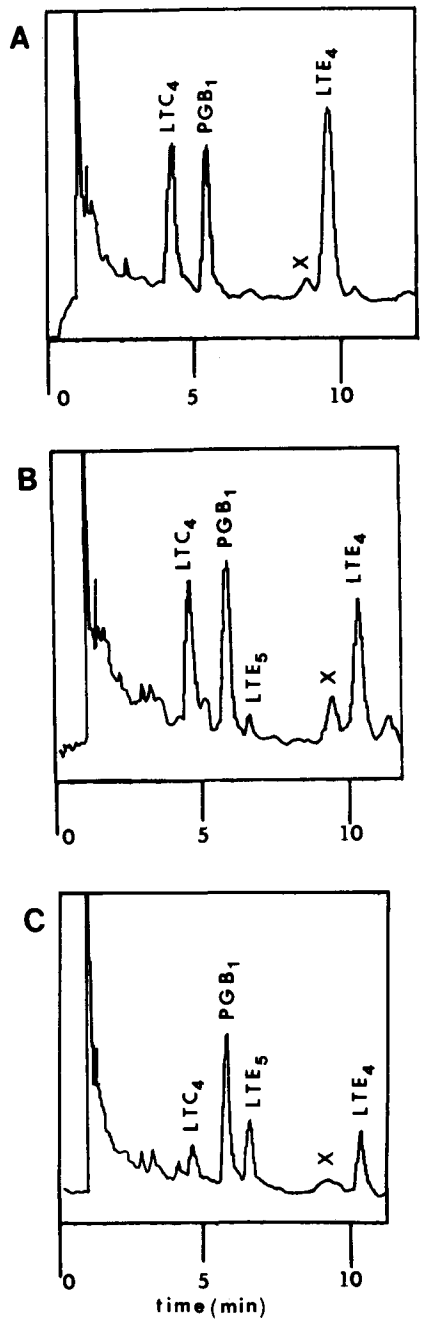

FIG. 2. RP-HPLC chromatograms of sulfidopeptide leukotrienes synthesized *in vivo* using animals maintained on diets A) devoid of n-3 PUFA (diet 1); B) containing α-linolenic acid (diet 4); or C) containing fish oil concentrate (diet 7). Conditions for RP-HPLC: Whatman partisphere C-18 column (6 mm × 12.5 cm); mobile phase, methanol/water (65:35, v/v) containing 5 mM ammonium acetate and 1 mM EDTA, adjusted to PH 5.6 with glacial acetic acid; flow rate, 0.9 mL/min.; diode array detector monitoring at 280 nm.

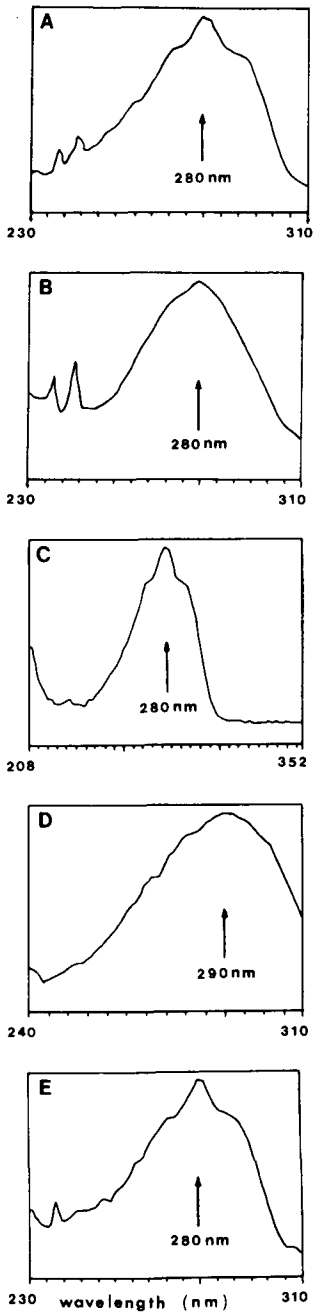

FIG. 3. UV absorption spectra of compounds isolated from mouse peritoneal exudates. The compounds were separated by RP-HPLC (see Fig. 2) and their spectra generated using a Hewlett-Packard 1040 diode array detector: A) LTC_4; B) PGB_1; C) LTE_5; D) X (unknown); and E) LTE_4.

the n-3/n-6 dietary ratio increased, SP-LT of the 5-series progressively increased in all animals consuming the fish oil diets (Fig. 5). In fact, LTE_5 production equaled LTE_4 formation in mice consuming a fish oil diet with an n-3/n-6 ratio of 1.0 (diet 7). In contrast, only the highest α-LNA dietary group (diet 4) demonstrated pentaenyl-LT formation. LTE_5 production in diet 4 was very low (6.0 ± 2.3 ng/mouse), even when compared to the LTE_5 produced (19.8 ± ng/mouse) by animals consuming the lowest fish oil diet (diet 5) with an n-3/n-6 ratio of 0.2.

Prostaglandins. The production of 6-keto-$PGF_{1\alpha}$ by the peritoneal cells significantly declined as a result of fish oil feeding (diets 6 and 7) when compared to the control group (Fig. 6), whereas diet 6 was as effective as diet 7. At the lower dietary intakes, α-LNA had no effect on 6-keto-$PGF_{1\alpha}$ production, but 6-keto-$PGF_{1\alpha}$ production declined 46% in diet 4. However, because of an outlying value (37 ng/mouse), this decrease was not significant.

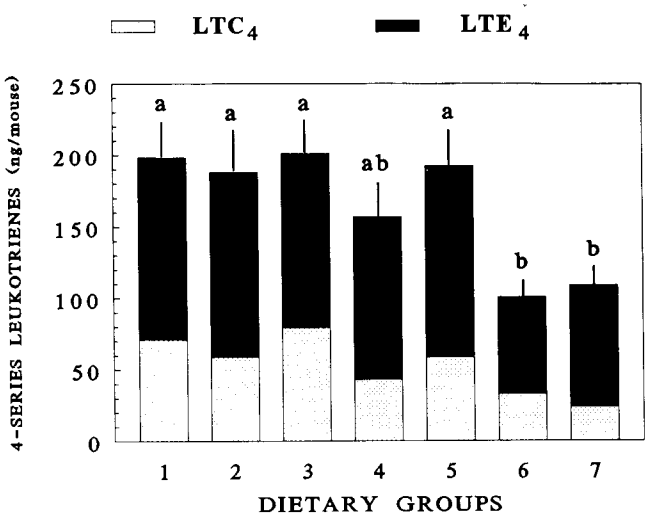

FIG. 4. Leukotriene C_4 (dotted bar) and leukotriene E_4 (solid bar) production *in vivo* by resident peritoneal cells following stimulation with opsonized zymosan from mice maintained on a diet devoid of n-3 PUFA (diet 1), progressive amounts of α-linolenic acid (diets 2–4) or fish oil (diets 5–7). Results are mean ± SEM of 10 experimental values. Bars with the same letter are not significantly different at $p < 0.05$.

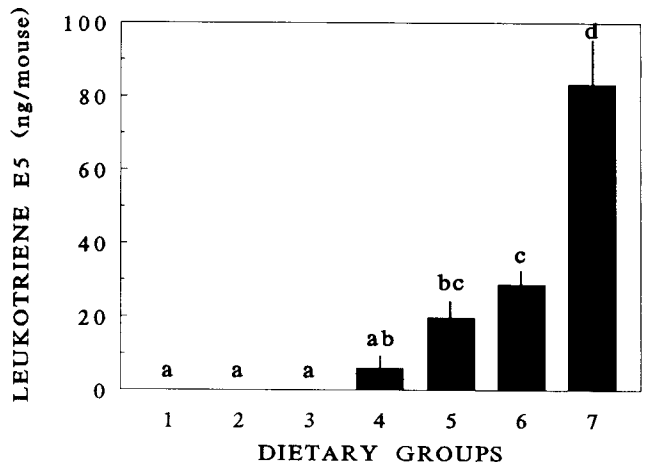

FIG. 5. Leukotriene E_5 formation *in vivo* by resident peritoneal cells following stimulation with opsonized zymosan from mice maintained on a diet devoid of n-3 PUFA (diet 1), progressive amounts of α-linolenic acid (diets 2–4) or fish oil (diets 5–7). Results are mean ± SEM of 10 experimental values. Bars with the same letter are not significantly different at $p<0.05$.

DISCUSSION

This study provides new information with regard to the relative effects of dietary n-3 PUFA, in the form of α-LNA or fish oil, on eicosanoid metabolism. Recently, we reported that LTE_5 was produced *in vivo* in peritoneal cells from mice consuming a diet containing fish oil (27). In this previous paper, LTE_5 formation *in vivo* was confirmed utilizing spectrophotometric, chromatographic and enzymologic techniques. A few studies have reported LTE_5 production *in vitro* from exogenous sources of 20:5n-3 (26,28,29), with only one report suggesting *in vivo* formation (31). However, with the exception of Örning

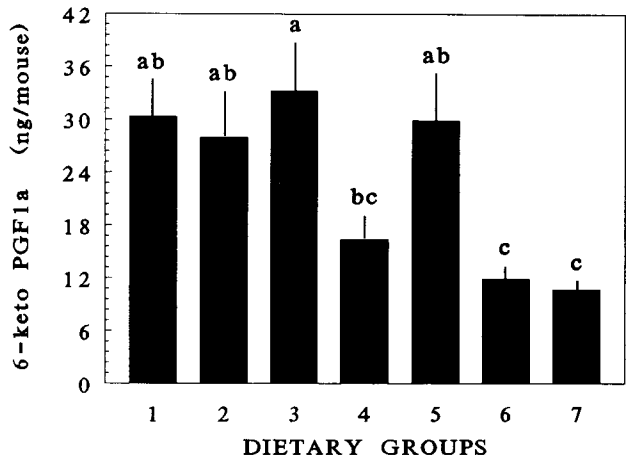

FIG. 6. 6-keto-$PGF_{1\alpha}$ formation *in vivo* by resident peritoneal cells following stimulation with opsonized zymosan from mice maintained on a diet devoid of n-3 PUFA (diet 1), progressive amounts of α-linolenic acid (diets 2–4) or fish oil (diets 5–7). Results are mean ± SEM of 10 experimental values. Bars with the same letter are not significantly different at $p<0.05$.

et al. (26), these studies could not verify the identity of LTE_5 and quantitate its production because of incomplete RP-HPLC resolution and the use of nonspecific radioimmunological binding assays.

The present study confirms that when fish oil is consumed in the diet, the 5-series SP-LT, produced by stimulated peritoneal cells, can significantly contribute to the total LT pool *in vivo*. This production is positively correlated with dietary n-3/n-6 ratios and as this ratio approaches 1.0, the contribution of 5-series SP-LT can approach the contribution by the 4-series SP-LT. A number of studies have shown that 20:5n-3 is a very good substrate for lipoxygenases (32–34) and LTA_5 is a substrate for the LTA hydrolase (35). Our results reveal that 20:5n-3 and its lipoxygenase-derived metabolites are also substrates for those enzymes responsible for SP-LT formation *in vivo*. Thus, the data presented here emphasize the need to account for SP-LT derived not only from n-6 PUFA, but also those generated from n-3 PUFA.

We also report, for the first time, that α-LNA, as a dietary component, can contribute to 5-series SP-LT formation, although not to the same extent as fish oil under the experimental conditions used. LTE_5 production was not detected in animals maintained on diet 2 and diet 3, with n-3/n-6 ratios of 0.2 and 0.4, respectively. Only animals consuming the highest levels of α-LNA (diet 4) produced detectable quantitites of LTE_5. Concomitantly, a reduction in 4-series SP-LT formation was observed only in animals on diet 4.

These findings agree with previous reports, indicating that α-LNA may have a significant effect on the lipoxygenase pathway, but only with elevated intakes (36). Hwang *et al.* (14), however, observed a progressional reduction in rat platelet 12-lipoxygenase activity *(in vitro)* with increasing dietary α-LNA, but a significant reduction in lung 5- and 12-lipoxygenase activities occurred only in animals maintained on a dietary regimen similar to the highest α-LNA intake in the present study.

In contrast, consumption of fish oil resulted in 5-series SP-LT formation in all dietary groups. In addition,

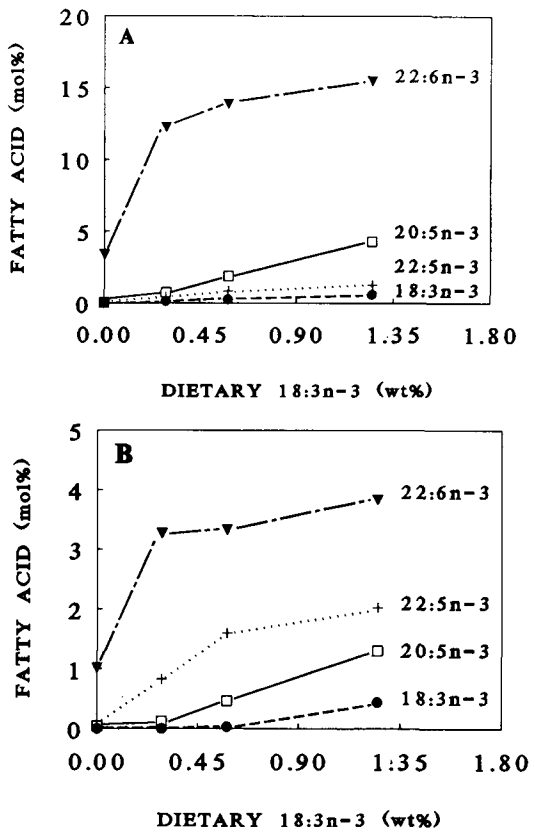

FIG. 7. The effect of increasing dietary α-linolenic acid on select tissue phospholipid n-3 PUFA levels of A) liver and B) peritoneal cell phospholipids.

tetraenyl LT formation, *i.e.*, LTC_4 and LTE_4, declined as the fish oil content of the diet increased, whereas a 48% reduction was observed in animals consuming diet 6 (n-3/n-6 ratio of 0.4) *vs.* the animals on the control diet, with no further reduction observed in animals on diet 7 (Fig. 4). The 20:5n-3 can compete with 20:4n-6 for enzymatic oxidation by the 5-lipoxygenase, thereby decreasing LTA_4 formation, and LTA_5 is a known inhibitor of tetraenyl LT formation (35).

The biological significance of 5-series SP-LT formation has yet to be elucidated. While LTB_5 has received increasing attention because it is biologically less active than LTB_4 (37,38), little attention has been focused on the pentaenyl SP-LT, possibly because the 4- and 5-series SP-LT have been shown to be equipotent physiological mediators in a limited number of bioassays (20,29,31) and only a few studies have reported *in vivo* production of these pentaenyl compounds (27,30,31).

There was no indication that α-LNA inhibited either Δ6, Δ5, or Δ4 desaturase activities, as dietary α-LNA appeared to be preferentially elongated and desaturated to 22:6n-3. It has been reported that n-3 PUFA, as derived from linseed oil and fish oil, can inhibit rat liver microsomal Δ6 desaturase activity (39). Therefore, desaturase inhibition cannot be ruled out. However, if there was inhibition of this activity in the mouse model, it was not reflected in the 18:2n-6 or α-LNA tissue levels, nor by the elongation products of α-LNA. The inclusion of dietary α-LNA resulted in the accumulation of 22:6n-3 in both the liver and peritoneal cell phospholipids (Fig. 7). Similar results have been observed elsewhere (14). Only after tissue phospholipid 22:6n-3 levels approached a maximum did 20:5n-3 levels rise. Alterations of phospholipid fatty acid composition in the liver appear to precede those changes seen in the peritoneal cells, since resident peritoneal cells, such as the macrophage, do not possess Δ4 desaturase activity nor the capacity for retroconversion (40). The increases in 22:5n-3 levels in peritoneal cells are most likely the result of the elongation of 20:5n-3. This is supported by other data demonstrating that 22:6n-3 is not retroconverted to 22:5n-3, but rather 22:5n-3 is derived from 20:5n-3 (36,40).

Though these conclusions appear consistent with our data, they may not strictly apply to all tissues or species. The 22:6n-3 of rat liver phosphatidylcholine is unaffected by dietary α-LNA levels (41). However, 22:6n-3 may be incorporated preferentially into other phospholipid classes, such as phosphatidylethanolamine (13,34). It has been demonstrated that liver phospholipid 22:6n-3 levels increase dramatically, even with low dietary intakes of α-LNA (similar to the present results), while the lung phospholipids may not be as responsive (14). It has been shown that the 22:6n-3 content of rat liver microsomal phospholipids is responsive to dietary α-LNA (39), as it is in those tissues which require 22:6n-3 (42). Therefore, the limited incorporation of 20:5n-3 and the significant elevation of 22:6n-3 into tissue phospholipids may have contributed to the poor 5-series SP-LT production in the peritoneal cells of animals fed α-LNA (36,40).

Fish oil feeding also resulted in a significant reduction in 6-keto-$PGF_{1\alpha}$ formation. The capacity of macrophages (95% of the peritoneal cell population are resident macrophages) or other tissues to produce PGI_2 could be of interest with regard to a number of metabolic processes, including cholesterol homeostasis. It has been observed that PGI_2 and 6-keto-$PGF_{1\alpha}$ can influence cholesterol efflux in cultured smooth muscle cells by elevating cholesteryl ester hydrolase activity (43). Macrophages appear to be intricately involved in scavenging extravascular LDL cholesterol and this uptake has been related to eicosanoid metabolism (44,45). Mouse peritoneal macrophages, incubated with oxidized LDL, produced twice as much 6-keto-$PGF_{1\alpha}$ and three times more SP-LT than controls (46). In addition, PGI_2 has been shown to be very important in thrombosis and hemostasis (47).

Depression of 6-keto-$PGF_{1\alpha}$ production in mice fed the α-LNA diets was observed only with diet 4. This is in contrast to the results reported in rat lung homogenates where α-LNA had an intermediate effect on decreasing 6-keto-$PGF_{1\alpha}$ production when compared with the control and fish oil groups (14). Other *in vitro* studies have shown that when the dietary 18:3n-3/18:2n-6 ratio exceeds 1.0, prostaglandin production is significantly depressed as compared to diets limited in α-LNA (36,48).

The mechanism by which n-3 PUFA depress prostanoids appear to be the result of competitive inhibition of PGH synthase by 20:5n-3 (11) and by decreasing tissue content of 20:4n-6. In addition, 20:5n-3 is a poor substrate for the formation of the 3-series prostanoids (14).

In summary, a limited amount of data exists in the literature which directly compares the effects of progressive increases of dietary n-3 fatty acids in the form of

α-LNA and fish oil on eicosanoid production. The present study revealed that dietary α-LNA can contribute to 5-series SP-LT formation when sufficient quantitites of α-LNA are provided in the diet to significantly alter tissue 20:5n-3 levels. However, α-LNA appears to be preferentially metabolized to 22:6n-3 in this animal model. In addition, the limited incorporation of long-chain n-3 PUFA (Fig. 1) into tissue phopholipids following a dietary regimen of α-LNA appears to influence the efficacy of α-LNA in altering eicosanoid metabolism. The effects observed with fish oil feeding suggest that preformed (dietary) n-3 HUFA appear to be readily incorporated into tissue phospholipids and that eicosanoid formation is related to the extent of this incorporation.

[Received August 3, 1990; Revision accepted December 7, 1990]

Effects of Age and Dietary Essential Fatty Acids on Desaturase Activities and on Fatty Acid Composition of Liver Microsomal Phospholipids of Adult Rats

L. Ulmann[a], J.P. Blond[a], C. Manniongui[a], J.P. Poisson[a], G. Durand[b], J. Bézard[a,*] and G. Pascal[b]
[a]Laboratoire de Physiologie Animale et de la Nutrition, Faculté des Sciences Mirandé, 21004 Dijon Cedex and [b]Station de Recherches de Nutrition INRA-CRJ, 78350 Jouy en Josas, France

The combined effects of age and dietary n-6 and n-3 fatty acids were studied in 3-, 6- and 9-month-old rats. At each age, two groups were fed diets containing 5% (w/w) of vegetable oils rich in either 18:3n-6 (borage group) or 18:3n-6 plus 18:4n-3 (black currant group), for a period increasing with age. A control group was fed the essential fatty acids 18:2n-6 and 18:3n-3 only. For each group, Δ6, Δ5 and Δ9 desaturase activities were measured in liver microsomes, and fatty acid composition was determined in microsomal phospholipids. Desaturase activity varied as a function of age and dietary lipids. Δ6 Desaturation of 18:3n-3 was more sensitive to these factors while Δ6 desaturation of 18:2n-6 and Δ9 desaturation were more dependent on season than the other two. Desaturase activity was influenced more by the black currant than by the borage diet, especially at 6 and 9 months of age. A large proportion of arachidonic acid was maintained in the microsomes independent of the diet. Changes in the fatty acid composition did not strictly reflect the differences in desaturase activities. The effects of the two factors (age and diet) on the activities of the desaturases are complex, suggesting that the enzymes are susceptible to other factors as well.
***Lipids 26,* 127–133 (1991).**

It is well established that in animals unsaturated fatty acids are synthesized by a series of alternating position-specific desaturation and malonyl-CoA-dependent elongation steps. The enzymatic conversion of fatty acids to their corresponding desaturated products has been particularly well studied in rat liver microsomes. Different desaturases introduce double bonds at Δ9, Δ6, Δ5 or Δ4 position in the fatty acid chain (1). Thus, γ-linolenic acid (18:3n-6) and stearidonic acid (18:4n-3) are synthesized by Δ6 desaturation, a rate-limiting step in the metabolism of linoleic acid (18:2n-6) and α-linolenic acid (18:3n-3), which are the main dietary essential fatty acids (EFA). Another enzyme, the Δ5 desaturase, converts dihomo-γ-linolenic acid (20:3n-6) into arachidonic acid (20:4n-6), whereas a Δ9 desaturase is responsible for the transformation of stearic acid, a non-essential saturated fatty acid (18:0), into oleic acid (18:1n-9). Desaturations of fatty acids by liver microsomes are influenced by numerous hormonal and nutritional factors (2–7) and are sensitive to circadian variations (5,8). Losada and Peluffo (9) observed that a cold environment decreased the Δ9 desaturase activity while Δ6 desaturation was insensitive to temperature variations.

Physiological factors, such as age, may induce modifications of desaturase activities. Strouve-Vallet and Pascaud (10) investigated Δ6 desaturation in liver microsomes and brain during the first month of rat growth. Satomi and Matsuda (11) examined the microsomal Δ6 desaturation of linoleic acid in rat liver fetus. Peluffo and Brenner (12) demonstrated that in rat liver Δ6 desaturation of 18:2n-6 and 18:3n-3 decreased while Δ9 desaturation of 18:0 increased at 12 months of age as compared to 3 months. Recently, Bordoni *et al.* (13) showed that a linear decrease of Δ6 desaturase activity occurred with age (1- to 22-month-old rats) and compared the Δ6 desaturation of 18:2n-6 to that of 18:3n-3 (14). However, the standard diets provided to the animals did not allow the influence of dietary essential fatty acids in enriched diets to be studied. Blond *et al.*(15) studied Δ6 and Δ5 desaturations in Zucker rats with age, but only during a short period of growth, *i.e.*, 6, 9 and 12 weeks.

Evening primrose seed oil is a well-known source of γ-linolenic acid. The use of dietary γ-linolenic acid avoids the Δ6 desaturation step. Other species, such as *Boraginaceae*, are also known to contain significant amounts of 18:3n-6 (16). Thus, borage oil also can be used to supply diets with this fatty acid. Black currant seed oil (17), a Ribes seed oil, is proposed currently as a source of both stearidonic acid and 18:3n-6. Hoy *et al.* (18) demonstrated that liver Δ6 and Δ5 desaturase activities were not modified by dietary 18:3n-6 when rats were fed evening primrose oil or safflower oil for 11 weeks. In contrast, the Δ5 desaturase activity was depressed in young animals fed a diet containing 18:3n-6 (19). Choi and Sugano (20), using a diet containing evening primrose oil, showed a decrease of liver Δ6 desaturase activity in 8-month-old rats but not in 3-week-old animals. These previous studies dealing with dietary fatty acids, age and desaturations usually reported results only for certain ages (often for young rats) and more particularly for Δ9 and Δ6 desaturation. A time-course investigation of Δ9, Δ6 and Δ5 desaturation together with a liver microsome fatty acid compositional study was needed.

Nutritional experiments were therefore carried out on 3-, 6- and 9-month-old rats. The use of borage and black currant seed oils permitted the study of the effect of a partial substitution of 18:3n-6 and 18:4n-3 for 18:2n-6 and 18:3n3, respectively, on the desaturation capacity of rat liver microsomes as well as on the composition of microsomal phospholipids.

MATERIALS AND METHODS

Animals and diets. Male Wistar rats, supplied by INRA (Jouy-en-Josas, France), were randomized into three groups according to age and housed in stainless steel cages in a well-ventilated room maintained at 22 ± 2°C on a 12 hr/12 hr light/dark cycle. Diets and tap water were provided *ad libitum*. After weaning, the rats were fed the basal diet (control diet) for 7, 16 and 26 weeks. It contained (g/kg): casein, 220; D,L-methionine, 1.6; cellulose, 20; starch, 440; saccharose, 218; mineral mixture, 40; vitamin mixture, 10; and oil mixture (50 % peanut oil + 50 % rapeseed oil), 50 (21). Then, within each group, the animals were again divided into three groups (three rats per group). The first group continued to receive the control diet (group C). The two other groups were given a diet in which the oil mixture was replaced by 5% (w/w) fat including borage oil (group Bg) or 5% (w/w) fat containing black currant seed oil (group Bc) for 2, 5 and 7 weeks, respectively, in the three increasing age groups. For 100 g of diet, the n-6 fatty acids represented 945, 973 and 988 mg for C, Bc and Bg groups, respectively; the n-3 fatty acids represented 188 mg for each diet. The three oil mixtures had a n-6/n-3 fatty acid ratio of about 5.2 and similar contents of n-6 and n-3 fatty acids. The fatty acid compositions of these mixtures are reported in Table 1. The three groups of animals were killed at 3, 6 and 9 months. To minimize seasonal variations in desaturase activities, two groups of three rats were used at 4–6 month intervals throughout the year, for a given age and for a given diet. Means were calculated on the 6 values.

Chemicals. [1-^{14}C]Stearic acid (52 mCi/mmol, 97.5% radiochemical purity) and [1-^{14}C]linoleic acid (58 mCi/mmol, 99% radiochemical purity), were purchased from CEA (Gif sur Yvette, France). [1-^{14}C]α-Linolenic acid and [2-^{14}C]dihomo-γ-linolenic acid (56 mCi/mmol, 96% radiochemical purity) were purchased from the Amersham Radiochemical Centre (Amersham, U.K.). The reported radiopurity of each substrate was that indicated by the manufacturer. Each substrate was diluted in ethanol with unlabelled fatty acid to a specific activity of 10 mCi/mmol. Unlabelled fatty acids, coenzymes and biochemicals were provided by Sigma Chemical Co. (St. Louis, MO) and by NuChek Prep (Elysian, MN). All other chemicals purchased from Sigma and Merck (Darmstadt, Germany) were of analytical grade.

Isolation of microsomes. Rats were killed by exsanguination between 07:00 and 08:00 hr to avoid any circadian variation (22) and to insure conditions of high desaturase activity (8). Livers were excised, rinsed with ice-cold physiological saline solution, blotted, weighed and cut into thin slices. Liver (3.5 g) was homogenized at 4°C in a Potter-Elvejhem homogenizer with 6 volumes of 0.05 M phosphate buffer (pH 7.4) and 0.25 M sucrose solution. Homogenates were centrifuged at 13,000 × *g* for 20 min to sediment cell fragments, mitochondria and nuclei. The microsomal pellet was obtained by centrifugation of the supernatant at 105,000 × *g* for 60 min.

Microsomal pellets were resuspended in 0.4 mL supernatant and 0.8 mL of 0.05 M phosphate buffer (pH 7.4) and 0.25 M sucrose solution for determination of desaturase activities. Microsomal proteins were estimated by the method of Layne (23) with fatty acid-free bovine serum albumin as standard.

Enzyme assays in vitro. Five mg of microsomal proteins were incubated in an open flask. Two quantities of each substrate in ethanolic solution were used: a nonsaturating level, 50, 60, 30 and 40 nmol and a saturating level, 100, 120, 80 and 120 nmol for 18:0, 18:2n-6, 20:3n-6 and 18:3n-3, respectively. These levels and the effect of microsomal protein concentration and incubation time were established in preliminary experiments (unpublished data). Incubations were performed at 37°C for 15 min in a shaking water bath with a total volume of 2.1 mL incubation medium containing 72 mM phosphate buffer, pH 7.4, 4.8 mM $MgCl_2$, 0.5 mM coenzyme A, 3.6 mM ATP and 1.2 mM NADPH. Incubations were stopped by adding 15 mL chloroform/methanol (1:1, v/v). Lipids were saponified and methylated as reported by Slover and Lanza (24). The distribution of radioactivity between substrate (stearic, linoleic, dihomo-γ-linolenic or α-linolenic acid) and desaturation product (oleic, γ-linolenic, arachidonic or stearidonic acid) was determined by the reversed phase high performance liquid chromatography (HPLC) method described by Narce *et al.* (25), using a Waters Chromatograph and a Lichrocart column (Superspher RP 18, 250 mm × 4 mm i.d. Waters, Milford, MA). After separation by HPLC, each fraction corresponding to a fatty acid methyl ester was collected at the detector outlet (differential refractometer) and its radioactivity was directly measured in the solvent by liquid scintillation counting. The conditions established by the authors permitted a good separation of the different unsaturated fatty acid methyl esters. Moreover, the desaturation product was eluted before its substrate,

avoiding possible radioactive contamination. Enzyme activity was calculated from the desaturation product/substrate ratio and was expressed as nmoles of substrate transformed in 15 min with 5 mg of total microsomal proteins.

Fatty acid analysis. Lipids from aliquots of liver microsomes were extracted according to Delsal (26). Phospholipids were obtained by liquid column chromatography following the procedure described by Hirsch and Ahrens (27). After addition of heptadecanoic acid, fatty acids were methylated in the presence of methanolic BF_3 and extracted as previously described (24). The fatty acid methyl esters were analyzed by capillary gas-liquid chromatography on a model 417 Becker-Packard apparatus (Packard Instrument, Rungis, France) equipped with a laboratory-made 50 m × 0.3 mm i.d. glass capillary column coated with Carbowax 20 M. Gas chromatographic peaks were identified on the basis of their retention time relative to methyl heptadecanoate. Peak area was measured using a Delsi model Enica 21 computing integrator (Delsi Instruments, Suresnes, France).

Statistical analysis. All data are presented as the mean ± SE for n=6 animals. After analysis of variance using a Duncan's multiple range test, means were compared according to the least significant difference ($p<0.05$).

RESULTS

Table 2 shows that, at each age, the composition of dietary lipids had no significant effect on body and liver weights and on microsomal protein content of liver microsomes. In each dietary group, body weight increased between 3 and 6 months, but in the control group it also increased between 6 and 9 months.

Tables 3 and 4 report the desaturation activity, first expressed as quantities in Table 3 (nanomoles of desaturation product) and second, as conversion percentages (Table 4). The Δ9 desaturase showed the highest activity independent of age and diet. This activity clearly increased between 3 and 6 months but then decreased at 9 months to approximately the three month-level. The diet had no significant influence. At a 50-nmol substrate concentration, the conversion percentage was about 1.5 times higher than at a substrate concentration of 100 nmol.

The two other desaturases were less active than the Δ9 desaturase. The Δ5 desaturation of 20:3n-6 was more active than the Δ6 desaturation of 18:2n-6 or 18:3n-3 in any of the experimental situations. As for Δ9 desaturation, Δ5 desaturation progressed at a higher rate in the presence of a lower concentration of substrate (30 nmol). The activity increased from 3 to 6 months, at which time it reached a plateau. The influence of diet appeared only at 6 and 9 months when black currant and borage oils had been ingested over a longer time period. In 3-month-old animals, the desaturation of n-3 fatty acid was much higher than that of n-6 fatty acid for all dietary groups. The difference disappeared by 6 and 9 months. The conversion percentage was the same at the two concentrations of the two substrates in contrast to results obtained with the Δ9 and Δ5 desaturases. The effect of season (Table 5) was investigated in the 6-month-old rats. The Δ9 desaturation activity markedly increased in winter in all dietary groups. Δ5 Desaturation activity was also higher in winter but only at high concentration of substrate and only for the C and Bc groups. At the same saturating concentration of substrate (120 nmol), the Δ6 desaturation of the n-3 fatty acid was not affected by the season, whereas the desaturation of the n-6 fatty acid was greatly increased in winter.

Table 6 presents the percentages of the major fatty acids of liver microsomal phospholipids at the different ages and for the different diets. Palmitic and stearic acids were the main saturated fatty acids. Their cumu-

[a]Results are means ± SE for n=6 animals in each group. After analysis of variance (Duncan's multiple range test), means were compared in each column (three groups and three diets) according to the least significant difference, and classified according to increasing order. Means assigned different manuscript letters were significantly different ($p<0.05$).

[b]Control diet.

[c]Black currant seed oil diet.

[d]Borage oil diet.

lated percentages generally decreased with age in the three groups. The influence of diet at each age was not evident. The decrease in saturated fatty acid content was generally compensated (especially in the control group) by an increase of the monounsaturated fatty acids 16:1n-7 and 18:1n-9, the products of Δ9 desaturation. The percentage of linoleic acid did not really change with age and diet. The arachidonic acid content did not increase with age in the C group. With the experimental diets containing γ-linolenic acid, an increase in arachidonic acid was observed, but only at 9 months (corresponding to ingestion of 18:3n-6 for a longer time). This caused a similar variation in the total n-6 fatty acid content. The ratio 20:4n-6/18:2n-6, which reflects the overall conversion of 18:2n-6 to 20:4n-6, did not generally change between 3 and 9 months in each dietary group. However, the ratio was higher in the black currant and borage dietary groups (especially the latter). Docosahexaenoic acid (22:6n-3) was the major n-3 fatty acid in the microsomal phospholipids. The percentage of 22:6n-3 tended to increase with age for each group. At 9 months, the total n-3 fatty acid content was higher than at 3 months, especially in the two groups on the experimental diets, Bc and Bg. The presence of stearidonic acid in the black currant oil did not induce any specific changes.

DISCUSSION

The purpose of this study was to see whether dietary manipulation could overcome a possible age-related decrease in PUFA content of tissue lipids due to a decrease in desaturation activity. A decrease in Δ6 desaturation is of special concern as Δ6 desaturation is the major regulating reaction step in EFA metabolism.

The experimental approach was to bypass the Δ6 desaturation reaction by adding to the diet γ-linolenic acid (n-6 series) or stearidonic acid (n-3 series). Δ9 Desaturase activity was also studied because it broadly reflects lipogenic activity. In studies with guinea pigs (28), humans (29) and rats (30), it was shown that administration of γ-linolenic acid results in the biosynthesis of arachidonic acid by shunting the Δ6 desaturase step. An increase of n-6 PUFAs has been observed in various organs after the addition to the diet of black currant seed oil or borage oil, both containing γ-linolenic acid.

In our experiments rats were fed low quantities of 18:3n-6 (206.8 mg and 169.1 mg per 100 g of Bc and Bg diets, respectively). Black currant and borage oils were mixed with other oils to maintain the same total levels of n-6 and n-3 fatty acids as in the control group. Experimental diets were given at different time points as a function of age, the duration of feeding being increased from 3 to 9 months of age. The protocol was justified by the aim of this study, which was to compensate for, and not to prevent a possible deficiency in desaturation capacity. Because the turnover rate of tissue lipids supposedly decreases with age, the duration of the substituted experimental diet was increased with age.

Results of *in vitro* desaturation by liver microsomes (Tables 3 and 4) showed that the Δ9 desaturase

was more active than the Δ6 and Δ5 desaturases. This high activity of Δ9 desaturation, especially at 6 months, may be related to active lipogenesis in the liver. Growth is most active between 3 and 6 months and the need for fatty acids for tissue synthesis is elevated. Saturated fatty acids provided by the dietary oils were relatively low, enhancing lipogenic reactions which give rise to saturated fatty acids that undergo desaturation by Δ9 desaturase.

In comparison, the activities of Δ5 and, more particularly, of Δ6 desaturases were clearly lower than that of the Δ9 desaturase. The Δ5 and Δ6 desaturations do not have the same physiological significance as the Δ9 desaturation, since they are required in the biosynthesis of PUFAs from dietary linoleic and linolenic acids. The low activity of the Δ6 desaturase means that it constitutes a limiting step in the biosynthesis of the essential PUFAs.

The difference observed regarding the activity of the enzymes with different substrates is in agreement with observations reported previously by others. Brenner and Peluffo (31) demonstrated a more rapid desaturation of α-linolenic acid than of linoleic acid by the Δ6 desaturase. This was confirmed by Marcel *et al.* (32) and by Sprecher (33). Data regarding the Δ5 desaturation rate are sparse and sometimes contradictory. Bernert and Sprecher (34) observed a rate lower than the Δ6 desaturation rate, but others (31,32) found it higher.

The activities of Δ6 and Δ5 desaturases toward n-6 fatty acids increased from 3 to 6–9 months. This corresponds to an active period of growth during which PUFA demand is high for membrane phospholipid synthesis in the newly formed tissues. Desaturation activities adapt themselves to this need probably by the synthesis of new enzyme under hormonal control. The Δ6 desaturation of the n-3 fatty acid was more active than that of the n-6 fatty acid only at 3 months. Nervous tissue is very rich in n-3 PUFAs and at three months of age the brain is still rapidly developing (35), increasing the demand for this type of PUFAs.

Our results regarding the influence of age on the desaturation rates (Tables 3 and 4) can be compared to those reported by Peluffo and Brenner (12) and Bordoni *et al.* (13). These authors studied the Δ6 desaturation in rats fed a diet containing two levels of proteins (12) or a commercial standard diet (13). They observed that Δ6 desaturation activity was lower at 12 or 14 months than at 3 months. This is not contradictory to our results since we observed the maximum at 6 and 9 months; the activity is then likely to decrease. The changes in Δ6 desaturation with age may be similar to those we observed with Δ9 desaturation, but at a slower rate. Results of studies at a more advanced age, *i.e.*, at 12, 18 and 24 months, may answer this question.

The presence of γ-linolenic acid in the diet did not induce any change in the Δ6 desaturation of linoleic acid. In contrast, Δ5 desaturation was slightly more active, especially at 9 months. These low effects are likely due to the low level of γ-linolenic acid in the experimental diets (Bc and Bg). When ingested for a longer time (rats of 9 months of age), the stimulating effect on Δ5 desaturation was more significant. The presence of stearidonic acid (18:4n-3) in black currant seed oil did not affect the Δ6 desaturation of α-linolenic acid, probably because the amount of this n-3 fatty acid in the diet was very low. Choi and Sugano (20) observed an inhibitory effect of dietary γ-linolenic acid on the Δ6 desaturation of linoleic acid. In these experiments, a higher amount of dietary evening primrose oil (9.3 % of γ-linolenic acid) was provided (10% weight of oil in the diet) than in our study.

Our studies confirmed the seasonal variations of desaturation previously observed by Peluffo and Brenner (12). The desaturations were generally more active

in winter (January) than in summer (June). Surprisingly, the Δ6 desaturation of α-linolenic acid was not affected in contrast to the Δ6 desaturation of linoleic acid. The variations in desaturation activity are likely to follow variations in hormonal secretions. The physiological significance of these modifications is difficult to understand since the rats were submitted to identical environmental conditions throughout the year. The results underline the importance of taking into account seasonal variations when studying the desaturation rates, especially in the course of aging. In our experiments with 3- and 9-month-old rats, two groups of three rats were tested at 4- to 6-month intervals to minimize seasonal variations. Modifications in Δ6 and Δ5 desaturation rates are likely to influence the rate of biosynthesis of essential PUFAs and to modify their pattern in membrane phospholipids. To test this hypothesis, we analyzed the fatty acid composition of microsomal phospholipids at the three different ages and with the three different diets. This choice of membrane appears appropriate for this study because the desaturases are thought to reside in the phospholipid bilayers of the endoplasmic reticulum. The question is often raised whether changes in desaturase activity would change the fatty acid composition of the phospholipids or, conversely, whether modification of phospholipid fatty acids would induce changes in the desaturation rate. Eventually, correlation between the two phenomena could be established. In this work, the fatty acid composition of microsomal phospholipids (Table 6) did not necessarily correlate with changes in desaturase activity. For example, the proportion of monounsaturated fatty acids was not modified between 6 and 9 months, whereas the Δ9 desaturation rate sharply decreased during this period (Tables 3 and 4). Similarly, the proportion of arachidonic acid did not change from 3 to 9 months, whereas the Δ6 and Δ5 desaturation rates increased from 3 to 6 months. However, the type of diet seemed to influence the phospholipid fatty acid composition. The presence of γ-linolenic acid in dietary black currant or borage oil tended to increase the Δ5 desaturation rate and, consequently, the arachidonic acid content of microsomal phospholipids. This property is important since the activity of the rate-limiting Δ6 desaturation step may decrease with age.

ACKNOWLEDGMENTS

This work was supported in part by the Ministère de La Recherche et de l'Enseignement Supérieur (MRES, Aliment 2000), France. We thank J. Gresti for technical assistance in performing chromatographic separations and Drs. M. Suschetet, P.O. Astorg and F. Sauvageot for assisting in the statistical evaluation of our data.

Change in Bile Salt Dependent Lipase in Human Breast Milk During Extended Lactation

Patricia Dupuy[a], J. Frédéric Saunière[a], Henry L. Vis[b], Michèle Leclaire[c] and Dominique Lombardo[d,*]
[a]Service de Gastroenterologie, Hôpital Sainte Marguerite, 13009 Marseille, [b]Hôpital des Enfants Reine Fabiola, 1020 Bruxelles, Belgium, [c]Service de Pédiatrie, Hôpital Michel-Levy, 13006 Marseille, and [d]Centre de Biochimie et de Biologie Moléculaire du Centre National de la Recherche Scientifique, 13402 Marseille, France

Two hundred eighty-one milk samples collected from Zaïrian nonprivileged, undernourished mothers, in series of nine groups from 1 month to 18 months after parturition, and 66 milk samples collected from French privileged mothers in series of four groups from 2 days to 16 months *postpartum*, were analyzed for their lactose, lipid and protein contents. In addition, the activity of bile salt-dependent lipase (esterase), which may play an important role in the newborn infant's lipids digestion, was measured. After the first month *postpartum*, independent of the nutritional state of the mother, sugar and protein concentrations were identical. Lipid content of French mothers' milk was lower in transitional milk, but appeared constant in mature milk with an average value of 29.1 ± 5.8 mg/mL of milk. In Zaïrian mothers' milk, the lipid content of mature milk plateaued at around 50–55 mg/mL independent of the stage of lactation. Bile salt-dependent lipase showed constant esterase activity within the lactation stage in privileged mothers' milk, but decreased by almost 80–90% during the first four months of lactation in undernourished mothers. The data suggest that milk from nonprivileged mothers may lose some of its ability to hydrolyze milk lipid esters, which could also be of consequence to the infant's normal growth in view of its effect on the esters of the lipid-soluble vitamins A, E and D.
Lipids 26, 134–138 (1991).

Human milk has been shown to contain two lipases (1). One, referred to as the bile salt-stimulated lipase (or bile salt-dependent lipase), is responsible for milk fat degradation and acts in the newborn's intestinal lumen (2). This enzyme is stable enough to withstand the acidic conditions of the stomach (2) and was shown to be structurally and functionally closely related to the human pancreatic carboxylic ester hydrolase (3–7). Both enzymes share rather wide substrate specificities. They hydrolyze water-insoluble long-chain fatty acid esters of glycerol and cholesterol as well as esters of vitamin A, D and E in the presence of primary bile salts (8). They also hydrolyze water-soluble esters such as short-chain fatty acid esters of glycerol, 4-nitrophenyl acetate, and methyl butyrate (9); however, in this case activation by bile salts is not essential. The wide specificity of the bile salt-dependent lipase suggests that in the presence of bile salt the enzyme may hydrolyze essentially any lipid ester. As a milk protein, the bile salt-dependent lipase appears to be unique to the highest primates and is carnivorous. So far, it has been found only in milk from man (1), gorilla (10), dog and cat (11), but not in milk from several other species including rat, pig, cow, horse and monkey (12,13).

In addition to the bile salt-dependent lipase, the occurrence of traces of lipoprotein lipase (or serum-stimulated lipase) in milk has been reported; it is likely to result from cell damage during the secretion of milk by mammary gland (14). In contrast to bile salt-dependent lipase, lipoprotein lipase is rapidly inactivated in the gastric environment (15). Hence, it serves no useful function in the newborn's gastrointestinal tract. The presence of lipoprotein lipase in the mammary gland is essential for the synthesis of milk lipids.

Previous investigations have established that the bile salt-dependent lipase is present in milk from Caucasian privileged and undernourished Ethiopian mothers (16–21). The aim of the present work was to extend these studies to other African mothers and to establish whether bile salt-dependent lipase is present in the milk of women living in an area where malnutrition is widespread. We also set out to determine whether the esterase activity changes as a function of length of lactation.

EXPERIMENTAL PROCEDURES

Collection of samples. Subjects were breast-feeding primiparous or multiparous women. Milk samples (401) representing 281 subjects were collected from nonprivileged African women living in the urban area of Bukavu (Kivu, Zaïre). In parallel, milk samples collected from 66 privileged Caucasian mothers living in the urban area of Marseilles (France) were also analyzed. Sixty-seven percent of the Zaïrian mothers and 25% of French mothers were less than 24-years-old; 6.5% of the Zaïrian mothers and 20% of French mothers were more than 35-years-old. Mothers were between 2 days and 18 months *postpartum* and nursing full-term infants who were generally fed on demand. Milk aliquots (5–10 g) were taken between nursing (fore-milk) and were expressed indistinctly from either breast by means of a breast-pump in the morning or in early afternoon (9 a.m. to 2 p.m.).

African milk samples were sent frozen and stored at −20°C until thawed slowly before analysis. European milk samples were also frozen and thawed before analysis. Note that freezing-thawing cycles (up to 3 cycles, at least) have no effect on the bile salt-dependent lipase activity (22). Nevertheless, multiple freezing and thawing was avoided.

Sampling. Milk from nonprivileged mothers were put into series of nine groups, from I to IX corresponding to: Group I, one month *postpartum* milk samples (n = 21); group II, two months (n = 36); group III, three months (n = 24); group IV, four months (n = 31); group V, six months (n = 15); group VI, nine months (n = 52); group VII, twelve months (n = 49); groups VIII, fifteen months (n = 44); and group IX, eighteen months (n = 9). Milk samples from privileged mothers were in a series of four

*To whom correspondence should be addressed at Centre de Biochimie et de Biologie Moléculaire-CNRS. 31, chemin Joseph Aiguier, B.P. 71, 13402 Marseille-Cédex 9, France.

groups from A to D, corresponding to: Group A, 2–5 days (transitional milk, n = 26); group B, 1–2 weeks (mature milk, n = 12); group C, 1–4 months (n = 18); and group D, 5–16 months *postpartum* (n = 10).

Chemicals. 4-Nitrophenyl acetate was provided by Ega-Chemie (Steinheim/Albuch, Germany) and sodium taurocholate and deoxycholate were purchased from Calbiochem-Behring (La Jolla, CA). Delipidized bovine serum albumin was a product from Sigma (St. Louis, MO) and α-DL-glucose came from Fluka (Buchs, Switzerland).

Protein determination. Protein concentrations were determined according to Lowry *et al.* (23) using bovine serum albumin as standard. Measurements were done on diluted skim milk samples obtained after centrifugation (6) to avoid turbidity and lipid interference (24). Under our conditions, sugars do not interfere with protein determination.

Lactose determination. Lactose was assayed by the phenol-sulfuric acid method of Dubois *et al.* (25), using glucose as standard.

Lipid determination. Total lipid content of milk was determined by gravimetry after extraction (26). Extracted lipids were dried under vacuum until no further weight loss was observed. Duplicate determinations were done on pools constituted from milk samples of nonprivileged groups (2–9 pools per group) and on each sample of milk from privileged groups.

Bile salt-dependent esterase activity assay. The bile salt-dependent esterase activity was determined at 25 ± 1°C using 4-nitrophenyl acetate as substrate in the presence of 6 mM sodium taurocholate (27). Bile salt is added to the assay to activate the bile salt-dependent esterase (1) and to inhibit, if any, the lipoprotein lipase activity (14). Controls with known enzyme activities were always run in parallel with the unknown samples. In a series of experiments, we determined intra-assay and inter-assay errors which were less than 5% and 10%, respectively.

One enzyme unit was the enzyme quantity able to hydrolyse 1 μmole of substrate per mL and minute (U/mL). The enzyme activity was also expressed as the number of enzyme units per mg of milk total protein (U/mg milk protein).

When milk samples were incubated for 2 hr at 4°C and pH 7.5 in the presence of 1 mM α-toluenesulfonyl fluoride as lipoprotein lipase inhibitor (28), within experimental error, no decrease in 4-nitrophenyl acetate hydrolysis by milk enzymes was observed. This shows that the contribution of lipoprotein lipase activity to this hydrolysis is negligible under our experimental conditions.

Bile salt-dependent lipase activity assay. Bile salt-dependent lipase activity was determined titrimetrically on emulsified tributyrin in the presence of 1 mM sodium deoxycholate as already described (9).

Cholesterol ester hydrolase activity assay. The cholesterol ester hydrolase activity of bile salt-dependent lipase was determined as described by Lombardo and Guy (29).

Bile salt-dependent lipase purification. The bile salt-dependent lipase was purified to homogeneity using the two Heparin-Sepharose columns procedure of Bläckberg and Hernell (6).

Statistical analysis. Data were statistically analyzed by Student's *t*-test. They were considered to be significantly different when $p < 0.01$.

RESULTS

Bile salt-dependent lipase and bile salt-dependent esterase activities of human milk. In an attempt to demonstrate that the bile salt-dependent lipase and bile salt-dependent esterase activities of human milk reside in the same protein molecule, we determined the activity on 4-nitrophenyl acetate and on tributyrin during the purification step of the bile salt-dependent lipase (6). The data presented in Table 1 show that the ratio of esterase *vs* lipase activities is independent of the purification step of the enzyme. Since the bile salt-dependent lipase of human milk also bears cholesterol ester hydrolase activity (3), we determined the milk activity as well as the homogenous enzyme activity on cholesteryl esters. The data are presented in Table 1 and show that the esterase *vs* cholesterol esterase activity ratios are not significantly different in the two fractions.

Incubation of skim milk and bile salt-dependent lipase with *p*-nitrophenyl-*N*-butyl-*N*-methyl carbamate, a specific active site titrator for bile salt-dependent lipases (Fourneron J.D., Abouakil, N., Chaillan, C. and Lombardo, D., unpublished data), also decreases to the same extent the esterase and lipase activities of skim milk and of pure bile salt-dependent lipase. These results indicate that the esterase activity of human milk is due to the bile salt-dependent lipase. The results cannot, of course, rule out the possibility that milk can contain different esterase activities too low to make a significant contribution to the activities recorded under our conditions.

Analysis of milk from Zaïrian nonprivileged mothers. Milk samples were put into a series of nine groups collected from 1 month up to 18 months *postpartum.* Samples were analyzed for the bile salt-dependent esterase activity, protein, lactose and total lipid contents. Lactose content of breast milk from nonprivileged mothers did not vary from 1 month to 18 months; the mean (± standard deviation) value for all samples was 71 ± 10 mg/mL. Lipid (mostly triglyceride) content also remained quite stable at 53.6 ± 13.4 mg/mL, independent of the stage of lactation (Fig. 1).

TABLE 1

Esterase *vs* Lipase and Cholesterol Esterase Activities in Human Milk and During the Purification of Bile Salt-Dependent Lipase[a]

	Esterase/lipase	Esterase/cholesterol esterase
Skim milk	0.21 ± 0.05 (n = 3)	2.11 ± 0.14 (n = 4)
First Heparin-Sepharose	0.20 ± 0.06 (n = 3)	n.d.
Second Heparin-Sepharose	0.19 ± 0.02 (n = 3)	2.56 ± 0.40 (n = 4)

[a]The values given are mean ± standard deviation. Bile salt-dependent lipase was purified from skim milk according to Bläckberg and Hernell (see ref. 6). The bile salt-dependent lipase activity was eluted from a first Heparin-Sepharose column with a linear gradient from 0.05 to 1 M NaCl in 5 mM Tris/HCl, pH 7.4 buffer. The fractions of lipase were then dialyzed and applied to an Affi-Gel blue column to eliminate albumin. Fractions containing lipase activity were then loaded onto a second Heparin-Sepharose column (5 mM Tris/HCl, 50 mM NaCl, pH 7.4 buffer), the column was washed step-wise with sodium chloride in buffer, and the lipase was eluted at 0.5 M NaCl.

Figure 1 shows that protein concentrations were statistically higher ($p < 0.01$) in group I (1 month *postpartum*, 12.0 ± 2.0 mg/mL) than in the other groups, where the average value was 10.0 ± 0.5 mg/mL. Despite the constant concentration of fat, the bile salt-dependent esterase activity decreased (Fig. 1) from 12.9 ± 2.3 U/mL in the first group to 1.6 ± 0.7 U/mL after six months *postpartum*. This value, which represents an 80% decrease, remained constant until the end of breast-feeding. The decrease of the enzyme activity over the period extending to the sixth month of lactation is likely to result from a decrease of the total amount of breast-secreted bile salt-dependent esterase as shown by the parallel decrease of the activity of the enzyme per mg of milk protein (Fig. 1).

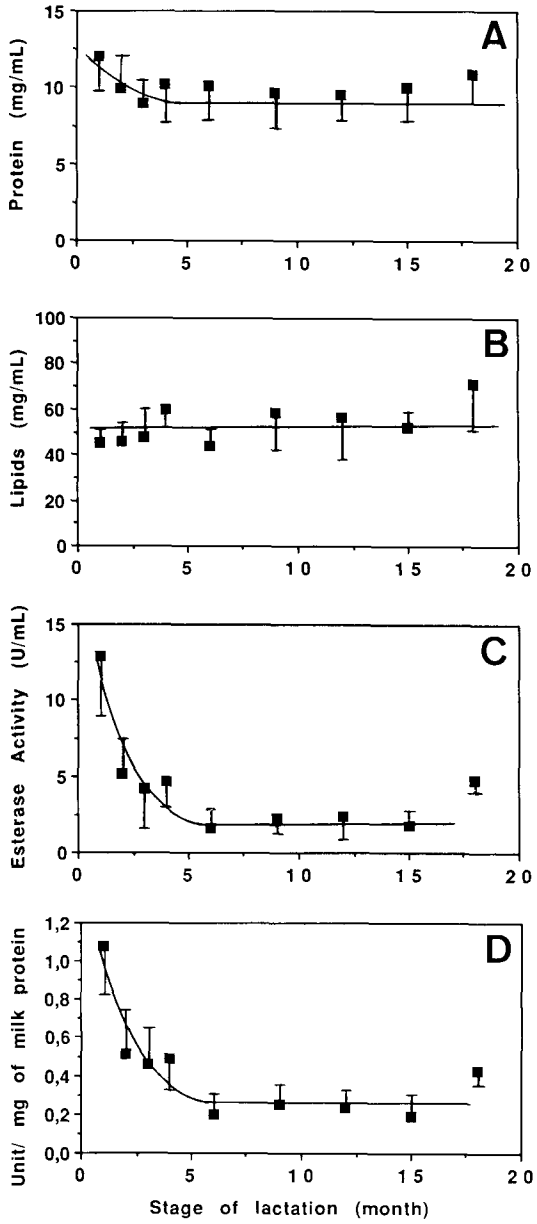

FIG. 1. Composition and enzyme content of milk samples from undernourished mothers. A, concentration of proteins; B, lipid concentration; C, bile salt-dependent esterase activity; D, bile salt-dependent esterase activity per mg of milk protein. Vertical bars represent the standard deviation.

Analysis of milk from French privileged mothers. Milk samples from privileged mothers were analyzed and the results compared to those obtained for undernourished mothers. The values obtained for lactose and lipids are presented in Table 2. In transitional milk samples (group A), the sugar content was significantly lower, then it increased slightly and reached a constant value between the first and the sixteenth month (group C and D). The sugar contents are identical to those found in the corresponding groups of milk samples from undernourished mothers (see Discussion section, Table 3). Total lipid contents of French milk increased slightly from transitional (group A) to mature milk (group B and C). A higher lipid content was then observed in group D (Table 2). This probably reflects the end of exclusive breast-feeding (20,30), since late lactation specimens of French women were taken during weaning. The lipid contents of Zaïrian milks did not increase significantly between the 1-4 months and the 5-16 months groups (Table 3).

Protein concentration (Table 2) decreased during the first month of lactation. Afterward the protein concentration remained constant at about 13 mg/mL, which is not very different from the value obtained for undernourished mothers' milk at the corresponding stage of lactation. All nutrient contents, independent of the milk source, agree with those found in the literature (31-34).

Bile salt-dependent esterase activity of milk from privileged mothers was constant and independent of the stage of lactation. Concomitantly to the protein decrease from transitional to mature milk, the enzyme activity per mg protein increased ($p < 0.01$) and reached its maximal level at one month *postpartum*. These data indicate that the amount of enzyme secreted by the breasts of privileged mothers was constant during the lactation period.

DISCUSSION

In adults, efficient fat digestion is achieved through the concerted action of three lipolytic enzymes, namely pancreatic colipase-dependent lipase, carboxylic ester hydrolase, and preduodenal acid lipase (9,35-37). In the breast-fed newborn infant, pancreatic colipase-dependent lipase secretion is low (38), while the time frame of the secretion of pancreatic carboxylic ester hydrolase is still unknown. The bile salt-dependent milk lipase, which has a very wide substrate specificity, appears to play an important role in fat digestion (2). Nevertheless, the amount of enzyme present in milk would account for no more than 40% hydrolysis in 2 hr, which is the estimated transit time from the duodenum to the ileum (39). Also, fat absorption is reduced by approximately one-third when raw milk is heated (40), but this value is improved when fresh milk is fed (41). Furthermore, the bile salt-dependent lipase seems unable to hydrolyze milk fat globules, without prior gastric lipolysis (42). Intragastric lipolysis depends upon the presence of preduodenal acid lipase in the stomach (43) and accounts for some 20% of formula fat hydrolysis (37). It is evident that the combined activity of the milk bile salt-dependent lipase and of the preduodenal lipase can lead to sufficient hydrolysis of dietary fats and can thus effectively substitute for the low level of pancreatic lipase secretion (37). Pancreatic lipase *in vitro*, even in the presence of bile salts and colipase, cannot initiate the hydrolysis of milk fat globules

TABLE 2

Esterase Activities and Nutrient Contents of Milk Samples from Privileged Mothers[a]

Group	Number of sample	Lactose (mg/mL)	Lipids (mg/mL)	Proteins (mg/mL)	Esterase activity (U/mL)	Esterase activity (U/mg milk protein)
2-5 Days (A)	26	59.3 ± 8.3*	19.2 ± 10.9*	21.2 ± 4.2*	6.6 ± 2.9	0.34 ± 0.14*
1-2 Weeks (B)	12	65.7 ± 9.6	24.3 ± 9.2	18.1 ± 4.5	7.5 ± 2.4	0.47 ± 0.20
1-4 Months (C)	18	78.4 ± 7.9*	25.7 ± 8.3	13.0 ± 3.0*	6.6 ± 2.1	0.52 ± 0.18*
5-16 Months (D)	10	73.7 ± 6.2*	37.2 ± 9.9*	13.5 ± 4.2*	6.6 ± 2.2	0.51 ± 0.16*

[a]The asterisks indicate a significance of $p < 0.01$ as compared to group A. The values given are mean ± standard deviation.

TABLE 3

Esterase Activities and Nutrient Contents of Milk Samples from Undernourished Mothers[a]

Group	Number of sample	Lactose (mg/mL)	Lipids[b] (mg/mL)	Proteins (mg/mL)	Esterase activity (U/mL)	Esterase activity (U/mg milk protein)
1-4 Months	112	72.3 ± 11.2	50.7 ± 9.5	10.2 ± 2.5	6.3 ± 2.2*	0.60 ± 0.34*
5-16 Months	169	70.0 ± 9.9	55.7 ± 1.54	9.0 ± 2.0	2.0 ± 0.8*	0.22 ± 0.09*

[a]The asterisks indicate a significance of $p < 0.01$. The values given are mean ± standard deviation.

[b]Lipids were assayed on pooled samples as described in Experimental Procedures (1-4 months, n = 26; 5-16 months, n = 35).

(44). This is consistent with the fact that rat milk lacks bile salt-dependent lipase, while pancreatic carboxylic ester hydrolase is the dominant lipolytic activity in newborn rat duodenum (45). The acid-stable lipolytic systems (bile salt-dependent and preduodenal lipases) in newborns appears to be preferred over the colipase-dependent lipase route.

No gross differences were noted between the French and Zaïrian groups with respect to the major nutrients, at least as far as protein and lactose are concerned. The main differences between the milks of undernourished and privileged mothers existed in the lipid contents and in the activities of the bile salt-dependent esterase.

The lipid content of the Zaïrian milk samples was significantly higher than that determined in the French milk samples (Table 3). Because an inverse relationship between fat content and milk volume exists (46), the higher lipid amounts could have been related to differences in daily milk volumes produced by Zaïrian *vs* French mothers. However, this does not seem to be the case since daily milk volumes of nonprivileged mothers were comparable to or even higher than those of privileged mothers (31,47,48). The higher amount of lipids in Zaïrian milk as compared to French milk thus may rather be due to the expression of hind-milk instead of fore-milk (34,49). Although it would have been more desirable to obtain milk samples by entire breast expression, this would have been difficult to control especially with Zaïrian mothers. Our collection procedure in France was therefore carefully standardized with respect to that used in Zaïre. Independent of the origin and the stage of lactation, the fat content of milk samples used here is compatible with that of fore-milk (or with mid-milk) but not with that of hind-milk (21,31,32,34,40,49).

In European and North-American milk, esterase and lipase activities decrease (16,18,19,21) or remain constant (17,19, this study) during lactation. These inconsistent observations cannot be due, firstly, to the mode of sampling because the enzyme activity is independent of within-feed variation (34) or the milk volume produced (20); secondly, to the fat content of milk which does not correlate with the lipase activity (21); and, thirdly, to the assay used *i.e.*, the determination of lipase or esterase activity, because we, as well as others (19,50), have demonstrated that both activities reside in the same enzyme. It is also consistent with the fact that the same amino acids are essential for lipase and esterase activities, indicating that the same catalytic site may be involved in both activities displayed by the pure human milk bile salt-dependent lipase (7). Inhibition studies also confirmed these data (51; Fourneron *et al.*, unpublished data). Therefore, within-group variation can explain the conflicting observations.

In Zaïrian milk, bile salt-dependent esterase activity is higher during the early stages of lactation, and then decreases to less than 20% of the initial value. This decrease of bile salt-dependent lipase activity in breast milk from nonprivileged mothers is apparently not in agreement with the study of Hernell *et al.* (17) which was done with breast milk from nonprivileged Ethiopean mothers. This latter study concluded that the activity of the bile salt-dependent lipase did not depend upon the nutritional state of the mother and did not change with time. Therefore, Zaïrian milk samples were divided in two groups (1-4 months and 5-16 months *postpartum*, see Table 3) as described by Hernell *et al.* (17). Table 3 shows that i) the average amount of bile salt-dependent esterase present in the first group (1-4 months) is identical to that of the corresponding French group (Table 2), and that ii) the bile salt-dependent esterase activity as well as its activity per mg of milk protein are still significantly lower ($p < 0.01$) in the second than in the first group and than

in the corresponding milk group of privileged mothers. This shows that our results differ from those mentioned above (17) only when considering late lactation, and that the difference cannot be due to the way the groups have been defined. French and Zaïrian fore-milk samples were used here, and differences between the two studies (17), which are only observed in non-privileged milk samples for longer lactation time (>5 months), cannot be due to sample collection (*i.e.,* fore-milk *vs* mid- or hind-milk study) because no variation of the bile salt-dependent lipase activity as a function of feeding time has been reported (34). However, it is conceivable that the Zaïrian mothers living in the urban area of Bukavu were under more severe nutritional stress than the low socioeconomic Ethiopian mothers. Thus, the 80% decrease of the bile salt-dependent lipase (esterase) activity in Zaïrian milk may reduce the ability of hydrolyzing lipid-soluble vitamin esters and triglycerides in the intestine of infants breast-fed by undernourished mothers.

Despite the large number of studies concerned with breast milk composition, only a few have been devoted to changes in bile salt-dependent lipase (16-21) over time in underprivileged populations (17). The present study extends previous findings and shows that the enzyme activity is present in human breast milk at all stages of lactation, although it is found in much lower amounts in undernourished populations. Interestingly, enzymatic secretion by the pancreas is also decreased in the malnutrition state.

ACKNOWLEDGMENTS

The authors would like to thank all the mothers who kindly provided milk samples for this study. We also address our special thanks to the nurse, Lucienne (Hôpital Michel-Levy, Marseille) for milk sampling in Marseille. We thank Prof. R. Laugier (Marseille) for fruitful discussions.

Unusual Product Ratios Resulting from the Gamma-Irradiation of Cholesterol in Liposomes

G. Maerker* and **K.C. Jones**
U.S. Department of Agriculture, Eastern Regional Research Center, Agriculture Research Service, Philadelphia, Pennsylvania 19118

Cholesterol in aqueous suspensions of multilamellar vesicles (MLV) was exposed to gamma-irradiation (0.5–10 kGy) at 0–4°C. Cholesterol oxidation products resulting from the irradiation were isolated by dry column extraction followed by preparative thin-layer chromatography (TLC) and were quantitated by on-column gas chromatography (GC). The ratio of 7-ketocholesterol/cholesterol 5,6-epoxides generated by irradiation was less than one, much lower than the ratio of ten commonly produced by autoxidation. Irradiation also produced relatively higher amounts of 7-hydroxycholesterol than did autoxidation. These unique product ratios may be suitable indicators of past exposure to irradiation.
Lipids 26, 139–144 (1991).

As part of our search for a diagnostic test capable of discriminating meat and poultry that have been irradiated from those that have not, we have studied the effect of gamma-radiation on cholesterol in liposomes. The identification of irradiated foods has been the subject of worldwide interest (1–3), but until now no discriminating method suitable for animal tissue has been perfected. Much of the research effort in the identification of irradiated foods has been on the attempted characterization and measurement of unique radiolytic products, *i.e.* compounds whose formation can be attributed solely to the effect of ionizing radiation. The extent to which this effort has been unsuccessful, despite determined efforts of a worldwide community of talented scientists, is perhaps a measure of the trivial effect that low-dose ionizing radiation has on the chemical structure of food components.

The interaction of ionizing radiation with fatty acids, triglycerides and food fats has been studied intensively for more than twenty years, and much of this work has been summarized (4,5). Among the radiolytic products formed are hydrocarbons, aldehydes, lactones, ketones and other volatile products that are also characteristic of lipid oxidation such as would be experienced when lipids are temperature-abused in the presence of air. In model lipid systems containing polyunsaturated fatty acids, radiation-induced peroxidation has been observed and measured (6–8).

The effect of oxidizing conditions on cholesterol has been studied in detail (9), and current knowledge of cholesterol autoxidation has been reviewed recently (10,11). The principal product of the autoxidation of cholesterol in aqueous sodium stearate dispersions (12), in organic solvents (13) and in liposomes (14,15) is 7-ketocholesterol (3β-hydroxycholest-5-en-7-one). Other prominent products of cholesterol autoxidation include 7α- and 7β-hydroxycholesterol (cholest-5-ene-3β,7α-diol and cholest-5-ene-3β,7β-diol, respectively) and the α- and β-epoxide (cholesterol 5α,6α-epoxide and cholesterol 5β,6β-epoxide, respectively). In aqueous dispersions, the 7-ketone/5,6-epoxides ratio has typically been determined to range from six to ten, while about twice as much 7-ketocholesterol was formed as total 7-hydroxycholesterol (12,16).

The effect of ionizing radiation on cholesterol has also been examined in various systems, and it has been shown that the chemical changes produced are similar in nature to those known to occur during autoxidation (17–19). Recently, work performed in our laboratory revealed that irradiation of cholesterol in aqueous sodium stearate dispersions produced relatively less 7-ketocholesterol and relatively more 5,6-epoxides than did autoxidation of similar dispersions. Ratios of 7-ketocholesterol/5,6-epoxides resulting from irradiation were less than unity (20), while autoxidation, although at higher temperatures, gave ratios between six and ten (21). These results suggested that unique product ratios, rather than unique radiolytic products, might be useful indicators of past exposure to irradiation.

The current work was undertaken to determine whether cholesterol dispersed in the relatively hydrophobic medium of model membranes, *i.e.* liposomes, might also give unusual product ratios when exposed to low-dose ionizing radiation. Our earlier work had provided an instance in which ionizing radiation affected 7-ketocholesterol quite differently in liposomes than it did in aqueous dispersions (22). In that study, 7-ketocholesterol exposed to gamma radiation experienced 90% degradation in aqueous sodium stearate dispersion but only 10% degradation in liposomes.

EXPERIMENTAL

Materials and reagents. Cholesterol (99 + %), 6-ketocholestanol (3β-hydroxycholestan-6-one), 7-ketocholesterol (3β-hydroxycholest-5-en-7-one), cholesterol 5α,6α-epoxide and Sephadex G 50–80 were purchased from Sigma Chemical Co. (St. Louis, MO), cholesterol 5β,6β-epoxide and 7α-hydroxycholesterol (cholest-5-ene-3β,7α-diol) from Research Plus, Inc. (Bayonne, NJ), and 7β-hydroxycholesterol (cholest-5-ene-3β7β-diol) from Steraloids, Inc. (Wilton, NH). Dipalmitoyl phosphatidylcholine (DPPC) and dipalmitoyl phosphatidylglycerol (DPPG) were obtained from Avanti Polar Lipids, Inc. (Pelham, AL). Celite 545 was purchased from Fisher Scientific (Malvern, PA), and thin-layer chromatography (TLC) plates, silica gel GHL (250 μm) from Analtech, Inc. (Newark, DE). All solvents used were "distilled in glass grade," and chemicals were of reagent grade quality. Water was double-deionized, glass-distilled.

Abbreviations: DPPC, dipalmitoyl phosphatidylcholine; DPPG, dipalmitoyl phosphatidylglycerol; GC, gas chromatography; MLV, multilamellar vesicles; TLC, thin-layer chromatography.

Liposome preparation. Multilamellar vesicles (MLV) were prepared from 70.5 mg (96.0 μmoles) DPPC, 23.1 mg (32.0 μmoles) DPPG and 24.8 mg (64.0 μmoles) of cholesterol. The phospholipids and cholesterol were dissolved in 3.0 mL chloroform in a 15-mL test tube provided with a Teflon-lined screw cap, and the solution was mixed thoroughly. Solvent was removed under a stream of nitrogen while the tube was rotated at an angle, so that the lower half of the tube was coated evenly with a mixture of solids. The remaining solvent was removed until the odor of chloroform was no longer detectable. The coated lipids were hydrated with 8 mL water and allowed to swell for 3 hr in a water bath held at 55°C with vortexing every 15 min.

The liposome preparation was allowed to cool to room temperature and was filtered through a 0.4 μm pore polycarbonate membrane to insure rather uniform size distribution (23). The suspension was chromatographed on a 26 cm × 1 cm column of Sephadex G 50-80 using double deionized water as eluent. Vesicles were collected, as eluted, in a total volume of 16 mL. The batch was vortexed to insure homogeneity, and 1 mL aliquots under air were placed into 2-mL glass vials provided with Teflon-lined screw caps. Samples were refrigerated (0–4°C) overnight prior to irradiation. Phospholipid content of the vesicles was determined by measuring inorganic phosphorus according to the procedure of Eng and Noble (24).

Irradiation of cholesterol in liposomes. Duplicate 1-mL aliquots of MLV were irradiated in a ^{137}Cs source (0.118 KGy/min) at 0–4°C at dose levels of 0.5, 1.0, 2.5, 5.0, or 10.0 KGy. Controls consisted of unirradiated, refrigerated (0–4°C) samples. Controls and irradiated samples were extracted immediately after irradiation.

Autoxidation of cholesterol in liposomes. Liposome suspension (10 mL) was placed in a 50-mL screw cap test tube equipped with magnetic stirring bar. The tube was sealed with air in the headspace. The tube was suspended in a water bath kept at 45°C and stirred for 48 hr. Unoxidized aliquots were kept 0–4°C. Duplicate 1-mL portions of oxidized and unoxidized controls were analyzed.

Dry column extraction of cholesterol oxides. Anhydrous, granular sodium sulfate (4.0 g) and Celite 545 (3.0 g, previously washed with methylene chloride) were ground in a porcelain mortar, and 1 mL of a liposome preparation was applied to the powder evenly. The mixture was ground thoroughly for three minutes and transferred in small increments to a 10-mL glass syringe containing a thin pad of glass wool that had been previously washed with methylene chloride. The dry mixture was tamped firmly into the syringe with a flattened glass rod to a total volume of 6–7 mL. The mortar was rinsed with 5 mL methylene chloride, and the rinse was added to the solids in the syringe. Additional methylene chloride was added gently to the top of the column until 10 mL eluate had been collected at a flow rate of <1 mL/min. Eluates were blanketed with nitrogen and stored in the refrigerator (0–4°C) pending isolation and analysis.

Isolation of cholesterol oxidation products. Each dry column eluate was evaporated to dryness with nitrogen. The residue was reconstituted in 250 μL chloroform and the solution streaked on the middle 10 cm section of a scored 20 × 20 cm TLC plate. The plate had been prewashed with chloroform/methanol (2:1,v/v), again with ethyl acetate, and activated at 110°C. The residue container was rinsed with 150 μL chloroform and the rinse streaked over the previously applied sample. The end sections of the scored plate were spotted with 2 μL each of 7-ketocholesterol and 7α-hydroxycholesterol solution (1 mg/mL). The plate was developed with benzene/ethyl acetate (60:40,v/v) and development continued for 10 min after the solvent front had reached the top of the plate. The end sections, intended for visualization, were snapped off and sprayed with 50% sulfuric acid and heated. They were used to locate the band containing both 7-ketocholesterol and 5,6-epoxide and the 7-hydroxycholesterol band in the center section of the plate. The corresponding bands of the middle section were scraped and separately extracted with 2 × 5 mL acetone. After each extraction the samples were centrifuged to pellet the silica. The two extracts of each band were combined, filtered through a 2 μm Nylon 66 filter and evaporated to dryness under nitrogen. To each residue was added internal standard 6-ketocholestanol (4 μL, 1 μg/μL in ethyl acetate), and the solvent was removed with nitrogen. The sample was reconstituted in 100 μL ethyl acetate for gas chromatography (GC) analysis.

Determination of cholesterol content of liposomes. The sample of MLV (1 mL) was ground with anhydrous sodium sulfate (4.0 g) and Celite 545 (3.0 g) as described above. Before the ground mixture was transferred to the 10-mL syringe, the latter was provided with 1.0 g of a mixture of Celite 545/$CaHPO_4 \cdot 2H_2O$ (9:1, w/w) which was tamped securely. Addition of the dry powder containing the sample then brought the total volume in the syringe to 8–9 mL. The column was eluted with methylene chloride, and approximately 10 mL of eluate was collected. Solvent was removed under nitrogen and the sample was reconstituted in methylene chloride to 10.0 mL in a volumetric flask. An aliquot (10 μL) was transferred to a vial, internal standard 6-ketocholestanol (4 μL, 1 μg/μL in ethyl acetate) was added, the solvent was removed under nitrogen, and the residue was reconstituted in 100 μL ethyl acetate prior to GC analysis.

Gas chromatography (GC). Samples were analyzed by GC as described previously (25) with the following modifications. The column was a 0.25 mm i.d. × 30 m bonded phase 5% phenylsilicone column with 0.25 μm film thickness (Durabond 5, J & W Scientific, Folsom, CA). A retention gap was not used. For cholesterol oxide determinations, the initial column temperature of 100°C was held 2 min, then programmed at 30°C/min to 265°C, then at 0.5°C/min to 275°C where it was held for 5 min, then programmed at 5°C/min to 300°C and held for 15 min. For cholesterol determinations the program was modified by programming from 275 to 300°C at 30°C/min and holding at 300°C for only 2 min. Sample size injected in all cases was 0.6–0.8 μL.

GS response factors. Response factors of cholesterol and of the five cholesterol oxidation products of interest relative to the internal standard 6-ketocholestanol were determined by the method of Lee *et al.* (26).

RESULTS AND DISCUSSION

Various types of liposomes have been employed as model membrane systems to study the reactions of lipids, including their peroxidation (27), in environments that approach those of biological membranes. We chose to study the effect of ionizing radiation in multilamellar vesicles (MLV), because these types of liposomes are easily prepared in the quantities that we required. In the current series of experiments the MLV were composed of the fully saturated phospholipids dipalmitoyl phosphatidylcholine (DPPC) and dipalmitoyl phosphatidylglycerol (DPPG), and cholesterol. The molar ratio DPPC/DPPG/cholesterol was 3:1:2. The liposomes were formed in double deionized water, because exploratory experiments with *N*-2-hydroxyethyl piperazine-*N'*-2-ethane sulfonic acid (HEPES) buffer and with phosphate buffer had indicated objectionable interactions of the buffer with the radiation. The liposomes were formed and swelled above 41°C, the transition temperature (T_c) for both phospholipids (28).

Swelling of the proper lipid components in aqueous media above the T_c of the lipids leads to spontaneous vesiculation with the formation of liposomes (29). While liposome formation is spontaneous, it is not necessarily complete. One of the techniques used to free liposomes from non-trapped solutes is molecular sieve chromatography (27,30). Table 1 lists six experiments in which liposomes were prepared under supposedly identical conditions, including separation of unincorporated lipids on a Sephadex G 50-80 column. The data indicate that 66–77% of the added cholesterol was found incorporated in the liposomes, while 80–96% of the phospholipids added were present in the vesicles. The actual cholesterol content of the liposomes ranged from 28–32 mol%, slightly different than the intended 33 mol%. The MLV were characterized by analysis of total phosphorus content (24) and by cholesterol determination.

To determine cholesterol and its major oxides it is necessary to extract the compounds from the vesicles. Since the sterols are fairly soluble in ethyl acetate while the phospholipids are not, a simple extraction was thought to be necessary. However, repeated extractions of the liposomes with ethyl acetate revealed that cholesterol was retained by the liposomes tenaciously, so that after five consecutive extractions more than 5% of the cholesterol remained in the vesicles. Jacobsohn *et al.* (31,32) also reported retention of cholesterol in MLV containing phosphatidylcholine and suggested that the phospholipid in the aqueous phase prevents access to cholesterol by nonpolar solvents. The difficulty of quantitative extraction of sterols from foods has also been noted (33).

Extraction of cholesterol from phospholipids should be facilitated if the aqueous phase is removed first. The dry column extraction procedure (34) is designed to remove water from partly aqueous systems such as animal tissue, and seemed suitable for the dehydration of liposomes. For the purposes of the current work the procedure was modified, so that a 10-mL glass syringe

TABLE 2

Purities and GC Response Factors of Various Cholesterol Oxidation Products

Compound	Purity	Response factor[a]
Cholesterol (5-cholesten-3β-ol)	95.1	0.87
α-Epoxide (cholesterol 5α,6α-epoxide)	100.0	1.10
β-Epoxide (cholesterol 5β,6β-epoxide)	96.0	1.09
7-Ketocholesterol (3β-hydroxycholest-5-en-7-one)	96.8	1.03
6-Ketocholestanol (3β-hydroxycholestan-6-one)	94.8	1.00
7α-Hydroxycholesterol (cholest-5-ene-3β,7α-diol)	93.2	1.11
7β-Hydroxycholesterol (cholest-5-ene-3β,7β-diol)	97.1	1.11

[a]Relative to 6-ketocholestanol.

could serve as the extraction column. Since cholesterol was the only neutral lipid in the liposomes, methylene chloride was a suitable solvent for its extraction. Elution with 10 mL of this solvent gave complete recovery of cholesterol, as judged by TLC. Unfortunately, however, small but significant amounts of phospholipids co-eluted. The latter compounds are not volatile in our GC procedure and constituted a potential contaminant for our capillary column.

Three procedures were investigated to overcome this difficulty. Reduction of the methylene chloride eluate in volume followed by preparative TLC gave a discrete cholesterol band, well resolved from the phospholipid band which remained at the origin. Extraction of the scraped cholesterol band with acetone led to a clean GC trace of cholesterol suitable for quantitation. This procedure was rather tedious and sometimes gave erratic recoveries. In an alternative procedure, 1-mL aliquots of liposome suspensions were saponified in a modification of the procedure of Slover *et al.* (35), which was effective in destroying phospholipids and hence made extraction of cholesterol feasible. In our hands this technique lacked reproducibility and was time-consuming, and hence was abandoned. Finally, the dry column procedure was modified by insertion of a Celite/$CaHPO_4$ trap (see Experimental) to minimize elution of the phospholipids. The technique gave 86% recoveries when applied to liposome suspensions containing known amounts of cholesterol, *i.e.* vesicles that were allowed to swell but were not filtered or passed through molecular sieves. The cholesterol values listed in Table 1 were determined by this method but were not adjusted to compensate for the 14% loss mentioned above.

Recovery and measurement of cholesterol oxidation products from irradiated liposomes was also carried out with use of the dry column procedure (no trap) followed by preparative TLC. To test the procedure, liposomes were prepared that, in addition to the usual components, also contained known amounts of 7-ketocholesterol (9.7 μg/mL of suspension), the two isomeric 5,6-epoxides (31.6 μg/mL) and the two isomeric 7-hydroxycholesterols (31.3 μg/mL). The vesicles were swelled but not filtered or passed through the Sephadex column to avoid losses of compounds that had failed to be incorporated into the MLV. Recovery of 7-ketocholesterol (92.9%) and 7-hydroxycholesterols (91.8%) validated the procedure. The two 5,6-epoxides, however, were unstable to the vesicle swelling conditions (55°C, pH 6.4) and were largely converted to 5α-cholestane-3β,5,6β-triol, as expected from a previous study (36). The triol was incompletely resolved from the phospholipids by TLC and was recovered only partially. Total recovery of 5,6-epoxides and triol was 63.4%.

Purities of standard compounds as determined by GC and GC response factors relative to the internal standard are shown in Table 2. The response factors were used in calculating the data reported in Table 3. The low response factor of cholesterol may be a function of its lower-than-expected purity.

Table 3 lists the ratios of 7-ketocholesterol/5,6-epoxides generated as a result of exposure of cholesterol in MLV to ionizing radiation at 0–4°C. The ratios of all irradiated samples are less than unity, and actu-

ally <0.35 in most experiments. The reason for the slight increase in the ratio at higher doses in some experiments requires further investigation. The unirradiated vesicles contained a somewhat higher ratio of 7-ketone/5,6-epoxide as would be expected, since these oxidation products were formed during the liposome swelling process in the presence of air, rather than by means of ionizing radiation. In addition it should be noted that the levels of 7-ketone and 5,6-epoxides in the unirradiated samples are very low, so that a greater amount of uncertainty is involved in their quantification. Irradiation, even at the low dose of 0.5 kGy, increases the amounts of cholesterol oxidation products greatly, so that these compounds can be measured at this dose with good precision.

The ratios of 7-ketone/5,6-epoxides produced by exposure of cholesterol to γ-radiation in the presence of air can best be understood by comparing them to the ratios of the same products, *i.e.* 6–10 (see introduction) generated by the principal alternative free radical reaction, autoxidation. It is apparent that the ratios that are now seen to result from irradiation, *i.e.* <1.0, are quite different from those generated by autoxidation. Hence in the current work concerning cholesterol in saturated liposomes the signature of the irradiation process is unique and easily distinguishable from the principal competing process, autoxidation.

In order to determine whether the higher 7-ketone/5,6-epoxides ratio holds for the autoxidation of cholesterol in saturated liposomes, a suspension of such vesicles was exposed to air oxidation at 45°C for 48 hr and the products were isolated. About 20% of the cholesterol oxidized during that period and the experimental 7-ketone/5,6-epoxide ratio was 10.6 ± 3.0.

It has been reported (37) that γ-irradiation of dispersions of cholesterol gave rise to a distinctly different ratio of 5α,6α-epoxide/5β,6β-epoxide, *i.e.* 3.5, than that obtained by autoxidation (~0.1). If confirmed, the α/β-epoxide ratio might also be a useful marker to distinguish irradiated from autoxidized cholesterol. In our earlier study of the irradiation of cholesterol in aqueous dispersions, we reported α/β-epoxide ratios of less than one, usually 0.3–0.4. In the current work the irradiation of cholesterol in liposomes gave an α/β-epoxide ratio of 0.2–0.3 consistently. It must be concluded that this ratio cannot be used as evidence for past irradiation.

Table 3 contains a list of the ratios of 7-ketocholesterol/7-hydroxycholesterols obtained when cholesterol in MLV was irradiated at 0–4°C with 0.5 to 10.0 kGy of γ-radiation. With the exception of two values at 0.5 kGy, all of the ratios are less than unity and most of them are less than 0.5. In calculating the values of Table 3, the 7α- and 7β-hydroxycholesterols, determined individually, but not always resolved completely, have been added.

Again it is useful to compare the ratios of Table 3 with those reported to have been produced by autoxidation. In aqueous dispersions, autoxidation of cholesterol produced about twice as much 7-ketocholesterol as 7-hydroxycholesterol (11,12,16,21), while uncatalyzed autoxidation of cholesterol in liposomes has been reported to give a ratio of about 1.5 (19). In the current work, autoxidation of cholesterol in liposomes gave a 7-ketone/7-hydroxycholesterol ratio of 3.4 ± 0.6. It is apparent, then, that the difference in this ratio between irradiated and autoxidized cholesterol is not as clear-cut as it is for the 7-ketocholesterol/5,6-epoxide ratio. Nevertheless, the two ratios taken together may serve as strong evidence of past irradiation.

Finally, there is the matter of the total amounts of measured cholesterol oxidation products. These include 7-ketocholesterol, the isomeric 5,6-epoxides, and the isomeric 7-hydroxycholesterols. Their sums are shown in Table 3. The level of oxidation products in the unirradiated samples is quite low. In a previous study (20), an aqueous dispersion of cholesterol was subjected to a flow of air at 0–4°C for two weeks without a detectable increase in cholesterol oxidation.

The amounts of cholesterol oxidation products increase dramatically with radiation dose, but the increase does not appear to be linear. As can be seen from Table 3, we experienced some difficulties in experiment-to-experiment reproducibility of the amounts, but not of the ratios, of cholesterol oxides. This in spite of exhaustive, detailed studies of the variables of each step of the procedure. Our investigations along these lines are continuing.

This research has clearly demonstrated that γ-irradiation of cholesterol, contained in MLV prepared from saturated phospholipids, leads to ratios of oxidation products that are substantially different from those generated by autoxidation. New procedures for isolating and measuring cholesterol and its oxidation products in aqueous liposome suspensions have been developed in the course of these studies and are reported here. Further research is in progress to identify and to define reaction parameters.

Several structural analogs of alkylphosphocholine (APC) were studied for their effects on protein kinase C (PKC) and 12-*O*-tetradecanoylphorbol-13-acetate (TPA) elicited biochemical and cellular events in HL60 cells. Hexadecylphosphocholine (He-PC_2), the APC prototype, inhibited PKC competitively with respect to phosphatidylserine and noncompetitively with respect to $CaCl_2$, both with an apparent K_i of about 15 μM. Inhibition of PKC by He-PC_2 was selective, since cyclic AMP dependent protein kinase and Ca^{2+}/calmodulin dependent protein kinase II were relatively unaffected. He-PC_2 inhibited TPA-induced depletion of PKC and TPA-stimulated phosphorylation of cellular proteins in HL60 cells. TPA-induced differentiation of HL60 cells was also inhibited by He-PC_2, and this inhibition was synergistic or additive to the effects of 1-(5-isoquinolinesulfonyl)-2-methylpiperazine (H-7), a PKC inhibitor. The present findings are consistent with the hypothesis that inhibition of PKC might be related, in part, to the antineoplastic effect of He-PC_2 and ether lipid analogs such as ET-18-OCH_3 (1-octadecyl-2-methyl-glycero-3-phosphocholine).

Lipids 26, 145–149 (1991).

Alkyllysophospholipids (ALP) are analogs of the cell membrane component 2-lysophosphatidylcholine, and represent a new class of antitumor agents (1). ET-18-OCH_3 (*rac*-1-*O*-octadecyl-2-*O*-methyl-glycero-3-phosphocholine), the ALP prototype, has been found to be cytotoxic to human leukemic cells (2,3) and solid tumors (4,5) *in vitro*, and is effective in purging murine leukemic cells from remission simulated bone marrow for autologous bone marrow transplantation (6) and treatment of experimental rat tumors (7,8). Recently, a TLP (thioether analog of ALP) derivative BM 41.440 (3-hexadecylmercapto-2-methoxymethyl-propylphosphocholine) has been shown to possess antineoplastic activity against a variety of leukemias and solid tumors (9,10). Both ET-18-OCH_3 and BM 41.440 are currently undergoing clinical trials (11,12), and the former is being used to purge leukemic cells from remission marrows (13). These compounds have different mechanisms of action than the conventional chemotherapeutic drugs. Several modes of action have been postulated to account for their biologic effects. These include enhancement of the cytotoxic properties of macrophages (1,7,14), alterations of phospholipid metabolism (15), and inhibition of protein kinase C (PKC) (16) and Na,K-adenosinetriphosphatase (ATPase) (sodium pump) (17,18). More recently, another subclass of antineoplastic agents, APC (alkylphosphocholine), has been developed (19). One of the agents, hexadecylphosphocholine (He-PC_2), has been shown in a recent clinical trial to be active topically against locally recurring breast cancer skin metastases without serious side effects on patients (20). In the present study, we investigated the effects of various APC analogs on the PKC system and 12-*O*-tetradecanoylphorbol-13-acetate (TPA)-induced differentiation of HL60 cells. We found that He-PC_2 inhibited PKC and TPA-induced differentiation of HL60 cells and protein phosphorylation in the leukemia cells.

MATERIALS AND METHODS

Materials. RPMI-1640 medium, fetal bovine serum, penicillin/streptomycin solution (× 100), L-glutamine (200 mM), trypsin/ethylenediaminetetraacetic acid (EDTA) solution (× 10) were obtained from GIBCO (Grand Island, NY); TPA was from L.C. Services Corp. (Woburn, MA); dimethylsulfoxide, phosphatidylserine (PS)—(bovine brain), histone H1 (type III-S), PMSF and H-7 were from Sigma Chemicals (St. Louis, MO); ET-18-OCH_3 was from Medmark Chemicals (Grünwald bei München, FRG); APC analogs were synthesized as described (21); ampholytes (pH ranges of 4–6, 4–7 and 3–10) were from LKB (Gaithersburg, MD) and Serva Biochemicals (Westburg, NY).

Cell culture and cell differentiation. HL60 and K562 leukemic cells were cultured in RPMI-1640 medium supplemented with 10% fetal bovine serum (heat-inactivated), L-glutamine (2 mM), and penicillin G (100 units/mL), and streptomycin (100 μg/mL) in a humidified incubator at 37°C in 95% air/5% CO_2. The cells at mid-log phase were harvested and used in all experiments reported herein. The TPA-induced differentiation toward the macrophage pathway was determined by cell adherence after treatment of cells with 10 nM TPA for 48 hr in the presence or absence of various PKC inhibitors. The adherent cells were washed once

with RPMI-1640 medium and resuspended by incubating with trypsin-EDTA solution (0.5 mL) for about 20 min. An equal volume (0.5 mL/well) of 20% fetal bovine serum in the RPMI-1640 medium was then added to each well in order to block the activity of trypsin, and cells were transferred to tubes. Each well was washed once with 1 mL of 10% fetal bovine serum in RPMI-1640 medium. Aliquots (200 μL) of cell suspension were counted for cell number using a Coulter counter, and viability was determined by trypan blue dye exclusion.

PKC preparation and assay. PKC was purified from pig brain extracts through the phenyl sepharose step (22). PKC was assayed under the standard conditions as described elsewhere (23). Briefly, the reaction mixture (0.2 mL) contained 5 μmol of piperazine-*N,N'*-*bis*(2-ethanesulfonic acid) (pH 6.5), 2 μmol of $MgCl_2$, 2 μg of PS, 40 μg of histone HI, 0.06 μmol of ethyleneglycol-*bis*-(β-aminoethyl ether) *N,N,N',N'*-tetraacetic acid (EGTA), with or without 0.1 μmol of $CaCl_2$, 1.0 nmol of [γ-^{32}P]ATP (containing about 1×10^6 cpm), and various kinds and concentrations of agents, as indicated. When present, the final concentration of $CaCl_2$ was 200 μM (in excess of 300 μM EGTA). The reaction was carried out at 30°C for 5 min.

Endogenous protein phosphorylation. Phosphorylation of endogenous proteins in intact HL60 cells and the subsequent two-dimensional gel electrophoresis and autoradiography of phosphoproteins were carried out as described (24), with a few modifications. Ampholyte mixtures used for isoelectric focusing gels consisted of 67% of pH 4-6, 16% of pH 5-7 and 17% of pH 3-10. Separation gels contained 8% acrylamide and 0.1% sodium dodecyl sulfate.

Other methods. A-PK (25) and CaM-PK-II (26) were purified and assayed as described. [γ-^{32}P]ATP was prepared by the method of Post and Sen (27).

RESULTS

The structures of APC analogs are shown in Figure 1. All compounds inhibited PKC, with IC_{50} values of about 15-20 μM (Fig. 2). By contrast, hexadecylphosphoserine (He-PS) was inactive, indicating that the phosphoserine group cannot substitute for phosphocholine. The data on the structure-activity relationship of the APC analogs further illustrated that neither the distance (2 to 6 carbons) between the negatively charged phosphate group and the positively charged ammonium group (*e.g.* He-PC_2 and He-PC_6), nor the deletion of the oxygen at either side of the phosphoric acid moiety (*i.e.* in He-P-O-C_2 and He-O-P-C_2) was critically important for activity. The IC_{50} of 10 μM observed for the ALP prototype ET-18-OCH_3 (Fig. 2) was the same as previously reported (16). Kinetic analysis indicated that He-PC_2 inhibited PKC competitively with respect to PS, with an apparent K_i value of 15 μM (Fig. 3), but it inhibited the enzyme noncompetitively with respect to $CaCl_2$, with a similar K_i value (data not shown). These findings on the inhibition mechanism of He-PC_2 were in good agreement with those reported previously for the glycerophospholipid analogs ET-18-OCH_3 (16) and BM 41.440 (23), consistent with the notion that He-PC_2 also likely inter-

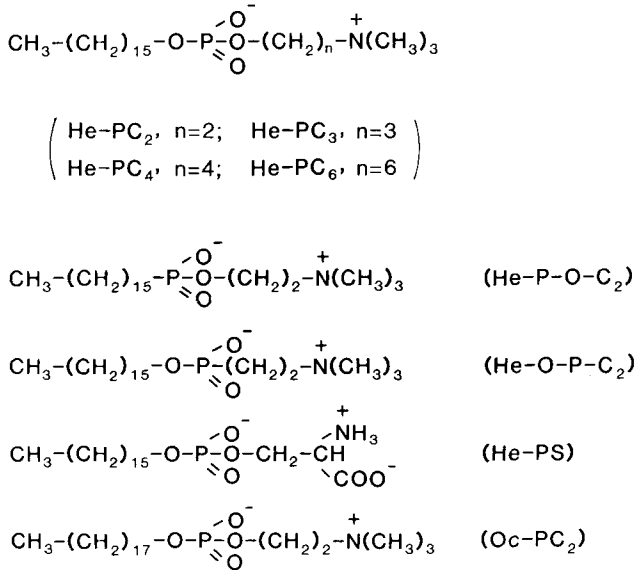

FIG. 1. Structure of alkylphosphocholines and analogues.

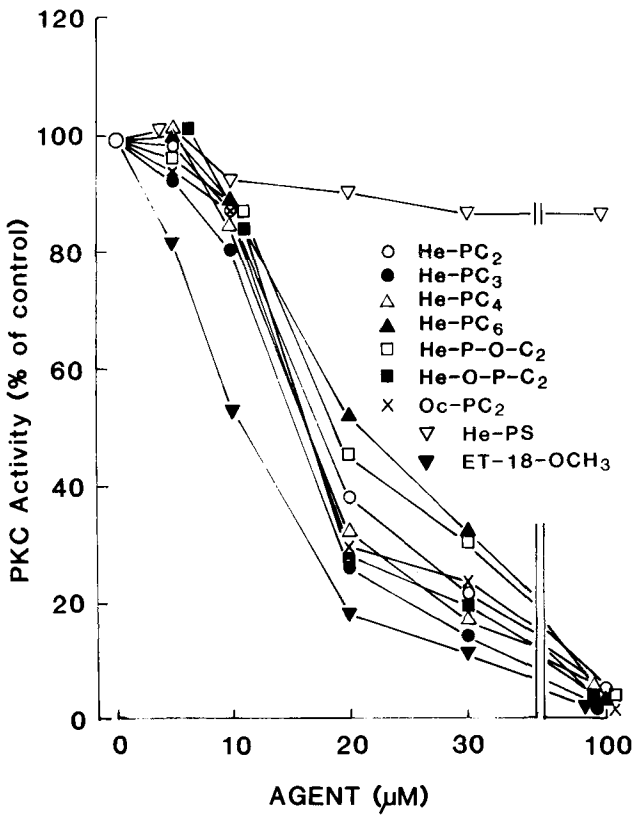

FIG. 2. Inhibition of PKC by alkylphosphocholine analogues compared with ET-18-OCH_3. The enzyme was assayed essentially as described previously (23) but in the presence or absence of the agents, as indicated. The agents were dissolved in water and added directly to the incubation mixture without presonicating with PS. The control enzyme activity obtained in the absence of the agent (18.4 pmol P transferred/min) was taken as 100%.

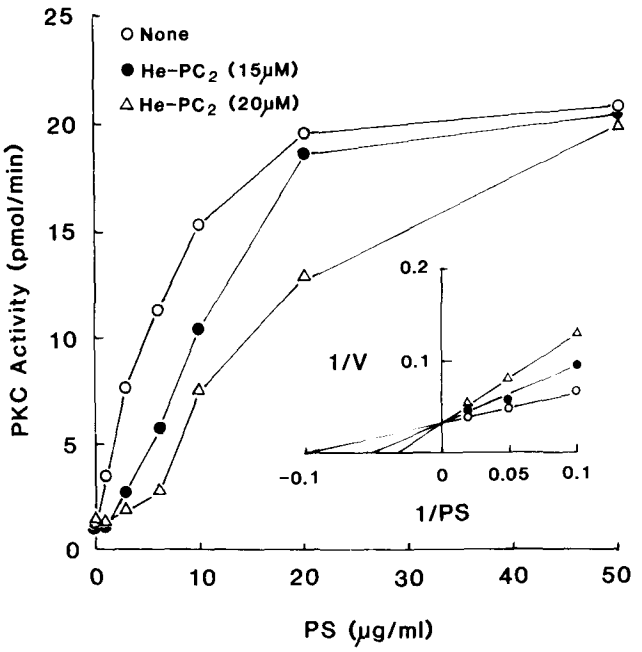

FIG. 3. Inhibition of PKC by He-PC_2 as a function of PS concentration. The enzyme was assayed under the standard condition except for various concentrations of PS and the agent, as indicated. The double-reciprocal plots of the data are shown in the inset.

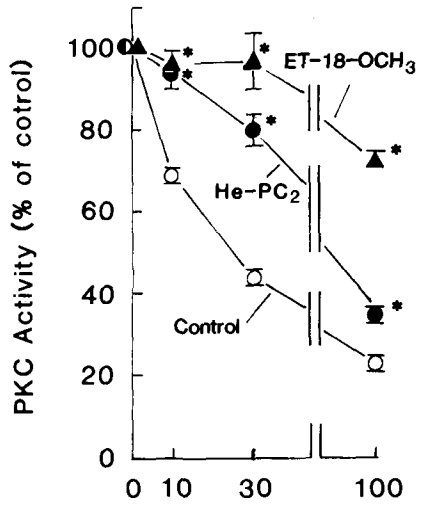

FIG. 4. Comparative effects of He-PC_2 and ET-18-OCH_3 on the TPA-induced depletion of PKC in HL60 cells. Cells were incubated with or without 40 μM of He-PC_2 or ET-18-OCH_3 for 1 hr, followed by incubation with various concentrations of TPA for 20 min, as indicated. Enzyme activity in the soluble fraction (1 μg of protein) was assayed under standard conditions. The enzyme activity levels seen in cells treated with 0.1% of DMSO (solvent control) were taken as 100% in all cases. The asterisk signifies a difference from the respective control ($p<0.05$). Similar results were obtained in three other experiments.

TABLE 1

Selective Inhibition of PKC by APC Analogs and ET-18-OCH_3[a]

Inhibitor	Inhibition (%) of PKC	CaM-PK-II	A-PK
APC (30 μM)	65–85[b]	12[c]	0–10[b]
ET-18-OCH_3 (20 μM)	80	10	8

[a]The data presented are means of triplicate incubations, with assay errors being less than 5%.
[b]Values obtained for He-PC_2, He-PC_3, He-PC_4, He-PC_6, He-P-O-C_2, He-O-P-C_2 and Oc-PC_2.
[c]Value obtained only for He-PC_2.

acted with site(s) on PKC shared by PS but not by Ca^{2+}.

Selective inhibition of PKC by APC analogs and ET-18-OCH_3 was substantiated by the findings that these agents, at concentrations that inhibited PKC up to 85%, had little or no effect on other classes of protein kinases, such as cAMP dependent protein kinase (A-PK) and Ca^{2+}/calmoduline dependent protein kinase II (CaM-PK-II) (Table 1).

We previously reported that TPA caused PKC translocation from the cytoplasm to the plasma membrane and the subsequent depletion of the cytoplasmic enzyme in HL60 (28) and KG-1 cells (29). The present study showed that He-PC_2 partially blocked the TPA-induced depletion of the cytoplasmic enzyme in HL60 cells (Fig. 4). ET-18-OCH_3 was more effective (Fig. 4) whereas He-PC_6 was less effective than He-PC_2 (data not shown) in this respect, in agreement with their relative potency in inhibiting PKC as shown in Figure 2 above. Exposure of HL60 cells to TPA resulted in an enhanced phosphorylation of a number of cellular proteins, notably those in block I (pI of 5.45–5.65; M_r of 60,000–67,000) (Fig. 5). He-PC_2 at 40 and 60 μM inhibited, to different degrees, the TPA-stimulated phosphorylation of these proteins, similar to the effects reported previously for ET-18-OCH_3 (24).

The TPA-induced differentiation of HL60 (28,30) and KG-1 cells (29,31) has been shown to be PKC-dependent, consistent with the findings that PKC inhibitors ET-18-OCH_3 (24), BM 41.440 (23) and H-7 (32,33) blocked this process. Because H-7 inhibited PKC by interacting with the ATP-binding sites (34) whereas the lipid analogs did so by interacting with PS-binding sites on PKC (16,23), it was of interest to examine the effects of these agents, having different mechanisms of action on HL60 cell differentiation, when they were used in various combinations. We found that the combined effects of the agents were either synergistic or additive, depending upon the types of the inhibitors and their concentrations used. Thus, 10 or 20 μM H-7 and 3 μM He-PC_2, while without significant effect on the TPA-induced differentiation when present alone, acted synergistically to decrease the differentiating cell population from a control value of

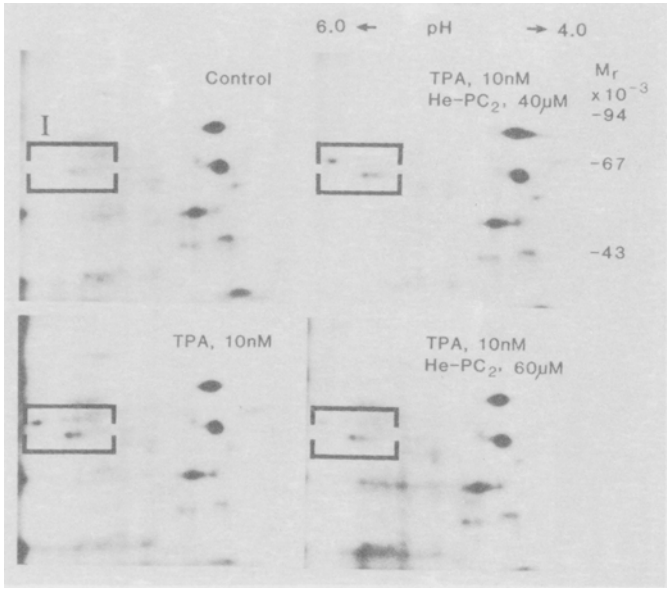

FIG. 5. Effect of He-PC_2 on protein phosphorylation in HL60 cells stimulated by 10 nM TPA. Cells were labeled with $^{32}P_i$ in the phosphate-free medium for the total of 4 hr. He-PC_2 was added to the cells in the final 1 hr, whereas TPA was added in the final 15 min of the labeling period. Other experimental details were as described under Materials and Methods and in Reference 24. Similar results were obtained in two other experiments.

78–86% to 42 and 32%, respectively (Table 2). Only a simple additive effect, however, was observed when a higher concentration (10 μM) of He-PC_2 (showing a marked inhibition by itself) was used in combination with 10 or 20 μM H-7. It was also observed that 1 μM ET-18-OCH_3, which decreased cell differentiation from 88 to 52%, decreased it further to 42% in the presence of 10 μM H-7 (Table 2). In separate experiments, He-PC_2 concentration up to 50 μM did not cause rounding up or detachment of the TPA-induced adherent HL60 cells in 1 hr (data not shown), indicating that its effects on HL60 cells were not likely due to a non-specific detergent-like activity of the agent.

DISCUSSION

In the present study the APC prototype He-PC_2 was found to be nearly as active as ALP (*e.g.* ET-18-O'CH_3) in all parameters studied. These include inhibition of PKC and various TPA-mediated events in HL60 cells (*i.e.* PKC down-regulation, cellular protein phosphorylation and differentiation to become macrophage-like cells). He-PC_2, again as ET-18-OCH_3, inhibited PKC by a similar mechanism and preferentially inhibited PKC over other classes of protein kinases. In addition, He-PC_2, like ET-18-OCH_3 and the TLP analog BM 41.440, has been shown to possess antineoplastic activity (19,20,35), displayed a greater cytotoxic effect toward

TABLE 2

Comparative Inhibition of TPA-Induced Differentiation of HL60 Cells by H-7, ET-18-OCH_3 or He-PC_2, Present Singly or in Combination[a]

[e]Significantly different from 7) ($p<0.01$).

leukemia HL60 line compared to K562 line (35,36), and similarly inhibited synaptosomal Na,K-ATPase (17,18) and sodium pump in HL60 cells (18). This strongly indicated that He-PC_2, a simple alkylphosphocholine lacking the usual glycerol backbone present in other ALP analogs, might have the minimal structural requirement essential for the general biological activities demonstrated for this group of membrane-active agents.

The selective cytotoxicity of He-PC_2 for HL60 and K562 cell lines (35,36) probably was not due to differences in uptake and intracellular distribution of the agent because we observed that the rate and extent of uptake of [^{3}H]He-PC_2 and its distribution in certain subcellular fractions (cytosol and crude membranes) of the two cell lines were practically the same (data not shown). Similar results on He-PC_2 uptake by the two cell lines have been recently reported (37). Because PKC inhibition is a common effect for He-PC_2 and ether lipid analogs, a basis for their cellular effects would likely reside on specific substrate proteins for PKC shown to be present, for example, in HL60 and K562 cells (24). Identification of functional properties of these cellular proteins would yield new insights into the mechanisms underlying the selective toxicity (or lack of it) of the drugs on various neoplastic cells lines.

Acyl-CoA:Cholesterol Acyltransferase Activity in the Rat Mammary Gland: Variation During Pregnancy and Lactation

J.H. Shand and D.W. West*
Hannah Research Institute, Ayr, KA6 5HL, Scotland

Cholesterol esterification by acyl-CoA:cholesterol acyltransferase (ACAT; EC 2.3.1.26) has been studied in microsomes isolated from the mammary glands of rats in late pregnancy, in early and mid-lactation, and following premature weaning. The mammary glands were freeze-clamped and the microsomes prepared in the presence of phosphatase inhibitors to preserve the phosphorylation status of the enzyme. Optimal conditions were established for the assay of enzyme activity in the presence of endogenous cholesterol. Supplementation of the microsomes with exogenous cholesterol as a dispersion in Triton WR-1339 was shown to lead to an increase in enzyme activity. Incubation of microsomes with MgATP led to an increase in ACAT activity which could be reversed by treatment of the microsomes with a phosphoprotein phosphatase preparation from rat liver. The results suggested that ACAT activity in the mammary gland was activated by phosphorylation in a similar way to that observed for the hepatic enzyme. The mammary glands from pregnant animals contained a higher level of ACAT activity than did the glands of the lactating animals and this correlated with the higher cholesteryl ester content of the pregnant glands. The highest level of ACAT activity was found in the weaned animals but the cholesteryl ester content of the microsomes was lower than expected. The influence of progesterone levels and changes in feeding patterns during gestation were considered as factors in these variations in ACAT activity.
***Lipids 26*, 150–154 (1991).**

Many cells respond to an increased uptake of cholesterol by esterifying it with fatty acids, a reaction catalyzed by the microsomal enzyme acyl-CoA:cholesterol acyltransferase (ACAT; EC 2.3.1.26) (1,2). Storage of the sterol in this form is an important part of the overall regulation of cholesterol metabolism. However, in recent years experimental work on the cellular metabolism of cholesterol has emphasized the importance of cholesterol esters in steroid hormone and lipoprotein synthesis, and in the regulation of cholesterol synthesis, rather than merely as a storage depot (3–5). ACAT activity has been shown to exist in the lactating rat mammary gland (6) and since a considerable amount of cholesterol is taken up by the gland during lactation (7) cholesteryl esters may be involved in cholesterol metabolism within the gland. However, ACAT activity in the lactating gland is low when compared with that present in the liver and adrenal cortex, two tissues with very active cholesterol metabolism. This low level of ACAT activity has been assumed to reflect the generally low level of cholesteryl ester found in the milk of most species. Nevertheless, recent studies (8,9) have indicated that milk obtained from the pregnant gland has an elevated cholesteryl ester content when compared with post-partum milk. This finding prompted us to investigate the activity of ACAT in the rat mammary gland before and during lactation to ascertain whether the ester content of the gland correlated with the activity of the cholesterol esterifying enzyme during these developmental changes.

In addition, since studies of ACAT activity in other tissues have suggested (4,10,11) that the activity of this enzyme could be regulated by a phosphorylation-dephosphorylation mechanism we have investigated the effect of such modifications on ACAT activity in the mammary gland.

MATERIALS AND METHODS

Materials. Cholesteryl [1-^{14}C]oleate (1.85–2.22 GBq/mmol) and [9,10-^{3}H]oleic acid (74–370 GBq/mmol) were purchased from Amersham International (Amersham, U.K.). [9,10-^{3}H]Oleoyl-CoA was synthesized from [9,10-^{3}H]oleic acid and coenzyme-A by the method of Goldman and Vagelos (12), yielding a product with specific activity of between 3.5 and 3.7 GBq/mmol. Intestinal alkaline phosphatase (EC 3.1.3.1., 1095 units/mg protein), cholesterol, cholesteryl oleate, coenzyme-A, dithiothreitol, oleoyl-CoA and Triton WR-1339 (tyloxapol) were obtained from Sigma Chemical Co. (Poole, Dorset, U.K.). Fatty acid-free bovine serum albumin was from Miles Scientific (Stoke Poges, U.K.). and was dialyzed before use. Protein phosphatase was partially purified from rat liver by the method described for sheep liver (13) and had 38 units/mL of activity when assayed by inactivation of phosphorylase a.

Preparation of microsomes. Female Wistar rats were kept on a constant light cycle (lights on 08:00–20:00) and were sacrificed at 14:30. The animals used were 18–19 days pregnant (late pregnant), 2 days post-partum (early-lactating) and 10–14 days post-partum (mid-lactating) and prematurely weaned (pups removed at day 10–12 post-partum and animals used 2 days later). They were anaesthetized (pentobarbital; 80 mg/Kg) and the abdominal mammary glands dissected free from the skin and abdominal wall before being rapidly freeze-clamped with tongs pre-cooled in liquid nitrogen. The glands were crushed at liquid nitrogen temperature and approximately 2 g were homogenized (Polytron, PMA20N probe, 17000 rpm, 30 sec) in 5 volumes of an ice-cold medium consisting of 250 mM sucrose, 100 mM KF, 1 mM EDTA and 50 mM KH_2PO_4 buffer, pH 7.1. The homogenate was centrifuged (10,000 × *g*,

*To whom correspondence should be addressed.

Abbreviations: ACAT, acyl-CoA:cholesterol acyltransferase; TLC, thin-layer chromatography; VLDL, very low density lipoproteins.

15 min), the pellet discarded and the supernatant split into two equal portions before being re-centrifuged for 30 min at 100,000 × *g*. One of the resulting pellets was resuspended in a medium containing 50 mM Tris, 50 mM MES, pH 7.1, 100 mM KF, 50 mM KCl and 7.5 mM glutathione, while the other was resuspended in a similar medium in which the KF had been replaced by an equimolar concentration of KCl. Both suspensions were centrifuged at 100,000 × *g* for 30 min and the resultant microsomal pellets resuspended at a concentration of 7 mg/mL in the appropriate resuspension medium containing either KF ("fluoride" microsomes) or KCl ("fluoride-free" microsomes). A portion of freeze-clamped gland was also homogenized in medium containing 50 mM Tris, 50 mM MES and 100 mM KCl before centrifugation (100,000 × *g* 30 min) to provide a "fluoride-free" cytosolic fraction. The cholesterol and cholesteryl ester content of the microsomes was determined by the procedure given by Gamble *et al.* (14). DNA content was determined according to the method of Labarca and Paigen (15) and protein as described by Bradford (16) with bovine serum albumin as standard.

Assay of ACAT activity. ACAT activity was measured both utilizing the cholesterol endogenous to the microsomes and in the presence of exogenous cholesterol (250 μg/mL) added as a dispersion in Triton WR-1339 (17). The reaction mixture contained 2 mM dithiothreitol, 50 mM KH_2PO_4 buffer (pH 7.1), 60 mM KCl, 175 μg microsomal protein, 100 μM [9,10-^{3}H]oleoyl-CoA (20 nmol; 2 × 10^6 dpm), 110 μM bovine serum albumin and a mixture of phosphatase inhibitors (10 mM KF, 10 mM Na pyrophosphate, and 0.2 mM Na orthovanadate), in a total volume of 200 μL. After pre-incubation (20 min at 37°C) the reaction was initiated by the addition of radiolabeled oleoyl-CoA (10 μL) and terminated after 20 min (3 min for microsomes from weaned animals) by the addition of methanol/water (3:2, v/v; 1.8 mL) followed by cholesteryl [1-^{14}C]oleate (500 dpm, 0.25 mg) as internal standard. The mixture was extracted by standard methods (18) and the labelled cholesteryl oleate separated by thin-layer chromatography (TLC). Incubations were performed in triplicate and loses during extraction and TLC were estimated from the recovery of the internal standard. Blank incubations without microsomes were incubated concurrently to assess non-enzymatic breakdown of the substrate.

Modulation of microsomal ACAT activity. Microsomes (fluoride-free, 75–150 μg) were preincubated at 37°C for 30 min with ATP (4 mM) with or without $MgCl_2$ (1 mM), 100,000 × *g* supernatant (fluoride-free) and KF (40 mM). Alternatively, the microsomes were preincubated for 10 min with a partially-purified preparation of rat liver phosphoprotein phosphatase or purified intestinal alkaline phosphatase. ACAT activity in the microsomes was then assayed in the presence of exogenous cholesterol.

RESULTS

Assay conditions. Initial experiments indicated that with microsomes prepared from mammary glands at mid-lactation the formation of cholesteryl ester correlated directly with increasing substrate concentration up to 100 μM provided that the molar ratio of bovine serum albumin to oleoyl-CoA was 1 or more (Fig. 1). At 100 μM oleoyl-CoA with a slight molar excess of albumin the rate of incorporation of substrate was linear with respect to both microsomal protein (up to 200 μg) and time of incubation (up to 40 min). Addition of cholesterol as a dispersion in Triton WR-1339 markedly increased ACAT activity although the detergent alone inhibited the enzyme (Fig. 2). Inclusion of high levels of KF in the assay inhibited ACAT activity but inhibition was not observed in the presence of 10 mM KF, 10 mM Na pyrophosphate, 0.2 mM Na orthovanadate or a com-

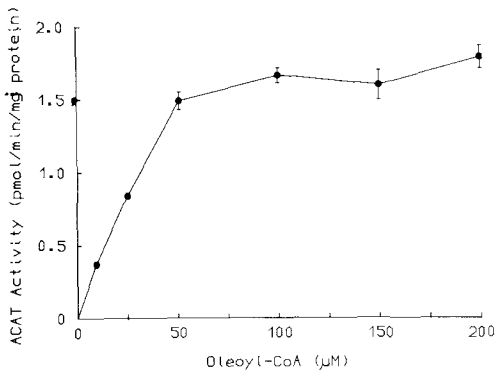

FIG. 1. The effect of the concentration of oleoyl-CoA on the yield of esterified cholesterol. Results were obtained by the appropriate variations of the oleoyl-CoA concentration in the presence of 110 μM bovine serum albumin and 175 μg microsomal protein (fluoride-free). Incubation time, 20 min. Other incubation details are listed in Materials and Methods. Data are the mean ± SEM of triplicate incubations corrected in each case for a blank value obtained in the absence of microsomes.

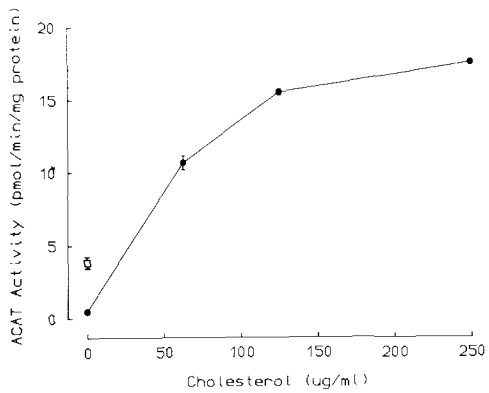

FIG. 2. The variation in microsomal ACAT activity with exogenous cholesterol. The cholesterol was added as a dispersion in Triton WR-1339 (0.3% w/v, final concentration). Microsomes (fluoride-free, 175 μg) were pre-incubated with the cholesterol-detergent suspension for 30 min under standard assay conditions. Reaction was initiated by the addition of labeled oleoyl-CoA and was terminated after 20 min. The results are the means ± SEM of triplicate incubations. The values obtained in the absence of Triton are indicated (□).

TABLE 1

Influence of MgATP on Mammary ACAT Activity[a]

Additions	Cholesteryl oleate formed (pmol/min/mg protein)
1. None	62.45 ± 2.35
2. ATP (4 mM)	85.02 ± 3.29
3. 2 + 100,000 × *g* supernatant (300 μg protein)	87.77 ± 4.65
4. 3 + KF (40 mM)	92.81 ± 0.57
5. 4 + $MgCl_2$ (1 mM)	117.19 ± 2.35
6. 5 + Phenylboronic acid (0.4 mM)	116.19

[a]Microsomes (fluoride-free, 120 μg) from weaned mammary glands were preincubated for 30 min at 37°C with the additions shown. The ACAT activity of the treated microsomes was then determined over 3 min in the presence of exogenous cholesterol and a mixture of phosphatase inhibitors (10 mM KF, 10 mM Na pyrophosphate, 0.2 mM Na orthovanadate and 1 mM EDTA). The results are the mean ± SEM of three different microsome preparations.

TABLE 2

Activation and Reversal of ACAT in Mammary Microsomes[a]

Treatment[b]	Cholesteryl oleate formed (pmol/min/mg protein)	
	Mid-lactation	Weaned
1	9.31 ± 0.49	78.54 ± 2.85
2	12.43 ± 0.25	108.49 ± 1.83
3	7.56 ± 0.43	82.65 ± 3.39
4	8.89 ± 0.17	78.20
5	Not determined	77.20

[a]Microsomes (fluoride-free) from weaned mammary glands were incubated at 37°C under a number of conditions[b] (shown below) before being assayed for ACAT. Enzyme activity was measured over 20 min (mid-lactators) or 3 min (weaned) in the presence of exogenous cholesterol in assays equalized with regard to the concentration of phosphatase inhibitors. Where indicated the results shown are the mean ± SEM for three microsomal preparations.

[b]Treatments: 1. Control microsomes were incubated for 30 min in buffer mixture without additions, recovered by centrifugation (100,000 × *g*, 30 min) and then incubated for an additional 30 min. 2. Microsomes (1.13 mg) were incubated with ATP (4 mM), $MgCl_2$ (1 mM), KF (50 mM) and 100,000 × *g* supernatant (fluoride-free, 2.7 mg protein) for 30 min before recovery and further incubated as in 1-3. As in 2, but the recovered microsomes were incubated with partially-purified rat liver phosphoprotein phosphatase (4.4 units/mg microsomal protein) for 30 min. 4. Microsomes were treated with the rat liver phosphatase (12 units/mg microsomal protein) for 30 min before the addition of KF (40 mM) and incubated for an additional 30 min. 5. As in 4, but using intestinal alkaline phosphatase (753 *p*-nitrophenyl phosphate units/mg microsomal protein).

bination of these phosphatase inhibitors (results not shown).

Modulation of ACAT activity. When microsomes obtained from weaned animals were preincubated with ATP a small increase was observed in the amount of cholesteryl ester formed (Table 1). The presence of 100,000 × *g* supernatant (2.5 mg protein per mg microsomal protein) caused no further increase nor did the inclusion of KF. However the inclusion of $MgCl_2$ provoked a larger elevation in enzyme activity. Assays were performed in the presence of phosphatase inhibitors and with exogenous cholesterol to ensure that endogenous phosphatases were inactive and that cholesterol substrate was not limiting. The inclusion of phenylboronic acid (0.4 mM), which inhibits cholesteryl ester hydrolase (19), did not modify the effects of Mg-ATP, which indicates that the esterase activity known to be present in these microsomes (20) did not interfere with the ACAT assay. A similar result was obtained when microsomes from mid-lactating animals were employed. Pre-incubation of microsomes with rat liver phosphoprotein phosphatase or high levels of intestinal alkaline phosphatase had no effect on their ACAT activity. Nevertheless, the elevated ACAT activity that resulted from treatment of microsomes with Mg-ATP and 100,000 × *g* supernatant containing KF (40 mM) could be reduced back to the control levels by incubation of the recovered microsomes with the rat liver phosphoprotein phosphatase (Table 2). This was observed in microsomes from both weaned and mid-lactating animals which represented the extremes of ACAT activity measured. In contrast, the intestinal alkaline phosphatase was not able to reverse the phosphorylation of ACAT which resulted from the treatment of the microsomes with ATP and $MgCl_2$ (Table 2). Microsomes prepared either in the presence or absence of phosphatase inhibitors exhibited the same ACAT activity (Table 3) when assayed under the same conditions.

Effects of pregnancy and lactation. ACAT activity and the free and esterified cholesterol content of microsomes prepared from mammary glands at different lactational stages are shown in Tables 3 and 4, respectively. ACAT activity, measured in the presence of endogenous cholesterol, was higher in the pregnant glands than in glands taken immediately post-partum, although there was no significant difference in the cholesterol contents of the two sets of microsomes. Enzyme activity was even lower at mid-lactation and this correlated with a reduction in the cholesterol content of the microsomes. There was a good correlation ($r=0.93$) between ACAT activity and the levels of cholesteryl ester in these three sets of microsomes (Fig. 3). The highest enzyme activities were observed in the microsomes from animals weaned for two days where the cholesterol contents of the microsomes were again elevated to the levels seen in the pregnant animals. The cholesteryl ester contents of these microsomes were much lower than would have been predicted on the basis of the correlation between enzyme activity and cholesterol ester levels observed previously (Fig. 3). The addition of exogenous cholesterol caused a greater than three-fold increase in ACAT activity in early and mid-lactators, but with the pregnant and weaned animals this increase was much more muted.

DISCUSSION

Our results demonstrate that the ACAT activity of the mammary gland late in pregnancy is elevated relative to the activity either immediately post-partum or at

TABLE 3

ACAT Activity in Microsomes Isolated from the Mammary Glands of Pregnant, Lactating and Weaned Rats: Influence of Exogenous Cholesterol and Fluoride[a]

	Cholesteryl oleate formed (pmol/min/mg DNA)		
	Fluoride-containing	Fluoride-free	
Animals	Endogenous cholesterol	Endogenous cholesterol	Exogenous cholesterol
Pregnant	8.81 ± 0.67 (5)	9.15 ± 0.45 (9)	16.00 ± 1.11 (9)
Early-lactators	5.03 ± 0.54 (5)[b]	5.49 ± 0.55 (8)[c]	17.06 ± 1.35 (8)
Mid-lactators	2.48 ± 0.42 (6)[c]	2.84 ± 0.41 (11)[c]	11.50 ± 0.89 (11)[b]
Weaned	26.24 ± 1.96 (4)[c]	22.35 ± 1.54 (6)[c]	35.89 ± 2.09 (6)[c]

[a]Fluoride-free and fluoride-containing microsomes were isolated from freeze-clamped mammary glands and ACAT activity determined in triplicate as detailed in Materials and Methods. Cholesterol was added as a dispersion in Triton WR-1339. The data are the means ± SEM for the number of animals given in parenthesis. Statistical differences (Student's *t*-test) are indicated between pregnant glands and the other glands in each column.
[b]$p<0.01$.
[c]$p<0.001$.

TABLE 4

Cholesterol and Cholesterol Ester Content of Mammary Gland Microsomes[a]

Animals	Cholesterol (μg/mg microsomal protein)	Cholesteryl ester (μg/mg microsomal protein)
Pregnant	109.9 ± 8.5 (9)	90.3 ± 10.9 (9)
Early-lactators	127.0 ± 3.3 (4)	42.0 ± 3.5 (4)[b]
Mid-lactators	59.1 ± 10.2 (11)[b]	15.4 ± 1.3 (11)[c]
Weaned	109.1 ± 5.0 (6)	57.3 ± 1.1 (6)[b]

[a]Cholesterol and cholesterol ester content of microsomes were determined as indicated in Materials and Methods. The results are means ± SEM for the number of animals given in parenthesis. Statistical differences (Student's *t*-test) are shown; [b]$p<0.01$, [c]$p<0.001$ compared with the appropriate pregnant glands.

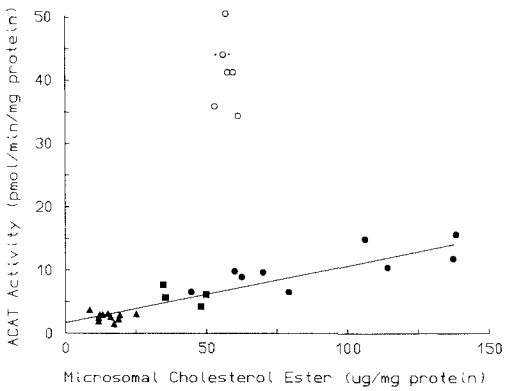

FIG. 3. Scatter diagram relating ACAT activities, assayed with endogenous cholesterol, to microsomal cholesteryl esters. Linear regression analysis was performed on the ACAT activities in "fluoride-free" mammary microsomes from pregnant (●), early-lactating (■) and mid-lactating (▲) rats and their corresponding cholesteryl ester contents. The relationship was linear with regression line $y = 1.67 + 0.096\ x$ and correlation coefficient $r = 0.93$. ACAT activity in microsomes from prematurely weaned animals are shown (○) for comparison.

mid-lactation. It is even further increased when milk is allowed to accumulate by premature weaning of the gland. In the latter situation there would be a large build-up of cholesterol in the gland and a consequent need to remove it by esterification for storage. Interestingly, the activity of the enzyme did not correlate with the ester content of these microsomes in the same way that was seen for the other three sets of microsomes (Fig. 3), suggesting that other mechanisms for removal of cholesterol were also operative in the weaned glands.

In the pregnant glands the enhanced level of ACAT activity may have been a compensatory response to the increasing concentrations of progesterone in the animals (21,22) since this hormone has been shown to inhibit the enzyme in a number of tissues (6). However, other factors may be important. A high cholesterol diet leading to an increased cholesterol level in the rat liver has been reported to give rise to elevated hepatic ACAT activity (23,24). The pregnant animal has an increased food intake and becomes hypercholesterolemic in late pregnancy (25–27), and this may cause a similar elevation in ACAT activity in the mammary gland. This effect would be accentuated in the preg-

nant gland and probably also in the weaned animal since neither has the high flux of cholesterol into milk characteristic of the fully lactating animal.

The activity of the enzyme in all of these microsomal samples could be stimulated by the addition of cholesterol, indicating that enzyme activity was at least partially regulated by substrate supply. However, there was no clear correlation between cholesterol content of the microsomes and ACAT activity at the different developmental stages, suggesting that other factors were also controlling enzyme activity. This was also indicated by the results observed when exogenous cholesterol was added since a similar stimulation (>three-fold) was obtained with microsomes from the early and mid-lactators, whereas only about half this increase was elicited with the microsomes from the pregnant and weaned glands.

In other experiments in which anti-hormone agents were used to arrest lactation the mammary gland ACAT activity was similar to that of the weaned animal, but was increased three-fold when assayed under the same conditions with exogenous cholesterol (28). Thus the smaller increase provoked by additional cholesterol seen with the weaned and pregnant microsomes was unlikely to be due either to the initially elevated ACAT or to insufficient equilibration of the exogenous cholesterol with the membranes. The cause of the relatively poor response to exogenous substrate in these particular microsomes is unknown, but clearly indicates that other mechanisms must act to control ACAT in the gland. Previous reports have suggested that ACAT could be regulated by a phosphorylation-dephosphorylation mechanism, although whether phosphorylation was associated with an increase or a decrease in enzyme activity was dependent on the tissue studied (4,8). In microsomes from both rat liver and rat intestinal cells ACAT activity was increased by incubation of the microsomes with the 100,000 $\times$ *g* supernatant fraction in the presence of MgATP and NaF (8), whereas a similar incubation of microsomes from the bovine adrenal cortex resulted in an inhibition of ACAT activity (4). The results presented here would suggest that the activity of ACAT in the mammary gland is increased on phosphorylation. Thus the enzyme in the mammary gland responds to this covalent modification in the same way as the hepatic and intestinal enzymes. The responses observed with the mammary enzyme were much smaller than those seen with the hepatic enzyme, and particularly the addition of the cytosolic fraction and KF had little effect. Hepatic microsomes prepared in the presence of fluoride to inhibit phosphatases did not show increased ACAT activity when compared with appropriate controls except in the situation where cholesterol-rich VLDL was first administered to the animals *in vivo* (29). In the present work tissue was obtained by freeze-clamping at liquid nitrogen temperatures, a technique extensively used in previous studies (see *e.g.*, ref. 30) to preserve the intracellular activity status of enzymes, and subsequently homogenized in media containing both phosphatase and kinase inhibitors. Nevertheless microsomes isolated in this manner did not differ significantly in ACAT activity from microsomes prepared without any of these precautions suggesting that the enzyme was not phosphorylated *in vivo*. This correlated with the failure of the partially-purified rat liver phosphoprotein phosphatase to alter the activity of the microsomal enzyme *in vitro* unless it had first been increased by treatment with Mg-ATP. Thus, although ACAT was responsive to phosphorylation *in vitro*, the function of this enzyme modification in controlling the activity of ACAT in the mammary gland requires further investigation.

METHODS

Analysis of Aldehydic Lipid Peroxidation Products by TLC/Densitometry

Jeffrey K. Beckman*, Samuel A. Morley, Jr. and **Harry L. Greene**
Department of Pediatrics, Division of Gastroenterology, Vanderbilt University Medical Center, Nashville, Tennessee

We have explored the use of thin-layer chromatography (TLC)/densitometry in both the reflectance and fluorescence mode for quantitation of specific products of lipid peroxidation. Aldehydic peroxidation products were generated by exposure of arachidonic acid to iron and ascorbic acid for 24 hr. Several methods for the quantitative analysis of peroxidation products by TLC/densitometry were compared using two different aldehyde-specific derivatizing reagents, namely dinitrophenylhydrazine (DNPH) and cyclohexanedione (CHD). DNPH hydrazones of the arachidonic acid-peroxidation products, upon TLC separation on silica gel, revealed prominent alkanal and hydroxyalkenal bands. Reverse phase high performance liquid chromatography confirmed that the primary alkanal component was hexanal, while the primary hydroxyalkenal was 4-hydroxynonenal. Semiquantitative methods for the direct analysis of these products by TLC/densitometry were worked out based on the use of external hydrazone standards. TLC/densitometry (fluorescence mode) was used to measure CHD adducts of aldehydes by forming the derivatives in the presence of decanal (used as an internal standard) and separating the derivatives by reverse phase TLC. Hexanal-CHD was detectable upon application of 0.5 nanomoles while 4-hydroxynonenal showed a lower response and was detectable with 10 nanomoles. Using appropriate response factors, hexanal and 4-hydroxynonenal were measured in the aldehyde sample from arachidonic acid and results were similar to those obtained by the DNPH method.

Similar approaches were used to analyze the peroxidation products of docosahexaenoic acid (24-hr exposure) and of rat liver microsomes exposed to iron for 30 min. The DHA peroxidation products contained extremely low levels of alkanals, while polar aldehydes and hydroxyalkenals were prominent. Formation of alkanals, osazones, hydroxyalkenals and phospholipid aldehydes from iron-exposed microsomes was also demonstrated. Uses and limitations of these methods of aldehyde measurement are discussed.
Lipids 26, **155–161 (1991).**

As an indicator of free radical injury, lipid peroxidation is usually assessed by the thiobarbituric acid (TBA) method (1,2) in which a complex of TBA with malondialdehyde is produced and measured by either absorbance or fluorescence monitoring. Although the TBA method is useful due to its rapidity and ease, the method is not specific and fraught with potential difficulties (3,4). The development of methods to detect and measure specific products of lipid peroxidation in recent years has increased the sensitivity of peroxidation analysis and has overcome many of the earlier problems. Various studies have shown that specific aldehydic peroxidation products, including the hydroxyalkenals, are of biological relevances, due, in part, to their high reactivity (5–7). Assays of specific products of lipid peroxidation are usually based on high performance liquid chromatography (HPLC) (8) or gas chromatography (GC)/mass spectrometry (MS) (9,10) and typically require preliminary fractionation of the products to be analyzed.

The purpose of the present investigation was to develop methods for the analysis of aldehydic lipid peroxidation products directly on thin-layer chromagraphy (TLC) plates using densitometric techniques. TLC/densitometry appears particularly useful in obtaining rapid estimates of the extent of formation of particular classes of lipid peroxidation products, which does not preclude more detailed subsequent analyses. Although certain aldehydes, including the hydroxyalkenals, may be detected directly by TLC/densitometry by monitoring at their absorbance maximum, such measurements are not applicable to complex samples where neutral lipids are likely to interfere. Derivatization allows the specific detection of aldehydes and increases the sensitivity of measurements, although it can also complicate assays. This study compares the use of two aldehyde-specific reagents for the densitometric detection of aldehydic peroxidation products. Polyenoic fatty acids (arachidonic acid and docasahexaenoic acid) and rat liver microsomes were used to study lipid peroxidation.

EXPERIMENTAL PROCEDURES

Arachidonic acid and docosahexaenoic acid (each approx. 99%) were purchased from Sigma Chemical Company (St. Louis, MO) and stored at −20°C under nitrogen prior to use. 1,3-Cyclohexanedione (CHD) was obtained from Aldrich Chemical Company (Milwaukee, WI) and recrystallized from methanol. Dinitrophenylhydrazine (DNPH) was obtained from Sigma and recrystallized from methanol.

Oxidation and extraction of fatty acids. Fatty acids (20–100 mg) were oxidized as a dry film by exposure to air for 20–24 hr. Fatty acids were dissolved in chloroform and the progress of oxidation was monitored by TLC (*n*-heptane/ethyl acetate/glacial acetic acid, 75:25:1, by vol) and densitometric assay at 205 and 235 nm. Fatty acid hydroperoxides, along with any residual unoxidized fatty acids (usually less than 25% of the total) were placed in Erlenmeyer flasks, chloroform was evaporated, and the lipids redissolved (1 mg/mL) with vortexing in 0.1 M Tris buffer, pH 7.4. Ferric chloride (20 μM) and ascorbic acid (500 μM) were added, and the solutions were incubated at 37°C for 24 hr. The solutions were acidified to pH 3 and extracted three times with equal portions of chloroform. The pooled chloroform extracts were evaporated under nitrogen (without heating) and redissolved in 2–4 mL of chloroform. The progress of secondary product

Abbreviations: AA, arachidonic acid; CHD, cyclohexanedione; DHA, docosahexaenoic acid (22:6n-3); DNPH, dinitrophenylhydrazine; GC/MS, gas chromatography/mass spectrometry; HPLC, high performance liquid chromatography; HNE, 4-hydroxynonenal; TBA, thiobarbituric acid; TLC, thin-layer chromatography.

formation was monitored by TLC using the system described above and by scanning at 220, 235 and 270 nm.

TLC densitometry. A Shimadzu CS 9000 dual wavelength TLC scanner (Shimadzu, Columbia, MD) equipped with a xenon lamp fluorometry attachment was used for densitometric monitoring of either absorbance or fluorescence. Absorbance was monitored using the reflectance photo mode and the zig zag scan mode (swing width 7.0 mm) with single wavelength monitoring. Precise prescribing of lanes on TLC plates [either by the manufacturer for the Whatman LK5D plates or using an Analtech (Newark, DE) plate scriber for the unscribed LKC18 plates] enabled automatic scanning of multiple lanes. Fluorescence of CHD-adducts was monitored at a 360 nm excitation wavelength using emission filter 2 (wavelength cutoff at 400 nm). Scanning was done in the linear mode for fluorescence with a beam of 0.4 × 0.4 mm.

Dinitrophenylhydrazine derivatization, thin-layer chromatography and standardization of hydrazone thin-layer densitometry. Aliquots of extracts of the secondary products of fatty acid peroxidation (a portion equivalent to 5 mg of the original fatty acid) were evaporated to near dryness, redissolved in one mL of DNPH reagent (0.34 mg/mL in 1 M HCl), and allowed to react for 2 hr at room temperature in the dark. Dinitrophenylhydrazones were extracted with methylene chloride (2 × equal volume), the extractions concentrated to 0.5 mL by evaporating under nitrogen, and the residue was redissolved in methylene chloride. The samples were applied to silicic acid TLC plates along with hydrazone standards of hexanal and HNE, and plates were developed in methylene chloride (8). TLC densitometry was done at 360 nm using an external standard of hexanal-DNPH and an extinction coefficient of 25,500 (8). Various concentrations of hexanal-DNPH were run in separate lanes of the TLC plate, and calibration curves were prepared using the data processing unit of the densitometer. Calibration curves were stored on floppy disks and recalled using the disk drive accessory and the data processing unit for automatic integration of hydrazone bands in respect to concentration.

Phospholipid hydrazones (from microsomal mixtures) were separated by thin-layer chromatography using ethyl acetate/n-propanol/chloroform/methanol/0.25% KCl (25:25:25:13:9, by vol) as solvent system. The plates were initially developed about 15 cm, then dried, and then further developed in methylene chloride to separate the neutral lipids. Hydrazones were analyzed using the densitometric methods and the calibration curves described above.

HPLC. Hydrazones of alkanals and of hydroxyalkenals were separated using a Beckman Gold HPLC system (Beckman Instruments, Fullerton, CA) and an analytical Ultrasphere ODS column (4.6 mm × 25 cm) equipped with a Model 166 UV detector. Samples were injected as 20-μL aliquots and separated using the gradient solvent system (11) initially consisting of methanol/water (3:1, v/v) and changing linearly to methanol/water (4:1, v/v) over the first ten min, and from 4:1 to 100% methanol over 10–25 min. Hydrazones were detected at 360 nm, and peaks were identified by comparison with those obtained for hydrazones prepared from commercially available alkanals or from HNE purified from AA-secondary products and identified by negative ion GC/MS of pentafluorobenzyl oximes as described (10).

CHD adducts of aldehydes were separated by reverse phase HPLC using a semipreparative Ultrasphere ODS column (10 mm × 25 cm) and detected using a McPherson Model FL-750 BX variable wavelength fluorescent detector (McPherson Instruments, Boston, MA) equipped with a Xenon excitation lamp and a 400 nm cut-off emmission filter. CHD adducts were monitored at an emission wavelength of 380 nm.

Cyclohexanedione derivatization and fluorodensitometry. Fluorescent decahydroacridine derivatives of aldehydes were analyzed by fluorescent TLC densitometry using derivatization methods developed by Yoshino *et al.* (12) for fluorometric HPLC assay. The CHD reagent (12) was first boiled for 1 hr and then extracted with three portions of methylene chloride (20 mL/100 mL of reagent). The CHD reagent was used to derivatize standard aldehydes or samples by heating for 90 min at 60°C. Instead of using C18 extraction cartridges as described by Yoshino *et al.* (12), we added methanol, water and chloroform in proportions to arrive at a Bligh and Dyer extraction (13). The chloroform layer was washed once with an equal volume of theoretical upper phase, evaporated to dryness under nitrogen, and redissolved in chloroform (500 or 100 μL as noted). Ten microliters were plated onto prescribed lanes of reverse phase TLC plates. The plates were developed initially about 5 cm in 80% methanol and then completely in 70% methanol. Plates were scanned in the fluorescent mode using an excitation wavelength of 360 nm and an emmission filter which excluded light of wavelengths less than 400 nm.

Microsomal peroxidation. Rat liver microsomes were prepared from animals on standard Chow diets as previously described (14) using a homogenization buffer of 0.1M KCl, 40 mM Tris, pH 7.4, containing 1 mM EDTA, and by resuspending the final pellet in the same buffer at 5–10 mg/mL protein. Microsomes (1 mg/mL final concentration) were incubated in 40 mM Tris buffer, pH 7.4, containing 1mM $CaCl_2$. Ferric chloride (20 μM) and ascorbic acid (500 μM) were used to induce nonenzymatic lipid peroxidation. Peroxidation reactions were stopped by the addition of 0.1% phosphoric acid for TBA-reactivity (1), by addition of methanol (containing decanal internal standard) for the CHD derivatization (12) or DNPH reagent (as described above) as appropriate.

RESULTS

Exposure of arachidonic acid as a dried film to air oxidation resulted in substantial (75%) conversion to fatty acid hydroperoxide as monitored by TLC densitometry at 235 and 205 nm (data not shown). Subsequent exposure to iron (20 μM) and ascorbic acid (500 μM) for up to 24 hr resulted in the conversion of the hydroperoxide and any residual unoxidized fatty acid to various secondary peroxidation products (termed AA-secondary products). TLC densitometry (with scanning) confirmed the formation of significant quantities of hydroxyalkenals (Abs max, 222 nm) and of bands exhibiting ketodiene chromophores (Abs max, 270–275 nm, 235 nm secondary). The formation of alkanals cannot be determined in this manner (without derivatization) due to the lack of a suitable chromophore. Direct densitometry of hydroxyalkenals is useful for TLC preparative work and will be reported separately.

The lipids of more complex systems include compounds that are likely to interfere with the direct assay of underivatized peroxidation products. Assays were therefore developed using aldehyde-specific derivatization reagents.

Derivatization of AA-secondary products with DNPH followed by thin-layer chromatography of extracts on silica plates separated the resulting DNPH hydrazones which were detected by their absorbance at 360 nm. TLC densitometry at 360 nm showed prominent bands of hydrazones of alkanals, hydroxyalkenals and polar aldehydes, the identity of which was confirmed by comparison with DNPH-alkanal and DNPH-hydroxyalkenal standards (Fig. 1). Direct (on-plate) spectra in the visible range confirmed that the bands all contained the hydrazone chromophore (Abs. max, 370 nm). A semiquantitative external standardization method for measuring hydrazone bands was developed as described in the methods section. A calibration curve for hexanal-DNPH was established (Fig. 2) which was found to be essentially the same for other hydrazone classes (hydroxyalkenals and phospholipid aldehydes). Alkanal and hydroxyalkenal TLC bands of the AA-secondary products were eluted and fractionated by reverse phase HPLC for further characterization. The alkanals included predominately (58%) hexanal (Fig. 3a), while the hydroxyalkenals included a major (57%) compound identified (by comparison with HPLC separation of standards) as 4-hydroxynonenal (Fig. 3b). Based on the percentage composition of the HPLC chromatograms and the TLC densitometric analysis of the classes we calculated the yield of hexanal and hydroxyalkenal hydrazones obtained from arachidonic acid (Table 1).

A fluorescent method involving the use of cyclohexanedione reagent (12) was also adapted to TLC densitometry and used to analyze the AA-secondary products. CHD adducts of varying concentrations of standard alkanals and hydroxyalkenals were prepared and separated by reverse phase TLC. Propanal, 4-hydroxynonenal, a diene analog of HNE (HNDE), hexanal and decanal CHD adducts gave separate peaks (Fig. 4a). The CHD reagent always yielded fluorescent peaks corresponding to acetaldehyde and propanal as well as a smaller peak comigrating with butanol [despite recrystallization of the CHD and extraction of the reagent (Fig. 4b)]. Standard curves for alkanals were generally linear up to about 100 μM (r=0.998 for hexanal) which corresponded to applying 25 nmole onto the plate. Response factors of individual alkanals, alkenals and hydroxyalkenals differed. Relative to a 1.0 value for hexanal, we observed the following response factors: Propanal, 0.8; pentanal, 1.0; decanal, 1.1; *trans*-2-hexenal, 0.3; *trans*-2-nonenal, 0.3; and HNE, 0.1. HNE-CHD was virtually undetectable after a 1 hr derivatization reaction (which is sufficient for hexanal and other alkanals). Higher temperature (75°C) did not enhance the response for HNE significantly and increased formation of reagent blank peaks. Malondialdehyde (prepared by hydrolysis of malondialdehyde dimethylacetal) did not react to form a detectable product.

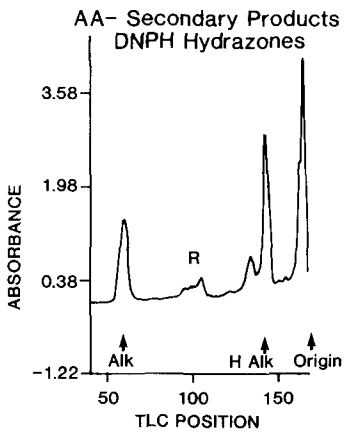

FIG. 1. TLC densitometry of DNPH hydrazones of peroxidation products of arachidonic acid. AA-secondary products of lipid peroxidation were generated and extracted as described in the Experimental section. Thin-layer chromatography on silicic acid plates (using methylene chloride as developing solvent) separated hydrazone classes which were identified using alkanal and hydroxyalkenal hydrazone standards (designated as Alk and H Alk, respectively). Densitometry was performed at 360 nm. TLC position is measured from the top of the plate with the border of the loading zone (origin) at position 168. "R" designates a reagent peak.

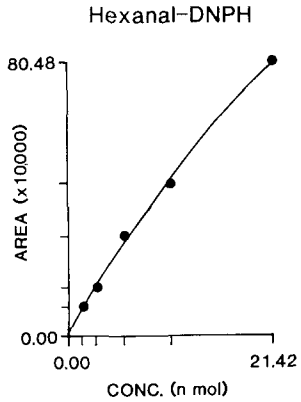

FIG. 2. Calibration curve for DNPH hydrazones. Hexanal-DNPH was isolated and quantitated by UV spectrometry. Various concentrations were plated on individual lanes in duplicate. TLC and TLC/densitometry were performed as in Figure 1. Odd numbers for concentrations reflect the use of even numbered volumes plated.

Aliquots of AA-secondary products were derivatized with CHD in the presence or absence of decanal which was added as an internal standard. Following reverse phase TLC, fluorescent densitometry revealed a substantial hexanal-CHD peak and a small peak of slightly greater R_f (Fig. 4c and Table 1) in addition to the reagent associated peaks. The latter product was subsequently identified by fluorescent HPLC as HNE and was quantified using its 0.1 relative response factor (Table 1).

The n-3 polyenic acid, docosahexaenoic acid, was used as a source for peroxidation products (DHA-secondary products) by the method described for AA-secondary products. DHA-secondary products wer analyzed by both the DNPH and the CHD method and compared with AA-secondary products. DNPH-hydrazones corresponding in R_f value to DNPH-hydroxyalkenal and to polar aldehydes were prominent (Fig. 5). The much lower yield of alkanals as compared with that seen for the AA-secondary products was noteworthy (Table 1). A DNPH hydrazone of R_f equivalent to the hydroxyalkenal (HNE) TLC band was observed which contained a lower concentration than the hydroxyalkenals of AA-secondary

TABLE 1

Comparison of DNPH and CHD TLC Densitometry Measurements of Aldehydic Lipid Peroxidation Products of Arachidonic Acid, Docosahexaenoic Acid and of Rat Liver Microsomes

Product[a] source	Aldehyde class	Method	
		DNPH	CHD
		(nmol/mg fatty acid or mg protein)	
Arachidonic acid	Alkanal[b]	32.4 ± 6.6[c]	57.6 ± 2.0
	Hydroxyalkenal	44.2 ± 8.1	50.4 ± 8.0
Docosahexaenoic acid	Alkanal	3.6 ± 2.4	nd[d]
	Hydroxyalkenal	13.2 ± 4.0	nd
Microsomes	Alkanal	25.0 ± 1.7	24.9 ± 2.9
	Hydroxyalkenal	1.4 ± 0.5	2.0 ± 0.7
	Polar aldehydes	53.0 ± 6.2	na

[a]The fatty acids were exposed to air (24 hr) followed by exposure of the resulting hydroperoxides and unoxidized fatty acid to iron/ascorbic acid (24 hr). Rat liver microsomes were exposed to iron/ascorbic acid for 30 min. Values for control microsomes are given in the text. Details of the methods are described under Experimental Procedures.

[b]The DNPH assay measured total alkanals while the CHD assay measured hexanal only.

[c]Values are expressed as mean ± SD for four analyses of a single representative sample of lipid peroxidation reaction mixtures from each source.

[d]Not determined.

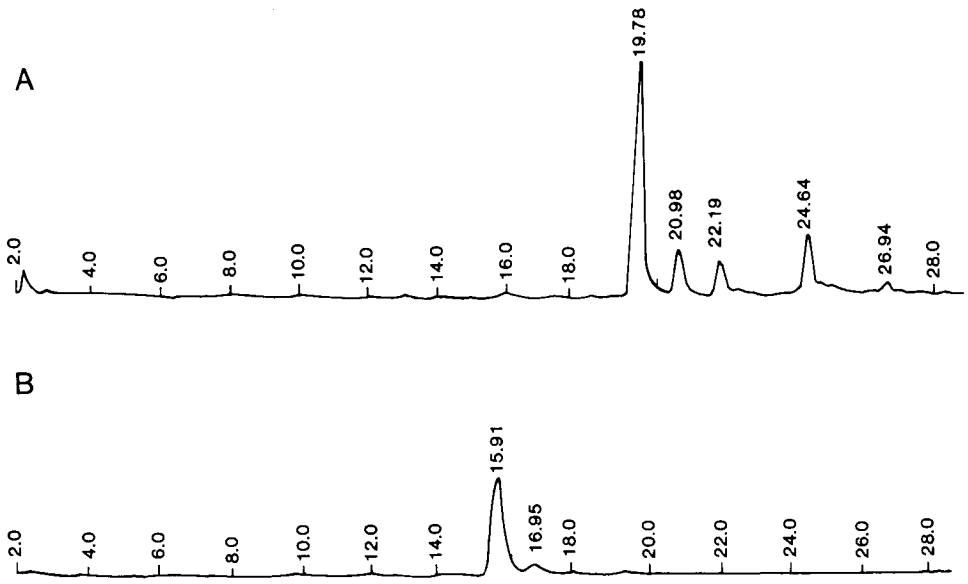

FIG. 3. *Panel A.* HPLC of DNPH hydrazones of alkanals formed from arachidonic acid. The peak at 19.78 min corresponds to hexanal-DNPH. *Panel B.* HPLC of DNPH hydrazones of hydroxyalkenals formed from arachidonic acid. The peak at 15.9 min corresponds to 4-hydroxynonenal-DNPH.

products. Most of the DHA hydrazones were "polar aldehydes" (more polar than the hydroxyalkenals), including a distinct peak at position 135 (Fig. 5), which was absent from the AA-secondary products. Three other preparations of iron-induced peroxidation products of DHA and of AA have been generated and have confirmed the relative lack of alkanal formation from DHA with DHA-hydroxyalkenal formation ranging from 55–82% of the hydroxyalkenals from AA.

Derivatization of DHA-secondary products with CHD followed by reverse phase TLC and fluorescent densitometry gave the chromatogram shown in Figure 4d. The profile was devoid of any peaks other than those found in the reagent blank. In addition, there was no evidence of an augmentation of the propanal peak (which is contained in the blank).

Rat liver microsomes were exposed to iron and ascorbic acid for 30 min and analyzed following derivatization

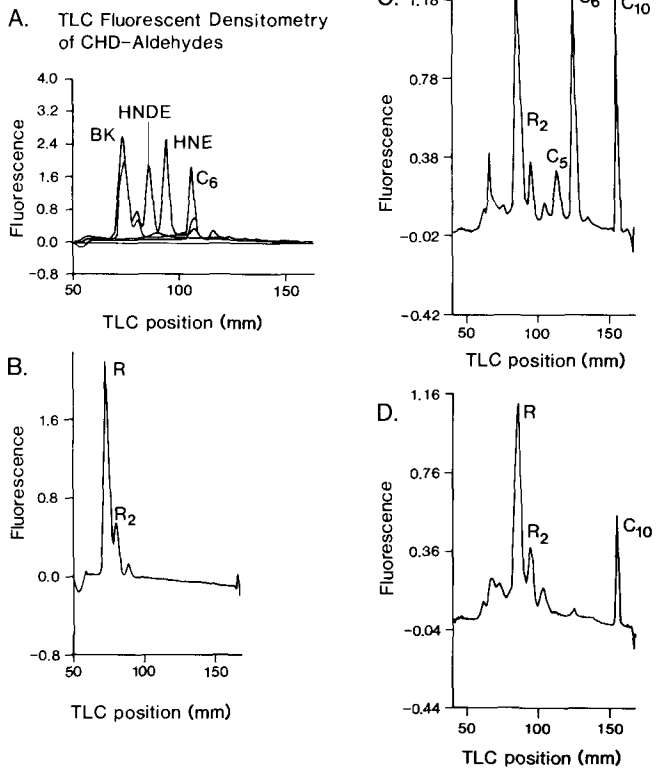

FIG. 4. Fluorescence TLC densitometry of alkanals and hydroxyalkenals of AA and DHA. Reverse phase TLC was used to separate fluorescent CHD acridine derivatives of aldehydes as described in the text. Panel A exhibits an overlay of several lanes of a TLC plate which includes various concentrations of hexanal (C_6) as well as HNE and a diene analog of HNE (HNDE). A separate TLC plate (which also included standards; not shown) was scanned for fluorescence and chromatograms of selected lanes containing either CHD-reagent blank (panel B), AA-secondary products (panel C) or DHA-secondary products (panel D). Decanal (C_{10}) was added to the fatty acid peroxidation products to serve as an internal standard. The propanal standard (not shown) coincides with the second blank peak (R2).

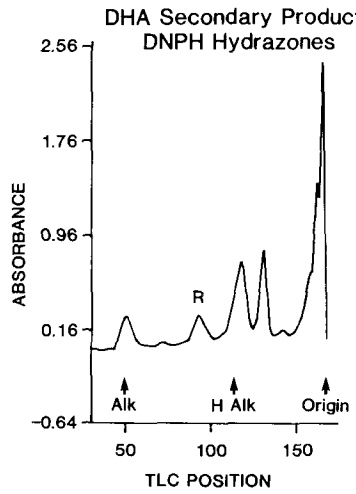

FIG. 5. TLC densitometry of DNPH-hydrazones formed from DHA. Methods wre those in Figure 1. The hydroxyalkenal band ran somewhat higher than in Figure 1, but was identified using the same HNE-DNPH standard.

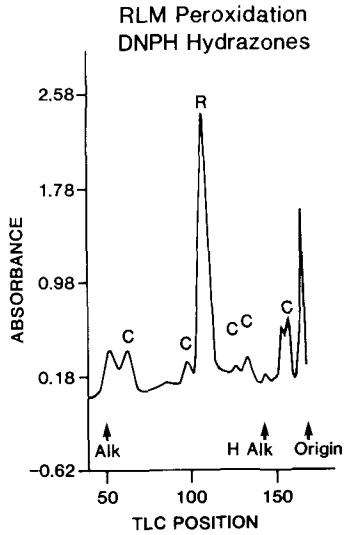

FIG. 6. TLC densitometry of DNPH-hydrazones formed from iron-exposed microsomes. The reagent peak is designated by an R, while peaks present and unchanged from control microsomes are designated with a C. A control alkanal peak was observed, but greatly augmented as described in the text. Alkanal and hydroxyalkenal hydrazones wre located using standards.

with either DNPH or CHD. A parallel sample was assayed for TBA-reactivity which established that at least 30 nmol/mg protein of MDA equivalents were formed. The TLC densitometic chromatogram of DNPH products (Fig. 6) showed the overwhelming reagent peak as well as other peaks (designated with a C) that were present in control microsomal incubations and not augmented by exposure to iron. The alkanal band increased from the control level of 9.2 nmol per mg protein to 25.6 nmol/mg protein while the hydroxyalkenal band increased from 0 to 1.42 nmol/mg protein. The polar aldehyde peak increased from 10 to 53 nmol/mg protein. The hydroxyalkenal band (identified using HNE-DNPH) was much smaller than observed previously using fatty acids as product source. Visible scans of the various bands demonstrated that while most of the bands were hydrazones, the band at position 153.8 gave a spectrum (Abs max, 430-440 nm) characteristic of osazones (8). HPLC fractionation of the alkanals demonstrated that hexanal was the predominant product (53% of the total), while no other peak exceeded 15%. Thin-layer chromatography of hydrazones of the same microsomal reaction mixtures was run in a solvent system designed to separate phospholipid classes. TLC densitometry (absorbance 360 nm) demonstrated that 55% of the polar aldehydes migrated in a band consisting of 4–5 peaks (not resolved) that migrated in the region of standard egg phosphatidylcholine (monitored at 205 nm) with the remainder about equally divided between a group of peaks that migrated with standard phosphatidylethanolamine and a peak that migrated at the polar solvent front (beneath the hydroxyalkenal band). The "phospholipid aldehydes" were absent in the control microsome sample whole the peak migrating at the polar solvent front was present at a level similar to that of the oxidized microsome sample.

Analysis of aldehydes (alkanals and hydroxyalkenals) of the microsome reaction mixtures by the CHD

densitometric method (confirming peak identification by fluorescent HPLC) similarly demonstrated the formation of hexanal as well as HNE (Table 1). Neither hexanal nor HNE were detected in control microsome samples by TLC densitometry.

DISCUSSION

Lipid peroxidation is most often assessed in general terms by use of the TBA assay which measures malondialdehyde and peroxidation products (such as hydroperoxides) which then degrade to form malondialdehyde under the acidic, high-temperature assay conditions (2). However, in an effort to enhance sensitivity of analysis and/or to explore the significance of lipid peroxidative processes in more detail, investigators have, in recent years, developed methods for the analysis of specific products of lipid peroxidation. The aldehydic lipid peroxidation products formed by degradation of lipid hydroperoxides are the major products that have been characterized in a number of biological lipid peroxidation systems both *in vitro* (8) and *in vivo* (15,16). One aldehyde that is particularly interesting is 4-hydroxynonenal (HNE), which has been shown by Esterbauer and co-workers to exhibit reactivity and toxicity in biological systems (5–7) and to be measurable *in vivo*. The method usually applied to measure aldehydic peroxidation products is tedious, involving reaction with DNPH, preparative TLC (multiple lanes per sample), elution of bands, quantitation of classes by spectrometry, and analysis of the individual molecular components by HPLC. In order to study the formation of aldehydes in multiple samples, it appeared advantageous to quantitate the compounds by automated TLC densitometry. In this study, we have explored the use of TLC densitometry for the measurement of two classes of aldehyde derivatives, DNPH hydrazones and CHD acridine adducts.

The applicability of TLC densitometry to the measurement of DNPH hydrazones of alkanals and hydroxyalkenal is hampered by the presence of unreacted reagent in the samples. DNPH reagent (the peak of which is seen prominently in the microsomal peroxidation sample) limits the concentration of extract that can be applied to the plate and hinders the analysis of samples containing low levels of peroxidation product. Reagent blanks also contain alkanal and other hydrazone bands which are insignificant for the highly peroxidized fatty acid extracts or even the iron-exposed microsomes, but which will lessen sensitivity for many peroxidation assays (such as for *in vivo* experiments). Polar lipid hydrazone fractions "phospholipid aldehydes" were more readily separated from interfering reagent bands, but consisted of multiple unresolved peaks that are difficult to accurately quantitate by densitometry. Another disadvantage of measuring hydrazones (in general) is the lack of a suitable internal standard. Reproducible spotting methods are therefore required for the method to be quantitative. We typically spot 20 μL onto the loading zone of prechanneled, precoated TLC plates. Mechanized spotting devices may prove useful as an alternative. Despite the limitations described above, DNPH derivatization with TLC densitometry is, however, a useful method for indentifying isolated peroxidation products by aldehyde class or for semiquantitative measurement of aldehydes in chemical or highly peroxidized biological samples. The detection limits were about 10 nmol of alkanal, 1 nmol of hydroxyalkenal and 1 nmol of "phospholipid aldehyde".

An alternative method for analyzing the aldehydes of lipid peroxidation uses CHD reagent to form fluorescent acridine adducts with peroxidation products. Reverse phase TLC effectively separated alkanals according to their chain length and permitted the use of decanal as an internal standard. We determined that the various alkanals and hydroxyalkenals differed in the extent to which they reacted with CHD and/or were detected by fluorescent TLC densitometry. The CHD-TLC densitometric method detected alkanals with fair sensitivity but was less sensitive for the measurement of hydroxyalkenals. The reported response factor of HNE relative to hexanal for the HPLC assay was 0.25 while our measured value was 0.1 for a 90-min derivatization reaction and 0.15 following a 3-hr reaction. In the presence of comparable levels of hexanal (AA-secondary products), HNE was detected as a much smaller peak. One would anticipate that it would be difficult to detect HNE by this method in most biological samples. Major fluorescent peaks were always observed with the CHD blank and samples that corresponded to two, three and four carbon aldehydes. Similar peaks were observed in the HPLC chromatograms reported by Yoshino *et al.* (12). These reagent peaks thus limit the sensitivity of the assay for these short-chain aldehydes even when using more sensitive detection methods, such as fluorescent HPLC. Despite this drawback and the difficulty of measuring HNE, the CHD-TLC densitometric method may prove useful for assessing hexanal content in multiple samples as a general index of peroxidation, and perhaps prior to HPLC analysis. The reproducibility of the method is excellent for hexanal measurement in iron-exposed microsomes and appeared to be specific for lipid peroxidation as hexanal was not detected in control microsomes. The CHD method for analyzing hexanal by TLC densitometry may detect less than 1 nmol of hexanal but requires about 10 nmol to measure HNE.

The methods described here were used to compare the AA-secondary products with those formed from DHA and from *in vitro* peroxidation of rat liver microsomes. A major finding confirmed by both assays was that considerably more alkanal/alkenal product was formed from arachidonic acid than from the n-3 fatty acid, DHA. It is possible that propanal and/or hexenal are formed from DHA but not detected due to their volatility. We have, for example, not detected substantially higher propanal contents in n-3 enriched microsomes (from rats on fish oil diets) following iron-induced peroxidation and assay by the DNPH and CHD methods (data not shown). Since the assays were performed by derivatization of the microsomal mixtures there was less of a chance for volatile compounds to be lost as would be during evaporation in a nitrogen stream, suggesting that volatility may not be the only cause for the lesser level of n-3 alkanals.

In agreement with previous studies, microsomal peroxidation mixtures contained hydrazones of all of the classes found in the fatty acid peroxidation samples as well as another TLC band exhibiting osazone characteristics (8). The levels of alkanal product were comparable to those obtained by Poli *et al.* (8) using ADP-iron and an NADPH

generating system for the study of enzymatic microsomal lipid peroxidation (8). In our study, the microsomal peroxidation products contained much lower levels of hydroxyalkenals than reported by Poli *et al.* (8). Our system induced lipid peroxidation by non-enzymatic means which may form less hydroxyalkenal than the enzymatic system. The osazone peak is likely underestimated by our current external standard method as the osazone absorbance at 360 nm is about 25% less than its peak value at 430 nm. The identity or significance of osazones has not been explored. Substantial levels of polar aldehydes were generated during microsomal peroxidation. Most migrated on TLC with either phosphatidylcholine or phosphatidylethanolamine standards but could not be accurately quantitated for the reasons described above. These products have been described previously (17), although they have not been fully characterized.

The CHD densitometric method confirmed the formation of hexanal from microsomes exposed to iron. The concentration so estimated was about 30% higher than that measured by DNPH assay (TLC densitometry and HPLC). Values for the AA-secondary product hexanal content were similarly higher, according to the CHD method. Perhaps the CHD derivatization reaction is more complete than the DNPH reaction. Reagent blanks and control microsomes (incubated without iron) did not show any hexanal formation by the CHD method while the DNPH method always exhibited significant levels of DNPH-alkanal including DNPH-hexanal.

Our results demonstrate the utility, as well as the limitations, of TLC densitometry for assessing the generation of aldehydic peroxidation products. TLC densitometry of hydrazones (DNPH method) may be used as a semiquantitative measure for a variety of alkanals, hydroxyalkenals and perhaps phospholipid aldehydes for *in vitro* samples. However, the limitations of the DNPH densitometric method (described above) will likely prevent its general use for *in vivo* peroxidation investigations. The fluorescent TLC densitometric assay of CHD adducts offers advantages as it uses milder conditions (12), is sensitive for measuring hexanal (usually a prominent peroxidation product), and uses an internal standard. Limitations include a low sensitivity to hydroxyalkenals and interference of reagent peaks with measurement of n-3 fatty acid peroxidation products, such as propanal. The CHD method may be particularly suited for the preliminary assessment of aldehyde formation which can be followed then by fluorescence HPLC in appropriate samples.

ACKNOWLEDGMENTS

The authors wish to thank Mrs. Kathie Williams for excellent assistance in the preparation of this manuscript. This work was supported by NIH research grants NIDDK 40121 and NIDDK 26657.

A New Eicosapentaenoic Acid Formed from Arachidonic Acid in the Coralline Red Algae *Bossiella orbigniana*

John R. Burgess[a,*], Roger I. de la Rosa[b], Robert S. Jacobs[a] and Alison Butler[b]
Departments of Biological Sciences[a] and Chemistry[b], University of California, Santa Barbara, California 93106

Aqueous extracts of the coralline red algae *Bossiella orbigniana* have been shown to catalyze the enzymatic oxidation of arachidonic acid to a previously unreported ω6 eicosapentaenoic acid product. This unique fatty acid contains a conjugated tetraene with absorption maxima at 293, 306, and 321 nm, and was identified by spectral methods as 5(Z),8(Z),10(E),12(E),14(Z)-eicosapentaenoic acid. The compound was given the trivial name bosseopentaenoic acid. Under experimental conditions, production of bosseopentaenoic acid was linear up to 2 hr and dioxygen was consumed. Bosseopentaenoic acid, along with several other conjugated tetraenes, was also present in the algae endogenously as revealed by a comparison of the ultraviolet (UV) spectra and the high-performance liquid chromatographic (HPLC) pattern of the purified product and the organic extract of *Bossiella*.
***Lipids 26,* 162–165 (1991).**

Oxidation of polyunsaturated fatty acids (PUFA) to biologically active localized hormones occurs in the majority of living systems analyzed (1). A large variety of PUFA metabolites have been identified and the number continues to grow. Some of the most unique metabolites of arachidonic acid (AA) and other PUFA have been isolated from marine invertebrates (1,2). Recently, attention has centered on the presence of eicosanoid and eicosanoid-like compounds as natural products in marine algae (3). Many of these compounds appear to be produced biosynthetically through an initial step involving a lipoxygenase (LO) enzyme (4) as evidenced by several reports on the presence of 12(S)-hydroxyeicosatetraenoic acid (12-HETE), 12(S)-hydroxyeicosapentaenoic acid, hepoxilins, and prostaglandins E_2 and $F_{2\alpha}$ in the organic extracts of several red algae species (5–8). We have recently examined the eicosanoid compounds and lipoxygenase activity present in coralline red algae (Burgess and Jacobs, manuscript in preparation). We report herein that aqueous extracts of *Bossiella orbigniana* spp. *orbigniana* Silva catalyze the oxidation of arachidonic acid, forming a previously unreported ω6 eicosapentaenoic acid product containing a conjugated tetraene. This enzyme catalyzed product, which is also present endogenously, is identified as 5(Z),8(Z),10(E),12(E),14(Z)-eicosapentaenoic acid.

Abbreviations: AA, arachidonic acid; BPA, bosseopentaenoic acid; HPLC, high-pressure liquid chromatography; 12-HETE, 12(S)-hydroxyeicosatetraenoic acid; LO, lipoxygenase; NMR, nuclear magnetic resonance spectroscopy; PUFA, polyunsaturated fatty acid; Tris-HCl, hydroxymethylaminomethane hydrochloric acid.

MATERIALS AND METHODS

Material. Bossiella orbigniana was collected off the coast of Goleta, California, between September 1989 and March 1990. The alga was kept in flowing seawater tanks until used. Arachidonic acid (99%, porcine liver), deuterated-benzene, and Tris-hydrochloride were obtained from Sigma Chemical Co. (St. Louis, MO). Organic solvents—high-performance liquid chromatography (HPLC)-grade or better—were obtained from Fisher Scientific (Pittsburgh, PA).

Algae and product preparation. Aqueous extracts (33%) of freshly collected *B. orbigniana* were prepared by homogenization in 20 mM Tris-HCl buffer pH 8.0 followed by centrifugation at 500 × *g* to remove particulate matter. The supernatant from this centrifugation was incubated in 3 vol of 0.1 M Tris-HCl buffer pH 7.1 in the presence or absence of AA (100 μM) for up to 2 hr at 37°C. The reaction was terminated by the addition of 1N HCl to pH 3.5 and extracted with 3 vol of solvent A (heptane/2-propanol, 4:1, v/v). After separation, the organic layer was scanned in the ultraviolet (UV) range and evaporated to dryness under a stream of N_2. The dried sample was resuspended in solvent B (heptane/hexane/2-propanol/acetic acid, 499:499:1:1, by vol) and the components separated by HPLC. The HPLC separation was conducted isocratically in solvent B at a flow rate of 4 mL/min using an LC5000 liquid chromatograph (Varian Instrument Group, Sugarland, TX) on a semi-preparative silica column (Supelco, Inc., Bellefonte, PA). Purification of the enzymatically produced product was conducted by first processing the crude extract by open-column silica chromatography (2.5 × 30 cm column) in solvent C (hexane/2-propanol/acetic acid, 994:5:1, v/v/v), followed by HPLC separation and collection of the fractions.

Spectroscopic techniques. UV-visible spectroscopy was conducted with an IBM 9430 UV-VIS scanning spectrophotometer. Mass spectral analysis by FAB was conducted with a *m*-nitrobenzylalcohol matrix on a VG analytical mass spectrometer. Proton, ^{13}C and, 2D correlation spectroscopy (COSY) nuclear magnetic resonance (NMR) spectroscopy were performed on a General Electric 500 MHz NMR spectrometer.

RESULTS

Bossiella was homogenized in Tris-buffer and, following centrifugation, the UV-spectrum of the organic extract of the homogenate showed absorption maxima at 293, 306, and 321 nm (Fig. 1b) indicating the presence of a conjugated tetraene (9). When AA was incubated with the aqueous algal homogenate prior to the organic extraction, a 5-fold absorbance increase in the total conjugated tetraene was observed (Fig. 1a), with no other observable

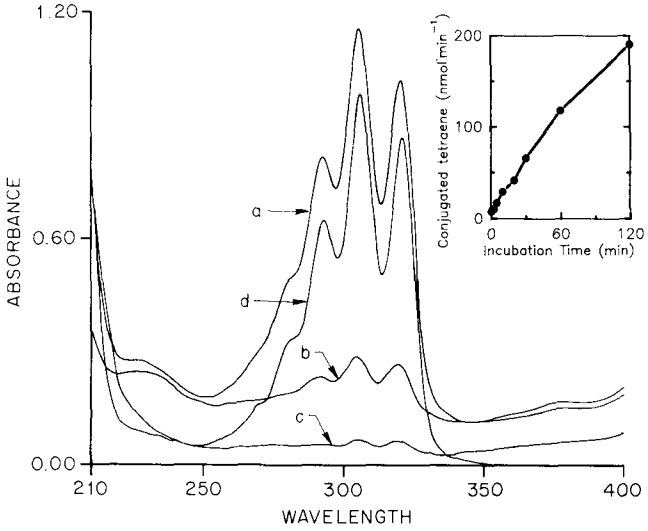

FIG. 1. UV spectrophotometric scans of organic extracts of *Bossiella orbigniana* incubations. Aqueous algal homogenates were incubated in the presence (a) or absence (b) of arachidonic acid (100 μM) and analyzed as described under Materials and Methods. (c) Heat-treatment of aqueous algal homogenate at 50°C for 30 min prior to incubation with AA eliminates conjugated tetraene formation. change in the UV spectrum. Product formation was roughly linear over 2 hr (Fig. 1 insert). Heat treatment of the aqueous homogenate prior to addition of arachidonic acid did not produce the conjugated tetraene (Fig. 1c), thus indicating that the conjugated tetraene is formed enzymatically from AA. When AA was incubated with the algal homogenate, oxygen was consumed as measured polarographically, which is consistent with the oxidation of AA to conjugated olefins. O_2 consumption was not observed upon prior heat-treatment of the homogenate.

Separation of the organic extract of the algal homogenate by HPLC yielded four fractions (Fig. 2A) all having the same UV-spectral pattern. Retention times were as follows: peak I, 18.0 min; peak II, 19.0 min; peak III, 20.5 min; peak IV, 22.0 min. Four fractions were also obtained when the AA incubated sample was resolved on HPLC, with an enhancement of the peak area for Fraction II (data not shown). To determine whether AA oxidation resulted in the formation of a single or multiple conjugated tetraene products, the algal homogenate was processed by repeated centrifugation and extracted with acetone (90%) to remove endogenous fatty acids. The resuspended protein pellet retained 100% of its original activity when incubated with AA. The organic extract of this incubation when injected on the HPLC resolved one major peak which eluted with the same retention time as Fraction II of the endogenous tetraene chromatogram (Fig. 2B). The two peaks co-eluted on HPLC when extracts from each sample were injected simultaneously (Fig. 2C).

Large scale preparation of the enzymatic product involved using the acetone-precipitated protein from 2 kg of algae, and 40 mg of AA. Fraction II was purified as

a colorless oil (5.2 mg) and showed the following UV spectral pattern (solvent A) λ_{max} 293, 306, 321 (ε=50,794; 71,958; 62,698 $M^{-1}cm^{-1}$, respectively). These results were very similar to those obtained for other naturally occurring fatty acids possessing a conjugated tetraene function (9-11). FAB-Mass spectrometry of the underivatized compound gave the following (rel. intensity): 303 $[M+1]^+$ (24), 302 $[M]^+$ (51), 119 (42), 105 (48), 91 (100), 79 (72), 67 (97), 55 (95). The ^{13}C NMR spectrum showed

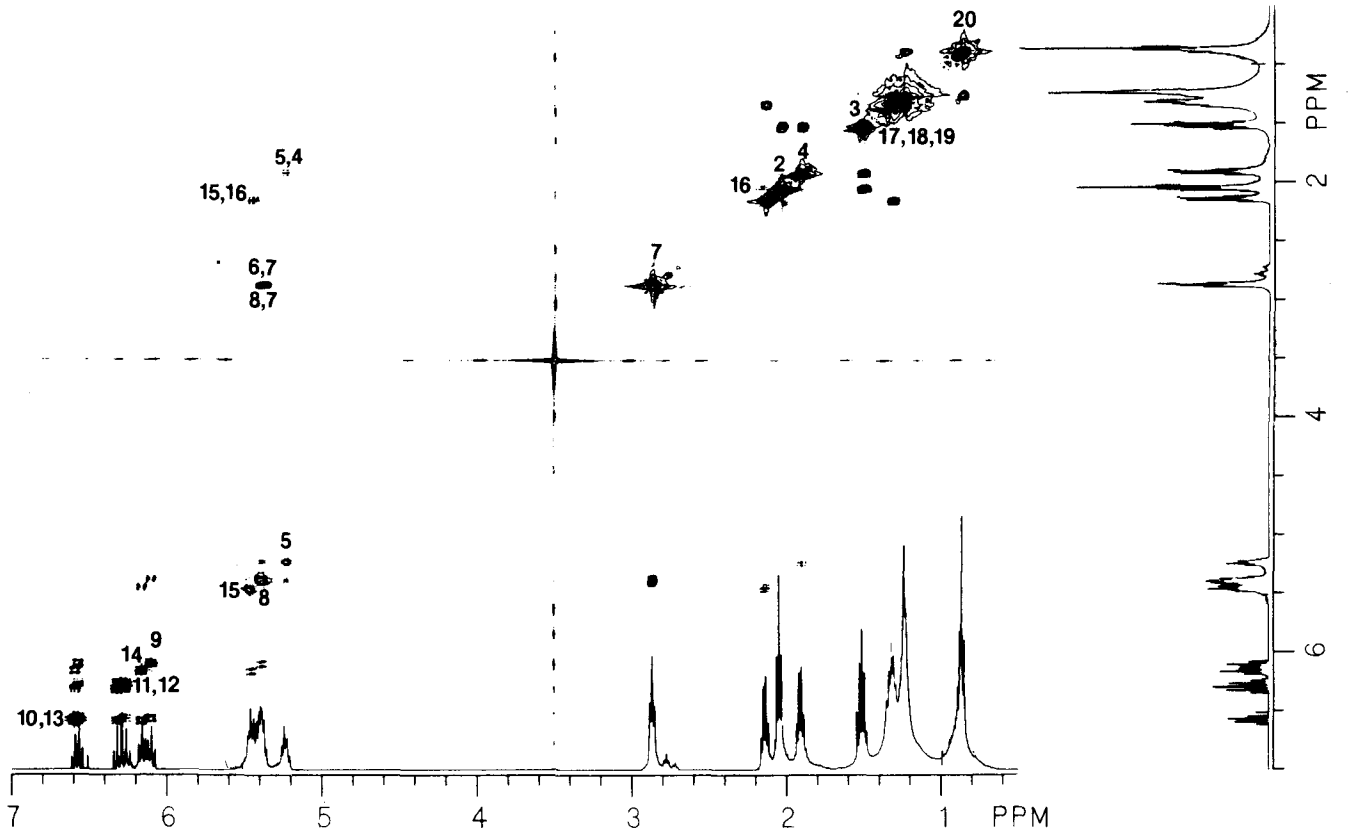

FIG. 3. ^1H-^1H correlation spectroscopy of 5(Z),8(Z),10(E),12(E),14(Z)-eicosapentaenoic acid showing key correlations between coupled protons (*ca.* 5 mg of BPA in 0.5 mL C_6D_6, 500 MHz).

10 olefinic carbon atoms, one aliphatic methyl carbon, and eight methylene carbons, indicating conversion of AA to a pentaene. The ^1H and ^{13}C NMR spectra are consistent with 10 vinylic, 2 allylic, 14 secondary, and 3 primary protons. These results yielded a molecular formula of $C_{20}H_{30}O_2$, and the compound was named bosseopentaenoic acid (BPA). The linear array of the methylene and olefinic groups of BPA and the stereochemical configuration were analyzed by ^1H-^1H 2D shift correlation spectroscopy (COSY) (Fig. 3). The chemical shift parameters and the coupling constants were assigned based on these results and are summarized in Table 1. Assignment of the *bis*-allylic methylene proton signal centered at δ 2.87 to C-7 was made based on coupling between this signal and the olefinic multiplet at δ 5.4, as well as, coupling of this multiplet with both the olefinic signal at δ 5.25 and the triplet peak centered at δ 6.1. These results confirmed the linear array of double bonds residing at positions 5,8, 10,12 and 14 of the carbon backbone. The symmetry of the COSY pattern suggested that the configuration within the conjugated tetraene was *cis,trans,trans,cis* which was confirmed by the large coupling constants (>13) obtained for carbons 10 through 13 (12).

DISCUSSION

Bosseopentaenoic acid is a unique and previously unreported polyunsaturated fatty acid. It is endogenous to *Bossiella orbigniana*, and can be enzymatically formed through the oxidation of arachidonic acid. Based on the

SCHEME 1. Possible biosynthetic pathway for BPA formation.

observed O_2 incorporation associated with the formation of BPA, we propose a possible biosynthetic pathway from AA through a more polar intermediate such as 12-HETE involving a lipoxygenase or cytochrome P450 (13,14) enzyme in the initial step (Scheme 1). A requirement for molecular oxygen has also been observed in the biosynthesis of the naturally occurring conjugated tetraene, parinaric acid, found in seed oils of *Impatiens balsamina* (15). Furthermore, the presence of 12-LO enzymatic activity has recently been documented in a marine red alga *Gracilariopsis lemaneiformis* (16). A 12-HETE intermediate could then undergo enzymatic dehydration to form bosseopentaenoic acid. A similar dehydration of hydroxyenes has been proposed as a biosynthetic step in the formation of parinaric acid and other naturally occurring conjugated polyenoates (17). Studies are currently underway to isolate and characterize the enzyme(s) involved in the biosynthesis of BPA, and to analyze the stoichiometry of O_2 consumption.

ACKNOWLEDGMENTS

We would like to gratefully acknowledge the assistance of W. H. Gerwick at Oregon State University, W. Fenical at Scripps Institution of Oceanography, and Fred O. Garces at UCSB in interpreting the spectral data for BPA. This research was supported in part by NOAA, National Sea Grant College Program, Department of Commerce, under Grant NA-85AA-D-SG140, through the California Sea Grant College Program, and in part by the California State Resources Agency, Project No. R/MP-38 (RSJ), R/MP-44 (AB). AB thanks NSF DMB87-16229. We also acknowledge the UC Biotechnology Program grant (AB) (RSJ) for postdoctoral support (JRB).

[Received October 2, 1990; Revision accepted December 12, 1990]

Dietary Supplementation with Ether-Linked Lipids and Tissue Lipid Composition

Merle L. Blank, Edgar A. Cress, Zigrida L. Smith and **Fred Snyder***
Medical Sciences Division, Oak Ridge Associated Universities, Oak Ridge, Tennessee 37831-0117

The goal of this investigation was to determine the effect of an alkylglycerol dietary supplement on the lipid composition of several major organs. Lipids from kidney, liver, and lung tissues of rats on a laboratory chow diet (controls) were compared to lipids from the same tissues of rats that had received oral supplements (300–600 mg/day) of 1-*O*-alkyl-2,3-diacetyl-*sn*-glycerol (alkyl groups were 65% 18:1 and 17% 16:1) for six days. Incorporation of the alkylglycerol into tissue lipids was indicated by both the presence of a neutral lipid in liver that had the same chromatographic migration as alkyldiacylglycerols and by a substantial increase (~150% of controls) in the octadecenyl group of the alk-1-enyl- and alkyl-glycerol side chains derived from total phospholipids of all three tissues. Compared to controls, there was a significant increase in the amount of alkylacylglycerophosphocholine in all three tissues of the alkylglycerol supplemented group. Total lipids, total phospholipid phosphorus, or the distribution of phospholipid classes (except for small differences in lung tissue) were not affected by the dietary supplement. The increase in ether lipids was offset by a corresponding decrease in the diacyl subclass in tissues from animals on the alkyldiacetylglycerol supplement. Our results indicate that the amount of ether-linked glycerolipids in rat tissues can be easily increased with dietary supplements of alkylglycerols.
***Lipids 26,* 166–169 (1991).**

Virtually all animal cells contain ether-linked aliphatic moieties as membrane lipid constituents. With few exceptions the *O*-alkyl moieties are most prominent in choline glycerolipids, whereas the *O*-alk-1-enyl chains are found primarily as ethanolamine plasmalogens. An exhaustive listing of available reports about the tissue distribution of ether-linked phospholipids in comparison to the diacyl types of lipids for tissues of various species has been compiled by Sugiura and Waku (1) and Horrocks (2). Although ether lipids were once thought to serve strictly as structural components of membranes, it is now apparent that some types of ether lipids possess biological activities. The most potent lipid mediator ever discovered is a novel ether-linked phospholipid subclass possessing the chemical structure 1-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (3–5). This phospholipid is commonly referred to as platelet-activating factor (PAF), although it elicits a wide variety of biological responses that involve many different types of cells (6–8).

Earlier studies have shown that orally administered fatty alcohols (9,10) or glycerol ethers (10–14) can be incorporated into the glycerol ether lipids of mammalian tissues. Incorporation into tissue glycerol ethers was based on either qualitative changes in composition of tissue alkyl/alk-1-enyl groups or the use of radioactive tracers. L-M fibroblasts grown in culture media supplemented with alkylglycerols were shown to contain increased amounts of glycerol ethers in their total phospholipids (15). However, except for the reported increase in the plasmalogen content of erythrocytes in one human subject (16) and no change in the plasmalogen content of rat tissues (12) after feeding a supplement of alkylglycerols, none of the earlier reports attempted to determine the quantitative levels of ether lipids found in tissues after feeding the glycerol ethers (or alcohols) to intact mammals. Because PAF can be biosynthesized from the precursor pool of 1-alkyl-2-acyl-*sn*-glycero-3-phosphocholine (alkylacyl-GPC) *via* a remodeling pathway (8), we felt that it was important to see if this precursor pool size could be increased in mammalian tissues by the oral administration of an alkylglycerol diacetate. An increase in the PAF precursor pool size could have important biological ramifications because of the multiple cellular responses produced by this autacoid.

MATERIALS AND METHODS

The dietary supplement of 1-*O*-alkyl-2,3-diacetyl-*sn*-glycerol (ADAG) used in these studies was a gift from Western Chemicals (Vancouver, Canada). Diacetyl derivatives of alkylglycerols were used as the dietary supplement in order to mimic the esterified forms of alkylglycerols that would occur in a normal diet. Analysis of the ADAG supplement by thin-layer chromatography (TLC) and high-performance liquid chromatography (HPLC) (17) revealed the supplement was >95% alkyldiacetylglycerols with the two major alkyl chains being 16:1 (17%) and 18:1 (67%); no other single species accounted for >5% of the total alkyl chains. Male CDF rats, seven weeks of age, were given 300-mg doses of carrier-free ADAG by stomach tube. The rats received one dose of ADAG on the first day of the experiment followed by two equivalent doses per day, 7 hr apart, on days two through five and a final single dose on day six. Rats were sacrificed six hours after the last dose of ADAG. Livers, lungs, and kidneys were removed and immediately frozen in liquid nitrogen until the time of lipid extraction. Both controls and the ADAG-fed rats (five animals per group) had access *(ad libitum)* to regular laboratory chow and water during the entire experimental period.

Lipids were extracted from the tissues by the method of Bligh and Dyer (18). TLC of neutral lipids was carried out on plates coated with 250 μm layers of Silica Gel G developed in a solvent system of hexane/diethyl ether/acetic acid (85:15:1, v/v/v). Alkyldiacylglycerols are easily separated from cholesterol esters, triacylglycerols, and fatty acids in this neutral lipid TLC system. Phospholipids were separated by TLC on 250 μm layers of silica gel H using a solvent system of chloroform/methanol/acetic acid/water (50:25:8:2, by vol). For preparative

[b] Values are significantly different from corresponding controls ($P < 0.01$).

purposes, the developed TLC plates were exposed to NH_3 fumes (3–4 min), then sprayed with a solution of 0.1% 2, 7-dichlorofluorescein in ethanol and viewed under ultraviolet (UV) light to locate the separated phospholipid bands. The phospholipids were extracted from the silica gel (18) for subsequent analysis. For quantitative analysis of phospholipid classes the developed TLC plates were charred with H_2SO_4 and the amount of phosphorus in the separated phospholipids was determined (19). The percentage of octadecenyl (18:1) groups in the alkyl- and alk-1-enyl-glycerol ethers derived by Vitride reduction, benzoylation, and HPLC of the total phospholipid fractions was determined by earlier methodology (17). Quantitation of the subclasses in diradyl-*sn*-glycero-3-phosphoethanolamine (GPE) and diradyl-GPC was performed *via* phospholipase C hydrolysis, benzoylation of the diradylglycerols, and HPLC of the benzoate derivatives, as previously described (20).

All data are expressed as means ± S.E. and statistical significance between groups was based on Student's t-test (only P values of <0.05 were considered significant).

RESULTS AND DISCUSSION

Except for an unexplained lower percent weight gain by rats fed the ADAG supplement (5.3 ± 1.7% *vs* 18.5 ± 0.8% for the controls), the glycerol ether supplement was well tolerated by the animals with no other visible indications of problems or morbidity. There were no significant differences in the amounts (as percent of tissue wet weight) of total lipids extracted from the tissues of the control *vs* the ADAG-fed rats (liver, 4.61 ± 0.08 *vs* 4.85 ± 0.17; kidney, 4.41 ± 0.13 *vs* 4.56 ± 0.23; and lung, 3.43 ± 0.17 *vs* 3.66 ± 0.15; for control *vs* ADAG-fed, respectively). Total tissue phospholipids (as mg P per g wet weight) were also not statistically different between the control and ADAG-supplemented animals (liver, 1.08 ± 0.06 *vs* 1.21 ± 0.04; kidney, 0.95 ± 0.05 *vs* 0.99 ± 0.01; and lung, 0.74 ± 0.03 *vs* 0.80 ± 0.03; for control *vs* ADAG-fed, respectively).

TLC analysis of the neutral lipids from the three tissues revealed livers from the ADAG-fed group contained significant amounts (estimated at 2–3% of the total lipid mass) of a lipid component having the same chromatographic mobility as alkyldiacylglycerols. This lipid component was also detected (in lesser amounts) in the lung lipids of the ADAG-fed rats but was present in no more than trace amounts in the lipids of these three tissues from control animals. These results indicate the alkylglycerol portion of the ADAG supplement was incorporated into the liver and lung lipids. Only trace amounts of this neutral lipid could be detected in the kidney lipids from both groups of rats. There was no evidence for the presence of alkyldiacetylglycerols in the TLC analysis of tissue neutral lipids from ADAG-fed rats.

The dietary supplement of ADAG had little effect on the distribution of phospholipid classes in the three rat tissues (Table 1). There were small, but statistically significant, changes noted in three of the phospholipid classes from lungs of the ADAG-fed group; sphingomyelin/lysoGPC and phosphatidylinositol/serine were increased and diradyl-GPC was decreased when compared to controls. The biological significance, if any, of these small changes is unknown. HPLC analysis of alkyl- and alk-1-enyl-glycerol dibenzoates, derived from total

TABLE 2

Effect of Dietary Supplements of Alkyldiacetylglycerol (ADAG) on the 18:1 Content of Ether Groups in the Total Phospholipid Fraction of Selected Rat Tissues[a]

Tissues and glycerol ether subclasses	% of glycerol ether chains as 18:1	
	Control	ADAG-fed
Kidney		
alk-1-enylacyl	19.2 ± 0.4	32.6 ± 0.4

alkylacyl	1.1 ± 0.1	2.6 ± 0.1	2.9 ± 0.2[b]	10.1 ± 0.4[b]

[a]Ether-containing subclasses of diradyl-GPE and diradyl-GPC were determined as described in Materials and Methods from the same tissues as in Table 1. All values are means ± S.E. (n=5, except as noted in Table 1). Values for the diacyl subclasses (not shown) are the difference between 100 percent and the sum of the two ether subclasses. Values that are significantly higher than corresponding data for controls are indicated by (b) = $P < 0.001$ and (c) = $P < 0.01$. Diacyl subclasses, except for diacyl-GPE of the kidneys, were significantly lower ($P < 0.01$) in tissues of the animals fed ADAG.

phospholipids of the tissues, showed that the ether chains were highly enriched in the 18:1 moiety in rats that were fed ADAG as compared to controls (Table 2). The increased content of 18:1 in the ether-linked moieties was so dramatic that we felt it was necessary to analyze the total phospholipid fractions of tissues from only three rats of each group. Also, others have fed unlabeled alkylglycerols to rats and reported a shift in the qualitative makeup of the tissue glycerol ether groups toward the composition of the dietary alkylglycerol (10,12). In one study, only the level and composition of the alk-1-enyl group of ethanolamine plasmalogens from several different rat tissues was analyzed (12) and in the other instance the chain length composition of both *O*-alkyl and *O*-alk-1-enyl groups were analyzed but only from liver (10). Our results (Table 2) support the findings of both of these papers.

We next examined the amounts of ether-containing subclasses present in the diradyl-GPE and diradyl-GPC phospholipid classes. Except for the diradyl-GPC of lung, the amounts of diradyl-GPC and diradyl-GPE were not significantly different between the tissues of controls and those of the rats on the ADAG-supplemented diet (mg P/g wet weight times the percent of the phospholipid class, Table 1); therefore, the percent distribution of subclasses shown in Table 3 is representative of actual changes in their relative mass (Table 3). In agreement with earlier results (1,2), these three tissues from both groups of rats showed a general pattern of higher concentrations of plasmenyl (alk-1-enylacyl-) ether lipid in the GPE class, whereas the GPC class was enriched in the plasmanyl (alkylacyl-) type. Except for the alk-1-enylacyl-GPE of kidney and the alk-1-enylacyl-GPC of liver, the plasmenyl subclasses were slightly increased in the tissues as a result of dietary supplementation with ADAG. In every instance, the concentration of the alkylacyl- subclasses was significantly increased, compared to controls, in both GPC and GPE phospholipid fractions from tissues of rats that received the ADAG supplement (Table 3). The precursor of PAF in the remodeling pathway, alkylacyl-GPC, was increased by a factor of almost four-fold (kidney and lung) to ten-fold (liver) in the three tissues of the ADAG-fed rats. The increase in alkylacyl and alk-1-enylacyl subclasses of the diradyl-GPE and diradyl-GPC fractions was compensated for by decreases in the corresponding diacyl subclasses (see legend of Table 3). We are unaware of any other experiments in which attempts were made to quantitate the levels of alkylacyl glycerolipids in tissues after feeding alkylglycerols to intact mammals. The exact mechanism for incorporation of the alkylglycerol portion of the dietary ADAG into rat tissues is presently unknown. However, one possible explanation is *via* hydrolysis of the acetate groups from ADAG by intestinal and/or other tissue lipases followed by phosphorylation of the resulting alkylglycerol (21,22) to produce alkylglycerophosphate. This compound serves an intermediate in the *de novo* biosynthesis of alkylacyl-GPE, and alkylacyl-GPC (23). The increased levels of alkylacyl-GPC (the precursor of PAF) found as a result of oral administration of alkyldiacetylglycerols in the current study could have a very pronounced influence on biological responses elicited by PAF and eicosanoid mediators. Future experimentation in this project is designed to explore this possibility.

Gas Chromatographic Analysis of Malonaldehyde and 4-Hydroxy-2-(E)-nonenal Produced from Arachidonic Acid and Linoleic Acid in a Lipid Peroxidation Model System

H. Tamura[1] and **T. Shibamoto***
Department of Environmental Toxicology, University of California, Davis, California 95616

Malonaldehyde (MA) and 4-hydroxynonenal (4-HN) formed upon oxidation with Fe^{2+}/H_2O_2 from arachidonic acid and linoleic acid, and their ethyl esters were analyzed by gas chromatography (GC). The MA and 4-HN produced were reacted with *N*-methylhydrazine (NMH) to give 1-methylpyrazole and 5(1′-hydroxyhexyl)-1-methyl-2-pyrazoline, respectively. The derivatives were analyzed by GC on a fused silica capillary column using a nitrogen-phosphorus detector. With arachidonic acid, more MA and 4-HN were formed from the ester (88 nmol/mg and 23 nmol/mg, respectively) than from the free acid (25 nmol/mg and 9 nmol/mg, respectively). In contrast, with linoleic acid, more MA and 4-HN were produced from the free acid (53 nmol/mg and 13 nmol/mg, respectively) than from the ester (39 nm/mg and 8 nmol/mg, respectively).
Lipids 26, 170–173 (1991).

It is well known that peroxidation of unsaturated fatty acids produces various carbonyl compounds. Some of these, in particular the low molecular weight aldehydes such as malonaldehyde (MA), were reported to be genotoxic (1). As a bifunctional reagent, MA can crosslink proteins or nucleotides (2), entailing the potential for carcinogenic activity (3). MA levels have also been used as diagnostic indicators of the freshness of lipid-rich foods because unsaturated fatty acids are decomposed by free radicals formed by sunlight (4), by metal ions such as Fe and Cu (5), or by lipoxygenases (6), resulting in MA formation. MA can also serve as biomarker of the hepatotoxicity of CCl_4 (7).

Recently, 4-hydroxy-2-(E)-nonenal (4-HN), which is one of the major aldehydes formed during the peroxidation of linoleic, γ-linolenic and arachidonic acids (8), has attracted attention as a cytotoxic agent (1). 4-HN inhibits various biological functions, including microsomal glucose-6-phosphatase and cytochrome P-450 activities (9), and it has been used as an indicator of lipid peroxidation in biological systems, such as rat liver microsomes (10).

Analysis of the complex mixture of carbonyl compounds formed by lipid peroxidation is rather difficult (1). The most common method of analyzing carbonyl compounds involves derivatization with 2,4-dinitrophenyl hydrazine. The hydrazones produced are then analyzed by either gas chromatography (GC) or high-performance liquid chromatography (HPLC) (8,11). However, MA does not yield a satisfactory derivative with 2,4-dinitrophenyl hydrazine (12). Recently, MA was analyzed by GC as *N*-methylhydrazine (NMH) derivative (13,14).

4-HN in biological samples, such as rat tissue or lipoprotein, was analyzed as pentafluorobenzyl oxime by gas chromatography-mass spectrometry (15,16). This method requires trimethylsilylation of the hydroxyls. In the present study, MA and 4-HN formed from arachidonic acid and linoleic acid, and their ethyl esters, in a model system were analyzed as the NMH derivatives 1-methylpyrazole (1-MP) and 5(1′-hydroxylhexyl)-1-methyl-2-pryazoline (HMP), respectively.

MATERIALS AND METHODS

Synthesis of 4-HN. 4-HN was synthesized by modification of a method reported previously (17). Magnesium (0.6 g) was added to 6 mL tetrahydrofuran (THF) in a 50-mL Erlenmeyer flask and then cooled to −5°C. Ethyl bromide (22 mmol) in 6 mL THF was added to the above solution. The viscous solution was left for 30 min at −10°C, then propargyl aldehyde diethyl acetal (21 mmol) in 6 mL THF was added. The reaction mixture was stirred with a magnetic stirrer for 2 hr at 0°C and then cooled to −10°C. Hexanal (22 mmol) in 6 mL THF was added and the reaction mixture was stirred for 4 hr at −10°C. Approximately 10 mL saturated ammonium sulfate solution was added, followed by 200 mL of distilled water to remove excess magnesium. The reaction solution was extracted with 20 mL of diethyl ether, and the extract was dried over anhydrous potassium carbonate for 12 hr.

After removal of the solvent, the reaction product 4-hydroxy-2-nonenal diethyl acetal (3.4 g) was obtained by fractional distillation *in vacuo* (*ca.* 0.1 mm Hg) at 107–112°C. 4-Hydroxy-2-nonenal diethyl acetal (2.5 g) was dissolved into 20 mL of diethyl ether, and $LiAlH_4$ (18.2 mmol) was added at −70°C over 2 hr under a nitrogen stream. The reaction solution was kept below −50°C with dry ice/acetone/acetonitrile for 5 hr to prevent formation of cyclic furanoid by-products (17). The temperature of the solution was then raised to between −20 and −30°C. After 2.5 hr, the reaction was terminated by adding ammonium sulfate at −70°C.

The reaction mixture was precipitated at room temperature, the white precipitate was washed with 20 mL of diethyl ether, and the filtrate was dried over anhydrous potassium carbonate for 12 hr. After removal of the solvent, 4-hydroxy-2-nonenal diethyl ace-

tal (1.7 g) was obtained by fractional distillation *in vacuo* at 105°C. The acetal (32 mg) was added to 2 mL of 1% citric acid solution at room temperature. After 15 hr, 10 mL of saturated sodium chloride solution was added to the reaction mixture, and the mixture was extracted with three 10-mL portions of dichloromethane. Removal of the solvent yielded 18 mg of 4-HN. Spectral data are shown in Table 1.

Synthesis of standard 5(1′-hydroxyhexyl)-1-methyl-2-pyrazoline (HMP). 4-HN (100 mg) was dissolved in 2 mL of diethyl ether, and then 80 μL NMH was added. The reaction mixture was stored in a refrigerator at 4°C for 4 hr. GC analysis of the mixture indicated the presence of two products. After the solution was cooled to 4°C, a white precipitate appeared, and the solution was filtered. The filtrate contained compound I (Fig. 1) as the major component. Compound I was purified by preparative thin-layer chromatography (TLC) using hexane/ethyl acetate (1:1, v/v) as developing solvent. The precipitate was washed with cold diethyl ether and dissolved in 2 mL ethanol, which was subsequently evaporated off, yielding 20 mg of compound II (Fig. 1). Because 4-HN forms two isomers (I and II), it is necessary to use the total amount of I and II for the quantitative analysis of 4-HN. Spectral data of I and II are shown in Table 1.

Oxidation of arachidonic acid, linoleic acid, and their ethyl esters in a Fe^{2+}/H_2O_2 model system. An aqueous solution (5 mL) containing a fatty acid or its ethyl ester (1.5 mg/mL), 0.25 mmol trizma buffer (pH 7.4), 0.75 mmol potassium chloride, and sodium dodecyl sulfate (0.2%), was stirred with or without 200 μmol ferrous chloride and 200 μmol hydrogen peroxide at 37°C for 16 hr. The reaction was stopped by adding 4 ppm butylated hydroxytoluene (BHT), 40 μL NMH was added, and stirring was continued for 1 hr. The aqueous reaction mixture was extracted with 20 mL of dichloromethane using a liquid-liquid continuous extractor for 3 hr. The solution was saturated with NaCl prior to extraction to mixture emulsion formation. The extract was analyzed for MA and 4-HN by GC.

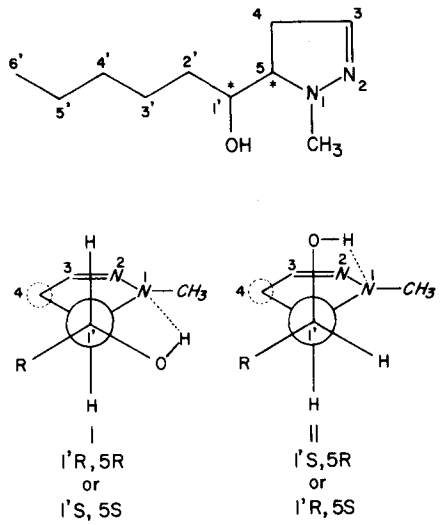

FIG. 1. Structure of 5(1′-hydroxyhexyl)-1-methyl-2-pyrazoline and the proposed configurations of diastereomers I and II.

Recovery of 1-MP and HMP. The test sample was prepared by spiking 36 nmol/mL of 1-MP and 30 nmol/mL of HMP in 5 mL aqueous solution containing the ingredients as mentioned above except for ferrous chloride and hydrogen peroxide. The spiked sample was stirred for 1 hr and then analyzed.

RESULTS AND DISCUSSION

With NMH, 4-HN yielded the isomeric pyrazoline derivatives I (55%) and II (45%). Figure 1 shows the proposed configurations for the two diastereomers. Isomer I should be more stable than isomer II. In isomer I, intramolecular hydrogen bonding between the hy-

[b]n=2.

droxy hydrogen and ring nitrogen-1 would tend to rotate the bulky R group away from the carbon-4 CH_2 group of the pyrazoline ring. In contrast, in isomer II the R group would rotate toward the carbon-4 methylene causing steric hindrance. It also could be expected that isomer I has a shorter GC retention time (Kovats Index, 2009) than does isomer II (Kovats Index, 2133) on a polar GC liquid phase such as DB-WAX due to intramolecular hydrogen bonding.

The lowest detection levels of 1-MP and HMP by nitrogen phosphorus detector (NPD) were 8.9 pg and 8.4 pg, respectively; these values are equivalent to 7.8 pg of MA and 7.1 pg of 4-HN, respectively. GC detection limits were the amounts of analyte that produced peak heights more than three times the noise level. The percent recoveries of the spiked 1-MP (36 nm/mL) and HMP (30 nm/mL) standards from the test mixture were 91.0 ± 0.6 (7) and 87.5 ± 0.2, respectively. The values are the means of three replicates ± standard deviation.

The results of MA and 4-HN analyses are shown in Table 2. Figure 2 shows a typical GC of NMH derivatives of the lipid peroxidation products formed from arachidonic acid in the Fe^{2+}/H_2O_2 model system. Some MA (4–10 nmol/mg) was already present in both the fatty acids and their ethyl esters. Thus, it was previously reported that 1 g of nontreated linolenic and linoleic acids contained 57 μg and 14 μg of MA, respectively (12). A trace amount of 4-HN was also found in nonoxidized arachidonic acid but not in its ethyl ester, nor in linoleic acid or its ethyl ester. The addition of an oxidizing agent increased MA and 4-HN formation significantly.

In the present study, more MA and 4-HN were formed from ethyl arachidonate than from arachidonic acid. In contrast, more MA and 4-HN were produced from linoleic acid than from ethyl linoleate.

MA is thought to be formed from polyunsaturated fatty acids *via* a cyclic peroxide intermediate (18) produced by $^1O_2$ (19). This mechanism is consistent with the observation that a more unsaturated fatty acid produces more MA than does a less unsaturated fatty acid. The oxidation of fatty acids initiated by a hydroxy radical also produced MA in the present study. However, linoleic acid produced more MA than did arachidonic acid. The results suggest that alternate pathways of MA formation do exist.

There has been no prior report on the simultaneous analysis of MA and 4-HN. The gas chromatographic method developed in the present study gives higher resolution and sensitivity than does the HPLC method, and it may be applied to multiple analyses of reactive carbonyl compounds formed in various biological systems.

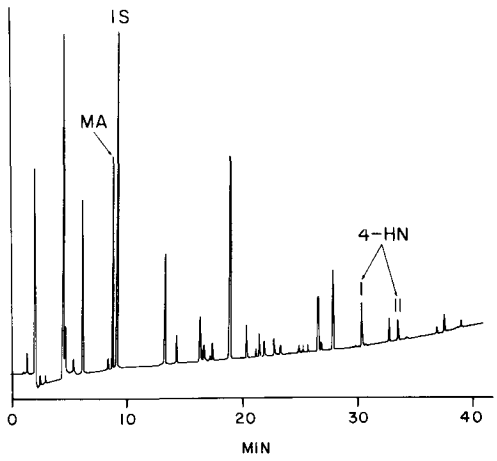

FIG. 2. Typical gas chromatogram of a mixture of *N*-methylhydrazine derivatives obtained from the products formed by arachidonic acid oxidation with Fe^{2+}/H_2O_2. MA, malonaldehyde; IS, internal standard (2-methylpyrazine); 4-HN, 4-hydroxynonenal.

Effect of Essential Fatty Acid Deficiency on Lipid Composition of Basolateral Plasma Membrane of Pig Intestinal Mucosal Cells

Véronique Duranthon, Lucie Frémont* and **Claude L. Léger**
Laboratoire de Nutrition et Securité Alimentaire, CRJ-INRA, Domaine de Vilvert, 78352 Jouy-en-Josas Cedex, France

The effect of essential fatty acid (EFA) deficiency on the lipid composition of basolateral plasma membranes (BPM) from intestinal mucosal cells was investigated in weaning pigs fed control or EFA-deficient diets for 12 weeks. The phospholipid and cholesterol contents relative to protein were similar in both groups, showing a cholesterol/phospholipid molar ratio of 0.6. The distribution of phospholipid classes was also unaffected by the diet. In contrast, fatty acid profiles of the two phospholipid main classes, phosphatidylcholine and phosphatidylethanolamine were altered by EFA deficiency. Linoleic acid (18:2n-6) was largely reduced, whereas arachidonic acid (20:4n-6) only slightly decreased in EFA-deficient pigs. The unsaturation index was essentially maintained by high levels of oleic acid (18:1n-9) and by conversion of oleic acid to 5,8,11-eicosatrienoic acid (20:3n-9). Finally, during the period of EFA deficiency, the lipid composition of BPM of the intestinal mucosal cells was little affected, suggesting a preferential uptake of 20:4n-6 and (or) precursor mobilized from other tissues. However, an effect of dietary treatment on the function of membrane-associated proteins cannot be ruled out.
Lipids 26, 175–181 (1991).

Evidence exists that the lipid matrix structure of a cell membrane influences the biological activities of intrinsic membrane proteins and that dietary lipids can change the fatty acid composition and modulate membrane function (1–3). The effect depends on the cell type, the subcellular membrane fraction and possibly the membrane domain. In the intestinal mucosal cell plasma membrane, the basolateral and brush-border regions differ in morphology, composition and function (4). The phospholipid and cholesterol patterns of the two regions have been described for rats (5–7) and other animals (6), and it is being recognized that large species differences do exist. Several reports have shown that changes in the lipid composition of the intestinal mucosal cell plasma membrane induced by dietary fats alter the physicochemical properties and biological functions in both plasma membrane regions (8–11).

The difficulty of carrying out such studies in humans implies the necessity of finding appropriate experimental animal models. As assessed by numerous reports (12,13), the pig is considered a well fitted model because its gastrointestinal system and pathways of lipid metabolism resemble those of humans. Moreover, the piglet exhibits biochemical and physiological similarities to man during the perinatal period (14).

Recent studies in our laboratory have focused on the effect of an essential fatty acid (EFA)-deficient diet on lipid composition and lipid-protein interactions in pig brush-border membrane vesicles (15,16). In pigs, the basolateral region has been investigated mainly for proteins and peptides (17), but little is known about the lipid composition. Therefore, the present study was undertaken to characterize the basolateral plasma membrane (BPM) and to determine the influence of EFA deficiency on lipid distribution and fatty acid composition of phospholipid classes.

*To whom correspondence should be addressed.

Abbreviations: BPM, basolateral plasma membrane; EFA, essential fatty acids; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PUFA, polyunsaturated fatty acids; SDS, sodium dodecylsulfate; SDS-PAGE, SDS-polyacrylamide gel electrophoresis; UNID, unsaturation index.

METHODS

Animals and diets. Eight male piglets of the Large-White breed were divided into two groups just after weaning (10-days-old). They were fed a semi-purified diet (INRA Institute, Jouy-en-Josas, France) *ad libitum,* containing 7% (w/w) lipids, in the form of either corn oil plus soybean oil mixture (control diet) or hydrogenated coconut oil (EFA-deficient diet). The composition of diets is given in Table 1.

Piglets were maintained on the experimental diets for 12 weeks and sacrificed after an 18-hr fast. The small intestine was rapidly removed, everted, washed with cold saline and immediately used for membrane preparation.

Membrane preparation. The isolation procedures were similar for piglets of both groups. Jejunal segments, free of mucus, were scraped and mucosal scrapings suspended

TABLE 1

Composition of Experimental Diets[a]

Fatty acids % total	Control diet	EFA-deficient diet
8:0		1.2
10:0		4.2
12:0		46.5
14:0	2.1	20.2
16:0	11.3	11.5
18:0	2.8	14.7
18:1n-9	20.4	0.8
18:2n-6	59.0	0.7
18:3n-3	4.4	0.2
Saturated	16.2	98.3
Monounsaturated	20.4	0.8
Polyunsaturated	63.4	0.9

[a]Fats were added to the basal diet in the following proportions: 35 g corn oil plus 35 g soybean oil (control diet); 70 g hydrogenated coconut oil (EFA-deficient diet) per kg of diet. The basal diet contained the following components (g/kg diet): potato starch, 300; cassava meal, 250; casein, 200; cellulose, 100; molasses, 36.5; dicalcium phosphate, 17; calcium carbonate, 17; sodium chloride, 4.5; and trace mineral and vitamin mixture, 5. Mineral and vitamin mixture (in mg/kg diet): $ZnSO_4 \cdot 7\ H_2O$, 44; $MnSO_4 \cdot H_2O$, 6; $CuSO_4 \cdot 5\ H_2O$, 3; KI, 0.1; $CoSO_4$, 0.1; Na_2Se, 0.1; vitamin A (500.000 I.U./g), 1.3; vitamin D_3 (100.000 I.U./g), 1.3; vitamin E (500 I.U./g), 2.5; vitamin K_3, 0.3; thiamin, 0.1; riboflavin, 0.5; pyridoxine hydrochloride, 0.1; nicotinic acid, 1.9; folic acid, 0.1; vitamin B_{12}, 5.10^{-3}; biotin, 25.10^{-3}; calcium pantothenate, 1.3; and choline, 63.

in 4 vol (w/v) of an ice-cold buffer consisting of 250 mM sucrose, 3 mM $MgCl_2$, 10 mM Tris-HCl (pH 7.4). All buffers contained 0.1 mM phenylmethylsulfonyl fluoride. The pooled suspension was homogenized using a motor-driven glass-Teflon homogenizer with twelve down and up strokes at 1500 rpm. The homogenate was then filtered through nylon gauze (150 μm) and diluted 1:1 with the cold 250 mM sucrose buffer. The procedure of purification was a modification to that reported by Scalera *et al.* (18) and del Castillo and Robinson (19) involving a Percoll (Pharmacia, Uppsala, Sweden) gradient. The crude homogenate was centrifuged at 300 × *g* for 10 min (MSE "high speed" 25 centrifuge, Crawley Sussex, U.K., 59582 angle rotor). The pellet, P_1, was discarded and the supernatant, S_1, centrifuged at 900 × *g* for 5 min to eliminate nuclei (pellet P_2). The supernatant fraction, S_2, was centrifuged at 18000 × *g* for 25 min to give a double pellet consisting of a lower layer (P_3) and a white, fluffy upper layer. The upper layer was gently collected, resuspended in 250 mM sucrose, 10 mM Tris-HCl (pH 7.4) and homogenized with six strokes of the glass-Teflon pestle. The fraction was mixed with Percoll and 500 mM sucrose, 10 mM Tris-HCl (pH 7.4) to a final concentration of Percoll 11%, 250 mM sucrose (initial density 1.046). Fractions of 25 mL of the mixture were centrifuged at 48000 × *g* for 40 min (Beckman ultracentrifuge, 50.2 Ti fixed angle rotor) to form a self-orientating continuous gradient. It was separated into 1-mL fractions numbered 1 to 25, from the bottom to the top, with a slow-rate peristaltic pump. The material-rich fractions 3–5 and 15–17 were named Layer 2 (L_2) and Layer 1 (L_1), respectively. They were diluted with 10 mM Tris-HCl buffer (pH 7.4) and centrifuged three times for 40 min at 50000 × *g* to remove the Percoll particles. Membranes were finally resuspended in 10 mM Tris-HCl buffer (pH 7.4) and immediately tested for yield and contamination. They were stored at −80°C until analysis.

The purity of fractions L_1 and L_2 was assayed using $(Na^+ + K^+)$-ATPase activity as a specific marker of BPM (20–23). Contamination with brush-border membrane and mitochondrial membrane was tested, estimating the marker enzymes of these organelles, namely sucrase (24) and succinic dehydrogenase (25).

Enzyme assays. Sucrase activity was measured by the method of Dahlquist (26). Succinic dehydrogenase activity was determined as described by Green *et al.* (25). The $(Na^+ + K^+)$-ATPase activity was considered as the ouabain-sensitive ATPase activity measured in the presence of Mg^{2+}, Na^+, K^+ and 1 mM ouabain (20). Phosphorus liberated from Na_2-ATP was measured by the method of Baginski *et al.* (27). Just before incubation, the samples were pretreated with 0.06% sodium deoxycholate, 1 mM EDTA (final concentrations) for 30 min at 20°C in order to open closed vesicles (19). Protein was determined by the method of Lowry *et al.* (28), using bovine serum albumin as a standard.

SDS-polyacrylamide gel electrophoresis. Membrane proteins were separated by slab gel electrophoresis on a linear gradient (3–15%) of polyacrylamide in 375 mM TRIS-HCl (pH 8.8) containing 0.1% SDS according to the method of Laemmli (29). Aliquots of membrane preparations (fraction L_1) were solubilized in the gel buffer containing 2% SDS, 10% glycerol, 80 mM dithiothreitol and traces of bromophenol blue. The proteins were dissociated by immersing the samples for 3 min in boiling water. The gels were run at 40 mA for 3–4 hr and the proteins stained with Coomassie blue R 250. Molecular weight markers (MW-SDS-200 Kit, Sigma Chemical Co., St. Louis, MO) were run as well.

Lipid analysis. Total lipids were extracted from BPM using $CHCl_3$/MeOH (2:1, v/v) (30). Phospholipids were separated from neutral lipids and glycolipids on a silica cartridge (SEP-PACK, Waters Associates, Milford, MA) by successive elutions with chloroform, acetone and methanol (31,32). Phospholipids were estimated by the amount of lipid phosphorus (33). Cholesterol was measured in the neutral lipids by an enzymatic method (Boehringer Mannheim, Meylan, France). Phospholipid classes were separated by high-performance liquid chromatography (34). The equipment used was a gradient liquid chromatograph (Beckman, Model 332) with a detector (UVICORD 2158 5D, LKB) set at 206 nm. The separation was done on a column (250 × 10 mm) packed with silica (5 μm Ultrasphere-Si). The mobile phases were: Solvent A, n-hexane/2-propanol/water (6:8:0.75, v/v/v), and Solvent B, n-hexane/2-propanol/water (6:8:1.4, v/v/v), at a flow rate of 2.5 mL/min. The column was eluted for 10 min with Solvent A. This was followed by a linear gradient of Solvent B in Solvent A developed from 0 to 100% over 10 min. In these conditions phospholipid classes were separated within 75 min. The percentages of phospholipid classes were estimated by the phosphorus content (33).

The fatty acid distribution in phospholipid classes was determined by gas-liquid chromatography of the fatty acid methyl esters obtained after transmethylation (35). A Packard Model 427 (Packard, Rungis, France) gas chromatograph was equipped with a flame ionization detector and a CP Wax 52 CB bonded fused silica capillary column (50 m × 0.2 mm internal diameter). Hydrogen was the carrier gas, at a flow rate of 1 mL/min. The injector and detector were set at 260 and 300°C, respectively, and the oven temperature was scheduled from 140 to 225°C at a rate of 4°C/min. Peaks were identified by comparing their equivalent chain lengths with those of authentic fatty acid methyl esters. Peak areas and automatic expression of data were obtained by an integrator (Enica 10, Delsi Instr., Surenes, France) coupled with a microcomputer.

Statistics. Results are presented as means ± S.D. Comparisons between groups were made by the Student's *t*-test. Values of $p<0.05$ were considered statistically different.

RESULTS AND DISCUSSION

Purity of BPM-preparation. The distribution of markers in the membrane fractions of control pigs isolated on the Percoll gradient showed that the two layers, L_1 and L_2, were enriched in BPM (Table 2). Fraction L_1 (mean density 1.03) appeared as the most enriched in $(Na^+ + K^+)$-ATPase relative to the initial homogenate. A twelve-fold increase in specific activity was found, whereas the sucrase specific activity remained close to that of the homogenate, revealing a minor contamination by the brush-border. Moreover, L_1 was free of any significant contamination by mitochondrial membranes as assessed by the enrichment factor of 0.6 for succinic

TABLE 2

Marker Enzyme Activities in Crude Homogenate and BPM-enriched Fractions (L_1 and L_2) of Intestinal Mucosal Cells from Pigs Fed Either a Control or an EFA-Deficient Diet

[a] Specific activities are expressed as nmol per mg protein per min (mean ± S.D. for four animals). Values significantly different from controls at *, $p<0.05$; **, $p<0.01$.

[b] Enrichment factor is the ratio of the specific activity of the membrane fraction to that of the homogenate.

[c] Recovery is the percentage of total activity of the membrane fraction relative to the homogenate.

[d] Not determined.

dehydrogenase. Fraction L_2, enriched in sucrase activity by a factor of 4.6, was discarded.

The $(Na^+ + K^+)$-ATPase specific activities measured in fractions isolated from EFA-deficient pigs were slightly lower than those measured in control pigs. This finding agrees with a previous study showing that $(Na^+ + K^+)$-ATPase specific activity was lower in BPM from rats on a saturated as compared to an unsaturated diet (8). The fact that homogenates from EFA-deficient pigs also exhibited a reduced specific activity indicates that the deficient material had not been damaged during the process of isolation as reported in the case of mitochondria (36,37). Hence, the difference in the enzyme activity might be related to changes in the membrane function induced by the diet. Accordingly, we considered that a similar degree of purification was achieved with membranes from both EFA-deficient and control pigs. Thus, fraction L_1 of either group was satisfactorily enriched in BPM, practically free of mitochondria and minimally contaminated by brush-border membranes.

SDS-PAGE of BPM proteins. The protein populations of BPM are presented in Figure 1. They show that the protein patterns were similar in preparations obtained from EFA-deficient pigs and from control pigs.

Several bands were observed with apparent molecular weights ranging from 100 to 29 kDa. The major band had a molecular weight of 46 kDa. Four secondary bands with higher molecular weights were found (56, 70, 78, 89 kDa). The fastest components consisted of two closed bands (35 and 37 kDa).

When compared to profiles previously described for the same region of the plasma membrane, the present protein pattern differed from that of mouse small intestine cells (38), but it resembled that of rat colonic epithelial cells (39).

Lipid composition of BPM. The lipid composition in fraction L_1 is given in Table 3. It reveals that phospholipid and cholesterol contents relative to protein were not significantly influenced by the dietary regimen. The cholesterol/phospholipid molar ratio of about 0.6 was

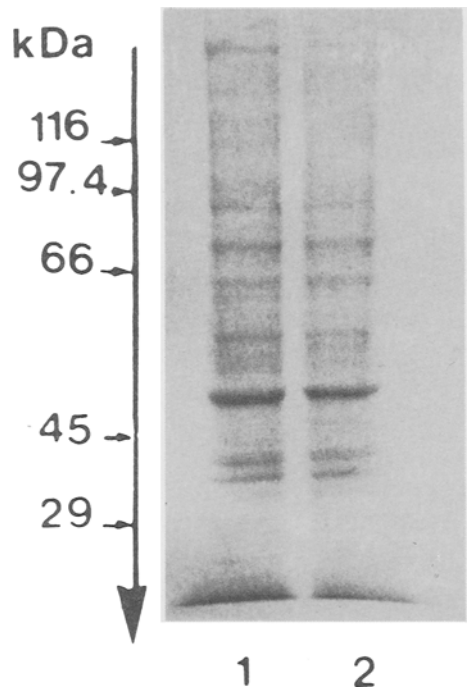

FIG. 1. SDS-PAGE of proteins from pig intestinal mucosal cell BPM. Lane 1 represents BPM from control pigs. Lane 2 represents BPM from EFA-deficient pigs. See text for experimental details. The position of molecular weight standards are shown to the left. The standards were: carbonic anhydrase, 29 kDa; albumin, egg 45 kDa; bovine albumin, 60 kDa; phosphorylase b, 97.4 kDa; and β galactosidase, 116 kDa.

in the same range as that found in rat BPM (5,40) although a higher ratio had been reported by others (7). The absence of any significant change in the lipid distribution due to the dietary fats was also observed by Brasitus *et al.* (8) in rat intestinal BPM.

The distribution of phospholipid classes did not differ in the two groups of pigs (Table 4). Phosphatidylcholine

TABLE 3

Lipid Composition of Intestinal Mucosal Cell BPM from Pigs Fed Either a Control or an EFA-Deficient Diet[a]

	Control	EFA-deficient
Phospholipid phosphorus (μg/mg protein)	15.0 ± 2.5	12.9 ± 0.8
Cholesterol (mol/mg protein)	0.28 ± 0.04	0.24 ± 0.03
Cholesterol/phospholipid (molar ratio)	0.59	0.60

[a]Values are means ± S.D. (four animals per group with two or three membrane preparations for each pig). There were no significant differences due to diet.

TABLE 4

Phospholipid Class Distribution of Intestinal Mucosal Cell BPM from Pigs Fed Either a Control or an EFA-Deficient Diet[a]

Phospholipid classes	Control	EFA-deficient
Phosphatidylcholine	45.8 ± 2.1	44.2 ± 3.3
Phosphatidylethanolamine	30.5 ± 1.9	31.1 ± 1.2
Phosphatidylserine	8.6 ± 0.9	9.1 ± 1.6
Sphingomyelin	6.9 ± 1.2	7.5 ± 0.9
Phosphatidylinositol	5.8 ± 1.6	5.8 ± 1.6
Lysophosphatidylcholine	1.1 ± 0.5	1.4 ± 0.9
Diphosphatidylglycerol	1.1 ± 0.4	0.8 ± 0.1

[a]Individual phospholipids are expressed as percentage (w/w) of total phospholipid phosphorus. Values are means ± S.D. (four animals per group) with two or three membrane preparations for each pig. There were no significant differences due to diet.

(PC) and phosphatidylethanolamine (PE) accounted for 45 and 31%, respectively, of total phospholipid phosphorus. They were also found as major classes in rat BPM (7), but according to another study on the same species, sphingomyelin was preponderant (8). In the pig intestinal mucosal cell, only the brush-border membrane has been investigated. In this membrane, a recent study (16) showed that the cholesterol/phospholipid ratio, as well as the phospholipid class distribution, were unchanged by dietary fats. Diets were similar to those we used but the experimental period only lasted six weeks after weaning.

The fatty acid distribution in the two main classes of BPM phospholipids is shown in Table 5. The major saturated fatty acids were 16:0 and 18:0, the sum of which

[a]Values are expressed as a percentage (w/w) of the total fatty acids and are means ± S.D. for four piglets. Values significantly different from controls at *, $p<0.05$, **, $p<0.01$; ***, $p<0.001$.

Unsaturation Index (UNID) = Σ (relative percentage of each unsaturated fatty acid times the number of double bonds for that particular fatty acid).

represented over 45% of total fatty acids in PC and 25% in PE regardless of the diet.

With the control diet, PC and PE contained similar levels of 18:1n-9 (about 13%) and 18:2n-6 (about 21%). By contrast, 20:4 only represented 3.9% in PC, whereas it accounted for 16.1% in PE. The proportions of 22:4 were 0.5% in PC and 4.3% in PE. A higher content of 20:4 in PE than in PC was also found in other fractions of intestinal mucosal cells, namely rat microsomal (41) and pig brush-border (16) membranes.

EFA deficiency altered the polyunsaturated fatty acid (PUFA) levels in BPM phospholipids. However, all fatty acids were not equally affected. The percentage of 18:2n-6 decreased by 82% in PC ($p<0.01$) and 69% in PE ($P<0.001$), whereas 20:4 was minimally reduced in both classes. It decreased 1.4 times ($p<0.05$) in PC and 1.2 times (non-significant) in PE.

Preliminary data revealed that after a six-week-post-weaning regimen, EFA deficiency already reduced the BPM levels of 18:2, but not 20:4 (Frémont, L., and Duranthon, V., unpublished data). The influence of dietary fats on phospholipids of the intestinal mucosal cells plasma membrane without changing the 20:4 levels has already been reported. In both PC and PE, the 20:4 percentages were also unaffected in pig brush-border membranes (16) and in rat plasma membranes (1) with a saturated diet. Nevertheless, Brasitus *et al.* (8) found a 50% decrease of 20:4 in the intestinal BPM of rats fed a saturated as compared to an unsaturated regimen. This finding could be due to the high lipid content of the diets (37%).

In both classes of phospholipids, EFA deficiency caused an approximately two-fold increase in 18:1n-9. Moreover, 20:3n-9 present in very small amounts in BPM phospholipids of control pigs accounted for 10.1% in PE and 2.9% in PC of EFA-deficient pigs.

The 20:3n-9/20:4n-6 ratio which expresses EFA deficiency (42) reached 1.1 in PC and 0.8 in PE, whereas it remained lower than 0.1 in control pigs. A similar but smaller effect was also observed in the pig brush-border membrane of intestinal mucosal cells after a six-week feeding of an EFA-deficient diet (16).

The essential fatty acids of the n-3 series were 20:5, 22:5 and 22:6. With the control diet, the overall content represented about 1% of total fatty acids in PC and 4% in PE. The EFA-deficient diet did not reduce the level of these fatty acids. Thus, the percentages were similar or even slightly higher (20:5 in PC and PE, 22:6 in PE). These findings show that PUFA with 20 and 22 carbons of both series, n-6 and n-3, were more incorporated in PE than in PC and that PE was also less affected by EFA deficiency than PC.

The unsaturation index (UNID) was higher in PE than in PC and with the EFA-deficient diet the value remained practically unchanged in PE and was minimally reduced in PC. The higher unsaturation of PE as compared to PC has been found in other tissues (3). The maintenance of n-3 PUFA and the partial replacement of n-6 PUFA by 18:1n-9 and 20:3n-9 levels might contribute to preserving the fluidity of the BPM. However, the position of the double bond largely influences the membrane properties (3). Hence, changes similar to those observed in our experiment in fatty acid profile of pig brush-border membranes by EFA deficiency were found to be associated with a low but significant decrease in lipid fluidity (16). Moreover, a harmful effect of 20:3n-9 cannot be ruled out (43).

The influence of dietary lipids on the fatty acid composition of BPM and serum phospholipids is shown in Figure 2. It is clear that with the EFA-deficient diet, the 20:4 levels remained unchanged in BPM, whereas it decreased by 65% ($p<0.01$) in the serum. On the contrary, the precursor 18:2 decreased in the same proportions in both BPM and serum (70%, $p<0.001$ *vs.* 73%, $p<0.01$).

It is well known that the conversion of 18:2 into 20:4 takes place mainly in the liver; however, the existence of a Δ6 desaturase activity has been described in rat intestinal mucosa (44). Assuming that such an activity also exists in pig intestinal mucosa, a fraction of 18:2 previously incorporated into the tissue could be converted into 20:4 *in situ*.

Endogenous PUFA are provided to the intestinal mucosal cell by reabsorbed bile and by circulating lipids mainly incorporated in lipoproteins. Serum lipoproteins might play a functional role in the regulation of certain cellular processes in maintaining membrane lipid composition (45,46). The authors suggest the existence of intact phospholipid molecule exchanges between lipoproteins and the cell plasma membrane. Moreover, lipoprotein binding sites have been described in rat (47,48) and human

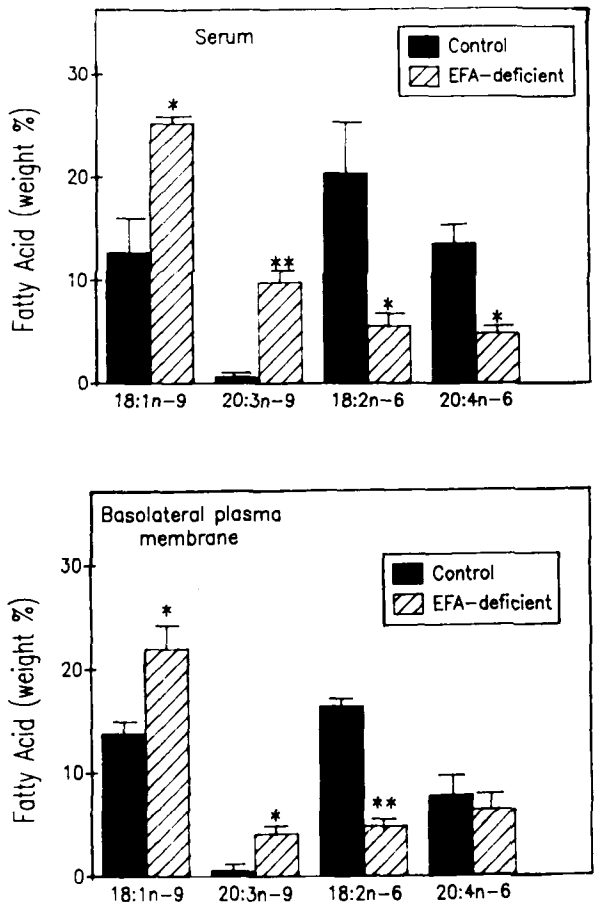

FIG. 2. Incorporation of fatty acids of the series n-9 and n-6 into phospholipids isolated from serum and intestinal mucosal cell BPM from pigs fed either a control or an EFA-deficient diet for 12 weeks post-weaning. Values significantly different from controls at *, $p<0.01$; **, $p<0.001$.

(49) intestinal plasma membrane. Binding has only been observed on BPM.

The intestinal mucosal cell has a rapid rate of turnover and in the present experiment, piglets were in a phase of intensive growth. Therefore, the demand of PUFA for the formation and replacement of structural phospholipids was very high. In the EFA-deficient group, these fatty acids were of maternal origin since pigs began to receive experimental diets just at weaning.

The placental transfer of 18:2 and 20:4 from the maternal blood to the fetus has been described in many species (50–52). In pigs, only trace amounts of free fatty acids cross the placental tissues (52,53), but the fetal piglet is capable of elongating and desaturating 18:2 into 20:4 (54). The newborn pig has very little body fat (1–2%), which contains 5–8% 18:2 and 5–6% 20:4 (55,56). For one or two days after birth, suckling pigs ingest colostrum containing 20–25% lipids (dry matter), in which 18:2 and 20:4 account for 12–18 and 1%, respectively, of total fatty acids (55,57). Afterwards, the sow's milk supplies very high fat levels (40% of dry matter) with 16% 18:2 and 1% 20:4 (56). It has been reported (58) that the lipid percentage of the total body increased eight-fold within a week after birth. At seven days, the backfat contained 11% 18:2 and traces of 20:4, whereas muscle and liver contained 12% 18:2 and 2–9% 20:4. Accordingly, one may assume that the PUFA reserves were still low when the diet treatment started.

The present findings show that the intestinal mucosal cell BPM of piglets is relatively resistant to a 12-week EFA deficiency. It therefore seems likely that PUFA previously incorporated into other tissues are preferentially mobilized for the synthesis of intestinal BPM. It has been suggested that the intestine might have a higher priority than certain organs, because of its role in the transport of nutrients between the environment and the body (59). However, EFA deficiency alters the structure and function of the jejunal epithelial cells impairing fat absorption (59,60).

During the period of dietary EFA deficiency, the uptake by BPM of endogenous PUFA vehicled by plasma lipoproteins depends on the efficiency of their mutual interactions. EFA deficiency modifies the lipoprotein profile and lipid supply to the cells (61). Thus, changes in the conformation of the particles might influence the transfer of PUFA to the intestinal mucosal cell. Moreover, it has been suggested that lipoprotein binding sites are protected against any enzyme attack by the membrane phospholipids in which they are embedded (62). It may thus be hypothesized that changes of fatty acid distribution in BPM phospholipids induced by EFA deficiency influence the binding activity of BPM specific sites for plasma lipoproteins. A reduced activity might impair the supply of endogenous PUFA for the synthesis of the other intestinal mucosal cell membranes.

Previous studies have provided evidence that Mg deficiency affects lipid metabolism. The present experiments were designed to assess whether the hypertriglyceridemia associated with Mg deficiency was related to alterations in post-heparin lipase activity (PHLA). Mg-deficient and control diets were pair-fed to weanling Wistar rats for eight days and plasma lipoproteins were separated into various density classes by sequential preparative ultracentrifugation. Triglycerides were significantly increased in chylomicrons and in the very low density lipoprotein, low density lipoprotein and high density lipoprotein (HDL) fractions. Cholesterol and phospholipid levels were significantly lower in the HDL fraction. PHLA in deficient rat was substantially lower than in control rats. The inverse correlation between plasma triglyceride concentration and PHLA strongly suggests that hypertriglyceridemia is the result of defective lipolysis of plasma triglycerides in Mg-deficient rats. Further examination of the PHLA was carried out by salt-mediated inhibition of lipoprotein lipase (LPL) and by heparin sepharose affinity chromatography and purified rat LPL antiserum. The results indicate that hepatic lipase is significantly decreased in Mg-deficient rats but the low PHLA is due mainly to a decline in LPL. However, total LPL activity, that is, both the intracellular and the extracellular pools of LPL in adipose tissue, heart and diaphragm, were unaffected by Mg deficiency. The results suggest that the decrease of LPL activity in the plasma of Mg-deficient rats may be due to a selective decrease in the heparin-releasable pool of enzyme.

Lipids 26, 182–186 (1991).

Several studies have provided evidence that magnesium deficiency affects lipid metabolism (1–5). Magnesium deficiency can have pronounced effects on the physical state of membrane bilayer lipids, and defective membrane function could be the primary lesion underlying the cellular disturbances that occur in magnesium deficient animals (6).

The mechanisms behind the hypertriglyceridemia of Mg-deficient rats have been addressed in several studies. Hyperlipemia can be produced either by excessive production and release of lipids into the circulation, by their impaired removal from the circulation, or by a combination of both. Previous experiments indicate that decreased clearance of circulating triglycerides is a major mechanism contributing to hyperlipemia in Mg-deficient rats (7). Because lipoprotein lipase is the rate-limiting enzyme in the removal process, reduction of its activity can lead to hypertriglyceridemia (8). The present experiment was designed to test the hypothesis that hypertriglyceridemia associated with Mg deficiency can be causally related to alterations in LPL activity.

MATERIALS AND METHODS

Weanling male Wistar rats weighing about 60 g were randomly divided into magnesium-deficient and control groups. They were housed four to a cage and pair-fed with the appropriate diets for eight days using an automatic feeding apparatus. The initial food intake of 6 g/day rose to 8 g/day per rat. Distilled water was provided *ad libitum.* The synthetic diets contained (g/kg) casein 200, sucrose 705, corn oil 50, mineral mixture 35, and vitamin mixture 10, as described previously (1). Their magnesium contents determined by analysis were 30 mg/kg (deficient) and 960 mg/kg (control).

The experiments were performed between 9–10 a.m. on non-fasting rats. In some studies, the rats were food deprived 12 hr before experimentation. Plasma or other tissue samples were obtained on rats anesthetized with sodium pentobarbital (40 mg/kg of body weight).

Lipoprotein isolation and analysis. Lipoprotein isolation and analysis were carried out on unfrozen plasma from non-fasting rats. NaN_3 (0.02%), merthiolate (0.005%) and Na_2-EDTA (0.04%) were added. Samples were overlayered with 0.15 M NaCl/0.01% EDTA (d=1.006 g/mL) and chylomicrons were recovered following two centrifugations for 30 min at 12000 × *g*. Lipoproteins were separated into various density classes by sequential preparative ultracentrifugation. Very low density lipoproteins (VLDL) (d < 1.006 g/mL), low density lipoproteins (LDL) (d=1.006–1.050 g/mL) and high density lipoproteins (HDL) (d=1.050–1.21 g/mL) were isolated after the density had been adjusted with solid KBr. Ultracentrifugation was performed at 20°C in a Beckman model L5-50B ultracentrifuge (Beckman Instruments Inc., Palo Alto, CA) with a Ti-50 rotor.

Post-heparin plasma. Blood samples were withdrawn from the subclavian venous plexus of fed or fasted rats into tubes containing heparin. The plasma was separated in a refrigerated centrifuge and was used for the determination of Mg and triglycerides. Blood was taken again 10 min after intravenous administration of heparin (Produits Roche, Neuilly, France) at 25 U per 100 g of body weight.

Tissue lipoprotein lipase activity. Epididymal fat pads in fed rats, and the diaphragm and heart in fasted rats were excised immediately. Tissues were rinsed in 0.15 M NaCl solution at 4°C, blotted on filter paper, weighed and frozen on dry ice.

Measurement of post-heparin lipase activity in plasma. Lipolytic activity was measured with an emulsion of glycerol tri[1-^{14}C]oleate as substrate (9,10). The stock substrate contained 25 μCi (926.10^3 Bq) glycerol tri-[1-^{14}C]oleate, 69 mg unlabelled triolein, 3.33 mg soybean phosphatidylcholine and 5 mL glycerol. The mixture was

emulsified on ice for 5 min using a polytron (IKA, Staufen, Germany). The emulsion was stable for six weeks. The assay mixture contained 150 μL of the enzyme solution and 100 μL of diluted substrate (40 μL of emulsified stock substrate, 40 μL of 5% bovine serum albumin solubilized in 0.62 M Tris/0.16 M NaCl and adjusted to pH 8.6, and 20 μL of fresh human serum). After incubation at 37°C for 20 min, the labelled fatty acid products released were extracted and radioactivity was counted. Enzyme activity (1 mU) was defined as the amount of enzyme required to catalyze the release of 1 nmol of fatty acid per min at 37°C.

Measurement of tissue lipoprotein lipase (LPL) activity. Acetone/diethyl ether powder was prepared, and the crude lipoprotein lipase was extracted with 25 mM NH_4OH/NH_4Cl buffer (pH 8.5). The enzyme preparation was then homogenized with a polytron, centrifuged for 30 min at 4000 × *g* at 4°C and the supernatant collected. Measurements were made on 50–150 μL of supernatant.

Characterization of post-heparin lipase activity in plasma. In some assays to measure the effect of 1 M NaCl and the serum dependence of the lipolytic activity, serum was omitted from the incubation medium and was replaced by 0.16 M NaCl. The incubation was carried out with 100 μL of enzyme plus 50 μL of 5 M NaCl and 100 μL of substrate.

Heparin-Sepharose affinity chromatography was done on CNBr Sepharose 4B containing covalently linked crude heparin. The 1 × 5 cm column was equilibrated with 0.005 M barbital buffer containing 0.4 M NaCl (pH 7.4), and chromatography was carried out at 4°C. Two mL of diluted post-heparin plasma 0.5 M NaCl (v/v) was applied to the column, and the column was washed with 10 mL 0.25 M NaCl buffer and 30 mL 0.5 M NaCl. Successive 2-mL fractions were eluted with NaCl solutions of increasing molarity [10 mL of 0.7 and 1.5 M NaCl in 0.005 M barbital buffer (pH 7.4)]. Measurements were made on 150 μL enzyme fractions.

Lipase activity was also measured by use of an antiserum against purified LPL from rat adipose tissue, raised in goats as previously described (11). This antiserum has been shown to partially inhibit whole post-heparin plasma and it did not inhibit hepatic triacylglycerol lipase separated from rat post-heparin plasma by affinity chromatography. Post-heparin plasma (75 μL) diluted 1:10 was preincubated for 5 min at 37°C with 75 μL antiserum. The mixture was then centrifuged and incubated with substrate. Lipolytic activity was measured before and after incubation with the antiserum.

Other analytical methods. Magnesium was determined with a Perkin-Elmer series 400 atomic absorption spectrophotometer. Plasma was analyzed directly after dilution in lanthanum chloride solution containing 1 g La/L. Plasma triglycerides (Biotrol, Paris, France), cholesterol (BioMérieux, Charbonnières-les-Bains, France) and phospholipids (BioMérieux, Charbonnières-les-Bains, France) in plasma were determined by enzymatic procedures (12–14).

Calculations and statistical analysis. Values are given as means ± SEM. Data were analyzed by Student's *t*-test or Mann-Whitney U test and regression analysis.

RESULTS

The mean final body weights of the magnesium-deficient and control rats were 85 and 91 g, respectively, at the end of the experimental period and clinical symptoms of Mg deficiency were observed. An obvious turbidity and hyperlipemia was visible in the plasma from deficient animals when rats were not fasted before sacrifice; this was due mainly to hypertriglyceridemia. Triglyceride, cholesterol and phospholipid distribution in lipoprotein fractions are shown in Table 1. With Mg deficiency, triglycerides were significantly increased in chylomicrons and in the VLDL, LDL and HDL fractions. Both phospholipids and cholesterol were significantly increased in the VLDL and LDL fractions, but significantly lower in the HDL fraction.

Plasma Mg levels were significantly lower in the Mg-depleted group. PHLA in non-fasting deficient rats was significantly lower than in control rats (Table 2) and was inversely correlated with plasma triglyceride concentration (Fig. 1). The plasma post-heparin activity of Mg-deficient rats was also lower than that of the control rats

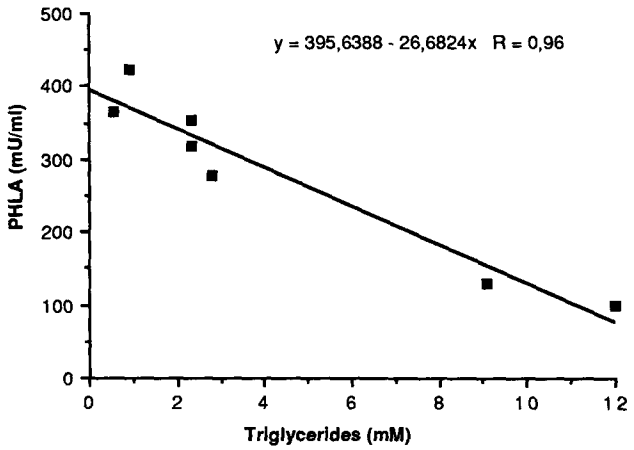

FIG. 1. Relationship between plasma triglyceride concentrations and post-heparin lipolytic activity in Mg-deficient animals.

when lipolytic activity was determined at 1.0 mol NaCl in the absence of human serum (Table 2).

For further characterization of PHLA (Table 3), the LPL fraction was separated on a heparin Sepharose affinity column. The fraction, which was inhibited by antilipoprotein lipase serum, was significantly reduced in Mg-deficient rats. When post-heparin plasma was incubated with antiserum, the lipolytic fraction of Mg-deficient rats was also lower than that of control rats. Thus, low PHLA was shown to be mainly due to a decline in LPL, but hepatic lipase (HL) was also significantly decreased. When rats were food deprived before sacrifice, the effect of Mg deficiency on plasma triglyceride concentration was also noticeable and PHLA was significantly lower than in control rats (Table 4). The adipose tissue LPL activity was the same in non-fasting control and Mg-deficient rats, and the heart and diaphram enzyme activity was not different in the two experimental fasted groups (Table 5).

DISCUSSION

The hyperlipemic effect of Mg deficiency was observed in post prandial conditions or following fasting. The post prandial phase is a non-static phase where activation of the processes of formation, catabolism and interchange of the different lipoprotein fractions takes place. The results are often variable since they depend, at least

partially, on the stage of intestinal absorption. An automatic feeding apparatus was therefore used in the present experiment in order to obtain the same pattern of feeding in both control and Mg-deficient rats. This was not the case in the previous experiment (1). Moreover, as the hyperlipemic effect of Mg deficiency was still observed when rats were food deprived 12 hr before sacrifice, this effect was not the consequence of a modification in intestinal absorption.

Chylomicrons, VLDL and LDL levels were higher in Mg-deficient rats, but HDL levels were lower than in controls. Triglycerides were elevated and this was primarily due to an increase in chylomicron and VLDL concentrations. Cholesterol levels increased in the VLDL and LDL fractions. Since plasma cholesterol levels tend to decrease as a result of the decrease in HDL levels, total cholesterol

levels were not modified. In fact, the contribution of VLDL and LDL cholesterol to the total plasma cholesterol is very small in the rat (15). In contrast to the slight modification in total cholesterol in severe magnesium deficiency of short duration, other experiments indicate a significant increase in total cholesterol during moderate magnesium deficiency of long duration (16).

Several defects can produce hyperlipemia. These defects can consist of either an overproduction of a lipoprotein or a decrease in catabolism. By studying intralipid clearance, we were able to show that hyperlipemia developed because triglyceride removal was impaired (7). Moreover Mg-deficient rats exhibited delayed clearance of ^{14}C-labelled VLDL compared to control rats, whereas the catabolism of [^{125}I]LDL was not affected (17).

The present experiment provides what is believed to be the first direct evidence that Mg deficiency decreases PHLA. After an intravenous injection of heparin, triglyceride hydrolase activity appears in plasma (8,18). LPL is not the only lipase released by heparin into the bloodstream, HL is also released. Both enzymes are located in the capillary bed where lipolytic activity is expressed. LPL is stimulated by apolipoprotein CII and inhibited by NaCl 1.0 M, whereas HL seems not to require any specific serum factor and is activated by high salt concentrations. The lipolytic degradation of circulating triglyceride-rich lipoproteins involves loss of triglyceride and phospholipid from the particles. The two enzymes are believed to participate in this process. LPL is associated primarily with adipose tissue, and skeletal muscle shows a particular affinity for chylomicrons and VLDL. The function of the other enzyme, HL, is less well documented (19) and has a higher affinity for smaller particles. Several studies have suggested that its actions may be directed primarily at the metabolism of small VLDL, LDL and HDL. The separation of enzymes was efficiently obtained by heparin-Sepharose chromatography, a useful procedure when it is imperative to exclude the possible effects on enzymatic activity of other components in the post-heparin plasma samples (20). Inhibition of LPL by specific antibodies was another way to assay for HL and to quantitate LPL by subtracting the resistant lipolytic activity from total post-heparin lipolytic activity. Suppression of LPL by NaCl was another approach.

Two factors may be responsible for defective lipolysis of plasma triglycerides in Mg-deficient rats—a reduction in the availability of LPL or an abnormality in the lipoproteins themselves, rendering them a poor substrate for the enzyme. The apolipoproteins of VLDL isolated from rats fed deficient diets differ significantly from those of rats fed adequate diets. The VLDL in Mg-deficient rats appear to have reduced proportions of apo E but increased apo C. The role of this altered VLDL composition on defective clearance has previously been discussed (10). In these studies, it could not be determined how the changes in apolipoprotein patterns were related to hyperlipoproteinemia. The question remained whether the alterations in pattern cause hyperlipoproteinemia or whether these alterations were the results of the metabolic changes that produces hypertriglyceridemia (17).

In the present study, the assays for post-heparin lipolytic activity were carried out in the presence of human serum, that is providing any lipoprotein lipase cofactor protein requirement. Plasma triglyceride concentration correlates inversely with post-heparin plasma lipolytic activity. The experiment suggests that the alterations in the lipoprotein profile are the result of a reduction in the availability of LPL and not of an abnormality in the lipoproteins themselves.

The low lipolytic activity provides an appropriate explanation for both elevated levels of VLDL fraction and chylomicrons and for the reduction of HDL, because LPL activity is one determinant of plasma HDL levels. The accumulation of lipids in the blood occurs when their rate of entry into the blood exceeds their rate of removal. Sucrose, as compared to starch, markedly increases the hyperlipidemic effect of magnesium deficiency (1). The hypertriglyceridemic effect of sucrose is associated with a greater conversion of fructose to fatty acids in liver into plasma relative to dietary glucose or starch. Impairment of triglyceride clearance following a reduction in PHLA in Mg-deficient rats may explain the synergistic hypertriglyceridemia in Mg deficiency and sucrose feeding.

Since magnesium deficiency was associated with a dramatic decrease in LPL, it seemed worthwhile to determine the LPL activity in adipose tissue and muscle. After a carbohydrate-rich meal, enzyme activity increases rapidly in adipose tissue and declines in muscle. During a fast, the lipolysis of triglycerides stored in adipose tissue accelerates. This change is accompanied by decreasing levels of LPL in adipose tissue, but by stable or even increasing levels of lipase in muscle (cardiac, skeletal) (21,22). Therefore, LPL activity of adipose tissue was measured in post prandial conditions, whereas LPL activity of muscles was measured following food deprivation. Assuming that LPL activity in epididymal adipose tissue reflects that in other localizations (23), and activity in the heart and diaphragm is representative of that of muscles (24), an interesting aspect of the decrease in plasma LPL in Mg-deficient rats is that it occurs without decreases in muscle and adipose tissue LPL.

LPL is synthesized as an inactive precursor in the endoplasmic reticulum. This inactive form is transported to the Golgi apparatus where terminal processing and activation occur (18). Active LPL is released from the cells and moves to the vascular lumen where it is bound at the endothelial surface by glycosaminoglycans. In tissues such as adipose tissue and muscle, LPL exists in both functional and non-functional forms. The functional form appears to be largely associated with the endothelial surface of tissue capillaries and is readily released by heparin. The non-functional form of LPL, which is not readily releasable by heparin, appears to be associated with the tissue parenchymal cells (20). Two techniques, acetone/diethyl ether powder preparations and heparin eluates, have been described for assay of enzyme activity in adipose tissue and muscle. It is generally considered that the acetone/diethylether preparation represents the total tissue activity, *i.e.*, both the intracellular and the extracellular pools, including the physiologically active fraction at the endothelial surfaces. Heparin eluates, however, largely reflect extracellularly located enzyme (20). It would be of interest to determine if there is a defect within the tissues from Mg-deficient rats in maintaining the heparin-releasable pool of enzyme activity. With the acetone/diethylether preparation in whole tissue only, this selective decrease may not be discernable.

The mechanism responsible for the effect of Mg deficiency on LPL activity is unclear. The role of Mg in secretion and mechanisms of endothelial binding of LPL is unknown, and there is still only a limited knowledge of the heparin releasable pool of enzyme activity and its important relationship to the *in vivo* function of the enzyme. There are several explanations for the low post PHLA in Mg-deficient rats. One possibility is that Mg deficiency could impair secretion and that Mg is necessary for the transport of the active enzyme, and relocation to the endothelium. Other possibilities could be that the enzyme is degraded by the endothelial cells or that Mg deficiency increases the removal of the enzyme from the circulation, thus explaining why low activity is found in post-heparin plasma. Severe acute Mg deficiency induces hypertriglyceridemia and a decrease in PHLA. The time course development and the reversibility of these modifications by Mg refeeding should be examined.

Since the effect of marginal Mg deficiency of long duration is more relevant to human nutrition (25), the influence of moderate Mg deficiency and whether long term adaptation may occur which would affect the response remain also to be determined. While acute Mg deficiency has been shown to induce hyperlipemia and vascular lesions in experimental animals (2), the possibility that chronic Mg deficiency may be one among several factors that favor vascular disease in humans, is often disregarded (2). However, several observations indicate that patients with ischemic heart disease (IHD) are often Mg-deficient and that Mg deficiency may, together with several other factors, be involved in the development of IHD. Recently, Rasmussen *et al.* (26) found that oral Mg supplementation reduced plasma concentrations of triglycerides, VLDL and apo B in patients with IHD, suggesting that LPL activity might be reduced by Mg deficiency and increased by oral supplementation. Future investigations should clarify the influence of magnesium on LPL activity and lipid metabolism.

Antioxidant Activity of Oxidation Products of α-Tocopherol and of its Model Compound 2,2,5,7,8-Pentamethyl-6-chromanol

Cacang Suarna and **Peter T. Southwell-Keely***
School of Chemistry, University of New South Wales, Kensington N.S.W., 2033 Australia

A variety of oxidation products (4-29) of α-tocopherol, 1 and of its model compound, 2,2,5,7,8-pentamethyl-6-chromanol (2) has been tested for antioxidant activity against autoxidizing safflower oil (ASO) and autoxidizing methyl linoleate (AML). The following compounds showed good antioxidant activity against both substrates: 5-hydroxymethyl-2,2,7,8-tetramethyl-6-chromanol (4), 5-(2,2,5,7,8-pentamethyl-6-chromanoxy)methyl-2,2,7,8-tetramethyl-6-chromanol (15), 1,2-*bis*(2,2,7,8-tetramethyl-6-chromanol-5-)ethane (16), 5-ethoxymethyl-7,8-dimethyltocol (19), 5-methoxymethyl-2,2,7,8-tetramethyl-6-chromanol (21), 5-ethoxymethyl-2,2,7,8-tetramethyl-6-chromanol (20), 5-propoxymethyl-2,2,7,8-tetramethyl-6-chromanol (22), 5-butoxymethyl-2,2,7,8-tetramethyl-6-chromanol (23), 5-(2-methyl-1-propoxy)methyl-2,2,7,8-tetramethyl-6-chromanol (24), 5-(2-methyl-2-propoxy)methyl-2,2,7,8-tetramethyl-6-chromanol (25), 5-heptoxymethyl-2,2,7,8-tetramethyl-6-chromanol (26), 5-undecoxymethyl-2,2,7,8-tetramethyl-6-chromanol (27), 5-phytoxymethyl-2,2,7,8-tetramethyl-6-chromanol (28) and 5-cholesteroxymethyl-2,2,7,8-tetramethyl-6-chromanol (29). 2,2,7,8-Tetramethylchroman-5,6-dione (17) and 1,2-*bis*(2,2,7-trimethylchroman-5,6-dione-8-)ethane (18) showed significant antioxidant activity against ASO but not against AML. If the corresponding oxidation products of 1 are formed *in vivo* it means that the antioxidant activity of 1 is not lost on oxidation. This may help to explain the outstanding capacity of 1 to protect cell membranes.
Lipids 26, **187-190 (1991).**

It is believed that α-tocopherol (1) functions *in vivo* as an antioxidant by being oxidized to the tocopheroxyl radical and then regenerated by a reducing agent such as ascorbic acid (1-8). This one-electron redox cycle offers an explanation for the remarkable efficiency of 1. The tocopheroxyl radical is easily formed due to its stabilization by the pyran ring oxygen (9).

Recent studies on the model compound of 1, 2,2,5,7,8-pentamethyl-6-chromanol (2), have suggested another reason for the extraordinary effectiveness of 1 as an antioxidant. Many of the oxidation products of 2 are themselves phenolic compounds and therefore potentially capable of acting as antioxidants (10-13). The present work was undertaken to determine the effectiveness of a variety of oxidation products of 2 as antioxidants.

MATERIALS AND METHODS

Compound 1 (Roche Products, Australia) and butylated hydroxyanisole (BHA, Embanox, May and Baker, Dagenham, England) were obtained commercially and used without further purification. Compound 2, 2,2,7,8-tetramethyl-6-chromanol (3) and 5-hydroxymethyl-2,2,7,8-tetramethyl-6-chromanol (4) were synthesized to satisfactory purity by established methods (10,11).

The following compounds were isolated from oxidation reactions of 1 and 2 as described previously (12-16): α-tocoquinone (5), 2-(3-hydroxy-3-methylbutyl)-3,5,6-trimethyl-1,4-benzoquinone (6), 1H-2,3-dihydro-3-(4,8,12-trimethyltridecyl)-7a-(3hydroxy-3,7,11,15-tetramethylhexadecyl)-3,5,6,9,10,11a-hexamethyl-pyrano[2,3-a]xanthene 8(7aH), 11(11aH) dione (7), 1H,2,3-dihydro-3,3,5,6,9,10,11a(R)-heptamethyl-7a(S)-(3-hydroxy-3-methylbutyl)-pyrano[2,3-a]xanthene 8(7aH), 11(11aH) dione (8), 5-ethoxycarbonyl-7,8-dimethyltocol (9), 5-formyl-7,8-dimethyltocol (10), 5-formyl-2,2,7,8-tetramethyl-6-chromanol (11), the spirodimer of 1 (12), the spirodimer of 2 (13), the spirotrimer of 2 (14), 5-(2,2,5,7,8-pentamethyl-6-chromanoxy)methyl-2,2,7,8-tetramethyl-6-chromanol (15), 1,2-*bis*(2,2,7,8-tetramethyl-6-chromanol-5)ethane (16), 2,2,7,8-tetramethyl-chroman-5,6-dione (17) (Suarna, C. and Southwell-Keely, P.T., unpublished data), 1,2-*bis*(2,2,7-trimethylchroman-5,6-dione-8)ethane (18) (Suarna, C., and Southwell-Keely, P.T., unpublished data), 5-ethoxymethyl-7,8-dimethyltocol (19), 5-ethoxymethyl-2,2,7,8-tetramethyl-6-chromanol (20), 5-methoxymethyl-2,2,7,8-tetramethyl-6-chromanol (21), 5-propoxymethyl-2,2,7,8-tetramethyl-6-chromanol (22), 5-butoxymethyl-2,2,7,8-tetramethyl-6-chromanol (23), 5-(2-methyl-1-propoxy)-methyl-2,2,7,8-tetramethyl-6-chromanol (24), 5-(2-methyl-2-propoxy)methyl-2,2,7,8-tetramethyl-6-chromanol (25), 5-heptoxymethyl-2,2,7,8-tetramethyl-6-chromanol (26), 5-undecoxymethyl-2,2,7,8-tetramethyl-6-chromanol (27), 5-phytoxymethyl-2,2,7,8-tetramethyl-6-chromanol (28), and 5-cholesteroxymethyl-2,2,7,8-tetramethyl-6-chromanol (29).

Safflower oil (400 g; Becel Pty. Ltd, Marrickville, N.S.W., Australia) was purified by passage over alumina (200 g) which had been activated at 600°C for 6 hr immediately before use. The alumina column (4.5 × 35 cm) and collection vessels were wrapped in aluminum foil and the oil pushed through the column using a slight nitrogen pressure. The peroxide value of the purified oil was 1.24 meq/kg and gas liquid chromatography (GLC) analysis gave the following fatty acid composition: palmitic acid, 7.5%; stearic acid, 3.3%; oleic acid, 14.7%; and linoleic acid, 74.5%.

Methyl linoleate was prepared from safflower oil by transesterification (17) followed by removal of the saturated methyl esters by urea clathration and, finally, fractional distillation (18,19). The fraction boiling at 150-152°C/0.3-0.6 mm Hg was shown by GLC analysis to be >99% pure.

Glass tubes (50 × 25 mm) for antioxidant testing were washed with detergent, tap water, immersed in 50% nitric acid overnight, washed again with tap water, distilled water and dried in an oven before use.

The substrates were analyzed for trace metals as follows: To the substrate (2 g) was added 50% nitric acid

(2 mL) and the mixture shaken at 50°C for 1 hr. The nitric acid layer was withdrawn, the substrate washed with nitric acid (2 × 2.5 mL), and the washings added to the original nitric acid layer. The combined nitric acid solution was taken to dryness, made up to 10 mL with 10% nitric acid and analyzed for trace elements by an Inductively Coupled Plasma Atomic Emission Spectrometer (Labtam, Melbourne, Australia). The experiment was performed in duplicate and compared with duplicate reagent blanks.

Antioxidants were dissolved in substrates to give solutions equimolar with 0.25% BHA and were diluted with substrates to a test concentration equimolar with 0.01% BHA as required.

Antioxidant test procedure. Duplicate test samples (1 g) in glass tubes (50 × 25 mm) in a two-tiered aluminum rack designed to accommodate 60 samples were placed in a convection oven at 40 ± 1°C for methyl linoleate or 60 ± 1°C for safflower oil. At daily intervals the tubes were cooled in a desiccator and weighed accurately. The procedure was continued until a significant weight gain was noted. Antioxidant activity was expressed as an induction period (in days; mean ± standard deviation) which was determined by the point of intersection of tangents drawn to the oxidation curve early in the run and late in the run after the oxidation rate had assumed its uninhibited value (20).

RESULTS AND DISCUSSION

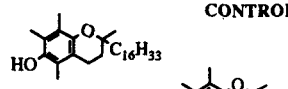
The variety of methods used to test for antioxidant activity is testimony to the fact that no one method is absolutely satisfactory in all situations. The oxygen uptake method is probably the most accurate, but can only handle limited numbers of samples at any one time (21-23).

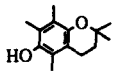
The weight gain method was chosen in this instance as being the only method available which would allow simultaneous comparison of a large number of compounds under identical conditions (24). Variation in antioxidant performance in different substrates is noted often, and therefore two substrates were chosen, safflower oil and methyl linoleate.

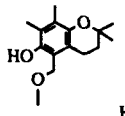
Both substrates were tested initially at 60°C, but it was found that no compounds protected methyl linoleate successfully at this temperature and subsequent experiments on methyl linoleate were performed at 40°C. Analysis of both substrates for trace elements revealed that only iron was present at a higher level than that of the reagent blank and that methyl linoleate contained 1.6 ppm of iron, whereas safflower oil contained 0.3 ppm. This was surprising since the isolation and purification (including distillation) of methyl linoleate had been carried out in glass vessels. However, the higher level of iron in methyl linoleate may help explain its greater ease of oxidation.

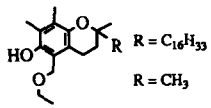
Compound 3 (the γ-tocopherol model compound) was more active than all of the products of 1 and 2 against both substrates and was only surpassed by BHA against methyl linoleate (Table 1). Compounds 1 and 2 were almost as active as 3 against safflower oil but, surprisingly, were much less active against methyl linoleate and, in fact, were inferior to many of the oxidation products of 2 against this substrate. The lack of agreement between different methods of antioxidant assay is shown clearly by a comparison of the activities of 1 and 2 using three methods—i) inhibition of weight gain (present results), ii) inhibition of the destruction of β-carotene by autoxidizing hydrogenated corn oil (25), and iii) inhibition of the initiated oxidation of styrene (9). In method i) the order of activities was 2 > 1, in method ii) 1 > 2 and in method iii) 2 > 1. Comparison of 1,2 and 3 using methods i) and ii) gave in method i) 3 > 2 > 1 and in method ii) 1 > 3 > 2. The relative activities of compounds 2 and 3 were as predicted from earlier literature on α- and γ-tocopherol (26,27) but were contrary to more recent results (9,28). The reason for the difference between the two sets of results has been related to the use of an uninitiated (present results) or initiated autoxidation test system (9). However, the recent results (9,28) were concerned only with the reaction of 1 and γ-tocopherol with peroxyl or phenoxyl radicals and did not take into account the influence of oxidation products of 1 and of γ-tocopherol on the overall autoxidation process. It may be that the main reason for the difference in the activities of 2 and 3 lies in the fact that a major product from the oxidation of 3 is the ortho quinone 17, which retains significant activity (see below) while the major products of 2 are the spirodimer 13, the spirotrimer 14 and the para quinone 6 (Suarna, C., and Southwell-Keely, P.T., unpublished data) all of which have little activity (see below).

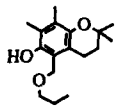
If the higher level of iron in the methyl linoleate is the main reason for its more rapid oxidation than safflower oil, an alternative explanation for the greater efficacy of 3 is possible. The intermediate in the oxidation of 3 to 17 is 2,2,7,8-tetramethyl-5,6-dihydroxy-chroman (30), which would be an excellent chelator of iron, and many other metals, and could function both by prevention of propagation and of initiation. Sufficient 30 to chelate all of the iron would have accumulated well before all of 3 had been oxidized.

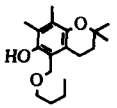


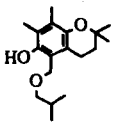


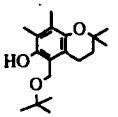


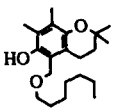


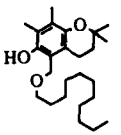


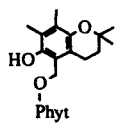


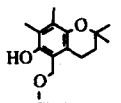


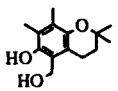


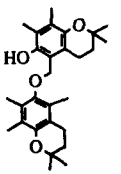




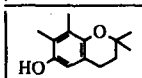


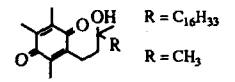


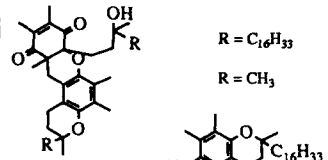


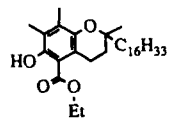


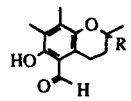
Compounds 5–8 showed no activity against either substrate while compounds 9–14 showed slight activity against both substrates. Compounds 4, 15, and 16 all showed good antioxidant activity against both substrates. This would have been predicted, since all of these compounds, although at a higher oxidation state than 2, are still phenols and, therefore, capable of further oxidation.

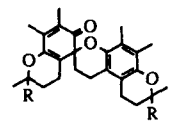


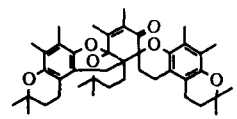


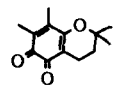


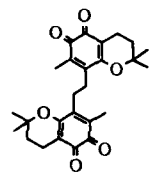


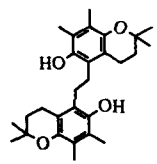












Compounds 17 and 18 showed no activity against methyl linoleate but significant activity against safflower oil. This is an interesting result since 17 and 18 are at a higher oxidation state than 5 and 6, which have no activity. The result with 17 confirms earlier observations on the ability of tocored, the equivalent compound from α-tocopherol, to inhibit the autoxidation of lard (29,30). The ability of 17 and 18 to protect safflower oil (0.3 ppm iron), but not methyl linoleate (1.6 ppm iron), may mean that 17 and 18 function predominantly by hydrogen transfer (prevention of propagation) rather than metal chelation (prevention of initiation). There is no doubt that 17 can function by hydrogen transfer since its conversion into 18 or into 2,2,7-trimethyl-6-hydroxy-chroman-5,8-dione are both oxidations which proceed by hydrogen abstraction (Suarna, C., and Southwell-Keely, P.T., unpublished data). Similarly, oxidation of 18 could occur readily with the loss of two hydrogen atoms from the ethane bridge between the two monomers to join the two ortho-quinone rings in a completely conjugated system.

All 5-alkoxymethyl derivatives of 2 showed good antioxidant activity against both substrates. The effect

of replacing the 5-methyl group of 2 by an alkoxymethyl group was to decrease its antioxidant activity against safflower oil but to increase its activity against methyl linoleate. The explanation for this may be that the 5-alkoxymethyl derivatives can function not only by hydrogen transfer (prevention of propagation) but also by metal chelation (prevention of initiation). The low level of iron in safflower oil may mean that, in this substrate, the 5-alkoxymethyl compounds function predominantly as propagation inhibitors rather than as initiation inhibitors. If this is so, internal chelation of the 6-hydroxy group by the 5-alkoxymethyl may make it more difficult to remove the hydrogen and therefore lead to a slower reaction with peroxyl radicals (and therefore less activity) than that of 1 and 2. By contrast, the higher level of iron in methyl linoleate may mean that prevention of initiation (by metal chelation) in that substrate is more important than prevention of propagation and therefore the 5-alkoxymethyl compounds, with their much greater metal chelation capacity, are superior to 1 and 2. It appears that an alkoxy group of almost any length attached to position 5 of a chromanol ring is more beneficial to antioxidant activity against methyl linoleate than the phytol residue at position 2 of compound 1. The activity of 29 against methyl linoleate was particularly noteworthy in view of the presence of cholesterol in all cell membranes.

Thus it is clear that many of the oxidation products of 2 and, by inference, of 1 possess substantial antioxidant activity and that, if formed *in vivo,* could help explain the outstanding capacity of 1 to protect cell membranes. Nonetheless one must be cautious in drawing too many conclusions since many derivatives of 1 and 2 have shown the ability to act as antioxidants but none has shown the capacity of 1 to protect against liver necrosis or resorption sterility in rats, encephalomalacia in chicks or muscular dystrophy in rabbits (25,31,32).

Implication of Steroid Saponins and Sapogenins in the Hypocholesterolemic Effect of Fenugreek

Yves Sauvaire[a,*], Gérard Ribes[b], Jean-Claude Baccou[a] and Marie-Madeleine Loubatieres-Mariani[b]

[a]Laboratoire de Physiologie Vegetale, Universite Montpellier II, 34095 Montpellier, Cedex 5 and [b]Faculte dé Médecine, Laboratorie de Pharmacologie, URA 599 du CNRS, Institut de Biologie, 34060 Montpellier, France

The transformation of fenugreek subfractions, rich in steroid saponins, was studied upon their passage through the digestive tract to determine the contribution of saponins and/or diosgenin and other steroid sapogenins to the hypocholesterolemic effect of fenugreek seeds. Feces of alloxan diabetic dogs fed fenugreek subfractions were analyzed, and diosgenin, smilagenin and gitogenin were identified and measured using capillary gas chromatography/mass spectrometry. Our results show that saponins are, in part (about 57%), hydrolyzed into sapogenins in the digestive tract. It appears that saponins may be implicated, alone or together with diosgenin, in the observed hypocholesterolemic effect of fenugreek seeds in diabetic dogs.

Lipids 26, 191–197 (1991).

Fenugreek (*Trigonella foenum graecum L., Leguminosae*) is an annual herb, cultivated in Southern Europe, Northern Africa and India. The seeds of fenugreek are known to have hypocholesterolemic activity (1,2). We have previously shown that this hypocholesterolemic effect was due to the defatted part (3) and especially to the saponin-rich subfraction (4). This subfraction, which contains most of the saponins present in the seed, reduced hypercholesterolemia and hypertriglyceridemia of alloxan-diabetic dogs. The hypocholesterolemic effect was not observed with the saponin-free subfraction (4).

Saponins are plant glycosides whose aglycone structure is triterpenoid or steroidal. Studies on the effects of saponins on cholesterol homeostasis concern mainly the triterpenoid saponin from alfalfa (5) and from soybean (6). It has also been reported that a steroidal saponin, digitonin, prevents hypercholesterolemia in monkeys (7).

Fenugreek seed saponins are of steroidal nature (type furostanol saponins) with diosgenin [(25 R)-spirost-5-en-3β-ol] as main sapogenin (Fig. 1) (8). Diosgenin has various effects on cholesterol metabolism, one of the most important being the capacity to lower plasma cholesterol concentration (9). This hypocholesterolemic effect appears to be dependent on the capacity of diosgenin to inhibit cholesterol absorption, to decrease liver cholesterol concentration and to increase biliary cholesterol secretion and fecal excretion of neutral sterols (10–12).

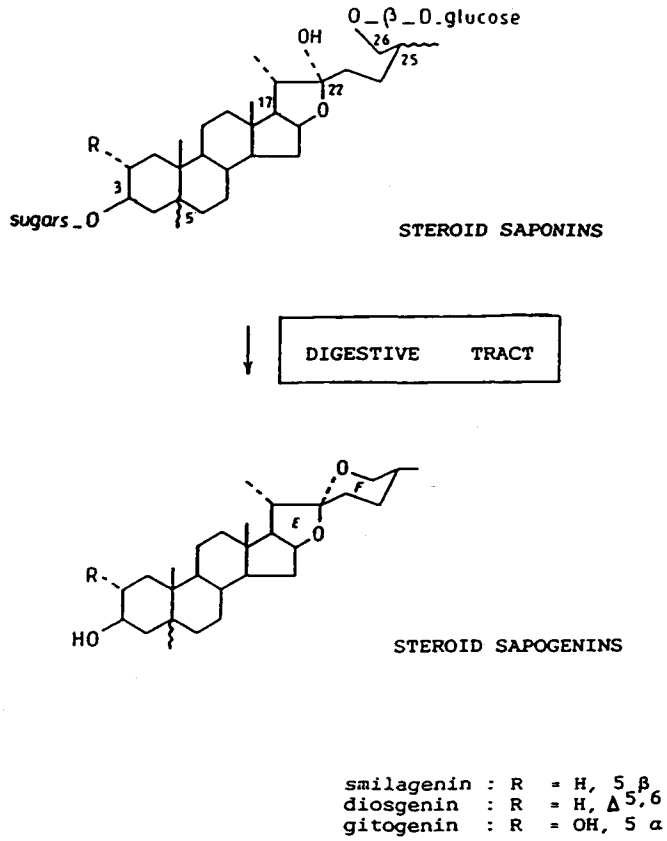

FIG. 1. Transformation of steroid saponins from fenugreek in the digestive tract.

Furthermore, Malinow (13) has shown that diosgenin glucoside was more efficient in reducing intestinal absorption of cholesterol than diosgenin. At comparable small doses, diosgenin glucoside inhibited cholesterol absorption, whereas diosgenin did not (13,14). Saponins and/or diosgenin could hence be involved in bringing about the hypocholesterolemic effect of fenugreek seeds. It was thus important to study the transformation of fenugreek subfractions upon their passage through the digestive tract. Toward this aim, we have carried out a study in alloxan-diabetic dogs.

MATERIALS AND METHODS

Plant material. Fenugreek seeds (cultivar Gouka) were obtained from our experimental field in Montpellier, France (Université des Sciences et Techniques du Languedoc).

The defatted fenugreek seeds were obtained as previously described (15) and were further fractionated to obtain subfractions enriched in saponins and pro-

Abbreviations: FAE, feces alcoholic extract; FLE, feces lipid extract; GC, gas chromatography; GC/MS, gas chromatography/mass spectrometry; HPLC, high-performance liquid chromatography; NMR, nuclear magnetic resonance; TLC, thin-layer chromatography.

tein. The defatted seeds were fractionated into two parts—a fraction containing testa plus endosperm (Subfraction A) and a fraction containing cotyledons plus axis (Subfraction B). The latter was extracted with isopropanol/water (70:30, v/v). The lyophylized extract contained practically all the saponins (Subfraction S), but not the sapogenins (aglycone part of saponins). The insoluble portion contained protein without saponin (Subfraction P).

The techniques used to determine the composition of the subfractions of defatted fenugreek seeds have been previously described (16). Subfraction B includes 7.2% saponins and 52.8% protein; Subfraction S contains 22.2% saponins without protein; Subfraction P contains 70.5% protein without saponins.

Alloxan-diabetic dogs. Conscious mongrel male dogs, weighing 18–21 kg, were made diabetic by an intravenous injection of alloxan (50 mg/kg) at least 45 days before the experiment. The animals were housed in individual cages. They were fed twice daily with a standard diet (30 g/kg at each meal, in the form of patties containing 9% protein, 5% lipid and 78% moisture; UAR, Epinay, France).

Each animal received two daily subcutaneous injections (14–24 IU) of soluble insulin (Endopancrine, Organon, France) so that they were clearly glycosuric (about 50 g/24 hr) and had high plasma levels of cholesterol, but they were not ketotic. The dose of insulin injected was kept constant throughout the experiment.

Experimental protocols. Fenugreek seed subfractions were administered with the animals diet for 21 days. Four sets of experiments were performed: i) Four dogs received Subfraction B at 1.13 g/kg corresponding to 0.08 g/kg per day of saponins and 0.59 g/kg per day of protein; ii) four dogs received Subfraction S at 0.37 g/kg corresponding to the same dose of saponins—0.08 g/kg per day; iii) four dogs received Subfraction P at 0.73 g/kg corresponding to 0.51 g/kg per day of protein; and iv) four dogs were fed the standard diet (control experiments). The doses were chosen so that the animals received an amount of saponins (Subfractions B and S) or protein (Subfraction P) corresponding to those of the total defatted fraction previously used (3).

Feces from each dog were collected before and during the treatments and the composition of fecal saponins or sapogenins was determined. Simultaneously, the effects on plasma cholesterol levels were evaluated, according to the colorimetric method of Watson (17), using blood samples collected from jugular vein.

Fecal saponin analysis. Feces were immediately sampled and freeze-dried; 5–15 g were ground in a mortar and extracted in a Soxhlet apparatus overnight with hexane under reflux. The hexane extract was called feces lipid extract (FLE). The defatted fecal samples were reextracted in a Soxhlet apparatus overnight with isopropanol/water (70:30, v/v). The alcoholic extract was called feces alcoholic extract (FAE).

The steroid sapogenins in FLE were characterized by thin-layer chromatography (TLC) on silica gel (precoated silica gel TLC plates, Merck, Darmstadt, Germany) developed with hexane/ethyl acetate (60:40, v/v). Fractions were made visible with $SbCl_3$/*6 N* HCL (1:1, w/v) or with methanol/H_2SO_4 (1:1, v/v) followed by heating.

To isolate the steroid sapogenins, the FLE was applied as band onto TLC plates and the plates were developed in hexane/ethyl acetate (40:60, v/v). The sapogenins were separated into an upper zone (R_f, 0.7–0.8), consisting of monohydroxylated sapogenin that co-developed with standard diosgenin, and a bottom zone (R_f, 0.2–0.3), consisting of dihydroxylated sapogenins that co-developed with standard gitogenin [(25 R)-5α-spirostan-2,3β-diol]. Silica gel from the two zones was scraped from the plates and eluted with a series of solvents, namely hexane, dichloromethane, and then ethanol. Five successive preparative TLC fractionations were necessary to obtain relatively pure fractions, as judged by GC.

The monohydroxy sapogenins recovered from the last TLC separation were further purified by reversed-phase high performance liquid chromatography (HPLC) (C18 column Ultrasphere ODS, 5 μdp, 4.6 mm i.d. × 250 mm) eluted with methanol/water (96:4, v/v). The flow rate was set at 1.6 mL/min, and the detector at 205 nm. Diosgenin was eluted in 7.5 min, cholesterol in 24 min, and sitosterol was eluted in 32.5 min. Monohydroxy sapogenins (like diosgenin) were collected after repeated injection onto the column. The identity of each isolated mono or dihydroxy sapogenin was established by a comparison of retention times in GC and of mass spectra (GC/MS) with those of standards.

Capillary gas chromatography (GC). A Delsi gas chromatograph (model D 1700) equipped with a FID and a Shimadzu integrator (model C-R4A, Shimadzu, Kyoto, Japan) were used. The chromatograph was fitted with a RSL 150 (Alltech, Deerfield, IL) 30-m fused silica capillary column of 0.25 mm i.d. bound and cross-linked with a polydimethylsiloxane film 0.2 μm thick. The analyses were run isothermally at 270°C; the injector and detector temperatures were 300°C. Hydrogen was used as carrier gas with a head pressure of 0.7 bar (10 psi).

Capillary gas chromatography/mass spectrometry (GC/MS). GC/MS was carried out with an LKB Bromma 209 equipped with Vg Digital pdp 8a computer. The gas chromatograph was fitted with a capillary column OV 1701 (25 m, 0.32 mm i.d., 0.20 μm film). Analyses were carried out isothermally at 260°C for monohydroxy sapogenins and at 290°C for dihydroxy sapogenins. Helium was used as carrier gas with a head pressure of 0.5 bar (7 psi). The jet separator was maintained at 230°C. Ionizer temperature was set at 250°C and electron energy and electron multiple voltage were 70 eV and 3.5 kV, respectively. Smilagenin [(25 R)-5β-spirostan-3β-ol] was from Merck, and diosgenin was from K and K Laboratories Inc. (Plainview, CA). Gitogenin was isolated from *Trigonella foenum graecum* and characterized by GC/MS and ^{1}H nuclear magnetic resonance (NMR).

RESULTS

Total food intake was kept the same in the different experimental groups. The data in Table 1 show that subfractions B and S induced a significant reduction

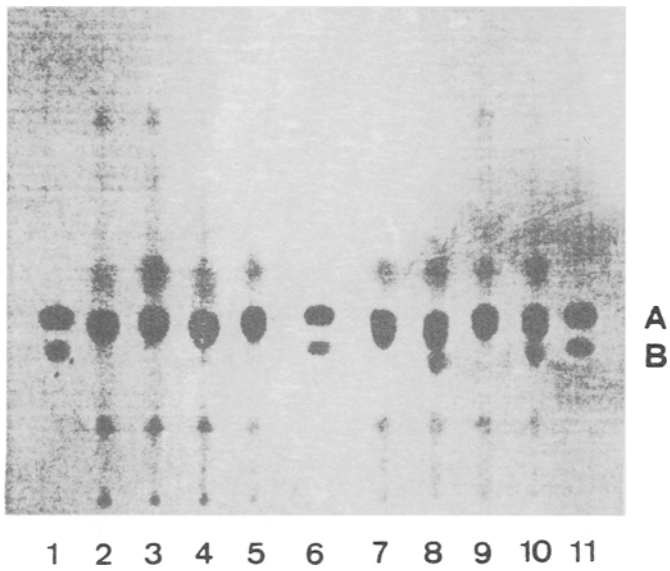

FIG. 2. Thin-layer chromatogram of feces lipid extracts (FLE) from dogs receiving Subfractions P and S of fenugreek. Lanes 1, 6, 11: Cholesterol (R_f, 0.37) plus diosgenin (R_f, 0.30). Lanes 2, 3, 4, 5: FLE from dogs receiving Subfraction P. Lanes 2, 4: Before treatment. Lanes 3, 5: After treatment. Lanes 7, 8, 9, 10: FLE from dogs receiving Subfraction S. Lanes 7, 9: Before treatment Lanes 8, 10: After treatment. A indicates the presence of substances with an R_f equal to that of cholesterol. B indicates the presence of substances with an R_f equal to that of diosgenin.

in plasma cholesterol in diabetic dogs; in contrast, Subfraction P had no effect.

Figure 2 shows a thin-layer chromatogram obtained with FLE from feces of dogs receiving either Subfraction S or Subfraction P. TLC clearly reveals the appearance of a new substance, but only in the feces from dogs given Subfraction S. The same substance was also detected in FLE from dogs given Subfraction B (saponins 7.2%) (results not shown). These chromatographic properties (R_f, chromophore) of the substance suggested that it belonged to the class of monohydroxylated sapogenins, such as diosgenin. Nevertheless, the results obtained by TLC needed to be confirmed by complementary methods.

After purification by preparative TLC and HPLC, several samples were analyzed by GC and GC/MS. The chromatogram of monohydroxy steroid sapogenins upon capillary GC shows three principal peaks, as well as several minor ones (Fig. 3). The retention times of peaks No. 1 and No. 2 correspond to smilagenin and diosgenin, respectively. For further confirmation, we analyzed the samples by capillary GC/MS. The chromatogram exhibits the same pattern as the two principal peaks 1 and 2 (Fig. 3A). The ionogram obtained by ion selective monitoring at *m/z* 139 is practically identical to the ion chromatogram in Figure 3B. It seems likely that the peak at *m/z* 139 $[C_9H_{15}O]^+$ arises from ring E fragmentation by a 1,2 shift of the C-20 hydrogen to C-17 (Fig. 1). The fragment is characteristic of a steroid sapogenin with a spiroketal side chain (18,19).

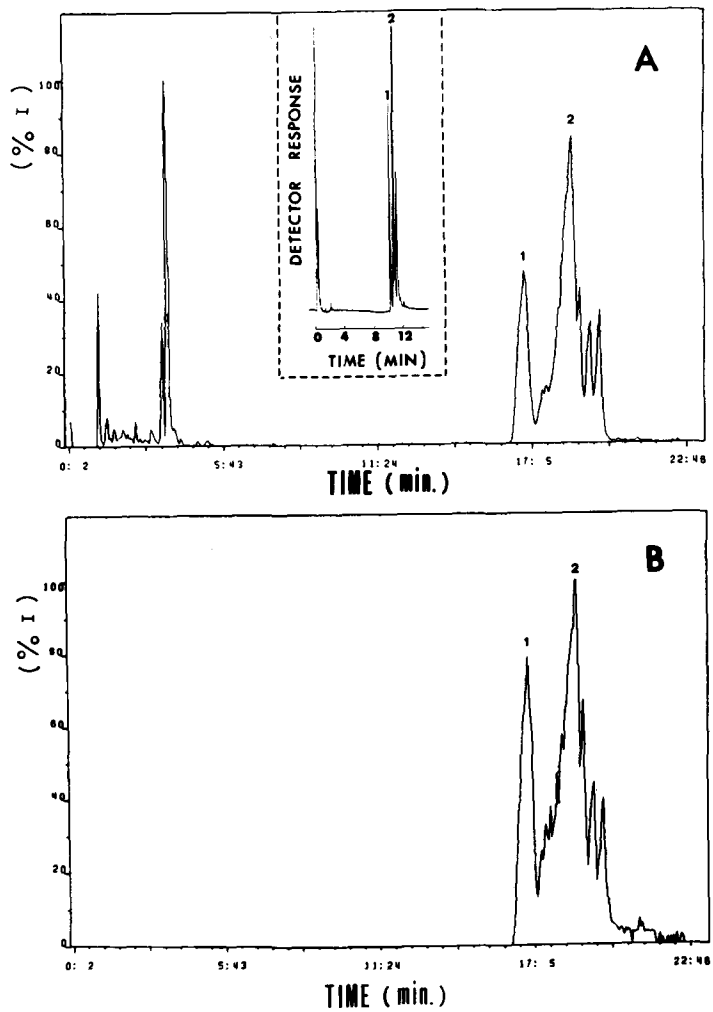

FIG. 3. Capillary GC/MS of isolated monohydroxy steroid sapogenins from feces of dogs receiving steroid saponins. A: Ion electron impact chromatogram (capillary GC). B: Ion current profile of selected ion *m/z* 139.

The mass spectrum of the substance corresponding to peak No. 1 reveals a molecular peak at *m/z* 416 which corresponds to the mass of smilagenin (Fig. 4A). Likewise, the mass spectrum of the substance corresponding to peak No. 2 shows a molecular peak at *m/z* 414 which corresponds to the mass of diosgenin (Fig. 4B).

The other fragmentations observed allowed us to confirm our assignments (Figs. 4A and 4B). Fission of the F ring produces ions $[M\text{-}C_4H_8O]^+$ at *m/z* 344 or 342. Corresponding to $[C_{23}H_{36}O_2]^+$ or $[C_{23}H_{34}O_2]^+$, and ions $[M-C_3H_7O]^+$ at *m/z* 357 or 355. Corresponding to $[C_{24}H_{37}O_2]^+$ or $[C_{24}H_{35}O_2]^+$, in the smilagenin or diosgenin spectra, respectively. Another group of characteristic ions arises by fragmentation in ring E, producing ions at *m/z* 302 or 300 corresponding to $[C_{21}H_{34}O]^+$ or $[C_{21}H_{32}O]^+$ in the smilagenin or diosgenin spectra, respectively. Other characteristic ion peaks occurred at *m/z* 255 (253), 269 (267), and 284 (282) due to hydrocarbon fragments. Standards of smilagenin and diosgenin showed spectra and fragmentation patterns very similar to those of peaks No. 1 and 2, respectively.

The chromatogram of dihydroxy steroid sapogenins obtained upon capillary GC shows several peaks and two principal ones, Nos. 3 and 4 (Fig. 5). The retention time of peak No. 3 corresponds to that of gitogenin. The assignment was confirmed by capillary GC/MS (Fig. 5A). The ionogram obtained by ion selective monitoring at *m/z* 139 is practically identical to the ion chromatogram in Figure 5B. The mass spectrum (Fig. 4C) exhibits a molecular peak at *m/z* 432 corresponding to the mass of gitogenin. The spectrum also shows prominent ions at *m/z* 360 $[C_{23}H_{36}O_3]^+$, *m/z* 363 $[C_{22}H_{35}O_4]^+$, and *m/z* 373 $[C_{24}H_{37}O_3]^+$. Another group of characteristic ions arises from cleavage at the spiroketal site. Ions *m/z* 318 indicates that the additional hydroxy group in gitogenin is nuclear. A standard of gitogenin showed a spectrum and fragmentation pattern very similar to those of

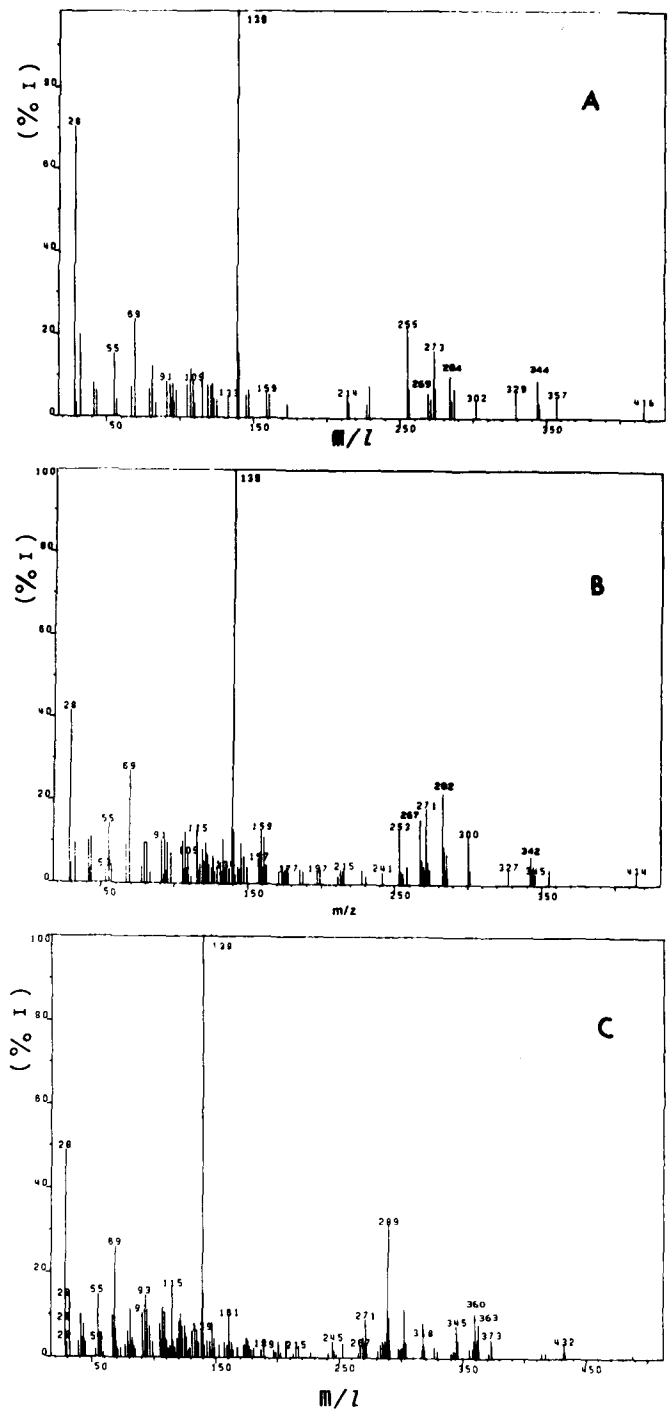

FIG. 4. Mass spectra of isolated steroid sapogenins from feces of dogs receiving steroid saponins. A: Mass spectrum of peak No. 1. B: Mass spectrum of peak No. 2. C: Mass spectrum of peak No. 3.

peak No. 3. Peak No. 4 has not been identified so far.

Assays of sapogenins either in the free form (in FLE) or in the glycosylated form (in FAE) were carried out to determine the extent of hydrolysis of steroid saponins in the digestive tract. The results obtained from six different feces samples indicated that 57.4 ± 5.3% (SD) of the saponins were hydrolyzed to sapogenins.

We also investigated *in vitro* whether β-glucosidase could hydrolyze a sample of fenugreek saponins to the sapogenins. For this purpose, the purified S subfraction was subjected to β-glucosidase digestion for 24 hr. The results showed that no sapogenin was released by this treatment, indicating that β-glucosidase is ineffective in cleaving the glycoside bond at C-3 (Fig. 1). However, the enzyme acted on the saponins releasing the glucose residue from C-26. The native saponins of the furostanic type were then converted to saponins of the spirostanic type. We also calculated the diosgenin/smilagenin ratio based on chromatographic analysis (GC). The ratio was 19 for the S subfraction before ingestion, and 2 for FLE.

DISCUSSION

Our study showed that fenugreek subfractions rich in steroid saponins are, in part, transformed in the gastrointestinal tract. Thus, smilagenin, diosgenin and gitogenin were detected in feces of dogs fed fenugreek (Fig. 1). Hydrolysis averaged 57%. The 25 S epimers corresponding to smilagenin, diosgenin and gitogenin, as well as their saturated or unsaturated derivatives, may also be present in the feces.

The location of fenugreek saponin hydrolysis in the digestive tract has not been determined. If sapogenins are able to partially prevent cholesterol absorption, saponin hydrolysis presumably occurs in the stomach or/and in the proximal small intestine. However, Gestetner *et al.* (20) had previously reported that ingested soybean saponins are hydrolyzed by cecal microflora in chicks, rats and mice. The apparent discrepancy may be due to differences in species or other experimental conditions.

Calculation of the diosgenin/smilagenin ratio revealed a clear difference between the composition of Subfraction S and the lipid extract obtained from the feces (19 *vs* 2). This greater amount of smilagenin in the feces seems to be due to transformation of the sapogenins from Subfraction S during their passage through the gastrointestinal tract.

Previous reports have shown that other plant steroids with a double bond in 5,6-position are reduced and transformed into 5β-hydroxy steroid analogues by gastrointestinal microorganisms in various animals (21,22). It is possible that in our experiments diosgenin was reduced and transformed to smilagenin in the digestive tract of the dogs. However, it is important to recall that differences in the biotransformation of diosgenin have been observed depending on the species studied and the conditions of administration employed (23).

As to the hypocholesterolemic effect of fenugreek seeds, the presence of steroid saponins seems to play an essential role (4). Other saponins have also been reported to modify cholesterol metabolism. Thus, alfalfa saponins, as well as digitonin, inhibited cholesterol intestinal absorption in the monkey (7,24). Soybean saponins reduced intestinal uptake of cholesterol

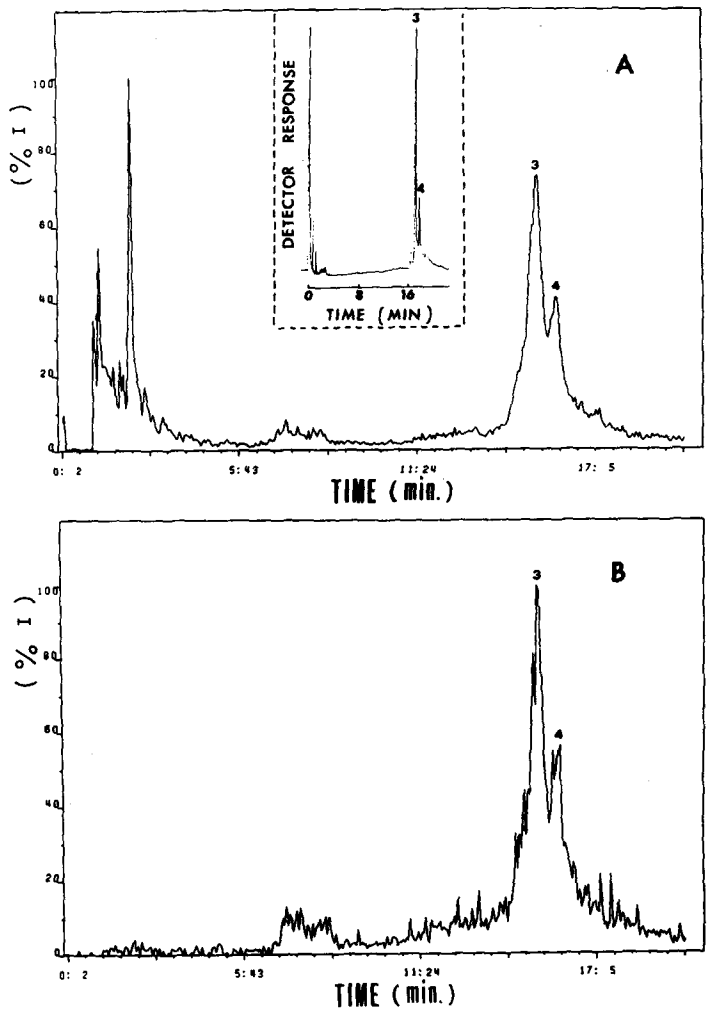

FIG. 5. Capillary GC/MS of isolated dihydroxy steroid sapogenins from feces of dogs receiving steroid saponins. A: Ion electron impact chromatogram (capillary GC). B: Ion current profile of selected ion *m/z* 139.

bean saponins reduced intestinal uptake of cholesterol in the rat (6). It appears likely that saponins and cholesterol form insoluble complexes (25–27) which may retard cholesterol absorption in the intestine. On the other hand, certain saponins from soapwort (*Saponaria officinalis L*), soybeans, and quillaya (*Quillaya saponaria*) also form large mixed micelles with bile acids (28). The increase in fecal excretion of bile acids and neutral steroids could thus be compensated for by an increased conversion of cholesterol to bile acids by the liver. Furthermore, in the rat fenugreek induced an increase in bile acid output (2,29), which suggests increased transformation of cholesterol into bile acids by the liver. This could contribute to the hypocholesterolemic activity of fenugreek.

Our results show that the ingested fenugreek saponins are partially hydrolyzed to diosgenin in the gastrointestinal tract. Other steroid sapogenins (smilagenin, gitogenin) were also found in the feces of the dogs. It is known that diosgenin interferes with the absorption of cholesterol (10). The decreased cholesterol absorption associated with enhanced secretion of cholesterol into bile resulted in increased excretion of neutral sterols (10,12).

Our results suggest that the hypocholesterolemic effect of fenugreek seeds might be due to saponins and that diosgenin produced by gastrointestinal hydrolysis may contribute to this effect.

Influence of Genotype on Diet-Induced Changes in Membrane Phosphatidylcholine and Phosphatidylethanolamine Composition of Splenocytes, Liver Nuclear Envelope and Liver Mitochondria

J.T. Venkatraman, R.K. Tiwari[1], B. Cinader[2], J. Flory, T. Wierzbicki and M.T. Clandinin*
Nutrition and Metabolism Research Group, Departments of Foods & Nutrition and Medicine, Division of Gastroenterology, University of Alberta, Edmonton, Alberta, Canada T6G 2C2

Inbred congenic mice of strains MRL/Mp-lpr/lpr (lpr/lpr) and MRL/Mp-+/+ (+/+) were fed nutritionally adequate semipurified diets containing 20% (w/w) fat and differing in linoleic acid content. Levels of linoleic acid (18:2n-6) and arachidonic acid (20:4n-6) in phospholipids of splenocytes, liver mitochondria and liver nuclear envelopes were determined. Membranes of lpr/lpr mice exhibited significantly lower levels of 18:2n-6 and 20:4n-6 in phospholipids compared with the +/+ strain. The high linoleic acid diet increased incorporation of 18:2n-6 and 20:4n-6 in most phospholipid fractions of these membranes. These observations indicate that genotype as well as dietary 18:2n-6 content significantly influenced incorporation of 18:2n-6 and 20:4n-6 into membrane phospholipids. The results also suggest that membrane compositional abnormalities found in the lpr/lpr mice, which develop lymphoma and age faster than +/+ mice, are not restricted to the immune system but also extend to other organs. Differences observed in phospholipid fatty acid composition in splenocytes and liver subcellular membranes for mice fed diets differing in linoleic acid content suggest that the early expression of the lpr gene resulting in progression of autoimmunity may be delayed through dietary manipulation.
Lipids 26, 198–202 (1991).

MRL/Mp-lpr/lpr (lpr/lpr) mice have a genetic predisposition for a particular age-related change in H1 Histone subtypes (1) and lipid composition (2). Age-related changes of this mouse represent extremes in the polymorphism of various immunologic features, involving proliferative disorder, autoimmunity and accumulation of lymphocytes bearing the immature phenotype Thy-1$^+$Lyt2$^-$L3t4$^-$ (3–6). The congenic partner, MRL/Mp-+/+ (+/+), does not manifest these abnormalities at an early age. Some of the abnormalities are inherent in the MRL/Mp-genome and are accelerated by the lpr/lpr but not by the +/+ gene (7).

Nutrition profoundly influences development of autoimmune disease, immune functions and life span (8,9). Dietary lipids may influence incidence of autoimmunity by altering the composition of the membrane lipid bilayer and thereby activate or inhibit several key enzymes (10). Through dietary lipid manipulation (11), molecular studies have revealed diminished ribonucleic acid (mRNA) levels for several oncogenes in lpr/lpr mice. The lipid composition of the membrane also influences the conformation of some receptors (12,13). The lpr/lpr mice exhibit impairment of membrane functions (14), altered membrane fluidity (15) and failure to produce regulatory factors which interrupt autoimmunity (16).

In the present investigation, lpr/lpr and +/+ mice were fed nutritionally adequate diets which were high or low in linoleic acid to examine the influence of genetic background and the level of dietary linoleic acid on the phospholipid fatty acid composition of splenocyte and hepatocyte subcellular membranes.

MATERIALS AND METHODS

Animals. Six-week-old female lpr/lpr and +/+ mice purchased from Jackson Laboratories (Bar Harbor, ME) were fed nutritionally adequate semipurified diets (17) *ad libitum*, providing 20% (w/w) fat containing a low (4% of calories) or high (22% of calories) level of linoleic acid (Table 1). The high linoleic acid fat was provided

TABLE 1

Composition of the Diets

Ingredients	g/kg of total diet
Fat	200
Starch	200
Casein	270
Glucose	212.65
Non-nutritive fiber	50
Vitamin mix[a]	10
Mineral mix[b]	50.85
L-Methionine	2.5
Choline	2.75
Inositol	1.25

[a]A.O.A.C. vitamin mix (Teklad Test Diets, Madison, WI) provided the following per kg of complete diet: 20,000 IU vitamin A; 2000 IU vitamin D; 100 mg vitamin E; 5 mg menadione; 5 mg thiamin-HCl; 8 mg riboflavin; 40 mg pyridoxine-HCl; 40 mg niacin; 40 mg pantothenic acid; 2000 mg choline; 100 mg myoinositol; 100 mg *p*-aminobenzoic acid; 0.4 mg biotin; 2 mg folic acid; and 30 mg vitamin B-12.

[b]Bernhart Tomarelli mineral mix (General Biochemicals, Chagrin Falls, OH) was modified to provide 77.8 mg of Mn^{2+} and 0.06 mg Se^{2+}/kg complete diet.

[a]Dietary linoleic acid.
[b]Weeks of feeding.

Statistical analysis as 2 × 3 factorial design *p<0.05; **p<0.01; ***p<0.001; NS — Not significant. Values are mean of 3 independent determinations. Significant interactions were not found.

by soybean oil and the low linoleic acid fat was a blend of beef tallow and sunflower oil. The fatty acid composition of these diets is as follows: the high linoleic acid diet contained 14:0, 0.3%; 16:0, 15.2%; 16:1, 0.2%; 18:0, 5.6%; 18:1, 29.3%; 18:2ω6, 42.3%; 18:3ω3, 3.4%; and the low linoleic acid diet contained 14:0, 3.6%; 16:0, 27.5%; 16:1, 2.1%; 18:0, 22.0%; 18:1, 34.4%; 18:2ω6, 7.5%; 18:3ω3, 0.6%. Mice were fed these diets for a period of one to six weeks in mouse boxes containing feed cups. All animals were housed in a light, temperature and humidity controlled room on a 12/12 hr light-dark cycle. Animals were sacrificed by cervical dislocation and livers and spleens were collected on ice.

Splenocytes. Spleens were minced and passed over a steel mesh (No. 110-150) with a spatula. The resulting suspension in CMRL 1066 medium was further purified (18), passed through cotton gauze and centrifuged at 900 × *g* for 10 min. Cells were washed with CMRL 1066 medium to free them of red blood cells by treatment with Tris NH_4Cl (pH 7.2) three times. Cells were suspended in 1 mL of medium, diluted appropriately and counted. Viability of splenocytes was measured by trypan blue dye exclusion test and cells with 95% viability were used.

Liver mitochondria. Liver mitochondria were prepared by the method of Dow (19). Liver (1 g) was homogenized in a Teflon homogenizer with 10 mL of 0.25 M sucrose buffer and centrifuged at 2500 × *g* for 15 min. The supernatants were pooled and centrifuged (10,000 × *g* for 30 min) to obtain the mitochondrial pellet. The mitochondria were washed again by resuspension with 0.25 M sucrose and centrifuged at 10,000 × *g* for 30 min. Mitochondrial purity was checked by assaying for the presence of succinic dehydrogenase activity and the absence of 5′-nucleotidase and glucose-6-phosphatase.

Nuclear envelopes. Liver nuclear membranes were prepared by extensive digestion of purified nuclei with deoxyribonuclease (DNase-1). Nuclei were isolated by modification of the procedure of Widnell and Tata (20). The resulting pellet of purified nuclei was used to prepare nuclear envelopes by modifications of the procedure of Kay *et al.* (21). The nuclei were resuspended in 0.25 M sucrose containing 1 mM $MgCl_2$ (pH 7.4) and centrifuged at 750 × *g* for 5 min. The pellet was resuspended in digestion buffer (10 mM Tris HCl, 0.30 M sucrose, 0.1 mM $MgCl_2$ and 5 mM 2-mercaptoethanol, pH 8.5) to which freshly dissolved DNase-1 was added to a concentration of 10 μg/mL. The suspension was incubated at room temperature for 20 min. Following centrifugation (12,000 × *g* for 5 min) the crude nuclear envelopes were resuspended in 10 mM Tris HCl (pH 7.4) and 2 mL of this suspension was layered onto a discontinuous sucrose gradient of 5 mL of 0.25 M sucrose and 10 mL each of 1.5 M, 1.8 M, and 2.0 M sucrose (sucrose solutions made up in 10 mM Tris HCl, pH 7.4). The sucrose gradients were centrifuged (100,000 × *g* for 90 min), and the major band of puri-

[a]Dietary linoleic acid.
[b]Weeks of feeding.

Statistical analysis as 2 × 3 factorial design *p<0.05; **p<0.01; ***p<0.001; NS — Not significant. Values are mean of 3 independent determinations.

fied nuclear envelopes was removed from the gradient and washed twice in 10 mM Tris HCl (pH 7.4) at 33,000 × *g* for 10 min. Membrane purity was assessed as described earlier (22,23). Nuclear envelopes prepared in this manner are free of other subcellular fractions (23).

Extraction of lipid and purification of membrane phospholipids. Lipids were extracted from membranes (24) in the presence of 2-ethoxyquin as an antioxidant, and extracts were dried under nitrogen. Lipid samples were subjected to thin-layer chromatography. High performance thin-layer plates, LHPK (HP T2C) (10 × 1.09 cm), were used for separating phospholipids. The solvent system chloroform/methanol/2-propanol-0.25% (w/v) potassium chloride/triethylamine (30:9:25:6:18, by vol) was used (25). Individual phospholipids were visualized by spraying the plates with 1% (w/v) 8-anilino-1-naphthalenesulfonic acid and viewing under ultraviolet (UV) light. Individual phospholipids were scraped directly into tubes to which hexane was added. Phospholipid fatty acids were methylated with BF_3 in methanol (26). Methyl esters were analyzed by automated capillary gas-liquid chromatography (27). Fatty acids analyzed included all saturated and unsaturated fatty acids of 14 to 24 carbons in chain length. Only data for major saturated, monounsaturated and polyunsaturated fatty acids are illustrated where significant effects were observed. Main effects (*i.e.* those due to strain, diet and duration) are presented where no significant interactions were observed.

Statistical analysis. The effect of strain, diet and duration of treatment was determined by analysis of variance procedures (28).

RESULTS

Fatty acid composition of splenocytes. Strain exhibited a significant effect on saturated fatty acid as well as on the 20:4n-6 content of phosphatidylcholine and phosphatidylethanolamine fractions of splenocytes (Table 2). In the phosphatidylcholine fraction, the +/+ strain exhibited higher levels of saturated fatty acids and 20:4n-6, compared to the lpr/lpr strain. The lpr/lpr strain exhibited higher 20:4n-6 and 18:0 levels in the phosphatidylethanolamine fraction. Change in linoleic acid to saturated fat level in the diet also influenced the fatty acid composition of the phosphatidylcholine and phosphatidylethanolamine fractions of splenocytes. Linoleic acid increased in the phosphatidylcholine fraction of the splenocytes for animals fed the high linoleic acid to saturated fat diet while an increase in 16:0, 18:1n-9 and 20:4 was observed in mice fed the low linoleic acid diet. In contrast, in the phosphatidylethanolamine fraction there was an increase in 16:0, 18:0 and 18:2, and a decrease in 18:1n-9 in splenocytes of animals fed the high linoleic acid diet.

[a]Dietary linoleic acid.
[b]Weeks of feeding.

Statistical analysis as 2 × 3 factorial design *p<0.05; **p<0.01; ***p<0.001; NS — Not significant. Values are mean of 3 independent determinations.

Fatty acid composition of liver mitochondria. Significantly higher levels of 18:1n-9 and 22:6n-3 and lower levels of 18:0 and 20:5n-3 were observed in phosphatidylethanolamine and phosphatidylcholine fractions from mitochondria of +/+ mice suggesting that strain had considerable influence (Table 3). The phospholipid content of 18:2n-5 was similar for both strains but the level of 20:4n-6 was significantly different in the mitochondrial phosphatidylcholine fraction. Dietary linoleic acid exhibited a significant influence on the composition of fatty acids in mitochondrial phosphatidylcholine while the fatty acid profile of the phosphatidylethanolamine fraction did not exhibit alterations due to dietary linoleic acid level.

Fatty acid composition of nuclear envelopes. The nuclear envelopes isolated were free of cytoplasmic tags and other subcellular membranes. Genetic strain was found to have a significant but small influence on 18:1n-9 and 18:2n-6 content of nuclear envelope phospholipids (Table 4). The concentration of 16:0 was higher in the phosphatidylcholine fraction of nuclear envelopes prepared from the lpr/lpr animals with the exception of animals fed the low linoleic acid diet for 6 wk. Dietary linoleic acid significantly increased levels of 18:2n-6 and 20:4n-6 in the phosphatidylcholine fraction as well as 18:2n-6 and 22:6n-3 content of the phosphatidylethanolamine fraction of the liver nuclear envelope.

DISCUSSION

Age-related changes in MRL/Mp-lpr/lpr mice occur relatively early in life due to the expression of the lpr/lpr gene (7). These mice develop a defect in the regulatory balance of the immune system and autoimmunity relatively early in life (15). Nutritional approaches to treatment of autoimmune disorders have shown that dietary components may prevent, delay or reverse expression of genetically determined autoimmune defects. The present study demonstrates that mice with the lpr/lpr gene exhibited altered membrane fatty acid composition in a variety of membrane types. It is possible to alter significantly the phospholipid fatty acid composition of membrane types by altering the level of dietary linoleic acid. Thus, the present results suggest that it is conceivable that we may be able to control early expression of the lpr gene or the effect of the gene on membrane phenotype through dietary manipulation.

The spleen is a central site for production of immunologically active prostaglandins (29). Arachidonic (20:4n-6) is an important precursor for prostaglandins involved in promoting lymphokine production (30). For example, Interleukin-2 (IL-2) is essential for maturation of specific T cell populations (31). Mice with the lpr/lpr gene develop generalized massive lymphadenopathy resulting from accumulation of immature Thy-1+Lyt2-L3T4- cells (4) due to the lack of secretion of adequate regulatory factors like IL-2 or biological modifiers like tumor necrosis factor α(TNFα) which modulate autoimmunity (32). Our earlier experiments on splenic T and B cells of lpr/lpr and +/+ mice suggested that the fatty acid composition of membranes was genetically determined and could be altered by ma-

nipulation of dietary lipid (2). Immune responses, such as cell-mediated cytolysis and binding of immunoregulatory hormone IL-2 to T-lymphocytes, are sensitive to changes in composition and physical properties of cell membranes suggesting that several molecular events involving receptors may also be involved in these processes.

Liver nuclear envelope phospholipid fatty acid composition between the two congenic strains of mice was markedly different. Moreover, the dietary linoleic acid level significantly altered this difference. Our studies on functions of the liver nuclear envelope of lpr/lpr mice demonstrate that these mice also possess subcellular abnormalities in mechanisms controlling nuclear activity. For example, lpr/lpr mice exhibit significantly higher nuclear envelope nucleoside triphosphatase activity and nuclear ribonucleic acid release in liver compared to +/+ mice that could be related to differences in the nuclear envelope lipid composition (33).

Perhaps it is reasonable to speculate that dietary lipid may influence the incidence of autoimmunity by altering the composition of membrane, and activate or inhibit several key enzymes or gene expression (10). In this regard, it is possible to alter the levels of mRNAs for several oncogenes in lpr/lpr mice through dietary lipid manipulation (11). Dietary lipid also alters the level of expression of oncogenes in mice (34). Age-related change in expression of the α2-globulin gene exists at the transcriptional level in response to diet (35). In the lpr/lpr autoimmune mouse, the lpr gene is expressed at very early stages of life. Whether or not membrane fatty acid composition is one factor contributing to early expression of the lpr gene or results from expression of the gene remains to be defined.

[Received February 20, 1990 and in revised form November 21, 1990; Revision accepted December 7, 1990]

Effect of Low Intake of n-3 Fatty Acids During Development on Brain Phospholipid Fatty Acid Composition and Exploratory Behavior in Rats

Marc Enslen, Hubert Milon and **Armand Malnoë***
Nestec Ltd., Research Centre, Vers-chez-les-Blanc, CH-1000 Lausanne 26, Switzerland

The effect of dietary restriction of n-3 fatty acids during development on brain phospholipid fatty acid composition and exploratory behavior has been studied in male Sprague Dawley rats. Female rats were fed semi-purified diets containing either 5.5% safflower oil or 6% soybean oil for 6 wk prior to mating and throughout gestation and lactation. Control rats were maintained on laboratory chow. The male pups were weaned to the diets of the dams except for one group which was switched from safflower to soybean oil at weaning. Behavioral studies and brain phospholipid analyses were conducted at 16–18 wk of age. Rats fed safflower oil showed significantly lower levels of 22:6n-3 in phospholipids of synaptic membranes and myelin than rats fed soybean oil or chow. The decrease in 22:6n-3 was compensated for by an increase in 22:5n-6, the total content of polyunsaturated fatty acids remaining approximately constant. The brain phospholipid fatty acid composition of rats switched from safflower to soybean oil at weaning was similar to that of rats fed soybean oil throughout the experiment. There was no difference in spontaneous locomotor activity among the different dietary groups. However, rats raised on safflower oil displayed a significantly lower exploratory activity (horizontal movements and rearings) in a novel environment than rats fed soybean oil or chow. In contrast to the brain phospholipid fatty acid composition, there was no recovery of exploratory behavior in rats raised on safflower oil and switched to soybean oil at weaning suggesting a specific requirement of n-3 fatty acids during development.
***Lipids* 26, 203–208 (1991).**

Docosahexaenoic acid (22:6n-3) is one of the major polyunsaturated fatty acids (PUFA) in the phospholipids of the central nervous system (CNS) (1). Although the brain is relatively resistant to diet-induced alterations in n-3 fatty acid levels (2), dietary deprivation of essential fatty acids during brain development, when requirements are particularly high (3,4), produces significant modifications in the fatty acid profile of brain phospholipids (5–9).

A low intake of dietary n-3 fatty acids has been associated with learning deficits in rats (5,10,11) as well as visual abnormalities in both rats and monkeys (11–14). This may be due to abnormal patterns of development as suggested by studies demonstrating the essentiality of these fatty acids for normal cell growth (15). Furthermore, modifications of the membrane phospholipid fatty acid composition may induce changes in the physical properties of membranes (*i.e.*, fluidity) and in the activity of membrane-bound enzymes (16,17) which may ultimately affect animal behavior, although evidence for such changes in the CNS is rather limited (for a review see Neuringer *et al.*, ref. 18). Alternatively, n-3 fatty acids may influence cellular processes in the CNS by interfering with the metabolism of arachidonic acid and the synthesis of eicosanoids (19). This may account for the behavioral effects observed after short dietary treatments with different fats when brain phospholipid fatty acid composition is not expected to be significantly affected (20–22).

In this study, we have investigated the effect of a reduced intake of n-3 fatty acids during development on locomotor activity and exploratory behavior in adult rats. The effect of diets on the phospholipid fatty acid composition of brain synaptic membranes and myelin is also reported. Finally, we have studied the reversibility of these effects upon feeding n-3 fatty acids to weanling n-3 deficient rats.

MATERIALS AND METHODS

Animal studies. Sprague Dawley rats (Iffa Credo, L'Arbresle, France) were used throughout these studies. Animals were housed individually in polypropylene cages (22 × 36 × 15 cm) and maintained in a room with controlled temperature (22°C), humidity (55%) and cyclic light (12 hr light/12 hr dark, light on at 7 a.m.). They were allowed food and water *ad libitum.* Female rats (3 mo old) were randomly assigned into three groups. Two groups were fed semi-purified diets containing either 6% soybean oil or 5.5% safflower oil (Table 1). A third group was maintained on a laboratory chow containing 5% (w/w) fat (Kliba AG, Kaiseraugst, Switzerland). The fatty acid composition of the diets is presented in Table 2. Rats from all groups were mated after 6 wk on the respective diets with male rats of the same age maintained on laboratory chow except during the mating period. The dams were continued on the respective diets during gestation and lactation. The litters were adjusted to 8 pups after parturition. The male pups were weaned on the same diet as the dams except for one group (labelled "safflower/soybean oil" in tables) in which safflower oil was replaced by soybean oil at weaning (21 days). Litter size and weight gains were not significantly different among the different dietary groups.

Exploratory behavior and locomotor activity. Recordings were carried out between 16 and 18 wk of age. Exploratory behavior was measured as the num-

ber of horizontal movements (crossings) and rearings of the animal exposed to a novel environment for 60 min. The novel environment consisted of Macrolon cages (48 × 38 × 28 cm) equipped with four infrared photocells (Datalogic) placed 4 cm above the floor for measurements of horizontal movements and three cells placed 10 cm above the floor for detection of rearing activity. The cages were located in a soundproof chamber with a 10 lux illumination. Measurements were started immediately after introduction of the animal into the cage and counts were recorded during 60 min using a SODECO-SAIA recorder (SODECO, Geneva, Switzerland). Activity was measured between 2 and 3 p.m.

The spontaneous locomotor activity was measured as the number of crossings and rearings accumulated in periods of 12 hr during a light/dark cycle. The recording was performed in the same cages and with the same rats as above after allowing the animals to adapt to their new environment for a period of 17 hr (from 2 p.m. to 7 a.m.). During behavioral testing, the animals had free access to their respective diets and water.

Brain membrane preparation. Rats were sacrificed at 16 wk of age by decapitation. The brain was rapidly removed and subcellular fractions consisting of synaptic membranes and myelin were prepared according to the method of Jones and Matus (23).

Fatty acid analyses. Membrane lipids were extracted with chloroform/methanol (2:1, v/v) according to the method of Folch *et al.* (24). The phospholipids were separated from neutral lipids and free fatty acids on Supelclean-NH2 (Supelco, Bellefonte, PA) resin as previously described (25). A phospholipid fraction containing both phosphatidylcholine and phosphatidylethanolamine was isolated by elution with methanol. The fatty acids of this fraction were methylated by alkaline methanolysis (26). The fatty acid methyl esters were analyzed by gas-liquid chromatography on a Carlo-Erba model 5160 Mega series gas chromatograph equipped with a flame ionization detector. The gas chromatographic conditions were: a capillary column of 30 m × 0.32 mm i.d. coated with Carbowax 20 M (Restek Corporation, Bellefonte, PA). The oven temperature program was: 100°C, 1 min isothermal; 15°C/min to 145°C, 1 min isothermal; 4°C/min to 195°C, 6°C/min to 220°C, 11 min isothermal. The detector was set at 320°C. Chromatograms were recorded with a Hewlett-Packard HP3354 Data System integrator. Identification of peaks was made by comparison of retention times with those of known standards run under the same conditions.

Statistics. Results of behavioral recordings and fatty acid compositions were analyzed using one- or two-way analyses of variance (ANOVA) followed by Tukey's test for comparison between groups. Differences between groups were considered statistically significant when p was <0.05.

RESULTS

Brain phospholipid fatty acid composition. In rats fed a diet low in n-3 fatty acids (safflower oil), the major change in brain phospholipid fatty acid composition was a significant reduction in the content of 22:6n-3 in both synaptic membranes and myelin as compared to rats fed soybean oil or chow (Tables 3 and 4). The decrease in 22:6n-3 was compensated for by an increase in the n-6 fatty acids, 22:5n-6 and to a lesser extent 22:4n-6. The total content of PUFA in synaptic membrane phospholipids was similar for all dietary groups. However, in myelin, there was a slight but

[a]Groups of rats were fed diets containing safflower or soybean oil throughout development and up to the age of 16 wk except for one group which was switched from safflower to soybean oil at 21 days (safflower/soybean oil). Control rats were raised on lab chow. Brain synaptic membranes were isolated and the fatty acid composition of a phospholipid fraction consisting of phosphatidylethanolamine and phosphatidylcholine was analyzed as described in Materials and Methods. Values are means ± S.E.M. (n=4) expressed as % (w/w) of identified fatty acids. Values with different superscripts in the same row are significantly different ($p<0.05$) from each other (one-way ANOVA followed by Tukey's test for comparison between groups).

*n=1.

significant increase (+15%) in total PUFA (n-3 + n-6) in rats fed safflower oil (Table 4). The levels of arachidonic acid in synaptic membranes (Table 3) were not significantly affected by the dietary fats. In myelin (Table 4), the levels were slightly lower in chow-fed rats than in the other groups but there was no difference between the safflower and the soybean oil group. The phospholipid fatty acid composition of both synaptic membranes and myelin was otherwise similar in rats fed chow or the soybean oil-based diet. Furthermore, rats raised on safflower oil and switched to soybean oil at weaning displayed the same phospholipid fatty acid profile as rats fed soybean oil throughout the experiment (Tables 3 and 4). Thus, the changes in phospholipid fatty acid composition induced by the diet low in n-3 fatty acids appear to be reversible since previous studies in this laboratory (27) have shown that in rats raised on safflower oil, low levels of 22:6 n-3 are already present at birth and throughout the lactation period.

Exploratory behavior. As shown in Table 5 the exploratory activity (crossings and rearings) following exposure to a novel environment was significantly lower in rats raised on safflower oil than in animals raised on soybean oil. The soybean oil- and chow-fed groups displayed similar crossing activities whereas rearing activity was slightly higher in the soybean oil group but the difference was not statistically significant. Rats raised on safflower oil and switched to soybean oil at weaning also displayed a decreased number of crossings and rearings, the latter being significantly lower ($p<0.05$) than that of rats fed soybean oil.

Spontaneous locomotor activity. The results of the spontaneous locomotor activity recorded over two consecutive 12-hr periods of a light/dark cycle are presented in Table 6. In all dietary groups there was a highly significant increase in spontaneous motor activity (crossings and rearings) during the night but no significant effect of diet over the two activity periods.

DISCUSSION

The results of the present study show that a dietary restriction of n-3 fatty acids during development causes profound modifications of the fatty acid composition of brain phospholipids and alterations of the exploratory behavior in rats. The changes in phospholipid fatty acid composition reported here are consistent with previous reports using similar although not identical dietary regimens (5,8,10,11). The phospholipids analyzed (phosphatidylcholine and phosphatidylethanolamine) are the major phospholipid species in brain (1). Thus the decreased levels of 22:6n-3 in these phospholipids are likely to reflect a decrease in the total brain

[a]Values are means ± S.E.M. (n=4) expressed as % (w/w) of identified fatty acids. Values with different superscripts in the same row are significantly different ($p<0.05$) from each other (one-way ANOVA followed by Turkey's test for comparison between groups). See legend to Table 3 for experimental conditions.

TABLE 5

Effect of Dietary Fats on Exploratory Behavior in Rats[a]

Diets	Crossings	Rearings
Safflower oil	321 ± 16^{a}	204 ± 17^{a}
Soybean oil	438 ± 26^{b,c}	297 ± 16^{b}
Safflower/soybean oil	341 ± 17^{a,b}	192 ± 15^{a}
Lab chow	445 ± 39^{c}	252 ± 24^{a,b}

[a]The exploratory activity was measured at the age of 16–18 wk as described in Materials and Methods. Values are means ± S.E.M. (n=12) of the number of crossings and rearings during a period of one hour after introduction in the novel environment. One-way ANOVA indicates a significant effect of diets on crossings ($p<0.002$) and rearings ($p<0.001$). Values with different superscripts within a column are significantly different ($p<0.05$) from each other (Tukey's test).

content of 22:6n-3 in rats raised on a safflower oil-based diet.

The levels of arachidonic acid were not significantly affected by the dietary restriction indicating that the brain content of this fatty acid is relatively resistant to large changes in the ratio of n-3 to n-6 fatty acids in the diets. However, as shown recently (28), brain arachidonic acid levels may be decreased by feeding large amounts of fish oil indicating that the type and amount of n-3 fatty acids in the diets, in addition to the n-3/n-6 ratio, may be important factors in determining the interactions of these fatty acids with arachidonic acid metabolism. Moreover, in this study, we found slightly lower levels of arachidonic acid in the myelin fraction of rats fed lab chow (which contains 20:5n-3 and 22:6n-3) than in rats fed safflower oil. There was no difference in the levels of 22:6n-3 between soybean oil- (which contains only 18:3n-3) and chow-fed rats indicating that, in the rat, 18:3n-3 is readily converted into docosahexaenoic acid.

In rats raised on safflower oil, a complete recovery of phospholipid fatty acid composition was observed on switching animals to a soybean oil-based diet from weaning to 16 wk of age. However, previous studies have shown that even if recovery of normal fatty acid composition eventually occurs in brain cells of n-3 deficient rats, it is much slower than in other tissues (29–31). Restriction of n-3 fatty acids during development significantly decreased the exploratory behavior in adult rats. This was not due to a depressing effect of the safflower oil-based diet on spontaneous locomotor activity which was similar in all dietary groups. The changes affected both the horizontal movements and the rearings. These results are consistent with those of Lamptey and Walker (5) who also observed a de-

TABLE 6

Effect of Dietary Fats on Spontaneous Locomotor Activity in Rats[a]

Diets	Period	Crossings	Rearings
Safflower oil	Day	328 ± 13	283 ± 12
Soybean oil	(7a.m.-7p.m.)	369 ± 16	272 ± 23
Safflower/soybean oil		325 ± 21	246 ± 13
Lab chow		470 ± 29	314 ± 22
Safflower oil	Night	1690 ± 150	1166 ± 70
Soybean oil	(7p.m.-7a.m.)	1652 ± 118	1128 ± 71
Safflower/soybean oil		1550 ± 68	1127 ± 38
Lab chow		1583 ± 101	1038 ± 64

[a]The spontaneous locomotor activity was measured in 16-18 week-old rats after an adaptation period of 17 hr in the measuring chamber as described in Materials and Methods. Values are means ± S.E.M. (n=12) for the number of crossings and rearings accumulated during periods of 12 hr. Two-way ANOVA (diet × period) with repeated measures (diet) indicates a main effect of period on both crossings ($p<0.001$) and rearings ($p<0.001$) but no main effect of diet on any parameters.

creased rearing activity in weanling rats raised on safflower oil. Interestingly, protein malnutrition during development in rats has also been shown to be associated with a reduced exploratory activity without changes in spontaneous motor activity (32).

Exploratory behavior has been proposed to reflect the emotional reactivity of the animal to a novel environment (33,34). This is supported by the observation that anxiolytic drugs increase exploratory activity in an open field (35). Moreover, lesions of the mesolimbic dopaminergic system (36) or dopaminergic drugs (37) which influence emotional states also affect the exploratory activity in rats.

Thus, dietary restriction of n-3 fatty acids appears to influence the animal's reactivity to a novel environment. This may be due to changes in sensory perception or to modifications of neural systems regulating emotional behavior. Visual perception may be involved since exploratory activity is known to be modulated by light (38). Moreover, previous studies have shown that dietary restriction of n-3 fatty acids during development was associated with visual abnormalities in rats (11-13) and monkeys (18) which in the latter species are not easily reversible upon supplementation with n-3 fatty acids. Alternatively, dietary n-3 fatty acids may influence neurotransmitter systems (receptors and second messengers) involved in the control of exploratory behavior including serotonin (39) prostaglandin (40) and opiate systems (41,42), some of which have previously been shown to be influenced by dietary fats (19,43).

The finding that the behavioral deficit of rats raised on safflower oil could not be reversed by feeding soybean oil after weaning points to the essentiality of n-3 fatty acids during development. Moreover, the behavioral deficit could be clearly dissociated from the biochemical effects on membrane phospholipid fatty acid composition which were found to be fully reversible. In a previous study (44) we had observed that if n-3 fatty acids were fed to n-3 deficient dams during the lactation period a reversal of the behavioral deficit (decreased exploratory activity) of the pups could be obtained. Thus, the lack of n-3 fatty acids during the early post-natal days may have a detrimental effect on normal brain development. This may be the consequence of an inadequate supply of 22:6n-3 during synaptogenesis and myelination which may ultimately affect brain function and behavior in the adult. Further studies will be necessary to delineate the biochemical mechanisms underlying these behavioral effects in the rat.

ACKNOWLEDGMENTS

The authors wish to thank Dr. J.A. Antonioli for the statistical analyses, and P. Reinhardt for skillful technical assistance.

The Effects of Polyoxyethylated Cholesterol on Fecal Bile Acids and Nitrogen and on Cholesterol Balance in Rats

L.F. Amorosa[a,*], C.P. Martucci[a], N.R. Stevenson[b] and A.K. Khachadurian[a]
[a]Department of Medicine and [b]Department of Physiology, University of Medicine and Dentistry of New Jersey, Robert Wood Johnson Medical School, New Brunswick, New Jersey 08903

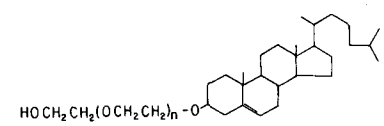
Polyoxyethylated cholesterol (POEC) is a water soluble derivative of cholesterol which decreases cholesterol absorption in rats without affecting body weight, fatty acid excretion, or intestinal histology. In the present study rat feces were analyzed for cholic, deoxycholic, chenodeoxycholic, muricholic and lithocholic acid following 3 months of feeding a standard or a 2% enriched cholesterol diet with or without 1.5% POEC. In rats maintained on the cholesterol free diet, POEC increased total bile acids (mg/day) by 50% from 14 ± 3 to 21 ± 3 (mean ± SEM) but only the increase in chenodeoxycholic acid was significant ($P<0.05$). The corresponding POEC effect in the 2% cholesterol diet was 31% (70 ± 8 to 93 ± 3, $P<0.01$). Fecal nitrogen and serum cholesterol did not vary among groups. Comparing these data with neutral steroid excretion previously determined showed that POEC in the cholesterol-free diet increased the negative cholesterol balance more than three-fold (34 ± 7 *vs* 118 ± 13 $P<0.01$). In rats fed 2% cholesterol, POEC caused a negative cholesterol balance of 222 ± 8 compared to the control of 27 ± 52 ($P<0.01$). The data indicate that POEC exerts complex effects in the intestinal tract which increase both bile acid and cholesterol excretion.
Lipids 26, 209–212 (1991).

Polyoxyethylated cholesterol (POEC) (Scheme 1) is a water soluble derivative of cholesterol which inhibits cholesterol synthesis in cultured human skin fibroblasts. In contrast to cholesterol and other cholesterol derivatives, POEC increases low density lipoprotein receptor activity (1,2). In addition, POEC decreases oleate incorporation into cholesteryl esters of cultured cells and has a direct inhibitory effect on acyl-CoA:cholesterol acyltransferase (ACAT), an enzyme which mediates intracellular cholesterol esterification and is implicated in cholesterol absorption. When fed to rats, POEC reduces cholesterol absorption by 66%, increases fecal cholesterol excretion two-three-fold, inhibits cholesterol synthesis in intestinal mucosal cells, and increases hepatic cholesterol synthesis. POEC does not significantly alter fatty acid absorption or intestinal histology after three weeks of feeding. Food intake and body weights were not significantly affected following three months of POEC administration (3).

The intestinal effects of POEC may be due to its physicochemical properties as a non-ionic surfactant. The ethoxy chain of the POEC molecule is quite hydrophilic, making the compound surface active at lipid/water interfaces. This property may also allow POEC to alter micellar structures or otherwise disturb the interaction of micelles and cholesterol at the surface of the unstirred water layer, thus limiting the passage of cholesterol into intestinal cells. Bile acids are reabsorbed by different mechanisms—passive diffusion in the upper intestine and sodium dependent active transport in the ileum. Because of structural and physicochemical similarities between POEC and bile acids, we postulated that POEC may also interfere with bile acid reabsorption.

Therefore, we studied the effects of POEC on fecal bile acids in rats fed a standard diet containing corn oil with and without cholesterol supplementation. We also measured fecal nitrogen content to determine if POEC decreases protein absorption, and measured serum cholesterol serially during the three-month feeding experiment. By combining the present results with previously published data on cholesterol excretion, we determined the effect of POEC on cholesterol balance.

MATERIALS AND METHODS



Animals and diets. Male Sprague-Dawley rats, which were previously utilized to determine the effects of POEC on cholesterol excretion, were used in these experiments (3). Animals were fed one of the following four diets: The standard diet contained 90% Purina rat chow (5001) and 10% corn oil (w/w). On this diet the rats consumed less than 1 mg/day of cholesterol. The standard diet was modified by the addition of 1.5% POEC (w/w), or 2% cholesterol (w/w) or both (combined diet). Animals were fed these diets for three months prior to collection of fecal samples over a four-day period.

Reagents. Bile acid standards for gas-liquid chromatography (GLC) were obtained from Steraloid, Inc. (Wilton, NH). 5α-Cholestane was from Sigma Chemical Co. (St. Louis, MO). Solvents used were high performance liquid chromatography (HPLC) grade, and other reagents were analytical reagent grade.

Fecal bile acid analysis. Feces were collected and

SCHEME 1. Polyoxyethylated cholesterol (POEC) with an average ethoxy chain length (n) of 20 was used in these experiments.

dried in a vacuum oven at 110°C overnight. The dried feces were ground in a mill and the ground material was stored at 4°C. Prior to extraction of bile acids, 10% (w/w) of the ground material from each rat for each of four consecutive days was pooled and further ground to a powder using mortar and pestle. Bile acid extraction was done following the procedure described by Tint *et al.* (4). One gram of powder was extracted for 18 hr with 250 mL of 95% ethanol in a Soxhlet extractor and later saponified for 2.5 hr with 0.5 N KOH and 50% ethanol and water. The volume of the aqueous phase and petroleum ether water washes was adjusted to 12 mL, and the concentration of KOH was brought to 3N. The samples were treated in a pressure cooker at 110°C for 3 hr and then acidified to pH 1-2 with HCl and extracted with 3 mL portions of dimethyl ether. The combined ether layers were dried over anhydrous Na_2SO_4 and evaporated to dryness with nitrogen gas. The residues were reacted with 0.2 mL of Sil-Prep (Alltech-Applied Science Laboratory, Deerfield, IL) for 30 min at 45°C, evaporated and taken up in heptane. Known amounts of 5α-cholestane were added as internal standard prior to duplicate analysis by GLC.

The trimethylsilyl ether derivatives of bile acid methyl esters were chromatographed on a 4 mm I.D. × 80 cm silanized glass column packed with 1% HIEFF-8BP on Gaschrom Q 100/120 mesh (Alltech-Applied Science Labs) at 240°C with helium/air/hydrogen at a flow rate of 40 mL/min. The instrument used was a Varian (Walnut Creek, CA) Model No. 3400 with flame ionization detector and injector temperatures set at 250°C.

The retention times of standards were compared to 5α-cholestane and the major bile acids were identified except for two late running peaks, 9 and 10, with retention times of 30.5 and 33.7 min, respectively. The ratios of these retention times to that of 5α-cholestane were 5.1 and 5.6. POEC in the feces did not chromatograph with the bile acids. Bile acid recovery was estimated to be greater than 90% as determined based on [^{14}C]deoxycholate.

Nitrogen determination. Fecal nitrogen was determined by standard methods based on the oxidation of organic nitrogen to ammonium ions and quantitation of the latter by reaction with Nessler's reagent (5). Nitrogen was determined in an aliquot obtained from the same four-day pooled fecal collection from each rat described above.

Serum cholesterol and triglycerides. Blood was obtained from the rat tail vein every two weeks. Serum cholesterol was determined using the microenzymatic method by Allain *et al.* (6).

Cholesterol balance. Neutral steroid excretion in these rats was previously reported (3). In the present paper, data on plant sterols and their degradation products have been excluded from the neutral steroid result. The addition of POEC to the standard and 2% cholesterol diets did not significantly alter plant sterol intake or β-[4-^{14}C]sitosterol recovery as previously noted. Thus, the cholesterol balance equals [cholesterol intake] minus [excretion of neutral steroids plus bile acids] (7).

Statistical analysis. All data are expressed as mean ± standard error of mean determined by summating the results of fecal or serum analysis for each individual rat. Data were analyzed by one-way analysis of variance (ANOVA) and Student-Newman-Keuls test for group differences (8).

RESULTS

We previously noted (3) that 1.5% dietary POEC did not significantly affect food intake or weight gain over three months. The latter is shown in Table 1 and compared with fecal weights and bile acid excretion. Both POEC and cholesterol supplementation of the standard diet significantly increased dried fecal weight over four days, but POEC did not significantly increase the

fecal weight of cholesterol fed rats. The increase in fecal weight between standard and 1.5% POEC diet is associated with a non-significant increase in bile acid excretion (14.03 ± 2.87 *vs* 21.38 ± 3.19 mg/day). Only the 92% increase in chenodeoxycholic acid excretion was significantly different (P<.05) on the 1.5% POEC diet. A corresponding increase in lithocholic acid, the secondary bile acid derived from bacterial conversion of chenodeoxycholic acid in the intestine, was not found. To determine whether POEC interfered with intestinal conversion of primary to secondary bile acids, we calculated ratios of the secondary to primary bile acids on both the standard and POEC diets. No change in the ratio of deoxycholic acid to cholic acid was found on either diet. In contrast, the ratio of lithocholic to chenodeoxycholic acid varied from 1.02 ± 0.20 on the standard diet to 0.33 ± 0.15, (P<0.05) on the POEC diet, as determined by summating the ratios from individual animals. Cholesterol added to the standard diet induced a five-fold increase in total bile acid excretion (P<0.01). The increase in the excretion of cholic acid and P10 (RT 33.7 min) accounted for almost 60% of the change associated with cholesterol feeding. Feeding of cholesterol plus POEC resulted in a greater than four-fold increase in total bile acid excretion as compared to the POEC diet (P<0.01). When compared to the cholesterol diet, POEC in the combined diet further increased total bile acid excretion by 31% (P<0.01).

Serum cholesterol was determined every two weeks. At no time point during the three-month study did cholesterol or POEC supplementation significantly alter serum cholesterol in these animals. The final serum cholesterol concentrations are shown in Table 2.

Nitrogen in feces was determind to detect protein malabsorption, which might suggest a non-specific toxic effect of POEC on gastrointestinal mucosa. The results (Table 2) show that POEC did not significantly alter nitrogen excretion.

Cholesterol balance data displayed in Table 3 show that POEC increased negative cholesterol balance in the standard diet from 34 ± 7 to 118 ± 13 mg/day (P<0.01). Rats fed a 2% cholesterol diet for three months were in cholesterol balance since −27 ± 52 mg/day does not significantly vary from zero. Addition of POEC to this diet caused a negative cholesterol balance of 222 ± 8 mg/day, P<0.01 from the reference diet.

DISCUSSION

We previously reported that oral administration of POEC to rats for three months inhibited cholesterol absorption and increased hepatic cholesterol synthesis (3). To determine whether the action of POEC was selective to cholesterol absorption, we measured bile acids and total nitrogen in the fecal specimens from the same experiments. These studies were delayed by technical difficulties with the extraction procedures for determining individual bile acids which prompted us to report the other data earlier. The total fecal bile acid excretion of 14.03 mg/day obtained in this study on rats ingesting 10% (w/w) corn oil is similar to the value of approximately 13 mg/day reported by Uchida *et al.* (9) in Sprague-Dawley rats of the same age in-

gesting a 4% fat diet. Uchida *et al.* (9) also reported the presence of an unidentified bile acid peak 10 which they considered to be ω-muricholic acid based on GLC/mass spectrometric analysis.

The increase in fecal weight associated with the 1.5% POEC and 2% cholesterol diets is, in part, due to the fecal content of POEC and increased steroids. POEC supplementation of the standard diet significantly increased chenodeoxycholic acid excretion. However, the excretion of lithocholic acid, the secondary bile acid derived by bacterial conversion of chenodeoxycholic acid, was so low in three of the six rats fed POEC that it was undetectable. This suggested that POEC might be impairing bacterial conversion or reducing the content of chenodeoxycholic acid in the intestine so that less is available for conversion to lithocholic acid. The latter is more likely because levels of deoxycholic acid, the secondary bile acid derived from cholic acid, were not depressed, indicating that POEC does not generally interfere with bacterial conversion of bile acids. Chenodeoxycholic acid, unlike cholic acid, affects the liver by decreasing synthesis and biliary excretion of cholesterol (10,11). Therefore, increased fecal loss of chenodeoxycholic acid may be partly responsible for the increased hepatic cholesterol synthesis and fecal losses of endogenous cholesterol previously observed (3).

There was a marked increase in excretion of all bile acids in response to a 2% cholesterol diet fed for three months consistent with the data of others (12,13). This can be related to the increase in hepatic cholesterol and its conversion to bile acids. The addition of POEC to the 2% cholesterol diet caused a further significant increase in total fecal bile acids by increasing each of the individual bile acids. The POEC effect on bile acid excretion in both the cholesterol free and enriched diets may be due to inhibition of bile acid reabsorption and/or increased bile acid synthesis. We speculate that the non-ionic surfactant and detergent properties of POEC may interfere with micellar function or reduce absorption of conjugated bile salts in the ileum. We do not know if POEC is competitively taken up by active bile acid transport mechanisms since we have been unable to measure POEC in tissues by high pressure liquid chromatography.

Fecal nitrogen was unaffected by POEC. This indicates that POEC does not cause gastrointestinal protein losses. Serum cholesterol was not altered by POEC and cholesterol feeding. This is due to the increase in hepatic cholesterol synthesis and excretion in response to POEC (3) and increased bile acid excretion in response to dietary cholesterol. This is confirmed by the cholesterol balance analysis of Table 3, which combines the current data with information previously published from the same experiments. Cholesterol balance can be obtained since serum cholesterol, rat and fecal weights within dietary groups were constant (13). The results show that POEC causes a negative cholesterol balance even with a 2% cholesterol intake. To maintain the serum cholesterol level in the presence of POEC requires net whole body cholesterol synthesis equal to the negative cholesterol balance.

The mechanisms by which POEC causes increased fecal losses of cholesterol and bile acids remain unclear. There is no evidence suggesting a non-specific toxic effect of POEC on intestinal mucosal cells since feeding behavior and nitrogen absorption are not significantly altered. Other compounds which inhibit cholesterol synthesis, such as simvastatin, ketoconazole, and 15-ketosterol derivatives have variable inhibitory effects on cholesterol absorption and intestinal ACAT activity, but are not known to significantly impair bile acid reabsorption (14-16). Thus, POEC combines the actions of two classes of drugs—those that interfere with cholesterol absorption and those that result in bile acid losses, such as cholestyramine. These actions in one compound may be therapeutically useful in the prevention and treatment of disorders of cholesterol metabolism.

[Received August 17, 1990; Revision accepted December 28, 1990]

Species Variation in the Atherogenic Profile of Monkeys: Relationship Between Dietary Fats, Lipoproteins, and Platelet Aggregation

A. Pronczuk[a], G.M. Patton[b], Z.F. Stephan[a,1], and K.C. Hayes[a,*]
[a]Foster Biomedical Research Laboratory, Brandeis University, Waltham, Massachusetts 02254 and [b]Boston Veterans Administration Medical Center, Boston, Massachusetts 02130

Because lipoproteins and platelet aggregation have been implicated in atherogenesis, relative differences in the response of these variables to dietary fat saturation were compared in three species of monkeys differing in their susceptibility to atherosclerosis (cebus, rhesus, and squirrel monkeys). Both long-term (8–12 years) and short-term (8 weeks) responses to diets containing 31% fat calories were examined in the same monkeys. As expected, long-term feeding of coconut oil by comparison to corn oil produced significantly higher plasma concentrations of total cholesterol, LDL cholesterol, apoB, and triglycerides, as well as higher ratios of LDL/HDL cholesterol and apo B/apo A-I. These responses were characteristic of all species with cebus being most responsive and rhesus the least. The short-term plasma cholesterol response to animal fats (butter, lard, beef tallow) was significantly less than that to coconut oil. When fish oil was substituted for two-thirds of either corn oil or coconut oil, exceptional decreases occurred in plasma cholesterol and triglycerides, as well as in HDL cholesterol and apo A-I concentrations despite the fact that the fish oil diets contained more saturated fat and less polyenes than the corn oil diet. Platelet aggregation tended to increase with saturated fat consumption and greatly decreased with fish oil intake in all monkeys, although cebus monkeys were ten-fold more resistant to platelet aggregation than the other two species. The molecular species of platelet phosphatidylcholine (PC) varied with both the dietary fat fed and species of monkey. An inverse correlation ($r=-0.60$; $p<0.001$) was found between changes in one such PC molecular species (18:0-20:4) induced by diet and the platelet aggregation threshold. These results demonstrate that the lipemic and platelet responses to dietary saturated fat depend upon both the type of fat (*i.e.*, the specific combination of dietary fatty acids, including the chain length of saturated fatty acids and the degree of polyunsaturation) and the species of monkey (genetic component) in which the response is elicited.
***Lipids 26,* 213–222 (1991).**

It is well documented that dietary saturated fat and cholesterol elevate plasma lipids and increase the risk of atherosclerosis, whereas polyunsaturated fat exerts the opposite effect (1–5). However, our evolving understanding of both lipoprotein metabolism and platelet aggregation in the process of atherogenesis (5,6), coupled with the questionable impact of monounsaturated fat intake on these processes (7), have raised questions concerning certain generalizations about dietary fat saturation and atherosclerosis. In humans not all "saturated fats" elevate plasma lipids to the same degree (1,8). On the other hand, highly polyunsaturated fats that lower serum cholesterol and low density lipoprotein (LDL) tend to lower high density lipoprotein (HDL) and apo A-I concentrations at high fat intakes (*i.e.*, 40% fat energy)(9,10). Recent findings suggest that although dietary monounsaturated fats may lower plasma cholesterol in humans under certain circumstances (7,11,12), this hypolipemic effect does not equal that of linoleic acid, under normal dietary exchanges (1,2,13), nor do monounsaturated fatty acids seem to reduce HDL (7,11,14).

In addition to the above caveats, it is well known that the plasma cholesterol response to dietary fat saturation among individuals and between animal species varies considerably (15–20). Furthermore, a variety of studies reported to date have addressed the issue under dissimilar experimental conditions, *e.g.*, normocholesterolemic or hypercholesterolemic subjects, and generally while evaluating one species of animal with individuals assigned to a single dietary treatment. These studies typically used either long-term (months) or short-term (weeks) feeding protocols, but seldom examined the relationship between both responses in the same individual.

For these reasons we designed a comprehensive study that considered the long-term and short-term effects of dietary fat saturation on plasma lipids, lipoproteins, and platelet aggregation in 24 monkeys representing three species known to differ in their susceptibility to atherosclerosis and in their cholesterolemic response to diet (21). We found significant differences between species of monkeys in their response to dietary saturated fat and in the *ex vivo* susceptibility of their platelets to aggregate under these dietary circumstances.

MATERIALS AND METHODS

The experimental plan and procedures involved in this study were approved by the Institutional Animal Use Committee. Twenty-four nonhuman primates (8 rhesus, 8 cebus and 8 squirrel monkeys; equal number of male and female of each species) had been raised (caged individually) from birth for 8–12 years with purified

Abbreviations: ANOVA, analysis of variance; apo, apolipoprotein; COCO+, coconut oil and cholesterol; CORN+, corn oil and cholesterol; EDTA, ethylenediaminetetracetic acid; GLC, gas-liquid chromatography; HDL, high density lipoprotein; HDL-C, high density lipoprotein-cholesterol, HPLC, high performance liquid chromatography; LDL, low density lipoprotein; LDL-C, low density lipoprotein-cholesterol; LSD, least significant difference; M/S, monounsaturated/saturated fatty acid ratio; PC, phosphatidylcholine; PPP, platelet poor plasma; P/S, polyunsaturated/saturated fatty acid ratio; PRP, platelet-rich plasma; stdPRP, standardized platelet rich plasma; VLDL-C, very low density lipoprotein-cholesterol; THF, tetrahydrofuran.

diets containing 31% kcal as either corn oil or edible coconut oil without cholesterol (Table 1). The initial data obtained from these monkeys represent the long-term aspect of the dietary trial. Body weight averaged (± S.D.) 7.8 ± 0.7 kg, 2.2 ± 0.4 kg and 0.7 ± 0.1 kg for rhesus, cebus and squirrel monkeys, respectively. During subsequent short-term feeding trials, these monkeys received diets containing 31% calories as lard, followed by butter, fish oil (2/3 fish oil and 1/3 corn or coconut oil), beef tallow, or their original dietary fat (corn oil or coconut oil) plus 0.045% cholesterol (CORN+ and COCO+) for 8 week periods. The diets (Table 1) and their fatty acid composition (Table 2) are tabulated for comparison. The cholesterol added to the basal diets (0.11 mg/kcal) represented the amount contained in the diets containing 2/3 fish oil. Other diets contained slightly less cholesterol—butter (0.10 mg/kcal), tallow (0.06 mg/kcal) and lard (0.05 mg/kcal). Between each short-term diet, monkeys received their original corn oil or coconut oil (no added cholesterol) diet for 2-3 weeks in an attempt to partially "restore" the original reserves of fatty acids prior to each subsequent, new, short-term fat. From a pilot experiment we determined that 2-3 weeks allowed a 80-90% return to original plasma cholesterol values and that this was preferable to having a carry over effect from one diet to the next. Twice during the final 10 days of each 8 week trial, monkeys were fasted overnight, sedated with ketamine, and blood was collected by plastic syringe from femoral venipuncture into ethylenediamine tetraacetic acid (EDTA)-wetted glass tubes or into a plastic tube containing 3.8% sodium citrate solution (9 vol blood to 1 vol of citrate solution). EDTA plasma was separated by centrifuging the blood at 4°C for 30 min at 1000 × *g*. Samples were kept at −30°C until analyzed. Platelets isolated from citrated plasma were tested for aggregation immediately.

TABLE 1

Composition of Semipurified Diet[a]

Ingredients	Amounts
	g/100 g dry diet
Lactalbumin	20.0
Cornstarch	29.2
Sucrose	20.0
Fat[b]	15.0
Cholesterol	(0 or 0.045)[c]
Salt mix[d] (Ausman-Hayes)	5.0
Vitamin mix[e] (Newberne-Hayes)	0.5
Choline chloride	0.3
Cellulose	10.0

[a]Diets were prepared by combining 5 kg dry diet mix with 4 L of boiling water and 60 g agar.

[b]Either corn oil, coconut oil, butter, beef tallow, 2/3 fish oil + 1/3 corn oil or + 1/3 coconut oil. Fish oil was MAXEPA®, kindly provided by Scherer Corp. (Troy, MI).

[c]45 mg Cholesterol/100 g of diet (0.11/kcal) was added to corn oil and coconut oil diets to formulate basal diets for short-term study. Other diets contained the following amount of cholesterol (mg/kcal): 2/3 fish oil (+1/3 corn oil or coconut oil) 0.11; butter 0.10; tallow 0.06; lard 0.05.

[d]Salt mix contained (g/kg): magnesium oxide, 32.0; calcium carbonate, 290.5; potassium phosphate dibasic, 314.2; calcium phosphate dibasic, 72.6; magnesium sulfate, 98.7; sodium chloride, 162.4; ferric citrate, 27.0; potassium iodide, 0.077; manganese sulfate, 1.22; zinc chloride, 0.92; calcium phosphate tribasic, 0.50; cupric sulfate, 0.29; chromium acetate, 0.04; sodium fluoride, 0.02; sodium selenite, 0.0043.

[e]Vitamin mix contained (g/kg): thiamine HCl, 0.80; riboflavin, 1.60; pyridoxine HCl, 0.8; calcium pantothenate, 5.00; niacinamide, 8.00; folic acid, 0.80; biotin, 0.04; cyanocobalamin, 0.03; menadione, 0.1; d,l-α-tocopheryl acetate (500 IU/g), 20.00; vitamin A acetate (500,000 IU/g), 5.00; vitamin D_3 (400,000 IU/g), 0.62; ascorbic acid, 120; inositol, 10; taurine, 50; made to 1 kg with 776 g dextrin.

Total cholesterol, HDL-cholesterol (HDL-C) and total triglycerides were determined by enzymatic assays (Sigma kit procedures 351 and 336; Sigma Chemical Co., St. Louis, MO). HDL was obtained following sodium phosphotungstate-Mg^{++} precipitation of the apo B- and apo E-containing lipoproteins (22), a procedure standardized against separation of the lipoproteins by ultracentrifugation (data not included). Since preliminary testing did not show significant differences in HDL-cholesterol values for fresh and once frozen (kept 2 weeks at −30°C) monkey plasma, the frozen samples were used in all instances. Low density lipoprotein cholesterol (LDL-C) was estimated after adjusting for VLDL-C based on plasma triglycerides according to the procedure of Friedwald *et al.* (22).

The level of apo B and apo A-I was measured in whole plasma by an immunoturbidometric method (23) using polyclonal antibodies raised against each apoprotein in rabbits. Turbidity in plasma and in the appropriate apoprotein standard solutions was measured at 340 nm with a Perkin-Elmer spectrophotometer (Perkin-Elmer Co., Oak Brook Instrument Division, Oak Brook, IL).

Platelet aggregation was measured according to the method of Born as described previously (24). In brief, citrated blood was centrifuged at room temperature at 200 × *g* for 10 min. The top 1-2 mL of platelet-rich plasma (PRP) was collected and the remaining blood was recentrifuged at 2000 × *g* for 10 additional min to obtain platelet-poor plasma (PPP). The platelet concentration was determined with a hemocytometer and the PRP was diluted with PPP to obtain stdPRP (standardized platelet-rich plasma) containing 2.5 × 10^8 platelets/mL. Aggregation was performed with a Payton aggregometer Model 402 (Payton Scientific Inc., Buffalo, NY) using 0.4 mL of stdPRP. Following 5 min of incubation at 37°C in 1 mL siliconized cuvettes, a metal siliconized stir-bar was added, followed by a measured quantity of purified collagen (equine tendon, Hormon-Chemie GmbH, München, Germany). The aggregation induced was quantified turbidimetrically as the percent difference in light transmission between stdPRP and PPP. For each monkey sample an aggregation "threshold" was determined by stimulating platelets with different concentrations of collagen (4-5 levels) until 10% of the predetermined maximum aggregation was elicited. The "threshold" was expressed as the amount (μg) of collagen required for a 10% maximum platelet aggregation response per 1 mL stdPRP. Thus, a low threshold was characteristic of platelets that aggregated readily.

Molecular species of platelet phosphatidylcholine (PC) were determined by high performance liquid chro-

[a]Fatty acids determined by GLC analysis of each fat as fed.

matography (HPLC) of the benzoyl esters as described previously (25). Platelets were separated from PRP and extracted with chloroform/methanol (2:1, v/v). Phosphatidylcholine was separated from the chloroform phase by HPLC on a silica column (Lichrosphere Si-100, 5μ). Next PC was cleaved to form diglycerides by phospholipase C hydrolysis and benzoyl esters were prepared. Finally, the benzoyl diglycerides were separated by HPLC on a silica column (Lichrosphere Si-100, 5μ) using 2.5% THF in hexane (1 mL/min) as solvent. Due to bleeding and analytical limitations, PC molecular species of platelets were analyzed for rhesus and cebus but not for squirrel monkeys, and only selected diets were included: basal diets (CORN+ and COCO+), fish oil (2/3 fish oil and 1/3 corn oil or coconut oil), and tallow.

Fatty acid analysis of formulated diets was accomplished by using the one-step transesterification method of Lapage and Roy (26). Gas-liquid chromatography (GLC) of fatty acid methyl esters was performed on a Hewlett-Packard 5790A GLC equipped with a flame ionization detector (Hewlett-Packard Co., Avondale, PA) and a 30-meter fused silica column (SP-2330, Supelco Inc., Bellefonte, PA).

Statistical analysis was performed on a Macintosh Plus® computer (Apple Computer Inc., Cupertino, CA) using appropriate statistical packages, Stat View™ 512+ and Cricket Graph 1.2™ (Cricket Software Inc., Philadelphia, PA). Statistical differences between the two original long-term dietary treatments and three species were assessed by two-factor analysis of variance. Since no fat times species interaction was noted, the data for all three species were collapsed and a direct dietary fat comparison was made using Student's *t*-test. Because all three species responded in the same fashion to the short-term dietary fat changes, data were combined and analyzed by repeated-measures analysis of variance (ANOVA) and Fisher's protected least significant difference (LSD) analysis (27).

RESULTS

Monkeys consumed their purified diet containing corn oil or coconut oil from birth without adverse effects in either group. They accepted the various fat substitutions without incident and without appreciable fluctuation in body weight over the 12 months required for these studies.

Fat saturation and plasma lipids. Several long-term effects of dietary fat saturation were apparent on plasma lipids and lipoproteins at the beginning of the study after long-term consumption (8–12 years) of either the corn oil or coconut oil diets. Although no sex or age effects were detected in the data by covariant analysis, analysis of variance did reveal that both fat and species affected the long-term responses (Table 3). Because no fat times species interactions were observed, within each dietary fat all three species were combined (n=12) for the comparison of dietary fat saturation (between corn oil and coconut oil). Within each species and for all monkeys, those raised on coconut oil tended to have higher plasma cholesterol and triglyceride concentrations than monkeys raised on corn oil. As for the species effect, the cebus plasma cholesterol and squirrel monkey triglyceride values were most severely elevated by coconut oil consumption. Other effects of long-term coconut oil intake included significantly higher LDL-cholesterol and apo B concentrations and higher LDL/HDL and apo B/apo A-I ratios. HDL-cholesterol values were not significantly affected by either oil (Table 3).

To obtain a "basal" value for comparison with data from monkeys fed cholesterol-containing animal fats (lard, butter and beef tallow) and fish oil in the short-term studies, corn oil and coconut oil diets were supplemented with 0.11 mg/kcal of cholesterol (equivalent to that in diets with 2/3 fish oil). Adding cholesterol caused about a 10% rise in plasma total cholesterol, LDL cholesterol, and the LDL-C/HDL-C ratio for both diet groups. The LDL-C/HDL-C ratio was also significantly higher in COCO+ monkeys than in CORN+ monkeys. A small increase in plasma triglycerides was also noted in CORN+ monkeys, but a 20% average increase occurred in COCO+ monkeys. Minimal changes in plasma HDL-C and apolipoproteins were induced by cholesterol feeding (Tables 3 and 4).

In order to determine whether the diet of origin, *i.e.*, corn oil *vs.* coconut oil, exerted a residual impact on the short-term response (8 weeks) to other dietary fats or whether the species of monkey made a difference, covariant analysis was applied. Although corn oil-fed monkeys tended to have somewhat lower values than their coconut oil counterpart for each short-term diet (and for all species), neither the original fat nor monkey species revealed a statistically significant effect. In the final analysis, a one-factor ANOVA was used to examine the response to the four short-term fats (dietary fat effect) for each of the two original groups of monkeys (corn oil and coconut oil, n=12 per group) since they were so different in their long-term responses.

The short-term plasma lipid responses were most affected by consumption of butter fat and fish oil. Butter induced the greatest increases in monkeys raised on corn oil while fish oil caused the largest decline in monkeys raised on coconut oil (Table 4). In addition, the plasma cholesterol of monkeys fed COCO+ decreased significantly (20–23%) during the short-term response to animal fats (butter, lard, and tallow), whereas the plasma cholesterol of monkeys fed CORN+ collectively increased between 4–11% (n.s.) when fed these animal fats (Table 4). By contrast, the short-term consumption of fish oil decreased the plasma cholesterol 20% and 37% in corn oil-fed and coconut oil-fed monkeys, respectively.

The short-term triglyceride response was also linked to the previous long-term fat intake. Specifically, in CORN+ monkeys the short-term consumption of all animal fats substantially increased plasma triglyceride (23–40%), whereas essentially no change was observed in the plasma triglyceride response of the COCO+ monkeys during the short-term feeding of animal fats (Table 4). Fish oil supplementation caused modest (17% and 37%), but significant, decreases in plasma triglycerides for all three species independent of whether they previously received CORN+ or COCO+ long-term.

Another short-term effect of animal fat consumption was its impact on LDL and HDL cholesterol concentrations. The LDL-C pool was increased substantially by butter in those monkeys fed CORN+ (Table 4), whereas replacing two-thirds of corn oil or coconut oil with fish oil caused significant declines in LDL-C for all monkeys, independent of their original long-term dietary fat intake. Although the basal HDL-C value tended to be lower for CORN+ than COCO+ monkeys, the difference was not significant. HDL-C scarcely varied when the CORN+ monkeys consumed animal fats, but it dropped significantly (proportionally even more than LDL-C) when these monkeys received fish oil. In monkeys fed COCO+, the HDL-C decreased significantly when either butter fat or fish oil was fed, but not with lard or tallow, both of which contained appreciable 18:1. The decline in HDL-C associated with fish oil intake was almost twice as great as that attributed to butter fat.

Not surprisingly, these fluctuations in LDL and HDL cholesterol, induced by varying the short-term

fat intake, affected the LDL/HDL ratio. Animal fats tended to increase this ratio 20–35% in monkeys fed CORN+ and decreased it 10–25% in monkeys fed COCO+. Fish oil increased the LDL/HDL ratio about 25% in CORN+ monkeys but lowered the ratio 10% in COCO+ monkeys (Table 4).

The short-term responses in plasma apo B and apo A-I concentrations generally reflected those in LDL and HDL, respectively (Table 4). Accordingly, the low apo B in corn oil-fed monkeys became elevated when animal fats were fed to this group on a short-term basis. In contrast to LDL cholesterol, the apo B tended to rise with fish oil supplementation of corn oil-fed monkeys and decreased slightly during fish oil supplementation of monkeys raised on coconut oil, but neither shift was significant. Apo A-I tended to be higher in monkeys raised on coconut oil and did not change as much as apo B during the short-term feeding trials. Fish oil, however, caused a major drop in plasma apo A-I when it replaced a major portion of either corn oil or coconut oil. Plasma apo A-I also decreased when lard and butter were fed short-term by comparison to monkeys fed COCO+. These fluctuations in apolipoproteins caused the apo B/apo A-I ratio to increase significantly during fish oil consumption for all monkeys combined, while butter increased this ratio significantly only in the CORN+ monkeys.

Fat saturation and platelet aggregation. Monkeys fed coconut oil long-term (8–12 years) tended to be more sensitive to collagen-induced platelet aggregation than monkeys fed corn oil (Table 5). Rhesus and squirrel monkey platelets demonstrated similar aggregability whereas those from cebus monkeys were about ten-fold more resistant to aggregation. Adding cholesterol to these diets (*i.e.*, the basal diets) did not alter platelet aggregation in any of the three species.

As was the case for the long-term response, cebus platelets were also more resistant to aggregation than the other two species during the short-term trials (Table 5). Using the basal diet (original fat + cholesterol) as the reference threshold for aggregation, most short-term dietary fats except butter and tallow tended to increase the platelet aggregation threshold in all monkeys. In the CORN+ monkeys, butter caused a significant 42% decrease in platelet stability (*i.e.*, lowered the platelet aggregation threshold) while tallow caused an insignificant 13% decrease. Platelets from monkeys fed butter were also more sensitive to aggregation

[i]Cebus platelets significantly less sensitive than rhesus or squirrel monkeys.

than monkeys fed lard. In contrast to butter, fish oil exerted a significant, positive stabilizing effect on platelet aggregation, with the threshold for combined species increasing about 43% and 73% over basal values for CORN+ and COCO+, respectively.

Platelet PC molecular species. Cebus and rhesus monkeys, which were inherently different in their sensitivity to platelet aggregation, also displayed characteristic differences in platelet PC molecular species (Table 6). Cebus fed CORN+ maintained lower levels of the PC molecular species 18:1-18:2 and 18:0-18:2 and higher 18:0-20:4 than comparable rhesus platelets. Cebus monkeys fed COCO+ maintained higher 16:0-20:4 and 18:0-20:4 in their platelet PC while 16:0-18:1 was lower than corresponding values in rhesus platelets.

Dietary fat saturation had a significant impact on most of the platelet PC molecular species (Table 6). All monkeys fed the saturated, COCO+ basal diet revealed much lower 18:1-18:2 and 18:0-18:2 and higher 16:0-18:1 platelet PC molecular species than monkeys fed the basal CORN+. When compared to these basal diets, feeding tallow caused only small differences in the platelet PC molecular species. In both cebus and rhesus, 8-week supplementation with fish oil produced a most dramatic (average about 300%) increase in all 20:5 fatty acid-containing platelet PC molecular species (16:0-20:5, 18:1-20:5 and 18:0-20:5) and a concomitant decrease in the corresponding 20:4-containing and 18:2-containing PC molecular species.

When correlations between diet-induced changes in platelet PC molecular species and the platelet aggregation threshold were examind, the PC molecular species that best described the relationship was 18:0-20:4 ($r=-0.60$; $p=0.001$) (Fig. 1), *i.e.*, the greater the increase in 18:0-20:4, the greater the tendency to aggregate.

DISCUSSION

Species variation in lipemic response to dietary fat saturation. The present experiment was unique from two points of view. First, the repeated-measures design using the same monkey fed different fats in sequence is relatively unique among monkey studies. Thus, each animal served as its own control as the short-term dietary fats were varied, allowing us to control interindividual variation in the lipemic response within each species. Second, the design allowed us to assess interspecies variation between the three species of monkeys fed identical diets in sequence.

Examination of species differences indicates that the plasma lipids in all three species tended to respond in the same direction to any given fat, but that cebus were most sensitive to saturated fat consumption, while the rhesus were least affected. The variability between individuals within species and the major difference in the magnitude of the response between species emphasizes the significant, and to date uncategorized, genetic component associated with the metabolism of specific fatty acids. Variation between individual humans (15,18) and between other African and Asian monkey species (20) in their sensitivity to saturated fat can be as great as the cebus-rhesus diversity. Whether this variability reflects one or several related aspects of fatty acid metabolism involving phospholipids, triglycerides, or cholesteryl esters remains unresolved. This raises the question of the mechanism(s) controlling the response and whether sensitivity to dietary fat saturation may be a function of an individual and/or species-dependent "aberration or limitation" in lipid metabolism.

From these data the cebus would appear to be the more sensitive model for evaluating the mechanism of

[b]Corn oil or coconut oil diet with 0.045% (0.11 mg/kcal) cholesterol added (CORN+ and COCO+).
[c,d]Significant effect of diet compared to basal ([c]) or between monkey species ([d]) by two-way ANOVA.

the cholesterol-elevating ability of specific dietary fats or fatty acids, even though cebus presented a relatively high HDL-C profile and the lowest LDL/HDL ratio. From these data and those reported by others in humans (4,15,28) and monkeys (17,20), the saturated fat-induced cholesterolemia typically reflects an expanded LDL pool, irrespective of whether the primate involved (man or monkey) maintains primarily an LDL or HDL transport system.

Although the qualitative response of cebus to saturated fat was similar to that in humans, the quantitative degree of the response was somewhat greater. For example, the typical differential in plasma cholesterol between coconut oil and safflower oil in humans was approximately 95 mg/dL (1), whereas the increment between CORN+ and COCO+ in cebus was on the order of 130 mg/dL. Cebus would also appear to have the greatest genetic propensity of the three species studied for production of HDL based on their plasma concentrations of apo A-I and HDL. A comparable contrast in the genetic influence over apo A-I and the plasma lipoprotein response elicited by saturated fat

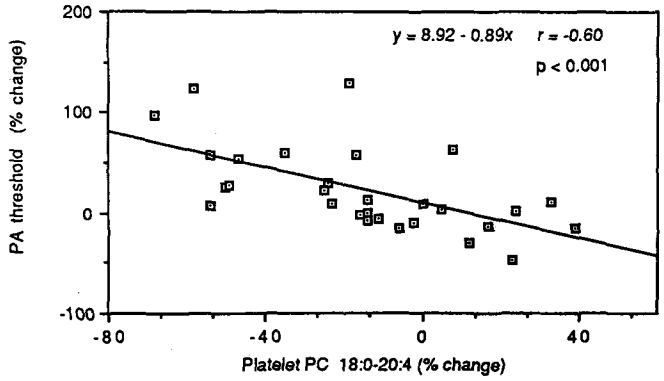

FIG. 1. Regression depicting the relationship between the observed changes in the platelet aggregation threshold and PC molecular species of 18:0-20:4 as affected by the various diet fat manipulations. The greater the diet-induced increase in 18:0-20:4, the lower the threshold.

and cholesterol feeding has been described between African green monkeys and cynomolgus macaques. The African green monkey, like the cebus, has a high HDL profile and would appear to be more resistant to atherosclerosis induction than the cynomolgus (20).

Specific dietary saturated fats and lipemia. From the data on total plasma cholesterol, triglycerides, and the LDL/HDL and apo B/apo A-I ratios, it was apparent that coconut oil (with 0.11 mg/kcal added cholesterol) elicited the greatest short-term lipemia. Not surprisingly, polyunsaturated corn oil produced much lower plasma lipid concentrations. Adding the human equivalent of 200–250 mg/day dietary cholesterol to either corn oil (CORN+) or coconut oil (COCO+) elicited a 10% increase in plasma cholesterol, which was reflected in the LDL cholesterol pool and a modest increase in the LDL/HDL ratio. We previously found this dietary cholesterol-induced expansion of plasma cholesterol to be associated with increased apolipoprotein E in VLDL and IDL of rhesus monkeys (29), in accord with the response in humans (30).

A second point emphasizes the notion that the term "saturated fat" must be qualified, at least when considering the lipemic response to a dietary fat that is accompanied by a low level of dietary cholesterol. This is supported by the fact that none of the so-called saturated animal fats were as hypercholesterolemic as coconut oil which contains large amounts of 12:0 and 14:0 fatty acids and minimal 18:2. Previous data in humans has indicated that myristic acid (14:0) may contribute most of the "saturated fat" effect (1). In our study neither lard nor tallow (rich in 16:0 and 18:0) differed appreciably from CORN+ (with 0.11/kcal cholesterol added) in terms of the total plasma cholesterol concentration produced when all three species were combined. Only the extremely sensitive cebus seemed to distinguish between these fats, and even these differences were not significant (data not shown). Part of this nonresponsiveness to lard and tallow may be attributed to the high 18:1 and 16:0 content of these two animal fats, a point that re-emphasizes the neutrality of 18:1 (1,2), or even its ability to lower cholesterol (under specific dietary and metabolic conditions) without depressing HDL-C (7,11,31), and the suggestion that 16:0 is not especially cholesterolemic (1,32). In this regard it is noteworthy that lard and tallow induced significant decreases in both total plasma cholesterol and LDL-C in monkeys raised on coconut oil without causing a significant depression in HDL-C. Accordingly, these were the only two fats to significantly improve the LDL/HDL ratio by comparison to COCO+, whereas butterfat (relatively rich in 14:0 and 12:0 and low in 18:2) was the only fat to raise this ratio in the CORN+ basal group.

The plasma triglyceride levels associated with lard, butter or tallow were similar to those for coconut oil, and all of these values were significantly greater than those observed when corn oil or fish oil were fed. Thus, an expanded triglyceride pool was consistently associated with consumption of all saturated fats, even when plasma cholesterol was not elevated. This interesting phenomenon may reflect an increased VLDL-TG secretion rate demonstrated *in vitro* by perfused livers from monkeys fed saturated fat compared to unsaturated fat (33) or saturated fat plus cholesterol as compared to polyunsaturated fat plus cholesterol (34). Another possibility includes decreased clearance of VLDL-TG by lipoprotein lipase, an observation that has been reported in humans consuming saturated fat (35).

A recurrent finding was the rise in plasma cholesterol concentration in the corn oil-raised monkeys during most short-term diets, whereas the high values attributed to the original coconut oil diet actually declined during the short-term dietary trials. Because of this convergence, the final concentrations between the two groups were similar for each short-term fat, although not completely equalized. One possible explanation for this failure to equilibrate may reflect adipose stores of fatty acids deposited during the long-term consumption of the original fat (*i.e.*, corn oil *vs* coconut oil) which exerted a residual effect on the plasma cholesterol level in the short-term. This same effect is apparent from the data from African green monkeys fed sequential diets, also for 8 week periods (36). Following a high-polyene intake (40% cal as fat), saturated fat consumption failed to raise the plasma cholesterol concentration to the original high level attained during a previous encounter with the same saturated fat. This putative difference in adipose fatty acids is documented for cebus monkeys fed corn oil or coconut oil. The combination of 12:0 and 14:0 represented more than 50% of the fatty acids accumulating in adipose tissue during clearance of chylomicrons absorbed during coconut oil consumption (37,38). We have subsequently found that the residual long-term fat effect on plasma cholesterol disappeared after 12 weeks of short-term fat feeding, as opposed to the 8 weeks used in this study (32), and that rhesus adipose maintains a much higher concentration of polyunsaturates than cebus when fed identical diets (unpublished data).

Response to fish oil. Fish oil was noteworthy because it caused the greatest decrease in total plasma cholesterol, an inconsistent response often observed in human and animal studies when a large amount of n-3 fatty acids are ingested (5,39–43). This decrease

was twice as great in the COCO+ monkeys as compared to those fed CORN+, more-or-less lowering plasma lipids in the two groups to equal concentrations. The decreases in plasma cholesterol attributable to fish oil were remarkable because the final concentrations for both the CORN-FISH and COCO-FISH periods were even lower than the CORN+ basal period. This depression in cholesterol occurred despite the fact that diets containing CORN-FISH, and especially COCO-FISH, had much higher total saturates and decidedly less total polyenes than the CORN+ basal diet. This confirms the exceptional ability of relatively large amounts of 20:5n-3 and 22:6n-3 to lower plasma cholesterol (44), even counteracting the sizable 12:0 and 14:0 contributed by the one-third portion of coconut oil. In essence, a diet with only 24% of its total fatty acids (about 6% total energy) as n-3 fatty acids (COCO-FISH) resulted in lower plasma cholesterol and triglycerides than the CORN+ basal diet contributing 60% of its fatty acids (about 18% total energy) as 18:2n-6 and containing only one-third the amount of saturates. This tendency for fish oil polyenes to substantially overshoot predictions generated by the Keys (2) or Hegsted (1) regression formulas (that treat all polyenes as equal) has been noted in the human response as well (45).

Also remarkable was the substantial drop in the plasma HDL-C and apo A-I concentrations when fish oil was fed. These decreases related to HDL were proportionally greater than those for LDL-C (in corn oil-raised cebus monkeys) or for apo B (in both corn oil- and coconut oil-raised monkeys), thereby increasing the LDL/HDL or apo B/apo A-I ratios during fish oil intake. Together these ratios would suggest an increase risk for atherogenesis. A similar adverse effect of fish oil on the distribution of lipoprotein cholesterol or apoproteins has been described by others for humans (42,43,46), monkeys (39), and pigs (47), and appears related to an increased rate of VLDL conversion to LDL (47) possibly coupled with reduced LDL clearance associated with decreased LDL receptor activity (48). The impact of these changes on atherogenesis has yet to be reconciled, but presumably the marked decrease in platelet aggregation in these monkeys and the lower transition temperature of their LDL cholesteryl esters (49) more than offsets the risk introduced by the adverse lipoprotein ratios.

Fish oil only modestly decreased the triglyceride level in these monkeys, unlike the rather striking decreases normally observed in humans (5,40,42), who typically have much higher initial plasma triglyceride concentrations. Presumably the lower plasma concentration reflects decreased triglyceride synthesis and secretion (43,50). Parks *et al.* (39) found slightly elevated triglycerides in African green monkeys fed fish oil and cholesterol and related this to a reduction of LDL particle size (49) which they previously found to be inversely correlated with the plasma triglyceride concentration. However, if that association were infallible, elevated triglyceride levels should have pertained as well in our monkeys fed fish oil, since their LDL size (based on apo B/LDL-C ratio) was also greatly reduced.

Platelet aggregation. The three species of monkeys differed inherently in their platelet sensitivity to aggregation as well as in their platelet response to changes in fat saturation. The species diversity in aggregation (cebus platelets were ten-fold more resistant to aggregation than rhesus or squirrel monkeys) was much more pronounced than the change in aggregation induced by dietary fat. On the other hand, differences in platelet PC molecular species induced by dietary fat were greater than the inherent differences in PC molecular species observed between cebus and rhesus monkeys, with the important exception of 18:0-20:4 which was consistently higher in cebus than rhesus. The extraordinary resistance of cebus (despite their inherently high 18:0-20:4) is in contrast to the enhanced platelet aggregation associated with increased 18:0-20:4 PC brought about by dietary fat in all monkeys. This implies that although the modest changes in aggregation attributed to dietary fat may have reflected the altered phospholipid fatty acid profiles, genetically modulated regulatory factors are much more important than dietary fatty acid-induced changes in platelet PC molecular species in terms of controlling the inherent aggregation difference between monkeys.

Consistent with data of others in humans and animals (40,51), fish oil (at the 20% energy level) significantly reduced platelet aggregability (increased threshold) in these monkeys. In fact, fish oil was the only fat to have a distinct effect on aggregation, although long-term coconut oil tended to enhance aggregation by comparison to corn oil, and butter tended to cause platelets to aggregate more quickly than most other fats. Reduced platelet aggregability associated with fish oil coincided with marked increase in all 20:5n-3 platelet PC molecular species and decrease in 20:4n-6 molecular species.

The exact mechanism responsible for the fish oil perturbation of platelet function is thought to relate to displacement of 20:4n-6 from platelet phospholipids by 20:5n-3 (51,52) which shifts the PGI_2/TXA_2 ratio to an antiaggregatory PGI_3/TXB_3 profile (53,54). The results of this study confirm this suggestion, *i.e.,* dietary fat-induced decreases in 18:0-20:4 PC molecular species reduced platelet sensitivity to aggregation.

In comparison to fish oil (rich in n-3 polyunsaturated fatty acids), the effect of other polyunsaturated fats (rich in n-6 fatty acids) on platelet aggregation is less well established (36,51,55-61). In this study corn oil seemed to exert a modest beneficial effect by comparison to coconut oil or butter fat. This unfavorable effect of saturated fats containing 14:0 on platelet aggregation is in agreement with Masi *et al.* (57), who reported that rabbit platelets were more sensitive to aggregation with collagen after a butter diet than corn oil. In addition, long-term diet modification of French farmers increased the dietary P/S ratio from 0.32 to 0.97 and produced a considerable decrease (81%) in platelet sensitivity to aggregation with thrombin (58). Lewis and co-workers (36,61), however, using ADP as agonist, failed to find a positive effect of polyunsaturated fat on platelet sensitivity in African green monkeys and, in some cases when the P/S ratio exceeded 1.50, noted an increase in platelet sensitivity which paralleled a significant drop in plasma HDL. In our experiment, a pilot study using collagen, thrombin, or ADP as agonist produced similar trends for all three

(data not included), with collagen being the most sensitive agonist and providing the most reproducible data.

The Effect of Lysophosphatidylcholine on Coronary and Renal Circulation in the Rabbit[1]

A. Wolf, T. Saito, R. Dudek and R.J. Bing*
Huntington Medical Research Institutes, Department of Experimental Cardiology, Pasadena, California 91105

It has been shown that different lysophosphatidylcholines (LPC) possess relaxing properties in vascular strips. We report on the effect of intraatrial injection of LPC micelles into white New Zealand rabbits. Changes in renal and coronary flow were determined by radioactive microspheres. Coronary blood flow increased significantly following administration of LPC, while no significant changes were observed in renal blood flow, cardiac output and myocardial contractility. Coronary, renal and total vascular resistance, as well as mean arterial pressure, dropped significantly. Cardiac arrhythmia and hemolysis were not noted. The results demonstrate the vasorelaxant effect of LPC *in vivo*.
***Lipids 26,* 223–226 (1991).**

The importance of endothelium dependent processes in the regulation of the caliber of arterioles and arteries has been well established. One of the compounds responsible for vasodilation is the endothelium-derived relaxing factor (EDRF) (1). Like nitrovasodilators such as nitroglycerin, EDRF acts through activation of guanylate cyclase and subsequent accumulation of cyclic-guanosine monophosphate (2). Lysophosphatidylcholine (LPC) is an endothelium dependent vascular smooth muscle relaxant. Relaxation of rabbit aortic strips induced by LPC is also accompanied by a rise of cyclic GMP content (3). LPC activates guanylate cyclase and is formed by phospholipase A_2 (PLA_2), which deacylates phosphatidylcholine (PC). LPC is a physiological constituent of cell membranes (4). During cardiac ischemia, LPC blood levels are diminished (5,6). Under certain conditions LPC is responsible for hemolysis and solubilization of membranes (7,8). It is known that LPC exerts certain physiological effects, such as inhibition of platelet aggregation (9), natriuresis and diuresis (10). The purpose of this study is to evaluate the *in situ* effects of LPC on coronary, renal and systemic hemodynamics and to investigate whether or not LPC causes hemolysis or myocardial damage under these experimental conditions.

MATERIALS AND METHODS

Eleven male white New Zealand rabbits weighing 2.0 to 2.8 kg were used for *in situ* experiments. After anesthesia with intravenous sodium pentobarbital (30 mg/kg body weight) and heparinization (600 IU/kg body weight) tracheotomy was performed. Ventilation was carried out by means of a Harvard Rodent ventilator (model 683, Harvard Apparatus, South Nattick, MA). The right femoral artery was then cannulated with an infant feeding tube (3.5 French, Mallinckrodt, Argyle, NY) which was connected to a pressure transducer (model P50, Gould Electronics Co., Cleveland, OH). After thoracotomy the heart was exposed, the pericardium incised and a catheter (Accumark, 5 French, Concord Laboratories Inc., Keene, NH) inserted into the left atrium and held in position by a tie. An angiocath (16 G, two inches, Deseret Medical Inc., Beckton Dickinson and Co., Sandy, UT) was inserted through the cardiac apex into the left ventricular cavity and connected to a pressure transducer (model P50). The signal of each transducer was processed by an amplifier (model 8188-3302-00, Gould Electronics). Systemic and left ventricular blood pressures were recorded and left ventricular dp/dt was determined using a differentiating circuit (model 8188-3302-00, Gould Electronics). To correct for changes in loading, contractility was expressed as dp/dt/IP, where IP equals the pressure at the end of the isovolumetric contraction (11). A blood sample was drawn from the right femoral artery for determination of blood gases, including pH, pO_2, pCO_2 and base excess using an acid base laboratory ABL 2a (Radiometer, Copenhagen NV, Denmark). Excessive variations in acid/base balance were corrected by adjustment of respiration or intravenous injection of sodium bicarbonate. Hemoglobin in heparinized plasma was determined with the method of Kohn and O'Kelly using tolidine reagent and peroxide (12). Coronary and renal blood flow, as well as cardiac output, were measured by means of radioactive microspheres using the method of Heymann *et al.* (13).

Two types of radioactive tracers (3M Company, Rochester, MN) 15 ± 3 micrometer in diameter were used — ^{141}Ce prior to and ^{51}Cr following injection of LPC. Microspheres were suspended in 0.05% Tween 80 in saline and vortexed for two minutes immediately prior to injection to prevent clumping. The reference sample was obtained from the femoral artery catheter by means of a Harvard Pump (model 901, Harvard Apparatus, Millis, MA), set at a speed of 1.25 mL per min. Fifteen seconds after commencing withdrawal of the reference sample, 0.3 mL of the ^{141}Ce microsphere suspension were injected through the atrial catheter over a period of 30 seconds and the catheter was flushed

Abbreviations: CBF, coronary blood flow; CO, cardiac output; CVR, coronary vascular resistance; cyclic GMP, cyclic guanosine monophosphate; EDRF, endothelium-derived relaxing factor; HE, hematoxilin-eosin; IP, pressure at end of isovolumic contraction; LPC, lysophosphatidylcholine; MAP, mean arterial pressure; OC, organ count; PC, phosphatidylcholine; pCO_2, partial pressure of carbon dioxide; PLA_2, phospholipase A_2; pO_2, partial pressure of oxygen; RBF, renal blood flowl; RC, counts/minute (reference sample); RVR, renal vascular resistance; TPR, total peripheral resistance; WR, reference blood flow withdrawal rate.

with 3 mL of saline. Withdrawal from the femoral artery (reference sample) continued for an additional 15 seconds (total withdrawal time 60 seconds). While both blood flows and cardiac output were determined only once prior to and again immediately following LPC injection, systemic and left ventricular blood pressures, as well as left ventricular dp/dt, were continuously recorded. Immediately after intraatrial injection of LPC micelles, ^{51}Cr microspheres were injected into the left atrium and a reference sample was again drawn as described above. The animals were then sacrificed by injection of potassium chloride, the heart and both kidneys were removed, weighed and divided into six specimens each. Samples were then counted in an automatic gamma counter (Gamma Trac 1191, Tracor Analytic, Elk Grove village, IL). Energy windows were set at 50-200 keV for ^{141}Ce and 280-360 keV for ^{51}Cr. Coronary or renal blood flows were calculated as follows:

$$\text{Coronary or renal blood flow (mL/min/g)} = \frac{\text{OC} \times \text{WR}}{\text{RC} \times \text{g}}$$

where OC (organ count) equals the total counts per min (CPM) of heart or kidney, WR is the reference blood flow withdrawal rate (1.25 mL/min) and RC is the CPM for the blood reference sample. Coronary and renal resistances (mm Hg/mL/min/g) were calculated as:

$$\text{Coronary (Renal) Resistance} = \frac{\text{Mean arterial pressure (mm Hg)}}{\text{Coronary (renal) blood flow (mL/min/g)}}$$

Cardiac output was obtained by a modified formula of Heymann *et al.* (13).

$$\text{Cardiac output (mL/min)} = \frac{\text{WR} \times \text{TIM}}{\text{RC}}$$

where WR is the reference sample withdrawal rate (mL/min), TIM is the CPM of the injectate and RC is the CPM of the reference sample. Total peripheral resistance (mm Hg/mL/min) was calculated as:

$$\text{Total Peripheral Resistance} = \frac{\text{Mean arterial pressure (mm Hg)}}{\text{Cardiac output (mL/min)}}$$

LPC micelles were prepared by suspending LPC (egg yolk) in 2 mL of saline, making a final dosage of 5 mg/kg. LPC derived from egg yolk was chosen because previous data demonstrated that it caused relaxation of arterial strips (14). Experiments with intravenous injection of LPC/cholesterol liposomes proved not to be successful, and were highly sensitive to small changes in the LPC/cholesterol ratio.

Specimens for histological examination were fixed in 10% formalin and stained with hematoxilin-eosin (HE). Statistical analyses were carried out according to Student's *t*-test for paired values. All chemical compounds were obtained from the Sigma Chemical Company (St. Louis, MO).

RESULTS

Intraatrial injection of 2 mL LPC micelles in saline caused a significant increase in coronary blood flow (CBF) (1.51 ± 12 to 1.93 ± 0.18 mL/min/g; Fig. 1) while coronary vascular resistance (CVR) decreased (58.4 ± 3.5 to 27.8 ± 6.3 mm Hg/mL/min/g; Fig. 1). As mean arterial pressure (MAP) declined (84.2 ± 3.0 to 69.9 ± 3.2 mm Hg; Fig. 2), the rise in coronary flow was mainly due to reduced coronary vascular resistance (correlation coefficient $r = 0.87$, $p<0.01$). Renal blood flow (RBF) showed no significant change (3.9 ± 0.4 to k3.8 ± 0.4 mL/min/g; Fig. 1), but renal vascular resistance (RVR) diminished (23.5 ± 2.3 to 20.6 ± 2.6 mm HKg/mL/min/g; Fig. 1). Systemic vascular resistance (SVR) also was significantly lower as compared to the control value (0.421 ± 0.039 to 0.323 ± 0.028 mm Hg/mL/min; Fig. 2.) No significant changes in cardiac output (CO), heart rate (HR) or contractility (dp/dt/IP) were recorded (Fig. 2). Intraatrial injection of LPC micelles did not result in hemolysis. Six samples drawn at one minute intervals prior to and following injection of LPC did not differ from the control samples ($n=4$; data not shown). Histological examination of HE-stained heart muscle in four animals showed no damage to the myocardium. Only minimal dilatation of epicardial veins and occasional extrusion of red cells into mycoardial parenchyma were noted. No cardiac arrhythmias were recorded after administration of LPC.

DISCUSSION

LPC is a physiological constituent of cell membranes (1.8% of total membrane lipid in rat liver plasma membranes) (4). It modifies the activity of membrane associated enzymes, such as guanylate cyclase, adenylate cyclase (15), sialytransferase (16) or galactosyltransferase (17). LPC may be involved in membrane transduction by diffusing through the lipid portion of membranes, thus activating enzymes at various locations in the cell (15). Furthermore, LPC changes general membrane properties such as fluidity and permeability (15). It is possible that the endothelium-dependent relaxation by LPC of isolated strips of rabbit aorta and bovine pulmonary arteries and veins is related to membrane alteration. LPC initiates the relaxation of endothelium-deprived strips of bovine pulmonary arteries upon superfusion from an endothelium intact bovine pulmonary artery (18).

Relaxation by LPC is inhibited by methylene blue and hemoglobin, indicating the involvement of cyclic GMP (14). Direct evidence of the activation of guanylate cyclase by LPC has recently been provided by Menon *et al.* (3). The decline in coronary and renal vascular resistance after injection of LPC is directly related to a smooth muscle relaxing effect on coronary and renal vessels.

LPC ($>10^{-6}$M) has also been shown to be cytolytic to red blood cells resulting in hemolysis (8) which appears to be the result of its detergent action (19). On the other hand, Menon *et al.* (3) have demonstrated that repeated administration of LPC (10^{-5}M) does not interfere with the functional integrity of the endothelium in rabbit aortic strips. In addition, the present study reveals that LPC (5 mg/k) does not cause *in vivo* hemolysis or marked histological damage of the myocardium.

Potential clinical effects of LPC have been investi-

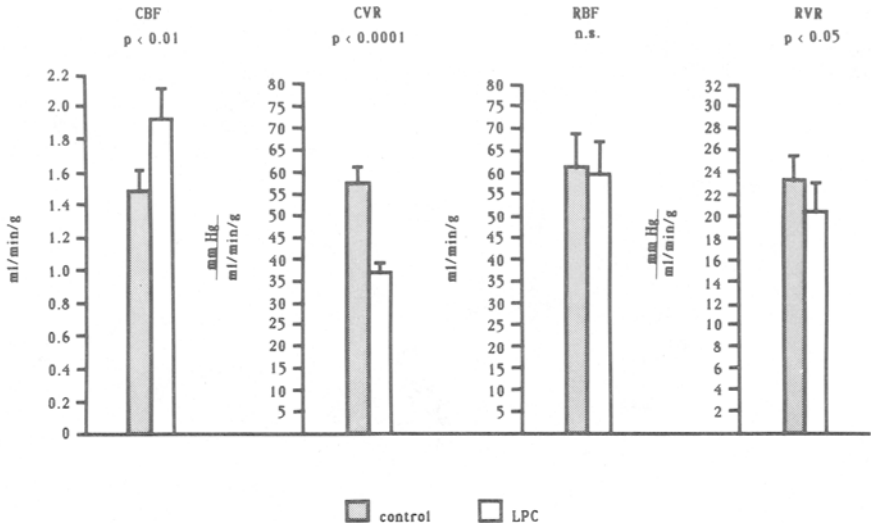

FIG. 1. Changes in coronary and renal blood flow and in coronary and renal vascular resistance following injection of LPC. The rise in coronary blood flow and the decline in coronary and renal vascular resistances are significant (n=11). Blood pressure was continuously recorded; determinations were performed simultaneously. Continuous blood pressure measurements allowed simultaneous determination of vascular resistances. CBF, coronary blood flow; CVR, coronary vascular resistance; RBF, renal blood flow; RVR, renal vascular resistance.

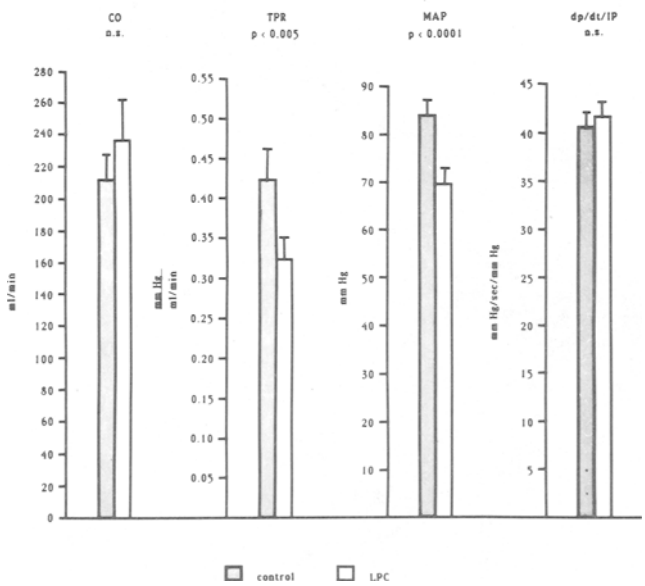

FIG. 2. Hemodynamic systemic changes following intraatrial injection of LPC micelles (5 mg/kg). The decline in total peripheral resistance (TPR) and mean arterial pressure (MAP) is significant (n=11). No significant changes in cardiac output (CO) and in cardiac contractility (dP/dt/IP) were noted.

gated by a number of workers; it has been established that LPC is diminished in plasma during myocardial ischemia (5,6). In our study no cardiac arrhythmias were recorded. The present study shows the vasodilating properties of exogenously administered LPC *in situ*. Administration results in a decline of coronary, renal and systemic vascular resistances. The question arises how LPC formed in vascular endothelium elicits vasodilation. Previous work indicates that the relaxation of arterial smooth muscle by LPC correlates with the deacylation of phosphatidylcholine (PC) to LPC (20). Deacylation of PC to LPC stimulated by mellitin, a potent activator of PLA_2, and the inhibition of the reacylation of LPC to PC by thimerosal, an inhibitor of lysolecithin acyltransferase, cause relaxation of arterial strips (20). Furthermore, Huang and Lee (21) and Bing and Saeed (22) demonstrated the relaxing effect of PLA_2 *in vitro*. Menon *et al.* (23) recently showed that activation of PLA_2 by thrombin results in production of LPC from PC in endothelium dependent relaxation.

The mechanisms of the action of LPC in the relaxation of blood vessels occurs *via* the activation of cyclic GMP. Phospholipase A_2 from various snake venoms, are activators of guanylate cyclase, especially the particulate form (24). This is probably the result of changes in membrane phospholipids and not of solubilization of the enzyme as was shown by Menon *et al.* (3) and by Zwiller *et al.* (24). Therefore, as previously proposed (3,14,24) conversion of PC to LPC by phospholipase A_2 may represent a mechanism in the regulation of vascular resistance. Ca^{2+} dependency of this mechanism is likely, since phospholipase A_2 requires Ca^{2+} for full activity. Although these results reveal that LPC infusion may cause coronary vasodilation, its therapeutic use is not suggested. In contrast to coronary vasodilators such as nitroglycerin and calcium blockers, the margin of safety of LPC appears limited.

[Received August 31, 1990; Revision accepted January 29, 1991]

Analysis of Polymers from Autoxidized Marine Oils by Gel Permeation HPLC Using a Light-Scattering Detector

Ivan C. Burkow[a,*] and **R. James Henderson**[b]
[a]Institute of Fishery Technology Research, N-9001 Tromsø, Norway and [b]NERC Unit of Aquatic Biochemistry, University of Stirling, Stirling FK9 4LA, Scotland

A high-performance gel-permeation chromatographic method was developed for the isolation and quantification of polymers from autoxidized fish oils. The chromatographic system consists of a single pump, a 500 Å styrene/divinylbenzene column, and a light-scattering "mass" detector. Dichloromethane was used as the mobile phase, and quantifications were carried out using glycerol as internal standard. The polymer content of commercially available fish oils was found to be around 2%, but the value increased rapidly during oxidation at 35°C in air under light. The oxidized oils were also characterized by peroxide value, thiobarbituric acid value, ultraviolet (UV) measurements, thin-layer chromatography (TLC)/densitometry, and capillary gas chromatography. No correlation between polymer content and standard oxidation assessment parameters for the fish oils analyzed was found. However, a relationship between the polymer increase and the decrease of total fatty acids was observed, indicating that the polymers may be the main oxidation product in autoxidized marine oils.
Lipids 26, 227–231 (1991).

Due to their high degree of unsaturation, marine lipids are prone to autoxidation. If oxidation occurs in fish oil, loss of biologically important components, deterioration of product quality, and formation of potentially harmful substances may result (1–3). Possibly deleterious effects may be due to the formation of toxic compounds and their reactions, for example, with proteins, carbohydrates, nucleic acids, and vitamins. As a consequence, much work has been done to determine the chemical, nutritional, and metabolic implications of rancid fats and oils. However, the oxidation of polyunsaturated fatty acids of fish oils is still not well understood.

Most reports on the mechanisms and products of lipid autoxidation have concentrated on hydroperoxides, which are primarily formed (4), and on low molecular weight volatile secondary products (5,6). In addition, high molecular weight products are thought to be formed, but the existence of these compounds has only been documented for oligomeric and polymeric fatty acids (7–10) and for polymers from frying fats (11–14). Polymers from fish oils air-oxidized at ambient temperature have so far received little attention. The reason for this may partly be due to difficulties in the isolation and quantification of the complex structures present in marine oils. In addition, polymer formation until recently (15) has not been considered an extensive problem with unheated fish oils.

Among the various analytical methods used for determining oligomeric and polymeric materials, gel permeation chromatography (GPC) seems to be most promising. Several low-pressure systems have been described using gels such as cross-linked polystyrene and porous styrene-divinylbenzene (16,17), Sephadex LH-20 (18–21), and Bio-beads SX1, SX2, and SX3 (7,8,20–23). However, these methods are very time-consuming. In contrast, high-performance liquid chromatography (HPLC) on macroporous styrenedivinylbenzene copolymers is more convenient (8–10,12,24); it has previously been used for the separation of high molecular weight compounds from oxidized fatty acids and vegetable oils.

In the present study a simple and rapid method for the isolation and quantification of polymers by high-performance gel permeation chromatography is described. The polymer content of oxidized fish oils of different purities and degrees of unsaturation is also reported.

MATERIALS AND METHODS

Chemicals. Cod liver oil (CLO) and encapsulated fish oil concentrates (FOC) were purchased from a local pharmacy. Crude cod liver oil (CCLO) was an unrefined oil supplied by British Cod Liver Oils (Marfleet, Hull, U.K.). CPL Fish Oil 30 was obtained from Karlshamns AB (Karlshamn, Sweden). All chemicals used were of *p.a.* quality. Solvents were HPLC grade. Polystyrene standards (MW 2510, MW 4080 and MW 7030) were supplied by Millipore (Milford, MA).

General methods. Ultraviolet (UV) measurements were done on a Pye-Unicam SP 30 spectrophotometer using methanol or cyclohexane as solvent.

High-performance thin-layer chromatography was carried out using Si 60 pre-coated glass plates (Merck; Darmstadt, Germany) and chloroform/methanol/acetic acid/water (90:8:1:0.8, by vol) or hexane/diethyl ether/acetic acid (80:20:1, v/v/v) as developing solvent. After charring with cupric acetate (25), fractions were quantified with a Shimadzu dual-wavelength flying-spot scanner CS-9000 with control unit DR-13. The extent of oxidation was assessed by measuring the polar material of low R_f value (<0.35, one broad band).

Abbreviations: CCLO, crude cod liver oil; CLO, cod liver oil; CPL, chromatographically purified fish oil; FOC, fish oil concentrate; GPC, gel permeation chromatography; HPLC, high-performance liquid chromatography; PUFA, polyunsaturated fatty acids; PV, peroxide value; TBA, thiobarbituric acid; TLC, thin-layer chromatography; UV, ultraviolet.

Methyl esters of fatty acids were prepared by acid-catalyzed methylation (26) and subsequent purification using a Bond Elut NH_2 (Analytichem International; Harbor City, CA) with hexane as eluent. An additional thin-layer chromatography (TLC) purification was necessary with the methyl esters of highly oxidized samples using hexane/diethyl ether/acetic acid (90:10:1, v/v/v) as developing solvent. Fractions were made visible with iodine, the methyl ester band was scraped off, and the derivatized acids were extracted with chloroform/methanol (2:1, v/v). The samples were taken up in hexane, and fatty acid methyl esters were analyzed on a Packard 439 gas chromatograph equipped with flame ionization detector (FID) and a Chrompack CP Wax 51 fused silica capillary column (25 m, i.d. 0.25 mm). Hydrogen was used as carrier gas. The detector temperature was maintained at 250°C. Sample application was by on-column injection. The component peaks were identified by comparison with authentic standards and quantified relative to 23:0 methyl ester used as internal standard. Peak areas were measured with a Shimadzu C-R3A computing integrator.

Polymers were analyzed using a high-performance liquid chromatography system consisting of a Waters 501 pump with a U6K injector and an Applied Chromatography Systems 750/14 mass (light-scattering) detector. The mass detector was operated at an internal air pressure of 24 psi with the evaporator set at 20. Analyses were done on a Waters Ultrastyragel™ 500 Å (30 cm, i.d. 7.8 mm, particle size 10 μm) GPC column with dichloromethane (0.8 mL/min) as mobile phase. Sample concentration was 10–60 mg/mL in dichloromethane and injection volume was 5–50 μL. Glycerol was used as internal standard and peaks were integrated using a Hewlett-Packard 3390A integrator.

The oxidation experiments were carried out in an incubation cabinet kept at 35°C with irradiation from an artificial daylight fluorescent tube at 200 $\mu Em^{-2}s^{-1}$. The oils were oxidized either in open 2-mL vials (i.d. 0.8 mm, 20 μL sample) or in Petri-dishes (i.d. 95 mm, 2.5 g sample) without stirring.

Peroxide values (PV) were measured by iodometric titration (27). Thiobarbituric acid (TBA) values were determined as described by Ke and Woyewoda (28).

RESULTS AND DISCUSSION

Separation and quantification of polymers. To determine optimum chromatographic conditions for polymer separation and quantification, a number of exploratory experiments were carried out using cod liver oils (CLO) of different oxidation levels as test materials. Dichloromethane was used as mobile phase, mainly on the basis of its solvent properties, since the mobile phase affects separation by GPC only to a minor degree. Although the separation of the triglycerides from the oligomeric and polymeric material was best at a flow rate of 0.6 mL/min, a flow rate of 0.8 mL/min was considered optimal when analysis time was also taken into account. Using glycerol as internal standard (*vide infra*), total analysis time was less than 15 min (Fig. 1).

Optimization of the mass detector turned out to be very critical, requiring careful aerosol adjustment and accurate temperature control (29,30). The quality of the aerosol depends on the mobile phase composition and flow rate, as well as on the inlet air flow to the nebulizer (Table 1). In addition, the temperature setting turned out to be a most important operating parameter affecting the different compounds to different degrees (Table 2). For a sample containing approximately 2% polymers, 2% glycerol, and 96% triglycerides, an increase in the evaporator temperature was followed by an enhanced polymer response whereas the response of the internal standard decreased. As to the air flow optimalization, the triglyceride response was not influenced by the temperature setting in the normal working range.

The detector response was not linear, most likely due to the complex sample composition. Injection of 130 μg to 520 μg CLO containing 2% polymers, the increase of the polymer area and the triglyceride area was found to be 7.3- and 2.0-fold, respectively, instead of the expected four-fold increase. Although the amounts injected are expected to be in the linear range of the detector (31–33), no linearity was observed and quantification was therefore carried out using an internal standard. Among several standards tested, glycerol seemed to be the most suitable one. Due to its low

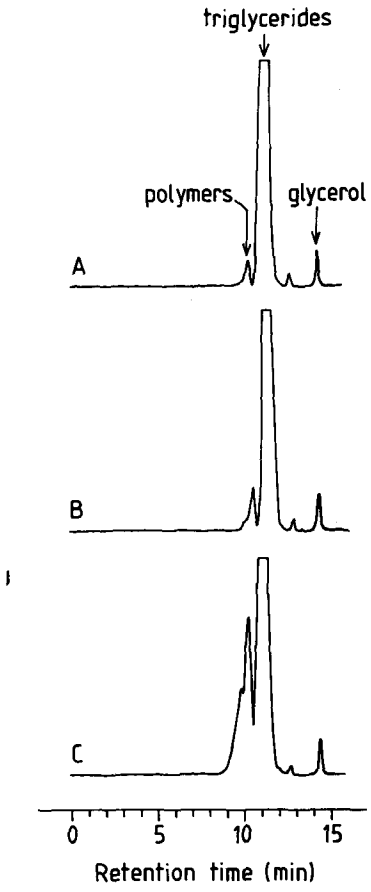

FIG. 1. GPC analyses of cod liver oil; A, starting sample; B, oxidized for two days; C, oxidized for four days. The oxidation was carried out at 35°C in light.

TABLE 1

Relative Response Factors as a Function of Nebulizer Air Pressure[a]

Pressure (psi)	Polymers	Triglycerides	Glycerol
20	1.03	0.98	1.04
24	1.00	1.00	1.00
27	0.81	0.99	0.78
30	0.74	1.01	0.74
35	0.70	1.01	0.62

[a]The response factors are measured with a cod liver oil sample containing approximately 2% polymers, 96% triglycerides, and 2% glycerol (analyzed by GPC). The other parameter settings of the light-scattering detector are as described in Materials and Methods.

solubility in dichloromethane, methanol was used as cosolvent (2-4%). The response of glycerol was approximately linear in the range of 30-200 µg, with a detection limit of 4 µg. However, as a consequence of the non-linear response relationship between glycerol and polymer, quantifications were based on a constant amount of internal standard added to the samples. Then the ratio observed was corrected according to a calibration curve giving the response-weight relationship between the polymers and the internal standard (Fig. 2). The reasons for this non-linear behavior may be several, including aerosol particle size, refractive index, and opacity of the particles (34,35). However, other detection systems have been reported to be even more troublesome (36).

Polymers from oxidized fish oil. The amount of polymers in CLO, crude unrefined cod liver oil (CCLO), and encapsulated fish oil concentrate (FOC) was found to be around 2%, whereas the polymers in the chromatographically purified fish oil (CPL) amounted to 0.4% of the total weight (Table 3). Pure fish oils may not only include several percent of polymers, the results also show a lack of correlation between polymer content and standard methods for oxidative rancidity assessment. Even though an oil seems to be of high quality with low PV and TBA-values (37), substantial amounts of polymers may be present (see FOC, Table 3). This observation is important when quality evaluation of marine oils is carried out. In addition, oils with identical PV and TBA-values are not always identical with respect to oxidation, as is clearly demonstrated by comparing the polymer content in FOC and CPL (Table 3). The insufficiency of PV and TBA-values for quality assessment can also be concluded from TLC measurements, but separation and quantification of polymers is impossible with this technique.

The polymer content of all oils rapidly increased during oxidation in air with values reaching as high as 35% to 45% after four days (Fig. 3). Using polystyrene standards, the molecular weights of the polymers were measured to range from 2000 to 8000 depending on the level of oxidation. The compounds with molecular weights of about 2000 predominated when the total polymer content was less than 10%. Although the in-

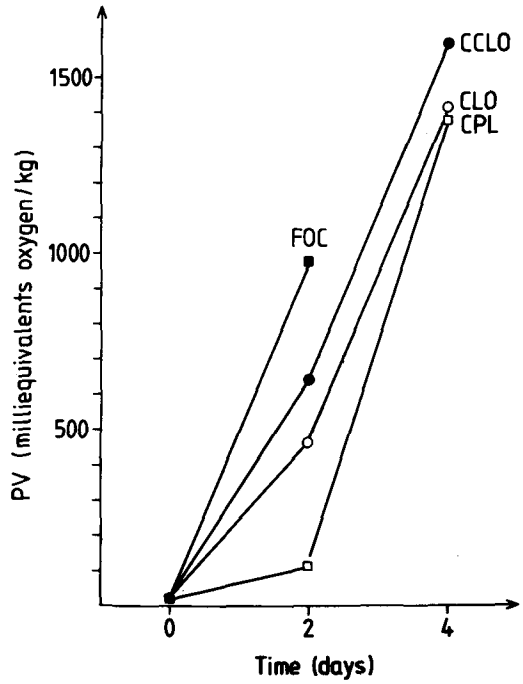

FIG. 4. Peroxide value of autoxidized fish oil; ■, fish oil concentrate; ●, crude cod liver oil; °, cod liver oil; □, chromatographically purified fish oil.

itial rate of polymer formation in CPL was lower than in the other oils, once initiated the rate was similar to that in the cod liver oils. For comparison, the standard quality assessment parameters, the PV values, TBA values, and the decrease of fatty acids are shown in Figures 3-5. The suceptibility towards oxidation was found to be in the order FOC>CCLO>CLO>CPL. FOC became so oxidized that the four-day sample was impossible to analyze. The differences observed can be explained on the basis of polyunsaturated fatty acid (PUFA) content and purity. The PUFA content was 29% of total fatty acids in the CCLO, 33% in the CLO, and 38% in the FOC and CPL. When the purity determined by TLC was taken into account, the oils could be classified as low PUFA oils with low and high purity, CCLO and CLO, respectively, and high PUFA oils with low and high purity, FOC and CPL, respectively.

The conditions employed in this study were deliberately chosen to induce autoxidation and are not representative of those employed normally for the storage of bulk oils. For this reason, and since the past history of the oils was not known, no conclusions can be drawn regarding the susceptibility of the different oils to autoxidation under commercial conditions.

An increase in the UV absorbance at 233 nm at the beginning of the reaction, due to formation of conjugated double bonds (37), was observed. Between the third and fourth day, a slight decrease in the absorbance was observed, a reduction which is probably caused by the formation of secondary oxidation products with a reduced number of double bonds. Whether

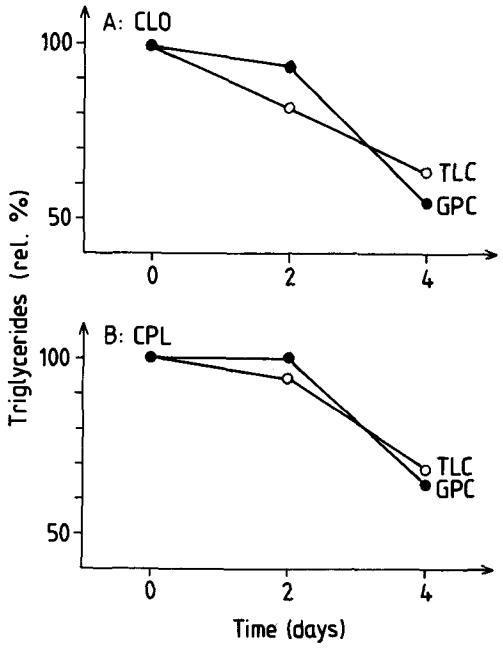

FIG. 6. Triglyceride content determined as sample weight minus polymer weight by GPC and nonpolar compounds minus polar compounds by TLC; A, cod liver oil; B, chromatographically purified fish oil.

these products also included polymers is difficult to determine from the UV measurements. However, a conspicuous relationship between the polymer increase and the decrease of the total amount of fatty acids was observed, indicating that the polymers may be the main oxidation product in autoxidized marine oils (Fig. 3).

TLC has been used for assessment of lipid oxidation measured as an increase in polar lipids (38). A comparison of triglyceride content determined as sample weight minus polymer weight (GPC) and nonpolar compounds minus polar compounds (TLC) are shown for CLO and CPL in Figure 6. As expected, in an early autoxidation state the triglyceride content is lower determined by the TLC-densitometry method, as peroxides would not be separated by the GPC method. However, after four days the TLC method gives a higher triglyceride value than the GPC method even though the autoxidized oil contains oxidation products other than polymers. The reason for this is most probably due to an inefficient staining of oxidation products caused by the lack of double bonds.

The method described here may find application in the routine assessment of fish oil quality. A more comprehensive study of polymer composition and structure is in progress.

Malonaldehyde Determination in Tissues and Biological Fluids by Ion-Pairing High-Performance Liquid Chromatography[1]

Willy A. Behrens* and **René Madère**
Food Directorate, Bureau of Nutritional Sciences, Health Protection Branch, Health and Welfare Canada, Tunney's Pasture, Ottawa, Ontario, Canada K1A OL2

A method for the analysis of malonaldehyde by ion pairing high-performance liquid chromatography is described. The method is direct; no thiobarbiturate chromogen formation is required, and sample preparation is simple. After deproteinization with 50% ethanol and removal of particulate by centrifugation samples were passed through a small silica amino column to remove contaminants. Diluted samples (20 μL) were injected onto an octadecylsilane column (25 cm × 4.6 mm ID, 5 μm) which is eluted with 30 mM sodium phosphate buffer, pH 6.5 containing 30% ethanol and 1 mM tetradecyltrimethylammonium bromide. Detection was accomplished by monitoring absorbance at 267 nm. The lower limit for reliable quantification was 5 pmol per injection. The method has been successfully applied to the quantification of malonaldehyde present in plasma, urine and tissues of rats kept under different dietary conditions as well as after *in vivo* treatment with CCl_4 and iron-dextran. The method was also applied to the quantification of malonaldehyde during liver microsomal lipid peroxidation and was compared to the thiobarbituric acid test.
***Lipids 26,* 232-236 (1991).**

Malonaldehyde (MA) is a volatile β-scission product formed from the peroxidation of certain polyunsaturated fatty acids and is considered an index of lipid peroxidation (1-3). MA has been implicated in aging (4), mutagenesis (5) and carcinogenesis (6). MA is a highly reactive compound and it is well documented that it undergoes reactions with amino acids (7,8) proteins (9-11) and nucleic acids (12,13).

Several methods have been developed to estimate the MA formed by lipid peroxidation either *in vivo* or *in vitro*. The most widely used method is the thiobarbituric acid (TBA) assay. In this procedure, heating of peroxidized lipids with TBA under acidic conditions produces a red pigment with an absorption maximum at 532 nm (14,15). The pigment has been considered to be the 1:2 adduct of malonaldehyde and TBA (16,17). However, the method is not specific for MA and often overestimates MA levels (18-22). More specific methods for MA determination have been developed using high-performance liquid chromatography (HPLC) (23-29) and gas chromatography (2,22,30). In spite of increased specificity and sensitivity, these methods are complex and time consuming; some attempted to separate the TBA-MA complex and others required the previous derivatization of MA. Others could not be reproduced in our laboratory nor were they able to measure MA in different biological fluids and tissues. For these reasons, a direct, simple, sensitive and specific HPLC method to measure MA in a variety of biological samples has been developed.

MATERIALS AND METHODS

Animals and diets. Male Wistar rats (Charles River Canada, St. Constant, Quebec, Canada) were used in the experiments and were fed a modified AIN (American Institute of Nutrition)-76 diet (31) for 2.5 months as follows: The diet for the basal group (group NE) contained casein, 20.0%; *dl*-methionine, 0.3%; corn starch, 15.0%; sucrose, 50.0%; cellulose, 5.0%; lard, 3.0%; corn oil-tocopherol stripped, 2.0%; AIN-76 mineral mixture, 3.5%; AIN-76A vitamin mixture, 1.0% (50 IU vitamin E/kg diet); and choline bitartrate, 0.2%. A second group of rats (group LE) was fed the same diet with vitamin E omitted from the vitamin mixture. In a third group (group HE), *d*-α-tocopherol acetate (ICN Nutritional Biochemicals, Cleveland, OH) was added to the vitamin mixture to give 250 IU vitamin E/kg diet.

Treatment of animals. CCl_4 (Sigma Chemical Co., St. Louis, MO) (2 mL/kg body weight) was administered by intraperitoneal injection in 50% tocopherol stripped corn oil. Control rats were given vehicle only. Animals were sacrificed after 2 hr. Iron dextran (Sigma Chemical Co.) (100 mg/kg body weight) was administered by gavage in 50% saline solution every second day. Animals were sacrificed after 7 days.

Blood and tissue collection. Blood was obtained by withdrawal from the abdominal aorta from animals anaesthetized with halothane (Fluothane, Ayerst Laboratory, Montreal, Canada) (2% in oxygen). The blood was transferred to a tube containing EDTA and centrifuged for 20 min at 2000 × *g*. Liver was perfused *in situ*, through the hepatic artery with 50-75 mL of cold saline. Spleen, white adipose tissue and muscle were also collected and kept at −75°C. Urine was obtained in metabolic cages during an overnight collection period.

Microsome preparation. Microsomes were prepared from a 25% liver homogenate (w/v) from rats fed the low vitamin diet (LE), according to Hogeboom (32). The final preparation was adjusted to 2 mg of protein/mL with 50 mM TRIS-HCl buffer, pH 7.5 containing 140 mM NaCl.

Microsomal lipid peroxidation system. The incuba-

tion mixture contained: 12 μM $FeCl_3$, 0.5 mM ascorbic acid, 0.2 mM ADP and 1 mg of microsomal protein. In some experiments ADP was omitted from the incubation mixture. Fifty mM TRIS-HCl, pH 7.5, containing 140 mM NaCl, was used to prepare all reagents and to bring the final volume of the incubation mixture to 2.0 mL. The reaction system was incubated in a shaking incubator for 45 min at 37°C.

Sample preparation for HPLC. Usually 1 mL of plasma was transferred to a 10-mL high-speed polycarbonate centrifuge tube containing 1 mL of absolute ethanol, mixed and kept cold for 1 hr, followed by centrifugation at 30,000 × *g* for 30 min in a refrigerated centrifuge. One mL of the clear deproteinized plasma was diluted with 3 mL of 30 mM sodium phosphate buffer, pH 5.5 containing 30% ethanol. One mL of this solution was cleaned by passing through a 1 mL silica-amino column (Supelclean LC-NH_2, Supelco Canada Ltd., Oakville, Ontario, Canada). This step was necessary to clean plasma of some interfering peaks, but mainly to eliminate some peaks that eluted very late in HPLC. Tissue homogenates and microsomes were treated in a similar manner. The urine extract was not cleaned. A 20-μL aliquot of deproteinized and cleaned sample was injected into the HPLC system. Recovery studies were performed by standard additions of MA to plasma, urine or tissue homogenates followed by 2 min of mixing. Between 15 to 20 min elapsed before the sample was deproteinized with 100% ethanol.

HPLC equipment and conditions. An HPLC system equipped with a Bas model PM-30A pump (Bioanalytical Systems Inc., W. Lafayette, IN), a model SP 8780 autosampler (Spectra-Physics, San Jose, CA), and a Linear model UVIS 204 variable-wavelength detector (Linear Instruments Corp., Reno, NV) was used for quantification of MA. The HPLC separations were performed on a reverse phase C18 column, 25 cm × 4.6 mm ID, 5 μm particle size (LC-18-DB Supelcosil, Supelco Canada Ltd.) with a mobile phase of 30 mM sodium phosphate buffer, pH 6.5 containing 30% ethanol and 1 mM tetradecyltrimethylammonium bromide (Sigma Chemical Co.) at a flow rate of 1.0 mL/min at ambient temperature. The absorbance was monitored at 267 nm. The detector was usually operated at a sensitivity of 0.006 AUFS. The data were recorded and electronically measured by a Spectra-Physics model SP4270 computing integrator.

Preparation of MA standard. A MA stock solution of approximately 10 mM was prepared by weighing 220 mg of malonaldehyde *bis*(dimethyl acetal) (Aldrich Chemical Co. Inc., Milwaukee, WI) into a 100-mL volumetric flask and diluting to the mark with 1% sulfuric acid. After standing overnight at 4–5°C, 1 mL of the solution was brought to a volume of 100 mL with 1% sulfuric acid and the MA concentration was determined by measuring the absorbance at 245 nm. A molar extinction coefficient of 13,700 was used (33). A solution of approximately 50 μM was prepared from the MA stock solution by dilution with phosphate buffer, pH 5.5 containing 30% ethanol. This solution was used to prepare a calibration curve in the range of 1 to 4 μM by dilution with the same buffer. Aliquots of 20 μL were injected into the HPLC system.

TBA test for rat liver microsomes. The TBA assay was performed according to Buege and Aust (14) with slight modifications. Standards diluted in 50 mM TRIS-HCl, pH 7.5, containing 140 mM NaCl and samples were heated at 80°C for 20 min. The mixture contained 0.1% butylated hydroxytoluene (Sigma Chemical Co.) in ethanol to prevent the formation of thiobarbituric reactive substances during color development (34). After cooling, the absorbance at 535 nm was measured for the quantification of MA.

Other analytical methods. Protein was estimated by the method of Bradford (35) using a protein assay reagent supplied by Bio-Rad Laboratories (Richmond, CA). Vitamin E (*d*-α-tocopherol) was estimated in plasma and tissues using the HPLC method of Thompson and Hatina (36), as previously described (37).

Statistical analysis. Student's *t*-test (38) was used for statistical evaluation of the results.

RESULTS AND DISCUSSION

A typical chromatogram of a pure MA standard is shown in Figure 1. The retention time remained constant for every batch of eluting solvent; variations from 8.0 to 8.5 min were observed and attributed to column aging. The lowest detection level of MA was set at 5.0 pmol, which is far greater than the generally accepted definition of chromatography detection limit, the amount of analyte which produces a peak height more than two times the noise level.

Figure 2 shows a typical MA calibration curve. The response was linear and detection, even at low levels, was accomplished with little variation. When two different standards were injected 15 times each to test reproducibility of the HPLC system, concentrations (pmol, mean ± SD) were 11.22 ± 0.26 and 22.5 ± 0.28.

MA was undetected or detected in trace amounts in plasma, urine and tissues from rats fed basal diet (AIN-76). Figure 3 shows representative chromatograms for plasma, liver and urine with and without standard added. Similar profiles were found for other tissues. Total time for each chromatogram was 10 min, with the exception of liver, which took 15 min due to a late

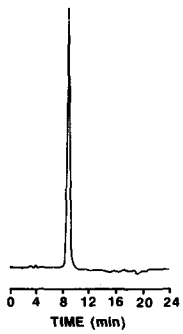

FIG. 1. Elution profile, at 267 nm absorbance, of a MA standard (51.6 pmol) on a C18 reverse phase column eluted with 30 mM sodium phosphate buffer, pH 6.5, containing 30% ethanol and 1 mM tetradecyltrimethylammonium bromide, at 1.0 mL/min.

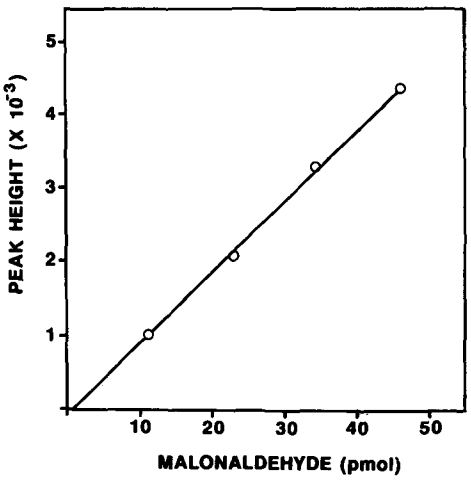

FIG. 2. Standard curve for HPLC of MA. The indicated amounts of MA standard were injected into the HPLC system (20 μL). Peak height *vs* injected amounts in pmol. Absorbance was measured at 267 nm.

non-MA peak. This short analysis time was achieved after cleaning the sample by passing it through a 1 mL silica-amino column to remove several contaminants that eluted very late (20–40 min), thus making the assay impractical in terms of timing. This clean-up procedure did not affect the recovery of MA. Table 1 shows the recoveries of various known concentrations of MA added directly to plasma, urine and tissue homogenates and carrying them through the entire procedure. It was found that extracted urine could be injected directly into the HPLC system without the cleaning step.

Of the tissue studied, muscle was the only one in which some difficulty was encountered due to the high content of ADP. This substance was not completely removed by the cleaning step, resulting in a relatively large peak which eluted immediately after MA. Nevertheless, preliminary experiments indicated that the interfering ADP peak could be successfully separated from the MA peak by decreasing the concentration of ion-pairing agent by 50%.

MA was found only in aged white adipose tissue homogenates kept under refrigeration for seven days. Extraction after that period showed a considerable amount of MA formed under these conditions (Fig. 4).

MA and vitamin E were measured in plasma and liver of rats fed low, normal and high vitamin E diets and after *in vivo* treatment with CCl_4 and iron-dextran. Different dietary levels of vitamin E produced the expected levels of vitamin in plasma and liver. These levels were not affected by treatment with CCl_4 and iron overload (Tables 2 and 3). Low levels of MA were detected in plasma of rats fed the low vitamin E diet, but could not be detected in rats fed the basal or high-vitamin E diet. Treatment with CCl_4 produced low levels of MA in plasma; however, no differences could be seen between rats fed low, normal or high vitamin E. No MA was found in liver under any circumstances despite the fact that obvious liver damage

was observed after CCl_4 treatment. The absence of MA, however, could be due to the short time (2 hr) that the chemical was allowed to act. Iron-overload resulted in death, within 48 hr, of all rats fed the low vitamin

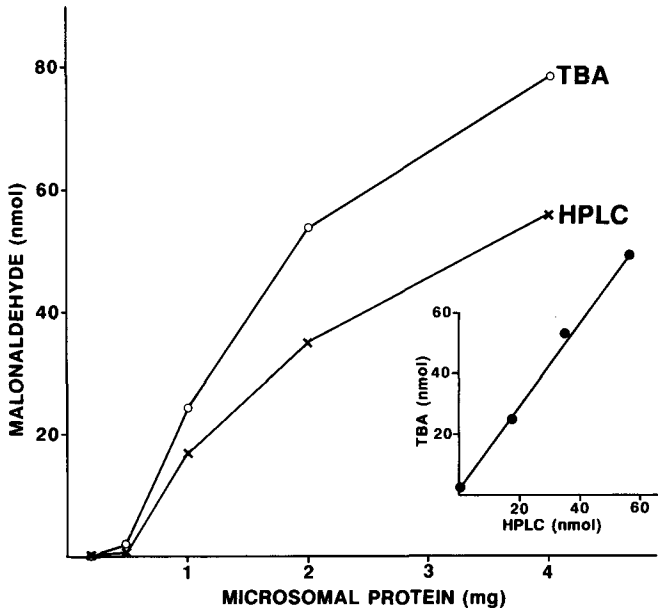

FIG. 5. MA produced during incubation of a liver microsomal preparation with ascorbate-Fe oxidative system. MA was estimated by the TBA assay and the HPLC method described herein.

E diet. However, no MA was detected in plasma or liver from rats fed normal and high vitamin E. The low levels or absence of MA in tissues of rats fed low vitamin E could reflect the fact that MA was not produced *in vivo* under these experimental conditions or the possibility that once produced, MA remained bound and could not be detected using the present method. To test this possibility, liver homogenates from rats fed the low vitamin E diet were submitted to acid hydrolysis according to Ichinose *et al.* (22) or to alkaline hydrolysis according to Lee and Csallany (39). These two procedures did not produce MA, indicating that it was not present at all, even in bound form. It appears from this that MA is not normally produced *in vivo* when vitamin E content is low. Only when an external chemical insult is added does production of MA take place. This is in apparent contradition to several reports that indicate that MA was produced in tissues (39) or excreted in urine (40) of rats fed diets depleted of vitamin E or after treatment with several chemicals (40,41). Moreover, Farris *et al.* (42) reported the absence of thiobarbituric acid-reactive substances in isolated rat hepatocytes during a toxic chemical insult. The reason for these contradictory results is not known, but probably could be found in the different methods used to estimate MA and in the diverse experimental conditions. The aim of the present work was to show the suitability of this HPLC method to measure MA in biological materials. The clarification of the contradictory results is beyond the scope of the objective of this study.

The HPLC method described herein measures MA without difficulty in a liver microsomal fraction obtained from rats fed the low-vitamin E diet and undergoing chemically induced lipid peroxidation *in vitro*

by an ascorbate-iron system. MA was also measured by the thiobarbituric acid assay in order to compare both methods (Fig. 5). The MA levels which were measured by the TBA method were 40-50% higher than those estimated by the HPLC method. The higher levels of TBA values may result from some substances other than MA, giving a positive TBA test. These results agree with the suggestion that results of the TBA assay should be referred to only as "TBA reactive substances" and should not be equated with MA levels (18-22). It should be indicated that microsomal chemical peroxidation was carried out in the absence of ADP, a common reactant in this type of experiment (34) because this compound interferes with the HPLC system as indicated above. As seen in Figure 5, the lack of ADP did not affect MA production. Previous experiments carried out in the presence of ADP gave higher values for MA with the HPLC method compared to the TBA assay.

In summary, a highly sensitive method for the analysis of MA by ion pairing HPLC is described. The method is direct without thiobarbiturate chromagen formation, sample preparation is simple and total time for each assay is short. The method is suitable for the quantification of MA in tissues, plasma and urine, as well as during chemically induced lipid peroxidation of microsomal fractions *in vitro*.

Fish Oil Tetracosenoic Acid Isomers and GLC Analyses of Polyunsaturated Fatty Acids[1]

N.C. Shantha and **R.G. Ackman***
Department of Food Science and Technology, Technical University of Nova Scotia, Halifax, Nova Scotia, Canada B3J-2X4

The total tetracosenoic acid (24:1) levels in nine marine oils examined ranged from 0.4 to 1.1% of the total fatty acids. Gas-liquid chromatography (GLC) analysis of whole fish oil fatty acid methyl esters usually shows a single 24:1 peak, as the dominant (60–90%) isomer is 24:1ω9, and the minor peaks are not seen. Isolation and oxidative fission demonstrate that the lesser isomers present in these oils (in the first peak to elute) include 24:1ω15, 24:1ω13 and 24:1ω11, which are not resolvable from each other on open-tubular GLC; 24:1ω9 is followed by a peak for 24:1ω7. The complex first 24:1 isomer peak of fish oil fatty acids tends to coincide with or just follows the 22:6ω3 peak in GLC analyses carried out on Carbowax-20M type open-tubular (capillary) columns.
Lipids 26, 237–239 (1991).

A peak for tetracosenoic acid (24:1) is commonly observed in open-tubular gas-liquid chromatographic (GLC) analyses of fatty acids of marine oils. While the presence of isomers other than 24:1ω9 was reported in lipids of algae, fungi and higher animals (1), the only isomer reported in fish oils has been the ω9 isomer (2,3). An exception is the presence of trace quantities of ω11 and ω7 accompanying a similar level of the ω9 isomer in the 24:1 of salmon *(Salmo salar)* lipids; the structures of these acids have been confirmed by gas chromatography/mass spectrometry(GC/MS) and by hydrogenation of the main peak alone (1).

The proximity of the 24:1 components to the docosahexaenoic acid (22:6ω3) peak in GLC analyses on Carbowax-20M based capillary columns (4) required that we investigate the isomers in some detail since the only commonly available acid standard is nervonic acid (24:1ω9). This isomer can also be found in the fatty acid methyl esters derived from rapeseed oil, which is useful as a secondary GLC standard (4) since it also contains two eicosenoic acid isomers (20:1ω9 and ω7) and two docosenoic acid isomers (22:1ω9 and ω7) (5). The present investigation deals with the study of the 24:1 isomers in various marine oils. Some aspects of possible errors in calculating the different positional isomers based on the ozonolysis products and the biosynthetic pathway for the formation of these various isomers are also discussed.

MATERIALS AND METHODS

cis-15-Tetracosenoic acid was purchased from Serdary Research Laboratory Inc. (London, Ontario, Canada). The oil of jurel fish *(Trachurus murphyi)* was a gift from Professor L. Masson Salaue, Universidad de Chile, Santiago, Cod *(Gadus morhua)* (liver) and Atlantic herring *(Clupea harengus)* (body) were purchased from a local market and lipids were extracted by the method of Bligh and Dyer (6). The triacylglycerols were purified using conventional thin-layer chromatography. The esters were transesterified using BF_3/MeOH, and the methyl esters were recovered into hexane. The methyl esters were treated with urea in ethanol for adduct formation (7); the urea-complexing (UCF) and the non-urea-complexing fractions (NUCF) were separated and the methyl esters recovered (8). Both fractions were analyzed by gas-liquid chromatography for the presence of 24:1 methyl esters. No detectable amount of 24:1 ester was present in the NUCF. The 24:1 ester, found to be concentrated in the UCF, was purified by reversed-phase semi-preparative high-performance liquid chromatography (HPLC). The pure 24:1 esters thus isolated were further tested for purity and the presence of positional isomers by GLC. The esters were then subjected to oxidative ozonolysis for determination of double bond positions. Ozonolysis was performed as described elsewhere (9,10) and the ozonolysis products were analyzed by GLC and GC/MS. The proportions of different isomers were calculated from the weight percent of the dicarboxylic acid esters obtained upon ozonolysis (10). The areas of peaks for different chain lengths were corrected to weight percentages using the theoretical response factors calculated based on their ionizable carbon contents (11).

High-performance liquid chromatography. A Waters Associates (Milford, MA) HPLC system including 6000A pump, U6K injector, and R 401 refractive index detector was utilized. A C-18 μ Bondapak (8 mm = 10 cm) column was used with a RCM-100 radial compression module. Methanol/water (95:5, v/v) at a flow rate of 1.5 mL/min served as the mobile phase.

Gas-liquid chromatography. GLC analyses were performed on a Perkin-Elmer model 8420 gas chromatograph equipped with a digital integrator, using a SUPELCOWAX-10 (bonded Carbowax-20M) column (30 m × 0.32 mm i.d., phase thickness 0.25 μm; Supelco Inc., Bellefonte, PA). GLC analyses of fish oil fatty acid methyl esters were temperature-programmed from 195°C to 240°C at 3°C per min after an initial 8 min at 195°C and held at 240°C for 10 min. The split ratio was 1:32, helium flow rate was 1.2 mL/min and injection port temperature was 250°C. For the analysis of the monomethyl and the dimethyl fatty acid esters obtained from ozonolysis, the oven temperature was programmed from 120°C to 240°C at 3°C per min after an initial 8 min at 120°C and held at 240°C for 10 min. The other parameters were the same as above. The peak area output was recorded on a Perkin-Elmer GP-100 graphic printer.

Gas chromatography/mass spectrometry (GC/MS). Electron impact mass spectra were obtained on a model 700 Finnigan MAT Ion Trap Detector (ITD) system (Finnigan MAT, San Jose, CA) interfaced to a Perkin-Elmer

METHODS

TABLE 1

Occurrence and Composition of 24:1 Isomers in Marine Oils

Marine oil	Weight % (% of total fatty acid)	Isomer distribution[a,b] (% of total 24:1)				
		ω15	ω13	ω11	ω9	ω7
Menhaden *(Brevoortia tyrannus)*	0.6	2.2	4.4	13.5	74.8	5.1
Jurel *(Trachurus murphyi)*	0.6	4.3	3.3	6.9	81.1	4.4
Tuna *(Thunnus alalunga)*	0.8	tr[c]	2.2	4.1	90.5	3.2
Herring *(Clupea harengus)*	0.9	3.0	6.5	17.7	71.1	1.7
Cod liver *(Gadus morhua)*	0.4	3.0	5.0	14.3	77.2	0.5
Dogfish liver *(Squalus acanthias)*	1.1	2.7	4.6	13.3	77.5	2.0
Redfish *(Sebastes marinus)*	0.8	5.5	11.2	15.6	66.3	1.3
Capelin *(Mallotus villosus)*	0.7	3.8	6.2	12.8	77.2	tr[c]
Whale *(Balaenoptera borealis)*	0.7	4.1	13.1	17.2	63.3	2.3

[a]Calculated on the basis of the wt% of dicarboxylic acid ester obtained by ozonolysis.

[b]Not corrected for secondary oxidation products (see text).

[c]Trace amounts (tr) are less than 0.1%.

model 990 gas chromatograph. The GLC fused silica capillary column was fed through a heated transfer line directly into the ITD gas inlet. For GC/MS, the separations were performed on a polyglycol DB-WAX column (30 m × 0.25 mm i.d., phase thickness 0.25 μm; J & W Scientific Inc., Folsom, CA). The oven temperature for analysis of 24:1 isomers was programmed from 180°C to 210°C at 3°C per min after an initial 8 min at 180°C, and held at 210°C for 48 min. For the analysis of ozonolysis products, the temperature was programmed from 110°C to 210°C at 3°C per min with an initial hold of 8 min at 110°C followed by a 48-min hold at 210°C. The helium pressure was 10 psi. The data system consisted of an IBM 286 compatible dtk TECH-1230 computer (Technida Ltd., Dartmouth, Canada). All studies were conducted with version 4.0 of the ITD software supplied by the Finnigan Corp. The ITD was tuned by using the procedure supplied by the manufacturer. The ITD was operated in the full scan mode and scanned with a 1-s cycle time.

RESULTS AND DISCUSSION

Table 1 gives the percentages of 24:1 fatty acids in the different fish oils and the percentages of different isomers present. In the fish oils examined, 24:1 was a minor component, ranging from about 0.4% of the total fatty acid methyl esters in cod liver oil to 1.1% in dogfish liver oil. In the ozonolysis products, the C_{15} diester and the C_9 monoester were always the major peaks. These fragments correspond to the 24:1ω9 isomer, calculated to be more than 60% of the total 24:1 in all the fish oils examined, and reaching 80–90% in the case of the jurel and tuna fish oils. The unresolved 24:1ω11 and ω13 were the next most prominent isomers, the ω11 exceeding the ω13 in all cases. The 24:1ω15 was also not resolved from the ω11 and ω13 isomers, but it and the ω7 isomer, identified as a separate GLC peak, were conspicuous in the ozonolysis products of all oils examined except for the capelin, where the 24:1ω7 was present in only trace amounts. The composition of different isomers in depot fat from sei whales, a mammal, did not differ much from that of the fish oils. This could well be related to the whales' marine fish diet (12) rather than being a species characteristic.

The various isomers were calculated from the weight percentage of the dicarboxylic acid diesters obtained upon ozonolysis. The corresponding monomethyl esters were used primarily as a qualitative match to verify that the complementary product was not an artifact since secondary oxidation products are known to be formed during oxidative ozonolysis (10). The 24:1ω9 isomer should give rise primarily to the C_9 monoester and the C_{15} diester upon ozonolysis. The C_{15} diester thus formed could undergo both α-oxidation to give rise to a C_{14} diester and β-oxidation to give rise to a C_{13} diester. α-Oxidation is known to usually amount to 2% (9). β-Oxidation is relatively minor, but the observed amount of C_{13} diester from 24:1ω11 could be slightly exaggerated, since the C_{15} diester present is the major product and will yield some C_{13} diester. A total correction of 2% must be added back to the C_{15} product. Similarly, some of the C_{11} and the C_9 diester could also be formed due to further secondary reactions. However, the values have not been corrected for added secondary oxidation products from longer chain lengths. The absence of a C_{10} monoester verifies that there is in fact no 24:1ω10 isomer such as might be deduced from the observed trace of C_{14} secondary diester product.

Under the conditions of the GLC analysis, the monomethyl and dimethyl esters are of similar equivalent chain lengths and tend to elute in close proximity. In order to avoid erroneous identifications, all ozonolysis products were subjected to GC/MS, and the peaks were identified based on their characteristic mass spectra. Ozonolysis with its various advantages is a well-accepted method for structure determination of unsaturated fatty acids (10). The formation of traces of the secondary products for most chain lengths complicates the chromatogram in one sense, but promotes identification in another. Usually the number of moles of the monomethyl and the corresponding dimethyl esters cannot be matched accurately due to the tendency of the shorter chain esters to be lost during extraction and/or concentration steps. Despite these mild disadvantages the formation of stable dicarboxylic and monocarboxylic acid products is advantageous and for quantitation of mixed isomer proportions is probably superior to sophisticated modern mass spectrometry (13,14).

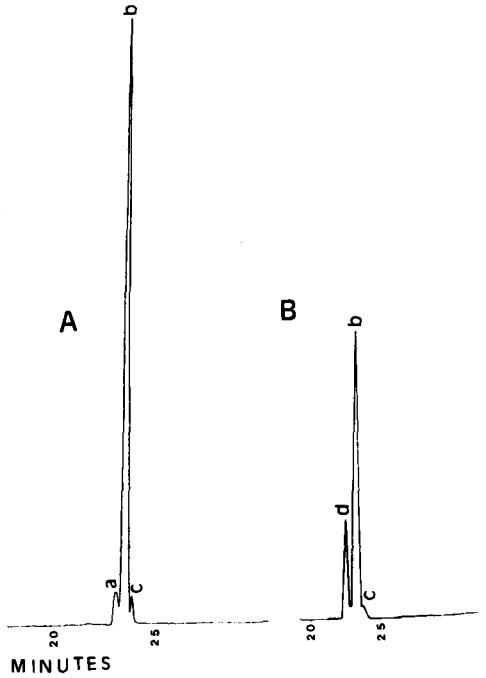

FIG. 1. (A) Gas-liquid chromatogram of methyl tetracosenoate (24:1) of the South Pacific fish jurel *(Trachurus murphyi)* showing resolution between its isomers. Peaks are: a, 24:1ω11+13+15; b, 24:1ω9; c, 24:1ω7. (B) Gas-liquid chromatogram of methyl tetracosenoate (24:1) of the South Pacific fish jurel (A) co-injected with methyl docosahexaenoate (22:6ω3) standard. Peaks are: d, 22:6ω3 + 24:1ω11+13+15; Other notations as in A.

Despite the presence of various isomers, only three peaks for 24:1 were observed on the SUPELCOWAX-10 column used (Fig. 1A). The composite peak for the 24:1ω11+13+15 isomers was possibly somewhat broader than one would expect for one component alone (Fig. 1A). It eluted before the 24:1ω9 isomer, and the 24:1ω7 isomer eluted after the 24:1ω9 isomer; however, there was no baseline separation between the three peaks which would correspond to the different isomers listed in Table 1. The lack of separation among the 24:1ω11, ω13 and the ω15 isomers would be expected since no separation is achieved between the ω11 and the ω13 isomers of 22:1 on polyester-based capillary columns of similar polarity (15). However, a 50-m methyl silicone column also separated 24:1ω11 and 24:1ω9 (14).

The 24:1 (ω11+13+15) peak coincided with the 22:6ω3 peak under our conditions of analysis on SUPELCOWAX-10, and on co-injection with 22:6ω3 the two emerged as a single peak (Fig. 1B). The overlap between 24:1ω11+13+15 isomers and 22:6ω3 on the SUPELCOWAX-10 column could potentially create a quantitation problem if high levels of the monoene isomers were present relative to 22:6ω3. Since 24:1 is a minor component in most fish oils, and ω11+13+15 isomers are much less conspicuous than ω9, this overlap could be overlooked. Equally, when working with mammalian brain lipid (16), which could have a considerable amount of 24:1 as well as 22:6ω3, care has to be taken in the analysis of the fatty acid methyl esters.

The structures of the monoethylenic fatty acids in fish oil were determined and inter-related over twenty years ago for herring oil, a common fish depot fat, in light of the information then available (17). The original discovery (18,19) that the important 22:1ω11 isomer originated in copepod fatty alcohols, oxidized to the corresponding fatty acids when ingested by fish, was later extended by detailed investigation of several marine fish oils (20,21). From Table 1 it is clear that 24:1ω9 is the dominant isomer and presumably accumulates for reasons not associated with chain extension from the marine 22:1 fatty acids which are known to be dominated by 22:1ω11. The menhaden is a short-lived planktonivorous fish and yet has a high proportion of 24:1ω9, similar to that of the longer-lived carnivorous Atlantic cod. Despite one report of algal 24:1ω9 from Antarctic waters (14), there is no obvious geographical factor for distribution of 24:1 isomers, as shown by the North Atlantic and South Pacific species analyses, and our comparisons thus suggest that the principal isomer, 24:1ω9, is biosynthesized specifically in fish, all other 24:1 isomers being inadvertent additions.

Plasma Lipid Profiling by Liquid Chromatography with Chloride-Attachment Mass Spectrometry

A. Kuksis*, L. Marai and J.J. Myher
Banting and Best Department of Medical Research, University of Toronto, Toronto, Canada M5G 1L6

A sensitive high-performance liquid chromatographic assay was developed using chloride attachment negative chemical ionization mass spectrometry for detection of glyceryl esters and ceramides, and positive chemical ionization mass spectrometry for detection of free cholesterol and cholesteryl esters in minimal quantities of plasma. The novel technique was validated by high temperature gas-liquid chromatography with flame ionization detection. Sample preparation was achieved by phospholipase C digestion of whole plasma, total lipid extraction and derivatization of any free carboxyl and hydroxyl groups by trimethyl- or *tert*-butyldimethylchlorosilane. The lipids were separated by reverse phase HPLC with 20–90% propionitrile in acetonitrile containing 1% dichloromethane, which served as the reagent and the source of chloride. Negative chemical ionization with chloride attachment is estimated to provide about 100 times higher response for the triacylglycerols and the trimethylsilyl or *tert*-butyldimethylsilyl ethers of diacylglycerols, and about 500 times higher response for the trimethylsilyl or *tert*-butyldimethylsilyl ethers of ceramides than positive chemical ionization mass spectrometry. Determination of the full negative chemical ionization mass spectra showed that each glycerolipid and ceramide species yielded a single ionic species corresponding to the chloride-attachment product of the parent ion. The cholesteryl esters and ethers failed to attach chloride and remained undetected by negative chemical ionization. However, the cholesteryl esters and ethers gave a high response for the steroid nucleus in positive chemical ionization mass spectrometry. Chloride attachment negative chemical ionization mass spectrometry is suitable for the unequivocal identification of plasma glycerolipids and ceramides in high-performance liquid chromatography and for the quantitation of molecular species in any unresolved peaks following appropriate calibration of the instrument response.
***Lipids 26,* 240–246 (1991).**

The application of reverse phase high-performance liquid chromatography (HPLC) for plasma lipid profiling has been explored only to a limited extent (1–8) because lipids lack chromophores which can be detected spectrophotometrically. Ultraviolet (UV) detection at 200–215 nm has been used most extensively (1,2,6) followed by differential refractometry (3,4), although very few solvents are entirely satisfactory for these methods. Free cholesterol and cholesteryl esters have been monitored by optical activity (5). Mass spectrometry coupled with reverse phase HPLC would seem to provide an ideal method for the detection and quantitation of molecular species in HPLC effluents, but difficulties have arisen as a result of a highly variable positive chemical ionization of different plasma lipid classes in the propionitrile/acetonitrile solvent system (7,8) when used with direct liquid inlet interface (9). The present study shows that under the same HPLC conditions chloride-attachment negative chemical ionization mass spectrometry (NCIMS) results in much more uniform response and greatly increased sensitivity of detection of ceramides as well as of glycerolipids, which yield $[M + 35]^-$ and $[M + 37]^-$ as the only readily detectable negative ions. However, the trimethylsilyl (TMS) and *tert*-butyldimethylsilyl (TBDMS) ethers and fatty acid esters of cholesterol do not yield negative ions with chloride attachment and must be determined in the positive chemical ionization mode.

MATERIALS AND METHODS

Various synthetic neutral lipid mixtures were available in the laboratory from previous studies (10). Normal human plasma (0.5 mL) was digested with phospholipase C *(Clostridium welchii)* and the lipids recovered by extracting the reaction mixture with chloroform/methanol as previously described (10). The extracts were dried and silylated with trimethylchlorosilane (TMSCl) or *tert*-butyldimethylchlorosilane (11) as previously described in detail. The overall workup of the sample including trimethylsilylation is summarized in Figure 1. For a rapid and complete digestion of the minor acidic phospholipids also present in plasma, a total lipid extract is first prepared and phospholipase C from *Bacillus cereus* is used (11).

The HPLC analyses were performed with a Hewlett-Packard Model 1084B liquid chromatograph (Hewlett-Packard Co., Palo Alto, CA) equipped with a 25 cm ×

0.46 cm OD Supelcosil LC-18 column (Supelco, Bellefonte, PA), using a gradient of 20–90% propionitrile in acetonitrile (8,9). The solvent mixture contained a constant concentration of 1% dichloromethane (12). The columns were operated at a flow rate of 1.5 mL/min and 30°C oven temperature. The mass spectrometry was done on a Hewlett-Packard Model 5985B quadrupole mass spectrometer equipped with a Hewlett-Packard direct liquid inlet interface based on the Baldwin-McLafferty split chemical ionization (CI) approach (8,9). The mass spectrometer scans were restricted to masses above 200 and were taken with a scan rate of 4.7 sec (*m/z* 200–950) over the entire elution profile. In some instances background subtractions were performed by the computer to compensate for impurities in the solvents. The positive and negative chemical ionization spectra were recorded at 210 eV from separate liquid chromatography/mass spectrometry (LC/MS) analyses. The ion source temperature was 200°C and 150°C for positive chemical ionization mass spectrometry (PCIMS) and negative chemical ionization mass spectrometry (NCIMS), respectively.

Control gas-liquid chromatography (GLC) analyses of TMS ethers of diacylglycerols were performed on polar (SP-2330, Supelco) capillary columns (10,11) while those of ceramides, cholesteryl esters and triacylglycerols were performed on polarizable (OV-22, Quadrex, New Haven, CT) capillary columns (13), as previously described.

RESULTS

Comparison of LC/PCIMS and LC/NCIMS profiles of plasma lipids. Figure 2 shows the total ion current profiles obtained by LC/MS for the TMS ethers of plasma lipids in the negative (A) and positive (B) chemical ionization. In the positive mode, the major peaks correspond to the TMS ether of free cholesterol (13.5 min) and the 20:4 (19.5 min), 18:2 (22 min), 18:1 (25 min) and 16:0 (25.5 min) esters of cholesterol. The TMS and TBDMS ethers of diacylglycerols as well as the triacylglycerols can be monitored by LC/MS in the positive chemical ionization mode, but the signal intensity is about 100 times lower than that recorded for the fatty acid esters of cholesterol (7,8). The diacylglycerols and triacylglycerols yield the $[MH - RCOOH]^+$ ions from which the structure of the molecular species can be deduced. In the chloride-attachment negative ionization mode, the triacylglycerols and the TMS ethers of both diacylglycerols and ceramides yield greatly increased response. The early peaks in Figure 2A correspond to the TMS ethers of the diacylglycerols, while the later peaks correspond to various common triacylglycerols, with the ceramides appearing in both diacylglycerol and triacylglycerol elution regions (see below).

A comparable LC/MS profile was obtained for the TBDMS ethers of plasma lipids in the negative and positive chemical ionization mode (chromatograms not shown). In the positive mode, only the TBDMS ether of cholesterol (19 min), which was eluted just before cholesteryl arachidonate, and the fatty acid esters of cholesterol are detected. In the chloride attachment negative chemical ionization, the triacylglycerols and TBDMS ethers of diacylglycerols and ceramides were detected with increased sensitivity. The early peaks corresponded to the TBDMS ethers of diacylglycerols, while the later peaks were due to the TBDMS ethers of ceramides, with the triacylglycerols appearing in both diacylglycerol and ceramide elution regions (see below). This behavior of the silyl ethers of glycerolipids and ceramides on reverse phase HPLC is similar to that observed previously with the propionitrile/acetonitrile system in the absence of dichloromethane (7–9). The LC/MS spectrum of cholesteryl linoleate as obtained in the positive CI mode for the TMS- and TBDMS-treated plasma lipids gave only the ion for the steroid nucleus (*m/z* 369) in the 300 to 900 mass range. The free cholesterol and the molecular species of the cholesteryl esters were identified from their relative retention times.

Nature of chloride-attachment NCI spectra. Figure 3A depicts the full mass spectrum of a diacylglycerol TMS peak taken at 13 min in Figure 2A. The diacylglycerols are identified by the number of their acyl carbons:number of double bonds. In addition to the major components

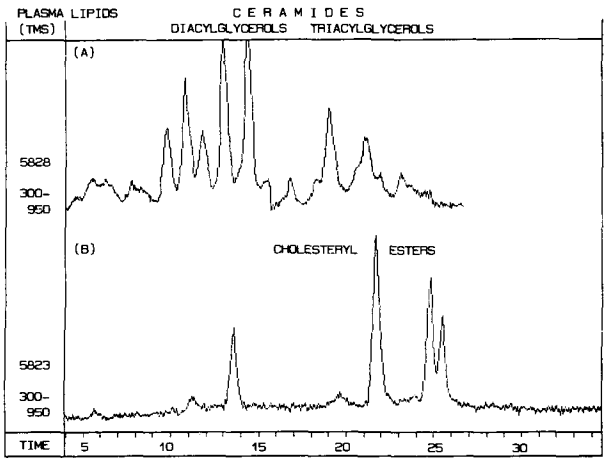

FIG. 2. Total ion current profiles obtained by LC/MS for the TMS ethers of plasma lipids with NCI (A) and PCI (B). Peak identification, as given in figure and explained in text. LC/MS conditions as given in text.

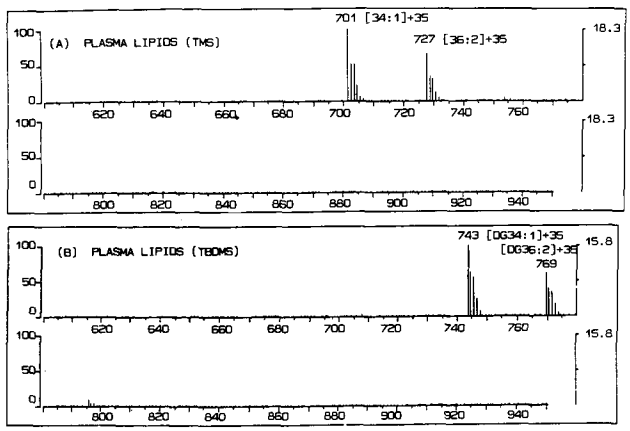

FIG. 3. Full mass spectra of corresponding diacylglycerol peaks as obtained by LC/MS of the TMS (13 min) (A) and TBDMS (16 min) (B) ethers in chloride attachment NCI. LC/MS conditions as given in Figure 2.

[DG34:1] + 35 (*m/z* 701) and [DG36:2] + 35 (*m/z* 727), minor components are seen for the chloride 37 attachment products [DG34:1] + 37 (*m/z* 703) and [DG36:2] + 37 (*m/z* 729) within the ion clusters accompanying the parent ions. No other negative ions are seen for these diacylglycerols or any other components in the 600–950 mass range. Figure 3B shows the full mass spectrum for the corresponding TBDMS diacylglycerol peak. Both DG34:1 and DG36:2 are seen as the $[M + 35]^-$ and the $[M + 37]^-$ ions at the corresponding *m/z* values. The chlorine isotopes 35 and 37 occur naturally in the ratio 3 to 1 (14).

The ceramide peaks are identified by the total number of carbons:number of double bonds. The full mass spectra of the ceramide TMS peaks also showed only one molecular species in most instances. Thus, the peak emerging at 13.5 min in Figure 2A showed the masses at *m/z* 716 [CER34:1] + 35 and *m/z* 718 [CER34:1] + 37. Likewise, the TBDMS ether of the same ceramide peak also yielded a single negative ion for each isotope species corresponding to $[M + 35]^-$ and $[M + 37]^-$ of CER34:1.

Figure 4 shows that each species of triacylglycerols yields only the chloride attachment ions $[M + 35]^-$ and $[M + 37]^-$ from both TMS- (Fig. 4A) and TBDMS- (Fig. 4B) treated plasma lipids. However, the triacylglycerol peaks in both TMS- and TBDMS-treated plasma lipids overlap with the ceramide peaks, as already noted. Thus, the triacylglycerol peak [TG52:2] + 35 (*m/z* 893) in the TMS plasma (23.5 min) overlaps with the ceramide peak [CER41:1] + 35 (*m/z* 814), while the same triacylglycerol peak [TG52:2] + 35 (*m/z* 893) in the TBDMS plasma (23.5 min) overlaps with the ceramides [CER36:1] + 35 (*m/z* 828) and [CER38:2] + 35 (*m/z* 854). Of course, each triacylglycerol and ceramide peak also is accompanied by the chlorine-37 peak, as explained above.

Identification of molecular species. Figure 5 shows the total ion current profile of the TMS ethers of plasma lipids along with the single ion plots for the major diacylglycerol species as obtained by LC/MS with chloride-attachment negative chemical ionization. Most *m/z* values represent two species of diacylglycerols differing by two mass units, one representing $[M + 35]^-$, the other $[M + 37]^-$ of a corresponding species having a molecular weight lower by two mass units. Thus, the [DG32:0] + 35 ion has the same mass as the [DG32:1] + 37 ion. The [DG32:1] + 37 (*m/z* 675) corresponds in retention time to [DG32:1] + 35 (*m/z* 673). The diacylglycerol species are eluted in order of increasing equivalent carbon number (ECN). All peaks of sufficient intensity represent Gaussian curves with minimum distortion. A similar single ion plot was obtained for the major diacylglycerol species when analyzed as the TBDMS ethers (figure not shown), which also yielded only one negative ion for each isotope species corresponding to the $[M + 35]^-$ and $[M + 37]^-$ ions of the TBDMS ethers of diacylglycerols, as shown in Figure 3.

Figure 6 shows the total ion current profile of the TBDMS ethers of plasma lipids along with the single ion plots for the major ceramide species as obtained by LC/MS with chloride attachment negative chemical ionization. Each species yields only one negative ion corresponding to $[M + 35]^-$ and one corresponding to the satellite isotope $[M + 37]^-$. All peaks, regardless of the molecular weight of the component species, are seen to tail, especially the less abundant ones. This is not due to overlap among species, which are eluted in order of increasing ECN values. A similar single ion plot was obtained for the major ceramide species when analyzed as the TMS ethers, which also yielded only one negative ion for each isotope (figure not shown).

Figure 7 shows the total ion current profile of the TBDMS plasma lipids along with the single ion plots for the major triacylglycerol species as obtained in negative chemical ionization with chloride attachment. The triacylglycerol species, which are identified by the number of acyl carbons: number of double bonds, range from 48:1 to 54:4. They emerge in order of increasing ECN values. Due to the rather low concentration of the solutes, the

peaks show somewhat more tailing than the more abundant diacylglycerols and ceramides examined above. An identical single ion plot was obtained for the TMS plasma triacylglycerols (figure not shown).

Quantitation of molecular species. The areas under the various single ion peaks can be calculated and expressed as a percentage of the uncorrected total peak area representing the sum of the peak areas of all the species belonging to each lipid class. Table 1 demonstrates that the quantitative estimates for molecular species of the TMS and TBDMS ethers of diacylglycerols agree closely with each other and deviate little from the control estimates derived by polar capillary GLC of the TMS ethers. For a more accurate comparison to the results of the GLC analysis with flame ionization detection, the negative ion current response would need to be calibrated using appropriate reference standards.

Table 2 shows an equally close agreement for the quantitative estimates of the molecular species of triacylglycerols between the TMS- and TBDMS-treated plasma lipids and those obtained by control GLC analyses on polarizable capillary column with flame ionization detection. These results indicate that chloride-attachment negative chemical ionization yields nearly correct quantitative response for the common glycerolipid species under the present working conditions and instrumentation.

Table 3 compares the recoveries of the ceramides as the TMS and TBDMS ethers, as obtained by LC/MS with chloride-attachment negative CI. The longer chain ceramides appear to have been recovered to a somewhat lower extent when analyzed as the TBDMS rather than the TMS ethers. However, the recoveries of the long chain ceramides as the TMS ethers are also significantly lower, when compared to those obtained by polarizable (13) or non-polar capillary GLC (15). It is unlikely, that the longer chain homologues of the ceramides would form the chloride adducts less readily than the shorter chain homologues, and other possibilities, such as "cold trapping" of the species of higher molecular weight and greater degree of saturation must be considered. Previously, "cold trapping" has been observed (16) in GC/CIMS analysis of cholesteryl esters. It was manifested in peak tailing and by loss of steryl esters of higher molecular weight than cholesteryl palmitate.

As pointed out above, the silyl ethers and fatty acid esters of cholesterol do not attach chloride and are not detected in the negative CI mode. Therefore, they were quantitated in the positive CI mode. Table 4 gives the relative response for the various cholesteryl esters in the TMS- and TBDMS-treated plasma lipid samples. It is seen that the LC/MS estimates for the individual molecular species agree closely with each other and with the control GLC analyses, except for cholesteryl arachidonate, which is not recovered from the polarizable capillary column (13). The silyl ethers of free cholesterol, however, give a lower response in LC/MS than in GLC/flame ionization detector (FID). Thus, the LC/MS estimates for the TMS (17%) and TBDMS (8.5%) ethers are significantly lower than the GLC/FID determinations (22%) for the free cholesterol in the sample. Nevertheless, these ion yields are reproducible and can be utilized in quantitative measurements following appropriate calibration of the instrument.

DISCUSSION

Parker *et al.* (14) have shown that successful chloride-attachment NCIMS, developed by Dougherty (17) can be adopted to the analysis of various biologically important substances by LC/MS with direct liquid introduction through the addition of a chlorinated solvent modifier. The present study shows that glyceryl esters and ceramide ethers can be readily detected by this method during

LC/MS, although other neutral lipids, such as cholesteryl esters and ethers, do not yield negative ions. Previously paraffinic hydrocarbons and methyl stearate had failed to give chloride attachment spectra when examined by direct probe mass spectrometry (17). The chloride-attachment NCIMS provides a significant improvement in the sensitivity of detection, identification and quantitation of glycerolipids and ceramides in the effluents of HPLC columns when compared to PCIMS. The increase in sensitivity stems from the high yield of the negative ions following chloride attachment and the apparent absence of their fragmentation under the direct liquid inlet chemical ionization conditions. It was estimated that the overall increase in sensitivity of detection over positive chemical ionization for the glycerolipids was about 100-fold, and for the ceramides about 500-fold.

The formation of a single chloride-attachment ion provided a ready indication of the molecular weight of each solute, which, together with the knowledge of the retention time, was usually sufficient for peak identification. In the absence of significant further fragmentation, however, it was not possible to confirm the exact combinations of the fatty acids in each diacylglycerol and triacylglycerol molecule. The formation of a readily detectable single chloride-attachment product in the NCIMS also simplified the quantitation of the molecular species, which appeared to be recovered in nearly correct mass proportions. The only exceptions were provided by the more saturated short chain ceramides which were overestimated and the long chain ceramides, which were underestimated. This effect, however, did not appear to be due to any difficulty in chloride attachment or in NCIMS, but to "cold trapping" of the less soluble higher molecular weight components in the 150°C ion source or to tailing in the direct liquid inlet probe. Increasing the temperature of the ion source resulted in increased relative recoveries of these components. However, the overall sample recovery (ionization) was reduced (Marai, L., Kuksis, A., and Myher, J.J., 1990, unpublished results).

The major shortcoming of the LC/MS with chloride-attachment NCI is the absence of response to the TMS and TBDMS ethers as well as the fatty acid esters of cholesterol (12,18). These cholesterol derivatives require PCI for detection, which is most effective due to high yield of the ion at *m/z* 369, corresponding to the steroid nucleus of the cholesterol molecule (7,8). The glycerolipids give much lower response than the cholesteryl esters in the PCI, while the TMS and TBDMS ethers of ceramides remain largely undetectable under normal conditions of plasma lipid profiling (7,8). The formation of the $[MH - RCOOH]^+$ ions in the positive CI spectra, however, is important for the exact determination of the pairing of the fatty acids in the diacylglycerol and triacylglycerol molecules, and we have employed this method for the LC/MS identification and quantitation of molecular species of natural glycerolipids in the past (19,20).

All our LC/MS studies have been performed with the direct liquid inlet probe, which allows admission of only 1% of the column effluent to the mass spectrometer. This decreases the overall sensitivity of detection of any component about 100-fold. The use of narrower bore HPLC columns would allow the admission of a higher proportion of the total solvent flow to the mass spectrometer and could increase the sensitivity of detection. Likewise, the use of other LC/MS interfaces (21), including thermospray (22), that permit the transfer of the entire HPLC column effluent to the mass spectrometer should increase the sensitivity of detection of all solutes. It is not known, however, whether or not these interfaces also yield negative ions in the chloride-attachment mode. It must be recognized that simultaneous determination of all the lipid classes present in plasma does not allow optimization of the analytical parameters for any one of the lipid classes or molecular species. A generally acceptable working routine must be found if the method is to be practical. With such limited objectives, chloride attachment negative CIMS provides a much improved method for the identification and quantitation of molecular species of the neutral glycerolipids, and the neutral lipid moieties of glycerophospholipids and sphingomyelins present in plasma. A parallel LC/PCIMS run would allow the determination of all the major lipid components of plasma. In view of the limited resolution and extensive peak overlap, current methods of reverse phase HPLC require interfacing with mass spectrometry for reliable peak identification and quantitation. It cannot be substituted by such universal detectors as flame ionization (23) and light scattering (24).

Identification of Ergosta-6(7),8(14),25(27)-trien-3β-ol and Ergosta-5(6),7(8),25(27)-trien-3β-ol, Two New Steroidal Trienes Synthesized by *Prototheca wickerhamii*

Robert A. Norton and **W. David Nes***
Plant and Fungal Lipid Research, Microbial Products Research Unit, Richard B. Russell Research Center, Athens, Georgia 30613

Ergosta-6(7),8(14),25(27)-trien-3β-ol, ergosta-5(6),7(8),25(27)-trien-3β-ol, ergosterol, 25(27)-dehydroergosterol (prototheca-sterol), ergosta-7,25(27)-dien-3β-ol and ergost-7-en-3β-ol have been isolated from cells of *Prototheca wickerhamii*. The structures of the compounds have been determined in stereochemical detail by a series of chromatographic and spectral techniques. The results are interpreted to imply that whereas *P. wickerhamii* is non-photosynthetic and yeast-like in appearance and synthesizes ergosterol, the organism can be biochemically distinguished from yeast and considered an alga in part through the detection of other sterols described herein, notably those with $\Delta^{25(27)}$ side chains.
Lipids 26, 247-249 (1991).

Recent studies show the kinds and amounts of 24-alkylated sterols which plants produce may vary during phylogeny and development (1-3). In those plants where ontogenetic regulation of sterol biosynthesis occurs, specific 24-alkyl sterols may play multiple stage-specific roles *e.g.,* hormonal and membranous (4-6). We considered the possibility that some of the novel minor sterols recently identified in fungi (7-9) and vascular plants (1,5,10) may be acting hormonally rather than acting as intermediates in the pathway and may have phylogenetic significance. For this reason we now have extended our chemotaxonomic survey of phytosterols to a unicellular alga, *Prototheca wickerhamii.* The major sterols of actively proliferating cells of *P. wickerhamii* were previously identified as ergosterol and 25(27)-dehydroergosterol (11). In this study we characterized four additional *P. wickerhamii* sterols, one of which (ergosta-6(7),8(14),25(27)-trienol) occurred at hormonal levels in the cells and for biosynthetic reasons seemingly is not a precursor of ergosterol (12).

MATERIALS AND METHODS

Prototheca wickerhamii, strain NRPL Y-6870, was obtained from Dr. C. P. Kurtzman, USDA Northern Regional Research Center, Peoria, IL. *P. wickerhamii* is a non-photosynthetic alga which is yeast-like in culture (ref. 11, and refs. cited therein). The cultures were grown on a medium of 1% Bacto-yeast extract, 2% Bacto-peptone and 2% glucose. Cultures (300 mL medium in 1-L flasks) were inoculated with *ca.* 0.5×10^6 cells/mL and shaken continuously for 48 hr (growth arrest) to 100 hr at 180 rpm on a G10 gyratory shaker. At stationary phase, *ca.* 6.5×10^7 cells/mL, the cell yield per flask was *ca.* 3.9 g fresh weight of pelleted cells. Cells at different stages of stationary phase were pooled and the combined pellets saponified by refluxing in a solution of 10% KOH, 10% H_2O, 80% MeOH (w/v/v) for 2 hr. A non-saponifiable lipid fraction (NLF) was obtained by partitioning the cooled solution between diethyl ether and water. NLF was chromatographed on Silica gel G plates using benzene/diethyl ether (85:15, v/v) to separate sterols into classes based on the degree of C-4 substitution (13,14). Final purification of the minor compounds from bulk sterols and from one another was accomplished by high-performance liquid chromatography (HPLC) column chromatography. An initial separation was achieved by reversed-phase HPLC using an Alltech Econosil C_{18} 25-cm semi-preparative (10 μm) column (Alltech Associates, Deerfield, IL), which was eluted with 4% aq. MeOH at ambient temperature, followed by injection of select HPLC fractions into a 25-cm Whatman partisphere reversed phase C_{18} analytical (5 μm) column (Whatman, Ltd., Maidstone, England), which were eluted with 4% aq. MeOH at 40°C (cf., Results). The relative retention time (RRT_c) and α_c values are given relative to cholesterol. Gas-liquid chromatography (GLC) (packed 3% SE-30 column operated at 245°), gas chromatography (GC) (30-m capillary SE-30 like column, DB-1701-mass spectrometry (MS) and ^1H nuclear magnetic resonance (NMR) were performed as described (12-14).

RESULTS AND DISCUSSION

Cells from a series of growth experiments, where the cells were harvested at various times from the logarithmic and resting phases of growth, were combined and saponified, and the resulting NLF chromatographed by thin-layer chromatography (TLC). From the GLC profile of the 4,4-desmethyl sterol TLC band, we observed 3 peaks, none of which was fully separated from the others, at RRT 1.20, 1.35, 1.42 in a ratio of 63:27:10, respectively. When the sterol mixture was examined by GC-MS, the first peak was shown to possess two components corresponding in retention time and fragmentation pattern to ergosterol and prototheca-sterol (25(27)-dehydroergosterol) (11). The second peak also contained two components corresponding to an ergostadienol and an ergostatrienol isomer of ergosterol. The third peak contained one component and it was tentatively identified

as the monoene, ergost-7-enol. When the sterol mixture was examined by reversed-phase high pressure liquid chromatography (RPHPLC) using 4% aq. MeOH as the eluant and the column oven operated at 40°C, a series of peaks was evident at α_c 0.66, 0.74, 0.84 and 1.10. However, using the multiple wavelength diode-array detector (DAD) and the peak purity method (14) to monitor each of the four peaks, we determined that six rather than four sterols were present in the mixture. The early eluting peak was due to a single component with a chromophore for the $\Delta^{5,7}$-system. The second peak represented two compounds with the ultraviolet (UV) absorption characteristic of a $\Delta^{5,7}$-system and a $\Delta^{6,8(14)}$ system (12). The third peak also represented a mixture of two compounds, one of which possessed UV absorption for a $\Delta^{5,7}$-system, one possessed end absorption. The late (fourth) eluting peak at α_c 1.10 possessed an end absorption spectrum similar in shape to the end absorption spectrum observed for peak 3. The end absorption spectra for monoenic sterols are not sufficiently descriptive to differentiate between Δ^8- or Δ^7-systems, but the shape of the curves are different when compared to an end absorption spectrum for a Δ^5-sterol (8,14).

The sterols purified by TLC were further separated by preparative HPLC into four fractions. Each one of these fractions, referred to as fractions 1 to 4 in order of polarity beginning with the least polar, was examined by GC-MS. Consistent with our previous determination using the DAD, fractions 1 and 4 appeared to be uniform while fractions 2 and 3 consisted of mixtures of sterols. In order to resolve the mixtures, fractions 2 and 3 were injected into an analytical HPLC C_{18}-column where several parameters were changed from those used to assess α_c values. In the new separation system, the column was operated at 25°C and the eluant was changed to a higher percentage (6%) of water. These small changes have a profound influence on the resolving power of the column. As shown in Figure 1, the steroidal trienes which cochromatographed in the preliminary analysis of the sterol mixture at α_c 0.74 (fraction 2) were easily separated with base line resolution. In order to reduce the level of ergosta-5,7,25(27)-trienol, the front portion of peak 2 was shaved during the preparative scale-up of the fractionation and the early eluting fraction was then reinjected into the HPLC operating under the new conditions. The same protocol was used to separate the sterols in fraction 3. At that point, we had obtained six pure sterols which could be further examined by ^{1}H NMR (Fig. 2). The total amount of sterol in the cells was determined to be *ca.* 73 fg/cell, whereas the level of ergosta-6(7),8(14),25(27)-trienol was two orders of magnitude lower at 0.52 fg/cell.

Comparison of the chromatographic behavior, and of mass, UV and ^{1}H NMR spectra (Table 1) of the six sterols with literature data (12,15,16) indicated that compounds 1, 2 and 5 (cf. Fig. 1) were new sterols. The configuration at C-24 was established by comparing the spectra of the Δ^{22}- and $\Delta^{25(27)}$-sterols isolated from *P. wickerhamii* with those previously reported for ergosterol and 24-epiergosterol (17) and of codisterol and 24-epicodisterol (18,19). The chemical shift for the olefinic methyl signal at δ 1.64 in 5 (Fig. 1) and the C-21 doublet at δ 1.048 in 3 supports the 24β-epimer orientation. The isolation of a $\Delta^{6,8(14)}$-sterol is rather unusual. To our knowledge this is the first time a $\Delta^{6,8(14)}$-sterol has been

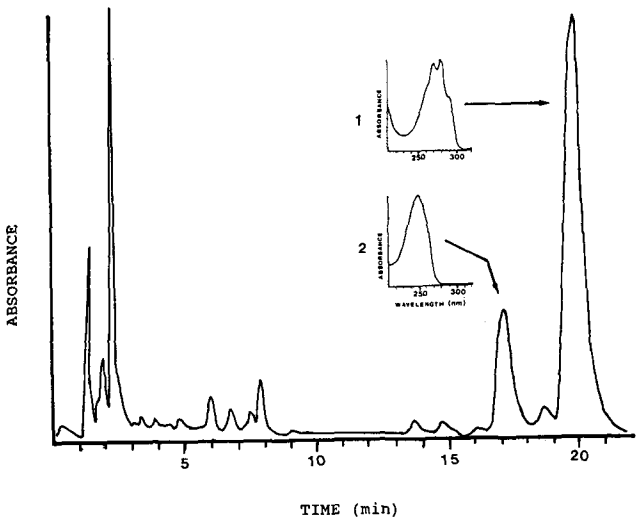

FIG. 1. HPLC chromatogram of a subfraction (peak 2 from preparative scale-up of sterol mixture, see text for details) containing two ergostatrienes. UV spectra were obtained on each compound by monitoring the eluant with the multiple wavelength diode array detector. HPLC conditions: solvent, 6% aq. methanol; pump speed, 1.5 mL/min; ambient temperature; Whatman C_{18}-column (5 μ); detector set at 205 nm.

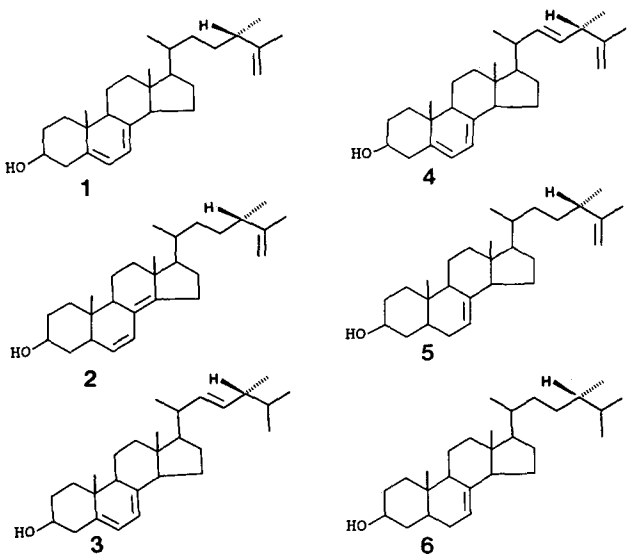

FIG. 2. Structures of sterols isolated from *Prototheca wickerhamii*.

isolated from algae and the second time it has been observed in nature, the other instance being the isolation from the fungus *Gibberella fujikuroi* which synthesizes ergosta-6,8(14),22-trienol (12). For mechanistic reasons, $\Delta^{6,8(14)}$-sterols are not assumed to be intermediates to $\Delta^{5,7}$-sterols (12). Alternatively, biosynthetic interrelationships of the other five sterols seem possible based on their structural similarities and on sterol transformation studies performed on related algae using sterols with similar functional groups as those now found to be synthesized by *P. wickerhamii* (20). Compound 2 (Fig. 2) was not detected in actively growing cultures of *Prototheca* (11, Norton, R.A., and Nes, W.D., unpublished data).

[a] ^{1}H NMR: Nicolet 200 MHz spectrometer operating at ambient temperature in the Fourier transform mode; solvent, $CDCL_3$; δ values are relative to Me_4Si. EIMS was obtained on an HP model 5970 table-top mass detector coupled to a GLC 30-m capillary column DB-1701 operated from 130°C to 260°C (10°C/min), then held at 260°C for another 10 min. SC = side chain and a dash indicates not present. GLC was obtained on an HP 5890 equipped for flame ionization detection, 3% SE-30 packed columns on gas chrom Q 100/120 mesh, 0.25-in. spiral glass columns; ionization detector temperature, 300°C; oven temperature, 245°C; flow rate of He (carrier) 30 mL min^{-1}. RRT = relative retention time. TLC was performed on Silica Gel G plates (250 μ, Analtech) with benzene/diethyl ether (85:15, v/v) as the developing solvent. HPLC, Whatman C_{18}-column (5 μ), 4.0 mm i.d. by 250 mm. Solvent, 4% aq MeOH; flow rate, 1.5 mL min^{-1}; Detector, 205 nm; temperature of oven, 40°C. UV, the samples were dissolved in 4% aq MeOH and the spectra obtained from the diode-array detector (UV/vis diode-array detector 1040A Hewlett-Packard) after passage thru the C_{18}-column.

Therefore, it is unlikely to be an artifact of the isolation methods.

The cyclopropyl steroid precursor which gave rise to the $\Delta^{25(27)}$-double bond in *P. wickerhamii* was earlier shown by us to be cyclolaudenol (11). *Chlorella*, its photosynthetic alga progenitor (11), also synthesized cyclolaudenol and ergosterol (20). *Chlorella*, however, reduces the side chain at an early step in the conversion of cyclolaudenol to ergosterol (20), whereas in *Prototheca* reduction of the $\Delta^{25(27)}$-double bond occurs at a late step, or not at all, *e.g.*, as in 2. Presumably, that is why prototheca-sterol and related 4,4-desmethyl $\Delta^{25(27)}$-sterols were not detected in *Chlorella*. Studies in progress with transition state sterol biosynthesis inhibitors incubated with *P. wickerhamii* at several stages of the algal life history should resolve whether 2 has functional importance.

The Solubilization of Calcium Soaps by Fatty Acids

R.J. Jandacek
The Procter & Gamble Company, Miami Valley Laboratories, Cincinnati, Ohio 45239-8707

The solubilization of the calcium soaps of long chain fatty acids by liquid fatty acids was observed. The solubilities of calcium palmitate, calcium laurate, and calcium oleate were 15.6, 22.8, and 53.3 wt%, respectively, in oleic acid at 40°C. The formation of an acid-calcium soap complex was demonstrated by x-ray diffraction studies of calcium laurate, lauric acid, and a mixture of these compounds that had been heated. Similar evidence was obtained for a calcium oleate-oleic acid complex. The solubility of calcium oleate in a bile salt micellar system was enhanced by oleic acid. The solubilization of calcium soaps by liquid fatty acids may explain the unexpectedly high bioavailability of some calcium soaps.
***Lipids 26,* 250-253 (1991).**

Dietary calcium can increase the excretion of ingested fat, presumably by the formation of insoluble calcium soaps that are unavailable for absorption from the intestine (1). Calcium primarily affects the absorption of long chain, saturated fatty acids, and has little effect on medium chain or unsaturated fatty acids (1).

It is generally assumed that the insolubility of calcium soaps in aqueous systems is the cause of their minimal absorption. This assumption is consistent with the low solubilities of calcium palmitate and calcium stearate in water (3-4 mg/100 mL) (2). We cannot, however, ignore the low solubility of the calcium soaps of lauric acid (4 mg/100 mL) and oleic acid (40 mg/100 mL) (2). In spite of the low solubility of the shorter chain and unsaturated fatty acid calcium soaps, dietary calcium has virtually no effect on the absorption of these fatty acids (1).

In addition to the observed effect of dietary calcium on fatty acid absorption, there is the possibility that dietary fatty acids interfere with dietary calcium absorption. A typical adult human ingests more than 100 g of triglyceride per day, and approximately two-thirds of that mass is converted to ionized fatty acids in the small intestine. This amount is in excess of that required to precipitate the 600-800 mg of ingested calcium as insoluble, nonabsorbable calcium soaps. Although most dietary calcium is typically not absorbed (3), one might predict that the formation of calcium soaps would prevent the absorption of calcium.

Two questions then arise from consideration of the physical properties and the biological behavior of calcium, fatty acids, and calcium soaps: (i) why are the unsaturated fatty acids not precipitated by calcium in the intestine? and (ii) why don't fatty acids precipitate all dietary calcium and prevent its absorption?

The milieu of the intestinal lumen contains many substances that might alter the chemical activity of calcium and fatty acid ions (*e.g.*, bile acids, chelators, sugars, bicarbonate) and thus hinder the formation of calcium soap precipitates. We found one class of compounds that does indeed markedly alter the solubility of calcium soaps—the fatty acids themselves. We report here our observations on the solubilization of calcium soaps by fatty acids and discuss possible implications in intestinal events related to calcium and fat absorption.

Abbreviations: AA, atomic absorption; GC, gas chromatography.

MATERIALS AND METHODS

Materials. Oleic acid (Sigma Chemical Co., St. Louis, MO) was shown by gas chromatographic (GC) analysis of its methyl ester to have a purity of >99%. Calcium oleate was prepared by dissolution of 0.02 moles oleic acid in 50 mL absolute ethanol, followed by the addition of 20 mL of 0.1N aqueous NaOH. This solution was added to a solution of 0.01 moles $CaCl_2.2H_2O$ in 50 mL absolute ethanol. The resulting milky suspension was centrifuged and the pellet was washed by repeated suspension in distilled water, centrifugation, and discarding of the supernatant. The sample was then frozen and lyophilized. Calcium palmitate and calcium laurate were obtained from Pfaltz and Bauer (Waterbury, CT). Triolein, lauric acid, and octanoic acid (all 99%) and sodium glycodeoxycholate were purchased from Sigma. A sample of a mixture of calcium stearate and calcium palmitate was purchased from Baxter Scientific Products (McGraw, IL).

The compositional analysis of the soaps was determined after dissociating the soap into aqueous and organic phases. Approximately 100 mg of the soap was dispersed into 80 mL of 1:1 (v/v) ethanol and water that was adjusted to pH of 2.0 with HCl. This suspension was extracted in a separatory funnel 3 times with 100 mL of hexane. The calcium in the aqueous phase was assayed by atomic absorption spectroscopy (AA). The results were: calcium laurate, 9.1% wt found (9.1% theory); calcium palmitate, 6.7% wt found (7.3% theory); calcium oleate, 6.7% wt (6.7% theory); and calcium stearate-palmitate mixture, 7.2% wt (7.1% theory). The fatty acids in the hexane phase were measured by GC analyses of the methyl esters, and the following fatty acid compositions resulted: Calcium oleate, 99.8% oleic acid; calcium laurate, 95% lauric, 4% decanoic acid; calcium palmitate, 92% palmitic, 6% stearic, 2% myristic acid; calcium stearate mixture, 67% stearic, 26% palmitic, 2% myristic, 2% heptadecanoic, 1% oleic, 1% arachidic acid.

Solubility measurements. The solubility of calcium soaps was determined by suspending an excess of the soap in the organic liquid in a capped vial and mixing on a rotary mixer for 48 hr in a room held at 39-40°C. After mixing, the samples were centrifuged at this temperature to precipitate the soap crystals. Examination of the supernatant by polarized light microscopy confirmed the absence of soap crystals in the liquid. The supernatant was then partitioned between the acidic aqueous ethanol and the hexane phases described above. The aqueous phase was analyzed for calcium by AA, and that value was converted to mass of calcium soap in the organic phase in question. The fatty acid composition of the hexane phase was also measured in the laurate, palmitate, and stearate-palmitate soaps. This method was validated by the measurement of calcium in systems in which known amounts of calcium soap were dissolved. Duplicate or triplicate determinations were used except for the

[a]Solubility based on fatty acid recovery in parentheses.

heptane-octanoic acid system on which a single measurement was made.

Calcium oleate solubility in an aqueous bile salt solution was measured by mixing an excess of calcium oleate with water or solutions of 0.01 M sodium glycodeoxycholate with or without oleic acid (3.6 mM). Mixing conditions and centrifugation were the same as described above except that the supernatant was filtered with a 0.45 micron filter and then analyzed by AA for calcium.

X-ray diffraction studies. The complexes of fatty acids and calcium soaps were prepared by raising the temperature of the mixtures to 150°C to form a translucent phase. The samples were then cooled and powder diffraction patterns obtained with a diffractometer using CuKα radiation at 25°C. This procedure has been previously shown to form fatty acid-potassium soap complexes (4). Resolution of the peaks allowed differences of 0.3 Å to be determined when second and third orders were used. The first order peaks allowed differences of 1.5 Å to be resolved.

RESULTS

The solubilities of calcium soaps in triolein, heptane, oleic acid, and octanoic acid with heptane (50/50 wt %) are given in Table 1. Measurements based on calcium and on the oil's fatty acid composition are presented. The solubility of all soaps in triolein was less than 1%. There was, however, a high level of miscibility of the soaps in oleic acid, with a maximum of 53% for calcium oleate in oleic acid. Both oleic and octanoic acids, liquids that are miscible with nonpolar phases such as heptane and triolein, solubilized calcium soaps in the nonpolar phase. The determination of solubility based on calcium was in agreement with that found by measurement of the fatty acid composition of the oil phase.

All calcium soaps were solubilized by oleic acid, and the solubility followed a trend related to the melting points of the fatty acids. Calcium oleate and laurate were thus more soluble than the soaps of the higher melting palmitic and stearic acids.

The fatty acid compositions of the oil phase showed that there was no preferential dissolution of the impurities of the calcium laurate or calcium palmitate in the oil. Lauric acid accounted for 95.0% of the fatty acids (other than oleic acid) in the oil phase of the calcium laurate soap solutions, unchanged from the added calcium laurate solute. Similarly palmitic acid was 90.3–91.4% of the fatty acids (other than oleic acid), compared with a value of 92% for the calcium palmitate solute.

The relatively high solubility of the mixed calcium stearate-palmitate soaps is consistent with the reduced melting point of the mixture. In addition the fatty acid composition of the oil phase from the soap mixture showed preferential solubility of the shorter chain, lower melting acids. The ratio of stearic/palmitic acids in the undissolved soap was 2.6. In the soap dissolved in the oil phase, however, this ratio decreased by 30% to 1.8, demonstrating a higher solubility of the palmitate compared with the stearate. Similarly the ratio of stearic/myristic acids decreased by 50% from 33.5 in the undissolved soap to 16.2 in the dissolved soap.

To determine whether or not a fatty acid would enhance the solubilization of a calcium soap by a micellar bile salt solution, we measured the solubility of calcium oleate in a solution of 0.1 M sodium glycodeoxycholate with or without 3.6 mM oleic acid present. The presence of oleic acid increased the calcium oleate concentration from 138 ± 5 to 309 ± 33 μg/mL (n=3, mean ± SEM).

We investigated the possibility of acid soap formation in the calcium laurate-lauric acid and the calcium oleate-oleic acid systems. The powder x-ray diffraction patterns showed evidence of the formation of an acid soap, and these are displayed in Figure 1. As shown in Table 2, the long spacing from lauric acid (27.6 Å) is distinct from that of calcium laurate (34.0 Å). Both values are consistent with those previously reported (27.6 Å, 34.8 Å,

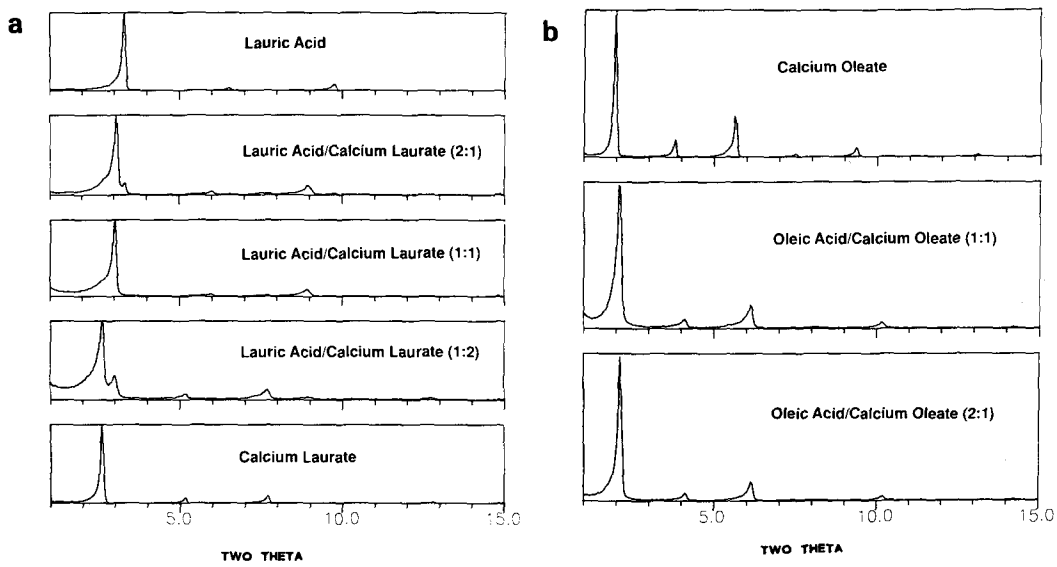

FIG. 1. (a) The x-ray diffraction pattern from lauric acid, calcium laurate, and varying molar ratios of the acid and soap that had been melted and cooled to 25°C. The 1:1 mixture displays a long spacing of 29.4 Å, distinct from the long spacing of 34.0 Å for calcium laurate and 27.6 Å for lauric acid, indicating a complex of the acid and soap. The pattern of the 1:2 mixture includes the spacings of the soap and the complex, while that of the 1:2 mixture includes those of the acid and the complex. (b) The x-ray diffraction pattern of calcium oleate and mixtures of 2:1 and 1:1 molar ratios of oleic acid and calcium oleate that had been melted and cooled to 25°C. The long spacing of both mixtures (42.1 Å) is distinct from that of calcium oleate (44.2 Å), suggesting the formation of a complex of the acid and soap of indeterminate stoichiometry.

TABLE 2

Diffraction Spacings (Å) from Calcium Soaps, Fatty Acids, and Mixtures After Melting and Cooling to Room Temperature

Calcium laurate	Lauric acid	Calcium laurate/lauric acid molar ratio			Calcium oleate	Calcium oleate/oleic acid molar ratio	
		2:1	1:1	1:2		2:1	1:2
34.0				34.0	44.2

respectively) (5). When mixtures of lauric acid and calcium laurate were heated to 150°C and then cooled, a long spacing appeared at 29.4 A, and those at 27.6 A and 34.0 A disappeared. Similarly the long spacing of calcium oleate shifted from 44.2 Å to 42.1 Å when it was heated with oleic acid.

DISCUSSION

The data presented are evidence for the solubilization of calcium soaps by low-melting fatty acids. This solubilization has not been reported previously and was observed both in an oil phase and in a bile salt micellar phase. The solubility of the soaps in oleic acid decreased with increasing melting point. In addition, the solubilities of oleate and laurate soaps in oleic acid suggest that this solubilization might prevent the precipitation of calcium oleate and calcium laurate in the intestine.

The solubilization effect was observed both for oleic acid and for octanoic acid and occurred in the presence of a liquid triglyceride or an organic solvent, heptane. Presumably, calcium soaps can dissolve in many liquid fatty acids or their solutions. Dietary linoleic acid, oleic acid, α-linolenic acid, octanoic acid, decanoic acid, and lauric acid would be expected to solubilize calcium soaps in the intestine.

The normal digestion process for dietary fat takes place at the surface of emulsified triglyceride droplets with lipase splitting interfacial triglycerides into

monoglyceride and free fatty acid. This interfacial region includes a high concentration of free fatty acids that may hinder the precipitation of calcium soaps. In addition, bile salt mixed micelles that include free fatty acids can partially solubilize calcium soaps. The inhibition of calcium soap precipitation and the solubilization of the soaps by low melting fatty acids may therefore enhance the pool of calcium and fat in the intestinal lumen that is available for absorption.

The x-ray data provide evidence for the previously unreported fatty acid-calcium soap complex formation. The melting method used to form the complex has been shown to form fatty acid-potassium soap complexes (4). The distinct diffraction lines for the acid-calcium soap mixture are evidence of a crystalline array that is distinct from either the calcium soap or the fatty acid. The multiple orders of diffraction d-spacing ratios of 1:1/2:1/3 correspond to a fatty acid bilayer structure. The dimension of the bilayer of the complex is distinctly different from those of the calcium soap and the fatty acid. The data suggest a complex of 1:1 molar ratio of lauric acid to calcium laurate since peaks corresponding to uncomplexed lauric acid appeared in the 2:1 mixture and peaks corresponding to uncomplexed calcium laurate, in the 1:2 mixture. The stoichiometry of the oleic acid calcium oleate complex is not indicated by the data given here since the 1:1 and 2:1 mixtures gave similar diffraction patterns. The pattern from the 2:1 mixture may, however, be explained by a 1:1 complex and an excess of amorphous liquid oleic acid.

The demonstration of the existence of fatty acid complexes with calcium soaps is consistent with the insertion of the acid into the soap lattice with the carboxyl group attracted to the calcium region in the crystal. Presumably the carboxyl groups of liquid fatty acids similarly approach the calcium atoms in the dissolution of calcium soaps. Disruption of the crystalline array of the fatty acid chains and formation of a nonpolar environment of fatty acids surrounding the calcium facilitate the dissolution of calcium soaps by fatty acids.

The solubility and x-ray diffraction data presented here describe two previously unreported interactions between fatty acids and calcium soaps—a high level of solubility of these soaps in fatty acids, and the formation of an acid soap complex. This evidence for calcium soap compatibility with fatty acids can explain, in part, the efficient absorption of fatty acids from a milieu that would apparently favor the formation of insoluble, nonabsorbable calcium soaps.

Identification of Diacylglycero-4′-*O*-(*N,N,N*-trimethyl)homoserine in Mushrooms

Victor E. Vaskovsky[a], Svetlana V. Khotimchenko[a] and Andrew A. Benson[b,*]

[a]Institute of Marine Biology, Far East Branch, Academy of Sciences of the USSR, Vladivostok 690032 USSR and [b]Scripps Institution of Oceanography, La Jolla, California 92093

An unusual polar lipid component was found in some mushrooms and was isolated from *Boletus edulis*. It has been identified as diacylglycero-4′-*O*-(*N,N,N*-trimethyl)-homoserine (DGTS) by its thin-layer chromatography (TLC) mobilities and staining behavior as well as by means of infrared (IR) and nuclear magnetic resonance (^{1}H NMR) spectroscopy and mass spectrometry. Identification of this lipid in mushrooms indicated that DGTS is widely distributed among a diverse group of lower plants and may have chemotaxonomic significance for fungi. It is interesting that DGTS is a component of some edible mushrooms commonly consumed in food.
***Lipids* 26, 254-256 (1991).**

During investigation of the lipid composition of lower plants, an unusual polar lipid in mushrooms attracted our attention. It was not any of the well-known plant polar lipids, yet had the same chromatographic characteristics as diacylglycero-4′-*O*-(*N,N,N*-trimethyl)homoserine (DGTS), which we had identified in the green alga *Ulva fenestrata* (1). DGTS, Figure 1, was first discovered in the golden brown alga, *Ochromonas danica* (2), and subsequently in micro- and macroalgae (1,3-9), lower plants (10-13) and soil amoebae (14). Nothing was known of the presence of this lipid in mushrooms (15-19). We report here identification of this "homoserine" lipid in the mushroom *Boletus edulis*, for example, by means of thin-layer chromatography (TLC) characteristics, infrared (IR) nuclear magnetic resonance (^{1}H NMR) and mass spectrometry.

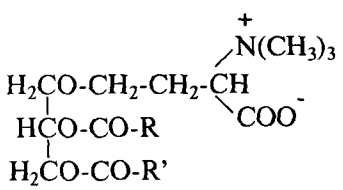

FIG. 1. Structure of DGTS (diacylglyceryltrimethylhomoserine ether).

MATERIALS AND METHODS

Materials. Mushrooms were harvested in summer and autumn in the maritime region near Vladivostok and Nakhodka. They were cleaned, cut into small pieces and heated in boiling water 2-3 min for inactivation of phospholipase D. Lipids were extracted using a modified Bligh and Dyer method (20) as described earlier (21).

Separation and detection. Lipid extracts were analyzed by two-dimensional TLC on silica gel plates (22) using solvent systems for separation of plant polar lipids (21) and phospholipids (23). Lipids were detected using the following spray reagents: 10% H_2SO_4 in methanol followed by charring for detection of all lipids, Dragendorff reagent for choline lipids (24), 0.25% ninhydrin in acetone for amino-containing lipids, anthrone reagent for glycolipids (25), molybdate reagent for phospholipids (26) and malachite-green reagent for phosphorus-containing lipids (27).

Identification. Total lipids (1.1 g) were extracted by the above procedure from 130 g *B. edulis*. The lipid X was isolated from the total lipids by column chromatography on silica gel. The column was washed with chloroform and lipid X was eluted with chloroform/methanol (4:1, v/v). It was purified by preparative TLC in a solvent system of chloroform/acetone/methanol/formic acid/water (100:40:20:20:8, by vol). Yield of the purified lipid was 90 mg.

Fatty acid methyl esters were obtained (28) and subjected to gas-liquid chromatography on a Shimadzu GC-9A instrument (Shimadzu Corp., Kyoto, Japan) equipped with flame ionization detector. A glass column (25 m × 0.25 mm) with Silar-5CP (SERVA, Heidelberg, Germany) was used. The column temperature was 190°; the flow rate of the carrier gas (helium) was 40 mL/min. Fatty acids were identified by comparison of the retention times with those of authentic standards and by equivalent chain length (29).

The infrared spectrum was recorded using a Specord 75 IR spectrometer (Jenoptik, Jena, Germany) with a sample prepared in chloroform. The NMR spectrum was obtained on a Bruker WM-250 (Bruker Instruments, Karlsruhe, Germany) spectrometer ($CDCl_3$ solution). Proton chemical shifts are given in ppm downfield from internal tetramethylsilane. Mass spectra of the lipid were obtained by the direct inlet mode using an LKB 9000 (LKB Produkter, Bromma, Sweden) instrument. The source temperature was 150° and the ionization voltage was 7 eV.

RESULTS

TLC demonstrated that all mushrooms contained well-known polar lipids (15-19). Phosphatidylcholine, phosphatidylethanolamine and phosphatidylserine were present as main components and phosphatidylinositol, phosphatidic acid and glycolipids as minor components (Fig. 2). Sugai *et al.* (19) reported pyrophosphatidic acid in some mushrooms, but we did not detect this lipid in any mushroom species investigated, even though we used high-performance thin-layer chromatography (HPTLC) with several solvent systems and a sensitive reagent for detection of phosphorus-containing substances (27). Besides the usual lipids, several unidentified mushrooms contained the lipid X as one of their major lipid components (see Fig. 2).

Abbreviations: DGTS, diacylglycero-4′-*O*-(*N,N,N*-trimethyl)homoserine; TLC, thin-layer chromatography; HPTLC, high-performance thin-layer chromatography; IR, infrared; NMR, nuclear magnetic resonance.

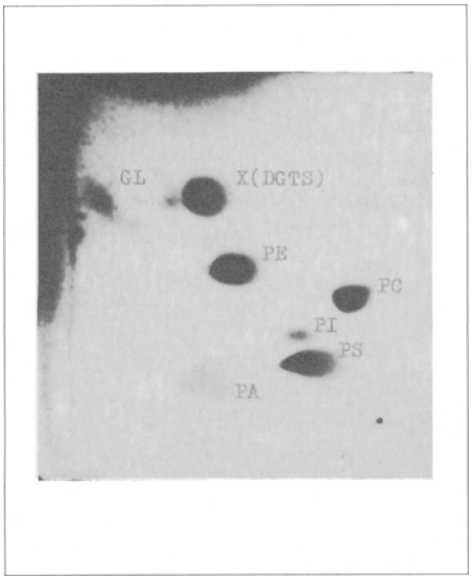

FIG. 2. Two-dimensional thin-layer chromatogram of polar lipids from a mushroom, *Boletus edulis*, containing DGTS. Solvent systems: first direction (vertical), chloroform/methanol/benzene/28% NH_4OH (65:30:10:6, by vol), second direction, chloroform/methanol/benzene/acetone/acetic acid/water (70:30:10:5:4:1, by vol). Visualization was by charring after spraying with 10% H_2SO_4 in methanol. Abbreviations: DGTS, diacylglycerotrimethylhomoserine; GL, glycolipids; PA, phosphatidic acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; O, origin.

The lipid X had a higher R_f than phosphatidylethanolamine. It was found that the lipid gave a positive reaction with Dragendorff reagent and was not stained with the anthrone reagent (25). With the molybdate reagent (26) it was stained as phospholipid, yet it did not give a positive reaction with the more specific malachite-green reagent for phosphorus-containing substances (27). Thus, the lipid was neither a phospholipid, a glycolipid nor an amino-lipid, but contained a quaternary ammonium group. Mobility on two-dimensional TLC and the color reactions with specific spray reagents pointed to the similarity of the lipid X to the DGTS in other organisms (1,3,5,7).

To identify the lipid X it was isolated from *Boletus edulis* by column and thin-layer chromatography and subjected to spectral analysis. The infrared spectrum of lipid X showed absorption bands at 3384cm^{-1} (OH, bonded), 3000cm^{-1} (HC = CH), 2940, 2870, 1370cm^{-1} (CH_2, CH_3), 1736cm^{-1} (C = O, ester), 1632cm^{-1} (COO-), 1470cm^{-1} (CH_2), 1174cm^{-1} (C-O-C, ester), and 970cm^{-1} $N(CH_3)_3$. This spectrum was identical to that reported for the DGTS in *Ulva fenestrata* (1) and in other organisms (3,5,7).

The proton NMR spectrum of lipid X showed signals at δ 0.88 ppm ($C\underline{H}_3$), 0.97 ppm (*t*, terminal $C\underline{H}_3$ of fatty acids), 1.30 ppm (*m*, $C\underline{H}_2$), 1.62 ppm (*m*, -$C\underline{H}_2$-CH_2-COO), 2.05 ppm (*m*, allylic $C\underline{H}_2$), 2.30 ppm (*m*, -$\underline{H}_2$C-C=O), 2.78 ppm (*m*, $C\underline{H}_2$ between two double bonds), 3.67 ppm (*m*, -$\underline{H}_2$C-O-$C\underline{H}_2$ and -O-CH_2-CH_2-$C\underline{H}$(N-)-COO^-), 4.16 ppm and 4.32 ppm (*m*, $C\underline{H}_2$, glycerol), 5.20 ppm (*m*, $C\underline{H}$, glycerol) and 5.35 ppm (*t*, $\underline{H}C = C\underline{H}$). A prominent singlet signal at δ 3.30 ppm indicated the presence of a $N^+(CH_3)_3$ group in the lipid. The NMR spectrum of the lipid X was virtually identical to that of DGTS from *Ulva fenestrata* (1). The observed chemical shifts for lipid X were compatible with those of DGTS from other organisms (5,10,30).

TABLE 1

Fatty Acid Composition of Total Lipids from *Boletus edulis* and DGTS (% of total fatty acids)

	16:0	16:1	18:0	18:1	18:2n-6	Other
Total lipids	9.2	0.5	0.3	41.9	46.3	1.8
DGTS	34.2	0.9	1.5	10.6	47.9	4.9

The mass spectrum of the lipid X showed ions corresponding to the polar group *N,N,N*-trimethylhomoserine (*m/z* 162), its dehydrated product (*m/z* 144), its dehydrated and demethylated product (*m/z* 130), its decarboxylated product (*m/z* 118), its decarboxylated, dehydrated and demethylated product (*m/z* 86) and finally to $(CH_3)_2$-N-CH_2^+ (*m/z* 58). The mass spectrum of lipid X also showed peaks corresponding to molecular ions at *m/z* 736 (a major peak), 759, 738, 734 and peaks at *m/z* 677, 700, 678, 675 $[M-59]^+$. It suggested that the lipid X was a mixture of several molecular species with fatty acids differing in their chain length and their degree of unsaturation. Thus, our results demonstrated that the lipid X is diacylglycero-4′-*O*-(*N,N,N*-trimethyl)homoserine.

Table 1 shows the composition of fatty acids of total lipids and DGTS from *B. edulis*. Major fatty acids in both the lipid extract and in DGTS were palmitic, oleic and linoleic acids. But in DGTS the 16:0 acid was present in much higher and the 18:1n-9 acid in much lower proportions than in the total lipids. On the basis of mass-spectral data revealing the molecular ion $[M+1]^+$ *m/z* 736 indicative for the 16:0-18:2 species and fatty acid analysis we propose that the major molecular species is palmitoyl,linoleoyl-glycero-4′-*O*-(*N,N,N*-trimethyl)-homoserine.

DISCUSSION

DGTS may play an important role in membrane biogenesis in plants and could be a substrate for desaturation of 18:1 and 18:2 fatty acids in the green alga *Chlamydomonas reinhardtii* (31). It was suggested that DGTS could be involved in biosynthesis of γ-18:3 acid (3) or in formation of the 18:4n-3 acid (1). The role of DGTS in mushroom membrane development remains to be clarified.

Although a large group of plant species was examined for DGTS (11-13), the mushrooms were not investigated. When Sugai *et al.* (19) described the occurrence of pyrophosphatidic acid in mushrooms, it is quite possible that they also observed DGTS in their lipid extracts as the TLC shown in Figure 1 of their paper revealed one major unidentified polar lipid. Previously, DGTS was found in a human pathogenic fungus, *Epidermophyton floccosum* (class Ascomycetes) (30). *Boletus edulis* and the majority of other edible mushrooms belong to Basidiomycetes. The results obtained in this paper are of chemotoxonomic and practical interest. Published data

(11-13) and our results (32) on DGTS distribution among plants showed that DGTS is absent in all investigated species of one plant taxon (Rhodophyta, Phaeophyta, Angiosperms, Gymnosperms) and present in all species of another (Pteridophyta, Bryophyta, Chlorophyta). Mushrooms were found to be an exception: all analyzed species of Boletales contained DGTS and the lipid was not found in representatives of the Russulales.

With the exception of several green algae used as food in Asia, DGTS had been found only in inedible organisms. Mushrooms from the family Boletaceae, however, are widely used as foodstuffs. In preliminary experiments we have found DGTS in fried and salted mushrooms. Thus, man may consume with a mushroom dish tens of milligrams of DGTS. Therefore, it is of interest to study the taste, metabolism, and biological activities of DGTS and its deacylated derivative.

ACKNOWLEDGMENTS

We are grateful to Ms. T. Tytluanova and Dr. E. M. Booluh for their help in the harvesting and identification of mushrooms. Invitation and support of the Academy of Sciences of the USSR for one of the authors, A.A.B., is much appreciated.

Platelet-Activating Factor Stimulates Expression of IL-1 beta mRNA in THP-1 Cells

Roger A. Barthelson* and **Frank H. Valone**
Department of Medicine, University of California San Francisco, and the Veterans Administration Medical Center, San Francisco, California 94121-1598

A human monocytic cell line (THP-1) was used to study the effects of PAF (platelet-activating factor) on the expression of IL-1 beta mRNA. THP-1 cells were incubated with 10 pM PAF in the presence or absence of 0.1 μg/mL endotoxin for 4 hr, after which cytoplasmic RNA was extracted and subjected to Northern hybridizations. PAF, alone and in combination with endotoxin, caused an increase in mRNA levels for IL-1 beta. The magnitude of the effects of PAF on IL-1 beta mRNA levels matched closely the effects seen at the level of protein synthesis, suggesting that the effects of PAF on IL-1 beta release may result largely from its effects on IL-1 beta mRNA levels.
***Lipids* 26, 257–260 (1991).**

Platelet-activating factor (PAF) is a potent lipid mediator of allergic reactions and other inflammatory conditions (1–3). PAF administered *in vivo* causes both short and long-term effects that may resemble asthma, anaphylaxis, acute serum sickness, or endotoxin shock (4–7). The long-term effects probably result from secondary mediators produced by immune cells in response to PAF, because PAF itself has a half-life of less than five min *in vivo* (2). These secondary mediators may include TNF alpha and IL-1 beta (8–13).

PAF stimulates the release of IL-1 beta and TNF alpha by human monocytes and macrophages, which are a major source of these cytokines (8–11). PAF alone has a relatively small effect on the release of IL-1 beta by monocytes, but in the presence of a co-stimulus, such as gamma-interferon, PAF has a substanital effect (8). Similarly, endotoxin is more potent than PAF for stimulating IL-1 beta release by THP-1 cells, and when PAF and endotoxin are combined, the two stimuli interact synergistically to yield even higher levels of IL-1 beta release (14). Studies with THP-1 cells demonstrate that PAF increases IL-1 beta release by increasing IL-1 beta protein synthesis and that the combination of endotoxin and PAF increases IL-1 synthesis synergistically (14). Increased IL-1 beta protein synthesis can result from increased levels of IL-1 beta mRNA or increased translation of pre-existing mRNA. This communication demonstrates that PAF increases levels of IL-1 beta mRNA.

Abbreviations: GAPDH, glyceraldehyde-3-phosphate dehydrogenase; LPS, lipopolysaccharide from E. coli, endotoxin; PAF, platelet-activating factor, 1-0-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine; SSC, 0.15 M sodium chloride, 0.015 M sodium citrate buffer, pH 7.0.

MATERIALS AND METHODS

PAF (1-*O*-hexadecyl-2-acetyl-*sn*-glycero-3-phosphocholine) was obtained from Bachem (Torrance, CA). cDNA to IL-1 beta inserted in a pSP64 plasmid at the PST I site was a gift from the Genetics Institute (Cambridge, MA). The cDNA to the glyceraldehyde-3-phosphate dehydrogenase gene was a gift from Dr. Alfredo Lopez (VA Medical Center, San Francisco, CA). The Multiprime random primer extension kit and ^{125}I-streptavidin were purchased from Amersham (Arlington Heights, IL). [^{32}P]dCTP (3000 Ci/mmole) was obtained from NEN/DuPont (Wilmington, DE). A Transvac TE80 transfer apparatus, Nylon 66 Plus blotting membrane, and Seakem GTG agarose were from Hoeffer Scientific (San Francisco, CA). Nitrocellulose membrane was purchased from Schleicher and Schuell (Keene, NH). Restriction endonucleases and ribonuclease-free deoxyribonuclease I were purchased from Promega (Madison, WI). Vanadyl ribonucleosides and proteinase K were from Bethesda Research Laboratories (Bethesda, MD). Fetal bovine serum was from Hyclone (Logan, UT). Bovine serum albumin (BSA) was certified low in endotoxin (<0.5 ng/mg) and came from Boehringer-Mannheim (Indianapolis, IN). LPS (endotoxin from Escherichia coli, serotype 0127:B8) was obtained from Sigma Chemical Co. (St. Louis, MO). Anti-IL-1 beta antibodies were from Endogen (Boston, MA). Biotinylated goat anti-rabbit antibodies were from Zymed (South San Francisco, CA). All other reagents were of the highest purity available and certified for use for molecular biology when possible.

Incubation of THP-1 cells. THP-1 cells were cultured and incubated as described (14). The cells were washed, suspended at 1 × 10^6/mL in RPMI 1640 containing 50 μM 2-mercaptoethanol, and 0.15% BSA, and then were incubated with control buffer, 10 pM PAF, 0.1 μg/mL LPS, and LPS + PAF. These concentrations of stimuli stimulate IL-1 beta synthesis optimally (14). After 30 min, fetal bovine serum was added to achieve a final concentration of 10% and the incubation was continued for 4 hr.

Western dot blots. THP-1 cells were centrifuged, resuspended at 2 × 10^6/mL in PBS, submitted to three cycles of freezing and thawing, and centrifuged again at 9000 × *g*. The resulting supernatants were applied directly to a nitrocellulose membrane (100 μL or approximately 2 × 10^5 cell equivalents) with a BioRad dot blot vacuum apparatus. The resulting blot was incubated with 5% non-fat milk as a blocking agent, rabbit anti-IL-1 beta antibodies, biotinylated goat anti-rabbit antibodies, and finally [^{125}I]streptavidin (20–40 μCi/μg) (14). All incubations contained PBS with 5% non-fat milk. The blot was rinsed in PBS, covered in plastic wrap, and exposed to x-ray film overnight with intensifying screens (14).

Preparation of RNA. Cytoplasmic RNA was pre-

pared by the NP-40 lysis method (15). Briefly, a cytoplasmic extract from 3×10^6 cells was digested with proteinase K, extracted with phenol/chloroform, and then incubated with deoxyribonuclease I. Vanadyl ribonucleoside complexes (10 mM) were present throughout the preparation to prevent degradation from ribonucleases. The final RNA samples were extracted twice with phenol/chloroform (1:1), and precipitated with ethanol to remove traces of the vanadyl ribonucleoside complexes. The RNA was quantitated by measuring the absorbance at 260 nM.

Preparation of cDNA. E. coli bearing plasmids were grown in LB media with the appropriate antibiotic (ampicillin and tetracycline for IL-1 beta and GAPDH, respectively). Chloramphenicol (34 μg/mL) was used for amplification of the plasmid DNA. The plasmid DNA was purified by alkaline lysis (15). The IL-1 beta cDNA insert was removed from the plasmid with PST I restriction endonuclease, and purified by electrophoresis on a 1% agarose gel made with TRIS/acetate/EDTA buffer (15). The appropriate band was located by ethidium bromide staining and was excised from the gel. The cDNA was eluted from the gel fragment and purified by using powdered glass (Geneclean kit, Bio 101, La Jolla, CA). The cDNA for GAPDH was isolated in the same manner except that two restriction enzymes, PST I and Bgl I, were used to excise a 949 base-pair fragment of the cDNA (16). The use of Bgl I was necessitated by a small mutation in the plasmid that had removed one PST I site.

Labelling of cDNA. cDNA was radiolabelled to be used as a hybridization probe for Northern blots. Labelling was accomplished by using the random primer extension method (Amersham Multiprime kit) and alpha-[^{32}P]dCTP. Labelled cDNA was separated from smaller contaminants by G-50 Sephadex chromatography.

Northern blots. RNA samples (20 μg) were heated to 65°C for 5 min and cooled rapidly on ice. The samples were applied to a 0.9% agarose gel for electrophoresis in formaldehyde-containing buffer (15). The resulting gel was stained for 10 min with 30 μg/mL acridine orange in 10 mM phosphate buffer, pH 7.0. The gel was rinsed 4–5 times in phosphate buffer over a period of 1 hr to destain. The separated RNA was seen by UV transillumination. The RNA was transferred to a nylon membrane with a Transvac vacuum blotting apparatus using 20X SSC (1X SSC = 0.15M NaCl, 0.015M Na citrate, pH 7.0) as the buffer and a vacuum of 4 mm Hg for 45–60 min. The blot membrane was rinsed in 5X SSC for 5 min and then dried at room temperature. The RNA was crosslinked to the membrane by exposure to a UV transilluminator for 5 min, and the membrane was incubated overnight with shaking at room temperature with approximately 1 mL/10 cm^2 prehybridization solution in a sealed plastic bag. The prehybridization solution consisted of 50% deionized formamide, 5X SSC, 1X Denhardt's, 0.2% SDS, 0.2 mg/mL heat-denatured salmon-sperm DNA and 5% dextran sulfate. Approximately 1×10^6 cpm/mL of ^{32}P-labelled, heat-denatured cDNA was added to the prehybridization mixture and the plastic bag was resealed and incubated at 42°C overnight with shaking. Then the hybridization solution was removed, and the membrane was washed three times with 2X SSC at room temperature for 10 min per wash. The final wash consisted of a 40 min incubation in 0.5X SSC plus 0.1% SDS at 55°C and a 20 min wash in 0.15X SSC plus 0.1% SDS at 55°C. The membrane was blotted with filter paper to remove excess moisture, wrapped in plastic wrap and exposed to x-ray film overnight.

RNA dot blots were performed in the same manner except that the RNA was not heated or submitted to electrophoresis. Instead, it was diluted into 150 μL final volume of 10 mM NaOH and 1 mM EDTA. The RNA was applied directly to the nylon membrane with a 96-well, vacuum blotting apparatus with a vacuum of 4 mm Hg. Autoradiographs of blots were quantitated by scanning with a BioRad densitometer.

Stripping blots. Northern blots were treated with a 1:1 solution of deionized formamide and 5X SSC at 65°C for 45 min to remove the ^{32}P-labelled IL-1 beta cDNA. The stripped blot was exposed to film overnight to confirm that all of the label had been removed before incubating it with a new cDNA probe.

RESULTS AND DISCUSSION

The human monocytic cell line THP-1 responds to stimulation by LPS by synthesizing IL-1 beta and releasing it (17). When 10 pM PAF and 0.1 μg/mL LPS are incubated together with THP-1 cells, the two stimuli interact synergistically to elevate IL-1 beta synthesis, as seen in Figure 1. PAF alone also causes a small increase in IL-1 beta synthesis over the buffer control. These data confirm previous studies that showed that human monocytes (8,10) and THP-1 cells (14) synthesize and release IL-1 beta in response to PAF, and that PAF and LPS interact synergistically to give a greater response. The increased synthesis of IL-1 beta in response to LPS results, in part, from increased expression of IL-1 beta mRNA by THP-1 cells, which peaks at about 3 hr (17). Similarly, at 3 hr (data not shown) or 4 hr (Fig. 2), 10 pM PAF increases the levels of IL-1 beta mRNA in THP-1 cells that are already stimulated with LPS. In the same experiment, PAF had no apparent effect on the levels of the mRNA of the normally unregulated gene, glyceraldehyde-3-phosphate dehydrogenase. This suggests that the differences in IL-1 beta mRNA levels were not due to variations in the amount of RNA loaded on the gel, but that PAF is specifically regulating the expression of IL-1 beta. Apparently the synergistic interaction between PAF and LPS in stimulation of IL-1 beta synthesis and release is due at least partly to synergy at the level of mRNA.

Earlier studies show that PAF, without any added co-stimulus, can stimulate IL-1 beta synthesis in THP-1 cells and in human monocytes (8,14). It is not clear if the relatively small effects of PAF alone are dependent on minute amounts of endotoxin that may be found in the delipidated BSA used as a carrier for PAF in the media, or in the fetal bovine serum. In any case, PAF alone under the conditions of these experiments does cause the synthesis (Fig. 1) and release (14) of IL-1 beta from THP-1 cells. The data in Table 1 suggest that 10 pM PAF may cause an increase in IL-1 beta synthesis in THP-1 cells by increasing IL-1 beta mRNA levels. For these same experiments, PAF had no effect

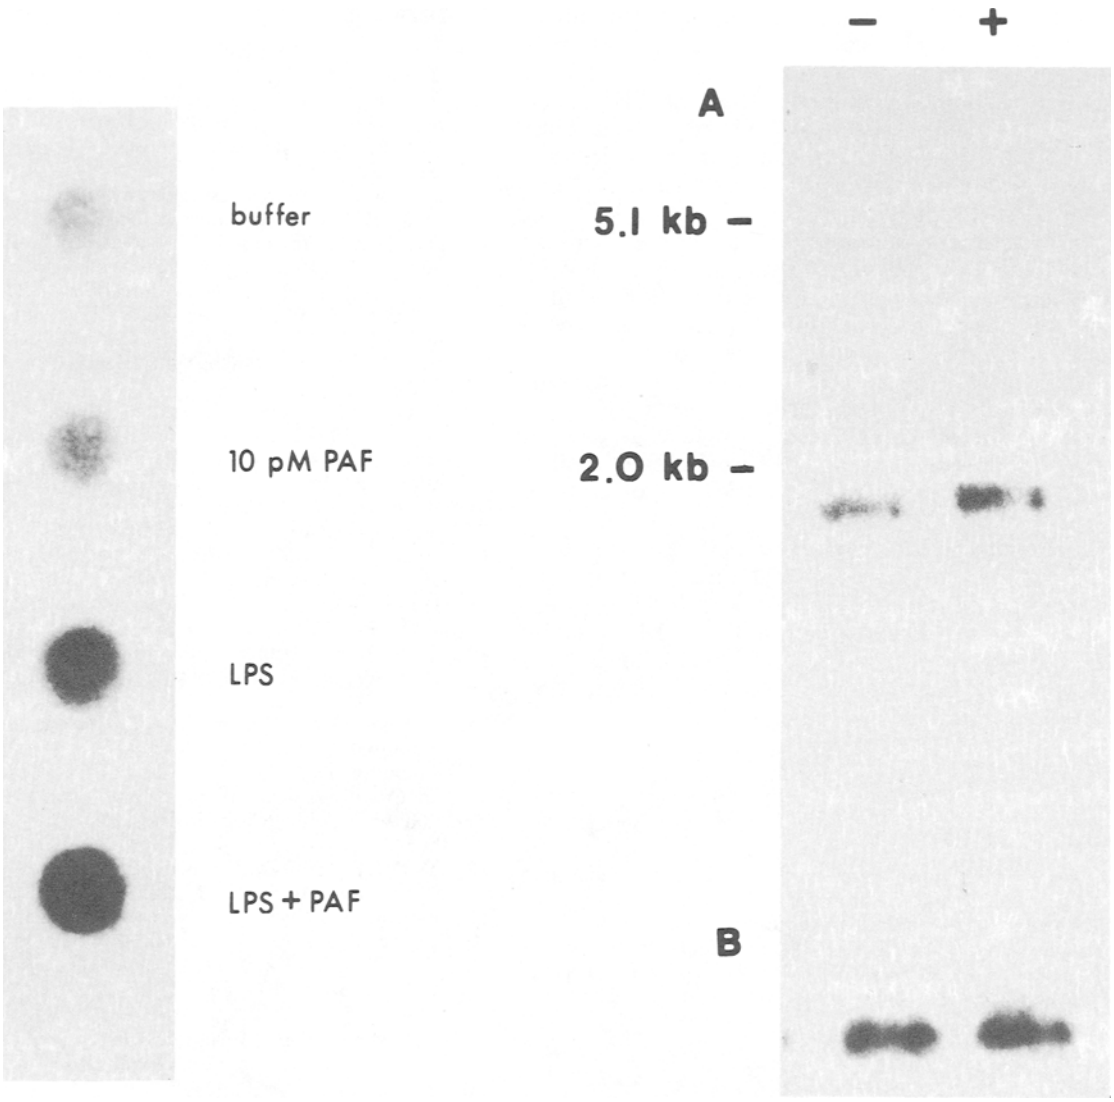

FIG. 1. Autoradiograph from a Western dot blot of THP-1 cell extracts. The THP-1 cells were incubated for 4 hr with buffer, 10 pm PAF, 0.1 μg/mL LPS or LPS + PAF, as indicated. Cell protein extracts were spotted directly on a nitrocellulose membrane for immunoassay using anti-IL-1 beta antibodies, a biotinylated secondary antibody, and [^{125}I]streptavidin.

FIG. 2. Autoradiographs of Northern blots of RNA from THP-1 cells. THP-1 cells were incubated in the presence of LPS (0.1 μg/mL), and in the absence (−) or presence (+) of PAF (10 pM) for 4 hr before the cells were harvested for extraction of RNA. The RNA (20 μg) was separated by electrophoresis on an agarose gel, transferred to a nylon membrane and hybridized with ^{32}P-labelled cDNA for (A) IL-1 beta and (B) GAPDH.

TABLE 1

mRNA on Northern Blot Autoradiographs (% of Control)[a]

Condition	IL-1 beta	GAPDH	IL-1 beta/GAPDH
Control	100	100	100[b]
+ 10 pM PAF	138[c] ± 25	95 ± 11	143[b] ± 19

[a]THP-1 cells were incubated for 4 hr before harvesting for preparation of RNA. The RNA was spotted on a nylon membrane, and probed with ^{32}P-labelled cDNA to IL-1 beta. After stripping, the blots were reprobed with labelled cDNA to glyceraldehyde-3-phosphate dehydrogenase as a control for total RNA.
[b]$P<0.05$, paired Student's t-test, n = 10.
[c]Values are means ± SEM.

on the mRNA levels for glyceraldehyde-3-phosphate dehydrogenase (GAPDH), which was used as an unregulated control. When the relative amount of GAPDH in each sample is used to normalize the mRNA levels for IL-1 beta, the resulting values should reflect the effects of PAF without the effects of variations in the amounts of RNA on the blot membrane. These values, given in the third column on Table 1, indicate again that PAF causes a significant increase in IL-1 beta mRNA levels in THP-1 cells.

PAF causes only a 40% increase in IL-1 beta mRNA levels, but this increase matches the 40% increase in IL-1 beta protein synthesis described previously for

THP-1 cells (14). This small percentage increase nonetheless can yield a biologically significant net increase in IL-1 beta protein when a co-stimulus such as LPS is present. It also should be noted that the THP-1 cell line is not as responsive to PAF as are human monocytes. PAF causes a 100–200% increase in IL-1 beta release in monocytes as compared to a 50–70% increase in THP-1 cells (8,14).

These experiments suggest that PAF may increase IL-1 beta release largely by increasing mRNA levels, and that synergy between PAF and LPS may also occur at this level. It is not clear from these experiments whether PAF increases transcription of IL-1 beta mRNA or if it decreases the rate of turnover of the IL-1 beta mRNA. For the studies with PAF alone, the extent of the effect at the mRNA level is enough to account for the increase at the protein level, so it is not likely that PAF alone affects the rate of translation.

PAF's ability to induce the production of IL-1 beta may be important to the persistent inflammation that results from administration of PAF *in vivo*. IL-1 beta can induce the synthesis of more PAF (18), thereby completing a cycle of a positive feedback loop. This positive feedback may provide sustained inflammation in the absence of any new stimulus.

[Received September 7, 1990; Revision accepted January 29, 1991]

The Effect of Dietary n-3 Polyunsaturated Fatty Acids on HDL Cholesterol in Chukot Residents *vs* Muscovites

E. Gerasimova*[a], N. Perova[a], I. Ozerova[a], V. Polessky[a], V. Metelskaya[a], I. Sherbakova[a], M. Levachev[b], S. Kulakova[b], Yu. Nikitin[c] and T. Astakhova[c]

[a]Department of Biochemistry, Institute of Noncommunicable Disease Prevention of the USSR Research Centre for Preventive Medicine, Moscow 101953, the [b]Institute of Nutrition, Moscow 109240 and the [c]Institute of Therapy, Novosibirsk 630003, USSR

Native Chukot Peninsula residents, in contrast to Muscovites, consume a diet rich in n-3 polyunsaturated fatty acids. This dietary peculiarity is reflected in differences in plasma lipid and apolipoprotein contents. The Chukot residents have lower contents of total cholesterol, triglyceride, LDL (low density lipoprotein) cholesterol and apolipoprotein B, but higher HDL (high density lipoprotein) cholesterol levels than do Muscovites. The apolipoprotein A-I levels were identical in both groups. A higher HDL cholesterol to apolipoprotein A-I ratio was determined in the coastline Chukot residents (0.52 ± 0.01) than in Muscovites (0.43 ± 0.01; $p < 0.01$). In contrast to Muscovites, the coastline Chukot residents also had higher n-3 and lower n-6 polyunsaturated fatty acid percentages in plasma and erythrocyte lipids, and lower phosphatidylcholine and higher sphingomyelin or phosphatidylethanolamine levels in HDL_{2b} and HDL_3. The higher HDL cholesterol levels in the plasma of the coastline Chukot residents appears to reflect the higher cholesterol-scavenging capacity of their HDL.

We conclude from this study that the regular consumption of dietary n-3 polyunsaturated fatty acids by the coastline Chukot residents decreased LDL cholesterol transfer from plasma to peripheral cells, and enhanced cholesterol efflux from cellular membranes toward HDL. *Lipids 26,* **261–265 (1991).**

Since the study of the effects of dietary n-3 polyunsaturated fatty acids (PUFA) on the plasma lipid content of Greenland and Danish Eskimos (1), the hypolipidemic effects of n-3 PUFA, which occur abundantly in marine organisms, have become a focus of considerable attention. Laboratory experiments and human trials have shown that seafood dietary supplements and "max-Epa" type drugs, that are rich in n-3 PUFA, decrease total cholesterol (Chol), triglyceride (TG), LDL cholesterol, and apoprotein B (apoB) contents of plasma (2–4). However, the data reported on the effects of dietary n-3 PUFA on HDL Chol levels are not consistent (3,5–7), and whether and how various n-3 PUFA supplements can be used to correct atherogenic dyslipoproteinemias remains an open question (5).

The present study was undertaken to determine the effect of dietary n-3 PUFA on lipoprotein profiles and fatty acid compositions of plasma and erythrocyte lipids of native male residents of the coastline Chucot Peninsula and of Muscovites. Both groups vary greatly in dietary n-3 PUFA consumption (8–10). Plasma Chol, TG, LDL Chol, HDL Chol, apo B and apo A-I levels were determined in both groups, and HDL phospholipid composition and plasma and erythrocyte fatty acid profiles were monitored. Erythrocytes were chosen as cellular model because their phospholipids and PUFA are known to be modulated by lipoproteins (11–13), and because the efflux of Chol from the erythrocyte membrane is known to depend on HDL lipid composition and unsaturation (14–16).

MATERIALS AND METHODS

Blood samples were obtained from 30- to 59-year-old males randomly chosen from Moscow residents (n = 650) and from coastline area residents of the Chukot Peninsula (n = 261). Plasma apolipoprotein B (apo B) and apo A-I levels were determined on 110 Muscovites and 157 Chukot residents. Fatty acid composition of plasma and erythrocytes were measured on 41 Muscovites and 61 Chukot residents. The composition of high density lipoprotein (HDL) phospholipids was analyzed in samples from 10 Muscovites and 58 Chukot residents.

Fasting blood was drawn from vein using Vacutainer tubes containing solid disodium EDTA (Sigma, St. Louis, MO; 1 mg/1 mL blood). Chol and TG levels were measured on a Technicon AutoAnalyzer-II (Technicon Ltd., Dublin, Ireland). HDL Chol was determined after heparin-manganese precipitation of low density lipoprotein (LDL) and very low density lipoprotein (VLDL) (17). LDL Chol levels were calculated as the difference between total plasma Chol content and the sum of HDL Chol and one fifth of total plasma TG (18). Lipid measurements standardizations were performed using a program available from the Center for Disease Control, Atlanta, GA (19). An electroimmunoassay was used to determine the concentrations of the major apolipoproteins, namely, apo B and apo A-I (20,21). HDL_{2b} and HDL_3 were separated by preparative ultracentrifugation at d 1.063–1.100 g/mL and d 1.125–1.210 g/mL, respectively (22). Lipids were extracted from HDL according to established procedure (23), and phospholipids were fractioned by two-dimensional thin-layer chromatography (TLC) using Solvent Systems A, chloroform/methanol/water (65:25:4, v/v/v) and B, chloroform/methanol/aqueous ammonia (14:6:1, v/v/v) (24). Lipid phosphorus was measured in each fraction (25), and the relative content of each phospholipid class was expressed as percentage of the total. Erythrocytes were treated as previously described (26). Plasma lipids (PL, Chol esters, TG) were separated by TLC on Silica Gel plates (24) using hexane/diethyl ether/acetic acid (85:15:3, v/v/v) as developing solvent; lipid fractions were scraped into tubes and methyl esters were prepared by transesterification (24).

Abbreviations: Apo A-I, apolipoprotein A-I; apo B, apolipoprotein B; Chol, cholesterol; HDL, high density lipoproteins; LDL, low density lipoproteins; MUFA, monounsaturated fatty acids; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PL, phospholipids; P/S, polyunsaturated fatty acid to saturated fatty acid ratio; PUFA, polyunsaturated fatty acids; SEM, standard error of the mean; SPH, sphingomyelin; TLC, thin-layer chromatography; TG, triglycerides; VLDL, very low density lipoproteins.

Gas-liquid chromatography of methyl esters was performed on an "Intersmat" gas chromatograph (JLD-Instruments, France) equipped with flame ionization detector and a 0.4 × 240 cm glass column with 10% Silar-10C on Chromosorb W/AW, 100–200 mesh (Serva, Heidelberg, Germany). Nitrogen was used as carrier gas at a flow rate of 40 mL/min. The temperatures of the column, the injector and the detector were held at 175°C, 230°C and 240°C, respectively. Fatty acids were identified by comparing the retention times with those of standards. Individual fatty acid levels are given as a percentage of the total.

Student's *t*-test was used for statistical data treatment. The tabulated data are given as mean ± SEM.

RESULTS

Table 1 shows data on the lipid composition of plasma of representative Muscovites (Group 1) and Chukot residents (Group 2). It is evident that the levels of plasma Chol, TG, and LDL Chol were lower in Chukot residents as compared to Muscovites, while the HDL Chol levels in Chukot residents were higher. Male subgroups which had representative plasma lipid levels (Chol, TG, HDL Chol) revealed lower apo B levels in the Chukot residents as compared to Muscovites. No differences in apo A-I levels were apparent between the two groups (Table 2). Moreover, the Chukot residents had a higher HDL Chol to apo A-I ratio (Table 2).

Dietary differences between Chukot residents and Muscovites were analyzed using a 24-hr recall method of food patterns (8). Total caloric intake was 3157 ± 82.9 kcal for the coastline Chukot residents and 2568 ± 32.6 kcal for Muscovites with respective intakes of protein of 32 ± 1.0% and 15 ± 0.1%; carbohydrates of 26 ± 1.0% and 43 ± 3.7%; and fats of 36 ± 0.9% and 38 ± 0.4%. In spite of the rather similar total fat intake by the two groups, considerable differences in the fat composition were detected. Thus, the dietary polyunsaturated fatty acid to saturated fatty acid (P/S) ratios were 0.52 and 0.31 for Chukot residents and Muscovites, respectively. PUFA sources also differed—Chukot residents consumed n-3 PUFA rich lipids from sea animals (whale, walrus, seal) and from ocean fish (salmon), while Muscovites used plant oils as the major n-6 PUFA source. Therefore, it seemed of interest to determine whether the observed differences in plasma lipid and apoprotein contents were related to the changes in fatty acid composition of plasma and erythrocyte lipids. Table 3 and Figure 1 show the composition of the major fatty acids from plasma and erythrocyte lipids. It is evident that Chukot residents, when compared to Muscovites, had lower levels of major n-6 PUFA (18:2 and 20:4) in plasma phospholipids and increased n-3 PUFA levels due to 20:5. In addition, in Chukot residents a lower content of 18:0 and higher levels of MUFA (monounsaturated fatty acids) (16:1 and 18:1) were observed in plasma phospholipids. Similar changes in PUFA composition, namely, lower n-6 PUFA levels

TABLE 1

Composition of Plasma Lipids in Muscovites and Coastline Chukot Residents[a]

Group	Chol	TG	HDL Chol	LDL Chol
	mg/dL			
Muscovites	203 ± 1.4	102 ± 2.4	53 ± 0.6	133 ± 4.1
Chukot residents	190 ± 1.5	79 ± 2.8	63 ± 1.1	115 ± 2.0
P[b]	<0.001	<0.001	<0.001	<0.001

[a] Blood samples were collected from 30- to 59-year-old men chosen randomly from the Moscow district (n = 650) and from the Chukot Peninsula (n = 261). Total plasma cholesterol (Chol), triglycerides (TG), HDL cholesterol (HDL Chol) and LDL cholesterol (LDL Chol) were determined as described in the Methods Section. Data are presented as mean ± SEM.

[b] P denotes the significance of the difference between groups according to Student's *t*-test. NS, not statistically significant (p > 0.1).

2 n=19	6.2 ± 0.26	14.2 ± 0.61	72.0 ± 4.9	132 ± 5.7	0.54 ± 0.037
3 n=11	8.9 ± 0.21	18.6 ± 0.79	77.0 ± 5.8	135 ± 7.8	0.56 ± 0.043
P 1-2		<0.001	<0.01	NS	<0.001
P 1-3		<0.001	<0.01	NS	<0.001
P 2-3		<0.001	NS	NS	NS

[a]Blood samples were collected from 30- to 59-year-old men chosen randomly from coastline Chukot residents (n = 41). HDL cholesterol (HDL Chol), apolipoprotein A-I (apo A-I) in plasma and also level 20:5 and n-3 PUFA in erythrocytes were determined as described in the Methods Section. Chukot residents were split into three groups according to the 20:5 contents in erythrocytes. Group 1 consisted of 25% of the samples with the lowest levels of erythrocyte 20:5; Group 2 consisted of 50% of the samples with medium values of 20:5. Group 3 consisted of 25% of the samples with the highest proportion of erythrocytes 20:5. Data are presented as mean ± SEM. P denotes significance of the difference between groups according to Student's *t*-test. NS, not statistically significant ($P > 0.1$).

(18:2 and 20:4) and a higher n-3 PUFA levels, mainly due to 20:5, were found in serum Chol esters and TG as well as in erythrocyte lipids (Table 3).

It should also be mentioned that the relative amounts of eicosapentaenoic acid (20:5) in erythrocytes and the HDL Chol levels considerably varied among the Chukot residents, namely from 1.3% to 10.4% and from 36 mg/dL to 126 mg/dL, respectively. To determine whether the differences in HDL Chol levels were related to the 20:5 changes in erythrocyte lipids, 41 samples obtained from Chukot residents were split into three groups according to their eicosapentaenoic acid contents. Group 1 consisted of 25% of the samples with the lowest levels of erythrocyte 20:5; Group 2 consisted of 50% of the samples with medium values for 20:5; Group 3 consisted of 25% of the samples with the highest proportion of erythrocyte 20:5. Table 4 shows that Group 3, with the highest 20:5 levels in erythrocyte lipids also had the highest HDL Chol levels. Since the apo A-I concentrations were similar in all three groups, the HDL Chol to apo A-I ratios were the highest for the subjects with the highest 20:5 contents in their erythrocyte lipids (Table 4).

We also studied the composition of HDL phospholipids, because in model systems the interaction between apo A-I and Chol was shown to depend upon HDL phospholipids (16,27). Table 5 shows that the Chukot residents, as compared to Muscovites, had lower percentage of phosphatidylcholine (PC) and higher percentage of sphingomyelin (SPH) and phosphatidylethanolamine (PE) in HDL_{2b} and HDL_3.

TABLE 5

Phospholipid Composition of HDL Subfractions in Muscovites and Coastline Chukot Residents[a]

Group	HDL Chol (mg/dL)	HDL_{2b} PC	HDL_{2b} SPH	HDL_{2b} PE	HDL_3 PC	HDL_3 SPH	HDL_3 PE
		%					
Muscovites	53 ± 2.1	75.0 ± 1.5	10.0 ± 0.5	6.6 ± 0.9	79.2 ± 2.3	9.8 ± 1.1	5.4 ± 0.3
Chukot residents	62 ± 1.9	67.8 ± 0.8	14.0 ± 0.5	9.0 ± 0.4	68.8 ± 0.8	13.1 ± 0.3	8.9 ± 0.3

[a]Blood was collected from 30- to 59-year-old Muscovites (n=10) and Chukot residents (n=58). HDL_{2b} and HDL_3 were isolated by preparative ultracentrifugation at d 1.063-1.100 g/mL and d 1.125-1.210 g/mL, respectively. Lipids were extracted from HDL_{2b} and HDL_3 according to the Folch's procedure (23), and phospholipids were separated by TLC as described in the Methods Section. Data are presented as mean ± SEM. P denotes significance of the difference between groups according to Student's *t*-test.

DISCUSSION

The present comparative study of plasma lipids of randomly chosen native coastline Chukot male residents *vs* Muscovites has demonstrated that the lower plasma total Chol content in Chukot residents is due to both lower LDL and VLDL levels, *i.e.*, the lipoprotein classes that are responsible for Chol transport into peripheral cells. This is supported by our observation that the Chukot residents had both lower lipoprotein Chol and apo B levels (Tables 1 and 2). This is consistent with the results of other studies which similarly revealed that apo B-containing lipoproteins decrease in population groups whose dietary intake includes considerable amount of seafood rich in n-3 PUFA (3,4). Considering the evidence that n-3 PUFA lowers the synthesis of apo B and VLDL in liver (2,4), one could suggest that this mechanism is essential in lowering plasma levels of apo B and TG, the main components of VLDL, and of LDL Chol with apo B as its main apoprotein component. However, a contribution from a more active Chol transport from apo B-containing to apo A-I-containing lipoproteins presently cannot be excluded as the Chukot residents as compared to Muscovites had higher HDL Chol levels without having elevated apo A-I concentrations (Table 2). This suggests that the higher HDL Chol levels in the Chukot residents are predominantly due to an increased portion of HDL particles rich in Chol.

The lipid and protein profiles observed for Chukot coastline residents and Muscovites cannot be explained merely by the differences in total daily caloric intake or in protein and carbohydrate consumption. According to Eisenberg (28), carbohydrate enrichment of the daily dietary intake resulted in a 20% increase of apo A-I and 32% increase of HDL Chol levels. The Chukot residents, consuming less carbohydrates, had the same apo A-I levels, but higher HDL Chol levels as compared to Muscovites.

The data suggest that the high intake of dietary n-3 PUFA by coastline Chukot residents could contribute to the increased Chol transport and, probably, to the increased Chol scavenging capacity of their HDL particles. Table 3 shows that the n-3 PUFA levels in PL, Chol esters, and TG of plasma and erythrocytes were higher in the Chukot residents as compared to Muscovites. It was found that plasma phospholipids from Chukot residents were enriched with MUFA and n-3 PUFA (Table 3). It had previously been demonstrated that the Chukot residents had higher 20:5 contents in HDL phospholipids as compared to Muscovites. It appears likely that accumulation of phospholipids containing MUFA and n-3 PUFA in the surface monolayer of HDL particles would increase fluidity. This, in turn, could result in a higher capacity of the particles to accept Chol.

Studies performed on model systems have demonstrated that Chol interaction with apo A-I in HDL is dependent upon the composition and the degree of unsaturation of the phospholipids involved (15,16,27). We had earlier shown (29,30) that Muscovites with higher HDL Chol levels also had higher PC levels with higher 18:2 and 20:4 contents and lower levels of SPH and PE. The Chukot residents with higher HDL Chol levels as compared to subjects with lower HDL Chol levels showed similar tendencies in changes in phospholipid composition not only in regard to n-6 PUFA, but also with respect to n-3 PUFA (20:5) (29,30). The Chukot residents had higher HDL Chol levels (Table 1) than the Muscovites that had lower PC levels and larger amounts of SPH and PE in the HDL subfractions (Table 4). The HDL phospholipids in the Chukot residents were enriched with n-3 PUFA and MUFA (Table 3), even when they had lower PC and higher PE contents as compared to Muscovites. Elevated levels of n-3 PUFA and MUFA would probably increase the fluidity of the HDL surface monolayer and thus enhance its ability to accept Chol, as is manifested in the higher HDL Chol level in the Chukot residents as compared to the Muscovites (Table 5).

We propose that the lower PC levels in HDL of Chukot residents *vs* Muscovites is due to decreased PC synthesis in the liver due to low dietary n-6 PUFA. In fact, it had been shown that the presence of n-6 PUFA and, in particular, of 18:2 in phosphatidic acid makes it a better substrate for PC synthesis (31,32).

We previously demonstrated that increased HDL Chol levels are associated with increased fluidity of the HDL surface monolayer (33), as we determined with spinlabeled probes (34) and by following changes in HDL particle molecular patterns (using fluorescent derivatives of phospholipids) (35). In addition, it has been shown that SPH and PE have a high capacity for complex formation with Chol when compared to PC (16). Therefore, we believe that the enrichment of HDL phospholipids with

n-3 PUFA ensures greater fluidity and, hence, capacity to accept Chol, and thus can explain the higher HDL Chol levels in the coastline Chukot residents as compared to Muscovites.

Moreover, n-3 PUFA enrichment of lipoprotein core lipids, namely Chol esters and TG, makes the lipoprotein a better substrate for lipoprotein lipase (36), which may explain the low plasma TG levels in Chukot residents.

The results of our study permit us to conclude that regular consumption of n-3 PUFA contributes to a decline in Chol transport to cells *via* LDL and to an increase in Chol efflux from the cells *via* HDL particles.

Rat Liver Outer Mitochondrial Carnitine Palmitoyltransferase Activity Towards Long-Chain Polyunsaturated Fatty Acids and Their CoA Esters

Grace R. Gavino and **Victor C. Gavino***
Department of Nutrition, Université de Montreal, Montreal, Quebec, Canada H3C 3J7

The activity of the overt form of rat liver mitochondrial carnitine palmitoyltransferase or CPT_0 (EC 2.3.1.21) towards different fatty acid substrates was studied. The following non-esterified fatty acids (NEFA) and their CoA esters in the presence of 1% bovine serum albumin (BSA) were tested: 16:0, 18:0, 18:1, 18:2, 18:3ω3, 20:4, 20:5ω3 and 22:6ω3. The data fit a square hyperbolic model for enzyme catalysis ($p<0.001$, non-linear regression). Asymptotic V_{max} and $K_{0.5}$, substrate concentration at one-half V_{max}, were calculated using total concentrations of acyl-CoA, or unbound concentrations of NEFA. BSA was found to act as a true substrate reservoir for NEFA in that the dissociation of the NEFA-BSA complex was 10–330 times faster than the CPT_0 reaction. Regardless of form (NEFA or CoA ester), 18:3ω3 gave the highest, while 22:6ω3 and 18:0 gave the lowest rates of acylcarnitine synthesis. Except for 18:3ω3 and 18:2, V_{max} for NEFA was generally lower than for acyl-CoA, with the greatest differences observed for 20:4, 20:5ω3 and 22:6ω3, suggesting that acyl-CoA synthesis may also be important in the control of the entry of these fatty acids into the mitochondria. The data provide an enzymatic rationale for the relatively low content of 18:3ω3 in esterified lipid.
***Lipids 26,* 266–270 (1991).**

The overt form of carnitine palmitoyltransferase (EC 2.3.1.21), or CPT_0, regulates the entry of long-chain fatty acyl-CoA into the mitochondria for β-oxidation (1–4). In a review on the partition of fatty acyl equivalents between oxidation and esterification, Zammit (5) noted that triglyceride synthesis increases upon attainment of the maximum capacity for the β-oxidation of fatty acids, indicating that CPT_0 plays a role in the control of this branchpoint (Fig. 1). Physiologically, the flux through acylcarnitine synthesis (Fig. 1) involves a mixture of different fatty acid substrates, each with potentially different kinetic properties towards CPT_0. These differences may affect the availability of the various types of fatty acids for glyceride synthesis. We therefore tested the rates of mitochondrial CPT_0-catalyzed acylcarnitine synthesis for a series of 16-, 18-, 20- and 22-carbon fatty acids both as nonesterified fatty acids (NEFA) and as acyl-CoA. Our results show that CPT_0 activity is highest towards 18:3ω3, and is relatively lower for 18:0 and the 20- and 22-carbon polyunsaturated fatty acids. By measuring the rate of dissociation of NEFA from bovine serum albumin (BSA), we further show that BSA, commonly used in assays involving lipophilic substrates, is not likely to affect NEFA-CPT_0 kinetics. Finally, the data suggest that mitochondrial fatty acyl-CoA synthetase (EC 6.2.1.3) may limit acylcarnitine synthesis from 20- and 22-carbon polyunsaturated fatty acids in NEFA form.

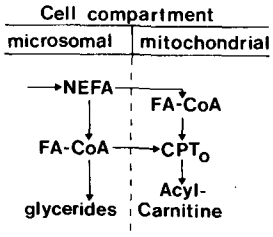

FIG. 1. Partitioning of fatty acids between acylcarnitine synthesis and glyceride formation. Acyl-CoA synthesis can occur in both microsomal and mitochondrial compartments.

MATERIALS AND METHODS

Chemicals. L-[^{3}H-*methyl*]Carnitine was from Amersham (Oakville, Ontario, Canada) and [1-^{14}C]fatty acids were from Dupont (Mississauga, Ontario, Canada). All other NEFA were from NuChek Prep (Elysian, MN). BSA (fatty acid-free), CoA esters of 16:0, 18:0 and 18:1, and other biochemicals were from Sigma (St. Louis, MO). The CoA esters of 18:2, 18:3ω3, 20:4, 20:5ω3 and 22:6ω3 were synthesized according to Singh *et al.* (6). The CoA ester of 18:1 was also synthesized for comparison with commercially obtained 18:1-CoA. The purity of the commercial and synthesized fatty acyl-CoA were assayed by thin-layer chromatography (TLC) and by gas-liquid chromatography (GLC) after transesterification to methyl esters with $NaOCH_3$. Transesterification was essentially complete as verified with synthesized [1-^{14}C]18:1-CoA. All acyl-CoA preparations used in the experiments were better than 98% pure. Affi-Gel was from BioRad (Richmond, CA). All other chemicals were reagent grade or better.

Preparation of mitochondria and CPT_0 assay. Liver mitochondria from 200–250 g male Sprague Dawley rats (Charles River, Montreal, Quebec Canada) were prepared according to McGarry *et al.* (7) using "Method C", which was reported to yield minimal contamination from other subcellular fractions. This method for obtaining a mitochondrial preparation was used without modification. The rats were fed *ad libitum* and sacrificed at 8:00 a.m. The livers were immediately perfused *in situ* with 150 mL ice-cold 0.25 M (pH 7.4) sucrose through the portal vein before homogenization. Using catalase (8) and glutamate dehydrogenase (9) as marker enzymes for peroxisomes and mitochondria, respectively, peroxisomal contamination of the mitochondrial preparation was determined to have been reduced 17–18 times relative to the crude homogenate. The conditions for the CPT_0 assay was as previously described (7), and the substrates used were either fatty acyl-CoA or NEFA. The overt CPT activity in these preparations was 93%, inhibited by 20 μM

Abbreviations: Acyl-CoA, fatty acid esters of coenzyme A; BSA, bovine serum albumin; CPT_0, overt form of mitochondrial carnitine palmitoyltransferase; GLC, gas-liquid chromatography; $K_{0.5}$, kinetic parameter designating the substrate concentration at half maximal velocity V_{max}; NEFA, non-esterified fatty acids; TLC, thin-layer chromatography.

malonyl-CoA, indicating intactness of the isolated mitochondria. When the substrate was NEFA, 12.5 μM CoA was included in the assay mixture. This concentration was found to be optimal for CPT_0 activity with NEFA. Carnitine concentration in the assay mixture was set at 0.2 mM for the following reasons: i) the K_m values for carnitine reported for the type of assay used (7) fall below 100 μM (7,10–12); and ii) Miyazawa *et al.* (12) reported that when fatty acid chain length increases from 2 to 18 carbons, the K_m for carnitine decreases from 100 μM to 40 μM. All lipid substrates were prepared from freshly opened bottles of neat fatty acid and used within 24 hr. The neat fatty acids were consistently more than 99% pure as determined by GLC. Fatty acyl-CoA or NEFA were initially dissolved at the appropriate concentrations in 105 mM Tris buffer (pH 7.4) containing 10% BSA. The exact substrate concentrations were determined by GLC after transmethylation of acyl-CoA with $NaOCH_3$ or methylation of NEFA with diazomethane. Mitochondria (0.5 mg protein) were pre-incubated for 2 min in 0.925 mL of assay mixture. The reaction was started by the addition of 75 μL substrate solution. The final concentration of the assay components (7) were: 4 mM $MgCl_2$, 15 mM KCl, 2 mM KCN, 0.25 mM glutathione, 4 mM ATP, 40 μg rotenone, 1% BSA, 105 mM Tris·HCl, 0.2 mM L-carnitine and 0.25 μCi of ^{3}H-labelled carnitine. Reactions were terminated by the addition of 1 mL of 1.2 N HCl. The radioactive acylcarnitine product was extracted with n-butanol and counted as described by McGarry *et al.* (13).

Determination of unbound NEFA in the presence of BSA. Spector *et al.* (14) used the general stepwise equilibrium model to describe the binding of the fatty acids 16:0, 18:0, 18:1 and 18:2 to BSA. We repeated and confirmed his data under conditions identical to the CPT_0 assays for selected concentrations of 18:1, using CPT_0 assay buffers at pH 7.4, 30°C, and with 1% (w/v) BSA. We therefore used the reported binding coefficients directly. We experimentally determined the BSA-binding isotherms under CPT_0 assay conditions for 18:3ω3, 20:4, 20:5ω3 and 22:6ω3, for which data are not yet available.

BSA-crosslinking to Affi-Gel 10. Two grams of BSA were incubated with 50 mL of Affi-Gel 10 in 80 mL of 0.1 N HEPES and 80 mM $CaCl_2$ at pH 7.5 for 4 hr at 4°C with gentle shaking. The reaction was stopped by an additional 1 hr incubation with 5 mL 1 N ethanolamine-HCl at pH 8.0. The Affi-Gel was washed free of excess BSA by filtration. The amount of crosslinked BSA was estimated to be 20 mg/mL Affi-Gel.

Rate of NEFA dissociation from BSA. The initial rate of dissociation of NEFA from the fatty acid-BSA complex was estimated using a method similar to that reported previously (15) which is based on the measurement of the exchange rate of NEFA between soluble and Affi-Gel-linked BSA, extrapolated to zero time. Briefly, [1-^{14}C]NEFA complexed to 150 μM BSA was added to an equal volume of crosslinked NEFA-free BSA under conditions identical to the CPT_0 assay. At short time intervals, crosslinked BSA was separated from soluble BSA by rapid filtration. The rate of disappearance of radioactivity from the filtrates extrapolated to zero time, was taken as the rate of dissociation of NEFA from the soluble NEFA-BSA complex.

Calculations and miscellaneous analytical procedures. GLC was performed on a Hewlett-Packard (Mississauga, Ontario, Canada) Model 5890 gas chromatograph equipped with a 30-m bonded phase Carbowax capillary column (Supelco, Oakville, Ontario, Canada) with H_2 as the carrier gas. Samples were injected at a split ratio of 1:50, and the column temperature was programmed from 80°C to 210°C. Detection was by flame ionization and peak areas were measured by electronic integration using a Hewlett-Packard Integrator Model 3392A. The system was calibrated using gas chromatograph standards obtained from NuChek Prep, and the internal standard technique was used for sample quantitation.

Kinetic constants were derived by non-linear regression of initial velocity data directly to a square hyperbola as described by Sagnella (16). Protein was measured according to Lowry *et al.* (17).

RESULTS AND DISCUSSION

Acylcarnitine production was linear during the incubation period (up to 6 min) at all concentrations for all substrates tested. Table 1 shows the results of the regression of data pairs of initial velocity and acyl-CoA concentration to a square hyperbola. The Michaelis-Menten model for enzyme catalysis is mathematically also a square hyperbola. The use of this function for the non-linear regression to obtain V_{max} and apparent $K_{0.5}$ is empirical and is not intended to ascribe Michaelis-Menten behavior to CPT_0. Figure 2 shows actual data points superimposed on substrate velocity plots generated from the calculated regression coefficients. Correlation coefficients ranged from 0.91 to 0.99, except for 20:4 and 22:6ω3. Although all regressions were statistically significant ($p<0.001$), we have arbitrarily chosen $r=0.80$ as the lower limit for an acceptable data fit. The low r values for 20:4 and 22:6ω3 were due in part to the high degree of data scatter for these substrates. Any sigmoidicity in the kinetic data (18) would also result in a poor fit to the hyperbolic model but we could not ascertain this from the data. Table 1 shows that the CPT_0-V_{max}, the asymptote of the square hyperbola, as well as the $K_{0.5}$, vary according to the fatty acid substrate. For example, at 10 μM total acyl-CoA, the reactivities in decreasing order are: 18:3ω3 > 18:2 > 20:5ω3 ≈ 16:0 > 20:4 > 18:1 > 22:6ω3 > 18:0. The concentration 10 μM is included within the experimental range of all the acyl-CoA substrates tested

TABLE 1

CPT_0 Apparent $K_{0.5}$ and V_{max} for Fatty Acyl-CoA Substrates[a]

Fatty acyl-CoA	$K_{0.5}$ M × 10^6	V_{max} nmol/mg × min	r	n
16:0-CoA	25 ± 8	4.6 ± 0.6	0.91	30
18:0-CoA	51 ± 12	1.9 ± 0.2	0.96	23
18:1-CoA	40 ± 7	4.4 ± 0.4	0.92	56
18:2-CoA	16 ± 3	5.0 ± 0.3	0.99	23
18:3-CoA	15 ± 3	7.1 ± 0.8	0.98	23
20:4-CoA	4 ± 2	1.5 ± 0.1	0.71	15
20:5-CoA	20 ± 4	4.1 ± 0.3	0.95	15
22:6-CoA	8 ± 3	1.2 ± 0.1	0.71	15

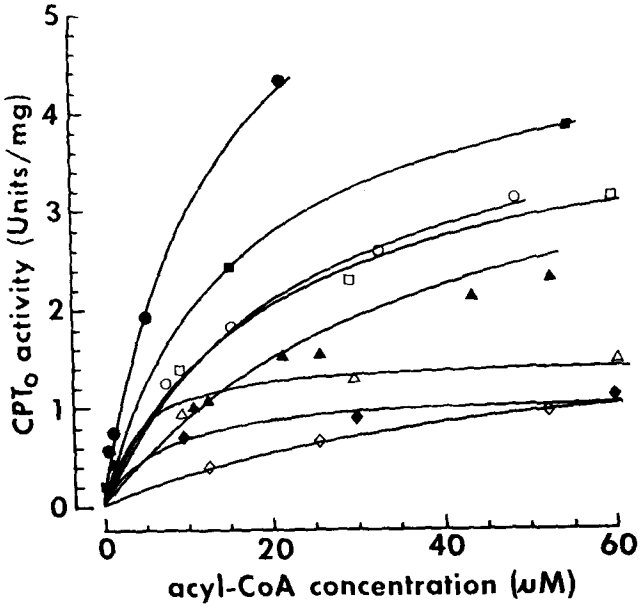

FIG. 2. CPT$_0$ initial velocity as a function of acyl-CoA substrate concentrations. Curves were generated from V_{max} and apparent $K_{0.5}$ values calculated by non-linear regression. Each point represents the average of 5 experiments. The fatty acyl-CoA substrates are: (○) 16:0; (◆) 18:0; (▲) 18:1; (■) 18:2; (●) 18:3ω3; (△) 20:4; (□) 20:5ω3; (◆) 22:6ω3.

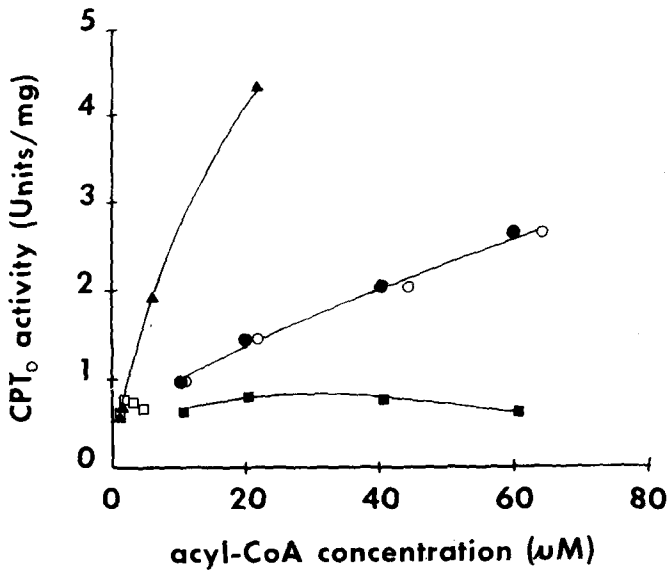

FIG. 3. Apparent differences in the CPT$_0$ substrate-velocity plots due to use of nominal concentrations of impure 18:3ω3-CoA preparations. The curves are: i) nominal (●) and analyzed (○) concentrations of 18:1-CoA; ii) commercial nominal (■) and analyzed (□) concentrations of 18:3ω3-CoA; and iii) (▲) analyzed concentration of synthesized 18:3-CoA.

and is therefore an interpolation rather than an extrapolation. The data agree with those of Borgeson *et al.* (19) for 18-carbon acyl-CoA up to 18:3ω3-CoA and provide an enzymatic rationale for the observation by Björntorp (20) and by Reid and Husbands (21) that the ketogenic potential of fatty acids increases with increasing unsaturation for the 18-carbon fatty acids. In contrast to our data, Clouet *et al.* (22) reported that CPT$_0$ activity for 18:3ω3-CoA was consistently lower than for either 18:1- or 18:2-CoA. We do not know the reason for the discrepancy. We have found, however, that all commercial preparations of 18:2-CoA and 18:3ω3-CoA we received were not more than 20% pure, analyzed immediately upon receipt (data not shown). Figure 3, for example, shows that the use of the commercial preparation of 18:3ω3-CoA at nominal concentrations yields data similar to those of Clouet *et al.* (22). Analysis of the true concentrations of the commercial 18:3ω3-CoA in the assay mixture and correction of the data for actual purity shows a different trend. In contrast, 18:3ω3-CoA that we synthesized and that we determined to be over 98% pure yields activities that are consistently higher than any of the various acyl-CoA tested. Finally, commercial 18:1-CoA that was more than 98% pure when received yielded identical results to laboratory-synthesized 18:1-CoA.

We tested the corresponding NEFA forms of the fatty acid substrates to determine whether mitochondrial fatty acyl-CoA synthetase, an obligatory enzyme when the substrate is NEFA, affects the order of reactivities determined for the analogous acyl-CoA substrates. As with fatty acyl-CoA, reaction progress curves were linear within the 6-min measurement period. The results of the regression analysis on the initial velocity-NEFA concentration data are shown in Table 2. As indicated by the correlation coefficients, the kinetic data for NEFA, similarly to those for acyl-CoA (Table 1), fit a hyperbolic

TABLE 2

CPT$_0$ Apparent $K_{0.5}$ and V_{max} for Non-Esterified Fatty Acid Substrates[a]

Fatty acid	$K_{0.5}$ M × 10^8	V_{max} nmol/mg × min	r	n
16:0	4.9 ± 0.8	3.4 ± 0.3	0.93	36
18:0	19 ± 9	1.2 ± 0.4	0.84	31
18:1	11 ± 3	3.2 ± 0.6	0.92	35

model except for 20:4. At 0.10 μM concentrations of unbound NEFA, the reactivities in decreasing order are: 18:3ω3 > 18:2 > 16:0 > 18:1 > 20:5ω3 > 20:4 > 18:0 > 22:6ω3. The comparison was made at 0.10 μM substrate, a concentration included within the range of all the NEFA tested. The results for the 18-carbon NEFA are consistent with data reported by Clouet *et al.* (22). We did not test for possible sigmoidicity; however, important aspects of this experiment are that: i) BSA-binding of NEFA was taken into account in the calculations; and ii) the kinetics of dissociation of NEFA from BSA was ruled out as a factor in overall rates of acylcarnitine synthesis. First, we verified and confirmed the data of Spector *et al.* (14) on BSA-binding of NEFA under CPT$_0$ assay conditions. We then evaluated BSA-binding for 18:3ω3, 20:4, 20:5ω3 and 22:6ω3, for which data are not available, using the

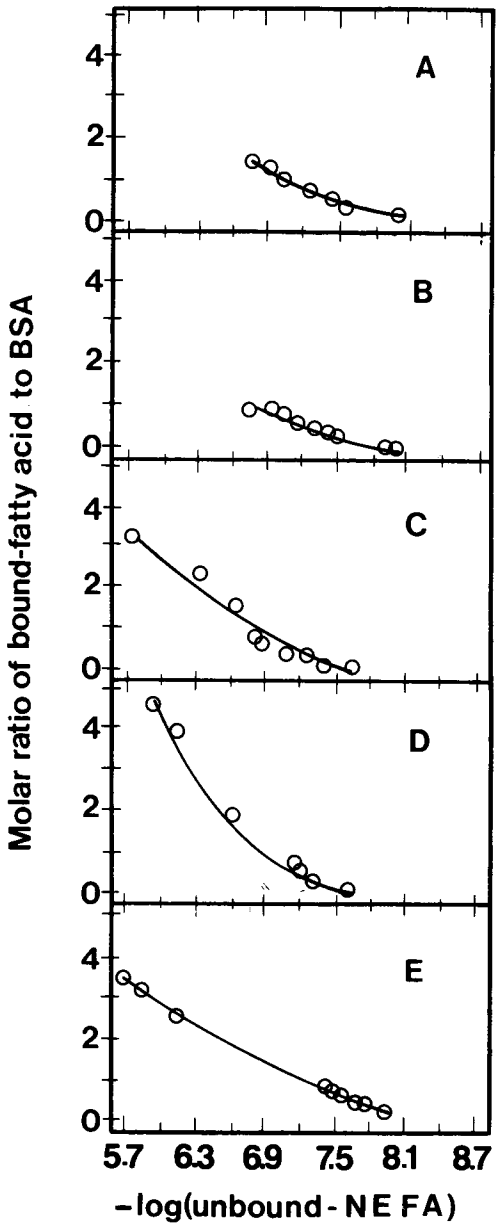

FIG. 4. Fatty acid binding to BSA. The heptane partition method was used to determine unbound-NEFA molar concentration as a function of the bound-NEFA to BSA ratio (14) for the following NEFA: A, 18:1; B, 18:3ω3; C, 20:4; D, 20:5ω3; E, 22:6ω3. Each point represents a duplicate determination.

heptane equilibrium partition method (14) under our CPT_0 assay conditions (Fig. 4). These data allowed us to use unbound NEFA instead of total NEFA concentration for the evaluation of apparent $K_{0.5}$ (Table 2). We did not take the further step of evaluating NEFA binding to mitochondrial proteins or membranes because we considered this phenomenon to be integral to acylcarnitine synthesis by intact mitochondria and, hence, physiologically relevant. Second, we verified that the dissociation rate of NEFA from the BSA complex was not limiting acylcarnitine synthesis. Table 3 shows that the rate of dissociation of NEFA from the BSA complex ranged from 10 to 330 times the rate of acylcarnitine synthesis.

In comparing kinetic data from acyl-CoA to those from NEFA experiments, it is understood that the apparent $K_{0.5}$ values for various acyl-CoA are overestimates. Therefore, in reality, the V_{max} for each of these acyl-CoA substrates is approached more rapidly than would be predicted from $K_{0.5}$ listed in Table 1. In contrast, the estimates for apparent $K_{0.5}$ for NEFA are devoid of BSA effects and is therefore more indicative of the physiological situation. The NEFA and corresponding acyl-CoA forms of either 18:3ω3 or 18:2 have similar V_{max}, suggesting that mitochondria can utilize both forms of these substrates with equal facility. We observed larger discrepancies between the acyl-CoA and NEFA forms of the 20- and 22-carbon polyunsaturated fatty acids. The ratio of V_{max} between the acyl-CoA and NEFA forms are 4.3 for 22:6ω3; 2.5 for 20:5ω3; and 1.8 for 20:4. This suggests that mitochondria use the cellular pools of the acyl-CoA and NEFA forms of these fatty acids differentially, and that mitochondrial fatty acyl-CoA synthetase, an additional obligatory enzyme in acylcarnitine synthesis from NEFA, may be responsible for this effect.

Derrick and Ramsay (23) reported that peroxisomal CPT accounts for 20% of the total activity in liver from adult fed rats. Peroxisomal contamination of our mitochondrial preparations was reduced to 6% relative to the homogenate, confirming the report of McGarry *et al.* (7). Therefore, peroxisomal contribution to the CPT activity in our final mitochondrial preparations should be no more than 1.2%. Furthermore, Clouet *et al.* (22), in comparing classical mitochondrial preparations to purified preparations devoid of peroxisomes reported that purification did not change the order of reactivities for the lipid substrates tested. Thus, it is unlikely that peroxisomal contamination was a problem in our experiments.

Figure 2 suggests that the absolute rates of acylcarnitine synthesis from the various fatty acid substrates will depend not only on substrate availability but also on the proportion of each fatty acid relative to the total substrate pool. Thus, the absolute rate of acylcarnitine synthesis from 18:3ω3 would be lower than for 16:0 if the proportion of 16:0 far exceeded that of 18:3ω3. However, when individual fatty acid pool sizes are taken into account, the turnover rate for 18:3ω3 is actually always faster than that for 16:0 within the concentration range used in our experiments. The reactivity of 18:3ω3 to CPT_0 is consistent with the well-known observation that 18:3ω3 is generally found only in minor quantities in esterified cellular lipid even when the diet contains significant quantities of this fatty acid (24).

Acylcarnitine synthesis is lowest for the 20- and 22-carbon polyunsaturated fatty acids. This is to be expected from a teleological point of view—the cell expends significant energy in chain elongation and desaturation of the shorter chain precursors of these 20- and 22-carbon polyunsaturated fatty acids and, therefore, they are to be protected from oxidation. It is understood that acylcarnitine synthesis is only one factor in the control of the hepatic flux of NEFA (Fig. 1). Other factors, such as desaturation of 18:0 to 18:1 and phospholipid synthesis from 18:1, 18:2 and the 20- and 22-carbon polyunsaturated fatty acids, may pre-empt oxidation.

The combined kinetic behavior of systems of enzymes acting on a common substrate, referred to as the branch-

TABLE 3

Comparison of CPT_0 Activity with the Initial Rates of Dissociation of NEFA from BSA

Fatty acid	FFA/BSA molar ratio	Dissociation rate (μmol/min)[b]	CPT_0[a] (μmol/min)	Ratio of rates dissociation/CPT_0
16:0	1.49	59.9 ± 15.1	1.16	51.6
16:0	0.27	19.7 ± 7.8	0.28	68.9
18:1	0.88	77.4 ± 15.4	0.77	100
18:3ω3	0.73	31.7 ± 5.4	1.81	17.5
18:3ω3	0.076	3.7 ± 0.9	0.37	9.9
20:4	0.93	39.3 ± 11.7	0.32	123
20:5ω3	1.49	74.2 ± 5.4	0.51	146
22:6ω3	0.68	29.7 ± 5.6	0.09	331
22:6ω3	0.062	1.60 ± 0.04	0.03	53.3

point effect, is beginning to be appreciated (25). An appreciation of the significance of the branchpoint effect to systems of lipid enzymes confronted with multiple analogous but kinetically different substrates requires data such as is reported in this paper. An understanding of the kinetics of such integrated lipid metabolism will provide an insight to the control of the partitioning and channelling of fatty acyl equivalents by the liver. This aspect will be pursued in future studies.

Eicosapentaenoic Acid Inhibits Tube Formation of Vascular Endothelial Cells *in Vitro*

Toshie Kanayasu[a,*], Ikuo Morita[a], Junko Nakao-Hayashi[b], Noriko Asuwa[c], Chiho Fujisawa[a], Toshiharu Ishii[c], Hideki Ito[b] and Sei-itsu Murota[a]

We previously have described a quantitative angiogenesis *in vitro* model, in which endothelial cells are cultured between two layers of type I collagen gel and become organized into tube-like structures. Using this model, the effect of eicosapentaenoic acid (20:5n-3) on tube formation was investigated. When the endothelial cells isolated from bovine carotid artery were treated for 2 days with 5 μg/mL of arachidonic acid (20:4n-6), eicosapentaenoic acid or docosahexaenoic acid (22:6n-3), these polyunsaturated fatty acids were extensively incorporated into cellular phospholipids. The content of arachidonic, eicosapentaenoic and docosahexaenoic acid increased from 9.58% to 23.29%, from 0.98% to 11.76% and from 6.88% to 18.40%, respectively. When the eicosapentaenoic acid-treated cells were cultured between collagen gels, the tube-forming ability of the cells was markedly inhibited. The inhibition was dose-dependent between 1.0 and 5.0 μg/mL of eicosapentaenoic acid. At 5.0 μg/mL of eicosapentaenoic acid the inhibition reached 76%. By contrast, arachidonic acid increased tube formation, and docosahexaenoic acid had no effect. To elucidate the mechanism of eicosapentaenoic acid induced inhibition of *in vitro* tube formation, we examined the effect of the acid on the proliferation of endothelial cells. Eicosapentaenoic acid at any dose (<5.0 μg/mL) had no effect on the proliferation of endothelial cells cultured on plastic plates without collagen gel. However, when the cells were cultured between collagen gels, eicosapentaenoic acid inhibited cell growth in a dose-dependent manner with maximum inhibition being observed at 2.5 μg/mL. These data suggest that eicosapentaenoic acid suppresses tube formation of endothelial cells, at least in part, *via* its inhibitory effect on cellular proliferation. Thus eicosapentaenoic acid may act as an endogenous inhibitor of angiogenesis under various pathological conditions, including tumor growth and chronic inflammation.
***Lipids* 26, 271–276 (1991).**

Angiogenesis, the generation of new blood vessels, is required not only in normal phenomena such as embryonic development, but also in pathological conditions such as tumor growth, proliferation of connective tissue, chronic inflammation, and in certain immune reactions (1). Therefore, it is important to find reliable and effective inhibitors to control pathological angiogenesis. A number of potential inhibitors were previously extracted from vascular tissues (2). Also protamine (3), angiostatic steroids (4,5), and a cancer-suppressor gene product (6) were reported to suppress neovascularization. However, there are few cases in which therapeutic or beneficial uses of these substances were demonstrated.

There are a number of papers, however, showing that eicosapentaenoic acid (EPA) affects various biological functions of endothelial cells. For example, EPA increased the generation of endothelium-derived relaxing factor (7) and decreased platelet-derived growth factor-like protein (8). It is commonly accepted that angiogenesis depends on endothelial cell functions, such as migration and proliferation. In the present paper, we demonstrate that EPA suppresses the tube-forming activity of vascular endothelial cells *in vitro* which may be beneficial for treatment of some angiogenic diseases.

MATERIALS AND METHODS

EPA and docosahexaenoic acid (DHA) were kindly supplied by Nippon Oil & Fat Co. (Tokyo, Japan). The purity of EPA and DHA was determined by capillary gas chromatography. EPA was 95% pure with contaminations consisting of 1.4% arachidonic acid (AA), 1.2% DHA, 1.3% 18:4, 0.7% 18:3 and 0.4% 18:2. DHA was 94.6% pure with contaminations consisting of 1.0% AA, 0.5% EPA and 3.9% 22:5. The stock solutions of EPA and DHA were kept under nitrogen gas to minimize oxidation. Vitrogen-100 was obtained from Collagen Co. (Palo Alto, CA). Eagle's minimum essential medium (MEM) was purchased from Gibco (Grand Island, NY). Fetal bovine serum (FBS) was obtained from Irvine Scientific (Santa Ana, CA).

Culture of endothelial cells and tube formation analysis. Endothelial cells were isolated from bovine carotid arteries and maintained as described previously (9). At confluence, the aortic endothelial cells showed the typical cobblestone patterned monolayer and stained positively with 1,1′-dioctadecyl-[3,3,3′,3′-tetramethylindo]carbocyanine perchlorate labeled acetylated low-density lipoprotein. Endothelial cells with passage numbers 7–14 were used for the present study.

The method used for examining tube formation of endothelial cells was previously reported (10). Briefly, the experiments on tube formation were conducted in triplicate in 12-multiwell dishes (Terumo Corp., Tokyo, Japan). Onto 0.75 mL of collagen gel, 1×10^5 endothelial cells in 2 mL of culture medium supplemented with 10% FBS were inoculated and incubated for 24 hr. Then the medium was aspirated, 0.75 mL of collagen gel was overlaid, and 2.0 mL of culture medium supplemented with 10% FBS was added. On the second day, the morphological changes were observed under a phase contrast microscope. Each well was photographed in 4 different fields at random, and tube length was measured quantitatively with an image analyzer (revealed as mm/mm^2).

*To whom correspondence should be addressed.

Abbreviations: AA, arachidonic acid; DHA, docosahexaenoic acid; EDTA, ethylenediaminetetraacetic acid; EPA, eicosapentaenoic acid; FBS, fetal bovine serum; L, lumen; MEM, Eagle's minimum essential medium; PG, prostaglandin; PGE_2, prostaglandin E_2; RIA, radioimmunoassay; TGF-β, transforming growth factor-β.

The culture medium was collected and used to determine prostaglandin E_2 (PGE_2) and 6-keto $PGF_{1\alpha}$ production. The quantitative determination of PGE_2 and 6-keto $PGF_{1\alpha}$ was carried out by the radioimmunoassay as previously reported (9,11).

Treatment of the cells with polyunsaturated fatty acids and lipid analysis. Endothelial cells at confluence in 75 cm^2 plastic dishes (Falcon, Oxnard, CA) were treated with various concentrations of polyunsaturated fatty acid in 10% FBS-MEM. The medium was changed the next day. After 48-hr treatment with polyunsaturated fatty acid, the incubation was terminated by removing the medium and by washing the monolayer with 3 mL of ice-cold phosphate-buffered saline solution. Polyunsaturated fatty acid-treated endothelial cells were harvested with 0.05% trypsin and 0.05% ethylenediaminetetraacetic acid (EDTA) solution and resuspended in 10% FBS-MEM for tube formation assay. For fatty acid analysis of cellular phospholipids, cells were harvested by scraping, and lipids were extracted by the methods of Bligh and Dyer (12). Separation of phospholipids was by thin-layer chromatography on silica gel (E. Merck, Darmstadt, Germany) using n-hexane/diethyl ether/acetic acid (90:10:1, v/v/v) as solvent. The phospholipids were transesterified in a mixture containing 1 mL of 5% HCl-methanol. After heating at 80°C for 2 hr, the fatty acid methyl esters were extracted with hexane and separated by gas-liquid chromatography using a 0.25 mm × 30 m column with Supelcowax 10 (Hewlett-Packard 5890A, Supelco, Inc., Bellefonte, PA). The temperatures of the injector, detector and column were 250°C, 270°C and 185°C, respectively.

Electron microscopy. For electron microscopic analysis, the cells in collagen culture were fixed on the second day *in situ* with 2% paraformaldehyde and 2.5% glutaraldehyde in 0.1 M cacodylate buffer (pH 7.2) at 4°C. The collagen culture was cut into small fragments perpendicular to the surface of the gel sheet, washed with 3 changes of the same buffer at 4°C, and postfixed in 1% osmium tetroxide in the same buffer at 4°C. Samples were dehydrated by serial passage through ethanol, then were transferred to n-butyl glycidylether, and embedded in Poly/Bed 812 (Polyscience Inc., Warrington, PA). Ultrathin sections were stained with uranyl acetate and lead citrate and observed under a JEM-100B electron microscope.

Effects of EPA on cell proliferation. Effects of EPA on cell proliferation were examined under two experimental conditions. Cells were grown in a monolayer culture on a plastic plate or in three-dimensional culture between collagen gels. Cells were treated with EPA as described in the tube formation analysis. In the monolayer culture, 1×10^5 cells were inoculated and incubated in the medium supplemented with 10% FBS in 12-multiwell plastic plates. On the second day after seeding, cell numbers were determined. The cell layer was washed with 1 mL of phosphate buffered saline; then a mixture of 0.4 mL of 0.05% trypsin and 0.05% EDTA was used to remove the endothelial cells. The reactions were terminated by the addition of 0.6 mL of 10% FBS. The cells were counted with a Coulter Counter ZM (Coulter Electronics LTD., Luton Beds, England). In three-dimensional culture, 1×10^5 cells were grown between collagen gels according to the methods described in the tube formation analysis. On the second day, the medium was aspirated, the gel was transferred to a test tube, and 0.5 mL of 1% collagenase (Wako Pure Chemical Industries, Osaka, Japan) in MEM was added to the gel. The mixture was then incubated at 37°C for 15 min. After vigorous pipetting, the cells were sedimented at 1000 rpm for 5 min at 4°C. Then 0.5 mL of 0.05% trypsin and 0.05% EDTA in phosphate buffered saline was added to the cell pellet, and the mixture was incubated at 37°C for 5 min. The incubation was terminated by the addition of 0.5 mL of 10% FBS. Single-cell suspensions were obtained after vigorous pipetting. The cells were sedimented at 1000 rpm for 5 min at 4°C, resuspended in 0.3 mL of 10% FBS, and counted using a hemocytometer.

Statistical analysis. The data were analyzed by Student's t-test.

RESULTS

Effects of polyunsaturated fatty acids on tube formation. Figure 1a shows a photomicrograph of bovine carotid artery endothelial cells cultured between collagen gels. Typical tubular network formation was observed on the second day. Figure 2a shows an electron photomicrograph of part of a longitudinally sectioned tube and Figure 2b shows a cross-sectioned tube composed of three cells. As shown in Figure 2a, the tubular structure had a lumen (L) composed of several endothelial cells linked to each other by some junctional complex (arrowheads) containing pinocytotic vesicles. The effects of various polyunsaturated fatty acids on tube formation were tested in this system. When the cells were treated with AA (5 μg/mL) and applied to this system, the total tube lengths increased (Fig. 1b). In contrast, as shown in Figure 1c, EPA treatment (5 μg/mL) resulted in a decrease while DHA failed to show any effect (Fig. 1d). When tube lengths were measured with an image analyzer, AA treatment was shown to increase tube formation up to 2.5 fold ($p<0.01$). EPA treatment decreased total tube lengths by 24% relative to controls. The data are summarized in Figure 3.

EPA dose response of the inhibition of tube formation. As EPA was found to have an inhibitory effect on tube formation, we examined the dose dependency of the effect. As shown in Figure 4, EPA inhibited tube formation in a dose-dependent fashion with significant inhibition occurring at concentrations over 1.0 μg/mL. The maximum inhibition of 75% occurred at 5.0 μg/mL.

The fatty acid compositions of the phospholipids from endothelial cells, which had been treated for 48 hr with 5.0 μg/mL of each of the polyunsaturated fatty acids, are summarized in Table 1. After EPA treatment, the content of EPA in cell phospholipids increased from 0.98% to 11.76%. The content of docosapentaenoic acid (22:5n-3), a product of EPA elongation, increased from 4.21% to 16.22%, while the content of AA decreased from 9.58% to 6.57%. After AA treatment of the cells, AA content increased from 9.58% to 23.29%. After DHA treatment, DHA content increased from 6.88% to 18.4%, while EPA content increased from 0.98% to 4.33%, and AA content decreased from 9.58% to 7.59%.

Effects of EPA on endothelial cell proliferation and prostaglandin (PG) production. To shed light on the mechanism of inhibition of tube formation by EPA, we tested whether EPA does affect endothelial cell proliferation and

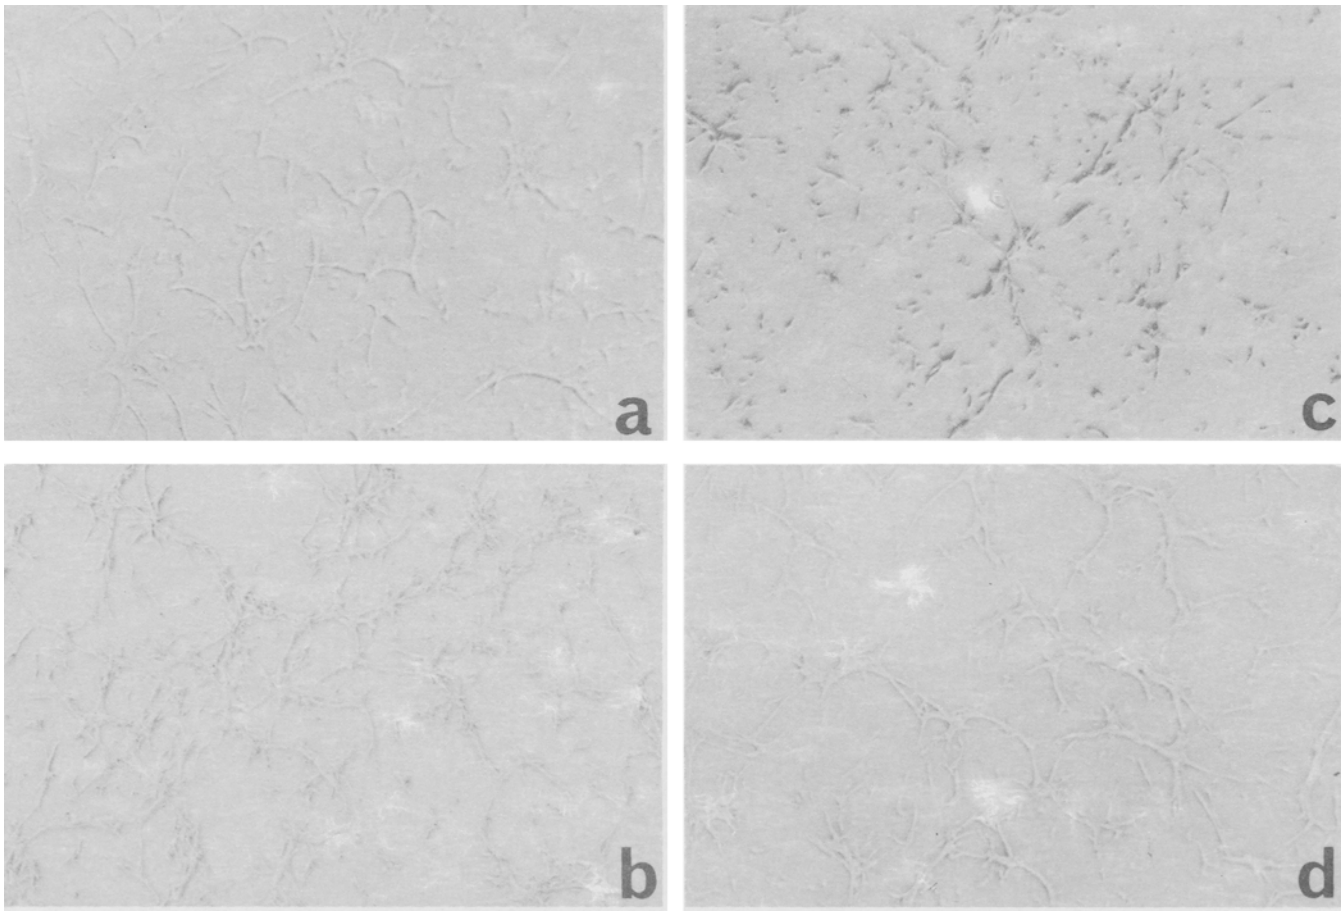

FIG. 1. ***In vitro*** **tube formation of bovine arterial endothelial cells. Microphotographs were taken on the 2nd day of incubation (phase contrast). a) Control, b) AA, c) EPA, d) DHA. Cells were treated with a fatty acid concentration of 5μg/mL.**

TABLE 1

Fatty Acid Composition of Endothelial Cells After Treatment with Polyunsaturated Fatty Acids[a]

	Fatty acid composition (%)							
	16:0	18:0	18:1	18:2n-6	20:4n-6	20:5n-3	22:5n-3	22:6n-3
Control	22.87	19.10	27.83	3.32	9.58	0.98	4.21	6.88
AA	29.13	20.40	16.88	2.97	23.29	n.d.	3.28	4.05
EPA	26.86	20.14	12.38	2.68	6.57	11.76	16.22	3.39
DHA	25.94	20.39	15.99	2.67	7.59	4.33	4.69	18.40

[a]Confluent endothelial cells were treated each with polyunsaturated fatty acid (5 μg/mL) for 48 hr, and fatty acid compositions in phospholipids were analyzed by capillary gas chromatography. The data represent the mean of duplicate assays of two (control) or three (polyunsaturated fatty acids) dishes. Values are the molar percentages of total fatty acids in the phospholipid fraction.

PG production. For this purpose, we first examined the effects of EPA on the proliferation of endothelial cells in two different systems, namely in monolayer culture on plastic plates and in three-dimensional culture between collagen gels. In the monolayer culture, EPA had no effect on cellular proliferation at any dose examined (Table 2). In the three-dimensional culture, cell proliferation was reduced in a dose-dependent manner by EPA treatment. Significant inhibition of cell growth was observed upon EPA treatment at doses over 2.5 μg/mL ($P<0.05$). Cell viability was checked by a dye exclusion method using 0.02% erythrosine-B; only a few of the cells were stained. By contrast, AA increased proliferation of endothelial cells in the three-dimensional culture. AA at 5 μg/mL stimulated cell growth 1.7-fold over controls (from $1.50 \pm 0.15 \times 10^5$ to $2.37 \pm 0.03 \times 10^5$, $P<0.01$).

Next, we examined the effects of pretreatment with EPA on PG production in three-dimensional culture,

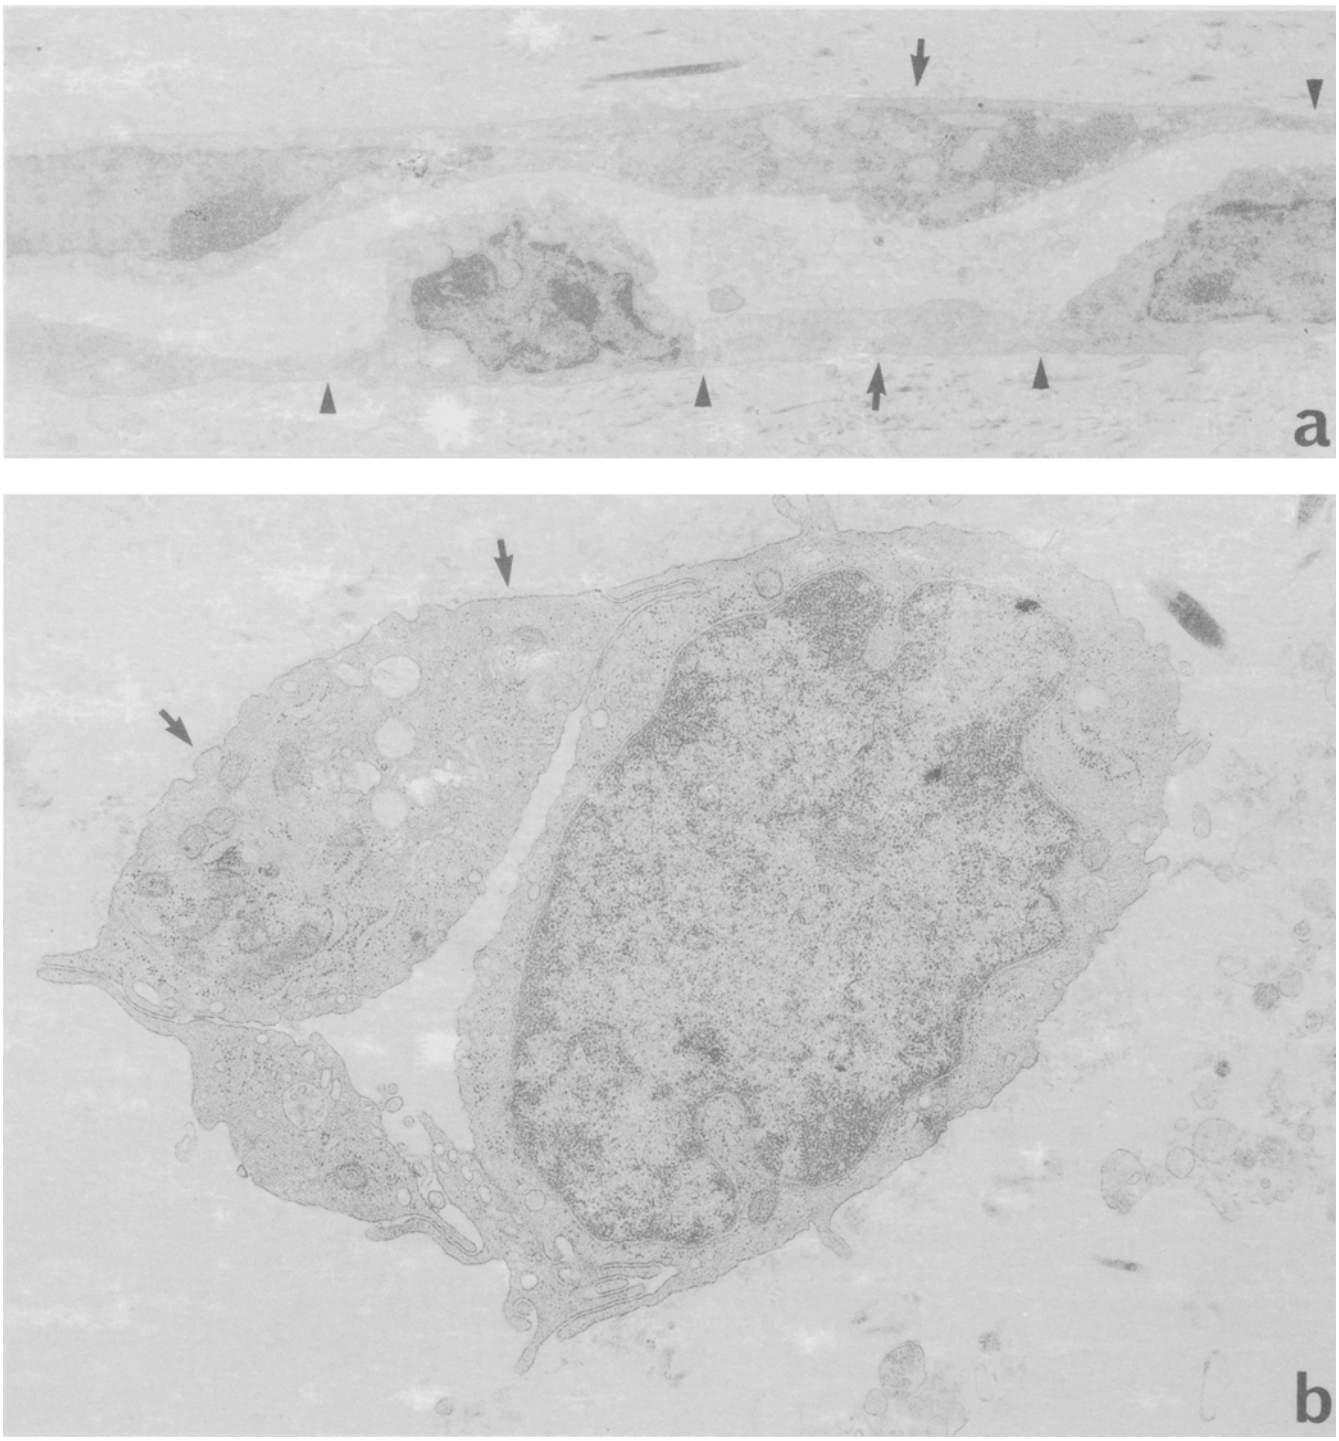

FIG. 2. Panel (a) : Part of a longitudinally sectioned tube on the 2nd day of culture between collagen gels. Endothelial cells are arranged around the narrow lumen (L) by overlapping cells (arrowheads). A number of pinocytotic vesicles are seen at the luminal side of the cells. The arrow indicates basal lamina-like material (× 12600). Panel (b) : A cross-sectioned endothelial cell tube composed of three cells. Pinocytotic vesicles are present in the peripheral part of the cells. Thin basal lamina-like material (arrows) is seen between the abluminal side of the endothelial cells and the collagen gel(× 20000).

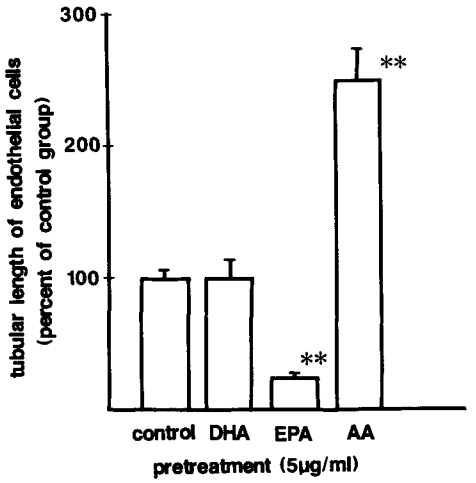

FIG. 3. Effects of EPA, DHA and AA on tube formation (image analyzer). Culture conditions were identical to those given in the legend of Figure 1. Each bar represents the mean value and SE (** P<0.01) of 4 analyses performed on 3 individual wells (n=12).

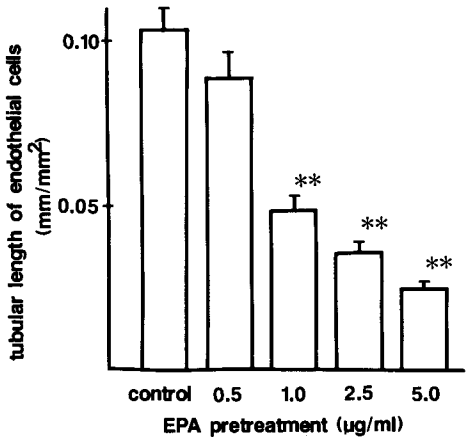

FIG. 4. Dose-dependency of the inhibitory effect of EPA on tube formation (image analyzer). Culture conditions were identical to those given in the legend of Figure 1. Each bar represents the mean value and SE (** P<0.01) of 4 analyses performed on 3 individual wells (n=12).

TABLE 2

Effects of EPA on the Proliferation of Endothelial Cells Grown in Monolayer or Three-Dimensional Cultures[a]

EPA concentration μg/mL	Cell number (× 10^5/well)	
	Monolayer culture[b]	Collagen gel culture[c]
0	6.94 ± 0.27	1.90 ± 0.15
0.5	6.54 ± 0.32	2.37 ± 0.17
1.0	6.01 ± 0.33	1.73 ± 0.18
2.5	6.72 ± 0.27	1.10 ± 0.17[d]
5.0	6.69 ± 0.46	1.13 ± 0.22[d]

[a]Data represent mean ± SE for three individual values.

[b]Cells treated with EPA were inoculated at the density of 1 × 10^5 cells/well in a plastic dish and incubated for 2 days.

[c]Cells treated with EPA were inoculated at the density of 1 × 10^5 cells/well onto collagen gel. After 1 day of incubation the cells were overlaid with collagen gel and incubated for another 2 days.

[d]Significantly different from the control, P<0.05.

TABLE 3

Effects of AA and EPA Treatment on the Release of PG from Endothelial Cells in Three-Dimensional Culture[a]

	6-keto $PGF_{1\alpha}$ (ng/mL)	PGE_2 (pg/mL)
Control	0.63 ± 0.16	13.26 ± 0.98
AA (5 μg/mL)	0.94 ± 0.17	14.06 ± 0.36
EPA (5 μg/mL)	0.72 ± 0.24	12.68 ± 0.27

[a]Cells treated with AA or EPA were inoculated at the density of 1 × 10^5 cells/well onto collagen gel. After 1 day of incubation, the cells were overlaid with collagen gel and incubated for another 2 days. On the second day, the medium was collected and 6-keto $PGF_{1\alpha}$ and PGE_2 were determined by radioimmunoassay (RIA). The data represent mean ± SE of ten (control) or five (polyunsaturated fatty acids) wells.

because some prostaglandins are known to stimulate angiogenesis (13,14). On the second day in three-dimensional culture, medium was collected and used to measure PGE_2 and 6-keto $PGF_{1\alpha}$ levels. As shown in Table 3, EPA-treated cells failed to decrease the release of both PG. AA treatment also failed to affect the level of both PG in the three-dimensional culture, but stimulated the release of 6-keto $PGF_{1\alpha}$ in the monolayer culture on plastic plates (data not shown).

DISCUSSION

It is of pathological importance that neovascularization occurs in processes such as solid tumor growth, microangiopathy, inflammation, and others. Therefore, many investigators have been searching for effective inhibitors to control these pathological phenomena. For example, D-penicillamine and gold compounds, therapeutic drugs for rheumatoid arthritis, were reported to inhibit angiogenesis (15,16). It has also been reported that fish oil ingestion resulted in the alleviation of subjective symptoms of active rheumatoid arthritis (17), and that the growth of some transplanted tumors was inhibited in rats given fish oil (18). Both diseases are accompanied by angiogenesis, and the improvement of symptoms may be due to the inhibitory effect of fish oil on neovascularization. The present data, which show that EPA inhibits *in vitro* angiogenesis, support this possibility. The mechanism of the inhibitory effect of EPA on tube formation *in vitro* still remains unclear. It is commonly accepted that several processes are essential for neovascularization, namely destruction of basement membrane by proteases, and migration and proliferation of endothelial cells and rearrangement of the tube structure. We therefore examined the effects of EPA on endothelial cell proliferation and migration. It is of interest that EPA treatment did not inhibit cell proliferation in the monolayer culture, but inhibited it in the three-dimensional collagen culture. This phenomenon was also observed with the transforming growth factor (TGF)-β, one of the well known angiogenic factors *in vivo*. Madri *et al.* (19) reported that TGF-β inhibited endothelial cell proliferation in monolayer culture; however, in three-dimensional culture TGF-β did not inhibit cell proliferation, but elicited rapid and extensive tube formation. Therefore, EPA inhibition on tube formation may be due to its effect on endothelial cell

proliferation. However, the minimum effective dose of EPA on cell proliferation was higher than that on tube formation, *i.e.*, 2.5 μg/mL and 1.0 μg/mL, respectively. It is therefore suggested that mechanisms other than the inhibition of cell proliferation may be involved in the inhibition on tube formation by EPA. However, we found no inhibitory effect of EPA on migration of endothelial cells (data not shown). Reich *et al.* (20) reported that EPA reduced invasive and metastatic activities of malignant tumor cells by a decrease in collagenase production. Therefore, specific changes in protein synthesis by EPA treatment cannot be ruled out. In contrast to EPA, AA stimulated tube formation (Fig. 1b and 3). In our previous paper (10), we reported that PGE_2 as well as leukotriene C_4 had stimulatory effects on tube formation of endothelial cells. Ohtsu *et al.* (13) reported that PGI_2 also stimulated angiogenesis in chicken chorioallantoic membranes (13). Therefore, we examined whether the inhibitory effect of EPA on tube formation was due to the inhibition of PG production. As shown in Table 3, however, the pretreatment of EPA as well as AA had no effect on PGE_2 and PGI_2 production in the three-dimensional culture. The data indicate that the inhibitory effect of EPA on tube formation might not be connected with PG production. Further experiments to elucidate the mechanism of *in vitro* inhibition of tube formation by EPA are required.

Recent studies have shown that the growth inhibitor of vascular endothelial cells *in vitro* also suppresses angiogenesis *in vivo*. For example, Maione *et al.* (21) reported that platelet factor-4 inhibited cell proliferation *in vitro* and also suppressed angiogenesis *in vivo*. We plan to examine the effects of EPA on angiogenesis *in vivo*.

ACKNOWLEDGMENTS

The authors would like to thank Dr. M. Miyajima and Dr. M. Kubota for their kind advice on lipid analysis and gas chromatography. We also thank Dr. T. Toyoda of The University of Electro-Communications, Tokyo, Japan, for his help with the English.

Thermal Adaptation in Biological Membranes: Functional Significance of Changes in Phospholipid Molecular Species Composition

Jeffrey R. Hazel*, E. Eugene Williams, Rochelle Livermore and **Nancy Mozingo**
Department of Zoology, Arizona State University, Tempe, Arizona 85287

Quantities of 1-palmitoyl 2-docosahexaenoyl phosphatidylcholine (16:0/22:6-PC or PDPC) increase from 24 to 40 weight percent as a consequence of cold acclimation in mitochondrial membranes of rainbow trout liver (*J. Comp. Physiol. 156,* 665–674, 1986). The present study was undertaken to assess the impact of such a large change in the proportions of a single molecular species on the fluidity, lateral packing (as sensed by phospholipase A_2), and permeability of biological membranes. These properties were examined in multilamellar liposomes prepared from binary mixtures of dipalmitoyl phosphatidylcholine (DPPC) and PDPC in proportions increasing from 10 to 40 mole% PDPC. Glucose permeability was positively correlated with both assay temperature and PDPC content. The temperature dependence of Na^+ permeability declined steadily as the mole fraction of PDPC increased; consequently, sodium permeability was positively correlated with PDPC content at 5°C, but inversely correlated at 20°C. Phospholipase A_2 activity was independent of both assay temperature and vesicle composition. Vesicles of all compositions displayed a single transition in the temperature dependence of 1,6 diphenyl-1,3,5-hexatriene (DPH) fluorescence polarization, which shifted to lower temperature and broadened as proportions of PDPC increased. At temperatures below the transition, fluidity was positively correlated with the mole fraction of PDPC, but interfacial and deeper regions of the bilayer were affected differently by variations in PDPC content. Nonelectrolyte permeability was the only index of membrane structure or function to be significantly correlated with the fluidity of the bilayer interior. The tendencies of PDPC to both fluidize the membrane and to reduce the temperature sensitivity of electrolyte permeation may promote the adaptation of membrane function to low temperature.
***Lipids 26,* 277–282 (1991).**

Temperature acclimation in biological membranes of poikilotherms is mediated, in part, by changes in the molecular species composition of phospholipids. Growth at cold temperature generally promotes the replacement of phospholipid species possessing short-chain mono- and dienoic fatty acids with species bearing long-chain polyunsaturated fatty acids (PUFA) (1). The retailoring of membrane lipid composition permits the physical properties of structural lipids to be matched to the prevailing ambient temperature and provides a mechanism by which thermal compensation (a degree of temperature independence in fully-acclimated animals) of membrane fluidity (*i.e.,* homeoviscous adaptation) and function are attained in a fluctuating thermal environment (2).

We have shown previously that the complex patterns of acclimational change in fatty acid composition of trout hepatocyte membranes can be accounted for by adjustments in the abundance of relatively few molecular species (1). Most strikingly, the proportions of 1-palmitoyl-2-docosahexaenoyl phosphatidylcholine (16:0/22:6-PC or PDPC) increased dramatically following cold acclimation in both mitochondrial (from 24 ± 1.9 to 38 ± 1.3%) and plasma membranes (from 28 ± 1.9 to 38 ± 2.2%). In addition, didocosahexaenoyl species (DDPC) account for from 15% to 20% of the molecular species of phosphatidylethanol (PE) and phosphatidylserine (PS), respectively, in brain phospholipids of trout acclimated to 4–6°C (3). These data suggest that modulation of the content of molecular species of phospholipid enriched in 22:6 (such as PDPC) may be an important mechanism of thermal adaptation and provide the basis for thermal compensation of membrane function (1).

Although PDPC is highly unsaturated, its impact on membrane organization and function is difficult to predict *a priori* because significant changes in the level of fatty acid unsaturation are not necessarily reflected in altered physical properties (4). For example, the chain melting point of PDPC (−12°C) is almost identical to that of 16:0/16:1-PC (−10°C) (5), perhaps due to the tendency of 22:6 to adopt a helical or 'angle-iron' conformation, with a consequent reduction in cross-sectional area and effective chain length (6). Furthermore, since all PUFA are fluid at temperatures well below those normally encountered by biological systems (7), the particular advantages imparted by selective enrichment with PDPC are not evident.

Consequently, the present study was undertaken to explore the physical and functional consequences of changes in the proportions of PDPC in liposomes of defined chemical composition. Physical properties were assessed by measurements of i) membrane fluidity [fluorescence polarization of diphenylhexatriene (DPH)] fluorescence polarization; and ii) the activity of phospholipase A_2 from *Crotalus atrox.* Passive permeability to both electrolytes (Na^+) and nonelectrolytes (glucose) was employed to assess membrane function. These properties were studied in two-component liposomes of dipalmitoyl phosphatidylcholine (PC) (DPPC; 16:0/16:0-PC) and PDPC mixed in proportions that match and extend the range of PDPC content encountered in hepatocyte membranes of thermally-acclimated trout (1). The results identify several features of membranes containing elevated proportions of PDPC that we consider to be cold adaptive.

MATERIALS AND METHODS

Materials. DPPC was obtained from Sigma Chemical Co. (St. Louis, MO) and used without further purification; thin-layer chromatography (see below) revealed no

*To whom correspondence should be addressed.

Abbreviations: DDPC, didocosahexaenoyl phosphatidylcholine; DPH, 1,6-diphenyl-1,3,5-hexatriene; DPPC, dipalmitoyl phosphatidylcholine; HEPES *N*-[2-hydroxyethyl]piperazine-*N'*-[2-ethansulfonic acid]; LPC, lysophosphatidylcholine; PDPC, 1-palmitoyl 2-docosahexaenoyl phosphatidylcholine; PE, phosphatidylethanolamine; PS, phosphatidylserine; PUFA, polyunsaturated fatty acid; SPLV, stable, plurilamellar vesicles.

detectable levels of lysophosphatidylcholine (LPC) and fatty acid analysis confirmed the acyl chain composition. [^{3}H-*methyl*]DPPC (60 Ci/mmole, NET-654) and $^{22}Na^+$ (946 mCi/mmole, NEZ-081) were products of New England Nuclear (Boston, MA); [U-^{14}C]glucose (270 mCi/mmole) was from Amersham (Arlington Heights, IL). PDPC was from Avanti Polar Lipids (Pelham, AL) (results of phospholipase A_2 digestion indicated that >97% of the 22:6*n*-3 was located at the *sn*-2 position). Phospholipase A_2 was purified from the venom of *Crotalus atrox* (Sigma) as described by Wells and Hanahan (8). Diphenylhexatriene (DPH) was from Molecular Probes (Eugene, OR). Spectrapore dialysis tubing (12–14,000 MW cutoff) was obtained from American Scientific Products (McGaw Park, IL). Organic solvents were freshly redistilled prior to use (9). All other chemicals were of analytical grade and aqueous solutions were prepared in glass-distilled, deionized water. Silica gel G and Ready-Safe™ liquid scintillation cocktail were from Sigma and Beckman (Fullerton, CA), respectively.

Liposome preparation. Stable, plurilamellar vesicles (SPLV) were selected for studies of solute permeation because of their stability, uniform solute distribution, and large entrapped solute volumes, and were prepared as described by Gruner *et al.* (10). SPLV containing 10, 20, 30 and 40 mole% PDPC in DPPC were prepared by drying a total of 25 mg of lipid in $CHCl_3$ solution under a stream of nitrogen and redissolving the residue in 5 mL of diethyl ether. After adding 0.3 mL of aqueous buffer (10 mM HEPES, pH 7.4, containing 72.5 mM of both NaCl and KCl—buffer A), the ether was removed under a stream of nitrogen as the mixture was gently agitated in a bath-type sonicator. Temperature was maintained at 45°C throughout the liposome preparation to facilitate vesicle formation by DPPC. The resulting paste was resuspended in 2.0 mL of buffer A and allowed to equilibrate at room temperature for 2 hr while gently shaken. All preparative steps were performed under a nitrogen atmosphere. Finally, the SPLV preparation was diluted with an additional 3 mL of buffer A and collected by centrifugation at 10,000 × *g* for 10 min. The resulting SPLV pellet was then washed an additional two times before being resuspended in 16 mL of buffer A. Vesicles of all composition behaved as simple osmometers in concentrations of KCl ranging from 50–400 mOsm and displayed similar optical properties at 520 nm, suggesting that they were of similar size, a conclusion consistent with the small effect of variations in acyl chain length (>C_{15}) on the size of multilamellar vesicles (11).

Fluorescence polarization. The fluorescent probe 1,6-diphenyl-1,3,5-hexatriene (DPH; 2 mM in tetrahydrofuran solution) was added to SPLV at a final probe-to-phospholipid molar ratio of 0.001. Following incubation at room temperature for 1 hr (under nitrogen), steady state depolarization of fluorescence was monitored employing a Perkin-Elmer (Norwalk, CT) LS-50 luminescence spectrophotometer. Excitation and emission monochromators were set at 356 and 430 nm, respectively. The temperature of the cuvette contents was varied by means of a water-jacketed cell holder and monitored to within ± 0.1°C. Fluidity as assessed by the fluorescence polarization of DPH reflects "the rate and extent of phospholipid acyl chain excursion away from some initial chain orientation during the lifetime of the fluorescence excited state" and does not imply isotropic probe motion in an isotropic liquid hydroarbon bilayer (12).

For establishing correlations between the fluidity of vesicle lipids and various indices of membrane function, polarization data were expressed in terms of an anisotropy parameter (Eq. [1]). This parameter has been shown to be a useful indicator of relative changes in fluidity (13).

$$\text{Anisotropy Parameter} = [(r_0/r)-1]^{-1} \qquad [1]$$

In equation [1], r is the fluorescence anisotropy and r_0 is the limiting value of r at infinite viscosity. A value of 0.395 was employed for r_0 of DPH (12).

Assay of phospholipase A_2 activity. For assays of phospholipase activity, 10 μCi of [^{3}H]DPPC in chloroform was added to 25 mg of nonradioactive phospholipid prior to removal of the chloroform. A sufficient volume of 100 mM $CaCl_2$ was then added to the final resuspension of SPLV to bring the concentration in the reaction mixture to 1.6 mM. The reaction was initiated by the addition of 7 μg of purified phospholipase to an SPLV suspension containing 5 mg of phospholipid in a total volume of 3.0 mL. The reaction was stopped after 15 min by transferring triplicate (0.5 mL) aliquots of the reaction mixture into 2 mL of methanol/chloroform/water (2:1:0.8, v/v/v). Lipids were extracted by the procedure of Bligh and Dyer (14) and total lipid extracts spotted onto 500-μm plates of silica gel G (prerun in hexane/acetone, 75:25, v/v, and preactivated at 110°C for 1 hr) and developed in $CHCl_3$/MeOH/H_2O/NH_4OH (120:75:6:2, by vol). Spots were visualized with iodine vapor and regions corresponding to authentic standards of PC and LPC were scraped into liquid scintillation vials. Radioactivity was determined by liquid scintillation counting (Beckman LS-7000) employing Ready-Safe™ scintillation cocktail. CPM were converted to DPM by quench correction.

Determination of vesicle permeability (15). For determination of vesicle permeabilities, the aqueous buffer added to the ether solution of phospholipid contained either 8 μCi of ^{22}NaCl or 2 μCi of [^{14}C]glucose (at a total glucose concentration of 5 mM). After washing (in nonradiolabeled medium), the SPLV suspension (0.60 mL) was pipetted into dialysis bags which were then placed in medium (1.3 mL) of a composition identical to the vesicle contents except for the absence of isotope. The appearance of radioactivity in the medium outside the bag was determined in 100 μL aliquots by liquid scintillation counting. The initial rate of isotope diffusion (v_0) from the interior of the vesicles to the medium outside the dialysis bag was computed using the KINFIT computer program of Knack and Rohm (16). No hydrolysis of PC to LPC was detected during the first 6 hr of these experiments; later sampling times were not assayed for LPC content.

Statistics. The statistical significance of experimental treatments (assay temperature and vesicle composition) was established by one-way analysis of variance. Differences between means (in vesicles of differing composition at a single assay temperature or of single composition at variable assay temperature) were tested employing an independent *t*-test. All statistics were computed using the ABSTAT™ (Anderson-Bell, Parker, CO) statistical package.

RESULTS

Vesicle permeability. As illustrated by representative time course data obtained at 25°C (Fig. 1), solute efflux for both Na^+ and glucose increased steadily for nearly 9 hr, before declining significantly at 20 hr. Similar kinetics were observed at lower assay temperatures (data not shown). Solute effluxes (used as an index of bilayer permeability) reported in subsequent figures are expressed as the initial rate of efflux computed as a percentage of the initially trapped radioisotope.

Vesicle permeability to glucose (Fig. 2, top) increased both as a function of rising temperature and increasing content of PDPC. The latter trend was significant at all assay temperatures above 10°C. The temperature dependence of glucose permeability (*i.e.*, the slope of Arrhenius plots of v_0 *vs* 1/°K, data not shown), however, was not significantly influenced by PDPC content and activation energies ranged between 9–13 kcal/mole.

Patterns of sodium ion permeability were complex (Fig. 2, bottom) and varied with the temperature range. At 5°C, Na^+ permeability was positively correlated with the content of PDPC. However, at higher assay temperatures (20° and 25°C), Na^+ efflux was inversely correlated with PDPC content. Consistent with this pattern, the temperature dependence of Na^+ permeation was monotonically reduced as a function of PDPC content (Fig. 3). Activation energies for Na^+ permeation varied from 16 kcal/mole at 10% PDPC to 3.6 kcal/mole at 40% PDPC (intermediate values were 9.6 and 7.0 kcal/mole for 20 and 30% PDPC, respectively).

Phospholipase A_2 activity. Phospholipase A_2 from *Crotalus atrox* was employed as a probe of membrane organization since the activity of this enzyme has been shown to depend on the lateral packing of bilayer

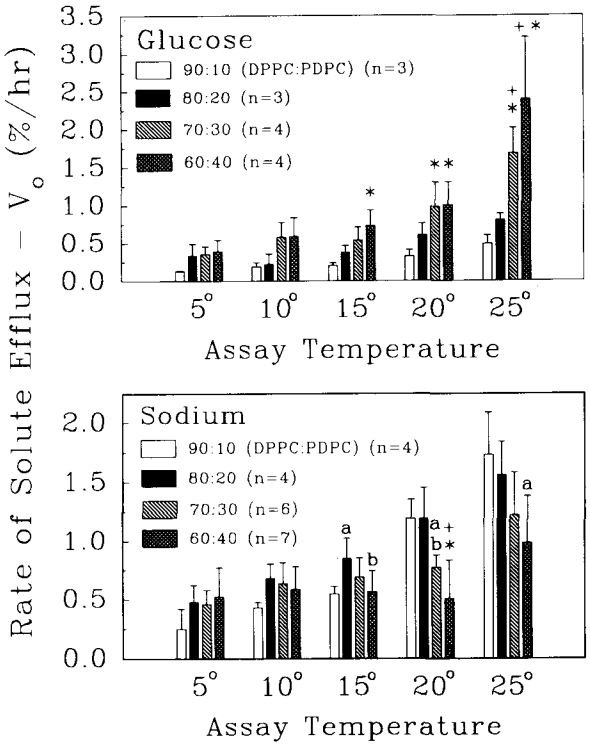

FIG. 2. Dependence of solute efflux (top, glucose; bottom, Na^+) from stable plurilamellar vesicles on assay temperature and vesicle composition. Results are presented as mean ± SD. An asterisk indicates a significant difference ($p < 0.05$) between the designated mean and vesicles comprised of 90:10 DPPC/PDPC; a plus sign indicates a significant difference in comparison to vesicles comprised of 80:20 DPPC/PDPC. Means indicated by an a or b are marginally ($0.10 > p > 0.05$) different from vesicles of 90:10 or 80:20, respectively.

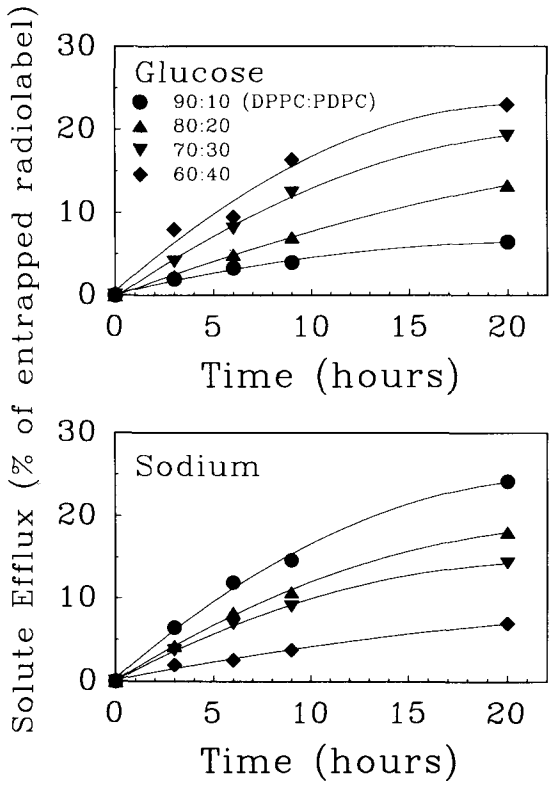

FIG. 1. Time course of solute efflux (top, glucose; bottom, Na^+) from stable plurilamellar vesicles comprised of binary mixtures of DPPC/PDPC. Results of a single typical experiment; assay temperature, 25°C.

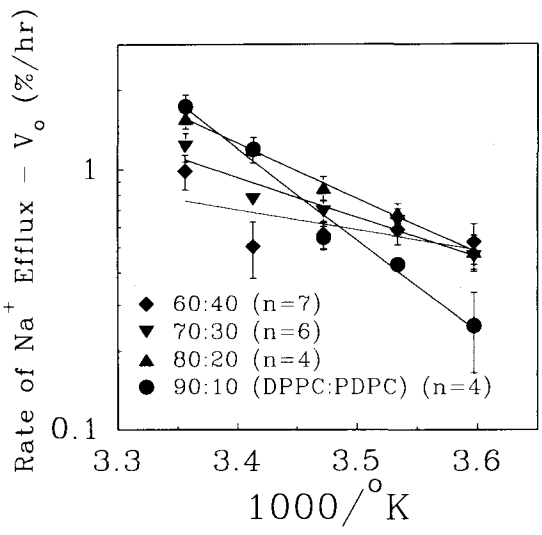

FIG. 3. Arrhenius plots for rates of Na^+ efflux from plurilamellar vesicles of DPPC/PDPC. Data are presented as mean ± SEM (n = 5). Least-square linear regression lines were calculated by SigmaPlot™ (Jandel Scientific, Corte Madera, CA).

phospholipids (17). Under the assay conditions adopted, the amount of LPC formed from vesicle preparations increased with both time and enzyme concentration (Fig. 4, top). Based on these observations, an enzyme concentration of 7 μg/assay and a time of 15 min were employed for the routine assay of phospholipase A_2 (PLA_2). PLA_2 activity was not significantly influenced by temperature in the range from 5–25°C (Fig. 4, bottom). Neither did activity of PLA_2 vary consistently with vesicle composition. Although there was a tendency for activity to decline with increasing contents of PDPC between 10 and 30%, at 40%, activity did not differ significantly from the 10% value. Consequently, PLA_2 displayed minimal activity in vesicles comprised of 30% PDPC at all assay temperatures (Fig. 4, bottom).

Fluorescence polarization measurements. The steady-state fluorescence polarization of DPH was strongly influenced by assay temperature in vesicles of all compositions (Fig. 5, top). A single transition was observed in all cases; however, the midpoint of the transition decreased (being 41.5°, 39°, 37°, 33°, and 32°C for vesicles containing 0, 10, 20, 30 and 40% PDPC, respectively) and the range of the transition broadened (from 2–3°C to 20°C) with increasing amounts of PDPC. In addition, the steady state polarization of DPH fluorescence declined as a linear function of PDPC content (up to 40%) at temperatures below 25°C (Fig. 5, bottom) and was negatively correlated with PDPC levels in all temperature ranges.

DISCUSSION

Correlations between acyl chain unsaturation and various indices of membrane function, including nonelectrolyte permeability (18), rates of cell growth (19), and rates of membrane-associated enzyme activities (20,21), have been reported. Furthermore, changes in acyl chain unsaturation generally alter membrane fluidity (22), and thus may contribute to the regulation/modulation of those membrane activities that are fluidity-dependent, including lipid (23) and water (24) permeabilities, and rates of both Na^+/H^+ exchange (25) and Ca^{++} transport in the sarcoplasmic reticulum (26). However, the relationship between the degree of acyl chain unsaturation and the physical properties of membrane lipids is not a simple function of double bond content (4). For example, whereas the melting point of dieicosanoyl PC (20:0/20:0-PC) is lowered 50°C by the introduction of a single double bond (20:0/20:1-PC) and reduced an additional 22°C by a second double bond (20:0/20:2-PC), further increases in unsaturation (in the form of 20:0/20:3-PC or 20:0/20:4-PC) have no significant additional effect on melting behavior (27). Furthermore, anomalous physical properties frequently emerge at extreme levels of acyl chain unsaturation. For example, 16:0/18:3-PC occupies a greater molecular area

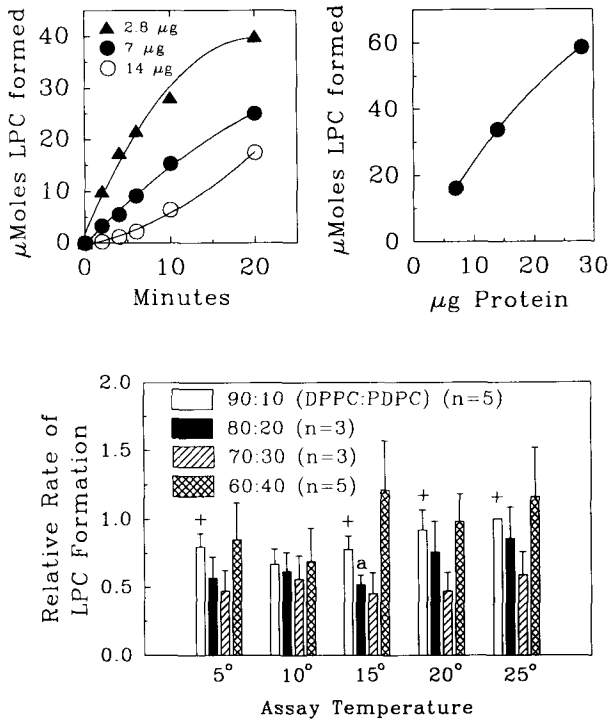

FIG. 4. Top: Lysophosphatidylcholine formation due to the action of phospholipase A_2 from *Crotalus atrox* acting on vesicles of 90:10 DPPC/PDPC at 20°C as a function of assay time (left) and enzyme concentration (right—at a fixed time of 15 min). Bottom: The influence of assay temperature and vesicle composition on rates of phospholipase A_2 activity expressed relative to the activity measured in vesicles of 90:10 DPPC/PDPC assayed at 25°C. Data are presented as mean ± SD. A plus sign indicates a marginal difference ($0.10 > p > 0.05$) between the mean designated and the mean for vesicles comprised of 70:30 DPPC/PDPC; similarly, the letter a indicates a difference ($0.10 > p > 0.05$) between the designated mean and the mean for vesicles of 90:10 composition.

than 16:0/20:4-PC (4) and 16:0/22:6-PC occupies less area than 18:3/18:3-PC (28), suggesting that some effective ordering is induced in unsaturated acyl chains by the presence of multiple double bonds (29). Docosahexaenoic acid (22:6*n*-3), in particular, appears to assume a compact conformation in phospholipids (28), perhaps due to a helical arrangement of the acyl chain (6). Therefore, it is not surprising that in *Dictostylium*, enrichment with fatty acids possessing three or four, rather than two double bonds did not markedly increase membrane fluidity (30). Nevertheless, the presence of highly unsaturated fatty acids in high concentration in some tissues (*e.g.*, muscle, brain, testes and retina) and their tenacious retention during dietary deprivation, indicate that long-chain PUFA play an essential role in membrane function. Temperature-induced adjustments in phospholipid molecular species composition (1) also suggest a unique role for PUFA-containing molecular species in the thermal adaptation of membrane function. The present studies identify several possible ways in which elevated proportions of PDPC may contribute to maintained membrane function at low temperature.

Fluorescence polarization data (Fig. 5, top) reveal a single, well-defined transition for all binary mixtures of DPPC/PDPC, the temperature of which declines significantly as a function of PDPC content. Polarization values at temperatures below the transition also decline steadily as a function of PDPC content, indicating that PDPC exerts a fluidizing effect. Furthermore, the fluidity of the membrane interior is a nearly linear function of PDPC content (Fig. 5, bottom) in the range of temperatures normally encountered by rainbow trout. It is not clear from the data collected whether DPPC and PDPC mix ideally, or whether the single transition reflects the melting of a DPPC-enriched phase, with the transition of a PDPC-enriched phase occurring only at subzero temperatures (31). Regardless, it is clear that PDPC has a significant effect on membrane properties, especially at temperatures below the transition. In fact, within the physiological temperature range of trout (0–25°C), PDPC content has a much more significant impact on membrane fluidity than temperature, suggesting that changes observed in the PDPC content of trout hepatocyte membranes (1) are more than adequate to counteract the direct effects of temperature on membrane fluidity. In addition, mitochondrial membranes, for which the efficacy of homeoviscous adaptation is greatest (31), also experience the largest temperature-induced changes in PDPC content (1). Elevated proportions of PDPC may also contribute to the maintenance of fluidity in biological membranes at low temperature due to a reduced tendency for PDPC (compared to more saturated species) to interact with cholesterol (28). It is worth noting that the native membranes of trout hepatocytes contain a mixture of phospholipid species much more complex than those present in the SPLV preparations. While this may account for the greater temperature dependence of DPH fluorescence polarization in native membranes (32), it should not substantially alter qualitative tendencies in membrane properties attributed to differences in PDPC content.

In order to distinguish between the effects of temperature and the fluidity of the bilayer on membrane function, indices of function are related to the anisotropy parameter in Figure 6. Of the membrane functions assayed, only

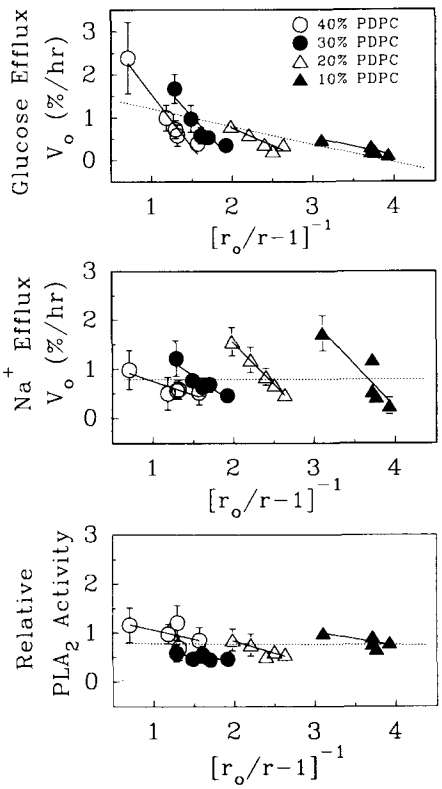

FIG. 6. Dependence of the rates of glucose efflux (top), Na^+ efflux (middle), and phospholipase A_2 activity (bottom) on the physical properties of the bilayer interior (expressed as an anisotropy parameter). Each data point within the data set for vesicles of similar composition was obtained at a different assay temperature. Data are presented as mean ± SD. The dashed line corresponds to the regression for all the data in the graph, regardless of assay temperature or vesicle compostion.

nonelectrolyte (glucose) permeation was significantly correlated ($r^2 = 0.6924$) with the physical properties of the acyl domain. For vesicles containing 10% and 20% PDPC, rates of glucose permeation closely tracked temperature-induced changes in membrane fluidity. However, in vesicles containing 30% and 40% PDPC, glucose permeation was more temperature-dependent than fluidity. Regardless, glucose permeation is negatively correlated with fluidity, suggesting that modulation of PDPC content may play a significant role in the thermal compensation of nonelectrolyte permeability. Similar correlations between the physical state of membrane lipids and bilayer permeability have been reported for lipid (23) and osmotic water fluxes (24,25).

In contrast, electrolyte (Na^+) permeation, although temperature dependent (Fig. 2, bottom) did not vary with membrane fluidity. Rates of sodium ion efflux varied in excess of three-fold at comparable anisotropy values, while similar rates of Na^+ permeation were observed at widely different membrane fluidities. Most remarkably, Na^+ permeation became significantly less temperature dependent as the concentration of PDPC increased, whereas membranes comprised of 40% PDPC were most permeable to Na^+ at 5°C, the opposite was true at 25°C. Although not causally linked to fluidity, elevated rates of Na^+ permeation, characteristic of membranes enriched in PDPC, may be a significant feature of membrane

adaptation to low temperature. Given the role of Na^+ permeation in determining the membrane potentials of excitable tissues (33), modulation of PDPC content may be a primary means of regulating electrical excitability in poikilotherms as body temperature changes.

In contrast to passive permeability, the activity of PLA_2 was not consistently influenced by either assay temperature or membrane lipid composition, which is surprising in light of reports that activity of this enzyme is sensitive to alterations in phospholipid packing (17). Although lipase activity declined with increasing PDPC content between 10 and 30%, activity rose abruptly (but not significantly) between 30 and 40% PDPC. We conclude either that: i) the phospholipase is not sensitive to changes in the fluidity of its environment; or ii) it does not experience the fluidity of the bulk phase phospholipid as detected by DPH fluorescence polarization. Since the former conclusion is not consistent with other data, it seems more likely that characteristics of the bilayer/water interface (to which the enzyme binds) are less (or differentially) affected by variations in PDPC content than those of the bilayer interior, a suggestion consistent with the dependence of nonelectrolyte permeability on both the content of PDPC and membrane fluidity.

In summary, we conclude that increased proportions of PDPC may contribute to the low-temperature acclimation of membrane function by: i) increasing the fluidity of the bilayer interior and thereby elevating nonelectrolyte (*i.e.,* glucose) permeation; and ii) decreasing the thermal sensitivity of transmembrane ion flux so that ion (*i.e.,* Na^+) permeability is higher in the cold than would be predicted from the temperature dependence of Na^+ permeation in membranes possessing only small quantitites (*i.e.,* 10%) of PDPC. Furthermore, variations in PDPC content influence interfacial phenomena (*i.e.,* PLA_2 activity) and those processes (*i.e.,* nonelectrolyte permeation) mediated by the bilayer interior in different ways.

[Received June 29, 1990; Revision accepted February 11, 1991]

Hydrolysis of Neutral Lipid Substrates by Rat Hepatic Lipase

Rebecca W. Wilcox*, Tom Thuren, Patricia Sisson, Gregory L. Kucera and Moseley Waite
Department of Biochemistry, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, North Carolina 27103

Rat hepatic lipase, an enzyme whose involvement in the catabolism of lipoproteins remains poorly defined, has both neutral lipid and phospholipid hydrolyzing activity. We determined the substrate specificity of hepatic lipase for 1-oleoyl-*sn*-glycerol, 1,2-dioleoyl-*sn*-glycerol, and 1,3-dioleoyl-*sn*-glycerol in the Triton X-100 mixed micellar state, and compared these results to those obtained previously in our laboratory for the phospholipid substrates phosphatidic acid (PA), phosphatidylethanolamine (PE), and phosphatidylcholine (PC). V_{max} values were determined by diluting the substrate concentration in the surface of the micelle by Triton X-100. The V_{max} values obtained were 144 μmol/min/mg for 1-oleoyl-*sn*-glycerol, 163 μmol/min/mg for 1,2-dioleoyl-*sn*-glycerol, and 145 μmol/min/mg for 1,3-dioleoyl-*sn*-glycerol. These values were higher than those obtained earlier for phospholipids which were 67 μmol/min/mg for PA, 50 μmol/min/mg for PE and 4 μmol/min/mg for PC. In addition, the mole fraction of lipid substrate at half maximal velocity (K) in the surface dilution plot was lower for the neutral lipid substrates as compared to those obtained for the phospholipid substrates. When the hydrolysis of 1,3-dioleoyl-*sn*-glycerol mixed micelles was studied as a function of time, cleavage at the *sn*-1 and *sn*-3 positions occurred at the same rate, suggesting that hepatic lipase is not stereoselective with respect to 1,3-diacyl-*sn*-glycerol substrates. To determine if the presence of one lipid could affect the hydrolysis of the other, all possible dual combinations of 1-oleoyl-*sn*-glycerol, 1,2-dioleoyl-*sn*-glycerol, and 1,3-dioleoyl-*sn*-glycerol in the same micelle were made and the hydrolysis rate of each substrate was determined. Interaction occurred only for the 1,2-dioleoyl-*sn*-glycerol/1,3-dioleoyl-*sn*-glycerol mixture where the hydrolysis of 1,2-dioleoyl-*sn*-glycerol was slightly inhibited and that of 1,3-dioleoyl-*sn*-glycerol slightly activated compared to the predicted theoretical rate. These findings demonstrate that when presented in similar physical states, the neutral lipid substrates tested were hydrolyzed at a higher rate by hepatic lipase than the phospholipid substrates.
***Lipids 26,* 283–288 (1991).**

Rat hepatic lipase (E.C. 3.1.1.32; HL) is located on the surface of endothelial cells lining the vascular lumen of the liver (1). The enzyme is heparin releasable and has a broad substrate specificity, hydrolyzing monoacylglycerols, diacylglycerols, and triacylglycerols as well as phospholipids *in vitro*. In some studies, *in vitro* activity was reported to be highest for trioleoylglycerol while in others phosphatidylethanolamine was found to be the preferred substrate (2–5). In addition to the hydrolysis of neutral lipid and phospholipid substrates, rat HL also has transacylase activity (6). The best acyl donors for transacylation were reported to be 1(3)-monoacylglycerol and phosphatidylethanolamine. The preferred acyl acceptor was 1(3)-monoacylglycerol although a number of primary and secondary alcohols were found to be acyl acceptors. When monoacylglycerol served as both the acyl donor and acceptor molecule, the products formed by transacylation were diacylglycerol and glycerol (7). The transacylation reaction occurred readily when pure lipids were used as substrates. In contrast, lipids in the presence of Triton X-100 (6) and in lipoproteins exhibited insignificant rates of transacylation *in vitro* (8).

The *in vivo* substrates for rat HL are plasma lipoproteins, although the exact role of HL in lipoprotein metabolism remains poorly defined. HL has been shown to hydrolyze phospholipids on the surface of HDL_2 particles *in vitro* (9), and a role for the enzyme in the conversion of HDL_2 to HDL_3 has been suggested (10,11). Involvement of the enzyme in the conversion of IDL to LDL in the VLDL-IDL-LDL cascade (12) and in the metabolism of chylomicron remnants (13–15) has also been proposed.

Here we report a study of the substrate specificity of rat HL employing 1-oleoyl-*sn*-glycerol, 1,2-dioleoyl-*sn*-glycerol, and 1,3-dioleoyl-*sn*-glycerol in mixed micelles with Triton X-100 as models for the hydrolysis of neutral lipids. Our laboratory has previously studied the substrate specificity of this enzyme for phospholipid mixed micelles (16). In mixed micelles the substrates are in relatively uniform physical states and are easily comparable. It is our goal to compare the current results to those obtained earlier with phospholipids in the same type of substrate preparation. The fact that both neutral lipid and phospholipid substrates are hydrolyzed by HL has been well established. However, to our knowledge this is the first report in which the hydrolysis of both lipid classes has been studied in a substrate system where each lipid tested has a similar physical state.

MATERIALS AND METHODS

1-Oleoyl-*sn*-glycerol, 1,2-dioleoyl-*sn*-glycerol, and 1,3-dioleoyl-*sn*-glycerol were obtained from Serdary Research Laboratories Inc. (Port Huron, MI). Triton X-100 and sodium azide were obtained from Fisher Scientific (Raleigh, NC). Tris-HCl, ethylenediaminetetraacetic acid (EDTA), and phospholipase A_2 from *Crotalus adamanteus* were obtained from Sigma Chemical Company (St. Louis, MO). Phospholipase C from *Bacillus cereus* was obtained from Boehringer Mannheim (Indianapolis, IN). Sephacryl S-200 was obtained from Pharmacia (Piscataway, NJ). Silica gel H (Merck, Darmstadt, Germany) was used for thin-layer chromatography. Silicic acid column chromatography was performed with Kieselgel 60 from EM Science (Cherry Hill, NJ). All neutral lipids were quantitated by the method of Sardesai and Manning (17). Briefly, samples were saponified and the glycerol moiety oxidized to formaldehyde. The formaldehyde was further converted to 3,5-diacetyl-1,4-dihydrolutidine, a yellow-

Abbreviations: DG, diacylglycerol; HDL, high density lipoprotein; HL, hepatic lipase; IDL, intermediate density lipoprotein; LDL, low density lipoprotein; PA, phosphatidic acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; TG, triacylglycerol; VLDL, very low density lipoprotein.

colored compound which was quantitated spectrophotometrically.

Enzyme purification. Rat HL was purified using a modification (18) of the method of Jensen and Bensadoun (19). The hepatic heparin perfusate was collected in a beaker containing heparin-Sepharose in equilibration buffer. The heparin-Sepharose/perfusate mixture was then transferred to a sintered glass funnel and washed using a gentle vacuum. After the washes, the gel was packed into a column, and the enzyme was eluted with a linear gradient between 0.5 and 1.8 M NaCl. The conductivity of the fractions was determined and those fractions containing between 0.65 and 1.0 M NaCl were pooled and dialyzed. After dialysis, the enzyme was further purified by ion-exchange chromatography on DEAE-Sephacel. The specific activity of the purified enzyme preparation determined using 1-oleoyl-*sn*-[2-^{3}H]glycerol (1.5×10^3 dpm/nmol) as substrate averaged 190 μmol/min/mg.

Preparation of radiolabeled substrates. Phosphatidylcholine was purified from rabbit liver (16) and hydrolyzed by phospholipase A_2 from *Crotalus adamanteus.* The lysophosphatidylcholine was acylated with either [^{14}C]-oleic acid or [^{3}H]oleic acid using the acyl-CoA acyltransferase of rat liver microsomes to form phosphatidylcholine radiolabeled in the acyl chain primarily at the *sn*-2 position (20). After acylation, greater than 99% of the ^{14}C-labeled fatty acid and greater than 95% of the ^{3}H-labeled fatty acid was located at the *sn*-2 position as determined by snake venom phospholipase A_2 cleavage (20). 1,2-Diacyl-*sn*-glycerol labeled at the *sn*-2 position was then prepared from radiolabeled phosphatidylcholine by phospholipase C cleavage (16). To prepare 1,3-diacyl-*sn*-glycerol radiolabeled at the *sn*-3 position, purified 1,2-diacyl-*sn*-glycerol with radiolabeled fatty acid at the *sn*-2 position was applied to a silicic acid column equilibrated with $CHCl_3$. The sample was left overnight to promote migration of the acyl group from the *sn*-2 to the *sn*-3 position. Diacylglycerols were then eluted with $CHCl_3$ and purified by thin-layer chromatography in a hexane/diethyl ether/formic acid system (90:60:4, v/v/v) that separated 1,2- and 1,3-diacyl-*sn*-glycerols. Radioactivity was localized with a Bioscan radiochromatogram imaging system. The migration of authentic standards was detected by iodine staining. Regions that migrated with 1,2- and 1,3-diacyl-*sn*-glycerol standards and contained radiolabel were scraped off and extracted by the method of Bligh and Dyer (21). The radiospecific activity of 1-acyl-2-[^{14}C]-oleoyl-*sn*-glycerol was 2.4×10^4 dpm/nmol.

1-Oleoyl-*sn*-[2-^{3}H]glycerol (1.5×10^3 dpm/nmol) used in the specific activity determination for purified HL preparations and for monoacylglycerol kinetic studies was synthesized by Dr. Craig Miller (Salem College, Winston-Salem, NC).

Characterization of mixed micellar substrates. In order to determine the size characteristics of the micelles, gel filtration chromatography of mixed micellar substrates was performed on Sephacryl S-200 (2.5 × 44 cm) at a flow rate of 42 mL/hr at room temperature (V_0 = 66 mL). The column was equilibrated and run in 100 mM Tris, pH 9.0, 2 mM EDTA, 0.12% sodium azide, and 0.3 mM Triton X-100. Triton X-100 was added to the buffer at its critical micellar concentration of 0.3 mM (22) to prevent a decrease in the lipid to Triton X-100 ratio that would result from the dissociation of Triton X-100 from the mixed micelles. Each substrate was prepared at two different mole fractions of lipid, 0.1 and 0.01, and the total lipid concentration in each sample was 2 mM. Samples were applied to the column in a total volume of 0.5 mL, and 3.6-mL fractions were collected. The elution of Triton X-100 was monitored by the absorbance at 280 nm. Radiolabeled lipid (2×10^4 dpm) was added to each sample and the elution of lipid was followed by liquid scintillation counting of a 0.5-mL aliquot from each fraction.

Light-scattering analyses of micelles prepared at lipid mole fractions of 0.1 and 0.01 were carried out by Dr. Roy Hantgan (Bowman Gray School of Medicine, Winston-Salem, NC).

Enzyme assay. The hydrolysis experiments were performed as described by Kucera *et al.* (16) for phospholipid/Triton X-100 mixed micelles. Each radiolabeled substrate (5×10^4 dpm/incubation) was dried under N_2, resuspended in an aqueous solution of Triton X-100 as indicated for each experiment, vortexed, and sonicated until a homogeneous dispersion was obtained. Additional Triton X-100 was added to each substrate preparation at its critical micellar concentration of 0.3 mM (22) to maintain the appropriate molar ratio of lipid to Triton X-100 in the micelles. When mixed micelles containing two different lipid substrates were hydrolyzed, one substrate was labeled with ^{3}H (5×10^4 dpm/incubation) and the other with ^{14}C (5×10^4 dpm/incubation). Assays were run in a total volume of 0.5 mL with 100 mM Tris-HCl, pH 9.0 at 37°C for 30 min. The purpose of the hydrolysis experiments was to obtain a V_{max} value for each substrate assayed under the same conditions. An incubation time of 30 min was necessary to obtain sufficient hydrolysis over the range of substrate concentrations tested. Therefore the V_{max} values obtained are relative values for the conditions employed since the reaction was not strictly linear with time during the incubation, as will be illustrated later (Fig. 2). However, hydrolysis was directly proportional to protein concentration over the 30-min incubation period. Hydrolysis was started by the addition of enzyme and stopped by the addition of 1.5 mL $CHCl_3$/MeOH (1:2, v/v). For the diacylglycerol studies, reaction mixtures were then extracted by the method of Bligh and Dyer (21) and the radiolabeled products separated by thin-layer chromatography in a hexane/diethyl ether/formic acid system (90:60:4, v/v/v). Monoacylglycerol, diacylglycerol, and fatty acid standards were visualized by iodine staining. The corresponding regions in each sample were scraped off and radioactivity was measured by liquid scintillation counting. Hydrolysis of 1-oleoyl-*sn*-[2-^{3}H]glycerol resulted in the release of [2-^{3}H]glycerol which partitioned into the methanol/water layer of the Bligh and Dyer (21) extract while 1-oleoyl-*sn*-[2-^{3}H]glycerol partitioned into the $CHCl_3$ layer. Glycerol liberation was measured by liquid scintillation counting of an aliquot from both phases of the Bligh and Dyer (21) extraction. The $CHCl_3$ aliquot was dried under N_2 before counting.

Kinetic model. Triton X-100 mixed micelles were used as substrates to determine the specificity of HL for neutral lipids in order to compare these substrates with the phospholipids studied previously in our laboratory (16). First a saturating bulk substrate concentration was determined with mixed micelles at a constant lipid mole fraction of 0.09. For these experiments the ratio of lipid

to Triton X-100 remained constant. The total amount of each was increased proportionally resulting in an increase in the total number of micelles while the surface concentration of lipid remained the same. Then experiments were conducted at a constant saturating bulk substrate concentration in which the surface concentration of lipid was varied by changing the concentration of Triton X-100. V_{max} values were determined from the plot in which the surface concentration of lipid was diluted with Triton X-100 by nonlinear regression analysis using the program EZ-FIT (23). The substrate specificity of HL for the mixed micellar substrates was expressed in terms of V_{max} values. In addition to comparing V_{max} values, a relative affinity value (K) was determined as the mole fraction of lipid at half maximal velocity in which the surface concentration of lipid was diluted with Triton X-100. This experimental approach is similar to that originally described by Hendrickson and Dennis (24) except that the assumptions and calculations concerning the binding to and hydrolysis of substrates made earlier were not applied here.

RESULTS

Characterization of Triton X-100 mixed micellar substrates. Gel filtration chromatography and light-scattering analysis were used to determine the size characteristics of the 1-oleoyl-*sn*-glycerol, 1,2-dioleoyl-*sn*-glycerol, and 1,3-dioleoyl-*sn*-glycerol mixed micellar substrates. It was observed that micelles with higher lipid content were larger in size as determined by gel filtration chromatography. The average relative molecular mass of the neutral lipid micelles prepared at a lipid mole fraction of 0.01 was 70,000. The average relative molecular mass of the neutral lipid micelles prepared at a lipid mole fraction of 0.1 was 170,000. As an example, the elution of lipid and Triton X-100 for 1,2-dioleoyl-*sn*-glycerol micelles prepared at a lipid mole fraction of 0.01 is shown in Figure 1. A slight enrichment of lipid at the peak front was observed. This did not appear to affect results because hydrolysis of mixed micellar preparations was linear with time (Fig. 2) and individual lipid-containing fractions were hydrolyzed by HL at approximately the same rate (data not shown).

Light-scattering analysis of the three substrates showed that mixed micelles of 0.01 and 0.1 lipid mole

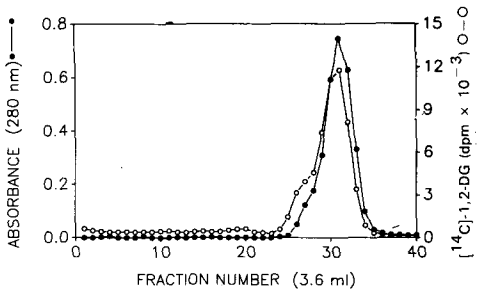

FIG. 1. Gel filtration chromatography of 1,2-dioleoyl-*sn*-glycerol mixed micelles. 1-Acyl-2-[^{14}C]oleoyl-*sn*-glycerol (2×10^4 dpm, 0.8 nmol) was added to unlabeled 1,2-dioleoyl-*sn*-glycerol (1 μmol) during mixed micelle preparation to follow lipid elution from the column. 1-Acyl-2-[^{14}C]oleoyl-*sn*-glycerol (open circles) and Triton X-100 (closed circles) were measured as described in Materials and Methods. [^{14}C]-1,2-DG, 1-acyl-2-[^{14}C]oleoyl-*sn*-glycerol.

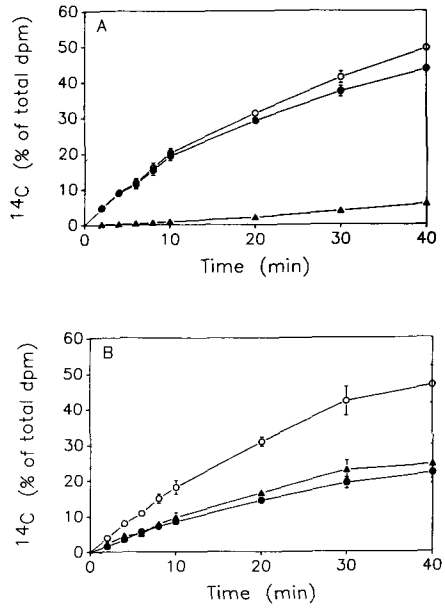

FIG. 2. Time-dependent hydrolysis by rat HL of A) 1,2-dioleoyl-*sn*-glycerol/Triton X-100 mixed micelles, and B) 1,3-dioleoyl-*sn*-glycerol/Triton X-100 mixed micelles. At each point, the initial bulk dioleoylglycerol concentration was 2 mM and the molar ratio of lipid to Triton X-100 was 0.1. Assay conditions were as described in Materials and Methods; the enzyme concentration used was 185 ng/mL. The radiolabeled substrates 1-acyl-2-[^{14}C]oleoyl-*sn*-glycerol (5×10^4 dpm, 2 nmol) and 1-acyl-3-[^{14}C]oleoyl-*sn*-glycerol (5×10^4 dpm, 2 nmol) were used to follow the hydrolysis of 1,2-dioleoyl-*sn*-glycerol and 1,3-dioleoyl-*sn*-glycerol, respectively. Enzyme activity is expressed as dpm of total diacylglycerol added to each assay recovered as monoacylglycerol (closed circles) or as free fatty acid (closed triangles); open circles show the recovery of both products in dpm. Each symbol represents the mean ± SD of two experiments done in duplicate.

fraction were homogeneous in size at each mole fraction although the 0.1 mole fraction preparations (10.4 ± 0.5 nm) were larger on average than the 0.01 preparations (7.9 ± 0.1 nm).

*Time-dependent hydrolysis of 1,2-dioleoyl-*sn*-glycerol and 1,3-dioleoyl-*sn*-glycerol mixed micelles.* Time course studies of the hydrolysis of 1,2-dioleoyl-*sn*-glycerol and 1,3-dioleoyl-*sn*-glycerol mixed micelles were conducted to determine the identity and temporal relationship of the radiolabeled products released. The hydrolysis of 1,2-dioleoyl-*sn*-glycerol was linear for the first 10 min after which the rate decreased somewhat (Fig. 2A). At 40 min, 44% of the radiolabeled 1,2-dioleoyl-*sn*-glycerol substrate was converted to radiolabeled monoacylglycerol, and 6% appeared as radiolabeled fatty acid. The release of radiolabeled fatty acid was apparently due to acyl migration from the *sn*-2 position to a primary position of the glycerol backbone of monoacylglycerol since greater than 99% of the labeled fatty acid had been determined to be at the *sn*-2 position of the original 1,2-diacyl-*sn*-glycerol substrate. We could not study the hydrolysis of triacylglycerol (TG) in this system because this substrate does not form micelles under the conditions used. However, diacylglycerol (DG) is a natural product of TG hydrolysis and is readily hydrolyzed by HL releasing 2-monoacylglycerol.

The hydrolysis of 1,3-dioleoyl-*sn*-glycerol had kinetics similar to that of 1,2-dioleoyl-*sn*-glycerol as shown by the total percentage of radiolabeled product released

(Fig. 2B). In this case [^{14}C]oleate was in position 3 since 1,3-dioleoyl-*sn*-glycerol was produced from 1-acyl-2-[^{14}C]oleoyl-*sn*-glycerol by acyl migration. Nearly equal amounts of [^{14}C]oleate and mono-[^{14}C]oleoylglycerol were formed, which suggests that the enzyme attacked positions 1 and 3 of 1,3-diacyl-*sn*-glycerol equally.

Kinetic analysis. Kinetic analysis of rat HL with 1-oleoyl-*sn*-glycerol, 1,2-dioleoyl-*sn*-glycerol and 1,3-dioleoyl-*sn*-glycerol mixed micellar substrates was performed using the surface dilution kinetic model described in Materials and Methods. When the bulk concentration of 1,2-dioleoyl-*sn*-glycerol mixed micelles with a constant lipid mole fraction of 0.09 was increased, a hyperbolic curve was obtained which approached saturation at 2 mM substrate (Fig. 3). Therefore, 2 mM lipid was chosen as a saturating concentration and used in obtaining the plot shown in Figure 4. In this plot the surface concentration of lipid was varied by maintaining the concentration of substrate at 2 mM and varying the Triton X-100 concentration (0.008 to 0.12 lipid mole fraction). The double reciprocal plots for each set of conditions were linear (mean correlation coefficient, 0.98) and are shown as insets in Figures 3 and 4. Plots resembling those in Figures 3 and 4 were also obtained for 1-oleoyl-*sn*-glycerol and 1,3-dioleoyl-*sn*-glycerol mixed micelles (data not shown); Table 1 shows the V_{max} values obtained for these three substrates. Those values for 1-oleoyl-*sn*-glycerol, 1,2-dioleoyl-*sn*-glycerol, and 1,3-dioleoyl-*sn*-glycerol were 144, 163, and 145 μmol/min/mg, respectively. We recalculated the data obtained earlier for phosphatidic acid (PA), phosphatidylethanolamine (PE), and phosphatidylcholine (PC) using the program EZ-FIT so that direct comparisons of neutral lipids and phospholipids could be made (Table 1). The V_{max} values obtained for the neutral lipid substrates were higher than those obtained for the phospholipid substrates which were 67 μmol/min/mg for PA, 50 μmol/min/mg for PE, and 4 μmol/min/mg for PC. Since we have analyzed each substrate under the same set of conditions, these V_{max} values should be a meaningful way to compare the hydrolysis of neutral lipid and phospholipid substrates realizing that these are relative values and apply only under the conditions employed. Relative affinity values were obtained for each substrate as described in Materials and Methods and are shown in Table 1. A K value of 0.02 mole fraction was obtained for both 1,2-dioleoyl-*sn*-glycerol and 1,3-dioleoyl-*sn*-glycerol. The K determined for 1-oleoyl-*sn*-glycerol was 0.05 mole fraction, somewhat higher than the value obtained for the diacylglycerol substrates. The relative affinity values for the phospholipid substrates were higher than those obtained for the neutral lipid substrates, 0.1, 0.14, and 0.11 mole fraction for PA, PE, and PC, respectively. The K values, which are the mole fractions of substrate at half maximal velocity in the surface dilution plot, suggest that the enzyme has a greater binding affinity for neutral lipid substrates reflecting the higher V_{max} values obtained.

Hydrolysis of two different lipids present in the same mixed micelle. The hydrolysis of two different lipids present in the same mixed micelle was examined to determine whether the presence of one lipid could affect the hydrolysis of the other since we had observed this earlier for phospholipid mixtures (16,25). All possible dual combinations of 1-oleoyl-*sn*-glycerol, 1,2-dioleoyl-*sn*-glycerol, and 1,3-dioleoyl-*sn*-glycerol were made. Enzyme activity plotted against the mole percent of 1,2-dioleoyl-*sn*-glycerol and 1,3-dioleoyl-*sn*-glycerol in the mixed micelles is shown in Figure 5. The total concentration of diacylglycerol was constant at each point (2 mM). Dashed lines were drawn

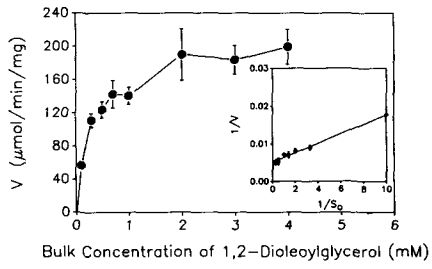

FIG. 3. Hydrolysis of 1,2-dioleoyl-*sn*-glycerol mixed micelles by rat HL as a function of the bulk 1,2-dioleoyl-*sn*-glycerol concentration. The mole fraction of dioleoylglycerol was held constant at 0.09. Assay conditions were as described in Materials and Methods; the enzyme concentration used was 18.5 ng/mL. The radiolabeled substrate 1-acyl-2-[^{14}C]oleoyl-*sn*-glycerol (5 × 10^4 dpm, 2 nmol) was added to follow the hydrolysis of 1,2-dioleoyl-*sn*-glycerol. Each symbol represents the mean ± SD of two experiments done in duplicate. The inset is the double reciprocal plot of the velocity *vs* bulk 1,2-dioleoyl-*sn*-glycerol concentration curve.

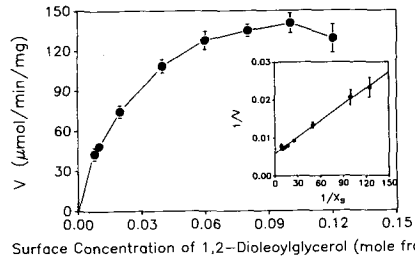

FIG. 4. Hydrolysis of 1,2-dioleoyl-*sn*-glycerol mixed micelles by rat HL as a function of the surface concentration of 1,2-dioleoyl-*sn*-glycerol. The bulk 1,2-dioleoyl-*sn*-glycerol concentration was held constant at 2 mM while the substrate concentration on the surface of the micelle was diluted with Triton X-100. Assay conditions were as described in Materials and Methods; the enzyme concentration used was 185 ng/mL. The radiolabeled substrate 1-acyl-2-[^{14}C]oleoyl-*sn*-glycerol (5 × 10^4 dpm, 2 nmol) was added to follow the hydrolysis of 1,2-dioleoyl-*sn*-glycerol. Each symbol represents the mean ± SD of three experiments done in duplicate. The inset is the double reciprocal plot of the velocity *vs* mole fraction of 1,2-dioleoyl-*sn*-glycerol curve.

TABLE 1

Summary of Rat HL Kinetic Values

Substrate	V_{max} (μmol/min/mg)	K (mole fraction)
MO[a]	144	0.05
1,2-DO	163	0.02
1,3-DO	145	0.02
PA	67	0.10
PE	50	0.14
PC	4	0.11

[a]Abbreviations: MO, 1-monooleoyl-*sn*-glycerol; 1,2-DO, 1,2-dioleoyl-*sn*-glycerol; 1,3-DO, 1,3-dioleoyl-*sn*-glycerol; PA, phosphatidic acid; PE, phosphatidylethanolamine; and PC, phosphatidylcholine.

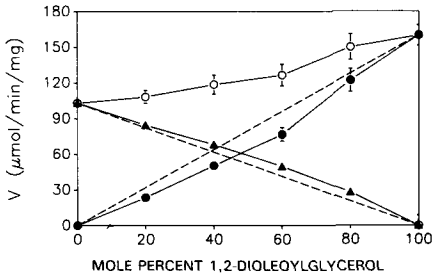

FIG. 5. Hydrolysis by rat HL of 1,2-dioleoyl-*sn*-glycerol and 1,3-dioleoyl-*sn*-glycerol present in the same mixed micelle. Mixed micelles were prepared with a constant total lipid concentration of 2 mM and diacylglycerols were mixed at different mole percents while maintaining the mole fraction of total lipid constant at 0.09. The enzyme concentration used was 100 ng/mL. The radiolabeled substrates 1-acyl-2-[^{14}C]oleoyl-*sn*-glycerol (5×10^4 dpm, 2 nmol) and 1-acyl-3-[^{3}H]oleoyl-*sn*-glycerol (5×10^4 dpm, 2 nmol) were used to follow the hydrolysis of 1,2-dioleoyl-*sn*-glycerol and 1,3-dioleoyl-*sn*-glycerol, respectively. The hydrolysis of 1,2-dioleoyl-*sn*-glycerol (closed circles), 1,3-dioleoyl-*sn*-glycerol (closed triangles), and total hydrolysis (open circles) calculated as the sum of the two is shown. Each symbol represents the mean ± SD of two experiments done in duplicate. Dashed lines are drawn from activity at 0 mole percent of each substrate to 100 mole percent.

to represent the predicted rate of hydrolysis of each substrate due to dilution by the addition of the alternate substrate. The hydrolysis of 1,2-dioleoyl-*sn*-glycerol increased with increasing mole percent to a final value of 150 μmol/min/mg at 100 mole percent. This hydrolysis appeared to be inhibited slightly by the presence of 1,3-dioleoyl-*sn*-glycerol since it fell below the predicted rate. The hydrolysis rate of 100 mole percent 1,3-dioleoyl-*sn*-glycerol was slightly lower than that of 100 mole percent 1,2-dioleoyl-*sn*-glycerol similar to the results reported in Table 1. 1,3-Dioleoyl-*sn*-glycerol hydrolysis decreased with increasing mole percent 1,2-dioleoyl-*sn*-glycerol at a slightly activated rate. In the other substrate combinations, 1-oleoyl-*sn*-glycerol plus 1,2-dioleoyl-*sn*-glycerol and 1-oleoyl-*sn*-glycerol plus 1,3-oleoyl-*sn*-glycerol, hydrolysis rates fell along the theoretical lines representing the predicted rate of hydrolysis due to substrate dilution by the addition of the alternate substrate (data not shown).

DISCUSSION

Here we report the substrate specificity of HL for the neutral lipid substrates 1-oleoyl-*sn*-glycerol, 1,2-dioleoyl-*sn*-glycerol, and 1,3-dioleoyl-*sn*-glycerol in Triton X-100 mixed micelles and compare the results with our previous findings on phospholipid substrates (16). The physical properties of neutral lipid mixed micelles have not been studied extensively in the past although phospholipid mixed micelles have been characterized rigorously (26–28). Using gel filtration chromatography and light-scattering analysis, we found that monooleoylglycerol and dioleoylglycerol mixed micelles prepared with the same lipid mole fraction were relatively homogeneous in size although micelles which had a higher lipid mole fraction were larger than those containing less lipid. Dennis (27) reported that phospholipid micelles also changed in apparent size when the ratio of lipid to Triton X-100 was varied, and this might influence the total surface area available for hydrolysis. However, based on the phospholipid substrates tested previously (16), this does not appear to affect our results noticeably. The emphasis here is on the comparison of lipids present in a relatively uniform physical state, and since the neutral lipid mixed micelles were found to be comparable in size and homogeneity to the phospholipid mixed micelles, we reasoned that these substrates were suitable for comparison of HL action on a range of substrates.

The V_{max} values obtained for the neutral lipids were higher than those found with phospholipids although both lipid classes were hydrolyzed readily by the enzyme. The bulk lipid concentration dependent affinity of HL did not differ significantly between the two lipid classes tested (data not shown). However, the affinity of HL for substrate diluted in the surface of the micelle was greater for the neutral lipid substrates, an additional reflection of the substrate specificity of HL. In preliminary monolayer studies conducted in our laboratory, HL demonstrated the same specificity based on V_{max} values which were ranked in the following order: 1,2-diacyl-*sn*-glycerol (DG) > 1,3-DG > PE > PA > PC.

Conflicting reports have been published concerning the stereoselectivity of rat HL in rat liver post-heparin perfusate preparations with respect to the primary ester bonds. Assmann and co-workers (29) compared the hydrolysis of 1-acyl-2,3-di-*O*-alkyl-*sn*-glycerol and 3-acyl-1,2-di-*O*-alkyl-*sn*-glycerol by rat liver post-heparin perfusate and found no difference in the hydrolysis of the 1- and 3-acyl residues of these triradylglycerols. Contrary to this finding, Åkesson and co-workers (30) compared the hydrolysis of 1-*O*-alkyl-2,3-diacyl-*sn*-glycerol and 3-*O*-alkyl-1,2-diacyl-*sn*-glycerol by rat liver post-heparin perfusate and found that the ester bond at the *sn*-1 position of triradylglycerol was preferentially hydrolyzed. However, when 1-*O*-alkyl-3-acyl-*sn*-glycerol and 1-acyl-3-*O*-alkyl-*sn*-glycerol were compared (30), hydrolysis rates were the same. This suggests that the hydrolysis of diradylglycerol substrates by the post-heparin perfusate was not stereoselective with respect to the primary ester bonds. Kucera *et al.* (31) observed a stereoselectivity for the ester bond at the *sn*-1 position of phosphatidic acid since a racemic mixture of monothioester phosphatidic acid was hydrolyzed at a 10-fold higher rate than the corresponding unnatural isomer. Those results suggested that the enzyme is not stereospecific with respect to the primary ester bonds of phospholipid substrates but stereoselective, hydrolyzing the ester bond at the *sn*-1 position preferentially. Our time course study of 1,3-dioleoyl-*sn*-glycerol mixed micelles using a purified rat HL preparation suggests that the hydrolysis of diacylglycerol substrates is nonselective between primary ester bonds. Therefore it appears from the various studies described above that the enzyme is stereoselective if all three glycerol hydroxyls are esterified, but if one glycerol hydroxyl is free the enzyme does not exhibit stereoselectivity. Porcine pancreatic lipase, an enzyme related to HL, was shown to be stereoselective for the *sn*-3 ester bond during the hydrolysis of monomolecular films of 1(3)-acyl-2-amino-2-deoxy-*sn*-glycerol (diradylglycerol). This stereoselectivity increased with decreasing surface pressure. However, when triradylglycerol analogs were studied, the enzyme no longer showed a preference for the *sn*-3 position (32). Thus, it appears that the stereoselectivity of many lipases may be regulated by the number of esterified hydroxyls on the glycerol backbone.

This is the first study to compare the hydrolysis by HL of neutral lipid and phospholipid substrates present in relatively uniform physical states and demonstrates that in a model system the neutral lipid hydrolase and phospholipase A_1 activities of HL are both active. These data suggest that physiologically both phospholipid and neutral lipid in lipoproteins could be hydrolyzed by HL, and support the postulate that HL could participate in the catabolism of triacylglycerol-rich lipoproteins in the VLDL-IDL-LDL cascade as well as in the catabolism of phospholipid in the conversion of HDL_2 to HDL_3. Further, the data suggest that factors other than lipid structure itself determine which substrate molecules are hydrolyzed most efficiently by HL. Possible factors participating in the regulation of HL are lipid composition, lipid packing, and the presence of apolipoproteins.

ACKNOWLEDGMENTS

We wish to thank Dr. Craig Miller for synthesizing 1-oleoyl-*sn*-[2-^{3}H]glycerol (1.5×10^3 dpm/nmol) and Dr. Roy Hantgan for performing light-scattering analyses. The study was supported by National Institutes of Health (NIH) grants DK-11799 and HL-31338 and by American Heart Association (AHA) Grant-in-Aid NC-90-G-26.

Lipoprotein Lipase in Rats Fed Fish Oil: Apparent Relationship to Plasma Insulin Levels

Janet K. Baltzell*, Joseph T. Wooten and **David A. Otto**
Department of Research, Baptist Medical Centers, Birmingham, Alabama 35211

To investigate the role of lipoprotein lipase (LPL) and hepatic lipase in the triacylglycerol lowering effects of fish oil, rats were fed lard (L), corn oil (CO) or menhaden oil (MO) as the primary fat source in otherwise identical diets. After 2 weeks, soleus muscle LPL differed between groups (MO>CO>L). Hepatic lipase did not differ between CO- and MO-fed rats but was elevated in L-fed rats. Adipose LPL did not differ between diet groups. Total epididymal fat weight was reduced in MO-fed rats. There was a significant positive correlation between adipose tissue weight and plasma free fatty acids. MO-fed rats had lower plasma insulin levels. Insulin was directly correlated with plasma triacylglycerol and glucose, consistent with a hyperinsulinemic, insulin-resistant state in CO- and L-fed rats, and a protective effect with MO feeding. In addition, insulin was directly correlated with adipose LPL. A negative relationship between soleus muscle LPL and insulin approached significance. Soleus muscle LPL was significantly inversely correlated with triacylglycerol. The data indicate that increased skeletal muscle LPL, in response to MO or a MO-induced decrease in insulin, may contribute to the triacylglycerol-lowering effects of fish oil. Decreased fat weight and adipose LPL and increased soleus muscle LPL and decreased plasma triacylglycerol suggest a shift from fat deposition to oxidation with MO feeding. The lack of response of hepatic lipase to MO feeding suggests that this enzyme does not contribute to the fish oil-stimulated lowering of plasma triacylglycerol *via* hepatic reuptake of very low density lipoproteins or other triacylglycerol-rich lipoproteins.
***Lipids 26,* 289–294 (1991).**

The documented beneficial effects of fish oil consumption by both human and the rat model include a lowering of plasma triacylglycerol (TAG) and often a lowering of plasma cholesterol (CH) (1). Thus the rat is a useful model for investigating potential mechanisms underlying the observed effects of fish oil feeding. Both skeletal muscle and adipose lipoprotein lipase (LPL) and hepatic lipase (HL) have a role in regulating the level of circulating plasma lipids (2). Fish oil-induced alterations in the activities of HL or LPL could contribute significantly to the observed effects of these oils. This would be especially true regarding any changes in LPL of skeletal muscle, a tissue which represents a major proportion of total body weight. Previous reports have shown no alterations in adipose tissue and post-heparin lipoprotein lipase in response to fish oil feeding in rats (3) and humans (4,5), respectively. However, Herzberg and Rogerson (6) have recently reported increased hind leg skeletal muscle LPL in rats fed fish oil.

Current evidence suggests that fish oil intake may in some way alter insulin metabolism (7–9). We have previously observed decreased plasma insulin levels in rats fed fish oil (9) and have suggested that this may have a role in the TAG-lowering effects of fish oil. Because insulin is of importance in regulating the activities of LPL (10), it is possible that ingestion of fish oil could alter the enzyme activities. For these reasons, the present study investigating the effects of fish oil consumption on the activities of HL and LPL was undertaken.

METHODS

Feeding study. Male Sprague-Dawley rats (225–250 g; Charles River Laboratories, Inc., Wilmington, MA) were housed in suspended transparent polycarbonate cages with stainless steel wire bottoms in an animal facility maintained at 22 ± 1°C, 70% humidity, with a 12 hr light/dark cycle. Animals were acclimated to surroundings and fed a standard purified diet (AIN-76A) (11) (Research Diets, Inc., New Brunswick, NJ) for one week. Animals had free access to deionized water at all times. Following the acclimation period, rats were matched for weight and assigned to one of three diet groups (six rats/group). The fish oil diet was prepared in the laboratory by addition of menhaden oil to the basal diet (Research Diets) as previously described (12). All other diets were custom-prepared by the manufacturer. The purified diets were based on the AIN-76A diet (11) (Table 1) and provided 30% of calories (14.4% by weight) as fat. The diets contained identical ingredients, except for the source of fat. Fat calories were balanced by reduction in carbohydrate (sucrose/corn starch, 2:1, w/w). The fat sources (Table 2) were menhaden oil (MO) (vacuum stripped menhaden oil provided by the Fish Oil Test Materials Program of the National Institutes of Health and the National Marine Fisheries Service), corn oil (CO), and lard (L). Corn oil was added to the MO and L diets (corn oil providing 4% of the 30% fat calories) to prevent essential fatty acid deficiency. As previously described (9,12) the diets were balanced for cholesterol (4.10 mg/g oil), β-sitosterol (9.68 mg/g oil) and antioxidant content (α- and γ-tocopherols, and *tert*-butylhydroquinone, 1.40, 1.20, and 0.2 mg/g, respectively). Rats consumed the diets *ad libitum* for two weeks, and were fasted overnight prior to sacrifice. We have shown two weeks to be sufficient time to observe MO-induced changes (9).

The rats were killed by exsanguination from the abdominal aorta following nembutal anesthesia (5 mg/100 g body weight, IP). Plasma was collected as described previously (9) from whole blood following centrifugation at 500 x *g* for 20 min at 4°C. Livers were removed, weighed, freeze-clamped, and ground into a powder under liquid nitrogen. Soleus muscles and epididymal fat pads were collected and immediately frozen in liquid nitrogen. All samples were stored at −80°C prior to assay.

Enzyme assays. LPL activities were determined using a modification of the method of Nilsson-Ehle and Schotz (13). HL was determined by the method of Nilsson-Ehle and Ekman (14). For each tissue assay system, separate trials were run to determine the ideal buffer, tissue concentration, and incubation time to achieve linearity (15). In the LPL assay, appropriate blanks, adjusted to 1 M NaCl, were run with each sample (15). All samples were run in duplicate. Partitioning coefficients of oleic acid into the fatty acid separation system were determined for each sample by including a small amount (500 dpm) of [^{14}C]-oleic acid in each sample system. Soleus muscle (approximately 50 mg) was homogenized on ice (Tissumizer, Tekmar Company, Cincinnati, OH) for four seconds (setting #65) in 80 volumes of 0.2 M Tris-HCl buffer, pH 8.3, containing 15 U heparin/mL. The homogenates were kept on ice for 30 min and then centrifuged for 15 min (300 × *g*, 4°C). Aliquots of this supernatant (100 μL) were then used for LPL determination. Epididymal fat (150–200 mg) was homogenized on ice in the same manner as the muscle tissue in 10 volumes of Krebs-Ringer-HEPES buffer (16), pH 7.4, with 15 U heparin/mL. Following chilling on ice for 30 min and centrifugation (1000 × *g*, 15 min, 4°C), 100-μL aliquots of the supernatant were used in the LPL assay. Liver (200–300 mg) was homogenized on ice in 10 volumes of Krebs-Ringer-HEPES buffer (pH 7.4) using a Potter-Elvehjem homogenizer. One-mL aliquots of the homogenates were centrifuged (6000 × *g*, 15 min, 4°C). The pellets obtained were then resuspended in 1.0 mL of 0.1 M Tris-HCl (pH 9.0) containing 15 U heparin/mL. After chilling on ice for 15 min, the samples were centrifuged again and 100-μL aliquots of the supernatants were used for the HL assay. Liver glucose-6-phosphate dehydrogenase (G6PDH) activity was assayed as previously described (9).

Other determinations. Plasma insulin levels were determined in duplicate using a standard insulin radioimmunoassay kit (Corning Medical and Scientific, Medfield, MA). Plasma TAG, CH, and glucose were measured using Baker kits with the Encore Chemistry System Centrifugal Analyzer (Baker Instruments Corp., Allentown, PA). The assay for free fatty acids (FFA) (ref. 17; Amano International Enzyme kit reagents, Troy, VA) was adapted for use on the Encore Chemistry System.

Statistical analysis. Statistical significance between groups was determined by the Tukey test using a 95% confidence level. Correlations between measured

parameters were determined by least-squares regression analysis. All statistical analyses were performed using the SYSTAT statistical software package (Systat, Inc., Evanston, IL).

RESULTS

There were no differences in final body weight, liver weight, or relative liver size [(liver weight/body weight) × 100] between groups (Table 3). Plasma FFA, CH, and TAG were lower in the MO-fed rats (Table 4). Glucose did not differ significantly between groups but tended to be lower in the MO-fed *vs* the CO- and L-fed groups (Table 4).

Soleus muscle LPL activity differed significantly between diet groups (Table 5). MO-fed rats had the highest muscle LPL, followed by CO- and L-fed rats. Although epididymal adipose LPL activity per g (Table 5) did not differ significantly between groups, epididymal fat depot weight (Table 3) and relative fat size [(fat depot weight/body weight) × 100] (Table 3) were significantly reduced in the MO-fed rats as compared to CO- and L-fed rats. This resulted in a tendency for less total adipose LPL activity with MO-feeding (Table 5). HL activity, expressed per g (Table 5) or per total liver (data not shown), was significantly higher in the L-fed group compared to the CO- and MO-fed groups. Liver G6PDH activity differed significantly between groups with the lowest values in the MO-fed group and the highest in the L-fed rats (Table 5).

Plasma insulin levels were significantly lower in the MO-fed rats (Table 4). Insulin was significantly correlated with adipose LPL activity (Fig. 1). Plasma insulin also

showed significant positive correlations with plasma TAG and glucose (Figs. 2 and 3) and G6PDH (not shown, $r = 0.533$, $p < 0.05$). Soleus LPL activity was negatively correlated with TAG (Fig. 4), and exhibited a borderline significant relationship with insulin (Fig. 5).

DISCUSSION

This study stemmed from our interest in understanding the role of fish oil (ω3 fatty acids) in reducing plasma TAG. Both LPL and HL could be of potential importance if their activities were, in fact, influenced by dietary intake of marine oil. This potential contribution, combined with our finding of decreased plasma insulin levels and a significant correlation between plasma TAG and insulin in rats fed a 30% fat calorie MO diet (9) led to the present investigations.

The present results suggest that fish oil consumption, at the level used in this study, may exert either a direct or indirect (perhaps mediated *via* reduced insulin levels) influence on the activities of adipose and skeletal muscle LPL. Insulin is a key regulator of adipose LPL (18). Adipose tissue LPL is increased in situations where insulin levels are expected to be elevated, such as the fed state or with high carbohydrate-feeding (18). Adipose LPL is lower in untreated insulin-dependent diabetics, but normalizes or becomes elevated with insulin treatment (10). The significant positive correlation between adipose LPL activity and plasma insulin observed in the present study are consistent with the established role of insulin in the positive regulation of adipose LPL.

The soleus muscle LPL activity was significantly increased in the MO-fed rats in this study and demonstrated a borderline significant relationship with insulin (Fig. 5). This again may be related to decreased insulin levels, as skeletal muscle LPL activity increases in situations with reduced circulating insulin, such as starvation (19). Soleus muscle LPL was found by others to be the highest of several rat muscles sampled, but showed no

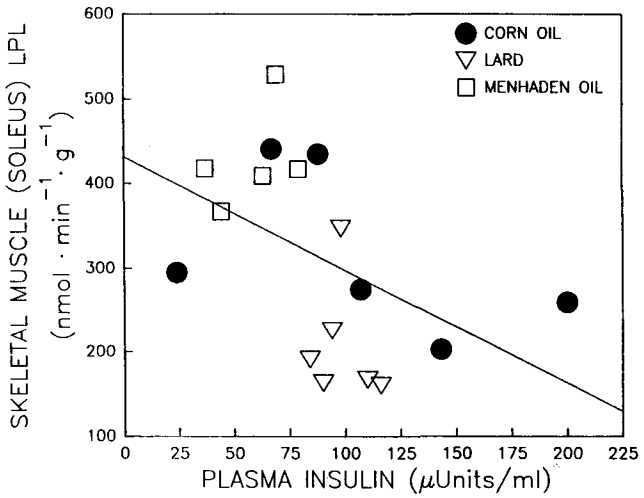

FIG. 5. Correlation between soleus LPL and plasma insulin (n = 17, r = 0.475, p = 0.059).

diet influenced difference between lard and glucose diets (67% of calories) (20). Skeletal muscle LPL activity was decreased with high-carbohydrate feeding and increased with fasting (21) and with high-fat feeding (21,22). The diets used in the present study provided 30% of total calories as fat, a percentage of dietary fat which is well above the recommended level for the rat (11), but not as high as the high-fat diets previously found to stimulate skeletal muscle LPL (21,22). Herzberg and Rogerson (6), in a recent report, demonstrated a stimulation of hind leg skeletal muscle LPL activity in rats fed fish oil (MaxEPA) at 10% by weight of diet (approximately 22% of calories). Insulin levels were not reported in this study and no effect of diet was observed on epididymal fat LPL.

In the present investigation, HL was increased in the L-fed group as compared to the MO-fed and CO-fed groups. This suggests that HL does not come under the same, possibly insulin related, regulatory system as skeletal muscle and adipose LPL. These data also provide evidence that HL does not contribute to the lowering of plasma TAG through hepatic reuptake of very low density lipoproteins (VLDL) or other TAG-rich lipoproteins.

Reaven and Chen (23) have reported that mature Sprague-Dawley rats are spontaneously insulin resistant and hyperinsulinemic. High-fat feeding may also promote this effect (24). Lower insulin and FFA levels after MO-feeding (Table 4) and the positive relationships between fasting plasma insulin and TAG, and between insulin and glucose (Figs. 2 and 3) are consistent with a protective effect of fish oil feeding against the development of an insulin resistant and hyperinsulinemic state. At first consideration, this interpretation appears in to be in contrast with reports from human diabetic studies, in which there is an apparent inhibition of insulin secretion and a worsening of glucose control with fish oil supplementation (25). However, the reduction of insulin in fish oil-fed animals in our present and previous studies (9) may be the result of decreased insulin secretion with a compensatory or independent improvement in insulin sensitivity. While this could be beneficial in normal individuals, it would be detrimental in a diabetic with an already compromised capacity for insulin secretion. Our results are consistent with a recent report showing that fish oil feeding prevents the insulin resistance induced by very high-fat feeding (59% of calories) in rats (24). Fish oil as compared to olive oil feeding has been shown to increase insulin action (glucose utilization) in adipose tissue (26). More recently, Zak *et al.* (27) observed increased glucose utilization (decreased blood glucose, decreased basal insulinemia and decreased urinary C-peptide excretion) following a glucose load in patients with primary hypertriglyceridemia treated with fish oil (10 g/day for three weeks). The authors suggested that the hypotriglyceridemic effects of fish oil were mediated by changes in insulin secretion and decreased tissue resistance to insulin. Similarly, Storlien *et al.* (28) recently reported increased insulin sensitivity (insulin-stimulated glucose metabolism) in red skeletal muscle (soleus, red gastrocnemius, red quadriceps) in rats fed ω3 fatty acids, and suggested a role for ω3 fatty acids in insulin action. Hepatic G6PDH activity (an insulin sensitive enzyme) was decreased in the MO-fed rats (Table 5) and correlated significantly with plasma insulin levels (not shown). This is in agreement with previous work in our laboratory (9) and suggests that the liver is not subject to the same fish oil-induced alterations in insulin sensitivity as observed in peripheral tissues. This is in apparent contrast to the recent report of Storlien *et al.* (28), who showed improved insulin sensitivity in both the liver and peripheral tissues. This difference may be related to the different fat concentrations used.

Soleus muscle represents a slow-twitch, primarily oxidative red muscle fiber (20). LPL activity results in the release of fatty acids from TAG. In the skeletal muscle, these fatty acids may be used as substrates for oxidation. Our finding of reduced epididymal fat depot size in the MO-fed rats is consistent with the recent report of Parrish *et al.* (29), who observed 35% less fat accumulation in the epididymal fat pads of fish oil-fed *vs* lard-fed rats, which was associated with a decreased cell volume, leading to speculation that this decrease in fat accumulation may represent reduced adipose LPL activity in the fish oil-fed animals. It is tempting to conjecture that the decreased epididymal pad weight and the increased skeletal muscle LPL activity we have observed in the MO-fed rats represent a metabolic shift from fat deposition to fat oxidation. This was similarly suggested in a preliminary report by Herzberg *et al.* (30), which demonstrated increased utilization of fatty acids by skeletal muscle from fish oil-fed rats. Since skeletal muscle contributes a substantial portion of total body weight (approximately 45% of body weight in the rat), increased fatty acid oxidation by this tissue could certainly contribute to the lowering of plasma TAG. Increased skeletal muscle fatty acid oxidation would be consistent with the proposal that fatty acid oxidation is involved in the TAG-lowering effects of fish oil (31) and the reports of increased peroxisomal oxidation in liver (32). From the present data, it is not possible to quantitate the total skeletal muscle LPL. We can only speculate that an increase in total skeletal muscle LPL in response to fish oil feeding, even with decreased adipose LPL, could result in increased catabolism of VLDL and contribute to the lowering of plasma TAG. This suggestion is strengthened by the strong correlation between soleus muscle LPL and TAG (Fig. 4). That VLDL catabolism could play a role is suggested by a recent report (33) demonstrating that a

reduction in VLDL pool size in miniature pigs fed fish oil was due, in part, to an increase in fractional catabolic rate. The possibility that insulin is involved in the TAG-lowering effect is supported by the highly significant relationship between insulin and TAG.

A further contribution to the lowering of plasma TAG could come from the significant decrease in FFA observed with the MO-fed rats (Table 4), resulting in reduced substrate for hepatic VLDL synthesis. Our observation of a positive correlation between FFA and relative fat size (not shown, $r = 0.510$, $p < 0.05$) suggests that this decrease in FFA could be due to reduced lipolysis as a result of smaller adipose TAG stores. An alternative explanation is that this results from the apparent improved peripheral insulin sensitivity caused by fish oil feeding.

This study sought to investigate the potential role of LPL and HL in the beneficial effects of fish oil feeding. The results do suggest that skeletal muscle LPL, together with other known effects on VLDL synthesis and secretion (9,31), could play a role in the reduction of plasma TAG by fish oil feeding. Our findings may also offer an explanation for the reduced postprandial TAG observed in humans following adaptation to fish oil-containing diets (34). The data further point toward changes in insulin levels and/or insulin sensitivity as a key regulator in the TAG-lowering effects of fish oil. Whether these effects will be seen at lower dietary fat levels is currently under investigation.

Methyl-Branched Octanoic Acids as Substrates for Lipase-Catalyzed Reactions[1]

Philip E. Sonnet* and **Mary Welch Baillargeon**
U.S. Department of Agriculture, ARS, Eastern Regional Research Center, Philadelphia, Pennsylvania 19118

Hydrolyses of racemic methyl-branched octanoic acid thiolesters are described using six commercial lipases as catalysts. Branching at positions 2, 4 and 5 greatly reduced activity; branching at the 3-position virtually eliminated activity. The reactivities of the racemic branched thiolesters relative to the unbranched ester were very similar for each lipase preparation examined. In reactions involving configurationally pure 2-methyloctanoic acids, the S-enantiomer reacted faster both in esterification of aliphatic alcohols and in hydrolyses of aliphatic alcohol esters with all of the lipases examined. Stereobiases in hydrolyses of the octanoic acid esters branched at other positions were low and variable. In sharp contrast to the hydrolyses of the thiolesters of 2-methyloctanoic acid, two aryl esters of 2-methyloctanoic acid catalyzed by *R. miehei* lipase hydrolyzed with a bias for the R-configuration. A view of the ester-enzyme complex is offered to explain the relative rates of reaction of the racemic esters.
***Lipids* 26, 295–300 (1991).**

Triacylglycerol hydrolases [EC 3.1.1.3], more often referred to as lipases, are targets of investigation for industries that employ animal fats and vegetable oils as feedstock. A recent symposium (1) highlighted this interest and indicated wide-ranging applications for these enzymes and a desire to better understand their structure and mechanism of action.

One way to probe the active site of a lipase is with chiral fatty acids, but few instances of stereoselection using acids bearing an asymmetric center have been reported thus far (ref. 2, and references therein). We felt that a series of configurationally pure methyl branched fatty acids would prove useful for this purpose and, therefore, have synthesized a set of methyl-branched octanoic acids (3,4). An initial survey of the reactivity of six commercial lipases with selected esters of these acids is reported here. The lipases employed were crude protein preparations, and are most likely mixtures of lipolytically active species. However, since few homogeneous lipases are readily available, we selected the commercial preparations for a preliminary study. Each lipase was employed to catalyze the hydrolysis of a series of esters, and comparisons of reactivities of the branched acid esters were made with the corresponding straight chain octanoic acid ester for each lipase.

MATERIALS AND METHODS

Infrared spectra (IR) were obtained on a Perkin-Elmer 1310 spectrophotometer (Norwalk, CT) using 3% solutions in CCl_4. ^1H and ^{13}C nuclear magnetic resonance (NMR) spectra were obtained with a Bruker 300 MHz spectrometer (Karlsruhe, Germany) using $CDCl_3$ solutions with tetramethylsilane as internal standard. Gas-liquid chromatography (GLC) was done using a Shimadzu GC-Mini 2 (Columbia, MD) with an SPB-1 column (0.25 mm i.d. × 30 m) fitted with a flame ionization detector. Thin-layer chromatography (TLC) was done on silica gel 60 plates obtained from Analabs (Foxboro, MA), and fractions were visualized with iodine. Spectrophotometric assays were conducted with a Hewlett-Packard (Palo Alto, CA) 8452A Diode Array Spectrophotometer interfaced with an HP89500 Chem-Station with kinetics software (HP89512A) supplied by the manufacturer. Titrations were performed with a Radiometer Titrilab II unit (Westlake, OH).

All organic solvents were reagent grade; hexamethylphosphoric triamide (HMPT), 99%, was purchased from Aldrich Chemical Co. (Milwaukee, WI) and was stored over 13Å molecular sieves. Ellman's Reagent, 5,5′-dithio-*bis*-(2-nitrobenzoic) acid (DTNB) was similarly obtained. All other chemicals were reagent grade and were obtained from commercial sources, or, in the case of the methyl branched octanoic acids, were synthesized and characterized in this laboratory (3,4). The enzyme preparations employed in this study, their suppliers, and their specific activities in hydrolysis of triolein in 0.05 M phosphate buffer (pH 7) (μmol/min/mg) are as follows: *Candida cylindracea* (Enzeco, New York, NY) 9.45; *Rhizomucor miehei* (Gist-Brocades, Charlotte, NC) 21.3; *Rhizopus delemar* (Seikagaku Kogyo, Tokyo, Japan) 140; *Pseudomonas fluorescence* (Amano, Troy, VA) 4.3; lipoprotein lipase (Amano) 2050; and porcine pancreas lipase (Sigma Chemical Co., St. Louis, MO) 2.0. The commercial preparations were assayed for protein content using the Bradford method (5) (Bio-Rad, Richmond, CA), and bovine serum albumin was used as the standard. The percent protein for each material was as follows: *C. cylindraea*, 1.25 ± 0.12; *R. miehei*, 7.78 ± 0.74; *R. delemar*, 6.04 ± 0.58; *P. fluorescence*, 0.53 ± 0.05; liprotein lipase, 4.28 ± 4.1; and porcine pancreas lipase, 3.32 ± 0.32. The lipases were also tested for protease activity using an agar diffusion method with casein as substrate (kit from Bio-

Rad). Only the porcine pancreatic lipase showed some protease activity.

Thiolesters of 2-mercaptoethanol. Octanoic or methyl branched octanoic acid (1.40 mmol) and 2-mercaptoethanol (105 μL, 1.48 mmol) were dissolved in 5 mL of CH_2Cl_2 under dry nitrogen and cooled to 0-5°C. Dicyclohexylcarbodiimide (0.31 g, 1.47 mmol) and a few mg of *N,N*-dimethylaminopyridine were added. The resulting mixture was stirred at 25°C overnight. Hexane (15 mL) was added and the mixture was filtered into a separatory funnel; two washes of 10 mL each of hexane were added. The organic phase was shaken with 20 mL of H_2O for 3-5 min and the layers were separated. After re-extraction with another 20 mL of water, the organic phase was dried over anhydrous $MgSO_4$ and concentrated. The oily product was chromatographed over 5 g of silica gel, using mixtures of hexane and diethyl ether as solvent. Fifteen-mL fractions were collected and assayed by TLC using $CHCl_3$/acetone (90:10, v/v) as developing solvent. The thiol ester (R_f 0.33) was collected in the fractions containing 25-35% diethyl ether as eluant. The fractions showing a single spot in TLC were combined, evaporated to dryness, and finally dried *in vacuo* (0.1 mm Hg) for 1-2 hr. IR, 1680 cm^{-1}. Some of these compounds had been characterized previously as racemates (6); the new compounds also gave satisfactory chromatographic and spectral data.

p-Nitrophenyl esters. The racemic acid (0.95 g, 6.0 mmol) was dissolved in 3 mL of dry pyridine under nitrogen and cooled to 0-5°C. *p*-Nitrophenyl trifluoroacetate (1.18 g, 5.0 mmol) (7) was added and the resulting mixture was stirred without cooling for 15 min (30 min for the 2- and 3-isomers). The mixture was diluted with hexane (50 mL) and washed with 2N HCl (35 mL) and 2 × 50 mL H_2O. The organic phase was dried over anhydrous $MgSO_4$ and concentrated. The resultant oil was chromatographed on 25 g of silica gel using hexane and diethyl ether. Fractions of 100 mL each were collected, and the ester was eluted with 5-10% diethyl ether: IR, 1710, 1530, 1350 cm^{-1}; TLC (ethyl acetate/hexane, 15:85, v/v), R_f 0.40-0.44; GLC (220°C), k' = 3.93 (octanoic), 4.23-4.85 (methyl branched esters). For the octanoic acid ester: ^1H NMR, δ 0.90 (3H, CH_3, *t*,J = 6.8 Hz), 1.3-1.8 (10 H, *m*), 2.60 (2H, CH_2C =),*t*,J = 7.2 Hz), 7.28, 8.21 (4H, aryl H, *d*,J = 5.2 Hz) ppm; ^{13}C NMR, δ 13.9, 22.5, 24.9, 28.8, 29.1, 31.6, 34.4, 122.3, 125.1, 145.6, 155.8, 171.1 ppm.

Enzyme kinetics for hydrolysis of thiolesters. The general procedure of Renard *et al.* (8) was followed. Solutions of substrate in HMPT (up to 100 μL of stock, maintaining a volume of 100 μL with HMPT), 400 μL of DTNB in HMPT (25 mg/mL), and 2.45 mL of 0.05 M Tris buffer (pH 8) were placed in UV cells. The final solute concentrations ranged from 10^{-5} to 4 × 10^{-4}. The absorption at 412 nm (ε = 13,600 $mol^{-1}cm^{-1}$) (9) was immediately monitored for background hydrolysis (none observed) and corrected for the small amount of free thiol present in the synthesized esters. A solution of the enzyme (50 μL) was then added to initiate the reaction. For the unbranched octanoate esters it was possible to obtain a quadratic fit based on least squares of the time course data to an equation of the form: $A = at + bt_2 + c$. The absorbance at time t (since scanning began) is A, and a is the slope of the time trace at t = 0 and is employed as the initial rate. Kinetic parameters (K_m, V) were then obtained by a nonlinear regression curve (Marquardt analysis) (10). Many of the other substrates were much less reactive, and solubility limitations allowed only a best fit to the initial rate data to obtain a value for a pseudo first order rate constant (k_2/K_m) (Table 1). Initial velocities, v_o, were obtained with at least three initial substrate concentrations, S_o, having standard deviations ⩽ 10% using a quadratic fit to the kinetic runs. The slope of the plot of v_o *vs* S_o was divided by mg of protein used to give an apparent k_2/K_m for each substrate and each lipase preparation examined. The correlation coefficient, ϱ, for these plots was > 0.95. The values k_2/K_m for each branched acid ester relative to that of the unbranched octanoate ester for a particular lipase is given in Table 1.

Enzyme kinetics for hydrolysis of p-nitrophenyl esters. Solutions were prepared as described above for hydrolyzing the thiolesters, using the aryl esters and employing a molar extinction coefficient of 18,600 mol^{-1} cm^{-1} for the *p*-nitrophenate chromophore determined experimentally in this medium at this pH at 408 nm. Initial velocities for background hydrolysis of these esters (the rates were 1-2% of the enzymatic rates) were determined and then were subtracted from the rates determined in the presence of enzyme. Eight to sixteen initial substrate concentrations were used, and the time course data were then treated by nonlinear regression and fitted to a curve based on quadratic fit to obtain V_{max} and K_m. The value for V_{max} was divided by mg of protein to obtain an apparent k_2. Standard deviations for V and K_m were ⩽ 5% and 15%, respectively.

Confirmation of stereobias in kinetic studies by esterification of racemic 2-methyloctanoic acid. Reaction mixtures consisted of 2.5 mmol each of 2-methyloctanoic acid and tridecane (as an internal standard for GLC), 10 mmol of 1-butanol, and 0.25 g of enzyme powder in 10 mL of hexane saturated with H_2O. The mixures were stirred magnetically at 30°C for several days and were monitored by GLC for conversion. Analysis for configuration was performed when the conversion exceeded 20% as follows: the mixture was filtered and the clear hexane solution was extracted with cold 1 N NaOH (10 mL; to minimize racemization of the acid), and cold H_2O (5 mL). The aqueous solution was washed with diethyl ether (10 mL), and was then acidified with cold 2 N HCl (5 mL). The liberated acid was extracted into diethyl ether and converted *via* its acid chloride to an amide of S-α-phenylethylamine. Thionyl chloride (0.22 mL, 3.0 mmol) and dimethylformamide (15 μL) were added to the recovered acid in dry diethyl ether (5 mL). After standing at 25°C for 1 hr, the mixture was decanted, concentrated, dissolved in CH_2Cl_2 (5 mL), and added to a solution of S-α-phenylethylamine (0.38 mL, 3 mmol) and triethylamine (0.42 mL, 3 mmol) in CH_2Cl_2 (6 mL). After standing at 25°C for 15 min, the mixture was washed with 2N HCl, H_2O, dried over anhydrous $MgSO_4$, and concentrated. Analysis by GLC (SPB-1/210°C) gave relative amounts of the diastereomers that allowed configuration analysis of the unreacted acid. The capacity fac-

tor, k′, for the S,S-diastereomer was 3.38; and 3.66 for the R,S. Since the latter was always in excess, the S-acid reacted faster with these lipases (details in text).

Procedure for hydrolysis of racemic 2-methyloctanoic acid phenyl ester. Phenyl ester (1.0 g, 4.03 mmol) was suspended in distilled H_2O (50 mL) containing 1.0 g of NOVO "Lipozyme" which is *R. miehei* lipase from Gist-Brocades on an inert resin. The reaction mixture was agitated and kept at pH 7 using automatic titration with 0.1 N NaOH for a period of 12 hr, at which time 39.3% conversion had been achieved. The mixture was then suction filtered using CH_2Cl_2 as a rinse, and the organic phase was separated. The organic phase was washed with another portion of CH_2Cl_2, and the combined organic phase was then extracted with cold NaOH (20 mL, 1.23 N) and H_2O (10 mL). The aqueous phase was acidified with cold 2N HCl, and the product was extracted with CH_2Cl_2. The recovered acid was coverted to diastereomeric amides as above and characterized by GLC as previously described. The R,S-diastereomer predominated (72.5:27.5), which meant that the R-acid had hydrolyzed more rapidly.

RESULTS AND DISCUSSION

Octanoic acid, and the synthesized methyl branched octanoic acids, racemic as well as individual enantiomers, were converted to thiolesters of 2-mercaptoethanol using dicyclohexylcarbodiimide and catalytic amounts of N,N-dimethylaminopyridine (5). Such thiolesters can be employed in a homogeneous medium comprised of 17% hexamethylphosphoric triamide, HMPT, in aqueous buffer at pH 8 using Ellman's Reagent for a continuous spectrophotometric assay of lipase activity (8,11). Because the reaction medium is homogeneous, no information can be obtained about the particular events that mediate the special enzyme activity at an oil-water interface (12,13). On the other hand, homogeneity permits spectrophotometric analysis, gives results that are easily reproduced, and avoids ambiguities in measuring concentrations in emulsions.

The branched acid esters were much less reactive than octanoic acid ester itself and enzyme saturating conditions could not be reached without exceeding the solubilities of the substrates (ca. 5×10^{-4} M). Therefore kinetic data points for several low concentrations (10^{-5} to 10^{-4} M) were accumulated as described in Materials and Methods, and reaction velocities were calculated. At low concentrations the velocities were approximately proportional to substrate concentrations, and allowed an estimate of a pseudo-first-order rate constant (k_2/K_m) that was taken as a measure of relative activity of the substrate (Table 1). The tabulated data represent the value of (k_2/K_m) for each racemic ester relative to that of the (unbranched) octanoic ester taken as 1.00. The actual values of (k_2/K_m) obtained for the more reactive octanoic acid ester itself with each lipase, as well as the ratio that was obtained by calculating each variable independently by Marquardt analysis of nonlinear regression plots based on a wider range of substrate concentrations are footnoted. These values are dependent on enzyme purity, so the relative selectivities of a set of substrates using a single enzyme allows a better comparison of the way selectivity varies with substrate structure for a particular enzyme preparation. In addition, each enantiomer of each branched acid thiolester was also examined, and the ratios (k_2/K_m) for one enantiomer relative to the other, shown with the R,S-convention for designating configuration, are used to indicate the faster reacting enantiomer in parenthese. These values are equivalent to enantiomeric ratios, E_R, that can be obtained from kinetic resolution of racemic mixtures (14). In general, stereoselectivity was

low, although the reactions of the 2-methyloctanoic acid esters were consistently selective for the S-enantiomer.

Experiments were conducted to confirm the uniform S-stereoselectivity for 2-methyloctanoic acid observed for the hydrolysis of the thiolesters. Several examples of preferential reaction of R-2-substituted acids, or acid derivatives, with lipase catalysis have been reported (2). However, in these cases the 2-substituent was always an electronegative atom, e.g., Cl, F, OC_6H_5, where nonbonded electron pairs offered electrostatic interactions that may alter stereoselection. Esterification of racemic 2-methyloctanoic acid with 1-butanol in wet hexane using lipases from *Pseudomonas fluorescence* and *Rhizomucor miehei* did indeed proceed at a faster rate for the S-2-enantiomer. For *R. miehei* at 57.0% conversion, the enantiomeric excess, ee, was 0.612, *i.e.*, the ratio of S to R in the recovered unreacted 2-methyloctanoic acid was 0.806:0.194, and therefore $E_R = 4.9$ (15). The selectivity of *P. fluorescence* was much greater and might even be synthetically useful; $E_R > 40$ (conversion: 24.8%, enantiomeric excess: 0.31). The selectivity for S-2-methyloctanoic acid, and likely 2-methyl substituted fatty acids, in hydrolysis of aliphatic esters and esterification of alcohols may be general.

The *p*-nitrophenyl esters were prepared from the trifluoroacetate of *p*-nitrophenol in pyridine (7). Lipase catalyzed hydrolysis was examined in the same medium as was used for the thiolesters, namely 17% HMPT buffered at pH 8. The maximum molar extinction coefficient for *p*-nitrophenate at that pH was determined to be 18,600 at 408 nm (at 3.33×10^{-4} M). Although the *p*-nitrophenyl esters were no more soluble than the thiolesters, their reactivity was considerably greater, and values of K_m and V were obtained using two of the lipases. *R. miehei* was chosen as a lipase characterized as positionally selective in its reactions with triglycerides, while *C. cylindracea* exemplified a lipase that is random in its action (16). The *p*-nitrophenyl esters underwent slow nonenzymatic hydrolysis at pH 8, and the kinetic data points for the enzymatic reaction were corrected by subtracting values obtained for the nonenzymatic hydrolysis rates. The background rate was 1-2% of the total rate and standard deviations for V and K_m were ⩽ 6 and 15%, respectively. Table 2 gives k_2, K_m, their ratio, and the ratio relative to that of the *p*-nitrophenyl octanoate. The enantiomeric 2-methyloctanoic acid *p*-nitrophenyl esters were treated with these

same two lipases, and the data are shown in Table 3. The S-ester hydrolyzed faster with *C. cylindracea* lipase, as had been the case for the thiolester. However, the lipase from *R. miehei* selected strongly for the R-enantiomer. This was confirmed by hydrolysis of the phenyl ester of racemic 2-methyloctanoic acid, which yielded predominantly the R-acid (E_R = 2.7). Changing the alcohol moiety from an aliphatic to an aryl alcohol had inverted stereoselection for the *R. miehei* lipase.

Although the enzymes employed were crude commercial preparations, there are features of the results that warrant discussion. Substitution at the 2-position by a methyl group markedly reduces reactivity for the esters examined. This observation has been made previously, albeit in a more limited study (17). Substitution at the 3-position generally causes a further reduction in reactivity for the lipases examined. The similarity among the lipases is quite striking, and the bar graph (Fig. 1) illustrates this using the three fungal lipases. We also noted that branching at the 5-position is often more deleterious to reactivity of the substrate than branching at positions 4 or 6. This variation in hydrolytic rate is consistent with a situation wherein the carbonyl oxygen of the ester is directed toward the enzyme in the complex (Fig. 2). Hydrophobically bound in this manner, carbons 3 and 5 of the chain would project similarly toward the enzyme, and branching at those positions would be predictably worse for binding. Branching further removed from the ester function could still affect binding but less severely; the substrate may still become hydrophobically associated with the enzyme, but use a shorter stretch of unbranched chain.

The relative rates of reaction of pairs of enantiomers of the branched acid esters are generally small. For the 2-methyl enantiomers, the K_m is similar, and the effect of the methyl branch is, perhaps predictably, on the catalytic event itself. Reaction of 2-methyloctanoic acid with these lipase preparations results in a faster reaction of the S-enantiomer when an aliphatic alcohol is involved as a nucleophile. Hydrolysis of an aryl ester, catalyzed by *R. miehei* lipase, however, displayed a reversed stereobias. This observation does not accord with a view of the enzyme binding site as a relatively static environment, but rather with one in which accommodation is possible with the stereochemical consequences reflecting the manner in which the alcohol (phenol) residue structures water in the immediate vicinity of the carbonyl group. Another possibility is the existence of a binding pocket that fortuitously accommodates an aryl ring and alters the favored direction of approach of the nucleophile to the carbonyl. The results emphasize the need for more specific protein structural information.

ACKNOWLEDGMENTS

We express our appreciation to Dr. Robert Dudley of our laboratory for obtaining NMR spectra, and to Dr. Harry Farrell for helpful discusions in the preparation of our manuscript. The lipases, excepting that of *R. delemar*, were generous gifts of the manufacturers.

Preparation of Methyl 11,14,17-Eicosatrienoate-8,8,9,9-d_4 and Methyl 8,11,14,17-Eicosatetraenoate-8,9-d_2[1]

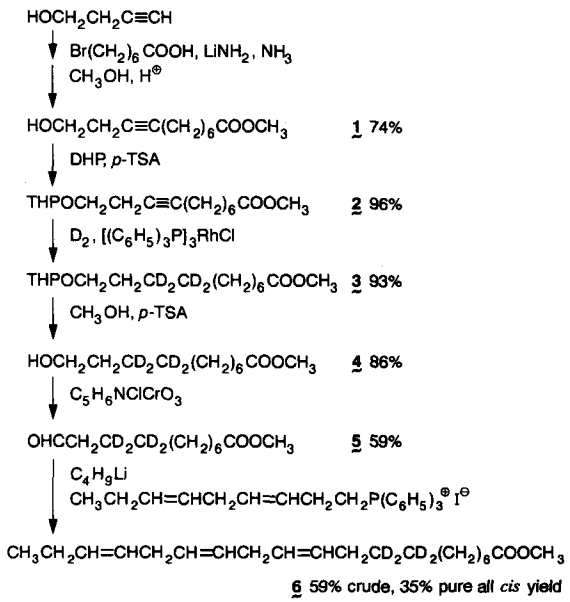
Henry Rakoff*
National Center for Agricultural Utilization Research, Agricultural Research Service, USDA, Peoria, Illinois 61604

Methyl 11,14,17-eicosatrienoate-8,8,9,9-d_4 was obtained by Wittig coupling of 3,6-nonadienyltriphenylphosphonium iodide with methyl 11-oxoundecanoate-8,8,9,9-d_4. For the synthesis of the phosphonium salt, 2-pentynol was converted to 1-bromo-2-pentyne with triphenylphosphine dibromide. Grignard coupling of 1-bromo-2-pentyne with 3-butynol in the presence of cuprous chloride gave 3,6-nonadiynol. The latter was hydrogenated in the presence of P-2 nickel catalyst to yield 3,6-nonadienol. The dienol was converted *via* the bromide and iodide to the phosphonium salt. The aldehyde ester was prepared starting with the coupling of 7-bromoheptanoic acid and 3-butynol with lithium amide in liquid ammonia. The hydroxyalkynoic acid obtained was converted to the methyl ester and the hydroxy group was converted to the tetrahydropyranyloxy group. Subsequent deuteration of the methyl 11-(2-tetrahydropyranyloxy)-8-undecynoate with deuterium gas and *tris*-(triphenylphosphine)chlorohodium gave the corresponding tetradeuterated product. The tetrahydropyranyl group was removed and the methyl 11-hydroxy-undecanoate-8,8,9,9-d_4 was oxidized to the aldehyde ester with pyridinium chlorochromate. Methyl 8,11,14,17-eicosatetraenoate-8,9-d_2 was obtained by a similar sequence of reactions. The methyl 11-oxo-8-undecenoate-8,9-d_2 required for the Wittig coupling was obtained by Lindlar deuteration of the protected alkynoic ester to methyl 11-(2-tetrahydropyranyloxy)-8-undecenoate-8,9-d_2. The unsaturated hydroxy ester was oxidized to the aldehyde ester by periodinane with negligible isomerization. The all *cis* isomers were isolated by silver resin chromatography.
***Lipids* 26, 301–305 (1991).**

For our study of the metabolism of fats in humans (1,2), we have synthesized various monoenoic (3), dienoic (4) and trienoic (5–7) fatty esters labeled with deuterium atoms in various positions. In this paper we describe the synthesis of deuterated analogs of methyl 11,14,17-eicosatrienate (11,14,17-20:3) and methyl 8,11,14,17-eicosatetraenoate (8,11,14,17-20:4), which are intermediates in the conversion of linolenate (9,12,15-18:3) to eicosapentaenoate (5,8,11,14,17-20:5). They have been prepared to study the path of this conversion.

RESULTS AND DISCUSSION

The syntheses of the two title compounds involve a combination of acetylenic, Grignard and Wittig couplings. The last coupling in both syntheses was a Wittig reaction between 3,6-nonadienyltriphenylphosphonium iodide and an appropriate aldehyde ester. With the compounds employed in these synthetic sequences, the Wittig Reaction usually yields the *cis* and *trans* isomers of the double-bond generated in the ratio of about 85:15. The phosphonium iodide was prepared by a sequence of reactions starting with 2-pentynol. The alkynol was converted to 1-bromo-2-pentyne with triphenylphosphine dibromide. Grignard coupling of this bromoalkyne with 3-butynol gave 3,6-nonadiynol, which was reduced with hydrogen and P-2 nickel catalyst to 3,6-nonadienol. The alcohol was converted to the bromide with triphenylphosphine dibromide, to the iodide with sodium iodide in acetone, and to the phosphonium iodide with triphenylphosphine in acetonitrile. Experimental details for all these steps have been published (6,7).



Methyl 11,14,17-eicosatrienoate-8,8,9,9-d_4 (6) was obtained by Wittig coupling of 3,6-nonadienyltriphenylphosphonium iodide with methyl 11-oxoundecanoate-8,8,9,9-d_4 (5). The synthesis of 5 is detailed in Scheme 1. 3-Butynol was condensed with 7-bromoheptanoic acid in the presence of lithium amide in liquid ammonia to give methyl 11-hydroxy-8-undecynoate 1 in 75% yield after esterification. The hydroxy group was protected as the tetrahydropyranyl ether (2) in 96% yield. Deuteration of 2 with deuterium gas in the presence of Wilkinson's catalyst, *tris*-(triphenylphosphine)chlororhodium, gave the tetradeuterated tetrahydropyranyl (THP) ester (3) in 94% yield. The THP group was removed with methanol and *p*-toluenesulfonic acid to give the tetradeuterated hydroxy ester (4) in 85% yield. Oxidation with pyridinium chlorochromate (6,8) gave methyl 11-oxoundecanoate-8,8,9,9-d_4 (5) in 59% yield. Reaction of 5 with the phosphonium iodide and butyl lithium gave 6 in 60% crude yield. The all *cis* isomer was separated by silver resin chromatography (9,10) with a 100% Ag/Na column using 3% acetronitrile in methanol as eluent. Nuclear magnetic resonance spectroscopy confirmed the structure and configuration assigned. Mass spectroscopy using the chemical ionization technique indicated 97% d_4.

Methyl 11-oxo-8-undecenoate-8,9-d_2 (9) was required for the synthesis of methyl 8,11,14,17-eicosatetraenoate-8,9-d_2 (10). Synthesis of this aldehyde ester is depicted in Scheme 2. Reaction of compound 2 with deuterium and Lindlar's catalyst, Pd on $CaCO_3$ poisoned with lead, gave the deuterated product (7) in 99% yield. The

SCHEME 1

SCHEME 2

THP group was removed with methanol and *p*-toluenesulfonic acid to give the β,γ-unsaturated hydroxy ester (8) in 82% yield. Numerous oxidizing agents were investigated to find one that would oxidize the β,γ-unsaturated hydroxy ester to the β,γ-unsaturated aldehyde ester (9) without isomerization to the α,β-unsaturated aldehyde ester. It was found that periodinane, 1,1,1-*tris*-(acetoxy)-1,1-dihydro-1,2-benziodoxol-3(1H)-one (11,12) would accomplish this in about 50% yield.

The unsaturated aldester (9) was treated with butyl lithium and 3,6-nonadienyltriphenylphosphonium iodide to give compound (10) in about 35% crude yield. The all *cis* isomer was obtained from this mixture by silver resin chromatography on a 62% Ag/Na column using methanol as eluent. Mass spectroscopy, using the chemical ionization technique, indicated at least 92% d_2. Nuclear magnetic resonance (NMR) spectroscopy supported the structure and configuration assigned.

EXPERIMENTAL PROCEDURES

Reagents. Butyl lithium, triphenylphosphine, dihydropyran, sodium borohydride, ethyl magnesium bromide, 3-butynol. Lindlar's catalyst, pyridinium chlorochromate, ethylene diamine and periodinane were obtained from Aldrich Chemical Company (Milwaukee, WI). Aldrich no longer offers periodinane ostensibly due to an explosion hazard with an intermediate in its preparation. However, periodinane can be prepared fairly readily (11). A discussion of the safety aspects and an improved preparation of periodinane will be published in *Journal of the American Chemical Society* by Dess and Martin (personal communication). 2-Pentynol was purchased from Farchan Laboratories (Gainesville, FL), *tris*-(triphenylphosphine)chlororhodium from Strem Chemicals (Newburyport, MA) and 7-bromoheptanoic acid from Pfaltz and Bauer (Waterbury, CT). Silica gel (60–200 mesh) and Florisil (100–200 mesh) were obtained from J.T. Baker (Jackson, TN).

Gas chromatography. A 50 m × 0.25 mm CPS-2 capillary column (Quadrex Corp., New Haven, CT) was used for analyzing binary mixtures of geometric isomers. For other analyses, a 6 ft × 4 mm column packed with 3% EGSS-X on 100/120 GasChrom Q or a 6 ft × 4 mm column packed with 3% OV101 on 80/100 Supelcoport (Supelco, Bellefonte, PA) was employed.

^{13}C NMR. ^{13}C Nuclear magnetic resonance (NMR) spectra were recorded with a Bruker (Karlsruhe, Germany) WM 300 WB pulsed Fourier transform spectrometer operating at 75.5 MHz and ambient temperature. Typically, 2500 transients were collected on $CDCl_3$ solutions, which served as both the internal lock and secondary reference, using 5-mm tubes. Sweep widths of 200 ppm and 8 K real data points limited acquisition time to 0.54 seconds and were used to obtain chemical shift values within ± 1.85 Hz, *i.e.*, ± 0.05 ppm. A pulse width of 3 μs (40°) was employed with no delay between pulses. Decoupling power was held to *ca.* 1 W to provide adequate broadband decoupling power while minimizing sample heating. The signal from carbons bearing two deuterium atoms or one deuterium atom and a double bond is diminished to such an extent that it was usually not detected. Thus, no peaks for the ethylenic carbons were obtained from compounds 7, 8 and 9.

Mass spectroscopy. Mass spectra were determined on a Finnigan (Sunnyvale, CA) 4500 mass spectrometer using isobutane chemical ionization with data processing of the isotope distribution against standards (13).

Silver resin chromatography. The macroreticular resin used for the separations was Rohm and Hass XN1010 sulfonic acid resin ground to the mesh sizes indicated. For the Ag/H columns, the indicated percentage of hydrogen ions was displaced by Ag ions. For the Ag/Na columns, the hydrogen ions were displaced by sodium ions, and then the indicated percentage of sodium ions was displaced by Ag ions (9,10).

Methyl 11-hydroxy-8-undecynoate (1). Liquid am-

monia (*ca* 800 mL) was charged to a 2-L 3-necked flask equipped with a mechanical stirrer and a dry-ice cooled condenser and surrounded by Vermiculite. Ferric nitrate (1 g) was added, followed by lithium metal (11.05 g, 1580 mmol) which was added in small pieces over 45 min. 3-Butynol (55.26 g, 789 mmol) dissolved in tetrahydrofuran (THF) (150 mL) was added over 35 min. Then 7-bromoheptanoic acid (33 g, 158 mmol) dissolved in THF (100 mL) was added over 25 min. Ten hours later stirring was stopped, the Vermiculite was removed, and the ammonia was allowed to evaporate overnight. The next day the flask was immersed in a warm water bath and flushed with inert gas to remove residual ammonia. Water (100 mL) was added to ease stirring and the reaction vessel was immersed in an ice bath while the contents were acidified with 5N H_2SO_4 (450 mL). The tan liquid was extracted with diethyl ether (EE; 1 × 250 mL, 2 × 100 mL) and the combined EE extracts were washed with saturated NH_4Cl solution (100 mL) and saturated NaCl solution (100 mL) and dried over anhydrous Na_2SO_4. The drying agent was removed by filtration and the solvent was removed on a rotary evaporator. Excess 3-butynol was removed by distillation under reduced pressure. Methanol (130 mL) and conc. H_2SO_4 (1 mL) were added to the residue and the mixture was heated at the reflux temperature for one hr. The acid was neutralized with solid $NaHCO_3$ and solvent was removed on the rotary evaporator. The viscous liquid remaining was diluted with water (150 mL) and extracted with EE (2 × 50 mL). The combined EE extracts were washed with saturated NaCl solution (70 mL) and dried (Na_2SO_4). After removal of the drying agent and solvent, the residue was distilled to give compound 1 (24.88 g; 74.3% yield) b.p. 123–146°C (0.25 torr). ^{1}H NMR ($CDCl_3$): δ 3.52–3.56 (*m*,2H,CH_2OH), δ 3.54 (*s*,3H,OCH_3), δ 2.67(*s*,1H,O*H*), δ 2.26–2.31(*m*,2H,CH_2CH$_2$OH), δ 2.19(*t*,2H,CH_2COO), δ 2.02(*m*,2H,CH_2C≡C), δ 1.50(*m*,2H,CH_2CH$_2$COO), δ 1.20–1.39(*m*,6H,(CH_2)$_3$). ^{13}C NMR (ppm): C-1, 174.0; C-2, 33.7; C-3, 24.5; C-4, 28.3; C-5, 28.2; C-6, 28.5; C-7, 18.4; C-8, 81.7; C-9, 76.4; C-10, 22.8; C-11, 61.1; OCH_3, 51.2. Values for carbons numbered 4, 5, 6, 8, and 9 were established by correlation experiments. Proton assignments were verified with a COSY experiment and carbon assignments were determined by HETCOR and long-range HETCOR experiments.

Methyl 11-(2-tetrahydropyranyloxy)-8-undecynoate (2). Methyl 11-hydroxy-8-undecynoate (74 g, 349 mmol) in EE (150 mL) and *p*-TSA (0.5 g) were placed in a 500-mL, 3-necked flask equipped with a mechanical stirrer, a dropping funnel and a reflux condenser. Dihydropyran (38 g, 454 mmol) dissolved in EE (100 mL) was added dropwise over 30 min to maintain a gentle reflux. Two hr later, saturated Na_2CO_3 (10 mL) was added. The organic layer was separated and dried over Na_2SO_4. After removal of the drying agent and solvent, the liquid remaining was passed through a column (30 mm × 50 cm) containing silica gel (100 g) in hexane. A total of 99.72 g (96% yield) of product was obtained by elution with mixtures ranging from 0 to 15% EE in hexane. ^{13}C NMR (ppm): C-1, 174.0; C-2, 33.9; C-3, 24.7; C-4, 28.5; C-5, 28.3; C-6, 28.6; C-7, 18.6; C-8, 80.9; C-9, 76.8; C-10, 20.1; C-11, 66.1; OCH_3, 51.3; THP group: C-2, 98.6; C-3, 30.5; C-4, 19.3; C-5, 25.4; C-6, 62.0.

Methyl 11-(2-tetrahydropyranyloxy)-undecanoate-8,8,9,9,-d_4 (3). Methyl 11-(2-tetrahydropyranyloxy)-8-undecynoate (50 g, 169 mmol) in benzene (1 L) was treated with deuterium gas in the presence of *tris*-(triphenylphosphine)chlororhodium (5 g) in the manner described previously (3). Benzene was removed on the rotary evaporator and the red liquid remaining was diluted with hexane (300 mL), filtered and then passed through a column (30 mm × 50 cm) containing silica gel (100 g) in hexane. Elution with 10% EE in hexane gave compound 3 (47.85 g, 93% yield). ^{13}C NMR (ppm): C-1, 174.1; C-2, 34.0; C-3, 24.9; C-4 through C-7, 29.0–29.2; C-10, 29.4; C-11, 67.5; OCH_3, 51.3; THP group: C-2, 98.7; C-3, 30.7; C-4, 19.6 C-5,25.4; C-6, 62.2.

Methyl 11-hydroxyundecanoate-8,8,9,9-d_4 (4). Compound 3 (31.84 g, 105 mmol), *p*-TSA (0.8 g) and methanol (600 mL) were placed in a 1-L round bottom flask which was then flushed with nitrogen, capped, and stored for 16 hr. The acid was neutralized with solid Na_2CO_3. After filtration, methanol was removed on the rotary evaporator. The residue was diluted with saturated aqueous $NaHCO_3$ and extracted with EE (2 × 50 mL). The EE extracts were dried (Na_2SO_4) and after removal of the drying agent and solvent the residue was distilled to give compound 4 (19.66 g, 85.5% yield) b.p. 123–142°C (0.3 torr). ^{1}H NMR($CDCl_3$): δ 3.61(*s*,3H,OCH_3), δ 3.56(*t*,2H,CH_2OH), δ 2.25 (*t*,2H,CH_2COO), δ 1.90(*s*,1H,O*H*), δ 1.48–1.56 (*m*,4H, CH_2CH$_2$COO and CH_2CH$_2$OH), δ 1.22(*m*,8H,(CH_2)$_4$). ^{13} NMR (ppm): C-1, 174.2; C-2, 34.0; C-3, 24.8; C-4 through C-7, 29.0–29.2; C-10, 32.4; C-11, 62.8; OCH_3, 51.3.

Methyl 11-oxoundecanoate-8,8,9,9-d_4 (5). Pyridinium chlorochromate (28.8 g, 134 mmol) was slurried in CH_2Cl_2 (200 mL) in a 500 mL, 3-necked flask equipped with a mechanical stirrer, a low temperature thermometer, and a dropping funnel. While a stream of nitrogen was passed through the apparatus immersed in an ice bath, compound 4 (19.6 g, 89 mmol), dissolved in CH_2Cl_2 (50 mL), was added over 15 min. Two hr later, EE (100 mL) was stirred into the black liquid. A lump formed and the liquid was decanted. The tarry lump was stirred with EE (2 × 50 mL), and the combined EE decantates were passed through a column (15 mm × 25 cm) containing Baker Florisil (20 g). The dark green liquid which was obtained was concentrated on the rotary evaporator and the residue (23 g) was distilled through a short path still. The product solidifies in the condenser so it is best to not pass cooling water through the condenser. A total of 11.41 g (59% yield) of compound 5 was obtained, b.p. 112–120°C (0.2 torr). ^{1}H NMR($CDCl_3$): δ 9.69 (*t*1H,C*H*O), δ 3.59(*s*,3H,OCH_3), δ 2.33(*s*,2H,CH_2CHO), δ 2.23 (*t*,2H,CH_2COO), δ 1.54(*m*,2H,CH_2CH$_2$COO), δ 1.21(*m*,8H, (CH_2)$_4$). ^{13}C NMR (ppm): C-1, 174.0; C-2, 33.9; C-3, 24.8; C-4 through C-7, 28.9–29.0; C-10, 43.5; C-11, 202.6; OCH_3, 51.2.

Methyl 11,14,17-eicosatrienoate-8,8,9,9-d_4 (6). 3,6-Nonadienyltriphenylphosphonium iodide (30.8 g, 60 mmol) was slurried in THF (200 mL) in a 500-mL 3-necked flask equipped with a mechanical stirrer, a dropping funnel, a low temperature thermometer, and a $CaCl_2$ tube. While a stream of N_2 was passed through the apparatus immersed in an ice bath, butyl lithium

(2.5 M, 28 mL, 70 mmol) was added in portions over 10 min while the temperature was maintained below 10°C. The reaction mixture was very dark red in color. Compound 5 (11.4 g, 52.3 mmol) in THF (10 mL) was added over 5 min. The ice bath was removed and one hr later the reaction mixture was diluted with saturated NaCl solution (200 mL). The organic layer was separated, dried (Na_2SO_4), and concentrated on the rotary evaporator to give a solid (31.2 g). This was triturated several times with petroleum ether and the petroleum ether (PE) solution was passed through a column (30 mm × 50 cm) containing silica gel (100 g) in PE. Elution with PE and with 5% EE in PE gave compound 6 (10.08 g, 59.0% yield). To isolate the all *cis* isomer, the reaction mixture was separated on a silver resin column (5 × 82 cm) containing Amberlyst XN1010 (60/200 mesh) 100% Ag/Na using as eluents 100% methanol and 3% acetonitrile in methanol. The all *cis* isomer of compound 6 was obtained (5.93 g, 35% yield based on the Wittig reaction, 12% overall based on the 7-bromoheptanoic acid used). It was better than 98% pure by GC analysis on a 30-m SP 2330 column. Deuterium distribution: 0.19% d_1, 1.22% d_2, 97.04% d_4, 1.54% d_5. ^{1}H NMR ($CDCl_3$): δ 5.27-5.34(*m*,6H,C*H*=C*H*), δ 3.60(*s*,3H,OCH_3), δ 2.75(*t*,4H,C=CCH_2C=C), δ 2.24(*t*,2H,CH_2COO), δ 1.98-2.05(*m*,4H,CH_2C=C), δ 1.57(*m*,2H,CH_2CH$_2$COO), δ 1.23(*m*,8H,(CH_2)$_4$ δ 0.92(*t*,3H,CH_3). ^{13}C NMR (ppm): C-1, 173.9; C-2, 33.9; C-3, 24.8; C-4 through C-7, 29.0-29.3; C-10, 26.9; C-11, 130.1; C-12, 127.5; C-13,16, 25.4-25.5; C-14, C-15, 128.1; C-17, 127.0; C-18, 131.7; C-19, 20.4; C-20, 14.1.

Methyl 11-(2-tetrahydropyranyloxy)-8-undecenoate-8,9-d_2 (7). Methyl 11-(2-tetrahydropyranyloxy)-8-undecynoate (14.8 g, 50 mmol) and ethyl acetate (100 mL) were placed in a 250-mL round-bottom flask equipped with a magnetic stirring bar and connected to an apparatus for maintaining one atmosphere of pressure. The apparatus was evacuated and flushed three times with D_2. Then, Lindlar's catalyst (0.5 g) and quinoline (0.3 mL) were added and a pressure of one atmosphere of D_2 was maintained as the reaction mixture was stirred rapidly. After absorption of D_2 had ceased, the reaction mixture was filtered through a pad of Celite to remove the catalyst. Ethyl acetate was removed on the rotary evaporator to yield compound 7 (14.9 g, 99% crude yield). ^{13}C NMR (ppm): C-1, 174.1; C-2, 34.0; C-3, 24.9; C-4 through C-6, 28.8-29.4; C-7 or C-10, 27.12 or 27.8; C-11, 67.0; OCH_3, 51.4; THP group: C-2, 98.7; C-3, 30.7; C-4, 19.6; C-5, 25.4; C-6, 62.2.

Methyl 11-hydroxy-8-undecenoate-8,9-d_2 (8). In a manner similar to the conversion of 3 to 4, compound 7 was converted to 8 in 81.5% yield, b.p. 120-126°C (0.2 torr). ^{1}H NMR($CDCl_3$): δ 3.57(*s*,3H,OCH_3), δ 3.54(*m*,2H,CH_2OH), δ 2.40(*m*,1H,O*H*), δ 2.19-2.24(*m*,4H,CH_2COO and CH_2CH$_2$OH), δ 1.96 (*m*,2H,CH_2C=C), δ 1.53(*m*,2H,CH_2CH$_2$COO), δ 1.23(*m*,6H, (CH_2)$_3$). ^{13}C NMR (ppm): C-1, 174.1; C-2, 33.8; C-3, 24.7; C-4 through C-6, 28.6-29.2; C-7, 26.9; C-10, 30.5; C-11, 62.0; OCH_3, 51.2.

Methyl 11-oxo-8-undecenoate-8,9-d_2 (9). Periodinane (6.49 g, 15.3 mmol) in methylene chloride (90 mL, distilled from CaH_2 and stored over Molecular Sieve 4A) was placed into a 500-mL 3-necked flask equipped with a mechanical stirrer, a dropping funnel, a thermometer and a $CaCl_2$ drying tube. Compound 8 (3.g, 13.9 mmol) in methylene chloride (100 mL) was added dropwise over 20 min while a slow stream of N_2 was maintained through the apparatus. After 50 min, EE was added, followed 15 min later by a solution of $Na_2S_2O_3.5H_2O$ (27.54 g) in saturated $NaHCO_3$ solution (100 mL). The aqueous layer was separated and extracted with EE (50 mL). The combined EE layers were washed with saturated $NaHCO_3$ solution (50 mL), saturated NaCl solution (50 mL), and dried (Na_2SO_4). Removal of the drying agent and solvent gave a thick orange liquid. Passage of this liquid through a small silica gel column with hexane gave compound 9 (1.54 g, 52% yield). This compound isomerizes partially to the conjugated isomer on passage through a column of 3% EGSS-X in a gas chromatograph. Infrared analysis showed a carbonyl band at 1737 cm^{-1} and no trace of a band for an α,β-unsaturated aldehyde. In addition, there is no infrared band for a *trans* double bond which would be expected in the conjugated unsaturated aldehyde. In the proton NMR, the area under the doublet (conjugated aldehyde) is about 1% of the area under the triplet (nonconjugated aldehyde). ^{1}H NMR ($CDCl_3$): δ 9.59(*t*,1H, C=CCH$_2$C*H*O), δ 9.52(*d*,1H,C=CC*H*O), δ 3.60(*s*,3H,OCH_3), δ 3.12(*s*,2H,CH_2C*H*O), δ 2.24(*t*,2H,CH_2COO), δ 1.97(*m*,2H,CH_2C=C), δ 1.55(*m*,2H,CH_2CH$_2$COO), δ 1.25-1.31(*m*,6H, (CH_2)$_3$). ^{13}CNMR (ppm): C-1, 174.0; C-2, 33.9; C-3, 24.7; C-4 through C-6, 28.7-28.9; C-7, 27.3; C-10, 42.3; C-11, 199.4; OCH_3 51.3.

Methyl 8,11,14,17-eicosatetraenoate-8,9-d_2 (10). 3,6-Nonadienyltriphenylphosphonium iodide (4.13 g, 8 mmol) was slurried in THF (50 mL) in a 100-mL, 3-necked flask equipped with a mechanical stirrer, a dropping funnel, a thermometer and a $CaCl_2$ tube. While a slow stream of N_2 was passed through the apparatus immersed in an ice bath, butyl lithium (2.5M, 3.4 mL, 8 mmol) was added. The temperature rose from 5 to 18°C and the reaction mixture assumed a blood red color. The ice bath was removed and 20 min later a solution of compound 9 (1.5 g, 7 mmol) in THF (10 mL) was added over 7 min with intermittent use of an ice bath to keep the temperature below 15°C. The reaction mixture was pale orange in color. One hour later, saturated NaCl (50 mL) was added. The organic layer was dried over Na_2SO_4. Removal of the drying agent and solvent gave a thick orange oil (4.3 g). This material was passed through a column (15 mm × 25 cm) containing silica gel (12 g) in PE. Two fractions were collected: Fraction 1 (from PE), 0.23 g, 62% tetraene; Fraction 2 (from 5% EE in PE), 0.69 g, 91% tetraene by analysis on a 50-m CPS-2 gas chromatographic column. Yield of tetraene at this point was 35%. The all-*cis* isomer was separated from Fraction 2 on a column (0.76 × 70 cm) containing Amberlyst XN1010 (80/120 mesh) 62% Ag/Na using 2% acetonitrile in methanol as eluent. No attempt was made to separate the small amounts of other isomers present. Yield of the all-*cis* isomer from the Wittig reaction was 12%; overall yield from 7-bromoheptanoic acid was 6%. Deuterium distribution: 2.3% d_0, 92.2% d_2, 0.3% d_3, 5% d_4, 0.3% d_5. ^{1}H NMR ($CDCl_3$): δ 5.34(*m*,6H, C*H*=C*H*), δ 3.63(*s*,3H,OCH_3), δ 2.78(*m*,6H,C=CCH_2C=C), δ

2.27(t,2H,CH_2COO), δ 2.04(m,4H,CH_2C=C), δ 1.58(m,2H,CH_2CH_2COO), δ 1.30(m,6H, (CH_2)$_3$), δ 0.95(t,3H,CH_3). ^{13}C NMR (ppm): C-1, 174.0; C-2, 34.0; C-3, 24.8; C-4 through C-6, 28.8-29.3; C-7, 26.9; C-10, C-13, C-16, 25.5; C-11, C-14, C-15, 128.3-128.4; C-12, 127.9; C-17, 126.9; C-18, 131.8; C-19, 20.5; C-20, 14.2.

ACKNOWLEDGMENTS

We thank D. Weisleder for NMR spectroscopy, W.K. Rohwedder and S. Duval for mass spectroscopy, and R.O. Adlof, E.A. Emken and R.J. Bartelt for helpful discussions.

Reactions of Dinitrogen Pentoxide and Nitrogen Dioxide with 1-Palmitoyl-2-Oleoyl-*sn*-Glycero-3-Phosphocholine

C.C. Lai and B.J. Finlayson-Pitts*
Department of Chemistry and Biochemistry, California State University, Fullerton, California 92634

The reactions of gaseous dinitrogen pentoxide (N_2O_5) and nitrogen dioxide (NO_2) with 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC) coated on the inside surface of a glass reaction cell were studied at 298 K. Unsaturated phosphatidylcholines are significant components of pulmonary surfactant in the alveolar region of the lung and hence serve as a simple model to examine reactions of pulmonary surfactant with these oxidant air pollutants. Using high-performance liquid chromatography (HPLC), Fourier transform infrared and fast atom bombardment mass spectroscopy, the major products of reactions of POPC with N_2O_5 and NO_2 were separated and identified. In the POPC-N_2O_5 reaction using either air or helium as a buffer gas, the nitronitrate, vinyl nitro and allylic nitro derivatives, as well as a small amount of the *trans*-isomer of the starting material, were obtained. The nature of the products obtained from the POPC-NO_2 reaction depends on the concentration of NO_2 as well as whether air is present. At low NO_2 concentrations ($P_{NO_2/N_2O_4} \leq$ 3.8 Torr) in air or in helium, the *trans*-isomer of POPC was formed almost exclusively. At higher NO_2 concentrations ($P_{NO_2/N_2O_4} \geq 20$ Torr) in helium, the dinitro, vinyl nitro and nitro alcohol derivatives were formed. In the presence of air (or 24% $^{18}O_2$ in helium), a nitronitrate and a dinitronitrate were additional products. Mechanisms for the formation of the observed products and implications for the inhalation of oxides of nitrogen are discussed.
***Lipids* 26, 306–314 (1991).**

At the alveolar surface of the lung where gas exchange occurs, there is a liquid lining containing a soap-like substance which plays an important role in lung function. This substance, known as pulmonary surfactant (PS) (1,2), lowers the surface tension of the liquid layer and hence is essential for proper lung function (3–6).

The major surface-active components of pulmonary surfactant are phosphatidylcholines. They are believed to align themselves as a monolayer at the air-water interface where the hydrophobic fatty acid chains are projected into the gas phase (7). Since as much as 30% of the fatty acid components of the phosphatidylcholines are unsaturated (8), these double bonds may be susceptible to the attack of oxidant air pollutants such as ozone and nitrogen oxides.

Inhalation of oxidant air pollutants such as O_3, NO_2 or their combination are known to have a variety of effects on lung function and morphology (6,9–15). However, the chemical interactions of these reactive species with the unsaturated phosphatidylcholines in pulmonary surfactant have not been studied in detail, partly due to the difficulty of finding suitable analytical techniques to separate and identify the reaction products.

As part of our program to investigate the effects of oxidant air pollutants on the pulmonary surfactant system, we have used a wide range of analytical methodologies to investigate the reaction products of phosphatidylcholines with oxidant air pollutants. For example, we have demonstrated for the first time that isomeric ozonides are formed when 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC) is exposed to ozone (16). These isomeric ozonides, although sufficiently stable to be isolated, separated and characterized, can decompose at elevated temperatures or after sitting at room temperature for long periods of time, presumably *via* a free radical route similar to that proposed in the literature for the ozonides of alkenes and fatty acid methyl esters (17–20). Thus, their formation may initiate free radical processes leading to some of the observed health effects of ozone inhalation.

Since ozone and nitrogen dioxide are both present in polluted air (ref. 21, and references therein), the nitrate radical (NO_3) and dinitrogen pentoxide (N_2O_5) are also formed (Equations [1] and [2]);

$$O_3 + NO_2 \rightarrow NO_3 + O_2 \quad [1]$$

$$NO_3 + NO_2 \leftrightarrow N_2O_5 \quad [2]$$

NO_3 has been detected in both polluted and remote atmospheres (21) and the concentration of N_2O_5 has been estimated to be as high as 10–15 ppb (22). N_2O_5 is known to rapidly hydrolyze on surfaces to give nitric acid (21):

$$N_2O_5 + H_2O \xrightarrow{\text{surface}} 2\,HNO_3 \quad [3]$$

However, if significant concentrations of N_2O_5 do survive to reach the alveolar region, reaction between the hydrophobic unsaturated moieties of phosphatidylcholine and N_2O_5 may occur.

We reported earlier that dinitrogen pentoxide reacts with 1,2-dioleoyl-*sn*-glycero-3-phosphocholine (DOPC) and POPC to form nitronitrates that can be identified in the unseparated reaction product mixtures (23) using Fourier transform infrared (FTIR) spectrometry. In the case of DOPC, the structure of the

nitronitrate was also confirmed by fast atom bombardment mass spectrometry (FAB-MS).

In the present, more extensive study, the major products of the reactions of N_2O_5 and NO_2 with a monounsaturated phosphatidylcholine, POPC have been separated using HPLC and identified using FTIR and FAB-MS. The products were studied as a function of the extent of reaction of the POPC and in the presence or absence of O_2, including isotopically labeled $^{18}O_2$. Possible mechanisms of formation of the observed products, as well as the implications for the inhalation of NO_x on pulmonary surfactant, are discussed.

MATERIALS AND METHODS

Materials. 1-Palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (99%) and the methyl esters of oleic, elaidic and stearic acid (all 99%) were obtained from Sigma (St. Louis, MO). Choline chloride (>99%) was obtained from Aldrich (Milwaukee, WI). High purity chloroform and methanol suitable for spectrophotometry and high-performance liquid chromatography were purchased from EM Science (Gibbstown, NJ). Nitric oxide (≥ 98.5%), and helium (>99.995%) were supplied by Union Carbide (Danbury, CT). Ultra-high purity grade air (>99.999%) was supplied by Scott-Marrin (Riverside, CA). Oxygen-18 (> 97 atom % ^{18}O) was obtained from Isotec (Miamisburg, OH). Reagent grade nitric acid was from Baker (Phillipsburg, NJ), and reagent grade sulfuric acid was from Fisher Scientific (Pittsburgh, PA).

Instrumentation. Nitro- and nitrated phosphatidylcholines were separated and isolated using high performance liquid chromatography (HPLC) with a Waters 600E multisolvent delivery system, a 30 cm × 0.39 cm Nova-Pak C18 4 μm reverse phase column (Waters, Milford, MA) preceded by a Waters Guard-Pak guard column module, and a Waters 900 photodiode array detector. The mobile phase was methanol/water (97:3, v/v), containing 40 mM choline chloride, at a flow rate of 1 mL/min.

Nitrate ion was analyzed using a Vydac 302-IC46 ion-exchange column (Hesperia, CA) with a Spectra Physics (St. Albans, U.K.) SP8700 solvent delivery system. A 2-mM aqueous solution of potassium hydrogen phthalate (KHP) was used as eluent, at a flow rate of 2 mL/min. The signal at 280 nm was followed using an UV detector; the mobile phase absorbs strongly at this wavelength so that nitrate appears as a negative peak on the continuous absorption due to KHP.

Gas chromatographic analyses were carried out on a Hewlett-Packard 5890 gas chromatograph (Palo Alto, CA) equipped with a flame ionization detector and an HP 3396A integrator. The *cis* and *trans* isomers of the monounsaturated C_{18} fatty acid methyl esters (*i.e.*, oleate and elaidate) were resolved using a high polarity cyanosilicone phase capillary column, SP-2330 (Supelco, Bellefonte, PA; 30 m × 0.25 nm i.d., 0.20 μm film). All GC samples were analyzed under isothermal conditions at 160°C for 12 min with helium as carrier gas at 5 mL/min. GC peak areas were converted to molar units using signal response factors referenced to an internal standard (methyl stearate) added just prior to analysis.

Samples for FTIR analysis were evaporated from chloroform onto the surface of a 25 × 10 × 2 mm 45° germanium crystal (Harrick Scientific, Ossining, NY) and spectra were recorded with a Mattson (Madison, WI) Cygnus FTIR spectrometer equipped with an optical accessory for attenuated total reflectance (ATR) measurements (24).

FAB mass spectrometric analysis was carried out in the positive ion mode using a 3-nitrobenzyl alcohol matrix, xenon gas and a VG-ZAB 1FHF (VG Analytical, Manchester, England) mass spectrometer.

Preparation of oxides of nitrogen. NO_2 and N_2O_5 were prepared using procedures described elsewhere (23,25). Gas-phase HNO_3 was prepared by distillation at 25°C of a 1:1 (v/v) mixture of fuming nitric and sulfuric acid into a trap at −196°C. The condensed HNO_3 was evaporated into a darkened 5-L bulb and was diluted with UHP grade air.

Exposure of POPC to nitrogen oxides. Approximately 2 mg of phospholipid was adsorbed from chloroform/methanol (2:1, v/v) onto the inner walls of 50-mL evacuable, tube-shaped borosilicate glass cells and, after evaporation of the solvent, exposed for 30 min in the dark to a gaseous mixture containing a known amount of nitrogen oxides (N_2O_5 or NO_2) in a buffer gas (helium or air) at one atm. The POPC reaction products were eluted from the walls of the reaction cells using 2 mL of chloroform or a chloroform solution containing a known amount of internal standard (cholesterol or methyl stearate). The extent of the reaction was calculated from the percentage recovery of the phospholipid using HPLC at a detector wavelength of 205 nm, or from the ratio of methyl oleate to methyl palmitate obtained by GC analysis of the sample which was esterified using acidified methanol and dimethoxypropane (26).

In experiments to isolate and characterize the reaction products, mixtures from at least three reaction runs were combined in order to obtain sufficient material for analysis. They were separated by HPLC and the peak fractions were collected from the outlet. The solvent from the HPLC fractions was evaporated on a water bath (~40°C) under a gentle stream of nitrogen. Most of the hydroscopic choline chloride salt, an additive to the HPLC mobile phase used to minimize peak tailing and facilitate peak separations of the phosphatidylcholine derivatives, was removed by extracting the moist residue from the fractions with chloroform, which was then concentrated and repeatedly filtered through a 0.45-micron Acrodisc filter (Gelman Sciences, Ann Arbor, MI).

RESULTS

Reaction of N_2O_5 with POPC. Table 1 summarizes the experiments carried out on the reaction of 2 mg of a solid film of POPC with N_2O_5. Since N_2O_5 also hydrolyzes on surfaces to form HNO_3 in competition with the POPC reaction, the ratios of the reactants shown in Table 1 are approximate upper limits.

The extent of the reaction as measured by the decrease in POPC increases with the ratio of N_2O_5 to POPC, and does not appear to be affected significantly by the presence of O_2 rather than He as the buffer gas.

[f]Experiments in which spectroscopic identification of products was carried out.

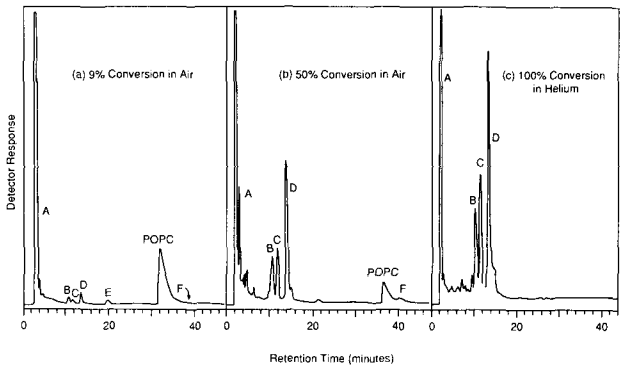

FIG. 1. HPLC chromatograms of the reaction mixture of N_2O_5 with POPC in air or in helium obtained at various percentage conversions of the POPC. See text for structural assignment of products.

The rather abrupt increase in the conversion of POPC from an N_2O_5/POPC ratio of 2.0 to 2.3 (Exp. 7 and 8) is probably due to the difficulty in reproducibly coating the solid POPC film on the surface of reaction cells, as well as the uncertainty in the amount of N_2O_5 available for the POPC reaction due to varying amounts of the competing N_2O_5 hydrolysis.

In order to make certain that the destruction of POPC was due to reaction with N_2O_5 (or its equilibrium mixture, containing NO_2 and NO_3) rather than the hydrolysis product HNO_3, the reaction of POPC with gaseous HNO_3 was also studied. No reaction products were observed by HPLC, and POPC was quantitatively recovered, indicating that the reaction of POPC with HNO_3, except to form the nitrate salt (23), can be discounted under our reaction conditions.

Figure 1 shows the HPLC chromatograms for experiments 2, 7 and 12, representing a low (9%), moderate (50%) and high (100%) conversion of POPC, respectively, either in air or in helium as the buffer gas. In all the reactions with less than 100% conversion, a small product peak, labeled F in Figures 1a and b, which eluted immediately after the POPC peak, was always observed. The UV, IR and FAB mass spectra of peak F are identical to those of POPC. However, esterification of peak fraction F shows that palmitic and elaidic (*trans* 18:1) acids are the component fatty acids. Peak F is therefore assigned to 1-palmitoyl-2-elaidoyl-*sn*-glycero-3-phosphocholine (PEPC), the *trans*-isomer of the starting material. The disappearance of PEAPC at higher extents of reaction suggests that, similar to POPC, PEPC can also react with N_2O_5.

The reaction of POPC with a large excess of N_2O_5 (N_2O_5/POPC ⩾ 3.3) in air or helium is relatively rapid. HPLC analysis of the reaction mixture indicated that POPC was completely consumed within the constant 30 min of reaction time used in these experiments.

At least four major reaction product fractions (labeled A, B, C and D in Fig. 1) were isolated from the reaction mixture by HPLC. The product fraction A, which eluted close to the solvent peak, consisted primarily of nitrate ion as determined by its characteristic UV spectrum, and by matching its retention time with that of sodium nitrate on an ion-exchange column.

The organic product fractions (B, C and D) were analyzed using FTIR (Fig. 2). The results of the mass spectral analysis are shown in Table 2 along with a summary of the product IR bands. For fraction B, the infrared spectrum shows that in addition to the C-H stretch (1475 cm^{-1}) and the C=O stretch (1750 cm^{-1}), which are also present in the starting material, two strong absorption bands at 1550 cm^{-1} and 1650 cm^{-1}, due to the asymmetric stretching mode of the $-NO_2$ (27,28) and $-NO_3$ (29) groups, respectively, are also

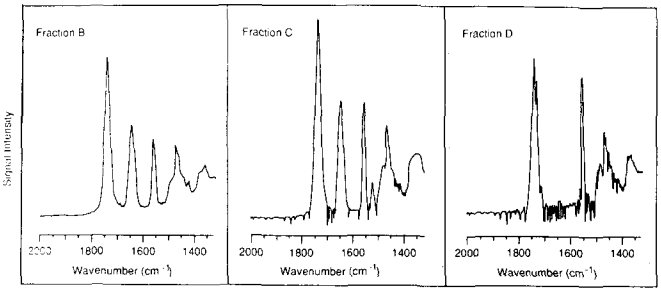

FIG. 2. FTIR spectra of the HPLC product peak fractions B, C and D obtained from the reaction of N_2O_5 with POPC in air or in helium (See Fig. 1).

observed. The FAB mass peak $[M+1]^+$ at *m/z* 869, suggests that both the $-NO_2$ and the $-NO_3$ groups, with a combined mass of 108 amu, have been introduced into the POPC molecule for which $[M+1]^+$ is found at *m/z* 761. The FTIR and FAB data are therefore consistent with a saturated nitronitrate phosphatidylcholine structure.

A new IR absorption band characteristic of a vinyl nitro group (27,28) at 1525 cm^{-1} was observed for product fraction C (Fig. 2). The mass spectrum of this fraction also showed an intense $[M+1]^+$ signal at *m/z* 806, consistent with a vinyl nitro phosphatidylcholine structure. The mass spectral [M+1] peak at *m/z* 869 and the IR bands due to the nitronitrate likely result from the overlapping of fractions B and C during chromatographic separation.

The infrared band at 1550 cm^{-1} (Fig. 2) and the mass peak $[M+1]^+$ at *m/z* 806 indicate that a nonconjugated nitro phosphatidylcholine is present in product fraction D. Based on previous work reported in the literature on the reaction of olefins with N_2O_5 (see Discussion section), these spectral peaks are tentatively assigned to an allylic nitro phosphatidylcholine structure.

Although the presence of O_2 did not appear to alter the nature or yields of the products (Table 1), the N_2O_5–POPC reaction was also carried out using 18% $^{18}O_2$ in helium as buffer gas (Exp. 13) in order to see if any of the observed reaction products incorporate oxygen from O_2. No incorporation of ^{18}O into the reaction products was found using FAB mass spectrometry.

A small peak due to a product labeled E in Figure 1a appears at low conversions of the POPC. This product showed an infrared band at 1650 cm^{-1} characteristic of an organic nitrate and a mass spectral peak $[M+1]^+$ at *m/z* 858, which corresponds to the addition of 97 amu to POPC. The peak at 858 was not observed during mass spectrometric analysis of an unseparated mixture of reactants and products, *i.e.*, a mixture that had never been chromatographed or in contact with methanol, water or choline chloride. The FAB peak at *m/z* 858 suggests that product E contains both a nitrate group (62 amu) and chlorine (35 amu), arising from the reaction of an initially formed product with choline chloride in the HPLC eluent. The formation of the product corresponding to peak E at low conversions suggests that the primary product which gives rise to peak E in the presence of choline chloride also reacts with N_2O_5 and/or NO_3.

Reaction of NO_2/N_2O_4 with POPC. The experiments carried out on the reaction of POPC with NO_2 are summarized in Table 3. Since nitrogen dioxide is always in rapid equilibrium with its dimer, that is,

$$N_2O_{4(g)} \leftrightarrow 2\ NO_{2(g)} \qquad K_{eq} \qquad [4]$$

the notation NO_2/N_2O_4 is used to signify the mixture

TABLE 2

Summary of FTIR and FAB-MS Analyses of HPLC Product Peak Fractions Obtained from the Reactions of POPC with Nitrogen Oxides

Nitrogen oxides	Buffer gas	Fraction[a]	Infrared bands[b] (cm^{-1})	Mass spectral $[M+1]^+$ peaks[b] (*m/z*)	Tentative product identification

[a]Unless specified otherwise, all runs were carried out at 298 ± 3 K for 30 min.
[b]Molar ratios of NO_2/N_2O_4 to POPC was calculated based on initial total pressure of NO_2/N_2O_4.
[c]Total pressure of NO_2/N_2O_4 used.
[d]Mole % of N_2O_4 in the mixture of NO_2/N_2O_4.
[e]Mole % was calculated based on initial amount of POPC used; analytical error is estimated to be ± 3%.
[f]% Other products = % POPC consumed − % PEPC observed.
[g]Experiments in which spectroscopic identification of products was carried out.
[h]This run was carried out for 1 hr.

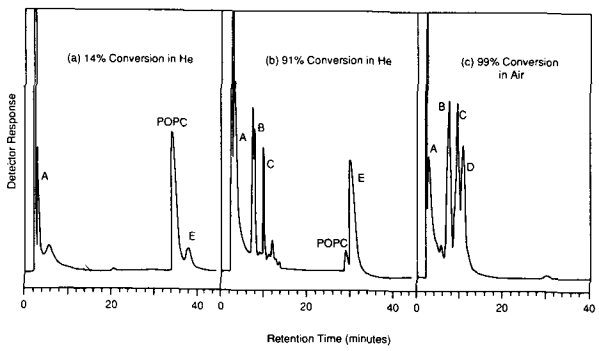

FIG. 3. HPLC chromatograms of the reaction mixture of NO_2/N_2O_4 with POPC in air or in helium obtained from experiments no. 5, 10 and 11 (Table 3). See text for structural assignment of products.

of the two throughout the text. The actual amount of N_2O_4 present in the equilibrium mixture was calculated using the known equilibrium constant, K_{eq} = 0.1461 atm at 298 K (30).

Figure 3 shows typical HPLC chromatograms at low (14%) and high (>90%) conversions of POPC, in either helium or in air as the buffer gas.

The reaction of POPC with NO_2/N_2O_4 is slower than that with N_2O_5. For example, in the reaction with N_2O_5, essentially all POPC was consumed at reactant ratios N_2O_5/POPC > 3.3 (Exp. 9, Table 1). However, in the reaction with NO_2/N_2O_4, complete destruction of the POPC in air within the 30 min reaction time required at least a 34-fold excess of NO_2/N_2O_4 (Exps. 10–16, Table 3).

At low molar ratios of NO_2/N_2O_4 to POPC with $P_{NO_2/N_2O_4} \leq 3.8$ Torr (Exps. 1–5), oxygen has no marked effect on the percent POPC consumed or on the amounts of PEPC and other products formed. The *trans*-isomer of the starting material, PEPC, labeled as peak E in Figures 3a and b, was the only major product.

For reactions that were carried out with a large excess of NO_2/N_2O_4 ($[(NO_2/N_2O_4)]$/POPC ≥ 18, P_{NO_2/N_2O_4} ≥ 20 Torr, Exps. 9–17), significant amounts of other products, in addition to PEPC, were also observed. The destruction of POPC, as well as the yield of these products, were enhanced by the increased concentration of NO_2/N_2O_4.

However, in contrast to the reactions of N_2O_5 with POPC, carrying out the reaction in air rather than in helium at these higher extents of reaction did decrease the yield of PEPC, as well as increase the yield of other products. In this case, the nature of the products observed was also affected by the presence of oxygen. For example, the major product peak fraction labeled D in the HPLC chromatogram of the product mixture obtained in air (Fig. 3c) is absent in the helium runs (Figs. 3a and b).

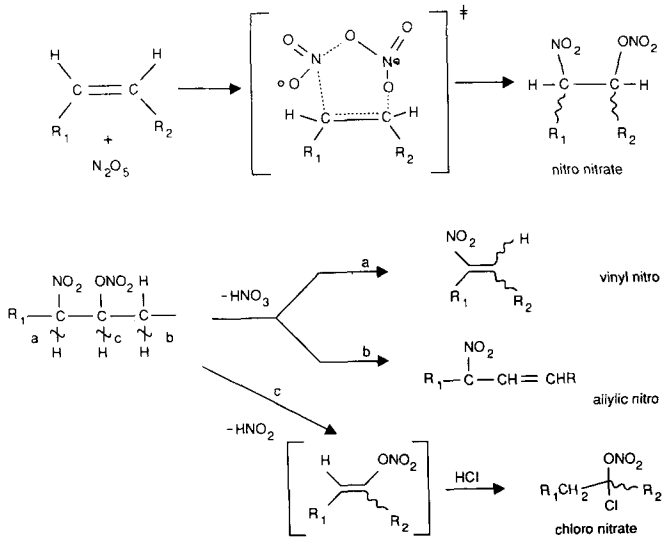
From ion-chromatography, fraction A in all NO_2 runs was found to be mainly nitrate ion present, at least in part, from trace amounts of HNO_3 in the NO_2 reactant.

The product peak fractions labeled B obtained from reaction in He or air were very similar, showing a strong IR absorption band due to a non-conjugated nitro group at 1550 cm^{-1}. Three $[M+1]^+$ mass spectral peaks were observed at *m/z* 806, 824 and 853, corre-

sponding to the addition of 45, 63 and 92 amu, respectively, to the POPC. Those at *m/z* 824 and 853 were attributed to the nitro alcohol and dinitro derivatives of the phosphatidylcholine, respectively. The peak at $[M+1]^+$ at *m/z* 806 was probably not due to a direct product because it corresponds to an unsaturated nitro derivative, yet it did not elute at the expected retention time for the vinyl or allylic nitro derivative. Thus it is attributed to fragmentation of one of the parent species in the mass spectrometer, *e.g.*, by elimination of HNO_2 from the dinitro derivative, or dehydration of the nitro alcohol.

In the runs with helium as a buffer gas, product fraction C mainly consisted of a vinyl nitro phosphatidylcholine, based on the infrared and FAB mass spectra. In the air runs, however, a small amount of nitronitrate was also detected. The infrared and mass spectral data of these products were similar to those obtained from the POPC-N_2O_5 reaction.

Product peak fraction D, which was only observed when air was present, showed infrared absorption bands at 1525, 1550 and 1650 cm^{-1} due to vinyl $-NO_2$, and unconjugated $-NO_2$ and $-NO_3$ groups, respectively. Two mass spectral peaks were observed. The infrared absorption at 1525 cm^{-1} and $[M+1]^+$ at *m/z* 806 in the mass spectrum are attributed to the vinyl nitro derivative resulting from the partial overlap of fractions C and D. The mass peak $[M+1]^+$ at *m/z* 914, which corresponds to the addition of 153 amu to the POPC, suggests a dinitronitrate structure, which is also consistent with the infrared spectrum.



In order to see if oxygen is directly incorporated into the products when the reactions were carried out in air, the NO_2/N_2O_4-POPC reaction was carried out using 24% $^{18}O_2$ in helium. Exact mass spectral analysis on the reaction mixture, as well as on the separated HPLC product peak fractions, showed that only one ^{18}O label was incorporated into the dinitronitrate ($[M+1]^+$ at *m/z* 916) and two ^{18}O labels were found in the nitronitrate ($[M+1]^+$ at *m/z* 873).

DISCUSSION

Reaction of N_2O_5 with POPC. Using a combination of HPLC and spectroscopic techniques, we have shown that in addition to the nitronitrate product identified in earlier studies (23), vinyl and allylic nitro phosphatidylcholine derivatives are also formed in the reaction of N_2O_5 with POPC.

In the gas phase, N_2O_5 is in thermal equilibrium with the NO_2 and NO_3 radicals (Eqn. [2]). Thus, sequential addition of NO_3 and NO_2 to the olefin bond could yield the nitronitrate, as could a concerted addition of N_2O_5 to the POPC double bond. However, the lack of any observable effects of oxygen on the nature or the yields of the reaction products, the lack of incorporation of ^{18}O, and the absence of any detectable amount of dinitro or dinitrate products support the earlier hypothesis (31) that the addition of N_2O_5 to olefins is likely to occur in a concerted manner as shown in Scheme 1.

The relative yields of the nitronitrate and vinyl nitro derivatives change with the extent of reaction. Thus, as seen in Figure 1, the HPLC peak height of C

SCHEME 1

relative to peak B increases as the extent of conversion of the POPC increases (Fig. 1). This suggests that the vinyl nitro phosphatidylcholine is a secondary reaction product, perhaps due to further reaction of the nitronitrate. One possibility is elimination of nitric acid from the nitronitrate (path a in Scheme 1), involving either NO_3, NO_2 or NO_3^- as the hydrogen (or in the case of NO_3^-, the proton) acceptor. Since products due to trapping of an intermediate were not observed, such a bimolecular elimination process must occur in a concerted manner.

The allylic nitro derivative (peak D, Fig. 1) also appears to increase relative to peak B, at least up to 50% conversion of the POPC. Since it is not affected by the presence of O_2, its formation *via* a concerted bimolecular elimination of the nitronitrate is also a possibility (path b in Scheme 1).

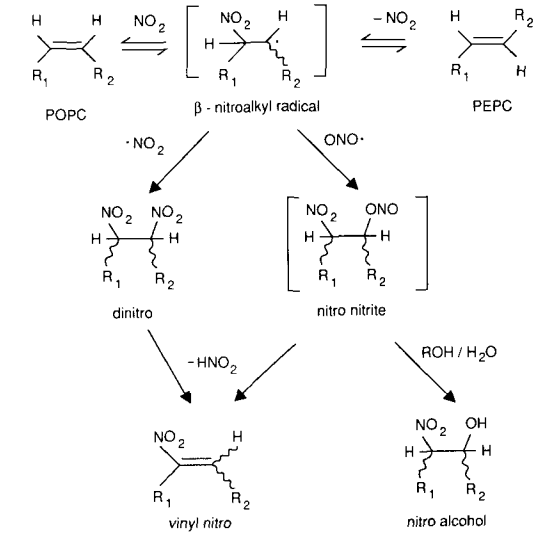
The formation of vinyl and allylic nitro derivatives is consistent with the work of Stevens and Emmons (31), who observed such products in their studies of the reaction of N_2O_5 with propylene and 1-butene in an inert solvent at lower temperatures (243–273 K). Thus, 1-nitropropylene, 2-nitropropylene, 1-nitro-2-butene and 1-nitrobutene were obtained as minor products, in addition to the nitronitrates.

The chloronitrate (peak E, Fig. 1) observed at low conversions in the presence of methanol, water and choline chloride could arise from the ionic addition of an equivalent of HCl to an unsaturated nitrate during HPLC analysis, perhaps as shown in Scheme 1.

The formation of PEPC, the *trans*-isomer of the starting material, at low ratios of N_2O_5 to POPC is discussed below in conjunction with the isomerization induced by NO_2.

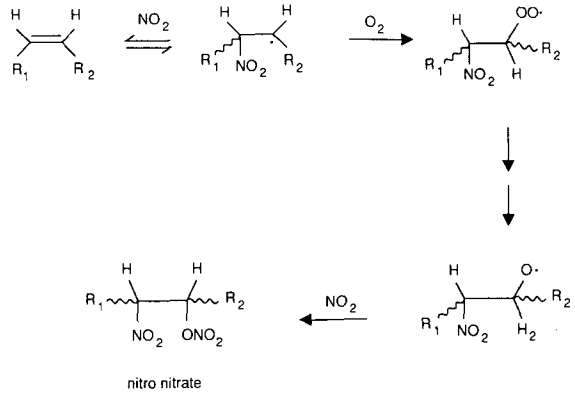
Reaction of NO_2/N_2O_4 with POPC. The reactions of NO_2/N_2O_4 with olefins are generally considered to be free radical in nature. For example, in the reaction of cyclohexene with NO_2/N_2O_4, the β-nitro alkyl radical intermediate can be trapped as β-nitrobromocyclohexane by abstraction of a bromine atom from a transfer

agent such as bromoform (32) or bromotrichloromethane (33). Thus, it is reasonable to assume that the initial step in the POPC-NO_2/N_2O_4 reactions is the addition of NO_2 to the double bond.



Thermal *cis-trans* isomerization of olefins normally requires a very high activation energy and can only occur at elevated temperatures (34). In the presence of free radicals, however, the isomerization can proceed smoothly at much lower temperatures. For example, in the presence of NO_2, a variety of alkenes have been observed to isomerize in solution, including *cis*-stilbene (35), unsaturated fatty acid esters (36), *cis*-2-butene and poly(*cis*-butadiene) (37). The same is true of NO_2 reactions with simple alkenes in the gas phase (38-40).

The mechanism of isomerization is believed to be as shown in Scheme 2 for POPC. The fact that oxygen does not change the PEPC yields at low pressures of NO_2/N_2O_4 (Table 3) suggests that both the C-C bond rotation and the loss of NO_2 in the β-nitro alkyl radical intermediate must be more rapid than the scavenging by molecular oxygen. Assuming a scavenging rate constant $k_{o_2} = 10^{-11}$ cm^3 molecule^{-1} s^{-1} for the addition of oxygen to a secondary radical (21,41,42) and $[O_2] = 4 \times 10^{18}$ molecule cm^{-3}, the first order rate constant for removal of the β-nitro akyl radical by O_2 is 4×10^7 s^{-1}. Thus, the rate of bond rotation and β-scission in the β-nitro alkyl radical would have to be faster than this for elimination of NO_2 to form PEPC to compete with scavenging of the radical by O_2. This is consistent with the results of Pitts and co-workers (38-40) who estimate that the rate constant for bond rotation of the NO_2 − *cis*-2-butene adduct in the gas phase is about 2×10^8 s^{-1} at 300 K.

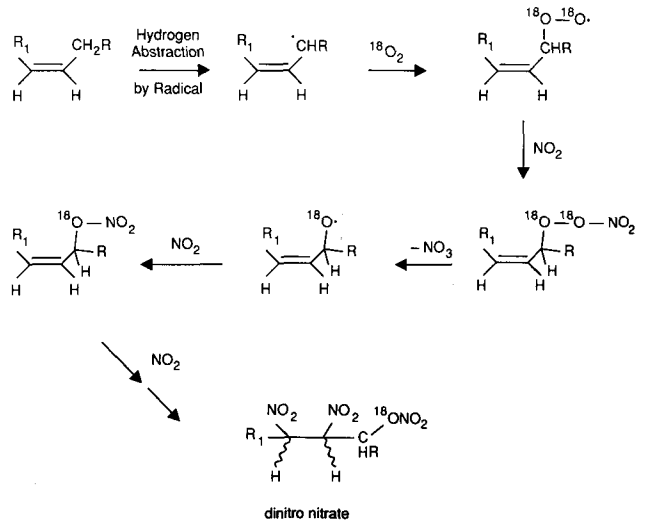


The yield of PEPC from the reaction of POPC with 0.5 Torr N_2O_5 is similar to those of the NO_2-POPC reactions at 3.8 Torr NO_2 (*i.e.*, Exps. 1-3 in Table 1 *vs* Exps. 1-2 in Table 3). The amount of NO_2 (and NO_3) in equilibrium with 0.5 Torr N_2O_5 can be calculated from the equilibrium constant (21) to be ~0.8 mTorr. Thus, NO_2 alone cannot be responsible for the PEPC formation in the N_2O_5-POPC system. This suggests that the nitrate radical must also isomerize POPC and, furthermore, is a more effective catalyst than NO_2 for this isomerization. Since there are no reports in the literature on the isomerization of alkenes by NO_3, this area warrants further study.

At high concentrations of NO_2 ($[NO_2/N_2O_4]$/POPC > 18, $P_{NO_2N_2O_4} \geq 20$ Torr, Table 3, Exps. 9-17), the β-nitro alkyl radical intermediate can be trapped by a second molecule of NO_2. Based on the literature (35,43-53), this can occur by either a C-N or a C-O attachment to give the dinitro or the nitronitrite (Scheme 2). Nitronitrites are unstable, and undergo elimination of nitrous acid to give the vinyl nitro compound (45,46), hydrolyze to the nitro alcohol in the presence of water or alcohol (43-53), or oxidize to the nitronitrate in the presence of excess oxygen (48-55). The results of this product study of POPC with NO_2/N_2O_4 are therefore consistent with earlier studies with alkenes.

In the NO_2/N_2O_4-POPC reaction, the nitronitrate and dinitronitrate can only be observed when air is present, indicating that these products likely result from oxygen scavenging of unstable intermediates. The

SCHEME 2



SCHEME 3

formation of nitronitrates in the NO_2/N_2O_4 reaction with simple alkenes in the presence of added O_2 has been suggested to proceed by a mechanism involving an unstable intermediate peroxynitrate (48,54-56), which decomposes to give an alkoxy radical. It has been proposed that this radical adds NO_2 to form the nitronitrate (Scheme 3). This mechanism, however, does not fully explain the formation of nitronitrate in the POPC reaction because the amount of oxygen in an atmosphere of air does not appear to efficiently scavenge the β-nitro alkyl radical as observed by the lack of effect of O_2 on the formation of PEPC at a low NO_x/POPC ratio (Exps. 1 and 2). Furthermore, this mechanism cannot explain the two ^{18}O labels observed in the nitronitrate by FAB-MS; as only one ^{18}O label would be expected, based on Scheme 3.

The mechanism of formation of nitronitrate is clearly complex. In solution, an unstable nitroso nitrate has been observed in the reaction of olefins with NO_2/N_2O_4 under anaerobic conditions at low temperatures (253 K); this species is slowly oxidized at room temperature to form a nitronitrate (55).

N_2O_3, which has been hypothesized to be an inter-

SCHEME 4

mediate in NO_2/N_2O_4/alkene reactions (49), is known to react with olefins to form nitroso nitrites (57). Two ^{18}O labels could be incorporated into the nitronitrate in the POPC-NO_2/N_2O_4 reaction by the formation and subsequent oxidation of such an intermediate:

$$N_2O_3 + R_1CH{=}CHR_2 \rightarrow R_1\overset{\overset{NO}{|}}{C}H-\overset{\overset{ONO}{|}}{C}HR_2$$

$$^{18}O_2/NO_x \quad \rightarrow\rightarrow \quad \overset{\overset{ON^{18}O}{|}}{R_1CH} - \overset{\overset{ONO^{18}O}{|}}{CHR_2} \qquad [5]$$

Clearly, the mechanism of the formation of the nitronitrate remains highly uncertain and warrants further investigation.

One mechanism for the formation of a dinitronitrate which contains only one ^{18}O label is shown in Scheme 4. In the studies of the reaction of NO_2/N_2O_4 with alkenes, Pryor and co-workers (58,59) have shown that at high NO_2 concentrations, direct allylic hydrogen abstraction by NO_2 is a minor process, consistent with our not finding allylic nitro phosphatidylcholine under anaerobic conditions. Thus, the allylic radical must result from hydrogen abstraction by species other than NO_2, such as peroxyalkyl radicals. Trapping of the allylic radical by molecular oxygen followed by scavenging by excess NO_2 would yield a peroxynitrate as proposed in earlier studies (48,54-56). Decomposition of the unstable peroxynitrate to an alkoxy radical followed by the reactions with NO_2 shown in Scheme 4 would form the ^{18}O labeled allylic nitrate.

The results of this study indicate that N_2O_5 reacts readily with the unsaturated fatty acid component of phosphatidylcholines, and hence if it reaches the alveolar region before hydrolyzing, it could form nitrated phosphatidylcholine derivatives. At the concentrations of NO_2 found in polluted air (<1 ppm), the formation of significant amounts of nitrogenated phosphatidylcholine derivatives from the NO_2 reactions is unlikely. However, a number of studies have shown that a change in configuration in the fatty acid chains of phosphatidylcholines can markedly affect the surface tension-reducing characteristics (60,61). Thus, isomerization of POPC to PEPC as we observed here, if it occurs in the lung, could alter the surface tension properties and hence the function of pulmonary surfactant. To investigate this possibility, the reactions of various nitrogen oxides with monolayers of phosphatidylcholines on a water surface in a film balance are currently being studied in this laboratory.

ACKNOWLEDGMENTS

We are grateful to the National Institute of Environmental Health Sciences for a grant (No. ES03484) to support this work. We thank Dr. Richard Kondrat and Mr. Ronald New for the mass spectrometric analyses and Mr. Stan Johnson for assistance with the inorganic nitrate analyses.

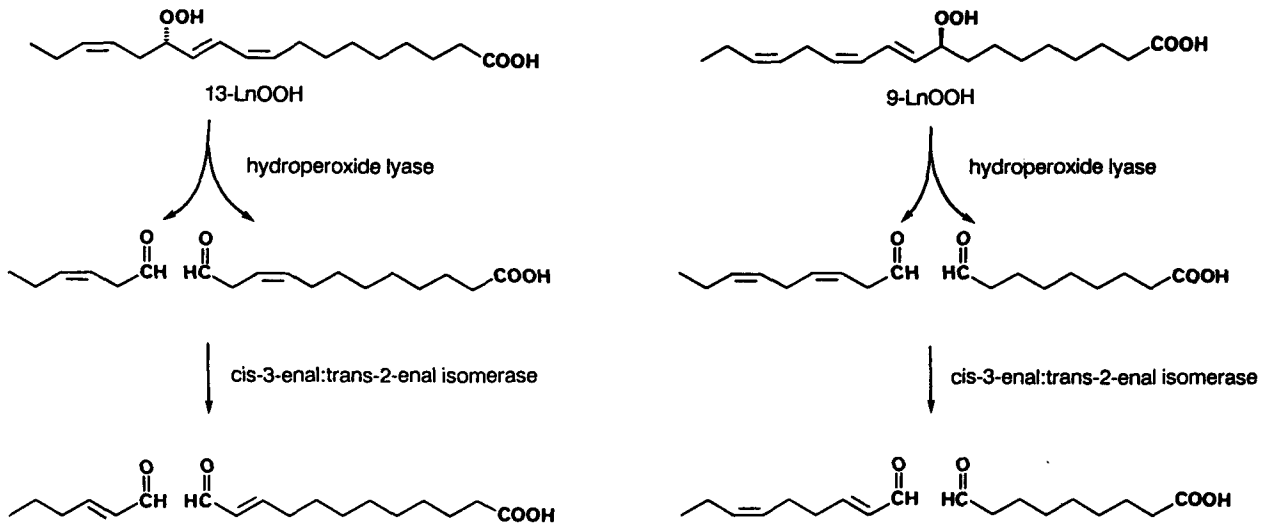
METHODS



A Spectrophotometric Assay for Hydroperoxide Lyase[1]

Brady A. Vick*
U.S. Department of Agriculture, Agricultural Research Service, Northern Crop Science Laboratory, Fargo, North Dakota 58105

Spectrophotometric assays for hydroperoxide lyase have traditionally measured the loss in absorption at 234 nm due to the disruption of conjugated diene in the fatty acid hydroperoxide. However, that assay does not distinguish between hydroperoxide lyase and hydroperoxide dehydrase activities, both of which cause a loss of conjugation in the substrate hydroperoxide. A new assay has been developed which is specific for hydroperoxide lyase. It is based on the ability of hydroperoxide lyase products, aldehydes and ω-oxoacids, to serve as substrates for yeast alcohol dehydrogenase. Thus, the new hydroperoxide lyase assay is a coupled enzyme assay, which is conducted spectrophotometrically at 340 nm and measures the oxidation of nicotinamide adenenine dinucleotide, reduced form (NADH). In addition to its specificity for hydroperoxide lyase, the coupled assay allows higher concentrations of both fatty acid hydroperoxide substrate and crude enzyme extracts than the assay conducted at 234 nm.
Lipids 26, 315–320 (1991).

Hydroperoxide lyase is an enzyme of lipid metabolism which cleaves hydroperoxides of certain polyunsaturated fatty acids into aldehyde products. Fatty acid hydroperoxides are formed by oxygenation of linoleic or linolenic acids in a reaction catalyzed by the enzyme lipoxygenase. Depending upon the enzyme source, oxygen attack usually occurs at either carbon 9 or 13. Likewise, plant hydroperoxide lyases differ in their specificities, some catalyzing cleavage of only 9-hydroperoxides, others only 13-hydroperoxides, and still others with dual specificity (1,2). The reactions are shown in Scheme 1. Several assays have been used to measure hydroperoxide lyase activity. One common method employs gas chromatography for headspace analysis of the volatile aldehyde products (3). This procedure is time-consuming and usually results in a single data point to estimate the total amount of aldehyde produced within a specified time. A second method involves the derivatization of the aldehyde products with 2,4-dinitrophenylhydrazine, followed by extraction, chromatographic separation, and spectrophotometric measurement (4). Like headspace analysis, this is also a tedious process that results in one data point representing the total products formed up to that time. In a third method, the hydroperoxide lyase reaction is monitored spectrophotometrically at 234 nm to measure the decrease in absorbance caused by loss of the conjugated diene chromophore in the fatty acid hydroperoxide (5). This method is convenient, but is not specific for hydroperoxide lyase. It does not differentiate between hydroperoxide lyase and hydroperoxide dehydrase activity because both enzymes alter the conjugated diene chromophore in the fatty acid hydroperoxide.

In this paper, an alternative spectrophotometric assay is described for hydroperoxide lyase. This new method has a distinct advantage because it does not measure the presence of hydroperoxide dehydrase. The method is based on the ability of yeast alcohol dehydrogenase (ADH) to reduce aldehydes of various chain lengths (6).

SCHEME 1. Hydroperoxide lyase reaction with 9- or 13-hydroperoxylinolenic acid substrates.

Abbreviations: ADH, alcohol dehydrogenase; NADH, nicotinamide adenenine dinucleotide, reduced form.

Several of the aldehyde products of hydroperoxide lyase serve as substrates for yeast ADH and are converted to alcohols in the presence of the reduced form of nicotinamide adenine dinucleotide (NADH). Thus, hydroperoxide lyase can be assayed by coupling it with yeast ADH and measuring the loss in absorbance at 340 nm as NADH is oxidized.

MATERIALS AND METHODS

Chemicals. Linolenic and linoleic acid were purchased from NuChek Prep (Elysian, MN). Diethylaminoethyl (DEAE) cellulose, NADH, Triton X-100R, yeast ADH, soybean lipoxygenase type I-B, hexanal, and *trans*-2-hexenal were from Sigma Chemical Company (St. Louis, MO). Nonanal, *trans*-2-nonenal, and *trans*-2,*cis*-6-nonadienal were obtained from Aldrich (Milwaukee, WI); *cis*-3-hexenal was a product of Bedoukian Research Inc. (Danbury, CT) and was further purified by silver nitrate thin-layer chromatography to remove *trans*-2-hexenal. Bicinchoninic acid (BCA) protein assay reagent was purchased from Pierce (Rockford, IL).

Other substrates for ADH were prepared enzymically or chemically from fatty acids. 12-Oxo-*trans*-10-dodecenoic acid was prepared by cleavage of 13-hydroperoxylinolenic acid with cucumber hydroperoxide lyase. Cucumber flesh (1 g/mL of buffer) was homogenized at full speed with a Polytron homogenizer in 50 mM K-phosphate (pH 6.0) containing 0.1% Triton X-100R and centrifuged for 10 min at 12,000 × *g*. The reaction mixture contained 500 mL of 50 mM K-phosphate (pH 6.,0), 75 mL of 1.2 mM 13-hydroperoxylinolenic acid (prepared as described below), and 180 mL of cucumber extract. After 30 min, the mixture was adjusted to pH 3 with HCl and extracted with dichloromethane. The organic phase was dried with anhydrous sodium sulfate and evaporated under reduced pressure. 12-Oxo-*trans*-10-dodecenoic acid was purified from the extract by silica gel thin-layer chromatography in a solvent of hexane/diethyl ether/acetic acid (60:40:1, v/v/v). 12-Oxododecanoic acid was prepared by bubbling hydrogen through a methanolic solution of 12-oxo-*trans*-10-dodecenoic acid in the presence of PtO_2. α-Ketol, γ-ketol, and 12-oxophytodienoic acid were prepared from linolenic acid and a flaxseed extract as described for their 20-carbon homologs in an earlier report (7). 9-Oxononanoic acid was produced by reductive ozonolysis of oleic acid and purified by thin-layer chromatography in the solvent system described above.

Plant materials. Cucumbers (*Cucumis sativus* L.) were purchased from a local market. Sunflower (*Helianthus annuus* L., cv. NK 7111, Northrup King) seeds were germinated 2 to 3 days in moist paper towels in a germination chamber at 30°C. The seeds were then transferred to flats containing a sand/Perlite mixture (2:3, v/v) and placed in a growth chamber at 25°C under a 16 hr light, 8 hr dark cycle.

Preparation of partially purified enzymes. 9-Lipoxygenase was obtained from an acetone powder of harvest mature corn kernels (*Zea mays* L., var. NK PX443, Northrup King). The acetone powder (3 g) was extracted with 6 mL of 50 mM K-phosphate (pH 7.0) for 30 min at 4°C and centrifuged at 12,000 × *g* for 10 min. Lipoxygenase was partially purified from the supernatant on a small DEAE cellulose column containing about 2 mL bed volume. One mL of the supernatant was applied to a small column of DEAE cellulose equilibrated with the extraction buffer and allowed to drain into the matrix. Immediately following, the column was eluted with 3 mL of extraction buffer and three 1-mL fractions were collected and assayed for lipoxygenase. Fraction 2 or 3 usually contained the most lipoxygenase activity, which was free from both hydroperoxide dehydrase and hydroperoxide lyase activities.

Cucumber and sunflower hydroperoxide lyases were partially purified in a manner similar to that described for corn kernel lipoxygenase. Cucumber flesh (5 g) was diced and then homogenized at full speed with a Polytron homogenizer for 30 sec in 10 mL of 50 mM K-phosphate (pH 7.0) containing 0.1% Triton X-100R. The extract was centrifuged at 12,000 × *g* for 10 min and the supernatant saved. The first leaves of 8 to 12-day-old sunflowers were extracted similarly, except that the extraction buffer was at pH 6.0. One mL of each supernatant was applied to a small column of DEAE cellulose equilibrated with the appropriate extraction buffer containing 0.1% Triton X-100R. After the extract had eluted into the matrix, 3 mL of the extraction buffer was applied to the top of the column and three 1-mL fractions were collected. These fractions contained partially purified hydroperoxide lyase, with most of the activity usually in fraction 2. Protein concentrations of the partially purified enzyme solutions were determined using Pierce bicinchoninic acid protein assay reagent, with bovine serum albumin (BSA) as the standard.

Preparation of fatty acid hydroperoxides. The 13-hydroperoxide of linolenic or linoleic acid was prepared by the addition of 3 mL of soybean lipoxygenase solution (10 mg/mL in 10 mM borate buffer, pH 8.9) to 34.5 mL of oxygen-saturated distilled water. A sparge was used to bubble oxygen continuously through the enzyme solution during mixing with a magnetic stirrer. Then 7.5 mL of 8 mM linolenic or linoleic acid prepared according to Surrey (8) was added, and the reaction was allowed to proceed for at least 20 min. The final concentration of 13-hydroperoxide substrate was about 1.2 mM, estimated from a molar absorptivity of 25000 L/mol·cm at 234 nm.

The 9-hydroperoxide of linolenic or linoleic acid was prepared by an oxygenation reaction catalyzed with corn lipoxygenase. A 1.25-mL vol of 8 mM linolenic or linoleic acid (8) was added to 4.75 mL of oxygen-saturated 50 mM K-phosphate (pH 7.0). With oxygen bubbling through the solution, 1.5 mL of the partially purified corn kernel lipoxygenase solution was added and the reaction was allowed to proceed at least 30 min. The final concentrations were estimated by their absorbances at 234 nm to be 1.3 mM 9-hydroperoxylinolenic acid and 0.6 mM 9-hydroperoxylinoleic acid.

Enzyme assays. Except where noted, a typical hydroperoxide lyase assay mixture contained, in order of addition, 100 mM K-phosphate (pH 6.0), 0.1 mM NADH, 50 units/mL yeast ADH (one unit converts 1.0 μmol of ethanol to acetaldehyde per min at pH 8.8 at 25°C), 0.1 mM linolenic or linoleic acid hydroperoxide, and 0.05 to 0.2 mL of enzyme extract in a final volume of 1 mL. The pH of 6.0 was chosen because the optimum activity of many hydroperoxide lyases is in the range of pH 6 to 7. Although the pH optimum of yeast ADH is pH 8.8, the enzyme has sufficient activity at pH 6.0 that it is not rate-

limiting. In reactions conducted below pH 6.0, we sometimes observed protein precipitation which made the assay unsuitable. The above reactants were mixed in the absence of enzyme and the background oxidation rate of NADH was measured. The lyase reaction was then initiated by the addition of enzyme extract, and the initial rate of decrease in absorbance at 340 nm was measured. After subtraction of the background rate, the net enzyme rate was expressed as moles of NADH oxidized per min, based on a molar absorptivity of 6220 L/mol·cm for NADH (9).

Hydroperoxide dehydrase was assayed according to Zimmerman and Vick (5) by measuring the decrease in absorbance at 234 nm due to disruption of the conjugated diene chromophore of 13-hydroperoxylinolenic acid. An extract of flaxseed acetone powder was used as the source of hydroperoxide dehydrase. The powder (1 g) was extracted in 50 mM K-phosphate (pH 7.0) for 30 min and then centrifuged 10 min at 12,000 × *g*.

ADH activity was measured with several aldehyde substrates. The reaction mixture contained 0.1 M K-phosphate (pH 6.0), 0.1 mM NADH, 0.5 to 50 units yeast ADH (depending upon the reactivity of the aldehyde substrate), and 0.1 mM aldehyde substrate in a total volume of 1 mL. The reaction was initiated by the addition of aldehyde solution. All stock solutions of aldehydes, except for acetaldehyde, were at a concentration of 10 mM in acetonitrile solvent.

RESULTS

Comparison of two spectrophotometric hydroperoxide lyase assays. The spectrophotometric assay of hydroperoxide lyase at 234 nm (Fig. 1A) was compared with the coupled spectrophotometric assay at 340 nm (Fig. 1C). Initially, both assay mixtures contained 0.05 mM 13-hydroperoxylinolenic acid, but the coupled assay additionally contained 0.1 mM NADH and 50 units/mL ADH. After 2 min, a partially purified sunflower leaf extract with hydroperoxide lyase was added. Both assays showed a decrease in absorbance due to the hydroperoxide lyase reaction.

In contrast, hydroperoxide dehydrase activity was only detected by the assay at 234 nm (Fig. 1B). When an extract of flaxseed acetone powder containing hydroperoxide dehydrase was added to the mixture, there was a rapid decrease in absorbance at 234 nm due to the loss of conjugated diene. However, when the flaxseed extract was added to the coupled enzyme assay at 340 nm (Fig. 1D), no activity was detected. Thus, the coupled enzyme assay measured only hydroperoxide lyase, and not hydroperoxide dehydrase.

There was a slow rate of oxidation of NADH by 13-hydroperoxylinolenic acid in the presence of ADH (Fig. 1C) prior to the addition of sunflower hydroperoxide lyase. At high concentrations of 13-hydroperoxylinolenic acid, this background oxidation rate becomes significant and should be subtracted from the measured hydroperoxide lyase rate.

Relative efficiencies of yeast ADH substrates. Several carbonyl compounds were tested for their effectiveness as substrates for yeast ADH. Among the compounds tested were various metabolites of the hydroperoxide lyase and hydroperoxide dehydrase pathways. Table 1

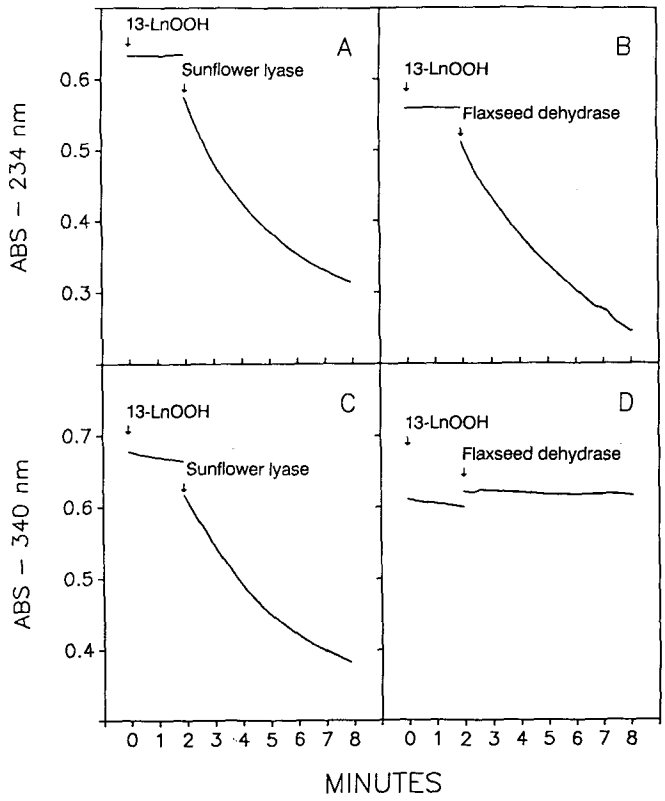

FIG. 1. Comparison of spectrophotometric assays for hydroperoxide lyase and hydroperoxide dehydrase monitored at 234 nm (hydroperoxide degradation) and at 340 nm (coupled with ADH). (A) Sunflower leaf lyase assay, 234 nm; (B) flaxseed acetone powder dehydrase assay, 234 nm; (C) sunflower leaf lyase assay coupled with ADH, 340 nm; (D) flaxseed acetone powder dehydrase assay coupled with ADH, 340 nm.

shows the relative rates of reduction of these compounds by NADH in the presence of ADH at pH 6.0. With the exception of nonanal, the NADH oxidation rates were quite low in comparison with acetaldehyde, the physiological substrate. At high concentrations of ADH (>50 units/mL), however, easily measurable rates were achieved.

Hexanal was a good substrate for ADH. Therefore, the coupled enzyme assay should always be applicable when 13-hydroperoxylinoleic acid is an effective substrate for hydroperoxide lyase, because hexanal is a product of that reaction. While *trans*-2-hexenal was also an effective substrate, *cis*-3-hexenal was not. Apparently, insertion of a *cis* double bond into the aldehyde chain remarkably reduces substrate efficiency. Consequently, one might predict that 13-hydroperoxylinolenic acid would be ineffective as a substrate for the ADH-coupled assay of hydroperoxide lyase, because the initial products of that reaction are generally thought to be *cis*-3-hexenal and 12-oxo-*cis*-9-dodecenoic acid (Scheme 1) (10). Both products possess *cis*-3 double bonds and neither would be expected to be a good substrate for ADH. Nevertheless, for reasons that are unclear, 13-hydroperoxylinolenic acid worked well as a substrate for all of the plant lyases we tested with this assay. For example, hydroperoxide lyase from tomato fruit was conveniently measured by the coupled assay, despite the fact that *cis*-3 aldehydes were reported by Galliard *et al.* (10) to be the major tomato

TABLE 1

Effectiveness of Various Aldehydes as Substrates for Yeast ADH[a]

Substrate	Rate of alcohol dehydrogenase
	nmol/min/unit
Acetaldehyde	200
Hexanal[b]	4.3
trans-2-Hexenal[b]	1.8
cis-3-Hexenal[b]	0
12-Oxo-*trans*-10-dodecenoic acid[b]	2.4
12-Oxododecanoic acid	0.5
Nonanal	51
trans-2-Nonenal[b]	7.4
trans-2,*cis*-6-Nonadienal[b]	3.9
9-Oxononanoic acid[b]	0.7
12-Oxophytodienoic acid	0
α-Ketol	0.05
γ-Ketol	0

[a]The assay mixture contained 0.1 M K-phosphate (pH 6.0), 0.1 mM NADH, 0.5 to 50 units alcohol dehydrogenase, and 0.1 mM aldehyde substrate.

[b]Metabolites of the hydroperoxide lyase pathway.

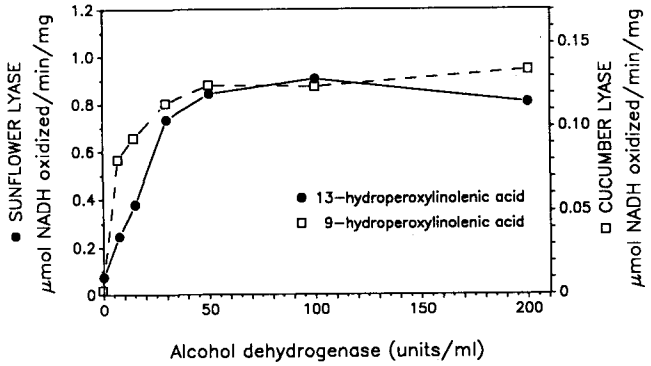

FIG. 2. Effect of yeast ADH concentration on the rate of the hydroperoxide lyase coupled enzyme assay.

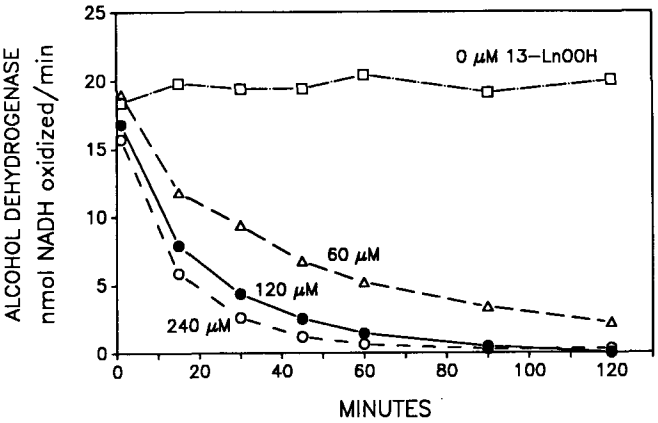

FIG. 3. Effect of 13-hydroperoxylinolenic acid concentration on the activity of yeast ADH. The concentration of ADH in each reaction was 50 units/mL.

lyase products. Our investigations of tomato hydroperoxide lyase have shown that both *cis*-3 and *trans*-2-hexenal are products in the ratio of approximately 2:1, respectively. It is possible that reduction of the *trans*-2-enal products to alcohols shifts the *cis*-3-enal/*trans*-2-enal equilibrium to favor production of the *trans*-2 isomer. This may explain the satisfactory results for the measurement of tomato lyase by the coupled assay.

Most plant extracts catalyze the *cis*-3 to *trans*-2 isomerization, albeit with various capacities. Evidence suggests that this isomerization is catalyzed by a separate isomerase enzyme (11), but the possibility that it may be catalyzed by the hydroperoxide lyase enzyme itself in some species cannot be excluded. If no isomerization to the *trans*-2 isomer occurs, then the coupled enzyme assay with ADH would not be expected to be as sensitive.

Three products of the hydroperoxide dehydrase reaction were also tested as substrates for ADH. All three compounds, 12-oxophytodienoic acid, α-ketol (13-hydroxy-12-oxo-*cis*-9,15-octadecadienoic acid), and γ-ketol (9-hydroxy-12-oxo-*trans*-10,*cis*-15-octadecadienoic acid), possess ketone functional groups rather than aldehydes. None were effective ADH substrates.

Effect of ADH concentration. To ensure that ADH was not rate-limiting in the coupled hydroperoxide lyase assay, reactions were conducted at several concentrations of ADH (Fig. 2). Substrates for the reaction were 9- or 13-hydroperoxylinolenic acid and the source of hydroperoxide lyase was partially purified cucumber flesh or sunflower leaf, respectively. The results showed that, at 50 units/mL, the ADH concentration was not rate-limiting in the measurement of hydroperoxide lyase from these typical plant extracts.

Inactivation of ADH by fatty acid hydroperoxides. Yeast ADH is affected by the presence of fatty acid hydroperoxides. Figure 3 shows the loss in activity of ADH over time at various concentrations of 13-hydroperoxylinolenic acid. Even at a hydroperoxide concentration of only 60 μM, over 36% of the ADH activity was lost after 15 min. To reduce this problem in the coupled assay, it is important to add the fatty acid hydroperoxide substrate immediately before the assay. The usual procedure was to first combine buffer, NADH, and ADH. Next the hydroperoxide substrate was added and the background NADH oxidation rate was measured for 1 to 3 min. Finally, the extract containing hydroperoxide lyase activity was added and the initial rate of decrease in absorbance at 340 nm was measured.

Stoichiometry. For every mole of fatty acid hydroperoxide cleaved by hydroperoxide lyase, two moles of aldehyde products are formed (Scheme 1). Accordingly, the coupled reaction with ADH should result in the oxidation of 2 mol of NADH for each mole of fatty acid hydroperoxide cleaved. Experimentally, spectrophotometric measurements of NADH oxidation showed that the aldehyde product yields were somewhat less than the expected 2 mol. The amount of NADH oxidized per mole of substrate was 1.5 mol for 13-hydroperoxylinoleic acid, 1.7 mol for 13-hydroperoxylinolenic acid, and 1.4 mol for 9-hydroperoxylinolenic acid. It is likely that some fatty acid hydroperoxide was converted non-enzymically to other products that were not substrates for ADH.

Effect of hydroperoxide dehydrase. Although the coupled hydroperoxide lyase-ADH assay does not measure

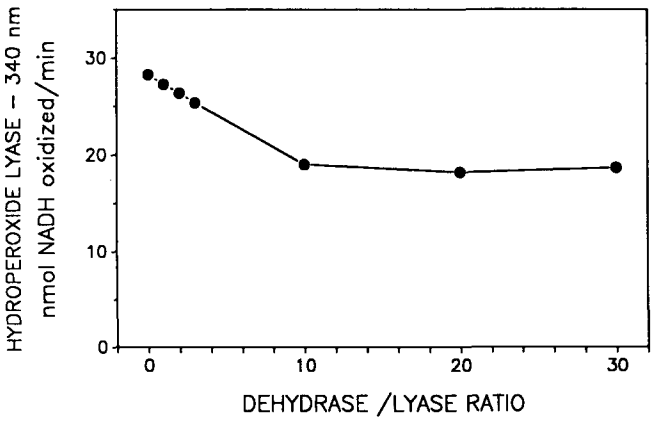

FIG. 4. Effect of various ratios of hydroperoxide dehydrase/hydroperoxide lyase activities (HD/HL) on the measurement of initial rates of the coupled hydroperoxide lyase/ADH reaction. Lyase activity was held constant and the HD/HL ratio was changed by adjusting the amount of dehydrase activity.

hydroperoxide dehydrase activity, the assay may be adversely affected by the presence of high levels of dehydrase. Hydroperoxide dehydrase competes for the same substrate as hydroperoxide lyase, and when dehydrase activity is high relative to lyase, the concentration of fatty acid hydroperoxide substrate available to hydroperoxide lyase is reduced. Consequently, the rate of the hydroperoxide lyase reaction declines. Figure 4 shows the effect of increasing the proportion of hydroperoxide dehydrase activity on the measurement of hydroperoxide lyase. Hydroperoxide dehydrase from a flaxseed acetone powder extract and hydroperoxide lyase from sunflower leaves were combined in various ratios based on their activities in the enzyme assay at 234 nm. As the proportion of hydroperoxide dehydrase increased, the initial rate of hydroperoxide lyase measured by the coupled assay at 340 nm decreased. When the ratio of dehydrase to lyase was greater than 10, the initial lyase rate was still about 66% of the rate observed when dehydrase was absent, but the total amount of NADH oxidized was reduced substantially.

DISCUSSION

The objective of this research was to develop a convenient spectrophotometric assay specific for hydroperoxide lyase. One common method to assay enzymes spectrophotometrically is to couple the product of the reaction with NADH and an appropriate dehydrogenase enzyme, and then measure the rate of oxidation of NADH by the decrease in absorbance at 340 nm. Two of the products of the hydroperoxide lyase pathway, hexanal and *trans*-2-hexenal, have been reported by Pietruszko *et al.* (6) to be good substrates for yeast ADH. Thus, the lyase reaction appeared to be a good candidate for a coupled enzyme assay, and this was confirmed by the present investigation.

The traditional spectrophotometric assay at 234 nm which measures the decomposition of fatty acid hydroperoxide is a convenient assay, but it does not discriminate between hydroperoxide lyase and hydroperoxide dehydrase. The coupled assay described here is specific for hydroperoxide lyase and is particularly useful in chromatographic separations to identify fractions containing lyase. Some plant tissues contain both lyase and dehydrase activities. Chromatographic separations of proteins from these tissues may yield two or more peaks with hydroperoxide degradation activity when the fractions are measured by the assay at 234 nm. Measurement of NADH oxidation by the coupled assay with ADH is a convenient method to establish which of the peaks correspond to hydroperoxide lyase.

Another disadvantage of the spectrophotometric assay at 234 nm is that proteins and other compounds present in crude and partially purified plant extracts often contribute to strong absorption in this region of the ultraviolet spectrum. This property often limits the amount of enzyme that can be added to the assay reaction mixture, and extracts with low enzyme activity often cannot be measured adequately. The assay at 340 nm allows five to ten times higher concentrations of enzyme extracts in the assay mixture because proteins do not absorb as strongly in this region. The same limitations are true for hydroperoxide concentration in the direct assay at 234 nm. This wavelength is used because the conjugated diene portion of the fatty acid hydroperoxide absorbs most strongly at 234 nm. Therefore, the concentration of hydroperoxide in the 234 nm assay is usually limited to less than 40 μM ($A \sim 1$).

Fatty acid hydroperoxides do not absorb significantly at 340 nm, and consequently higher concentrations of hydroperoxide can be used in the coupled assays conducted at this wavelength. The hydroperoxide concentration is limited only by its contribution to the background NADH oxidation rate and its adverse effect on ADH. Typically, the upper limit of hydroperoxide concentration is approximately 200 μM for the coupled lyase assay. The expanded concentration range permits acquisition of better kinetic data for enzyme properties such as K_m.

A few drawbacks to the coupled assay at 340 nm were noted. One disadvantage is that not all aldehyde products of the lyase reaction are effective substrates for ADH. Hexanal and *trans*-2 aldehydes are good substrates, but *cis*-3 aldehydes apparently are not. Thus, a situation could exist in which a plant hydroperoxide lyase is substrate specific for 13-hydroperoxylinolenic acid, resulting in *cis*-3-hexenal as a product. If the sample is devoid of *cis*-3-enal:*trans*-2-enal isomerase to convert the product to the *trans*-2-isomer, then the coupled assay may not be sensitive to the lyase activity. Such a situation could also occur during lyase purification procedures if the lyase became separated from the isomerase. Another consideration is the apparent reduction in the initial rate of hydroperoxide lyase when hydroperoxide dehydrase is present and competing for substrate (Fig. 4). However, all lyase assay methods in which hydroperoxide concentrations are in the region that displays first order kinetics are subject to the same competition by dehydrase.

In the process of developing this assay method, several plant tissues have been extracted and assayed, including young watermelon cotyledons, cucumber fruit, young soybean cotyledons, sunflower leaves, and tomato fruit. Hydroperoxide lyase activity was successfully assayed in each of these tissues by the coupled oxidation of NADH described here. In each tissue, the oxidation only occurred in the presence of a hydroperoxide substrate. There were

no endogenous substrates or NADH-requiring enzymes that interfered with the assay. Thus, the assay should be applicable to a wide range of plant sources. Despite minor limitations of the coupled assay, problems can be minimized or eliminated by following the precautions outlined here. The method should prove to be a useful alternative to investigators interested in the measurement of hydroperoxide lyase.

Determination of Phospholipase D-Mediated Hydrolysis of Phosphatidylethanolamine

Zoltan Kiss
The Hormel Institute, University of Minnesota, Austin, Minnesota 55912

While phospholipase D-mediated hydrolysis of phosphatidylcholine is well documented, we have recently shown that phospholipase D-mediated hydrolysis of phosphatidylethanolamine (PtdEtn) [Kiss, Z., and Anderson, W.B., *J. Biol. Chem. 264,* 1483-1487 (1989); *J. Biol. Chem. 265,* 7345-7350 (1990)] is equally prominent. This made it necessary to define in detail the conditions required for the detection of agonist-stimulated PtdEtn hydrolysis. Using the [^{14}C]ethanolamine-prelabeled rat-1 fibroblast model and 12-*O*-tetradecanoylphorbol 13-acetate (TPA) as a model compound with the known ability to stimulate phospholipase D, we demonstrated that optimal detection of TPA-induced ethanolamine release requires i) fractionation of water-soluble ethanolamine products; ii) addition of unlabeled ethanolamine to quench the phosphorylation of newly formed [^{14}C]ethanolamine; and/or iii) prolonged preincubation of prelabeled cells in an isotope-free medium before the addition of TPA. This preincubation step reduces the cellular content of unincorporated ^{14}C-labeled ethanolamine metabolites and improves the signal-to-noise ratio.
***Lipids 26,* 321-323 (1991).**

Phospholipase D has recently emerged as an important enzyme component of the *trans*-plasma membrane signaling system. A number of agonists, including several growth factors, have been shown to stimulate its activity (reviewed in refs. 1 and 2). Phosphatidylcholine (PtdCho) has been widely regarded as the predominant substrate for this enzyme (1,2), with little consideration given to phosphatidylethanolamine (PtdEtn), usually the second most abundant phospholipid in mammalian membranes. Apart from our studies showing that 12-*O*-tetradecanoylphorbol 13-acetate (TPA) (3), adenosine triphosphate, guanosine triphosphate, and sphingosine (4) each stimulate PtdEtn hydrolysis, TPA has been shown only in one study to similarly stimulate the hydrolysis of PtdEtn and PtdCho (5).

The issue whether PtdEtn is also a substrate for phospholipase D activity (not necessarily identical with phospholipase D involved in PtdCho hydrolysis) is important to understanding the biological role of enhanced phospholipid metabolism. This requires utilization of a technique suitable for the detection of PtdEtn hydrolysis. Such a technique has not yet been fully defined. In this paper, we describe in detail optimal conditions which must be met in order to be able to demonstrate agonist-induced PtdEtn hydrolysis.

EXPERIMENTAL PROCEDURES

Materials. TPA, sphingosine, Dowex 50X8-400-WH$^+$ cation exchange resin, phospholipase C (Type IX; from *C. perfringens*), phospholipase A_2 (from bee venom) and phospholipase B (from vibrio species) were purchased from Sigma Chemical Company (St. Louis, MO). [2-^{14}C]-Ethanolamine (20 mCi/mmol) was from Amersham (Arlington Heights, IL), tissue-culture reagents were bought from GIBCO (Grand Island, NY), and fetal calf serum was bought from Flow Laboratories (McLean, VA).

Cell culture. Rat-1 fibroblasts were cultured continuously in Dulbecco's modified Eagle medium (DMEM) supplemented with 10% fetal calf serum, penicillin-streptomycin (50 U/mL and 50 μg/mL, respectively), and glutamine (2 mM). Cells used in the experiments were seeded (1-2 × 10^5/dish) in 100-mm plastic dishes, and growing (60-80% confluent) cell populations were harvested after two days in culture.

Determination of water-soluble products of phosphatidylethanolamine degradation in [^{14}C]ethanolamine-prelabeled cells. Rat-1 fibroblasts were incubated with [2-^{14}C]ethanolamine (0.20 μCi/mL) for 48 hr in DMEM containing 10% fetal calf serum. Cells were then washed and incubated in fresh medium (containing 10% serum) for an additional 3 hr or used without preincubation, as described. Cells were harvested by gentle scraping from the dish. Cells collected from 3-5 dishes (150 cm^2) were washed with fresh DMEM. At this step, 95-98% of cells were viable, determined by the trypan blue dye exclusion assay. Aliquots (0.3 mL) of the intact cell suspension (1.2-1.6 × 10^6 cells in 1 mL DMEM) were incubated (final volume 0.30 mL) in polypropylene tubes in an incubator at 37°C in the absence or presence of 2 mM unlabeled ethanolamine, as indicated, along with 100 nM TPA, as specified. Incubations were terminated by the addition of 4 mL of an ice-cold mixture of chloroform/methanol (1:1, v/v). Cells were extracted in this mixture for 60 min, followed by the addition of 3 mL of water. Complete phase separation was achieved by centrifuging the mixtures at 2,000 × *g* for 5 min. Five-milliliter aliquots of the water/methanol phase were used for the separation of ethanolamine metabolites using the method of Cook and Wakelam (6), with some modifications. Dowex-50-WH$^+$ resin was treated with two volumes of 1 M HCl for 2 hr. The Dowex-50-WH$^+$ packed columns (1 mL bed volume) were washed with water until the washings were approximately pH 5.5. The initial flow-through (5 mL), along with a following 3-mL wash, contained [^{14}C]glycerophosphoethanolamine. [^{14}C]Ethanolamine phosphate was eluted by 15 mL water, while [^{14}C]ethanolamine was eluted by 8 mL 1 M HCl. For the preparation of appropriate ^{14}C-labeled standards, the ^{14}C-prelabeled cells were treated with either phospholipase A_2 (1 U/mL) + phospholipase B (1 U/mL) or phospholipase C (1 U/mL), respectively, for 60 min, and extracts were prepared as above. Two-mL fractions were collected for the determination of the elution profiles of standards (determined in each experiment). The metabolites of [^{14}C]ethanolamine present in the peak fractions were further identified by thin-layer chromatography (3). Phospholipids were separated and their ^{14}C content was determined as previously described (7).

Abbreviations: DMEM, Dulbecco's modified Eagle medium; PtdCho, phosphatidylcholine; PtdEtn, phosphatidylethanolamine; TPA, 12-*O*-tetradecanolylphorbol 13-acetate.

TABLE 1

Effect on TPA on the Formation of Ethanolamine Products in Rat-1 Fibroblasts[a]

Preincubation (3 hr)	Ethanolamine (2 mM)	[^{14}C] Total water-soluble fraction (dpm/10^5 cells) None (0 min)	None (30 min)	TPA (30 min)
−	−	26,125 ± 670	24,130 ± 360	27,540 ± 690
−	+	26,930 ± 1000	26,760 ± 440	33,690 ± 400
+	−	4,576 ± 250	4,650 ± 540	7,690 ± 240
+	+	4,720 ± 350	5,500 ± 200	9,910 ± 450

[a][^{14}C]Ethanolamine-prelabeled rat-1 cells were incubated for 30 min under the conditions shown in the absence or presence of 100 nM TPA. After phase separation, aliquots were taken to determine ^{14}C activity in the total released water-soluble fraction. The ^{14}C content of PtdEtn at the beginning of incubation was 115,000 dpm/10^5 cells. Data are the mean ± S.E. of four determinations and are representative of four experiments.

TABLE 2

Effect of TPA on the Formation of Ethanolamine[a]

+	+	720 ± 120	1,460 ± 110	6,580 ± 470

[a]In the same experiment described in the legend to Table 1, aliquots of the upper phase were separated on Dowex-50-WH$^+$ columns as described in Experimental Procedures. Data are the mean ± S.E. of four determinations and are representative of four experiments.

RESULTS AND DISCUSSION

The purpose of this study was to establish conditions best suited for the determination of phospholipase D-mediated PtdEtn hydrolysis. Because TPA is one of the best activators of phospholipase D, this agent was used to enhance PtdEtn metabolism. Rat-1 fibroblasts were chosen for this work as these cells exhibit an average response to TPA compared to well-responding (such as NIH 3T3 fibroblasts) and less well-responding cells (such as the HL60 leukemic cell line). Thus, it is likely that data presented here will be applicable for many other cell lines. Data presented in Tables 1–4 are derived from the same experiment performed with [^{14}C]ethanolamine-prelabeled cells.

Effect of TPA on the release of total water-soluble [^{14}C]ethanolamine products. Some investigators who found no agonist-stimulated PtdEtn hydrolysis (*e.g.*, ref. 8) added the agonist to cells immediately after the removal of radiolabeled material, with no unlabeled ethanolamine added to the incubation medium. As shown in Table 1, under these conditions cells contain large amounts of water-soluble [^{14}C]ethanolamine metabolites, and TPA appears to have only minor effects, if any at all, on the release of [^{14}C]ethanolamine. Even under these conditions, addition of 2 mM ethanolamine to the incubation medium was beneficial in demonstrating some [^{14}C]ethanolamine release in response to TPA. The relatively small experimental errors in these experiments were due to the ability to control cell number by using scraped cells. With attached cells, the experimental error was much higher (in the range of 20%), which made it impossible to demonstrate any significant TPA effect.

Incubation of prelabeled cells for a 3-hr period in the absence of [^{14}C]ethanolamine before the addition of TPA resulted in a large reduction of the cellular pool of ^{14}C-labeled water-soluble ethanolamine metabolites. This significantly increased the signal-to-noise ratio, particularly in the presence of 2 mM unlabeled ethanolamine (Table 1). However, even under the latter condition, the background ^{14}C activity (present in untreated cells) was still relatively high.

Effect of TPA on the formation of [^{14}C]ethanolamine. After separation of ethanolamine from the other water-soluble products it becomes clear that ethanolamine is only a relatively minor component of the total water-soluble fraction in these fibroblasts (Table 2). Accordingly, the chromatographic step employed made the stimulatory effect of TPA more apparent on a percentage basis. Addition of 2 mM ethanolamine to cells preincubated for 3 hr appeared to be optimal for demonstrating the effect of TPA on [^{14}C]ethanolamine release (Table 2). Under these latter conditions, in four experiments 100 nM TPA stimulated [^{14}C]ethanolamine formation four–six-fold.

Effect of TPA on the formation of ethanolamine phosphate. As shown in Table 3, ethanolamine phosphate was the predominant water-soluble derivative of ethanolamine

TABLE 3

Effect of TPA on the Formation of Ethanolamine Phosphate[a]

TABLE 4

Effect of TPA on the Formation of Glycerophosphoethanolamine[a]

Preincubation (3 hr)	Ethanolamine (2 mM)	[^{14}C]Glycerophosphoethanolamine (dpm/10^5 cells) None (0 min)	None (30 min)	TPA (30 min)
−	−	4,690 ± 900	5,110 ± 560	3,960 ± 640
−	+	5,680 ± 440	4,350 ± 310	4,850 ± 630
+	−	1,420 ± 40	1,460 ± 90	1,410 ± 70
+	+	1,490 ± 170	2,130 ± 240	1,780 ± 180

[a]Data are the mean ± S.E. of four determinations and are representative of four experiments.

present in cells. Additional incubation of prelabeled cells for 3 hr resulted in a dramatic decrease in the cellular content of ethanolamine phosphate. In preincubated cells, TPA slightly enhanced the level of [^{14}C]ethanolamine phosphate in the absence of unlabeled ethanolamine (Table 3); this effect of TPA was prevented by the addition of 2 mM ethanolamine to the medium. These data indicate that in the absence of unlabeled ethanolamine a portion of newly formed [^{14}C]ethanolamine is further phosphorylated. In certain cell lines, such as HL60 cells (3), TPA stimulates PtdEtn resynthesis, which results in rapid elimination of the newly formed [^{14}C]ethanolamine pool. For this reason, in HL60 cells addition of unlabeled ethanolamine to the medium was important to demonstrate ethanolamine release (3). By comparison, in rat-1 fibroblasts TPA does not stimulate PtdEtn synthesis (data not shown). Thus, addition of unlabeled ethanolamine, while beneficial, is not essential for demonstrating the TPA effect on [^{14}C]ethanolamine release (Table 2).

Effect of TPA on the formation of glycerophosphoethanolamine. Glycerophosphoethanolamine represents the second largest pool of water-soluble ethanolamine derivatives (Table 4). Its intracellular level was also decreased during a 3-hr preincubation period; however, TPA did not significantly affect its metabolism.

In conclusion, the results establish the conditions required for the optimal detection of the TPA effect on PtdEtn hydrolysis in [^{14}C]ethanolamine-prelabeled cells. It is hoped that these data will stimulate further work on the regulation of PtdEtn hydrolysis.

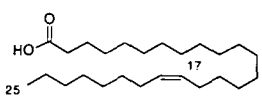
Two Novel Phospholipid Fatty Acids from the Caribbean Sponge *Geodia gibberosa*



Néstor M. Carballeira* and **Jaime Rodriguez**
Department of Chemistry, University of Puerto Rico, Rio Piedras, Puerto Rico 00931

The novel fatty acids (Z)-6-nonadecenoic acid (1) and (Z)-17-pentacosenoic acid (2) were characterized in the sponge *Geodia gibberosa*. These fatty acids were mainly found in phosphatidylethanolamine and phosphatidylcholine.
***Lipids* 26, 324-326 (1991).**

The myriad of novel secondary metabolites arising from marine organisms have attracted the attention of an active group of marine natural products chemists (1). One particular area of interest has been that of novel lipids from marine sponges such as sterols and fatty acids (2). Fatty acids from sponges have recently provided numerous examples of structures of unusual biosynthetic origin, which are mostly without counterpart in the terrestrial environment (3). Most of the early research by Jeffert's group (4) indicated that these unusual acids were non-methylene interrupted polyenes, rather than the more commonly occurring methylene interrupted polyenes. Two rather interesting biosynthetic routes are thought to be operative in these invertebrates, namely the even sequences 18:1n-9 to either 24:1n-9 or 26:1n-9, and the route 18:1n-7 to either 24:1n-7 or 26:1n-7. There is no evidence that the biosynthetic route 19:1n-8 to 25:1n-8 is operative in nature. In fact, few nonadecenoic acids are known to exist, the most unusual examples being the 19:1n-11 and 19:1n-9 acids from the dolphin *Tursiops truncatus* (5). In the present communication, we report the identification of two novel odd-chain fatty acids, namely (Z)-6-nonadecenoic acid (1) and (Z)-17-pentacosenoic acid (2) from the phospholipids of the sponge *Geodia gibberosa*.

EXPERIMENTAL PROCEDURES

Geodia gibberosa was collected in July 1989 near the shelf edge of La Parguera, Puerto Rico, at a depth of 10 m. The sponge (500 g) was washed in sea water, carefully cleaned of all nonsponge debris and cut into small pieces. Immediate extraction with 600 mL of chloroform/methanol (1:1, v/v) yielded the total lipids (350 mg). The neutral lipids, glycolipids and phospholipids (100 mg) were separated by column chromatography on Silica Gel (60-200 mesh) using a procedure similar to that described by Privett *et al.* (6). The phospholipid classes were fractionated by preparative thin-layer chromatography (TLC) using Silica Gel G and chloroform/methanol/water (25:10:1, v/v/v) as solvent, affording mainly phosphatidylethanolamine and phosphatidylcholine. The fatty acyl components of these phospholipids were obtained as their methyl esters by reaction with methanolic hydrogen chloride (7) followed by column chromatographic purification and elution with hexane/diethyl ether (9:1, v/v). The resulting methyl esters were analyzed by gas chromatography/mass spectrometry using either a Hewlett-Packard 5995 A gas chromatograph/mass spectrometer (Hewlett-Packard Company, Palo Alto, CA) or a Hewlett-Packard 59970 MS ChemStation equipped with a 30-m × 0.25-mm nonpolar fused silica column coated with DB-1. Gas chromatographed/Fourier transform-infrared (GC/FT-IR) spectra were recorded on a Nicolet (Madison, WI) 740 FT-IR spectrometer. For the localization of double bonds, dimethyldisulfide derivatives were prepared by dissolving the esters (2 mg) in dimethyldisulfide (0.2 mL) and adding a solution (0.05 mL) of iodine in diethyl ether (60 mg/mL). The solution was heated at 50°C for 24 hr and the product was purified (8). Hydrogenations were carried out in 10 mL of absolute methanol in the presence of catalytic amounts of platinum oxide (PtO_2). Mass spectral data for the key fatty acids described are presented here:

RESULTS AND DISCUSSION

Capillary GC and gas chromatography/mass spectrometry (GC/MS) analysis of the fatty acid methyl esters from *Geodia gibberosa* gave the data presented in Table 1. As can be seen, the mixture contained large amounts of odd-chain fatty acids (60% of the total composition). The longest acids found belong to the *iso-anteiso* $\Delta^{5,9}$-27:2 series (3), while several aldehydes (arising from plasmalogens) with chain lengths between 22 and 24 carbons were also observed, including the common sponge aldehyde 17-tetracosenal (9). The compounds were characterized by comparison with authentic standards, based on equivalent chain length (ECL) values and mass spectral data. Two of the more abundant compounds arising from phosphatidylethanolamine and phosphatidylcholine were characterized as (Z)-6-nonadecenoic acid (1) and (Z)-17-pentacosenoic acid (2). Capillary GC on a DB-1 column and GC/MS were the principal tools of characterization. The (Z)-6-nonadecenoic acid (1) methyl ester gave a molecular ion peak at *m/z* 310 (M^+, 1%), a base peak at *m/z* 55 (100%), and typical fragmentation ions at *m/z* 278 (M^+-MeOH, 10%), *m/z* 236 (M^+-74, 4%), *m/z* 194 (M^+-116, 5%), *m/z* 87 (40%), and *m/z* 74 (62%). The data support the nonadecenoic acid methyl ester structure. Upon catalytic hydrogenation (PtO_2), the compound was transformed to nonadecanoic acid methyl ester as was confirmed by GC upon coinjection with an authentic standard. The bound bond position was determined on the corresponding dimethyldisulfide adduct (8,10). The mass spectrum of the adduct afforded a molecular ion peak at *m/z* 404 (M^+, 12%). The double bond was localized between carbons 6 and 7 based on the abundant fragmentations at *m/z* 175 ($C_8H_{15}SO_2^+$, 55%) and *m/z* 229 ($C_{14}H_{29}S^+$, 68%). These fragments reflect the cleavage exemplified in 3. We could also observe a characteristic peak at *m/z* 143 ($C_7H_{11}SO^+$, 100%) which is due to *m/z* 175 and the loss of methanol. The double bond was assigned to be *cis* because there was no absorption in the 968–980 cm^{-1} region. The experimental data thus support structure 1.

The other fatty acid, namely (Z)-17-pentacosenoic acid (2), as methyl ester, gave a molecular peak at *m/z* 394 (M^+, 1%), a base peak at *m/z* 55 (100%), and typical fragmentation ions at *m/z* 362 (M^+-MeOH, 11%), *m/z* 320 (M^+-74, 3%), *m/z* 87 (38%), and *m/z* 74 (56%). All the data are consistent with the structure of a pentacosenoic acid methyl ester. Upon catalytic hydrogenation (PtO_2), the compound yielded pentacosanoic acid methyl ester. The double bond position was determined by preparing the dimethyldisulfide adduct, which afforded a molecular ion peak at *m/z* 488 (M^+, 1%). The

double bond was determined to be between carbons 17 and 18 based on the abundant fragments at *m/z* 329 ($C_{19}H_{37}SO_2^+$, 100%) and *m/z* 159 ($C_9H_{19}S^+$, 80%) as exemplified in 4. We also observed a typical peak at *m/z* 297 ($C_{18}H_{33}SO^+$, 100%) which is due to *m/z* 329 plus loss of methanol. The double bond was identified as *cis* because of the absence of absorption in the 968–980 cm^{-1} region.

Over one hundred naturally occurring monoenoic acids have been identified in nature (11). In general, these acids have an even number of carbon atoms and the double bond has *cis* or Z configuration. As examples of Δ6 fatty acids we could mention 16:1n-10 from the seed oil of *Picramnia sellowii,* from sea anemones, and from other marine animals, or petroselinic acid 18:1n-12 which is common in umbelliferous seed oils (11). Our present report of the novel 19:1n-13 acid from *G. gibberosa* describes one of the first naturally occurring odd-chain Δ6 acids. *G. gibberosa* seems to possess a Δ6 desaturase system capable of utilizing long, odd-chain fatty acids as substrates. The second acid, (Z)-17-pentacosenoic acid (2), seems to have originated from a 19:1n-8 acid. The even-chain 24:1n-7 and 26:1n-9 acids have been identified before in other sponges (9), but the 25:1n-8 acid reported here had not been found in nature before. Research is in progress to delineate the biosynthetic routes that are operative in these invertebrates.

ACKNOWLEDGMENTS

Dr. Vance Vicente from the United States Department of the Interior Fish and Wildlife Service collected and classified the sponge. This work was supported by the National Science Foundation under Grant No. CHE-8715649 and the National Institutes of Health under Grant No. S06 RR08102-17.

Leukotriene B_4 Promotes Phospholipid Acylation in Human Neutrophils

Jen-sie Tou* and **Sean Healey**
Department of Biochemistry, Tulane University School of Medicine, New Orleans, Louisiana 70112

The present study was undertaken to test the hypothesis that leukotriene B_4 (LTB_4) may promote extracellular fatty acid incorporation into neutrophil choline glycerophospholipids (PC) to replenish phospholipids after deacylation. Incubation of human neutrophils with LTB_4 (1.5 to 150 nM) for 1 to 5 min resulted in increased fatty acid incorporation into phosphatidylinositol (PI), diacyl-*sn*-glycero-3-phosphocholine (diacyl-GPC) and alkylacyl-GPC. The magnitude of stimulation (percentage of control) of fatty acid incorporation appears to reflect increased activity of the acyltransferases catalyzing acylation of the respective lysophospholipids. LTB_4 stimulation of arachidonic acid incorporation into PI was greater than into PC, whereas the stimulation of palmitic acid incorporation into PC was greater than into PI. LTB_4 stimulated phosphatidic acid labeling by palmitic acid but not by arachidonic acid. LTB_4 and 1-*O*-alkyl-2-*N*-methylcarbamyl-*sn*-glycero-3-phosphocholine (cPAF) exhibited a similar stimulatory effect on fatty acid incorporation into the PC fraction. Phosphate analysis could not detect changes in the mass of PI or of PC in neutrophils exposed to LTB_4 or cPAF. The results suggest that increased fatty acid incorporation into phospholipids in LTB_4-activated neutrophils reflects activation of phospholipase A_2 and acyltransferases as well as of *de novo* phospholipid synthesis.
***Lipids* 26, 327–330 (1991).**

Human neutrophils synthesize leukotriene B_4 (LTB_4) in response to chemotactic peptide (1–4). The precursor fatty acid of LTB_4, arachidonic acid, is liberated from cellular phospholipids by phospholipase A_2 (1,2) or can be provided in the extracellular medium (3,4). Neutrophils also synthesize LTB_4 in response to platelet-activating factor (PAF;5,6), and LTB_4 in turn promotes PAF formation (7,8). Both LTB_4 (9,10) and PAF (11) are agonists for neutrophil chemotaxis and aggregation, thereby amplifying inflammatory reactions. Increased PAF synthesis in LTB_4-stimulated neutrophils (7,8) suggests an activation of alkylacyl-*sn*-glycero-3-phosphocholine (alkylacyl-GPC) deacylation. The present study was undertaken to test the hypothesis that LTB_4 may promote extracellular fatty acid incorporation into both diacyl-GPC and alkylacyl-GPC to replenish phospholipids after deacylation. We demonstrate that LTB_4 promotes the incorporation of extracellular arachidonic acid and palmitic acid into phosphatidylinositol (PI), diacyl-GPC and alkylacyl-GPC. We also demonstrate that LTB_4 and a non-metabolizable platelet-activating factor analog, 1-*O*-alkyl-2-*N*-methylcarbamyl-*sn*-glycero-3-phosphocholine (cPAF), (12), exhibit a similar stimulatory effect on fatty acid incorporation into choline glycerophospholipids (PC).

MATERIALS AND METHODS

Materials. [1-^{14}C]Arachidonic acid (52.0 Ci/mol) and [1-^{14}C]palmitic acid (56.0 Ci/mol) were purchased from DuPont-New England Nuclear (Boston, MA). LTB_4, *Bacillus cereus* phospholipase C and fatty acid-free bovine serum albumin (BSA) were obtained from Sigma Chemical Co. (St. Louis, MO). cPAF was obtained from Calbiochem (San Diego, CA). Silica gel H plates were from Analtech (Newark, DE).

Preparation of human neutrophils. Human neutrophils were prepared as previously described (13). Cells were suspended in Dulbecco's balanced salt solution (14) containing 5 mM glucose at a concentration of 20 $\times$ 10^6 cells/mL. Cell counts were made in a hemocytometer, and cell viability was measured by trypan blue exclusion. Cell preparations contained more than 95% neutrophils.

Incubation of cells with LTB_4 or with cPAF. Each radiolabeled fatty acid was suspended in 0.9% NaCl containing BSA (4 mg/mL) at a concentration of 38–39 μM. LTB_4 and cPAF were each suspended in 0.9% NaCl containing BSA (2.5 mg/mL) at a concentration of 30 μM. Each incubation tube in a final volume of 2 mL contained 0.97 μM (0.1 μCi) [1-^{14}C]arachidonic acid or 0.95 μM (0.1 μCi) [1-^{14}C]palmitic acid, 0.15 to 150 nM LTB_4 or 150 nM cPAF, and 20 $\times$ 10^6 cells. Control tubes contained an equivalent volume of 0.9% NaCl containing BSA (2.5 mg/mL). Incubations were done at 37°C and started by adding 20 $\times$ 10^6 cells per tube.

Lipid analysis. Incubations were terminated by adding 5 mL methanol to each tube. Total lipids were extracted according to the method of Bligh and Dyer (15) and dissolved in chloroform/methanol (2:1, v/v) containing 0.01% butylated hydroxytoluene. Individual phospholipids were resolved by thin-layer chromatography (TLC) on Silica gel H plates (16). Phospholipid phosphorus and radioactivity were measured as previously described (16). Since phosphatidic acid (PA) levels could not be accurately measured by phosphate assay, the radioactivity of individual phospholipids was expressed as dpm/6 $\times$ 10^6 cells.

The distribution of labeled fatty acids in diacyl-GPC and alkylacyl-GPC was analyzed as previously described (16). Purified PC fractions from the control and LTB_4-activated neutrophils were each treated with

Abbreviations: BSA, fatty acid-free bovine serum albumin; cPAF, 1-*O*-alkyl-2-*N*-methylcarbamyl-*sn*-glycero-3-phosphocholine; GPC, *sn*-glycero-3-phosphocholine; LTB_4, leukotriene B_4, 5S,12R-dihydroxy-6,14-*cis*-8,10-*trans*-eicosatetraenoic acid; PA, phosphatidic acid; PAF, platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; TLC, thin-layer chromatography.

Bacillus cereus phospholipase C, and the resulting 1,2-diradylglycerols were acetylated in the presence of acetic anhydride/pyridine (10:1,v/v). The resulting 1-radyl-2-acyl-3-acetylglycerols were resolved into 1-alkenyl-2-acyl-3-acetylglycerol, 1-alkyl-2-acyl-3-acetylglycerol, and 1,2-diacyl-3-acetylglycerol fractions by TLC (16), and the radioactivity in each fraction was measured by liquid scintillation counting. Mild alkaline hydrolysis of the palmitic acid-labeled PC fraction was performed as previously described (13).

RESULTS AND DISCUSSION

LTB_4 promoted [1-^{14}C]arachidonic acid incorporation into PC and PI in a concentration-dependent manner. Figure 1 illustrates that LTB_4 at 0.15 to 150 nM did not significantly change the radioactivity of PA after a 2-min incubation. In contrast, LTB_4 enhanced the incorporation of labeled arachidonic acid into the PI and PC fractions from 1.5 to 150 nM. In the presence of 150 nM LTB_4 after a 2-min incubation, the radioactivity of PI and PC reached 400% and 250% of control cells, respectively. LTB_4 at 0.15 nM showed no stimulatory effect on arachidonic acid incorporation into PI or PC. Under the experimental conditions, there were no changes in the labeling of phosphatidylethanolamine and phosphatidylserine.

LTB_4 (150 nM) enhanced [1-^{14}C]arachidonic acid incorporation into PC and PI at all time points (1 to 5 min) examined (Fig. 2). Figure 3 shows that LTB_4 enhanced the incorporation of [1-^{14}C]palmitic acid into PA, PI and PC. The magnitude of stimulation (percentage of control) of fatty acid incorporation into phospholipids appears to reflect the specificity of the acyltransferases catalyzing the acylation of the respective lysophospholipids. LTB_4 stimulation of arachidonic acid incorporation into PI was greater than into PC, whereas stimulation of palmitic acid incorporation into PC was greater than into PI. Phospholipid phosphorus assays did not detect changes in individual phospholipid mass. The LTB_4 effect on labeled fatty acid distribution in diacyl-GPC and alkylacyl-GPC was examined as described previously (16). Figure 4 shows that LTB_4 stimulated the incorporation of labeled arachidonic acid and palmitic acid into both diacyl-GPC and alkylacyl-GPC. While more radioactivity appeared in the diacyl species, stimulation was more pronounced in the alkylacyl species than in the diacyl species (Fig. 4). In the presence of 150 nM LTB_4, the radioactivities of [^{14}C]arachidonic acid-labeled diacyl-GPC and alkylacyl-GPC reached 159% and 308% of control cells, respectively. Similarly, the radioactivities of [^{14}C]palmitic acid-labeled diacyl-GPC and alkylacyl-GPC reached 177% and 222% of control cells, respectively. The positional distribution of the [^{14}C]palmitoyl moiety in alkylacyl-GPC was examined by mild alkaline hydrolysis of the palmitic acid-labeled PC fraction (13). The radioactivity of the palmitic acid-labeled PC fraction was completely recovered in the fatty acid fraction; the resulting "alkaline-stable lysoPC" fraction contained no radioactivity.

The effects of a non-metabolizable PAF (12), cPAF and LTB_4 on fatty acid incorporation into diacyl-GPC and alkylacyl-GPC were compared. Figure 5 shows that

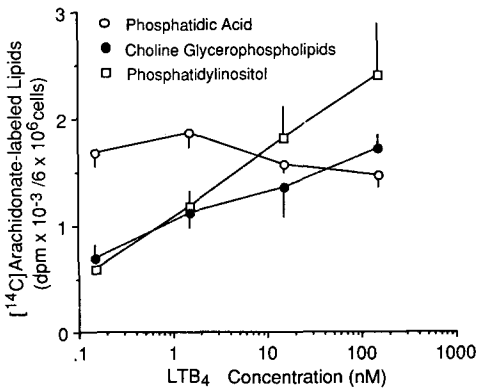

FIG. 1. The effect of LTB_4 concentrations on [1-^{14}C]arachidonic acid incorporation into phospholipids. Neutrophils (20 × 10^6 in 2 mL), 0.1 μCi [1-^{14}C]arachidonic acid (0.97 μM) and different LTB_4 concentrations (0.15 nM to 150 nM) were incubated at 37°C for 2 min. Each point represents the mean value ± standard deviation from three separate experiments.

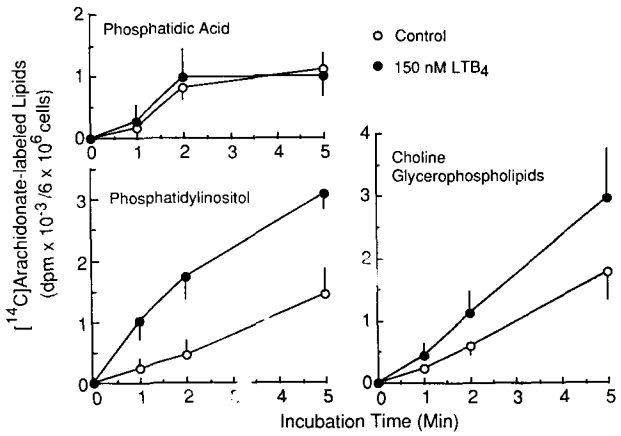

FIG. 2. Time course of LTB_4 stimulation of [1-^{14}C]arachidonic acid incorporation into neutrophil phospholipids. Neutrophils (20 × 10^6 in 2 mL) were incubated at the indicated time (1-5 min) with 0.1 μCi [1-^{14}C]arachidonic acid (0.97 μM) in the absence or presence of 150 nM LTB_4. Each point represents the mean value ± standard deviation from three separate neutrophil preparations.

cPAF promoted the incorporation of both arachidonic acid and palmitic acid into diacyl-GPC and alkylacyl-GPC. It appears that cPAF and LTB_4 exhibited a similar stimulatory effect on fatty acid incorporation into the PC fraction. In the presence of 150 nM cPAF after a 5-min incubation, the radioactivities of [^{14}C]arachidonic acid-labeled diacyl-GPC and alkylacyl-GPC reached 144% and 338% of control cells, respectively. Under identical conditions, the radioactivites of [^{14}C]palmitic acid-labeled diacyl-GPC and alkylacyl-GPC increased to 157% and 236% of control cells, respectively.

LTB_4 has been shown to enhance phospholipase A_2 activity in neutrophils (7,8). LTB_4 stimulation of phospholipid acylation as demonstrated in the present study may be brought about by a combined activation of phospholipase A_2 and acyltransferases. Activation

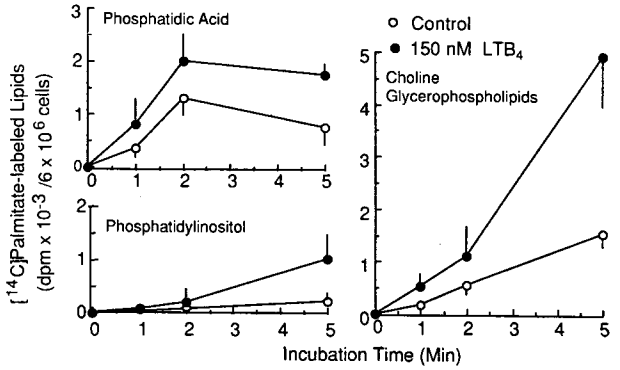

FIG. 3. Time course of LTB_4 stimulation of [1-^{14}C]palmitic acid incorporation into neutrophil phospholipids. Neutrophils (20×10^6 in 2 mL) were incubated at the indicated time (1–5 min) with 0.1 μCi [1-^{14}C]palmitic acid (0.95 μM) in the absence or presence of 150 nM LTB_4. Each point represents the mean value ± standard deviation from three separate neutrophil preparations.

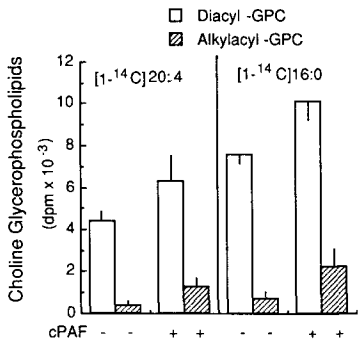

FIG. 5. cPAF promotes the incorporation of [1-^{14}C]arachidonic acid and [1-^{14}]palmitic acid into diacyl-GPC and alkylacyl-GPC. The incubation condition and method of lipid analysis were identical to those described in Figure 4, except that 150 nM cPAF was included in the incubation medium. The data presented are mean values ± standard deviation from three separate experiments.

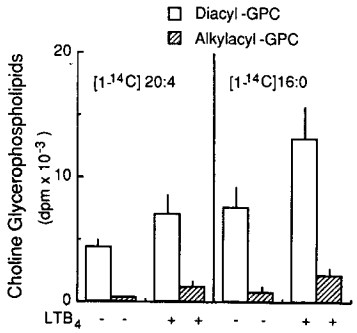

FIG. 4. LTB_4 promotes the incorporation of [1-^{14}C]arachidonic acid and [1-^{14}C]palmitic acid into diacyl-GPC and alkylacyl GPC. Neutrophils (20×10^6 in 2 mL) were incubated for 5 min with 0.1 μCi [1-^{14}C]arachidonic acid (0.97 μM) or 0.1 μCi [1-^{14}C]palmitic acid (0.95 μM) in the absence or presence of 150 nM LTB_4. An aliquot of PC (3 μg phosphorus) isolated from three incubation tubes was resolved into diacyl-GPC and alkylacyl-GPC as described in Materials and Methods. The radioactivity in each fraction was counted by liquid scintillation. The data presented are mean values ± standard deviation from three separate experiments.

of oleoyl-CoA acyltransferase but not arachidonoyl-CoA acyltransferase has been demonstrated in ionophore A23187-stimulated neutrophils (17). However, increased *de novo* synthesis of phospholipids may also contribute to increased fatty acid incorporation in view of the observed rapid incorporation of fatty acids into PA (Figs. 2 and 3) and increased labeling of PA by palmitic acid (Fig. 3). Increased glycerol incorporation into phospholipids has been shown in neutrophils activated by chemotactic peptide (17) and by ionophore A23187 (17,18). Increased incorporation of extracellular fatty acids into PI and PC in LTB_4-activated neutrophils may serve to replenish these phospholipids following deacylation. This may also divert extracellular arachidonic acid from the 5-lipoxygenase pathway, thereby attenuating the formation of LTB_4 and 5-hydroxy-eicosatetraenoic acid both of which are mediators of inflammation (9,10). Furthermore, increased acylation of 1-*O*-alkyl-*sn*-glycero-3-phosphocholine in LTB_4-activated cells may allow rapid termination of further PAF synthesis.

Increased incorporation of extracellular fatty acids into diacyl-GPC and alkylacyl-GPC by neutrophils also occurred in neutrophils challenged with PAF (13). The present study demonstrates that cPAF enhances fatty acid incorporation into both species of PC, indicating that the increased incorporation of extracellular fatty acids into alkylacyl-GPC in PAF-activated neutrophils (13) did not solely result from exogenous PAF after deacetylation. Since both LTB_4 (7,8) and PAF (7,19) promote PAF synthesis, the possibility remains that LTB_4 may induce its own synthesis from arachidonic acid. Furthermore, extracellular arachidonic acid may serve as a potential source for LTB_4 synthesis in neutrophils activated by LTB_4 or by PAF.

Plasma Lipoproteins and Liver Lipids in Two Breeds of Geese with Different Susceptibility to Hepatic Steatosis: Changes Induced by Development and Force-Feeding

Dominique Hermier[a,b]*, Ali Saadoun[b], Marie-Rose Salichon[b], Nadine Sellier[c], Daniel Rousselot-Paillet[c] and M. John Chapman[a]

[a]INSERM Unite 321, Hopital de la Pitié, 75651 Paris Cedex, [b]INRA, Station de Recherches Avicoles, Nouzilly, 37380 Monnaie, and [c]INRA, Station experimentale de l'Oie, Artigueres, 40002 Mont de Marsan Cedex, France

Susceptibility to fatty liver in the force-fed goose is partly under genetic control. However, the mechanisms leading to liver steatosis in this avian model are poorly understood, but may involve perturbation in hepatic lipoprotein synthesis. Plasma lipoproteins were fractionated by density gradient ultracentrifugation from plasma of geese differing in their susceptibility to liver steatosis (Landes breed, highly susceptible; Rhine breed, partly resistant). The concentrations and chemical compositions of the major lipoprotein classes (VLDL, IDL, LDL and HDL) were characterized at 8, 22 and 27 wk of age and compared to the lipid composition of the corresponding liver. In non-force-fed geese, the lipoprotein profile was typical of birds, with high-density lipoprotein (HDL) predominating (4–5 g/L). However, at 22 and 27 wk of age, very low-density lipoprotein (VLDL) levels were significantly lower in Landes geese suggesting that this breed may possess a lower ability to export liver lipids, which would explain its susceptibility to liver steatosis when overfed. The livers of force-fed geese were specifically enriched in triglyceride, and to a lesser extent, in cholesteryl esters and non-esterified fatty acids as compared to those of control geese of the same age (27 wk). This accumulation of lipids was more pronounced in the Landes breed and was responsible for the higher liver weight in that breed. In both breeds, liver steatosis was accompanied by an increase in plasma levels of HDL (11 g/L), whereas low-density lipoproteins were essentially absent. An increase in VLDL plasma levels occurred in the Landes breed only (2.51 g/L *vs* 1.85 g/L in the Rhine breed), and was positively correlated with liver weight. However, VLDL in force-fed geese in both breeds were deficient in triglyceride (28–29% by wt) but enriched in cholesterol (41% by wt). These results indicate that a defect in the incorporation of triglyceride into nascent hepatic VLDL may result in liver steatosis in this species.

Lipids 26, 331–339 (1991).

Geese which have been force-fed with a carbohydrate-rich diet develop a fatty liver or "foie gras". This "foie gras" involves the development of a dramatic liver steatosis, in which the weight of the liver may increase ten-fold in two weeks and may account for up to 10% of the weight of the animal. Liver steatosis in the goose represents a quasi-pure form of acquired steatosis of nutritional origin, resulting in a specific accumulation of triglyceride by the parenchymal cells (1).

The induction of a marked fatty liver by force-feeding occurs only in specific breeds of geese, and more specifically in those derived from the French Landes grey geese. In other breeds, such as Rhine white geese, the resulting steatosis from force-feeding remains moderate. Moreover, even in Landes geese, there is considerable variability between individual birds in the response of the liver to force-feeding. Thus, the nutritional induction of fatty liver is modulated by an intrinsic susceptibility of genetic origin, for which no metabolic explanation is presently available. Despite the fact that this avian model constitutes a useful tool for the further understanding of the metabolic processes which underlie development of liver steatosis, the mechanisms which lead to specific accumulation of hepatic triglyceride in the goose remain poorly understood. While some studies have described the histological accumulation of intracellular lipids (2,3), and modifications in plasma lipids during force-feeding (4,5), others have attempted to document alterations in hepatic enzymes in both liver and plasma, and have related changes in these parameters to the development of liver steatosis (1,6).

Since very low-density lipoproteins (VLDL) are the predominant form in which triglyceride is secreted by the liver, we hypothesize that an increase in hepatic lipogenesis in response to force-feeding, associated with deficient synthesis or secretion of VLDL, may explain the occurrence of liver steatosis in the goose. However, there is a paucity of data on the qualitative and quantitative modifications of plasma VLDL and of other lipoproteins which may occur in association with force-feeding. Nevertheless, we have previously demonstrated that the plasma lipoprotein profile of young Landes geese did not reveal any specific feature which might explain the high susceptibility of this breed to liver steatosis (7).

For these reasons, we were led to investigate changes in plasma lipoproteins which occur during growth and force-feeding in two breeds of geese differing in their genetic susceptibility to liver steatosis. Inter-and intra-breed variations in lipoprotein profile were then related to the lipid composition of the livers.

MATERIALS AND METHODS

Animals and diets. The geese were males of the Landes

Abbreviations: IDL, intermediate density lipoproteins; HDL, high density lipoprotein; LDL, low density lipoprotein; mRNA, messenger ribonucleic acid; Na_2EDTA, disodium ethylenediamine tetraacetate; TG, triglyceride; VLDL, very low density lipoprotein.

breed (highly susceptible to liver steatosis and used for the production of fatty liver) and of the Rhine strain (less susceptible to liver steatosis and used for the production of meat). Twenty birds of each breed, hatched on the same day, were bred under natural conditions of light and temperature at the Experimental Station for Goose Breeding (INRA, Artiguères, France). From hatching to 8 wk, young animals were fed *ad libitum* a starting and growing diet (2780 Kcal and 150 g protein/kg) with added grass. From 8 to 22 wk, they were restricted to 150 g/day of a diet containing 2601 Kcal and 133 g protein/kg and to 500 g/day of grass. At 22 wk of age, 15 birds of each strain received the same diet *ad libitum* for 18 days in order to stimulate liver cell proliferation and to increase the stability of parenchymal cell membranes before force-feeding. They were then force-fed for 2 wk up to sacrifice with a carbohydrate-rich diet consisting mainly of boiled, salted maize with 0.5% lard added (3368 Kcal, 90 g protein and 4.5 g fat/kg). The five remaining birds of each strain were used as non-force-fed controls and continued to receive the same diet *ad libitum* from 22 wk to the time of sacrifice.

Blood and liver samples. At 8 wk, 22 wk (one day before the removal of dietary restriction) and 27 wk (one day before slaughter), all birds were fasted overnight for 18 hr, with water provided *ad libitum*. Blood (20 mL) was then withdrawn by puncture of the occipital venous sinus, collected on 0.12% (w/v) disodium ethylenediamine tetraacetate (Na_2EDTA) in a vacuum tube and kept at 2–4°C during the subsequent procedures. Individual plasma samples were separated by low-speed centrifugation. Antibacterial agents (sodium azide and sodium merthiolate, at final concentrations of 0.01% and 0.001% (w/v)) and a chelator of metal cations (EDTA, 0.04% w/v) were then added to each plasma sample. Plasmas were frozen at −80°C until further analyses.

After slaughter, the livers were removed, weighed and refrigerated at 4°C; a 10-g sample was taken from the ventromedial portion of the main lobe (right lobe) of each liver and stored at −20°C for subsequent analyses.

Lipoprotein isolation. Lipoproteins were isolated from plasma on the basis of their hydrated density in a single step according to the ultracentrifugal gradient procedure described by Chapman *et al.* (8) and modified by Hermier *et al.* (9). Ultracentrifugation was performed in a Beckman L8-55 ultracentrifuge using a Beckman SW41 rotor (Beckman Instruments, Palo Alto, CA) at 40,000 rpm (19.4×10^5 g) for 48 hr at 15°C. The gradients were fractionated by collecting fractions from the meniscus of each tube by aspiration with a narrow bore Pasteur pipette. The fractionation procedure took into account the alternance of pigmented and non-pigmented bands corresponding to the successive lipoprotein classes, as described previously in man (8) and chicken (10). Four lipoprotein classes were thus separated from the top to the bottom of the gradient, with the following respective densities: VLDL (d <1.013), intermediate density lipoproteins (IDL, d 1.013–1.020), low-density lipoproteins (LDL, d 1.020–1.040) and high-density lipoproteins (HDL, d 1.065–1.165) (7).

Lipoproteins were dialysed in Spectrapor tubing (Spectrum Medical Industries, Los Angeles, CA; mol wt cut-off 12,000) for 48 hr at 4°C against a solution containing 0.05 M NaCl, 0.005 M NH_4HCO_3, 0.04% EDTA and 0.01% sodium azide at pH 7.4.

Chemical analyses. The following components were quantified in each lipoprotein fraction and in whole plasma as follows: protein by the Lowry method (11) using bovine serum albumin (Sigma Chemical Co., St. Louis, MO) as a standard; triglyceride, free cholesterol, total cholesterol and phospholipids by enzymatic methods (12–14), using the kits provided by Bio-Merieux (Charbonnière-les-Bains, France). The amount of plasma free glycerol was determined using the kit provided by Biotrol (Paris, France) and was subtracted from the values obtained for plasma triglyceride. The amount of cholesteryl esters was calculated using the formula:

$$\text{cholesteryl ester} = (\text{total cholesterol} - \text{free cholesterol}) \times 1.67$$

In this calculation, it was assumed that the factor for the ratio of the average molecular weight of goose plasma cholesteryl esters to that of the molecular weight of free cholesterol (*i.e.* 1.67), was the same in man and the goose. The precision of these analyses was estimated by calculation of the technical error, the latter being defined as $\sqrt{\Sigma d^2/2N}$, where d is the difference between duplicate estimations and N the number of duplicates. The technical errors were: triglyceride 3.8%, cholesterol 1.2%, phospholipid 2.0% and protein 5.7%. Lipoprotein concentrations have been calculated by addition of the concentrations of the individual protein and lipid components.

Lipids were extracted from liver samples by the method of Folch *et al.* (15), and then quantified by thin-layer chromatography and flame ionization detection, using an Iatroscan TH 10 (Iatron Laboratories, Tokyo, Japan), as previously described (16). Eight liver samples from force-fed geese of each breed and all samples from control geese (5 in each breed) were submitted to such analysis.

Statistical analysis. Results were expressed as mean ± SD and their significance was tested using a one-way analysis of variance after verification of the homogeneity of variance by Barlett's test (17).

RESULTS

Effects of growth on plasma lipids and lipoproteins. Changes in plasma lipid and lipoprotein concentrations occurred independently of force-feeding and were documented at 8, 22 and 27 wk of age (Table 1). The plasma levels of free cholesterol (0.30–0.40 g/L) and cholesteryl esters (1.80–2.00 g/L) were not modified by growth and development, whereas phospholipid concentrations increased slightly from 2 g/L at 8 and 22 wk to 2.7–2.9 g/L in 27 week-old birds. In contrast, plasma triglyceride levels increased progressively with age from 0.40–0.45 at 8 wk to 1.3–1.6 g/L at 27 wk. However, no significant differences were detected between the Landes and the Rhine breed, irrespective of the age and class of lipid studied.

TABLE 1

Plasma Lipid Concentrations During Growth (age in wk) and Force-Feeding in Geese of the Rhine and Landes Strains[a]

	Growing (8 wk)[b]		Immature (22 wk)[b]		Control (27 wk)[b]		Force-fed (27 wk)[b]	
Concentration (g/L)	R[c] (20)[c]	L[c] (20)	R (20)	L (20)	R (5)	L (5)	R (15)	L (15)
Free cholesterol	0.34 ± 0.04	0.36 ± 0.05	0.31 ± 0.05	0.29 ± 0.04	0.38 ± 0.09	0.37 ± 0.09	0.84 ± 0.20	0.83 ± 0.15
Cholesteryl esters	1.84 ± 0.21	1.90 ± 0.32	1.84 ± 0.20	1.77 ± 0.20	1.79 ± 0.09	1.97 ± 0.30	4.31 ± 0.86	4.51 ± 0.84

[a]Values for lipid concentrations are mean ± SD.
[b]Details of diets for physiological status—growing, immature, control and force-fed birds— are provided in the Methods section.
[c]The strain is R, Rhine geese, L, Landes geese; the number of geese in each group is given in parentheses.

The progressive increase in plasma triglyceride levels was paralleled by a concomitant increase in plasma VLDL, whose concentrations were 7- to 10-fold higher in the oldest birds as compared to the younger ones (Table 2). On the other hand, the chemical composition of VLDL was grossly similar to that observed in other species, and varied but little with aging. Proportions of free cholesterol (6.5–7.0%) and phospholipids (17–18%) remained remarkedly constant, whereas the percentages of cholesteryl esters and triglycerides fluctuated between 15 and 20%, and 42 and 51%, respectively. The proportion of protein was higher (20%) in the VLDL of younger birds than in that of older animals (11–15%). At 22 and 27 wk of age, VLDL level was significantly higher in Rhine geese. At the latter age, the breed-related differences in VLDL were not only quantitative, but also qualitative, since VLDL in Landes geese contained significantly less triglyceride and more cholesteryl esters and protein than in the Rhine geese.

The denser classes of lipoproteins, *i.e.* IDL, LDL and HDL, were distinct from VLDL in that their concentrations and compositions exhibited little variation as a function of age or genetic origin. IDL concentrations (Table 3) fluctuated between 0.25 and 0.38 g/L; these lipoprotein particles exhibited similar contents of cholesteryl esters, triglyceride, phospholipid and protein, with lesser proportions of free cholesterol. The circulating concentrations of LDL (Table 4) and HDL (Table 5) (approximately 1 g/mL and 5 g/L, respectively) were typical of avian lipoproteins irrespective of the age or breed of geese. The major chemical constituent of LDL was cholesterol (8–10% free cholesterol and 28–34% cholesteryl esters) whereas that of HDL was dominated by protein (40–48%). No significant quantitative or qualitative difference could be detected between the relative concentrations and chemical compositions of corresponding lipoprotein classes in Rhine and Landes geese, whatever their age.

Effects of force-feeding on plasma lipids and lipoproteins. The effects of force-feeding on plasma lipids and lipoproteins were then evaluated by comparison with corresponding data in control birds of the same age (27 wk). Plasma cholesterol and phospholipid concentrations were approximately two-fold higher in force-fed birds than in controls, while differences in triglyceride levels were not significant (Table 1). Indeed, force-feeding induced considerable alterations in lipoprotein profile (Fig. 1), which were associated with dramatic modification in the lipid composition of individual lipoprotein classes. VLDL levels (Table 2) were markedly increased in Landes geese in which they attained a value (2.51 g/L) higher than that in Rhine geese (1.85 g/L) and significantly different from their nonforce-fed counterparts (0.76 g/L). By contrast, force-feeding did not modify the VLDL concentration in Rhine geese. However, the major effect of force-feeding on goose VLDL concerned the elevated proportion of cholesteryl esters (32–33%), and diminished proportion of triglyceride (28–29%), the contents of phospholipid and protein remaining comparable in both force-fed and control birds.

The denser classes of lipoprotein were also modified considerably by force-feeding (Fig. 1). The pig-

mented band corresponding to LDL (d 1.020–1.040) in control geese had disappeared, with the consequence that fractions corresponding to IDL, LDL and the fraction intermediate between LDL and HDL (d 1.013–1.065) could not be distinguished visually and were therefore isolated together. However, the concentrations of lipoprotein particles which float in the density range 1.006–1.065 and which correspond to both IDL and LDL were increased when compared to those in the other groups (Table 6). This increase is probably due either to a major contribution of IDL which accompanies the increase of VLDL during force-feeding, or to a contamination of this fraction with residual VLDL. Moreover, the chemical composition of the d 1.006–1.065 lipoproteins resembled that of VLDL from force-fed animals, presenting elevated proportions of free and esterified cholesterol and a reduced content of triglyceride.

Finally, the most striking feature of the lipoprotein pattern in the force-fed geese concerned the considerable increase in HDL concentrations (approx. 11 g/L as compared to 5 g/L in control birds of the same age) (Table 5). In contrast to VLDL, the chemical composition of these HDL was modified but slightly; thus the increase in HDL level was a consequence of parallel increases in each of its lipid and protein components. It is noteworthy that the amount of triglyceride secreted as HDL is far from negligible. However, in HDL particles from force-fed geese, 50% of triglyceride in weight is replaced by a similar amount of cholesteryl esters, resembling our findings for VLDL.

It must be emphasized that, with the notable exception of VLDL concentration, the response to force-feeding of the two strains regarding either the plasma level or the chemical composition of the various lipoprotein classes was not significantly different.

Effects of force-feeding on body weight and liver composition. Force-feeding modified not only the liver, but also the whole body weight (Table 7). Thus, in both breeds, body weight remained constant from 8 to 22 wk of age, *i.e.* as long as the birds were submitted to food restriction. The release of dietary restriction and the subsequent force-feeding led to a two-fold increase in body weight in only 5 wk. However, and despite the fact that mean liver weight was considerably higher in the Landes (469 g) than in the Rhine geese (285 g), there was no parallel breed-related difference in body weight at the day of sacrifice. It is noteworthy that net weight gain during the two weeks of force-feeding was exactly the same (1.8 kg) in the two strains, and as such corresponds primarily to an overdevelopment of adipose tissue.

Control, non-force-fed animals exhibited no breed differences in their liver weight or composition. In both breeds, the liver contained only 4–6 g of lipid, among which phospholipids were the major component (Table 8). After force-feeding, liver composition was dramatically modified in both breeds, but the phenomenon was much more pronounced in the Landes geese which are susceptible to fatty liver. Indeed, the liver weight of force-fed geese is significantly higher ($p<0.05$) in the Landes breed, although each of the hepatic components was not modified by the same proportion. Indeed, the non-lipid weight of the liver increased two-

fold during force-feeding to reach approximately 200 g in both strains, as compared to 115 g in control birds of the same age. Thus the difference in liver weight between the two strains arose from a specific accumulation of lipids, which was higher in geese of the Landes breed (190 g) than of the Rhine breed (81 g).

Moreover, such lipid accumulation was mainly due to triglyceride rather than cholesteryl esters and non-esterified fatty acids. The elevation in the amounts of hepatic free cholesterol and phospholipids was less pronounced and similar in both breeds. Thus, the genetic difference in the susceptibility to liver steatosis is associated with a higher accumulation of triglyceride, and to a lesser extent of cholesteryl esters and non-esterified fatty acids, in the Landes breed.

Since force-feeding is associated with an increase in the circulating concentrations of lipoproteins of hepatic origin, *i.e.* VLDL and HDL, we have tested the correlation between VLDL or VLDL-triglyceride on the one hand, with liver weight or liver triglyceride content on the other (Table 9). In both Landes and Rhine geese, there was a significant positive correlation between the plasma level of VLDL or VLDL-triglyceride (TG) during force-feeding and whole liver weight. However, the triglyceride content of the liver is positively associated with VLDL or VLDL-TG concentration in the force-fed state only in the Landes strain. Despite the fact that plasma VLDL levels were significantly higher in the Rhine strain at 22 wk of age, there was no significant correlation beween VLDL levels before force-feeding and liver weight or composition. Finally, we could not demonstrate any relationship between the plasma levels or chemical composition of HDL and the different hepatic parameters (data not shown).

DISCUSSION

The production of "foie gras" relies on the induction of liver steatosis in specialized breeds of ducks and geese. In order to enhance *de novo* fatty acid synthesis in the liver (16,18), these birds are force-fed with a

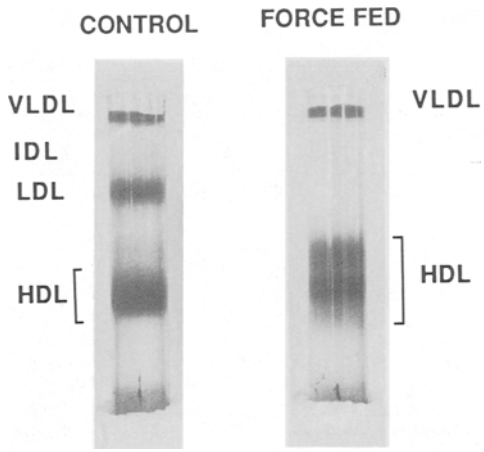

FIG. 1. Separation of plasma lipoproteins from control and force-fed geese (at 27 wk of age) by density gradient ultracentrifugation.

carbohydrate-rich feed essentially consisting of maize. In the present study, we have confirmed that fatty liver in the goose is due mainly to the accumulation of triglyceride (Table 8) (2,3). Moreover, other chemical components of the liver were modified by force-feeding. Thus, the hepatic non-lipid moiety and phospholipid content were increased two-fold, whereas free cholesterol was increased 6–10 fold, in both breeds of geese. Thus, it may be postulated that, since force-feeding has been shown to induce cellular proliferation (2), the increase in phospholipid and free cholesterol reflects the need for newly synthesized cell membranes, and is a feature independent of genetic susceptibility to liver steatosis. Furthermore, the increase in hepatic triglyceride and cholesteryl ester content, which was significantly higher in the Landes breed, may reflect the intracytoplasmic accumulation of lipids, whose level clearly depended upon the genetic origin of the geese.

The greater accumulation of triglyceride and cholesteryl esters in the liver of Landes geese is clearly related to genetic differences in lipid metabolism between the two breeds. Indeed, in non-force-fed Landes geese of 22 and 27 wk, the plasma concentration of VLDL was lower than in Rhine geese (Table 2). Moreover, when control birds were allowed to refeed *ad libitum* at 27 wk of age, VLDL particles contained significantly less triglyceride in the Landes breed. Consequently, the plasma level of VLDL triglyceride was only 0.345 g/L in the latter breed as compared to 0.959 g/L in Rhine geese. Thus, when considering birds before force-feeding, the genetic difference in the basal level of VLDL could be related to the relative ability of the liver to secrete VLDL-triglyceride, and thus to the variable susceptibility to further liver steatosis. This hypothesis is supported by the fact that, in bird species, VLDL level is more indicative of the ability of liver to secrete triglyceride than of the rate of VLDL catabolism (19). Nevertheless, even if this finding could explain the difference between the two breeds, it can-

TABLE 6

Plasma Concentration and Chemical Composition (mean wt %) of the Lipoprotein Population of d 1.013–1.065 g/mL in Control and Force-Fed Geese of the Landes and Rhine Breeds (at 27 wk)[a]

[b]Parameter.

not account for the intrabreed variability in the Landes geese, since there was no significant correlation between VLDL or VLDL-triglyceride concentration in non-force-fed geese and liver weight or triglyceride content in the same birds after force-feeding (Table 9).

Moreover, the relationship between circulating VLDL levels and liver triglyceride content is not so simple when one considers the changes occurring in lipoprotein profile after force-feeding. In this latter state, VLDL levels did not differ in control and force-fed Rhine geese (1.82 and 1.85 g/L) (Table 2). However, since VLDL from force-fed Rhine geese contained only 28% triglyceride, the amount of plasma VLDL-triglyceride decreased to 0.501 g/L (as compared to 0.959 g/L in controls). By contrast, VLDL from the Landes geese increased from 0.76 g/L in controls to 2.51 g/L in force-fed birds; consequently, plasma VLDL-triglyceride reached 0.982 g/L as compared to 0.345 g/L in controls, and this despite the fact that VLDL contained only 29% triglyceride.

It appears then that Landes geese may respond to the increase in liver lipogenesis induced by force-feeding by an increase in VLDL production, in accordance with a number of previous studies showing that feeding birds with a carbohydrate-rich diet enhances hepatic lipogenesis and increases plasma VLDL levels (16,18). Nevertheless, this process is not sufficient to prevent liver steatosis, probably because of a specific retention of triglyceride by the liver. This latter hypothesis derives from the observation that VLDL from force-fed geese contained considerably less triglyceride (29%) than that from controls (Table 2). A defect in VLDL assembly may therefore occur, leading to the secretion of VLDL deficient in triglyceride, the latter remaining in the liver where they accumulate. The reason why force-fed geese of the Rhine breed do not develop a full fatty liver is unclear. It may be hypothesized that hepatic lipogenesis is lower in the Rhine breed, with the consequence that VLDL, even though deficient in triglyceride, are secreted at a rate sufficient to prevent marked accumulation of liver triglyceride. Clearly, this question requires further study. It is however noteworthy that, despite similar chemical compositions, VLDL in these geese are probably different from β-VLDL found in animals fed cholesterol, since their diet was essentially devoid of this component.

The biochemical basis of the accumulation of triglyceride in the liver remains indeterminate. Under normal feeding conditions, triglycerides are synthesized in the liver on the cytosolic surface of the endoplasmic reticulum, and are then transferred into the lumen of the endoplasmic reticulum to be assembled with phospholipid and apo B (20). In the chicken (21), as in the rat (22), triglycerides synthesized in excess are normally stored by the liver in temporary cytoplasmic droplets when their production exceeds the capacity of their secretion as VLDL. In the rat, stimulation of triglyceride synthesis leads to a saturation of the process of triglyceride assembly into nascent VLDL and enhances their transfer to lipid droplets (23). However, it remains doubtful that triglyceride assembly into VLDL is saturated in geese, since VLDL in force-fed geese contain less than 30% triglyceride. It is more likely that there is an imbalance in the channeling of triglyceride between that destined for storage and that destined for incorporation into nascent VLDL, or alternatively that triglyceride stored in cytoplasmic vesicles is no longer available for further VLDL assembly and secretion and remains sequestered in the liver, leading to steatosis.

A further alteration observed in the goose lipoprotein profile after force-feeding concerns the disappearance of LDL (Table 4), which may be related to the abnormal composition of VLDL. Indeed, VLDL particles containing only 28–29% triglyceride and 40–42% cholesterol may be less susceptible to be hydrolyzed by lipoprotein lipase, which preferentially attacks triglyceride rather than phospholipids or cholesteryl esters (24). However, some of these VLDL have to be catabolized, since the fattening of birds during force-feeding is considerable.

As for HDL, they represent the second major form of lipid secretion from the liver, in birds as in mammals (19). In force-fed geese, plasma HDL concentrations were two-fold higher than those in controls, but did not show any difference between the two breeds (Table 5). This phenomenon is accompanied by an increase during force-feeding in the amount of liver messenger ribonucleic acid (mRNA) coding for apo A-I, the major protein component of HDL (Forgez, P. and Hermier, D., unpublished results). These results suggest that the increase in plasma HDL level is due to an increase in HDL synthesis by the liver rather than to a decrease of their catabolism.

In conclusion, we propose the following putative

mechanism to explain both the occurrence of fatty liver in the goose and the difference in susceptibility between the Landes and the Rhine breeds. Initially, force-feeding is responsible for the stimulation of hepatic lipogenesis, which is reflected in an increase in circulating VLDL and HDL concentrations. However, for reasons which remain to be elucidated, newly synthesized triglycerides tend to be stored in the cytoplasm rather than incorporated into nascent VLDL, finally leading to steatosis. This phenomenon is associated with the preferential enrichment of VLDL in cholesteryl ester. The resulting steatosis is more pronounced in the Landes geese, probably as the result of (i) a higher rate of lipogenesis, this hypothesis being supported by the higher VLDL concentration when force-fed; and (ii) a reduced ability to transport triglyceride as VLDL, as demonstrated in non-force-fed birds. These two parameters may explain the difference in susceptibility to fatty liver between the two breeds. However, the regulation of the synthesis and secretion of VLDL in the goose must now be investigated, and particularly as concerns hepatic lipogenesis and intracytoplasmic storage of triglyceride. Finally, the defect in VLDL assembly which leads to particles that lack triglyceride is apparently common to the two breeds. Such an uncoupling of triglyceride synthesis and secretion represents a useful model in which to improve our knowledge of the regulation of hepatic lipoprotein production.

The Hypercholesterolemic Effect of Dietary Coconut Fat *versus* Corn Oil in Hypo- or Hyperresponsive Rabbits Is Not Exerted Through Influencing Cholesterol Absorption

G.W. Meijer*, A.G. Lemmens, A. Versluis, L.F.M. Van Zutphen and **A.C. Beynen**
Department of Laboratory Animal Science, State University, 3508 TD Utrecht, The Netherlands

In two inbred strains of rabbits with high or low response of plasma cholesterol to dietary saturated *versus* polyunsaturated fatty acids, the efficiency of intestinal cholesterol absorption was measured. The feeding of a cholesterol-free purified diet containing saturated fatty acids in the form of coconut fat, when compared with a diet containing corn oil as polyunsaturated fatty acids, did not influence the efficiency of cholesterol absorption in the two rabbit strains. Irrespective of the dietary fat source, the hyperresponsive rabbits absorbed cholesterol more efficiently. It is concluded that the hypercholesterolemic effect of dietary coconut fat *versus* corn oil is not exerted by influencing cholesterol absorption.
***Lipids* 26, 340–344 (1991).**

Replacement of dietary polyunsaturated fatty acids by saturated fatty acids generally causes an increase in plasma cholesterol levels, but the mechanism by which this occurs is unclear (1). The hypercholesterolemic effect of saturated fatty acids is diminished by a background diet rich in soybean protein instead of casein (2,3). Since soybean protein decreases the efficiency of cholesterol absorption (4–6), dietary saturated fatty acids may stimulate cholesterol absorption from the intestinal lumen.

The objective of the present study was to investigate the effect of polyunsaturated *versus* saturated fatty acids on cholesterol absorption. In order to increase the sensitivity of measuring such a dietary effect, if any, we used two inbred strains of rabbits which differ markedly in their cholesterolemic response to dietary saturated fatty acids (7). It was anticipated that any effect of the type of dietary fat would be more pronounced in the hyperresponsive than in the hyporesponsive rabbits. To have better control on the within-animal variation, cholesterol absorption measurements were performed according to a repeated measures design.

MATERIALS AND METHODS

Animals and housing. Male rabbits of two inbred strains were used for two experiments in which cholesterol absorption was determined. The animals were 0.5–5 years old, the average age being 2.7 years for both strains in the two experiments. For a third experiment, male and female rabbits were used. They were aged 1.2–4 years; the average age of each strain was 2.3 years. The strains were IIIVO/JU and AX/JU, and originated from the Jackson Laboratory colony, Bar Harbor, ME (8). The IIIVO/JU strain has previously been shown to be hyporesponsive and the AX/JU strain to be hyperresponsive to dietary cholesterol (7,9), saturated *versus* polyunsaturated fatty acids and casein *versus* soybean protein (7). The animals were maintained at the Department of Laboratory Animal Science, State University (Utrecht, The Netherlands) as described (9). They were fed 100 g daily of commercial pellets (LKK-20^{R}, Hope Farms, Woerden, The Netherlands).

Experimental designs. Two experiments were performed to study cholesterol absorption. Rabbits of both strains underwent all treatments simultaneously. In the first experiment (expt. 1), the effect of dietary casein *versus* soy protein was studied in order to validate the method for measurement of cholesterol absorption and to demonstrate in our inbred strains of rabbits that casein enhances cholesterol absorption, as would be expected on the basis of literature data concerning outbred rabbits (4). It is well-known (10) that casein, when compared with soybean protein, produces hypercholesterolemia in rabbits. In the second experiment (expt. 2), we studied the effect on cholesterol absorption of saturated fatty acids in the form of coconut fat *versus* polyunsaturated fatty acids as corn oil. In the third experiment (expt. 3), the diet compositions of those in expt. 2 were used again, and liver cholesterol concentrations were measured. Cholesterol-free diets were used throughout. The rabbits were allowed to practice cecotrophy.

On day 0 of expt. 1, six hypo- and nine hyperresponsive rabbits were transferred from the commercial diet to the purified diet containing soy protein and coconut fat (Table 1). From day 55, they received the

TABLE 1

Composition of the Cholesterol-Free, Experimental Diets

Ingredient	Dietary variables		
	Casein coconut fat	Soy protein coconut fat	Casein corn oil
Casein	21	—	21
Soy isolate	—	20.8	—
Methionine	—	0.2	—
Coconut fat	9	9	—
Corn oil	1	1	10
Constant components[a]	69	69	69

[a]The constant components consisted of (g/100 g diet): corn starch, 17; dextrose, 21; molasses, 5; sawdust, 18; dicalcium phosphate, 2.9; sodium chloride, 0.6; potassium bicarbonate, 1.8; magnesium carbonate, 0.3; magnesium oxide, 0.2; vitamin premix, 1.2; mineral premix, 1. The compositions of the vitamin and mineral premixes have been described elsewhere (7).

Abbreviations: apo, apolipoprotein; FNS, fecal neutral steroids; OD; oral dose.

casein/coconut fat diet and from day 132 they were fed on the soy protein diet again. Body weights were measured on days 0, 14, 28, 35, 105, 112, 126, 133, 154, 168, 196 and 210; the results were averaged per rabbit per dietary period. On days 35, 118 and 209, after an 18 hr fast, each rabbit ingested a mixture of [1α, 2α(n)-^{3}H]cholesterol (255-511 kBq) and β-[4-^{14}C]sitosterol (39-79 kBq) which had been added to a cube of whole wheat bread. The feces of individual rabbits were collected daily as described previously (9) on five consecutive days after each administration of both labels. Percentage cholesterol absorption was calculated as described (9):

$$\text{Cholesterol absorption (\%)} = \left\{1 - \frac{(^3\text{H in FNS})}{(^{14}\text{C in FNS})} \times \frac{(^{14}\text{C in OD})}{(^3\text{H in OD})}\right\} \times 100\%,$$

where FNS stands for fecal neutral steroids, and OD for oral dose. Radioactivities are expressed in dpm.

On day 0 of expt. 2, six rabbits of each strain were transferred from the commercial diet to the purified diet containing corn oil and casein (Table 1). On day 46, the animals were switched to the coconut fat/casein diet, and from day 121 they received the corn oil diet again. Body weights were measured on days 0, 14, 28, 49, 63, 77, 98, 112, 147, 161, 182 and 196; the results were averaged per rabbit per dietary period. Radioactive cholesterol and β-sitosterol were administered on days 35, 112 and 196. The feces of individual rabbits were collected daily during three periods: days 36-40, 113-117 and 197-201. Two rabbits of the hyperresponsive strain refused to eat the purified diets, and had to be excluded. Thus, data analyses on this experiment were performed using four hyperresponders.

From day 0 of expt. 3, six male and six female rabbits of each of the two strains received the corn oil diet for 21 days. Then, the animals were divided into two dietary groups, each consisting of three female and three male rabbits per strain. For another 42 days, one group remained on the corn oil diet and the other received the diet containing coconut fat. Body weights were measured on days 21 and 63. On day 63, the animals were killed and liver cholesterol concentrations determined.

The rabbits were fed 75 g (expt. 1 and 2) or 100 g (expt. 3) of the purified diets per day and had free access to tap water. The daily feed intake was recorded throughout all experiments. Plasma total cholesterol and body weights were determined regularly.

Analytical methods. Samples of blood were taken from the marginal ear vein of the rabbits into heparinized tubes. Sampling and body weight measurements were performed between 07:00 and 10:00 hr after the removal of any remaining food at 16:00 hr the previous day. Total cholesterol in the plasma was measured enzymatically using a test-combination (Monotest^R) supplied by Boehringer-Mannheim GmbH, Mannheim (Germany). The feces samples were extracted and radioactivity in neutral steroid fractions was determined as previously described (9,11). Liver samples were homogenized in 2 vol of distilled water, and cholesterol was extracted and analyzed according to Abell *et al.* (12).

Statistics. The effects of the type of dietary protein and the type of dietary fat (as "within-rabbits" factors) and the degree of responsiveness (as "between-rabbits" factors) were evaluated using a repeated measures analysis of variance, using orthonormalized contrasts. In expt. 3, comparisons between the hypo- and hyperresponsive strains and the effects of the diets within one strain were evaluated by Student's two-tailed t-test. The level of statistical significance was pre-set at $p<0.05$.

RESULTS

The feed intake was consistently lower in the hyperresponsive rabbits than in the hyporesponsive rabbits (Tables 2 and 5; $p<0.05$ in each experiment). The rabbits tended to reduce feed intake while on the coconut fat/casein diet, this effect reaching statistical significance ($p<0.05$) in the hyperresponders in expt. 1 and expt. 2. Tables 2 and 5 also show that group mean body weights of the hyporesponders were higher than those of their hyperresponsive counterparts ($p<0.05$ in each experiment), which probably explains the strain difference in feed intake. In the course of experiments 1 and 2, body

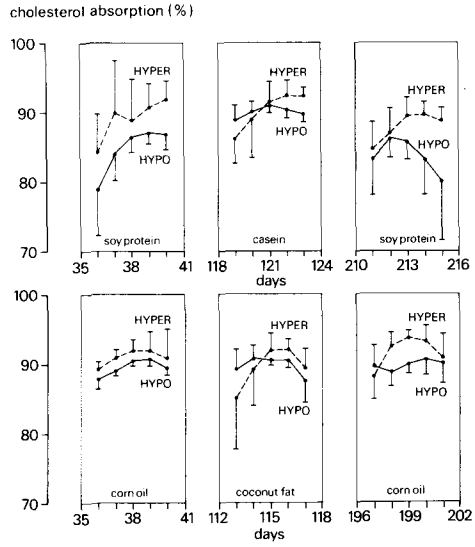

FIG. 2. Calculated percentages of cholesterol absorption after oral administration of [^{3}H]cholesterol and β-[^{14}C]sitosterol in hypo- and hyperresponsive rabbits fed purified diets differing in the type of dietary protein (upper panel) or fat (lower panel). Results, expressed as means ± SD for 4, 6 or 9 rabbits per strain.

weight of the hyporesponsive rabbits increased significantly ($p<0.05$).

The replacement of soy protein in the diet by casein caused a more pronounced increase of plasma cholesterol in the hyperresponsive rabbits than in the hyporesponders (Fig. 1). After the rabbits had been switched back to the soy protein diet, plasma cholesterol concentrations dropped, but did not reach baseline levels.

Figure 2 illustrates the calculated percentages of cholesterol absorption during 5 consecutive days after oral administration of [^{3}H]cholesterol and β-[^{14}C]sitosterol. Calculated efficiencies of cholesterol absorption varied during the course of fecal collection after administration of the 2 labels. Nevertheless, cholesterol absorption was almost always more effective in the hyper- than in the hyporesponders. The maximum value of cholesterol absorption is not biased by any error introduced by re-excretion of absorbed [^{3}H]cholesterol (13). Thus, these values were calculated and presented in Table 3. The hyperresponders absorbed higher percentages of cholesterol than did the hyporesponders ($p<0.005$), but in both rabbit strains dietary casein, when compared with soy protein, increased cholesterol absorption ($p<0.001$). Table 4 shows the recoveries of radioactive β-sitosterol in feces. Recoveries on the soy protein diet were lower in the hyper- than in the hyporesponsive rabbits ($p<0.01$). After feeding the casein diet, recoveries were similar in the two strains.

When rabbits were transferred from the corn oil to the coconut fat diet, plasma cholesterol concentrations rose significantly (Fig. 1). The increase in plasma

[b]Cumulative recovery in fecal neutral steroids up to 5 days after the radioactive dose was administered.

cholesterol was more pronounced in the hyper- than in the hyporesponders. After feeding the corn oil diet again, plasma cholesterol concentrations fell, but did not reach baseline values in the hyperresponders. The type of fat in the diet did not influence the efficiency of cholesterol absorption (Fig. 2, Table 3). The hyperresponders systematically absorbed cholesterol more efficiently than the hyporesponders ($p<0.05$), irrespective of the type of fat in the diet. β-Sitosterol recoveries in feces were similar in both strains (Table 4).

In keeping with expt. 2, expt. 3 also showed that plasma cholesterol levels were significantly increased in rabbits fed the coconut fat diet, when compared with rabbits fed the corn oil diet (Table 5). The coconut-fat-induced increase in plasma cholesterol concentration in the hyperresponders ($p<0.01$) was greater than in the hyporesponsive rabbits ($p<0.025$); the difference between the two strains was statistically significant ($p<0.01$). In hyporesponsive rabbits, liver cholesterol concentrations tended to be higher on the coconut fat than on the corn oil diet. In hyperresponders the fat type effect was seen more clearly ($p<0.025$). Irrespective of diet composition, hyperresponders had significantly higher liver cholesterol concentrations than hyporesponders ($p<0.005$).

DISCUSSION

As would be expected (4–6), dietary casein increased cholesterol absorption, when compared with dietary soy protein. This "casein effect" was seen in both strains. Irrespective of the type of dietary protein, the hyperresponsive rabbits absorbed cholesterol more efficiently than the hyporesponders. This observation is in agreement with our earlier work (9) and suggests that the increased efficiency of cholesterol absorption in the hyperresponsive rabbits is an important determinant of their increased susceptibility of cholesterol-induced, "exogenous" hypercholesterolemia (9) as well as casein-induced, "endogenous" hypercholesterolemia. Although the difference in percentage cholesterol absorption between hypo- and hyperresponders is small, it may have a significant impact on cholesterol metabolism. There is an enterohepatic cycle of cholesterol through which this sterol may circulate up to seven times per day (14). Cholesterol absorption as calculated in the present study does not include the contribution of previously absorbed and re-excreted radiolabelled cholesterol (13).

Dietary coconut fat, when compared with corn oil, caused a more pronounced increase in plasma cholesterol concentrations in hyper- than in hyporesponsive rabbits. This confirms previous studies (7). The type of dietary fat did not influence the efficiency of intestinal cholesterol absorption in either strain. However, it could be argued that true diet-induced differences in the percentage of cholesterol absorption are obscured by differences in recovery in the feces of orally administered labelled β-sitosterol, which could be related to diet-induced differences in colonic bacterial activity. However, β-sitosterol recovery was not systematically

Change	−0.16 ± 0.21	0.40 ± 0.16[c]	0.30 ± 0.51[b]	1.19 ± 0.45[b,c]
Liver cholesterol (μmol/g)	6.9 ± 0.2	9.2 ± 2.4	16.8 ± 3.7[b]	25.9 ± 6.7[b,c]

[a]Results are expressed as means ± SD; (n=6).
[b]Significant difference between hypo- and hyperresponsive strain fed the same diet.
[c]Significantly different from rabbits of the same strain but fed the corn oil diet.

influenced by the type of fat in the diet. In hyperresponders fed the coconut fat diet, β-sitosterol recovery was lower than after feeding the corn oil diet. Thus, the efficiency of cholesterol absorption in hyperresponders fed the diet containing coconut fat would be over-, rather than underestimated. The apparent lack of an effect of dietary fat type on cholesterol absorption in the two inbred strains of rabbits has also been observed in other animal species. In rats, either no effect of fat saturation on cholesterol absorption (15) or increased cholesterol absorption after feeding corn oil, when compared with coconut fat (16), has been found. Likewise, in baboons, cholesterol absorption was not affected by the type of dietary fat (17).

Dietary coconut fat, when compared with corn oil, caused increased liver cholesterol concentrations, this effect being most pronounced in the hyperresponders. The effect of coconut fat on liver cholesterol may be caused by a higher rate of hepatic cholesterol synthesis as has been shown in hamsters and rats (18,19). This would imply that hyperresponsive rabbits are more sensitive than hyporesponders to stimulation of cholesterol synthesis as induced by coconut fat. Since increased liver cholesterol pools will reduce the number of hepatic apoB/E receptors (20), these receptors may be more depressed in hyper- than in hyporesponsive rabbits when fed diets containing coconut fat. This could explain the increased sensitivity of plasma cholesterol concentration to dietary coconut fat in hyperresponders.

Protective Effect of Vitamin E on Linoleic Acid Hydroperoxide-Induced Injury to Human Endothelial Cells[1]

Takao Kaneko, Shun-ichiro Nakano and Mitsuyoshi Matsuo*
Tokyo Metropolitan Institute of Gerontology, 35-2 Sakaecho, Itabashiku, Tokyo 173, Japan

The protective effects of vitamin E (α-tocopherol) and its model compounds, which act as antioxidants, on linoleic acid hydroperoxide-induced injury to human umbilical vein endothelial cells were examined. When incubated at 50 μM with endothelial cells at 37°C for 24 hr, α-tocopherol protected the cells from injury, and 2,2,5,7,8-pentamethylchroman-6-ol showed a similar protective effect. Trolox C, a water-soluble vitamin E model compound, had no protective effect. Tocol, a poor antioxidant, proved toxic. During preincubation, α-tocopherol was incorporated into the cells at 16.6 nmol/mg protein, while the pentamethylchromanol was incorporated at 0.5 nmol/mg protein; Trolox C was not incorporated at all. The results suggest that agents having both high antioxidant activity and lipophilicity can protect endothelial cells from linoleic acid hydroperoxide-induced injury.
***Lipids* 26, 345–348 (1991).**

Injury to endothelial cells, which line the blood vessels, appears to be a prerequisite for the progression of atherosclerosis (1–3). One cause of endothelial cell injury may be oxidative stress, such as a rise in lipid peroxidation and exposure to active oxygen species (4). In fact, lipid peroxides and secondary products of lipid peroxidation are toxic toward cells. Recently, we reported that linoleic acid hydroperoxide and its degradation products, unsaturated aliphatic aldehydes, are toxic toward cultured human endothelial cells (5) and human diploid fibroblasts (6). Lipid peroxide-induced injury to endothelial cells is considered a risk factor of cardiovascular disease. Hence, agents to protect cells from such injury are of interest for the prevention and treatment of the disease.

In the present study, we investigated the protective effects of α-tocopherol and its model compounds on linoleic acid hydroperoxide-induced injury to human umbilical vein endothelial cells.

MATERIALS AND METHODS

Materials. α-Tocopherol, gelatin, and heparin were purchased from Sigma Chemical Co. (St. Louis, MO). α-Tocopherol was purified by high-performance liquid chromatography (HPLC) before use. Epidermal growth factor (EGF) was obtained from Collaborative Research (Waltham, MA), MCDB-104 medium from GIBCO Laboratories (Grand Island, NY), and fetal bovine serum (FBS) from Biocell Laboratories (Carson, CA). Endothelial cell growth factor (ECGF) was isolated from newborn-bovine brains by the method of Lobb and Fett (7). 2,2,5,7,8-Pentamethylchroman-6-ol was synthesized by the method of Nilsson *et al.* (8). Linoleic acid hydroperoxide (13-hydroperoxy-9,11-octadecadienoic acid) was prepared as described previously (9). Trolox C (6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid) and tocol were kindly provided by Dr. K.U. Ingold and Dr. S. Urano, respectively (see Acknowledgments). Trolox C was purified by HPLC before use. Falcon 24-well culture plates and 60-mm culture dishes were purchased from Becton Dickinson Labware (Oxnard, CA).

Cell culture. Endothelial cells were isolated from the veins of human umbilical cords as described previously (5), and identified by an indirect immunofluorescence technique using an antibody to coagulant factor VIII. Cells were grown in gelatin-coated 24-well plates or 60-mm dishes at 37°C under an atmosphere containing 5% carbon dioxide and 95% air. Culture medium used was MCDB-104 medium supplemented with 10% FBS, 30 ng/mL ECGF, 10 ng/mL EGF, and 10 ng/mL heparin (hereafter, referred to as the MCDB-104 system). Cells at passage 6 to 14 were used for the experiments.

Estimation of the extent of cell injury. Endothelial cells at confluency were incubated for 24 hr in multiwells containing the MCDB-104 system and either each antioxidant solubilized with ethanol or ethanol alone. The final ethanol concentration was less than 0.1%, which had no effect on the cells. Cells were rinsed with phosphate buffered saline (PBS) and then incubated for 3 hr in Earle's solution with LOOH. After removal of the medium, the cells were rinsed with PBS. Cell viability was examined by the trypan blue exclusion test of adhering cells as described previously (6).

Quantification of α-tocopherol and its model compounds in cells. α-Tocopherol and its model compounds were extracted from cells and quantified as described below (10,11). Cells grown on a 60-mm dish were washed twice with PBS, treated with 0.025% trypsin, suspended in MCDB-104 medium (2 mL) supplemented with 10% FBS, and then sedimented at 150 × *g* for 5 min. The cells in a pellet were resuspended in distilled water (1 mL) and homogenized at 4°C for 30 sec with a Model W-10 sonicator (Heat System Ultrasonics Inc., Plainview, NY). After the addition of 80 mM sodium dodecyl sulfate (1 mL), ethanol (0.5 mL), and an ethanolic solution (2 μL) of 2,2,5,7,8-pentamethylchroman-6-ol (PMC) or tocol (1 μg/mL), the homogenate was mixed by shaking, and to it was added a hexane/ethyl acetate mixture (9:1, v/v; 2 mL). PMC and tocol were added as internal standards for the HPLC quantitative analysis of cell α-tocopherol and PMC, respectively; the peak intensity of α-tocopherol was calibrated relative to that

Abbreviations: ECGF, endothelial cell growth factor; EGF, epidermal growth factor; FBS, fetal bovine serum; HPLC, high-performance liquid chromatography; LOOH, linoleic acid hydroperoxide; PBS, phosphate buffered saline; PMC, 2,2,5,7,8-pentamethylchroman-6-ol.

of PMC and the peak intensity of PMC was calibrated relative to that of tocol. The mixture obtained was vigorously mixed by vortex-stirring for 1 min and then centrifuged at 1,200 × *g* for 10 min. A portion of the organic layer (1.5 mL) was pipetted into a flask and the solvent was evaporated under reduced pressure. The residue was redissolved in 100 μL of hexane/isopropyl alcohol (99.25:0.75, v/v) and the solution (50 μL) was subjected to HPLC analysis. HPLC was conducted on a Model 5560 high-performance liquid chromatograph (Varian, Walnut Creek, CA) equipped with a MicroPak Si-5 column (Varian) and a RF-535 fluorometric detector (Shimadzu, Kyoto, Japan; Ex. 295 nm and Em. 330 nm). The same hexane/isopropyl alcohol mixture was used as mobile phase at a flow rate of 2 mL/min. The extraction recoveries of α-tocopherol, 2,2,5,7,8-pentamethylchroman-6-ol, and Trolox C from cell homogenates were 66.6, 90.2, and 9.4%, respectively. Protein content was measured as described by Bradford (12).

RESULTS AND DISCUSSION

Figure 1 depicts the molecular structures of α-tocopherol and its model compounds, the protective effects of which were examined.

Figure 2 shows that preincubation with α-tocopherol protects human umbilical vein endothelial cells from injury induced by linoleic acid hydroperoxide (LOOH). We have already shown that LOOH, with a 50% lethal concentration of 20 μM, is injurious toward endothelial cells (5). α-Tocopherol acts as a protective agent against LOOH-induced injury to the cells, because more than 80% of the cells treated with 50 μM α-tocopherol survived after exposure to 50 μM LOOH for 3 hr.

Hennig *et al.* (13,14) reported that α-tocopherol protected porcine pulmonary artery endothelial cells from LOOH-induced injury. Our results are consistent with their observations. This suggests that irrespective of animal species, vitamin E plays an important role in the protection of endothelial cells against oxidative injury.

2,2,5,7,8-Pentamethylchroman-6-ol (PMC), a vitamin E model compound, also protected the cells from LOOH-induced injury, although the effect was slightly less pronounced than that of α-tocopherol (Fig. 2). Trolox C, a water-soluble vitamin E model compound, showed no effect (Fig. 2). However, tocol was toxic toward endothelial cells (data are not shown). When incubated with tocol for 24 hr, cell viability was reduced to less than 40%. Tocol is a vitamin E model compound corresponding to α-tocopherol without the three methyl groups attached to the aromatic ring (Fig. 1): *i.e.*, it has an unhindered, phenolic hydroxyl group and hence shows a poor antioxidant activity (15). Although the mechanism of tocol toxicity is unclear, tocol appears to exert its toxic effect as an unhindered phenol (16).

α-Tocopherol, PMC, and Trolox C are homologs of 2,5,7,8-tetramethylchroman-6-ol and each has a very lipophilic isoprenoid side-chain, a lipophilic methyl group, or a hydrophilic carboxyl group, respectively, at the C-2 position (Fig. 1). Although their structures are identical except for having these different substituents at the C-2 positions, there are large differences in their protective effects on LOOH-induced injury to endothelial cells. The differences may at least in part be due to their different lipophilicities, as the lipophilic agents are more readily incorporated into cells.

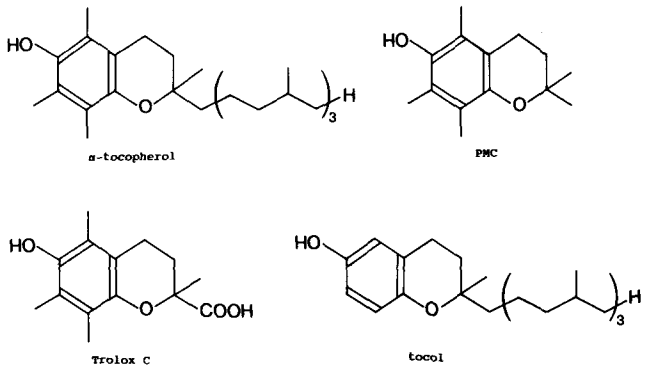

FIG. 1. Molecular structures of α-tocopherol, 2,2,5,7,8-pentamethylchroman-6-ol, Trolox C, and tocol.

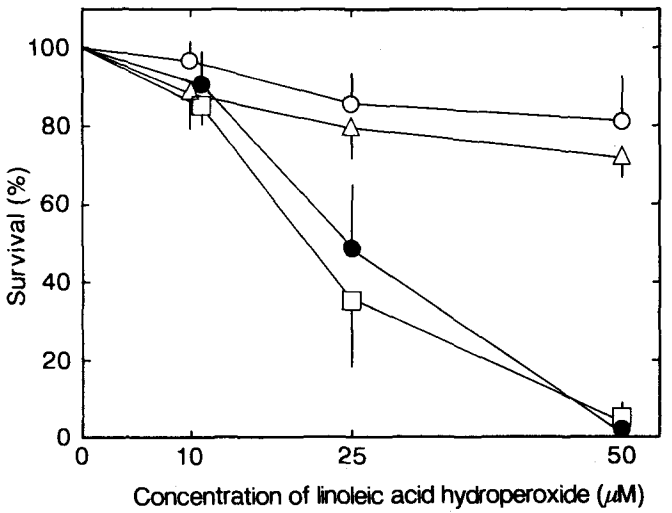

FIG. 2. Effect of preincubation with α-tocopherol, 2,2,5,7,8-pentamethylchroman-6-ol, or Trolox C on the cytotoxicity of linoleic acid hydroperoxide toward human umbilical vein endothelial cells. Percent survivals of cells exposed to the hydroperoxide for 3 hr are given. Cells were preincubated in culture medium with α-tocopherol (open circles), PMC (triangles), Trolox C (squares), each of which was solubilized in ethanol, or ethanol alone (closed circles). The concentration of each antioxidant was 50 μM. Each point represents the mean ± the standard deviation of three separate experiments performed in duplicate.

Table 1 shows the amounts of antioxidants incorporated into endothelial cells during 24-hr preincubation at 37°C. When incubated at 50 μM with endothelial cells, α-tocopherol was incorporated into the cells at 16.6 nmol/mg protein, while PMC was incorporated at 0.5 nmol/mg protein; Trolox C, however, was not incorporated at all. This means that endothelial cells take up α-tocopherol better than PMC and do not take up Trolox C. The ineffectiveness of Trolox C appears

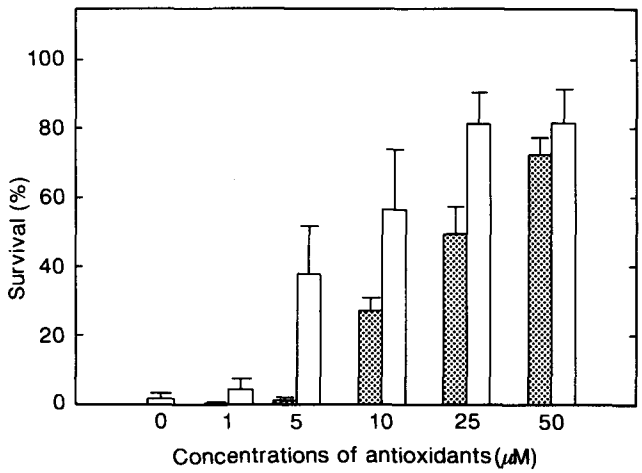

FIG. 3. Effect of α-tocopherol or 2,2,5,7,8-pentamethylchroman-6-ol on the cytotoxicity of 50 μM linoleic acid hydroperoxide toward human umbilical vein endothelial cells as a function of concentration. Percent survivals of cells exposed to the hydroperoxide for 3 hr are given. Cells were preincubated in culture medium with α-tocopherol (open bars) or PMC (shaded bars), each solubilized in ethanol. Each value represents the mean ± the standard deviation of three separate experiments performed in duplicate.

to be due to its hydrophilicity. The results suggest that agents having both high antioxidant activity and lipophilicity can protect endothelial cells from LOOH-induced injury.

α-Tocopherol bears both an isoprenoid side-chain with high affinity for the lipophilic interior region of cell membranes and a hydroxyl group with a high affinity for the hydrophilic exterior region. Thus, α-tocopherol incorporated into membranes is probably oriented in such a manner that its isoprenoid side-chain is located in the interior region and its hydroxyl group is projected toward the exterior region. This orientation would anchor α-tocopherol in the membrane. In contrast, PMC having no isoprenoid side-chain cannot be anchored and may be moveable without orientation in the membrane (17).

Figure 3 shows the effects of various concentrations of α-tocopherol and PMC in the preincubation medium on the survival of endothelial cells exposed to 50 μM LOOH. At 25 μM or lower concentrations, the protective effect of α-tocopherol was greater than that of PMC; *e.g.*, at 10 μM, the former was twice as effective as the latter.

As presented in Table 1, α-tocopherol was incorporated at 0.8 nmol/mg protein into endothelial cells in 5 μM α-tocopherol-containing medium, and PMC was incorporated at 0.5 nmol/mg protein into the cells in 50 μM PMC-containing medium. Under these conditions, the cellular concentrations of α-tocopherol and PMC were similar. As shown in Figure 3, however, α-tocopherol protected about 38% of endothelial cells from 50 μM LOOH-induced injury, while PMC protected about 73% of the cells. When the antioxidants are incorporated at a relatively low concentration into endothelial cells, PMC appears to protect the cells more efficiently than does α-tocopherol.

The reason for this is unclear. It has been reported though that the activity of phenolic antioxidants correlates with the reactivity of their phenolic hydrogens (18); the greater the rate constant of the hydroxyl group of a phenolic antioxidant for hydrogen abstraction by the peroxyl radical, the more effective the phenolic antioxidant. It has been further reported that the reactivities of phenolic hydrogens in PMC and α-tocopherol are similar (18); the rate constants of PMC and α-tocopherol in homogeneous solution are 3.8×10^6 and 3.2×10^6 M^{-1} s^{-1}, respectively. As mentioned before, PMC may be moveable in cell membranes, and hence its phenolic hydrogen may be both in the exterior and interior regions of cell membranes, while the phenolic hydrogen of α-tocopherol may be mainly in the exterior region. If LOOH is incorporated into cell membranes containing a small amount of α-tocopherol or PMC and then decomposed to produce radicals, the PMC might scavenge the radicals more efficiently than would α-tocopherol.

The underlying mechanism of LOOH-induced injury to endothelial cells is still unknown. We do know, however, that the typical radical scavengers α-tocopherol and PMC have protective effects on LOOH-induced injury to the cells. Thus, we presume that some LOOH-induced radicals, such as the alkoxyl radical (19) and the αβ-epoxy carbon-centered radical (20), are causative factors of cell injury.

ACKNOWLEDGMENTS

The authors thank Dr. K.U. Ingold of the National Research Council of Canada and Dr. S. Urano of our Institute (Tokyo

Metropolitan Institute of Gerontology, Tokyo, Japan) for providing Trolox C and tocol, respectively.

Age-Related Changes in the Metabolism of Cholesterol in Rat Liver Microsomes

Dagny Ståhlberg*, Bo Angelin and Kurt Einarsson
Department of Medicine, Karolinska Institutet at Huddinge University Hospital, Stockholm, Sweden

The effects of aging on the hepatic metabolism of cholesterol were studied in 1-, 6- and 24-month-old male Sprague-Dawley rats. Microsomal 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase activity, which regulates cholesterol biosynthesis, decreased from 835 ± 144 (SEM) pmol/min/mg protein in the youngest group to 219 ± 34 and 205 ± 53 pmol/min/mg protein ($p<0.001$) in the 6- and 24-month-old groups, respectively. Cholesterol 7α-hydroxylase activity, which governs bile acid synthesis, was gradually reduced from 70 ± 14 pmol/min/mg protein in the 1-month-old group to 32 ± 7 and 16 ± 3 pmol/min/mg protein ($p<0.05$) in the 6- and 24-month-old groups, respectively. Acyl coenzyme A:cholesterol acyltransferase activity, which catalyzes the esterification of cholesterol, averaged 431 ± 47 and 452 ± 48 pmol/min/mg protein in the 1- and 6-month-old groups, respectively, and was increased to 585 ± 55 pmol/min/mg protein ($p<0.05$) in the 24-month-old group. The level of total cholesterol showed an age-related increase from 1.56 ± 0.16 mg/g liver in the 1-month-old group to 1.70 ± 0.15 and 2.20 ± 0.19 mg/g liver ($p<0.05$) in the 6- and 24-month-old groups, respectively. The increase was mainly caused by an accumulation of esterified cholesterol. We conclude that a marked decrease in HMG-CoA reductase occurs between 1 and 6 months of age; thereafter the enzyme activity stays unchanged. The activity of cholesterol 7α-hydroxylase decreases progressively and drastically with age, whereas the capacity for esterifying cholesterol increases slightly. We speculate that the reduced conversion of cholesterol to bile acids may be one explanation of the age-related increase of plasma cholesterol seen in rats.
***Lipids* 26, 349–352 (1991).**

Hypercholesterolemia is considered one of the main causes of atherosclerosis in humans and it is well known that serum cholesterol levels rise with advancing age. Also, age-related increases of plasma lipids are observed in rats (1–3). The mechanism of the rise in serum cholesterol with age is not well understood. Since the liver has a central role in cholesterol metabolism, some studies on the influence of age on hepatic metabolism of cholesterol in rats have been reported. Using radio-labeled acetate, Yamamoto and Yamamura (4) found a decreasing hepatic cholesterogenesis with age in Wistar rats 2- to 18-months-old. The activity of the rate-determining enzyme in hepatic cholesterol biosynthesis, 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase was studied by Story *et al.* (2) in Fisher rats. The activity decreased from 2 to 9 months and then stabilized at that level through 24 months of age. These authors also determined the activity of cholesterol 7α-hydroxylase, the regulatory enzyme in the formation of bile acids, and found that it was unchanged from 2 to 24 months of age (2). In a later study, Story *et al.* (3) did not find any changes with age, between 2 and 24 months, for the two enzymes in either Fisher 344 or Sprague-Dawley strains of rats. Choi *et al.* (5) reported lower activities of HMG-CoA reductase and cholesterol 7α-hydroxylase in adult (8-month-old) than in young (5-week-old) Sprague-Dawley rats. Stange and Dietschy (6) studied cholesterol synthesis, using ^{3}H-labeled water, in immature (4-week-old) and mature (15-week-old) Sprague-Dawley rats, and they found a marked decrease in the rate of cholesterol synthesis in the mature rats. Previous studies of acyl-CoA:cholesterol acyltransferase (ACAT), which catalyzes the esterification of cholesterol, have not shown any age-related changes in enzyme activity (7,8).

We considered it important to more thoroughly study the influence of age on the three key enzymes of cholesterol metabolism in rat liver. In the present work we have simultaneously determined the activities of HMG-CoA reductase, cholesterol 7α-hydroxylase, and ACAT in three different age groups of male Sprague-Dawley rats. In addition, the concentrations of free and esterified cholesterol in liver tissue and microsomes were analyzed.

MATERIALS AND METHODS

Materials. Deuterium-labeled cholesterol was obtained from Larodan Fine Chemicals (Malmo, Sweden). Deuterium-labeled 7α-hydroxycholesterol was synthesized as described previously (9). [3-^{14}C]HMG-CoA (sp. act. 19 mCi/mmol), [1-^{14}C]oleoyl coenzyme A (sp. act. 57.8 mCi/mmol), and [1,2,6,7-^{3}H]cholesteryl oleate (sp. act. 82.7 Ci/mmol) were obtained from New England Nuclear Corp. (Boston, MA). DL-[2-^{3}H]mevalonic acid (sp. act. 125 mCi/mmol) was obtained from Radiochemical Centre (Amersham, England). Unlabeled mevalonic acid lactone, cholesteryl oleate, NADP, NADPH, EDTA, dithiothreitol (DTT), glucose-6-phosphate, glucose-6-phosphate dehydrogenase, and human serum albumin were purchased from Sigma Chemicals Co. (St. Louis, MO).

Experimental procedure. Male Sprague-Dawley rats of three different ages, 1 month, 6 months and 24 months, were used in the experiment. Each age group was comprised of 12 rats, and the mean weights of the rats at the different ages were 78 g, 465 g and 600 g, respectively. The 1-month-old group was not sexually mature. All groups had free access to water and rat chow (R3; Ewos AB, Södertälje, Sweden), a commercial pellet diet. The 1-month-old group had been fed chow for at least 10 days after weaning.

The animals were killed in the morning by a blow on the head after a 12-hr fast. The livers were immediately

Abbreviations: ACAT, acyl-coenzyme A:cholesterol acyltransferase; DTT, dithiothreitol; EDTA, ethylenediaminetetraacetic acid; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A.

removed, weighted, cut into two pieces and put into cold buffer solutions.

Preparation of liver microsomes. One aliquot of the liver was minced and homogenized with a loose-fitting Teflon pestle in nine volumes of 50 mM Tris-HCl buffer, pH 7.4, containing 0.3 M sucrose, 10 mM DTT, 10 mM EDTA and 50 mM NaCl. The homogenate was centrifuged at 20,000 × *g* for 15 min. The supernatant was centrifuged at 100,000 × *g* for 60 min. Half of the microsomal fraction was resuspended in homogenizing medium and recentrifuged at 100,000 × *g* for 60 min. This fraction was then suspended in 20 mM imidazole buffer, pH 7.4, containing 10 mM DTT in a volume corresponding to that of the 20,000 × *g* supernatant, and used for the assay of HMG-CoA reductase. Half the original microsomal fraction was recentrifuged at 100,000 × *g* in a homogenizing medium lacking DTT. The resulting fraction was suspended in 0.1 M phosphate buffer, pH 7.4, containing 1 mM EDTA and used for the assay of cholesterol 7α-hydroxylase activity.

The remaining piece of the liver was minced and homogenized in 50 mM Tris-HCl buffer, pH 7.4, containing 0.3 M sucrose and 1 mM EDTA as described above. The homogenate was centrifuged at 20,000 × *g* for 15 min. The supernatant solution was centrifuged at 100,000 × *g* for 60 min. The pellet obtained was resuspended in 0.1 M phosphate buffer, pH 7.4, containing 1 mM EDTA and used for the assay of ACAT activity.

Microsomal and liver homogenate protein were determined by the method of Lowry *et al.* (10).

Assay of HMG-CoA reductase activity. The HMG-CoA reductase activity was assayed according to Brown *et al.* (11), essentially as described recently (12). An aliquot of the microsomal fraction, 40 μL, was preincubated for 15 min at 37°C in a total volume of 0.2 mL containing 100 mM phosphate buffer, pH 7.4, 10 mM imidazole buffer, pH 7.4, 5 mM DTT, 10 mM EDTA, 3 mM NADP, 12 mM glucose-6-phosphate and 1 unit of glucose-6-phosphate dehydrogenase. The HMG-CoA reductase assay was then initiated by the addition of 90 nmoles of [3-^{14}C] HMG-CoA (0.5 μCi) dissolved in 25 μL distilled water. The incubation was run for 15 min and was stopped by the addition of 25 μL 6M HCl. Tritium-labeled mevalonic acid (0.01 μCi) was added as internal standard together with 3 mg of unlabeled mevalonic acid lactone, and the incubation mixture was allowed to stand overnight at room temperature for complete lactonization. The incubation mixture was then subjected to thin-layer chromatography with toluene/acetone (1:1, v/v) as the developing solvent. The mevalonic acid lactone band was located, scraped off and analyzed for radioactivity. Corrections for losses were made based on use of an internal standard.

Assay of cholesterol 7α-hydroxylase activity. The standard assay system consisted of 1.0 mL of the microsomal fraction, 0.1 M phosphate buffer, pH 7.4, containing 1 mM EDTA, and 1 mM NADPH. The enzyme assay was carried out in duplicate for 15 min at 37°C according to the method of Björkhem and Kallner (9) with the product 7α-hydroxycholesterol being analyzed by gas-liquid chromatography/mass spectrometry. Each set of experiments also included two assays in which the mass of 7α-hydroxycholesterol was determined in the incubation mixture extracted at zero-time. The amount of 7α-hydroxycholesterol formed during an incubation was estimated by subtracting the amount present in the zero-time assay from the amount present at the end of the incubation and was expressed as pmol/min/mg protein.

Assay of ACAT activity. ACAT activity was assayed both in the absence and presence of exogenous cholesterol according to Billheimer *et al.* (13), as described recently (14). The assay system contained 0.1 mL of the microsomal preparation. 0.1 M phosphate buffer, pH 7.4, 1 mM EDTA, and 1 mg of fatty acid-free bovine serum albumin in a total volume of 1.0 mL. The mixture was preincubated for 5 min at 37°C, or for 30 min at 37°C after the addition of 50 nmol of unlabeled cholesterol dissolved in 600 μg of Triton. The reaction was initiated by the addition of 25 nmol (1.45 μCi) of [1-^{14}C]oleoyl coenzyme A. After 4 min the assay was stopped by the addition of 10 mL chloroform/methanol (2:1, v/v). Tritium-labeled cholesteryl oleate (0.01 μCi) was added as an internal standard to estimate recovery followed by 1 mL 0.9% (w/v) NaCl. The chloroform phase was collected and evaporated to dryness under N_2. The residue was resuspended in chloroform/methanol (2:1, v/v) and subjected to thin-layer chromatography. Unlabeled cholesteryl oleate was added as marker. The chromatogram was developed in hexane/ethyl acetate (95:5, v/v). The cholesteryl oleate band was made visible with iodine vapor, scraped off into a counting vial, and analyzed for radioactivity.

Determination of liver cholesterol. The concentrations of total cholesterol in liver homogenates and microsomal fractions were determined by isotope dilution-mass spectrometry after the addition of deuterium-labeled cholesterol as an internal standard, as described previously (15) with the modifications described by Schaffer *et al.* (16). Free cholesterol was determined by the same method except that the hydrolysis step was omitted. The concentration of esterified cholesterol was calculated as the difference between total and free cholesterol in the same sample. The cholesterol levels in the homogenates are given as mg cholesterol/g liver.

Statistical analysis. Data are presented as means ± SEM (standard error of the mean). The significance of differences was evaluated by Student's *t*-test.

RESULTS

The relative liver weights, expressed as % of total body weight, were 4.3 ± 0.2% for the 1-month-old group, 3.6 ± 0.1% for the 6-month-old group, and 3.3 ± 0.1% for the 24-month-old group (Table 1). The amount of protein in liver homogenates and microsomes was the same in the three groups.

HMG-CoA reductase activity decreased by about 75% from 1–6 months of age (835 ± 144 and 219 ± 34 pmol/min/mg protein, respectively; $p<0.001$), and remained essentially unchanged from 6–24 months of age (Table 2).

The cholesterol 7α-hydroxylase activity showed a successive decrease with age (Table 2). The activity declined by 55% from 1 to 6 months of age, and by another 50% between 6 and 24 months of age.

ACAT activity increased gradually with age (Table 2). The activity for the 1-month-old group was 431 ± 47, for the 6-month-old group 452 ± 49, and for the 24-month-old group 585 ± 55 mol/min/mg protein. The increase was significant between the 1- and 24-month-old groups ($p<0.05$). In eight of the rats from each group, ACAT activity was also determined when exogenous cholesterol

[d]Significantly different from 6-month-old rats; p<0.05.

was added to the assay system. The activity was stimulated about seven-fold in all groups (Table 2).

The level of total cholesterol in the liver increased with age from 1.56 ± 0.16 mg/g liver in the 1-month-old group to 1.70 ± 0.15 and 2.20 ± 0.19 mg/g liver (p<0.05) in the 6- and 24-month-old groups, respectively. The amount of esterified cholesterol showed a corresponding increase from 0.19 ± 0.02 mg/g liver in the 1-month-old group to 0.32 ± 0.04 (p<0.05) and 0.45 ± 0.05 mg/g liver (p<0.001) in the 6- and 24-month-old groups, while the amount of free cholesterol did not significantly differ between the age groups. No significant changes were observed in microsomal cholesterol levels (Table 3).

DISCUSSION

In the present study, the HMG-CoA reductase activity, which regulates the synthesis of cholesterol in the liver, decreased by about 75% from 1 month to 6 months of age, and then remained unchanged up to 24 months of age. Previously Yamamoto and Yamamura (4) reported reduced incorporation of acetate into hepatic cholesterol from 2 to 18 months of age in Wistar strain rats. Similar observations were made by Story *et al.* in the Fischer 344 strain, while in Sprague-Dawley strain rats acetate incorporation into cholesterol was unchanged from 2 to 18 months of age, and was significantly reduced at 24 months of age. The activity of HMG-CoA reductase, however, was unchanged with advancing age (2-24 months of age) in both rat strains. Choi *et al.* (5) reported reduced HMG-CoA reductase activity in 8-month-old as compared to 5-week-old Sprague-Dawley rats. Our results indicate a considerably higher activity of HMG-CoA reductase in immature (1-month-old) rats compared to mature (6- and 24-month-old) rats. The activity of HMG-CoA reductase seems to decrease drastically during sexual maturation, a process that starts at about 40 days and ceases at about 3 months of age. This interpretation is also consistent with the previous results mentioned above (2-5). One explanation for the increased synthesis of cholesterol in immature rats would be a higher demand for cholesterol during the phase of rapid growth. Stange and Dietschy (6) had previously arrived at similar conclusions upon measuring the rate of cholesterol synthesis in different organs of immature (4-week-old) and mature (15-week-old) Sprague-Dawley rats. Suggested malabsorption of bile acids during the first weeks of life and increased activity of cholesterol 7α-hydroxylase (see below), may also contribute to stimulated cholesterol synthesis in immature rats. Other factors, such as hormonal changes at maturity, may contribute to the decline in HMG-CoA reductase activity.

The activity of the cholesterol 7α-hydroxylase gradually decreased with advancing age. The activity was reduced by about 55% from 1 to 6 months of age, and by another 50% from 6 to 24 months of age. Previously, Choi *et al.* reported a reduction of cholesterol 7α-hydroxylase activity in Sprague-Dawley rats between 5 weeks and 8 months of age. This decrease in cholesterol 7α-hydroxylase activity can at least in part explain the reduced excretion of bile acids with age observed in previous studies (4). Fetal and neonatal animals show only a passive transport of bile acid absorption in jejunum and ileum. Lester *et al.* (17) found that the ileal mechanism

for active bile salt transport in dogs was not activated until at least 2 weeks after birth, and adult levels were reached between 2 and 5 weeks of age. Similar results have been reported for an *in vivo* study with Wistar rats (18). Cholesterol 7α-hydroxylase activity is considered to be regulated by the portal inflow of bile acids (19). A decreased capacity to absorb bile acids may cause malabsorption of bile acids and thereby an upregulation of bile acid synthesis and of cholesterol 7α-hydroxylase activity. This change in intestinal absorption of bile acids may be of importance to explain the higher activity of cholesterol 7α-hydroxylase in the 1-month-old compared to the 6-month-old rats.

ACAT activity increased slightly with advancing age. When exogenous cholesterol was added, the activity increased about seven-fold in all groups, which indicates that differences in activity cannot be explained solely by differences in access to free cholesterol as substrate. Our results are at variance with two previous studies, which showed that ACAT activity did not change with aging (7,8). However, in accordance with our finding of increased ACAT activity with aging, we observed a concomitant rise in esterified cholesterol in liver tissue. Thus, our results could be interpreted as demonstrating the importance of ACAT activity as a modulator of intracellular cholesterol balance, which would contribute to the maintenance of a critical concentration of free cholesterol. The reason for the accumulation of liver cholesterol, which occurs with age, can only be speculated upon. One interesting possibility would be that the imbalance between cholesterol synthesis and bile acid production would progress with age, as is reflected in the increased ratio between HMG-CoA reductase and cholesterol 7α-hydroxylase activities for 6-month-old and 24-month-old rats (Table 2). The relatively stable HMG-CoA reductase activity, which is maintained in spite of the increased hepatic cholesterol levels, suggests that regulation of cholesterol synthesis becomes more sluggish with age.

In conclusion, the present study has shown that a marked decrease in hepatic HMG-CoA reductase activity occurs in rats between 1 and 6 months of age, whereas the activity remains essentially unchanged during adult life. Cholesterol 7α-hydroxylase activity gradually decreases with age, while the capacity to esterify cholesterol increases slightly. We suggest that the declining cholesterol 7α-hydroxylase activity, which reflects a decreased capacity to metabolize cholesterol to bile acids, may contribute to the age-related increase of plasma cholesterol in rats. If so, the well-known age-related rise in serum cholesterol levels in humans could at least in part be due to the decrease in bile acid synthesis with age reported previously (20).

ω3 Fatty Acids Increase Spontaneous Release of Cytosolic Components from Tumor Cells

Laura J. Jenski*, Laura Kathleen Sturdevant, William D. Ehringer and **William Stillwell**
Department of Biology, Indiana University-Purdue University at Indianapolis, Indianapolis, Indiana 46205

Mice fed menhaden (fish) oil or coconut oil-rich diets were inoculated intraperitoneally with a rapidly growing leukemia, T27A. After one week, the tumor cells were harvested, and ^{51}Cr was used to label intracellular molecules. Spontaneous release of ^{51}Cr was used as a measure of plasma membrane permeability. Compared to cells from mice fed coconut oil (rich in saturated fatty acids), tumor cells from mice fed menhaden oil (rich in long chain polyunsaturated ω3 fatty acids) showed an increased level of spontaneous ^{51}Cr release, which was exacerbated by increased temperature and reduced by extracellular protein. At physiological salt concentrations, the released ^{51}Cr was detected in particles of ~2700 daltons. Enhanced permeability correlated with the incorporation of dietary (fish oil) ω3 polyunsaturated fatty acids docosahexaenoic and eicosapentaenoic acid into the tumor cells. The results demonstrate that ω3 fatty acids are incorporated into cellular constituents of tumor cells and change properties associated with the plasma membrane. This result suggests that dietary manipulation may be used to enhance tumor cell permeability and contribute to tumor eradication.
Lipids 26, 353-358 (1991).

Diets rich in cold water fish are associated with a reduced incidence of certain cancers (1). Beyond the epidemiologic evidence, however, we understand very little about how fish oil-rich diets may prevent cancer. The unique components of fish oil, ω3 polyunsaturated fatty acids (PUFA) such as docosahexaenoic acid (DHA, 22:6) and eicosapentaenoic acid (EPA, 20:5), may play critical roles hormonally by altering prostaglandin and leukotriene synthesis; and structurally, by altering the composition of lipid bilayers in cellular membranes (2).

There is evidence that dietary ω3 PUFA become incorporated into membranes of various tissues (3-5); furthermore, rapidly growing tumors also utilize dietary fats (6). It is not clear, however, whether structural alterations of tumor cell membranes, resulting from incorporation of highly unsaturated fatty acids into phospholipids of the bilayer, affect human health. The unique shape of ω3 PUFA (7-9) suggests that phospholipid bilayers containing DHA and EPA are likely to display packing, domain, and fluidity characteristics distinct from bilayers with saturated fatty acyl chains. Thus, events that involve the cell surface may be affected by the PUFA content of the membrane, as suggested by altered methotrexate uptake and melphalan and phenylalanine transport (10), enhanced protein kinase C activity (11), and increased membrane fluidity (12).

Abbreviations: ANOVA, analysis of variance; BSA, bovine serum albumin; CCCP, carbonyl cyanide *m*-chlorophenylhydrazone; DHA, docosahexaenoic acid; 2,4-DNP, 2,4-dinitrophenol; EPA, eicosapentaenoic acid; FBS, fetal bovine serum; PUFA, polyunsaturated fatty acid; RBC, red blood cell; SFA, saturated fatty acid.

Immunologic effector mechanisms directed against tumor cells (*e.g.*, cell-mediated cytolysis) are among the many biological phenomena occurring at the cell surface. Cytolysis occurs when a killer cell, in intimate contact with a tumor cell, delivers a lethal hit to the tumor cell membrane. Historically, the definitive assay for killer cell activity has been the release of ^{51}Cr-labeled intracellular components from prelabeled targets after delivery of the lethal hit. Tumor cell destruction is accompanied by the release of intracellular components to the environment; under certain conditions, intracellular components are released spontaneously without killer cell activity or tumor death (13). In this study we have compared spontaneous release of ^{51}Cr-labeled molecules from a transplantable leukemia grown in mice fed diets rich in ω3 PUFA or saturated fatty acids (SFA). We have shown here that a diet containing 10-20% (w/w) menhaden (fish) oil produces tumor cells with increased permeability to certain molecules.

MATERIALS AND METHODS

Mice and experimental diets. BALB/c mice, purchased from Harlan Sprague Dawley (Indianapolis, IN), were bred and maintained in the animal facilities at the Purdue University School of Science at Indianapolis. Prior to enrollment on experimental diets, the animals were given Chow #5001 (Purina Mills, St. Louis, MO) and water *ad libitum*. Experimental food pellets were prepared by soaking menhaden oil (Zapata Haynie Corp., Reedville, VA) or hydrogenated coconut oil (ICN Nutritional Biochemicals, Cleveland, OH) to a final concentration of 10% (w/w) into Chow #5001 (which contains fish meal). Experimental powdered diet was prepared with 20% (w/w) menhaden oil or hydrogenated coconut oil blended into a fat-free basal diet (ICN Nutritional Biochemicals) containing 21.10% casein, 16.45% alphacel, 58.45% sucrose, 4.00% salt mixture USP XIV, and ICN vitamin diet fortification mix with choline chloride (6.008 g/kg). The major fatty acids in coconut oil are 12:0 and 14:0 (14), the major saturated and monounsaturated fatty acids in menhaden oil are 14:0, 16:0, 16:1, and 18:1, and the major polyunsaturated fatty acids are 20:5 and 22:6 (15). The diets were protected from fluorescent lights and stored frozen at −20°C. In the afternoon, mice were given an amount of experimental diet twice their expected consumption. The food was removed the following morning, and fresh food was again provided in the afternoon; tap water was available at all times. Age and sex matched mice, four mice per group per experiment (three experiments), were fed the experimental diet for five weeks, inoculated with tumor cells, and then maintained on the experimental diet for one additional week.

Tumor line. T27A is a transplantable non-T, non-B leukemia that originated in a BALB/c mouse infected with Friend murine leukemia virus (16). These cells were obtained from the American Type Culture Collection (Rockville, MD). The subline we are maintaining readily adapts to either ascitic growth or culture *in vitro;* an

intraperitoneal inoculum between 1 and 5 × 10^5 cells will generally kill a normal syngeneic host in less than nine days. Ascites T27A were passed weekly in normal syngeneic (BALB/c) mice fed Purina chow #5001.

Radiolabeling and radiolabel release assay. T27A cells were harvested from mice by peritoneal lavage with Hanks' balanced salt solution (Gibco Biologicals, Grand Island, NY) plus 5 mM HEPES buffer (Aldrich Chemical Co., Milwaukee, WI). The tumor cells were depleted of red blood cells (RBC) on Ficoll-Hypaque (Histopaque,Sigma Chemical Co., St. Louis, MO) and diluted in medium composed of equal volumes of RPMI 1640 and Dulbecco's modified Eagle medium plus antibiotics, 25 mM HEPES buffer, 2 mM glutamine, and 5% fetal bovine serum (FBS). ^{51}Cr (100 μCi) as sodium chromate (New England Nuclear, Boston, MA) was added to 5 × 10^6 cells in 0.3 mL of medium, and the cells were incubated at 37°C for 1 hr, with occasional agitation. The ^{51}Cr-labeled cells were washed three times in phosphate-buffered saline plus 5% FBS, counted, and diluted in medium.

^{51}Cr release assays were performed in 96-well plates with 5 × 10^3 T27A cells per well in a total volume of 200 μL of medium supplemented with FBS or bovine serum albumin (BSA, 98–99% pure, essentially fatty acid free, Sigma). To determine the maximum releasable cpm of ^{51}Cr, cells were similarly incubated in detergent (4% cetrimide, Sigma). Unless otherwise stated, the plates were centrifuged at 200 × *g* for 5 min to pellet the cells, and then incubated for 4 hr at 37°C in a humidified incubator containing 7.5% CO_2. A 100-μL aliquot of supernatant was removed from each well, and the released ^{51}Cr present in the supernatant was measured in a Beckman 5500 gamma counter (Arlington, IL). The statistical difference between groups was assessed by one-way analysis of variance (ANOVA) with the program ABSTAT (Anderson Bell, Parker, CO).

Gel filtration. ^{51}Cr-labeled molecules released from T27A cells spontaneously or after two freeze-thaw cycles were chromatographed on Sephadex G-25-80 (Sigma) in a 1 × 60 cm column. Chromatography was performed at room temperature in 10 mM Tris buffer (pH 7.2) containing 0, 0.15, or 0.5 M NaCl. The ionic conditions were varied to assess aggregation and the minimal size of the released material. The flow rate was ~7 mL/hr; 0.7-mL fractions were collected and the radioactivity present in each fraction was measured in a gamma counter.

Analysis of fatty acids by gas chromatography. Tumor cells devoid of RBC were suspended in 20 mL of distilled water and extracted three times with 80 mL of $CHCl_3/CH_3OH$, 2:1 (v/v). Extracts were then rotovaporated to a small volume and saponified with 0.5 N methanolic NaOH. The fatty acids were then methylated with BF_3 in methanol (17). Methyl esters of the fatty acids were quantified by gas-liquid chromatography on a Varian 1400 Gas Chromatograph (Varian Associates, Sunnyvale, CA) equipped with a flame ionizing detector and interfaced to a Hewlett-Packard 3394-A integrator (Palo Alto, CA). The 1/8 × 36 inch glass column was packed with 10% SP-2330 on 100/120 Chromosorb WAW. The column conditions were as follows: oven temperature, 225°C; injector temperature, 210°C; detector temperature, 250°C; carrier gas flow rate, 40 cm^3/min; sample size, 1.5 μL. Retention times of the fatty acids were compared to standards of the methyl esters purchased from Sigma.

RESULTS

Tumor cells from menhaden oil fed mice demonstrate significantly more spontaneous release of intracellular components than do cells from coconut oil fed mice. Transplanted tumor cells (T27A) were harvested from mice fed menhaden oil or hydrogenated coconut oil-rich diets, ^{51}Cr-labeled, and then incubated for 4 hr in medium plus 5% FBS. As shown in a representative experiment in Figure 1, spontaneous release of ^{51}Cr-labeled molecules was significantly higher in tumor cells exposed to ω3 PUFA in the menhaden oil diet compared to cells exposed to dietary SFA ($P<0.01$, ANOVA). Trypan blue exclusion, an accepted measure of cell viability, performed hourly during the 4 hr incubation indicated that the cells remained greater than 97% viable. The maximal releasable radioactivity from PUFA and SFA cells was similar, and thus the difference in spontaneous ^{51}Cr release was not due to disparate levels of labeling.

RBC in ascites fluid take up and release ^{51}Cr, but spontaneous ^{51}Cr release from RBC alone did not account for the results observed. If RBC were not removed from the T27A preparation, we observed a higher level of spontaneous release; importantly, however, even partial RBC-depletion reduced overall spontaneous release to the level of RBC-free preparations. T27A cells, harvested from chow-fed mice and freed of RBC, gradually released ^{51}Cr at ~2–3% per hour over a 4-hr period, depending upon the incubation medium (Fig. 2).

Gel filtration at low ionic strength revealed that the ^{51}Cr-labeled molecules released from T27A ranged from ⩾ 5000 (excluded from the gel) to ~2700 daltons. At higher ionic strengths (0.15 and 0.5 M NaCl), a minority of the ^{51}Cr-labeled material remained in the void volume, whereas most of the label was found associated with a 2700 dalton species (Fig. 3A). A similar profile was

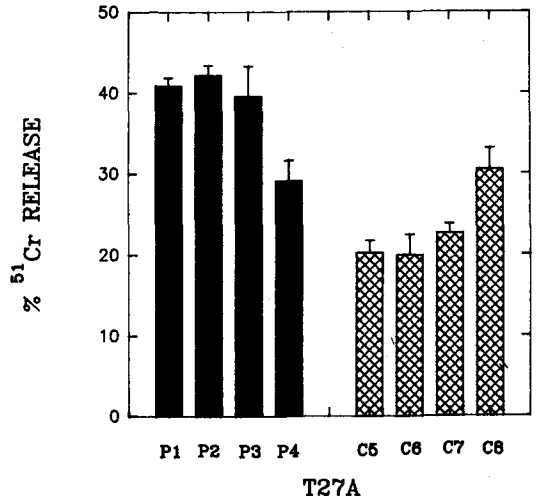

FIG. 1. Compared to cells from coconut oil-fed mice, tumor cells from menhaden oil-fed mice are more permeable to ^{51}Cr-labeled molecules. T27A cells were grown in mice fed chow diets supplemented with 10% menhaden oil (P1–P4, solid bars) or coconut oil (C5–C8, hatched bars), labeled with ^{51}Cr, and incubated at 37°C in wells with medium plus 5% FBS. After 4 hr, supernatant was removed from each well and the radioactivity present in the supernatant was measured. The error bars are SD of triplicate determinations.

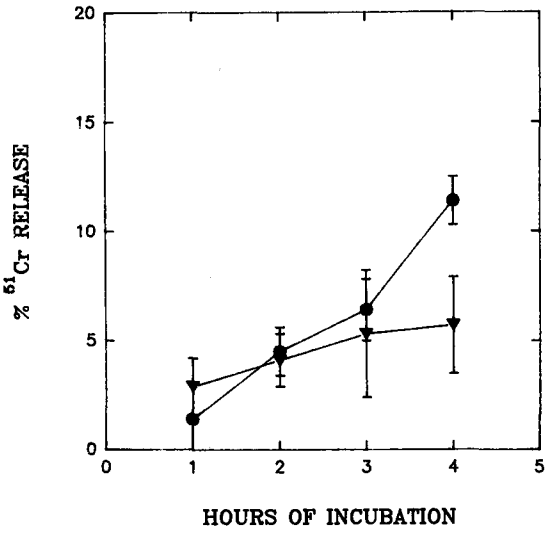

FIG. 2. Spontaneous ^{51}Cr release from tumor cells is approximately linear over a 4-hr period. T27A cells from a mouse fed standard rodent chow were ^{51}Cr-labeled and incubated at 37°C in many replicate wells in medium plus 5% (circles) or 20% (inverted triangles) FBS. At various time points, supernatant was removed from different wells, and the radioactivity present in the supernatant was measured. The error bars are SD of triplicate determinations.

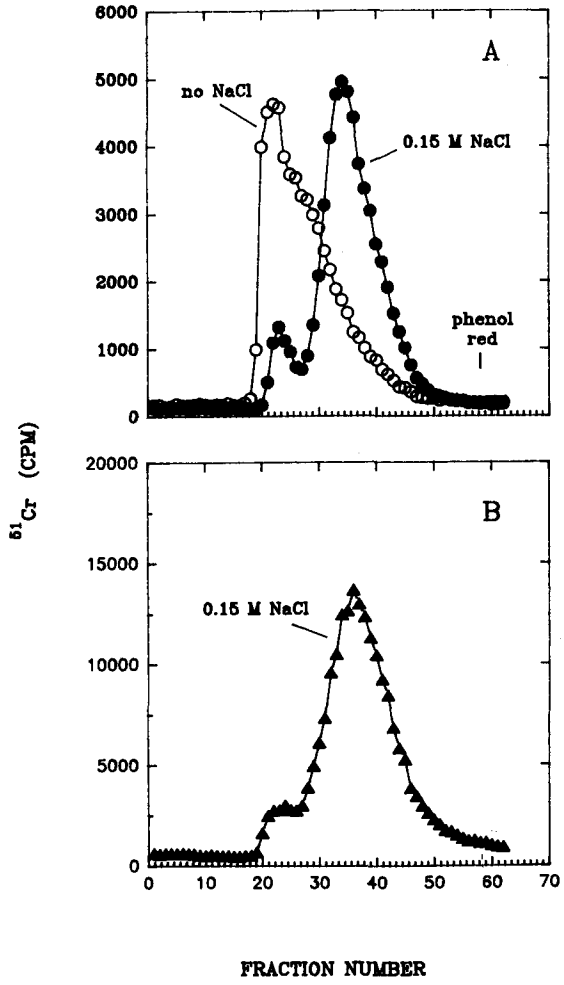

FIG. 3. Sephadex G-25 chromatography of spontaneously ^{51}Cr-labeled molecules. A, spontaneously released, ^{51}Cr-labeled molecules were subjected to gel filtration in 10 mM Tris buffer (pH 7.2) without (open circles) or with (closed circles) 0.15 M NaCl. The void volume was fraction 19–20; phenol red, smaller than the fractionation range, eluted at fraction 58. B, chromatography of intracellular ^{51}Cr-labeled molecules obtained from T27A cells by freezing and thawing.

obtained with material spontaneously released from a cultured human leukemia line, K562 (data not shown). ^{51}Cr-labeled molecules released spontaneously and those retained intracellularly had similar elution profiles on Sephadex G-25 (Fig. 3B), suggesting that a representative portion, not a select subset of ^{51}Cr-labeled molecules permeated the plasma membrane.

The dramatic spontaneous release of ^{51}Cr is reduced by supplementation of the incubation medium with serum or serum albumin. In vivo, serum proteins play an important role in maintaining osmotic balance between cells and their milieu. FBS (fetal bovine serum) is often added to cells *in vitro* to preserve osmotic balance and to supply growth factors. To test their response to osmotic pressures, PUFA and SFA cells were incubated for 4 hr at 37°C in culture medium supplemented with 2.5–20% FBS (Fig. 4) or 0.1–10% (1–100 mg/mL) purified BSA (Fig. 5). In both media, PUFA cells and, to a lesser extent, SFA cells displayed reduced spontaneous ^{51}Cr release as increased serum or protein was added. Because ≥5% albumin reduced spontaneous ^{51}Cr release as effectively as 20% FBS, it would appear that protein (*i.e.*, albumin) is the vital component in the serum-dependent osmotic gradient. These results suggest that PUFA cells are more permeable to ^{51}Cr-labeled molecules, having responded dynamically to the osmotic gradient applied by the reduction in serum protein. Importantly, augmented permeability of PUFA cells implies that *in vivo*, under conditions of moderate osmolarity, tumor cells exposed to dietary fish oil would be highly permeable.

Spontaneous ^{51}Cr release is exacerbated by increased temperature. We anticipate that several temperature dependent processes may affect spontaneous ^{51}Cr release, including increase in energy of the transported solute, increase in the number and size of the statistical "membrane pores", and change in the nature and size of domains and domain boundaries. Because of disparity in the response of saturated and unsaturated fatty acids to temperature changes, we predicted that PUFA and SFA cells would be differentially affected by changes in temperature. To test this prediction, PUFA and SFA cells were ^{51}Cr-labeled and incubated in medium plus 5% FBS for 4 hr at room temperature (22°C), 30°C, or 37°C. As shown in Figure 6, PUFA cells released significantly more ^{51}Cr at 30 and 37°C when compared with the SFA cells. At 22°C, there was little spontaneous release, and there was no difference between the two groups.

Dietary PUFA are incorporated into ascites cells. RBC-depleted T27A from mice fed menhaden oil contained significant amounts of DHA (22:6) and EPA (20:5), 5–10% of the total fatty acids (Fig. 7). Importantly, tumor cells from coconut oil fed mice did not contain detectable levels of these ω3 PUFA unless the diet also contained fish meal. The analyses suggested a direct correlation between the amount of EPA and DHA in the diet and the amount of these fatty acids in the tumor cells (Spearman rank correlation, $P<0.001$). In all cases, the incorporation

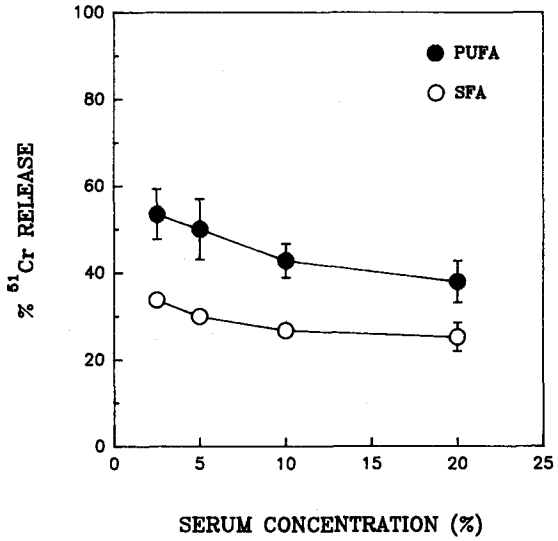

FIG. 4. Increased serum in the incubation medium reduces the spontaneous release of ^{51}Cr-labeled molecules. T27A cells from mice fed fat-free basal diets supplemented with 20% menhaden oil (closed symbols) and coconut oil (open symbols) were ^{51}Cr-labeled and incubated for 4 hr in medium containing 2.5 to 20% FBS. Radioactivity present in the medium was then measured. Mean ± SD (four mice/group).

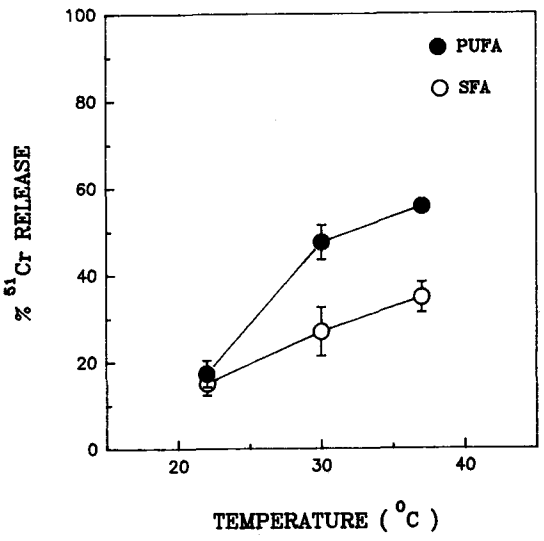

FIG. 6. Spontaneous ^{51}Cr release from tumor cells of menhaden oil-fed mice is particularly sensitive to increased incubation temperature. T27A cells from mice fed fat-free basal diets supplemented with 20% menhaden oil (closed symbols) and coconut oil (open symbols) were ^{51}Cr-labeled and incubated at room temperature (22°C), 30°C, and 37°C for 4 hr. Radioactivity present in the medium was then measured. Mean ± SD (four mice/group).

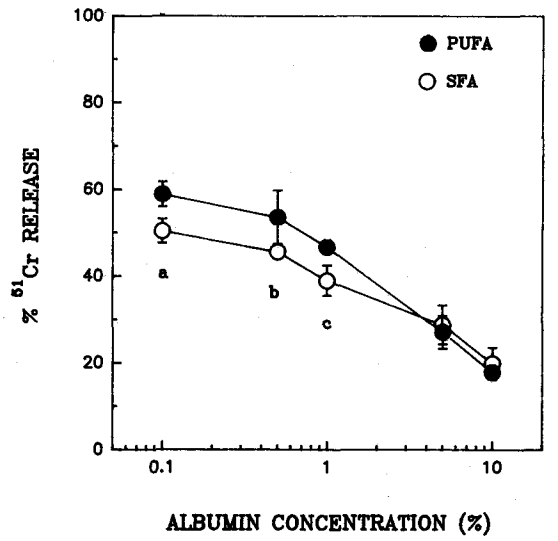

FIG. 5. Purified serum albumin will reduce spontaneous ^{51}Cr release. T27A cells from mice fed chow supplemented with 10% menhaden oil (closed symbols) and coconut oil (open symbols) were ^{51}Cr-labeled and incubated for 4 hr in medium containing 0.1 to 10% BSA. Radioactivity present in the medium was then measured. Mean ± SD (four mice/group). Statistically significant differences between diets were tested by ANOVA: a, P=0.0069; b, P=0.0467; c, P=0.0056.

of DHA into tumor cell lipids was greater than for EPA.

Plasma membranes were isolated by the method of Kaduce *et al.* (6), and their fatty acid compositions were determined. The percent of total fatty acids represented by nine fatty acids (14:0, 16:0, 18:0, 18:1, 18:2, 18:3, 20:4, 20:5, 22:6) was calculated for PUFA and SFA membranes, respectively: 2.7, 25.7; 32.2, 23.9; 6.2, 7.8; 13.1, 15.6; 5.7, 7.5; 1.4, 16.3; 7.1, 0; 2.1, 0; 4.8, 0 (each value is an average of duplicate analyses). As was shown for whole cells, isolated membranes contained EPA and DHA only if these fatty acids were present in the diet.

Tumor growth in mice on a menhaden oil diet is less than in mice fed coconut oil. Table 1 shows that mice on the two diets maintained comparable body weights. The difference in weight between menhaden oil and coconut oil-fed mice observed on day 35 in experiment 1 was not seen on day 33 or earlier, and therefore was likely to be coincidental. On day 42, after tumor transplant and before the onset of cachexia, mice on the coconut oil diet had significantly greater body weights as compared to menhaden oil fed mice, suggesting greater tumor burdens. The relative change in body weight (weight on day of tumor harvest minus weight on day of tumor inoculation) was 2.37 ± 0.98 g for menhaden oil-fed mice and 4.13 ± 0.60 g for hydrogenated coconut oil-fed mice (ANOVA, P=0.0566). The term "tumor burden" refers to the tumor cell mass and the peritoneal fluid that accumulates during exponential tumor growth. Because menhaden oil-fed mice ate as much food as the hydrogenated coconut oil-fed mice (data not shown), and showed no signs of premature cachexia, lower body weight was likely to result from a smaller tumor burden.

DISCUSSION

In this report we have shown that dietary menhaden oil leads to the incorporation of ω3 PUFA into a rapidly growing ascites tumor, and that tumor cells modified in this way spontaneously release more ^{51}Cr-labeled intracellular molecules than do tumor cells lacking ω3 PUFA. We do not, at this time, know the mechanism for PUFA-augmented spontaneous release; however, heightened spontaneous release may be due to increased

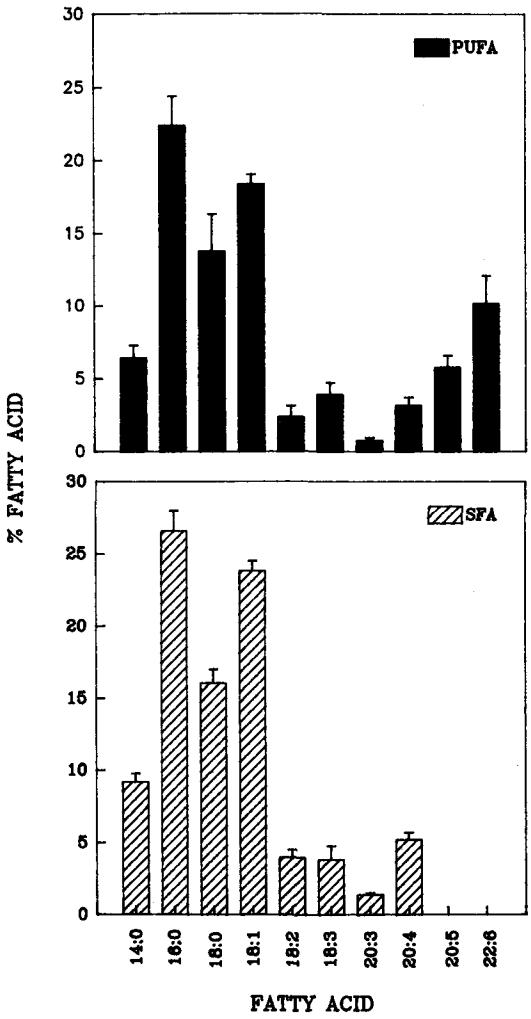

FIG. 7. Dietary ω3 PUFA are incorporated into ascites tumor cells. T27A cells were harvested from mice fed fat-free basal diets supplemented with 10% menhaden oil or hydrogenated coconut oil. After RBC depletion, the fatty acid content of the cells was analyzed by gas-liquid chromatography. The tumors shown in the top panel (solid bars) are from menhaden oil-fed mice; the tumors shown in the bottom panel (hatched bars) are from coconut oil-fed mice. EPA and DHA are 20:5 and 22:6 fatty acids, respectively.

permeability of the surface membrane. Permeability does not correlate directly with cell disintegration, as ω3 PUFA modified cells remained viable during the spontaneous release process. Increased permeability, particularly at elevated temperatures, is consistent with the effect of DHA and EPA incorporation into membranes as predicted from experiments on phospholipid bilayers (8). DHA exhibits a profound effect on bilayer membrane permeability and fusion while not altering membrane fluidity from that of a linolenic acid (18:3)-containing membrane. This implies DHA is not universally affecting membrane properties but instead is acting at specific membrane regions or domains.

It is generally accepted that lipid oxidation products have deleterious effects on cells. Introduction of additional polyunsaturated fatty acids to the diet dilutes the antioxidant vitamin E and other components of the diet, increasing susceptibility of the lipids to oxidation. To minimize oxidation-related problems, the diets were stored frozen, protected from light, and removed promptly after feeding. Furthermore, because the mice were provided with food essentially *ad libitum* during the dark period, small reductions in vitamin and mineral concentration were abrogated by increased food consumption. Essential fatty acid deficiency was unlikely to play a role in increased permeability because the chow-based diets contained essential fatty acids as well as the menhaden oil or hydrogenated coconut oil supplementation.

It is remarkable that the substantial loss of ^{51}Cr-labeled molecules ensues without concomitant loss of cell viability. At this time we cannot unequivocally rule out the possibility that cellular components chelated with chromium are subject to active transport, but very preliminary data from our laboratory suggest that metabolic inhibitors, carbonyl cyanide *m*-chlorophenylhydrazone, 2,4-dinitrophenol, and sodium azide, do not significantly decrease ^{51}Cr release (Table 2).

Sodium chromate is thought to enter the cell by an energy-independent mechanism, and be reduced to chromic ion (18). Although some data indicate that ^{51}Cr released from lysed target cells is bound to macromolecules (19), numerous reports suggest (as we have observed) that ^{51}Cr-labeled molecules have molecular weights less than 4000 (13,20). Ronai (21) reported that released ^{51}Cr displayed electrophoretic behavior similar to ^{51}Cr-labeled peptides and distinct from ^{51}Cr-lysine and ^{51}Cr-arginine. The theory advanced by Ronai is that ^{51}Cr-labeled peptides lost from the cell are the result of protein turnover. Thus, increased protein turnover in the PUFA cells may account for increased ^{51}Cr-labeled peptide available for release. Because internal and released ^{51}Cr-labeled molecules did not differ in molecular size, and PUFA and SFA cells attained comparable levels of ^{51}Cr-labeling, we doubt that augmented protein turnover in PUFA cells induces high spontaneous ^{51}Cr release in an environment of moderate osmolarity.

We have also entertained the possibility that ^{51}Cr was adsorbed onto the external tumor cell surface, and was maintained in this fashion during the washing procedures, only to be released during incubation at 30° or 37°C. Similar radioactivity incorporation by PUFA and SFA cells implies that adsorption, if it occurred, was the same for both cell types, whereas release was more extensive for PUFA cells. We do not favor this interpretation because, typically, membrane-associated ^{51}Cr is only a minor component of the total incorporated ^{51}Cr (18). Additionally, the released ^{51}Cr-labeled material did not cochromatograph with sodium chromate.

Tumor cell membrane function, whether it is bilayer permeability or membrane protein activity, is important to immunologic surveillance for cancer because cytolytic cells and antibodies act initially at the tumor cell membrane. ω3 PUFA may alter the tumor cell membrane by affecting phospholipid packing and domain formation, rotational movement, or fluidity of distinct domains. In turn, these structural changes may affect the conformation and motility of critical membrane antigens, the membrane insertion of pore forming substances such as perforin or complement, and the temporal kinetics of irreparable membrane damage. Furthermore, when cell-mediated tumor cell cytolysis is viewed as an active process of the

tumor cell itself (22), fatty acid composition of the tumor cell membrane may influence the activity of membrane-associated enzymes involved in cellular activation, such as protein kinase C (11). Thus, there is potential for ω3 PUFA-enriched diets to modify immune surveillance at the level of the tumor cells, regardless of effects on cells of the immune system. The temperature dependence of ^{51}Cr permeability may provide another means to selectively eradicate tumor cells. When combined with the fish oil diet, increasing local temperature of tumor cells relative to adjacent healthy cells (local hyperthermia) may make the tumors even more susceptible to immunologic or pharmacologic destruction. We have observed increased permeability of tumors in mice fed experimental diets during adulthood, not as weanlings. Thus, dietary modification may be useful in the aged, when cancer incidence is increased.

[Received July 31, 1990; Revision accepted February 16, 1991]

Do Rat Kidney Cortex Microsomes Possess the Enzymatic Machinery to Desaturate and Chain Elongate Fatty Acyl-CoA Derivatives?

Sanoj K. Suneja, Mahmoud N. Nagi, Lynda Cook, Peter Osei and Dominick L. Cinti*
Department of Pharmacology, University of Connecticut Health Center, Farmington, Connecticut 06030

Rat kidney cortex microsomal preparations were unable to catalyze Δ9, Δ6 and Δ5 desaturation of stearoyl-coenzyme A (CoA), linoleoyl-CoA and dihomo-γ-linolenoyl-CoA, respectively. The kidney cortex microsomal fraction, however, did catalyze the malonyl-CoA dependent fatty acyl-CoA elongation. The biochemical properties of palmitoyl-CoA elongation were studied as a function of protein concentration, time, reduced nicotinamide adenine dinucleotide phosphate (NADPH), malonyl-CoA and substrate concentrations; of the substrates investigated, Δ6,9,12-18:3 was the most active. Unlike what was observed in the hepatic system, a high-carbohydrate, fat-free diet did not induce kidney fatty acid chain elongation. All intermediate kidney cortex microsomal reactions, *i.e.*, β-ketoacyl-CoA reductase, β-hydroxyacyl-CoA dehydrase and *trans*-2-enoyl-CoA reductase activities, were significantly higher (greater than one order of magnitude) than the condensing enzyme activity, suggesting that the rate-limiting step in total elongation is the initial condensation reaction. Contrary to other reports, the results suggest that the kidney cannot synthesize arachidonic acid needed for eicosanoid production.
***Lipids 26,* 359-363 (1991).**

The general catalytic mechanism of the microsomal fatty acid chain elongation system (FACES) in liver involves the sequential activity of condensing enzyme, β-ketoacyl-coenzyme A (CoA) reductase, β-hydroxyacyl-CoA dehydrase and *trans*-2-enoyl-CoA reductase (1-5). Although the fatty acid chain elongation system has been studied extensively in liver and brain (1,5,6), the biosynthetic pathway responsible for the synthesis of such physiologically important fatty acids as arachidonic acid has received less attention in other tissues, *e.g.*, kidney (7).

Another fatty acid metabolic pathway which appears to be coupled to or interact sequentially with the elongation system is the desaturation pathway. The liver contains, at least, three separate desaturase enzymes—Δ9, Δ6 and Δ5, all of which receive electrons from the microsomal hemoprotein, cytochrome b_5. The latter has also been implicated in providing reducing equivalents to the first reduction step of FACES (8).

More than ten years ago, Cinti and Montgomery (9) reported the inability of rat kidney cortex microsomes to catalyze the Δ9 desaturation of either palmitoyl-CoA or stearoyl-CoA. Oshino and Sato (10) also observed no measurable Δ9 desaturase activity in kidney microsomes. These results were unexpected because the microsomes contained significant amounts of cytochrome b_5 and its flavoprotein, reduced nicotinamide adenine dinucleotide (NADH) cytochrome b_5 reductase (9,11). By contrast, Chern and Kinsella (12) reported the presence of radiolabeled arachidonic acid in cultured rat kidney cells which had been incubated with [1-^{14}C]linoleic acid, suggesting that these cells possess Δ5 and Δ6 desaturase activities. Clark and Queener (13) reported "little or no activity" in rat kidney cortex microsomal fractions assayed for Δ6 and Δ9 desaturase, but found detectable activities when "fraction 3 homogenate" replaced the microsomal fraction. More recently, Mandon *et al.* (14) compared Δ6 desaturase activities in liver, kidney and lung microsomes and found that the renal microsomal activity was very low ranging from 5-9 pmol/min/mg protein. Similar values were reported for kidney microsomal Δ6 desaturase by Kawata *et al.* (15).

The present study was designed to fully characterize the biochemical properties of the rat kidney cortex microsomal fatty acid chain elongation system and to re-evaluate the presence of Δ9, Δ6 and Δ5 desaturase activities in the renal cortex microsomal fraction.

MATERIALS AND METHODS

Chemicals. All biochemicals were obtained from Sigma Chemical Co. (St. Louis, MO); general chemicals were purchased from Baker (Phillipsburg, NJ) and fatty acid methyl ester standards were obtained from Nu Chek Prep Inc. (Elysian, MN). Radioactive compounds, [2-^{14}C]malonyl-CoA, [1-^{14}C]linoleic acid, [1-^{14}C]dihomo-γ-linolenic acid and [1-^{14}C]palmitic acid or [1-^{14}C]stearic acid were obtained from DuPont NEN Company (Wilmington, DE). Fatty acyl-CoA derivatives were prepared by the acid chloride method (16).

Isolation of kidney cortex microsomes. Male Sprague-Dawley rats weighing 175-200 g were given access to Purina rat chow or deprived of food for 24 hr and then fed a high-carbohydrate diet (fat-free diet, United States Biochemical Corporation, Cleveland, OH) and tap water for 2 days. Forty-eight hours after feeding, the animals were killed by decapitation between 8:00 and 9:00 A.M. Kidneys were removed and placed into ice-cold saline, followed by decapsulation and excision of the medulla. The kidney cortex microsomes were prepared as described previously (17). Protein was determined by the method of Bradford (18).

Enzyme assays. The assay conditions for measuring total elongation activity, unless otherwise noted, were as described earlier (19). The reaction mixture for measuring the condensing enzyme activity was the same as for total elongation, except that 500 μM reduced nicotinamide adenine dinucleotide phosphate (NADPH) was omitted from the mixture.

Thin-layer and gas-liquid chromatographic separation of elongated products. The pooled hexane extracts of fatty acid chain elongation products were evaporated under N_2. Either the residues were redissolved in 50 μL $CHCl_3$, spotted on 0.25mm-thick, activated silica gel G plates and

developed in petroleum ether/diethyl ether/formic acid (75:25:1 v/v/v) or converted to their methyl esters by diazomethane for radio gas-liquid chromatography as described previously (20,21).

Chemical synthesis of CoA esters. [3-^{14}C]β-Ketostearoyl-CoA was synthesized according to the procedures of Stoffel and Pruss (22) and Al-Arif and Blecher (23). The β-keto fatty acid methyl esters were reduced with sodium borohydride to form the β-hydroxy derivatives. The coenzyme A esters of *trans*-2-enoate and β-hydroxy acid were synthesized by the mixed anhydride procedure as described by Fong and Schulz (24). The concentrations of the synthesized CoA esters of β-keto acid, β-OH acid, or *trans*-2-enoate were measured by the method of Ellman (25) after cleavage of the thioester bond with hydroxylamine.

β-Ketoacyl-CoA reductase. The β-ketoacyl-CoA reductase activity was measured and products identified as described earlier (20).

β-Hydroxyacyl-CoA dehydrase. The activity of β-hydroxyacyl-CoA dehydrase was assayed in the forward direction, *i.e.,* by following the conversion of the β-hydroxy derivative to the *trans*-2-enoyl-CoA (26).

Trans-*2-enoyl-CoA reductase. Trans*-2-enoyl-CoA reductase activity was followed by measuring the rate of oxidation of NADPH at 340 nm–400 nm with the Shimadzu UV-3000 spectrophotometer (Kyoto, Japan) as described earlier (17).

Kidney cortex microsomal desaturases. Δ9 Desaturation of stearoyl-CoA was assayed in kidney cortex microsomes as described previously (9). Δ6 Desaturation of linoleoyl-CoA (18:2ω6) was assayed by measuring the formation of γ-[1-^{14}C]linolenoyl-CoA. The reaction medium (1.0 mL) contained: 100 mM Tris-HCl, pH 7.4, 1.0 to 3.0 mg kidney cortex microsomal protein and 1.0 mM NADH. Following 1 min preincubation at 37°C, the reaction was initiated with 40 μM [1-^{14}C]linoleoyl-CoA, incubated for 20 min, and terminated by addition of 1.0 mL 15% KOH in methanol. The reaction products were processed as described earlier (19) and methylated using diazomethane in diethyl ether and redissolved in 50 μL of $CHCl_3$ and spotted on activated silica gel G plates impregnated with 10% $AgNO_3$. Carrier methyl esters of linoleic and γ-linolenic acid were included with the labeled acids. Plates were developed in a solvent system of toluene/acetone (95:5 v/v, containing 0.05% butylated hydroxytoluene (BHT) as an antioxidant). The spots were visualized and counted with betafluor as described earlier (20). The reaction products were also identified by radio gas-liquid chromatography.

Δ5 Desaturation of eicosatrienoic acid (20:3ω6) was estimated in kidney cortex microsomes by measuring the conversion to arachidonic acid (5,8,11,14-eicosatetraenoic acid) (27). The 1.0-mL reaction medium contained: 100 mM Tris-HCl, pH 7.4, 2.0 mg microsomal protein, 5 mM adenosine triphosphate (ATP), 200 μM CoA, 5 mM $MgCl_2$ and 1 mM NADH. After 1 min preincubation at 37°C, the reaction was started by adding 40 μM [1-^{14}C]-dihomo-γ-linolenic acid, and the mixture was incubated for 20 min at 37°C. The product processing and identification was done as above (see also 20,21). The oven temperature was 160°C. The post-mitochondrial supernatant (4.0 mg protein/mL) was also used to assay Δ6 and Δ5 desaturase activities in kidney cortex.

RESULTS

Desaturase activities. Microsomes isolated from kidney cortex of rats fed either a Purina rat chow (controls) or a high carbohydrate, fat-free diet were shown to be devoid of stearoyl-CoA desaturase activity, confirming our earlier results (9,10).

When [1-^{14}C]linoleoyl-CoA was employed as a substrate, hepatic microsomal Δ6 desaturase activity was 136 and 180 pmol γ-linolenate formed/min/mg protein in control and fat-free diet rats, respectively. However, kidney cortex microsomes from either group had no detectable Δ6 desaturase activity even after a one-hour incubation period and a microsomal protein concentration of 4 mg/mL in the assay.

When Δ5 desaturase activity was measured following incubation of [1-^{14}C]dihomo-γ-linolenoyl-CoA with hepatic microsomes, 250 and 480 pmol arachidonate formed/min/mg protein in control and fat-free diet rats, respectively. By comparison, under identical assay conditions, kidney cortex microsomes from either diet were unable to catalyze Δ5 desaturation of dihomo-γ-linolenoyl-CoA. Varying assay conditions, such as extending the incubation up to 6 hr in the presence of a NADPH-generating system and increasing the microsomal protein to 4 mg/mL, did not result in any demonstrable Δ5 desaturase activity. Substitution of the post-mitochondrial supernate or total kidney cortex homogenate for the microsomal fraction still resulted in no desaturase activity.

Renal cortex microsomal fatty acid chain elongation. Although the microsomal fraction of the renal cortex did not possess any detectable Δ9, Δ6 and Δ5 desaturase activities using our assay conditions, the same fraction did possess fatty acid chain elongation activity. The elongation of palmitoyl-CoA as a function of microsomal protein is shown in Figure 1 and was linear to approximately 1.0 mg per mL. Total elongation activity was calculated as 160 pmol (range 150–300 pmol) per min per mg microsomal protein. Renal cortex microsomes from rats on a fat-free diet did not have induced elongation activity, contrary to microsomes obtained from liver. Condensation activity was linear only to 400–500 μg microsomal protein (Fig. 1), and the diminished activity in contrast

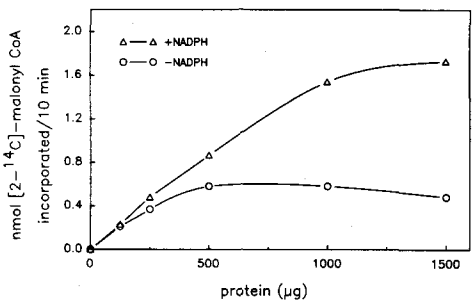

FIG. 1. Effect of varying amounts of rat kidney cortex microsomal protein on the condensation and elongation of palmitoyl-CoA. The incubation mixture contained microsomal protein, 20 μM palmitoyl-CoA, 10 μM BSA, 50 μM [2-^{14}C]malonyl-CoA (50,000 cpm) and 500 μM NADPH (for elongation assay only) in 0.1 M Tris-HCl buffer, pH 7.4. The incubation was carried out at 37°C for 10 min. Values are means from two different experiments done in duplicate.

to total elongation can be attributed to product inhibition, *i.e.*, the β-ketoacyl-CoA product of the condensation reaction is a potent inhibitor of the condensing enzyme (Cinti, D.L., unpublished observations).

Condensation of palmitoyl-CoA with malonyl-CoA was linear up to 10 min, whereas total chain elongation was linear for 20 min. Both condensation and elongation activities increased as a function of malonyl-CoA concentration, plateauing at approximately 40 μM, with apparent K_m values of approximately 6 μM for both activities.

As shown in Figure 2, total elongation activity increased linearly with increasing concentration of palmitoyl-CoA to approximately 5 μM, plateauing at 20 μM palmitoyl-CoA; condensation activity followed a similar pattern. The apparent K_m values for palmitoyl-CoA were 3.3 μM and 6.3 μM for the elongation and condensation reactions, respectively. For NADPH, the apparent K_m value for total elongation approximated 24 μM (data not shown).

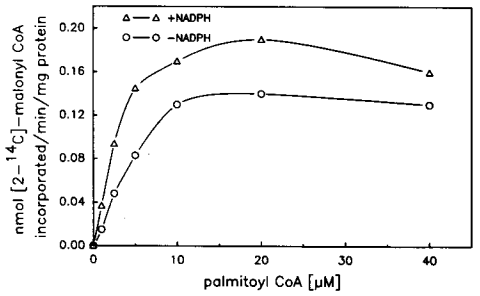

FIG. 2. Rat kidney cortex microsomal palmitoyl-CoA condensation and elongation as a function of substrate concentration. The assay mixture, which was incubated for 10 min at 37°C, contained 50 μM [2-^{14}C]malonyl-CoA, 500 μM NADPH (in the elongation reaction only), 1 μM to 40 μM palmitoyl-CoA and BSA at 2:1 ratio of substrate/BSA in 0.1 M Tris-HCl buffer, pH 7.4; microsomal protein concentration was 250 μg/mL.

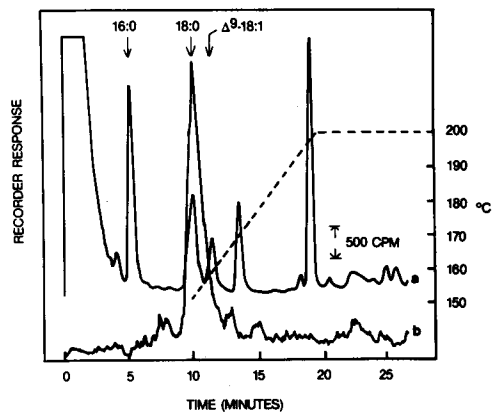

FIG. 3. Determination of the products of rat kidney cortex microsomal NADPH-dependent palmitoyl-CoA elongation by radio gas-liquid chromatography. Radio-chromatogram depicts the reaction products formed after incubation of 20 μM palmitoyl-CoA, 10 μM BSA, 500 μM NADPH, 50 μM [2-^{14}C]malonyl-CoA with 250 μg/mL kidney cortex microsomes in 0.1 M Tris-HCl buffer, pH 7.4 for 10 min at 37°C; a, mass trace; b, radioactive trace.

The palmitoyl-CoA elongation products were identified by both thin-layer and radio gas-liquid chromatography (Fig. 3). Using 20 μM palmitoyl-CoA, greater than 95% of the radioactivity was associated with a single peak identified as stearate (tracing b). There was no identifiable radiolabeled oleate peak (28) reconfirming the absence of Δ9 desaturase activity in kidney cortex microsomes.

Similar to what was observed with liver microsomes (5,29), both condensation and elongation activities were stimulated by the presence of bovine serum albumin (BSA) (fraction IV, Sigma) with maximal activity occurring at a substrate/BSA ratio of 1.5:1 or 2.0:1. When several CoA derivatives were tested as substrates for kidney cortex microsomal FACES, γ-linolenoyl-CoA was found to be the most active substrate, with a specific activity of approximately 700 pmol 8,11,14-20:3 formed per min per mg protein (Fig. 4); least activity was noted with stearoyl-CoA and oleoyl-CoA. In one experiment utilizing 25 μM 9,12-18:2-CoA and 5,8,11,14-20:4-CoA as substrates, kidney cortex microsomal elongation activities were 45 and 44 pmol/min/mg protein, respectively.

β-Ketoacyl-CoA reductase activity. Employing chemically synthesized [3-^{14}C]β-ketostearoyl-CoA, the reductase activity reached a maximum in the presence of 50

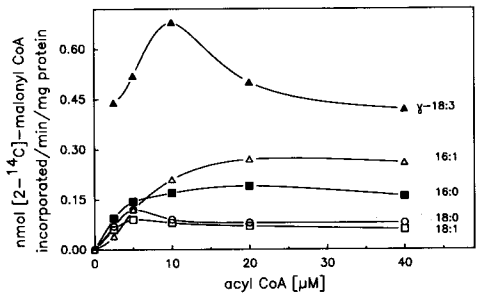

FIG. 4. Fatty acyl-CoA substrates for the kidney cortex microsomal elongation system. The various acyl-CoA substrates used were: ■—■, palmitoyl-CoA (16:0); △—△, palmitoleoyl-CoA (Δ9-16:1); O—O, stearoyl-CoA (18:0); □—□, oleoyl-CoA (Δ9-18:1), and ▲—▲, γ-linolenoyl-CoA (6,9,12-18:3). These substrates were chain elongated in an assay mixture containing 2:1 ratio of substrate/BSA, 500 μM NADPH, 50 μM [2-^{14}C]malonyl-CoA and 250 μg/mL of microsomal protein in 0.1 M Tris-HCl buffer, pH 7.4.

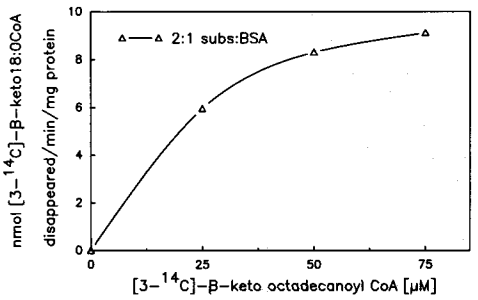

FIG. 5. The effect of increasing concentrations of β-keto octadecanoyl-CoA on rat kidney cortex microsomal β-keto reductase activity. The assay medium contained [3-^{14}C]β-keto 18:0-CoA with a substrate/BSA ratio of 2:1, 500 μM NADPH and 200 μg microsomal protein/mL in 0.1 M Tris-HCl buffer, pH 7.4. The incubation was carried out at 37°C for 5 min. Thin-layer chromatography (TLC) was employed to separate the reaction products.

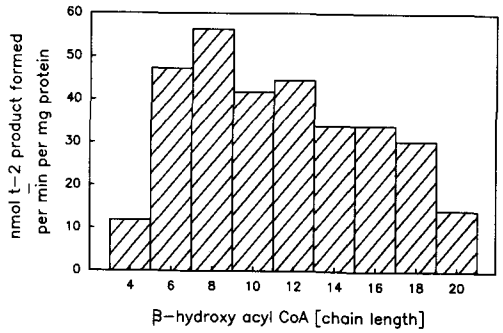

FIG. 6. β-Hydroxyacyl-CoA substrates for rat kidney cortex microsomal dehydrase. The assay mixture contained optimal amounts of β-hydroxyacyl-CoA derivatives (C_4, 200μM; C_6, C_8, C_{10}, 100μM; C_{12}, 75μM; C_{14}, C_{16}, C_{18}, C_{20}, 50μM) and 100 μg microsomal protein/mL in 0.1 M Tris-HCl, pH 7.4; dehydrase activity was recorded by the increase in absorbance at 37°C at 280 nm minus 350 nm (dual wavelength) on a Shimadzu UV-3000 spectrophotometer.

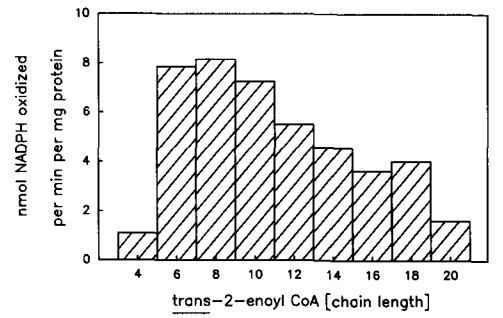

FIG. 7. *Trans*-2-enoyl-CoA substrates for rat kidney cortex microsomal *trans*-2-enoyl-CoA reductase activity. The spectrophotometric cuvette contained various substrates (*t*-2-4:1, 50μM; *t*-2-6:1, 8:1, 10:1, 12:1, 30 μM; *t*-2-14:1, 16:1, 18:1, 20 μM; *t*-2-20:1, 10 μM), 150 μM NADPH, substrate to BSA ratio of 1:2 except for *t*-2-4:1 (1:1) and *t*-2-20:1 (1:4) and 100 μg microsomal protein/mL in 0.1 M Tris-HCl buffer, pH 7.4; decrease in absorbance was recorded at 37°C at 340 nm - 400 nm (dual wavelength) using a Shimadzu UV-3000 spectrophotometer.

to 75 μM substrate (Fig. 5); the apparent K_m value was 20 μM. The β-ketoacyl-CoA reductase activity was linear i) with protein to at least 200 μg/mL, ii) with time for at least 5 min and iii) with NADPH to about 200 μM (apparent K_m: 130 μM). The specific activity of this reduction step was markedly greater than that of either the condensing enzyme step or the overall elongation reaction (8 nmol *versus* 200 pmol/min/mg microsomal protein). Due to the unavailability of various β-keto derivatives and the difficulty in their chemical synthesis and purification, substrate specificity analysis was not performed.

β-Hydroxyacyl-CoA dehydrase activity. The dehydrase activity in the presence of β-hydroxyoctadecanoyl-CoA (βOH18) was linear to about 200 μg microsomal protein/mL and was maximal at 40–50 μM substrate; the apparent K_m for the βOH18 was 10 μM. Highest activity was observed with β-hydroxyoctanoyl-CoA (about 55 nmol/min/mg protein) (Fig. 6). Chain lengths from C_4 to C_{20} were tested and provided activities ranging from 10 to 55 nmol. These specific dehydrase activities were 100–200-fold greater than the overall chain elongation activity.

Trans-2-enoyl-CoA reductase activity. The terminal reaction was studied with *trans*-2-octadecenoyl-CoA (*t*-2-18:1) and its conversion to stearoyl-CoA was followed by monitoring NADPH oxidation and verified by both gas-liquid chromatography and thin-layer chromatography. The reductase activity was linear to at least 150 μg/mL protein and 50 μM NADPH and reached a maximum of 4 nmol/min/mg protein in the presence of 20 μM substrate; higher substrate concentrations showed a slightly reduced activity. Lineweaver-Burk analysis yielded apparent K_m values of 12 μM and 45 μM for the substrate and NADPH, respectively. Substrates, varying in chain length from C_4 to C_{20}, generated *trans*-2-enoyl-CoA reductase activities ranging from 1 to 8 nmol NADPH oxidized/min/mg microsomal protein (Fig. 7); these values were 5- to 20-fold higher than the overall elongation rate.

DISCUSSION

It is now well established that several 20-carbon atom polyunsaturated fatty acids are substrates for lipoxygenation, cyclooxygenation and epoxygenation (30,31). The products of these reactions possess a variety of important biological activities (30). The precursors for these products are generated in the cell by a series of sequential desaturation-elongation reactions.

In recent years, it has been shown that the kidney also contains the enzymatic machinery to carry out lipoxygenation, cyclooxygenation and epoxygenation (32–34). Recent evidence suggests that some of the renal eicosanoid products (*e.g.*, PGE_2, PGI_2) of these reactions play a major role in the regulation of renal hemodynamics (34). Although the kidney can synthesize various physiologically important eicosanoid products, does it also possess the enzyme systems to synthesize the precursor substrates, *i.e.*, arachidonic acid? To respond affirmatively, the kidney must have the capability to catalyze both desaturation and elongation reactions. However, Oshino and Sato (10) and Montgomery and Cinti (11) reported the lack of Δ9 desaturation activity in rat kidney cortex microsomes. By contrast, Clark and Queener (13) noted Δ6 and Δ9 desaturase activities in a non-microsomal fraction of rat kidney.

Brenner (35) reported measurable Δ6 desaturase activity in liver, adrenals and testicles, but none in heart, brain and kidney. More recently, Mandon *et al.* (14) reported a Δ6 desaturase activity of 5–8 pmols per min per mg protein in kidney microsomes. However, this low activity could be due to as little as a 1% contamination of the highly radioactive substrate employed in the incubation.

In the present study, under conditions in which liver Δ9, Δ6 and Δ5 desaturase activities were optimally expressed, we could not detect any desaturase activity in kidney microsomes. Variations in protein, substrate and co-factor concentrations and incubation period resulted in no detectable renal activities. Furthermore, no measurable desaturase activity was observed following replacement of the microsomal fraction with either the post-mitochondrial supernate (cytosol plus microsomes) or total homogenate. At the present time, we have no reasonable explanation for the discrepancy between our

data and those of Chern and Kinsella (12) who reported radiolabeled arachidonic acid in cultured renal cells incubated with [1-^{14}C]linoleic acid.

Kidney cortex microsomes did, however, have an active malonyl-CoA dependent fatty acid chain elongation system. The biochemical characteristics of the kidney FACES are similar to that of liver. It requires an activated acyl moiety (CoA derivative), and malonyl-CoA acts as the 2-carbon elongating unit. Both condensation and total elongation activities are enhanced by BSA, with an optimal substrate to BSA ratio of 2:1. The analysis of each of the four reactions suggests that condensation is the slowest and therefore a rate-limiting step since the β-keto reductase, dehydrase and enoyl reductase had catalytic activities at least one order of magnitude greater than did the condensation step. Total elongation activity was highest with γ-18:3-CoA.

A difference between kidney and liver FACES is the inability of a high-carbohydrate diet (fat-free) to induce the kidney system.

Recently, Hagve and Sprecher (36) employing radio gas-liquid chromatography reported that rat heart myocytes were not capable of either elongation or desaturation. Furthermore, Lefkowith *et al.* (37) described similar uptake mechanisms for arachidonate in both heart and kidney. These results suggest that both heart and kidney obtain arachidonate from the circulation possibly from lipoproteins derived from liver. Such a mechanism would circumvent the need for kidney cells to synthesize arachidonic acid.

Thermotropic Phase Properties of the Hydroxyceramide/ Cholesterol System

Timothy S. Wiedmann* and **Amir Salmon**[1]
University of Minnesota, College of Pharmacy, Department of Pharmaceutics, Minneapolis, Minnesota 55455

The interaction of cholesterol with ceramides containing α-hydroxy fatty acyl chains (hydroxyceramides) has been studied as a foundation for characterizing the lipid bilayers of the *stratum corneum*. A relatively large quantity of cerebrosides was obtained from bovine brain and converted to ceramides through removal of the carbohydrate side chain. The ceramides were separated based on the absence or presence of hydroxy fatty acyl chains. The lyophilized hydroxyceramides showed a broad melting region at 92°C. Hydroxyceramides dispersed in water produced a relatively narrow, thermotropic transition at 75°C. The effect of cholesterol on this thermotropic phase transition of hydroxyceramides was determined by differential scanning calorimetry. With respect to the main transition, cholesterol caused a broadening of the phase transition at relatively low levels as well as a decrease in the peak transition temperature. The presence of cholesterol at levels in excess of 7 wt% gave rise to an additional low-temperature transition at 55°C. Upon immediate rescanning, this transition was exothermic, but with increasing incubation time the area under the excess heat capacity curve as a function of temperature became smaller. After two days or more, the transition observed was endothermic. At cholesterol levels between 40 and 50 wt%, multiple peaks were observed. From comparisons with related systems, the cooperative thermal transitions of hydroxyceramides with cholesterol are suggested to result from changes in hydrogen bonding or be due to phase separation. The composition of isolated brain ceramides is being compared with that reported for the *stratum corneum*.
***Lipids* 26,** 364–368 (1991).

Ceramides are *N*-acyl linked bases that act as precursors for cerebrosides (1). While cerebrosides are primarily found in brain and epidermal tissue, ceramides occur in abundance only in the *stratum corneum* (2) where they have been implicated to contribute to the water impermeability of this tissue (3–5). The relatively small polar head group consisting of two hydroxy groups at the 1 and 3 positions of the sphingosine base and an amide-linked acyl chain are unique, structural features which appear to contribute to an effective permeability barrier. Ceramides have also been implicated in the control of epidermal turnover (2). Furthermore, the asymmetric chain lengths together with the terminal hydroxyl groups could form an interdigitated multilamellar arrangement and thus may provide cohesive links within the intercellular region of the *stratum corneum* (5,6).

Cholesterol is also a relatively abundant component of *stratum corneum* and has been proposed to modulate the properties of the lipid bilayers in this system (2,7). In addition, it appears likely that cholesterol affects permeability properties and the control of epidermal turnover. Changes in the relative amounts of cholesterol present occur in certain disease states which results in perturbations of normal *stratum corneum* function (3,8,9).

Although the interactions of cholesterol with various polar lipids have attracted considerable attention (10), cholesterol/ceramide interactions have not been studied. It would appear that investigations on the physiological role of ceramides in the *stratum corneum* would be greatly facilitated by understanding their interaction with other lipid components. In this study, the effect of cholesterol on the thermotropic phase behavior of hydroxyceramides has been investigated.

MATERIALS AND METHODS

Isolation of ceramides. Cerebrosides were isolated from bovine brain following the procedure of Radin (11). The cerebrosides were converted to ceramides by cleaving off the carbohydrate moieties using the procedure of Carter *et al.* (12). The resulting ceramides were separated into two subclasses, containing either fatty acids or hydroxy fatty acids, by silica (Bio-Sil A, 100–200 mesh, Bio-Rad, Richmond, CA) column chromatography using a chloroform/methanol gradient.

Thermal analysis. Ceramides were lyophilized from cyclohexane to obtain a dry powder that readily dispersed in water. Pure hydroxyceramide, 1–2 mg, was weighed and placed in a coated aluminum differential scanning calorimeter pan (DuPont, Wilmington, DE). Mixtures of ceramide and cholesterol were prepared by dissolving both in chloroform and adding the appropriate volumes to preweighed pans. The solution was dried overnight under high vacuum and excess distilled water was added to bring the solid content to less than 33 wt%. Uniform hydration was achieved by heating in a steam bath (85°C) for 20 min. Due to the metastability of mixtures of hydroxyceramides and cholesterol, variable incubation conditions were used. Thin-layer chromatography (TLC) ascertained the chemical stability of the compounds throughout these procedures (13).

Calorimetric scans were usually performed at 5°/min on a DuPont 910 differential scanning calorimeter. The melting point was determined by extrapolation to the baseline of the most rapid rise in the excess heat capacity curve as a function of temperature. This value is more reproducible than the maximum value of the excess heat capacity as a function of temperature curve and compensates for the rapid scan rate. The enthalpy was determined by integrating the area under the curve from a plot of the excess heat capacity as a function of temperature.

RESULTS AND DISCUSSION

In Figure 1, the differential scanning calorimetry traces of lyophilized and hydrated multilamellar dispersions of

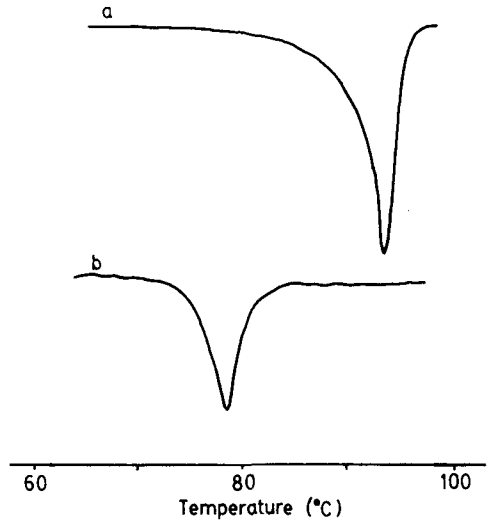

FIG. 1. Calorimetric scans at 5°C/min of (a) lyophilized hydroxyceramide and (b) hydrated hydroxyceramide (66 aqueous wt%).

hydroxyceramide are given. The lyophilized material undergoes an endothermic transition at 92°C (Fig. 1a). This involves conversion from a dry, solid form to an isotropic liquid as observed in a capillary tube. The transition is reversible and reproducible in repeated scans.

In Figure 1b, the endothermic transition of hydrated hydroxyceramide is illustrated. The transition occurs at 75.3 ± 0.2°C; the transition is reproducible and reversible. The width of the transition is reduced in comparison with the anhydrous material as can be expected because hydrating the lipid often enhances the cooperative nature of the phase transition. The opaque hydroxyceramide became slightly translucent when undergoing the transition as observed with a hot stage microscope or in a melting point apparatus. This is also a characteristic of the transition that occurs with phospholipids undergoing the gel-to-liquid crystalline phase transition. Thus, the endothermic transition observed with the hydroxyceramides may be analogous.

Previous investigators had indicated that difficulties exist in dispersing ceramides in water (14). The problems that were encountered may in part be due to the use of mixtures of hydroxyceramides and ceramides without hydroxy fatty acids, because the latter do not appear to undergo well-defined transitions and to form a lamellar phase. Although a detailed study was not undertaken, hydration of the sample could be accomplished by maintaining the temperature between 75 and 92°C, *i.e.* above the main endothermic transition of the hydrated material, but below the melting point of the lyophilized material. Another interesting observation is the lack of any decomposition, as judged by TLC, while maintaining the samples at these elevated temperatures for up to 30 min. This apparent stability may be significant in light of the presence of ceramides in the *stratum corneum.*

The enthalpy of hydrated hydroxyceramide was found to be 57 ± 8 J/g. Using an average molecular weight of 650, this corresponds to an enthalpy of 8.8 kcal/mol. Enthalpies of transition have been reported to be about 16 kcal/mol for kerasin and 7.4 kcal/mol for phrenosin, which are the corresponding fractions of nonhydroxy and hydroxy fatty acid galactosylceramides, respectively (15,16). Maggio *et al.* (14) reported enthalpies of kerasin and phrenosin of 6.2 and 5.0 kcal/mol. However, a later report revealed that the value given for phrenosin corresponded to a metastable phase change (17). The temperature of the main transition was apparently not altered, but upon long-term storage there was an increase in the enthalpy. The value obtained, 15.9 cal/g, is thus comparable to that observed with kerasin. In addition, fractionated hydroxy-containing galactosylceramides displayed a similar metastable behavior (17).

Based on Raman spectroscopic data, the differences in the enthalpies of transition were attributed to a higher disorder in the aliphatic chains in the gel state of phrenosin as compared to kerasin (15). In light of more recent results, phrenosin appears to also have highly ordered acyl chains in the gel state, but the presence of the hydroxyl group interferes with the rate of formation of the stable state (17). For both hydroxy and nonhydroxygalactosylceramides, the phase transition temperature appears to be relatively independent of acyl chain length which is in sharp contrast to the marked dependence seen with polar lipids such as phosphatidylcholines (17). This observation suggests that head group interactions are very important in the gel-to-liquid crystalline phase transition. Overall, the transition no doubt reflects a contribution from disruption of the acyl chain order as well as of intermolecular hydrogen bonding that exists in the gel state.

At this time it is not known whether the hydroxyceramides undergo a similar metastable-to-stable transition upon long-term storage as was found with phrenosin. Clearly the presence of the hydroxyl group would be expected to interfere with the formation of a highly ordered gel state. On the other hand, ceramides do not possess a galactosyl head group which contributes to the strong intermolecular interactions of cerebrosides in the gel state.

Another major lipid component found in *stratum corneum,* as in other membranes, is cholesterol; thus the effect of cholesterol on the thermal properties of hydroxyceramides was examined. Preliminary investigations revealed that above 7 wt%, but below 30 wt% cholesterol, a second transition was observed at a lower temperature. This was further followed with a sample of 25 wt% cholesterol in hydroxyceramide, and the results are shown in Figure 2.

The sample was prepared by drying a solution of cholesterol and ceramide under high vacuum overnight. Water was introduced and hydration was achieved by incubating at 85–90°C for 20 min. The sample was stored at room temperature for 2 days. The scan which appears in Figure 2a shows that the main transition is broadened and lowered. The interesting feature in this scan is the lower temperature transition seen between 55 and 60°C. After obtaining this scan, the sample was cooled rapidly to 20°C in an ice bath, and another scan was obtained immediately (Fig. 2b). As can be seen, the lower temperature transition occurs at about the same temperature, but is no longer endothermic but exothermic. Again the sample was cooled and thereafter stored in the refrigerator for 2 days. The calorimetric scan obtained is shown in Figure 2c which fails to reveal any low-temperature transition; however the low-temperature endotherm is reproduced

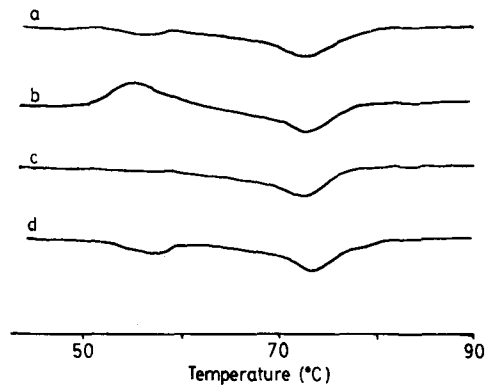

FIG. 2. Calorimetric scans at 5°C/min of hydrated 25 wt% cholesterol in hydroxyceramide after the following sequential storage conditions of (a) hydrated at 85°C for 20 min and cooled to room temperature and stored for 2 days, (b) immediate scan after quenching the sample used above to 20°C with ice, (c) stored in refrigerator for 2 days, and (d) cooled to room temperature and stored for 2 days.

(Fig. 2d) after holding the sample at room temperature for 2 days. Storage of samples for longer periods of time at room temperature, 5 days and 14 days, led to scans which had larger areas under the curve for the low-temperature endotherm suggesting that equilibrium still had not been obtained.

It should be noted that the temperature scan began at 30°C with a flat baseline obtained at 33–34°C. No transitions between 35 and 40°C were observed which would correspond to the polymorphic change of pure cholesterol hydrate (39°C) (18).

Since the temperature of each transition was apparently not affected by the length of incubation time, a somewhat arbitrary minimum time of 2 days at room temperature was used for all cholesterol/ceramide mixtures. Thereafter, thermal analyses of mixtures of cholesterol and hydroxyceramides were performed, and the results are shown in Figure 3. The high-temperature transition was broadened and lowered with increasing cholesterol content. The transition was still visible up to 40% cholesterol, although the transition was broadened to the extent that resolution from the baseline and the other endotherms became difficult. As mentioned, above 7 wt% a second endothermic transition was observed which occurred at a lower temperature (Fig. 3c and 3d). The temperature of this transition did not appear to vary with cholesterol content over the range of 15 to 30 wt% cholesterol. At 40 wt% and above, an additional transition was observed (Fig. 3h). The position of each of the two lower peaks varied in different samples and on occasion almost merged into one peak.

All calorimetric scans were analyzed in order to obtain an estimate of the peak transition temperature. The results are plotted in Figure 4 as a function of weight fraction cholesterol. The region of the diagram corresponding to temperatures above the high-temperature transition in all likelihood arises from miscible mixtures of hydroxyceramides with cholesterol in the liquid crystalline state. The other regions require further study for complete characterization, but it is of interest to consider several possibilities in the light of findings obtained with related lipid systems.

Thermal transitions with hydroxyceramides and cholesterol mixtures may arise from a geometric reorientation, rearrangement of hydrogen bonds, or phase separation. With pure *N*-palmitoylgalactosylsphingosine (nonhydroxy fatty acid galactosylceramide), the endothermic transition is believed to be the result of geometric reorientation associated with the hydration of the head group (19).

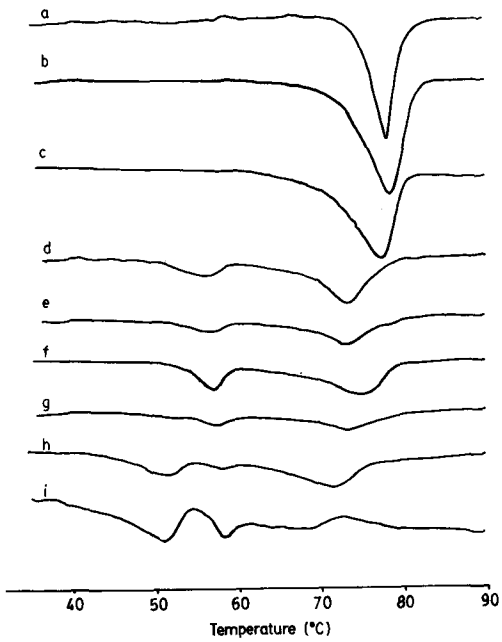

FIG. 3. Calorimetric scans at 5°C/min of hydrated mixtures of cholesterol and hydroxyceramide with percentage of cholesterol being (a) 0, (b) 3.9, (c) 7.3, (d) 15, (e) 20.8, (f) 25.2, (g) 31, (h) 40.4, and (i) 50%.

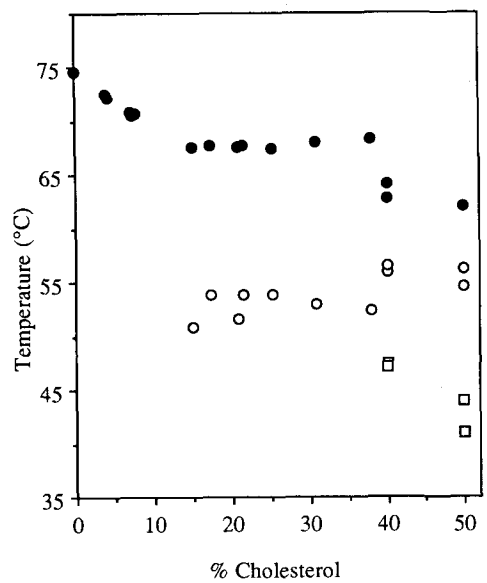

FIG. 4. Transition temperatures, which were determined by extrapolation of the most rapid rise of the calorimetric trace to the baseline, of cholesterol and hydroxyceramide mixtures as a function of percent cholesterol. Symbols indicate the (●) high-temperature, (○) intermediate-temperature, or (□) low-temperature thermal events. Most samples had only two thermal transitions.

Specifically, the low-temperature metastable state appears to have characteristics similar to those of the anhydrous lipid; however, as time-dependent hydration of the head group occurs, the increase in effective area causes a tilt in the lipids within the bilayer. For hydroxyceramides, the cross sectional area of the head group has been estimated by analysis of the surface pressure/surface area isotherm (20,21). The limiting area was found to be 40.5 $Å^2$/molecule which is roughly the same area as would be expected from the two aliphatic chains. Thus, there does not appear to be an energetic advantage for a change in the tilt angle.

Since the head groups of hydroxyceramides and cholesterol consist of amide and hydroxyl moieties, explanation for the observed thermal behavior is likely to account for changes in hydrogen bonding. Pascher and Sundell (22) have determined the crystal structure of β-D-galactosyl-*N*-(2-D-hydroxyoctadecanoyl)-D-dihydrosphingosine. They found that the hydrogen of the amide nitrogen was involved in intramolecular hydrogen bonding with the oxygens of the glycosidic linkage as well as the fatty acid hydroxyl group. This aspect played a pivotal role in determining the molecular conformation; and since this hydrogen bonding arrangement can also occur in hydroxyceramides, it may also be of importance in the interaction of hydroxyceramides with cholesterol.

It has been suggested that thermal transitions are a consequence of changes in the hydrogen bonding network. Specifically, bovine brain galactocerebrosides (type II, nonhydroxy fatty acid) shows metastable behavior which has been characterized by Fourier transform infrared spectroscopy (FTIR) (23). Initially, formation of hydrogen bonds with the carbonyl oxygen occurs; however, hydrogen bonds involving N-H groups in a plane perpendicular to N-H bending are formed with conversion to the stable form. Incorporation of cholesterol into galactosylceramide causes a disruption of the hydrogen bonds involving either the galactosyl or the sphingosine hydroxyl group; and since only one of the vibrational modes of the head group is affected, a very specific interaction between the cerebroside and cholesterol is indicated (23).

The importance of hydrogen bonding in the formation of the stable gel states has also been demonstrated in mixtures of phrenosin (bovine brain hydroxy fatty acid galactosylceramide) and cholesterol. In this study, low concentrations of cholesterol (9%) were observed to disrupt the cerebroside-cerebroside interaction (24). Thermal transitions were interpreted to be a result of two phases formed consisting of pure cerebroside and a mixture of cerebroside and cholesterol. As the cholesterol content was increased, four domains were noted. This was believed to be the result of a phase separation of the heterogeneous cerebroside sample. Thus, the studies indicate the intrinsic relationship between hydrogen bonding and phase separation in cerebrosides.

Finally, the thermal analysis shown in Figure 4 bears a striking similarity to that obtained with *N*-palmitoylgalactosylsphingosine and cholesterol mixtures where phase separation accounted for thermal transitions. In this study, Ruocco and Shipley (25) identified the region near the high-temperature transition as coexistence of a mixture of palmitoylgalactosylceramide and cholesterol in the liquid-crystalline state in combination with a cholesterol-free region of palmitoylgalactosylceramide in the gel state. The region about the low-temperature transition involved the transformation of cholesterol hydrate crystals and gel state palmitoylgalactosylceramide. Several possibilities were suggested for the region between the low- and high-temperature transitions.

In the present work, the use of samples containing a mixture of hydroxyceramides did not result in complicated phase separation as was seen with the phrenosin/cholesterol system. This may be due to weaker intermolecular attractions between ceramides which do not possess the galactosyl head group. The similarity between the thermal transitions observed with galactosylceramide/cholesterol and the hydroxyceramide/cholesterol mixtures makes the conclusion, that thermal behavior is a result of phase separation, tempting. If this is the case, then the region below the low-temperature transition would consist of an immiscible mixture of hydroxyceramide and cholesterol crystals. Furthermore, the low-temperature transition would correspond to the formation of a hydroxyceramide/cholesterol mixture coexisting with pure gel-state hydroxyceramide. Finally, the upper transition region would be a result of the melting of the gel-state hydroxyceramide with the eventual formation of a uniform liquid-crystalline mixture. Obviously, further studies are needed to characterize each phase with special emphasis on inter- and intramolecular hydrogen bonding occurring in the hydroxyceramide/cholesterol system.

For the study of the lipid interactions in the *stratum corneum*, use of the abundant ceramides isolated from bovine brain offers advantages (26,27). However, a careful examination of the composition of both the *stratum corneum* as well as the model system is necessary in order to identify potential pitfalls. With respect to bovine brain ceramides, the sphingosine base consists of a 88.5:8.5:3 ratio of C_{18}-sphingenine/C_{18}-sphinganine/C_{20}-sphingosine of which the sphinganine does not have a double bond in the 4,5 position (28,29). In the *stratum corneum*, the composition varies somewhat with the species under study (30–33). The amount of sphingolipids ranges from 15 to 35% of the total lipid weight. Upon further fractionation into glycosylated and non-glycosylated ceramides, the latter appear to become more abundant in the outer layers of the *stratum corneum*. Only about 22% of the pig epidermal ceramides have structural similarities to the hydroxyceramides used in the present study (32). By comparison, other laboratories have found in the pig (29), neonatal mouse (29), and human (28,30,31) that about one-third of the sphingolipids contain the sphingenine base, 15 to 20% 16:1, 15% 20:1, and about 3% representing phytosphingosine. Thus the *stratum corneum* would appear to have greater variability with respect to the sphingosine base than is observed with bovine ceramides.

With consideration of the amide-linked acyl chain, the bovine brain lipids consist of primarily 18:0, 24:0, and 24:1 with a smaller amount of 22:0 and trace amounts of the other fatty acids (34). In the present study, all the fatty acids contain an α-hydroxy group. In comparison, the skin contains primarily chains of 20, 24, 26 and to a lesser extent 28 carbons (28–32). In addition, only 10 to 15% of the ceramides contain α-hydroxy groups, and in one case, only negligible amounts were reported (29). Thus the bovine lipids have on average shorter acyl chains. The phase transition of galactosylceramides does not appear to be strongly dependent on chain length; however,

unsaturation does appreciably decrease the transition temperature (17). In addition, the metastability can be greatly affected by both chain length as well as unsaturation with galactosylceramides.

In summary, hydroxyceramides appear to form hydrated lamellar arrays which undergo endothermic phase transition. In the presence of cholesterol, there is a lowering and broadening of this transition. At cholesterol levels greater than 7%, a second transition is observed at a lower temperature which exhibits metastability. Finally, although mixtures of ceramides isolated from brain have a more uniform sphingosine base composition and relatively shorter *N*-acyl chains than found in *stratum corneum*, they should be useful for analysis of the lipid interactions that occur in *stratum corneum*.

ACKNOWLEDGMENTS

The assistance of Vincent Wong, supported by the Pharmaceutical Manufacturing Association-Undergraduate Research Opportunity Program, and Mark Sorsenson in preparation of the samples for thermal analysis is gratefully acknowledged. We appreciate the recommendation of Professor Stephen White to analyze the thermal properties of the lipids of the *stratum corneum*. Funding was provided in part by the University of Minnesota Graduate School.

[a]Laboratory of Nutrition Chemistry, Kyushu University School of Agriculture 46-09, Hakozaki, Fukuoka 812 and [b]Nisshin Oil Mills Co., Nihonbashi, Tokyo, 103 Japan

The effects of various structured triglycerides containing medium-chain (caprylic or capric acids) and long-chain (linoleic acid) fatty acids on fatty acid and cholesterol absorption were studied in lymph-cannulated rats. A considerable portion of capric and caprylic acid was absorbed through the lymph duct, although to a lesser extent than was linoleic acid. Capric and linoleic acid located at the 2-position of 2-decanoyl-1,3-dilinoleoyl-glycerol (18:2/10:0/18:2) and 2-linoleoyl-1,3-didecanoyl-glycerol (10:0/18:2/10:0), respectively, tended to be absorbed more efficiently than those located at the 1- and 3-position or those from tricaprin (10:0/10:0/10:0) or trilinolein (18:2/18:2/18:2). A similar trend was observed when the medium-chain fatty acid was caprylic acid instead of capric acid. Caprylic acid absorption from 2-octanoyl-1,3-dilinoleoyl-glycerol (18:2/8:0/18:2) was significantly greater ($p<0.05$) than from 2-linoleoyl-1,3-dioctanoyl-glycerol (8:0/18:2/8:0) or tricaprylin (8:0/8:0/8:0). Preferential absorption of caprylic and linoleic acid was not observed when the 1 to 2 and the 2 to 1 mixtures of 8:0/8:0/8:0 and 18:2/18:2/18:2, respectively, were administered. The structured lipids did not affect the lymphatic absorption of cholesterol. The results suggest that structured triglycerides composed of medium-chain fatty acids and linoleic acid may be more useful for the treatment of lipid malabsorption than are mixtures of medium-chain triglyceride (MCT) and long-chain triglyceride (LCT).

Lipids 26, 369–373 (1991).

The absorption of medium-chain triglycerides (MCT) in the intestine is different from that of long-chain triglycerides (LCT). LCT is hydrolyzed to 2-monoglyceride and free fatty acids by pancreatic lipase in the upper intestine, and the hydrolysis products are absorbed as components of mixed micellar solutions into the intestinal mucosa (1–3). 2-Monoglycerides are micellarized and absorbed more readily than are free fatty acids. The hydrolysis products are reutilized to form triglycerides in the mucosal cells and are transported to the lymph in chylomicrons. In chylomicrons, approximately 75% of the fatty acids located in the 2-position of the triglyceride are conserved in the original position, whereas fatty acids released from the 1- and 3-positions bind to glycerol at random (4).

Abbreviations: 18:2/10:0/18:2, 2-decanoyl-1,3-dilinoleoyl-glycerol; 10:0/18:2/10:0, 2-linoleoyl-1,3-didecanoyl-glycerol; 8:0/18:2/8:0, 2-linoleoyl-1,3-dioctanoyl-glycerol; EDTA, ethylenediaminetetraacetic acid; HPLC, high-performance liquid chromatography; LCT, long-chain triglyceride; MCT, medium-chain triglyceride; TLC, thin-layer chromatography; 18:2/8:0/18:2, 2-octanoyl-1,3-dilinoleoyl-glycerol; 10:0/10:0/10:0, 1,2,3-tridecanoyl-glycerol (tricaprin); 18:2/18:2/18:2, 1,2,3-trilinoleoyl-glycerol (trilinolein); 8:0/8:0/8:0, 1,2,3-trioctanoyl-glycerol (tricaprylin).

MCT are hydrolyzed readily and completely to free fatty acids and glycerol *via* 2-monoglyceride not only by pancreatic lipase but also by lingual or gastric lipase, and are then incorporated into mucosal cells. Medium-chain fatty acids are more hydrophilic than are their long-chain counterparts, and hence solubilization as micelles is not a prerequisite for absorption. MCT can also be incorporated into mucosal cells without hydrolysis (5) and can readily be hydrolyzed in the cell. The medium-chain fatty acids that are liberated are directly transported into the portal vein and readily oxidized in the liver to serve as an energy source. Thus, MCT have been used as a preferable fat source in the treatment of lipid malabsorption, such as pancreatic insufficiency and intestinal resection (6–10). Since MCT do not provide essential fatty acids, they are for enteral alimentation usually supplemented with polyunsaturated fats. However, there is a strong possibility that supplemented polyunsaturated fat may not be sufficiently absorbed by the intestine of patients with malabsorption disorders.

Recently, structured triglycerides which contain both medium-chain and polyunsaturated fatty acids in the same molecule have become available, and they are expected to be an efficient source for both medium-chain and essential fatty acids (7,11). However, the role of these structured lipids in intestinal absorption and fatty acid transport is not fully understood.

In the present study, the characteristic absorption patterns of structured glycerolipids containing medium-chain fatty acids, *i.e.* caprylic or capric acid, and linoleic acid, have been investigated in lymph-cannulated rats. The effect of these structured lipids on cholesterol absorption was also investigated.

MATERIALS AND METHODS

[4-^{14}C]Cholesterol (60 mCi/mmole) was purchased from NEN Research Products (Boston, MA) and purified prior to use by thin-layer chromatography (TLC) with benzene/ethyl acetate (7:3, v/v) as developing solvent. Fatty acid-free bovine serum albumin was obtained from Miles Inc. (Kankakee, IL). Sodium taurocholate (purity >98%) and cholesterol were purchased from Nacalai Tesque (Kyoto, Japan). Caprylic, capric and linoleic acid (purity>99%) were purchased from Wako Pure Chemicals Co. (Osaka, Japan). Tricaprylin (8:0/8:0/8:0), tricaprin (10:0/10:0/10:0) and trilinolein (18:2/18:2/18:2) were synthesized by direct esterification of glycerol with fatty acid (12). 2-Decanoyl-1,3-dilinoleoyl-glycerol (18:2/10:0/18:2), 2-linoleoyl-1,3-didecanoyl-glycerol (10:0/18:2/10:0), 2-octanoyl-1,3-dilinoleoyl-glycerol (18:2/8:0/18:2) and 2-linoleoyl-1,3-dioctanoyl-glycerol (8:0/18:2/8:0) were prepared by transesterification of 8:0/8:0/8:0, 10:0/10:0/10:0 or 18:2/18:2/18:2 with caprylic, capric or linoleic acid using 1,3-specific lipase (13). The crude preparations of LCT, MCT and structured

triglycerides were purified with preparative high-performance liquid chromatography (HPLC) (ODS column, 20 cm × 1 m) using ethanol as eluent. The purity of the structured lipids obtained was estimated by the IUPAC method (14). In short, after hydrolysis of the triglycerides with pancreatic lipase, the free fatty acids and 2-monoglycerides formed were separated by TLC using hexane/diethyl ether/formic acid (70:30:1, v/v/v) as developing solvent. Lipids were transmethylated with BF_3/methanol, and fatty acid methyl esters were subjected to gas-liquid chromatography on a 10% SILAR 10C column (15). Purities of the triglycerides were as follows: 18:2/18:2/18:2, 95.3%; 10:0/10:0/10:0, 98.2%; 8:0/8:0/8:0, 99.5%; 18:2/10:0/18:2, 92.2%; 10:0/18:2/10:0, 90.4%; 18:2/8:0/18:2, 91.0%, and 8:0/18:2/8:0, 91.2%. The major impurities of the structured lipids were the corresponding positional isomers. For example, 18:2/10:0/18:2 contained 1,2-dilinoleoyl-3-decanoyl-glycerol as major impurity.

Male Sprague-Dawley rats (Seiwa Experimental Animals, Fukuoka, Japan) weighing 290–350 g were given *ad libitum* a commercial non-purified diet (type NMF, Oriental Yeast Co., Tokyo, Japan) and drinking water. Rats were subjected to cannulation of the left thoracic lymphatic channel, and an indwelling catheter was placed in the stomach. Physiological saline/5% glucose solution was infused continuously, at a rate of 3 mL/hr until the end of lymph collection (15). After surgery, animals were placed in restraining cages in a warm recovery room and allowed free access to drinking water containing physiological saline/5% glucose. Each animal was administered 2 mL of a test emulsion in experiments 1 to 3, and 3 mL in experiment 4, through the gastric tube; lymph was collected for 24 hr beginning at 10:00 a.m. The composition of the test emulsion is shown in Table 1. In experiment 4, the composition of test emulsion was changed to emulsify cholesterol more completely. The mole amount of triglyceride used was adjusted to be the same for each type of triglyceride in each experiment. A control emulsion that did not contain lipid was administered to a control group in each experiment.

The emulsions were prepared by sonication and contained 18:2/18:2/18:2, 10:0/10:0/10:0, 18:2/10:0/18:2 or 10:0/18:2/10:0 in experiment 1, and 18:2/18:2/18:2, 8:0/8:0/8:0, 18:2/8:0/18:2 or 8:0/18:2/8:0 in experiment 2. Although the mole amount of triglyceride administered to the rats was the same in experiments 1 and 2, the number of moles of linoleic acid administered differed. In experiment 3, to adjust the number of moles of both triglyceride and linoleic acid, the absorption of fatty acids from structured lipids was compared with the absorption of mixtures of LCT and MCT which resembled the fatty acid composition of the structured lipids. Thus, the test emulsions contained 8:0/18:2/8:0, 18:2/8:0/18:2 or the 1 to 2 or the 2 to 1 mixtures of 18:2/18:2/18:2 and 8:0/8:0/8:0. In experiment 4, radioactive cholesterol was added to the emulsion to determine the effect of the structured lipids, LCT and MCT on cholesterol absorption. The lymph was collected in a tube containing ethylenediaminetetraacetic acid (EDTA) at 3 hr-intervals during the first 9 hr after administering the test or control emulsion and as a single collection from 9–24 hr thereafter.

Chylomicrons from the lymph were collected by ultracentrifugation (16). Lipids were extracted with 20 vol of chloroform/methanol (2:1, v/v) according to the method of Folch *et al.* (17). Pentadecanoic acid (Aldrich, Milwaukee, WI) was added as an internal standard. After the chloroform extract was dried under nitrogen, lipids were analyzed by gas-liquid chromatography as described above. The fatty acid absorption rate was calculated by subtracting the fatty acid amount in blank lymph of the control group from that of the groups administered a test emulsion.

In experiment 4, 1-mL aliquots of the lymph were transferred into scintillation vials and 10 mL of Aquasol II (NEN Research Products) was added. Radioactivity was measured using an Aloka liquid scintillation counter (LSC-900, Aloka, Tokyo, Japan).

Statistical analysis. One-way analysis of variance was followed by Duncan's new multiple-range test to determine the exact nature of the difference between groups (18).

TABLE 1

Composition of Test Emulsion

	Experiments 1, 2 and 3	Experiment 4
Sodium taurocholate	47 mg	192 mg
Albumin	8.3 mg	33.3 mg
Cholesterol	—	10 mg
[4-^{14}C]Cholesterol	—	1 μCi
Structured lipid	0.2 mmole	0.3 mmole
Water	to 2 mL	to 3 mL

RESULTS

The lymph flow rates are summarized in Table 2. Although there were significant differences in the lymph flow rates in different experiments, no consistent pattern of change was observed.

Experiment 1. The lymphtic absorption of capric and linoleic acid is shown in Figure 1. The absorption of capric acid was considerably lower than that of linoleic acid. Absorption of linoleic acid in the case of 10:0/18:2/10:0 (81.4 ± 11.0%) for 24 hr tended to be higher than for 18:2/18:2/18:2 (66.5 ± 8.3%) and 18:2/10:0/18:2 (58.8 ± 13.0%). Similarly, more capric acid was absorbed from 18:2/10:0/18:2 (34.3 ± 4.9%) as compared to 10:0/10:0/10:0 (25.9 ± 7.8%) and 10:0/18:2/10:0 (26.4 ± 2.9%). However, the portion of these fatty acids carried as chylomicrons tended to decrease in the structured lipids when compared to 18:2/18:2/18:2 and 10:0/10:0/10:0, although the differences were not significant (Table 3).

Experiment 2. The lymphatic absorption of caprylic and linoleic acid is shown in Figure 2. The results are similar to those for capric and linoleic acid which were studied in experiment 1. Lymphatic absorption of caprylic acid was much lower than that of linoleic acid, and was also lower than that of capric acid (compare Figs. 1 and 2). Linoleic acid absorption from 8:0/18:2/8:0 (92.4 ± 9.7%) for 24 hr tended to be higher than from 18:2/18:2/18:2 (77.2 ± 7.2%) and 18:2/8:0/18:2 (75.3 ± 9.1%). The trend toward efficient absorption of medium-chain fatty acids located at the 2-position of the triglyceride was more pronounced when caprylic acid rather than capric acid was used.

Caprylic acid absorption from 18:2/8:0/18:2 (15.0 ± 2.9%) was significantly higher ($p<0.05$) than from 8:0/8:0/8:0 (4.3 ± 1.0%) or 8:0/18:2/8:0 (6.5 ± 1.7%). The portion of absorbed caprylic and linoleic acid carried in chylomicrons was significantly lower when these fatty acids were given as 8:0/18:2/8:0 rather than as 18:2/18:2/18:2, 18:2/8:0/18:2 or 8:0/8:0/8:0 (Table 4).

Experiment 3. Absorption of linoleic and caprylic acid as structured lipids (8:0/18:2/8:0 and 18:2/8:0/18:2) and as the 1 to 2 and the 2 to 1 mixtures of 18:2/18:2/18:2 and

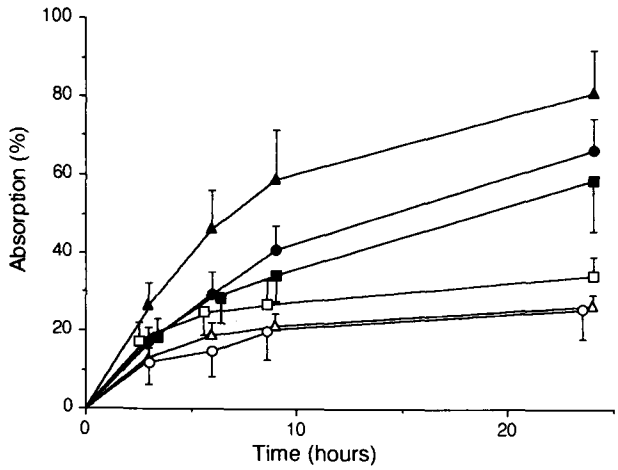

FIG. 1. Absorption of capric and linoleic acids into thoracic duct lymph of rats upon intragastric administration of fat emulsions containing sodium taurocholate and albumin. ●, ■ or ▲ shows linoleic acid absorption in rats given 18:2/18:2/18:2, 18:2/10:0/18:2 or 10:0/18:2/10:0, respectively. ○, □ or △ shows capric acid absorption in rats given 10:0/10:0/10:0, 18:2/10:0/18:2 or 10:0/18:2/10:0, respectively. Data are means ± SE of 5 or 6 rats. Significant differences were not observed in this experiment.

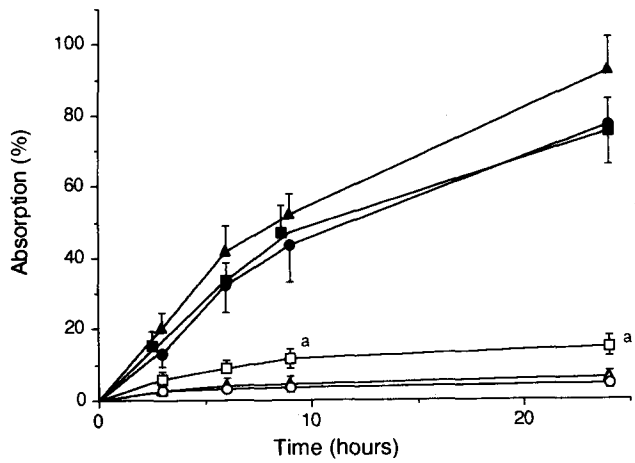

FIG. 2. Absorption of caprylic and linoleic acids into thoracic duct lymph of rats. ●, ■ or ▲ shows linoleic acid absorption in rats given 18:2/18:2/18:2, 18:2/8:0/18:2 or 8:0/18:2/8:0, respectively. ○, □ or △ shows caprylic acid absorption in rats given 8:0/8:0/8:0, 18:2/8:0/18:2 or 8:0/18:2/8:0, respectively; a, caprylic acid absorption was significantly higher in 18:2/8:0/18:2 than in 8:0/8:0/8:0 and 8:0/18:2/8:0 groups at $p<0.05$. Data are means ± SE of 5 to 7 rats.

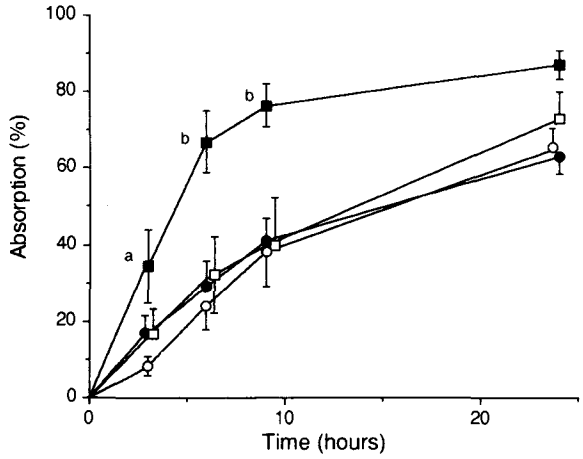

FIG. 3. Absorption of linoleic acid into thoracic duct lymph of rats. ●, ■, ○ or □ shows linoleic acid absorption in rats given 18:2/8:0/18:2, 8:0/18:2/8:0, a 1 to 2 or a 2 to 1 mixture of 8:0/8:0/8:0 and 18:2/18:2/18:2, respectively; a, significantly higher than the other three groups at $p<0.05$; b, significantly higher than the 1 to 2 mixture of 8:0/8:0/8:0 and 18:2/18:2/18:2 at $p<0.05$. Data are means ± SE of 5 or 6 rats.

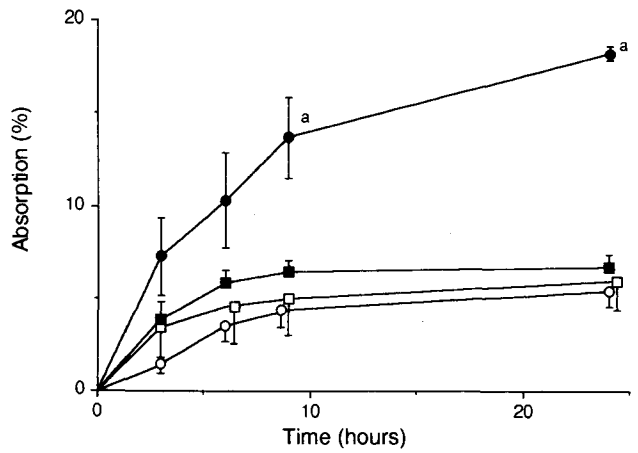

FIG. 4. Absorption of caprylic acid into thoracic duct lymph of rats. ●, ■, ○ or □ shows caprylic acid absorption in rats given 18:2/8:0/18:2, 8:0/18:2/8:0, a 1 to 2 or a 2 to 1 mixture of 8:0/8:0/8:0 and 18:2/18:2/18:2, respectively; a, significantly higher than the other three groups at $p<0.05$. Data are means ± SE of 5 or 6 rats.

8:0/8:0/8:0 is shown in Figures 3 and 4, respectively. The rate of absorption of linoleic and caprylic acid located at the 2-position of the structured lipids was more efficient than that of the fatty acids from a mixture of single-acid triglycerides and of the fatty acids located at the 1- and 3-positions of the structured lipids. Linoleic acid absorption from 8:0/18:2/8:0 for 24 hr was 87.2 ± 3.8% as compared to 73.2 ± 6.8% for the 1 to 2 mixture of 18:2/18:2/18:2 and 8:0/8:0/8:0, 63.1 ± 4.6% for 18:2/8:0/18:2, and 65.5 ± 5.0% for the 2 to 1 mixture of 18:2/18:2/18:2 and 8:0/8:0/8:0. Caprylic acid absorption from 18:2/8:0/18:2 (18.3 ± 0.4%) was significantly higher ($p<0.05$) than that from the 2 to 1 mixture of 18:2/18:2/18:2 and 8:0/8:0/8:0 (5.4 ± 0.9%), from 8:0/18:2/8:0 (6.7 ± 0.6%) and from the 1 to 2 mixture of 18:2/18:2/18:2 and 8:0/8:0/8:0 (5.9 ± 1.6%).

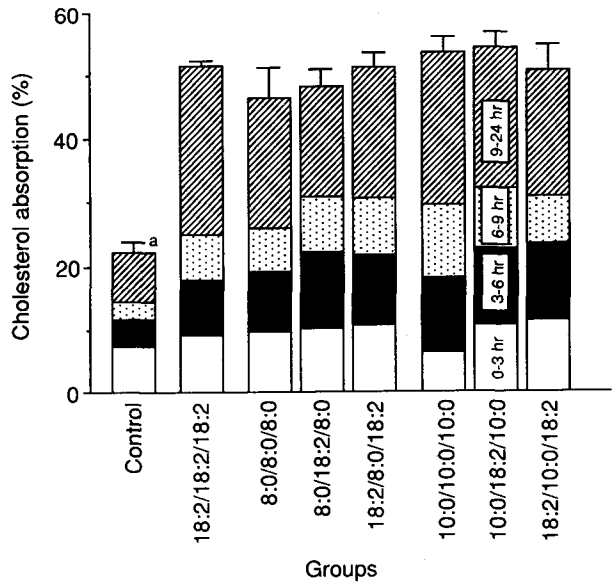

FIG. 5. Absorption of cholesterol into thoracic duct lymph of rats after intragastric administration of fat emulsions containing sodium taurocholate, labeled cholesterol and albumin; a, significantly lower than all other groups at $p<0.05$. Data are means ± SE of 5 to 7 rats.

Experiment 4. The effect of the structured lipids, 18:2/18:2/18:2, 8:0/8:0/8:0 and 10:0/10:0/10:0 on cholesterol absorption is shown in Figure 5. Lipid administration stimulated cholesterol absorption to a considerable extent as compared to the control group given a fat-free emulsion. However, the type of dietary fat did not significantly influence cholesterol absorption.

DISCUSSION

It is widely believed that medium-chain fatty acids are mainly absorbed and transported through the portal vein and that lymphatic absorption is minimal (19). However, as far as we know, the extent of lymphatic absorption of medium-chain fatty acids has not been investigated. We have shown in the present study that a portion of the medium-chain fatty acids is absorbed through lymph, but to a much smaller extent than is linoleic acid. Lymphatic absorption of capric acid is greater than that of caprylic acid. The differential absorption of these two medium-chain fatty acids may be due to their different hydrophobicity.

Based on the observed absorption characteristics of MCT and LCT, it would seem reasonable that structured lipids which contain medium-chain fatty acids in the 1- and 3-position and linoleic acid in the 2-position may have some beneficial effects both as an energy source and as a source of essential fatty acid. This could be of particular importance for patients with malabsorption syndromes receiving enteral alimentation. As shown in the present study, even in rats with normal pancreatic function, lymphatic absorption of linoleic acid from the 2-position was consistently higher than from the 1- and 3-positions, or from trilinolein (Figs. 1 and 2).

The mole amounts of linoleic acid and medium-chain fatty acids administered to the rats were different in these

experiments. Therefore, in experiment 3, the absorption of fatty acids from structured lipids was compared with that from mixtures of LCT and MCT with the same fatty acid composition. The results of the preceding experiments were confirmed and we could show that linoleic acid located in the 2-position of 8:0/18:2/8:0 was absorbed preferentially as compared to linoleic acid from the 18:2/18:2/18:2 and 8:0/8:0/8:0 mixture.

Jandacek *et al.* (20) reported that hydrolysis of triglycerides with medium-chain fatty acids in the 1- and 3-position and a long-chain fatty acid in the 2-position was more rapid *in vitro* than of LCT. The incorporation of radioactivity from 2-[^{14}C]linoleoyl-1,3-dioctanoyl-glycerol (8:0/18:2/8:0) into an isolated, irrigated intestinal loop was 2.5 times higher than that from 2-[^{14}C]linoleoyl-1,3-dioleoyl-glycerol. Therefore, the rapid and complete hydrolysis of the medium-chain fatty acids located in the 1- and 3-positions of the structured lipids appears to be responsible for the higher lymphatic absorption of linoleic acid located in the 2-position. In patients with an insufficient supply of pancreatic lipase, structured lipids with medium-chain fatty acids in the 1- and 3-position and polyunsaturated fatty acid in the 2-position should also be useful.

It has been reported that some long-chain fatty acids are transported through the portal vein (19). However, since portal absorption of linoleic acid is extremely low, the contribution of this pathway to the lower lymphatic absorption of linoleic acid in the 1- and 3-position of structured lipids can be disregarded.

Our results also show that the lymphatic absorption of medium-chain fatty acids located in the 2-position of the structured lipids was more efficient than of those located in the 1- and 3-position. The results suggest that prior to complete hydrolysis of medium-chain 2-monoglycerides to free fatty acid and glycerol, a portion of the 2-monoglycerides would be absorbed intact and utilized in triglyceride resynthesis in intestinal mucosa for lymphatic transport. It is plausible that the medium-chain fatty acids released from the 1- and 3-position are predominantly transported through the portal vein without resynthesis to triglyceride.

Several studies have shown that the concentration of serum and liver cholesterol is lower in rats fed MCT than in rats fed LCT. It would be possible that MCT decrease intestinal absorption of cholesterol (6). However, our results do not support this conclusion, as in our experiments MCT and structured lipids did not influence lymphatic cholesterol absorption. However, this would not preclude that long-term feeding of MCT or structured lipids may affect the various functions of intestinal cells including cholesterol absorption. Redgrave *et al.* (21) suggested that the 2-monoglyceride transiently formed during hydrolysis of chylomicron triglyceride by lipoprotein lipase in the capillaries may be an important factor in the metabolic control of chylomicrons and hence, serum cholesterol concentration.

Structured lipids clearly influence the incorporation of fatty acids into chylomicrons, and several dietary components affect the size and composition of chylomicrons. Phospholipids also modify the particle size of chylomicrons in the lymph (22). Vahouny *et al.* (23) furthermore showed that dietary fiber alters the rate of incorporation of cholesterol and oleic acid into lymphatic chylomicrons. However, the reasons and the metabolic significance of these differential distributions of fatty acids are not clear at present.

Effect of 4,7,10,13,16,19-Docosahexaenoic Acid on Triglyceride Accumulation and Secretion in Rat Hepatocytes in Culture

L.J. Martin, G.B. Reaidi, G.R. Gavino and V.C. Gavino*
Department of Nutrition, University of Montréal, P.O. Box 6128 Station "A", Montréal, Québec, Canada H3C 3J7

We have investigated the effect of oleic (18:1) and 4,7,10,13,16,19-docosahexaenoic (22:6ω3) acids on triglyceride (TG) accumulation, secretion and reuptake in rat hepatocytes in culture. We also calculated the percentage of total TG, TG-esterified 18:1 and TG-esterified 22:6ω3 that were secreted relative to the total accumulation (intra + extracellular TG). Both fatty acids were incorporated mainly in the intracellular TG fraction. Treatment with 18:1 but not with 22:6ω3 increased the quantity of TG secreted into the culture medium relative to controls. Treatment with 22:6ω3 caused a greater accumulation of intracellular TG than 18:1. This arises in part from the preferential retention of 22:6ω3-enriched TG by the hepatocytes. At 24 hr, there was no longer any difference in the net secretion of TG by 18:1 and 22:6ω3-treated cells, which may be a consequence of the reuptake of TG-esterified 18:1. There was no reuptake of TG-esterified 22:6ω3. We conclude that inhibition of hepatocyte TG synthesis is not obligatory for 22:6ω3-induced diminution of TG secretion.

Lipids 26, 374-380 (1991).

It is generally stated that the hypotriglyceridemic effect of dietary fish oil arises from an inhibitory effect of long-chain ω3 polyunsaturated fatty acids (PUFA) on triglyceride (TG) synthesis in the liver (1). Several investigators have reported that the inhibition of TG synthesis may be due to changes in the activity of diacylglycerol acyltransferase (2,3), of phosphatidate phosphohydrolase (4), or of a general reduction in the activity of lipogenic enzymes involved in fatty acid synthesis (5-7).

There are, however, other reports indicating that a decrease in TG secretion induced by ω3 PUFA is not necessarily linked to inhibition of TG synthesis. These contradictory results are probably due to dissimilarity in the experimental models used, and to possible metabolic differences between 20:5ω3 and 22:6ω3, the two major PUFA in fish oil. For example, Haug and Hostmark (8) reported that dietary fish oil increases hepatic TG content despite a significant hypotriglyceridemic effect. Wong *et al.* (9) showed that 22:6ω3 but not 20:5ω3 was just as effective as 18:1 in stimulating TG accumulation in HepG2 cells although both ω3 PUFA inhibited TG secretion. Davis and Boogaerts (10) found that the degree of unsaturation of 18-carbon fatty acid (FA) was inversely related to TG secretion in cultured rat hepatocytes, but not at all correlated with intracellular TG accumulation. In an abstract, Fox and Hay (11) reported that 20:5ω3 reduced TG secretion but not TG synthesis in rat hepatoma cells.

It is in this context that we have decided to investigate further the effects of 22:6ω3 on TG accumulation, secretion and reuptake in primary cultures of rat hepatocytes. Our data show that 22:6ω3-induced decrease in TG secretion is not necessarily due to a decrease in TG synthesis, and that the TG-esterified 22:6ω3 is preferentially retained by the hepatocytes.

MATERIALS AND METHODS

Preparation and culture of hepatocytes. Hepatocytes from *ad libitum* chow-fed male 300-g Sprague-Dawley rats (Charles River, Montréal, Québec Canada) were isolated under sterile conditions by collagenase perfusion according to the method of Seglen (12). Cells were preincubated for 30 min in culture medium consisting of Dulbecco's Modified Eagle medium (Gibco, Burlington, Ontario Canada) containing 24 mM glucose, 1 mM pyruvate, 70 mM 4-hydroxyethyl-1-piperazineethanesulfonic acid (Sigma, St. Louis, MO) and 50 μg/mL of gentamycin (Gibco, Burlington, Ontario Canada). Hepatocytes were plated at a concentration of 3.0×10^6 viable cells per 25-cm^2 flask in culture medium supplemented with 20% newborn calf serum (Gibco) and insulin (10 μg/mL) as described by Nossen *et al.* (13). After 4 hr, the culture medium was changed to remove non-adherent cells. The remaining attached cells were incubated overnight at 37°C in an atmosphere of 5% CO_2 in air.

Experiments with cultured hepatocytes. The fatty acids (FA) 18:1 and 22:6ω3 were obtained from NuChek Prep (Elysian, MN). These were 97-98% pure as evaluated by gas-liquid chromatography (GLC). At the beginning of each experiment, cells were incubated with culture medium containing 4% essentially fatty acid-free bovine serum albumin (BSA) (Sigma), 1 mM FA and 1 μM butylated hydroxytoluene (BHT) as antioxidant. The cells were incubated for 2, 8 and 24 hr at 37°C. At the end of the incubation period, the media were removed and centrifuged at 5000 rpm (4°C) for 10 min prior to analysis. The attached cells were rinsed twice with phosphate buffered saline before lipid extraction.

Cells were detached from flasks with trypsin and viable cells, distinguished by Trypan blue exclusion, were counted with a hemocytometer. Protein was measured by the method of Lowry *et al.* (14). The quantity of lactate dehydrogenase released into the medium was measured as described previously (15) at the end of the 24-hr incubation period as an indicator of the extent of cell death.

TG reuptake. Parallel hepatocyte cultures were incubated with [1-^{14}C]18:1 (100 dpm/nmol), [1-^{14}C]22:6ω3 (100 dpm/nmol), unlabeled 18:1, or unlabeled 22:6ω3 under

Abbreviations: BHT, butylated hydroxytoluene; BSA, bovine serum albumin; CE, cholesteryl ester; FA, fatty acid; GLC, gas-liquid chromatography; NEFA, non-esterified fatty acid; PL, phospholipid; PUFA, polyunsaturated fatty acids; TG, triglyceride; TLC, thin-layer chromatography; VLDL, very low-density lipoprotein.

the conditions described above. After 8 hr, the culture media from cells treated with the labeled FA were recovered, centrifuged (5000 rpm, 4°C) for 10 min, and supplemented with 200 μM chloroquine. The recovered media contained [1-^{14}C]18:1-enriched TG or [1-^{14}C] 22:6ω3-enriched TG and were used for the next step of the experiment. After 8 hr of incubation, 200 μM chloroquine was added to the parallel hepatocyte cultures treated with non-radioactive FA. After a 30-min incubation with chloroquine, the non-radioactive culture media of these cells were discarded and replaced with radioactive media recovered from the hepatocytes treated with labeled FA. Cells originally treated for 8 hr with unlabeled 18:1 were incubated for a further 6 hr with media containing either [1-^{14}C]18:1-enriched TG or [1-^{14}C]22:6ω3-enriched TG. Cells originally treated with unlabeled 22:6ω3 were also incubated for a further 6 hr with media containing either [1-^{14}C]18:1-enriched TG or [1-^{14}C]22:6ω3-enriched TG. At the end of the 6-hr incubation period, ^{14}C-labeled TG in the culture media was isolated by thin-layer chromatography (TLC) using ^{3}H-labled triolein (DuPont, Mississauga, Ontario Canada) as recovery standard. Incubation of radioactive culture media in culture flasks without cells served as controls.

Extraction and separation of lipids. BHT was added at 4 ppt to all redistilled solvents used in the extraction, separation and storage of lipids. Lipids in the culture medium were extracted by the method of Bligh and Dyer (as described in ref. 16). Cellular lipids were extracted as previously described (17). Heptadecanoic acid, triheptadecanoin, cholesteryl heptadecanoate and 1,2-diheptadecanoyl phosphatidylcholine (Sigma) were added to cells and media as internal standards for quantitation of lipids. Non-esterified fatty acids (NEFA), TG, phospholipids (PL) and cholesteryl esters (CE) were separated by thin-layer chromatography (TLC) using pre-coated Whatman type-LK6D silica gel plates (Supelco, Oakville, Ontario Canada) with the solvent system hexane/diethyl ether/acetic acid (80:20:1, v/v/v). Radioactivity in lipid fractions was determined by liquid scintillation counting of scrapings from the TLC plates. Lipid fractions were recovered from TLC for gas-liquid chromatography (GLC) by eluting the TLC plates with diethyl ether for CE and TG, chloroform for NEFA, and methanol/water (96:4, v/v) for PL.

Determination of fatty acid composition. Lipid fractions isolated by TLC were transesterified to FA methyl esters by treatment with sodium methoxide (18). NEFA were derivatized with diazomethane. FA methyl esters were separated on a 30-m bonded Carbowax-30N fused silica capillary column installed in a Hewlett-Packard HP5890 gas chromatograph equipped with a flame ionization detector. Quantitation was achieved with a HP3392A integrator using the internal standard method.

RESULTS

Table 1 shows that FA treatments did not affect viable cell counts nor total cell protein. This indicates that under our incubation conditions, the FA treatment did not exert a toxic effect on the hepatocytes. This was confirmed by measuring lactate dehydrogenase in the culture medium as an indicator of cell death. The enzyme level was similar across all groups and was in agreement with a previous report concerning cultures of viable cells (19).

The disappearance of 22:6ω3 and 18:1 from the culture medium during the incubation period with hepatocytes is shown in Figure 1. NEFA concentration

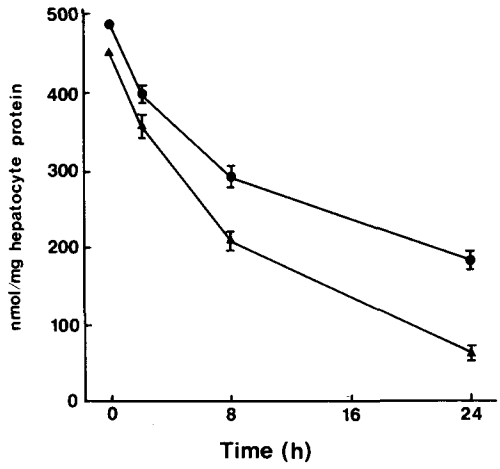

FIG. 1. Uptake of fatty acid by hepatocytes in culture. Cells were incubated with 18:1 (●) or with 22:6ω3 (▲). The decline in NEFA concentration during the incubation period, measured by quantitative GLC, was assumed to represent cellular uptake. Each point is the mean ± s.e.m. of three separate experiments.

TABLE 1

Effect of Fatty Acid Treatment on Hepatocyte Viability[a]

	Treatment group		
	Control	18:1	22:6ω3
	mean ± s.e.m. (n = 3)		
Viable cells (× 10^{-4}/cm^2)	1.67 ± 0.26	1.57 ± 0.09	1.53 ± 0.09
Cell protein (mg/25 cm^2 flask)	5.5 ± 0.4	5.4 ± 0.3	4.7 ± 0.2
LDH activity, culture medium (nmol/s × mg protein)	5.5 ± 0.2	4.7 ± 0.4	3.4 ± 0.5

[a]Rat hepatocytes were isolated by collagenase perfusion, placed in cell culture, and treated for 24 hr with 1 mM total NEFA bound to BSA. Dye-exclusion was used as the criterion for cell viability after NEFA treatment. Cell protein represents attached cells. There was no statistical significance between treatment groups at $\alpha = 0.01$ (Scheffe).

TABLE 2

Uptake of [1-^{14}C]-labeled 22:6ω3 and 18:1 Analyzed by Two-Way ANOVA

Treatment group	Incubation time (hr)	
	0[a]	8
	Dpm (mean ± s.e.m., n = 3)[b]	
[1-^{14}C] 18:1	39200 ± 4000	23200 ± 2600
[1-^{14}C] 22:6ω3	38500 ± 2600	18900 ± 1400

[a]Hepatocytes were treated with BSA-complexed 1 mM radiolabeled 18:1 or 22:6ω3 and radioactivity in the culture medium was assayed at time 0 and after 8 hr.

[b]Dpm per culture flask. The two classifications used in the ANOVA analysis were treatment group *vs* incubation time. The between group interaction term was significant at $p<0.001$.

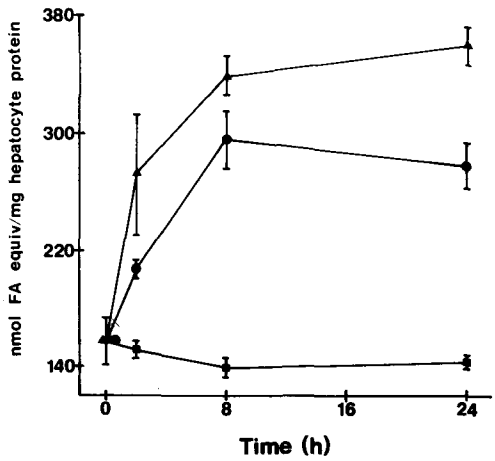

FIG. 2. Accumulation of intracellular triglyceride in hepatocytes in culture. The TG of cells, control (■) or incubated with 18:1 (●) or 22:6ω3 (▲), were extracted and separated by TLC using triheptadecanoin as a recovery standard. Each point represents the mean ± s.e.m. of three experiments. The data were subjected to ANOVA using Newman-Keuls multiple range testing to detect differences between means. Significance was declared at $p<0.05$.

did not change in culture medium incubated under the same conditions but without hepatocytes (data not shown). The rate of disappearance of 22:6ω3 was faster than that of 18:1 even when the data are normalized to initial NEFA concentrations. At 8-hr incubation time, the cells took up 40% and 54% of the initial 18:1 and 22:6ω3, respectively. These results were confirmed using [1-^{14}C]-labeled NEFA (Table 2). Two-way ANOVA analysis of the data showed that the interaction term "incubation time × FA treatment" was significant ($p<0.001$, F-test). This means that the extent of decrease in radioactivity differed significantly between the two treatment groups. At 8-hr incubation, 41% and 51% of the initial radioactivity in 18:1 and 22:6ω3, respectively, was taken up by the hepatocytes.

Figure 2 shows that 22:6ω3 stimulated more TG accumulation in hepatocytes than did 18:1 during the incubation period. However, statistically significant differences between means were found only at the 24-hr incubation time. TG accumulation in cells treated with 18:1 appeared

TABLE 3

Uptake of [1-^{14}C]NEFA in Different Lipid Classes

	Treatment group[a]	
	18:1	22:6ω3
	mean ± s.e.m. (n = 4)	
Cholesteryl ester[b]	1.50 ± 0.08[c]	0.50 ± 0.02[d]
TG	87.2 ± 0.4	90.9 ± 0.2[d]
NEFA	3.1 ± 0.2	2.8 ± 0.1
PL	8.2 ± 0.2	5.8 ± 0.2[d]

[a]Cultured hepatocytes were treated with 1 mM of the indicated [1-^{14}C]NEFA for 8 hr.

[b]Intracellular lipids were extracted and separated into lipid classes by TLC. The radioactivity in each fraction was determined by liquid scintillation counting.

[c]Data are presented as the relative percentage of radioactivity in each lipid class. Arcsin transformation of data was performed prior to statistical analysis. Significant differences between treatment group means within each lipid class is denoted by "d" ($p<0.001$, Student's t-test).

to be slower and to reach a plateau earlier than 22:6ω3-treated cells. The relative distribution of [1-^{14}C]-labeled FA in the major lipid classes after an 8-hr incubation is shown in Table 3. Both 18:1 and 22:6ω3 were largely incorporated in the TG fraction with a slightly but statistically significant higher TG-incorporation for 22:6ω3. In contrast, more labeled 18:1 than 22:6ω3 accumulated in the CE and PL fractions.

The amount of intracellular CE was unaffected by the FA treatments (Table 4). However, the enrichment of the CE fraction with 18:1 was greater than with 22:6ω3. This is consistent with the known specificity of acyl-CoA:cholesterol acyltransferase for 18:1 (20,21). No retroconversion or chain elongation derivatives of the treatment FA were detected in the CE fraction.

The treatment FA did not significantly affect the amount of cellular total PL (Table 5). Treatment with 22:6ω3 resulted in the accumulation of 20:5ω3 in the PL (Table 5) and of 20:5ω3 and 22:5ω3 in the TG (Table 6) fractions. The distribution of 22:6ω3 and 20:5ω3 was, however, dissimilar in these two lipid fractions. The molar ratio of 22:6ω3 to 20:5ω3 was 1.7 in PL but was 7.6 in TG, indicating that the metabolic control for these two ω3 PUFA is distinct from each other.

Table 7 shows TG secretion by hepatocytes treated with NEFA over a period of 24 hr. The medium of cells treated with 22:6ω3 for 2 and 8 hr contained less TG relative to cells treated with 18:1. However, at 24 hr, the three treatment groups no longer differed in the amounts of TG in the culture medium. We were unable to detect CE in any of the culture media.

We next investigated TG reuptake as a factor that could have affected TG accumulation in the culture medium (Table 8). This experiment was designed to mimic a continuous incubation with the treatment FA but without the confounding effect of radiolabel recycling. It therefore permitted the testing of the effect of 18:1-*versus* 22:6ω3-enrichment of hepatocytes on TG reuptake. First, the incubation conditions in the parallel hepatocyte cultures were identical in all respects except for the use of radiolabeled-NEFA in one and not the other. Therefore, the transfer of culture medium from the radioactive treatment group to replace the medium of the corre-

sponding non-radioactive group at the same stage of incubation should perturb the system minimally. Second, the target hepatocytes were treated with chloroquine, a known inhibitor of very low density lipoprotein (VLDL) secretion (22). In our system, chloroquine reduced TG secretion to less than 5% of that in NEFA-treated hepatocytes (data not shown). Consequently, the decrease in TG radioactivity subsequent to the culture medium exchange would be directly due to reuptake, *i.e.*, it is not a net result of simultaneous TG secretion and reuptake. Results shown in Table 8 indicate that TG reuptake may affect TG accretion in the culture medium of hepatocyte culture systems treated with 18:1 but not with 22:6ω3.

The results for the homologous experiments (Table 8,

	dpm in TG/culture well[c], mean ± s.e.m. (n = 3)	
(A) Without cells (control)	6620 ± 680	2860 ± 130
(B) With cells preincubated with same FA (homologous)	4830 ± 320	2730 ± 160
(C) With cells preincubated with other FA (crossover)	5410 ± 310	2740 ± 150
Range test (LSD)[d]	B C A	B C A

[a]Parallel hepatocyte cultures were incubated with either [1-^{14}C]-labeled or cold 18:1 or 22:6ω3. At 8 hr, the culture medium of cells incubated with radio-labeled NEFA was transferred to plates without cells (A), or used to replace the culture media of cells incubated in parallel with the same but unlabeled NEFA (B), as well as of cells incubated with the opposite and unlabeled NEFA (C). The hepatocytes were treated with 200 μM chloroquine in the 30-min interim period between the media exchange, and through the subsequent 6-hr incubation period.

[b]The TG source refers to culture media taken from cultures of hepatocytes incubated for 8 hr with [1-^{14}C]-labeled 18:1 or [1-^{14}C]-labeled 22:6ω3 (see footnote "a" above). As a result of the preliminary 8-hr incubation, the culture media contained the corresponding radio-labeled TG.

[c]TG in culture medium were separated by TLC before counting. The disappearance of TG-radioactivity was considered to represent reuptake by the hepatocytes.

[d]Statistical analysis was similar to Table 4 except that the criterion for significance ($p<0.05$) was calculated by the least significant difference (LSD) method. Homogeneous groups are connected by an underscore.

row B) demonstrate that during the course of a 14-hr incubation with 18:1 and 22:6ω3, there is significant reuptake by hepatocytes of TG-esterified 18:1, but not of TG-esterified 22:6ω3. The lower initial radioactivity in the culture medium from [1-^{14}C]22:6ω3-treated cells (Table 8, row A) reflects the lower secretion of TG-esterified 22:6ω3 relative to TG-esterified 18:1 (see Table 7). The crossover experiments (Table 8, row C) involved replacing the incubation medium of the FA-treated hepatocytes with non-homologous culture medium obtained from parallel cultures incubated with the other FA. There was no reuptake of TG-esterified 22:6ω3 by cells pre-treated with 18:1 (row C, last column). In contrast, there was a reduction in radioactivity when 22:6ω3-treated cells were treated with TG-esterified [1-^{14}C]18:1 (row C, middle column). The reduction in radioactivity, however, was not statistically significant, and was lower than what was observed when TG-esterified (1-^{14}C)18:1 was incubated with 18:1-pretreated cells (row B, middle column). Taken together, the results indicate that 22:6ω3-enrichment of either the hepatocyte or the secreted TG interferes with TG reuptake. Reuptake of 18:1-TG but not of 22:6ω3-TG may explain why at 24 hr, there was no longer any difference between the FA-treatment groups with respect to TG accumulation in the culture media (Table 7). No further attempt was made to distinguish which cellular lipid enriched with 22:6ω3 was linked to the inhibition of TG-reuptake.

DISCUSSION

The calculations presented in Table 9 indicate that 22:6ω3 esterified in the TG fraction is not efficiently secreted by the hepatocyte relative to 18:1. The comparisons were made based on a calculated "index of TG secretion" which is the percentage of TG that has accumulated in the culture medium (TG_o) relative to the net total TG (TG_{tot}) synthesized by the cell. TG_{tot} is the sum of intracellular TG and TG_o. Specific indices of TG secretion were also calculated for 18:1-containing TG ($18:1TG_o$) relative to 18:1-

containing total TG ($18{:}1TG_{tot}$), and for 22:6ω3-containing TG ($22{:}6\omega3TG_o$) relative to 22:6ω3-containing total TG ($22{:}6\omega3TG_{tot}$). The first set of indices for total TG at 2- and 8-hr incubation (Table 9, row 1) reflects the results shown in Figure 2 and Table 7, in that 22:6ω3 treatment diminished total TG secretion in spite of the fact that it also caused a greater accumulation of intracellular TG. At 24 hr, the total TG secretion indices were no longer statistically different although the lower index for the 22:6ω3-treated cells reflected the higher intracellular TG content for these cells (Fig. 2). The second set of indices which are specific for 18:1 (Table 9, row 2) shows that the secretion of TG-esterified 18:1 is not sensitive to either FA treatment. The third set of indices, which are specific for the secretion of TG-esterified 22:6ω3 (Table 9, row 3), was significantly lower than the corresponding 18:1-indices for either 18:1- or 22:6ω3-treated hepatocytes. The 22:6ω3-specific indices for the 18:1-treated cells were zero because there was no detectable 22:6ω3 in these cell cultures. These calculations demonstrate that TG-esterified 22:6ω3 is not as efficiently secreted as TG-esterified 18:1. This conclusion is consistent with the results in Table 7 and 8 (row A, middle and right columns) in that at 8-hr incubation: i) extracellular TG-esterified [1-^{14}C]18:1 was 2.3-times higher than the corresponding extracellular TG-esterified [1-^{14}C]22:6ω3; whereas ii) total extracellular TG in the 18:1-treated hepatocytes was actually only 1.5-times higher than that in 22:6ω3-treated cells.

Yao and Vance (23) reported that phosphatidylcholine synthesis is obligatory for the secretion of VLDL particles. We did not evaluate the effect of 18:1 and 22:6ω3 on the rate of synthesis of this phospholipid in our system. However, inhibition of phosphatidylcholine synthesis by 22:6ω3 would not account for the differential secretion of TG-esterified 18:1 and TG-esterified 22:6ω3. One would otherwise have expected identical effects of 22:6ω3 on the secretion efficiency on all types of TG (Table 9). Nossen *et al.* (22) reported that 95% of TG secreted by cultured hepatocytes is recovered with the VLDL fraction. It is therefore unlikely that secretion of TG in a form other than VLDL will account for the differences in the secretion efficiency of TG-esterified 18:1 and 22:6ω3.

Rustan *et al.* (3) reported that for 20:5ω3 and 18:1, the FA to BSA ratio affected the rate of TG synthesis and secretion by cultured hepatocytes. In contrast, Wong *et al.* (9) reported that changing the FA to BSA ratio from 5:1 to 2:1 did not change the relative effects of 18:1, 20:5ω3 and 22:ω3 on TG production by HepG2 hepatocytes. In our experiments, we used a constant and physiological FA to BSA ratio of 1.67 (24,25) at which to compare 18:1 to 22:6ω3. While it is true that the absolute values of the results of our experiments may vary depending on the FA to BSA ratio (3), the relative metabolic effects of 18:1 and 22:6ω3 in our system (Tables 2, 3, 6 and 7) will likely remain the same. Rustan *et al.* (3) also reported that 22:6ω3 as well as 18:1 stimulated TG secretion by cultured hepatocytes and to a much higher degree than what we observed relative to controls (Table 7). We cannot account for this discrepancy, except for differences in the source of hepatocytes, in the culture conditions and in methods for the assay of TG secretion. During the review of this manuscript, Lang and Davis (26) published a similar study on the effects of 18:1, 20:5ω3 and 22:6ω3 on TG secretion by cultured hepatocytes. It is interesting to note that their results, when expressed as absolute TG mass, are consistent with our observations on TG synthesis and secretion. However, when they used [^{3}H]glycerol incorporation to measure TG synthesis and secretion, the effects of 18:1 and 22:6ω3 relative to controls were similar to those reported by Rustan *et al.* (3) who had used (^{3}H)glycerol incorporation as the basis for their TG measurements.

TABLE 9

Efficiency of Secretion of 18:1- and 22:6ω3-Containing TG

		Incubation time (hr)		
		2	8	24
Treatment groups[a]	Index of TG secretion[b]	mean ± s.e.m. (n = 3)[c]		
18:1	$\frac{TG_o}{TG_{tot}} \cdot 100$	2.96 ± 0.18	5.18 ± 0.14	6.88 ± 0.73
22:6ω3		1.66 ± 0.19[d]	3.09 ± 0.16[d]	5.37 ± 0.24
18:1	$\frac{18{:}1TG_o}{18{:}1TG_{tot}} \cdot 100$	3.05 ± 0.32	4.79 ± 0.31	6.72 ± 0.73
22:6ω3		2.29 ± 0.41	5.25 ± 0.55	6.88 ± 0.75
18:1	$\frac{22{:}6\omega3TG_o}{22{:}6\omega3TG_{tot}} \cdot 100$	0	0	0
22:6ω3		0.98 ± 0.13[e]	2.00 ± 0.28[e]	5.31 ± 0.11[e]

[a]Hepatocytes were incubated with 1 mM 18:1 or 22:6ω3 for the indicated time periods.

[b]Index of TG secretion is the percentage of secreted TG (TG_o) relative to the total accumulated TG (TG_{tot}) in the culture system. It represents the efficiency by which TG is secreted by the hepatocytes. Specific indices of TG secretion were also calculated to reflect the efficiency by which TG-esterified 18:1 ($18{:}1TG_o$) or TG-esterified 22:6ω3 ($22{:}6\omega3TG_o$) were secreted by the cells.

[c]Intracellular and extracellular (culture medium) TG were extracted and isolated by TLC in the presence of added internal standards. Quantitation was by GLC. Arcsin transformation was used prior to statistical analysis. Significant differences between treatment group means are denoted by "d" ($p<0.005$) for the indices of total-TG secretion and by "e" ($p<0.005$) for the indices of secretion of TG-esterified 18:1 in the 18:1-treatment group *versus* the indices of secretion of TG-esterified 22:6ω3 in the 22:6ω3 treatment group. There were no significant differences between the treatment group means for the indices of secretion of TG-esterified 18:1.

While the *in vitro* system used in our experiments is necessarily a short-term model, our data has certain similarities to *in vivo* data. For example, the differences in the uptake of 18:1 *versus* 22:6ω3 (Fig. 1, Table 2) are similar to those reported by Parks *et al.* (27) for 18:1 *versus* 20:5ω3 uptake in perfused livers from African green monkeys fed a long-term fish oil diet. Furthermore, their results on the diversion of 20:5ω3 to PL are consistent with our observations (Tables 5 and 6). Secondly, hepatic TG accumulation might be expected when TG secretion, but not synthesis, is inhibited. This was the case in fish oil-feeding experiments reported by Haug and Hostmark (8).

Our results provide further evidence that TG secretion can occur without reduced TG synthesis. Figure 3 summarizes the hepatic flux of FA through successive metabolic branchpoints that ultimately determine the rate of TG secretion. Multiple and varying effects of the ω3PUFA (described in the literature and alluded to in the introduction) may arise from changes in the relative importance of each one of the steps in Figure 3, depending on experimental conditions used. For example, Beynen and Katan (28) proposed and cited evidence that inhibition of TG secretion due to dietary PUFA may arise from diversion of these PUFA to β-oxidation away from esterification. Our results indicate that the partition of nascent TG between VLDL assembly and accumulation of cystosolic TG is directed toward the retention of 22:6ω3. In support of this hypothesis, others have shown that the three cellular TG pools, namely cytosolic, nascent microsomal and VLDL, have distinct turnover kinetics (29-31). This indicates that the interchange between these TG pools is regulated by specific mechanisms. It is conceivable that these mechanisms are able to distinguish between different molecular species of TG.

Oxysterol Incorporation into Rat Aorta Resulting in Elastin Compositional Changes

J.W. Blankenship[a,b,*], C.M. Van Gent[a], L.B. Sandberg[a,c], P.J. Roos[a,d], and J.A. Scharffenberg[e]

[a]Jerry L. Pettis Memorial Veterans Hospital, Loma Linda, California 92357, Departments of [b]Nutrition, [c]Pathology, and [d]Medicine, Loma Linda University, Loma Linda, California 92350, and [e]Pacific Health Education Center, Bakersfield, California 93301

The incorporation of dietary cholestan-3β, 5α, 6β-triol (triol) into rat thoracic aortic tissue and changes in amino acid composition of the elastin were investigated to identify the cytotoxic properties of the triol. Weanling male Sprague-Dawley rats were fed the following diets for three months: (i) normal chow, (ii) normal chow with 1% (w/w) cholesterol added, or (iii) normal chow with 0.9% (w/w) cholesterol and 0.1% (w/w) triol added. Triol levels in the blood and in the thoracic aortic tissue were measured. Compositional changes of elastin were also determined. After three months on the triol-containing diet, triol was found in the thoracic aorta but was not detected in the blood. Amino acid analyses of the aortic tissue elastin revealed that the proline levels in the triol-fed animals were significantly greater than in the other two diet groups, while the elastin levels of leucine, aspartate, arginine, and phenylalanine decreased significantly. The mechanism for these observed changes induced by triol may reflect alternate splicing of elastin messenger ribonucleic acid (mRNA) resulting in structual changes in the elastin molecule. Dietary triol does contribute to tissue triol content and is associated with aortic elastin compositional changes. How these changes may contribute to the development of cardiovascular disease is not known.

Lipids 26, 381-384 (1991).

When the cytotoxicity of oxysterols in connective tissue, *e.g.* fibroblasts and vascular smooth muscle cells, was investigated in tissue culture, a particularly marked inhibition of cellular growth was observed due to cholestan-3β, 5α, 6β-triol (triol) (1). The toxicity of triol has also been observed in whole animals. Intravenous injections of triol into rabbits produced within 24 hr lesions in the luminal surface of the aorta (2). Also by long-term feeding of triol at 0.1% of the ration, Cook and MacDougall (3) observed the development of atherosclerotic lesions in rabbits resembling those found in the humans. Connective tissue involvement in triol toxicity has been noted by Matthias *et al.* (4), who found that oral administration of triol to rats produced distinct loosening of the elastin integrity at the endothelial edge of the internal elastic lamina of the aorta as evidenced by electron microscopy. The possibility of dietary cholesterol oxides being involved in human atherosclerosis has also been proposed by Jacobson (5). The observation was made on two Indian populations that used ghee (a butter with high cholesterol oxide content) and which experienced a high incidence of mortality and morbidity from atherosclerosis even though serum cholesterol levels were not elevated.

In this context, the effects of cholesterol oxidation products, which occur in normal human foods containing cholesterol, are of interest. A typical mixed diet as normally consumed by the Dutch has been analyzed for oxysterols by van de Bovenkamp *et al.* (6). They found that the normal intake of total oxysterols would amount to only a few mg per day with the known cytotoxic triol being present in only trace amounts. However, cholesterol-5α,6α-epoxide (α-epoxide) occurred at a concentration of about 0.5 mg per 500 g (dry wt) food eaten per day. Although the food contained only traces of the cytotoxic triol, Maerker *et al.* (7) have shown that the normal acidity of the stomach largely hydrolyzes the α-epoxide to the triol. Thus, the normal human food that contains cholesterol may be the source of a small but significant quantity of triol. The potential for triol absorption, incorporation into tissue, and storage or accumulation is unknown.

The present study is concerned with the contribution of dietary triol to the presence of triol in blood and thoracic aortic tissue of rats. In addition, because of reported loss of aortic elastin integrity of the internal elastic lamina (4), the amino acid compositional characteristics of aortic elastin as related to tissue incorporation of triol have been investigated.

MATERIALS AND METHODS

Animals and diets. Weanling male (21-29-day-old) Sprague-Dawley rats (37) were placed on three different diets for three months (Table 1). The triol and cholesterol for diet preparation were purchased from Sigma Chemical Company (St. Louis, MO). The cholesterol used in this feeding study did not contain measurable amounts of triol as contaminant as determined by gas-liquid chromatography (GLC). At the end of the experimental period, the thoracic aorta along with blood samples were collected from each animal. Total serum cholesterol concentra-

tions were determined on 37 animals. The quantities of triol in thoracic aortic tissue and serum were determined by GLC. Samples of aortic tissue elastin were also hydrolyzed, and amino acid contents were measured. Aortic tissue from some of the animals was used in another study not reported here.

Serum cholesterol determination. The colorimetric cholesterol oxidase method for total serum cholesterol determination utilized Kit #352 from Sigma.

Isolation of the triol. Total lipid extractions were done by the Bligh and Dyer procedure (8) on plasma (1 mL) or thoracic aorta tissue (0.5-1.0 g) with 40 μg of 5α-cholestane added as an internal standard (9). Baker analyzed reagent grade $CHCl_3$ and methanol were used without further purification. The $CHCl_3$/methanol mixture contained 0.1% butylated hydroxytoluene as antioxidant. The chloroform extract was evaporated to dryness on a rotary evaporator and the lipid residue was saponified in 2 mL 1N KOH in 95% ethanol at room temperature for 12-15 hr (10), which was sufficient to complete hydrolysis of steryl esters as ascertained by thin-layer chromatography. Low temperature hydrolysis was done to avoid decomposition of triol, which has been reported to be sensitive to saponification conditions (6). Treatment of a cholesterol containing sample under these conditions did not produce a measurable amount of triol.

Park and Addis (9) isolated the nonsaponifiables from the saponification mixture by multiple diethyl ether extraction. However, we noted that the triol was much more soluble in chloroform than in diethyl ether. The extraction procedure we used was compared to that by Park and Addis (9) and was considered preferable.

The ethanolic KOH (2 mL) was diluted to 6 mL with water in a Teflon-lined screw-capped tube (12 × 125 mm). Six mL of chloroform was added, and upon mixing, the mixture was centrifuged to facilitate phase separation. The upper aqueous phase was removed by pipette and discarded. To remove residual free fatty acids, the $CHCl_3$ solution was washed two times with 0.1N KOH in 40% ethanol. Finally, the $CHCl_3$ phase was washed with 5 mL water to remove residual KOH and then evaporated to dryness on a rotary evaporator. Residual water was removed by repeated evaporation in the presence of absolue ethanol. The dried residue was redissolved in $CHCl_3$ for storage at -20°C until analyzed.

Determination of triol by GLC. The sterol containing preparation can be dissolved in $CHCl_3$ and analyzed as such or as trimethylsilyl ether (TMS). TMS derivatives are formed by dissolving the dry nonsaponifiable residue in 0.1 mL pyridine followed by the addition of 0.05 mL of Sylon BTZ (Supelco, St. Louis, MO) (9). The derivative is formed within 10-15 min and is directly injected into a capillary GLC column. Parallel analysis of derivatized and non-derivatized sterols corroborates the assignments made. A Varian model 3700 gas chromatograph equipped with a DB1 column (megabore 0.53 mm × 30 m; J&W Scientific, Inc., Rancho Cordova, CA) was used. The injector temperature was 260°C and the detector temperature was held at 280°C. Helium was used as carrier gas at a flow rate of 6 mL per min. The oven temperature was held at 100°C for 2 min, then raised at a rate of 20°C/min to 270°C, and held for 25 min. Under the above conditions, the following relative retention times were observed: 5α-cholestane (internal standard), 1.00; TMS-cholesterol, 1.40; cholesterol, 1.28; TMS-triol, 2.00; triol, 2.22. Quantifications were made by comparing peak areas with those of internal standards.

Tissue was extracted with chloroform/methanol by Bligh and Dyer extraction (8). The delipidated tissue was air-dried and weighed. The data reported in Table 3 were measured on non-derivatized sterols.

Elastin preparation, high-performance liquid chromatography (HPLC) peptide analysis and amino acid analysis. Thoracic aortic elastin was isolated by subjecting the tissue to hot alkali treatment following the Lansing procedure (11). Elastin was quantified by thermolytic peptide analysis. The thoracic aorta elastin was digested with thermolysin for 6 hr using conditions described by Sandberg *et al.* (12), and the resulting peptides were quantitated by reverse-phase HPLC.

Aliquots of each of the thermolysin digests containing the elastin peptides were hydrolyzed with 3 N mercaptoethanesulfonic acid at 110°C for 24 hr (13). The amino acid content of the elastin peptide hydrolysates was determined by ion exchange chromatography using a ninhydrin system (Biotronik model 500l, Maintal, Germany).

RESULTS AND DISCUSSION

The animals that received 1% cholesterol (group 2) in the diet showed a modest increase in serum cholesterol (Table 2), while the serum cholesterol levels of animals that received 0.9% cholesterol plus 0.1% triol (group 3) were not significantly changed by the dietary treatment. It has been reported that the triol inhibits the activity of 3-hydroxy-3-methylglutaryl coenzyme A reductase in cell culture (15). This may account for the lack of a significant difference between groups 1 and 3.

Group 2	*vs*	Group 3	n.s.

[a]Number of animals per group in parentheses. Analysis of variance followed Bonferroni's procedure for the statistical comparison of mean values for groups (14).

Both the serum and thoracic aortic tissues were subjected to triol analyses. The amounts of triol in the serum were below our detection level (0.003 mg/mL) which raised questions concerning the absorption of the triol. However, the triol does accumulate in the tissues (see Table 3). The animals that received 0.1% triol in the diet over a three-month period showed significant levels of triol in the thoracic aorta. The presence of the triol appears to influence cholesterol incorporation into tissue, as cholesterol contents in arteries of triol-fed animals were higher than in controls (Table 3).

Elastin very well lends itself to compositional studies because of its unusual amino acid composition. It is high

in hydrophobic amino acids (glycine, alanine, valine, proline), and very low in hydrophilic ones (aspartate, glutamate, lysine, arginine). It is also characterized by the presence of the unique desmosine crosslinks and the absence of histidine and methionine (17). In addition, the nucleotide composition of the rat elastin message has recently been determined, allowing us to tie transcriptional and translational events to protein expression for smooth muscle cells of the aorta (18). To evaluate qualitative changes in the elastin, aliquots of all the thermolysin digests were acid hydrolyzed and the amino acid compositions determined (Table 4). In our hands, the mercaptoethanesulfonic acid hydrolysis procedure (13) gave better reproducibility than the usual 6N HCL method when applied to elastins (Blankenship, J.W., and Sandberg, L.B., unpublished observations). Furthermore the isodesmosine/desmosine contents were not different for any of the groups which indicates that the triol did not influence the degree of crosslinking during elastogenesis. Also, in the control and cholesterol-fed animals, no differences in amino acid compositions were detected. However, the elastin amino acid composition of group 3 (triol-fed rats) was significantly different from either the control or cholesterol-fed groups with respect to five amino acids (Table 4). The proline was increased in the triol group compared to both control and cholesterol groups, while leucine, aspartate, arginine, and phenylalanine were decreased in the same group (see Table 4 for statistical analysis).

In Table 5 we list the amino acid compositions resulting from translation of exons 30 through 36 in the rat (18). These exons are located at the 3′ end of the message representing the carboxyl terminal portion of the protein. The C-terminus of the tropoelastin molecule is proline-poor and arginine-rich. In elastin, the even-numbered exons code for hydrophobic regions of the protein while odd-numbered exons code for more hydrophilic regions (crosslinking). Notably, crosslink content was not affected by triol but the hydrophobic residues were. Deletion of several of the even-numbered exons shown in Table 5 would account for most of the amino acid compositional changes observed within the triol group. Alternate splicing in the rat has been noted with exon 33 (18).

[a]From data by Pierce *et al.* (18). Rat elastin exons 29 to 36 represent 152 contiguous amino acid residues of the C-terminal portion of the secreted protein (one-fifth of the total protein). Proline (P) and arginine (R) are underlined. Of 9 orginine residues, 4 are contained herein, but of 110 proline residues only 11 are present. Thus the area is arginine-rich and proline-poor with respect to the remainder of the protein. These two amino acids manifested the most dramatic changes from controls in aortic elastin from rats treated with triol (proline increasing and arginine decreasing).

Because the C-terminus of tropoelastin contains the probable deletions, other mechanisms that might be invoked are premature termination of the translation process on the ribosome, or clipping of the C-terminal portion of the protein prior to its incorporation into the elastin fiber. Activation of a tissue elastase by triol could bring about the latter process.

The physiological consequences of the above alterations are presently not appreciated. However, administration of oxysterols, with triol being the most toxic, has been shown to produce arterial endothelial injury in one study (2). *In vitro* studies have demonstrated oxysterol toxicity to smooth muscle cells (1,15,19) and fibroblasts (1), and oxysterols have been shown to induce alterations in membrane structure and function (20).

Thus, modification of connective tissue elastin upon triol feeding merits further investigation inasmuch as elastin modification also affects tissue morphology (4). Formation of atherosclerotic lesions upon triol feeding (3) would suggest that triol may contribute to the pathologic changes noted in atherosclerotic disease involving connective tissue modifications.

ACKNOWLEDGMENTS

[Received April 16, 1990, and in revised form March 7, 1991; Revision accepted March 8, 1991]

Effect of n-3 Fatty Acids on the Key Enzymes Involved in Cholesterol and Triglyceride Turnover in Rat Liver

Ayman AL-Shurbaji[a]*, Carin Larsson-Backström[b], Lars Berglund[a], Gösta Eggertsen[a] and Ingemar Björkhem[a]

[a]Department of Clinical Chemistry, Karolinska Institute at Huddinge University Hospital, Huddinge and [b]Kabi Nutrition, Research and Development, Stockholm, Sweden

The effect of long-chain n-3 fatty acids on hepatic key enzymes of cholesterol metabolism and triglyceride biosynthesis was investigated in two rat models. In the first model, rats were intravenously infused for two weeks with a fat emulsion containing 20% of triglycerides in which either n-6 or n-3 fatty acids predominated. The treatment with n-3 fatty acids led to a reduction primarily of serum cholesterol (45%), but also of serum triglycerides (18%). HMG-CoA reductase activity and cholesterol 7α-hydroxylase activity were reduced by 45% and 36%, respectively. There were no significant effects on diacylglycerol acyltransferase (DGAT) or phosphatidate phosphohydrolase (PAP) activities. In the second model, rats were fed a diet enriched with sucrose, coconut oil and either sunflower oil (n-6 fatty acids) or fish oil (long-chain n-3 fatty acid ethyl esters). The treatment with n-3 fatty acids decreased serum triglycerides (41%) and, to a lesser extent, serum cholesterol (17%). Neither glycerol 3-phosphate acyltransferase (GPAT) or DGAT were affected by n-3 fatty acids. In contrast, PAP activity was reduced by 26%. HMG-CoA reductase was not significantly affected, whereas cholesterol 7α-hydroxylase activity was reduced by 36%. The results indicate that part of the TG-lowering effect of long-chain n-3 fatty acids may be mediated by inhibition of the soluble phosphatidate phosphohydrolase. The effect on serum cholesterol may be partly due to inhibition of HMG-CoA reductase.

Lipids 26, **385-389 (1991).**

The triglyceride (TG)-lowering effect of marine fish oils rich in n-3 polyunsaturated fatty acids is well documented (1-4). However, the underlying mechanism has not yet been elucidated in detail. Results of studies using perfused rat liver as model seem to indicate that several mechanisms might be operative. Reduced hepatic lipogenesis, retarded very low density lipoprotein (VLDL) secretion, and enhanced fatty acid oxidation have all been suggested (5).

Suppression of synthesis and secretion of triglycerides by n-3 fatty acids has been demonstrated in cultured rat hepatocytes (6), as well as in human hepatoma cells (7). Metabolic studies in humans have also indicated that n-3 fatty acids inhibit the production of VLDL TG in the liver (2), and that this inhibition is not due to a decrease in the availability of circulating fatty acid substrate. The possibility that reduced synthesis of TG induced by n-3 fatty acids might be due to an inhibition of one or more of the enzymes involved in TG biosynthesis has therefore been investigated. Infusion of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) in perfused rat liver has been reported to decrease total phosphatidate phosphohydrolase (PAP) activity (8). In another study, a significant reduction in the Mg^{++}-dependent PAP activity in rat liver was observed as a result of feeding a fish oil-enriched diet (9). This result is somewhat hampered, however, by the lack of suitable controls.

Different results on the effect of n-3 fatty acids on diacylglycerol acyltransferase (DGAT) activity have been reported. In some studies treatment with n-3 fatty acids reduced hepatic synthesis and secretion of TG by inhibiting DGAT activity (10). In other studies, such an inhibition could not be demonstrated (9).

n-3 Fatty acids reduce serum cholesterol levels in humans, as well as in experimental animals (1,11,12). In general, the effect on serum cholesterol is less pronounced than that on serum TG, and in some studies no effect on serum cholesterol was observed (13). Again, the underlying mechanisms are still not clear. In a recent study, HMG-CoA reductase activity was found to be decreased in rats fed sardine oil (n-3 fatty acids) compared to rats fed safflower oil (n-6 fatty acids). However, cholesterol 7α-hydroxylase was not affected (14).

In the present work we have investigated in two rat models the effect of n-3 fatty acids on the rate-limiting enzymes in the synthesis and degradation of cholesterol, and on certain key enzymes of TG biosynthesis. We found that in the infusion model, n-3 fatty acids markedly reduced serum cholesterol levels, and in the dietary model they markedly reduced serum TG levels.

MATERIALS AND METHODS

Animals and animal treatment. Male Sprague-Dawley rats were used. The animals were housed in metal cages maintained at a 12-hr light-dark cycle.

In the first animal model used, Sprague-Dawley rats weighing about 200 g were divided in two groups, one of which was intravenously infused with Intralipid® (Kabi Nutrition, Stockholm, Sweden) containing 20% soybean oil, in a dose of 25 mL/kg body weight/24 hr for two weeks. The other group was infused in the same way with a corresponding fat emulsion supplemented with 20% marine oil. The composition of both oils is shown in Table 1. The infusion was carried out as described previously (15). The animals had free access to water and pellet diet (R_3; Ewos AB, Södertälje, Sweden). Each day the infusion was stopped for a period of 4 hr (9 a.m.-1 p.m.). With the equipment used, the animals were able to move freely in the cages. There was no significant difference in weight

Abbreviations: DGAT, diacylglycerol acyltransferase; DHA, docosahexaenoic acid; DTT, dithiotheitol; EPA, eicosapentaenoic acid; GPAT, glycerol 3-phosphate acyltransferase; PAP, phosphatidate phosphohydrolase; TG, triglycerides, triacylglycerols; VLDL, very low density lipoprotein.

gain between the two groups during the experimental period. On the day of sacrifice, the infusion was terminated (9 a.m.), 2 hr later the animals were anaesthetized using Mebumal (60 mg/kg). Blood was collected by heart puncture, and livers were removed.

TABLE 1

Fatty Acid Composition of Marine Oil and Soybean Oil Used in the Infusion Experiments[a]

Fatty acid	Marine oil %	Soybean oil %
Eicosapentaenoic acid	18	<1
Docosahexaenoic acid	12	<1
α-Linolenic acid	1	6-12
Total n-3 fatty acids	37	6-12
18:2 Fatty acid	1	47-57
Total n-6 fatty acids	4	48-58
Saturated fatty acids	25	10-20
Monoenoic fatty acids	25	19-29

[a]The soybean oil was commercial Intralipid. The fatty acid composition in the different batches used varied as shown. Only one batch of the marine oil was used, with the fatty acid composition as given.

In the second animal model, 3-week-old rats weighing about 100 g each were fed a diet containing 45% sucrose, 15% coconut oil and 5% fish oil, which contained 85% n-3 fatty acid ethyl esters (55% eicosapentaenoic acid and 30% docosahexaenoic acid) for 3 weeks. The control rats were fed a corresponding diet with the fish oil substituted by sunflower oil (containing 66% linoleic acid and less than 1% n-3 fatty acids). There were no differences in weight gain between the two experimental groups. The animals were decapitated in the morning (8 a.m.), blood was collected, and the livers were removed. No anaesthesia were used.

The animal experiments were approved by the ethical committee for animal experiments.

Materials. [1-^{14}C]Palmitic acid with a specific activity of 54 mCi/mmol, [1-^{14}C]palmitoyl-CoA with a specific activity of 56 mCi/mmol and *L*-[U-^{14}C]glycerol 3-phosphate with a specific activity of 171 mCi/mmol were purchased from the Radiochemical Centre (Amersham, England). [4-^{14}C]Cholesterol and [3-^{14}C]hydroxymethylglutaryl-CoA with specific activities of 55-60 mCi/mmol were obtained from New England Nuclear Corp. (Boston, MA). $^{2}H_3$-Labeled 7α-hydroxycholesterol was synthesized as described previously (16).

The marine oil emulsion was kindly supplied by Kabi Nutrition, Research and Development (Stockholm, Sweden). Fish oil was a generous gift from Dr. Knut Dahl, Norsk Hydro (Porsgrunn, Norway). All other chemicals used were products of Sigma Chemical Company (St. Louis, MO).

Enzyme assays. For assay of the enzymes involved in triglyceride synthesis, rat livers were rinsed, minced, and homogenized with 4 volumes of 250 mM sucrose, 20 mM Tris/HCl, pH 7.4, 1 mM EDTA, and 1 mM dithiothreitol (DDT). The homogenates were centrifuged at 20,000 × *g* for 15 min at 4°C, and the resulting supernatant was spun at 100,000 × *g* for 60 min at 4°C. The microsomes obtained were suspended in the homogenization buffer and used for GPAT and DGAT assays. The 100,000 × *g* supernatant was precipitated with ammonium sulfate as described by Lamb and Fallon (17), and used as a source of cytosolic PAP activity. PAP activity was assayed for 15 min. at 37°C as described earlier (18). The extraction procedure, thin-layer chromatography, and radio-scanning of chromatography plates were performed as described above (18).

Microsomal GPAT was assayed for 3 min at 30°C, essentially as described by Bates and Saggerson (19). The incubation mixture contained 120 mM KCl, 50 mM Tris/HCl pH 7.4, 65 μM palmitoyl-CoA, 0.7 mM DTT, 1 mM *L*-glycerol 3-phosphate, and 1.75 mg fatty acid-poor bovine serum albumin. The reaction was started by the addition of microsomes (200 μg protein) and terminated by the addition of 2.0 mL of 1-butanol. The incorporation of ^{14}C into butanol-soluble products was determined as described (19,20).

DGAT was assayed for 5 min. at 37°C. The incubation mixture contained 100 mM Tris/HCl pH 8.0, 4 mM $MgCl_2$, 250 μM 1,2-dioleoyl-*sn*-glycerol, 30 μM [1-^{14}C]palmitoyl-CoA (200,000 cpm/incubation), and 1 mg/mL fatty acid-poor bovine serum albumin in a final volume of 1 mL. The reaction was initiated by the addition of microsomes (30-40 μg protein) and terminated by the addition of 7.5 mL of 2-propanol/hexane/water (80:20:1, v/v/v). The extraction of TG into hexane was done as described by Coleman and Bell (21).

For assay of HMG-CoA reductase and cholesterol 7α-hydroxylase, a 10% (w/v) homogenate of rat liver was prepared in 50 mM Tris/HCl buffer (pH 7.4) containing 0.3 M sucrose, 50 mM NaCl, 10 mM EDTA, and 10 mM DTT. The microsomal fraction was prepared by centrifugation of the homogenate at 20,000 × *g* for 15 min and recentrifugation of the supernatant at 100,000 × *g* for 60 min. Half the microsomal fraction was resuspended in the homogenizing buffer and recentrifuged at 100,000 × *g* for 60 min. The resulting fraction was suspended in 20 mM imidazol/HCl buffer (pH 7.4) containing 10 mM DTT, and used for assay of HMG-CoA reductase. The other half of the original microsomal fraction was suspended in a homogenizing buffer lacking DTT and recentrifuged at 100,000 × *g* for 60 min. This fraction was resuspended in 0.1 M potassium phosphate buffer, pH 7.4, and used for assay of cholesterol 7α-hydroxylase.

HMG-CoA reductase activity was assayed essentially as described by Brown *et al.* (22). The incubation was run for 15 min and terminated by addition of 25 μL 6N HCl. [^{3}H]Mevalonic acid was added as internal standard. The incubation mixture was further lactonized, subjected to thin-layer chromatography (TLC), and analyzed for radioactivity (22).

For assay of cholesterol 7α-hydroxylase, the microsomal fraction was incubated with [4-^{14}C]cholesterol as described previously (16). In this procedure, the conversion of [4-^{14}C]labeled cholesterol into 7α-hydroxycholesterol is measured by radio-scanning after separation of the product from the substrate by TLC. The conversion of the endogenous microsomal cholesterol into 7α-hydroxycholesterol is measured by isotope dilution/mass spectrometry (16).

Analytical methods. Serum triglycerides and cholesterol were determined by an enzymatic procedure (Boehringer Mannheim) using a Hitachi 737 automatic enzyme analyzer (Hitachi Co., Tokyo, Japan). Triglycerides and phospholipids were extracted from liver homogenates using bonded phase (Bond Elut) columns as described by

Kalazny *et al.* (23). The fatty acid composition of the separated lipids was determined by gas chromatography (24). Protein was measured by the Lowry procedure (25). Results were evaluated for statistical significance by Student's *t*-test.

RESULTS

Several rat models were tried to obtain reproducible effects of n-3 fatty acids on the serum cholesterol and triglyceride levels. Rats on a conventional pelleted chow have low levels of serum triglycerides, and in our study, significant and reproducible effects of n-3 fatty acids were obtained only with a diet which increases serum triglyceride levels in itself. Similar results also have been obtained by another group (Hoestmark *et al.*, personal communication). In the present study, significant effects on serum cholesterol levels were only observed after prolonged and excessive exposure to n-3 fatty acids by intravenous infusion.

As shown in Table 2, treatment with dietary n-3 fatty acids resulted in a slight reduction in serum total cholesterol (17%) and a marked reduction in serum triglycerides (41%). This was accompanied by a 26% decrease in soluble PAP activity. In contrast, GPAT and DGAT were not significantly affected. No effect on HMG-CoA reductase activity was observed. However, cholesterol 7α-hydroxylase activity was depressed when assayed with exogenous substrate (Table 2).

TABLE 2

Effect of Dietary n-3 and n-6 Fatty Acids on Serum Lipids and Hepatic Enzymes[a]

Enzyme activity or lipid level	Fish oil (n-3 fatty acid-enriched)	Sunflower oil (n-6 fatty acid-enriched)
Serum cholesterol mmol/L	2.88 ± 0.28	3.45 ± 0.28
Serum triglycerides mmol/L	0.72 ± 0.15[b]	1.22 ± 0.41
Soluble phosphatidate phosphohydrolase nmol/min/mg protein	1.45 ± 0.12[b]	1.97 ± 0.11
Diacylglycerol acyltransferase nmol/min/mg protein	4.6 ± 0.4	4.3 ± 0.5
Glycerol-3-P-acyl-transferase nmol/min/mg protein	1.1 ± 0.1	1.2 ± 0.1
HMG-CoA reductase pmol/min/mg protein	471 ± 218	563 ± 299
Cholesterol 7α-hydroxylase activity (exogenous substrate) pmol/min/mg protein	3.1 ± 1.2[b]	6.2 ± 2.5
Cholesterol 7α-hydroxylase activity (endogenous substrate) pmol/min/mg protein	18.3 ± 6.3	28.4 ± 8.8

[a]The values represent the means ± SEM of two experiments, n = 12.
[b]$p<0.05$.

More intensive exposure to n-3 fatty acids by intravenous infusion resulted in a marked reduction of serum cholesterol (45%) and a slight reduction of serum triglycerides (18%) (Table 3). Under these conditions HMG-CoA reductase activity was substantially reduced (45%). In parallel, cholesterol 7α-hydroxylase activity was also reduced (64% and 36% when assayed with exogenous and endogenous substrate, respectively). However, PAP activity was not affected. Similarly, no effect on DGAT activity could be demonstrated (Table 3).

TABLE 3

Effect of Infusion of n-3 and n-6 Fatty Acids on Serum Lipids and Hepatic Enzymes[a]

Enzyme activity or lipid level	n-3 Fatty acid-enriched emulsion	n-6 Fatty acid-enriched emulsion
Serum cholesterol mmol/L	1.78 ± 0.33[b]	2.71 ± 0.28
Serum triglycerides mmol/L	0.73 ± 0.09[c]	0.89 ± 0.16
Soluble phosphatidate phosphohydrolase nmol/min/mg protein	2.11 ± 0.52	2.43 ± 1.0
Diacylglycerol acyltransferase nmol/min/mg protein	4.02 ± 0.48	4.56 ± 0.71
HMG-CoA reductase pmol/min/mg protein	265 ± 108[b]	484 ± 121
Cholesterol 7α-hydroxylase activity (exogenous substrate) pmol/min/mg protein	1.40 ± 0.51[b]	3.83 ± 1.57
Cholesterol 7α-hydroxylase activity (endogenous substrate) pmol/min/mg protein	25.9 ± 8.1[b]	40.3 ± 7.61

[b]$p<0.01$.
[c]$p<0.05$.

Treatment with n-3 fatty acids resulted in a marked enrichment of hepatic phospholipids and neutral lipids with n-3 fatty acids in both animal models (Table 4), indicating a significant uptake and assimilation of these fatty acids. The incorporation of n-3 fatty acids into hepatic lipids was, however, not identical in the two models. As shown in Table 4, the n-6/n-3 ratio of liver phospholipids was considerably lower in the dietary model.

DISCUSSION

The TG-lowering effect of n-3 fatty acids observed may result from a reduced influx of TG from the liver or an increase in plasma TG clearance, or both. However, evidence is mounting which suggests that this effect is probably due to a reduction in the influx of TG from the liver. In humans, dietary n-3 fatty acids were found to decrease the biosynthesis of VLDL TG (26). Moreover, n-3 fatty acids have been shown to reduce the secretion of VLDL TG from cultured rat hepatocytes without inhibiting the secretory mechanism *per se* (27). Therefore, it seems probable that the TG-lowering effect was due to a reduction in TG biosynthesis. Such a reduction could result from a decrease in the amount of fatty acids available for TG biosynthesis, or an inhibition of one or more of the enzymes involved in the synthetic pathway. However, previous results argue against the former possi-

TABLE 4

Distribution of n-3 and n-6 Fatty Acids in Liver Lipids

A: Infusion model[a]

	Marine oil	Soybean oil
Phospholipids		
n-6 FA	27.7 ± 0.3	41.5 ± 0.1
n-3 FA	21.8 ± 0.4	9.8 ± 0.2
n-6/n-3 ratio	1.27 ± 0.04	4.23 ± 0.08
Neutral lipids		
n-6 FA	20.4 ± 0.7	43.6 ± 0.5
n-3 FA	27.9 ± 1.0	9.9 ± 0.5
n-6/n-3 ratio	0.73 ± 0.03	4.42 ± 0.20

B: Dietary model[b]

	Fish oil	Sunflower oil
Phospholipids		
n-6 FA	14.7	37.1
n-3 FA	35.7	11.0
n-6/n-3 ratio	0.41	3.36
Neutral lipids		
n-6 FA	11.9	36.4
n-3 FA	12.8	4.9
n-6/n-3 ratio	0.93	7.44

[a]The values represent percentage of the total fatty acid content measured in five rats, with the variation given as SEM.

[b]The values represent percentage of the total fatty acid content from a pool of six rats.

bility (2). Therefore, the latter possibility was investigated in the present study.

Glycerol 3-phosphate acyltransferase catalyzes the first esterification step in TG biosynthesis, and is a potential site for regulation. However, consistent with the results obtained by Wong *et al.* (5), this enzyme was not found to be affected by n-3 fatty acids (Table 2).

Phosphatidate phosphohydrolase is a key enzyme in the regulation of triglyceride biosynthesis. The enzyme activity has been shown to vary in response to hormonal and dietary stimuli affecting TG biosynthesis (28). In a recent study, reduction of plasma TG has been suggested to be partially due to inhibition of PAP activity (29). In the present study, inhibition of the soluble enzyme activity could be demonstrated when serum TG levels were substantially reduced (the dietary model). This strongly suggests that the TG-lowering effect could be mediated by inhibition of the soluble PAP activity. PAP occurs, however, in the microsomes as well, and it has been suggested that stimulation of the enzyme activity might be mediated by a translocation of the cytosolic enzyme onto the microsomes. Thus, an inhibition of such a mechanism could result in suppression of the enzyme activity (30,31). With the assay employed, the microsomal activity was too low to be measured under accurate enzymological conditions (18). However, in a short-term study using the perfused liver model, no effect of n-3 fatty acids on the distribution of the enzyme activity could be demonstrated (8).

The effect of n-3 fatty acids on DGAT activity has been controversial. In the present study, no significant effect on the enzyme activity (Tables 2 and 3) was observed. This is in contrast to the findings of Rustan *et al.* (10) that eicosapentaenoic acid reduced hepatic synthesis and secretion of TG by decreasing the activity of DGAT. These conclusions were, however, mainly based on the finding that eicosapentaenoyl-CoA constituted a "poor" substrate for DGAT activity. A genuine effect of n-3 fatty acids on the enzyme *per se* was not demonstrated. In accordance with our results, Marsh *et al.* (9) did not find any significant effect of n-3 fatty acids on DGAT activity. It cannot be ruled out, however, that differences in the experimental design might at least in part explain the discrepancies noted.

The finding that among the key enzymes involved in TG biosynthesis only PAP was affected by dietary n-3 fatty acids indicates that the TG-lowering effect of these fatty acids could partially be explained by inhibition of PAP activity. Moreover, the results further underscore the significance of PAP as a rate-limiting enzyme in triglyceride biosynthesis.

The effect of n-3 fatty acids on serum cholesterol levels could be due to a number of factors. Of prime significance is the possibility that this effect could be mediated through retarded cholesterol synthesis and/or increased degradation. It is well documented that HMG-CoA reductase is rate-limiting in the synthesis of cholesterol under almost all experimental conditions. Moreover, inhibition of this enzyme has been shown to reduce serum cholesterol levels (32). The infusion of n-3 fatty acids led to a depression of the enzyme activity of a magnitude which was very similar to that of the reduction of serum cholesterol. Thus, it is tempting to suggest that the effect on serum cholesterol was mediated by an inhibition of the reductase. However, the rate-limiting enzyme in the degradation of cholesterol into bile acids, *i.e.*, cholesterol 7α-hydroxylase, was also depressed to a similar degree. The effect of n-3 fatty acids on cholesterol 7α-hydroxylase was about the same in the two animal models, whereas a significant effect on HMG-CoA reductase was obtained only with the infusion model. Since a marked effect on circulating levels of cholesterol was obtained only with the latter model, it seems likely that part of this effect was mediated by suppression of HMG-CoA reductase. Other possible mechanisms include retarded VLDL secretion resulting in decreased LDL levels, increased biliary secretion of cholesterol, and enhanced LDL clearance in plasma.

Although the rats used in the two experimental models were not identical in regards to weight and sexual maturity, the observation that the physiological response varied between the two models used in the present study indicate that the mode of administration of n-3 fatty acids is important. In the dietary model, the intestinal fat load results in production of intestinally derived lipoprotein particles enriched in n-3 fatty acids. However, by infusion of synthetic triglyceride-rich particles the gastrointestinal absorption system is circumvented. It therefore seems likely that the circulating lipoprotein particles in the two models differ with respect to their properties and that the fate of these particles may be dissimilar. This is strengthened by the observation that the incorporation of n-3 into hepatic phospholipids was clearly higher in the dietary model. The fact that different results on triglyceride and cholesterol metabolism were obtained even when using two *in vivo* models underscores the complex action of long-chain n-3 fatty acids on lipoprotein metab-

olism, and emphasizes the value of using whole animal models when studying the physiological impact and mechanisms of action of these fatty acids.

ACKNOWLEDGMENTS

The skillful technical assistance of Ulla Andersson, Irma Johansson, Ingegärd Fried and Anita Lövgren is gratefully acknowledged. The authors are also most grateful to Dr. Knut Dahl, Norsk Hydro, for a generous supply of ethyl esters of n-3 fatty acids. Thanks are also due to Leslie Sisfontes (MSc), who expertly performed the fatty acid analyses. This work was supported by a grant from Hans and Loo Ostermans fond, from Svenska Margarinindustrins Förening för Näringsfysiologisk Forskning, from Nordisk Insulinfond and from the Swedish Medical Research Council (project 03x-3141).

Synthesis of 6-Phosphatidyl-L-Ascorbic Acid by Phospholipase D

Akihiko Nagao*, **Nobuaki Ishida** and **Junji Terao**
National Food Research Institute, Ministry of Agriculture, Forestry and Fisheries, Tsukuba, Ibaraki, 305 Japan

Phospholipase D (EC 3.1.4.4) of *Streptomyces* species was found to catalyze transphosphatidylation to L-ascorbic acid from phosphatidylcholine (PC) in a biphasic reaction system. The product was identified as 1,2-diacyl-*sn*-glycero-3-phospho-6′-L-ascorbic acid (PA-AsA) by mass spectrometry and nuclear magnetic resonance spectroscopy. The optimal pH of transphosphatidylation was 4.5 and the rate of PA-AsA formation increased as concentrations of L-ascorbic acid increased. The conversion of PC to PA-AsA was greater than 80%. PA-AsA was found to be more resistant to hydrolysis by phospholipase D than was PC.

***Lipids* 26, 390–394 (1991).**

Phospholipase D (PLD) catalyzes the hydrolysis of the terminal phosphoester bond of phospholipids and can bring about transphosphatidylation (1,2). By using the transphosphatidylation reaction with PLD, the head group of phospholipids can be modified easily. Thus, phosphatidylglycerol can be produced from phosphatidylcholine and glycerol by catalysis with PLD (3,4). The transphosphatidylation technique also has been shown to be useful for preparing phosphatidylserine and plasmenylethanolamine (5–10). In addition, novel types of phospholipids with various physiological or therapeutic activities can be synthesized by catalysis with PLD. Thus, Shuto *et al.* (11) synthesized phosphatidylnucleosides with antileukemic activity, and Brachwitz *et al.* (12) prepared *O*-alkylglycerophospho-L-serine with cytostatic activity.

We have been working on the cellular defense system against oxygen toxicity, and especially against membrane lipid peroxidation (13–15). The defense against active oxygen radicals at the interface between membrane lipids and the aqueous phase is of considerable importance because the attack of active oxygen radicals originating in the aqueous phase is believed to be one of the initiation steps of membrane lipid peroxidation (16,17). To prevent active oxygen radicals from attacking membrane lipids, it seems effective to arrange an appropriate antioxidant on the surface of a membrane. One possible approach would be to substitute the polar head group of a membrane phospholipid with a functional group having antioxidant activity. L-Ascorbic acid, one of the important antioxidants in the cellular defense against active oxygen radicals (18), is an excellent candidate for a polar head group substitution that would produce phospholipid with antioxidant activity. Moreover, L-ascorbic acid has a primary hydroxy group available for transphosphatidylation by PLD. In this paper, the synthesis of phosphatidyl-L-ascorbic acid by phospholipase D is described.

Abbreviations: COSY, correlation spectroscopy; FAB, fast atom bombardment; HPLC, high performance liquid chromatography; MS, mass spectrometry; NMR, nuclear magnetic resonance spectroscopy; PA, phosphatidic acid; PA-AsA, 6-phosphatidyl L-ascorbic acid; PC, phosphatidylcholine; PLD, phospholipase D; TLC, thin-layer chromatography.

MATERIALS AND METHODS

Phospholipase D from *Streptomyces lydicus* (78.3 U/mg protein) was obtained from Honen Co. (Yokohama, Japan). The two PLD preparations from *Streptomyces* species (1130 and 391 U/mg protein) and PLD from cabbage (0.67 U/mg protein) were purchased from Toyo Jozo Co. (Tokyo, Japan), Sigma Chemical Co. (St. Louis, MO) and Boehringer Mannheim GmbH (Mannheim, Germany), respectively. Phosphatidylcholine (PC) from egg yolk (99% purity) and dimyristoyl PC were purchased from Sigma. Thin-layer chromatography (TLC) plates (Art. 5721) were purchased from Merck (Darmstadt, Germany). Other chemicals were reagent grade.

Enzyme reaction. The enzyme reaction was carried out in a biphasic system consisting of a diethyl ether and an aqueous phase using an 8-mL vial. The standard reaction mixture contained 1 mL of 10 mM egg yolk PC in diethyl ether, 0.8 mL of 1 M L-ascorbic acid, 0.05 mL of the PLD solution which contained 90 U of PLD from *S. lydicus* in 1 mL of 10 mM sodium acetate buffer, pH 5.1, and 0.15 mL of deionized water. The pH of 1 M L-ascorbic acid was adjusted to 4.5 with KOH. The enzyme reaction was initiated by the addition of the enzyme and the mixture was shaken (120 rpm) at 37°C. The reaction was stopped by adding 0.2 mL of 6 N HCl. The product was extracted three times from the reaction mixture with 4 mL of chloroform/methanol (2:1, v/v). The combined chloroform layer was washed with 5 mL of deionized water and evaporated in a rotary evaporator. The extract was dissolved in 5 mL of *n*-hexane/isopropanol (4:1, v/v) and then centrifuged. The supernatant was analyzed by TLC and high performance liquid chromatography (HPLC). PLD units were determined by the method of Kato *et al.* (19).

The hydrolytic activity of the PLD with PC or 6-phosphatidyl-L-ascorbic acid (PA-AsA) as substrate was determined by measuring the amount of phosphatidic acid (PA) formed. The reaction mixture contained 5 μmol of egg yolk PC or PA-AsA prepared from egg yolk PC in 1 mL of diethyl ether and 4.5 U of the PLD of *S. lydicus* in 1 mL of 0.1 M potassium citrate buffer, pH 6.0. The reaction was stopped by adding 0.2 mL of 6 N HCl, and PA was extracted as described above and analyzed by HPLC.

TLC analysis. The lipid extract of the reaction mixture was subjected to thin-layer chromatography using the developing solvent chloroform/methanol/water (65:35:5, by vol). Phospholipids were visualized with Dittmer's reagent or iodine vapor. Substances with reducing activity were detected using ferric ion reagent (20).

HPLC analysis. HPLC was performed on a Shimadzu (Shimadzu Co., Kyoto, Japan) LC-5A equipped with a Rheodyne 7125 manual loop injector (20 μL), a Shimadzu SPD-2A variable wavelength detector (AUFS 0.01) and a Shimadzu C-R3A data processor. PA-AsA was analyzed on a silica gel column (YMC-Pack SIL-06, 4.6 × 150 mm, YMC Co., Kyoto, Japan) with *n*-hexane/isopropanol/10% phosphoric acid (85:15:0.4, by vol) serving as eluent at a flow rate of 2 mL/min. The column temperature was maintained at 40°C for the analysis of PA-AsA. The retention time of PA-AsA was 3.3 min. PC was analyzed on

the same column with *n*-hexane/isopropanol/10% phosphoric acid (20:30:5, by vol) serving as eluent at a flow rate of 1.2 mL/min. The retention time of PC was 3.7 min. PA was analyzed on SHIM-PACK FLC-NH_2 column (4.6 × 50 mm, Shimadzu) with *n*-hexane/isopropanol/10% phosphoric acid (80:20:0.5, by vol) serving as eluent at a flow rate of 2 mL/min. The retention time of PA was 2.0 min. PA-AsA, PC and PA were monitored at 245, 206 and 206 nm, respectively. Sample was injected using a sample loop of 20 μL.

Spectral analyses. Infrared spectra were measured on potassium bromide pellets using a Shimadzu FTIR-4200 infrared spectrophotometer. Mass spectra were measured in the negative fast atom bombardment (FAB) mode with a JEOL (Japan Electronic Optics Laboratory Co., Tokyo, Japan) JMS-HX 100. The FAB gun was operated at 6 KV; xenon atoms were used to ionize the sample in the desorption mode from a triethanolamine matrix. ^1H and ^{13}C nuclear magnetic resonance (NMR) spectra were measured with a JEOL GSX-270 FT NMR spectrometer at 270 and 67.9 MHz, respectively. Samples were dissolved in $CDCl_3/CD_3OD$ (2:1, v/v); tetramethylsilane was used as internal standard.

RESULTS

A new product derived from egg yolk PC and L-ascorbic acid was proposed by catalysis with PLD of *S. lydicus*. The product (R_f 0.25) was separated from PC (R_f 0.35) and PA (R_f 0.41) by TLC. The function gave a blue spot with Dittmer's reagent and a red spot with ferric ion reagent indicating the presence of a phospholipid with reducing activity. The phospholipid was tentatively identified as phosphatidyl-L-ascorbic acid (PA-AsA) having an ester linkage between either the 5- or 6-hydroxy group of L-ascorbic acid and the phosphatidyl moiety.

The structure of PA-AsA was confirmed by spectral analysis of dimyristoyl PA-AsA. PA-AsA was synthesized from 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine and L-ascorbic acid using the same procedure as described in Materials and Methods, except that the concentration of L-ascorbic acid in the aqueous phase of reaction mixture was 2 M. A conversion of 93.6% was attained after 24 hr. PA-AsA was purified on a silicic acid column using the same solvent mixture as for TLC; the isolated yield of PA-AsA was 54.2% relative to PC used. The infrared spectrum of the purified PA-AsA indicated the presence of a phosphate ester and of the double bond of L-ascorbic acid (KBr, cm^{-1}: 1738 $\nu_{C=O}$, 1600 $\nu_{C=C}$, 1231 $\nu_{P=O}$, 1109 $\nu_{P\text{-}O\text{-}C}$). PA-AsA showed the expected UV spectrum for the L-ascorbic acid moiety. The FAB mass spectrum of PA-AsA showed a $[M+Na-2H]^-$ ion at *m/z* 771, a $[M-H]^-$ ion at *m/z* 749, a carboxylate anion at *m/z* 227, and a phosphatidate anion at *m/z* 591 (Fig. 1).

^{13}C NMR chemical shift assignments for PA-AsA in $CDCl_3/CD_3OD$ (2:1, v/v) were made based on the chemi-

cal shifts of dimyristoyl PC and L-ascorbic acid in the same solvent (Table 1). The ^{13}C chemical shift assignments for dimyristoyl PC were consistent with those reported for dioctanoyl PC (e.g., ref. 21). The assignments for L-ascorbic acid were also based on literature values (22). The ^{13}C chemical shift assignments for PA-AsA were confirmed by DQF correlation spectroscopy (COSY) and ^{1}H-^{13}C COSY experiments. The ^{13}C chemical shifts of the dimyristoyl glycerol moiety of PA-AsA essentially resembled those of dimyristoyl PC. The ^{13}C chemical shifts of the L-ascorbic acid moiety of PA-AsA were essentially those of L-ascorbic acid, except for the C-5 and C-6 shifts. The C-6 signal of PA-AsA showed a significant downfield shift relative to that of L-ascorbic acid, while the C-5 signal was slightly shifted upfield. This ^{13}C chemical shift pattern for carbons proximal to phosphate were previously observed for other phosphoesters such as 5′-(3-*sn*-phosphatidyl) nucleosides (11) and L-ascorbic acid 6-phosphate (23). Moreover, the ^{13}C-^{31}p couplings observed (Fig. 2) for C-6(J=5.5Hz) were smaller than those for

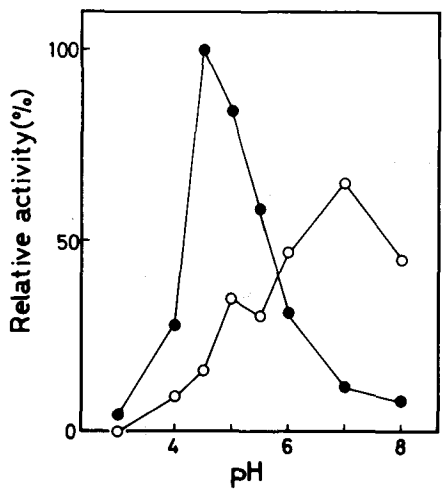

FIG. 3. Effect of pH on the synthesis of PA-AsA and on the hydrolysis to PA. The reaction was done as described in Materials and Methods, except that the pH was varied. The pH of the aqueous medium was adjusted to 3.0, 4.0, 4.5, 5.0 and 5.5 with KOH; to 6.0 with 0.1 M succinic acid-KOH buffer; and to 7.0 and 8.0 with 0.1 M Tris-HCl buffer. The reaction was terminated after 30 min. Relative activities were calculated based on the amount of PA-AsA formed at pH 4.5 (100%). ●, PA-AsA; and ○, PA.

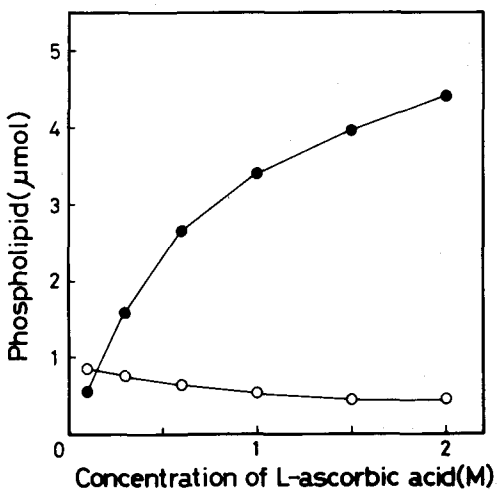

FIG. 4. Effect of L-ascorbic acid concentration on the synthesis of PA-AsA. The reaction was terminated after 30 min. ●, PA-AsA; and ○, PA.

C-5(J=8.25Hz). Based on the $^{2}J_{CP}$ and $^{3}J_{CP}$ values reported for various phospholipids (24), our data strongly suggest that the phosphatidyl moiety in PA-AsA is linked *via* the hydroxy group at C-6 of L-ascorbic acid rather than *via* C-5. Thus, PLD of *S. lydicus* catalyzes transphosphatidylation from PC to L-ascorbic acid to form 1,2-diacyl-*sn*-glycero-3-phospho-6′-L-ascorbic acid.

Figure 3 shows the effect of pH of the reaction mixture on the synthesis of PA-AsA and on the hydrolysis of PC to PA by PLD of *S. lydicus*. The optimum pH for PA-AsA synthesis was in the range of 4.5 to 5.0. The optimum pH for the hydrolysis of PC to PA in the presence of L-ascorbic acid was 7.0. Therefore, the pH of the reaction mixture of subsequent experiments was kept at 4.5.

The effect of L-ascorbic acid concentration on the synthesis of PA-AsA is shown in Figure 4. PA-AsA formation markedly increased as the concentration of L-ascorbic acid increased. The amount of PA formed decreased only slightly as the concentration of L-ascorbic acid increased. Hence, higher concentrations of L-ascorbic acid clearly favored conversion of PC to PA-AsA.

Among the organic solvents tested for use in the transphosphatidylation, ethyl acetate gave the same level of PA-AsA as did diethyl ether. However, twice as much PA was produced when ethyl acetate was used. Other solvents such as *n*-hexane, cyclohexane, chloroform, acetonitrile and *tert*-butanol gave lower conversions to PA-AsA and produced a higher ratio of PA to PA-AsA. Thus, diethyl ether appeared most suitable as organic phase for the synthesis of PA-AsA.

The synthesis of PA-AsA proceeded in a linear fashion during the initial 30 min and then gradually reached a plateau. After 6 hr, conversion of PC to PA-AsA reached about 80%. PA was also formed, but at a much lower level. PC decreased rapidly and entirely disappeared after prolonged reaction. After 24 hr, PA-AsA started to decrease gradually while PA increased (Fig. 5).

The susceptibility of PA-AsA to hydrolysis by PLD was compared with that of PC in the biphasic reaction system (Fig. 6). PC was rapidly hydrolyzed to release PA, where as PA-AsA was more resistant to hydrolysis. The initial rate of hydrolysis of PA-AsA was about 6% of that of PC in this condition.

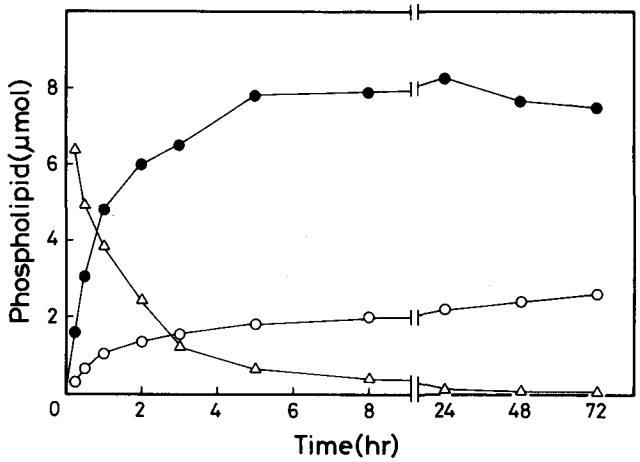

FIG. 5. Time course for the synthesis of PA-AsA. ●, PA-AsA; △, PC; and ○, PA.

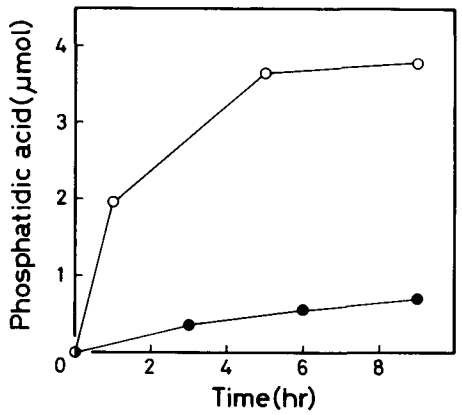

FIG. 6. Hydrolysis of PA-AsA and PC to PA. ●, PA-AsA; and ○, PC.

The synthetic activities of four different phospholipase D were compared using the same reaction conditions (see Materials and Methods) except that in the case of cabbage PLD the reaction mixture contained 40 mM $CaCl_2$ (Table 2). PLD-A showed the highest conversion of PC to PA-AsA. On the other hand, PA-AsA could not be synthesized and PC could not be significantly hydrolyzed by cabbage PLD under the conditions tested. However, PC was completely hydrolyzed by cabbage PLD within 30 min, when the 0.8 M L-ascorbic acid was replaced by 80 mM sodium acetate buffer, pH 4.5. This may suggest that the activity of cabbage PLD is suppressed at the higher L-ascorbic acid concentration.

DISCUSSION

The present study demonstrates that 6-phosphatidyl-L-ascorbic acid can be produced in high yield by utilizing the transphosphatidylation activity of phospholipase D. Maximum conversion of PC to PA-AsA was 93.6%. This value is similar to the conversion reached for phosphatidylethanolamine to phosphatidylglycerol (97.3%) and for PC to phosphatidylglycerol (83%) by this enzyme (25,26). PLD of *Actinomycetes* has been shown to have a broad substrate specificity for acceptor alcohols including geraniol, glucose and nucleosides (27-29). L-ascorbic acid was found to also be a good acceptor alcohol for the phospholipase D of three different *Streptomyces* species. Transphosphatidylation *vs.* hydrolysis varied among the phospholipases. The transphosphatidylation activity of cabbage PLD in respect to L-ascorbic acid remains unknown because activity is suppressed in the presence of ascorbic acid at high concentrations. However, it is likely that cabbage PLD does not exhibit transphosphatidylation activity in respect to L-ascorbic acid, because cabbage PLD was shown to catalyze transphosphatidylation to several primary alcohols, but not to sucrose, glucose, galactose (2) and nucleosides (29).

It has been reported that the optimal pH was 6.0 for the hydrolysis of egg yolk PC (solubilized with Triton X-100) by PLD from *S. lydicus*. However, in the present study, optimal formation of PA occurred at pH 7.0 in the presence of L-ascorbic acid. This difference may be due to the different physical states of PC which would affect the enzyme reaction at the ether/water interface. Shuto *et al.* (29) reported that the optimum pH for the synthesis of 5'-phosphatidyl-nucleosides by PLD was equal to the pK of nucleoside bases. Similarly, the optimum pH for the synthesis of PA-AsA (pH 4.5) was about equal to the pK (4.17) of L-ascorbic acid. It appears that PLD has a higher affinity for the non-ionized form of L-ascorbic acid.

Juneja *et al.* (30) reported that the initial rate of transphosphatidylation from PC to ethanolamine by several phospholipases D, including *S. lydicus*, reached a maximum at about 0.3 M ethanolamine. At higher concentrations of ethanolamine, the initial reaction rate decreased. The rate of hydrolysis of PC was also low at higher concentrations of ethanolamine. Both transphosphatidylation and hydrolysis activities of cabbage PLD decreased at higher concentrations of acceptor alcohol, such as glycerol, choline, ethanolamine, methanol and ethanol (6,8). By contrast, the rate of formation of PA-AsA was not suppressed at higher concentrations of L-ascorbic acid and the Km value for ascorbic acid was *ca.* 1 M in the present study. A similar dependence of transphosphatidylation on the concentration of an acceptor alcohol was observed in the case of L-serine (6,31). The activity of PLD was not depressed at higher concentrations of L-serine and maximum conversion to PS was attained at the saturation level of L-serine.

Several solvents, such as diethyl ether, chloroform and ethyl acetate, have been used to facilitate dispersions of phospholipids in the transphosphatidylation mixture. Surfactants such as Triton X-100 and SDS have alternately been used. It also has been reported that chloroform can be a suitable solvent to disperse dimyristoyl PC for the synthesis of phosphatidyl-L-homoserine (9) and phosphatidylnucleosides (29). In the synthesis of PA-AsA, however, chloroform resulted in low yields and high PA-to-PA-AsA ratios. Diethyl ether was found to be the best solvent for the transphosphatidylation reaction of L-ascorbic acid. Although dimyristoyl PC does not dissolve completely in diethyl ether, 93.6% of the PC was converted to PA-AsA.

Conversion to PA-AsA reached a maximum (about 80%) after 24 hr. Thereafter, PA-AsA decreased gradually while PA increased slowly. It is likely that the decrease of PA-AsA is due to its hydrolysis to PA after consumption of PC. This is consistent with the fact that PA-AsA can be hydrolyzed to PA by PLD, although the rate of hydrolysis is much slower than that of PC. The resistance of PA-AsA to hydrolysis by the PLD favors the synthesis of PA-AsA. It also seems unnecessary to stop the reaction at a specific time point as prolonged reaction does not significantly diminish final PA-AsA levels.

The phospholipase D of *Streptomyces* catalyze the transphosphatidylation to L-ascorbic acid and the PA-AsA formed retains the reducing activity of L-ascorbic acid. We have confirmed the antioxidant activity of PA-AsA in the peroxidation of methyl linoleate in apolar solvent and of egg yolk phosphatidylcholine in liposomal suspension (32).

ACKNOWLEDGMENT

The authors wish to thank Mr. K. Shinbo of Honen Co. for kindly supplying PLD and Dr. H. Oe of Eisai Co. for FAB mass Spectra.

Effect of Chitosan Feeding on Intestinal Bile Acid Metabolism in Rats

Yasuhiko Fukada, Koji Kimura and **Yoshikazu Ayaki***
Department of Biochemistry, Tottori University School of Medicine, Yonago, Tottori 683, Japan

The effect of chitosan feeding (for 21 days) on intestinal bile acids was studied in male rats. Serum cholesterol levels in rats fed a commercial diet low in cholesterol were decreased by chitosan supplementation. Chitosan inhibited the transformation of cholesterol to coprostanol without causing a qualitative change in fecal excretion of these neutral sterols. Increased fiber consumption did not increase fecal excretion of bile acids, but caused a marked change in fecal bile acid composition. Lithocholic acid increased significantly, deoxycholic acid increased to a lesser extent, whereas hyodeoxycholic acid and the 6β-isomer and 5-epimeric 3α-hydroxy-6-keto-cholanoic acid(s) decreased. The pH in the cecum and colon became elevated by chitosan feeding which affected the conversion of primary bile acids to secondary bile acids in the large intestine. In the cecum, chitosan feeding increased the concentration of α-,β-, and ω-muricholic acids, and lithocholic acid. However, the levels of hyodeoxycholic acid and its 6β-isomer, of monohydroxy-monoketo-cholanoic acids, and of 3α, 6ξ, 7ξ-trihydroxy-cholanoic acid decreased. The data suggest that chitosan feeding affects the metabolism of intestinal bile acids in rats.

***Lipids* 26, 395-399 (1991).**

Chitosan (glucosamine polymer) is known to have a marked hypocholesterolemic effect in cholesterol-fed rats (1-4). Sugano *et al.* (5) recently reported that the hypocholesterolemic effect of chitosan did not differ within the viscosity range tested (17-1620 cps), while glucosamine oligomer proved ineffective. Vahouny *et al.* (6) found that chitosan was effective in lowering cholesterol absorption in thoracic duct lymph.

Sugano *et al.* (1,4) also showed that chitosan lowered the transformation of cholesterol to coprostanol and increased the excretion of these neutral sterols. In contrast, the fecal excretion of bile acids was essentially unchanged (4). It is well known that primary bile acids are converted into secondary bile acids by intestinal bacteria (7-9). The secondary bile acids, lithocholic acid and deoxycholic acid, have been correlated with the risk of bowel cancer and gallstones (10-12). Because the ingestion of some types of dietary fibers has been shown to influence the intestinal flora (13-15), it appeared possible that chitosan may also influence bile acid metabolism. In the present study we investigated the effect of chitosan supplementation of a normal diet (0.1% cholesterol) on the metabolism of intestinal bile acids in rats.

MATERIALS AND METHODS

Materials. The chitosan used in this study was donated by Professor S. Hirano, Faculty of Agriculture, Tottori University, Tottori, Japan. It was a high viscosity grade preparation with a mean molecular weight of 250,000. The degree of deacetylation was approximately 94%.

3α-Hydroxy-6-keto-5β-cholanoic acid and 3α-hydroxy-6-keto-5α-cholanoic acid were synthesized according to Thomas *et al.* (16) and Bergström *et al.* (17), respectively.

Reagents and organic solvents were of analytical grade. Solvents were distilled, if necessary, before use.

Animals and diet. Male Wistar strain rats were purchased from the Shizuoka Agricultural Cooperative Association for Laboratory Animals (Shizuoka, Japan), and were housed individually in an air-conditioned room (23 ± 1°C) with lighting from 6 a.m. to 6 p.m. After acclimation for two weeks, the animals were divided into three groups. One group was fed a control diet consisting of a commercial powder diet (Clea CA-1, Nihon Clea Co., Tokyo, Japan), supplemented with 0.5% cellulose and 4.5% sucrose; the second group was fed a diet supplemented with 0.5% cellulose, 2.5% sucrose and 2% chitosan; the third group was fed a 5% chitosan-supplemented diet. The stock powder diet contained 25.6% protein, 4.6% fat, 4.0% fiber and all vitamins at recommended values. The diet contained 1.05 ± 0.09 mg/g of cholesterol (mean ± S.D., n=4) and 98.0 ± 5.1 μg/g (mean ± S.D., n=4) of cholic acid as analyzed in our laboratory. The animals were maintained on these diets *ad libitum* for 21 days. Food intake was measured daily, and body weight was determined every second day. Feces were collected for the two days prior to killing. Animals were sacrificed by cardiac puncture under diethyl ether anesthesia. The serum was separated from blood, and the intestine was excised. The entire small intestine was divided into three segments: duodenum, jejunum and ileum, as described by Dietschy and Siperstein (18). The large intestine was divided into two parts: the cecum and colon. The intestinal contents were removed from each segment for measurement of pH and bile acid analysis. The pH of the intestinal contents was estimated directly from the samples using a Horiba Electrometer pH meter. All sampling procedures were performed between 9 and 11 a.m., and all samples were stored at -20°C prior to analysis.

Analysis. Frozen fecal samples were lyophilized, pulverized, and weighed before analysis; 500 mg specimens of blended feces were used for crude extraction of bile acids by refluxing in 90% ethanol for 2 hr. Refluxing was repeated twice, and the pooled extracts were evaporated. The extracts were hydrolyzed by refluxing in 5% NaOH/50% ethanol for 2 hr, and after cooling, the neutral sterols were extracted with n-hexane. The neutral sterols, analyzed by gas-liquid chromatography, were cholesterol and coprostanol. The alkaline solution was adjusted to neutrality by adding dilute HCl dropwise and then evaporated to dryness. The extracts were chromatographed on Amberlite XAD-2 (Rohm and Haas, Philadelphia, PA) to obtain the bile acid fraction. The steps used in the analysis of bile acids were absorption, elution, solvolysis, hydrolysis, extraction, and preparation of methyl ester acetate

derivatives. All these steps have been previously described in detail, including the analysis of samples by GLC at 230°C using a Shimadzu Model GC-3BF unit with a coiled glass column (3 mm × 1.75 m), filled with 1.5% OV-1 on Gas Chrom Q 100-120 mesh (Shimadzu Co., Kyoto, Japan) (19). Quantitative results were obtained by comparing peak areas with those of known amounts of reference compounds.

In order to identify the fecal bile acids, aliquots of the bile acid fraction were fractionated on a column of silicic acid (AR, 100 mesh; Mallinckrodt, St. Louis, MO) (20), and the bile acid samples were analyzed by gas-liquid chromatography/mass spectrometry (GC/MS) using a JMS-DX 303 mass spectrometer (JEOL, Tokyo, Japan) connected to a Hewlett-Packard HP 5890A gas chromatograph. A glass column (2 mm × 1.2 m) packed with 1% OV-1 on Gas Chrom Q (100-120 mesh) was used. The conditions for analysis were: injection temperature, 270°C; column temperature, 250°C; ion source temperature, 250°C; ionization voltage, 70 eV; ionization current, 300 μA; carrier gas, He (27.5 mL/min).

The significance of differences between the means of the control and test groups was determined by one-way analysis of variance followed by Student's t-test.

RESULTS

As shown in Table 1, there were no significant differences in growth, food intake, liver weight and dried fecal weight between the control and either of the chitosan-fed groups after 21 days. The serum cholesterol level was depressed by the 5% chitosan-supplemented diet group compared with the control group. There was no significant difference in fecal excretion of neutral sterols and bile acids between the control group and either of the chitosan-treated groups.

The same bile acids that were found in the intestine and/or feces of control rats were also present in the respective samples from both chitosan-treated groups (Table 2). Three of the compounds found in the feces—X, Y, Z—remain unidentified. The fecal bile acids were fractionated into monohydroxy (I and II), dihydroxy (III and IV), dihydroxy plus trihydroxy (V and VI), and trihydroxy (VII and VIII) fractions by chromatography on a silicic acid column. Both compounds X and Y were eluted in fraction II. The mass spectra of these compounds showed peaks at *m/z* 446 (M^+), 386 (M^+-60), 371, 313, 271 and 253 [M^+-(18+60+115)], indicating that they were monohydroxy-monoketo-cholanoic acid deriva-

tives. Fragments *m/z* 231 and 121 from compound X are indicative of a keto group at C-12. Compound Y showed an ABC ring fragmentation ion at *m/z* 229, indicating a keto group at position 3 or 6. Fragment *m/z* 244 is indicative of a keto group at C-6. 6-Keto-5β-cholanoic acids are transformed to their 5α-forms in the presence of excess OH^- or H^+ (21), but this allomerization is incomplete (data from capillary gas chromatographic analysis, not shown). The mass spectra of compound Z showed peaks at *m/z* 428, 368, 353, 313, and 253 [M^+-(3×60+115)], indicative of a triacetoxy derivative. The intense peak at *m/z* 386 [M^+-(60 plus an epoxide between C-6 and C7)] is characteristic for the 3,6,7-triacetoxy compound but there were no specific fragments at *m/z* 446 and 271 as found for α- and β-muricholic acid. From these results, compounds X and Y appear to be 3α-hydroxy-12-keto-5β-cholanoic acid and 5-epimeric 3α-hydroxy-6 ketocholanoic acid(s), respectively. Compound Z appears to be 3α, 6ξ, 7ξ-trihydroxycholanoic acid.

The composition of fecal bile acids and neutral sterol is shown in Table 3. In control rats, 3α-hydroxy-12-keto-5β-cholanoic acid, ω-muricholic acid, and hyodeoxycholic acid and its 6β-isomer were the predominant bile acids (>15%); small amounts (<5%) of α-muricholic acid, lithocholic acid, and 3α,6ξ,7ξ-trihydroxycholanoic acid were also present. Feeding 5% chitosan to rats resulted in an increase in lithocholic acid, a smaller increase in deoxycholic acid ($p<0.2$), and a decrease in hyodeoxycholic acid and its 6β-isomer, and in 5-epimeric 3α-hydroxy-6-ketocholanoic acid(s). There was a decrease in coprostanol and an increase in cholesterol in the 5% chitosan-treated group compared with controls.

Table 4 shows the pH of the contents of various intestinal segments. The pH of the contents of the cecum and of the colon in the 5% chitosan-treated group was higher than for the controls.

Table 5 shows the bile acid composition in the duodenum. In the chitosan-treated group, hyodeoxycholic acid and its 6β-isomer, as well as chenodeoxycholic acid were decreased as compared to controls.

As shown in Table 6, in the cecum of the chitosan-fed group, lithocholic acid, and α-, β- and ω-muricholic acids increased. By contrast, hyodeoxycholic acid and its 6β-isomer, monohydroxy-monoketo-cholanoic acids, and 3α,6ξ,7ξ-trihydroxy-cholanoic acid decreased. Chitosan feeding expanded the neutral sterol pool and concomitantly caused a decrease in coprostanol and an increase in cholesterol.

TABLE 6

Composition of Bile Acids and Neutral Sterols in the Cecum[a]

Composition	Control (n=5)	5% Chitosan (n=6)
Bile acid[b] (%)		
Lithocholic	3.1 ± 0.7	5.0 ± 0.5[c]
Deoxycholic	25.2 ± 4.1	30.3 ± 2.5
Hyodeoxycholic and its 6β-isomer (HD)	25.9 ± 2.2	4.6 ± 0.6[c]
α-Muricholic	0.9 ± 0.0	4.1 ± 1.1[c]
β-Muricholic	8.2 ± 1.1	17.5 ± 2.2[c]

DISCUSSION

Chitosan feeding induced a significant reduction of plasma cholesterol in rats fed a hypercholesterolemic diet consistent with previous reports (1-5). The present study also shows that chitosan feeding (5%) reduces serum cholesterol levels in rats fed a low cholesterol diet (0.1%). Dietary fiber may alter the excretion or metabolism of cholesterol and bile acids in the gut and thus influence plasma cholesterol levels. Cholesterol is converted to coprostanol by intestinal microflora (22). In our experiments, chitosan feeding suppressed the formation of coprostanol, as was observed earlier by Sugano *et al.* (1,4). While chitosan increased the excretion of neutral sterols in rats fed a high cholesterol diet, there was no increase in fecal neutral sterols in our experiments with rats fed a low cholesterol diet. The cholesterol pool in the cecum was expanded by chitosan feeding; however, the amount of cholesterol that accumulated in the cecum may have been insufficient to increase the excretion of cholesterol. It is, therefore, likely that cholesterol that was not absorbed by the proximal region of the small intestine, the site of cholesterol absorption (23), accumulated in the cecum which may explain decreased plasma cholesterol levels.

Dietary fiber affected the composition of fecal bile acids but did not alter their excretion. Primary bile acids are converted to secondary bile acids by intestinal bacteria in the cecum and colon (24). Bacterial 7α-dehydroxylation converts cholic acid to deoxycholic acid (7), and chenodeoxycholic acid to lithocholic acid (8). Lithocholic acid and deoxycholic acid are carcinogenic and toxigenic (10, 11). Although lithocholic acid and deoxycholic acid are detoxified by hydroxylation in liver in the course of enterohepatic circulation (25-28), chitosan feeding caused an increase in lithocholic acid and a smaller increase in deoxycholic acid in cecum and feces. 7α-Dehydroxylation of primary bile acids *in vitro* is stimulated at a pH greater than 6.5 (29). Chitosan may cause an increase in pH in the cecum by degradation to glucosamine or ammonia by colonic bacteria.

Hyodeoxycholic acid and ω-muricholic acid are the most abundant bile acids in the feces of normal male rats (30-33). Chitosan feeding caused a marked increase in the ω-muricholic acid (ω-MC)/hyodeoxycholic acid (HD) ratio in the cecum and feces. If one would assume that β-muricholic acid is converted to hyodeoxycholic acid and ω-muricholic acid by colonic bacteria, the increased ω-MC/HD ratio would suggest that one of these metabolic pathways is blocked causing the accumulation of β-muricholic acid (34,35). The bile acid composition in cecum and feces is specifically changed by chitosan feeding. In rats, chitosan feeding caused a marked effect on the metabolism of bile acids as well as cholesterol in the large intestine, with no quantitative changes being observed in the excretion of neutral sterols and bile acids. However, the changes in bile acid composition may not always be significant, particularly when high cholesterol is included in the diet, because cholesterol feeding can mask the effects of dietary fiber on intestinal bile acids (36).

Digestion and Absorption of Free and Esterified Fish Oil Fatty Acids in Rats

Remi De Schrijver*, **Daniel Vermeulen** and **Suzanne Backx**
Laboratory of Nutrition, Catholic University of Leuven, B-3001 Leuven, Belgium

This study was designed to test the hypotheses that digestibility and post-absorption metabolism of fish oil are influenced by impaired lipolysis and by the stereospecific composition of its triacylglycerols. Male Wistar rats were fed nonpurified diets containing one of the following fat sources: 9% native fish oil (NFO), 9% autorandomized fish oil (RFO), 8.1% fish oil-derived free fatty acids (FO-FFA) plus 0.9% glycerol, or 9% soybean oil (SO) as a reference fat. In a 24-day balance study, apparent digestibility of total dietary fat averaged 93.1% in the SO, NFO and RFO groups, and 90.9% in the FO-FFA group. Randomization of fish oil had no effect on apparent digestibility of individual fatty acids. In rats fed FO-FFA, apparent absorption of saturated and monounsaturated fatty acids was lower when compared to the NFO and RFO groups. Feeding the FO-FFA diet tended to increase plasma triglyceride content. The hypocholesterolemic effect of polyunsaturated n-3 fatty acids was not influenced by the dietary source. Similar effects on fatty acid profiles of plasma and liver phospholipids were caused by the NFO, RFO and the FO-FFA diets. We conclude that once polyunsaturated n-3 fatty acids are absorbed, their effect on lipid metabolism is not determined by the dietary source.

Lipids 26, **400–404 (1991).**

Fish oil consumption has been shown to have beneficial effects on cardiovascular disease. The anti-atherogenic effect of fish oils has been attributed to long-chain n-3 polyunsaturated fatty acids, in particular eicosapentaenoic (EPA) and docosahexaenoic (DHA) acids, which appear to reduce the plasma concentrations of total triglyceride and VLDL-triglyceride in animals and humans (1–4). The effect of dietary fish oil on plasma cholesterol is equivocal (5). Fish oil is ingested either as a component of fish or as encapsulated dietary supplement consisting of the stabilized and purified oil. Controversy exists regarding the digestibility of fish oil and the absorbability of the digested products. Fatty acid recovery in the lymph of rats was considerably less when fish oil instead of corn oil was fed (6). An explanation for this could be that the EPA-glycerol ester bond may be more resistant to hydrolysis by pancreatic lipase. On the other hand, fish oil was readily digested in neonatal piglets as determined by analysis of stomach and intestinal contents collected 12 hr after fish oil intubation (7). Digestion of fish oil may be different when ingested as part of a diet rather than as a single dose. Also, the stereospecific composition of the triacylglycerols of fish oil may determine digestibility and, possibly, the metabolic fate of the fatty acids absorbed (8). It has been shown for peanut oil (9) and oleoyl stearoyl triacylglycerols (10) that the triacylglycerol structure can influence lipid metabolism.

In the present study carried out with rats, we compared the digestibility of fat in nonpurified diets supplemented with native (NFO) or randomized fish oil (RFO). In order to determine whether lipolysis of fish oil is a factor contributing to impaired fatty acid absorption (6), the digestive hydrolysis process in one of the experimental groups was circumvented by feeding fish oil-derived free fatty acids (FO-FFA) as dietary supplement. Because of its high digestibility, soybean oil (SO) was also included as a control in this study. Plasma lipid contents and fatty acid profiles of plasma and liver phospholipids were determined in order to establish whether the chemical form in which fish oil fatty acids are ingested affects post-absorption lipid metabolism.

MATERIALS AND METHODS

Experimental design. Male Wistar rats (University Animal Center, Leuven, Belgium), weighing approximately 150 g each, were individually housed in metabolism cages. The animal room was maintained at 23°C at a 12-hr light-dark cycle. Rats were fed a nonpurified, cereal-based diet containing 9% beef tallow for a 25-day adaption period. The diet contained 205 g crude protein, 130 g crude fat, 35 g crude fiber, 65 g crude ash, and 1 g butylhydroxytoluene per kg. A beef tallow diet was chosen in order to induce a hyperlipidemic effect before feeding the experimental fat sources. At the end of the pre-experimental period, after a 24-hr fast, six rats were killed under diethyl ether anesthesia and plasma lipids were measured. Twenty-four rats were assigned to four dietary treatment groups; the average starting weight in each of the groups was 230 $\pm$ 3 g (mean $\pm$ SEM). The experimental diets were similar to the diet fed during the adaption period, except that beef tallow was replaced by NFO, RFO, SO or FO-FFA, respectively. However, the latter diet contained 8.1% FO-FFA and 0.9% added glycerol to equalize fatty acid and glycerol contents of the diets. Beef tallow and soybean oil were purchased at a local store. Native but purified fish oil was obtained from Seven Seas Health Care Ltd. (Kingston-upon-Hull, U.K.); it contained 1 g of α-tocopherol and 0.1 g of dodecylgallate per kg. Diets were prepared every six days and kept at 0°C under N_2 to minimize lipid autoxidation. Diets were fed as meal and provided fresh daily. Animals had free access to tap water and food. The experimental period lasted 24 days. Food intake was measured daily, with corrections made for spilled food. Feces were collected daily and frozen at -18°C. At the time of analysis, feces samples from each rat were pooled per 6-day subperiod. At the end of the assay period, rats were fasted for 24 hr and weighed. Trunk blood from each rat was obtained after decapitation under diethyl ether anesthesia. The liver was removed,

washed with cold saline/phosphate solution, blotted dry, and frozen at -70°C until lipid analysis.

Analytical procedures. Crude fat contents of diets and feces were analyzed by diethyl ether extraction, following hydrolysis with 3N HCl (11). Fatty acid profiles of diets, dietary supplemented fats, feces, and plasma and liver phospholipids were determined by gas-liquid chromatography of the methyl esters prepared by transmethylation with BF_3/methanol. A Shimadzu gas chromatograph (Model 15A, Shimadzu Corp., Kyoto, Japan) was used, equipped with an on-column injection system and a flame ionization detector. Samples were injected onto a fused silica capillary column (RSL 500, 25 m × 0.25 mm, 0.2 μm film, Bio-Rad RSL, Eke, Belgium). Retention times were verified by comparison with standards (Nu-Chek Prep, Elysian, MN). To isolate phospholipids from plasma and homogenized liver, samples were extracted with chloroform/methanol (2:1, v/v) containing 0.1% butylhydroxytoluene, and the extracts were washed with 0.9% KCl in water. The solvent was evaporated by a stream of N_2, and total lipids were redissolved and concentrated in chloroform. The neutral and polar lipid fractions were separated on a silica cartridge (Extract Clean column, Alltech Associates Inc., Laarne, Belgium) by elution with chloroform and methanol, respectively. Plasma triglyceride and total cholesterol were determined by enzymatic methods using Boehringer kits (Boehringer Pharma, Mannheim, Germany).

Preparation of randomized fish oil. Autorandomized fish oil was prepared by adding 0.2% sodium methoxide, heating at 75°C for 3 hr under continuous stirring, and flushing with N_2. The reaction was stopped by cooling to room temperature and adding 1% citric acid. The randomized fish oil was freed from free fatty acids by adding 0.5 N NaOH and washing with water containing 3% NaCl. The oil was dried over anhydrous Na_2SO_4. The efficiency of the washing procedure was checked by thin-layer chromatography using silica gel LK plates (Whatman, Maidstone, U.K.) and hexane/diethyl ether/formic acid (80:2:2, v/v/v) as solvent. The interesterified fish oil used in the nutritional experiments consisted almost exclusively of triglycerides. The acid values (11) of the native and randomized fish oils were 0.06 and 0.13%, respectively. Redistribution of fatty acids by randomization was tested by hydrolysis with pancreatic lipase (12) and by subsequent separation of the monoacylglycerol fraction by thin-layer chromatography on borate impregnated silica gel G plates using chloroform/acetone (8:12, v/v) as solvent (13). Gas-liquid chromatography of the fatty acids in the 2-acylglycerol fraction showed that 31-34% of each fatty acid was present in position 2 relative to its abundance in the oil. The fatty acid patterns of NFO and RFO were very similar (Table 1).

Preparation of free fatty acids from fish oil. Saponification of fish oil was brought about by adding 2 L of 10% NaOH in 70% ethanol to 1 kg of oil. The reaction was carried out at 50°C for 12 hr while flushing with N_2. Water was added, and the mixture was acidified (pH 1) while cooling. The free fatty acid layer was separated, washed with 3% NaCl in water until neutral, and dried over anhydrous Na_2SO_4. Thin-layer chromatography on silica gel LK plates (Whatman, Maidstone, U.K.) with hexane/diethyl ether/formic acid (80:2:2, v/v/v) as solvent as well as determination of the acid value (11) showed that the prepared fraction consisted entirely of free fatty acids.

[b]The difference between the sum of the percentages and 100 represents trace amounts (<0.5%) and unidentified components.

Data analysis. Results are presented as means ± SEM. Data were analyzed by one-way analysis of variance, except for the digestibility data. The latter results were subjected to two-way analysis of variance with repeated measures in order to evaluate possible differences that occurred over time. The least significant difference test with equal replication was used to compare individual means when significant F ratios were calculated (14). Differences were considered significant when $p<0.05$.

RESULTS AND DISCUSSION

Body weight and food consumption. Feeding the experimental diets for 24 days resulted in an average body weight gain of 169 g. Average daily food intake was 18.8 g. There were no significant effects of the dietary treatment on final body weight and food consumption (data not shown).

Effects of dietary fat on lipid digestibility. Apparent digestibility of total dietary fat as well as of individual fatty acids was not affected by age. Therefore, only average data regarding the entire 24-day experimental period are presented in Table 2. Digestibility of total fat was not significantly different among experimental groups, although the group fed the FO-FFA diet showed a tendency toward lower utilization. This was even more apparent from the digestibility data of individual fatty acids. Whereas apparent fatty acid digestibility was not different in rats fed NFO or RFO, feeding FO-FFA resulted in significantly lower digestibility of the saturated (14:0, 16:0, 18:0) and the monounsaturated (18:1, 20:1n-9, and 22:1n-9) fatty acids. By contrast, digestibility data for polyunsaturated fatty acids as well as for 16:1 in the FO-FFA group were not significantly different from the corresponding data in the NFO and the RFO groups. Also, within each group, lowest digestibility was obtained for 18:0, while 20:5n-3 and 22:6n-3 showed the highest digestibilities. These results indicate i) that lipolysis of fish oil and absorption of digestive products is not

[a]Diets containing SO, soybean oil; NFO, native fish oil; RFO, randomized fish oil; FO-FFO, free fatty acids from fish oil.

[b]Means ± SEM of six rats; apparent digestibility of fat or fatty acid was determined in a 24-day experiment and was calculated according to the following formula: 100 × difference between intake and fecal excretion of fat or fatty acid/fat or fatty acid intake.

[c–e]Values having different superscript letters in one row are significantly different ($p<0.05$).

influenced by positional redistribution of fatty acids in the triglycerides; ii) that micellar solubilization and absorption of fatty acids are favored by a higher degree of unsaturation and by a shorter chain length (Table 2) thus confirming earlier findings (15); and iii) that the monoglycerides formed in digestion appear to serve as emulsifiers of fatty acids and thus contribute to micellar solubilization; the latter was concluded from the greater apparent digestion of total fat and of saturated and monounsaturated fatty acids in the NFO and RFO groups as compared to the FO-FFA group. Also, the 16:0, 18:0 and 18:1 fatty acids, which were less digestible when fed as free acids, showed higher digestibility when fed as SO, probably due to the micellization effect of 2-monoglycerides. This suggested role of monoglycerides in lipid digestion is consistent with the finding that digestibility of beef tallow in piglets decreased when fed in hydrolyzed form (16). Similarly, rats showed higher fat absorbability when fed corn oil instead of free fatty acids isolated from corn oil (17). In our experiments, the digestibility of the total fat in the FO-FFA group was, on average, only 2.2% lower than in the other groups. This could be explained by i) the types of fatty acids derived from fish oil, which are characterized by low levels of fatty acids that are less readily solubilized; and ii) the 4% crude fat inherently present in the dietary ingredients, which may have contributed to absorption of FO-FFA by virtue of the digestive products liberated. It is not known whether the presence of a high amount of free fatty acids in the intestinal lumen changed the pH in such a way that formation of micelles was impaired (18) leading to somewhat lower fat absorption in the FO-FFA group. The effect of glycerol addition to the FO-FFA diet on absorption of free fatty acids was probably small. This follows from experiments with rats (17) which showed only a 4% difference ($p<0.05$) in apparent absorbability when purified diets were fed containing either 35% corn oil or 35% corn oil-derived fatty acids without having equalized the glycerol contents of the diets.

The present finding that apparent absorption of EPA and DHA was not influenced by the dietary source is in contradiction with the reported substantially lower absorption in humans when these fatty acids were ingested as fish oil (19) or as 1,3-dioctanoyl-2-eicosapentaenoyl glycerol (20). This was explained by assumed reduced activity of pancreatic lipase toward triacylglycerols containing EPA and DHA and by the suggestion that once triglycerides are hydrolyzed, the n-3 fatty acids are totally absorbed. In addition, discrepancy with the present results may also be explained by the way lipid absorption was measured. In the studies mentioned (19,20), a single dose of test fat was administered and the transient rise of EPA and DHA *vs.* either 18:3n-3 or 20:4n-6 in plasma triglycerides was measured. In the present experiments, a possibly slower rate of lipolysis of FO-triglycerides, and thus slower absorption of fatty acids, did not affect digestibility because of the extended experimental time periods. Slower EPA and DHA absorption in lymph, when rats were administered menhaden oil *vs.* both fatty acids in the free form, has recently been reported (21). Moreover, our finding regarding the high digestibility and absorbability of FO and FO-FFA was substantiated by the fact that the rats fed these supplemented fat sources showed similar EPA and DHA contents in the plasma (Table 3). Also, FO-FFA and FO-fed rats showed the same efficiency of food utilization as the rats fed the SO diet. Thus the availability of FO and FO-FFA was not substantially different from SO, which is usually regarded as highly digestible. This conclusion is supported by the finding that rats digested fish oil at least as efficiently as peanut oil in experiments based on measurement of fecal digestibility (De Schrijver, R., Vermeulen, D., and Viaene, E., unpublished data).

Digestibility of 14:0, 16:0, 18:0 and 16:1 was significantly higher in groups fed NFO or RFO, as compared to rats fed SO. As a consequence, apparent digestibility of fatty acids, which are less readily absorbed, appeared to depend on the nature of the other fatty acids present in the dietary

triacylglycerols. The higher apparent absorption of 18:0, when fed as NFO or RFO, was remarkable and may be related to the better emulsifying properties of the digestive products formed from fish oils. This could also explain the controversy regarding the degree of absorption of 18:0 (22-25).

Effects of dietary fat on plasma and liver lipids. Plasma triglyceride contents (Table 4) were similar in the groups fed SO, NFO or RFO. Moreover, the transfer from the beef tallow diet to the diets containing one of the unsaturated oils did not affect plasma triglyceride content. By contrast, elevated plasma triglyceride levels were found in rats which received the FO-FFA diet. A similar tendency toward hypertriglyceridemia, although not statistically significant, was observed in rats given a purified diet containing 35% free fatty acids derived from corn oil (17), as well as in experiments with chicks fed nonpurified diets containing 6% free fatty acids isolated from either soybean oil, palm oil or beef tallow (26). The high availability of dietary free fatty acids indicates that the glycerol phosphate pathway must have become activated in the course of mucosal triglyceride synthesis. The increased amount of plasma triglyceride in animals fed free fatty acids may result from over-stimulation of the glycerol phosphate pathway in the enterocytes, as well as from increased endogenous triglyceride contributions during fat absorption (27).

TABLE 4

Effects of Experimental Diets on Plasma Lipid Concentrations[a]

Dietary groups	Total cholesterol (mg/dL)	Triglyceride (mg/dL)
Beef tallow[b]	166 ± 14[c]	72 ± 8[c,d]
Soybean oil[e]	178 ± 18[c]	65 ± 10[c]

[e]Values at termination of experimental period.

Contrary to SO, feeding NFO or RFO resulted in decreased plasma cholesterol contents (Table 4) by approximately 40%. Moreover, rats fed the FO-FFA diet showed a similarly large decrease in cholesterol consistent with the finding that FO-FFA and fish oils were equally digested and absorbed. Given the difference in the positional distribution of fatty acids in native and randomized fish oil and admitting that the 2-position of the dietary triglycerides survived intestinal lipolysis, it may be assumed that the fatty acids in the 2-position of chylomicron triglycerides differed in both experimental groups. Nevertheless, differences in the positional distribution of fatty acids in triglycerides released from the enterocytes influenced neither the contents of plasma triglyceride and cholesterol, nor the fatty acid profiles of plasma (Table 3) and liver phospholipids (Table 5). Thus, post-absorptive effects from ingested fish oil were only related

to the nature of its constituting fatty acids. This conclusion was supported by the observation that the animals fed FO-FFA also showed the same plasma cholesterol content and the same fatty acid profiles in plasma and liver as did rats fed NFO or RFO; the only exception was the plasma triglyceride content. However, as mentioned above, slightly elevated triglyceride levels in plasma upon feeding free fatty acids may be a normal phenomenon (17,26) which may not necessarily be related to the nature of these fatty acids.

In conclusion, our experiments demonstrated i) that fish oil is readily digested in rats; ii) that autorandomization of fish oil has no effect on its metabolism; and iii) that despite possibly slow digestion rates, fish oil is somewhat better utilized than are fish oil-derived fatty acids.

METHODS

Separation of Cholesterol, and Fatty Acylglycerols, Acids and Amides by Thin-Layer Chromatography[1]

Alexander Bilyk, George J. Piazza, Raymond G. Bistline, Jr. and Michael J. Haas*

A rapid unidimensional thin-layer chromatographic (TLC) method for the separation of neutral lipids is described, using two sequential solvent systems of different polarity. Excellent separations of mono-, di- and triglycerides, fatty acids, fatty amides, and cholesterol are thereby achieved. Separation is accomplished at room temperature and requires 25 min.
***Lipids 26,* 405–406 (1991).**

In the course of our investigations on the modification and hydrolysis of natural lipid mixtures, we found it necessary to rapidly separate and detect fatty acids, fatty amides, mono-, di, and triacylglycerols, as well as cholesterol. Numerous reports (1–9) describe the separation of several of these compounds from each other using thin-layer chromatography (TLC). However, none of the methods was capable of separating all of these compounds from one another. We describe here a TLC method that can achieve this goal. The procedure is efficient, rapid, and reproducible and achieves excellent resolution for both analytical and preparative applications.

MATERIALS AND METHODS

Solvents. Toluene was purchased from J. T. Baker Chemical Co. (Phillipsburg, NJ). Methanol and n-hexane were from Burdick and Jackson (Muskegon, MI). Ethyl acetate and formic acid were from Eastman Kodak Co. (Rochester, NY). Acetone, diethyl ether, chloroform and sulfuric acid were from Mallinckrodt (Paris, KY). Acetic acid was from Aldrich Chemical Co. (Milwaukee, WI). Lipid standards were from Sigma Chemical Co. (St. Louis, MO). *N*-Butylpalmitamide was prepared according to the Krafft-Stauffer procedure (10). Silica Gel G TLC plates (20 × 20 cm, 250 μm) were obtained from Analtech (Newark, DE).

Thin-layer chromatography. Stock solutions were prepared by dissolving 25 mg of each of the reference compounds in 2.5 mL of chloroform. Part of the stock solutions were combined to prepare a standard mixture containing triolein, 1,3-diolein, 1,2-diolein, 1-monoolein, oleic acid, *N*-butylpalmitamide and, as required, cholesterol, each at a concentration of 1.67 mg/mL. TLC plates were washed in a tank of methanol for 5 min. After removal, plates were air-dried for at least 30 min. Samples were applied with a Hamilton syringe 2 cm from the lower edge of the plates. Plates were developed sequentially with solvent A (toluene:diethyl ether:ethyl acetate:acetic acid, 75:10:13:1.2, by vol) to 8 cm above the level of application and dried under nitrogen. The TLC plates were then developed with solvent B (hexane:diethyl ether:formic acid, 80:20:2, v/v/v) to 14 cm above the level of application. After air-drying of the plates, the samples were made visible by spraying the TLC plates with 60% aqueous sulfuric acid and charring on a hot plate.

RESULTS AND DISCUSSION

With the dual development system described in Materials and Methods, the compounds under examination are separated on the basis of polarity, with triacylglycerols exhibiting the greatest mobility, followed by fatty acids (which are protonated in the acidic solvent systems), diacylglycerols, fatty amides, and, finally, monoacylglycerols. Figure 1 illustrates the need for dual solvent development to separate these components. As shown in lane 1 of Figure 1, the attempted separation of individual components with solvent system B alone produced very poor results. Two of the components remained unresolved and another (1-monoacylglycerol) remained at the origin. With solvent system A (Fig. 1, lane 2), all acylglycerols had greater mobility. However, oleic acid and 1,3-diolein

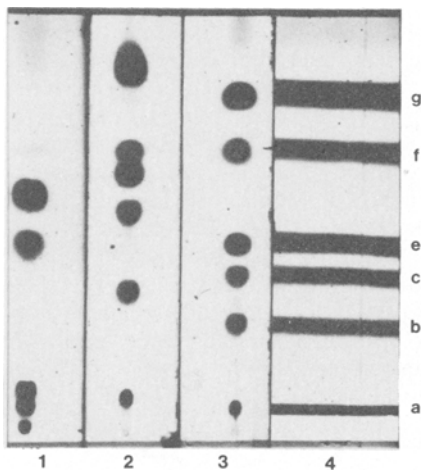

FIG. 1. Thin-layer chromatography of a standard mixture. Lane 1—standard mixture, 25 μg of each component, developed in solvent system B; lane 2—standard mixture, 25 μg of each component, developed in solvent system A; lane 3—standard mixture, 25 μg of each component, developed sequentially in solvent systems A and B; lane 4—preparative TLC of standard mixture, 1.67 mg of each component per plate, developed sequentially in solvent systems A and B; for lanes 3 and 4: a, 1(3)-monoolein; b, *N*-n-butyl palmitamide; c, 1,2-diolein; e, 1,3-diolein; f, oleic acid; g, triolein.
