were not separated (lane 2). By sequentially using the two solvent mixtures, A and B, excellent separation of the acylglycerols, fatty acid and fatty amide was achieved (Fig. 1, lane 3). Individual components were well resolved from one another and migrated as tight, circular entities. The relative mobilities and the extent of separation of these compounds are unaffected by chain length (at least between C_8 and C_{22}) and degree of unsaturation (up to at least five double bonds; data not shown). However, hydroxylated fatty acids, and acylglycerols containing them, do not exhibit the characteristic mobilities reported here. For example, ricinoleic acid (12-hydroxy-(9Z)-octadecenoic acid) migrates to a level just below that of 1,2-diacylglycerols. Castor oil, which is rich in triacylglycerols containing ricinoleic acid, exhibits two prominent species, one just below ricinoleic acid, and the other just above the 1,2-diacylglycerol fraction. In this system, fatty acid methyl esters and triacylglycerols migrate together.

Successful separations were achieved when the TLC technique described here was used for preparative-scale separations of the components of the standard mixture: lane 4 of Figure 1 illustrates the separation of more than 1.5 mg of each of the components of the standard mixture. We have also found this method useful for the quantitation of individual lipid components, which can be achieved by means of a TLC plate scanner after the plates have been sprayed with sulfuric acid and charred. Alternatively, spraying the preparative plates with an ethanolic solution of 2,7-dichlorofluorescein, visualizing the bands under ultraviolet light, scraping the fractions from the plate and extracting and weighing each fatty component gives quantitative results (data not shown).

The separation of sterols in crude lipid mixtures from the glyceride components is often difficult. Figure 2 illustrates the effectiveness of the method described here in resolving cholesterol from acylglycerols and free fatty acids. As shown in lanes 1 and 2, the mobility of cholesterol is intermediate to that of 1,3- and 1,2-diacylglycerol. The detection and identification of this compound is facilitated by the fact that when the plate is sprayed with aqueous sulfuric acid and then heated for 2–5 min a very bright pink color arises from cholesterol. With further heating, the spot turns black. The separation of cholesterol from diacylglycerols is critically dependent upon the height to which solvent mixture A is allowed to rise on the TLC plate. The optimal development height (usually between 6 and 10 cm) is dependent upon the materials used, and must be determined by trial and error using standard compounds.

The two-solvent, unidimensional thin-layer chromatographic procedure described here is a rapid means for identifying components of fatty mixtures containing mono-, di- and triacylglycerols, fatty acids, fatty amides and cholesterol. The procedure uses inexpensive, readily available solvents and simple laboratory equipment, and results are obtained in a short period of time. We have found this technique to give satisfactory and highly reproducible separations of the components of a wide range of natural lipid mixtures, and to be useful in studies of the hydrolysis and other modifications of these materials.

Regio- and Stereochemical Analysis of Trihydroxyoctadecenoic Acids Derived from Linoleic Acid 9- and 13-Hydroperoxides

Mats Hamberg*
Department of Physiological Chemistry, Karolinska Institutet, S-104 01 Stockholm, Sweden

The methyl esters of 9*S*,10*S*,13*R*-trihydroxy-11*E*-octadecenoic acid, 9*S*,10*S*,13*S*-trihydroxy-11*E*-octadecenoic acid, 9*S*,10*R*,13*S*-trihydroxy-11*E*-octadecenoic acid, and 9*S*,10*R*,13*R*-trihydroxy-11*E*-octadecenoic acid were prepared from 9*S*-hydroperoxy-10*E*,12*Z*-octadecadienoic acid *via* the epoxy alcohols methyl 10*R*,11*R*-epoxy-9*S*-hydroxy-12*Z*-octadecenoate and methyl 10*S*,11*S*-epoxy-9*S*-hydroxy-12*Z*-octadecenoate. The trihydroxyesters, as well as four stereoisomeric methyl 9,12,13-trihydroxy-10*E*-octadecenoates earlier prepared [Hamberg, M., *Chem. Phys. Lipids 43,* 55–67 (1987)], were characterized by thin-layer chromatography, gas-liquid chromatography, mass spectrometry, and by chemical degradation. Availability of these chemically defined trihydroxyoctadecenoates made it possible to design a method for regio- and stereochemical analysis of 9,10,13- and 9,12,13-trihydroxyoctadecenoic acids obtained from various sources. Application of the method revealed that the mixture of 9,10,13- and 9,12,13-trihydroxyoctadecenoic acids formed during autoxidation of linoleic acid in aqueous medium contained comparable amounts of the sixteen possible regio- and stereoisomers. Furthermore, hydrolysis of the allylic epoxy alcohol, methyl 9*S*,10*R*-epoxy-13*S*-hydroxy-11*E*-octadecenoate, yielded a major trihydroxyoctadecenoate, *i.e.,* methyl 9*S*,10*S*,13*S*-trihydroxy-11*E*-octadecenoate, together with smaller amounts of methyl 9*S*,10*R*,13*S*-trihydroxy-11*E*-octadecenoate, methyl 9*S*,12*R*,13*S*-trihydroxy-10*E*-octadecenoate, and methyl 9*S*,12*S*,13*S*-trihydroxy-10*E*-octadecenoate.

Lipids 26, 407–415 (1991).

Trihydroxyoctadecenoic acids containing the 1,2,5-trihydroxy-3*E*-pentene moiety were first described by Graveland (1) in a study of oxygenation of linoleic acid in suspensions of wheat flour. Two trihydroxy acid isomers were isolated and characterized, *i.e.,* 9,10,13-trihydroxy-11*E*-octadecenoic acid and 9,12,13-trihydroxy-10*E*-octadecenoic acid. Since then, a large number of studies have been concerned with the formation of trihydroxyoctadecenoic acids from linoleic acid *via* linoleic acid 9- and 13-hydroperoxides (2–10). In addition, trihydroxy acids derived from linoleic and/or α-linolenic acids have been isolated from the marine blue-green alga *Lyngbya majuscula* (11), from higher plants (12–16), from the culture medium of the primitive fungus *Saprolegnia parasitica* (17), and from beer (18). Furthermore, trihydroxyoctadecenoic acids constitute a considerable portion of the stable end-products formed on autoxidation of linoleic acid in aqueous systems (19). Linoleic acid-derived trihydroxyoctadecenoic acids have been reported to exert prostaglandin E-like activity on a number of smooth muscle preparations (14) and to be bitter tasting (20).

The present paper is concerned with preparation and characterization of eight stereoisomeric 9,10,13- and 9,12,13-trihydroxyoctadecenoic acids and with a method for regio- and stereochemical analysis of these compounds and their enantiomers.

MATERIALS AND METHODS

Linoleic acid was purchased from Nu-Chek Prep (Elysian, MN). [1-^{14}C]Linoleic acid and $H_2{}^{18}O$ (98 atom% ^{18}O) were obtained from Amersham Laboratories (Amersham, UK).

9*S*-[1-^{14}C]HPOD (specific radioactivity, 3.0 kBq/μmol; enantiomeric composition: 9*S*/9*R*, 98:2) was prepared by incubation of [1-^{14}C]linoleic acid with whole homogenate of tomato essentially as earlier described (21). 13*S*-[1-^{14}C]HPOD (specific radioactivity, 7.2 kBq/μmol; enantiomeric composition: 13*S*/13*R*, 99:1) was obtained by incubation of [1-^{14}C]linoleic acid with soybean lipoxygenase (22). Methyl 9*R*,12*S*,13*S*-trihydroxy-10*E*-octadecenoate (**9a**), methyl 9*S*,12*S*,13*S*-trihydroxy-10*E*-octadecenoate (**10a**), methyl 9*S*,12*R*,13*S*-trihydroxy-10*E*-octadecenoate (**11a**), and methyl 9*R*,12*R*,13*S*-trihydroxy-10*E*-octadecenoate (**12a**) were prepared by hydrolysis of the epoxy alcohols methyl 11*R*,12*R*-epoxy-13*S*-hydroxy-9*Z*-octadecenoate (**3**) and methyl 11*S*,12*S*-epoxy-13*S*-hydroxy-9*Z*-octadecenoate (**4**) as described (ref. 9; see Fig. 1). Methyl *erythro*- and *threo*-2,3-dihydroxyoctanoates were prepared by OsO_4 hydroxylation of methyl 2*Z*- and 2*E*-octenoates, respectively (23).

Methyl 9S,10R-epoxy-13S-hydroxy-11E-octadecenoate. A mixture of methyl 9*S*,10*R*-epoxy-13*S*-hydroxy-11*E*-octadecenoate and methyl 9*R*,10*S*-epoxy-13*S*-hydroxy-11*E*-octadecenoate (91:9, w/w) was obtained following incubation of 13*S*-HPOD with *Vicia faba* epoxygenase as recently described (24). The minor epoxy alcohol was removed by thin-layer chromatography (TLC) using ethyl acetate/toluene (3:7, v/v) as solvent (9*S*,10*R*-epoxy alcohol, R_f, 0.44; 9*R*,10*S*-epoxy alcohol, R_f, 0.48).

Methyl 10R,11R-epoxy-9S-hydroxy-12Z-octadecenoate (1) and methyl 10S,11S-epoxy-9S-hydroxy-12Z-octadecenoate (2). Treatment of the methyl ester of 9*S*-HPOD (10 mg) with 10 mL of hexane saturated with vanadium oxyacetylacetonate at 22°C for 1 hr (9) yielded two diastereomeric α,β-epoxy alcohols in a 1:1 ratio. The compounds were obtained in pure form following thin-layer chromatography (TLC) using ethyl acetate/hexane (3:7, v/v) as solvent. As recently described, the more polar epoxy alcohol (R_f, 0.49) was identical with methyl 10*R*,11*R*-epoxy-9*S*-hydroxy-12*Z*-octadecenoate (10).

The less polar epoxy alcohol (R_f, 0.59) was found to be the diastereomeric methyl 10*S*,11*S*-epoxy-9*S*-hydroxy-12*Z*-octadecenoate on basis of the following results. Infrared spectrometry showed bands at 3620–3350 cm^{-1}

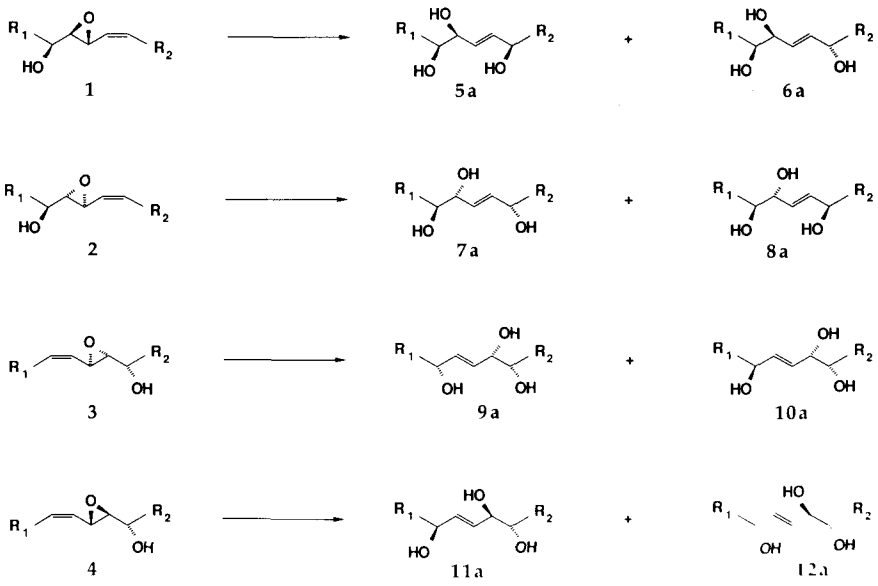

FIG. 1. Structures of trihydroxyesters prepared by hydrolysis of epoxy alcohols. R_1 = $(CH_2)_7$-$COOCH_3$; R_2 = $(CH_2)_4$-CH_3.

(hydroxyl), 1735 cm^{-1} (ester carbonyl) and 890 cm^{-1} (*trans* epoxide). No absorption band appeared in the range 950–1000 cm^{-1}, demonstrating the absence of *E* double bond(s). The mass spectrum of the trimethylsilyl (Me_3Si) ether derivative was virtually identical to that of the corresponding derivative of the 10*R*,11*R*-epoxy alcohol (10). Furthermore, $KMnO_4$ oxidation (23) performed on the (−)-menthoxycarbonyl (MC) derivative afforded the MC derivative of 2*S*-hydroxysebacate showing the presence of a hydroxyl group at C-9 (*S* configuration). Catalytic hydrogenation yielded methyl *erythro*-9,10-dihydroxyoctadecanoate as demonstrated by gas-liquid chromatography (GLC) using references of authentic methyl *erythro*- and *threo*-9,10-dihydroxyoctadecanoates (C-values of Me_3Si derivatives, 21.41 and 21.25, respectively; see ref. 24). Assignment of the absolute configuration of the epoxide carbons C-10 and C-11 as *S,S* followed from the established configuration at C-9 (*S*) coupled with the facts that the relative configuration of C-9/C-10 was *erythro*, and that the epoxide group had the *trans* configuration.

Dimethyl 2E-*undecene-1,11-dioate.* Malonic acid (6.4 g; 62 mmol) was slowly added to pyridine (14 mL). The solution was stirred at 22°C for 30 min and subsequently added to methyl 9-oxononanoate (8.8 g, 47 mmol) in pyridine (10 mL) containing piperidine (0.4 mL). The mixture was kept at 55°C for 1 hr and at 85°C for 4 hr. Extraction with diethyl ether afforded an oily residue that was treated with 10% (w/v) sodium hydroxide in 80% aqueous methanol at 22°C for 15 hr. The crude 2*E*-undecene-1,11-dioic acid (12 g) thus obtained was purified by crystallization from ethyl acetate/hexane. The identity of the compound was based on i) ultraviolet (UV) spectrometry (λ_{max} = 208 nm in ethanol; α,β-unsaturated carboxyl), ii) infrared spectrometry [dimethyl ester; 1730 cm^{-1} (ester carbonyls), and 985 cm^{-1} (*E* double bond)], iii) mass spectrometry [dimethyl ester; prominent ions at *m/e* 211 (M-31, 8%), 182 (M-60; loss of $COOCH_3$ + H, 20), 178 (M-2*32, 27), 150 (182-32, 60), and 55 (100)], and iv) oxidative ozonolysis (performed on the dimethyl ester; affording methyl hydrogen azelate).

Dimethyl erythro-*2,3-dihydroxyundecane-1,11-dioate.* Dimethyl 2*E*-undecene-1,11-dioate (484 mg; 2 mmol) was refluxed for 72 hr with *m*-chloroperbenzoic acid (500 mg) in methylene chloride (20 mL). Material obtained by extraction with diethyl ether was subjected to preparative TLC [solvent system, ethyl acetate/hexane (2:8, v/v)] to afford pure dimethyl *trans*-2,3-epoxyundecane-1,11-dioate [mass spectrum, *m/e* 226 (M-32; 1%), 209 (M-[18+31]; 4), 201 (23), 167 (M-[59+32], 22), 137 (33), and 55 (100)].

Attempts to hydrolyze the epoxide by treatment with perchloric acid in aqueous dimethoxyethane were unsuccessful. Instead, the diol was obtained by treatment of the epoxide (200 mg) with formic acid (10 mL) at 22°C for 15 hr followed by hydrolysis of the formate ester by treatment with 5% (w/v) sodium hydroxide in 80% aqueous methanol at 50°C for 1 hr. Material obtained by extraction with ethyl acetate was esterified by treatment with diazomethane and subjected to preparative TLC [solvent, ethyl acetate/hexane (1:1, v/v; R_f, 0.30)]. Analysis of the Me_3Si derivative of the dimethyl *erythro*-2,3-dihydroxyundecane-1,11-dioate gave a C-value of 17.70 and a mass spectrum which showed prominent ions at *m/e* 405 (M-15, 1%), 389 (M-31, 2), 373 [M-(15+32), 2], 361 (M-59; loss of $\cdot COOCH_3$, 2), 345 (5), 273 (14), 271 [M-(59+90), 9], 259 (Me_3SiO^+=CH-$(CH_2)_7$-$COOCH_3$, 42), 234 (M-186; migration of Me_3Si from C-3 to C-1 followed by elimination of OHC-$(CH_2)_7$-$COOCH_3$, 50), 155 (OHC-$(CH_2)_7$-C≡O^+; 43), and 73 (100).

Dimethyl threo-*2,3-dihydroxyundecane-1,11-dioate.* Dimethyl 2*E*-undecene-1,11-dioate (50 mg) was *cis*-hydroxylated by treatment with OsO_4 as previously described (23). The resulting dimethyl *threo*-2,3-dihydroxyundecane-1,11-dioate was purified by preparative TLC [solvent system, ethyl acetate/hexane (1:1, v/v; R_f, 0.34)]. An aliquot was analyzed by gas chromatography-mass spectrometry (GC-MS) as the Me_3Si derivative. The C-value

was 17.81 and the mass spectrum was virtually identical to that of the corresponding *erythro* isomer given above.

Cyclic carbonate derivatives of dimethyl erythro- *and* threo-*2,3-dihydroxyundecane-1,11-dioates.* Dimethyl *erythro-* and *threo*-2,3-dihydroxyundecane-1,11-dioates (200 μg) were converted into their cyclic carbonate (CC) derivatives by treatment with phosgene in chloroform/toluene/pyridine (23; see also below). Material obtained by extraction with diethyl ether was purified by TLC using ethyl acetate/hexane (25:75, v/v) as the solvent system. The CC derivatives were analyzed by GLC as shown in Figure 2B. The CC derivatives of methyl *erythro-* and *threo*-2,3-dihydroxyoctanoates (23) were analyzed in a similar way (Fig. 2A).

Autoxidation of linoleic acid. Linoleic acid (250 mg) was dissolved in ethanol (50 mL). The mixture was heated and water (75 mL) was slowly added. The solution was refluxed under a stream of oxygen gas for 42 hr. Material obtained by extraction with diethyl ether was treated with diazomethane. Methyl 10*Z*-nonadecenoate (1.47 mg) was added to an aliquot (5%) of the esterified autoxidation product. The mixture was subjected to silicic acid column chromatography and the fatty acid ester fraction was isolated and analyzed by GLC. From the ratio of the areas of the peaks of methyl linoleate and of the added internal standard it was calculated that the amount of remaining linoleate was 4–5 mg, *i.e.,* the extent of autoxidation of linoleic acid was *ca.* 98%. The yield of 9,10,13- and 9,12,13-trihydroxyoctadecenoates present in the autoxidation product was not precisely determined in the present study. However, from the weights of trihydroxyesters recovered following TLC it was estimated that the yield of trihydroxy acids under the conditions used for autoxidation was 5–10% based on the starting amount of linoleic acid.

Steric analysis. Determination of the absolute configuration of allylic alcohol groups was carried out by gas-liquid chromatographic analysis of MC derivatives of short-chain esters formed upon oxidative ozonolysis (25). Epoxy alcohols (100–500 μg) were derivatized by treatment with toluene (50 μL), pyridine (10 μL) and a toluene solution (50 μL) of (−)-menthoxycarbonyl chloride (Aldrich-Chemie, Steinheim, Germany; 1 μmol/μL) at 22°C for 30 min. The MC derivatives were purified by TLC [solvent system, ethyl acetate/hexane (1:9, v/v)] and subjected to oxidative ozonolysis. The esterified product containing the MC derivatives of methyl 2-hydroxyheptanoate or dimethyl 2-hydroxysebacate was analyzed by GLC using authentic reference compounds (25). Methyl trihydroxyoctadecenoates were derivatized by treatment with toluene (50 μL), pyridine (25 μL) and menthoxycarbonyl chloride solution (100 μL) at 60°C for 3 hr. The tris-MC derivatives were purified and further analyzed as described above. Formation of MC derivatives of dienols, *i.e.,* the methyl esters of 9- and 13-HOD, was found to be accompanied by partial racemization with the batch of reagent used in the present study. In order to avoid this problem, these compounds were directly ozonized and subsequently treated with toluene (50 μL), pyridine (10 μL), and menthoxycarbonyl chloride solution (50 μL) at 22°C for 30 min. Hexane (3 mL) was added and the organic phase was washed twice with 0.5 mL of water. The residue obtained after evaporation of the solvent was oxidized with peracetic acid at 50°C for 15 hr (25). The product was esterified and subjected to TLC [solvent system, ethyl acetate/hexane (1:9, v/v)] using references of the MC derivatives of methyl 2*R,S*-hydroxyheptanoate and dimethyl 2*R,S*-hydroxysebacate. The zones corresponding to the spots of the reference compounds were scraped off and the recovered materials were analyzed by GLC.

The relative configuration of the 1,2-diol structure of trihydroxyoctadecenoates was determined by gas-liquid chromatographic analysis of CC derivatives of 2,3-dihydroxyesters obtained following oxidative ozonolysis. The trihydroxyesters (100–500 μg) were dissolved in chloroform (0.2 mL) and pyridine (0.1 mL) and treated with 0.05 mL of a solution of phosgene in toluene (20%, w/w) at 0°C for 5 min. After an additional 30 min at 22°C, excess reagent was destroyed by treatment with methanol (2 mL) for 15 min. Material obtained by extraction with diethyl ether was subjected to oxidative ozonolysis (25), and the esterified product was analyzed by GLC.

Chromatographic and instrumental methods. For most analyses TLC was carried out with precoated plates (Kieselgel 60, 0.25 mm) from E. Merck (Darmstadt, Germany). *Erythro-* and *threo*-isomers of methyl trihydroxyoctadecenoates were separated using plates coated with sodium arsenite/silica gel Gel G (1:9, w/w) and a solvent system consisting of methanol/chloroform (3:97, v/v). Material was located by spraying with 2′,7′-dichlorofluorescein and viewing under UV light. Radioactivity on TLC plates was determined by a Berthold Dünnschichtscanner II (Wildbad, Germany) interfaced with a Macintosh SE/30 PC. GLC was performed with a Hewlett-Packard (Avondale, PA) model 5890 gas chromatograph equipped with a methyl silicone capillary column (length, 25 m; film thickness, 0.33 μm). Helium at a flow rate of 25 cm/s was used as the carrier gas. GC-MS was carried out with a Hewlett-Packard model 5970B mass selective detector connected to a Hewlett-Packard model 5890 gas chromatograph. Ultraviolet spectrometry was carried out with a Hewlett-Packard model 8450A UV/VIS

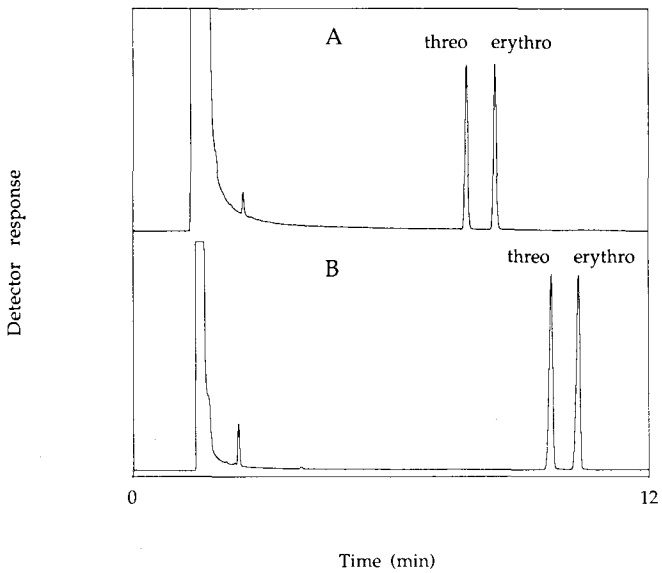

FIG. 2. Gas chromatograms of CC derivatives of methyl *erythro-* and *threo*-2,3-dihydroxyoctanoates (A), and of dimethyl *erythro-* and *threo*-2,3-dihydroxyundecane-1,11-dioates (B). Column temperatures, 160°C (A) and 220°C (B); carrier gas, helium at a flow rate of 25 cm/s.

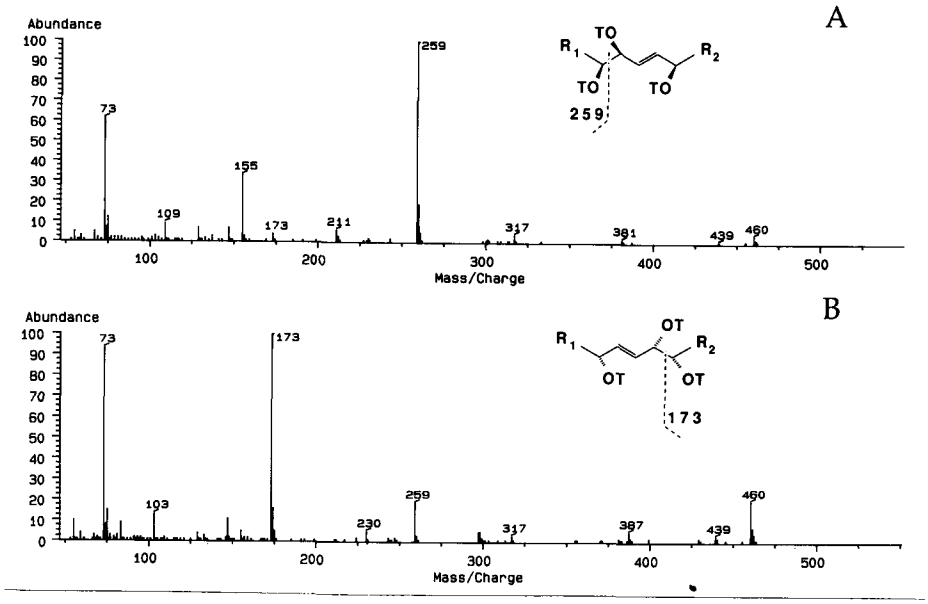

FIG. 3. Mass spectra of Me_3Si derivatives of compounds 5a (A) and 9a (B). "T" = Me_3Si; R_1 =$(CH_2)_7$-$COOCH_3$; R_2 = $(CH_2)_4$-CH_3.

spectrophotometer and infrared spectra were recorded with a Perkin-Elmer (Überlingen, Germany) model 257 infrared (IR) spectrophotometer. Radioactivity was determined with a Packard (Downers Grove, IL) Tri-Carb model 4450 liquid scintillation counter.

RESULTS

Methyl 9S,10S,13R-trihydroxy-11E-octadecenoate (5a) and methyl 9S,10S,13S-trihydroxy-11E-octadecenoate (6a). Methyl [1-^{14}C]10*R*,11*R*-epoxy-9*S*-hydroxy-12*Z*-octadecenoate (2 mg; compound 1 in Fig. 1) was dissolved in methanol (0.5 mL) and glass-distilled water (50 mL) was added. The solution was acidified to pH 3 by addition of dilute hydrochloric acid. After 5 min at 22°C the solution was extracted with diethyl ether, and the material obtained was subjected to radio-TLC using ethyl acetate as solvent. Two major peaks of radioactivity appeared (ratio, *ca.* 1:1), *i.e.,* compounds **5a** and **6a**. In addition, smaller peaks of less polar material were observed. This material was not fully characterized although the mass spectra of the Me_3Si derivatives indicated that it was due to two stereoisomeric methyl 9,10,11-trihydroxyoctadecenoates (cf. ref. 9).

The UV spectra of **5a** and **6a** did not show any specific absorption in the range 205–300 nm. The IR spectra of the compounds were similar and showed absorption bands at 3620-3200 cm^{-1} (hydroxyls), 1730 cm^{-1} (ester carbonyl), and 980 cm^{-1} (*E* double bond).

The mass spectra of the Me_3Si derivatives of **5a** and **6a** were virtually identical and showed prominent ions at *m/e* 460 (M-100; rearrangement with elimination of OHC-$(CH_2)_4$-CH_3, 4%), 439 [M-(31+90), 1], 387 [(CH=CH-CH($OSiMe_3$)-CH($OSiMe_3$)-$(CH_2)_7$-$COOCH_3$)$^+$, 1], 317 (4), 259 (Me_3SiO^+=CH-$(CH_2)_7$-$COOCH_3$, 100), 211 (6), 173 (Me_3SiO^+=CH-$(CH_2)_4$-CH_3, 4), 155 (OHC-$(CH_2)_7$-C≡O^+, 33), 109 (9), and 73 (Me_3Si^+, 61) (Fig. 3A). For comparison, Figure 3B shows the mass spectrum of the Me_3Si derivative of a methyl 9,12,13-trihydroxyoctadecenoate, *i.e.,* compound **9a**. This spectrum showed prominent ions at *m/e* 460 (M-100; rearrangement with elimination of OHC-$(CH_2)_4$-CH_3, 20%), 439 [M-(31+90), 3], 387 (Me_3SiO^+=CH-CH=CH-CH($OSiMe_3$)-$(CH_2)_7$-$COOCH_3$, 5), 317 (3), 259 (Me_3SiO^+=CH-$(CH_2)_7$-$COOCH_3$, 19), 230 (5), 173 (Me_3SiO^+=CH-$(CH_2)_4$-CH_3, 100), 103 (Me_3SiO^+=CH_2, 13), and 73 (Me_3Si^+, 94).

Oxidative ozonolysis performed on the MC derivatives of **5a** and **6a** yielded the MC derivatives of 2*R*- and 2*S*-hydroxyheptanoic acids, respectively. This result showed that both compounds possessed a double bond in the Δ^{11} position as well as a hydroxyl group at C-13 (*R* in **5a**, *S* in **6a**). Oxidative ozonolysis of the CC derivatives of **5a** and **6a** followed by esterification afforded the CC derivative of dimethyl *threo*-2,3-dihydroxyundecane-1,11-dioate. On the basis of these results, **5a** was identified as methyl 9*S*,10*S*,13*R*-trihydroxy-11*E*-octadecenoate and **6a** as methyl 9*S*,10*S*,13*S*-trihydroxy-11*E*-octadecenoate (Fig. 1).

Methyl 9S,10R,13S-trihydroxy-11E-octadecenoate (7a) and methyl 9S,10R,13R-trihydroxy-11E-octadecenoate (8a). Methyl [1-^{14}C]10*S*,11*S*-epoxy-9*S*-hydroxy-12*Z*-octadecenoate (2 mg; compound 2 in Fig. 1) was hydrolyzed at pH 3 as described above and the product was subjected to TLC. Two major labeled compounds appeared, *i.e.,* compounds **7a** and **8a**. In addition, less polar compounds tentatively identified as two stereoisomeric methyl 9,10,11-trihydroxyoctadecenoates were observed in the chromatogram.

The UV, IR, and mass spectral data obtained for compounds **7a** and **8a** were similar to those obtained for **5a** and **6a** as described above, indicating that **7a** and **8a** were stereoisomeric methyl 9,10,13-trihydroxy-11*E*-octadecenoates. Oxidative ozonolysis performed on the MC derivatives of **7a** and **8a** produced the MC derivatives of 2*S*- and 2*R*-hydroxyheptanoic acids, respectively, whereas ozonolysis of the CC derivatives followed by esterification yielded the CC derivative of dimethyl *erythro*-2,3-di-

hydroxyundecane-1,11-dioate. On the basis of these results, compound **7a** was identified as methyl 9*S*,10*R*,13*S*-trihydroxy-11*E*-octadecenoate and compound **8a** as methyl 9*S*,10*R*,13*R*-trihydroxy-11*E*-octadecenoate (Fig. 1).

Characterization of trihydroxyesters by TLC and GLC. Figure 4 and Table 1 show results of thin-layer chromatographic analysis of trihydroxyesters **5a–12a**. As seen, a group separation was observed between trihydroxyesters **5a, 7a, 9a, 11a**, and trihydroxyesters **6a, 8a, 10a, 12a**. The factor underlying this separation was the steric relationship between the two allylic hydroxyl groups, *i.e.*, those trihydroxyesters in which the two hydroxyl groups were located on the same side with respect to the plane of the double bond were more polar than those in which the hydroxyl groups were located on opposite sides. The terms "*cis*-1,4-diol" and "*trans*-1,4-diol" were introduced to designate trihydroxyesters in which the two allylic, non-vicinal hydroxyls were located on the same and opposite sides, respectively, with respect to the plane of the double bond. A small superimposed effect on the TLC separation was exerted by the 1,2-diol structure, *i.e.*, the presence of a *threo* diol in a trihydroxyester slightly reduced the polarity compared to that of the corresponding *erythro* compound. On the other hand, 9,10,13- and 9,12,13-trihydroxyoctadecenoates having the same steric relationship did not separate.

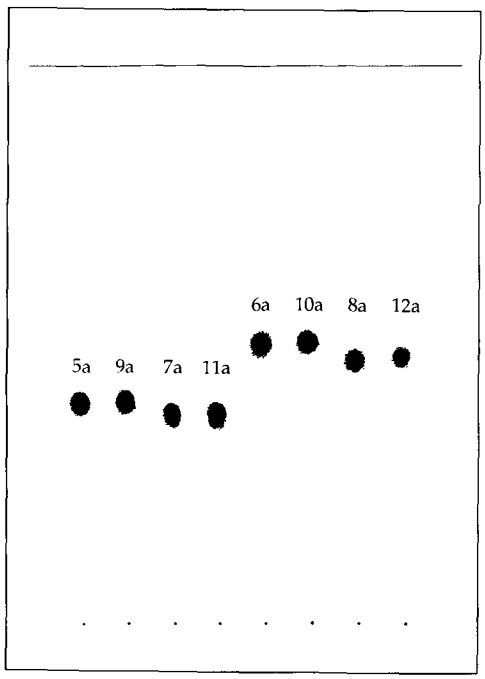

FIG. 4. TLC separation of trihydroxyesters 5a–12a. Solvent system, ethyl acetate.

Erythro- and *threo*-trihydroxyesters were separated by sodium arsenite-TLC (Fig. 5, Table 1). As expected (26), a *threo* trihydroxyester was less polar than the corresponding *erythro* compound. In addition, a superimposed effect of the relative configuration of the 1,4-diol structure was observed. As with regular TLC, pairs of 9,10,13- and 9,12,13-trihydroxyoctadecenoates having the same stereochemical features did not separate.

GLC was useful for separation of *erythro/threo* isomers and of positional isomers (Table 1). However, because of overlapping of the retention times of the Me_3Si derivatives of certain trihydroxyesters, analysis of mixtures of trihydroxyoctadecenoates by GLC was performed following separation of trihydroxyesters into *cis*- and *trans*-1,4-diols by regular TLC. This is illustrated by Figure 6 which shows analysis by GLC of Me_3Si derivatives of trihydroxyesters formed upon autoxidation of linoleic acid.

Method for determination of individual isomers of 9,10,13- and 9,12,13-trihydroxyoctadecenoic acids. The following method was developed for complete analysis of the 16 possible isomers of 9,10,13- and 9,12,13-trihydroxyoctadecenoates. In the first step, the mixture of methyl trihydroxyoctadecenoates (0.2–1 mg) was subjected to TLC using ethyl acetate as the solvent. Two bands of

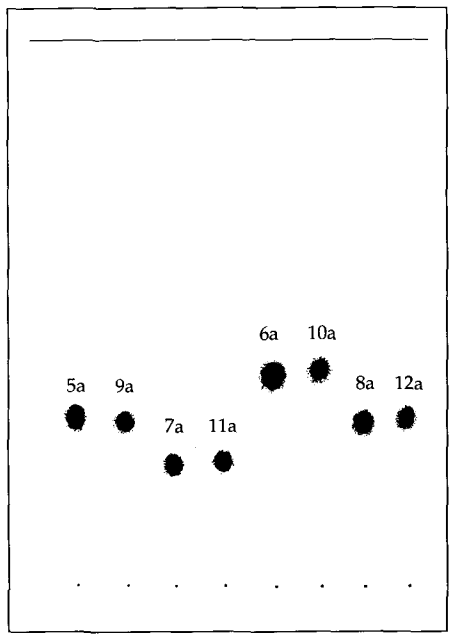

FIG. 5. TLC separation of trihydroxyesters 5a–12a using silica gel impregnated with $NaAsO_2$. Solvent system, methanol/$CHCl_3$ (3:7, v/v).

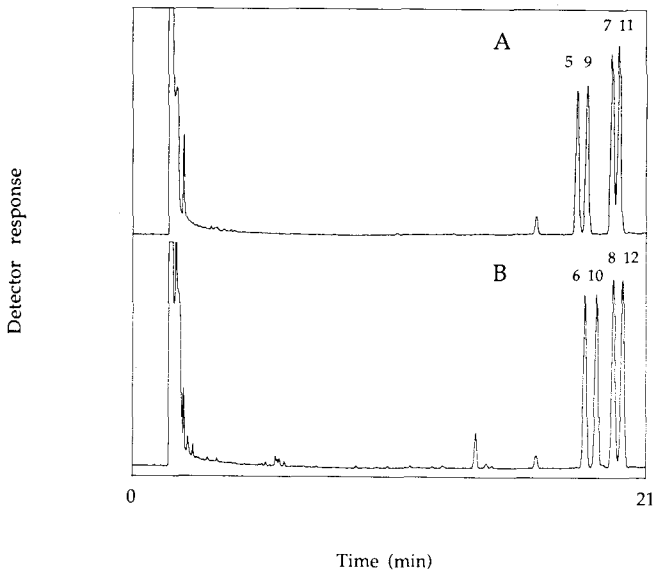

FIG. 6. Gas chromatograms of Me_3Si derivatives of trihydroxyesters obtained by autoxidation of linoleic acid. Separate analyses were performed of trihydroxyesters containing the *cis*-1,4-diol structure (compounds 5, 7, 9, and 11; panel A) and trihydroxyesters containing the *trans*-1,4-diol structure (compounds 6, 8, 10, and 12; panel B). Column temperature, 230°C; carrier gas, helium at a flow rate of 25 cm/s.

material appeared, *i.e.*, trihydroxyesters having the *cis*- and *trans*-1,4-diol structures (R_f = 0.37–0.39 and 0.47–0.50, respectively; see Fig. 4 and Table 1). Methyl ricinoleate (221 μg) was added to the fractions of *cis*- and *trans*-1,4-diols to serve as an internal standard. An aliquot of each fraction was converted into the Me_3Si derivatives and analyzed by GLC. The percentage composition of the mixture of compounds 5–12 was calculated from the peak areas of the trihydroxyesters and the peak area of the internal standard. The remaining parts of the fractions of *cis*- and *trans*-1,4-diols were used to determine the enantiomeric composition of the compounds detected by GLC. In situations where GLC analysis had shown that the fractions of *cis*- and *trans*-1,4-diols were due to a single diastereomer of methyl 9,10,13-trihydroxy-11*E*-octadecenoate and/or of 9,12,13-trihydroxy-10*E*-octadecenoate steric analysis was performed directly on the material present in the two fractions. With more complex mixtures of trihydroxyesters, each fraction contained two 9,10,13- and/or two 9,12,13-trihydroxyoctadecenoates (*erythro* and *threo* isomers). In this case, materials present in the *cis*- and *trans*-1,4-diol fractions were separately subjected to sodium arsenite-TLC in order to obtain fractions of *threo*/*cis*-1,4-, *threo*/*trans*-1,4-, *erythro*/*cis*-1,4-, and *erythro*/*trans*-1,4-diols. These fractions, which contained only one methyl 9,10,13-trihydroxyoctadecenoate and/or one methyl 9,12,13-trihydroxyoctadecenoate (Table 2), were subjected to steric analysis.

TABLE 2

Characteristics and Structures of Trihydroxyoctadecenoates 5–12

Compound	Regiochemical feature	Stereochemical feature	Enantiomer	Structure
5	9,10,13-trihydroxy	*threo*/*cis*-1,4-diol	5a	Methyl 9*S*,10*S*,13*R*-trihydroxy-11*E*-octadecenoate

12	9,12,13-trihydroxy	*erythro*/*trans*-1,4-diol	12a	Methyl 9*R*,12*R*,13*S*-trihydroxy-10*E*-octadecenoate
			12b	Methyl 9*S*,12*S*,13*R*-trihydroxy-10*E*-octadecenoate

Regio- and stereochemical analysis of trihydroxyoctadecenoates formed by autoxidation. The method described was used to determine the percentage amounts of individual isomers present in the mixture of 9,10,13- and 9,12,13-trihydroxyoctadecenoic acids formed upon autoxidation of linoleic acid in aqueous medium. An aliquot of the esterified autoxidation product (21 mg; containing 1–2 mg of 9,10,13- and 9,12,13-trihydroxyoctadecenoic acid isomers) was subjected to TLC (solvent, ethyl acetate). The bands due to the *cis*- and *trans*-1,4-diol isomers of methyl trihydroxyoctadecenoates were scraped off and added to methyl ricinoleate (221 μg). One-tenth of each fraction was converted into the Me_3Si derivatives and analyzed by GLC (cf. Fig. 6) and the percentages of compounds **5–12** were determined. The remaining part of each fraction was subjected to sodium arsenite-TLC. The materials present in the fractions of *threo/cis*-1,4-, *threo/trans*-1,4-, *erythro/cis*-1,4-, and *erythro/trans*-1,4-diols were recovered and subjected to steric analysis. As expected, the methyl 2-hydroxyheptanoates and the dimethyl 2-hydroxysebacates formed upon oxidative ozonolysis were racemic. This fact coupled with the results of determination of **5–12** by GLC showed that the trihydroxyoctadecenoate fraction formed upon autoxidation of linoleic acid was a mixture of isomers in the following percentage amounts: **5a**, 5%; **5b**, 5%; **6a**, 6%; **6b**, 6%; **7a**, 7%; **7b**, 7%; **8a**, 7%; **8b**, 7%; **9a**, 5%; **9b**, 5%; **10a**, 6%; **10b**, 6%; **11a**, 7%; **11b**, 7%; **12a**, 7%; and **12b**, 7% (Fig. 7).

Regio- and stereochemical analysis of trihydroxyoctadecenoates formed by hydrolysis of methyl 9S,10R-epoxy-13S-hydroxy-11E-octadecenoate. Methyl 9*S*,10*R*-epoxy-13*S*-hydroxy-11*E*-octadecenoate (0.4 mg) was dissolved in methanol (0.5 mL) and water (50 mL) was added. The solution was acidified to pH 3 and kept at 22°C for 5 min during which time the initially cloudy solution became clear. The product isolated by extraction with diethyl ether was subjected to TLC. Part of the materials forming the bands of *cis*- and *trans*-1,4-diols was added to the methyl ricinoleate internal standard and analyzed by GLC. Four isomers were detected, *i.e.*, compounds **6** and **10** (*threo/trans*-1,4-diol isomers of methyl 9,10,13- and 9,12,13-trihydroxyoctadecenoates, respectively; see Table 2), as well as compounds **7** and **11** (*erythro/cis*-1,4-diol isomers of methyl 9,10,13- and 9,12,13-trihydroxyoctadecenoates, respectively). Steric analysis of the tris-MC derivatives of these materials showed that the 9,10,13-trihydroxyoctadecenoates present in the two fractions had the *S* configuration at C-13 (1% or less of the *R* configuration) and that the 9,12,13-trihydroxy isomers had the *S* configuration at C-9 (1% or less of the *R* configuration). The composition of trihydroxyoctadecenoate isomers formed by hydrolysis of methyl 9*S*,10*R*-epoxy-13*S*-hydroxy-11*E*-octadecenoate was thus found to be: compounds **6a**, 61%; **7a**, 16%; **11a**, 15%; and **10a**, 8% (Fig. 7).

Hydrolysis of methyl 9S,10R-epoxy-13S-hydroxy-11E-octadecenoate in $H_2{}^{18}O$. Methyl 9*S*,10*R*-epoxy-13*S*-hydroxy-11*E*-octadecenoate (0.4 mg) was dissolved in methanol (40 μL) and treated with $H_2{}^{18}O$ (250 μL) and 2 M hydrochloric acid (2 μL) at 22°C for 5 min. Material extracted with diethyl ether was esterified and subjected to TLC (solvent, ethyl acetate). The *cis*-1,4-diol fraction (containing **7** and **11**) and the *trans*-1,4-diol fraction (containing **6** and **10**) were recovered, and the Me_3Si derivatives were analyzed by selected monitoring of the ions *m/e* 173 and 175 (Me_3SiO^+=CH-$(CH_2)_4$-(CH_3)), 259 and 261 (Me_3SiO^+=CH-$(CH_2)_7$-$COOCH_3$), and 387, 389, and 391 (due to Me_3SiO^+=CH-CH=CH-CH$(OSiMe_3)$-$(CH_2)_7$-$COOCH_3$ in the mass spectra of **10** and **11**, and to $[CH{=}CH\text{-}CH(OSiMe_3)\text{-}CH(OSiMe_3)\text{-}(CH_2)_7\text{-}COOCH_3]^+$ in the mass spectra of **6** and **7**). The fragment containing the C-9 hydroxyl group (*m/e* 259) and that containing the C-13 hydroxyl group (*m/e* 173) did not contain ^{18}O (less than 0.5% ^{18}O species), whereas the fragment containing the C-9 hydroxyl group and either of the C-10 or C-12 hydroxyl groups (*m/e* 387) was due to 95% $^{18}O_1$ species and 5% $^{18}O_0$ species. These findings demonstrated that solvent attack in epoxy alcohol hydrolysis occurred exclusively at C-10 and C-12.

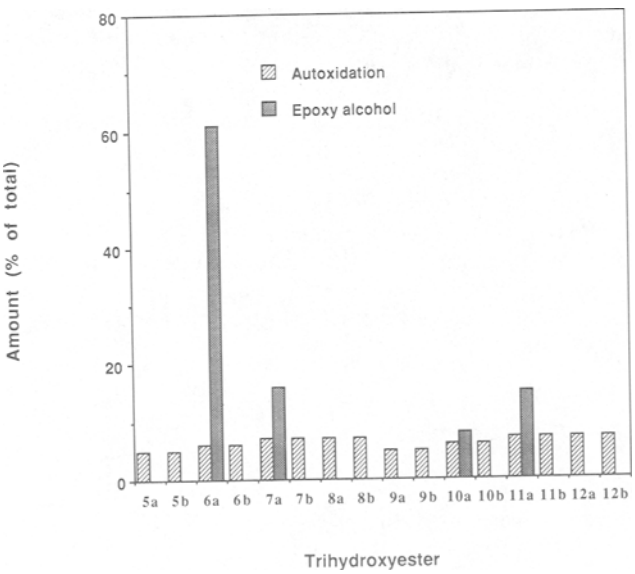

FIG. 7. Percentage compositions of isomeric trihydroxyoctadecenoates formed upon autoxidation of linoleic acid, and upon hydrolysis of methyl 9*S*,10*R*-epoxy-13*S*-hydroxy-11*E*-octadecenoate.

DISCUSSION

Several studies have been concerned with the formation of 9,10,13- and 9,12,13-trihydroxyoctadecenoic acids following incubation of linoleic acid with preparations of plant and animal tissue (1,2,4,5,7,8,10) and with the isolation of linoleic- and α-linolenic acid-derived trihydroxy acids as natural products from various sources (11–18). Arachidonic acid serves as the precursor of related series of compounds, *e.g.* trioxilin A_3 (27). The mechanism of formation of trihydroxyoctadecenoic acids containing the 1,2,5-trihydroxy-3*E*-pentene structure has been studied *inter alia* in chemical model systems (3,6,9) and has been found to involve initial lipoxygenase-catalyzed oxygenation of linoleic acid into its 9- or 13-hydroperoxide derivatives. The hydroperoxides can be further converted, enzymatically as well as non-enzymatically, into epoxy alcohols. Non-allylic epoxy alcohols are fairly stable compounds, whereas the allylic ones (containing either the 2,3-epoxy-1-hydroxy-4-pentene structure or the 4,5-epoxy-1-hydroxy-2-pentene structure) are rapidly hydrolyzed into isomeric trihydroxyoctadecenoic acids. As would be expected, the rate of hydrolysis is greatly accelerated at

acidic pH. For example, the half-lives of the arachidonic acid-derived allylic epoxy alcohols methyl 11*S*,12*R*-epoxy-15*S*-hydroxy-5*Z*,8*Z*,13*E*-eicosatrienoate and methyl 13*R*,14*R*-epoxy-15*S*-hydroxy-5*Z*,8*Z*,11*Z*-eicosatrienoate in aqueous medium at pH 3.0 and 22°C were found to be about 50 s and 100 s, respectively (28).

Linoleic acid-derived trihydroxyoctadecenoates possessing the 1,2,5-trihydroxy-3*E*-pentene structure can exist as 2 positional isomers, each having 3 asymmetrical carbon atoms. Thus, 16 isomers, *i.e.*, 8 separable compounds (5–12) each consisting of 2 enantiomers (**5a**, **5b**, etc.) are possible. In the present study, one of the two enantiomers of each of the 8 compounds was characterized by chemical and chromatographic methods. Preparation of **5a–8a** (Fig. 1) was accomplished by intermolecular epoxidation of the methyl ester of 9*S*-HPOD in the presence of vanadium oxyacetylacetonate into two diastereomeric *trans*-10,11-epoxy-9*S*-hydroxy-12*Z*-octadecenoates (1 and 2) followed by hydrolysis. Trihydroxyesters **9a–12a** were obtained in an analogous way starting with the methyl ester of 13*S*-HPOD (9). The structures of **5a–12a** were established by IR spectrometry and mass spectrometry, as well as by chemical degradation of the cyclic carbonate and (−)-menthoxycarbonyl derivatives followed by steric analysis of the short-chain esters by GLC.

The main factor determining the mobility of **5a–12a** on regular TLC (Fig. 4; Table 1) was the relative configuration of the two hydroxyl groups which are allylic to the *E* double bond. In agreement with previous work (9,10,23), trihydroxyesters having a *cis*-1,4-diol structure were more polar than trihydroxyesters having a *trans*-1,4-diol structure. A slight effect of the relative configuration of the 1,2-diol structure was also noticed. No separation between positional isomers having the same stereochemical features was observed. Separation of trihydroxyesters on sodium arsenite-TLC was influenced by the relative configurations of both the 1,2- and the 1,4-diol structures but not significantly by positional isomerism (Fig. 5; Table 1). As seen from Figure 6 and Table 1, separation of the Me_3Si derivatives of trihydroxyesters by GLC was affected mainly by the relative configuration of the 1,2-diol structure *(erythro/threo)*. In addition, GLC was capable of separating positional isomers (9,10,13-trihydroxy *vs* 9,12,13-trihydroxy-) having the same stereochemical features. By contrast, the retention times found on GLC were only marginally influenced by the relative configuration of the 1,4-diol structure.

The method developed for regio- and stereochemical analysis of individual isomers of trihydroxyoctadecenoates involved preliminary separation of the trihydroxyesters into *cis*- and *trans*-1,4-diols by regular TLC. Part of each fraction was analyzed by GLC in order to determine the percentages of compounds **5–12**, *i.e.*, isomers having known regiochemistry and known relative configurations of the 1,2- and 1,4-diol structures (Table 2). The absolute stereochemistry of the compounds detected by GLC was established by oxidative ozonolysis of the tris-MC derivatives followed by gas-liquid chromatographic analysis of the MC derivatives of methyl 2-hydroxyheptanoate and dimethyl 2-hydroxysebacate. The configuration of the first and last mentioned compound corresponded to the configuration of C-13 of the 9,10,13-trihydroxyesters and to the configuration of C-9 of the 9,12,13-trihydroxyesters, respectively. Application of the method to trihydroxyesters formed upon autoxidation of linoleic acid showed the presence of comparable amounts of compounds **5–12** (Fig. 7). As expected, each diastereomer was racemic. In another application, trihydroxyesters formed by hydrolysis of the epoxy alcohol methyl 9*S*,10*R*-epoxy-13*S*-hydroxy-11*E*-octadecenoate were analyzed. Four compounds appeared. Steric analysis showed that each of these compounds were pure enantiomers, *i.e.* **6a**, **7a**, **10a**, and **11a** (Fig. 7).

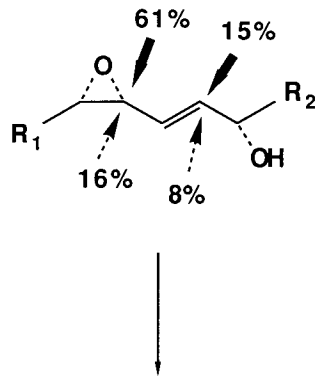

FIG. 8. Hydrolysis of methyl 9*S*,10*R*-epoxy-13*S*-hydroxy-11*E*-octadecenoate. Percentages indicate the extent of attack by solvent at the two faces of C-10 and C-12. R_1 = $(CH_2)_7$-$COOCH_3$; R_2 = $(CH_2)_4$-CH_3.

The composition of trihydroxyoctadecenoates formed upon hydrolysis of methyl 9*S*,10*R*-epoxy-13*S*-hydroxy-11*E*-octadecenoate, coupled with the $H_2{}^{18}O$ experiments which showed that solvent attack occurred exclusively at C-10 and C-12, demonstrated that hydrolysis of the epoxy alcohol occurred mainly (61%) by solvent attack at C-10 with inversion of the configuration of that carbon atom (Fig. 8). In addition, hydrolysis occurred by solvent attack at C-10 with retention of the configuration (16%), as well as by attack at C-12 with isomerization of the double bond into the Δ^{10} position and opening of the epoxide function (23%). Interestingly, solvent attack at C-12 did not occur to the same extent from the two sides of the plane of the Δ^{11} double bond. It may be speculated that water molecules behind the plane of the double bond (Fig. 8) were less reactive in attacking C-12 because of hydrogen bonding to the C-13 hydroxyl group.

The regio- and stereochemical profiles of trihydroxyoctadecenoic acids obtained from a number of natural sources and from epoxy alcohols in the presence of a plant epoxide hydrolase are presently under investigation in our laboratory.

[Received January 2, 1991; Revision accepted March 29, 1991]

Comparative Specificity of Plasma Lecithin:Cholesterol Acyltransferase from Ten Animal Species

Douglas Grove and **Henry J. Pownall***
Division of Atherosclerosis and Lipoprotein Research, Department of Medicine, Baylor College of Medicine and The Methodist Hospital, Houston, Texas 77030

The molecular specificities of plasma lecithin:cholesterol acyltransferase (LCAT) from ten animal species have been compared. Using a reassembled high density lipoprotein containing a mixture of phosphatidylcholines, the relative rates of liberation of different species of cholesteryl ester were measured. All but two species of LCAT clustered according to one of three patterns of substrate specificity. The LCAT from six species, including human, did not transfer highly polyunsaturated fatty acyl chains. In addition, human LCAT transesterified saturated fatty acyl chains more effectively than unsaturated fatty acyl chains. We conclude that the structures of the active sites of the enzymes differ, and that this may be related to size constraints that prevent efficient binding of large bulky phosphatidylcholines.
***Lipids 26,* 416–420 (1991).**

Lecithin:cholesterol acyltransferase (LCAT) catalyzes the production of nearly all plasma cholesteryl esters and is one of the key enzymes involved in reverse cholesterol transport (1–4). The enzyme is composed of a single polypeptide chain containing six cysteines, two of which are essential for activity; the other four form disulfide bridges that are believed to stabilize the enzyme structure (5,6). LCAT has both acyltransferase and phospholipase A_2 activity; the major protein of high density lipoprotein (HDL), apoA-I, stimualtes both activities (7). The major cholesteryl esters found in human plasma are cholesteryl linoleate, oleate and palmitate (2). In model systems in which reassembled high density lipoproteins (R-HDL) are used as substrates, the most reactive acyl donors are phosphoglycerides containing myristic and palmitic acid (8,9). The differences between the *in vitro* and *in vivo* specificities originate from two sources. First, the fatty acyl moieties of native phosphatidylcholines (PC) in HDL, which typically consist of palmitoyl or stearoyl groups in the *sn*-1 position and linoleoyl or oleoyl in the *sn*-2 position, are important determinants of the composition of the resulting cholesteryl esters. Thus the high yield of cholesteryl linoleate and oleate is due to the high abundance of these acids at the *sn*-2 position, which is the preferred, but not the exclusive acyl donor site (7). Second, the model systems were composed of symmetrical diacyl phosphatidylcholines, which are in low abundance in native HDL. There is also some evidence that the identity of the chain at the *sn*-1 position will determine, in part, the reactivity of the acyl group at *sn*-2 (10). The major advantage of model systems is that substrate composition can easily be controlled. Therefore, such a system was used to show that the specificities of human and rat LCAT differ, with the latter having a greater specificity for arachidonate (11,12). This finding suggests that the two enzymes differ, with the rat LCAT having a greater specificity for arachidonate (11,12). This, in turn, may indicate that the two enzymes differ, with the rat LCAT active site being larger and thus more readily able to accommodate bulky groups, such as arachidonate. To understand the differences in specificity, we compared the activity of LCAT derived from 10 species. The data show different patterns of specificity for plasma LCAT activity.

Abbreviations: HDL, high density lipoproteins; HPLC, high-performance liquid chromatography; LCAT, lecithin:cholesterol acyltransferase; PC, phosphatidylcholines; POPC ether, 1-*O*-hexadecyl-2-*O*-*cis*-9′-octadecenyl-*sn*-glycero-3-phosphocholine; R-HDL, reassembled HDL.

EXPERIMENTAL PROCEDURES

Materials. LCAT was isolated from the pooled sera of human and nine animal species. The animals were chicken *(Gallus gallus),* rabbit *(Oryctolagus cuniculus),* pig *(Sus scrofa),* horse *(Equus caballus),* dog *(Canis familiaris),* rat *(Rattus species),* sheep *(Ovis aries),* guinea pig *(Cavia cobaya)* and cow *(Bos species).* All animal sera were obtained from Pel-Freeze Biologicals (Rogers, AR).

Preliminary tests showed that the molecular specificities of partially purified and of purified human and rat LCAT were identical. Therefore, the enzymes used in our tests were partially purified. Partial purification was accomplished by flotation of the plasma lipoproteins at d = 1.21 g/mL, after which the colorless zone in the middle one-third of the centrifuge tube was passed through phenyl sepharose in high salt. The activity was then eluted with distilled water, dialyzed against a standard buffer composed of 0.1 M NaCl and 10mM Tris (pH 7.4), and used in this form for assays (8,13). Sodium dodecylsulfatepolyacrylamide gel electrophoresis of these preparations demonstrated the absence of apoA-I. Human apoA-I was obtained from human plasma as previously described (14,15).

Synthetic PC were either purchased from Avanti Polar Lipids (Birmingham, AL) or synthesized (16,17). Gas chromatographic analyses of the fatty acid methyl esters liberated by transesterification of PC gave compositions consistent with their respective structures. 1-*O*-hexadecyl-2-*O*-*cis*-9′-octadecenyl-*sn*-glycero-3-phosphocholine (POPC ether) was prepared from 3-benzylglycerol, as described previously (8). All phospholipids migrated as a single fraction in thin-layer chromatography on silica gel using chloroform/methanol/water (65:25:4, v/v/v) as the developing solvent.

LCAT assays. R-HDL were prepared by a detergent removal technique using sodium cholate (18,19). POPC ether, cholesterol and the other phospholipids were combined with human apoA-I, and sodium cholate was added to the mixture until optical clarity was achieved. The mixture was then exhaustively dialyzed against standard buffer, giving R-HDL with a defined chemical composition. Four different mixtures of PC in equimolar amounts were combined with POPC ether, which composed 67% of the

phospholipid content of the R-HDL. All R-HDL were prepared with a 100:1 molar ratio of phospholipid (PC mixture plus POPC ether) to apoA-I and contained 2 mol% cholesterol and a trace of [^{3}H]cholesterol that was used to quantify cholesteryl ester formation. The POPC ether, which provides a fluid environment similar to that of HDL, was used as an inert matrix that would be similar in all test mixtures (8). The four groups of substrates that were prepared contained equimolar amounts of the following phosphatidylcholines, all of which were symmetrically substituted and in which the chain length, n, and number of double bonds, m, were represented by n:m. The four groups are as follows: I. 9:0, 12:0, 14:0, 16:0, 18:0. II. 16:0, 18:1, 18:2, 18:3, 22:1. III. 14:0, 20:1, 20:3, 20:4ω6, 22:6ω3. IV. 16:0, 18:2, 20:0.

Typically, LCAT assays were performed at 37°C in a final volume of 0.2 mL containing 2% human serum albumin, 0.5 mM dithiothreitol, 100 mM NaCl and 10 mM Tris, pH 7.4. All assays were performed within a time range where the velocity was linear with respect to time. The substrate concentration was high enough to give a rate that was greater than 90% V_{max}. Each assay used an amount of activity approximately equal to 1 μg of the pure enzyme.

The relative production rates for various molecular species of cholesteryl esters were determined by high-performance liquid chromatography (HPLC) (20,21). Briefly, the reaction mixtures were quenched by the addition of 0.1 mL methanol and 0.5 mL hexane. After vortexing, the upper phase was transferred to vials, and the solvent was removed under a stream of nitrogen. The individual species of cholesteryl esters were separated and quantified on a Hewlett Packard (Andover, MA) 1090 HPLC equipped with an LKB Model 1208 Betacord radioisotope monitor. Chromatography was performed on a 4.6 × 250 mm C_{18} Adsorbosphere column (All-Tech Applied Science, State College, PA). The cholesteryl esters were applied to the column in 50–100 μL of acetonitrile/tetrahydrofuran (68:32, v/v) and then eluted with the same solvent at a flow rate of 0.75 mL/min.

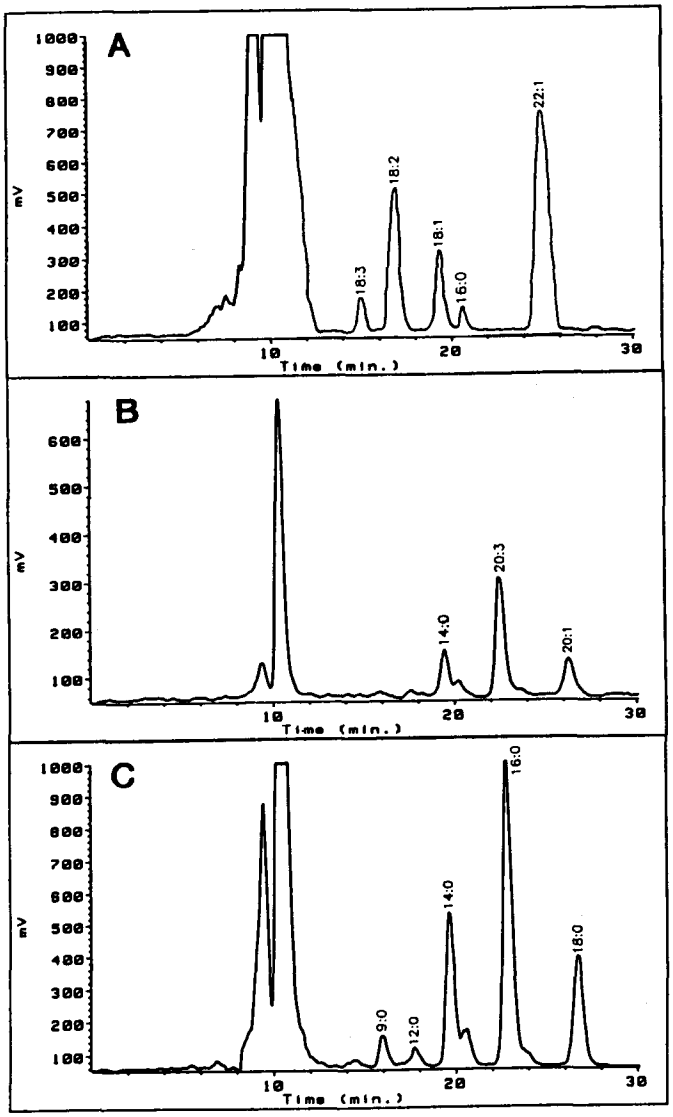

FIG. 1. High-pressure liquid chromatography analysis of human LCAT activity. Substrates for the reactions were R-HDL containing 2.5 μmoles of five symmetrical diacyl phosphatidylcholines with various chain lengths and numbers of double bonds, 25 μmoles POPC ether, 375 nmoles apoA-I, 2 mol% free cholesterol and a trace of [^{3}H]cholesterol to permit quantification of ester formation. Incubations were performed at 37°C for 6 min in final volumes of 220 μL. All experiments were conducted at substrate concentrations of > 90% of V_{max}. Molecular species of cholesteryl esters were liberated by human LCAT using R-HDL containing diacyl PC with the following chain lengths: (A) 18:3, 18:2, 18:1, 16:0, and 22:1 (B) 14:0, 20:3, 20:1, 20:4, and 22:6. (C) 9:0, 12:0, 14:0, 16:0, and 18:0.

RESULTS AND DISCUSSION

The molecular specificity of LCAT from ten different species was analyzed by measuring the relative rates of production of cholesteryl esters liberated from a series of mixtures of R-HDL having equimolar amounts of various PC. Figure 1 (A–C) is representative chromatograms obtained from the cholesteryl esters formed by the incubation of human LCAT with three different kinds of R-HDL. Even though the acyl donors were in the R-HDL in equimolar concentrations, the relative amount of each molecular species of cholesteryl ester that was formed differed. In the mixture that contained PC with the acyl chains 18:0, 18:1, 18:2, 18:3 and 22:1, the last was the best acyl donor (Fig. 1A). The PC that contained 20:3 was the most reactive of those analyzed in Figure 1B. Of the cholesteryl esters that were liberated from the series of saturated PC shown in Figure 1C, 14:0 and 16:0 were the most reactive.

The reactivities of the various PC in these and other HPLC runs were compiled using either 16:0 or 14:0, one of which was present in all of the mixtures, to normalize pairs of runs. These data are shown in Figure 2 for all ten mammalian species studied. The data on the ordinate are plotted on a logarithmic scale so the differences in reactivity are much larger than they appear. In the case of human LCAT (Fig. 2A), the data show that the enzyme from this species prefers saturated chains, with those for 20:4 and 22:6 being almost totally unreactive. Under our experimental conditions, the radioactivity corresponding to the formation of the cholesteryl esters of 20:4 and 22:6 was close to background. In contrast, some of the other species readily utilized these two fatty acids—these were cow, dog, rat and sheep. A log-log plot compared the normalized data from each non-human species with that of

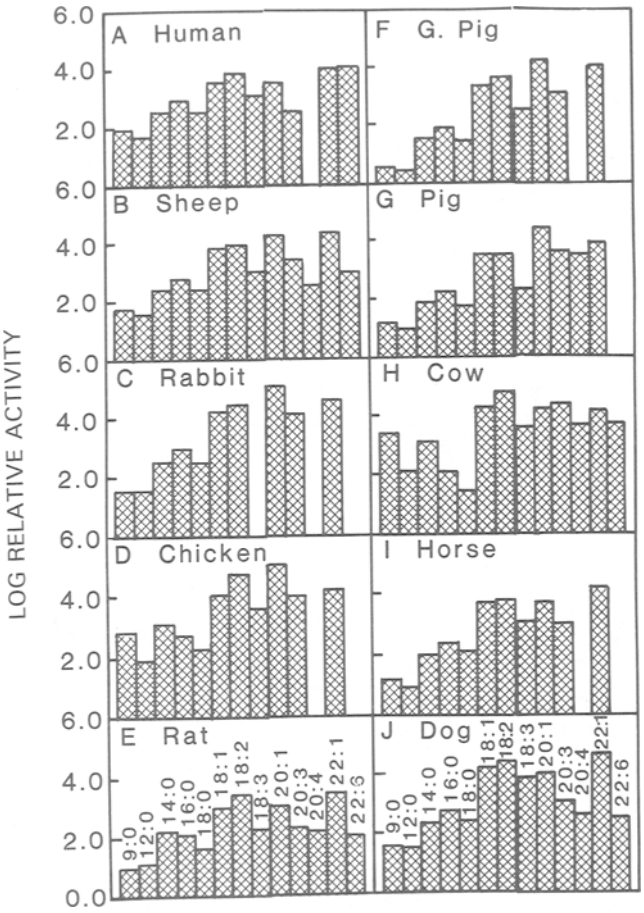

FIG. 2. Relative LCAT specificity for various species using R-HDL containing diacyl PC of differing lengths and numbers of double bonds. (A) human; (B) sheep; (C) rabbit; (D) chicken; (E) rat; (F) guinea pig; (G) pig; (H) cow; (I) horse; (J) dog. Activity on ordinate is relative to the total amount of cholesteryl ester formed.

the human (Fig. 3). The data show that human LCAT prefers saturated diacyl chains (points below the lines in Fig. 3) relative to the nine other species shown; the diacyl chains 20:3 and 20:1 are utilized to a larger extent by all species except human. More striking is the preference of all species, relative to human, for the polyunsaturated diacyl PC chains.

Visual inspection of Figure 3 leads to some qualitative statements. LCAT specificities of rat and dog were very similar to that of the human enzyme, with both having a correlation coefficient of 0.97 (Fig. 3C and 2E). LCAT from chicken and cow were the least similar to human LCAT, with correlation coefficients of 0.75 and 0.64, respectively (Fig. 3, A and D). (These correlations exclude 20:4 and 22:6, for which human LCAT had no measurable activity). Both chicken and cow LCAT were similar to human LCAT in their preference for saturated diacyl PC. The other species utilized unsaturated PC to a greater extent than humans except that chicken and cow LCAT utilized diacyl PC 9:0 far more than human LCAT did.

Those species that used di20:4 and di22:6 as a substrate were clearly distinct from those, such as human, that did not. Cow LCAT transesterified di20:4 and di22:6 from PC to cholesterol relatively efficiently. Sheep, dog and rat followed cow in their utilization of di20:4 and di22:6 PC as substrates. The LCAT from all other species, like human LCAT, did not use these two diacyl chains efficiently (Fig. 2).

To determine whether the molecular species specificity of the LCAT from different sources formed clusters of reactivity, a more quantitative approach was employed. If all species are compared in a normalized correlation matrix using a transposed data matrix according to the equation:

$$[Z]_n = [D]^T [D] \quad [1]$$

and analyzed using principal component analysis (PCA), a scatter plot can be generated (22). In producing this plot (Fig. 4), the data matrix was decomposed into a product of an abstract row matrix and an abstract column matrix as defined previously using the equation:

$$[D] = [R]_c \text{ PCA } [C]_c \text{ PCA} \quad [2]$$

Factors were ranked according to their accounting for variation in the data. To avoid reproducing experimental error, two factors were used. These factors were associated with the most significant eigenvalues and, therefore, the greatest variation in the data.

The scatter plot of the principal component analysis reveals clusters of data points that represent different species of LCAT of similar enzyme specificity (these data include diacyl di20:4 and di22:6, which were not LCAT substrates for six species). Five distinct clusters were identified. Human LCAT was closely associated with chicken (Cluster I), while rabbit, pig and horse formed their own group (Cluster II). Dog, rat and sheep formed another distinct cluster of similar enzyme specificity (Cluster III). Guinea pig (Cluster IV) and cow (Cluster V) had a unique specificity relative to the other LCAT from other mammalian species.

The original data obtained with human LCAT were compared with those corresponding to each of the other four clusters to determine the structural features that distinguish the human enzyme from the others. Table 1 shows that Cluster I, which represents human and chicken LCAT, is much more reactive than Clusters II, III and IV when the substrate contains diacyl chains 9:0 and 12:0. Cluster I is distinct from Clusters II, IV and V with

TABLE 1

Comparison of Clusters of LCAT Activity[a]

Cluster	Cholesteryl esters formed (% change)			
I *vs* II	9:0 (46)	12:0 (36)	14:0 (25)	20:3 (−36)
I *vs* III	9:0 (38)	12:0 (20)	20:4 (−100)	22:6 (−100)
I *vs* IV	9:0 (75)	12:0 (73)	14:0 (44)	16:0 (32)
	18:0 (38)	18:3 (26)	20:3 (−26)	
I *vs* V	19:0 (40)	9:0 (−30)	20:3 (−48)	20:4 (−100)
	22:6 (−100)			

[a]This Table identifies the major differences in the reactivities of di n:m PC in cluster I, which includes human LCAT, with the other clusters, cluster II, rabbit, pig, horse; cluster III, dog, rat, sheep; cluster IV, guinea pig; and cluster V, cow. The value in parentheses represents the percent change in reactivity relative to human LCAT. Only the acyl donors that exhibit more than 25% difference are shown.

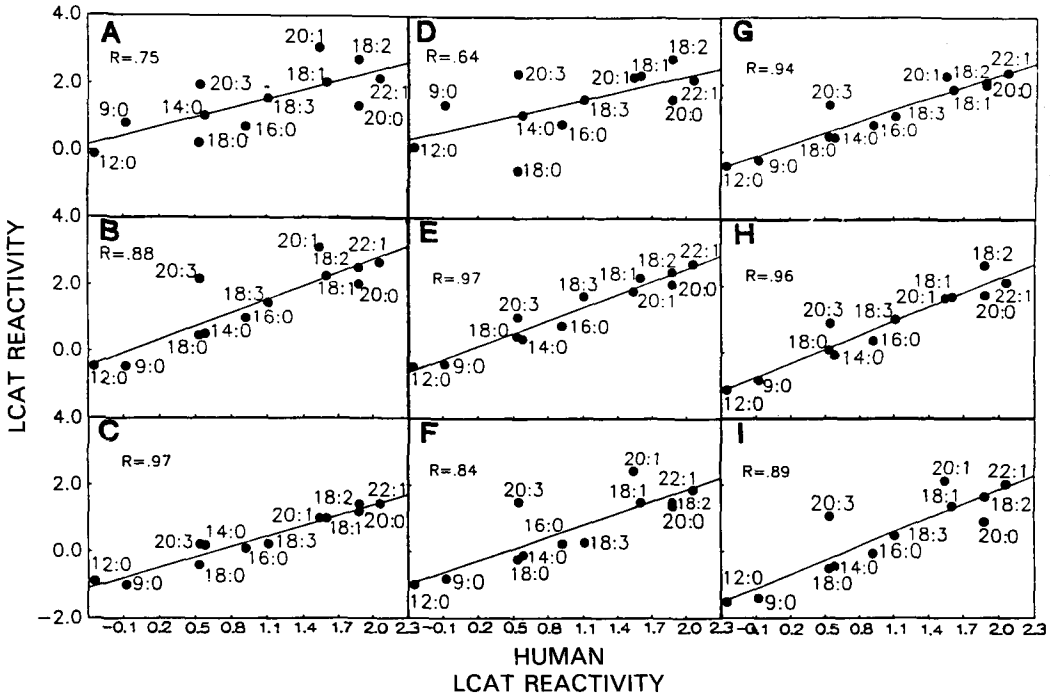

FIG. 3. Correlation of specificity between human LCAT (abscissa) and various other species (ordinate) for diacyl PC of differing chain lengths and double bonds in R-HDL. The PC to apolipoprotein ratio (by weight) of the R-HDL was 100:1, with a free cholesterol content of 2 mol% and a trace of [^{3}H]cholesterol for quantification. Incubations were performed at 37°C in final volumes of 220 μL using 143 μg LCAT in each experiment. Substrate concentrations were > 90% of V_{max}. Measurements were made using high-pressure liquid chromatography; the results are presented in log% area/min. (A) chicken, r = 0.75; (B) rabbit, r = 0.88; (C) rat, r = 0.97; (D) cow, r = 0.64; (E) dog, r = 0.97; (F) pig, r = 0.84; (G) sheep, r = 0.94; (H) horse, r = 0.96; (I) guinea pig, r = 0.89.

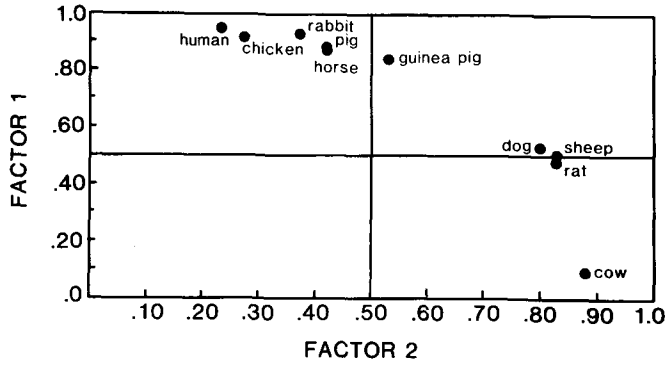

FIG. 4. The scatter plot generated when all species of LCAT were analyzed using principal component analysis. Two factors were associated with the most significant eigenvalues and, therefore, the greatest variation in data. The scatter plot reveals clusters of data points that represent LCAT of similar specificity (this data includes all diacyl chains). Three distinct clusters can be identified. These are human and chicken LCAT; rabbit, pig and horse; dog, rat, and sheep. The LCAT specificities of guinea pig and cow did not cluster with those of any other species.

respect to its relatively low reactivity towards diacyl chain 20:3. Compared to Cluster I, Cluster IV, which consists solely of guinea pig, was relatively inactive in six of the thirteen diacyl chains tested. The other cluster (Cluster V, cow) consisted of only one species and was more reactive with the diacyl chains 9:0, 12:0, 20:4 and 22:6 than was Cluster I.

In general, substrate specificity is caused by molecular species selectivity and not a peculiar microenvironment or surface afforded by a particular phosphatidylcholine (8,9,12,23,24). The unique specificity for substrates of different diacyl chain lengths and double bonds exhibited by various species of LCAT is consistent with different active site structures. The tendency for LCAT from all species except human to transesterify highly unsaturated phosphatidylcholines to cholesterol suggests that the active sites of LCAT from these species are suited to handle the larger molecular volumes that are characteristic of polyunsaturated substrates. Diacyl chains 20:4 and 20:6, which were the bulkiest substrates used, were utilized by only four of the ten species (cow, sheep, dog and rat). The high content of plasma cholesteryl esters of arachidonate in rat HDL correlates well with the unusually high amounts of arachidonate at the *sn*-2 position of phosphatidylcholine and the high reactivity of the LCAT with respect to arachidonate (12).

LCAT from cow was also unique in its fairly indiscriminate specificity for substrates. Only the diacyl chains 18:0 and 16:0 had a relatively low reactivity. Guinea pig and chicken LCAT also transesterified diacyl PC chains 18:0 and 16:0 to cholesterol to a lesser extent than human LCAT, which revealed an active site compatible with bulky polyunsaturated substrates, but it was not as compatible with longer, fully saturated PC.

The source of the specificity differences of LCAT from different species is not clear. As the primary structures

of the various LCAT species become available, it may be possible to assign differences in specificity to specific parts of the polypeptide chain. These, in turn, may permit a correlation of the specificity and structure of different species with their evolutionary relatedness.

[Received February 18, 1991; Revision accepted April 18, 1991]

Fatty Acid Composition of Brain Phospholipids in Aging and in Alzheimer's Disease

M. Söderberg*, C. Edlund, K. Kristensson and G. Dallner
Division of Medical Cell and Neurobiology, Clinical Research Center, Huddinge University Hospital, Karolinska Institutet, S-141 86 Huddinge, Sweden

The two major phospholipid classes, namely, phosphatidylethanolamines (PE) and phosphatidylcholines (PC), were studied in four different regions of human brain, *i.e.*, in frontal gray matter, frontal white matter, hippocampus and in pons. The fatty acid (FA) compositions of these phospholipids were found to be specific for the different regions. PC contains mostly saturated and 18:1 FA, while PE is rich in polyunsaturated FA. Aging has no influence on the FA compositions, while in Alzheimer's disease (AD) PE is modified in all four regions, particularly in frontal gray matter and in hippocampus. The abundance of the major monounsaturated FA of PE, 18:1, is not significantly altered in Alzheimer's disease, but there is a substantial increase in the relative amounts of the saturated components 14:0, 16:0 and 18:0. This is paralleled by a decrease in the polyunsaturated FA 20:4, 22:4 and 22:6. It is not clear whether the changes observed are specific for AD. Changes in saturated/polyunsaturated FA ratio are likely to influence cellular function, which in turn may cause certain neural deficiencies. The findings do not support the hypothesis that AD reflects an accelerated aging process.
Lipids 26, 421–425 (1991).

Phospholipids (PL) are structurally and functionally important constituents of membranes. They regulate membrane structure and permeability, as well as the activities of membrane-bound enzymes. The lipid composition of the brain—especially in regard to the high concentrations of cholesterol, of the polyisoprenoid compounds dolichol and ubiquinone, and of glycolipids—differs significantly from those of other tissues (1,2). It is generally assumed that cholesterol in model membranes preferentially associates with phosphatidylcholine (PC) (3) and that isoprenoids located in the hydrophobic portion of phospholipid bilayers prefer phosphatidylethanolamine (PE) (4). Changes in the amounts and types of PL could thus, in turn, also affect the neutral lipid components of membranes.

Changes in the composition and metabolism of brain lipids have been proposed to contribute to the deterioration of central nervous system function with increasing age (2,5). It has also been proposed that phosphoinositide levels in brain, and of some of the metabolites of PE and PC, are involved in the processes that cause various types of senile dementia (6,7). In one study, the content of polyunsaturated fatty acids (FA) (PUFA) in total PL from frontal brain cortex was found to decrease with increasing age, while the PUFA content in Alzheimer's disease (AD) varied (8). In contrast, another investigation found no differences in FA composition in aging (9). In this latter study a decreased n-6 PUFA content was observed in PC from the frontal cortex of AD patients, while no significant changes in the FA composition of PE were found.

In light of these facts, it appeared timely and important to initiate a study of the lipid compositions of different parts of the brain in AD. The study is concerned with changes in the FA composition of PE and PC in four different regions of the brain.

Abbreviations: AD, Alzheimer's disease; FA, fatty acids; GLC, gas-liquid chromatography; NADH, nicotinamide adenine dinucleotide; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PL, phospholipids; PUFA, polyunsaturated fatty acids; TLC, thin-layer chromatography.

MATERIALS AND METHODS

Brain samples were obtained during autopsy approximately 24 hr after death. The contralateral brain hemisphere was fixed for histopathological examination. In histological preparations various silver staining techniques were employed. Patients with clinical dementia were diagnosed according to the criteria established for AD by the National Health Institute/American Association of Retired People (NHI/AARP) working group (10). All patients included in this study showed substantial quantities of neuritic plaques, well above the minimum number required to verify the diagnosis by the above-mentioned criteria. In addition, neurofibrillary tangles were present in the neocortex in all patients with AD.

Patients from which control samples were taken died from causes unrelated to the nervous system and showed no clinical manifestations of dementia or other mental disorders. Microscopic investigation of the control brains revealed normal cytoarchitecture in the neocortex. In some of the older patients small numbers of neuritic plaques were found as is usual at advanced age.

Brain regions chosen for lipid analysis were removed and homogenized in 0.25 M sucrose with an Ultra-Turrax blender (Janke & Kunkel, Staufen, Germany) for 2 min (24000 rpm). The resulting 10% homogenate was stored at −20°C until assayed, which was usually within 1–2 wk. White matter was taken from the frontal lobe.

To extract lipids, 6 mL methanol and 6 mL chloroform were added to 2 mL of the homogenate to obtain a final chloroform/methanol/water ratio of 1:1:0.3 (v/v/v). Extraction was performed at 40°C for 60 min with magnetic stirring. Phase separation was obtained by addition of chloroform and water to give a final chloroform/methanol/water ratio of 3:2:1 (v/v/v). The tubes were then centrifuged for 5 min at 250 × *g*. The lower phase was washed 4 times with theoretical upper phase (chloroform/methanol/water, 3:48:47, v/v/v) and evaporated under nitrogen. The lipid residue was dissolved in 5 mL chloroform and placed onto a Silica-SepPak cartridge (Millipore, Waters Associates, Milford, MA), which was then washed with 25 mL chloroform to remove neutral lipids. PL were eluted from the Silica-SepPak with 25 mL methanol. The solvent was evaporated under N_2 and lipids were dissolved in 200 μL chloroform/methanol 2:1 (v/v). Twenty μL of the extract was applied to a Silica gel 60 plate (Merck, Darmstadt, Germany) for two-dimensional thin-layer chromatography (TLC). The plates were developed with

[a]The values are the means ± SD of 8–10 measurements.

[b]PE, phosphatidylethanolamine; PC, phosphatidylcholine.

[c]Significantly decreased compared with the youngest age group ($p<0.05$). Statistics were performed using Kruskal-Wallis one-way analysis of variance followed, if group differences existed, by Wilcoxon-Mann-Whitney test.

chloroform/methanol/acetic acid/water (106:50:12:6, by vol) in the first direction and with chloroform/acetone/methanol/acetic acid/water (50:20:10:10:5, by vol) in the second direction. The plates were dried and sprayed with an aqueous solution of Rhodamin 6G to visualize fractions. Fractions were scraped off and PL were extracted with 5 mL chloroform/methanol, 2:1 (v/v). The recoveries of PE and PC were between 79 and 92%. Half of the solution was used to measure phosphate content, as described previously (2). The other half was used to determine the FA composition of the PL after transesterification with boron trifluoride/methanol (11). Antioxidants were not added. PUFA recoveries in the presence and absence of antioxidants were identical, when methanolysis was performed in a N_2 atmosphere. FA methyl esters were analyzed by gas chromatography on a Shimadzu GC-9A (Kyoto, Japan) with a flame ionization detector and with hydrogen as the carrier gas. The column was a fused silica capillary with cyanosiloxane 60 as the stationary phase (30 m × 0.25 mm I.D., df = 0.18 μm). From an initial temperature of 140°C, which was maintained for 2 min, the temperature was raised 2.5°C/min for 18 min, then 0.4°C/min for 5 min and, finally, 2.0°C/min until a final temperature of 195°C was attained, which was then maintained for 4 min. The total time per gas-liquid chromatography (GLC) run was 33 min. Peaks were integrated on a Shimadzu Chromatopac C-R3A. FA methyl esters were identified by comparison with commercial FA methyl ester standards (Sigma Chemical Co., St. Louis, MO). Solvents were from Merck.

RESULTS

Phospholipid composition. The amount of PL in human brain varies between 32 and 70 mg per gram wet weight, depending on the anatomical location and age (Table 1). In white matter and pons, the amount is about double that found in frontal gray matter and hippocampus. At ages above 70, a moderate decrease in the total amount of PL is observed at all locations, which agrees with previous findings (2). About 80% of total PL consists of the two major components, PE and PC. PE plasmalogen content was determined in some samples. The amounts of plasmalogen found in AD patients and controls were identical (not shown in tables). For practical reasons, plasmalogen content was therefore not routinely determined.

Fatty acids of PE in aging. The FA composition of PE shows extensive variation depending on the source of the lipid (Table 2). While some FA, such as 16:0 and 20:4, occur in similar amounts in all regions, others vary within wide limits. For example 18:0 and 18:1, respectively, constitute 8–35% and 10–46% of the total FA in PE in various regions of the brain. Saturated FA in white matter and in pons contributes 16% and 18% of the total, respectively, while for gray matter and hippocampus these values are 45% and 35% (see also Fig. 1). The specific role of PUFA makes the distribution of these species particularly interesting. While arachidonic acid levels fluctuate only to a limited extent, the relative amounts of 22:4 and 22:6 vary substantially, with 22:6 being the most variable with levels ranging from 4% to 24% for different regions

TABLE 2

Fatty Acid Composition of PE in Different Regions of the Human Brain[a]

	89-92	9.2	9.2	41.1	10.6	8.7	12.3	5.8

[a]The values are the means of measurements from 8-10 different individuals. SDs were 2-12% of the means.

[b]Small amounts (<1%) of other FA, *e.g.* 16:1 and 18:2, also occurred.

of the brain. FA species comprising less than 1% of the total amount, *e.g.*, 20:3 and 22:5, are not included in the tables.

Fatty acids of PE in Alzheimer's disease. The FA composition of PE is characteristically altered in both the gray matter and the hippocampus in the brains of patients afflicted by AD (Table 3). Most typically, a sizeable increase in the relative amounts of saturated FA (14:0, 16:0 and 18:0) is apparent. By contrast, the levels of the three PUFA species (20:4, 22:4 and 22:6) are decreased considerably in gray matter and in hippocampus. To some extent, similar changes can be observed in white matter and pons.

The calculated values for total saturated, monounsaturated and polyunsaturated FA in PE in various regions of the brain in control patients and Alzheimer victims are presented in Figure 1. Taking into consideration the great variations in the extent of histological changes in the brains affected by AD, it is not surprising that there are also considerable differences in the degrees to which the FA compositions of these brains are modified. The principal changes are decreases in PUFA content in gray matter and hippocampus, compensated for by an increase in their saturated counterparts. The white matter demonstrates similar, but less accentuated changes. In pons the difference between control and diseased brains is even smaller, but still significant.

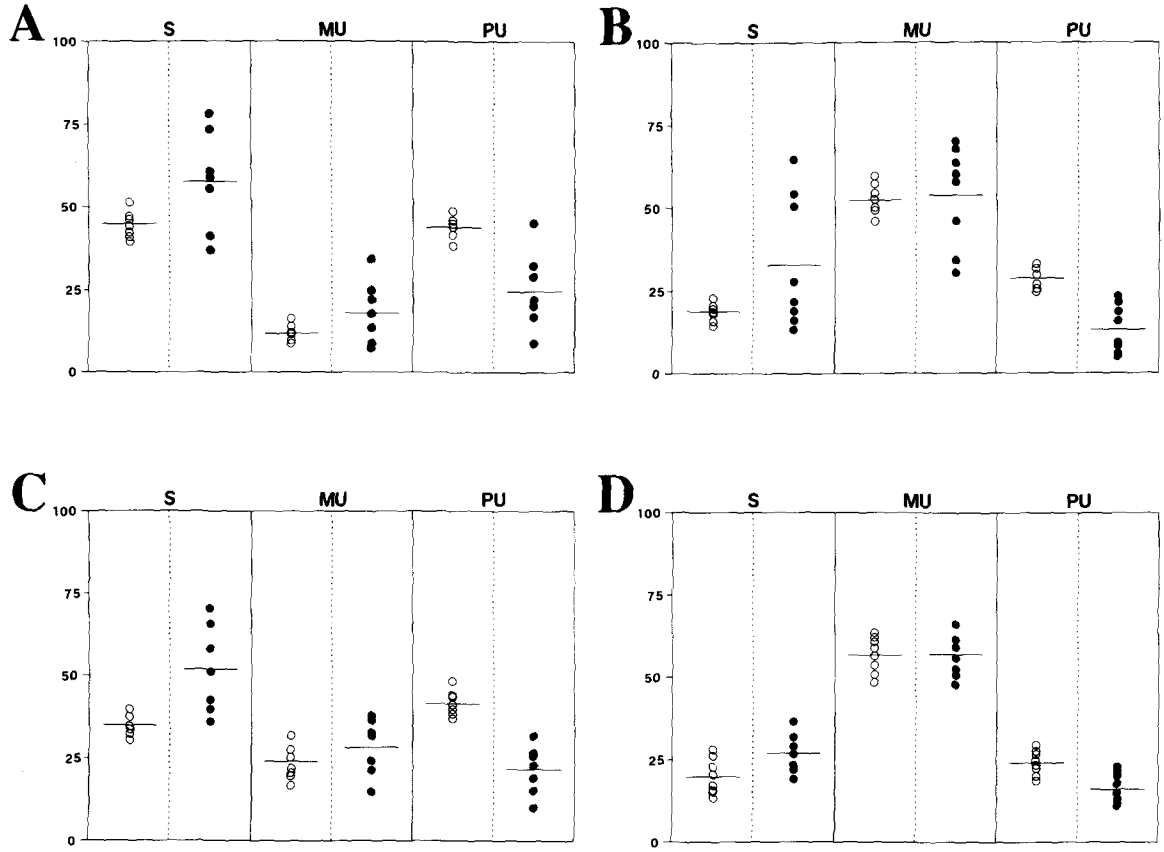

FIG. 1. Distributions of saturated and unsaturated fatty acids in PE of various regions of the brain. A: frontal gray matter; B: white matter; C: hippocampus; D: pons. The individual values were plotted separately. Open circle, control; filled circle, Alzheimer's disease; S, saturated fatty acids; MU, monounsaturated fatty acids; PU, polyunsaturated fatty acids. The horizontal bars represent the means. The numbers on the vertical axis represent percentage of total FA.

[a]The values are the means of measurements from 8–10 different individuals. SDs were 5–16% of the means. Traces are identified as tr.

Fatty acids of PC in aging. The FA composition of PC is very different from that of PE. Saturated components constitute one-half to two-thirds of the total, and 18:1 is the only unsaturated component present in appreciable amounts (Table 4). The only significant polyunsaturated FA present is arachidonic acid (2–3% of the total). Thus, the heterogeneity of FA patterns of PC is less pronounced than for PE, but an individual pattern characteristic for the histological location is preserved. Two- to three-fold differences in the relative amounts of certain FA are observed between regions. As is the case for PE, no significant changes in the FA pattern of PC occur during aging.

[c]Alzheimer's disease.

[d]The values are significantly different from the controls ($p<0.05$).

Fatty acids of PC in Alzheimer's disease. Because of the more limited regional variations in the FA compositions of PC, the changes observed in brains affected by AD were much less pronounced than those found in PE (Table 5). The small decreases seen in 18:1 and 20:4 are paralleled by minor increases in certain saturated components.

DISCUSSION

Compared with other organs, the brain has an unusually high content of lipids, some two-thirds of which consists of PL. Even limited alterations in PL structure are therefore thought to be of considerable functional importance. Many physical properties of membranes, such as permeability and fluidity, are greatly influenced by phospholipid FA composition (12), and several integral membrane proteins are dependent on certain types of PL (13). Membrane phospholipids also participate in compartmentalization (14–16). Variations in the FA compositions of certain PL in various regions of the brain are extensive. At all locations PC differs from PE, in that the former contains mostly saturated and 18:1 FA, while the latter possesses 30–40% PUFA. Variations in different regions create specific patterns, particularly in the case of PE. In most cases, the ratio of saturated-to-monounsaturated FA varies widely, while the percentage of PUFA is more stable. The lipid compositions of specific brain regions are highly dependent on the abundance of myelin and synapses, since these structures have markedly different FA profiles (17).

During aging some of the brain lipids are considerably modified (2). However, the FA compositions of PL are not changed. In AD the FA composition of PC exhibits minimal changes. In PE, the amounts of the saturated FA 14:0, 16:0 and 18:0 are elevated, while the polyunsaturated FA 20:4, 22:4 and 22:6 are significantly decreased. The

relatively modest changes in PC may be explained by the absence of substantial amounts of PUFA in PC even in normal brain tissue, thereby reducing the margin for change.

PE in the brain is made up of two subclasses, namely diacylglycerophospholipids and plasmalogens. The ratio between these two subclasses does not appear to be changed in AD. We have not examined individual FA compositions, nor the composition of the ether-linked chains in the 1-position of the plasmalogens. Still, the decrease in PUFA is likely to affect both PE subclasses. It is established that PUFA occur almost exclusively in ester-linked form in PE (18).

It is not known whether the changes in FA patterns found in the brains of Alzheimer victims are specific for this disease, or whether patterns similar to those found in AD appear in other neurodegenerative diseases. The changes observed do, however, not appear to be typical of normal aging, because no change in the relative amounts of PUFA is seen with advancing age. This would also speak against the possibility that AD just represents an accelerated aging process (19).

The moderate FA changes that were observed in a previous study on AD material (9) may be explained by different sampling procedures. FA changes varied greatly between affected brains (see Fig. 1), and in less advanced cases the PUFA levels were close to the control values.

There could be several reasons for the disappearance of PUFA in AD. One, for example, could be the modification of the microsomal desaturation system (20). Since no intermediary PUFA appeared in our material, a possible mechanism could be a decrease in nicotinamide adenine dinucleotide (NADH)/cytochrome b_5 reductase activity, the initial enzyme common to various desaturation processes (21). An alternative explanation for the absence of PUFA in AD may be a deficiency in uptake thus decreasing the supply of appropriate substrates. Linoleic and linolenic acids are essential FA, and their depletion in the brain would explain the loss of the longer PUFA, most of which are synthesized in the brain from linoleic and linolenic acids (22). A third possible explanation for the altered FA composition may be a change in the cellular makeup of the brain in AD, possibly involving gliosis or a reduction in the number of dendrites. Such changes also occur, however, in normal aging (23), which is not accompanied by a decrease in PUFA. A specific decrease in the number of synaptic structures, where PE rich in PUFA is abundant (24), has been proposed to occur in AD (25). This would also result in some reduction of total PUFA content. Isolated and purified subcellular fractions from AD brains are presently being investigated in our laboratory.

The substantial decrease in polyunsaturated FA may have serious consequences for cellular function. The large decrease in arachidonic acid content, for example, could hamper the production of important active metabolites, such as prostaglandins and leukotrienes, which, in turn, could cause the functional changes observed in Alzheimer's disease.

Activation and Solubilization by Triton X-100 of Membrane-Bound Phospholipase D of Rat Brain

Hiroyuki Kanoh*, Yasunori Kanaho and Yoshinori Nozawa
Department of Biochemistry, Gifu University School of Medicine, Gifu 500, Japan

In the present study, we examined the ability of detergents to stimulate and solubilize phospholipase D (PLD) of a particulate fraction of rat brain. PLD activity was assayed by measuring the [^{3}H]choline produced from the exogenous substrate dipalmitoyl phosphatidyl[^{3}H]choline (dipalmitoyl [^{3}H]PC). In the absence of detergents, PLD activity was not detectable. Of the detergents examined, Triton X-100 was found to markedly enhance PLD activity, whereas other detergents including sodium deoxycholate, sodium cholate, CHAPS and Lubrol-PX caused only a small, if any increase in activity. Enhancement by Triton X-100 was maximal at 0.1–0.2% (w/v) and decreased at higher concentrations. The optimal pH was 7.1–7.3. Both Ca^{2+} and Mg^{2+} inhibited enzyme activity stimulated by Triton X-100 in a concentration-dependent manner. Triton X-100 effectively solubilized PLD from the particulate fraction of rat brain; more than 70% of the activity of the particulate fraction was extracted by 0.5–1.0% (w/v) Triton X-100. Furthermore, when the PLD activities in brains of three different species (rat, rabbit and bovine) were measured under optimal conditions, the activities were found to differ greatly. PLD activity was highest in rabbit brain, followed by rat and bovine brains; the activity in bovine brain was extremely low compared to the activities in rat and rabbit brains. We conclude that Triton X-100 is potentially useful for the purification of PLD and that rabbit and rat brains are the preferred sources.
Lipids 26, 426–430 (1991).

Phospholipase D (PLD, EC 3.1.4.4) is a unique enzyme which catalyzes the hydrolysis of phospholipids as well as transphosphatidylation reaction. Hydrolysis of phospholipids by PLD leads to the generation of phosphatidic acid and alcohols, *e.g.*, choline, ethanolamine and serine. Based on the phosphatidyltransferase activity of PLD, the phosphatidyl moiety of substrate phospholipids is transferred to nucleophilic primary alcohols to produce their corresponding phosphatidylalcohols; *e.g.*, in the presence of ethanol, PLD produces phosphatidylethanol (PEt) (1–3). In intact cells, whose endogenous phosphatidylcholine (PC) is radiolabeled, PLD activity can be easily detected by measuring the radiolabeled PEt formed in the presence of ethanol.

More recent studies have demonstrated that PLD exists in mammalian cells (4–10), although it had earlier been believed that PLD is present only in plant tissue. Recent studies have furthermore shown that PLD is activated in response to a variety of specific receptor agonists in several types of cells (5,8,9,11–15), which suggests that PLD activation of cells by agonists is part of a signal transduction pathway.

Abbreviations: PC, phosphatidylcholine; PEt, phosphatidylethanol; PLD, phospholipase D; PNPP, *p*-nitrophenylphosphate.

Kanfer and co-workers (16–18) have reported that the particulate fraction of rat brain contains PLD, but the activity was barely detectable in the absence of appropriate activators, such as unsaturated fatty acids. The fatty acids, however, did not appear to have a detergent effect in the sense that they failed to solubilize membrane-bound PLD (17). Although Taki and Kanfer (19) have solubilized and partially purified PLD from rat brain using Miranol, this detergent is not commercially available.

In the present study, we have therefore tested the ability of various commercially available detergents to stimulate and solubilize PLD using a particulate fraction from rat brain, and have attempted to establish optimum conditions for the assay of PLD activity. Furthermore, we have compared PLD activities in the brain of three different species (rat, rabbit and bovine) to find an optimal source for the purification of PLD.

MATERIALS AND METHODS

Materials. 1,2-Dipalmitoyl-*sn*-glycero-3-phospho[*methyl*-^{3}H]choline (dipalmitoyl [^{3}H]PC, 73 Ci/mmol) was purchased from Amersham (Buckinghamshire, U.K.). 1,2-Dipalmitoyl-*sn*-glycero-3-phosphocholine (dipalmitoyl PC) and [*methyl*-^{3}H]choline chloride (85 Ci/mmol) were obtained from Avanti Polar Lipids Inc. (Pelham, AL) and American Radiolabeled Chemicals Inc. (St. Louis, MO), respectively. AG 50W-X8 resin (100–200 mesh, hydrogen form) was from Bio-Rad (Richmond, CA).

Preparation of particulate, crude membrane and microsomal fractions. Rats and rabbits were sacrificed by decapitation or by injection of air into a vein, respectively. Immediately after sacrifice, brains were removed and frozen in liquid nitrogen. Bovine brain was removed immediately after sacrifice, cut in about 0.5-cm thick slices, and then frozen in liquid nitrogen. Brains were stored at −80°C until use.

To study the effect of detergents, pH and divalent cations on PLD activity, the particulate fraction of rat brain was prepared as follows. Rat brains (6 g, wet wt) were minced and homogenized in 30 mL of buffer A consisting of 20 mM Tris-HCl (pH 7.4), 1 mM EDTA, 1 mM dithiothreitol and 0.2 mM phenylmethylsulfonyl fluoride, and then an additional 30 mL of buffer A was added. After sedimentation of nuclei and unbroken cells at 400 × *g* for 10 min, the resultant supernatant was centrifuged at 105000 × *g* for 60 min to obtain the particulate fraction.

To study species difference in PLD activity, crude membrane and microsomal fractions of brain of three different species (rat, rabbit and bovine) were prepared according to Natarajan *et al.* (20). Rat, rabbit and bovine brains were minced and homogenized (20% w/v) in 0.32 M sucrose containing 1 mM EGTA. The homogenate was centrifuged at 1000 × *g* for 10 min and the postnuclear supernatant was centrifuged at 22000 × *g* for 30 min to obtain the crude membrane fraction that contained myelin, synaptosomes and mitochondria. The supernatant was centrifuged at 105000 × *g* for 60 min to obtain the microsomal

fraction. The protein concentration was determined with a BCA protein assay kit (Pierce Chemical Company, Rockford, IL) using bovine serum albumin as standard.

Assay of PLD activity. Dipalmitoyl [^{3}H]PC was used as a substrate for PLD. Unilamellar vesicles were prepared in buffer warmed above the phase transition temperature of dipalmitoyl PC (41.5°C) (21). To dipalmitoyl [^{3}H]PC dried under nitrogen was added 100 mM Tris-maleate buffer (pH 7.0) prewarmed to 55°C. The dipalmitoyl [^{3}H]PC suspension was vigorously vortexed and sonicated for 5–10 min in a bath sonicator (Funakoshi A-10F, Tokyo, Japan) which was kept with water at 55°C.

PLD activity was assayed by measuring [^{3}H]choline generated from dipalmitoyl [^{3}H]PC. For the standard assay, the reaction mixture contained 40 mM Tris-maleate (pH 7.0), 30 μM dipalmitoyl [^{3}H]PC (0.2 μCi), 0.1% (w/v) Triton X-100, 0.1 mM EDTA and 100 μg protein in a total volume of 100 μL. Incubations were carried out at 37°C for 30 min. PLD activity was also assessed in the presence of sodium oleate, which is known to activate PLD activity (17,18), according to the method by Chalifa *et al.* (22) except that [^{3}H]choline produced in the absence of ethanol was determined. Briefly, the reaction mixture (100 μL) contained 50 mM Na-Hepes buffer (pH 7.2), 2.7 mM dipalmitoyl [^{3}H]PC (0.4 μCi), 4 mM sodium oleate, 1 mM EGTA, 1 mM $MgCl_2$, 5 mM *p*-nitrophenylphosphate (PNPP) and 30 μg protein of crude membrane or microsomal fraction. The phosphatase inhibitor PNPP was included to prevent the conversion of phospho[^{3}H]choline formed by the PC-specific phospholipase C to [^{3}H]choline by phosphocholine phosphatase (23,24). Incubations were carried out at 37°C for 15 min. The reaction was stopped by adding 400 μL of chloroform/methanol (1:2, v/v), and the phases were separated by adding 100 μL of chloroform and 100 μL water. [^{3}H]Choline partitioned into the resultant aqueous phase was separated on an AG 50W-X8 column and radioactivity was counted.

Isolation of [^{3}H]choline by AG 50W-X8 column chromatography. [^{3}H]Choline was separated from other radiolabeled [^{3}H]choline derivatives by AG 50W-X8 cation-exchange column chromatography using a slight modification of the method reported by Cook and Wakelam (25). The AG 50W-X8 column (0.5 mL) was washed with 5 mL of 1 M HCl and then with 10 mL of water before use. Samples diluted to 5 mL with water were applied to the column, and the column was washed three times with 5 mL of water to elute glycerophosphocholine and phosphocholine. [^{3}H]Choline was eluted by five successive additions of 1 mL of 1 M KCl, with the recovery being over 90%, and radioactivity was counted. When 1 M HCl was employed to elute [^{3}H]choline as reported by Cook and Wakelam (25), 12 mL of 1 M HCl was required to recover more than 90% of [^{3}H]choline in a relatively broad fraction (data not shown). Use of 1 M KCl considerably shortened [^{3}H]choline elution time.

Solubilization of PLD from the particulate fraction of rat brain by Triton X-100. One milliliter of the particulate fraction of rat brain in buffer A (5.5 mg protein/mL) was mixed with an equal volume of buffer A containing various concentrations of Triton X-100. The mixture was incubated at 4°C for 2 hr with stirring and then centrifuged at 105000 × *g* for 1 hr to obtain the Triton X-100 extract. Twenty microliters of the extract was used for the assay of PLD activity and 100 μL was used for the protein determination. The concentration of Triton X-100 was adjusted to 0.2% (w/v) in the PLD assay.

RESULTS AND DISCUSSION

Effects of detergents on PLD activity in the particulate fraction of rat brain. Of the detergents employed in this study, including Triton X-100, sodium deoxycholate, sodium cholate, CHAPS and Lubrol-PX, only Triton X-100 was found to significantly activate PLD in the particulate fraction of rat brain; maximum stimulation occurred at 0.1–0.2% (w/v) (Fig. 1). Other detergents caused only little activation. In the absence of detergents, PLD activity was not detectable. In the presence of 0.1% (w/v) Triton X-100, [^{3}H]choline formation was linear with time for 30 min and with protein concentration up to 50 μg/assay (data not shown). This would indicate that [^{3}H]choline was produced enzymatically. [^{3}H]Choline can also be produced from [^{3}H]PC by the sequential action of PC specific-phospholipase C and phosphocholine phosphatase. When the PLD assay was carried out in the presence of 5 mM PNPP, a phosphatase inhibitor which inhibits phosphocholine hydrolysis (23,24), [^{3}H]choline formation was the same as in the absence of PNPP (data not shown). This confirms that the [^{3}H]choline formed under our experimental conditions reflects PLD activity only.

Solubilization of PLD from the particulate fraction of rat brain by Triton X-100. We found that Triton X-100 significantly stimulates PLD activity, which confirms what was reported by Qian *et al.* (24). If Triton X-100 can solubilize PLD of the particulate fraction, this should prove useful for the purification of the enzyme. As shown in Table 1, Triton X-100 solubilized PLD from the

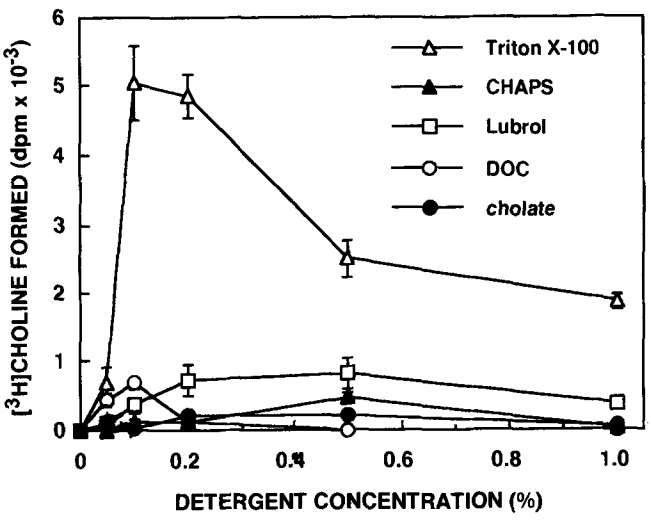

FIG. 1. Effects of detergents on phospholipase D activity in the particulate fraction of rat brain. The reaction mixture (100 μL) contained 40 mM Tris-maleate (pH 7.0), 30 μM dipalmitoyl [^{3}H]PC (0.2 μCi), 0.1 mM EDTA, 100 μg protein of the particulate fraction of rat brain and the indicated concentration of sodium deoxycholate (DOC), (○), sodium cholate (●), Triton X-100 (△), CHAPS (▲) or Lubrol-PX (□). After incubation at 37°C for 30 min, [^{3}H]choline formed was determined as described in Materials and Methods. The results shown are the mean ± S.D. of three independent experiments.

TABLE 1

Solubilization of Phospholipase D from the Particulate Fraction of Rat Brain by Triton X-100[a]

	Triton X-100 (%)			
	0.1	0.2	0.5	1.0
Protein (mg/mL)	0.95 ± 0.07 (31.9 ± 2.5)[b]	1.02 ± 0.16 (35.1 ± 6.6)[b]	1.20 ± 0.20 (41.0 ± 4.0)[b]	1.21 ± 0.28 (41.5 ± 7.3)[b]
Specific activity (nmol/hr/mg protein)	0.53 ± 0.18	1.58 ± 0.71	1.76 ± 0.80	1.94 ± 0.87
Extractability[c] (%)	21.2 ± 6.9	53.6 ± 14.9	73.6 ± 27.9	79.0 ± 31.0

[a] PLD was extracted from the particulate fraction of rat brain as described in Materials and Methods. The concentration of Triton X-100 in the reaction mixture of the PLD assay was adjusted to 0.2% (w/v). PLD activity of the particulate fraction before solubilization, that was also assayed in the presence of 0.2% (w/v) Triton X-100, was 0.99 ± 0.24 nmol/hr/mg protein. The results shown are the mean ± S.D. of four independent experiments.

[b] Values in parentheses represent the percentage of protein solubilized when protein of the particulate fraction before solubilization was taken as 100%.

[c] Extractability represents the percentage of PLD activity in the extracts when the activity of the particulate fraction before solubilization was taken as 100%.

particulate fraction of rat brain in a concentration-dependent manner. Maximal solubilization was observed at 0.5–1.0% (w/v) Triton X-100, with more than 70% of the initial activity present in the particulate fraction being extracted. The efficiency varied substantially from one experiment to another. Although PLD activity decreased at Triton X-100 concentrations higher than 0.2% (w/v) (Fig. 1), the activity recovered when the concentration of Triton X-100 was lowered again to 0.2% (w/v). The results may suggest that higher concentrations of Triton X-100 could interfere with interaction of PLD with the substrate. The specific activity of PLD in the 1.0% (w/v) Triton X-100 extract was about 4 times higher than that in the 0.1% (w/v) Triton X-100 extract (Table 1). Thus, rat brain PLD appears to be tightly associated with the particulate fraction. The sum of the PLD activities in the extract and in the residual pellet exceeded the initial activity in the particulate fraction present before extraction (data not shown). This would indicate that PLD activity is enhanced by solubilization by Triton X-100. We thus conclude that Triton X-100 is highly effective in activating and solubilizing membrane-bound PLD and that this detergent could be utilized for the purification of PLD.

Effects of pH and divalent cations on PLD activity in the particulate fraction of rat brain. To optimize PLD assay conditions in the presence of Triton X-100 (0.1%, w/v), we have examined the pH dependency and the effects of divalent cations Ca^{2+} and Mg^{2+}. The PLD activity in the particulate fraction of rat brain was maximal at pH 7.1–7.3 (Fig. 2). Either above pH 7.5 or below pH 6.5, the activity was significantly decreased.

Figure 3 shows the effects of Ca^{2+} and Mg^{2+} on PLD activity. In order to suppress the effect of endogenous Mg^{2+} contained in water and other reagents, the reaction mixtures for studying the effects of Mg^{2+} contained 0.1 mM EDTA. It has been reported that phosphatidylinositol 4,5-bisphosphate-specific phospholipase C is activated by free Ca^{2+} at micromolar concentrations (26), whereas phospholipase A_2 requires higher concentrations

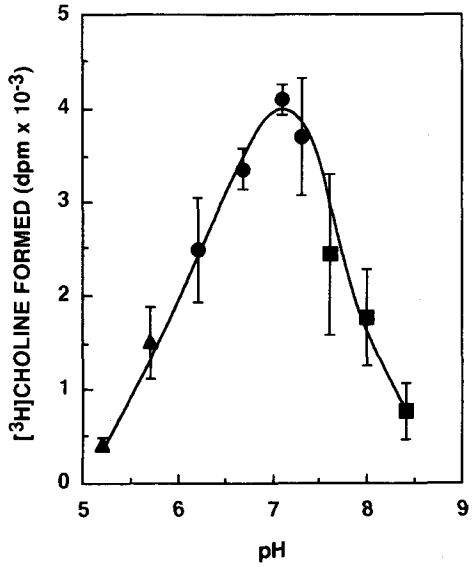

FIG. 2. Effects of pH on phospholipase D activity of the particulate fraction of rat brain. The reaction mixture (100 μL) contained 30 μM dipalmitoyl [^{3}H]PC (0.2 μCi), 0.1% (w/v) Triton X-100, 0.1 mM EDTA, 100 μg protein of the particulate fraction of rat brain and the following buffers: 40 mM citrate, pH 5.2 and 5.7 (▲); 40 mM Tris-maleate, pH 6.2, 6.7, 7.1 and 7.3 (●); and 40 mM Tris-HCl, pH 7.6, 8.0 and 8.4 (■). Incubations were carried out at 37°C for 30 min. After termination of the reaction, [^{3}H]choline formed was determined as described in Materials and Methods. The results shown are the mean ± S.D. of three independent experiments.

of free Ca^{2+} (27). This would indicate that it is advisable to examine the effects of Ca^{2+} over a wide range. To provide such a wide range of free Ca^{2+} concentrations, Ca^{2+}-EGTA buffer was used by supplementing with 2 mM EGTA. Under these conditions, both Ca^{2+} and Mg^{2+} inhibited PLD activity in the particulate fraction of rat brain in a concentration-dependent manner. By contrast, it has been reported that Ca^{2+} is required for PLD

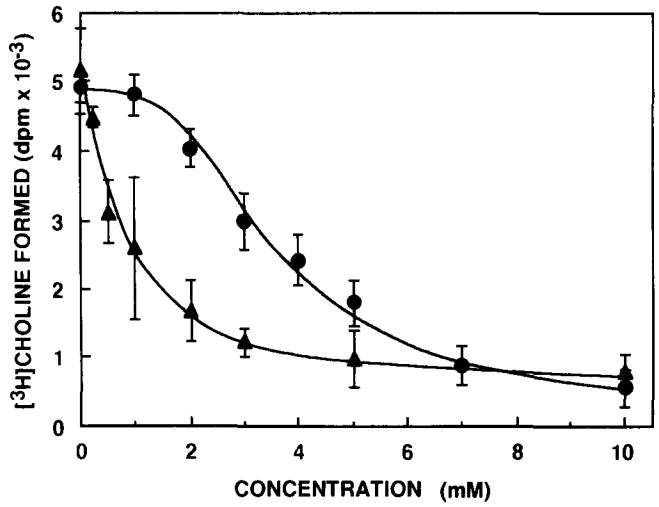

FIG. 3. Effects of Ca^{2+} and Mg^{2+} on phospholipase D activity of the particulate fraction of rat brain. The reaction mixture (100 μL) contained 40 mM Tris-maleate (pH 7.0), 30 μM dipalmitoyl [^{3}H]PC (0.2 μCi), 0.1% (w/v) Triton X-100, 100 μg protein of the particulate fraction of rat brain and the indicated concentration of Ca^{2+} (●) in the presence of 2 mM EGTA or Mg^{2+} (▲) in the presence of 0.1 mM EDTA. After incubation at 37°C for 30 min, [^{3}H]choline formed was determined as described in Materials and Methods. The results shown are the mean ± S.D. of three independent experiments.

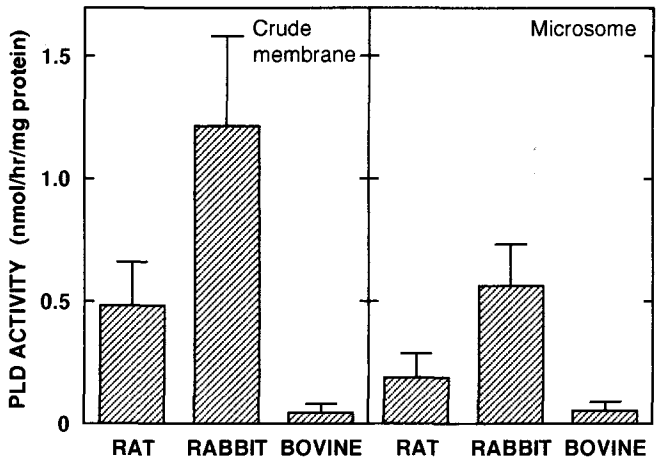

FIG. 4. Species differences in phospholipase D activity in brain stimulated by Triton X-100. Crude membrane and microsomal fractions from brain of rat, rabbit and bovine were prepared as described in Materials and Methods. The reaction mixture (100 μL) contained 40 mM Tris-maleate (pH 7.0), 30 μM dipalmitoyl [^{3}H]PC (0.2 μCi), 0.1% (w/v) Triton X-100, 0.1 mM EDTA and 50 μg protein of crude membrane or microsomal fraction. After incubation at 37°C for 30 min, [^{3}H]choline formed was determined as described in Materials and Methods. The results shown are the mean ± S.D. of three independent experiments.

activation in intact cells and homogenates. For example, in human neutrophils, agonist-stimulated PLD activity requires extracellular Ca^{2+} (28). Calcium ionophore A23187 in the presence but not in the absence of extracellular Ca^{2+} activates PLD in human neutrophils (29), erythroleukaemia cells (14) and HL-60 granulocytes (30). Furthermore, PLD activity in HL-60 homogenates is activated by Ca^{2+} (31). These findings, taken together with our result that Ca^{2+} is not required for PLD activity in the particulate fraction of rat brain, suggest that some Ca^{2+}-dependent factor(s) such as calmodulin may be involved in the Ca^{2+}-induced activation of PLD.

Species difference of PLD activity in brains. We have studied PLD activity in rabbit and bovine brain as well as in rat brain under optimum conditions (Fig. 4). Crude membrane and microsomal fractions were prepared to localize PLD activity. PLD activity in the crude membrane fraction from rat and rabbit brain was higher than in the microsomal fraction, whereas no significant difference was observed between the respective fractions of bovine brain. Furthermore, we found that rabbit brain had the highest PLD activity, followed in order of decreasing activity by rat and bovine brain. The activity of bovine brain was extremely low compared to the activity of rat or rabbit brain. Thus, it appears that PLD activity in brain varies between animal species. To determine whether species differences in PLD activity are assay-specific, we also measured PLD activity upon stimulation with sodium oleate, a well-established activator of brain PLD (17,18) (Fig. 5). Again, PLD activity in bovine brain was extremely low compared to the activity in the two other species. However, PLD activity in rat brain was higher than in rabbit brain and the activity in crude membrane of rat brain was lower than in the microsomal fraction, differing from the result obtained with Triton X-100 (Figs. 4 and 5). Although, these discrepancies have not

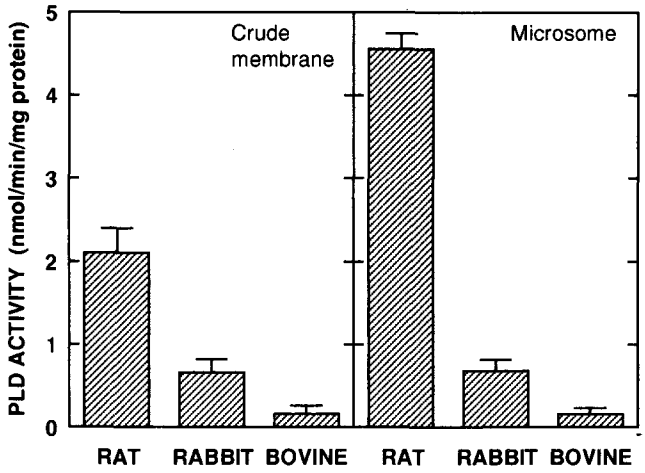

FIG. 5. Species differences in phospholipase D activity in brain stimulated by sodium oleate. Crude membrane and microsomal fractions from brain of rat, rabbit and bovine were prepared as described in Materials and Methods. The reaction mixture (100 μL) contained 50 mM Na-Hepes buffer (pH 7.2), 2.7 mM dipalmitoyl [^{3}H]PC (0.4 μCi), 4 mM sodium oleate, 1 mM EGTA, 1 mM $MgCl_2$, 5 mM *p*-nitrophenylphosphate and 30 μg protein of crude membrane or microsomal fraction. After incubation at 37°C for 15 min, [^{3}H]-choline formed was determined as described in Materials and Methods. The results shown are the mean ± S.D. of three independent experiments.

further been explored, it is conceivable that different isozymes of PLD, which have different sensitivity to Triton X-100 and sodium oleate, are expressed in rabbit and rat brains, and in the crude membrane and microsomal fractions.

Stimulation of PLD activity with sodium oleate was much greater than with Triton X-100 (Figs. 4 and 5). The

level of stimulation attained with sodium oleate in the present study was similar to that previously reported by others (16-18,22). Although, both Triton X-100 and sodium oleate activate PLD, the enzyme can be solubilized only with Triton X-100 (Table 1), not with sodium oleate (17). Furthermore, the optimal concentration of sodium oleate to stimulate PLD activity depends on the concentration of substrate PC (17,18). This may suggest that Triton X-100 directly activates the enzyme, whereas sodium oleate interacts with the substrate thereby giving rise to an apparent stimulation of enzyme activity.

In summary, we conclude that Triton X-100 should prove useful for the purification of PLD because of its ability to stimulate and to solubilize PLD. Rabbit and rat brain are the preferred sources for the isolation and purification of the enzyme.

Lipid Composition and Peroxide Levels of Mucosal Cells in the Rat Large Intestine in Relation to Dietary Fat

M.E. Turini, A.B.R. Thomson and **M.T. Clandinin***
Nutrition and Metabolism Research Group, Departments of Foods & Nutrition and Medicine, University of Alberta, Edmonton, Alberta, Canada T6G 2C2

To examine whether dietary fat alters membrane lipid composition and peroxidation of polyunsaturated fatty acids in "non-proliferative" and "proliferative" cells in the large intestine, Sprague-Dawley rats were fed diets providing a polyunsaturated-to-saturated fatty acid ratio of 1.2 or 0.3 at a high or low level of fat intake for a 25-day period. Cell populations were isolated and the effect of dietary fat on membrane polyunsaturated fatty acid content and peroxide levels was determined. Neither fat level nor fatty acid composition of diet influenced total cholesterol, total phospholipids, and percentage of phospholipid classes in membrane phospholipids. Feeding the high fat and/or high polyunsaturated-to-saturated fatty acid ratio diet increased polyunsaturated fatty acid content of mucosal cell phospholipids. Increase in polyunsaturated fatty acid content was paralleled by a decrease in the monounsaturated fatty acid content of mucosal cell phospholipids. Membrane content of total saturated fatty acids was not significantly affected by diet. Variation in phospholipid fatty acid composition between "non-proliferative" and "proliferative" cells was observed. Lipid peroxide levels in mucosal cell lipid fractions were altered by dietary fat treatment. Animals fed high fat diets, compared to groups fed low fat diets, exhibited higher membrane peroxide levels when results are expressed as nmol/mg protein. Higher peroxide levels were observed in mucosal cells for rats fed high polyunsaturated-to-saturated fatty acid ratio diets when results were expressed per nmol of phospholipid. It is concluded that changes in fat level and fatty acid composition of the diet alters the mucosal cell membrane lipid composition in the rat large intestine and influences susceptibility of mucosal cell lipid to peroxidation. Further research is required to delineate which dietary factors — fat level, polyunsaturated-to-saturated fatty acid ratio, or both — have a primary influence on the degree of lipid peroxidation.

Lipids 26, 431-440 (1991).

Dietary fat intake has been associated with increased incidence of skin, breast and colon cancer (1-5). Colon cancer is the leading cause of death among all patients with malignancies in the United States. Previous studies have shown that dietary fat influences membrane structure and function (6,7) and have also demonstrated that membranes with a high unsaturation index are more sensitive to peroxidation (8,9). Susceptibility to peroxidation is influenced by free radical scavengers and antioxidants such as vitamin E, vitamin C, glutathione, superoxide dismutase, catalase, and Se^{++} and non-Se^{++}-dependent glutathione peroxidases (10-12). As vitamin E is a membrane soluble antioxidant, interactions with cystolic antioxidants occur (10,13-15). Lipid peroxides may affect regulations of DNA synthesis and cell division (16-18) and may also be involved in a number of diseases such as inflammation of the large bowel and cancer.

Studies of mucosal cell membranes from the small and large intestine have been reported (19-23). However, the effect of dietary fat on colonocyte cell membrane lipid composition and peroxidation is not well understood. The objective of this study was first to determine if dietary fat influences colonocyte cell membrane lipid and phospholipid fatty acid composition, and secondly to determine if dietary fat content of unsaturated fatty acids influences colonocyte lipid peroxide levels. Colonocytes were fractionated into "non-proliferative" and "proliferative" cell populations to determine differences in the lipid composition between these cell types.

MATERIALS AND METHODS

Animals and diets. Four weanling, male, Sprague-Dawley rats were obtained weekly for an eight-week period. Animals were fed chow (Allied Mills, Inc., Specialty Feeds Department, Chicago, IL) for 3-5 days and then fed semi-purified diets (Table 1) for 25 days. Each week, four rats were distributed into one of four treatment groups (total n=8 for each diet group). Diets and water were supplied *ad libitum* to rats housed individually in a temperature (22°C) and light controlled room with a 12/12 hr light/dark cycle. Diets were freshly prepared each week and animals were fed on alternate days. The four semi-purified diets fed were high fat or low fat with high (P/S=1.2) or low (P/S=0.3) polyunsaturated-to-saturated fatty acid (P/S) ratios (Table 2). High fat diets provided 50% of energy from fat while low fat diets provided 15% of energy from fat. Mixtures of safflower oil, hydrogenated beef tallow and linseed oil were used to provide the dietary fat source. To ensure similar essential nutrient intakes, the essential nutrient densities for non-fat components were similar for the four diets on a per calorie basis. Vitamin E levels of the four diets were equalized to the vitamin E content of the high fat high polyunsaturated-to-saturated fatty acid ratio diet by addition of *d*-α-tocopheryl acetate (a gift from Veris, La Grange, IL) to give a final vitamin E density of 17.63 IU/1000 kcal for each diet. Diets were prepared using vitamin-free constituents and a vitamin mix free of vitamin E. This vitamin mix was otherwise prepared according to the composition of the AOAC vitamin mix (Teklad Test Diets, Madison, WI). Rats were sacrificed by decapitation and

Σω3[a,b]	1.6	1.7	4.4	4.4
P/S[a,c]	1.17 ± 0.05	0.32 ± 0.01	1.17 ± 0.03	0.31 ± 0.02

[a]Abbreviations: P/S, polyunsaturated-to-saturated fatty acid ratio; Σsaturated, total saturated fatty acids; Σmonounsaturated, total monounsaturated fatty acids; Σpolyunsaturated, total polyunsaturated fatty acids; Σω6, total ω6 fatty acids; and Σω3, total ω3 fatty acids.

[b]Densities (g/1000 kcal) of ω3 fatty acids are similar for the four experimental diets.

[c]Values are means ± S.D. of 11 freshly prepared diets.

[d]ND, not detected.

the large intestine removed for mucosal cell isolation. For serum vitamin E determination, blood was collected into non-heparinized glass test tubes and protected from light. Tubes were kept in the dark at room temperature for 30 min before being centrifuged at 500 × *g* for 15 min at 10-15°C. The supernatant (serum) was collected and stored in the dark at -20°C until analyzed.

Cell isolation. The cell isolation procedure used is a modification of methods described by Brasitus (24) and Weiser (25). Solutions used were: cold 0.9% (w/w) saline solution; solution A containing 1.5 mM HCl, 96.0 mM NaCl, 27.0 mM sodium citrate, 8.0 mM KH_2PO_4, 5.6 mM Na_2HPO_4, 0.5 mM dithiothreitol at pH 7.3; solution 8 consisting of Ca^{++}- and Mg^{++}-free Hank's buffer containing 10.0 mM triethanolamine-HCl and 0.5 mM dithiothreitol at pH 7.3; and standard buffer containing 139 mM NaCl and 10 mM Na_2HPO_4 at pH 7.3. It was crucial to eliminate contamination by intestinal bacteria. Thus, solutions A and B, as well as cold saline solution, were supplemented with Penicillin-G (K-salt, 660 U/mL) and streptomycin (1.6 mg/mL). Solution B was also supplemented with mycostatin (118.2 U/mL); 0.1 mM phenylmethanesulfonyl fluoride was added to solution A and B just before use as were antibiotics to solution A. Ca^{++}- and Mg^{++}-free Hank's buffer and antibiotics were stable for only one to two weeks. Therefore, these solutions were freshly prepared each week.

The large intestine was exised, feces carefully removed by means of cold saline solution, and the intestine was flushed three times with 40 mL of cold saline. The intestine was then tied at its proximal end, filled with solution A and closed at its other end with a hemostat. This slightly distended sac was placed in a 250-mL flask containing 125 mL of standard buffer solution (37°C) and incubated for 15 min at 37°C in a shaking waterbath (75 osc./min). The sac was then emptied, the solution discarded and replaced by solution B (pre-incubated at 37°C) and incubated. After each incubation, the solution containing each fraction of cells was collected in a 15-mL Corex glass centrifuge tube and the sac was refilled. Subsequent fractions of cells were collected after 2 × 10-min followed by 10 × 15-min incubation times. The 12 tubes were kept on ice until centrifuged at 484 × *g* at 4°C for 10 min. Supernatants were discarded and cell pellets were resuspended in 5 mL of standard buffer. Cell fractions were pooled as follows: fractions 2 and 3 (tube I), 4 and 5 (tube II), 6 and 7 (tube III), 9 and 10 (tube IV), and 11 and 12 (tube V), and the tubes were centrifuged at 484 × *g* at 4°C for 10 min. Supernatants were discarded. Cell pellets were resuspended in standard buffer, filtered on a 100-micrometer nylon mesh (Nitex) and pooled. Fractions I-III, and fractions IV and V were pooled to give two 12-mL fractions (A and B, respectively). These two tubes were centrifuged (484 × *g* at 4°C for 10 min), supernatants were discarded, and pellets were resuspended in 1 mL of standard buffer. Cell fractions were assessed for bacterial contamination by microscopy. Fractions prepared in this manner were essentially free of bacterial contamination. Protein was determined by a modified method of Lowry *et al.* (26) using bovine serum albumin (BSA) as a standard.

[^{3}H]Thymidine incorporation. Preliminary experiments were performed to determine fractions containing proliferative cells using [*methyl*-^{3}H]thymidine as a marker for DNA synthesis. Rats weighing 300-305 g were injected intraperitoneally with 100 μCi of 2-[*methyl*-^{3}H]thymidine 3 hr prior to sacrifice (24,25). Rats were killed by decapitation and cells isolated similarly to the method previously described. Fractions were not pooled and cell pellets were transferred into flint tubes (10 mm × 75 mm), dissolved in 500 μL of protosol, transferred into a scintillation cocktail (100 mg POPOP, 5 g PPO per liter of toluene) in 7-mL counting vials and counted to determine [^{3}H]thymidine incorporation. Counting was done in a Beckman LS 5801 liquid scintillation spectrometer at an efficiency of 45%. Results were expressed as dpm/mg protein.

Thymidine kinase assay. To differentiate "proliferative" from "non-proliferative" cells during the main experiment, thymidine kinase activity was measured according to the method of Salser and Balis (27). Reactions were carried out at 37°C in capped flint tubes (10 mm × 75 mm) in a waterbath. The reaction mixture containing 90-110 μg of homogenate protein (100-μL volume), adjusted if necessary by using cell resuspending buffer (pH 7.3), 12 mol Tris-HCl (pH 8.0), 1.8 mol $MgCl_2$, 1.8 mol ATP, 1.5 mol 3-phosphoglyceric acid, and 0.6 μmol NaF, was pre-incubated for 10 min at 37°C. Reactions were initiated by addition of 50 μL of 2 [2-^{14}C]deoxythymidine (9 nmoles; 500,000 dpm), bringing the total volume to 250 μL, and were incubated for 45 min. Reactions were stopped by immersing the tubes into boiling water for 3 min and then cooling the tubes in an ice bath until centrifugation (3020 × *g*) at 10°C for 15 min. Aliquots (50 μL) were applied onto DEAE-cellulose filters (Whatman No. DE-81; 2 cm diam.) and filters washed according to the method described by Bresnick and Karjala (28). The filters were quickly immersed in a beaker containing 30 mL of 0.001 M ammonium formate for 10 min. The discs were then washed in distilled H_2O and placed in a new beaker containing 30 mL of 0.001 M ammonium formate for 10 min. The discs were again washed with distilled water, placed in distilled water for 5 min and finally immersed in 95% (v/v) ethanol before being dried at 80°C and placed in counting vials containing 5 mL of a toluene-based cocktail (5 g PPO, 100 mg POPOP per liter of toluene). This procedure removes the precursor [2-^{14}C]deoxythymidine while retaining [2-^{14}C]deoxythymidinemonophosphate. Counting was done in a Beckman LS 5801 liquid scintillation system (Beckman Instruments, Fullerton, CA) with an efficiency of 97%.

Lipid analysis. Total lipids were extracted (29), total phospholipid was estimated (30), and total cholesterol was determined (31-33) using an enzymatic kit (cholesterol C-system kit, Boehringer Mannheim Canada, Montreal, Canada). Different phospholipids were estimated by densitometry (34). For densitometry, samples were spotted on high performance thin-layer chromatography plates (Whatman, HP-K high performance Silica Gel plates, 10 cm × 10 cm) and phospholipids were separated using a solvent system comprised of chloroform/methanol/propanol/triethylamine/0.25% (w/v) KCl (14:4.5:12.5: 6.5:3.5, by vol).

For fatty acid analysis, phospholipids were separated using Silica Gel H plates (20 × 20 cm) and developed in a solvent system composed of chloroform/methanol/2-propanol/0.25% (w/v) KCl/triethylamine (30:9:25:6:18, by vol) (35). Fatty acids were methylated for 1 hr at 100°C using borontrifluoride/methanol reagent (36). Separation of fatty acid methylesters was performed by auto-

mated gas-liquid chromatography (Vista 6000 GLC and Vista 654 data system; Varian) Instruments, Georgetown, Ontario, Canada) using a fused silica BP20 capillary column (25 mm × 0.25 mm i.d.; Varian) and a splitless injection mode (37). Helium was used as the carrier gas at a flow rate of 1.8 mL/min. Injector and detector temperatures were maintained at 250°C. The initial oven temperature of 90°C was increased to 172°C at 20°C/min and held for 13.2 min, then increased again to 220°C at 3.5°C/min for a total analysis time of 45 min.

Lipid peroxide determination. Lipid peroxides were determined using a "Determiner LPO" or leuco-methylene blue derivative assay kit (a generous gift from Kyowa Medics Co., Tokyo, Japan) with some modifications to increase test sensitivity (38). Tests were performed in borosilicate glass test tubes (13 mm × 100 mm). The first reagent (150 μL of 30 U/mL of ascorbic oxidase in 100 mM 3-[*N*-morpholino]propanesulfonic acid, MOPS, pH 5.8, (stabilizer) was added to 100 μL of lipid extract containing 1.0-1.5 mg protein equivalent in methanol. Tubes were vortexed and incubated 5 min at 30°C in a shaking water bath before adding 300 μL of the second reagent (52.7 mM of 10-*N*-methyl-carbamoyl-3, 7-dimethylamine-10H-phenothiazine, 100 mM MOPS pH 5.8, 68 mg/L of hemoglobin, surface active reagent, chelating agent and stabilizer). Tubes were vortexed and incubated for 10 more min. Absorbency was determined at 675 nm in a Perkin-Elmer model Lambda 3b spectrophotometer. Sample concentrations were calculated using a standard curve in the range of 0-1.0 nmole of cumen hydroperoxide. Change in blank absorbency with time was determined against water. The test was performed in a dark room with red light. Lipid peroxide determination was performed on batches of one blank and five samples starting the reaction in each tube at 1-min intervals. Results are expressed as nmole equivalents of cumen hydroperoxide.

Vitamin E determination. Oil samples for vitamin E determination were prepared using a modification of the method described earlier (39). Safflower oil supplemented with *d*-α-tocopheryl acetate was dissolved in distilled hexane and injected directly onto the high performance liquid chromatography (HPLC) column. Serum samples were prepared using the simplified clarification method described by Nierenberg and Lester (40). The organic upper layer (250 μL) was transferred by automatic pipette into a borosilicate glass tube (10 mm × 75 mm) and dried in 5 to 10 min at 75°C under N_2. No loss occurred during this process when verified with a standard mixture of *dl*-α-tocopherol and *d*-α-tocopheryl acetate. The residue was resuspended in 250 μL of distilled hexane, transferred to a 0.4-mL polypropylene microcentrifuge tube and centrifuged at 13,000 × rpm for 1 min at 4°C. The clarified distilled hexane (100 μL) was injected onto the HPLC column. Butylated hydroxytoluene (BHT) was present in the extraction system to avoid vitamin E oxidation.

Tocopherols were analyzed using the HPLC method described by Buttris and Diplock (41). Chromatography utilized a Micropack Si-5 column (4.5 mm I.D. × 15 cm; Varian). Solvents were filtered and degassed by N_2 prior to use. The system was standardized by injection of a 100-μL mixture containing 50 μg/mL of *dl*-α-tocopherol (Sigma Chemical Co., St. Louis, MO) and *d*-α-tocopheryl acetate (Veris) in hexane after being checked for linearity in the range of 5-100 μg/mL.

Statistical analysis. The effect of diet treatment and differences between "non-proliferative" and "proliferative" cell fractions were examined by least square analysis of variance (ANOVA) (42). Effect of diet treatment on total protein released, serum vitamin E concentrations and lipid peroxide levels were examined by two-way ANOVA procedures. [^{3}H]Thymidine incorporation into DNA of "non-proliferative" and "proliferative" cells was analyzed by a Student's *t*-test.

RESULTS

Effect of diet treatment. Mean body weights of animals after the diet treatments were not significantly different. Body weights (mean ± S.D.) were 77.6 ± 4.5 g on initiation of treatment and 252.7 ± 20.8 at the time of sacrifice.

Mucosal cell isolation and thymidine kinase assay. Prior to initiation of experimental procedures, rats fed chow were injected with [^{3}H]thymidine to localized "proliferative" cell vs. "non-proliferative" cell fractions. Initial experiments were performed without pooling the collected fractions (data not shown). Fractions to be pooled as "non-proliferative" and "proliferative" cell fractions were determined from these preliminary experiments based upon [^{3}H]thymidine incorporation. "Proliferative" cell fractions incorporated 2.5-fold more [^{3}H] thymidine than "non-proliferative" fractions ($p<0.002$). Diet fatty acid composition, but not diet fat level, altered the total yield of cells isolated ($p<0.005$; Table 3). During experimental procedures the relative yield of cell protein was similarly distributed between "non-proliferative" and "proliferative" cell fractions (34.26% and 65.74%, respectively) irrespective of the diet treatment. Linearity between time and rate of thymidine incorporation was observed for up to 45 min (data not shown). No effect of treatment was observed on thymidine kinase activity. Mean enzyme specific activity was 4.1 nmole of product formed per mg protein in the "proliferative" cell fraction as compared to 2.9 nmole/mg protein in the "non-proliferative" cell population ($p<0.05$; data not shown).

TABLE 3

Effect of Diet Treatment on Mucosal Cells Released from the Rat Large Intestine (Total mg of Protein[a])

	Fat level	
	High	Low

Effect of Treatment[e]:	Fat level	P/S ratio	Cell fraction	Interactions at $p<0.05$
Cholesterol	NS	NS	<0.05	NS
Phospholipids	NS	NS	NS	P/S ratio × cell fraction
Cholesterol/phospholipid ratio	NS	<0.05	NS	NS

[a]Abbreviations: P/S Ratio, polyunsatured-to-saturated fatty acid ratio; n, number of replicates.

[b]Non-prolif. cells, "non-proliferative" cell fraction; Prolif. cells, "proliferative" cell fraction.

[c]Values are means ± S.D.; number of replicates, n = 5-7.

[d]Cholesterol, MW 386.7; Phospholipids, MW 730.

[e]Significant effects by least square analysis of variance procedures are indicated ($p<0.05$); NS. not significantly different.

Effect of diet treatment on lipid composition of mucosal cells. Experimental day, amount of fat, or polyunsaturated-to-saturated fatty acid ratio in the diet did not alter mucosal cell total cholesterol content. The "non-proliferative" cell population exhibited a 12% higher total cholesterol level as compared to the "proliferative" cell fraction ($p<0.05$; Table 4). Day of experiment, diet fat level, polyunsaturated-to-saturated fatty acid ratio in the diet, or cell fraction tested did not significantly affect the total phospholipid content of mucosal cells in the large intestine (Table 4). Cholesterol to phospholipid molar ratio was not affected by day of cell isolation or diet fat level. "Non-proliferative" and "proliferative" cell fractions exhibited similar ratios of cholesterol to phospholipid. Groups fed diets providing a high polyunsaturated-to-saturated fatty acid ratio (P/S = 1.2) showed a 32.5% increase ($p<0.05$) in cholesterol-to-phospholipid ratio compared to groups fed diets containing a low polyunsaturated-to-saturated fatty acid ratio (P/S = 0.3; Table 4). Phosphatidylethanolamine and phosphatidylcholine represented greater than 50% and 22% of total mucosal cell phospholipid, respectively (Table 5). Minor phospholipids consisted of phosphatidylinositol, phosphatidic acid plus phosphatidylserine, and sphingomyelin compared to the "non-proliferative" cell population ($p<0.05$). The phosphatidylcholine content in the "proliferative" cell fraction was 20.8% lower ($p<0.05$) as compared to the "non-proliferative" cell population.

Effect of diet treatment on fatty acid composition of mucosal phospholipid. Each phospholipid class responded similarly to the diet. Major fatty acids in phosphatidylethanolamine were 20:4ω6, 18:0, 18:1ω9, and 18:2ω6, representing 32.8%, 18.9%, 13.3%, and 9.1%, respectively (Table 6). For groups fed high fat diets, phosphatidylethanolamine 18:2ω6 and total ω6 fatty acid content increased ($p<0.005$), as did the unsaturation index ($p<0.01$). The content of 16:1, 18:1ω9, 18:1(ω5, ω7), total monounsaturated fatty acids, and total ω3 fatty acid decreased ($p<0.05$) when compared to groups fed low fat diets. Membrane phosphatidylethanolamine from rats fed the low polyunsaturated fatty acid diet exhibited a significantly higher level of 18:1ω9, 18:1(ω5, ω7) and total monounsaturated fatty acids when compared to animals fed diets high in polyunsaturated fatty acid content ($p<0.005$). Amounts of 18:2ω6, total ω6 fatty acids, and the unsaturation index were significantly lower for rats fed diets providing the low polyunsaturated-to-saturated fatty acid ratio as compared to animals fed diets providing the high polyunsaturated fatty acid-to-saturated fatty acid ratio ($p<0.01$). Levels of 20:4ω6, 16:1, 16:0, 18:0, as well as the total saturated fatty acid content of phosphatidylethanolamine, were not altered by change in the diet fatty acid composition.

"Non-proliferative" and "proliferative" cell fractions also showed differences in the fatty acid profile. The "proliferative" cells exhibited lower ($p<0.005$) content of total monounsaturated fatty acid, and of 16:0 and 18:0 in phosphatidylethanolamine compared to "non-proliferative" cells. Increased levels of total monounsaturated fatty acids, 18:1ω9, and polyunsaturated fatty acid, ω6 series and 20:4ω6 ($p<0.05$), as well as increased unsaturation index ($p<0.005$) in phosphatidylethanolamine of the "proliferative" cell population was observed when compared to the "non-proliferative" cell population. No significant difference between cell fractions for 18:1 (ω5,ω7), 18:2ω6, and the total ω3 fatty acid content was observed.

Diet altered the major fatty acyl constituents of phosphatidylcholine in both "non-proliferative" and "proliferative" cell fractions (Table 7). A significant decrease in 16:1, 18:1ω9, and 18:1(ω5,ω7) accounted for the lower total monounsaturated fatty acid content of phosphatidylcholine in animals fed high fat diets as compared to animals fed low fat diets ($p<0.005$). Higher levels of 18:2ω6 and 20:4ω6 occurred in phosphatidylcholine for animals fed high fat diets ($p<0.005$). While the total ω6 fatty acid content of phosphatidylcholine increased ($p<0.005$) in rats fed high fat diets, neither the total ω3 nor total

[a]Abbreviations: P/S Ratio, polyunsaturated-to-saturated fatty acid ratio; Σsaturated, total saturated fatty acids; Σmonounsaturated, total monounsaturated fatty acids; Σ(ω6), total ω6 fatty acids; Σ(ω3), total ω3 fatty acids.

[b]Non-Prolif., "non-proliferative" cell fraction; Prolif., "proliferative" cell fraction.

[c]Values are means ± S.D. for major fatty acids; number of replicates, n = 5–7.

[d]Significant effects by least square analysis of variance procedures are indicated.

saturated fatty acid content was significantly altered. However, 16:0 increased ($p<0.05$) and 18:0 decreased ($p<0.005$) in animals fed low fat diets. The unsaturation index of phosphatidylcholine decreased ($p<0.005$) for animals fed low fat diets.

Diet fatty acid composition also influenced phosphatidylcholine fatty acid composition (Table 7). Levels of 16:1, 18:1ω9, and 18:1(ω5,ω7), as well as the sum of monounsaturated fatty acids, were significantly lower ($p<0.005$) for rats fed diets having a high polyunsaturated fatty acid content. Increased levels ($p<0.005$) of total ω6 fatty acids were observed in groups fed diets of high polyunsaturated-to-saturated fatty acid ratio. However, 16:0 was not significantly different between groups fed diets varying in fatty acid composition; phosphatidylcholine 18:0 content was lower in animals fed diets with a low polyunsaturated-to-saturated fatty acid ratio (16.0%, $p<0.005$). Variation in level of these fatty acids led to significant alteration of the unsaturation index with a 13.5% decrease observed in mucosal cell phosphatidylcholine for animals fed low fat diets compared to animals fed high fat diets.

Phosphatidylcholine fatty acid composition also varied between cell populations (Table 7). The fatty acid content of 16:0, 16:1, and 18:1(ω5,ω7) was higher by 11.1% ($p<0.005$), 64.2% ($p<0.005$), and 16.2% ($p<0.01$) in phosphatidylcholine of "proliferative" cells compared to "non-proliferative" cells, respectively. The level of 18:2ω6 and 20:4ω6 was lower by 5.5% ($p<0.05$) and 9.1% ($p<0.005$) in "proliferative" cells. 18:0 and 18:1ω9 content was not significantly different between cell fractions. Higher total saturated ($p<0.05$) and total monounsaturated ($p<0.01$) fatty acids, and lower total ω6 ($p<0.01$) fatty acids were observed for the "proliferative" cell population as compared to "non-proliferative" cells. No significant difference occurred in phosphatidylcholine total polyunsaturated ω3 fatty acid content between cell fractions. The unsaturation index was higher by 6.8% in "proliferative" cells compared to "non-proliferative" cells.

Effect of diet treatment of serum vitamin E and lipid peroxide levels in mucosal cell lipid. Serum vitamin E levels. To avoid the saponification step, which may be accompanied by loss of vitamin E, a modification of the clarification method described by Nierenberg and Lester was used (40). Recoveries for *dl*-α-tocopherol and *d*-α-tocopheryl acetate were 105% and 123%, respectively. Neither experimental day, fat level, nor fatty acid composition of the diet altered the serum vitamin E level when determined as α-tocopherol (1495 μg/dL; n=23).

Spectra comparison between cumen hydroperoxide and peroxide from the mucosal cell lipid fraction demonstrated no interference due to turbidity or other factors within the linear range of 0–1.0 nmole of cumen hydroperoxide (data not shown). The fat level did not affect lipid peroxide values when expressed as nmol equivalent of cumen hydroperoxide/mg cell membrane phospholipid. However, animals fed a polyunsaturated-to-saturated fatty acid diet ratio of 1.1 exhibited a 73% increase ($p<0.006$) in lipid peroxide content compared to groups fed a polyunsaturated-to-saturated fatty acid diet ratio of 0.3 (Table 8). Feeding high fat diets increased "proliferative" cell lipid peroxide values by 64% ($p<0.05$) compared to animals fed the low fat diets (Table 8) when results are expressed as nmol equivalent of cumen hydroperoxide/mg cell protein.

TABLE 8

Effect of Diet Treatment on Lipid Peroxidation of "Proliferative" Mucosal Cell Lipid Fraction from the Rat Large Intestine

Lipid peroxide values[a]						
P/S ratio[b]	High	Low	High	Low	Significant fat level	Effects of P/S ratio[d]
nmole/mg protein[c]	0.11 ± 0.02	0.07 ± 0.04	0.05 ± 0.01	0.06 ± 0.01	0.05	NS
nmole/μmole phospholipids	0.80 ± 0.22	0.38 ± 0.21	0.66 ± 0.24	0.44 ± 0.11	NS	0.006
n	5	5	2	6		

[a]Lipid peroxide values are expressed as nmole of cumen hydroperoxide.

[b]Abbreviations: P/S ratio, polyunsaturated-to-saturated fatty acid ratio.

[c]Values are means ± S.D.

[d]Significant effects ($p<$) by two-way analysis of variance procedures are indicated; NS, not significantly different.

DISCUSSION

Previous studies demonstrate that dietary fat affects membrane lipid content and phospholipid fatty acyl composition (7). Membrane lipid peroxide levels also increase as membrane polyunsaturated fatty acid content and membrane unsaturation index increase (8,9). Experiments examining brush-border membrane and basolateral membrane in the small and large intestine demonstrate alteration of membrane structure and function by change in diet fat treatment (7,22,43). The present experiment extends current knowledge by establishing that change in dietary fat level and fatty acid composition alters colonocyte membrane content of polyunsaturated fatty acids which, in turn, affects lipid peroxide levels in this cell type.

"Non-proliferative" and "proliferative" cell populations from the small (25,44,45) and large intestine (24,46,47) have been successfully isolated. Direct comparisons with other studies are difficult as the procedure and tissue sites used varied. For example, Brasitus (24) utilized the cecum and proximal colon while Craven and DeRubertis (46) sampled the distal colon from the colonic flexure to 1 cm above the anal orifice, pooling cells from two colons. The "non-proliferative" or differentiated cell population is complex consisting of columnar epithelial cells, goblet cells, some endocrine cells and lymphocytes (48). As observed by others (49), variability in total colonocyte material released (mg of protein) was found between animals. Unexpectedly, diet treatment exhibited an effect on the cell isolation procedure, with a 55% greater amount of cell material collected from groups fed diets with low polyunsaturated-to-saturated fatty acid ratio as compared to animals fed diets with a high polyunsaturated-to-saturated fatty acid ratio. This effect is apparently not due to the procedure as the percentage of protein distributed between "non-proliferative" and "proliferative" cell populations appeared similar for each dietary group. It is conceivable that diet induced change in cell membrane composition altered cell cohesion or mucus properties.

Cholesterol and phospholipid values and cholesterol-to-phospholipid ratios reported for brush-border membrane of rat small (7,48,50-53) and large (22,54) intestine are generally higher than values observed in the present study for mucosal cells from the large bowel.

In aggreement with results obtained for brush-border membrane of the small intestine (43,48), no significant effect of fat level or diet fatty acid composition was observed on the phospholipid class content. Colonocytes contain a high percentage of phosphatidylethanolamine (55) in the microsomal fraction of rat small intestine, thus differing from most other membranes with phosphatidylcholines being predominant.

Dietary fat altered the phospholipid fatty acid composition and the unsaturation index of "non-proliferative" and "proliferative" mucosal cells from rat large intestine. The effects observed will primarily be attributed to dietary fat manipulation, since intake of all other essential nutrients remained constant for non-fat components. Feeding either high fat diets (50% as energy) or high polyunsaturated fatty acid diets (P/S=1.17) decreased the total monounsaturated fatty acid level and increased the total polyunsaturated fatty acid content of the colonic cell phospholipds. Increasing the dietary polyunsaturated-to-saturated fatty acid ratio altered the $\omega 6$ fatty acid series in phospholipids but did not change $\omega 3$ fatty acids. This finding is consistent with previous observations (7,56) and indicates that dietary fat alters both the phospholipid fatty acid composition and the unsaturation index of mucosal cells from the rat large intestine. The effect of diet varied between cell populations for "non-proliferative" and "proliferative" cell types.

The serum α-tocopherol values observed in the present study are in the upper range of those reported earlier (57-60). No difference in serum α-tocopherol status for animals reflects a similar vitamin E intake between each group and thus it is likely that the vitamin E status in "proliferative" cells of the rat large intestine was similar among dietary groups.

Lipid peroxides and free radicals are known to induce cell membrane damage and DNA mutation. Increased lipid peroxidation occurs under various conditions, including septic conditions (61), in vitamin E deficient animals (62), as well as after irradiation with gamma-rays (63) and UV light (8), or after injection of various types of carcinogens (64). Several methods for lipid peroxide determination are available (65). To assay peroxides, the thiobarbituric acid reactive substance procedure is most widely used. However, this method does not measure lipid peroxide *per se*, but the end product, malondialdehyde, resulting from the breakdown of lipid peroxides and other non-lipid compounds. The procedure is sensitive to parameters such as tempera-

ture and pH, involves an acid-heating step which may initiate lipid peroxidation, thus potentially increasing product formation. It is also important to differentiate results obtained by non-induced lipid peroxidation systems (66-68) from those measuring susceptibility of sample to lipid peroxidation induced by ascorbate-iron or NADPH-iron (69-71). Recently, Ohishi *et al.* (38) described a new methylene blue derivative for use in a calorimetric method to specifically detect hydroperoxides, endoperoxides and peroxy radicals. This method has also been used by others to determine lipid peroxide levels in rat liver homogenates (72). Although animals fed diets that reflect human consumption of dietary fats exhibit very low levels of hydroperoxide, change in fat level and fatty acid composition of the diet significantly altered the membrane level of lipid peroxides.

Discrepancies between data published on membrane peroxide levels may partly be explained by differences in physiological states of the animals examined but also in the antioxidant status and in the activity of various enzymes (73) in the tissue or membrane studied. A radical scavenger or the collision of two free radicals is needed to stop propagation of lipid peroxidation. An environment with high polyunsaturated fatty acid levels will facilitate the propagation step compared to an environment with lower polyunsaturated fatty acid levels, assuming both contain similar free radical defense systems. The present experiment supports the hypothesis that increased membrane polyunsaturated fatty acid content in animals fed high fat or high polyunsaturated-to-saturated fatty acid ratio diets compared to groups fed low fat or low polyunsaturated-to-saturated fatty acid ratio diets, will increase membrane lipid peroxide levels in proliferative cells. However, it is not yet possible to determine which of the dietary factors—fat level, polyunsaturated-to-saturated fatty acid ratio, or both—primarily affect lipid peroxidation as both factors influence substrate availability for peroxidation and, secondly, both factors also affect membrane peroxide levels depending on the units used to express the results. These findings contradict those of Buckingham (74) who, based on a different assay method, reports an effect of diet vitamin E content, but not of diet fatty acid composition (P/S ratio) on lipid peroxidation in rats. The biological significance of the difference in the lipid peroxide levels observed between diet treatments is not yet known. Further studies are needed to determine the extent of possible cell damage induced by small amounts of peroxides and to delineate the precise relationships between dietary fat and cell membrane injury.

Effect of Dietary Fat on Diabetes-Induced Changes in Liver Microsomal Fatty Acid Composition and Glucose-6-Phosphatase Activity in Rats

J.T. Venkatraman[a,b,1], D. Pehowich[a,b], B. Singh[c], R.V. Rajotte[d], A.B.R. Thomson[a,e], and M.T. Clandinin[a,b,e,*]

[a]Nutrition and Metabolism Research Group, Departments of [b]Foods & Nutrition, [c]Immunology, [d]Surgery and [e]Medicine, University of Alberta, Edmonton, Alberta, Canada T6G 2C2

Experimental diabetes may manifest itself in a defect in liver microsomal fatty acid desaturation and increased activity of glucose-6-phosphatase (G-6-Pase). The present study was designed to determine whether these changes could be normalized by a change in the dietary fat consumed. Control and streptozotocin-induced diabetic rats were fed nutritionally adequate diets which varied in fatty acid composition. Fatty acid analysis of liver microsomal phospholipids revealed that non-diabetic control animals fed saturated fat (beef tallow) or a diet high in ω3 fatty acids (fish oil) exhibited a significantly higher level of 18:2ω6 and a lower level of 20:4ω6 in the phosphatidylcholine and phosphatidylethanolamine fractions compared with diabetic animals. Control and diabetic animals fed the high linoleic acid diet had similar levels of 18:2ω6 in the microsomal phosphatidylcholine and phosphatidylserine fractions. Microsomal G-6-Pase activity was higher in diabetic than in control animals. Activity of G-6-Pase was lower in microsomes of control animals fed the soybean oil or the fish oil diet, but was not significantly reduced in diabetic animals fed high polyunsaturated fats. Blood glucose levels were similar in control groups fed the different diets, but the plasma hemoglobin A1c level was lower in diabetic animals fed the soybean oil diet. Cholesterol and triglyceride levels were lower in diabetic animals fed the fish oil-based diet. The results suggest that dietary fat manipulation has the potential to change at least some of the abnormalities in the microsomal membrane in experimental diabetes.

Lipids 26, 441-444 (1991).

A defect in fatty acid desaturation is one of the complications associated with experimental diabetes (1-4). As diabetes causes alterations in lipid composition and in the physical state of liver microsomal membranes (5,6), these changes may also affect microsomal membrane-bound enzymes. Microsomal glucose-6-phosphatase (G-6-Pase), which plays a key role in dephosphorylation and transport of liver glucose into the blood (7), was reported to increase in the diabetic state (8). Abnormalities in lipoprotein metabolism have also been described in patients with non-insulin-dependent diabetes mellitus (9). Dietary polyunsaturated fatty acids may alter lipoprotein metabolism and are generally associated with a cholesterol-lowering effect and altered membrane lipid composition (10,11). The present study was designed to determine whether saturated ω6 or ω3 fatty acids normalize the changes that occur in microsomal membrane phospholipid fatty acid composition, plasma lipids, glucose and glucose-6-phosphatase activity in the experimental diabetes.

MATERIALS AND METHODS

Three semipurified diets containing 20% w/w fat were fed to rats. All diets were nutritionally adequate and differed only in fatty acid composition (Table 1). The beef tallow diet was based on a blend of beef tallow (18%), safflower oil (1%) and soybean oil (1%). The high linoleic acid diet contained 20% soybean oil. The fish oil diet consisted of a blend of 10% fish oil concentrate, 8% beef tallow and 2% safflower oil.

Male Wistar-Furth strain rats, weighing 230-250 g, were placed in individual metabolic cages and monitored weekly for plasma glucose, urine volume, urine glucose, food consumption and body weight. Animals were rendered diabetic using 55 mg/kg streptozotocin (a gift from the Upjohn Company, Kalamazoo, MI) which was injected intravenously *via* the penile vein using citrate buffer (pH 4.5). Following induction of diabetes, the animals were

Abbreviations: G-6-Pase, glucose-6-phosphatase; HgA1c, hemoglobin A1c.

fed Wayne lab Blox diet (Teklad Premier, Madison, WI) for three weeks and then the experimental diets for seven weeks. Non-diabetic control rats were similarly injected with citrate buffer, fed chow and then fed the experimental diets for seven weeks. Blood samples were taken for determination of plasma cholesterol and triglyceride (Dri-Stat, Beckman, Fullerton, CA) during the baseline period and at four and eight weeks. Clinical parameters of urine volume, urine glucose, plasma glucose, body weight, food consumption, plasma cholesterol, plasma triglyceride and HgA1c were recorded. Plasma glucose concentration was measured with glucose oxidase using a Beckman (Fullerton, CA) ERA 2001 analyzer. Plasma total cholesterol was measured using the Dri-Stat (Beckman, Fullerton, CA) cholesterol-ES Reagent kit (12); plasma triglyceride concentration was measured using the Dri-Stat triglycerides-UV endpoint reagent (13). HgA1c (hemoglobin A1c) was assayed courtesy of Dr. L. Oliver (The Upjohn Company). Microsomes were prepared from the livers, and phospholipid fatty acid composition and G-6-Pase activity were determined.

Isolation of liver microsomes. The liver was rinsed in 0.25 M sucrose, and 5 g liver tissue has homogenized in 25 mL of 0.25 M sucrose buffer. The homogenate was centrifuged twice at 16,000 × *g* for 20 min and the postmitochondrial supernatant was centrifuged at 115,000 × *g* for 90 min to sediment microsomes. The surface of the microsomal pellet was washed with 0.1 M potassium citrate buffer (pH 6.5) and resuspended in the same buffer to provide a microsomal isolate of high purity (4). Protein content of the microsomal membrane was determined (14).

Enzyme assay. G-6-Pase activity was measured in freshly prepared microsomes, as described by Freedland and Harper (15), by incubating 0.1 mL of freshly prepared microsomal membrane (100 μg protein) in 0.1 mL potassium citrate buffer (pH 6.5) in the presence of 100 mM glucose-6-phosphate at 37.5°C for 15 min. The reaction was stopped by adding 2 mL of 10% trichloroacetic acid (w/v). After centrifugation, 1-mL aliquots were taken to determine the amount of inorganic phosphate released (16).

Lipid extraction. Total lipids were extracted from liver microsomes (17) in the presence of 2-ethoxyquin as an antioxidant. Lipid extracts were dried at 40°C under nitrogen. Liver microsomal phospholipids were separated on silica gel H plates using the solvent system chloroform/methanol/2-propanol/0.25% potassium chloride/triethylamine (30:9:25:6:18, by vol) (18). Individual phospholipid fractions were visualized under UV light after spraying with 1% (w/v) 8-anilino-1-naphthalenesulfonic acid. Fractions were scraped off and methyl esters were prepared. Phospholipid fatty acids were transmethylated with boron trifluoride in methanol (19). Methyl esters were analyzed by fused silica capillary gas-liquid chromatography (20).

Statistical analysis. The effect of treatments was determined by analysis of variance procedures (21). Individual treatments were compared by student Neuman Keuls multiple range test after a significant effect of treatment was shown by analysis of variance. Significant interactions are indicated where found.

RESULTS

Body weight, plasma glucose and plasma lipid and urinary glucose levels. Weight gain was lower in diabetic animals than in control animals. Diabetic animals fed the soybean oil diet had higher body weights as compared with the other two groups (Table 2). Plasma glucose levels in diabetic animals were not altered by diet treatment. The diabetic condition resulted in a significant increase in plasma cholesterol levels, with diabetic animals fed fish oil having significantly lower cholesterol levels compared with the other dietary groups. Diabetes increased the level of plasma triglycerides but dietary treatment did not influence plasma triglyceride level. Hemoglobin A1c levels were lower in diabetic animals fed soybean oil as compared with the other diabetic groups.

Fatty acid composition. Fatty acid analysis of liver microsomal phospholipids revealed that fatty acid composition was influenced by the lipid composition of the diets as well as by the diabetic condition (Tables 3 and 4).

Phosphatidylcholine fraction. Diabetes increased 16:0 and decreased 18:0 levels in the microsomal phosphatidylcholine fraction compared with controls (Table 3). The level of ω6 fatty acids decreased in the diabetic state. A decrease in 20:5ω3 and an increase in 22:6ω3 concentration was also associated with diabetes. Feeding diets high in beef tallow or fish oil resulted in a significant increase

[a]Values without a common superscript are significantly different at $p<0.05$ level. Replicates of five independent determinations.
*$p<0.05$; **$p<0.01$; ***$p<0.001$; NS, not significant.

in 16:0 levels and decreased 18:0 and 18:2ω6 levels compared with animals fed the soybean oil-based diet. Feeding fish oil led to increased levels of ω3 fatty acids and decreased levels of ω6 fatty acids in the phosphatidylcholine fraction of liver microsomes.

Phosphatidylethanolamine fraction. Saturated fatty acid levels in the microsomal phosphatidylethanolamine fraction were not affected by the diabetic state while 18:2ω6 and 20:4ω6 levels decreased (Table 3). Levels of 22:5ω3 increased in diabetes; 18:2ω6 levels were high when the soybean oil diet was fed. Omega-3 fatty acid levels were considerably higher for the diabetic group fed fish oil.

Phosphatidylinositol fraction. Saturated fatty acid and 20:5ω3 contents of the phosphatidylinositol fraction were not altered by diabetes, while all other fatty acid levels were significantly changed (Table 4). Elevation in 18:2ω6 and 22:6ω3 occurred in the diabetic condition and diabetic animals fed fish oil exhibited markedly reduced levels of 20:4ω6. A significant increase in ω3 fatty acid levels was observed in animals fed the fish oil diet, while the change induced by diet was not very pronounced for animals fed a diet high in ω6 fatty acids.

Phosphatidylserine fraction. Unlike the other phospholipid fractions, diabetes did not alter the fatty acid composition of the phosphatidylserine fraction (Table 4). Levels of 18:0 and 18:2ω6 were higher when soybean oil was included in the diet while the level of 20:5ω3 in the microsome increased when fish oil was fed.

G-6-Pase activity. Liver microsomal G-6-Pase activity was influenced by the diabetic state as well as by feeding the polyunsaturated fats to control animals (Fig. 1). G-6-Pase activity was significantly higher in liver microsomes of diabetic animals as compared with control groups, but was not reduced by feeding the polyunsaturated fat diet.

DISCUSSION

Streptozotocin-induced diabetes is associated with impaired conversion of linoleic acid to arachidonic acid due to depressed activity of liver microsomal fatty acid desaturases (1-4). The present study demonstrates a

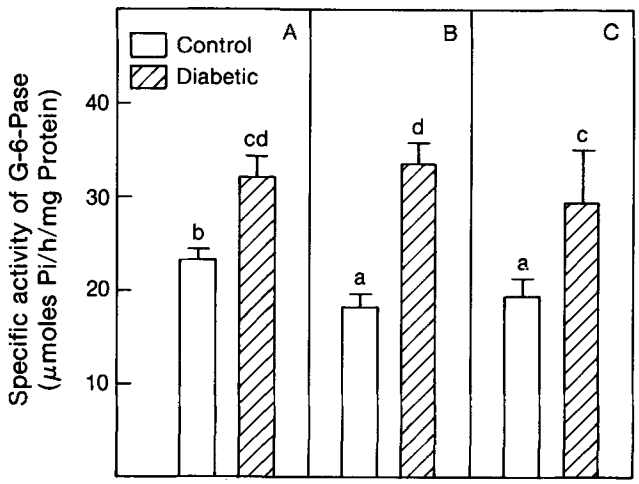

FIG. 1. Effect of diet on liver microsomal glucose-6-phosphatase activity for control and diabetic rats. Values are mean ± S.D. Values without common superscript are significantly different at 5% level. A, Beef tallow diet; B, soybean oil diet; C, fish oil diet.

decrease in 20:4ω6 and an increase in 22:6ω3 in the liver microsomal phospholipid fractions of the diabetic rats. Feeding a diet high in saturated fat (beef tallow) or fish oil decreased the levels of 18:2ω6 in diabetic animals, while the fish oil diet also markedly reduced the 20:4ω6 levels in the phosphatidylcholine and phosphatidylethanolamine fractions. Although desaturase activity was not measured in this study, it is conceivable that altered desaturase activity may be responsible for the changes that occur in the microsomal membranes in the diabetic state. Insulin treatment has been suggested to repair this defect (3), although the arachidonic acid level was shown to be further diminished by insulin treatment (3). Several other factors, such as fatty acid chain elongation, membrane lipid turnover, and fatty acid oxidation, may also contribute to the changes observed in membrane lipid composition.

Diabetes is known to change G-6-Pase activity in rat liver (8). Our results indicate that liver microsomal G-6-Pase activity significantly increases in the diabetic state as compared to controls. Feeding fish oil significantly lowered G- 6-Pase activity in liver microsomes of diabetic rats as compared with diabetic rats fed diets containing beef tallow or soybean oil. G-6-Pase is known to play a key role in the maintenance of normal blood glucose levels because of its involvement in the terminal reactions of glycogenolysis and gluconeogenesis (22). G-6-Pase is a membrane-bound enzyme and has been reported to be lipid-dependent (13,22), functioning in a system composed of a specific G-6-Pase transporter and a nonspecific phosphohydrolase phosphotransferase (8). In the diabetic liver, an increase in the phosphohydrolase portion of the enzyme has been reported, while the enzyme's transport component is limited (8). The change in microsomal G-6-Pase activity observed may be explained on the basis of changes occurring in the phospholipid fatty acid composition and associated effects on the lipid microenvironment affecting glucose-6-phosphatase function. Transitions occurring in substrate availability in transcriptional or translational events, and possibly in the phosphorylation state may also explain the changes observed in G-6-Pase activity. It is suggested that glucose-6-phosphatase activity can be modulated in the diabetic state by careful control of dietary ω6 and ω3 fatty acid intake.

The Effect of Dietary Linoleic Acid on the Fatty Acid Composition of Individual Phospholipids and Lipoxygenase Products from Gills and Leucocytes of Atlantic Salmon (*Salmo salar*)

J. Gordon Bell[a,*], Robert S. Raynard[b] and John. R. Sargent[a]

[a]NERC Unit of Aquatic Biochemistry, University of Stirling, Scotland, U.K. and [b]D.A.F.S. Marine Laboratory, Aberdeen, Scotland

Diets containing either fish oil or sunflower oil, both of which supplied the minimum required level of n-3 fatty acids, were given to Atlantic salmon *(Salmo salar)* post-smolts for a period of 16 weeks. In fish fed sunflower oil, the phospholipids of gills showed increased 18:2n-6 (2–13-fold), 20:2n-6 (4.5–12-fold) and 20:3n-6 (2–8-fold). In addition, phosphatidylethanolamine had increased 20:4n-6 (1.5-fold). Changes of a similar magnitude were observed in the phospholipids of blood leucocytes except that, in addition, 20:4n-6 was elevated in phosphatidylserine (1.7-fold) and phosphatidylinositol (1.4-fold). Both tissues showed a general decrease in phospholipid 20:5n-3 (up to 3-fold), which caused an increase in 20:4n-6/20:5n-3 ratio (1.3–6-fold). The elongation and desaturation products of 20:4n-6, 22:4n-6 and 22:5n-6 were not increased as a result of feeding sunflower oil. When isolated gill cells were stimulated with the calcium ionophore A23187, 12-hydroxy-8,10,14,17-eicosapentaenoic acid (12-HEPE) was the major lipoxygenase product from salmon given fish oil. 12-HEPE was significantly reduced in salmon given sunflower oil. When stimulated with A23187, the lipoxygenase products derived from whole blood of fish given sunflower oil showed decreased levels of leukotriene B_5, 12-HEPE and 12-hydroxy-5,8,10,14-eicosatetraenoic acid. *Lipids 26,* 445–450 (1991).

Most mammals can metabolize linoleic acid (LA), 18:2n-6 by Δ6 desaturation to gamma-linolenic acid 18:3n-6 which, after elongation to dihomogamma-linolenic acid 20:3n-6, can subsequently undergo Δ5 desaturation to arachidonic acid (AA), 20:4n-6 (1). Generally freshwater fish are capable of utilizing the same pathway (2), whereas marine species, such as turbot *(Scophthalmus maximums),* apparently lack Δ5 desaturase and thus require their diet to supply the highly unsaturated fatty acids (HUFA), eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA) and probably AA (3,4). Studies with an anadramous species, Atlantic salmon *(Salmo salar),* indicated an apparent inability to metabolize LA to AA during smolting (the transition from freshwater to seawater) (5), although post-smolts given linoleic acid as corn oil showed increased AA in the phospholipids of liver and muscle (6).

AA and EPA can be metabolized by cyclooxygenase and lipoxygenase enzymes to yield a group of biologically active products known collectively as eicosanoids. While the AA-derived eicosanoids are powerful agonists in a number of pathophysiological conditions such as psoriasis and cardiovascular disease (7,8), the EPA-derived eicosanoids are generally of decreased efficacy, and thus their generation *in vivo* may allow them to function as anti-inflammatory mediators (9). This fact underlies the use of n-3 HUFA-rich fish oils in the treatment of a number of inflammatory conditions in humans (10).

Fish are an ideal model system for studying the production and interaction of AA- and EPA-derived eicosanoids because their tissues are naturally rich in n-3 HUFA. In this study Atlantic salmon post-smolts were given diets in which the lipid was supplied either as fish oil or sunflower oil. Although the latter diet had a markedly reduced n-3/n-6 ratio, it contained sufficient n-3 HUFA derived from the dietary fish meal to meet the normally recommended requirements of salmon (11). Our aims were i) to study the incorporation of LA and its metabolic products into the individual phospholipids of gills and leucocytes. These tissues are highly active in eicosanoid production (12–14). ii) To determine lipoxygenase products from endogenous fatty acid precursors in isolated gill cells and whole blood challenged with the calcium ionophore A23187.

MATERIALS AND METHODS

Materials. Leukotriene B_5 (LTB_5), 12-hydroxyeicosatetraenoic acid (12(R,S)-HETE) and 12-hydroxyeicosapentaenoic acid (12(S)-HEPE) were purchased from Cascade Biochem Ltd. (Reading, U.K.). Leukotriene B_4 (LTB_4), A23187 and "Sigmacote" were from Sigma Chemical Co. Ltd. (Poole, U.K.). 15-Hydroxyeicosatetraenoic acid (15(S)-HETE) and 5-hydroxyeicosatetraenoic acid (5(R,S)-HETE) were purchased from Novabiochem Ltd. (Nottingham, U.K.).

Thin-layer chromatography (TLC) plates (20 × 20 cm × 0.25 mm) precoated with Silica Gel 60 were obtained from Merck (Darmstadt, Germany). All solvents were of high-performance liquid chr tography (HPLC) grade and were obtained from Rathb..n Chemicals Ltd. (Walkerburn, U.K.).

Animals and diets. Three hundred Atlantic salmon S1 smolts (Salmon undergoing transition to seawater in one year, mean wt. *ca.* 51 g) were obtained from the D.A.F.S. Fish Cultivation Unit (Aultbea, Wester Ross, Scotland) and transferred to sea water tanks at the same unit. The diets were supplied by automatic feeders which were adjusted to provide 20 g/kg biomass per day, 7 days each week. Fish were bulk weighed every 28 days and the ration adjusted accordingly. Samples for analytical measurements were collected after 16 weeks of the feeding experiment. The fish meal-based diets were formulated to meet the nutritional requirements of salmon (15) and contained 46% crude protein and 17% lipid (Table 1). The

Total n-6	2.5	43.6
Total n-3	23.8	9.9
n-3/n-6	9.4	0.2

dietary lipid was supplied either as fish oil (FO) or sunflower oil (SFO), and both diets fulfilled the requirement for n-3 fatty acids to be *ca.* 1% of the dry diet. The fatty acid compositions of the two diets are shown in Table 2.

Leucocyte preparation and lipid extraction. Five mL of blood were collected in heparinized syringes from the caudal vein of six fish from each dietary treatment. The blood was diluted with two volumes of phosphate buffered saline (PBS). Four mL of the diluted blood were layered onto 6 mL of lymphocyte separation medium (Gibco Ltd., Paisley, Scotland) and centrifuged at 400 × *g* for 30 min at 4°C. The cells around the interface of the erythrocytes were harvested and washed in PBS. If erythrocyte contamination was greater than 1%, the gradient centrifugation was repeated. The leucocytes obtained from six samples per dietary treatment were pooled and the lipids extracted by the method of Folch *et al.* (16). The extracts were stored at −20°C prior to further analysis. All solvents contained 0.05% butylated hydroxytoluene (BHT) as an antioxidant.

Extraction of gill lipids. Intact gill arches were dissected from three fish per treatment, blotted on paper tissue to remove excess blood and immediately frozen in liquid nitrogen. Samples were stored at −20°C prior to lipid extraction. After thawing, the gill filaments were dissected from the gill arches, weighed and homogenized in chloroform/methanol (2:1, v/v) using a "Polytron" tissue macerator. The remaining procedures were as described for leucocyte lipid extraction. Lipids were extracted from 1.0 g samples of the diets by a similar procedure.

Lipid class separation and fatty acid analysis. Lipid extracts were separated into phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS) and phosphatidylinositol (PI) fractions by TLC as described by Vitiello and Zanetta (17). The plates were sprayed with 0.1% 2′,7′-dichlorofluorescein in 97% methanol containing 0.05% BHT, and the lipid bands were visualized under UV light. Acid-catalyzed transmethylation was performed overnight at 50°C by the method of Christie (18). The fatty acid methyl esters were separated and quantified by gas-liquid chromatography (Carlo Erba Fractovap 4160, Fisons Ltd., Crawley, U.K.) using a capillary column (50 m × 0.22 mm i.d.) coated with free fatty acid phase (S.G.E. Ltd., Milton Keynes, U.K.). Individual methyl esters were identified by comparison with known standards and by reference to published data (19,20).

Preparation of isolated gill cells. Fish were killed by a blow to the head. The pericardium was opened and the bulbus arteriosus was perfused with 20 mL of ice-cold 0.9% NaCl (w/v) to flush blood from the gills. The gill arches were then removed and placed in ice-cold Hank's medium. This is a calcium-free medium which is specially modified for use with salmonid fish as described by Moon *et al.* (21). The composition was: 10.29 g/L NaCl, 0.4 g/L KCl, 0.2 g/L $MgSO_4.7H_2O$, 0.06 g/L KH_2PO_4, 0.13 g/L $Na_2HPO_4.12H_2O$, 0.5 g/L $NaHCO_3$, and 2.38 g/L HEPES. The arches were then blotted on tissue and the epithelial layer scraped with a blunt scalpel blade to remove cells. The cells were then suspended in ice-cold Ca^{2+}-free Hank's medium, gently separated by stirring with a magnetic stirrer and filtered through a 100 μm nylon gauze. The cells were collected by centrifugation at 100 × *g* for 5 min.

Ionophore challenge. Glass test tubes (15 mL) used in the incubations were pre-coated with "Sigmacote" prior to use. Gill cells were suspended in modified Hank's medium (containing 2 mM $CaCl_2$) at a concentration of 100 mg wet weight per mL. An aliquot of the suspension was retained for protein determination (22). One mL of whole blood was mixed with an equal volume of modified Hank's medium and both blood and gill cell suspensions were incubated in a shaking water bath at 15°C for

10 min. Calcium ionophore A23187 was added in 5 μL dimethylsulfoxide at a final concentration of 20 μM.

Eicosanoid extraction. After 30 min incubation, the samples were centrifuged at 12,000 × *g* for 2 min and the eicosanoids extracted by the method of Pettitt *et al.* (14).

High-performance liquid chromatography. The profiles of the hydroxy fatty acids and leukotrienes from the gill and blood extracts were determined by reverse phase high-performance liquid chromatography (HPLC) using a Spherisorb 5 μm octadecylsilica (ODS2) column (25 cm × 4.6 mm i.d., Scotlab, Bellshill, Scotland). The chromatographic system was equipped with Waters Model M-45 pumps and 680 Automated Gradient Controller and the effluent was monitored at 280 nm and 235 nm to detect leukotrienes and hydroxy fatty acids, respectively, using a Pye Unicam LC-UV detector. Two isocratic solvent systems were used at a flow rate of 1 mL/min. To separate the monohydroxy acids, solvent A containing methanol/water/acetic acid (80:20:0.05, v/v/v) was used. To separate leukotrienes and monohydroxy acids, solvent B containing acetonitrile/methanol/water/acetic acid/phosphoric acid/ammonia (40:29:30:0.5:0.3:0.2, by vol) was used. Quantitations were based on external standards of 12-HEPE, 12-HETE, LTB_5 and LTB_4. A representative chromatogram of leukotriene and hydroxy fatty acid standards is shown in Figure 1.

Preparation and chromatography of hydroxy acid methyl esters. Methyl esters of standard hydroxy acids and peaks collected from HPLC were methylated using diazomethane as described by Schwartz and Bright (23). The methyl esters were purified using HPLC (Solvent A) and analyzed by gas-liquid chromatography (Philips PU 4500 chromatograph) using a CP Sil 5 column (50 m × 0.32 mm i.d.; Chrompak, Middelberg, The Netherlands). Hydrogen was used as carrier gas and the temperature was programmed from 50°C to 260°C at 4°C/min.

Statistical analysis. Significance of difference ($P<0.05$) between dietary treatments was determined by Student's *t*-test.

RESULTS

The fatty acid compositions of leucocyte phospholipid classes are shown in Tables 3 and 4. In PC from SFO fish there were increases in 18:2n-6, 18:3n-6, 20:2n-6 and 20:3n-6 as compared to FO fish. The SFO fish also showed decreased 20:5n-3, 22:6n-3, total saturated acids and total monoenes. In PE a similar pattern of changes was observed, although 20:4n-6 was also increased in SFO fish as compared to FO fish. In both lipid classes of SFO fish the n-3/n-6 ratio was reduced. In PS of SFO fish the n-6 PUFA were also elevated compared to the FO fish, and 20:5n-3 and 22:6n-3 were reduced. In PI 20:3n-6 and 20:4n-6 were increased in SFO fish but the n-3 HUFA were also elevated. In general, PI was the least altered by dietary lipid and this was reflected by little change in either the n-3/n-6 ratio or the 20:4n-6/20:5n-3 ratio. In PS, as with PC and PE, the n-3/n-6 ratio was decreased and the 20:4n-6/20:5n-3 ratio was increased.

The fatty acid compositions of gill phospholipid classes are shown in Tables 5 and 6. PC from SFO fish showed significantly increased 18:2n-6, 20:2n-6 and 20:3n-6. The SFO fish also had decreased 20:5n-3 and total n-3 PUFA, but increased total PUFA as compared to FO fish. Similar

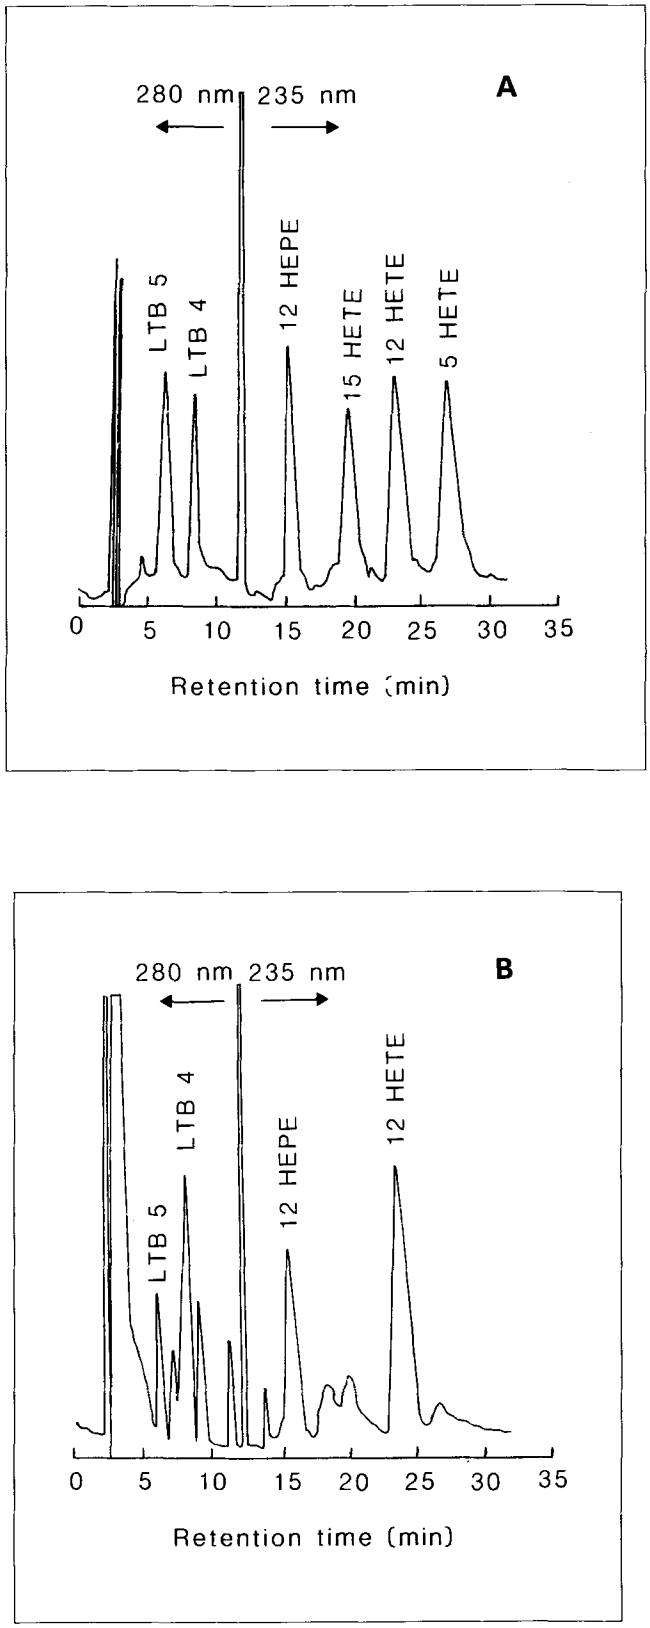

FIG. 1. (A) A typical HPLC chromatogram of leukotriene and hydroxy acid standards separated using solvent system described in Materials and Methods. (B) A typical HPLC chromatogram of lipoxygenase products obtained after stimulation of whole blood with A23187 (20 μM). Experimental conditions are described in Materials and Methods.

Footnotes as for Table 3.

changes were apprent in gill PE. In gill PS, 18:2n-6, 20:2n-6 and 20:3n-6 were significantly elevated in SFO fish, while significant decreases were observed in 20:5n-3 and 22:5n-3. Similar changes were observed in gill PI. The n-3/n-6 ratio in all gill phospholipids was reduced in fish given the SFO diet. The mean value of the ratio 20:4n-6/20:5n-3 was generally increased in SFO fish but, due to large standard deviations, the increase was only significant in PS. In the phospholipids from both

of the products produced by incubation of blood with A23187 is shown in Figure 1. Peak identity was confirmed by high resolution capillary GC of methyl esters prepared from hydroxy fatty acids recovered from the HPLC separation. No HPLC peaks were detected when blood was incubated with dimethylsulfoxide alone (data not shown).

Gill cells from both dietary treatments produced substantial amounts of both 12-HEPE and 12-HETE. The amount of 12-HETE produced did not vary with dietary n-3/n-6 ratio but the amount of 12-HEPE produced was significantly reduced in fish given SFO. No LTB_4 or LTB_5 were detected in gill cell extracts. A reduction in the dietary n-3/n-6 ratio did not alter production of leucocyte LTB_4, but the production of LTB_5 was significantly reduced in fish given SFO. However, SFO significantly reduced the formation of both 12-HEPE and 12-HETE as compared to leucocytes from fish given FO.

DISCUSSION

The increased levels of 20-carbon n-6 fatty acids present in the individual phospholipids of gill and leucocytes from fish given SFO indicate that both Δ6 and Δ5 desaturation are occurring in these tissues. In gill cells Δ5 desaturase appears less active than Δ6 desaturase. This is confirmed by the accumulation of 20:3n-6 in all phospholipids, whereas 20:4n-6 is only increased in PE. There was a similar accumulation of 20:3n-6 in leucocytes, although 20:4n-6 was also increased in PE, PS and PI. This relatively low Δ5 desaturase activity also was observed in isolated hepatocytes from a related salmonid, the rainbow trout (24).

While trout gill homogenates have a 12-lipoxygenase capable of converting exogenous radiolabeled AA and EPA to their 12-hydroxy metabolites (25), there has been no information on the production of these metabolites from endogenous precursor fatty acids derived from gill phospholipids. This study demonstrates that in Atlantic salmon given a FO containing diet, the major 12-lipoxygenase product from gill cells is EPA-derived 12-HEPE. The reduced production of 12-HEPE in gills of SFO fish corresponds with a reduction of EPA and an increase in the AA/EPA ratio in the gill phospholipids. The ratio of 12-HETE/12-HEPE produced by gill cells and the ratio of the precursor fatty acids in gill PC suggest a possible relationship between the levels of these fatty acids in PC and their metabolism by gill lipoxygenase. A similar relationship has also been suggested by Fischer *et al.* (26) and Takayama *et al.* (27) for mammalian platelets and cultured mammalian umbilical tissue, respectively.

The precise physiological role of 12-HETE is not presently well established, although recent studies have postulated a possible role for this eicosanoid in the control of ion channels (28,29). This role would be particularly important in gills which, along with renal tissue, are responsible for osmoregulation in fish. In general, EPA-derived eicosanoids have less biopotency relative to their AA-derived counterparts (30,31). Therefore, the alteration of 12-HETE/12-HEPE ratio as a result of SFO intake could have a profound effect on gill physiology and function.

The quantity of lipoxygenase products derived from endogenous precursors in salmon gill was very substantial in that the recorded value of approximately 100 ng 12-HEPE/mg tissue protein represents 0.3 mg 12-HEPE/g tissue lipid or 0.7% of total precursor fatty acid metabolized by lipoxygenase. The significance of this high lipoxygenase activity is not clear.

We used whole blood, instead of isolated leucocytes, to study eicosanoid production because this most closely resembled the *in vivo* situation where interactions between different cell types are known to have profound influences on eicosanoid production (32). Studies with rainbow trout have indicated that leucocytes are the only blood cells which are directly capable of eicosanoid production and that no eicosanoids are generated by ionophore-stimulated erythrocytes (14). Salmon given SFO showed decreased production of LTB_5 and, consequently, an increased LTB_4/LTB_5 ratio as compared to those given FO. LTB_4 is an extremely powerful chemotactic agent and is a potent agonist in increasing intracellular calcium (33). EPA-derived LTB_5, however, is up to 30 times less potent than LTB_4 (34). Clearly the changes induced by high n-6 PUFA intake could have significant consequences for immune function.

Both 12-HEPE and 12-HETE production were reduced in fish given SFO even though AA was slightly increased in their phospholipids. However, 20:3n-6 was increased from 1.5% (in FO fish) to 13% (in SFO fish) of the total 20-carbon PUFA in leucocyte total phospholipids (Tables 3 and 4) and this fatty acid, which is also a substrate for lipoxygenase, is known to inhibit production of AA-derived eicosanoids in guinea-pig epidermis (7). In trout, endogenous 20:3n-6 was not utilized directly for prostaglandin production, but it was an effective inhibitor of AA-derived prostaglandin formation (35). Changes in dietary

n-3/n-6 PUFA ratio can increase (36) or decrease (37) the activity of phospholipase A_2 depending on the tissue. A decrease in phospholipase A_2 activity, which would result in less available substrate for lipoxygenase, could explain the decline in both 12-HETE and 12-HEPE production in leucocytes of fish given SFO. Under our experimental conditions, no lipoxygenase products of 22:6n-3 were detected in the eicosanoid extracts from either gill cells or leucocytes. Similar studies with rainbow trout (38) and mammals supplemented with 22:6n-3 (7,39) also found no lipoxygenase-derived products of this fatty acid. While this may be surprising in cells containing large amounts of 22:6n-3, it may reflect a selective conservation mechaism for a fatty acid considered vital in maintaining membrane structure and function (40,41).

In general, therefore, the inclusion of linoleic acid in the diets of salmon results in alterations in the phospholipid fatty acid compositions in gills and leucocytes paralleled by an altered eicosanoid spectrum in these tissues. The biological consequences of these changes remain to be assessed. However, the very high biological activity of AA-derived eicosanoids suggest that caution is required in over-supplementing commercial fish oils with n-6 rich vegetable oils in fish feeds, especially under conditions where the fish are likely to be stressed.

ACKNOWLEDGMENT

We would like to thank all D.A.F.S. personnel involved in running the Fish Cultivation Unit, Aultbea for their expertise and assistance with fish husbandry.

[Received June 14, 1990, and in revised form March 26, 1991; Revision accepted April 3, 1991]

Effect of Chronic Glucagon Administration on Lipoprotein Composition in Normally Fed, Fasted and Cholesterol-Fed Rats

Catherine Guettet, Najmuddin Rostaqui, Denis Mathé*, Bernard Lecuyer, Nicole Navarro and Bernard Jacotot

Unité de Recherches sur les Dyslipidémies et l'Atherosclérose, INSERM U 32 Hôpital Henri-Mondor, 94010 Créteil, France

Male adult Wistar rats received daily (at 9 a.m. and 5 p.m.) 10 μg of zinc-protamine glucagon by subcutaneous injection for 8 days. Plasma cholesterol levels were decreased by 36% in fed rats, 33% in cholesterol-fed rats and by 55% in fasted rats. Lipoproteins were separated into 22 fractions by ultracentrifugation using a density gradient. Glucagon administration decreased the cholesterol content in all lipoproteins except low density lipoprotein (LDL_1) (1.006–1.040) and very low density lipoprotein (VLDL) from cholesterol-fed rats. The main decrease (−57 to −81%) was observed in 1.050–1.100 g/mL lipoproteins (LDL_2 and HDL_2), which contained a large amount of apo E, while HDL_3 cholesterol was not affected. Triacylglycerol levels were decreased only in chylomicrons and VLDL (−70%) of fed and cholesterol-fed rats, while plasma and lipoprotein triacylglycerol levels were not changed in fasted rats treated with glucagon. In normally fed rats glucagon administration increased by 42% the fractional catabolic rate of [^{125}I]HDL_2 while the absolute catabolic rate appeared to be unchanged. Glucagon seems to be a potent hypolipidemic agent affecting mainly the apo E-rich lipoproteins. Its chronic administration limits lipoprotein accumulation which occurs upon cholesterol feeding.

Lipids 26, 451–458 (1991).

Glucagon is known to be a potent hypolipidemic agent. In man and in animals, glucagon administration produces a significant decrease in plasma lipid levels (1–5). However, little is known how lipoproteins are affected by glucagon. In a previous study (6), we showed that chronic administration of glucagon decreased the concentration of cholesterol, triacylglycerol (TG), phospholipids (PL), and proteins, in all lipoproteins except low density lipoprotein (LDL_1) (1.006–1040 g/mL). The lipoprotein fraction isolated between 1.040 and 1.063 g/mL and rich in apo E was most affected by glucagon. The decrease in plasma TG levels was essentially due to a decrease in chylomicron and very low density lipoprotein (VLDL) TG.

In order to obtain insights into the effects of glucagon on plasma lipids, we now separated plasma lipoproteins on a continuous density gradient. The experiments were performed on rats under three nutritional states: fasted, normally fed, or cholesterol-fed. During fasting, the glucagon/insulin ratio increases (7), while the hepatic secretion of VLDL is reduced (8). After ingestion of a cholesterol-rich diet, a moderate hypercholesterolemia appears in rat, characterized by an increase in chylomicrons, VLDL, and LDL_1, while LDL_2 (1.040–1.063 g/mL) and high density lipoprotein (HDL)-cholesterol levels are decreased (9–11).

*To whom correspondence should be addressed.

Abbreviations: ACR, absolute catabolic rate; FCR, fractional catabolic rate; VLDL, very low density lipoprotein; LDL, low density lipoproteins; HDL, high density lipoproteins; TC, total cholesterol; TG, triacylglycerol; PL, phospholipids.

In the present study, glucagon appeared to be effective in decreasing plasma lipid levels under the three nutritional conditions used. Decreased secretion and/or increased catabolism of lipoproteins could explain the effects of glucagon. In order to explore this question, the turnover of HDL_2 (1.063–1.117 g/mL) was studied in control rats and in glucagon-treated rats.

MATERIALS AND METHODS

Animals and diets. Male Wistar rats (from Janvier, 53940 Le Genest, France), weighing about 350 g, were housed individually in an air-conditioned animal house at 25°C with a light-dark cycle of 12 hr (8 a.m.–8 p.m.). Rats were fed *ad libitum* during one month a semi-purified diet containing: sucrose, 53%; casein, 23%; lard, 9.2%; walnut oil, 0.8%; skimmed milk, 4%; salt mixture, 5%; cellulose with vitamins, 2.5%; and yeast, 23.% (12). The cholesterol content of the diet was 0.015%. Three different dietary conditions were studied: rats fed the semi-purified diet and killed with (fasted group, n = 6) or without (normally fed group, n = 6) 24-hr fasting. A third group of rats (cholesterol-fed group, n = 6) received the semi-purified diet enriched with cholesterol (1%) for a period of one month. Ten μg of zinc-protamine glucagon, donated by Novo Industries (Copenhagen, Denmark), were administered subcutaneously twice a day (at 9 a.m. and 5 p.m.) to each rat for 8 days. Control rats were treated identically as were experimental animals, except that saline was injected in place of glucagon.

Rats were killed (at 1 p.m.) by intra-aortic puncture under pentobarbital anesthesia 4 hr after the last injection of glucagon. Blood from each rat was collected in syringes containing 0.3 mL of EDTA (4%) and monoiodoacetamie (4%) for 10 mL of blood and was centrifuged at 2200 × *g* for 20 min at 4°C.

Lipoprotein isolation. Chylomicrons were isolated by overlaying 4 mL of plasma with 2 mL of 1.006 g/mL NaCl solution and centrifuging fro 30 min at 15,000 rpm in a 50 Ti rotor using a Beckman L8-70 ultracentrifuge (Beckman, Gagny, France) at 20°C. Chylomicrons were collected from the meniscus. The infranatant was adjusted to 1.21 g/mL by the addition of solid KBr and centrifuged in a 50 Ti rotor at 40,000 rpm for 40 hr at 15°C. Total lipoproteins collected from the meniscus were incorporated in a density gradient adapted from Redgrave *et al.* (13) and prepared in tubes with saline solutions of densities as follows: 1.5 mL, 1.006 g/mL; 1.5 mL, 1020 g/mL; 2 mL, 1.040 g/mL; 3 mL, 1.063 g/mL; 2 mL of total lipoprotein solution (1.21 g/mL) and 1 mL, 1.25 g/mL. The tubes were centrifuged for 24 hr at 15°C in a SW 41 Ti Beckman rotor at 40,000 rpm. The first 18 fractions (0.5 mL each) were collected from the meniscus of the tubes. A control tube containing only saline solutions was also centrifuged and used to determine by refractometry (refractometer, Atago, Tokyo, Japan) the density of fractions. Each fraction of lipoproteins was assayed for cholesterol content.

The chemical composition of lipoproteins was determined in pooled fractions corresponding to VLDL (d<1.006 g/mL; fractions 1 and 2), LDL_1 (low density lipoproteins of density between 1.006 and 1.040 g/mL; fractions 3 to 6), LDL_2 (low density lipoprotein of density between 1.040 and 1.063 g/mL; fractions 7 to 11) and HDL (high density lipoproteins of density between 1.063 and 1.210 g/mL; fractions 12 to 18). Lipid content of lipoprotein fractions was corrected for loss during ultracentrifugation procedure. The mean recoveries were 92 ± 3, 87 ± 5 and 89 ± 5% for total cholesterol (TC), TG and PL, respectively.

Apolipoprotein analysis. Lipoprotein samples from fractions 7 to 18 were extensively dialyzed against 0.05% EDTA, 0.02% NaN_3, NaCl 0.9%, pH 7.4 at 4°C, and then lyophilized. Each sample was dissolved in a buffer containing Tris HCl 0.02 M and sodium dodecyl sulfate 0.1 M, pH 8.4, and assayed for protein content prior to SDS-PAGE. The separating gels consisted of a discontinuous gradient of 5 and 10% polyacrylamide according to Connelly and Kuksis (14). With this system, delipidation of the sample prior to electrophoresis was unnecessary. Gels were stained with Coomassie Brilliant Blue R 250 (0.05%) and destained in the solution described by Weber and Osborn (15). All gels were scanned with a laser densitometer (LKB 2202 Ultrascan, LKB, Ulis, France) connected to a Delsi Enica (Delsi, Argenteuil, France) 10 integrator. The apolipoprotein bands were identified on the basis of molecular weight as determined by reference to purified protein standards and by comparison to published SDS gel electrophoretograms of rat apolipoproteins (16,17). In assessing the composition of apolipoproteins, no correction was made for the difference in binding of dye to each protein. The actual mass of each apolipoprotein within lipoprotein fractions was estimated as follows: % dye uptake × protein concentration (μg/mL plasma).

HLD turnover studies. HDL_2 (1.063–1.117 g/mL) were isolated by sequential ultracentrifugation in a Beckman 50 Ti rotor at 10°C using a Beckman L8-70 centrifuge. Rat plasma, adjusted to 1.063 g/mL with solid KBr, was centrifuged for 24 hr at 40,000 rpm (10^8 g × min). After the removal of the d < 1.063 g/mL lipoproteins, the subnatant was adjusted to 1.117 g/mL with solid KBr and centrifuged for 48 hr (2×10^8 g × min). HDL_2 were collected and centrifuged again in a NaCl/KBr solution of 1.117 g/mL density. HDL_2 were extensively dialyzed against 0.15M NaCl and 0.04% Na_2 EDTA. They were passed through a 0.22 μm filter (Cera-Labo, Aubervilliers, France). HDL_2 contained apo A-I (50%), apo A-IV (10%), apo E (12%) and apo C (28%).

^{125}I-labelling of HDL_2 was performed according to the method of MacFarlane (18) as modified for lipoproteins (19). After iodination, unbound iodine was removed by chromatography on Sephadex G 25. Labelled HDL contained 220 cpm/ng protein; 96% of total radioactivity was precipitated by trichloroacetic acid (TCA) while less than 4% were present in lipids (Folch lower layer).

Normally fed rats (control and glucagon-treated) received intravenously (jugular vein) 0.1 mL of HDL_2 solution (0.46 mg/mL) at 9 a.m. Blood samples were collected periodically from the tail vein, plasma was separated in an Eppendorf-type centrifuge, and radioactivity was measured in a MR 80 Kontron gamma spectrometer (Kontron, St. Quentin, France). At the end of the experiment (33 hr after [^{125}HDL_2 injection), rats were killed by intraaortic puncture under diethyl/ether anesthesia. Lipoprotein fractions were separated and their radioactivity was measured. The fractional catabolic rate (FCR) was estimated by the method of Matthews (20) with the assumption of a two-compartmental model for the metabolism of apo-HDL. The absolute catabolic rate was determined as FCR × intravascular pool of apo-HDL. Plasma volume was taken as 4.18% of body weight.

Chemical analyses. Cholesterol, phospholipid and triacylglycerol concentrations in plasma and lipoprotein fractions were determined by enzymatic methods using commercial kits (Wako, Biotrol, Paris, France and Boehringer-Mannheim, Mannheim, Germany). Proteins were assayed by the method described by Lowry *et al.* (21) using bovine serum albumin as standard. Samples were extracted with chloroform after color development in order to avoid turbidity due to lipids. Results are expressed as mean ± S.E.M. and statistical differences were analyzed by means of the Student's t-test.

RESULTS

Plasma lipid levels. Plasma concentrations of total cholesterol (TC), triacylglycerol (TG) and phospholipids (PL) in the rats fed the semi-purified diet were respectively 806, 2683 and 1781 mg/L (Table 1). When the rats were fasted, TC, TG and PL concentrations decreased by 20, 73 and 38%, respectively. When the animals were fed the cholesterol-rich diet, plasma lipid levels were slightly increased and reached 1163 mg/L for cholesterol, 4814 mg/L for triacylglycerol and 2014 mg/L for phospholipids.

Chronic glucagon administration significantly decreased plasma cholesterol levels under all three dietary conditions, but the greatest effect was observed in fasted rats (±55%). Plasma phospholipid concentrations were decreased, respectively, by 38%, 37% and 33% in normally fed, fasted and cholesterol-fed rats. Triacylglycerol levels were significantly decreased only in normally fed (−70%) and in cholesterol-fed rats (−69%).

Lipoproteins. The distribution of total cholesterol among the lipoprotein fractions isolated on a continuous density gradient is presented in Figure 1. In control rats, 15% of plasma cholesterol was found in chylomicrons, while 11% was in VLDL, 2% in LDL_1 (1.006–1.040), 14% in LDL_2 (1.040–1.063) and 58% in HDL. The cholesterol distribution was identical in fasted rats, except for the absence of chylomicrons and a lower contribution of VLDL. In control rats fed the cholesterol-rich diet, the lipoprotein profile was markedly changed. The distribution of cholesterol was as follows: chylomicrons, 30%; VLDL, 31.7%; LDL_1, 3.3%; LDL_2, 4.9%; and HDL, 29.9%.

Chronic glucagon administration significantly modified the cholesterol distribution in lipoproteins (Fig. 1). In normally fed rats, glucagon decreased the cholesterol concentration in chylomicrons (−51%), VLDL (−42%), LDL_2 (−57%), and HDL (−28%), but not in LDL_1. It should be noted that heavy HDL fractions (1.125–1.210 g/mL) were not affected by glucagon. In fasted rats the same observations can be made with the geatest effect on lipoproteins isolated between 1.050 and 1.100 g/mL (LDL_2, −81%; HDL_2, −70%). In cholesterol-fed rats the effect of glucagon was moderate on chylomicron cholesterol

(−48%), not significant on VLDL and LDL_1 cholesterol, and marked on LDL_2 (−72%) and HDL (−46%) cholesterol.

The concentrations of lipoprotein constituents are presented in Tables 2 to 4. Independent of the dietary condition, glucagon administration decreased cholesterol concentration of LDL_2 (−57 to − 81%) and HDL (−27 to −59%). Cholesterol levels were decreased in chylomicrons and VLDL only in fed and cholesterol-fed rats. Similarly TG levels were decreased in all lipoproteins of fed and cholesterol-fed rats with great decreases (−70 to 76%) in chylomicrons and VLDL. The relative content of lipids and proteins in the different lipoproteins were not markedly changed either by dietary conditions or by

glucagon administration. However, it should be noted that cholesterol feeding increased cholesterol content of chylomicrons and VLDL. Glucagon administration decreased the cholesterol content of LDL_2 and HDL of fasted rats, while TG were decreased in chylomicrons, VLDL and LDL_1 of cholesterol-fed rats.

The apolipoproteins of fractions 7 to 18 were determined by PAGE in each fraction pooled from 6 control or 6 glucagon-treated rats fed *ad libitum*. Dye-uptake was proportional to the apolipoprotein content within a range of 0 to 50 μg per gel. The major effect of glucagon administration was a decrease in the apo E content of each fraction from 7 to 18, while the apo A-I content was slightly increased (Fig. 2). Since the protein content of the lipoprotein fractions was decreased, it is clear that the plasma concentrations of apo E were greatly decreased in all

fractions, fraction 13 to 15 being the most affected (−86%), while apo A-I concentration was decreased in fractions 12 to 16.

Decay of iodine-labelled HDL_2 apolipoproteins in plasma. HDL_2 labelled in the protein moiety were injected into control and glucagon-treated rats. At the end of the experiment, 79% (control) and 74% (glucagon-treated) of the plasma radioactivity was present in HDL. Therefore the decay of plasma radioactivity can be considered as representative of the decay of HDL apolipoproteins. The plasma radioactivity decay was biexponential with an initial rapid phase and a quantitatively more important slow phase (Fig. 3). Kinetic parameters of the decay curves are presented in Table 5. Half-time of the slow phase was decreased in glucagon-treated rats (11.9 ± 0.5 hr) when compared to control rats (14.9 ± 0.8 hr). In contrast, the half-time of the rapid phase did not differ in control and glucagon-treated rats. The fractional catabolic rate (FCR) was increased by 42% in glucagon-treated rats, while the absolute catabolic rate (ACR) appeared to be unchanged.

DISCUSSION

In a previous study, we reported that glucagon, administered twice a day at the dose of 20 μg/day/rat, consistently decreased the plasma cholesterol levels measured 4 hr after the last injection. Body weight and food intake were not markedly changed (5). The effect appeared only after the fifth injection and was not observed after a single injection. Glucagon concentration increased in the plasma for 2 to 3 hr after the injection of glucagon (5). Plasma insulin was also increased but only moderately. Four hours after the last injection, the glucagon/insulin ratio was enhanced two-fold (5). This dose of glucagon is similar to that previously used in man (40 μg/kg/day) (2). As already reported (5,22), glucagon administration significantly decreased plasma lipid levels in fed rats. In the present study the rats were fed a diet enriched in sucrose, a carbohydrate known to increase plasma triacylglycerol concentration (23,24). This diet provided an interesting condition to study the effects of the hypolipidemic hormone glucagon.

Previous fasting of the animals induced a slight decrease in plasma cholesterol and plasma phospholipid concentrations but the distribution among the d > 1.006 g/mL lipoproteins was not modified (see Fig. 1 and compare Table 2 and Table 3 for control rats) as previously reported (17). The main change occurred in triacylglycerol-rich lipoproteins which were absent (chylomicrons), or reduced (VLDL). VLDL-cholesterol (−53%) and VLDL-triacylglycerol (−45%) were decreased by fasting. Ingestion of a diet enriched with cholesterol (1%) raised plasma lipid concentrations. However, the hypercholesterolemia obtained remained moderate as observed by others (9–11), when cholesterol feeding was not associated with hypothyroid drugs or bile acid ingestion. Cholesterol distribution among the lipoprotein fractions isolated by density gradient ultracentrifugation, was greatly modified (Fig. 1A): 62% of plasma cholesterol was carried by chylomicrons and VLDL, while the contribution of LDL_2 and HDL fell to 5 and 30%, respectively.

Glucagon administration decreased plasma cholesterol in these different dietary conditions, but the effect was greater in fasted rats. Triacylglycerol levels were decreased only in fed and cholesterol-fed rats, while no further decrease was observed in fasted rats consistent with what was reported by Byers *et al.* (25).

The three dietary conditions used provide very different situations in regard to the source of the lipoproteins. In fasted rats, most VLDL are synthesized in the liver, while in fed and cholesterol-fed rats a significant amount of VLDL is produced by both intestine and liver. Glucagon administration affected the triacylglycerol-rich lipoproteins differently according to the nutritional state. Cholesterol and triacylglycerol concentrations of chylomicrons were decreased by glucagon in fed and cholesterol-fed animals. Since the absorption coefficient of dietary cholesterol was not markedly decreased by glucagon (5), an increased catabolic rate of these lipoproteins is indicated.

In addition, it should be noted that the decrease observed after glucagon administration was greater for triacylglycerol than for cholesterol, suggesting a specific action of glucagon on the synthesis or the catabolism of lipoprotein triacylglycerol. Glucagon appeared to have no effect on VLDL-cholesterol of cholesterol-fed rats, while triacylglycerol, phospholipid and protein levels were decreased. Consequently the composition of the VLDL was significantly changed. This result suggests that the metabolic fate of some of the cholesterol-rich VLDL produced during cholesterol feeding (26) is differently affected by glucagon administration as we have previously suggested (6). VLDL and LDL_1 (fractions 1 to 6) have not been analyzed for apolipoproteins in this study. We reported previously that relative proportions of apo B_{100} were increased in VLDL and LDL_1 and those of apo C were decreased while the secretion of VLDL-apo B_{100} was enhanced and VLDL-apo_{48} was decreased in glucagon-treated rats (6).

VLDL-cholesterol levels observed in fasted rats were the same as in fed rats treated with glucagon. No additional decrease could be induced by glucagon administration, suggesting that the metabolism of some of the VLDL, particularly those secreted in fasted rats, was not affected by glucagon. A similar conclusion can be drawn concerning plasma TG, since values obtained in fasted rats, and in fasted or fed rats treated with glucagon, were not significantly different.

Separation of lipoproteins by ultracentrifugation on a continuous gradient allowed precise identification of the lipoproteins affected by glucagon administration. The cholesterol concentration of lipoproteins isolated between densities 2.050 and 1.110 g/mL was strikingly decreased in the three nutritional conditions. They correspond to the lightest part of HDL (HDL_2) and to a fraction named LDL_2. In Tables 2 to 4, lipoprotein fractions have been grouped into VLDL, LDL_1, LDL_2 and HDL in order to determine their composition. The lipoproteins of density range 1.006–1.063, currently named LDL, have been separated into 2 fractions: LDL_1 (1.006–1.040) and LDL_2 (1.040–1.063) according to Fidge and Poulis (27). LDL_1 are generally considered to be a product of VLDL lipolysis (27). Glucagon did not significantly affect the plasma concentration of LDL_1, whatever the nutritional state. LDL_2 ($1.040 < d < 1.063$) contain mainly apo E, apo C and apo A and small amounts of apo B (28). This lipoprotein fraction is probably largely composed of apo E-rich HDL (HDL_1). Glucagon administration decreased the concentration of this lipoprotein with the greatest effect in fasted rats. Although apo E-HDL was already decreased in cholesterol-fed rats, glucagon produced an additional decrease. The analysis of apolipoproteins within fractions 7 to 18 showed that glucagon administration decreased the apo A-I concentration in fractions 11 to 16, while the apo E concentration was greatly decreased in all fractions. From this study, it clearly appears that HDL, which contain apo E, are markedly decreased by glucagon administration. This effect can be the result of either a decreased secretion or an increased catabolism, or both. To explore these possibilities, $[^{125}I]HDL_2$ turnover studies were performed in normally fed control and glucagon-treated rats. This fraction (1.063–1.117 g/mL) contained both apo A-I and apo E. The results clearly showed that glucagon administration increased the fractional catabolic rate of HDL_2, while the absolute catabolic rate remained unchanged and the HDL_2 pool was decreased by 30% in glucagon-treated rats. Since the animals were in physiological steady state, it can be concluded that glucagon does not modify the rate of HDL_2 production, but stimulates the catabolic pathways. In cultured hepatocytes, MacKinnon *et al.* (29) showed that an increased catabolism of apo E-rich HDL stimulated bile acid synthesis. Moreover we have reported that chronic glucagon administration enhanced bile acid synthesis (5). Therefore it can be suggested that the decrease in the plasma concentration of LDL_2 and HDL_2 could be the consequence of accelerated turnover of these lipoproteins in glucagon-treated rats.

In conclusion, glucagon appears to be a potent hypolipidemic agent in various nutritional states. Its chronic administration limits lipoprotein accumulation which occurs in cholesterol feeding. Glucagon markedly decreased cholesterol levels in LDL_2 and HDL, while LDL_1 were not affected regardless of the dietary condition. The effects on cholesterol and triacylglycerol content of chylomicrons were also consistent, but the effects on VLDL-lipids varied according to the nutritional state. The relative proportions of cholesterol, triacylglycerol, phospholipid and proteins were virtually unchanged by either dietary conditions or by glucagon administration, suggesting a reduced number of some lipoprotein particles in plasma. However a specific decrease in triacylglycerol content of chylomicrons and VLDL can be noted together with a reduction of plasma apo E concentrations. The hypocholesterolemic action of glucagon can be explained by increased catabolism of HDL rather than decreased secretion. Hypolipidemic effects of glucagon in man have been already reported (1,2,30,31). Hypertriglyceridemic patients with impaired carbohydrate tolerance were those who exhibited the greatest decrease during chronic administration of glucagon (2). In addition normal and hyperlipidemic subjects receiving glucagon had lower esterified cholesterol levels in plasma and lower cholesterol esterification rates than untreated subjects (31). A similar observation was made in rats treated with glucagon (6). Interestingly Eaton *et al.* (32,33) proposed that decreased glucagon activity or a modified insulin/glucagon ratio characterizes genetic or acquired endogenous hyperlipemia, while the hypolipidemic drug clofibrate would modify this ratio. Further examination of the role of glucagon in lipoprotein metabolism would be of interest.

ACKNOWLEDGMENTS

Mrs. Thérèse Ghembaza is thanked for her help in the preparation of the manuscript. NOVO Industries kindly supplied us with Zn-protamine glucagon.

The Effect of Dietary Zinc Deficiency on the Lipid Composition of the Rat Erythrocyte Membrane

Eric R. Driscoll and William J. Bettger*
Department of Nutritional Sciences, College of Biological Science, University of Guelph, Guelph, Ontario, Canada N1G 2W1

The effect of dietary zinc deficiency in the rat on the lipid composition of the erythrocyte membrane was determined. Weanling male Wistar rats were fed an egg white-based diet containing <1.0 mg Zn/kg diet *ad libitum*. Control rats were either pair-fed or *ad libitum*-fed the basal diet supplemented with 100 mg Zn/kg diet. A zinc refed group was fed the −Zn diet until day 18 and then pair-fed the +Zn diet until day 21. The voluntary feed restriction associated with dietary zinc deficiency resulted in erythrocyte membranes that had depressed phospholipid/protein and elevated cholesterol/phospholipid ratios. Similarly, all feed restricted groups had elevated 22-carbon n-3 polyunsaturated fatty acids (PUFA) and depressed 22-carbon n-6 PUFA concentrations in alkenyl-acyl and diacyl glycerophosphoethanolamine, phosphatidylserine and phosphatidylcholine; they also had depressed 24:2n-6 levels in sphingomyelin. The relative concentrations of phospholipids in the membrane was similar between −Zn and +Zn (*ad libitum*) groups; however, the −Zn group had significantly less phosphatidylserine relative to +Zn (pair-fed) controls.
***Lipids 26,* 459–466 (1991).**

Zinc has been proposed to have a critical physiological role in the structure and function of biomembranes (1). Dietary zinc status appears to affect the composition and functional properties of the lipid phase of cell membranes. An interaction of dietary zinc and essential fatty acids has been reported in rats (2) and chicks (3); however, the biochemical basis for this interaction is unknown. Zinc deficiency has been reported to alter fatty acid desaturase activities (4), cholesterol metabolism (5,6) and phospholipid biosynthesis (7,8) in rat tissues. An interaction of zinc and vitamin E has been described in rats (9–11) and chicks (12). Recently, Bray and Bettger (13) have reviewed data suggesting that zinc may function as an antioxidant for specific macromolecules. The "fluidity" of the lipid phase of the liver microsomal fraction (6,14) and from erythrocyte ghosts (15) has been reported to be altered in zinc-deficient rats. In spite of these reports, the effect of dietary zinc deficiency on the detailed lipid composition of a purified plasma membrane fraction has not previously been determined; a preliminary report (16) suggests that there may be substantial alterations in the lipid composition of rat liver plasma membranes from zinc deficient rats.

Abbreviations: ANS, 8-anilinonaphthalene-1-sulfonic acid; FAME, fatty acid methyl ester; FFA, free fatty acids; GPE, glycerophosphoethanolamine; LPC, lysophosphatidylcholine; MCV, mean corpuscular volume; MECL, modified equivalent chain length; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PUFA, polyunsaturated fatty acids; SPH, sphingomyelin; TLC, thin-layer chromatography; −Zn, zinc deficient; +ZnAL, zinc-adequate, *ad libitum*; +ZnPF, zinc-adequate, pair-fed; +ZnRF, zinc refed.

This study was performed to determine the effect of dietary zinc deficiency on the composition of the major lipids in the rat erythrocyte membrane. Changes in lipid composition will be discussed relative to their potential impact on membrane fluidity, red cell osmotic and peroxidative fragilities and on the interaction of zinc and essential fatty acids.

MATERIALS AND METHODS

Male weanling Wistar rats (43–54 g) were divided into zinc deficient (−Zn), zinc refed (+ZnRF), zinc-adequate, pair-fed (+ZnPF), and zinc-adequate *ad libitum* (+ZnAL) treatment groups and were fed the appropriate diet for three weeks. The basal diet containing <1 μg/g Zn, based on egg white, glucose hydrate and corn oil, has been described in detail (17). Control diets were supplemented to contain 100 μg/g Zn. The +ZnRF group was pair-fed the zinc-adequate diet for the last three days of the feeding period the amount consumed by the −Zn group. For the analysis of plasma lipids and the unsaturation index of total erythrocyte membrane phospholipids, the +ZnRF and +ZnPF groups were fed at 4 hr and the food removed from all groups at 3 hr before blood was taken. For all other analyses, food was removed from all groups at 12 hr before killing. The rats were killed by decapitation after light anesthesia with diethyl ether, and trunk blood was collected into heparinized tubes.

Erythrocyte ghost preparation. Ghosts were prepared according to the method of Steck *et al.* (18) as modified by Avery and Bettger (19) with all steps executed at 4°C or on ice. Briefly, the heparinized blood was centrifuged at 300 × *g* for 10 min and the buffy coat removed. The red cells were washed three times in 145 mM NaCl, 10 mM glucose, 5 mM phosphate buffer at pH 8, then lysed in 5 mM phosphate buffer with protease inhibitors (Sigma, St. Louis, MO) leupeptin (1 μM), pepstatin (1 μM), and phenylmethylsulfonylfluoride (100 μM). The lysate was centrifuged at 20,000 × *g* for 10 min to yield a pellet of red cell membranes. After three washes with lysing solution, a pellet of approximately 1 mL of white ghosts was collected and frozen at −20°C until analyzed.

Thin-layer chromatography. The methods used for lipid analysis have been previously described (20). Lipids were extracted from 40 μL of ghosts according to the method of Bligh and Dyer (21) and the phospholipids were separated using chloroform/methanol/acetic acid/water (50:37.5:3.5:2, by vol) on silica gel 60 thin-layer chromatographic (TLC) plates (Merck, Darmstadt, Germany) that had previously been activated at 75°C for at least 1 hr (22). The lysophosphatidylcholine (LPC) extracted from plasma was separated by TLC into 1- and 2-position species using the basic solvent system chloroform/methanol/ammonium hydroxide/water (45:35:8:4, by vol) (23). Plasma free fatty acids were determined by TLC separation of neutral lipids using heptane/isopropyl ether/acetic acid (60:40:3, by vol) (24). The lipids were visualized by spraying with 0.1% 8-anilinonaphthalene-1-sulfonic acid

(ANS) (25). The phosphatidylethanolamine (PE) spot was exposed to fumes of concentratedhydrochloric acid in a closed system for four minutes to hydrolyze the alkenyl PE leaving lysoPE and diacyl species of PE (26). The PE species were extracted (27) and separated by TLC (22).

Sphingomyelin was transmethylated in 6% sulfuric acid in methanol at 75–80°C for 14 hr (28) with a known quantity of internal standard of 17:0 fatty acid (Nu-Chek-Prep, Elysian, MN). The other phospholipids were similarly transmethylated for 3 hr. The fatty acid methyl esters (FAME) were extracted with hexane and analyzed by gas-liquid chromatography.

Gas-liquid chromatography. FAME samples were dissolved in hexane and separated on a Hewlett-Packard 5890A gas chromatograph (Hewlett-Packard, Palo Alto, CA) using a 30-m DB-255 megabore column (J&W Scientific, Rancho Cordova, CA) at a column temperature of 210°C. FAME were identified by comparing retention times with those of standards (Nu-Chek-Prep), and FAME mass was calculated by integration of peak areas. Unknown fatty acids in sphingomyelin (24:1n-7, 24:2n-6) were first tentatively identified by calculating the Modified Equivalent Chain Length (MECL) (29). Then, argentation chromatography (30) was employed to identify 24:1n-7 and 24:2n-6 as monoenes and dienes, respectively. Plates were spread with a slurry of 8 g of silver nitrate and 50 g of silica gel G (CAMAG D-5) in 90–100 mL of water. After drying for 20 min and activating at 120°C for at least 1 hr, FAME were separated, using chloroform/methanol (99:1, v/v) as solvent, into bands according to the number of double bonds. Dimethyl acetals (16:0, 18:0, 18:1) were tentatively identified by their elution times relative to the corresponding FAME. Dimethyl acetals were separated from FAME by TLC with 1,2-dichloroethane as solvent (20).

Phospholipid, cholesterol, and protein. Phospholipid phosphorus, cholesterol and protein were measured by colorimetric assays. Phosphorus in triplicate aliquots of 40 μL of ghosts was measured by the method of Bartlett (31). Cholesterol from duplicate aliquots of 50 μL of ghosts was measured using modification of the method employed in a kit from Sigma (St. Louis, MO) (32). An aliquot of chloroform lipid extract was dried and 200 μL of ethanol was added and warmed in a heating block to 70–75°C (5–10 seconds). The sample was vortexed for three seconds to dissolve the lipid, 2 mL of reagent was added, and the mixture was vortexed for three seconds. The samples were incubated at room temperature for 18 min before absorbance was measured. Protein was determined according to the method of Markwell *et al.* (33).

Statistics. Data were analyzed by a general linear modeling procedure followed by Tukey's test and a least square means analysis comparing −Zn to +ZnRF and +ZnPF groups. All data were examined to determine whether they represented a normally distributed population by calculation of the Shapiro-Wilk statistic on the residuals. Data were transformed prior to analysis, if necessary, to obtain a normal distribution (34).

RESULTS

After 3 weeks on the dietary regimen, the rats had the following weight gains: −Zn 8.3 ± 0.8 g, +ZnRF 12.7 ± 1.9 g, +ZnPF 29.5 ± 2.1 g, and +ZnAL 127.6 ± 2.3 g. Plasma Zn concentrations were: −Zn 0.26 ± 0.03, +ZnRF 1.30 ± 0.06, +ZnPF 1.22 ± 0.03, and +ZnAL 1.52 ± 0.05 μg/mL. The refeeding regimen reverses plasma Zn concentrations to levels that are equivalent to those of pair-fed controls and causes Zn deficient rats to improve their appetite—all rats consume at least 90% of their feed on the last day within 1 hr. There were no mortalities associated with any dietary treatment.

The reduced feed intake associated with dietary zinc deficiency resulted in a significant lowering of the membrane phospholipid/protein ratio and the unsaturation index of the dimethylacetals derived from total phospholipid. The cholesterol/phospholipid ratio was significantly elevated. Zinc deficiency or the associated decrease in voluntary food intake did not alter the erythrocyte membrane cholesterol/protein ratio, the phosphatidylcholine/sphingomyelin ratio or the unsaturation index of the fatty acids derived from the total phospholipids. Zn deficiency, *per se*, caused a significant decrease in the unsaturation index of the dimethylacetals (Table 1).

Dietary zinc deficiency, and the associated drop in voluntary food intake, did not alter the relative composition of erythrocyte membrane alkenyl acyl glycerophosphoethanolamine (Alkenyl acyl GPE) and (diacyl GPE), total glycerophosphoethanolamine (PE), phosphatidylinositol (PI), phosphatidylcholine (PC) and sphingomyelin (SPH). Dietary zinc deficiency resulted in a significantly lower phosphatidylserine (PS) concentration (% of total) compared to the +ZnPF controls (Table 2).

TABLE 1

Effect of Dietary Zinc Deficiency on Erythrocyte Membrane Phospholipid, Cholesterol Concentration and Fatty Acid Unsaturation Index

Index[c]	Treatment group[a,b]				Standard error[d]
	−Zn	+ZnRF	+ZnPF	+ZnAL	
PL/mg P[e]	0.73^{A}	0.72^{A}	0.75^{A}	0.88^{B}	0.01
chol/mg P[f]	0.61	0.61	0.63	0.62	0.01
chol/PL[g]	0.84^{A}	0.86^{A}	0.84^{A}	0.71^{B}	0.02
PC/SPH[h]	3.4	3.6	4.0	3.9	0.1
UI[i]	4.55	4.75	4.61	4.54	0.04
UI of DMA[j]	0.22^{A}	$0.23^{A,B}$	0.27^{B}	0.36^{C}	0.01

[a] Mean (n=5).

[b] Means that do not share a common superscript capital letter are significantly different by Tukey's ($p<0.05$).

[c] Abbreviations used in the Table: PL, phospholipid; P, protein; chol, cholesterol; PC, phosphatidylcholine; SPH, sphingomyelin; UI, unsaturation index; DMA, dimethylacetal.

[d] Pooled standard error.

[e] μmol Phospholipid (PL)/mg protein. Data transformed (square root) prior to statistical analysis distribution.

[f] μmol Cholesterol (chol)/mg protein. Data analyzed by a nonparametric statistical test (Kruskal-Wallis).

[g] Cholesterol/phospholipid (m/m). Data transformed (hyperbolic tangent).

[h] Phosphatidylcholine/sphingomyelin (m/m).

[i] Unsaturation index of the fatty acid methyl esters from membrane total phospholipids.

[j] Unsaturation index of the dimethylacetals from membrane total phospholipids. (Calculation based on area% of 16:0, 18:0 and 18:1 dimethylacetals).

The reduced food intake associated with dietary zinc deficiency caused a significant reduction of 22:4n-6 and 22:5n-6 and a corresponding increase in 22:5n-3, 22:6n-3 and in the double bond index of membrane alkenyl acyl GPE. Membranes from zinc deficient rats have significantly lower 22:4n-6 and 22:5n-6 compared to pair-fed controls in alkenyl acyl GPE (Table 3). In diacyl GPE, the decreased food consumption associated with dietary zinc deficiency results in a decrease in 22:4n-6 and 22:5n-6 and an increase in 22:5n-3 and 22:6n-3 (Table 4).

The depression of voluntary food intake associated with dietary zinc deficiency results in a decrease of 22:4n-6 and 22:5n-6 and an increase in 22:5n-3 and 22:6n-3 in PS. Dietary zinc deficiency, *per se*, is associated with increased 22:5n-3 and 22:6n-3 (Table 5). In PI, the depression of food intake associated with dietary zinc deficiency results in a decrease in 22:4n-6 and 22:5n-6 (Table 6).

The depression of voluntary food intake associated with dietary zinc deficiency results in a significant decrease in 20:4n-6, 22:4n-6 and 22:5n-6 in erythrocyte membrane PC. Membranes from zinc deficient rats have significantly less total monounsaturated fatty acids and more 20:4n-6, 22:5n-3 and 22:6n-3 than those from +ZnPF controls in PC (Table 7). In SPH, the result of reduced feed intake was a decrease in 24:2n-6 content and double bond index.

[e]DBI, double bond index.

Dietary zinc deficiency was associated with a decrease in 24:1n-9 compared to +ZnPF controls (Table 8).

The depression of voluntary feed intake associated with dietary zinc deficiency results in increased total saturated fatty acids and decreased polyunsaturated fatty acids and 20:4n-6 and 22:4n-6 in plasma PC. Dietary zinc deficiency results in a decrease in 18:2n-6 and an increase in 20:4n-6, 22:6n-3 and in the double bond index compared to +ZnPF controls (Table 9). In plasma SPH, reduced food intake results in a decreased content of 24:1n-9 and 24:2n-6; dietary zinc deficiency results in a increased 24:1n-7 compared to pair-fed controls (Table 10). In plasma free (unesterified) fatty acids (FFA), reduced food intake results in decreased 22:4n-6; zinc deficiency causes reduced 20:4n-6 compared to +ZnPF controls (Table 11).

An analysis of the relative phospholipid content of plasma from rats fed the zinc-adequate diet *ad libitum* yielded the following results: PC 59.5%, SPH 9.1%, LPC 22.8%, PI 6.7%, PE 2.0%, and PS not detectable (n=3).

[f] DBI, double bond index.

The fatty acid composition of the LPC fraction suggested that it was a mixture of LPC containing fatty acid bound in the 1-position (16 and 18 saturated and monounsaturated fatty acids) or 2-position (18 and 20 carbon PUFA). Indeed, the two species were separated by TLC with the putative 2-position LPC species running ahead of the 1-position species. The PC and SPH content of plasma was determined in rats on the dietary treatments. The PC content was 0.92, 1.1, 0.94 and 0.92 μmol/mL (P>0.05) for −Zn, +ZnRF, +ZnPF and +ZnAL, respectively; SPH was 0.13, 0.11, 0.13 and 0.13 (μmol/mL) (P>0.05); and PC/SPH was 7.4^{a}, 10.6^{b}, 7.2^{a} and 7.1^{a} (means that do not share a common superscript letter are significantly different by Tukey's test, P<0.05, pooled standard error = 0.3). The FFA content was as follows: −Zn 0.43^{a}, +ZnRF 0.28^{ab}, +ZnPF 0.14^{b} and +ZnAL 0.41^{a} μmol/mL (P<0.05, pooled standard error = 0.03).

In addition to the major effects of zinc deficiency and feed restriction on the relative content of individual n-6 and n-3 PUFA in erythrocyte membrane and plasma phospholipids, dietary zinc deficiency had distinctive effects on the levels of 20 and 24 carbon n-9/n-7 monoenes in phospholipids and free fatty acids in plasma and in the erythrocyte membrane. For example, the 20:1n-9/20:1n-7 ratio in ghost total phospholipids is 0.374^{a}, 0.471^{ab}, 0.503^{ab} and 0.772^{b} (P<0.05, pooled standard error = 0.04) for −Zn, +ZnRF, +ZnPF and +ZnAL, respectively. Plasma FFA has a 20:1n-9/20:1n-7 ratio of 0.187^{a}, 0.301^{a}, 0.566^{b} and 0.617^{b} (P<0.05, pooled standard error = 0.03), while plasma PC has 0.228^{a}, 0.263^{a}, 0.477^{a} and 0.972^{b} (P<0.05, pooled standard error = 0.03). Similarly, plasma SPH has 22:1n-9/22:1n-7 ratios of 0.125^{a}, 0.256^{a}, 0.303^{a} and 0.64^{b} (P<0.05, pooled standard error = 0.04) while it has a 24:1n-9/24:1n-7 ratio of 6.89^{a}, 8.4^{ab}, 13.1^{bc} and 15.0^{c} (P<0.05, pooled standard error = 0.68). SPH in erythrocyte ghosts had non-detectable levels of 22:1n-7 and 24:1n-7 in all groups.

DISCUSSION

The role of zinc in lipid and fatty acid metabolism and in biomembranes has been reviewed recently (4). It is clear that the effect of dietary Zn deficiency on lipid metabolism in rats depends upon the age and sex of the rat, the composition of the diet and the length and severity of the deficiency. The model for short-term severe Zn deficiency in the rat used in our study is an extension of one of the original models that defined an interaction of Zn and EFA in the rat (2). Extensive data on the feed consumption and eating pattern of rats on this dietary regimen have been described (35,36); a discussion of the results is limited to this model of dietary Zn deficiency.

The lipid composition of the rat erythrocyte membrane is uniquely controlled. Mature erythrocytes are incapable of synthesizing cholesterol, phospholipids or fatty acids from simple precursors. The cholesterol content of the membranes of mature erythrocytes can be increased by assimilation from cholesterol-enriched plasma lipoproteins. The composition of the molecular species of individual phospholipids in mature erythrocytes can be altered by exchange and/or assimilation of PC and LPC from the plasma pool. Mature erythrocytes have a variety of base exchange reactions and phospholipases which could, in theory, modulate the relative concentration of individual phospholipid species within the membrane. Finally, free fatty acids can be taken up from plasma and incorporated into lysophospholipids (37–39). The data in this report must be interpreted with several facts kept in mind. First, though the dynamics of erythrocyte production (hematocrit/reticulocyte count) and the volume of individual red cells (MCV) is dramatically altered by the severe feed restriction that occurs in zinc deficiency in this experimental system (40), the 'age' of the circulating red

cells, as determined by cell density, is not significantly altered (40). Second, dietary zinc deficiency and severe feed restriction apparently have pronounced effects on plasma lipids and lipoprotein composition but this effect is difficult to precisely define because of the lability of the composition of the plasma lipid pool. An additional complication stems from the fact that Zn-adequate, pair-fed rats are 'meal-feeders', an eating pattern which has pronounced effects on lipid metabolism (41,42). However, a consistent finding in rats is that plasma cholesterol concentration is not elevated in dietary Zn deficiency, and, in some cases, is depressed relative to *ad libitum*-fed controls (4,5,43).

The relative concentration of phospholipids in rat plasma, described for *ad libitum*-fed zinc adequate rats, is in close agreement with the values reported by Diagne *et al.* (44) and Nelson (45). In rat serum, the major phospholipids are in descending order: PC > LPC > SPH > PI > PE. PS is virtually non-detectable in plasma, in agreement with the report of Diagne *et al.* (44) and Nelson (45), but in contrast with the report of Cunnane (46), which suggests that PC and PS are the two main phospholipid subclasses in serum. The LPC fraction of rat plasma has a fatty acid composition suggesting that a significant portion of the fraction is 2-position LPC. In fact, the single spot from our acid-TLC solvent plate can be resolved into two spots on an alkali one-dimensional plate. These spots have fatty acid compositions suggestive of 1- and 2-position LPC (data not shown). The phospholipid composition of the rat erythrocyte membrane is in close agreement with that reported by others (44,47). The cholesterol/phospholipid ratio in the erythrocyte membrane from our study is similar to the values reported by most researchers (48–52); however, it is less than that reported by Johanning and O'Dell (53). Our data on phosphatidylcholine fatty acid composition are similar to reported values (48,49, 53–55) and the summation of our data on PE plasmalogen plus PE (other) resembles the fatty acid composition of total PE reported by other workers (49,53–55). Rao *et al.* (54) report very high levels of 22 carbon PUFA in PI, while our data suggest that PI from rat erythrocytes has low levels of 22 carbon PUFA and consists largely of 18:0 and 20:4n-6 in approximately a 1:1 ratio. Our data and those of Rao *et al.* (54) are consistent in suggesting that PS is the phospholipid in erythrocyte membranes that is most enriched with 20:4n-6, containing roughly 50 mole % arachidonic acid. This may imply a special role for arachidonyl-containing PS or for molecular species of PS containing 20-carbon PUFA in both the 1- and 2-position in this membrane. The fatty acid composition we determined for sphingomyelin is similar to that reported by Rao *et al.* (54), but contains far more 24-carbon fatty acids than reported by Innis (49) and Moses and Craig (55). Sphingomyelin in erythrocyte membranes is apparently enriched with 24:2n-6 in the rat and other species when there is a high dietary intake of 18:2n-6 (54,56,57); the function of molecular species of sphingomyelin containing this unusual fatty acid is unknown (56,58–60). The unsaturation index of total erythrocyte membrane phospholipids is similar to the index that can be calculated from the data by Moses and Craig (55).

Dietary zinc deficiency in rats does not cause changes in lipid composition of the erythrocyte membrane that would predict an increased mobility of lipid phase probes. Of the three major indices that have some predictive value of membrane fluidity (Chol/PC, PC/SPH, and UI) (61,62), only the cholesterol/phospholipid ratio is significantly altered compared to *ad libitum*-fed, but not pair-fed, controls. However, in the erythrocyte membrane from Zn-deficient rats the cholesterol/phospholipid ratio is elevated, a condition which would predict a decreased mobility of spin or fluorescent probes. Cholesterol/phospholipid ratios have been reported to be elevated in liver (6,7,16), intestine (7), erythrocyte (53) and testes (6) membrane fractions from zinc-deficient and pair-fed, zinc-adequate control rats. This is consistent with reports of decreased fluidity of the lipid phase in liver microsomal membranes (6,14). The report of increased fluidity in erythrocyte membranes (15) is opposite to the effect predicted by an elevated cholesterol/phospholipid ratio. By contrast, dietary zinc deficiency, *per se*, results in a significantly lower unsaturation index of total membrane dimethylacetals. It does not alter the content of total membrane plasmalogens (data not shown). The impact of these changes is unknown. Recently, it has been demonstrated that plasmalogens may play a unique role in determining membrane fluidity (63). Finally, zinc-deficient and feed restricted rats may have relatively equivalent values of 'total' membrane fluidity but may have a significant alteration of membrane fluidity in the inner and outer layer of the membrane. Erythrocyte membranes are distinctly sided in their phospholipid composition; rat erythrocyte membranes have been reported to have 62–63% of their PC, all of their SPH and 20% of their GPE directed toward the outer surface (64,65). It has been demonstrated that erythrocyte membranes actively maintain this asymmetry by an energy-requiring process and this causes a distinctly lower 'fluidity' in the outer *vs.* the inner membrane leaflet (66,67). In zinc deficient and feed restricted rats, erythrocytes have an increased double bond index in their alkenylacyl GPE (Table 3) and a decreased double bond index (Table 8) in their SPH. This could result in decreased fluidity in the outer layer and an increased fluidity in the inner layer which are 'masked' when measuring total membrane fluidity by various methods. Such an alteration would have an unknown relationship to the alterations in cell size (40) and cell filterability (68) which are attributed to the effect of feed restriction in dietary zinc deficiency.

The changes in lipid composition seen in the erythrocytes from zinc-deficient rats give conflicting predictions about osmotic fragility (69–71) and fragility due to certain hemolysins (71). Osmotic fragility has been inversely correlated to 18:1 content of the total erythrocyte membrane phospholipids in the rat (47,72). In this study we have demonstrated that erythrocytes from zinc deficient rats have a significantly reduced ($P<0.05$) content of 18:1 in total erythrocyte membrane phospholipids; 7.54^{a}, 7.51^{a}, 7.86^{ab} and 8.38^{b} mole % in −Zn, +ZnRF, +ZnPF and +ZnAL rats, respectively. However, the increased osmotic fragility of erythrocytes of zinc-deficient rats has been demonstrated to be reversed by two days of zinc supplementation *in vivo* (53); our data suggest that total phospholipid 18:1 is not increased by zinc supplementation over this time period. An elevated cholesterol/phospholipid ratio has generally been associated with decreased osmotic fragility of erythrocytes (52,73,74). In both this study and another, erythrocytes of zinc-

deficient rats, while having increased osmotic fragility (70,71), have been shown to have significantly elevated cholesterol/phospholipid ratios (53). Finally, erythrocytes from zinc-deficient rats which are also deficient in vitamin E have increased H_2O_2-induced fragility as compared to zinc-adequate, vitamin E-deficient controls (9). Membranes from erythrocytes of zinc-deficient, six-week-old rats are enriched in 22-carbon n-3 PUFA. These fatty acids in phospholipids are likely to be the most extensively peroxidized in a membrane fraction (75,76); vitamin E has been suggested to be more effective in protecting n-6 PUFA from peroxidation than n-3 PUFA (75). The 22-carbon n-3 PUFA content of erythrocyte membranes may be a variable in the observed effects of zinc deficiency on membrane peroxidative fragility (9,77).

The major effects of dietary zinc deficiency on the fatty acids of phospholipids in the erythrocyte membrane can be attributed to the effects of the voluntary drop in food intake associated with the deficiency (78). In short, these effects are dominated by elevated 22-carbon n-3 PUFA and depressed 22-carbon n-6 PUFA relative to *ad libitum*-fed controls. Effects on sphingomyelin, in plasma and erythrocyte membranes, are marked by a depression of the mole % of 24:2n-6. The effect on PC in plasma and red cells is unique, 18:2n-6 is elevated and 20:4n-6 is depressed (53). These general effects can be characterized as an inhibition of the developmental shift to 22-carbon n-6 PUFA from 22-carbon n-3 PUFA in rapidly growing rats fed diets containing 10% corn oil. For example the total phospholipid n-3 PUFA/n-6 PUFA ratio is 2.38 in rat erythrocyte from weanling rats (experimental time zero), while it is 5.20^a in ZnD, 5.08^a in ZnR, 5.81^bin ZnPF and 9.17^c in ZnAL. Similarly, the large effect of feed restriction on the unsaturation index of the total membrane dimethylacetals is 0.17 in time zero, while it is 0.22^a in ZnD, 0.23^{ab} in ZnR, 0.27^b in ZnPF and 0.36^c in ZnAL. Growth inhibition caused by a lack of food intake impairs normal developmental processes associated with the dietary fat. A similar phenomenon may occur with the 20-plus carbon n-9/n-7 monoenes, because of the abundance of 18:1n-9 relative to 16:1n-7 in corn oil. The dampening effect of dietary Zn deficiency on diet-induced changes in tissue fatty acid composition has recently been reported; rats fed fat-free diets have a slower rate of arachidonate depletion and Mead acid build-up when they are zinc-deficient compared to zinc-adequate controls (79). The lack of food intake associated with dietary zinc deficiency resists the influence of dietary fat composition on cell membrane lipid composition. Our data on the fatty acid composition in the erythrocyte membrane and on blood plasma support the concept that zinc deficiency has minimal effects on PUFA distribution in the major phospholipids of the erythrocyte membrane relative to pair-fed controls. However, a relatively normal PUFA distribution may be maintained in erythrocytes of Zn-deficient rats by depleting arachidonic acid in plasma and in other pools (Tables 9 and 11). Refeeding zinc in the diet while limiting food intake for a 3-day period caused no significant change in erythrocyte membrane lipid composition but caused a normalization of the mole % of plasma FFA 20:4n-6 and an elevation of the plasma PC/SPH ratio. The biochemical basis for the interaction of zinc and EFA, in this model of short-term, severe dietary Zn deficiency (2), remains an enigma.

Effect of Dietary α-Linolenate/Linoleate Balance on Endotoxin-Induced Hepatitis in Mice

Shiro Watanabe* and **Harumi Okuyama**
Department of Biological Chemistry, Faculty of Pharmaceutical Sciences, Nagoya City University, Mizuhoku, Nagoya, 467 Japan

Mice were fed diets with three different ratios of α-linolenate (18:3n-3) to linoleate (18:2n-6), and the severity of hepatitis during endotoxic shock was compared. Dietary enrichment with α-linolenate increased the severity of hepatitis and the mortality induced by lipopolysaccharide (LPS) in combination with D-galactosamine (GalN). Differences in the dietary α-linolenate/linoleate balance were mainly reflected in the levels of arachidonate and eicosapenatenoate in liver phospholipids. Pretreatment of mice with indomethacin was found to also enhance the severity of GalN/LPS-hepatitis. This indicated that cyclooxygenase products of arachidonate may suppress the development of GalN/LPS-hepatitis. The enhancement by high α-linolenate diets was not observed when a lethal dose of LPS in the absence of GalN was given. Our results indicate that there are pathophysiological conditions of endotoxin-induced hepatitis under which cyclooxygenase products of arachidonate play protective roles.
Lipids 26, 467-471 (1991).

Bacterial lipopolysaccharide (LPS) is known to cause endotoxic shock in experimental animals; this effect is accompanied by widespread tissue damage (1,2). The circulating levels of prostaglandins and thromboxane are elevated during the development of endotoxic shock, and the pathological changes can be reduced with cyclooxygenase/lipoxygenase inhibitors (3-6). These observations suggested that eicosanoids derived from arachidonate (20:4n-6) stimulated the development of the LPS-induced endotoxic shock.

Several species of rodents are known to be relatively resistant to LPS, but treatment with LPS plus D-galactosamine (GalN) considerably increases their sensitivity to the toxic effect of LPS (7). This GalN/LPS-induced endotoxin shock model is reported to exhibit characteristics common to human fulminant hepatitis (8). In this GalN/LPS model, several lipoxygenase inhibitors were shown to be effective in suppressing the development and lethality of hepatitis (8-10).

Linoleic acid (18:2n-6) and α-linolenic acid (18:2n-3) are desaturated and elongated to form arachidonate (20:4n-6) and eicosapentaenoate (20:5n-3) (EPA), respectively. Both linoleate and α-linolenate compete with each other in the elongation/desaturation systems (11). Both arachidonate and EPA are precursors for eicosanoid synthesis. However, EPA is known to competitively inhibit the incorporation of arachidonate into phospholipids (12) and the conversion of arachidonate into eicosanoids (13,14). In addition, eicosanoids derived from eicosapentaenoate are generally less potent than those derived from arachidonate (13-15). Therefore, the relative proportions of linoleate and α-linolenate in diets could directly affect the proportions of arachidonate and eicosapentaenoate in cellular phospholipids, thereby modulating the eicosanoid balance and resultant cellular physiology (16,17).

The purpose of the present study was to clarify whether or not the dietary α-linolenate/linoleate balance affects the severity of tissue damage during endotoxic shock. A mouse hepatitis model was used in which hepatitis was induced by LPS in the presence and absence of D-galactosamine.

MATERIALS AND METHODS

Animals and feeding protocols. Three-week-old, male C57BL/6 and ICR mice (Sizuoka Laboratory Animal Co., Ltd., Shizuoka, Japan) were randomly divided into three groups and were fed diets with three different ratios of α-linolenate to linoleate (Table 1) for 5-6 weeks and 4-5 weeks, respectively. The test diets were supplemented with: i) α-linolenate rich perilla seed oil; ii) linoleate rich safflower seed oil; or iii) a mixture (65:35, w/w) of perilla oil and safflower oil. The basal diet was prepared by extracting conventional laboratory diet (CE-2, Nippon Clea Co., Tokyo, Japan) with n-hexane by a method commonly used to prepare vegetable oils, and then supplementing the defatted diet with a vitamin mixture (2%, w/w) (Nippon Clea Co., Tokyo, Japan) and the above-mentioned oils (10%, w/w) (18,19). The vitamin mixture supplement contains (per 100 g diet) vitamins A (2400IU), D_3 (480IU), B_1 (3 mg), B_2 (3 mg), B_6 (2 mg), B_{12} (10 μg), E (20 mg), K (0.4 mg), biotin (0.2 mg), dl-pantothenic acid (4 mg), *p*-aminobenzoic acid (20 mg), nicotinamide (20 mg), inositol (30 mg), folic acid (0.4 mg) and choline chloride (600 mg). The validity of using these diets was assessed by examining the reproductive physiology and the growth rates of

the offspring (20). The diets had peroxide values below 50 meq/kg.

Induction of endotoxic shock and the assessment of hepatitis. In C57B1/6 mice, GalN (Sigma, St. Louis, MO) and LPS (*Salmonella abortus equi*, Sigma) dissolved in physiological saline were injected i.p. at doses of 300 mg/kg and 10 μg/kg, respectively. The severity of the hepatitis was evaluated by measuring alanine aminotransferase (ALT) and sorbitol dehydrogenase (SDH) (21,22) in serum from treated mice 5 hr after injection of GalN/LPS. In ICR mice, 833 mg GalN/kg was required to induce an acute hepatitis by LPS at a dose of 33 μg/kg, and the severity of hepatitis was evaluated 6 hr after the administration of GalN/LPS. Mortality was determined at LPS doses of 0.33, 3.3 and 33 μg/kg in combination with 833 mg GalN/kg in ICR mice fed the test diets. When LPS alone was used, higher doses of LPS (−10 mg/kg) were necessary to induce a significant hepatitis. In this endotoxin shock model, serum ALT activity was measured at 24 hr and the mortality was observed for up to 72 hr after the i.p. injection of LPS. In one experiment, LPS from *Eschericha coli* (055: B5, Difco, Detroit, MI) was also used.

Indomethacin treatment. One hour prior to injection of GalN/LPS, indomethacin (Wako Pure Chemical Co., Osaka, Japan) dissolved in 1/15 M phosphate buffer (pH 8.0) was injected i.p. at doses of 1 and 10 mg/kg into ICR mice (nine-weeks-old) fed a conventional laboratory diet (CE-2, Clea, Tokyo, Japan).

Analysis of fatty acid composition of liver phospholipids. At the end of feeding the test diets, mouse livers were harvested and stored at −80°C until analyzed. The liver was homogenized with chloroform/methanol (1:2, v/v), and the total lipids were extracted according to the method of Bligh and Dyer (23). Phospholipid fractions were separated on Silica Gel thin-layer chromatography (TLC) using a solvent system of chloroform/methanol/acetic acid/water (25:15:4:2, by vol). Phosphatidylethanolamine and phosphatidylcholine were located by spraying with an ethanolic Rhodamine solution (0.03%, w/v) and were recovered from the adsorbent by extracting with chloroform/methanol/6%-ammonium hydroxide (6:5:1, v/v/v). Fatty acids in phosphatidylethanolamine and phosphatidylcholine were transesterified by heating with 5% HCl/methanol (100°C, 1 hr) and were analyzed by gas-liquid chromatography on a capillary column coated with Supelcowax-10 (0.25 mm diameter, 30 m length, Supelco Ltd., Bellefonte, PA). Fatty acid methyl esters were identified by comparing the retention times with those of authentic standards (Supelco). Heptadecanoate (17:0) was used as an internal standard.

Statistical analyses. Statistical analyses of the data were carried out using Student's *t*-test. The values for the serum ALT and SDH activities in mice injected with GalN/LPS were logarithmically transformed and then analyzed, while those in mice injected with LPS alone were directly analyzed. Mortality rates were compared by using Fisher's exact test.

RESULTS

Effect of dietary fatty acids on GalN/LPS-induced hepatitis. Serum ALT and SDH levels of C57B1/6 mice were elevated more than 100- and 85-fold, respectively, at 5 hr after i.p. injection of GalN/LPS (300 mg/kg and 10 μg/kg) (Figs. 1a and 1b) in all the dietary groups. Serum ALT and SDH activities were found to be significantly higher in the high α-linolenate group than in the high-linoleate group ($p<0.01$ and $p<0.05$, respectively). The group fed the mixed diet showed intermediate levels of both enzyme activities, although the differences were not statistically significant. Contrary to C57BL/6 mice, ICR mice did not develop acute hepatitis at a GalN dose of 300 mg/kg, even when the dose of LPS was increased to 1.5 mg/kg (data not shown). However acute hepatitis was induced in ICR mice by injecting a higher dose of GalN (833 mg/kg) in combination with 33 μg LPS/kg. Thus, the responsiveness to GalN/LPS in terms of inducing acute hepatitis was different between the two strains of mice. Nevertheless, similar differences in the severity of GalN/LPS-induced hepatitis were observed among the three dietary groups; the serum ALT activities 6 hr after GalN/LPS injection in ICR mice fed the high α-linolenate diet (1023 ± 1181 U/L, n = 8) and the mixed diet (659 ± 472 U/L, n = 8)

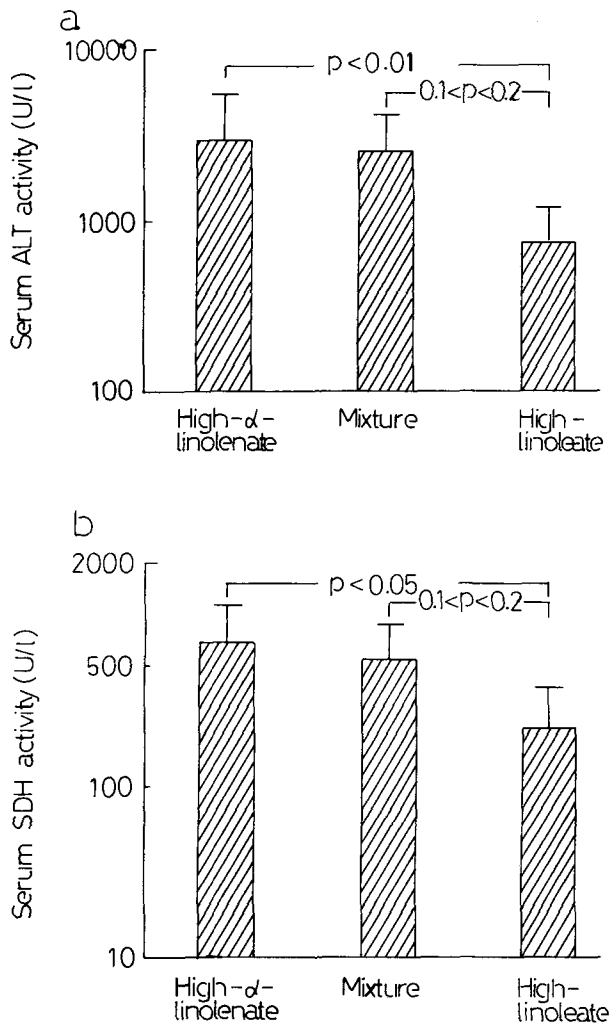

FIG. 1. Serum alanine aminotransferase (ALT) (a), and sorbitol dehydrogenase (SDH) (b), activities in male C57BL/6 mice 5 hr after i.p. injection of GalN/LPS (300 mg/kg and 10 μg/kg). From 8 to 9 mice in each group were used. The serum ALT and SDH activities from untreated mice were below 30 and 10 U/L, respectively. There was no difference in serum ALT and SDH activity in the untreated mice among the dietary groups tested.

were significantly higher than the ALT activity of mice fed the high linoleate diet (236 ± 174 U/L, n = 8, $p<0.05$).

Since diets enriched in α-linolenate increased the severity of GalN/LPS-induced hepatitis, the mortality during the development of hepatitis was also compared among the three dietary groups (Fig. 2). When LPS was injected at doses of 33 and 3.3 μg/kg in combination with 833 mg GalN/kg, more than 80% of the treated mice died within 7 to 12 hr after GalN/LPS injection (Figs. 2a and 2b). However, at an LPS dose of 0.33 μg/kg combined with 833 mg GalN/kg, mice in the high α-linolenate group and the mixture group died more rapidly after GalN/LPS injection than in the high-linoleate group (Fig. 2c). Cumulative mortalities 24 hr after GalN/LPS injection were statistically higher both in the high α-linolenate and the mixed diet groups ($p<0.02$ and $p<0.05$, respectively) than in the high linoleate diet group.

Fatty acid compositions of liver phospholipids. The fatty acid composition of liver phosphatidylethanolamine samples from ICR mice fed the three test diets are shown in Table 2. Differences in the dietary α-linolenate/linoleate ratios did not cause changes in the proportions of unsaturated and saturated fatty acids in the phospholipids or in the liver contents of phosphatidylethanolamine. The α-linolenate/linoleate ratios of diets were, however, reflected in the proportions of n-3 and n-6 polyunsaturated fatty acids in the phospholipids. The most notable differences among the three dietary groups were found in the levels of arachidonate (20:4n-6) and eicosapentaenoate (20:5n-3), with a smaller difference in the proportions of 22:5n-3. The docosahexaenoate (22:6n-3) contents were essentially unchanged by these diets. Similar differences in the fatty acid composition were also found in phosphatidylcholine of liver from mice fed the three test diets (data not shown).

Effect of indomethacin pretreatment of hepatitis induced by GalN/LPS. The findings that dietary enrichment with α-linolenate reduced arachidonate levels in liver phospholipids and accelerated GalN/LPS-induced hepatitis suggested that arachidonate metabolites play protective roles ameliorating the development of GalN/LPS-induced hepatitis. Therefore, we evaluated the effect of pretreatment with indomethacin, a cyclooxygenase inhibitor, on the severity of GalN/LPS-induced hepatitis. Pretreatment

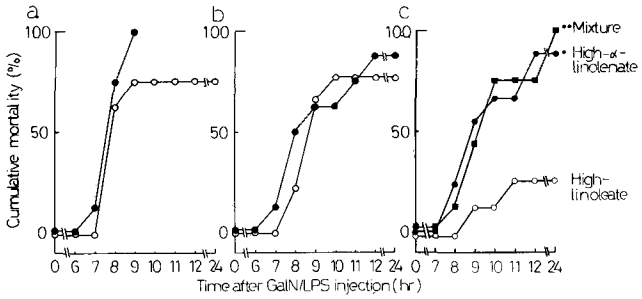

FIG. 2. Mortality of male ICR mice injected with LPS. Eight to nine mice were injected with LPS at doses of (a) 33, (b) 3.3 and (c) 0.33 μg/kg in combination with GalN (833 mg/kg). Cumulative mortalities were not different between the high α-linolenate (●) and the high linoleate (○) groups (a and b). At an LPS dose of 0.33 μg/kg (c), cumulative mortalities in the high α-linolenate group and the mixture group (■) were significantly higher(*, $p<0.02$; and **, $p<0.005$; respectively) than in the high linoleate group.

of mice fed a conventional laboratory diet with doses of indomethacin of either 1 or 10 mg/kg was found to significantly accelerate the GalN/LPS (833 mg/kg and 33 μg/kg)-induced hepatitis in a dose-dependent manner (Fig. 3a). The mortality induced by a lower dose of LPS (0.33 μg LPS-833 mg GalN/kg) tended to be enhanced by the pretreatment with indomethacin, but the difference was not statistically significant (Fig. 3b). These results were inconsistent with the observation of protective effects of eicosanoid synthesis inhibitors on hepatic damages induced by LPS alone. Therefore, we next examined the effect of the dietary α-linolenate/linoleate balance on hepatitis induced by injection of LPS alone.

By using male ICR mice fed a conventional laboratory diet, the minimum dose of LPS needed to induce 100% death was found to be 10 mg/kg LPS *(Salmonella abortus)* and 20 mg/kg LPS *(Escherichia coli)*. The onset of death was delayed 12 hr beyond the LPS injection. The severity of hepatitis was evaluated 24 hr after the injection of 10 mg/kg of LPS *(S. abortus)*. Only a moderate increase in ALT activities was observed and there was no statistically significant difference among the three dietary groups (Table 3). The mortalities induce by LPS *(S. abortus)* and LPS *(E. coli)* were followed for 72 hr (Fig. 4). No

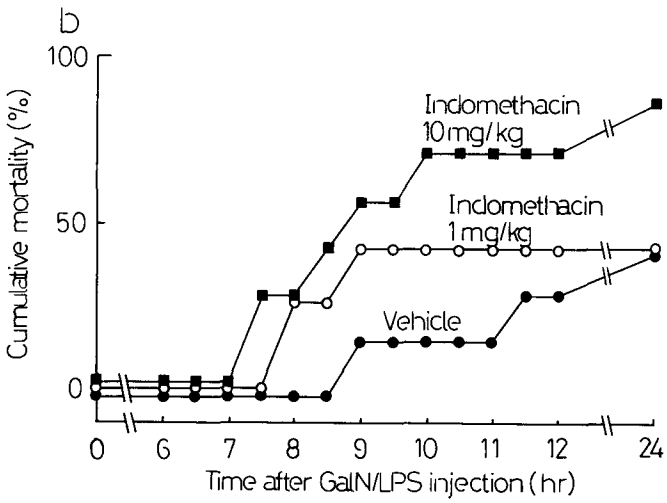

FIG. 3. Effects of pretreatment of mice with indomethacin on GalN/LPS-induced hepatitis. Male ICR mice fed a conventional laboratory diet were injected i.p. with indomethacin (1 and 10 mg/kg, i.p.) 1 hr prior to the injection of GalN/LPS. The serum ALT activity (a) 6 hr after i.p. injection of GalN/LPS (833 mg/kg and 33 μg/kg) in the high dose group (10 mg indomethacin/kg, n=6) was significantly higher ($p<0.01$) than in the vehicle group (n=7). However, statistically significant difference was not observed between the low dose group (1 mg indomethacin/kg, n=6) and the vehicle group ($0.05 < p < 0.1$). Mortalities (b) in the low dose (n=7) and high dose (n=7) groups tended to be higher than in the vehicle group (n=7), but the differences were not statistically significant.

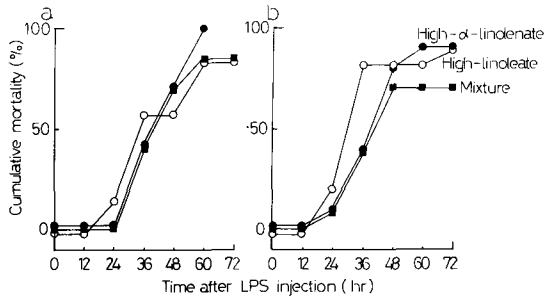

FIG. 4. Mortality of male ICR mice fed the test diets after i.p. injection of LPS alone. Male ICR mice fed the test diets were injected i.p. with LPS from *S. abortus* (a) or *E. coli* (b) at doses of 10 or 20 mg/kg, respectively. There was no difference in the mortality rates among the three dietary groups.

difference was found in the mortality rates of the three dietary groups when LPS *(S. abortus)* was used. With LPS *(E. coli)*, the patterns of the mortality rates were generally similar to those induced with LPS from *S. abortus*, but the rate was slightly higher in the high-linoleate group than in the other two dietary groups at 36 hr after the injection of LPS *(E. coli)* ($0.05<p<0.01$).

DISCUSSION

In general, dietary n-3 fatty acids suppress the production of eicosanoids from n-6 fatty acids; moreover, 20 carbon n-3 fatty acids are themselves converted to eicosanoids with relatively lower physiological activities. In the present experiments, dietary enrichment with α-linolenate was shown to exert relatively little effect on LPS *(S. abortus)*-induced hepatitis and a slight suppressive effect on LPS *(E. coli)*-induced hepatitis (Fig. 4); these same effects are seen when mice are pretreated with low doses of aspirin (4).

Elevated responsiveness of mice to LPS toxicity induced by GalN treatment results from enhancement of host susceptibility to tumor necrosis factor (TNF) (24), a known crucial mediator of LPS toxicity (25,26). TNF production in macrophages is stimulated by the 5-lipoxygenase products of arachidonate, the leukotrienes (27). In contrast, prostaglandin E_2, one of the major cyclooxygenase products of macrophages, is reported to be an endogenous suppressor of macrophage TNF production (28), and plays protective roles in target organs (29). Furthermore, the prostaglandin I_2/thromboxane A_2 balance is known to affect the severity of endotoxic shock (4). Thus, the balance of cyclooxygenase and lipoxygenase products of arachidonate appears to affect the severity of hepatitis.

Both dietary enrichment with n-3 fatty acids and indomethacin pretreatment enhanced the severity of GalN/LPS-induced hepatitis in mice (Figs. 1–3), which suggests that these treatments suppressed the production of protective eicosanoids, such as prostaglandin E_2 and I_2, relatively more than that of stimulatory eicosanoids, such as leukotrienes. Consistent with this interpretation is the

observation that feeding with fish oils enriched in n-3 fatty acids suppressed prostaglandin E_2 production effectively, but not leukotriene B_4 production, in mouse peritoneal macrophages, leading to the enhancement of the footpad anaphylactic response (30). Another study also showed that fish oil supplement affected B_4/B_5 ratios of leukotrienes in macrophages (31). In fact, the protective effects of prostaglandin E_2 or E_1 on viral hepatitis have been shown both in mice (32) and in humans (29). Very recently, we demonstrated that α-linolenate rich diet increased LPS-induced TNF production in mouse peritomeal macrophages (33).

Recent studies in our laboratory have revealed beneficial effects of feeding high α-linolenate diets in preventing several kinds of chronic diseases in animals (18,34-38). However, as shown in the present study, feeding a high α-linolenate diet had a detrimental effect in GalN/LPS-induced hepatitis. Although the applicability of GalN/LPS-induced hepatic damage in mice to human diseases is not certain, these results establish that there are pathophysiological conditions under which eicosanoids derived from n-6 fatty acids play protective roles.

Study on the Lipid Composition of Aging Fischer-344 Rat Lymphoid Cells: Effect of Long-Term Calorie Restriction

Serge Laganiere[1] and **Gabriel Fernandes***
Department of Medicine, The University of Texas Health Science Center at San Antonio, San Antonio, Texas 78284-7874

Long-term calorie restriction (LCR) is widely known to increase the survival rate of laboratory rodents and appears to retard the aging and senescence process. The present study was undertaken in Fischer-344 male rats maintained on *ad libitum* (AL) or LCR (40% less food intake than AL starting at 6 weeks of age). Age-associated changes in the proliferative response of lymphoid cells to mitogenic stimuli were studied in relation to alterations in the fatty acid composition of adherent and non-adherent-enriched subpopulations of spleen cells. Increases in spleen cell long-chain highly unsaturated fatty acids (20:4, 22:4 and 22:5) were accompanied by decreases in linoleic acid (18:2) in aging AL-fed rats. However, LCR stabilized levels of 18:2 and prevented the rise in highly unsaturated fatty acids. In addition, LCR markedly modulated the fatty acid profiles of thymocytes and bone marrow cells. A 70% decline in concanavalin A (Con A) stimulated [^{3}H]thymidine uptake of spleen cells from AL animals was normalized by LCR. Splenic reduced glutathione (GSH), a potential modulator of the mitogenic response, was unaffected by age and nutritional regimen. Thus, normalization of lymphoid cell fatty acid composition by LCR parallels the preservation of mitogenic responsiveness to Con A.
***Lipids 26,* 472–478 (1991).**

Long-term calorie restriction (LCR) is a powerful nutritional intervention that increases both the mean and maximum lifespan of laboratory rodents. LCR retards, attenuates or abolishes the age-related decline of many immunological (1–3) and physiological functions (4,5) as well as autoimmune disease and malignant diseases (6,7). The underlying mechanisms for prolongation of longevity by calorie restriction are still unknown. Recent reports have emphasized that LCR can influence age-associated changes in neuroendocrine hormones, free radicals, gene expression and several immune functions. Previous observations have demonstrated that LCR-induced delay in age-related loss of immune function correlates with preservation of lymphoid cell proliferative responsiveness in various strains of mice and rats (3,8,9).

Reactivity of lymphoid cells can be affected by dietary fatty acid composition (10–13). Therefore, we hypothesized that the age-related decline in immune response may be associated with age-related alterations in the lymphoid cell subsets and their composition of fatty acids and that LCR can reverse age-related immune deficiency by modulation of both Interleukin-2 (IL-2) receptors and IL-2 production (14,15). Our hypothesis is also based primarily on our recent finding that LCR can prevent age-related changes in subcellular membrane lipid composition of liver tissue (16). The present detailed studies show effects of diet and aging on lymphoid cell fatty acid composition, mitogenic response and GSH levels. Implications of age-related changes in membrane lipids and the role of LCR in maintaining immune function throughout the lifespan are further discussed in this paper.

MATERIALS AND METHODS

Animals and diet. Male specific-pathogen-free Fischer-344 rats (Charles River Lab, Portage, MI), 28 ± 2 days of age were maintained in a barrier facility. They were housed singly in plastic cages with wire mesh floors suspended on the Hazelton-Enviro Rack System (Hazelton Systems, Inc., Aberdeen, MD). The procedures for monitoring and operating the barrier facility and composition of the diets (Table 1) have been reported in detail previously (5).

All weanling rats were fed Diet A (Ralston-Purina, St. Louis, MO) *ad libitum* (AL) until six weeks of age. Afterwards, only rats belonging to the AL-fed group were continued on Diet A until they were sacrificed. Calorie restricted rats (LCR) were provided Diet B in daily allotments, 60% of the mean amount of diet consumed by the AL-fed group cohort, which was measured regularly from 6 weeks until 18 months of age. Thereafter, the caloric intake of the LCR rats was maintained at the 18-month level of intake. Food intake, body weight, organ weight and lifetime caloric intake did not differ significantly from previous reports (5). Diet B was identical to Diet A, except that the concentration of dietary supplements (vitamin, minerals and choline, Ralson Purina) was modified in order to provide both groups of rats with the same intake. Dextrin concentration was adjusted to meet the restricted caloric requirements. Both AL-fed and LCR rats were provided their daily food allotment about 1 hr before the start of the dark phase of a 12-hr light/12-hr dark

TABLE 1

Composition of Diets[a]

Dietary components	Diet A (%)	Diet B (%)
Casein (vitamin-free)	21.00	21.00
Sucrose	15.00	15.00
Dextrin	43.65	39.55
Corn oil	10.00	10.00
Mineral mix	5.00	7.64
Vitamin mix	2.00	3.33
Choline chloride	0.20	0.33
DL-methionine	0.15	0.15
Solka-Floc	3.00	3.00

[a]The concentration of the vitamin, mineral mixes and choline chloride in Diet B was modified to provide a daily intake that is the same as the mean intake of the rats fed on Diet A.

[1]Present Address: Department of Pharmacology and Experimental Therapeutics, Loyola University Chicago, 2160 First Avenue, Maywood, IL 60153.

Abbreviations: AL, *ad libitum*; Con-A, concanavalin A; FBS, fetal bovine serum; GSH, glutathione; IL-2, Interleukin-2; LCR, long-term calorie restriction; PBS, phosphate-buffered saline.

cycle in order to maintain their circadian-based normal feeding pattern throughout the study.

Lymphoid cell isolation. Rats under anesthesia were sacrificed by exsanguination. Spleen and thymus were aseptically collected only from those rats which were visibly tumor-free. Connective tissue was removed and single cell suspensions were prepared. Briefly, the minced tissue was gently homogenized in complete RPMI-containing medium at room temperature and the cell suspension was centrifuged at 100 × *g* and washed three times in RPMI. The cell suspension free of debris was placed on plastic Petri dishes, that had been coated previously with 10% fetal bovine serum (FBS), and was incubated for 2 hr at 37°C, and the non-adherent cell fraction was obtained by washing with warm (37°C) phosphate-buffered saline (PBS). Adherent spleen cells were scraped off and washed in cold PBS or RPMI at 4°C. To obtain a bone marrow-enriched fraction, femurs were removed and cleaned, and the bone cavity was tightly fitted to a needle and slowly flushed with cold PBS. Large clumps of cells were further dispersed through a 27-gauge needle, and cells were washed as described before. For each cell fraction, red blood cells were lysed using Tris/ammonium chloride solution.

Assessment of mitogenic response. Concanavalin A (Con-A) in appropriate serial dilutions, was used to measure *in vitro* mitogenic responses of splenocytes in microtiter plates as described previously (15).

Glutathione assessment. Total and reduced glutathione (GSH) were assayed spectrophotometrically by the enzymatic method of Anderson (17) and by the chemical method of Moron *et al.* (18), respectively.

Fatty acid analysis. Lipids were isolated by chloroform/methanol (2:1, v/v) extraction according to the procedure of Folch *et al.* (19). Extracted lipids were redissolved in chloroform/methanol (2:1, v/v). Fatty acid methyl esters were obtained by transesterification with methanolic HCl (90°C, 2 hr) (Alltech-Applied Science, Deerfield, IL). The esters were extracted and then redissolved in hexane and analyzed on a Hewlett-Packard Model 5880A gas chromatograph equipped with a fused silica megabore column (DB-225, J&W Scientific, Folsom, CA). Oven temperature was 205°C, the flame ionization detector was set at 250°C, and helium served as carrier gas at a flow rate of 9 mL/min. Peaks were identified by comparison of retention times with those of fatty acid standards (Nu-Check-Prep, Elysian, MN).

Data analysis. All data were compared by using multiple analyses of variance. Post-hoc analysis of individual group means was performed by the Duncan multiple-range test.

RESULTS

The body weights of the AL-fed and LCR animals are presented in Figure 1. LCR rats maintained a significantly lower body weight compared to AL animals throughout their lifespan. Although calories were restricted by 40%, LCR rats consumed between 0.13 and 0.15 kcal/g body weight/day after 6 months of age, which was very close to the amount of food consumed by the AL-fed rats (4,5). Therefore, it is of interest to analyze the possible relationship between immune function and the fatty acid

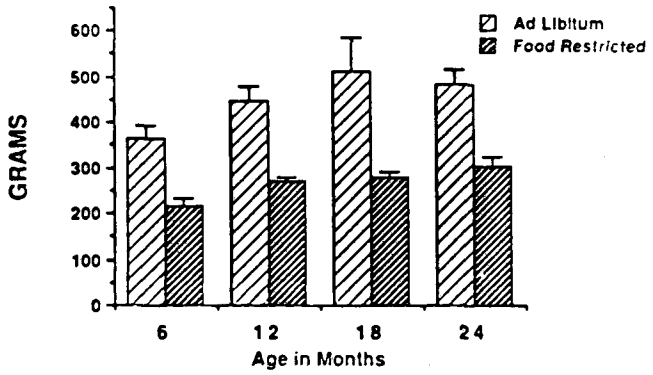

FIG. 1. Effect of aging and LCR on the body weights of rats.

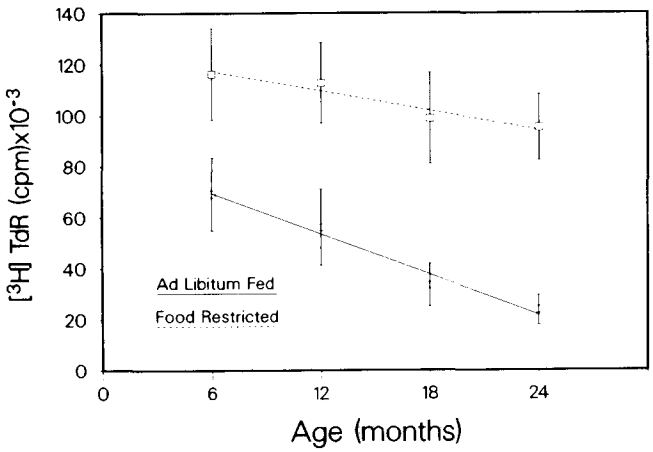

FIG. 2. Spleen cells from *ad libitum* and food restricted rats of various age groups were cultured at a concentration of 5 × 10^6 cells/mL for 48 hr in the presence of various levels of Con-A and pulsed with tritiated thymidine for a further 16 hr before harvest and thymidine uptake was determined. The results reported here are CPM obtained for optimal doses of Con-A (2.5 mg/mL) after subtracting background counts of medium alone, which ranged from 2000–4500 CPM.

composition of lymphoid cells from LCR rats and AL-fed controls (4,5).

The splenocyte mitogenic response to Con-A in aging rats is illustrated in Figure 2. The proliferative response decreased linearly ($r=0.59$, $p<0.005$) in AL-fed rats between the ages of 6 and 24 months. Approximately 70% of the proliferative response was lost during this age interval. In contrast, the slight reduction in Con-A-induced incorporation of [^{3}H]thymidine in LCR rat splenocytes was not statistically significant from 6 to 24 months of age (Fig. 2).

The effect of LCR on whole spleen fatty acid composition was first analyzed in animals of both dietary groups at 12 and 18 months of age and the results are presented in Table 2 and Figure 3. Spleen cell fatty acids were affected by calorie restriction in both age groups. Specifically, linoleic acid (18:2) was higher, whereas polyunsaturated fatty acyls such as arachidonic (20:4), docosatetraenoic (22:4) and docosapentaenoic (22:5) acids were lower in LCR rats as compared to AL rats (ANOVA

$p<0.01$, <0.05, <0.05 and <0.01, respectively). The saturated fatty acids 16:0 and 18:0 were also significantly lower in LCR rats than in AL-fed rats at 12 and 18 months of age ($p<0.05$ and <0.01, respectively.).

These findings were further investigated in isolated splenic lymphoid cells obtained from rats aged 6, 12, 18 and 24 months. Data pertaining to non-adherent spleen cells are presented in Table 3. None of the saturated fatty acids were modulated either by age or by calorie restriction. However, percent composition of 18:2, 20:4, 22:4 and 22:5 were found to be significantly affected by age in the lymphocyte-enriched fraction of aged AL-fed rats. Linoleic acid content decreased between 12 and 24 months of age, whereas 20:4, 22:4 and 22:5 levels increased steadily during this period in AL-fed animals ($p<0.01$, <0.01, <0.01 and <0.001, respectively). These age-related changes in fatty acid composition were completely prevented by LCR. Accordingly, linoleic acid was higher at 18 and 24 months ($p<0.01$) and 20:4 was significantly lower in the lymphocyte-enriched fraction of 24-month-old LCR rats. Levels of 22:4 and 22:5 remained significantly lower in LCR rats after six months of age.

Fatty acids of the adherent cells were also altered by age. The data presented in Table 4 and Figure 4 show that 18:1 and 18:2 progressively decreased from 6 to 24 months ($p<0.005$ and $p<0.001$, respectively) and that 22:4 ($p<0.01$) and 22:5 ($p<0.005$) levels increased steadily between 12 and 24 months of age in the AL-fed rats. Although 18:2 was also decreased with age in the LCR rats, levels of this fatty acid were consistently higher than in AL-fed rats, at all ages studied (ANOVA, $P<0.05$). Arachidonic acid content was significantly lower in LCR rats at 12, 18 and 24 months of age (ANOVA, $p<0.025$). However, no significant diet-related differences in 22:4 or 22:5 were noted during this age interval.

Interestingly, the fatty acid composition of bone marrow cells was not markedly altered by age in the AL-fed rats, as described in Table 5. On the other hand, except for 16:0, all of the major fatty acids were strikingly modulated by long-term calorie restriction. Higher levels of oleic and linoleic acids were found in LCR rat bone marrow cells at all ages tested (ANOVA, $p<0.01$). Also, 18:0, 20:4, 22:4 and 22:5 were all significantly lower in LCR rats at all ages tested (ANOVA, $p<0.01$, <0.005, <0.01, <0.005, respectively) and differences in contents were more accentuated at 24 months of age.

Data pertaining to thymocyte fatty acids are reported in Table 6 and Figure 5. Proportions of 18:1 and 18:2 were dramatically increased with age in both dietary groups,

[a]Values represent mean ± S.E.M. of 5–6 independent observations. Results are expressed as percent composition. AL, *ad libitum* fed rats; LCR, long-term calorie restricted rats. Age effect in AL-fed rats (one-way ANOVA from 6 to 24 months): 18:0, 18:1, 18:2, 20:2, 20:4 ($p<0.001$). Age effect in LCR rats: 18:0, 18:1, 18:2, 20:2, 20:4, 22:4 ($p<0.001$). Diet effect (two-way ANOVA from 12 to 24 months): 18:0, 18:2 ($p<0.005$).

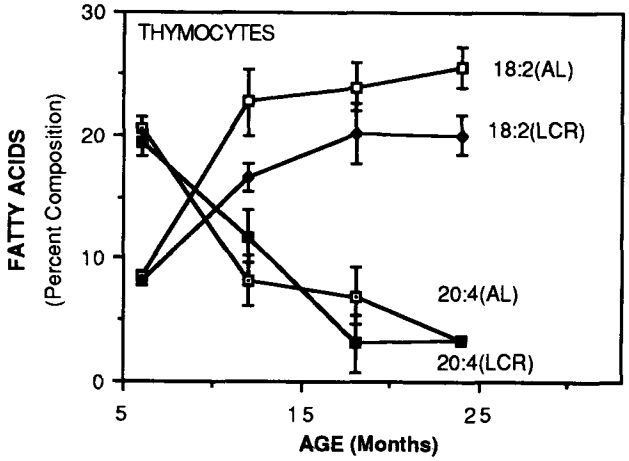

FIG. 5. Influence of LCR on 18:2 and 20:4 levels in thymocytes of 3- to 24-month-old Fischer-344 rats.

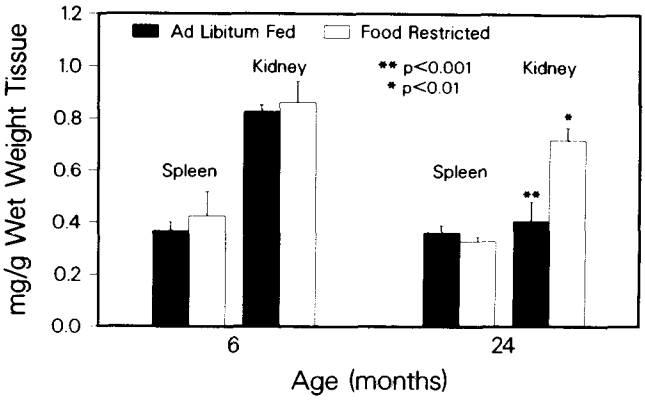

FIG. 6. Effects of age and food restriction on glutathione reductase activity in spleen and kidney tissues obtained from 6- and 24-month-old Fischer-344 male rats maintained on *ad libitum* and food restricted dietary regimens.

whereas 18:0, 20:2 and 20:4 were decreased (one-way ANOVA, $p<0.001$ for each fatty acid). No age-related change in proportions of 22:4 or 22:5 were observed in AL-fed rats, although 22:4 was significantly decreased with age in LCR rats. Diet-related changes in 16:0, 18:0, 18:1 and 20:4 failed to reach significance. However, 18:2 content was significantly lower in thymocytes of 12-, 18- and 24-month-old LCR rats.

Because reduced GSH modulates blastogenesis, we decided to measure GSH levels in the whole spleen supernatant fraction. The data presented in Figure 3 indicate that reduced GSH concentration, which was measured at 6 and 24 months of age in both dietary groups, remained constant at approximately 0.35 mg/g wet weight of spleen. This finding was not replicated in the kidney as shown in Figure 6. Reduced GSH concentration was lowered by 50% in the kidney supernatant of 24-month-old AL-fed rats. In contrast, reduced GSH was only slightly lowered ($p>0.05$) in LCR rat kidney. These results strongly suggest that regulation of spleen GSH concentration is well sustained in aged Fischer-344 male rats as opposed to the aging kidney in the same rats.

DISCUSSION

Our results confirm and extend previous observations that aging alters fatty acid distribution in organs and cells. Our studies of major lymphoid organs indicate that, except in thymocytes, the aging effect showed the following pattern of change: an increase in long chain highly unsaturated fatty acids concomitant with losses in linoleic acid levels. LCR counteracted the age-related loss of 18:2 in spleen cells and bone marrow cells. Therefore, long-term calorie restriction stabilized the fatty acid content of aging animals, and forestalled the loss of mitogenic responsiveness in splenocytes of Fischer-344 rats. Our results confirm the findings of Cheung and Richardson (20), who described the loss of immune function with age in Fischer-344 rats. Hence, alterations of splenocyte fatty acids may underlie the modulation of the response to mitogens in aging rats.

This postulate is in agreement with the paradigm that immune cell reactivity is directly influenced by the enrichment of lymphoid cell membranes with particular fatty acids (20,21). Specifically, membrane enrichment in linoleic acid was associated in various instances with immunosuppression (22–24), as seen in dietary-supplemented multiple sclerosis patients (21,25), experimental allergic encephalomyelitis (26) and rejection of skin allografts (23). Immunosuppression is most likely to occur through the subsequent increase in the content of membrane phospholipid arachidonic acid, which usually results from high linoleic acid supplementation (27). Arachidonic acid is the principal desaturated-elongated derivative of the essential fatty acid, linoleic acid. It is released from membrane phospholipids by the action of phospholipase A_2 (28,29), and is then taken up as precursor for the 2 series prostaglandins (PG) (30).

The PG suppresses blastogenesis, lymphokine production and cytotoxicity (31), especially in the spleen, which is a major site for the production of immunologically active PG (32). In the aging AL-fed rats, increasing membrane content of 20:4 may augment precursor availability for PG release, which may interfere with mitogenic responsiveness of non-adherent spleen cells. Conversely, maintenance of adequate 20:4 content in aging LCR rat lymphoid cells appears to regulate the synthesis of PG, and thereby prevent or delay the fall in splenocyte immune responsiveness.

Most importantly, modulation of cellular fatty acids by LCR was most prominent in the aging bone marrow. The mechanism underlying this finding is not clear, but the bone marrow is the major source of all lymphoid cells for distribution to the organism. Thus, changes in the fatty acid composition of bone marrow lymphoid precursors may be one of the mechanisms by which LCR regulates the lipid composition of mature lymphoid cell subsets, particularly the populations which reside in the spleen.

Because of the strikingly similar trend in the changes reported previously in liver subcellular membrane fatty acids (15,33) and the present results that desaturation of 18:2 into long-chain polyunsaturated derivatives is accelerated with age, this may be a general phenomenon that is inhibited efficiently by chronic calorie restriction. It has been shown earlier that serum 18:2 concentration decreased with age in AL-fed rats (34). Long-term calorie restriction has also been found to alter the profile of serum fatty acids in aging Fischer-344 rats and to reduce the loss of serum 18:2 levels with age (34). The effects of long-term calorie restriction on the fatty acid composition of lymphoid cells is of particular interest since approximately the same amount of food is consumed per gram of body weight by both the dietary groups throughout their lifespan (5,7). The present study further supports the evidence that age-related changes in serum fatty acids are also reflected in the lymphoid cell fatty acid composition, and this finding is in agreement with previous reports (21,25,35).

The marked increase in 18:2 content observed after six months of age for thymus gland reflects the gradual accumulation of adherent cells and surrounding fat tissue which is rich in 18:1 and 18:2 that accompanies the early onset of involution and degeneration of this organ (36). Interestingly, the age-related increase in 18:2 was significantly blunted in LCR rats, in agreement with the previous view that either the function of the thymic tissues or its age related involution may have been forestalled by long-term protein and/or calorie restriction (37–39).

Although the role of reduced GSH in immune activity is still unresolved (40), an increase in lymphocyte proliferation to mitogen stimulation has been reported after enhancing intracellular GSH levels (41). Furthermore, Chaplin and Wedner (42) have shown that depletion of intracellular GSH inhibited [^{3}H]thymidine incorporation and lymphocyte blastogenesis. Therefore, we speculated that possibly higher levels of splenic reduced GSH might influence the sustained proliferative response of aging LCR rats (Fig. 1). A previous report also showed that calorie restriction was able to blunt the age-related loss of reduced GSH in liver (43). Our data suggest that reduced GSH alone probably may not account for diminished lymphoid responsiveness to Con A as lymphoid cells from LCR and AL animals had similar levels of reduced GSH, but markedly different mitogenic responsiveness. However, in the present study, a significant age-related loss of kidney GSH was noted for AL rats which was markedly prevented by calorie striction (Fig. 6). Indeed, caloric restriction is known to reduce renal disease both in Fischer-344 rats as well as in short-lived autoimmunity prone mice (5–7). It appears that reduced GSH may play a role in modulating the renal disease, but more defined studies are required to confirm such a possibility in caloric restricted animals.

In conclusion, our study has provided new evidence that lymphoid cell membrane fatty acids are characteristically altered with age and offers clues regarding one of the possible mechanisms by which long-term calorie restriction prevents the age-dependent decline in lymphoid cell immune reactivity. Calorie restriction may prevent or forestall the increase of suppressor PG production in adherent cell populations. Another consideration (possibly related) is that LCR rats show a higher rate of induction for high affinity IL-2 receptors than AL-fed rats (15). The changes in fatty acid composition measured in this study for non-adherent cells may also relate to preservation of IL-2 receptors and their functions (14,15).

METHODS

Headspace Gas Chromatography of Volatile Lipid Peroxidation Products from Human Red Blood Cell Membranes

E.N. Frankel* and **A.L. Tappel**
Department of Food Science and Technology, University of California, Davis, California 95616

An improved headspace capillary gas chromatographic (GC) method was developed to measure the oxidative susceptibility of human red blood cell (RBC) membranes. This method analyzed volatile peroxidation products of both n-6 (hexanal and pentane) and n-3 (propanal) polyunsaturated fatty acids. Oxidative susceptibility tests were standardized by incubating in a sealed 10-mL headspace bottle 0.25 or 1 mL of human RBC membrane in 40 mM phosphate buffer for 1 hr at 37°C with a mixture of Fe^{++}, ascorbic acid and H_2O_2. Sodium dodecyl sulfate increased significantly the amount of hexanal measured by headspace GC. By this standard headspace method, in one series of red blood cell membranes (RBCM) samples a four-fold variation in oxidative susceptibility was observed in RBCM from blood freshly drawn from six healthy subjects. In another series of RBCM samples a sixteen-fold variation in oxidative susceptibility was noted in frozen RBCM from blood freshly drawn from five healthy subjects. Correlation between hexanal formation and polyunsaturated fatty acids (PUFA) depletion provided good evidence that under these standard conditions hexanal is exclusively derived from the oxidation of arachidonic acid. Hydroperoxides of arachidonic acid are more readily formed and decomposed than those of linoleic acid in the presence of Fe^{++}, ascorbic acid and H_2O_2 to produce hexanal as the main product that can be readily analyzed by headspace GC. This method may provide a useful tool to study susceptibility toward lipid peroxidative damage in human RBC membranes.
Lipids 26, 479–484 (1991).

Many *in vitro* studies indicate that free radical stress can damage hemoglobin (1,2), membrane lipids, and proteins (3–5). Polyunsaturated fatty acids (PUFA) and oxidative susceptibility vary in human red blood cells (RBC) in health and disease. Lipids of red blood cell membranes (RBCM) vary in fatty acid patterns with dietary fat (6). The susceptibility of RBC to lipid peroxidation increases by deficiencies in vitamin E (3), in glucose-6-phosphate dehydrogenase (7,8), or by the presence of abnormal hemoglobin (2,5,9). The genetic disease sickle cell anemia lowers the vitamin E content of the RBCM and increases the susceptibility of RBCM to lipid peroxidation (10–13). Neonatal erythrocytes undergo significant lipid peroxidation apparently because of lower levels of vitamin E in the plasma, deficiency of glutathione peroxidase, and increased levels of PUFA and cellular hemoglobin (14).

Abbreviations: AA, ascorbic acid; AAPH, 2,2′-azo*bis*(2-aminidopropane) dihydrochloride; EDTA, ethylenediaminetetraacetic acid; FA, total fatty acids; GC, gas chromatography; PUFA, polyunsaturated fatty acids; RBC, red blood cells; RBCM, red blood cell membranes; SDS, sodium dodecyl sulfate; TBA, thiobarbituric acid; TBARS, thiobarbituric acid reactive substances.

Oxidative stress in RBC was induced by H_2O_2 in sodium azide to inhibit catalase (15), by sodium nitrite causing the formation of methaemoglobin (16), by adding mixtures of $FeSO_4$ and ethylenediaminetetraacetic acid (EDTA) (17), *tert*-butyl hydroperoxide (1), *tert*-butyl hydroperoxide in the presence of hemoglobin (18), cumene hydroperoxide in the presence of hemin-Fe^{3+} (19), and Fe^{2+}, ascorbate and H_2O_2 (20). PUFA in the lipids of human and rat RBCM were oxidized exclusively in the presence of an azo initiator, 2,2′-azo*bis*(2-aminido-propane) dihydrochloride (AAPH), after an induction period during which α-tocopherol was depleted (21). Oxidation of RBC with AAPH resulted in hemolysis, which developed when the tocopherol concentration fell below a critical low level (22). The final oxygen uptake correlated better with PUFA than the initial oxygen uptake in RBCM of cord, mother and healthy adults (23).

Measurements of the susceptibility of RBC toward oxidative stress were based on determinations of thiobarbituric acid reactive substances (TBARS) (15,24), fluorescent products (19,25), volatile hydrocarbons (16,17), and oxidized protein products (26,27). Better methods are needed to measure oxidative stress (28). The popular thiobarbituric acid (TBA) test is not only strongly influenced by reaction conditions, but the results obtained by different modifications of the test in human serum can vary as much as ten-fold (29). Because of lack of specificity, Halliwell and Gutteridge (30) do not recommend the TBA test for human biological material.

To elucidate how lipid oxidation products act in the complex mechanism of lipid repair in RBCM, a more specific assay than the TBA test would be desirable. Recently a rapid headspace gas chromatographic (GC) method was described for the determination of hexanal as an important volatile decomposition product of n-6 PUFA peroxidation in rat liver samples (31). This method was used to study effects of dietary lipids and vitamin E on *in vitro* lipid peroxidation in rat liver and kidney (32) and on *in vivo* lipid peroxidation in rats induced by iron (33).

The present paper describes an improved headspace capillary GC method for the determination of volatile peroxidation products of n-6 PUFA (pentane and hexanal) and n-3 PUFA (propanal). This method was used to determine the susceptibility of human RBCM to lipid peroxidation.

MATERIALS AND METHODS

Materials. Hexanal and propanal used as standards for the headspace GC analyses were purified by passing a 0.5-mL sample of each (Aldrich Chemical Co., Milwaukee, WI) through a Waters Sep-Pak silica cartridge (Waters Associates, Milford, MA) and sealing it in a serum bottle under nitrogen. Ferrous sulfate (10 mM $FeSO_4$, Fisher Scientific, Fairlawn, NJ) solutions used as oxidant were prepared fresh daily. Ascorbic acid (0.1 M) and hydrogen

peroxide (0.1 M, Fisher Scientific) solutions were stored at 4°C.

Red blood cell membranes (RBCM). Samples of freshly drawn and outdated packed blood cells were obtained from the Sacramento Blood Center (Sacramento, CA). The method of Burton *et al.* (34) was used to prepare white or pink RBCM. For some preparations, the final concentration of each sample was equalized to the same protein content by dilution with 40 mM phosphate buffer. All analyses of volatile oxidation products and fatty acids were based on the initial volume of packed blood cells and expressed per mL RBC. Final RBCM solutions were stored either at 0°C for oxidative susceptibility assays made within 24 hr, or stored at −5°C for assays made after 24 hr.

Headspace capillary GC method. A procedure was developed to determine hexanal, propanal and pentane within 6 min, using a Perkin-Elmer Sigma 3B gas chromatograph with an H-6 headspace sampler (Norwalk, CT), a capillary DB-1701 column (30 m × 0.32 mm, 1 μm thickness, J & W, Folsom, CA) heated isothermally at 80°C. The GC conditions were: He linear gas velocity, 20 cm/sec (He pressure gauge of 60 psi); splitless injector temperature, 180°C; and detector temperature, 200°C.

Samples of 0.25 or 1.0 mL RBCM (containing 0.9 to 2.1 mg protein/mL RBC) diluted in 40 mM phosphate buffer and standard solutions of hexanal were measured into special headspace 10-mL bottles sealed with silicone rubber Teflon caps with a crimper, and incubated in a water-bath shaker at 37°C for 60 min. After incubation, the bottles were retained with an insulated holder, inserted manually through the stationary injection needle in the headspace sampler, and pressurized for 30 sec before injection.

A method was standardized in which pentane, propanal and hexanal were separated with respective retention times of 1.18, 1.42 and 5.10 min. A fourth peak of retention time of 2.90 min, which corresponded to pentanal, was detected in highly oxidized samples of RBCM. Standards of 20 and 30 nmol hexanal in 1 mL 40 mM phosphate buffer were analyzed daily with each group of experimental samples. A linear standard curve was obtained with a series of headspace bottles containing 2.5 to 12.5 nmol hexanal per mL 40 mM phosphate buffer. Regression analysis gave correlation coefficients of 0.98, $p < 0.005$, for the increase in GC peak areas with hexanal concentration. Standards of 20 nmol and 30 nmol propanal were analyzed in 1 mL 40 mM phosphate buffer. Standards of 20 and 30 nmol pentane, made up in 95% ethanol/water (1:1, v/v), were analyzed in 1 mL 40 mM phosphate buffer.

Lipid analyses. Total lipids were extracted with ethanol, hexane, and sodium dodecyl sulfate (SDS) (35). An aliquot of the lipids was methylated with acetyl chloride (36) in the presence of tridecaheptadecanoin added as internal standard. Fatty acid methyl esters were separated by GC (Hewlett-Packard model 5890, Avondale, PA, equipped with a flame ionization detector) with a polar DB-225 capillary column (50% cyanopropylphenyl, J & W, 30 m × 0.25 mm) and identified by comparison with authentic standards (NuChek Prep, Elysian, MN).

Other determinations. The protein content of RBCM samples was estimated by the method of Bradford (37). Hemoglobin was determined in fresh RBCM by the hemochrome method of Fuhrhop and Smith (38) and values ranged between 0.2 and 0.8 mmol/mg protein, averaging 0.4 (n = 7).

RESULTS

The previously described headspace GC method for hexanal in rat liver samples (31) was improved by using a special headspace attachment with a stationary injection system to obviate the use of gas-tight syringes, which are prone to leakage after extensive use. A more polar column was also used to separate the early peaks and to resolve pentane and propanal. This improved method was first applied to different samples of human RBCM obtained from outdated packed cells. Lipid peroxidation was induced by various amounts of Fe^{++}. In contrast to previous results obtained with rat liver tissues (31), addition of ascorbic acid to RBCM decreased the catalytic effect of Fe^{++} (Table 1). At concentrations of 10 and 50 mM, ascorbic acid alone also decreased the amount of volatiles compared to the control. Although the relative amounts of pentane and pentanal produced were much smaller than the amount of hexanal, they correlated well with the corresponding amounts of hexanal formed ($r = 0.94$ and 0.91, respectively). As expected, the correlation coefficient between hexanal and propanal was lower ($r = 0.80$).

The combination of Fe^{++}, ascorbic acid and H_2O_2 was very effective in inducing lipid peroxidation in RBCM. A typical gas chromatogram of a sample of RBCM oxidized with Fe^{++}, ascorbic acid and H_2O_2 is shown in Figure 1. The GC peak preceding pentane was not identified, but was found in all samples including blanks and may be due to some atmospheric contaminant.

The addition of excessive ascorbic acid decreased the amount of peroxidation. The ratio of Fe^{++}, ascorbic acid and H_2O_2 was optimized. At constant concentrations of

[b] RBCM was prepared from outdated packed cells, frozen and thawed before the oxidative susceptibility test. This sample contained 1.28 mg protein/mL RBC. Fe^{++} was added as ferrous sulfate.

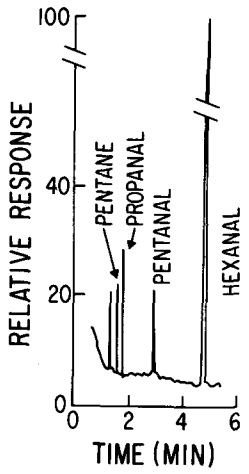

FIG. 1. Capillary gas chromatogram of a 1-mL sample of red blood cell membrane (containing 1.6 mg protein/mL RBC) in 40 mM phosphate buffer after incubation 1 hr at 37°C in the presence of 0.1 mM Fe^{++}, 0.25 mM ascorbic acid, and 0.5 mM H_2O_2.

ascorbic acid (1 mM) and H_2O_2 (2 mM), hexanal formation increased with Fe^{++} concentration up to a maximum between 0.4 and 0.5 mM (Fig. 2). Hexanal formation showed a sharp maximum at 1 mM ascorbic acid, and decreased at concentrations of 2 and 4 mM. At constant levels of ascorbic acid (1 mM) and Fe (0.4 mM), hexanal formation also increased with H_2O_2 concentration. To minimize the H_2O_2 concentration, a molar ratio of Fe/ascorbic acid/H_2O_2 of 1:2.5:5 was chosen for studies to test the susceptibility of RBCM to lipid peroxidation under standardized conditions.

Copper salts were compared with iron salts as catalysts for the oxidation of RBCM. In the presence of 0.2 mM metal, 0.5 mM ascorbic acid and 1 mM H_2O_2, three times more hexanal was produced with $FeSO_4$ than with $CuSO_4$ (Table 2). In the presence of 0.2 mM metal and 0.5 mM ascorbic acid, twice as much hexanal was formed with $FeSO_4$ as with $CuSO_4$. Therefore, Fe^{++} is a better catalyst than Cu^{+} for the oxidation of RBCM as measured by hexanal formation.

The peroxidation of RBCM under different conditions was investigated to optimize a method to estimate biological susceptibility to peroxidative damage. One sample of frozen RBCM was treated with various concentrations of Fe^{++}/ascorbic acid/H_2O_2. A linear relationship was obtained between hexanal formation and Fe^{++}/ascorbic acid/H_2O_2 concentrations varying from 0.05 to 0.4 mM Fe^{++}, 0.1 to 1 mM ascorbic acid, and 0.25 to 2.0 mM H_2O_2. Plots of hexanal formation *versus* incubation time at 37°C were initially linear and the slope decreased after 1 to 2 hr.

Other factors investigated included the effect of phosphate buffer concentrations and surfactants. No significant difference was noted in hexanal formation between 2.5 and 40 mM phosphate, and the use of a 40 mM phosphate buffer was adopted. Tween-20 and sodium dodecyl sulfate (SDS) were tested as surfactants in the oxidation of RBCM. In the presence of 0.5 and 1% Tween-20, a small increase in hexanal formation was observed with 0.2 mM Fe^{++}, 0.5 mM ascorbic acid and 1 mM H_2O_2, but a significant decrease in hexanal was noted with 0.4 mM Fe^{++}, 1 mM ascorbic acid and 2 mM

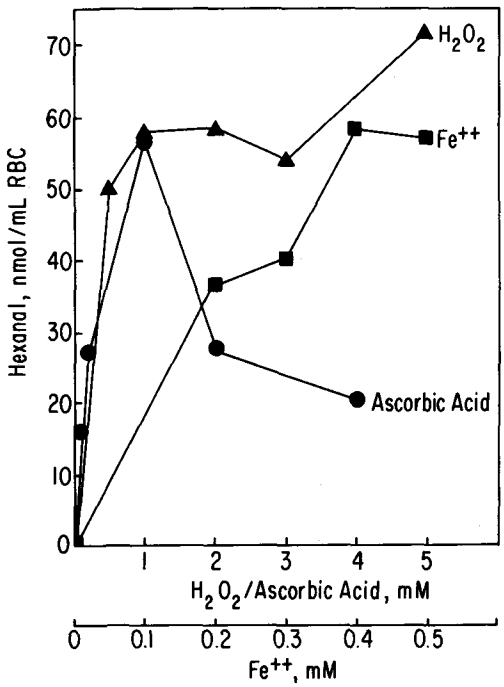

FIG. 2. Effect of Fe^{++}, ascorbic acid and H_2O_2 on the susceptibility of red blood cell membranes to hexanal formation measured by headspace capillary gas chromatography (see Table 2, footnote a). The Fe^{++} concentration was varied in the presence of 1 mM ascorbic acid and 2 mM H_2O_2. The ascorbic acid concentration was varied in the presence of 0.4 mM Fe^{++} and 2 mM H_2O_2. The H_2O_2 concentration was varied in the presence of 0.4 mM Fe^{++} and 1 mM ascorbic acid.

[b] Fe^{++} added as $FeSO_4$; Cu^{++} added as $CuSO_4$.

H_2O_2. With 0.4 mM Fe^{++}, 1 mM ascorbic acid and 2 mM H_2O_2, hexanal formation increased with increasing concentrations of SDS up to a maximum of 1.8 mM. The amount of hexanal formed in a sample of RBCM increased 2.6-fold by the addition of 1.8 mM SDS in the presence of 0.2 mM Fe^{++}, 0.5 mM ascorbic acid and 1 mM H_2O_2, and 1.8-fold in the presence of 0.4 mM Fe^{++}, 1 mM ascorbic acid and 2 mM H_2O_2.

METHODS

The oxidative susceptibility of RBCM was tested in samples prepared from freshly drawn blood of six healthy subjects. Final preparations were kept at 0°C overnight and analyzed by headspace GC within 24 hr. Lipid and protein analyses were later carried out in frozen aliquots of the same samples. Total fatty acid contents varied from 2.9 to 4.4 μmol/mL RBC, and the protein contents varied from 1.1 to 2.1 mg/mL RBC. Because of this variation in protein content, hexanal values were expressed in nmol/mg protein. In the presence of a standard mixture of Fe^{++}/ascorbic acid/H_2O_2, the formation of hexanal varied about four-fold from 26 to 108 nmol/mg protein. All fresh RBCM samples produced no volatiles in the absence of Fe^{++}, ascorbic acid and H_2O_2.

Analyses of fatty acid composition of fresh RBCMs show significant variations in linoleic acid, arachidonic acid, PUFA, and total fatty acids (Fig. 3). Percent conversion of total PUFA to hexanal varied from 2.4 to 6.2. Hexanal values correlated significantly with initial total fatty acids, arachidonic acid and PUFA ($p < 0.01$ to 0.02). The correlation between hexanal and linoleic acid was not significant. It was concluded therefore that hexanal is derived mainly from oxidation of arachidonic acid.

In another experiment, RBCM were prepared on the same day as the blood was drawn from five healthy subjects. The final concentration of each sample was equalized on the basis of protein content determined on the freshly prepared RBCM. The RBCM were frozen and stored at −5°C for 24 hr before headspace GC analyses. Changes in fatty acid composition were also determined after oxidation as an alternate method to measure lipid peroxidation in RBCM. Duplicate samples were incubated under the same conditions, and fatty acids were analyzed in the lipid extracts of RBCM samples stored at −5°C after oxidation. In the presence of a mixture of 0.1 mM Fe^{++}, 0.25 mM ascorbic acid and 0.5 mM H_2O_2, and 1.8 mM SDS, the formation of hexanal varied about sixteen-fold, from 6.5 to 113 nmol/mg protein (Table 3). All RBCM samples produced no volatiles in the absence of Fe^{++}, ascorbic acid and H_2O_2. Analyses for pentane and pentanal correlated well with those for hexanal (results not shown) with respective $r = 0.97$ and 0.97 ($p < 0.005$). The correlation ($r = 0.70$) of propanal with hexanal was not significant (Table 4).

Analyses of fatty acid composition of frozen RBCM showed significant variations in linoleic acid, arachidonic

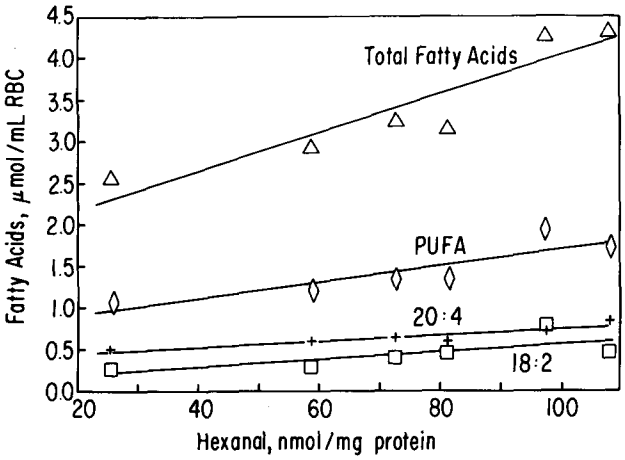

FIG. 3. Relation between hexanal formation and fatty acid composition of red blood cell membranes (RBCM) oxidized in the presence of Fe^{++}/ascorbic acid/H_2O_2 (0.4 mM:1 mM:2 mM). RBCM were prepared from freshly drawn blood from healthy subjects and stored 12 hr at 0°C. Fatty acids were determined by gas chromatography using triheptadecanoin as internal standard. The following correlation coefficients (r) were calculated (n = 6) for hexanal *vs* initial fatty acids: total fatty acids, 0.92 ($p < 0.01$), 20:4, 0.91 ($p < 0.01$), PUFA, 0.87 ($p < 0.02$), and 18:2, 0.73 (N.S.).

Hexanal *vs* −18:2	0.37	N.S.

[a] See footnote a in Table 3.

[b] See footnotes b and c in Table 3.

acid, PUFA, and total fatty acids (Table 3). Total fatty acid contents varied from 1.9 to 4.2 μmol/mL RBC. Conversion of PUFA to hexanal varied from 0.93 to 6.0%. Highly significant correlations were calculated for hexanal *versus* initial total fatty acids, arachidonic acid, and PUFA ($p < 0.001$ to 0.002). The correlation between hexanal and linoleic acid was less significant ($p < 0.03$).

Hexanal expressed per milligram protein was also correlated with changes in different PUFA after oxidation (Table 4). An excellent correlation was calculated between hexanal formation and decrease in 20:4 ($p < 0.001$). The correlation ($r = 0.76$) between hexanal formation and decrease in PUFA was not significant. No correlation was found between hexanal and decrease in 18:2. These results provide good evidence that under the standard conditions used for oxidative susceptibility, hexanal is exclusively derived from the oxidation of arachidonic acid.

DISCUSSION

A large variety of conditions have been used to investigate lipid peroxidation in RBC and RBCM (1,15,16,19,21,22). Such terms used in the literature as oxidative stress, antioxidant capacity, lability or susceptibility to lipid peroxidation or to autoxidative breakdown, are often difficult to interpret because a large variation in experimental conditions and methods has been used to determine the extent of peroxidation. Under the assay conditions of the TBA test, TBARS generated reflect not only the extent of lipid peroxidation but also the amounts of peroxide and aldehyde precursors (39,40), which are also related to the susceptibility of the tissue to peroxidation. The determination of TBARS in biological tissues can thus also be interpreted as a measure of susceptibility against oxidative damage.

In this paper a headspace GC method was developed to estimate oxidative susceptibility in RBCM, which are good models to study peroxidative damage. The commonly used mixture of Fe^{++} and ascorbic acid produced low levels of volatile lipid peroxidation products as measured by this assay (Table 1). However, the addition of H_2O_2 to this mixture significantly increased the amount of hexanal (Fig. 2). A mixture of Fe^{++}, ascorbic acid and H_2O_2 produced significant amounts of hexanal as measured by this headspace technique. These results are in agreement with the literature that active oxygen species are generated by iron in the presence of both reducing and oxidizing agents. These conditions promote the formation of OH^- radicals by the Fenton reaction (30,41). The addition of 1.8 mM SDS increased about four-fold the amount of hexanal formed from RBCM at two levels of Fe^{++}/ascorbic acid/H_2O_2 concentrations. As a powerful surface-active compound, SDS may increase the surface of the phospholipid mixed micelles. The resulting increased accessibility of the PUFA lipid substrate to the metal catalyst and oxygen would accelerate hydroperoxide formation and decomposition to hexanal. In combination with ascorbic acid and with or without H_2O_2, Fe^{++} was a better catalyst than Cu^{++} for the peroxidation of RBCM as measured by hexanal formation (Table 2).

By this standard headspace GC method, in one series of RBCM samples a four-fold variation in oxidative susceptibility was observed in fresh RBCM from blood freshly drawn from six healthy subjects. In another series of RBCM samples, a sixteen-fold variation in oxidative susceptibility was noted in frozen RBCM from blood freshly drawn from five healthy subjects. Correlation between hexanal formation and PUFA depletion provides good evidence that under the standard conditions of the headspace assay, hexanal is exclusively derived from oxidation of arachidonic acid. Previous reports (21,22) showed that all PUFA decreased when RBC ghosts were oxidized in the presence of AAPH, and arachidonic acid was consumed faster than linoleic acid. Under the conditions used in this study, the Fe^{++}-ascorbic acid/H_2O_2 catalyst is therefore more selective for the oxidation of arachidonic acid than is the free radical initiator AAPH. In the presence of an azo initiator, the oxidizability of arachidonic acid is 2.8 times greater than that of linoleic acid (42). Therefore, in the presence of Fe^{++}-ascorbic acid/H_2O_2 catalyst used in this study, the hydroperoxides of arachidonic acid are more readily formed and decomposed than those of linoleic acid to produce hexanal as the main volatile product that can be readily analyzed by headspace GC.

The headspace assay described in this paper may have potential application to study the susceptibility of RBCM toward oxidative damage resulting from pathological conditions. This headspace oxidative susceptibility assay has advantages over many other assays in permitting the specific analysis of multiple products of lipid peroxidation. In nutritional studies, this assay should permit the study of how dietary polyunsaturated lipids affect the relative amounts of n-6 (hexanal and pentane) and n-3 (propanal) PUFA peroxidation. However, some applications of this assay may be limited in stable systems because of the relatively high concentrations of Fe^{++} required and the method may not be sensitive to minor changes in antioxidants and oxidation products.

Incorporation of Lipids Labeled with Various Fatty Acids into the Cytoskeleton of Aggregating Platelets

M.A. Packham*, M.A. Guccione, N.L. Bryant and A. Livne[1]
Department of Biochemistry, University of Toronto, Toronto, Ontario, Canada M5S 1A8

Earlier studies showed that during the first 20 to 25 seconds of aggregation induced by thrombin (0.1 U/mL) or adenosine diphosphate (ADP) (2 μM) of rabbit or human platelets prelabeled with [^{3}H]palmitic acid, labeled lipid became associated with the cytoskeleton (isolated after lysis with 1% Triton X-100, 5 mM EGTA [ethylene glycol-*bis*-(β-aminoethyl ether)*N,N,N',N'*-tetraacetic acid] in the presence of 0.5 mM leupeptin and 50 mM benzamidine). In comparison with labeled lipid in intact platelets, the labeled lipid that was associated with the cytoskeleton was enriched in phospholipids and ceramide. To determine whether these effects were specific for lipids labeled with palmitic acid, we studied rabbit platelets in which lipids had been labeled by incubation of the platelets with pairs of ^{14}C- or ^{3}H-labeled palmitic, stearic, arachidonic, and linoleic acids. Examination of the distribution of label among the lipid classes of intact platelets showed that phospholipids contained most of the label. Under the conditions of limited, thrombin-induced aggregation used, labeled lipids were not lost from the platelets and the distribution of label among the lipid classes was essentially unchanged. There were major differences in the incorporation of labeled lipids into the cytoskeleton. The greatest incorporation (2.1 to 2.8% of the label in the platelets) was observed with palmitic acid-labeled lipids; by direct comparison, only 44% as much of the label of stearic acid-labeled lipids, 21% as much of the label of linoleic acid-labeled lipids, and only 6% as much of the label of arachidonic acid-labeled lipids was incorporated into the cytoskeleton. Thus the pool of phospholipid that is readily labeled with arachidonic acid appears to be selectively excluded from the cytoskeleton. Also noteworthy is the 4- to 5-fold enrichment of the cytoskeleton with labeled ceramide; an average of 16% of the label from stearic acid in the cytoskeleton was in ceramide. We suggest that ceramide and phospholipids that are readily labeled with saturated fatty acids are selectively incorporated into the cytoskeleton during the early stages of aggregation and may be specifically associated with the points of contact between platelets.
Lipids 26, 485–491 (1991).

In earlier studies (1,2), we found that during the early stages of platelet aggregation induced by thrombin or adenosine diphosphate (ADP), labeled phospholipids and ceramide were selectively incorporated into the cytoskeleton of both human and rabbit platelets that had been prelabeled with [^{3}H]palmitic acid. Cytoskeleton from aggregating platelets had 1.5 to 8% of the label of intact platelets, whereas the cytoskeleton of unactivated platelets had only 0.03% (1). The association of labeled lipids with the cytoskeleton appeared to be related to the number of sites of contact between platelets and was dependent on aggregation, but not on the release of granule contents. Most of the label that became associated with the cytoskeleton during limited aggregation was in phospholipids, mainly in phosphatidylcholine (PC). The distribution of label among the phospholipids in the cytoskeleton was similar to that in intact platelets, but the small amounts of label in triacylglycerol and cholesteryl ester (as a percentage of the total label in lipids) were reduced in the cytoskeletons (2). In contrast, the label in ceramide was enriched 3-fold in the cytoskeletons. This was particularly pronounced with rabbit platelets which contained a higher percentage of the label in ceramide than did human platelets.

To determine whether some of these effects are specific for lipids that are readily labeled with palmitic acid, we have carried out experiments with rabbit platelets labeled with the following pairs of fatty acids: [^{3}H]palmitic acid and [^{14}C]stearic acid; [^{14}C]palmitic acid and [^{3}H]arachidonic acid; [^{14}C]stearic acid and [^{3}H]arachidonic acid; and [^{3}H]palmitic acid and [^{14}C]linoleic acid.

MATERIALS AND METHODS

Materials. Albumin fraction V was from ICN Immunobiologicals (Lisle, IL); bovine thrombin was from Parke Davis (Detroit, MI); ADP, ethylene glycol-*bis*-(β-aminoethyl ether)*N,N,N',N'*-tetraacetic acid (EGTA), palmitic acid, leupeptin, benzamidine, and lipids (standards, including ceramide III) were from Sigma Chemical Co. (St. Louis, MO). Ceramide (natural mixture, bovine) was from Serdary (London, Ontario, Canada); petroleum hydrocarbon (80–100°C) was from BDH Chemicals (Toronto, Ontario, Canada); Triton X-100 was molecular biology grade, ultra pure reagent, and was obtained from International Biotechnologies (New Haven, CT). Soluene-350 and Hionic-fluor were purchased from Packard Instruments (Mississauga, Ontario, Canada). Apyrase (adenosine triphosphate diphosphohydrolase, EC 3.6.1.5.) was prepared from potatoes by the method of Molnar and Lorand (3) and used as described previously (4). Labeled palmitic acid ([9,10-^{3}H], 30 Ci/mmol or [1-^{14}C], 56 mCi/mmol), [5,6,8,9,11,12,14,15-^{3}H(N)]arachidonic acid (100 Ci/mmol) and Aquasol were obtained from Du Pont, Canada (NEN Products, Lachine, Quebec, Canada). [1-^{14}C]Stearic acid (57.5 mCi/mmol) was from ICN Radiochemicals (Irvine, CA). [1-^{14}C]Linoleic acid (54.7 mCi/mmol) was from Amersham Canada (Oakville, Ontario, Canada). Labeled and unlabeled fatty acids were dissolved in ethanol.

Preparation of suspensions of platelets. Suspensions of washed platelets from rabbits were prepared from blood anticoagulated with acid-citrate-dextrose according to the method of Ardlie *et al.* (5,6). Platelets were labeled at a platelet count of approximately 500,000/μL. Preliminary

Abbreviations: ADP, adenosine diphosphate; EGTA, ethylene glycol-*bis*(β-aminoethyl ether)*N,N,N',N'*-tetraacetic acid; PA, phosphatidic acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; TLC, thin-layer chromatography; UV, ultraviolet.

experiments were done to determine the conditions that gave the greatest incorporation of labeled fatty acids into the platelet lipids; these conditions differed for each pair of labeled fatty acids.

[^{3}H]Palmitic acid and [^{14}C]stearic acid labeling. Platelets were labeled in the third washing fluid (modified Tyrode solution, pH 7.35, with no added Ca^{2+}, no albumin, but with apyrase). For each milliliter of platelet suspension, 1 μL of unlabeled palmitic acid and 1 μL of [^{3}H]-palmitic acid were added to give a final concentration of 3.6 μM, and 2 μL of [^{14}C]stearic acid was also added to give a final concentration of 3.6 μM. The mixture was incubated for 30 min at room temperature and then albumin was added to give a final concentration of 0.35%.

[^{14}C]Palmitic acid and [^{3}H]arachidonic acid labeling. Platelets were labeled in the second washing fluid (modified Tyrode solution, pH 6.5, with no albumin). For each milliliter of platelet suspension, 2 μL of [^{14}C]palmitic acid was added (final concentration 3.6 μM) and after 15 min of incubation at 37°C, albumin was added to give a final concentration of 0.35%. Lastly, [^{3}H]arachidonic acid (2 μL/mL of platelet suspension, final concentration 0.002 μM) was added and the incubation was continued for 30 min.

[^{14}C]Stearic acid and [^{3}H]arachidonic acid labeling. Platelets were labeled as above, but [^{14}C]palmitic acid was replaced with [^{14}C]stearic acid.

[^{3}H]Palmitic acid and [^{14}C]linoleic acid labeling. Platelets were labeled with [^{3}H]palmitic acid (1 μL/mL of platelet suspension, final concentration 0.18 μM) for 15 min at 37°C in the second washing fluid, as described above. [^{14}C]Linoleic acid was mixed with 3.5% albumin before addition to the platelet suspension to give final concentrations of 3.6 μM linoleic acid and 0.35% albumin. Incubation was continued for 30 min.

After labeling, the platelets were recovered by centrifugation and resuspended for aggregation studies at a platelet count of 300,000/μL in a modified Tyrode-albumin solution containing 1.8 mM Ca^{2+}, and apyrase (pH 7.35). Samples of intact platelets for radioactivity determinations and lipid extraction were obtained by centrifugation.

Aggregation and isolation of cytoskeletons. At least 60 min elapsed from the end of the incubation until the platelets were aggregated and the cytoskeletons prepared. Aggregation was measured at 37°C by recording the changes in light transmission through 1-mL samples of platelet suspension stirred at 1100 rpm in a cuvette in an aggregometer (Payton Associates, Scarborough, Ontario, Canada). No aggregation (0%) is defined as the lowest point of the light transmission curve after addition of the aggregating agent, and 100% as light transmission after addition of Triton X-100-EGTA (see below). The aggregating agents used were ADP (2 μM) and thrombin (0.1 U/mL). The amounts of all materials added to the platelet suspensions are expressed as final concentrations after all additions. Aggregation was stopped at the same extent of change in light transmission (approximately 25%, which occurred between 20 and 25 sec) by the addition of a lysis solution containing 10% Triton X-100, 50 mM EGTA, leupeptin, and benzamidine, pH 7.35, to give final concentrations of 1% Triton, 5 mM EGTA, 0.5 mM leupeptin and 50 mM benzamidine. The material that is insoluble in this medium is commonly defined as cytoskeleton (7). Cytoskeletons were isolated and washed by the methods of Phillips *et al.* (8) and Burn *et al.* (9), and radioactivity was determined as described previously (1,2). To assess the extent of incorporation of labeled lipids into the cytoskeleton that formed upon aggregation, the amounts of ^{3}H and ^{14}C in the cytoskeletons were determined and expressed as a percentage of the total cpm in ^{3}H and ^{14}C in the platelet pellets.

Lipid extraction. Lipids were extracted from intact platelets (obtained from 1-mL samples of platelet suspension) and from ten combined platelet cytoskeletons (each prepared from 1 mL samples of platelet suspension) by a modification of the method of Bligh and Dyer (10), as described earlier (11).

Thin-layer chromatography (TLC). Lipids were separated by one- and two-dimensional chromatography on thin-layer plates (TLC-plates precoated SIL G-50, 0.5 mm with fluorescent indicator, Brinkmann, Rexdale, Ontario, Canada). The solvent used for separation of phospholipids in one dimension was Solvent I, *i.e.* chloroform/methanol/acetic acid/water (90:40:12:2, by vol). For two-dimensional separation of neutral lipids and glycolipids from each other and from phospholipids, Solvent II, *i.e.* petroleum hydrocarbon/diethyl ether/acetic acid (120:25:1.5, v/v/v) was used in the first dimension and Solvent III, *i.e.* chloroform/methanol/acetic acid (95:5:5, v/v/v), was used in the second dimension. Non-radioactive standards were run with the radioactive samples so that the positions of the various phospholipids could be visualized by ultraviolet (UV) light or after exposure to iodine vapor. These standards were: phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS), phosphatidylinositol (PI), phosphatidic acid (PA), sphingomyelin, ceramide type III, a natural mixture of ceramides, monoacylglycerol, diacylglycerol, triacylglycerol and cholesteryl ester. Squares of the silica layer containing the respective lipid fractions were scraped from the plates into counting vials containing Aquasol. The approximate average numbers of dpm determined by liquid scintillation counting for each radioisotope in the samples of the lipid extracts applied to the chromatographic plates are shown in Table 1. The very low incorporation of arachidonic acid-labeled lipids into the cytoskeletons of aggregating platelets is responsible for the low number of dpm of arachidonic acid-labeled

TABLE 1

Approximate Average Number of dpm in Lipid Extracts Applied to Chromatographic Plates

Fatty acid used to label platelet lipids	dpm in lipid extract of 5×10^8 intact platelets[a]	dpm in lipid extract of 10 cytoskeletons (from 5×10^9 platelets)[b]
[^{3}H]Palmitic	100,000	13,000
[^{14}C]Palmitic	90,000	9,000
[^{14}C]Stearic	90,000	5,000
[^{3}H]Arachidonic	160,000	1,000
[^{14}C]Linoleic	2,000	150

[a] Lipid extracts of intact, unstimulated platelets in 1-mL samples of platelet suspension.

[b] Lipid extracts of cytoskeletons from ten 1-mL samples of platelet suspension after aggregation for 20 to 25 sec with 0.1 U/mL thrombin.

lipids that could be applied to the chromatographic plates. The extremely low uptake of [^{14}C]linoleic acid into the intact platelets, and the low incorporation of linoleic acid-labeled lipids into the cytoskeleton prevented reliable detailed analysis of individual cytoskeletal lipids labeled with linoleic acid.

Analysis of data. Means ± S.D. are shown. Paired t-tests were used to calculate the significance of differences. Differences were considered to be significant when $P < 0.05$.

RESULTS

The labeling pattern of the lipids of intact platelets was determined after the platelets had been isolated from their suspending medium by centrifugation so that any radioactivity in the medium was not included. Table 2 shows the distribution of the labels among the lipids separated in two dimensions by solvent Systems II and III. Nearly all of the label of arachidonic acid and linoleic acid appeared in phospholipids, and in contrast to the saturated fatty acids, less than 1% of labeled arachidonic acid was in the ceramide fraction and less than 2% in triacylglycerol. The percentages of labeled linoleic acid in ceramide and triacylglycerol were even lower (Table 2). The unstimulated platelets contained very little free, labeled fatty acids (Table 2).

Table 3 shows data for the major phospholipid classes in which the distribution of the labels from the four different labeled fatty acids are compared. A higher proportion of labeled stearic acid than labeled palmitic acid appeared in PE and PS/PI when these labeled fatty acids were used together at the same concentration to label the platelets. There was more labeled material from the saturated fatty acids than from the unsaturated fatty acids at the solvent front. (The solvent front contains the label of triacylglycerol, diacylglycerol, monoacylglycerol, free fatty acids, cholesteryl ester, ceramides, cardiolipin and cerebrosides (12).)

During the limited aggregation (20 to 25 sec) of the platelets with 0.1 U/mL of thrombin, there was no detectable loss of radioactivity from labeled palmitic acid or labeled stearic acid into the suspending medium. In four experiments with rabbit platelets in which this measurement was made for [^{14}H]arachidonic acid, a mean of 1.3 ± 1.3% of the label was lost from the platelets upon aggregation, but by paired difference analysis with control samples, this loss was not statistically significant. In four experiments in which platelets had been labeled with both [^{14}C]stearic acid and [^{14}H]arachidonic acid, there were no significant differences between unstimulated platelets and intact, thrombin-stimulated platelets, in the distributions of either of the labels among the lipid classes (Table 4). We showed previously (2) with labeled palmitic acid that the distribution of label among the lipid fractions was unchanged during limited aggregation in response to thrombin.

TABLE 2

Intact, Unstimulated Rabbit Platelets: Distribution of Label (%) Among Lipids[a]

Lipid	[^{14}C]Palmitic acid (3.6 μM)	[^{14}C]Stearic acid (3.6 μM)	[^{3}H]Arachidonic acid (0.002 μM)	[^{14}C]Linoleic acid (3.6 μM)
Phospholipids	86.5 ± 4.2	88.4 ± 4.5	94.0 ± 3.6	93.6 ± 5.3
Ceramide	2.1 ± 0.8	2.3 ± 0.8	0.6 ± 1.0	0.2 ± 0.2
Triacylglycerol	5.1 ± 1.6	4.8 ± 4.0	1.9 ± 1.4	0.8 ± 0.7
Diacylglycerol	1.0 ± 0.4	1.1 ± 0.6	0.8 ± 0.7	0.7 ± 0.5
Free fatty acid	2.7 ± 2.6	1.7 ± 1.4	0.6 ± 0.7	0.5 ± 0.6
	(n = 6)	(n = 6)	(n = 12)	(n = 4)

[a]Lipids were separated in two dimensions with Solvents II and III. Column headings indicate the type of labeled fatty acid used to label the platelet lipids. In the incubation of platelets with labeled fatty acids, [^{14}C]palmitic acid or [^{14}C]stearic acid was paired with [^{3}H]arachidonic acid; [^{3}H]palmitic acid was paired with [^{14}C]linoleic acid. Values are means ± S.D. of the percentages of the label applied to the chromatographic plates.

TABLE 3

Intact, Unstimulated Rabbit Platelets: Distribution of Label (%) Among the Phospholipids[a]

Lipid	[^{14}C]Palmitic acid (3.6 μM)	[^{14}C]Stearic acid (3.6 μM)	[^{3}H]Arachidonic acid (0.002 μM)	[^{14}C]Linoleic acid (3.6 μM)
PC	53.1 ± 5.2	35.8 ± 7.1	55.6 ± 7.7	77.1 ± 0.9
PS/PI	6.0 ± 3.0	10.8 ± 4.9	11.9 ± 3.1	7.2 ± 1.5
PE	20.1 ± 4.3	40.0 ± 3.8	21.5 ± 7.2	10.9 ± 1.7
Sphingomyelin	3.9 ± 1.5	2.2 ± 1.9	4.1 ± 1.1	1.4 ± 0.4
Solvent front	18.7 ± 7.9	11.3 ± 3.6	7.0 ± 1.6	3.1 ± 1.5
	(n = 5)	(n = 4)	(n = 7)	(n = 4)

[a]Phospholipids were separated by Solvent I. Column headings indicate the type of labeled fatty acid used to label the platelet lipids. The solvent front contained label associated with triacylglycerol, diacylglycerol, monoacylglycerol, free fatty acid, cholesteryl ester, ceramide, cardiolipin and cerebroside (12). In the incubation of platelets with labeled fatty acids, [^{14}C]palmitic acid or [^{14}C]stearic acid was paired with [^{3}H]arachidonic acid; [^{3}H]palmitic acid was paired with [^{14}C]linoleic acid. Values are means ± S.D. of the percentages of the label applied to the chromatographic plates.

In experiments with two differently labeled fatty acids, there were major differences among the labeled lipids in their incorporation into the cytoskeleton isolated after lysis with 1% Triton X-100, 5 mM EGTA, 0.5 mM leupeptin and 50 mM benzamidine. Upon aggregation of the platelets to the extent of 20 to 25% with 0.1 U/mL of thrombin, the incorporation of the label into the cytoskeleton was highest when the lipids had been labeled with palmitic acid (2.1 to 2.8%) (Table 5). In contrast, only 1.2% of lipids labeled with stearic acid became associated with the cytoskeleton during this limited aggregation (Table 5). By direct comparison, the incorporation of lipids labeled with stearic acid was 44% of the incorporation of lipids labeled with palmitic acid. The incorporation of lipids labeled with arachidonic acid into the cytoskeleton was much less (Table 5); by direct comparison with palmitic acid-labeled lipid, only 6% as much arachidonic acid-labeled lipid was incorporated; by direct comparison with stearic acid-labeled lipids, only 19% as much arachidonic acid-labeled lipid was incorporated. The incorporation of linoleic acid-labeled lipid was 21% of the incorporation of palmitic acid-labeled lipid. When the platelets were aggregated with 2 μM ADP, similar differences were found between palmitic acid-labeled lipid and arachidonic acid-

TABLE 4

Comparison of Intact, Unstimulated Platelets and Intact Platelets Aggregated with Thrombin: Distribution of Label (%) Among Lipids[a]

	[^{14}C]Stearic acid		[^{3}H]Arachidonic acid	
Lipid	Unstimulated	Aggregated with thrombin	Unstimulated	Aggregated with thrombin
Phospholipids	88.4 ± 5.3	88.8 ± 5.9	97.0 ± 0.9	93.6 ± 5.5
Ceramide	2.6 ± 2.2	2.2 ± 0.3	0.1 ± 0.1	0.4 ± 0.3
Triacylglycerol	6.5 ± 3.9	6.2 ± 4.0	1.8 ± 0.9	3.0 ± 2.2
Diacylglycerol	0.9 ± 0.3	1.0 ± 0.7	0.5 ± 0.1	1.1 ± 1.2
Free fatty acid	0.8 ± 0.4	0.6 ± 0.3	0.2 ± 0.1	0.5 ± 0.6

[a]Platelets were aggregated with 0.1 U/mL thrombin for 20 to 25 sec. Platelet lipids had been labeled by incubation of the platelets with [^{14}C]stearic acid (3.6 μM) and [^{3}H]arachidonic acid (0.002 μM). Values are means ± S.D. of the percentages of the label applied to the chromatographic plates (n = 4). By paired difference analysis, there were no significant differences between the values for unstimulated platelets and platelets aggregated with thrombin.

TABLE 5

Comparisons of Incorporation of Labeled Lipids into the Cytoskeleton of Rabbit Platelets Aggregated by Thrombin or ADP[a]

Aggregating agent	Pairs of fatty acids used to label platelet lipids	n	Label in cytoskeleton (percent of label in intact, unstimulated platelets)	P
Thrombin	[^{3}H]Palmitic (3.6 μM)	12	2.7 ± 0.8	<0.001
	vs [^{14}C]stearic (3.6 μM)		1.2 ± 0.4	
Thrombin	[^{14}C]Palmitic (3.6 μM)	22	2.1 ± 1.3	<0.001
	vs [^{3}H]arachidonic (0.002 μM)		0.1 ± 0.2

[a]Platelets were aggregated with 0.1 U/mL thrombin for 20 to 25 sec. Column headings indicate the type of labeled fatty acid used to label the platelet lipids. In the incubation of platelets with labeled fatty acids, palmitic acid was paired with [^{14}C]stearic acid or [^{3}H]arachidonic acid; [^{14}C]stearic acid was paired with [^{3}H]palmitic acid or [^{3}H]arachidonic acid; [^{3}H]arachidonic acid was paired with [^{14}C]palmitic acid or [^{14}C]stearic acid. Values are means ± S.D. of the percentages of label applied to the chromatographic plates.

TABLE 7

Paired Difference Analysis of Enrichment of Cytoskeletons with Labeled Ceramide[a]

	Percentage of label in ceramide		
	Palmitic acid	Stearic acid	Arachidonic acid
Intact platelets	2.4 ± 1.2	3.6 ± 1.3	0.5 ± 0.4
Cytoskeleton	9.7 ± 3.2	16.0 ± 5.8	3.4 ± 2.3
P	<0.001	<0.02	<0.05
Fold enrichment	4.0	4.4	7.1
	(n = 5)	(n = 4)	(n = 5)

[a]To obtain cytoskeletons, platelets were aggregated with 0.1 U/mL thrombin for 20 to 25 sec. Column headings indicate the type of labeled fatty acid used to label the platelet lipids. In the incubation of platelets with labeled fatty acids, palmitic acid was paired with [^{14}C]stearic acid or [^{3}H]arachidonic acid; [^{14}C]stearic acid was paired with [^{3}H]-palmitic acid or [^{3}H]arachidonic acid; [^{3}H]arachidonic acid was paired with [^{14}C]palmitic acid or [^{14}C]stearic acid. Values are means ± S.D. Paired difference analysis (two-tailed) between intact platelets and cytoskeletons.

labeled lipid, and between stearic acid-labeled lipid and arachidonic acid-labeled lipid (Table 5).

Table 6 shows the distributions of the labels among the lipids in platelet cytoskeletons following aggregation for 20 to 25 sec with 0.1 U/mL thrombin. In comparison with Table 2, the most noteworthy difference between the distributions in intact, unstimulated platelets and the distributions in the cytoskeletons was the enrichment of the cytoskeletons with labeled ceramide. Table 7 shows that on average, the cytoskeletons were enriched 4-fold with palmitic acid-labeled ceramide and 4.4-fold with stearic acid-labeled ceramide. Although a low percentage of the lipids labeled with arachidonic acid was found in the cytoskeletons in comparison with lipids labeled with the saturated fatty acids, and the percentage of arachidonic acid-labeled ceramide in intact platelets was only 0.6%, arachidonic acid-labeled ceramide appeared to be enriched in the cytoskeletons. However, the dpm in arachidonic acid-labeled ceramide was so low that the calculation of enrichment of the cytoskeletons (7-fold) can be only approximate. The percentage of linoleic acid-labeled ceramide in the intact platelets and in the cytoskeletons was too low to permit determination of whether or not enrichment occurred in the cytoskeletons. However, as in the intact platelets, nearly all of the label of linoleic acid in the cytoskeletons was in phospholipids (data not shown).

Labeled triacylglycerol of intact, unstimulated platelets was largely excluded from the cytoskeletons (Tables 2 and 6), as observed previously for platelets labeled with palmitic acid (2). The difference in the percentage of label in palmitic acid-labeled triacylglycerol between intact platelets and cytoskeletons was significant ($P < 0.05$, n = 6, paired difference analysis).

Table 8 shows the distribution of labeled phospholipids in the cytoskeletons. In comparison with intact platelets (Table 3), there was less label from palmitic acid in PS/PI in the cytoskeletons ($P < 0.005$) and less label in PE in the cytoskeletons ($P < 0.005$) (n = 5, paired difference analysis). There were no significant differences for stearic acid-labeled phospholipids (n = 3). For arachidonic acid-labeled lipids, the only significant difference between intact platelets and the cytoskeletons was the lower amount of label in PC in the cytoskeletons ($P < 0.05$) (n = 5).

TABLE 8

Cytoskeletons of Rabbit Platelets Aggregated with Thrombin: Distribution of Label (%) Among the Phospholipids[a]

Lipid	[^{14}C]Palmitic acid (3.6 μM)	[^{14}C]Stearic acid (3.6 μM)	[^{3}H]Arachidonic acid (0.002 μM)
PC	45.7 ± 9.9	24.8 ± 5.7	42.8 ± 11.3
PS/PI	4.5 ± 3.0	9.4 ± 2.3	9.0 ± 9.1
PE	15.9 ± 5.2	23.7 ± 9.5	24.0 ± 8.3
Sphingomyelin	5.7 ± 3.3	4.5 ± 3.9	4.9 ± 4.9
Solvent front	28.1 ± 15.8	35.5 ± 9.1	20.2 ± 6.2
	(n = 5)	(n = 3)	(n = 5)

[a]Platelets were aggregated with 0.1 U/mL thrombin for 20 to 25 sec. Column headings indicate the type of labeled fatty acid used to label the platelet lipids. In the incubation of platelets with labeled fatty acids, [^{14}C]palmitic acid was paired with [^{3}H]arachidonic acid; [^{14}C]stearic acid was paired with [^{3}H]arachidonic acid; [^{3}H]arachidonic acid was paired with [^{14}C]palmitic acid or [^{14}C]stearic acid. Values are means ± S.D. of the percentages of label applied to the chromatographic plates.

DISCUSSION

These results show that during the early stages of platelet aggregation induced by a low concentration of thrombin or ADP, lipids that are readily labeled with palmitic acid are preferentially incorporated into the cytoskeleton. In all the experiments, platelet lipids had been labeled by incubation of the platelets with two differently labeled fatty acids. Direct comparison of palmitic acid-labeled lipids with stearic acid-labeled lipids showed that only 44% as much stearic acid-labeled lipid as palmitic acid-labeled lipid became associated with the cytoskeleton of platelets aggregating under the influence of thrombin, 21% as much linoleic acid-labeled lipid, and only 6% as much arachidonic acid-labeled lipid. Thus, in contrast to the lipids that are labeled with the saturated fatty acids (particularly with palmitic acid), very little lipid that is readily labeled with arachidonic acid is associated with the cytoskeleton during the initial stages of aggregation. Burn *et al.* (9) reported that under their conditions of thrombin stimulation of platelets, "the binding of lipid components to the cytoskeleton of activated platelets labeled with palmitic acid is six times higher than that of control platelets labeled with arachidonic acid." The finding that the pool of phospholipid which is readily labeled with arachidonic acid is largely excluded from the cytoskeleton of aggregating platelets is of interest in relation to an early report of Bills *et al.* (13) that only 30% of the PC in human platelets is readily labeled with arachidonic acid. It appears that very little of this pool is incorporated into the cytoskeleton, in contrast to the pool(s) of phospholipids that are labeled with palmitic and stearic acids. This selective incorporation into the cytoskeleton of aggregating platelets of what must be different pools of phospholipid has not been emphasized previously. It may be related to the known preponderance of saturated fatty acids at position 1 of phospholipids and the preponderance of unsaturated fatty acids (particularly arachidonic acid) at position 2 (14).

In general, the extent of incorporation of labeled phospholipids into the cytoskeleton did not depend on the phospholipid class. The lower percentage of arachidonic acid-labeled PC in the cytoskeletons (in comparison to the percentage in intact platelets) is unlikely to have been caused by the loss of labeled arachidonic acid from PC as free fatty acid due to the action of phospholipase A_2 because we found that the mean 1.3% loss of label into the suspending fluid of intact platelets upon thrombin stimulation was not statistically significant. It should be emphasized that our conditions of limited aggregation with a low concentration of thrombin are probably responsible for the lack of mobilization of arachidonic acid. Stearic acid-labeled lipids in intact platelets were also not changed by aggregation.

The low percentage of arachidonic acid-labeled lipid in the cytoskeleton (compared to palmitic acid-labeled lipid or stearic acid-labeled lipid) was also observed when the platelets were aggregated with ADP. Unlike thrombin, ADP does not cause the release of granule contents from rabbit platelets, nor induce the mobilization of arachidonic acid for the formation of thromboxane A_2 (15). Thus the observations are related to aggregation *per se*, rather than to the more extensive reactions that occur when platelets are stimulated with high concentrations of thrombin.

In earlier studies (1,2) we established in several ways that the incorporation of the label of palmitic acid into the cytoskeleton does not represent the nonspecific trapping of membrane fragments due to incomplete lysis by Triton X-100. This previous conclusion is further supported by the observations in the present experiments that although most of the label of all the fatty acids was in phospholipids, there were major differences in percentages of the labeled lipids that were incorporated into the cytoskeleton.

The distribution of the label of palmitic acid among the phospholipid classes of intact, unstimulated platelets in the present experiments differs slightly from that reported previously (2). This difference appears to be related to the changes in the labeling conditions that were necessary to obtain optimum uptake of the other labeled fatty acids with which palmitic acid was paired (data not shown). These differences do not affect the direct comparisons between the distribution of the label in intact, unstimulated platelets and in the cytoskeleton.

The most noteworthy finding was the enrichment of the cytoskeleton with labeled ceramide; this enrichment was particularly pronounced with stearic acid-labeled ceramide. An average of 16% of the labeled stearic acid in the cytoskeletons was in ceramide. We had noted previously the enrichment of palmitic acid-label in the ceramides of the cytoskeleton (2). Although very little labeled arachidonic acid was detected in ceramide in intact platelets, ceramide labeled with arachidonic acid was higher in the cytoskeleton.

In earlier experiments (1), we found that incorporation of palmitic acid label into the cytoskeleton of rabbit and human platelets increased exponentially as aggregation proceeded and decreased exponentially during deaggregation, and we suggested that the extent of incorporation was related to the number of points of contact between platelets. It is tempting to speculate that ceramide and phospholipids that are readily labeled with saturated fatty acids may be specifically associated with these sites of contact.

Schick (16) suggested that certain lipids may anchor the cytoskeleton to the plasma membrane and a number of investigators have reported non-covalent associations of lipids with cytoskeletal proteins (17). Phospholipids and ceramide that are readily labeled with saturated fatty acids may thus play a part in the involvement of the cytoskeleton in the early stages of platelet aggregation.

Effect of 3-Hydroxy-3-methylglutaryl Coenzyme A Reductase Inhibition on Human Gut Mucosa

Roger L. Gebhard*, Stephen L. Ewing, Linda A. Schlasner, Donald B. Hunninghake and William F. Prigge

Mevalonic acid is an important biochemical intermediate in cholesterol synthesis and other processes involved in cell replication. 3-Hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase is the enzyme which catalyzes mevalonic acid synthesis. To determine whether a potent competitive inhibitor of this enzyme, the drug simvastatin, may have an adverse effect on enterocyte cell replication and cholesterol metabolism, small intestinal biopsies from nine hypercholesterolemic subjects were obtained before and during treatment with simvastatin as a lipid-lowering agent. Histologic review of biopsies in a blinded manner detected no change in ratio of villous length to crypt length or in mitotic index which might indicate altered cell replication. Similarly, no significant change in measured activity of HMG-CoA reductase activity was observed. In spite of the high exposure of jejunal mucosal cells to this potent competitive inhibitor of a key enzyme, no adverse effect on growth could be detected.

***Lipids 26,* 492–494 (1991).**

3-Hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase is the rate-determining enzyme of cholesterol synthesis (1,2). The enzyme catalyzes formation of mevalonate, an important precursor not only for cholesterol, but also for ubiquinone, dolichols and isopentanyl adenine (3). All of these mevalonate products are involved in cell replication (3–5). Competitive inhibitors of HMG-CoA reductase are an important new class of drugs with potent cholesterol lowering activity. Such drugs include lovastatin (formerly mevinolin), simvastatin, and pravastatin.

In tissue culture experiments, competitive inhibitors of HMG-CoA reductase have been shown to prevent cell growth and replication (5–7). This inhibition of growth can be reversed by providing mevalonate (the enzyme product) to the cells (6,7). Reductase inhibitors *in vitro* and *in vivo* have also been shown to induce HMG-CoA reductase levels within cells in response to activity inhibition (8–10). Gut mucosal cells are rapidly replicating cells, having a renewal time of 4–6 days (11). Gut enterocytes are also the portal of entry for therapeutic reductase inhibitors, so these cells are exposed to a high drug concentration. For these reasons, gut mucosa may be particularly susceptible to any adverse effects of reductase inhibitors on cell growth and reductase enzyme inhibition. Stange *et al.* (12) have reported evidence for decreased enterocyte differentiation when gut mucosal explants were cultured in the presence of compactin.

Abbreviations: HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; LDL, low density lipoprotein.

The focus of the present study was to evaluate the effect of one potent reductase inhibitor on mucosal histology and HMG-CoA reductase activity. A subset of hypercholesterolemic patients participating in larger clinical trials of simvastatin (synvinolin; Merck, Sharp, and Dohme, West Point, PA), which have previously been reported (13,14), underwent pre- and post-treatment small bowel biopsy for histologic measurements and for determination of mucosal HMG-CoA reductase activity. Simvastatin is structurally similar to lovastatin and is about twice as potent as lovastatin for competitive inhibition of reductase enzyme *in vitro* (15).

METHODS

The study protocols were approved by human subjects committees at the University of Minnesota and the Minneapolis VA Medical Center, and informed consent was obtained from each subject. Type IIa and IIb hypercholesterolemic subjects entering two lipid-lowering drug trials were asked to undergo studies of bile lipids and/or small bowel mucosa before and during their treatment, and a subgroup of subjects volunteered (13,14). Following overnight fast, these volunteers for the intestinal intubation substudy underwent duodenal intubation for collection of gallbladder bile stimulated by 10% protein hydrolysate solution, followed by mucosal biopsy with the same Carey capsule-tipped biopsy tube. Results of the gallbladder bile studies have been previously reported (16). Mucosal biopsy samples were briefly rinsed in ice-cold saline and, if size permitted, divided into two pieces. If sufficient tissue was available, one portion was oriented with villous side up on filter paper and placed in formalin for subsequent histologic studies. A second portion (or the entire sample, in the event of small biopsies) was placed in sucrose/phosphate buffer, homogenized, and processed as previously described for measurement of HMG-CoA reductase activity in the whole mucosal homogenate (17). Total reductase activity was expressed as pmol mevalonate formed per mg mucosal protein per minute. Assays were done in duplicate and were shown to be linear with respect to protein.

Initial mucosal samples were obtained while subjects were treated only with American Heart Association Step I diet for at least four weeks. A second sample was obtained after subjects had been treated with this diet plus 7–22 wk of therapy with a study drug in accordance with the protocol of the broader cholesterol-lowering studies (13,14). Once the drug study code had been broken, pre- and post-treatment HMG-CoA reductase values for the nine subjects treated with 20 or 40 mg per day of simvastatin were compared. For histologic studies, the formalin-fixed tissue samples from seven simvastatin-treated subjects with both pre- and post-treatment biopsies were sectioned and stained with hematoxylin and eosin for histologic evaluation by standard criteria (18,19).

Criteria included villous/crypt ratio, villous surface cell morphology, number of mitoses/500 crypt cells, and lamina propria cellularity. Histologic sections were coded and independently evaluated in random sequence by two observers, a pathologist with special interest in GI histology and a gastroenterologist with experience in GI histopathology. The observers were not aware of the sequence for the paired biopsies.

RESULTS

All subject volunteers for intubation studies were males with a mean age of 56 years. Mean ± SE serum total cholesterol fell from 332 ± 15 mg/dL to 214 ± 11 mg/dL for the nine simvastatin subjects during the treatment period, while low density lipoprotein (LDL) cholesterol fell from 250 ± 15 mg/dL to 144 ± 14 mg/dL. These changes are consistent with our previous report (16). Individual subject data for intestinal HMG-CoA reductase activity are shown in Figure 1. Mucosal HMG-CoA reductase activity for these nine subjects prior to simvastatin treatment was 2.0 ± 0.3 pmol mevalonate formed/mg protein/min (mean ± SE). Mucosal reductase activity after 7-22 wk of simvastatin therapy (but at least 8 hr after last oral drug dose) was also 2.0 ± 0.3 pmol mevalonate formed/mg protein/min. Thus, there was no change in measured total reductase activity with simvastatin therapy. Values for five subjects were numerically greater during treatment, while values for four subjects were numerically lower during treatment, but all differences were minor.

Histologic assessment of jejunal biopsies from seven subjects having paired samples, as well as three subjects with only one sample, was independently completed by two reviewers without knowledge of the randomization pattern. A high degree of concordance existed for the grading by the reviewers. Interobserver variability for villous-to-crypt length ratio was within one unit difference for 94% of biopsies, mitotic index was within one mitosis/500 cells for 81% of biopsies, and inflammatory infiltrate rating was within one unit for 100% of biopsies. No differences existed for direction of change in biopsy pairs. Thus, ratings by the two reviewers were averaged for final tabulation.

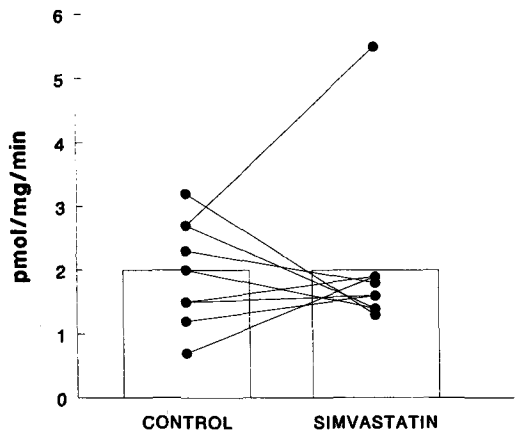

FIG. 1. HMG-CoA reductase activity for individual subjects before (control) and during oral treatment with simvastatin.

There were no significant histologic changes related to simvastatin treatment. All biopsies, pre- and post-treatment, demonstrated normal morphology of columnar cells lining the mucosa. The cellular infiltrate in the lamina propria consisted of the usual plasma cells and lymphocytes in normal numbers (all were graded 0-1 on a scale of 0-5 for increase in cellular density). No pattern of change occurred during treatment with the HMG-CoA reductase inhibitor. Villous/crypt length ratio and mitotic index pre- and post-treatment for each subject are shown in Figure 2 and Figure 3. No pattern of change in these features of mucosal regeneration occurred during inhibitor therapy, with equal numbers of pairs falling above and below the lines of identity. Furthermore, there were no correlations

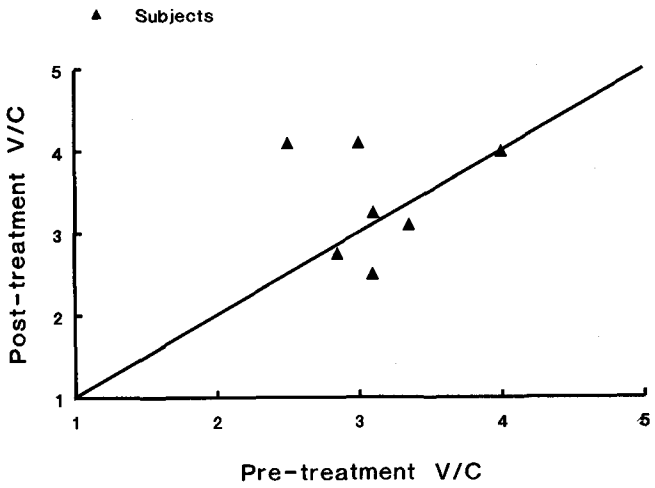

FIG. 2. Villous-to-crypt length ratios in jejunal biopsies from seven subjects before and after chronic simvastatin treatment. Individual values pre- and post-treatment are the mean of measurements from two observers blinded as to origin of specimens. No pattern of deviation from the line of identity is apparent.

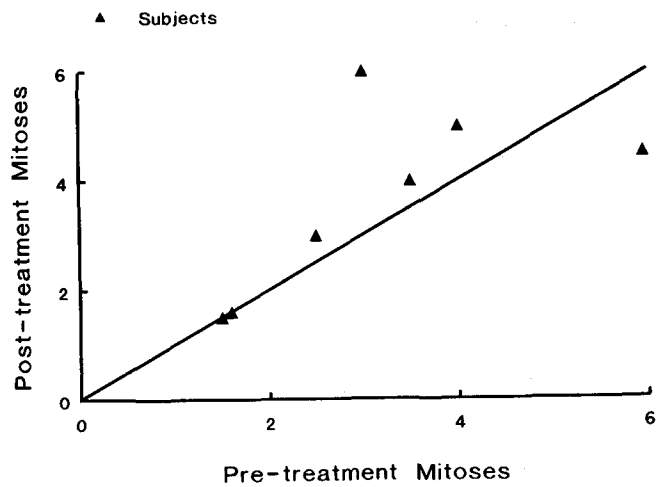

FIG. 3. Mitotic index (mitoses per 500 crypt cells) in jejunal biopsies from seven subjects before and after chronic simvastatin treatment. Individual values pre- and post-treatment are the mean of measurements from two observers blinded as to origin of specimens. No pattern of deviation from the line of identity is apparent.

between change in reductase activity or absolute level of post-treatment reductase activity and either villous/crypt ratio change or mitotic index change. Finally, three subjects had unpaired biopsies (two pretreatment and one post-treatment) for evaluation. Values for villous/crypt ratio, mitotic index, and inflammation for these samples were quite consistent with those of the paired samples.

DISCUSSION

In this study, simvastatin was clearly quite effective in reducing levels of serum cholesterol. Virtually all of the reduction occurred in the LDL cholesterol fraction. Simvastatin, similar to the other reductase inhibitors, is absorbed through the mucosal cells of the small intestine, and its metabolites are excreted into bile (20). In spite of high enterocyte exposure to this potent drug, and in spite of prior experience with the effects of reductase inhibitors on deoxyribonucleic acid synthesis and cell replication (5–7,21), no adverse histologic changes in gut mucosa morphology were observed. A significant decrease in enterocyte replication would be expected to result in consistently diminished crypt mitotic index and decreased villous/crypt length ratio. A shortened life span for mature enterocytes would be expected to result in increased crypt mitotic index and decreased villous/crypt length ratio, as seen in celiac sprue. Absence of either of these changes in a consistent manner suggests that this reductase inhibitor does not produce an adverse effect on enterocyte replication, in spite of results of *in vitro* studies (12).

Treatment with HMG-CoA reductase inhibitors has been shown to induce the quantity of enzyme mass and activity, after removal of the drug, in rat liver (9,22), human liver (23), human mononuclear leukocytes (10), fibroblasts (8) and rat and canine ileum (22). Our current finding, that measured HMG-CoA reductase activity in human jejunal homogenate is not induced by simvastatin, is consistent with our previous findings for lovastatin in human jejunal homogenates (17) and mouse jejunal mucosa microsomes (24). It is also consistent with the lack of effect on observed parameters of cell replication.

There are several possible explanations for the failure to measure jejunal enzyme induction by reductase inhibitors. Since activity was measured in whole mucosal homogenate, it is possible that simvastatin or an active metabolite remained present in the homogenate and served to inhibit measured enzyme activity. Prior studies with lovastatin suggested this possibility, since inhibitory activity was observed in some post-treatment homogenate samples (17). Similarly, enzyme induction in human mononuclear leukocyte microsomes was associated with a reduction in effective cholesterol synthesis *in vivo*, so that inhibitory drug activity was able to overcome enzyme induction in this circumstance (10). Studies reported in mice, however, measured reductase activity in microsomal pellets and also failed to show apparent enzyme induction of measured enzyme activity (24). Thus, it is also possible that jejunal mucosa may differ from other tissues, including rat ileum, in its ability for HMG-CoA reductase induction by enzyme inhibitors. Species differences are one possibility. Alternatively, parent drug absorbed by jejunal enterocytes may be less active intramucosally than metabolites following hepatic metabolism (20). Since biopsies were obtained at least 8 hr after last drug dose, it is also possible that any acute drug effect on this enzyme with known rapid turnover may have been too transient to have been detected. Finally, the previous study which did report enzyme induction in rat ileum (22) used proportionally much larger drug doses in rats (0.075% of diet weight) and in dogs (180 mg/kg/d).

The McGill Unit for the Prevention of Cardiovascular Disease, McGill University, Royal Victoria Hospital, Montreal, Quebec, Canada H3A 1A1

Acylation stimulating protein (ASP) is a 14 kDa plasma protein which causes *in vitro* triacylglycerol synthesis in human adipocytes and fibroblasts to increase substantially. ASP was found to stimulate human adipose tissue microsomal glycerophosphate acyltransferase and diacylglycerol acyltransferase activities by 23% and 90%, respectively. However, phosphatidate phosphohydrolase activity showed no increase in activity, nor did microsomal acyl-CoA synthetase activity. Moreover, ASP did not decrease the apparent K_m of diacylglycerol acyltransferase (DGAT), but rather increased its apparent V_{max} suggesting direct interaction of ASP with DGAT. *Lipids 26,* 495–499 (1991).

We have recently reported the purification and partial characterization of acylation stimulating protein (ASP) from human plasma (1). ASP is a 14 kDa protein which stimulates triacylglycerol synthesis in human adipocytes (300% stimulation) and skin fibroblasts (170% stimulation) (1,2). Indeed, ASP appears to be the most potent *in vitro* stimulant yet described of triacylglycerol synthesis in human adipocytes. Beyond this, there is now evidence ASP may play an important role *in vivo* in the normal response to an oral fat load in that the higher the plasma ASP, the more rapid the clearance of triacylglycerol from plasma (3). Moreover, a reduced response of fibroblasts to ASP in terms of triglyceride synthesis appears to be characteristic of a subgroup of patients with hyperapobetalipoproteinemia (4,5).

In preliminary experiments with cell-free systems, ASP has been shown to stimulate fatty acid incorporation into triacylglycerol in the microsomal fraction of human adipose tissue (2). Since ASP is internalized after binding to a specific receptor in the cell membrane (5), this observation suggests that it may exert its physiological effect by interacting intracellularly with the enzymes involved in fatty acid metabolism. Therefore, in this study we have determined the effect of ASP on the *in vitro* activity of glycerolipid synthetic enzymes.

MATERIALS AND METHODS

Palmitoyl-CoA, oleic acid, diolein, L-α-glycero-3-phosphate, sodium phosphatidate (from egg yolk), ATP, CoA and bovine serum albumin (BSA) (essentially fatty acid free) were obtained from Sigma (St. Louis, MO). [9,10-^{3}H]Oleic acid (9 Ci/mmol), [2-^{3}H]L-glycerol-3-phosphate (10.6 Ci/mmol) and [1-^{14}C]palmitoyl-CoA (58 Ci/mol) were from New England Nuclear (Boston, MA).

ASP was purified from human plasma as previously described (3). Adipose tissue was obtained at surgery from obese patients undergoing gastroplasty, and the corresponding microsomal and cytosolic fractions were prepared by differential centrifugation of the homogenized tissue (6,7).

All enzyme assays were performed in duplicate at 37°C. Our assay of acyl-CoA synthetase activity is a modification of the method described by Bar-Tana *et al.* (8). An aliquot of microsomal preparation (from 1–5 μg protein) was incubated with 2.5 mM ATP, 0.5 mM CoA and 18 μM [^{3}H]oleic acid (46 Ci/mol, New England Nuclear) in 250 μL of 0.1 M Tris/HCl, pH 7.5, containing 2mM DTT and 10 mM $MgCl_2$. The tritiated fatty acid was delivered first in 2-propanol to the empty glass tube followed by evaporation of the solvent under an N_2 stream. After 1-min incubation at 37°C, 1 mL of Dole's reagent (2-propanol/heptane/1 N H_2SO_4, 40:10:1, v/v/v) was added to stop the reaction. Following addition of 0.3 mL H_2O and 0.6 mL heptane and vortexing, the lower phase was washed three times with heptane and an aliquot of 250 μL was transferred to a vial containing 7.5 mL Scintiverse II (Fisher Scientific Co., Montreal, Canada) for counting in a Beckman LS-1800 beta counter (Beckman Instruments, Inc., Irvine, CA).

Microsomal glycerophosphate acyltransferase activity was determined by measuring the incorporation of 1 mM [^{3}H]glycero-3-phosphate into butanol-soluble products in the presence of oleic acid, ATP and CoA. The incubation mixture had essentially the same composition as previously, except that 1 mM [^{3}H]glycerophosphate (2.5 Ci/mol) was added, and oleic acid was not radioactive. At the indicated times, the reaction was stopped with 0.75 mL of butanol saturated with water. The butanol phase was washed three times with 1 mL of water saturated with butanol. An aliquot of 400 μL was counted in Scintiverse. When resolved by thin-layer chromatography (TLC), neutral lipids (diacylglycerol and triacylglycerol) accounted for 4% of the extracted radioactivity, whereas phosphatidate and lysophosphatidate accounted for about 95%.

Phosphatidate phosphohydrolase (PAPH) activity was assayed by measuring the rate of phosphate release from exogenous phosphatidate (9). Aliquots of microsomes (about 10 μg protein) were incubated for 1 hr in 0.5 mL of 25 mM tris-maleate, pH 6.5, containing 1 mM DTT, 5 mM $MgCl_2$, and 0.8 mg/mL of sodium phosphatidate. The reaction was stopped with 100 μL of 60% trichloracetic acid and 10 μL of 30 mg/mL BSA. After 20 min at 0°C, the protein was centrifuged down and a 400 μL aliquot from the supernatant was removed for phosphate determination (10). Under these conditions, the apparent K_m of the enzyme for phosphatidate was 50 μg/mL.

Abbreviations: ASP, acylation stimuating protein; BSA, bovine serum albumin; DGAT, diacylglycerol acyltransferase; DTT, dithiothreitol; FABP, fatty acid binding protein, GPAT, glycerophosphate acyltransferase; PAPH, phosphatidate phosphohydrolase; TLC, thin-layer chromatography.

Microsomal diacylglycerol acyltransferase was assayed by measuring the rate of esterification of the acyl-CoA formed *in situ* with exogenous diacylglycerol. The incubation mixture was the same as in the acyl-CoA synthetase assay, but 30 nmol of diolein were delivered in 2 μL of acetone at the beginning of an 8-min incubation. Following addition of 1 mL of Dole's reagent, the top phase was washed three times with 1 mL of 2-propanol/heptane (4:1, v/v) and 1 mL of 0.05% KOH, and a 500-μL aliquot was counted in Scintiverse. When the extracted lipids were resolved by TLC on silica gel, about 90% of the radioactivity migrated with the triacylglycerol fraction and 5% with the diacylglycerol fraction.

Protein concentrations were measured by the dye-binding method of Bradford (11), using BSA as standard. Neutral lipids were resolved by TLC on silica gel developed with hexane/diethyl ether/acetic acid (85:15:1, v/v/v).

Kinetic parameters were determined by non-linear regression to the Michaelis Menten equation by using the program Enzfitter (Biosoft, Cambridge, U.K.).

RESULTS

ASP effect on microsomal acyl-CoA synthetase. We first investigated the effect of ASP on microsomal acyl-CoA synthetase from human adipose tissue. As shown in Figure 1, the initial rate of acyl-CoA formation declined rapidly with time and after 15 min incubation approached a plateau level of acyl-CoA formation corresponding to about 40% of the added [^{3}H]oleic acid. This plateau level increased with the amount of microsomes in the incubation medium and likely reflected product inhibition of the enzyme. Addition of up to 60 μg/mL of ASP to the assay medium did not result in any significant change in either the rate of oleoyl-CoA synthesis: 112 ± 16 (SEM) nmol/min/mg *vs* 115 ± 19 nmol/min/mg for the control (averages of six independent experiments), or the plateau levels. This was confirmed by measuring the amount of acyl-CoA formed at 1- and 15-min incubation in the presence of increasing amounts of ASP (not shown). Under our experimental conditions, microsomal acyl-CoA synthetase showed an apparent K_m for oleic acid of about 5 μM, and thus the experiment of Figure 1 was performed at a saturating concentration of fatty acid (18 μM). However, when the experiment was repeated with 5 μM oleic acid, a similar result was obtained.

ASP effect on microsomal GPAT. Microsomal glycerophosphate acyltransferase activity (GPAT) was determined by measuring the esterification of [^{3}H]glycero-3-phosphate with *in situ* formed oleoyl-CoA. The initial rate of GPAT activity at 18 μM oleate (9.1 ± 0.24 nmol/min/mg) was more than ten times lower than the rate of acyl-CoA formation; thus no lag is observed in Figure 2. Addition of ASP (60 μg/mL) to the incubation medium resulted in a slight but significant increase of glycerophosphate incorporation into lipids. The stimulation of 23% ± 7.8% (SEM) with 10-min incubation was significant (n=5, $p<0.05$ paired *t*-test). The effect was concentration dependent and reached a plateau at 30 μg/mL ASP. No change in the level of GPAT stimulation by ASP

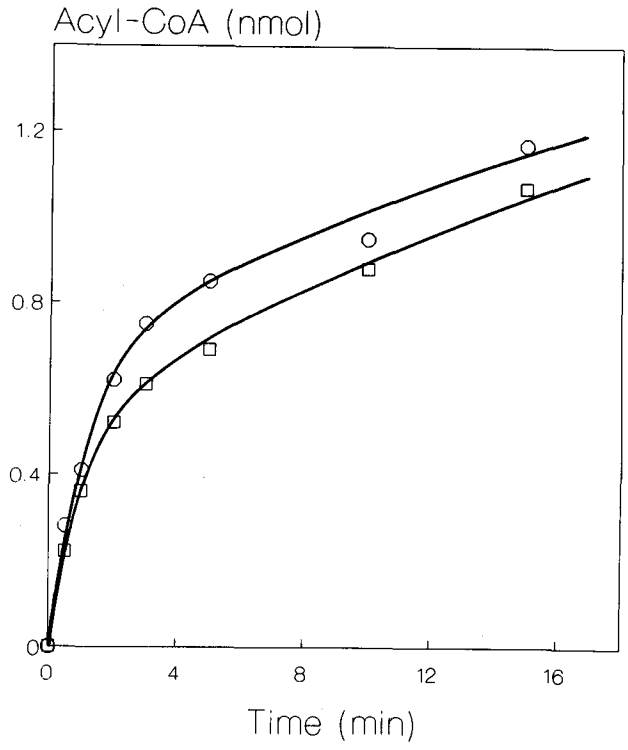

FIG. 1. ASP effect on acyl-CoA synthetase activity. Human adipose tissue microsomes (10 μg/mL) were incubated with (□) and without (○) 60 μg/mL ASP under the conditions described for acyl-CoA synthetase assay. At indicated times, 250 μL aliquots were removed and their [^{3}H]oleoyl-CoA content determined.

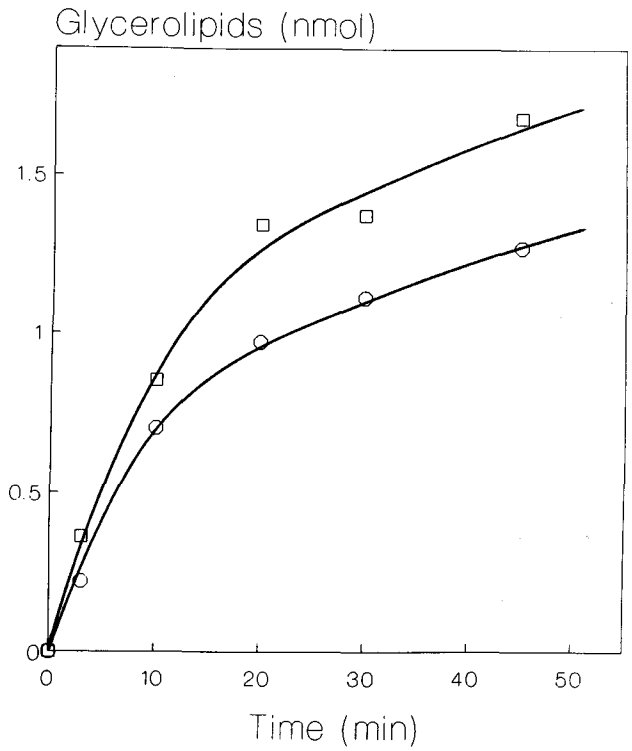

FIG. 2. ASP effect on glycerophosphate acyltransferase. Human adipose tissue microsomes (8 μg) were assayed for glycerophosphate acyltransferase activity in the presence (□) and absence (○) of 60 μg/mL ASP.

was observed in the range of oleate concentration from 1 to 36 μM (below saturation of the enzyme). A similar degree of stimulation was observed when fatty acid, CoA and ATP were substituted by 20 μM oleoyl-CoA in the assay.

ASP effect on PAPH. We then investigated the effect of ASP on phosphatidate phosphohydrolase activity by using exogenous phosphatidate delivered as an aqueous emulsion. ASP was found not to increase the rate of phosphate release (19.8 ± 1.4 nmol/min/mg *vs* 20.2 ± 0.5 nmol/min/mg in the absence of ASP) at high phosphatidate concentration (0.8 mg/mL). Similarly, ASP did not change the activity of cytosolic PAPH, whose specific activity was about 2.5 times lower than the microsomal activity (data not shown).

By contrast, at a non-saturating concentration of phosphatidate (33 μg/mL), ASP inhibited PAPH activity by 40 ± 6% (n=6, $p<0.01$, paired *t*-test). The effect was dose dependent and plateaued at about 20 μg/mL ASP.

Using a different approach, we measured the effect of ASP on the glycero-3-phosphate dependent synthesis of neutral lipids. In these experiments we proceeded as for the DGAT assay, but diolein was replaced with 1 mM glycero-3-phosphate. In the presence of 0.2 mg/mL cytosolic fraction, the rate of incorporation of oleic acid into neutral lipids was 0.6 ± 0.2 (SEM) nmol/min/mg. Upon addition of 80 μg/mL ASP that rate increased by 43 ± 12% (SEM) (n=6, $p<0.05$, paired *t*-test).

ASP effect on DGAT. Under our experimental conditions, microsomes from human adipose tissue catalyzed the esterification of oleic acid with diolein in the presence of ATP and CoA at an average rate of 5.0 ± 0.25 nmol/min/mg (SEM) (13 determinations). Addition of ASP resulted in an increase in the rate of triacylglycerol synthesis (Fig. 3a). The effect is dependent on the concentration of ASP, reaching a plateau of maximal stimulation at about 80 μg/mL of ASP (Fig. 3b). The average maximal stimulation observed in 12 experiments with different preparations of microsomes and ASP was 90 ± 10% (SEM) ($p<0.001$ paired *t*-test). A similar degree of stimulation was observed when fatty acid, CoA and ATP were substituted by 20 μM oleoyl-CoA in the incubation medium. Substitution of 6 μM ASP (84 μg/mL) by 20 μM BSA did not stimulate diacylglycerol acyltransferase activity; in fact, addition of BSA to the incubation medium prevented stimulation by ASP (results not shown).

To investigate whether the ASP effect was due to improved delivery of substrates or to increased specific activity of the enzyme, we followed the fatty acid and diacylglycerol dependence of DGAT activity in the presence and absence of ASP (Fig. 4). Stimulation was observed at all oleate concentrations assayed in the range of 1-36 μM (Fig. 4a) and at all diolein concentrations in the range of 15-250 μM (Fig. 4b). The results were analyzed by non-linear regression to the Michaelis Menten equation in order to obtain the apparent kinetic parameters for both substrates (Table 1). At 120 μM diolein, the apparent V_{max} for oleate saturation (7.2 ± 0.36 nmol/min/mg) (SEM) was increased by 100% in the presence of ASP. No significant change was observed for the apparent K_m for oleate. A similar degree of stimulation (150%) by ASP was observed for the V_{max} corresponding to diolein saturation in the presence of 18 μM oleate, even though the microsomal preparation for this experiment showed

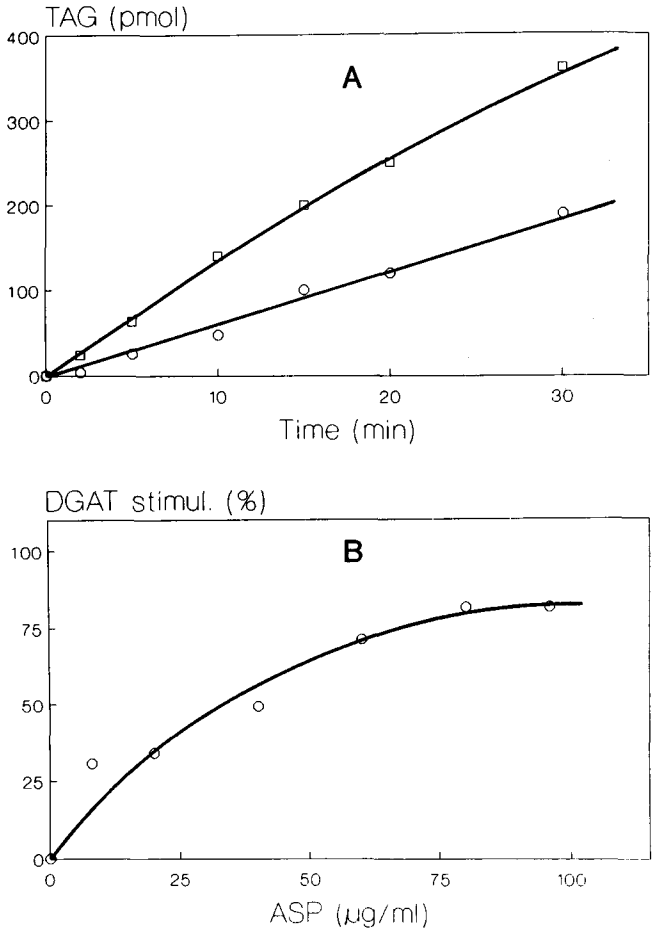

FIG. 3. ASP effect on diacylglycerol acyltransferase activity. A) Microsomes (1.7 μg) were assayed for incorporation of [^{3}H]oleic acid into triacylglycerol (TAG) in the presence (□) and absence (○) of 80 μg/mL ASP as described for the DGAT assay. B) Microsomes (6 μg) were assayed for DGAT activity in the presence of increasing amounts of ASP and the results expressed as percentage stimulation over the control rate (3.2 nmol/min/mg).

TABLE 1

ASP Effect on DGAT Kinetic Parameters

Substrate	Parameter[a]	Control	ASP	p[b]
Oleate[c]	V_{max} (nmol/min/mg)	7.2 ± 0.36	14.5 ± 1.3	<0.001
	K_m (μM)	8.3 ± 1.1	10.7 ± 2.1	n.s
Diolein[d]	V_{max} (nmol/min/mg)	3.2 ± 0.53	8.0 ± 1.1	<0.01
	K_m (μM)	51 ± 25	58 ± 24	n.s

[a] Apparent kinetic parameters for the experimental conditions described in the legend of Figure 4.

[b] For *t*-test.

[c] Three independent experiments were performed with variable concentrations of oleate as described in the legend of Figure 4a. Non-linear regression to the Michaelis Menten equation was computed for each experiment. Average values ± SEM are given.

[d] Results in Figure 4b were analyzed by non-linear regression as above. Fitted parameters ± standard error are given.

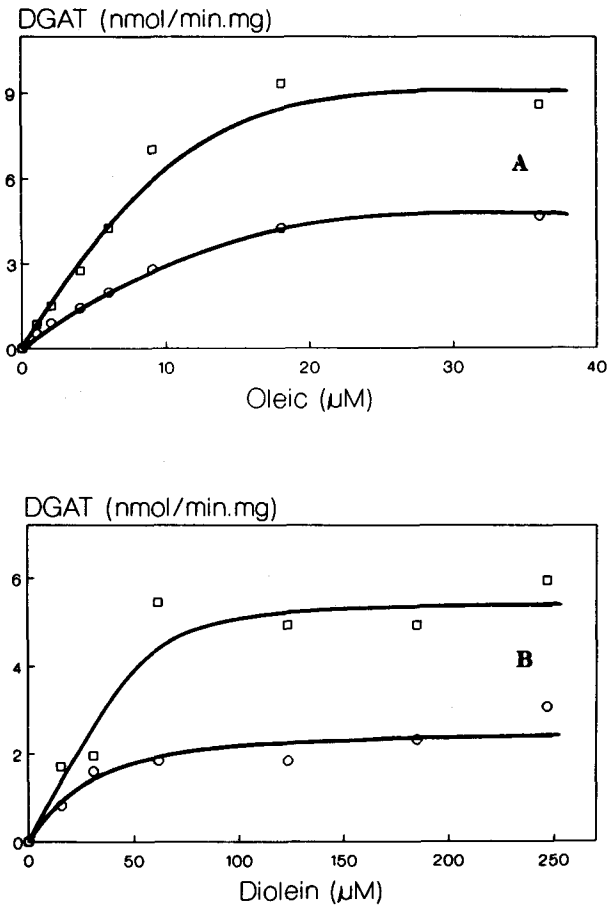

FIG. 4. Substrate dependence of ASP effect on DGAT. A) Microsomes (4 μg) were assayed for diacylglycerol acyltransferase activity with 0.12 mM diolein and different oleic acid concentrations in the presence (□) and absence (○) of 80 μg/mL ASP. B) Microsomes (5 μg) were assayed for diacylglycerol acyltransferase activity with 18 μM oleic acid and different diolein concentrations in the presence (□) and absence (○) of 60 μg/mL ASP. Results were corrected for activity with no diolein added.

lower DGAT activity. By contrast, estimates of K_m for diolein showed no significant change in the presence of ASP.

DISCUSSION

A number of cytosolic proteins, in particular fatty acid binding protein (FABP) have been reported to stimulate *in vitro* triacylglycerol synthesis in microsomes (12–16), and it has been proposed that FABP stimulates *in vivo* lipid synthesis by enhancing delivery of fatty acid and/or acyl-CoA to the lipid synthetic enzymes in the endoplasmic reticulum (17).

ASP also stimulates triacylglycerol synthesis in adipocytes but, in contrast to FABP, does so in intact cells (1,2). Because ASP is internalized after binding specifically to the cell membrane (5), and because the degree to which ASP stimulates triacylglycerol synthesis is proportional to the extent of its binding and internalization (5), and because ASP stimulates triacylglycerol synthesis in broken cell preparations (2), we have considered the hypothesis that it may be the internalized ASP which is the active metabolic agent. If so, it seemed likely that ASP would affect one or more of the enzymes involved in microsomal triacylglycerol synthesis.

Since at present there is no consensus as to which enzyme controls the rate limiting step in adipose tissue triglyceride synthesis, it was decided to investigate all the enzymes involved with the exception of monoacylglycerophosphate acyltransferase. Monoacylglycerophosphate acyltransferase was not assayed because of the difficulty involved in assaying this enzyme, and because it has been established that GPAT controls the rate limiting step in phosphatidate synthesis in microsomes.

Two possibilities were considered—either that ASP was acting to increase delivery of fatty acid or acyl-CoA to the microsomal enzymes as has been shown for FABP, or that it was directly affecting enzyme activity. The assays, therefore, were designed to avoid any fatty acid or acyl-CoA delivery system such as BSA or cytosolic proteins since, in their absence, any enzyme activity stimulated by ASP could then be analyzed for an effect on K_m, which would suggest an effect on substrate delivery. No such effects were found.

Microsomes readily take up oleic acid, and in the presence of ATP and CoA synthesize oleoyl-CoA at a much higher rate than can be utilized by the triglyceride synthetic enzymes. Therefore, a relatively constant pool of acyl-CoA is created which can be used for the assay of GPAT and DGAT activities. ASP has no significant effect either on acyl-CoA synthetase initial rate or plateau level at both saturating and non-saturating fatty acid concentrations.

The slight, but statistically significant, effect of ASP on GPAT activity (23%) is independent of oleate concentrations in the range of 1–36 μM, a concentration range below saturation of the enzyme. This suggests an increase in the intrinsic GPAT activity rather than increased delivery of *in situ*-formed oleoyl-CoA. A complete study of the effect of ASP on the kinetic parameters of the enzyme was prevented by the difficulty of achieving saturation of the enzyme with oleate and by the small net changes observed.

The inhibitory effect of ASP on PAPH activity with exogenous phosphatidate at subsaturating concentration may not reflect a specific effect on the enzyme, but rather interference with the delivery of substrate to the membrane vesicles. Indeed, when we used *in situ*-formed phosphatidate from acyl-CoA and glycerophosphate, the rate of neutral lipid (di- and triacylglycerol) formation was significantly increased by 40%. This stimulation cannot be fully accounted for by the 23% stimulation of GPAT activity.

The clearest effect of ASP was observed in the assay of DGAT activity with exogenous diacylglycerol. ASP doubles the maximal activity of the enzyme at saturating concentrations of both oleate and diolein, suggesting that it increases the intrinsic DGAT activity rather than improving substrate delivery. Indeed, the K_m of the enzyme for both substrates are not significantly changed by ASP.

The percent stimulation of DGAT was independent of fatty acid or diacylglycerol concentration, but was dependent on ASP concentration and shows saturation. Thus, ASP could be a cofactor of DGAT similar to the way in which apo-CII is a cofactor of lipoprotein lipase. Other less specific mechanisms could also explain our results. For

instance, modification of membrane structure resulting in conformational changes of enzymes or inhibition of phosphatidate and triglyceride lipase(s) could occur.

Whether the observed effect on DGAT fully explains the mechanism of action of ASP is not clear since maximal stimulation in broken cell preparations is less than that in intact cells. Also, we have as yet to establish that intact ASP is present in adipocytes. Nevertheless, we believe that the present data constitute further evidence that ASP may play a fundamental role in fatty acid metabolism in humans.

Effect of Fish Oil Supplementation on the Excretion of the Major Metabolite of Prostaglandin E in Healthy Male Subjects

Aldo Ferretti[a,*], Joseph T. Judd[a], Rachel Ballard-Barbash[b], Padmanabhan P. Nair[a], Philip R. Taylor[b] and Beverly A. Clevidence[a]

[a]Lipid Nutrition Laboratory, Beltsville Human Nutrition Research Center, ARS-USDA, Beltsville, Maryland 20705 and [b]Division of Cancer Prevention and Control, National Cancer Institute, NIH, DHHS, Bethesda, Maryland 20892

We investigated the effect of fish oil supplementation on the synthesis of prostaglandin E (PGE) *in vivo* by measuring the excretion of its catabolite, PGE-M, in 24-hr urine by gas chromatography/mass spectrometry. Forty healthy male volunteers (24–57 years of age) consumed a controlled basal diet providing 40% of energy from fat (P/S ratio about 0.8:1), 130 mg/1000 kcal cholesterol, and a minimum of 22 mg/day of α-tocopherol (α-T), for three experimental periods lasting a total of 28 weeks. During period 1 (10 weeks) the diet was supplemented with placebo (PO) capsules (15 × 1 g/day) consisting of a blend of fats approaching the fatty acid profile of the basal diet. This was followed by a second 10-week period during which the subjects received 15 × 1 g/day capsules of fish oil concentrate (FOC). During period 3 (8 weeks) they continued the 15 g/day intake of FOC but received an additional 200 mg/day of α-T. PO and FOC capsules contained 1 mg α-T/g fat as antioxidant. A 14% reduction of PGE-M excretion was observed after 10 weeks of FOC supplementation (period 2), compared to an identical period of placebo supplementation (period 1), P=0.009. PGE-M excretion during the last week of period 3 was not significantly different from that at the end of period 2. The reduction in PGE synthesis in response to the relatively high marine oil supplementation was large in many subjects participating in this study.
***Lipids* 26, 500–503 (1991).**

A protective effect of ω3 polyunsaturated fatty acids (PUFA) against atherothrombotic disorders has been established reasonably well from studies with humans and animal models (1–5). The underlying biochemical mechanisms of this protective action are not entirely understood, but a major role has been attributed to effects on ω6 fatty acid metabolism with resultant changes in the profile of products of arachidonate cyclooxygenation (5,6). Considerable work has been done to evaluate the effects of ω3 PUFA on thromboxane (TXA_2) and prostacyclin (PGI_2) synthesis (4,6–10). This is justified in view of the preeminent roles of these eicosanoids in vascular biology. It is a reasonable assumption, however, that in addition to thromboxane and prostacyclin, other eicosanoids may also respond to dietary manipulations of adequate magnitude.

Abbreviations: α-T, α-tocopherol; EPA, eicosapentaenoate; FOC, fish oil concentrate; GC/MS, gas chromatography/mass spectrometry; PGE, prostaglandin E; PGE-M, 11α-hydroxy-9,15-dioxo-2,3,4,5,20-pentanor-19-carboxyprostanoic acid; PGI_2, prostacyclin; PO, placebo oil; P/S, ratio dietary linoleate to saturated fatty acids; PUFA, polyunsaturated fatty acids; TXA_2, thromboxane A_2.

Prostaglandin E_2 (PGE_2) has been characterized as the most common and most potent of mammalian prostaglandins. It is clearly involved in mechanisms of blood pressure regulation (11,12), tumorigenesis (13–15), and immune response modulation (16–18). Notwithstanding these critical roles, surprisingly little is known about the capacity of dietary fish oil to modulate PGE_2 synthesis in humans *in vivo* and attendant physiologic consequences (4).

The present study was designed to determine if some changes in physiological variables attributed to fish oil consumption might be explained by altered PGE biosynthesis. Based on the ubiquity and potency of PGE, we expected this work to help identify other, yet uncovered, effects of fish oil consumption. We quantified the effect of a relatively high supplementation of a marine oil concentrate on prostaglandin E biosynthesis, by measuring the urinary excretion rate (μg/24 hr) of 11α-hydroxy-9,15-dioxo-2,3,4,5,20-pentanor-19-carboxyprostanoic acid (PGE-M). This compound is commonly regarded (19,20) as an index of systemic production of E-series prostaglandins (E_2+E_1).

MATERIALS AND METHODS

Subjects. Forty non-smoking male subjects, 24–57 years of age (mean 37.6 ± 8.8, SD), were selected among volunteers from the area surrounding the Beltsville Agricultural Research Center (Beltsville, MD). They were screened by a preliminary medical questionnaire to eliminate those with complicating health problems and unusual dietary habits. Regular users of dietary supplements (especially vitamin E) and of excessive quantities of alcohol were also excluded. Potential subjects were examined by a physician, and by hematological and chemical screening of blood and urine. Those with plasma α-tocopherol (α-T) levels outside of the normal range were excluded. Body weights were between 90 and 120% of the desirable weights as given in the 1983 Metropolitan Life Insurance tables. Aspirin, aspirin-containing drugs and other anti-inflammatory drugs were not allowed during the study. Occasional use of tylenol was the only permitted analgesic. Antibiotics and other medications taken during the study under a physician's direction were evaluated for possible effects on study parameters. All procedures were approved by the Human Studies Committees of the National Institutes of Health and the Georgetown University School of Medicine.

Controlled diets. The basal diet for the controlled dietary periods was designed to reflect the typical dietary pattern of Beltsville area volunteers as determined in earlier studies, except that the fat level of the diet was reduced to allow isoenergetic supplementation with 15 g/day placebo oil (PO) or fish oil concentrate (FOC) without permitting energy from fat to exceed 40% of total. Cholesterol intake was about 130 mg/1000 kcal. All nutrients

for which food data are available were provided by the diets in amounts to meet the Recommended Dietary Allowances (21). Caloric intake was adjusted in increments of 400 kcal to maintain constant body weights throughout the study. The contents of long-chain (C_{20}, C_{22}, and C_{24}) ω3 fatty acids were minimized in the basal diet by excluding fish from the menus, while vitamin E content was minimized by excluding highly fortified foods from the diet.

A fourteen-day menu cycle provided variety and helped maintain acceptability of the diets. During the controlled diet periods, breakfast and supper were consumed in the Beltsville Human Nutrition Research Center, Human Studies Facility (HSF), Monday through Friday. A box lunch was provided at breakfast time. Weekend and holiday meals were pre-packaged in the HSF for home consumption and used the same menus as other days of the menu cycle. No foods other than those provided by the study were permitted, and alcohol consumption was not allowed during the controlled diet periods.

Lipid supplementation/placebo oil (PO). The placebo consisted of a blend of commonly available fats (corn oil, beef tallow, lard) approaching the fatty acid profile of the basal diet, and was encapsulated in one-gram amounts with one mg α-T per capsule as antioxidant. PO was prepared and encapsulated by Hoffmann-La Roche, Inc. (Nutley, NJ), and was indistinguishable in external appearance from the fish oil concentrate.

Fish oil concentrate (FOC). The ω3 fatty acid supplement (ROPUFA®) was an anchovy oil derivative prepared in one batch sufficient for the duration of the study. FOC was prepared by Hoffmann-La Roche by a distillation/deodorization process which increases the ω3 fatty acid content to about 50%, compared to about 30% for most commercial fish oil supplements. FOC was also provided as hard gelatin capsules containing one gram of fat and one mg α-T. Table 1 shows the main fatty acid constituents of the placebo and fish oil supplements. Both supplements were administered to participants at the rate of 15 g/day, 7 capsules at breakfast and 8 capsules at supper.

Experimental protocol. Prior to supplementation, the subjects were on a self-selected diet for two weeks while baseline measurements were taken. This was followed by the controlled diets described above for a total of 28 weeks divided into three periods according to the supplement given: Period 1 (ten weeks) 15 g/day PO; Period 2 (ten weeks) 15 g/day FOC; Period 3 (eight weeks) 15 g/day FOC plus 200 mg/day α-tocopherol in two equal doses. Dieticians observed the subjects as they consumed the oil capsules and the vitamin E supplements. No attempt was made to provide a placebo for the vitamin E supplement. The estimated daily intake of nutrients for the three periods was (in percent of energy): fat, 40%; carbohydrate, 45%; and protein, 15%. α-Tocopherol intake from natural foods was at least 22 mg. Table 2 shows the estimated daily fatty acid intakes during the controlled-diet periods.

Urine collection. Three consecutive 24-hr urines were collected during the last week of each period. Samples were collected in silanized glass bottles and kept on ice during the collection period. After the 24-hr collections were completed, the volumes were measured, 2%-portions of each 24-hr collection were pooled and either analyzed immediately or stored at −22°C.

Measurement of PGE-M. Analyses of 11α-hydroxy-9,15-dioxo-2,3,4,5,20-pentanor-19-carboxyprostanoic acid (PGE-M) were done on 20-mL aliquots of the 72-hr pools prepared as described above. This enabled us to assess the mean daily excretion of PGE-M during the 72-hr period. Procedures and instruments were described previously by Ferretti *et al.* (22). When prolonged urine storage was unavoidable, the PGE-M values were adjusted to compensate for decay according to a first-order rate constant determined in our laboratory (23). PGE-M excretion rates are expressed as μg/24 hr.

Statistical analysis. Twenty-four-hr PGE-M excretion rates and lipid intakes were evaluated by paired *t*-tests with the computer methodology of the Statistical Analysis System (SAS Institute, Inc., Cary, NC). All P values less than 0.05 were considered statistically significant.

RESULTS

Four subjects were withdrawn entirely from the study because they developed health conditions that required administration of interfering prescription drugs. This left 36 subjects for analysis. Period 3 PGE-M excretion data from one subject (No. 35) were disregarded because of a health problem that required prescription drugs during period 3, and period 3 PGE-M data from another subject (No. 36) were disregarded because of non-adherence to study protocol. The data were analyzed by analysis of variance. There were no significant carryover effects. A paired *t*-test was therefore utilized for comparison between diets as planned in the study design.

[a]Reduction calculated as period 1 minus period 2.
[b]Data not recorded (see Results).

The mean PGE-M urinary excretions (μg/24 hr) during the last week of periods 1, 2 and 3 were 15.41 ± 2.12 (SEM) (N=36), 12.51 ± 1.78 (N=36) and 12.77 ± 1.85 (N=34), respectively. Paired *t*-tests indicated a significant reduction of PGE-M excretion during period 2, compared to that of period 1 [difference = 2.90 ± 0.89 (SEM) μg/24 hr, P=0.002]. The reduction based on individual contributions was 14% (P=0.009). Excretion rates of each subject for the three feeding periods are shown in Table 3. PGE-M excretion during the last week of period 3 was not significantly different from that at the end of period 2.

DISCUSSION

PGE-M excretion rates during periods 1 and 2 provide clear evidence that fish oil supplementation inhibits *in vivo* production of E-series prostaglandins in most individuals. PGE synthesized in the kidneys and seminal vesicles are excreted virtually unmetabolized, thus they escape measurement with our methodology. The rationale for disregarding their contribution to total synthesis has been discussed (24). PGE-M excretion reflects PGE production at sites easily accessible to systemic clearance. In a study of much shorter duration (four weeks), Knapp and FitzGerald (4) reported a non-significant trend toward lower PGE-M values in a group of eight volunteers receiving 50 mL/day of fish oil. In a rat study, Hornstra and Stegen (25) demonstrated a diet-induced shift in the ratio monoic to dioic prostaglandin metabolites. Although our work is concerned with the synthesis and metabolism of PGE alone—and not of the aggregate PGE + PGF, as is the paper by Hornstra and Stegen (25)—it is still possible that our results were similarly influenced by the dietary manipulation, if indeed the metabolic shift observed in rats also occurs in humans.

Research by other investigators on the effect of α-tocopherol on arachidonate cyclooxygenation has produced conflicting results. In our study, a large vitamin E supplement was provided during period 3. Vitamin E was given to counteract the effects of oxidative stress (26) from prolonged intake of several grams of ω3 PUFA and to determine if a large daily dose of vitamin E has any measurable effect on PGE synthesis when other dietary parameters were held constant. Two-hundred mg/day of α-T had no significant effect on PGE-M excretion.

In view of the high simultaneous intake of linoleate (25 g/day), the magnitude of PGE-M excretion rate reduction (14%) during FOC supplementation is, in our opinion, remarkable. The relevant issue we have to address is: What is the biological impact of changes in PGE production of the magnitude measured in this study? The synthesis of PGE is not localized in a specific tissue as is the case with thromboxane A_2 (platelets) and most of prostacyclin (vascular endothelium). The biological functions of PGE are manifold depending on the tissue where the synthesis takes place; hence the physiologic consequences of reduced PGE production are not as obvious or predictable as those of a reduced synthesis of TXA_2 and PGI_2.

In a recent pilot study on long-term fish oil supplementation Ferretti *et al.* (27) demonstrated that, in addition to a reduction of renal PGE_2 synthesis in absolute terms, the pre-supplementation (renal) synthetic ratio PGE_3/PGE_2=O changed to PGE_3/PGE_2>O following fish oil administration. Thus, in this specific case, to assess the

effect of marine oil on renal physiology as modulated by arachidonate metabolism we must consider not only the effects of reduced PGE_2 synthesis but also the different biological activity of PGE_3 as compared to that of PGE_2. In view of the central role of PGE_2 in renal physiology (28), we wondered whether a shift in the PGE_3/PGE_2 ratio might have a detrimental effect on renal function (27). This is an issue of obvious concern which has been expressed by other investigators, expecially in reference to subjects with impaired renal function (4). Presumably, similar shifts in the PGE_3/PGE_2 synthetic ratio take place concurrently in other tissues.

Present knowlege of PGE biology strongly suggests that, in addition to renal function, the impact of PGE modulation is most likely to be manifested in the cardiovascular (11,12,29-32) and immune (16,17,33-38) systems, and possibly in tumorigenesis (13,15,39-41). Therefore, it is desirable to assess the long-term effects of a diet-induced reduction of PGE biosynthesis. Perhaps the most critical question that must be answered is: What is the extent of dietary lipid manipulation necessary to influence the eicosanoid system to a clinically significant degree? We also need to know more about the biological activity of PGE_3 *vis-à-vis* that of PGE_2.

In conclusion, the results of this study, if considered in conjunction with the regulatory roles attributed to prostaglandin E in critical areas of human physiology, suggest that prolonged use of fish oil supplements should not be incorporated into dietary recommendations until the pharmacology of marine lipids is better understood.

ACKNOWLEDGMENTS

Synthetic PGE-M, used to prepare the internal standard for the quantitative analyses, was supplied by Dr. J. Pike, The Upjohn Co. We are indebted to Cmdr. W. Campbell, USPHS, and M. Sunkin for keeping medical records, for recruiting, instructing and supervising the subjects, and for blood drawing. V. P. Flanagan and E. J. Maida provided excellent technical assistance. This study was supported in part by a Grant-in-aid from Hoffmann-La Roche, Inc., Nutley, NJ.

[Received August 6, 1990, and in revised form May 10, 1991; Revision accepted May 18, 1991]

Metabolism of n-3 Polyunsaturated Fatty Acids by the Isolated Perfused Rat Liver

Zu Jun Zhang[1], Henry G. Wilcox, Marshall B. Elam, Lawrence W. Castellani and Murray Heimberg*
Departments of Pharmacology and Medicine, The University of Tennessee, Memphis, Memphis, Tennessee 38163

The hepatic metabolism of oleic acid and n-3 fatty acids (eicosapentaenoic acid, EPA and docosahexaenoic acid, DHA), and secretion of very low density lipoprotein (VLDL) were studied in isolated perfused rat livers from normal chow fed male rats. The basal perfusion medium contained 30% bovine erythrocytes, 6% bovine serum albumin (BSA), and 100 mg/dL glucose, in Krebs-Henseleit bicarbonate buffer (pH 7.4), which was recycled through the liver for 2 hr. Individual fatty acids (EPA, DHA or oleic acid), as complexes with 6% BSA, or albumin alone, were infused at a rate of 70 μmol/hr. When any of these fatty acids was infused at this rate, the ambient concentration in the medium was maintained at 0.3–0.4 μmol/mL, indicative of similar hepatic rates of uptake for each fatty acid (*i.e.*, approximately 6 μmol/g liver/hr). When fatty acid was not infused, the ambient free fatty acid level was 0.16 μmol/mL. The concentrations of infused free fatty acids increased appropriately in the perfusion medium; however, with infusion of EPA, DHA, or oleate, the concentrations of perfusate palmitate and linoleate were the same as when fatty acid was not infused. Additionally, the perfusate concentration of oleate in the free fatty acid fraction was not affected by infusion of EPA and DHA. These data indicate a constant outflow of endogenous fatty acid unaffected by the presence of the exogenously supplied fatty acid.

The net secretion rate of VLDL lipids and protein was stimulated by infusion of oleate, whereas when EPA was infused, secretion rates were lower and similar [except for VLDL cholesterol (C), which was greater] to those occurring when fatty acid was not provided. DHA stimulated the secretion of VLDL triacylglycerol (TG), phospholipid (PL) and C to a similar rate, as did oleate, but secretion of VLDL cholesteryl ester (CE) and protein was lower and similar to that with EPA. VLDL and hepatic TG and CE were enriched with the infused fatty acids, compared to experiments without fatty acids, as determined by gas chromatography. Enrichment of PL, however, was significant only in liver upon infusion of EPA. The formation of $^{14}CO_2$ and perchloric acid soluble products from [1-^{14}C]EPA, considered separately, did not differ statistically from that obtained with [1-^{14}C]oleate, although the mean values were higher with [1-^{14}C]EPA. However, the sum of oxidation products derived from EPA was significantly greater than that from oleate. Incorporation of [1-^{14}C]EPA into TG and CE, but not into PL, was lower as compared to that from [1-^{14}C]oleate. These lower rates of incorporation of [1-^{14}C]EPA into VLDL lipids therefore paralleled the mass fatty acid enrichment patterns. It may be concluded that EPA is used to a similar extent as oleate for synthesis of PL, but is a poorer substrate for synthesis of TG. The reduced output of newly synthesized (radioactive) PL reflected the lower hepatic output of VLDL. Since hepatic uptake of EPA, DHA or oleate was identical, utilization of EPA for TG synthesis was less than that of oleate or DHA. Furthermore, utilization of endogenous fatty acids for TG synthesis and secretion of the VLDL was reduced in the presence of EPA. The decreased TG synthesis resulted in reduced formation of VLDL for transport of TG from the liver. These effects taken together with an apparently increased oxidation of EPA provide substantial evidence for a decrease in formation of VLDL and transport of TG, PL, C and CE into the circulation in response to EPA. DHA, however, appears to be an adequate substrate for TG synthesis and stimulates VLDL secretion. The reduced transport of CE may reflect lower selectivity of DHA by acyl-CoA; cholesterol acyltransferase for CE formation.

***Lipids 26,* 504–511 (1991).**

Several studies describing the hypolipidemic effects of fish diets, or dietary supplements of fish oil, on concentrations of blood lipids and lipoproteins have been published. Fish oils contain significant quantities of eicosapentaenoic acid (EPA, 20:5) and docosahexaenoic acid (DHA, 22:6), n-3 polyunsaturated fatty acids, which may be the primary components responsible for the reduction of plasma lipids. The ingestion of fish oils has been reported to reduce plasma concentrations of triacylglycerol (TG), very low density lipoprotein (VLDL), and cholesterol in humans (1,2) and in animals (3–5). Suppression of hepatic synthesis of TG and apolipoprotein (apo) B after ingestion of fish oil has been observed in humans (6), in cultured human hepatoma cells (Hep G2) (7), in perfused rat liver (8,9) and in cultured rat hepatocytes (10) and may be the principal mechanism by which the n-3 fatty acids lower plasma levels of TG and VLDL. Parks *et al.* (11), however, did not observe any suppression of apo B synthesis, although hepatic VLDL lipid synthesis and secretion were reduced in perfused livers from non-human primates (African green monkeys) which had been maintained for 2.5 years on a diet containing fish oil (11). The results were compared to livers from animals fed a lard enriched diet (11). More recently, Homan *et al.* (12), in studies with Hep G2 cells concluded that both oleate and EPA were equally effective for TG synthesis, while oleate was a better substrate for PL synthesis. Nevertheless, the release of newly formed lipids was lower by 20–40% in response to EPA. Interestingly, Wong *et al.* (13) also observed in Hep G2 cells that EPA was inhibitory to TG synthesis, but that DHA was not. However, both n-3 fatty acids were inhibitory to apo B synthesis resulting in depressed VLDL

Abbreviations used: ACAT, acyl-CoA:cholesterol acyltransferase; apo, apolipoprotein; BSA, bovine serum albumin; C, cholesterol (unesterified); CE, cholesteryl esters; EPA, eicosapentaenoic acid (20:5); DHA, docosahexaenoic acid (22:6); FA, fatty acid; FFA, free (unesterified) fatty acid; GC, gas chromatography; PL, phospholipid; TG, triacylglycerol; VLDL, very low density lipoprotein.

secretion. A similar result was obtained by Lang and Davis (14) in studies with rat hepatocytes, except that they did not observe EPA to be inhibitory to TG synthesis.

We studied the effects of EPA and DHA on hepatic lipid metabolism and the formation and secretion of VLDL by isolated perfused livers from normal chow fed rats, a system more suitable for studies of VLDL secretion. This was done to evaluate differences in metabolism of n-3 fatty acids reported by others using perfused livers or liver cells in tissue culture. We observed that EPA was a poorer substrate for synthesis of TG and secretion of VLDL than was oleic acid when the fatty acids were provided to the liver at a modest level (70 μmol/hr for 2 hr). However, under identical conditions, the incorporation of DHA into TG and the secretion of VLDL occurred to an extent comparable to that of oleic acid, suggesting TG synthesis and secretion are not inhibited by DHA, as appears to be the case with EPA. A preliminary report of some of these studies has appeared (15).

MATERIALS AND METHODS

Materials. EPA (>99% purity) was obtained from Cayman Chemical Co. (Ann Arbor, MI). DHA (>95% purity) and oleic acid (>99% purity) were obtained from NuCheck Prep (Elysian, MN). Purity of these fatty acids was confirmed by gas chromatography, as described below. [1-^{14}C]Oleic acid was purchased from NEN (Boston, MA) and [1-^{14}C]-EPA from Amersham Corp. (Arlington Heights, IL). Bovine serum albumin (BSA; fraction V) was obtained from Sigma Chemical Co. (St. Louis, MO). The BSA was delipidated with methanol as described previously (16). Biocount and hyamine hydroxide were obtained from Research Products, Inc. (Elk Grove, IL). All other chemicals were reagent grade.

Animals. Male Sprague-Dawley rats were obtained from Harlan, Inc. (Indianapolis, IN). Animals (225–250 g) were housed for 1–3 weeks with free access to Purina Rodent Chow and water before being used in these studies.

Liver perfusions. Livers were perfused in a recycling system *in vitro*, as described previously (17,18), for 2 hr with a basal medium (80 mL) consisting of washed bovine erythrocytes (30%) and purified (16) bovine serum albumin (6%) in Krebs-Henseleit bicarbonate buffer, pH 7.4, gassed continuously with 95%5%-O_2/CO_2. After 20 min equilibration, a pulse of 12 μmol fatty acid, as a complex with albumin (or albumin alone in buffer) was added. During the 2-hr perfusion, the complex of fatty acid (oleic acid, EPA or DHA) with BSA (6%), or albumin alone, in Mg^{++} and Ca^{++} free buffer (19) was infused at a rate of 11.7 mL/hr (70 μmol fatty acid/hr). The molar ratio of free fatty acid/BSA in the complex was 6.9. During perfusion, this ratio was reduced to 0.8 because of free fatty acid (FFA) uptake. When albumin was infused alone, the amount of free fatty acid associated with the delipidated albumin was negligible (0.3 μmol/g), resulting in an infusion rate of only 0.2 μmol FFA/hr. In some of the experiments, 1 μCi [1-^{14}C]EPA or [1-^{14}C]18:1 was included in the medium as an initial pulse and 2 μCi infused/hr for the 2-hr experiment.

Analyses. Samples of perfusate were taken hourly for chemical analysis. A 60-mL aliquot of the final perfusate, after sedimentation of the erythrocytes, was obtained for isolation of VLDL (19). Lipids were extracted from aliquots of perfusate plasma and VLDL with chloroform/methanol (2:1, v/v) using 20-mL solvent/mL sample (16). At the end of each perfusion experiment, the liver was flushed with 60 mL ice-cold 0.9% NaCl, blotted and weighed. Samples were minced and homogenized in a Polytron homogenizer with 20 volumes of chloroform/methanol (2:1, v/v)/g liver. Lipid classes were isolated by thin-layer chromatography (TLC) from $CHCl_3$/CH_3OH extracts of liver, perfusate, and VLDL (16). Appropriate bands scraped off the plate were analyzed chemically for TG (20), PL (21), C or CE (22), and FFA (23). When radioactive fatty acids were used, an aliquot of whole perfusate was added to an equal volume of 15% perchloric acid. Incorporation of [1-^{14}C]oleic acid and [1-^{14}C]EPA into acid soluble products, an indication of soluble oxidative metabolites, was determined on aliquots of the perchloric acid soluble material of perfusate samples by liquid scintillation spectrometry (24). Radioactive CO_2 generated during the perfusions was trapped by passing the gas through a series of three traps containing 10% KOH (w/v) (25). Contents of the traps wre changed after each hr and combined for analysis. $^{14}CO_2$ was determined on filter paper strips saturated with hyamine hydroxide (25) after release of the CO_2 from the KOH solution with HCl.

When the radiolabeled fatty acids were used, bands of PL, TG, and CE isolated from liver and VLDL extracts were scraped directly from TLC plates into vials for determination of radioactivity. All measurements of radioactivity were made with a Beckman LS3150 counter (Beckman Instruments, Fullerton CA) using Biocount scintillation fluid. Data were obtained as DPM, calculated from the H number quench curve efficiency correction program of the instrument.

Gas chromatography (GC) analyses of fatty acid methyl esters (16,26) were carried out with a Varian 3300 system (Varian Associates, Palo Alto, CA) using a column of SP2340 (16). Methanolic BF_3 was used to prepare the methyl esters of the fatty acids (16). Integration of peak areas was carried out with a Model 4290 Varian Integrator. Eluted fatty acid methyl esters up to DHA were included in the total area analyzed (equal to 100%). The percentage of each fatty acid, therefore, is expressed in relation to this area total. The specific radioactivity of perfusate oleate and EPA was calculated from chemical and radioactivity analyses of perfusate FFA and GC analysis of that fraction.

Protein content of dialyzed VLDL was estimated by the method of Lowry *et al.* (27) as modified by Markwell *et al.* (28) for elimination of turbidity with SDS.

Statistics. All data are shown as means ±SE. Data were analyzed using one-way ANOVA. The statistical significance of differences between the means of groups was established by a protected Fisher least significant difference test (PLSD) and significance is reported for levels of $p<0.05$.

RESULTS

The concentrations of perfusate FFA remained essentially constant during the experiments; they were 0.47 ± 0.05 (n=11), 0.33 ± 0.03 (n=9) and 0.34 ± 0.05 (n=4) μmol/mL during infusion of oleate, EPA or DHA, respectively. Means were calculated from the average concentration at the second and fourth hr in each separate experiment.

When albumin alone was infused, the ambient concentration of FFA was lower, 0.16 ± 0.02 (n=5) μmol/mL, but relatively constant, presumably resulting from a small, outward flow of FFA from the liver (29). The rates of uptake by the liver of EPA, DHA or oleic acid were not different, 5.3 ± 0.4 (n=5), 5.8 ± 0.4 (n=3) and 5.9 ± 0.1 (n=5) μmol/g liver/hr, respectively. The absolute concentrations of perfusate palmitate and linoleate were not significantly affected by the infusion of oleate, EPA or DHA, although percentage composition varied (Table 1). Similarly, the concentration of oleate was not affected when either EPA or DHA was infused, compared to that when exogenous fatty acid was not provided.

The concentrations of hepatic lipids measured at the end of the 2 hr perfusion with oleic acid, EPA, or DHA were not different from that when fatty acid was not provided (data not shown). The average values for a total of 34 of the experiments are 2.44 ± 0.21, 25.1 ± 1.6, 4.24 ± 0.28 and 0.86 ± 0.09 μmol/g liver for TG, PL, C, and CE, respectively.

When EPA was infused, secretion of all VLDL lipids, except for cholesterol, as well as of protein was reduced when compared to oleic acid and, except for cholesterol which was greater, was similar to the secretion observed when fatty acid was not infused (Table 2). The stimulation of VLDL cholesterol output may reflect specific, unusual requirements for the surface of the particle (see below). Unexpectedly, infusion of DHA stimulated secretion of VLDL TG, C and PL (Table 2) to the same extent as did oleic acid; output of VLDL CE was less than that with oleate, and was not different from that when fatty acid was not infused. Secretion of VLDL protein was

[a] Values are means ±SEM. Only the values for the major fatty acids are reported. After each group the number of observations is given in parentheses. Fatty acids were infused for 2 hr at a rate of 70 μmol/hr into the medium perfusing isolated livers from normal male rats. An initial pulse of 12 μmol of fatty acid was added to the medium. "None" refers to experiments in which the albumin solution was infused, but which contained no free fatty acid.

[b] The data were derived from the product of the "% of Total FFA" and the average of the concentration of the total FFA (nmol FFA/mL) at the first and second hr in each separate experiment. These values are given in the Results section of the text.

stimulated by infusion of oleate, but not by DHA or EPA. The secretion of total TG in the whole perfusate was similar to that for VLDL TG (85% of that in perfusate in all experiments) (data not shown).

Incorporation of [1-^{14}C]EPA, infused at 70 μmol/hr, into VLDL TG, PL and CE was also less than with [1-^{14}C]-oleic acid (Table 3). Incorporation into hepatic TG and CE, but not into PL, was reduced for EPA, even though concentrations of hepatic lipids were not different when either oleic acid or EPA were infused (see above). Although the formation of radioactive oxidation products measured as incorporation into $^{14}CO_2$ and into perchloric acid, soluble products tended to be greater from EPA than with oleate, the mean values were not statistically different. A comparison of total oxidation products, however, indicated that conversion from EPA was statistically greater.

Under the experimental conditions described, the molar ratios of the surface lipids of VLDL produced from oleate, DHA or endogenous sources only, relative to TG + CE (core lipids) were not different from one another, indicating similarity in particle size (Table 4). The higher ratio in experiments with EPA suggests a population of smaller particles. The relationship between PL and C of the surface was similar for VLDL produced by DHA or endogenous sources, but higher than that for 18:1 and 20:5. Except for DHA infusion, from which less CE was secreted, the ratio of TG/CE was constant. Although apo B *per se* was not determined in these experiments, it is evident that differences seem to exist between the surface protein and the core lipid contents. Particularly, a greater proportion of protein (as with the surface lipids) is required to form VLDL with EPA, whereas relatively less protein is required for the particles formed in response to DHA. Alterations in the amount of VLDL lipids secreted resulted primarily from differences in numbers of VLDL particles formed and secreted, although specific differences in size and composition of the VLDL also must have contributed to the quantity of lipid secreted.

The degree to which the infused fatty acids were incorporated into VLDL and hepatic TG was also evaluated by GC (Tables 5 and 6). Included in these Tables are calculated amounts of the various fatty acids present in TG. These latter data provide a better appreciation of the utilization of fatty acids of exogenous and endogenous origin for TG synthesis. When FFA was not infused, the fatty acid compositions of hepatic and VLDL TG were quite similar. When FFA was infused, the percentage of the exogenous fatty acid in VLDL TG was considerable and always exceeded that of the liver (Tables 5, 6; refs. 16,30). It is probable that utilization of the endogenous pool of fatty acid was diminished when EPA was supplied exogenously, since the amount of palmitate and linoleate present in the secreted VLDL TG was 40–60% of that present when only endogenous fatty acid was available for synthesis (Table 5). This was also the case with stearate

[e]$p<0.05$ *vs.* 20:5.

and oleate, but the assigned level for significance was not attained.

The stimulated output of TG by oleate is accounted for by increased oleate and palmitoleate content only. However, the stimulated output by DHA is represented by significant increase in output of linoleate as well as DHA in the secreted TG. Compared to perfusion without the addition of exogenous fatty acids, hepatic TG was not enriched with "endogenous" fatty acids, *e.g.*, palmitate, palmitoleate, stearate, linoleate, or arachidonate, when oleate, EPA, or DHA was infused. Enrichment of the TG occurred only with the infused fatty acid (Table 6).

Compared to hepatic TG, the composition of hepatic PL, under our experimental conditions, showed a very small but statistically significant enrichment only by EPA when it was infused (Table 7). The percentage fatty acid composition of VLDL and hepatic CE is shown in Table 8. Enrichment of CE by infused oleate was about two-fold,

while that for EPA was ten-fold in VLDL and three-fold in the liver. Enrichment by DHA was much less in that only a 50% increase was obtained.

DISCUSSION

Alterations in rates of synthesis, secretion, or clearance of the VLDL may account for the decreased concentrations of plasma lipids in humans (1,2) and animals (3–5) when relatively large amounts of the n-3 fatty acids become available. The reduction in the utilization of preformed endogenous fatty acids for synthesis of TG, an important stimulus to VLDL secretion, or inhibition of *de novo* synthesis of fatty acid might account for reduction of VLDL secretion by the liver. Since plasma concentrations of VLDL will vary with rates of clearance, as well as secretion, more rapid clearance of VLDL particles enriched with n-3 fatty acids might also account for decreased plasma concentrations of VLDL.

Hepatic formation and secretion of VLDL is dependent on the rate of TG synthesis which is stimulated by fatty acids and is a saturable phenomenon (31,32). Furthermore, the particle size and lipid composition of VLDL is a function of the rate of TG synthesis, and the structure of the fatty acids from which the TG is derived (16,30). In general, rates of TG secretion are greater and larger VLDL particles are formed when monounsaturated and polyunsaturated fatty acids are the substrates for TG synthesis,

rather than saturated fatty acids. Regardless of fatty acid structure, larger particles are formed and secreted at high rates of TG synthesis. We reported previously that less TG was secreted by the perfused liver as the number of double bonds increased, in a series of 18 carbon atom fatty acids (18:3<18:2<18:1<18:0) (30). These observations have been confirmed in studies with isolated hepatocytes (7), although in a later liver perfusion study from our laboratory such an absolute relationship was less apparent (16). The VLDL formed in response to fatty acids containing 1 or 2 double bonds was larger and, therefore, required relatively less surface lipid (PL and free C) per mole TG to stabilize the particle for transport than did VLDL particles synthesized principally from saturated fatty acids (16). The particles assembled when saturated fatty acids predominated in the TG contained relatively more surface components (C, PL and apoproteins), indicating that they were smaller than when mono- or polyunsaturated fatty acids predominated. Therefore, depending on the rate of TG synthesis and the structure of the fatty acid from which TG is derived, the same amount of TG may be transported in fewer, but less dense, larger particles, or in more numerous, but smaller, denser particles. In our present study, differences in lipid output in VLDL appeared to reflect the number of VLDL particles secreted, rather than differences in the size of the particles. The size was not correlated with the TG secretion rate, perhaps because TG synthesis rates were not maximal and did not exceed the availability of some potentially limiting component (*e.g.*, cholesterol), as we suggested (33). A limitation of availability of cholesterol for VLDL formation may occur when TG synthesis is stimulated to some as yet undefined level, or when preformed hepatic C (as CE) is depressed. The fatty acid composition of the synthesized and secreted VLDL TG affected the lipid composition and size of the particle in these experiments only modestly, even though TG ranged in composition from about 25–50% monounsaturated fatty acid, and up to to 37% polyunsaturated n-3 fatty acid.

Dietary TG is an important source of plasma free fatty acids. We reported previously (34) that the composition of the circulating free fatty acid pool reflects that of the ingested TG fatty acids, which may differ significantly from adipose tissue TG fatty acids. Long periods of time on diets of specific fatty acid composition are necessary for adipose tissue TG fatty acids to reflect the composition of dietary fatty acids (34). The immediate question pertinent to this study is whether a substantial increase in the availability of n-3 fatty acids to liver when an individual consumes large amounts of fish, or supplements of fish oil, significantly affects VLDL formation, secretion, and composition. Experiments with the isolated perfused liver by Wong *et al.* (9) demonstrated that the basal secretion of TG in the absence of exogenous FFA was diminished in livers from rats fed chow with fat content rich in fish oil. A similar finding was derived from *in vivo* studies of roosters fed fish oil (3). Studies with cultured hepatocytes from fish oil fed rats produced similar observations. In hepatocytes from normal chow fed rats, both EPA and DHA were reported to be poorer substrates for TG synthesis than was oleic acid (35,36); EPA, however, was incorporated more readily into PL than was 18:1 (7). In our studies, we observed similar amounts of oleate and EPA incorporated into PL, as was suggested by lack of enrichment of PL and similarity of PL mass compared to basal levels (Table 7) or incorporation of labeled fatty acid (Table 4). In perfused livers from fish oil-fed rats, lipogenesis from ^3H_2O was less than that by livers from safflower oil-fed rats, while in hepatocytes, EPA and DHA depressed the synthesis of TG from [^{3}H]glycerol (7). These authors suggested that EPA depressed TG synthesis *via* inhibition of acyl-coenzyme A:1,2-diacylglycerol acyltransferase (35). Wong and Marsh (8) reported recently that the secretion of TG by livers from chow fed rats perfused with DHA or EPA was less than that of livers perfused with oleate or without fatty acid. Wong and Marsh (8) also noted that VLDL apoprotein synthesis and hepatic phosphatidate phosphohydrolase activity was decreased by DHA or EPA, compared to infusion of either oleate or omission of exogenous fatty acid (8). This latter observation could, in part, explain the decrease in TG synthesis from EPA or DHA (8). In a later study using Hep G2 cells, EPA, but not DHA, was found to be inhibitory of TG synthesis (13).

The hepatic uptake of fatty acids in our studies was similar for EPA, DHA, and oleate. Our data support previous observations of the reduction of TG synthesis and VLDL TG secretion from EPA, but also indicate that DHA was similar to oleate as a substrate for TG synthesis and VLDL TG secretion, when examined in an experimental system in which VLDL formation and secretion is a substantial reflection of the integrated metabolic processes occurring in the liver as a whole. These data emphasize that the inhibitory influence of EPA results from its being a poor substrate for TG synthesis at lower concentrations, as measured by the lower enrichment of hepatic and VLDL TG by this fatty acid, as compared with oleate. Additionally, EPA may exert an inhibitory influence on the incorporation of *de novo* synthesized fatty acid into TG.

We did not observe any statistically significant difference in the metabolism of EPA and oleate to CO_2 or oxidation products individually, although the mean values of either were 25% greater for EPA than for oleate. Total conversion, however, was statistically higher for EPA; therefore, hepatic oxidation of EPA may, indeed, exceed that of oleate, and thus contribute to the decreased synthesis of TG through a relative limitation in availability of EPA.

Since in our hands, the measured effects of DHA were basically not different than oleate, we did not continue to examine effects of DHA in this study. In this regard, our studies do differ from those of other workers using hepatocytes (35,36) or perfused rat liver (8), who observed that DHA reduced VLDL secretion. The reasons for these differences are presently unclear. Interestingly, it has been proposed that there is a distinct correlation between apo B synthesis and CE availability, *i.e.*, that CE synthesis is more a stimulus to apo B synthesis than TG (37). As noted in the present study, DHA stimulated TG synthesis and secretion to a similar extent as did oleate, but VLDL CE and protein output were depressed compared to that of oleate.

In support of previous reports from this laboratory (16,30), the exogenously supplied DHA, EPA and oleate enriched the VLDL TG to a greater extent than hepatic TG with the specific infused fatty acid. The current and previous data are indicative of the slower turnover of the

total hepatic TG compared to that transported in VLDL (*i.e.*, the existence of a separate metabolic pool of TG). When it is considered that a substantial portion of the secreted nascent VLDL is taken up by the liver and metabolized (19), the existence of at least two pools of TG in the liver which are not in rapid equilibrium (*e.g.*, storage and metabolic pools) becomes even more evident. Enrichment of PL by the infused fatty acid was insignificant, and differences between hepatic and VLDL PL were not apparent. This would suggest that any putative metabolic pool of PL, separate from the large membrane and/or storage pool of PL, equilibrates much more rapidly with the secreted VLDL PL pool, than do the pools of TG.

As shown in Table 5, when oleate was infused, the amount of oleate secreted in TG was 0.784 μmol/g liver/2 hr. A value similar to this was obtained from radioactive data (0.800 μmol 18:1/g liver/2 hr) (Table 4) suggesting little conversion of 18:1 to other long chain fatty acids incorporated into VLDL-TG. A similar comparison of data for EPA, 0.200 *vs.* 0.350 μmol EPA/g liver/2 hr (Table 5 and Table 4, respectively), suggests that EPA is converted to other fatty acids and incorporated into VLDL TG. Comparable calculations for hepatic TG could not be interpreted similarly, since both fatty acids were present in the relatively large pool of TG in the liver prior to the perfusion experiments.

Fish oil is enriched with similar amounts of DHA and EPA (20–30%, total), but the proportion of each may differ depending on the source, compared to the negligible amounts in most vegetable oils. Oleic acid is also present in considerable quantiatites in fish oils, and in amounts equal to or exceeding that of the n-3 fatty acids. Perhaps the hypolipidemic effect of fish oil diets requires chronic treatment with major modification of the composition of plasma FFA and hepatic TG, prior to any significant change in output and composition of the VLDL, and enrichment by EPA predominating.

In summary, it appears that the reduced secretion of VLDL in the presence of relatively low substrate amounts of EPA (0.3–0.4 μmol EPA/mL medium) resulted, in part, from decreased TG synthesis because of low specificity of the substrate for esterification to TG, reduced utilization of endogenous fatty acids for TG synthesis and, in part, from increased oxidation of EPA. In contrast to TG synthesis, EPA and oleate appear to be incorporated into PL to similar degrees. DHA, however, was esterified efficiently to form TG, which was transported in VLDL at a rate comparable to that resulting from infusion of oleate.

ACKNOWLEDGMENTS

This research was supported by grants HL-39228 and Biomedical Research Support Grant 90-02 from the National Institutes of Health, U.S. Public Health Service. We greatly appreciate the technical assistance of Bennett Bicknell, Lynda Disney and Michele Walker. We wish to thank Donna Jackett and Christa Ingram for their excellent assistance in preparation of the manuscript.

Sesamin Is a Potent and Specific Inhibitor of Δ5 Desaturase in Polyunsaturated Fatty Acid Biosynthesis

Sakayu Shimizu[a,*], Kengo Akimoto[a,1], Yoshifumi Shinmen[a,1], Hiroshi Kawashima[a,2], Michihiro Sugano[b] and Hideaki Yamada[a]

[a]Department of Agricultural Chemistry, Kyoto University, Sakyo-ku, Kyoto 606 and [b]Department of Food Science and Technology, Kyushu University, Higashi-ku, Fukuoka 812, Japan

Incubation with sesame oil increases the mycelial dihomo-γ-linolenic acid content of an arachidonic acid-producing fungus, *Mortierella alpina*, but decreases its arachidonic acid content [Shimizu, S., K. Akimoto, H. Kawashima, Y. Shinmen and H. Yamada (1989) *J. Am. Oil Chem. Soc. 66*, 237–241]. The factor causing these effects was isolated and identified to be (+)-sesamin. The results obtained in experiments with both a cell-free extract of the fungus and with rat liver microsomes demonstrated that (+)-sesamin specifically inhibits Δ5 desaturase at low concentrations, but does not inhibit Δ6, Δ9 and Δ12 desaturases. Kinetic analysis showed that (+)-sesamin is a noncompetitive inhibitor (K_i for rat liver Δ5 desaturase, 155 μM). (+)-Sesamolin, (+)-sesaminol and (+)-episesamin also inhibited only Δ5 desaturases of the fungus and liver. These results demonstrate that (+)-sesamin and related lignan compounds present in sesame seeds or its oil are specific inhibitors of Δ5 desaturase in polyunsaturated fatty acid biosynthesis in both microorganisms and animals.
***Lipids 26*, 512–516 (1991).**

Sesame seed oil, which has long been used as an edible oil, contains considerable amounts of sesamin and related lignan compounds (1,2). Little is known about the biological activity of these compounds, except that some of them show potent antioxidative activity (3). During our studies on the biosynthesis of C_{20} polyunsaturated fatty acids (PUFA) in *Mortierella alpina* and related filamentous fungi (4–11), we found that the mycelial dihomo-γ-linolenic acid (DGLA or 20:3) content of *M. alpina* drastically increases, while arachidonic acid (AA or 20:4) decreases upon incubation with sesame oil. This phenomenon was explained by specific inhibition of the conversion of DGLA to AA, *i.e.*, inhibition of Δ5 desaturation (7,8). To clarify the mechanism by which sesame oil exerts this inhibitory effect, we searched for factors that could be responsible for this effect. We report here that (+)-sesamin and related lignan compounds, which are commonly present in sesame oil, are potent and apparently specific inhibitors of mammalian and microbial Δ5 desaturases involved in PUFA biosynthesis.

MATERIALS AND METHODS

Chemicals. Crude and refined oils from unroasted sesame seeds were obtained from Kitamura Shokai Co. (Osaka, Japan). [1-^{14}C]Stearic acid (18:0) (2.07 GBq/mmol), [1-^{14}C]-oleic acid (18:1) (1.92 GBq/mmol), [1-^{14}C]linoleic acid (18:2) (1.89 GBq/mmol) and [2-^{14}C]DGLA (2.13 GBq/mmol) were purchased from Amersham (Buckingham, U.K.). (+)-Episesamin and (+)-sesaminol were prepared from refined sesame oil as described previously (3). Sesamol was obtained from Aldrich (Milwaukee, WI). All other reagents used in this work were obtained as described previously (4,5,9).

Microorganism and cultivation. The fungus *Mortierella alpina* 1S-4 (AKU 3998) (4,5) was grown aerobically for 7 days at 28°C in a 10-mL Erlenmeyer flask containing 2 mL of a basal medium (4% glucose and 1% yeast extract, pH 6.0), unless otherwise stated.

Extraction and determination of mycelial fatty acids. Fungal mycelia were harvested by suction filtration, washed with 50 mL water and then dried overnight at 100°C. Transmethylation of the fatty acids in the mycelia, extraction of the fatty acid methyl esters and analysis by gas-liquid chromatography were carried out as described previously (5,6,9).

Fractionation of sesame oil by high-performance liquid chromatography (HPLC). An acetone-extractable non-oil fraction of crude oil was prepared as described previously (7). The non-oil fraction (1.5 g) was dissolved in chloroform (*ca.* 3 mL) and the resultant solution (150 μL each) was subjected to HPLC on a reversed phase $10C_{18}$ Cosmosil packed column (20 × 250 mm; Nakarai Tesque, Kyoto, Japan). The chromatograph was operated with a mobile phase of methanol/water (67:33, v/v) at a flow rate of 9.9 mL/min and the effluent was monitored at 205 nm. Six fractions of 100 mL each were collected and concentrated under reduced pressure. The same separation was repeated 20 times.

Assay of inhibitors of Δ5 desaturation reaction with M. alpina *culture.* Fractions from 1 of the 20 HPLC runs were used for the assay. Each of the concentrated fractions was dissolved separately in 150 μL of chloroform, and 40 μL of the resultant chloroform solution was added to the sterilized basal medium. The assay of inhibitors of the Δ5 desaturation reaction was carried out by monitoring the changes in the fatty acid profile of *M. alpina* grown in the basal medium supplemented with each of the concentrated fractions as described above (see also Fig. 1).

Isolation of Δ5 desaturase inhibitors. The other fractions obtained from the remaining 19 HPLC runs were used for the isolation of the inhibitors. (+)-Sesamin was obtained from the fractions corresponding to fraction 4 in Figure 1 by repeated crystallization from ethanol until the compound was homogenous as judged by thin-layer chromatography (TLC) (yield from 1.5 g of the non-oil fraction, 137 mg; *Anal.* Calcd for $C_{20}H_{18}O_6$: C, 67.79; H, 5.12%; Found: C, 67.86; H, 5.20%; mp, 123.2–123.9°C; MS (direct inlet, 200°C) *m/z* (%): 354 (45, M^+), 323(5), 203(19), 178(12), 162(8), 149(100), 135(42), 122(25), 103(13), 89(6),

65(15), 39(10); $[\alpha]_D^{25}$ (c=1, $CHCl_3$), +64.7°; ^1H NMR δ ($CDCl_3$): 3.05 ppm (*m*, 2H), 3.87 (*dd*, *J*=4.0 and 8.5Hz, 2H), 4.24 (*dd*, *J*=6.0 and 8.5Hz, 2H), 4.74 (*d*, *J*=4.0Hz, 2H), 5.96 (*s*, 4H), 6.85 (*m*, 6H). In a similar manner, (+)-sesamolin was isolated from the fractions corresponding to fraction 5 in Figure 1 (yield, 70 mg; *Anal.* Calcd for $C_{20}H_{18}O_7$: C, 64.86; H, 4.90%; Found: C, 64.93; H, 4.97%; mp: 93.5°C; MS (direct inlet, 200°C) *m/z* (%): 370 (12, M^+), 233(36), 203(43), 173(3), 149(24), 135(100), 115(12), 81(41), 65(11), 52(7), 39(7); $[\alpha]_D^{25}$ (c=1, $CHCl_3$), +213°; ^1H NMR δ ($CDCl_3$): 2.95 ppm (*m*, 1H), 3.30 (*dd*, *J*=9.0 and 16.5Hz, 1H), 3.64 (*dd*, *J*=7.5 and 9.0Hz, 1H), 3.96 (*dd*, *J*=1.0 and 9.0Hz, 1H), 4.13 (*dd*, *J*=6.0 and 9.0Hz, 1H), 4.40 (*d*, *J*=7.5Hz, 1H), 4.44 (*t*, *J*=9.0Hz, 1H), 5.50 (*s*, 1H), 5.94 (*d*, *J*=18.5Hz, 4H), 6.50 (*dd*, *J*=3.5 and 8.5Hz, 1H), 6.62 (*d*, *J*=2.5Hz, 1H), 6.71 (*d*, *J*=8.5Hz, 1H), 6.78 (*dd*, *J*=8.0Hz, 1H), 6.82 (*dd*, *J*=1.5 and 8.0Hz, 1H), 6.88 (*d*, *J*=1.5Hz, 1H).

Preparation of cell-free extract of M. alpina. This was done as described previously (5).

Preparation of rat liver microsomes. Male Wistar rats maintained on a standard pelleted diet for eight weeks were killed and the livers were immediately removed and rinsed in cold homogenizing medium (12). They were homogenized in four volumes of the same medium in a Teflon pestle homogenizer and then centrifuged at 10,000 × *g* for 20 min at 4°C. Microsomes were recovered by centrifuging the supernatant at 100,000 × *g* for 1 hr at 4°C. The pellet was resuspended in the homogenizing medium to give a protein concentration of 30 mg/mL. The sample was stored at −80°C till use.

Assay of desaturase activities. The cell-free extract of *M. alpina* was assayed for Δ9, Δ12, Δ6 and Δ5 desaturase activities using labeled 18:0, 18:1, 18:2 and 20:3 as substrates, respectively. The standard reaction mixture contained, in 1.0 mL, 250 μmol of sucrose, 100 μmol of potassium phosphate buffer (pH 7.4), 40 μmol of NaF, 150 μmol of KCl, 4 μmol of *N*-acetyl-L-cysteine, 0.3 μmol of nicotinamide, 15 μmol of $MgCl_2$, 7.5 μmol of ATP, 0.4 μmol of CoA, 1.5 μmol of NADH, 100 μmol of fatty acid (18:0, 18:1, 18:2 or 20:3 containing 3.7 KBq of the respective labeled fatty acid) and the cell-free extract (1.0 mg protein). The reactions were carried out at 28°C for 30 min and terminated by the addition of 5 mL of ethanol and 1 mL of 4N KOH. Each of the resultant mixtures was saponified at 60°C for 30 min. After addition of 3 mL of water, 100 μg of the corresponding unlabeled substrate and product fatty acids, and 1 mL of 6N HCl, the fatty acids were extracted twice with *n*-hexane (5 mL each). The procedures for the preparation of fatty acid methyl esters and silica gel/silver nitrate TLC, and the quantitative analysis of radioactive fatty acid methyl esters were as described previously (13). The liver microsomes were assayed for Δ9, Δ6 and Δ5 desaturases. Each incubation mixture contained, in 1 mL, 250 μmol of sucrose, 100μmol of potassium phosphate buffer (pH 7.4), 45 μmol of NaF, 150 μmol of KCl, 1.5 μmol of glutathione, 0.5 μmol of nicotinamide, 5 μmol of $MgCl_2$, 7.5 μmol of ATP, 0.4 μmol of CoA, 1.5 μmol of NADH, microsomal suspension (1.2 mg protein) and 100 μmol of the desired labeled fatty acid as described above. The incubations were carried out for 10 min (except as stated) at 37°C. Other conditions were the same as those for the assays with the *M. alpina* cell-free extract.

Other methods. TLC on lignan compounds was performed on a $60F_{245}$ silica gel plate (Merck, Darmstadt, Germany) with chloroform/diethyl ether (9:1, v/v) as a solvent. Fractions were localized under an ultraviolet lamp. Protein concentrations were determined by the method of Bradford (14). Mass spectra were recorded on a Hitachi M-80B instrument at 70eV; ^1H NMR spectra were recorded on a Nicolet 360-MHz instrument with tetramethylsilane as internal standard.

RESULTS

Isolation and identification of Δ5 desaturase inhibitors. Two major fractions (Rf=0.65 and 0.81) were detected by TLC of the non-oil fraction together with several minor ones. The separation of the non-oil fraction into six fractions by preparative HPLC (see Fig. 1) and TLC of each of the six fractions demonstrated that the compounds corresponding to Rf=0.65 and 0.81 were present in fractions 4 and 5, respectively. The inhibitor assays as judged by the change of mycelial fatty acid profile of *M. alpina* showed that only fraction 4 caused an increase in mycelial DGLA content and a decrease in AA content, as shown in Figure 1. The mycelial DGLA/AA ratio was 0.51. By contrast, no significant change in mycelial fatty acid profile was observed on cultivation with the remaining five fractions. In each case, the ratio was only about 0.09. The compound isolated from fraction 4 was identified as (+)-sesamin based on the data of MS, ^1H NMR, optical rotation and melting point in comparison to literature values

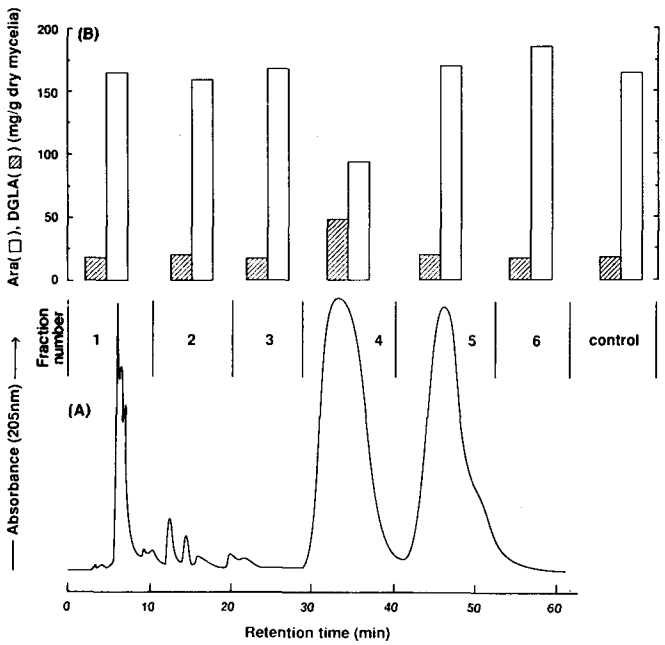

FIG. 1. Separation of the factor(s) which cause(s) the increase in mycelial DGLA content and the decrease in AA content from an acetone-extractable non-oil fraction of crude sesame oil by HPLC. *M. alpina* was grown in the basal medium supplemented with each of the fractions obtained on HPLC as described under Materials and Methods. (A) Elution profile of the acetone-extractable non-oil fraction of sesame oil at 205 nm. The numbers in the Figure indicate fraction numbers. (B) Production of DGLA and AA by the fungus grown in a medium supplemented with the concentrated fractions. Control represents no supplementation.

(3,15-17). When *M. alpina* was grown in the basal medium supplemented with 0.1 mg of (+)-sesamin under the conditions described in Materials and Methods, the mycelial content of DGLA reached 51 mg/g dry mycelia (DGLA/AA ratio, 1.45). The compound from fraction 5 was identified as (+)-sesamolin based on the analytical data in comparison with literature values (17). No significant change in mycelial fatty acid profile was observed when *M. alpina* was grown in the basal medium supplemented with 0.03-0.5 mg of (+)-sesamolin.

Specific inhibition of fungal and rat liver Δ5 desaturases by sesamin. The above results strongly suggest that sesamin (or its metabolites) was incorporated into the mycelia during growth of the fungus and caused specific inhibition of the Δ5 desaturation reaction, which resulted in a marked increase in mycelial DGLA content and a decrease in AA content. We measured the activities of several desaturases involved in the biosynthesis of AA in the presence or absence of sesamin using both cell-free extracts of the fungus and rat liver microsomes as enzymes. Figure 1 shows that sesamin specifically inhibits only Δ5 desaturase in both the microbial and rat systems. The concentrations inducing 50% inhibition were 5.6 μM (0.002 mg/mL) and 75 μM (0.002 mg/mL) for microbial and rat enzymes, respectively. By contrast, no significant decrease with sesamin was observed for Δ6, Δ9 and Δ12 desaturases in the fungal extract (Fig. 2A). Rat liver Δ6 and Δ9 desaturases also were not sensitive to sesamin (Fig. 2B).

The rat enzyme was studied in more detail to clarify the sesamin-induced inhibition of Δ5 desaturation. Double reciprocal plots of reaction velocity against DGLA concentration gave convergent lines that intersected at the *abscissa* for various sesamin concentrations. This result indicates that the inhibition proceeded noncompetitively (Fig. 2C). The K_i values estimated by Cornish-Bowden (18) was 115 μM.

Inhibition of Δ5 desaturation by other sesamin-related compounds. Table 1 compares the effects of several sesamin-related compounds (see Fig. 3 for chemical structures) on desaturase activities with those of sesamin. Sesamolin, which did not cause any increase in mycelial DGLA content and decrease in AA content (see Fig. 1), also inhibited only Δ5 desaturase, when it was incubated with either fungal extract or liver microsomes. Episesamin and sesaminol isolated from refined sesame oil also showed specific inhibition of Δ5 desaturase. The inhibitory effects on the Δ5 desaturase in either *M. alpina* cell-free extract or rat liver microsomes of these compounds were in the order of sesamin > sesamolin > sesaminol > episesamin. However, no significant inhibition was observed with sesamol, which does not carry the 3,7-dioxabicyclo[3.3.0]-octane ring.

DISCUSSION

The present study demonstrated that (+)-sesamin and related lignans specifically inhibit Δ5 desaturase in PUFA biosynthesis. This inhibitory activity seems to be unrelated to the known antioxidative activity of sesamin related lignans because only the compound carrying a hydroxyl group at the 6 position of the methylenediox-

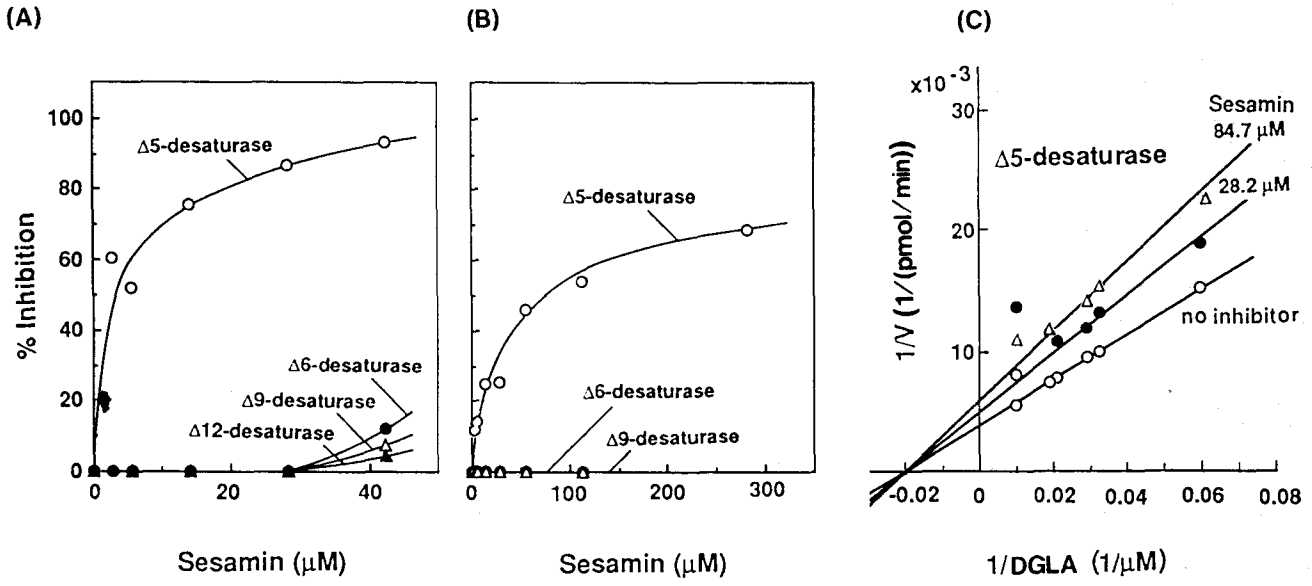

FIG. 2. The effect of sesamin concentration on various desaturase activities of *M. alpina* cell-free extract (A) and rat liver microsomes (B and C). (C) shows double reciprocal plots for Δ5 desaturase activities in the presence (●,△) or absence (○) of sesamin. Assay of desaturases were carried out under the conditions described in Materials and Methods, except that the indicated amount of sesamin was present in the incubation mixtures in (A) and (B) and concentrations of substrate (DGLA) and sesamin were changed as indicated in (C). In (A) and (B), the values without sesamin were taken as 0% inhibition (see Table 1 for absolute values) and each point represents percentage of inhibition. All values are means of three independent assays (standard deviation, within ±10%).

TABLE 1

Specific Inhibition of Fungal and Rat Liver Δ5 Desaturases by Sesamin-Related Compounds[a]

Compound[b] added	Desaturase activity (pmol/min/mg protein)						
	M. alpina				Rat liver		
	Δ9	Δ12	Δ6	Δ5	Δ9	Δ6	Δ5
None	10.1	8.16	18.2	21.2	37.2	15.0	116
Sesamin	10.5	9.27	19.1	2.80	34.9	16.4	71.8
Episesamin	10.3	8.40	18.2	5.20	36.1	17.5	92.1
Sesaminol	10.1	8.37	18.4	4.67	36.0	15.4	87.9
Sesamolin	9.93	8.77	17.7	3.97	37.7	18.6	86.6
Sesamol	9.86	8.10	17.2	16.8	34.3	14.7	114

[a]Desaturase activities were measured as described under Materials and Methods except that each of the indicated compounds were added and incubations with the liver microsomes were carried out for 30 min. All the compounds were present at 28 or 85 μM in the reaction mixtures with *M. alpina* extract or rat liver microsomes, respectively. Values are means of three independent assays (standard deviation, within ±7%).

[b]See Figure 3 for chemical structures.

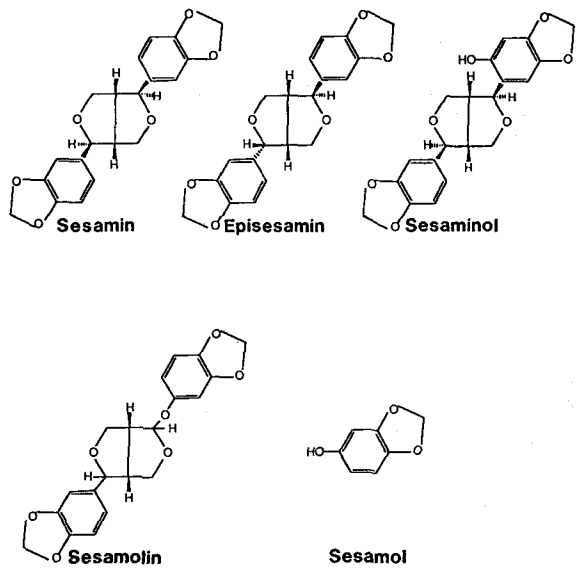

FIG. 3. Chemical structures of sesamin and related compounds.

yphenyl moiety (*i.e.*, sesaminol, episesaminol and sesamol) exhibit antioxidative activity, and sesamin itself is inactive as an antioxidant (1–3). The synergistic activity of sesamin for some insecticides, such as pyrethrin, has been suggested to be due to inhibition of the cytochrome P-450 oxygenase system catalyzing degradation of the insecticides (2). Since fatty acid desaturases are also of the oxygenase family, there may be some relation between the inhibitory activity on Δ5 desaturase and the synergistic activity. The finding that sesamol, which lacks the dioxabicyclo[3.3.0]octane ring, does not show any inhibitory activity suggests that this ring (or some other bulky substituent equivalent to the ring) is necessary for the activity. The inability of sesamolin to cause the increase in DGLA production and the decrease in AA production in the fungus *M. alpina* might be due to degradation of the lignan during the growth of the fungus.[3]

Our study is the first to demonstrate the occurrence of desaturase inhibitors in nature. Several unnatural desaturase inhibitors have been synthesized; most of them are analogs of fatty acids and they rather nonspecifically inhibit any of the desaturases involved in PUFA biosynthesis. For example, several *trans*-octadecenoic acids are competitive inhibitors of Δ9, Δ6 and Δ5 desaturases of rat liver microsomes (13,19). By contrast, sesamin or related lignans inhibit only Δ5 desaturase noncompetitively. This suggests that the inhibition induced by sesamin differs from those previously reported (13,19). The enzyme may have a site different from the substrate binding site, which shows high affinity toward sesamin.

The enzyme assay system used here involves acylation of the substrate with CoA, and the rates of the desaturation reactions measured here are the results of at least two sequential reactions, acylation and desaturation. Since the acylation step is not the rate-limiting step in rat liver microsomes and a single enzyme is responsible for the activation of all desaturase substrates used here (13,20), we can exclude the possibility that sesamin inhibited the acylation reaction.

The present results suggest that sesamin alters *in vivo* metabolism and composition of PUFA. Nutritional experiments are in progress in our laboratories.

Acylation of Lyso Platelet-Activating Factor by Splenocytes of the Rainbow Trout, *Oncorhyncus mykiss*

G.L. Pool, B. Samples, M.R. Turner and R.H. Lumb*
Mountain Aquaculture Research Center, Western Carolina University, Cullowhee, North Carolina 28723

In mammalian systems, platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine, (PAF) is rapidly inactivated by a deacetylation/reacylation system that produces 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholine which is highly enriched in arachidonic acid. There is some evidence that n-3 fatty acids may have an impact on this system in humans but the nature of this impact is unclear. In rainbow trout, n-3 fatty acids are known to be essential dietary components which are derived through the food chain. Substantial quantities of n-3 fatty acids are found in trout membrane phospholipids. We show here that in sharp contrast to mammalian cells, trout cells acylate lyso platelet-activating factor, alkyl-GPC, 1-*O*-alkyl-2-lyso-*sn*-glycero-3-phosphocholine, (lyso-PAF) with a high degree of specificity for n-3 fatty acids. When [^{3}H]lysoPAF was incubated with these cells, only three molecular species of alkylacylglycerophosphocholine were produced, and 92% contained n-3 fatty acids. Since isolated membranes yielded similar results, it appears that the acylation proceeds *via* a coenzyme A-independent transacylase as found in mammalian systems. *Lipids 26,* 517–520 (1991).

Recent findings demonstrate that a variety of lipid mediators play a major role in eliciting cellular responses to various stimuli. Platelet-activating factor (PAF, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine), diradylglycerols, inositol triphosphate, and eicosanoids (prostaglandins, leukotrienes and lipoxins) all have important biological activities and all are derived from the products of membrane phospholipid hydrolysis. Membrane phospholipid metabolism must therefore play a central role in signal transduction systems, and the diversity of phospholipid molecular species present may in part reflect the functional requirements of these systems. It is quite clear that the type of mediator produced is highly dependent upon the molecular species of phospholipid selected as precursor; what is less clear is how the selection is achieved.

Arachidonic acid, the precursor of the eicosanoids, can be released from several phospholipids, and one mechanism appears to involve hydrolytic cleavage of the *sn*-2 acyl group of 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholine (alkylacyl-GPC) which is enriched in arachidonate in polymorphonuclear leukocytes (1). This enzymatic activity simultaneously releases lyso platelet-activating factor (lysoPAF, 1-*O*-alkyl-2-lyso-*sn*-glycero-3-phosphocholine) which can be acetylated to form PAF or acylated in a coenzyme A-independent manner to yield alkylacyl-GPC. In mammalian cells this latter activity shows a high degree of specificity for arachidonate (2), implying a link between PAF and eicosanoid metabolism. In fact, the biosynthesis of PAF is frequently (1), but not always (3), accompanied by the generation of eicosanoids.

More recently, health benefits in man have been associated with the intake of dietary fish oil containing n-3 fatty acids (4,5). These fatty acids may in fact be a requirement in human diet (6), but the mechanisms involved have remained largely obscure. The n-3 fatty acids have unambiguously been shown to be essential in rainbow trout (7). We have previously demonstrated that cells of the rainbow trout synthesize PAF (8) and that the alkylacyl-GPC fraction contains primarily n-3 fatty acids and little arachidonate (9). We have now examined the specificity of the acylation reaction by trout splenocytes and report here that lysoPAF is acylated with a high degree of specificity for n-3 fatty acids from endogenous sources in a coenzyme A-independent fashion both *in vivo* and *in vitro*.

MATERIALS AND METHODS

Cell preparation. Rainbow trout were obtained from hatchery-reared stock populations and maintained in laboratory flow-through culture tanks. Spleens were removed and minced with scissors in RPMI 1640 (Sigma Chemical Co., St. Louis, MO) buffered with HEPES at pH 7.2. In some experiments the minced preparations were stirred for one hr at 4°C to increase cell yield and viability. The cells were filtered through cheesecloth and nylon mesh (150 μ) and then centrifuged at 350 × *g* for 8 min. The erythrocytes were lysed by hypotonic washing and the recovered splenocytes suspended in RPMI 1640. Cells were counted with a hemocytometer and viability determined by Trypan blue exclusion. To prepare membrane fractions, the cells were disrupted using a tissue grinder or by nitrogen cavitation (10) in Tris/HCl buffer containing 0.25 M sucrose and 1 mM EDTA, pH 7.4. The homogenates were centrifuged at 1000 × *g* for 10 min to remove unbroken cells and nuclei and the supernatants recentrifuged at 100,000 × *g* for 60 min to obtain the membrane fraction. The membrane pellets were resuspended in 50 mM Tris/HCl pH 7.1 using a small Dounce homogenizer.

Incubations. Intact cells or isolated membranes were incubated with 1-*O*-[^{3}H]hexadecyl-*sn*-glycero-3-phosphocholine (a generous gift of Dr. R. L. Wykle, The Bowman Gray School of Medicine, Winston-Salem, NC) at 15–20°C in plastic containers. The radiolabeled substrate had a specific radioactivity of 56 Ci/mmole and was added to the incubation mixtures in 10 μL of ethanol. At the end of the incubation periods, lipids were extracted according to the method of Bligh and Dyer (11) and kept under nitrogen at −20°C until analyzed.

Analysis of products. Lipids were analyzed by thin-layer chromatography (TLC) on silica gel plates (Brinkmann

Abbreviations: alkylacyl-GPC, 1-*O*-alkyl-2-acyl-*sn*-glycero-3-phosphocholine; DHA, docosahexaenoate; HPLC, high-performance liquid chromatography; lysoPAF, lyso platelet-activating factor, alkyl-GPC, 1-*O*-alkyl-*sn*-glycero-3-phosphocholine, 1-*O*-alkyl-2-lyso-*sn*-glycero-3-phosphocholine; PAF, platelet-activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; PC, phosphatidylcholine; PUFA, polyunsaturated fatty acids; TLC, thin-layer chromatography.

Instruments Co., Westbury, NY) using chloroform/methanol/acetic acid/water (50:30:8:5, by vol) as solvent. Absorbant bands corresponding to phosphatidylcholine (PC) and lysophosphatidylcholine were eluted and radioactivity determined by liquid scintillation counting. The PC fraction was hydrolyzed with phospholipase C (*B. cereus*, Sigma), and benzoate derivatives were formed from the resulting diradylglycerols as reported previously (8,12). Subclasses were separated by normal phase high-performance liquid chromatography (HPLC) using a 4.6 × 250 mm Econosphere 5 μ Si column (Alltech Associates, State College, PA) eluted with cyclohexane/diethyl ether/acetic acid (97:3:0.07, v/v/v). Molecular species were separated by reverse phase HPLC on a 4.6 × 250 mm Microsorb C18 column (Rainin Instruments, Woburn, MA) eluted isocratically with acetonitrile/isopropanol (65:35, v/v) and monitored at 230 nm. Identification of molecular species was accomplished by comparison with authentic standards kindly supplied by Dr. R. L. Wykle. All HPLC solvents were from Burdick and Jackson (Muskegon, MI).

RESULTS

Incubation of trout splenocytes in the presence of 1-*O*-[^{3}H]hexadecyl-GPC resulted in the incorporation of radiolabel into a fraction which migrated with authentic phosphatidylcholine (PC) in thin-layer chromatography (TLC). Incorporation was time-dependent and resulted in decreased recovery of radiolabel in the alkyl-GPC fraction (Fig. 1). Maximum incorporation was about 70% after 2 hr of incubation. More than 90% of the radioactivity was recovered from the alkyl-GPC and alkylacyl-GPC regions of TLC plates. The labeled "PC fraction" was isolated by TLC; following phospholipase C treatment and benzoylation, more than 90% of the radioactivity eluted with the alkylacyl-glycerobenzoate subclass in normal phase HPLC. Incorporation of alkyl-GPC into alkylacyl-GPC was completely eliminated by heating the cells to 60°C for 15 min while treatment of the cells with 1 mM *N*-ethylmaleimide for 15 min resulted in a 70% loss of incorporation. The incorporation was not appreciably altered by complete loss of cell viability through treatment with sodium azide (Table 1).

When the alkylacyl-glycerobenzoate fraction that was recovered from normal phase HPLC was applied to reverse-phase HPLC, the elution pattern showed radioactivity in only three peaks (Fig. 2A). The molecular species corresponding to these peaks were identified using authentic diradylglycerol benzoate standards prepared from 1-*O*-hexadecyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine (16:0-22:6n-3), 1-*O*-hexadecyl-2-eicosapentaenoyl-*sn*-glycero-3-phosphocholine (16:0-20:5n-3) and 1-*O*-hexadecyl-2-arachidonoyl-*sn*-glycero-3-phosphocholine (16:0-20:4n-6). Upon addition of these standards to the diradylglycerol benzoates derived from the [^{3}H]alkylacyl-GPC produced by the cell preparations, virtually all of the radioactivity co-eluted with the standards. Peak identification was confirmed by hydrogenation of the standards and labeled products in the presence of palladium oxide followed by reverse-phase HPLC. The radiolabel co-eluted with the hydrogenated standards at 130 min (16:0-20:0) and 180 min (16:0-22:0) with evidence for the presence of some partially-hydrogenated products.

When the isolated membrane fraction was incubated with 1-*O*-[^{3}H]hexadecyl-GPC, the pattern of incorporation was similar to that observed in intact cells (Fig. 2B). While the amount of eicosapentaenoate-containing species was the same, slightly more arachidonate-containing species were produced (Table 2). Thus the n-3 containing molecular species dropped slightly from 92% to 84%.

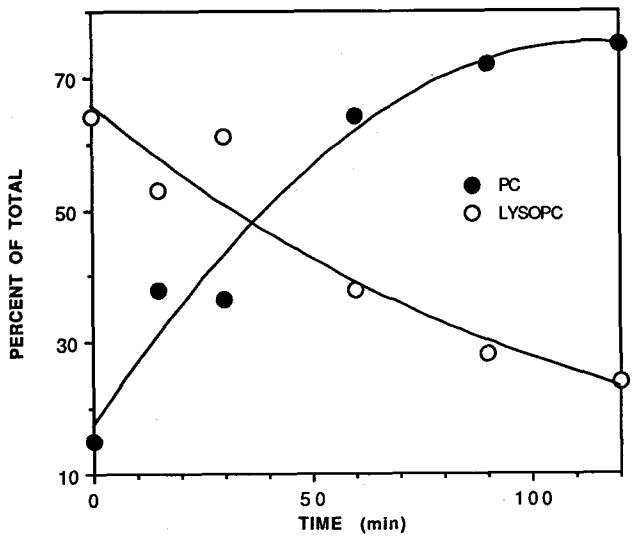

FIG. 1. Time course of the disappearance of 1-*O*-[^{3}H]alkyl-*sn*-3-phosphocholine (lysoPAF) and the appearance of [^{3}H]alkylacyl-GPC. Cells were incubated for the indicated times and terminated by lipid extraction. Precursor and product were separated by TLC; small amounts of radioactivity chromatographed in other areas of the TLC plate.

DISCUSSION

The metabolism of polyunsaturated fatty acids (PUFA) and the membrane phospholipids with which they are associated is recognized as an important process in cell regulation. In some mammalian cells there is evidence for a tight coupling between the metabolism of PAF and

TABLE 1

Inhibition of Acylation of LysoPAF by Treatment with Heat, *N*-Ethylmaleimide or Sodium Azide

Treatment[a]	Percent radioactivity in PC
Control	40.4
Heat (60°C, 15 min)	0.0
N-Ethylmaleimide[b] (1 mM, 15 min)	12.5
Sodium azide[c] (1%, 60 min)	35.0

[a]Each incubation contained 0.5 μCi 1-*O*-[^{3}H]alkyl-*sn*-glycero-3-phosphocholine.

[b]Cells (1.65×10^6) were preincubated for 15 min at 20°C with *N*-ethylmaleimide before addition of label.

[c]Cells (5×10^7) were treated for 60 min until Trypan blue showed complete loss of viability before addition of label.

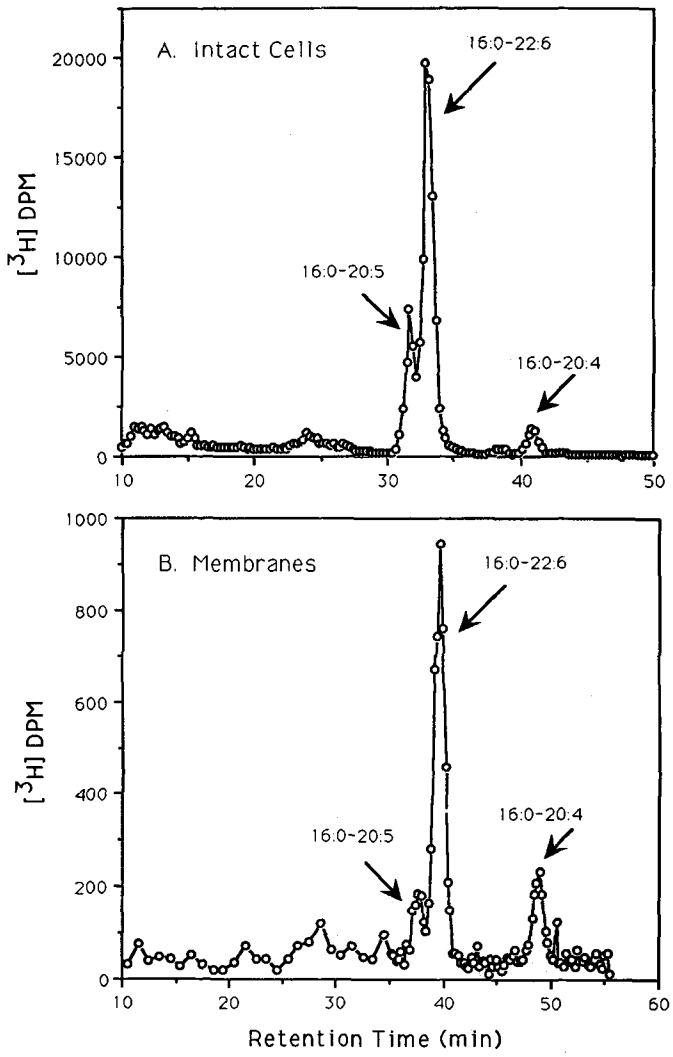

FIG. 2. Reverse-phase HPLC elution profiles of the 1-*O*-[^{3}H]alkyl-acyl-glycerobenzoates. Intact cells or membrane fractions from disrupted cells were incubated with [^{3}H]lysoPAF for 60 min. The PC fraction was isolated by TLC, derivatized to the glycerobenzoates, and the alkylacyl-glycerobenzoate fraction was isolated by normal phase HPLC. This fraction was then chromatographed on a Microsorb C18 column (4.6 × 250 mm) with acetonitrile/isopropanol (65:35, v/v) as the mobile phase. Peak identification was by cochromatography with authentic standards and by analysis of the products of palladium oxide-catalyzed hydrogenation.

TABLE 2

Specificity of Acylation of LysoPAF by Trout Splenocytes and Isolated Membranes

	% Distribution ± S.E.M.	
Molecular species	Intact cells	Membrane
16:0-20:5n-3	22.1 ± 1.28	14.0 ± 0.32
16:0-22:6n-3	69.7 ± 2.97	70.1 ± 2.17
16:0-20:4n-6	8.1 ± 1.70	15.8 ± 2.45

arachidonic acid (1,13). There is also evidence that some eicosanoids act synergistically with PAF (14,15). In other mammalian systems, however, it appears that the two mediator families are independently regulated (3). Some studies point toward other subclasses of phospholipids, such as alk-1′-enyl-2-acyl-*sn*-glycero-3-phosphoethanolamine, as a major store of n-6 PUFA (16) and precursors of other phospholipid mediators (17). The precursors of eicosanoids as well as of PAF can be released on hydrolysis of membrane-associated alkylacyl-GPC (13). Thus the nature of the acyl moiety in the *sn*-2 position can be crucial in determining how a cell responds to a stimulus. Associated with the generation of lipid mediators is the production of lysophospholipids, which, because of their detergent properties, cannot be allowed to accumulate; several lysophospholipid acylation systems which can remove these compounds have been described in mammalian cells. One acylation system uses acyl-coenzyme A as acyl donor while another system is independent of coenzyme A and catalyzes a direct transfer of an acyl moiety from a donor phospholipid to the acceptor lysophospholipid (2,18–20). The latter transacylation system in mammals appears to have a high degree of selectivity for arachidonoyl-containing donor species, implicating this system in stimulus-coupled lipid mediator generation.

Arachidonate may not be the only precursor of bioactive eicosanoids in mammals. Evidence of a cardiovascular health benefit in man derived from dietary n-3 fatty acids has been reported (4,5), but the reasons for this effect are not understood. There are reports that dietary n-3 fatty acids may be essential in man (6); it has been clearly demonstrated that docosahexaenoate (DHA) is required for normal growth and development in humans, particularly with respect to the growth of the brain and eye (21). DHA has been shown to accelerate differentiation of HL-60 cells (22) and to activate protein kinase C in sponges (23). Lipoxygenase products have been shown to be produced from DHA in human platelets (24) and canine retina (25), but the functions of these metabolites are unclear.

Certainly, mammalian cells will incorporate (26,27) and utilize (28) n-3 fatty acids when they are available. When $P388D_1$ cells were supplemented with n-3 fatty acids, the acids were selectively incorporated into the ether-linked phosphatidylethanolamines (27). When monkeys were fed a fish oil supplemented diet, much of the 20:5n-3 was found in the phosphatidylethanolamine fraction; interestingly, neutrophils from these animals preferentially acylated lysoPAF with 20:5 as compared to control cells which utilized predominantly 20:4 (27). It has also been demonstrated that 20:5n-3 stimulates PAF synthesis in 20:4-depleted granulocytic HL-60 cells, but synthesizes less PAF than cells supplemented with 20:4 (29). Sperling *et al.* (30) found that in human monocytes, containing normal levels of 20:4, 20:5 supplementation inhibits PAF synthesis. Thus while 20:4 plays a major role in the reacylation of PAF in mammalian cells, 20:5 appears to have an impact on this system when it is available. We have shown here that in rainbow trout cells endogenous 22:6n-3 and 20:5n-3 are the major fatty acids used in the acylation of lysoPAF, representing more than 90% of the alkylacyl-glycerophosphocholine produced.

The role of n-3 fatty acids in mammals has remained unclear, perhaps obscured by the predominance of arachidonate, whereas in the rainbow trout n-3 essentiality has been documented (7). The concentration of n-3 fatty acids is enriched in the ether-linked subclasses of phosphatidylcholine and phosphatidylethanolamine (9), while

arachidonic acid (20:4n-6) is almost entirely associated with diacyl phosphatidylinositol (9). Tissues of the rainbow trout have been shown to synthesize PAF (8) and thus provide a model for studying the metabolism of lipid mediators in organisms that balance the utilization of n-3 and n-6 fatty acids differently than is known to occur in mammals. We have shown that trout splenocytes and an isolated membrane fraction from these splenocytes acylate alkyl-GPC with a high degree of specificity for n-3 fatty acids. This acylation appears to be independent of cellular energy as it is unaffected by treatment of the cells with sodium azide. The process is coenzyme A-independent and shows sensitivity to N-ethylmaleimide in a manner similar to that system in mammals. The reported observations that trout cells generate oxygenated products from n-3 fatty acids (31–37) and also show physiological responses to them (38), together with the specific n-3 acylation of lysoPAF reported here, defines a basis on which PAF and PUFA metabolism may be linked. Rainbow trout thus offer a good model system for obtaining a better understanding of that interface.

The effect of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) on acetyl-CoA carboxylase (ACC) activity and synthesis was examined. Male Wistar rats received a single *i.p.* injection of TCDD (53 μg/kg), and nine days later body weight, liver weight, hepatic lipid, ACC activity and mass were determined and compared to pair-fed controls. Body weights of TCDD-treated animals decreased, while liver weights increased resulting in an increase in liver to body weight ratios. ACC activity was decreased by 65%, however sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and Western analysis using a biotin specific probe revealed that ACC protein levels were not appreciably changed. In addition, there was a large increase in exogenous lipid material in TCDD-treated livers as determined by osmium tetroxide staining. These data suggest that the decrease in ACC activity may be due to direct inhibition of the enzyme by negative allosteric interactions with free fatty acids released from adipose tissue that subsequently accumulate in liver.

Lipids 26, 521–525 (1991).

The chlorinated dioxin 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), a contaminant formed during the production of chlorophenoxy herbicides, is a toxic environmental and occupational pollutant (1–3). TCDD toxicity, coupled with its persistence in organisms and in the environment, have made this compound the focus of extensive investigations aimed at identifying the mechanism(s) that account for its toxicity (4–14). These studies have produced valuable information on the physiological and biochemical effects of TCDD, but they have not revealed a clear molecular mechanism(s) for its toxicity.

The most obvious reoccurring physiological and toxicological change observed in animals exposed to TCDD is the "wasting syndrome". Weight loss in TCDD-treated animals is greater than in pair-fed controls (6,10,11). This implies that decreased food consumption alone is insufficient to account for the accelerated weight loss and death in exposed animals. The mechanism by which TCDD induces mortality may be indirectly linked to the wasting syndrome *via* alterations in lipid metabolism. Animals exposed to TCDD also show alterations in thyroid and insulin levels. These hormones control a wide range of metabolic responses, including changes in lipid and carbohydrate metabolism (6,7,9–11,15).

Large amounts of TCDD accumulate in the liver after oral or intraperitoneal administration (16). A dose dependent decrease in the *de novo* synthesis of fatty acids in the liver of TCDD-treated (1–20 μg/kg) Wistar rats has been reported (17). In contrast, Sprague-Dawley rats receiving a single high dose of TCDD (125 μg/kg) show an increase in hepatic fatty acid synthesis (18). A molecular mechanism that explains these observations remains to be determined.

In all organisms examined to date, *de novo* synthesis of fatty acids requires acetyl-CoA carboxylase (ACC) [EC 6.4.1.2] and fatty acid synthase (FAS) [EC 2.3.1.85]. Other enzymes, such as pyruvate carboxylase (PC) [EC 6.4.1.1] and malic enzyme [EC 1.1.1.40] that shunt carbon into citrate may be an important factor in the stress response (19–21). For example, in TCDD stressed rats the level of malic enzyme increases (22). In plants ACC is the target of several chlorophenoxy herbicides (23–25). These authors suggested that plant death was linked to inhibition of ACC that caused a decrease in acyl lipid and membrane synthesis.

Here we report the effects of TCDD on the activity and mass of ACC in rats. In animals exposed to TCDD, the activity of ACC was drastically reduced, but the apparent mass of ACC remained unchanged. The amounts of FAS and PC also appear to decrease in treated animals.

MATERIALS AND METHODS

Chemicals. 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin, presolubilized in nonane at 50 μg/mL, was purchased from Cambridge isotope Laboratories (Woburn, MA). [^{14}C]$NaHCO_3$ was obtained from Amersham, Inc. (Arlington Heights, IL). Polyacrylamide (99% pure), protein molecular weight standards, 1-methyl-2-pyrrolidinone (MPO), Tween-20, avidin-HRP, HRP-developer and Zeta Probe membrane were purchased from BioRad (Richmond, CA).

Preparation of TCDD for injection. All procedures were performed under a fume hood in a contained area. Double layer gloves were worn when handling TCDD and all contaminated disposable materials were placed in biohazard bags and incinerated. Nondisposable glassware was rinsed with toluene and then washed with soap and water. Solutions for injection were prepared by adding 2.0 mL of the TCDD solution to 10 mL of corn oil in a 50-mL glass beaker. The mixture was stirred under a fume hood for 48 hr in order to insure uniform mixing and to allow complete evaporation of the nonane carrier. A fraction of the corn oil/TCDD solution was removed and analyzed by gas chromatography to determine the TCDD concentration.

Animals. Male Wistar rats weighing 140–160 g were purchased from Simonsen Laboratories (Gilroy, CA) and housed individually in wire bottom cages. The animal room was maintained at 22°C at 50–60% humidity with a 12-hr light/dark cycle.

Diets and TCDD treatment. The animals were paired according to weight, and separated into two groups with eight animals in each group. They were fed Wayne Rodent Blox lab chow (Wayne Pet Food, Chicago, IL) *ad libitum* for five days after their arrival to the laboratory. On the

Abbreviations: ACC, acetyl-CoA carboxylase; FAS, fatty acid synthase; MPO, 1-methyl-2-pyrrolidinone; PC, pyrivate carboxylase; SDS-PAGE, sodium dodecyl sulfate-polyacrylamide gel electrophoresis; TCDD, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin.

sixth day, eight animals were injected *i.p.* with 53 μg/kg TCDD in 1 mL of corn oil and placed on a pair-feeding regime. The pair-fed controls were injected *i.p.* with corn oil only. Five days after injection, TCDD-treated and pair-fed control animals were fasted for 48 hr and then fed standard rat chow diet for an additional 48 hr. No difference in food intake between control and experimental animals was observed. This dietary procedure is the same as that described by Lakshman *et al.* (26) that ensures optimal conditions for lipogenic enzyme activity.

Tissue preparation. Animals were weighed before decapitation. Livers were removed immediately and weighed, and portions were taken for histopathological analysis. To obtain sufficient material for biochemical analyses, two liver homogenates were combined from the pair-fed and TCDD-treated animals to give 4 samples (N = 4). The samples were placed into ice-cold buffer (Tris-HCl, 20 mM, pH 7.4.; mannitol, 0.3 M; EDTA, 2 mM; dithiothreitol, 1 mM; and phenylmethylsulfonyl fluoride, 0.2 mM) and homogenized in a blender by pulsating (5–10 seconds) at high speed for ~30 seconds (27). The homogenate was filtered through gauze to remove fibrous material. The filtrates were centrifuged for 10 min at 20,000 × *g* at 4°C. The supernatant was removed and centrifuged again at 100,000 × *g* for 1 hr at 4°C. Portions of the supernatant were used for enzyme activity assays. The remaining supernatant was aliquoted and stored in 10% glycerol at −70°C.

Histopathologic preparation. Tissue samples for pathologic analysis were placed in Bouin's fixative (23.3% formaldehyde, 4.8% acetic acid, and 0.7% picric acid) for two days. The samples were stained with osmium tetroxide prior to being embedded in paraffin. With this stain lipids appear as black spots (28).

Activity assays. Cytosolic ACC was assayed as previously described (29). The method is a modification of that reported by Allred and Roehrig (30). The final reaction mixture (0.5 mL) contained: Tris-acetate, 70 mM, pH 7.5; potassium acetate, 120 mM; reduced glutathione, 4 mM; potassium citrate, 10 mM; ATP, 1 mM; bovine serum albumin, 0.6 mg/mL; acetyl-CoA, 0.35 mM; magnesium acetate, 10 mM; and [^{14}C]$NaHCO_3$, 7 mM (0.25 μCi). Blanks were assayed without protein and without substrate. Pyruvate carboxylase (PC) activity was assayed as described by Ballard and Hanson (31). The reaction was started with addition of protein and incubated 2–3 min for ACC and 10 min for PC at 37°C. Reactions were stopped with 0.05 mL of concentrated HCl. Unincorporated label was removed by drying samples (0.2 mL) of the reaction mixture at 95°C for 30 min. Samples were resolublized with 0.2 mL distilled water and counted in Aqueous Counting Scintillant fluid (Amersham).

Polyacrylamide gel electrophoresis of cytosolic protein. Cytosolic proteins were separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), as previously described (32).

Western blotting and avidin-horse radish peroxidase stain for biotin. Protein (200 μg) was separated according to size by SDS-PAGE as described. Following electrophoresis the gel was cut in half; one section was stained with Coomassie Blue and the other was equilibrated in transfer buffer (Tris/HCl 2.5 mM; and glycine 192 mM pH 8.3) for 30 min at room temperature to swell the gel and remove excess SDS. The gel was then put in the transfer cassette and placed on two pieces of 3 MM filter paper and a Scotch pad. Zeta Probe® membrane (BioRad), presoaked in transfer buffer, was then put on the anode (+) side of the gel. Ice-cold buffer (3.5 L) was added and the proteins were transferred in a BioRad Trans-Blot apparatus at 50 V (~0.560 amps) for 6.5 hr. After transfer, the membrane was incubated with 100 mL of borate Tween blocking buffer ($Na_2B_4O \times 10\ H_2O$; 0.05 M; NaCl 0.5 M; 5% MPO; 0.2% Tween-20, pH 9.3) for 10 min; the incubation was repeated two times. The membrane was then washed three times with 100 mL Tris-Tween buffer (0.02 M Tris; 0.5 M NaCl, pH 7.5; 0.2% Tween-20; and 5.0% MPO) for 5 min. Avidin-HRP was prepared by adding 150 μL of premixed avidin-HRP (BioRad) to 100 mL of the Tris-Tween buffer. The membrane was put in the avidin-HRP solution and then placed on a rotating shaker for 1.5 hr at room temperature. Excess avidin-HRP was removed by washing two times with 100 mL Tris-Tween buffer and two more times with 100 mL Tris-buffered saline (0.02 M Tris; 0.5 M NaCl, pH 7.5). The samples were visualized using HRP-developer (60 mg developer in 20 mL ice-cold methanol, 0.015% H_2O_2 in 100 mL distilled water for 30 min). Development was stopped by soaking in distilled water.

RESULTS

Rats given a single *i.p.* injection of (53 μg/kg) TCDD showed a weight loss relative to control animals at the end of the nine-day period. Liver enlargement was apparent visually and the liver weight to body weight ratios increased from approximately 4 to 6% (Table 1). The observed increase in liver mass is associated with a dramatic increase in the lipid content of TCDD treated *vs.* control livers (Fig. 1, A and B) as judged by lipid specific histological evaluation of the status of livers from TCDD-treated animals.

ACC specific activity was suppressed 65% in TCDD exposed animals (Table 1). To assess the effects of TCDD on the actual amount of ACC present in liver samples, equal amounts of cytosolic protein from control and TCDD-exposed livers were analyzed by SDS-PAGE (Fig. 2). The location of ACC on the gel was determined using purified rainbow trout hepatic ACC as a standard (M_r = 230,000) (lane 3). The trout ACC has been shown previously to have the same biochemical and electrophoretic properties as rat hepatic ACC (29). Initially it appeared from Figure 2 that the 230,000 dalton protein, putatively ACC, had dramatically decreased in TCDD-treated (lane 1) *vs.* pair-fed animals (lane 2). However, carboxylases are characterized by the presence of a covalently linked biotin moiety. If the observed decrease in ACC activity was due to reduced ACC protein levels, then the biotin content of the 230,000 dalton band should be reduced proportionately. A western transfer of a gel comparable to that shown in Figure 2 was done. The blot was incubated with avidin-HRP, which has a high binding affinity for biotin. This enabled visualization of all the biotin-containing proteins present in the soluble fraction. Figure 3 shows a typical blot. This experiment was done four times with no indication of differences between amounts of ACC in control and in experimental animals. The amount of ACC protein (M_r = 230,000) was equivalent in TCDD (lane 4) to that observed in control preparations (lane 3). We have

TABLE 1

Effects of 2,3,7,8-Tetrachlorodibenzo-*p*-Dioxin on Animal Body Weight, Liver Weight and Acetyl-CoA Carboxylase (ACC) Specific Activity[a]

Group	(N)	Body wt.	Liver wt.	Liver wt. Body wt. × 100	ACC activity (U/mg) %	Inhibition	Total protein (mg/g liver)
Control (corn oil only)	(8,6)	228.1 ± 17.5	9.30 ± 1.64	4.0	.40 ± .07	0.0	34.8 ± 2.90
Experimental (53 μg/kg TCDD)	(8,6)	202.0 ± 13.7[b]	12.02 ± 1.71[b]	6.0	.14 ± .02[c]	65.0	30.8 ± 3.13

[a]Statistical analysis was by Student paired *t*-test; all values are means ± S.D. (U) equals nmoles of malonyl-CoA produced per min at 37°C. Activity is expressed as per mg total protein. ACC activity has been corrected for acid stable products other than malonyl-CoA.

[b]$p<0.01$.

[c]$p<0.001$.

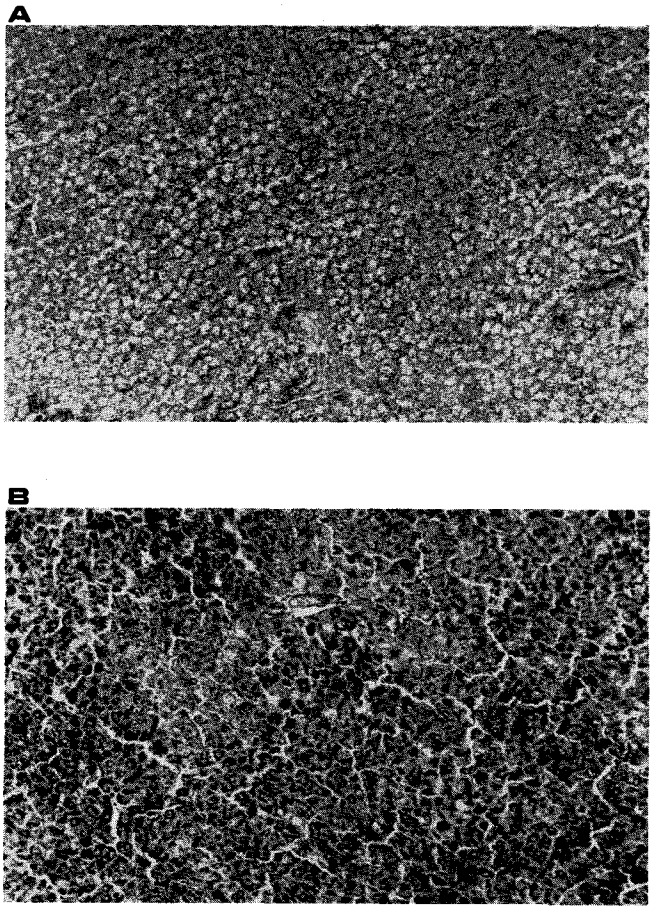

FIG. 1. Photomicrographs (250x) of control (A), and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD)-treated (B), liver stained with osmium tetroxide to visualize fat. The large black areas apparent in (B) represent fat deposits.

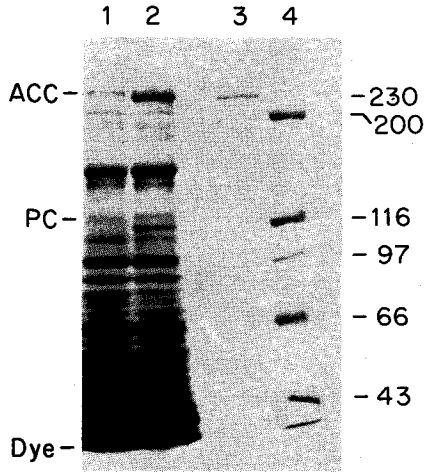

FIG. 2. SDS-PAGE analysis (5% polyacrylamide) of cytosolic proteins. Lane 1, 200 μg TCDD treated liver cytosolic protein. Lane 2, 200 μg of control liver cytosolic protein. After electrophoresis for 4 hr at 21 mA the gel was stained with Coomassie Blue. Acetyl-CoA carboxylase (ACC) and pyruvate carboxylase (PC) bands are identified. Lane 3 is an avidin-Sepharose purified rainbow trout liver ACC, which has been shown to have essentially the same biochemical and electrophoretic properties as rat liver ACC (ref. 29). Lane 4 contains BioRad high molecular weight standards ($\times 10^{-3}$). Samples were fractionated on an SDS-PAGE (18 cm × 16.5 cm × 0.2 cm) consisting of a 3% stacking gel and a 5% resolving gel at 21 mA constant current for 4 hr at 4°C. Gels were stained overnight with Coomassie Blue and destained with 50% methanol, and 10% acetic acid.

no explanation for the slight change in migration observed between ACC protein in lanes 3 and 4. The higher molecular weight form of ACC that is visible using the avidin-HRP probe appears as doublet. The doublet was present in all of the control and experimental crude cell preparations. Although this higher molecular weight band has been reported by several authors, its exact source has not been clearly defined (23,33). It is important to note, however, that in all control and TCDD samples analyzed in this study, there was no visible difference between the high and low molecular weight forms. The data in Figure 3 suggest that reduced staining intensity for the putative ACC observed for TCDD-treated animals in Figure 2, lane 1, was due to co-migration of ACC with one or more protein(s). FAS has been shown to co-migrate with ACC on low-percentage acrylamide gels such as those used in this work (21,34). Tentatively, we believe that a reduction in the amount of FAS may account for the reduced Coommassie Blue staining intensity observed in Figure 2.

On the western blots, a smaller biotin-containing protein (M_r = 125,000) was observed (Fig. 3). It was reproducibly present in lower amounts in TCDD-treated animals (lane 4) relative to control animals (lane 3). The mitochondrial protein pyruvate carboxylase (PC) has a molecular weight of 130,000 daltons, and the presence of

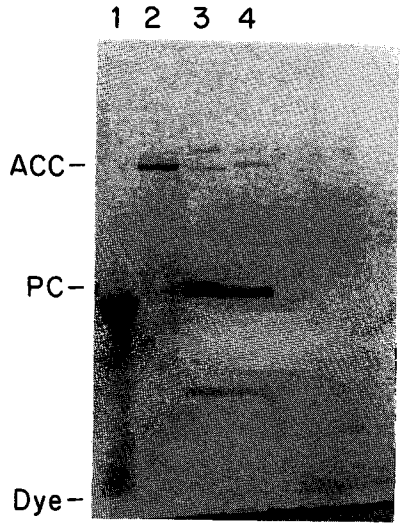

FIG. 3. Western transfer and biotin specific staining of protein with avidin-HRP. Lane 1 is a prestained β-galactosidase (M_r = 116,000) standard obtained from Diversified Biotech (Newton Centre, MA). Lane 2 is 3 μg purified rainbow trout liver ACC. Lane 3, 200 μg cytosolic protein from control liver. Lane 4, 200 μg cytosolic protein from TCDD liver.

this enzyme in preparations such as those employed here has been previously established (31,35). Activity assays were done to establish a relationship between the gel data and PC activity. These assays revealed the presence of PC in our normal preparations; however, PC specific activity in preparations from TCDD-treated animals was reduced. The average value for control-fed animals and for TCDD animals was 10.5 nmol/min/mg protein and 4.0 nmol/min/mg/protein, respectively. Previous work by others using these procedures has shown that this carboxylase appears in the supernatant fractions (27); we presume that mitochondria were disrupted. We attribute the reduction in activity to decreased amounts of PC in TCDD-treated animals. Tentatively, this conclusion is supported by SDS-PAGE analysis (Fig. 2, lanes 1 and 2), western blots analyzed with a biotin carboxylase specific probe (Fig. 3, lanes 3 and 4), and PC specific activity assays.

DISCUSSION

Animals given TCDD showed a reduction in body weight after nine days as compared to pair-fed controls. Hepatomegaly was also observed in TCDD-treated animals, with liver weight to body weight ratios increasing relative to controls. The increase in liver weight was due principally to lipid accumulation in the liver (Fig. 1). TCDD is known to increase the activity of hormone sensitive lipoprotein lipase activity in adipose tissue. This leads to an increase in the levels of serum fatty acids (33,36). Serum fatty acids accumulate in the liver and are converted principally to triacylglycerols. We observed that TCDD had a suppressive effect (65% inhibition) on ACC, a key enzyme in *de novo* synthesis of fatty acids. The actual mass of the enzyme is nevertheless comparable to that observed in control animals (Fig. 3). This suggests that post-translational regulation is the initial response to TCDD, which is most likely due to the accumulation of acyl-CoA fatty acids. These fatty acids are known negative effectors of acetyl-CoA carboxylase activity (37).

Fatty acid synthase (FAS) is the only protein that is known to co-electrophorese with ACC on low-percentage acrylamide gels (21,34). Both ACC and FAS activities are greatly increased following a fasting/refeeding protocol as used in the present study. The increased activity of FAS is most likely due to increased translational efficiency that produces more enzyme (38,39). Lakshman *et al.* (26) have shown that FAS activity is greatly reduced by TCDD. Our data strongly suggest that the reduction in FAS activity is a consequence of decreasd amounts of the enzyme, possibly due to a reduction in translation. This interpretation is based upon our preliminary observation that the primary staining component of the 230,000 dalton band in Figure 3 is FAS, and therefore it is this protein that decreases in TCDD-treated animals (Fig. 2, lane 1).

A second biotin-containing protein was detected in the western transfer/avidin-HRP procedure. This 125,000 dalton protein has the same molecular weight as that reported for PC. PC enzymatic activity was present in our preparations. The PC enzymatic activity was at least ten times greater than ACC activity, but the activity was greatly decreased in TCDD treated animals. Based on molecular weight, biotin content and enzyme activity, we conclude that the 125,000 dalton band in Figures 2 and 3 is PC. PC is a gluconeogenic enzyme. Our observations are consistent with recent data showing TCDD-mediated decreases in two gluconeogenic enzymes (phosphoenolpyruvate carboxykinase and glucose-6-phosphatase) in exposed rats (40).

Clearly ACC and PC are suppressed in the presence of TCDD. We also have indirect evidence of TCDD suppressive effects on FAS. The observed inhibitory effects on ACC enzymatic activity and mass reductions of FAS are significant. A diminution in *de novo* fatty acid biosynthesis could alter membrane synthesis, structure and function through aberrant incorporation of salvaged fatty acids into triacylglycerols and phospholipids. Such a response in terms of phospholipids may alter cellular ion flux and effective membrane/protein interactions. This possibility is supported by a recent report showing a substantial increase in the influx of exterior Ca^{2+} into TCDD-treated thymocytes (13).

The data presented here complement previous studies that have examined the *in vivo* regulation of ACC as well as the effects of TCDD on hormones, fat disposition and enzyme activities. We suggest that post-translational regulation of ACC is the initial response to TCDD exposure. It has been shown that ACC is regulated rapidly and specifically by phosphorylation of specific sites within the enzyme. The kinase responsible for this phosphorylation is AMP-phosphokinase (AMP-PK) and it is activated by nanomolar amounts of fatty acyl-CoA *via* a kinase-kinase cascade (41–43). Under normal circumstances, the negative allosteric affects of fatty acyl-CoA on ACC may be negligible due to the presence of acyl-binding proteins and low levels of free fatty acyl-CoA (44). However, the dramatic increase in hepatic lipids caused by TCDD exposure may saturate these binding proteins, and in combination with the AMP-PK allow the fatty acyl-CoA to exert their effect on ACC both allosterically and by

activation of the AMP-PK, resulting in the phosphorylation of ACC. We propose that the reduction in ACC activity without loss of protein may be due initially to an increase in phosphorylation and/or allosteric inhibition of ACC by fatty acyl-CoA.

Differential Effects of Ursodeoxycholic Acid and Ursocholic Acid on the Formation of Biliary Cholesterol Crystals in Mice

Kiyohisa Uchida*, Takashi Akiyoshi, Hirotsune Igimi, Haruto Takase, Yasuharu Nomura and Shouichi Ishihara

Shionogi Research Laboratories, Shionogi & Co., Ltd., Fukushima-ku, Osaka 553, Japan

The preventive effect of 3α,7β,12α-trihydroxy-5β-cholanoic acid (ursocholic acid) and ursodeoxycholic acid on the formation of biliary cholesterol crystals was studied in mice. Cholesterol crystals developed with 80% incidence after feeding for five weeks a lithogenic diet containing 0.5% cholesterol and 0.25% sodium cholate. When 0.25% ursocholic acid or ursodeoxycholic acid was added to the lithogenic diet, the incidence as well as the grade (severity) of the gallstones were reduced. Plasma and liver cholesterol levels were decreased by ursodeoxycholic acid but not by ursocholic acid. Gallbladder cholesterol and phospholipid levels were decreased by both bile acids. The biliary bile acid level was decreased by ursocholic acid but not by ursodeoxycholic acid. After feeding ursocholic acid, its level in the bile was about 25% and the levels of cholic acid and β-muricholic acid decreased. Fecal sterol excretion was not changed by ursocholic acid, but was increased by ursodeoxycholic acid. After feeding ursocholic acid, fecal excretion of deoxycholic acid, cholic acid, and ursocholic acid increased. No differences were found between mice, with or without gallstones, in plasma and liver cholesterol levels, biliary phospholipid and bile acid levels, fecal sterol and bile acid levels, and biliary and fecal bile acid composition. The results suggest that the lower incidence of crystal formation after treatment with ursocholic acid is probably by a different mechanism than with ursodeoxycholic acid. In the mouse model, ursodeoxycholic acid exerts its effect at least partially, by decreasing cholesterol absorption. Ursocholic acid is well absorbed and excreted into bile and transformed into deoxycholic acid by the intestinal microflora in mice.
***Lipids* 26, 526–530 (1991).**

Biliary cholesterol crystals are produced in mice that are fed excess cholesterol and cholic acid (1–3). Crj:ICR (Charles River Japan, Kanagawa, Japan) male mice develop cholesterol crystals with an incidence of 70% after being fed a diet containing 0.5% cholesterol and 0.25% sodium cholate for 5–10 weeks (4). When a high cholesterol diet without added sodium cholate was fed to mice, no crystals formed (1,4). In addition, no crystals developed (6) when cholic acid was replaced with chenodeoxycholic acid, which is less effective in enhancing cholesterol absorption (5). Diabetic mice have a markedly enlarged pool of cholic acid and develop cholesterol gallstones even when fed cholesterol alone (4). These results suggest that the mechanism by which cholesterol crystals form in gallbladder bile seems to be dependent on cholesterol absorption in the gut.

Ursodeoxycholic acid is well known as an oral gallstone solubilizer and recently 3α,7β,12α-trihydroxy-5β-cholanoic acid (ursocholic acid, 7β-hydroxy-isocholic acid, or 7β-cholic acid) has been studied for the same purpose, because it is the 7β-hydroxyepimer of cholic acid, possessing a 7β-hydroxyl group as well as ursodeoxycholic acid (7–11). This bile acid is reported to resemble cholic acid but not ursodeoxycholic acid in its response to biliary bicarbonate excretion and has a low cytotoxicity (7). Ursocholic acid is also reported to be well absorbed by the intestine and excreted into the bile without biotransformation in the liver, and it decreases biliary excretion of cholesterol and phospholipids, thus decreasing bile cholesterol saturation (8–11). The critical micellar concentration is higher for this bile acid than for cholic acid (12), which suggests that ursocholic acid has a low micelle-forming capacity (8). In the present study, we examined whether ursocholic acid has the same effect as ursodeoxycholic acid on biliary cholesterol crystal formation in mice.

MATERIALS AND METHODS

ICR strain male mice, six-weeks-old, obtained from Charles River Japan (Crj:ICR), were kept in an air-conditioned room (25 ± 1°C, 50–60% humidity) lighted 12 hr a day (8:00 a.m. to 8:00 p.m.). An ordinary powder diet (CA-1, Clea Japan Inc., Tokyo, Japan) was provided as a basal diet. The lithogenic diet was prepared by adding 0.5% cholesterol and 0.25% sodium cholate to the basal diet. The composition of the basal diet was as follows: 25.5% protein, 4.0% lipids, 53.5% carbohydrate, 4.0% fiber, 7.0% ash, and 6.0% water. The content of cholesterol was about 0.1%.

The test compounds ursocholic acid (>99.5%, Shionogi Research Laboratories, Osaka, Japan) and ursodeoxycholic acid (≥98%, Tokyo Kasei Kogyo Co., Ltd., Tokyo, Japan) were added (0.25% each) to the lithogenic diet. The animals were given *ad libitum* tap water and the diets, utilizing a powder diet feeding apparatus (Natsume Seisakusho Co., Ltd., Tokyo, Japan) for five weeks. Two-day feces were collected during the last week of the experiments.

Before being killed, the mice were fasted for 5 hr and the gallbladder was removed under sodium methylhexabital anesthesia (125 mg/kg, i.p.). Blood was then withdrawn from the abdominal aorta and the liver was removed.

The gallbladder was visually examined for cholesterol crystals under a dissecting microscope. The severity of crystal formation was classified from Grade 0 (cholesterol content <10 mg/mL), I(11–20), II (21–30), III (31–40), IV (41–50) to Grade V (>50), as reported previously (4).

The gallbladder was crushed in ethanol with a glass rod and biliary lipids were extracted by refluxing for 10 min at 80–90°C (4,13). After filtration, a portion was evaporated to dryness under a stream of nitrogen and the residue was hydrolyzed in 2 mL of 1.25 N NaOH solution at 120°C for 6 hr. Cholesterol was extracted from the NaOH solution with diethyl ether; then the bile acids were extracted with diethyl ether after the solution had been

Abbreviations: GLC, gas-liquid chromatography; TFA, trifluoroacetate; UCA, ursocholic acid; UDCA, ursodeoxycholic acid.

acidified with 2 N HCl (14). Cholesterol was determined by gas-liquid chromatography (GLC), with a GC-7A chromatograph (Shimadzu, Kyoto, Japan), using a 1.5% SE-30 column (15). The bile acids were converted into trifluoroacetate (TFA) methyl ester derivatives and subjected to GLC on 1.5% QF-1 and 1.5% AN-600 columns (4,15,16), though TFA derivatives are not well suited for GLC of α-muricholic acid (17). Cholesterol in plasma and liver, and sterols and bile acids in feces were determined by procedures described previously (4,13,16). Biliary phospholipid levels were determined by the Gomori method (18).

Statistical analyses (19,20) were performed as follows: Bartlett's test was applied to test for heterogeneity of variance between treatment groups. If no significant heterogeneity was detected, a (one-way) analysis of variance was carried out, and then the pooled standard error was calculated. If significant heterogeneity was found, typical transformations of data, such as log- and root-transformation, were applied. When no transformation satisfied the homogeneity of variance, the Kruskal-Wallis analysis of ranks was used. Analysis of variance was followed by Tukey's multiple comparison test. The Kruskal-Wallis analysis was followed by the non-parametric equivalents of Tukey's test.

RESULTS

The effects of ursocholic acid and ursodeoxycholic acid on the incidence of cholesterol crystals are shown in Table 1. After feeding the lithogenic diet for five weeks, the incidence was 80% in the control mice, but decreased after treatment with ursocholic and ursodeoxycholic acid.

The body weight, liver weight, and plasma and liver cholesterol levels are given in Table 2. The body weights were almost identical for all the groups; however, the liver weight was higher after feeding the lithogenic diet as compared with the ordinary diet. The liver weight was not changed by ursocholic acid treatment, but was decreased by the ursodeoxycholic acid treatment. Plasma and liver cholesterol levels were increased by the lithogenic diet and were decreased by ursodeoxycholic acid; ursocholic acid, however, had no effect.

The gallbladder lipid levels of the mice are shown in Table 3. The cholesterol level markedly increased. Since the amount of bile in one gallbladder was small, we analyzed the gallbladder, including the cholesterol crystals. Therefore, the cholesterol level measured did not correspond to the cholesterol concentration in the bile, but rather to the grade of the gallstones.

The biliary phospholipid level almost doubled after feeding the lithogenic diet compared to the ordinary diet; the levels after the treatment with both bile acids were intermediate. The biliary bile acid level was high in mice fed the lithogenic diet. The level was lower with ursocholic acid treatment, but not with ursodeoxycholic acid treatment.

The biliary bile acid composition is given in Table 4. Mouse bile contained a greater variety of bile acids than is shown in Table 4, *e.g.*, lithocholic, hyodeoxycholic, and some oxo-bile acids; however, their levels were small (less than 1-2%) and they are not listed. Since the lithogenic diet contained cholic acid, the mice fed this diet had more cholic and deoxycholic acids, and less β- and ω-muricholic and ursodeoxycholic acids than mice fed the ordinary diet.

After feeding ursocholic acid, the proportion of ursocholic acid was high, while cholic and β- and ω-muricholic acid levels were lower than in mice fed the lithogenic diet. Treatment with ursodeoxycholic acid increased α-muricholic, chenodeoxycholic and ursodeoxycholic acids and decreased cholic and β- and ω-muricholic acids.

Dietary intake, feces dry weight, and fecal sterol and bile acid levels are listed in Table 5. No significant change was found in dietary intake and feces dry weight among these mice. Fecal sterol excretion increased about four-fold in mice fed the lithogenic diet which contained 0.5% cholesterol. When ursocholic acid was given, the fecal cholesterol level did not change but the amount of coprostanol increased. When mice were fed ursodeoxycholic acid, fecal sterol excretion was higher than that of control mice fed the lithogenic diet. Fecal bile acid excretion also increased about five-fold in mice fed the lithogenic diet, and further increased, almost two-fold, after treatment with ursocholic acid and ursodeoxycholic acid.

Fecal bile acid composition is shown in Table 6. After feeding the lithogenic diet, the proportions of deoxycholic, cholic and 3α,12α,7=O bile acids were higher, while those of α- and ω-muricholic acids were lower, than when the ordinary diet was fed. Treatment with ursocholic acid increased the level of this bile acid, but decreased cholic, chenodeoxycholic, ω-muricholic, and 3α,12α,7=O bile acid levels. Treatment with ursodeoxycholic acid increased the proportions of ursodeoxycholic, hyodeoxycholic, and lithocholic acids, but decreased those of deoxycholic, cholic, ω-muricholic, and 3α,12α,7=O bile acids.

[a]Akiyoshi *et al.* (4).

[b]Lithogenic diet was given for five weeks *ad libitum*.

[c]Compounds were supplemented at the ratio of 0.25% to the lithogenic diet.

[d]Significant difference from control was detected at 0.05 by Wilcoxon's test.

DISCUSSION

The experiments demonstrate that ursocholic acid, like ursodeoxycholic acid, reduced the formation of biliary cholesterol crystals in mice fed a lithogenic diet. Plasma and liver cholesterol levels were decreased by treatment with ursodeoxycholic acid, but not by ursocholic acid treatment. These cholesterol levels were not related to biliary cholesterol crystal development. It is possible that the plasma and liver cholesterol levels reflect cholesterol absorption in the experimental mice (5). Therefore, we conclude that ursodeoxycholic acid reduced cholesterol absorption while ursocholic acid did not.

Development of biliary cholesterol crystals was reduced by treatment with these bile acids. The biliary phospholipid levels were low in the mice treated with both bile acids. These results are consistent with previous observations that ursocholic acid decreases biliary cholesterol and phospholipid levels (8–11).

After feeding ursocholic acid, this bile acid was well absorbed and constituted about 23% of the biliary bile acids; it was less than 1% in the control mice. These results agree with the observation of Loria *et al.* (11) who examined changes in biliary bile acids in patients after feeding them ursocholic acid. The proportions of cholic acid and β-muricholic acid in the bile decreased in our mice, while deoxycholic acid increased, although not significantly. In humans, deoxycholic acid in the bile markedly increased after oral administration of ursocholic acid (11). This difference between mice and humans might be due to the presence of deoxycholic acid 7α-hydroxylation activity in mouse liver. Ursocholic acid was dehydroxylated by the intestinal microflora forming deoxycholic acid, and deoxycholic acid was absorbed and transformed into cholic acid in mouse liver. Actually, the fecal excretion of deoxycholic acid increased from 2.3 mg/day/mouse in the control to 4.2 mg/day/mouse in the control to 4.2 mg/day/mouse after feeding ursocholic acid. The fecal excretion of cholic acid also increased after feeding ursocholic acid (1.1 mg/day *vs.* 1.6 mg/day). These results suggest that ursocholic acid is dehydroxylated to deoxycholic acid, and that ursocholic acid may compete with cholic acid absorption.

After feeding ursodeoxycholic acid, biliary ursodeoxycholic acid increased without resulting in any increase in muricholic acid, which suggests but does not prove that

ursodeoxycholic acid was not biotransformed to muricholic acid. Biliary cholic acid was decreased by ursodeoxycholic acid, which suggests that ursodeoxycholic acid may also compete with the absorption of cholic acid. Supporting these results are the findings that fecal excretion of ursodeoxycholic and lithocholic acids and of cholic and deoxycholic acids increased in mice fed ursodeoxycholic acid.

Our data suggest that ursocholic acid and ursodeoxycholic acid reduce crystal formation in mice fed the lithogenic diet in this animal model. Ursodeoxycholic acid decreases cholesterol absorption which results in a reduction of plasma and liver cholesterol levels compared with mice fed the lithogenic diet. Ursocholic acid, however, does not decrease these cholesterol levels. This suggests that the mechanism by which ursocholic acid reduces crystal gallstone formation differs from that of ursodeoxycholic acid. Crystal formation in this animal model does not seem to be related to plasma and liver cholesterol levels, but to bile acid composition. The relevance of the animal model to the human situation remains obscure.

ACKNOWLEDGMENTS

We sincerely thank M. Katayama and K. Suzumura for help in preparing the manuscript.

Phospholipid Requirement of Progesterone 5α-Reductase from Gastric Mucosa Microsomes of Guinea Pig

Kosuke Ichihara* and **Chikage Tanaka**
Department of Biochemistry, Kawasaki Medical School, Kurashiki, Okayama 701-01, Japan

Progesterone 5α-reductase partially purified from gastric mucosa microsomes was stimulated by short-chain synthetic phosphatidylcholines (PC), such as dilauroyl PC, but not by various PC from biological sources. Phosphatidylserine (PS) activated the gastric 5α-reductase to a limited extent compared to the liver 5α-reductase described previously [Ichihara, K., and Tanaka, C. (1987) *Biochem. Biophys. Res. Commun. 149,* 482–487]. In search of more effective phospholipid activators, we tested the effects of various lysophospholipids on 5α-reductase activity. Strongly stimulatory effects were observed when lysophosphatidylcholine (lysoPC) and lysophosphatidylethanolamine (lysoPE) were used instead of PC and phosphatidylethanolamine. Examination of synthetic lysoPC and lysoPE differing in acyl chain lengths showed that fatty chains of 12 to 16 carbons were effective in stimulating the 5α-reductase. By contrast, other lysophospholipids such as lysophosphatidic acid, lysophosphatidylglycerol or lysophosphatidylserine (lysoPS) greatly inhibited 5α-reductase activity. These findings suggest that gastric 5α-reductase may be under dual regulation; lysoPC and lysoPE may play important roles as positive effectors, whereas lysophosphatidic acid, lysophosphatidylglycerol and lysoPS act as negative effectors in progesterone 5α-reductase regulation.
***Lipids 26,* 531–535 (1991).**

In recent years, the modulation of enzyme activities by phospholipids has been extensively investigated in biological membranes (1). Phospholipid activation has been observed for some membrane-bound enzymes when they are solubilized and purified by the use of detergents. Phospholipids also have been shown to influence the activity of soluble enzymes, such as protein kinase C (2,3).

Phospholipid stimulation of steroid 5α-reductase in microsomal membranes, first recognized by Golf and Graef (4) in rat liver, was subsequently observed by Cooke and Robaire (5) in rat epididymis. The phospholipid requirement was specific for phosphatidylcholine (PC) in both liver and epididymis (4,5). In conflict with these reports, we have recently shown that endogenous phosphatidylserine (PS) isolated from rat liver microsomes specifically stimulated progesterone 5α-reductase that had been solubilized from liver microsomes (6).

The most recent report from our laboratory (7) showed that gastric progesterone metabolism was initiated by reduction at C-5 of the steroid, which was catalyzed by steroid 5α-reductase. Furthermore, we demonstrated that 5α-reductase activity of stomach mucosa was the highest among gastrointestinal tissues of guinea pig. For further characterization of gastric 5α-reductase, we have examined the effect of phospholipids on reductase solubilized from gastric microsomes. The present study shows that some lysophospholipids, such as lysoPC and lysophosphatidylethanolamine (lysoPE), are effective stimulators of steroid 5α-reductase that had been partially purified from gastric mucosa microsomes of guinea pigs.

Abbreviations: PA, phosphatidic acid; PAF, platelet activating factor, 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; PI, phosphatidylinositol; PS, phosphatidylserine.

MATERIALS AND METHODS

Materials. [4-^{14}C]Progesterone was purchased from Amersham International (Buckinghamshire, England). Natural PC (bovine liver, heart, brain and egg yolk), natural PE (bovine brain and liver), phosphatidic acid (PA) (egg yolk), phosphatidylglycerol (PG) (egg yolk), phosphatidylinositol (PI) (soybean), cardiolipin (heart), natural lysoPC (egg yolk), synthetic lysoPC (C_8, C_{10}, C_{12}, C_{14}, C_{16}, C_{18} and $C_{18:1}$), natural lysoPE (bovine brain and liver), synthetic lysoPE (C_{16}), lysoPI (soybean), lysoPG (soybean), lysoPS (bovine brain) and lysoPA ($C_{18:1}$) were obtained from Sigma Chemical Co. (St. Louis, MO). Synthetic PC (C_8, C_{10}, C_{12}, C_{14}, C_{16} and $C_{18:1}$) and PI (soybean) were purchased from Pharmacia Fine Chemicals (Uppsala, Sweden) and P-L Biochemicals (Milwaukee, WI), respectively. PS ($C_{18:1}$), lysoPE (C_{12}, C_{14}, C_{18} and $C_{18:1}$) and PAF were from Avanti Polar Lipids Inc. (Pelham, AL). PS (bovine brain) and precoated Silica Gel F_{254} plate were from Serdary Research Laboratories Inc. (London, Ontario, Canada) and Merck (Darmstadt, Germany), respectively. Dye reagent for protein determination was purchased from Bio-Rad Laboratories (Richmond, VA) and NADPH was from Oriental Yeast Co. (Tokyo, Japan). Digitonin and cholic acid were obtained from Wako Pure Chemical Co. (Osaka, Japan) and Nakarai Chemical Co. (Kyoto, Japan), respectively.

Endogenous phospholipids were separated from rat liver microsomes and guinea pig gastric microsomes exactly as described in our preceding paper (7).

Preparation of progesterone 5α-reductase. Solubilization and partial purification of 5α-reductase from gastric mucosa microsomes of guinea pig were carried out as described previously (7,8) with some modifications. Preparation of gastric mucosa microsomes and solubilization of 5α-reductase activity were performed as described previously (7). A cold 50% polyethylene glycol solution was added dropwise to the solubilized supernatant to arrive at a final concentration of 6.5% (w/v). After stirring for 10 min, the mixture was centrifuged at 10,000 × *g* for 15 min. Cold 50% polyethylene glycol was then added to the resulting supernatant to a final concentration of 13% (w/v). After centrifuging at 10000 × *g* for 20 min, the resulting precipitate was dissolved in 30 mM potassium phosphate buffer (pH 7.4)/0.4% (w/v) cholate/0.2 mM NADPH/20% (v/v) glycerol (designated 30 mM buffer), and then centrifuged at 100000 × *g* for 40 min. The supernatant was directly applied to a column (1.5 × 2.5

cm) of hydroxylapatite mixed with cellulose (1:1, w/w), which had been equilibrated with 30 mM buffer. After successive washes with 30 mM, 100 mM and 160 mM buffers, the column was eluted with 300 mM buffer. Cold 50% polyethylene glycol solution was added dropwise to the eluate to a final concentration of 20% (w/v). After being stirred for 20 min, the mixture was centrifuged at 100000 × *g* for 20 min. The resulting precipitate was dissolved in 30 mM potassium phosphate buffer (pH 7.4)/0.2 mM NADPH/20% (v/v) glycerol to yield a partially purified 5α-reductase preparation.

Assay methods. Progesterone 5α-reductase activity was determined as previously described (8) with minor modification. The standard reaction mixture contained potassium phosphate buffer (pH 7.0, 10 μmol), [4^{14}C]progesterone (2.4×10^4 dpm, 0.4 nmol) dissolved in 2 μL of methanol, NADPH (40 nmol) and enzyme preparation (2–3 μg of protein) in a final volume of 0.1 mL. After the substrate dissolved in methanol was evaporated to dryness, other reaction components were added. The various phospholipids tested were dispersed in 20 mM Tris-acetate buffer (pH 8.0) and 1 mM EDTA by sonicating for 1.0–1.5 min until no further decrease in turbidity of the sample was observed. The incubation was usually carried out at 37°C for 20 min. The enzyme assay was performed in duplicate and average values were calculated.

Protein was measured by using the Bio-Rad protein assay with bovine serum albumin as a standard.

RESULTS

Previous studies using endogenous phospholipids isolated from rat liver microsomes indicated that a lipid requirement for the steroid 5α-reduction in liver microsomes was specific for PS (6). These results were in conflict with the reports of Golf and Graef (4) and Cooke and Robaire (5), who had demonstrated an activation by PC in liver and epididymis, respectively. To clarify the possible role of phospholipids in gastric progesterone 5α-reduction, we examined the effects of commercially available PC (synthetic and naturally-occurring) on 5α-reductase activity. Although synthetic dilauroyl PC showed a significant stimulatory effect, most natural PC (from heart, egg yolk and liver) did not show any activation over a wide range of concentrations (Fig. 1). Upon examining a series of PC differing in the length of their saturated fatty acid chains (C_8 to C_{16}), and a PC with two unsaturated fatty acid chains ($C_{18:1}$), maximum stimulation was noted with dilauroyl PC (Fig. 2). It is of interest that dioleoylPC, like natural PC, did not exhibit any appreciable effect of 5α-reductase activity.

Among other phospholipids tested, synthetic PS which contained unsaturated fatty acid chains (dioleoyl) and a natural PS from bovine brain activated 5α-reductase (Fig. 3) to about the same extent as did dilauroyl PC (Figs. 1 and 2). Other phospholipids, such as PE (bovine liver and brain), PI (soybean), PA (egg yolk), PG (egg yolk) and cardiolipin (heart), were neither inhibitory nor stimulatory.

These results agree with our previous observations that endogenous PS specifically stimulated hepatic 5α-reductase activity (6), while natural PS from bovine brain activated gastric 5α-reductase only to a limited extent (130%) (Fig. 3). In search of more effective phospholipids

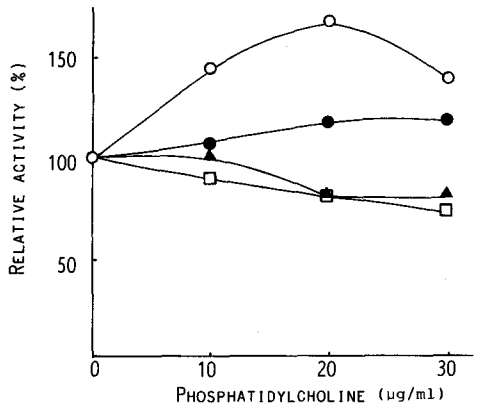

FIG. 1. Effect of various phosphatidylcholines on gastric progesterone 5α-reductase. Incubations were carried out under standard condition with 2 μg of 5α-reductase partially purified from gastric mucosa microsomes as described in Materials and Methods. PC at the concentration indicated was added to the incubation mixtures; synthetic dilauroyl PC (○) and natural PC, from the following sources: bovine liver (●), bovine heart (▲) and egg yolk (□). The enzyme activity was 0.42 nmol of products formed/min/mg, when PC was omitted from the reaction mixture.

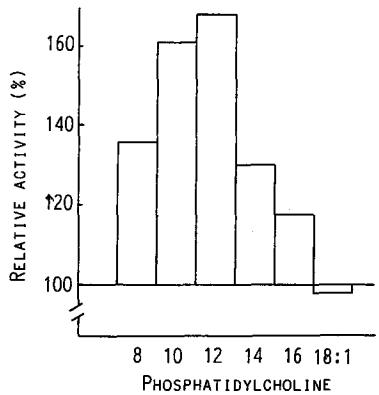

FIG. 2. Effect of synthetic phosphatidylcholines, differing in acyl chain lengths, on gastric progesterone 5α-reductase. Gastric 5α-reductase (2 μg) was incubated with 2–3 μg of PC, where maximum stimulation was observed. The numbers 8, 10, 12, 14 and 16 designate dicapryloyl, didecanoyl, dilauroyl, dimyristoyl and dipalmitoyl PC, respectively. 18:1 represents dioleoyl PC. The enzyme activity was 0.42 nmol of products formed/min/mg, when PC was omitted from the reaction mixture.

other than natural PS, we tested the effects of various lysophospholipids on 5α-reductase activity. A dramatic stimulatory effect was observed with oleoyl lysoPC and natural lysoPC from egg yolk (Fig. 4). PAF, which resembles lysoPC in molecular shape, activated reductase activity to a slightly lesser extent than did lysoPC (data not shown). It was of interest, therefore, to examine the effects of a series of lysoPC differing in the length of their fatty acid chains (C_8 to C_{18}), and to compare the results with those of the series of PC containing diacyl chains with 8 to 18 carbons (Fig. 2). Figure 5(A) shows the effects of various synthetic lysoPC compounds; maximum

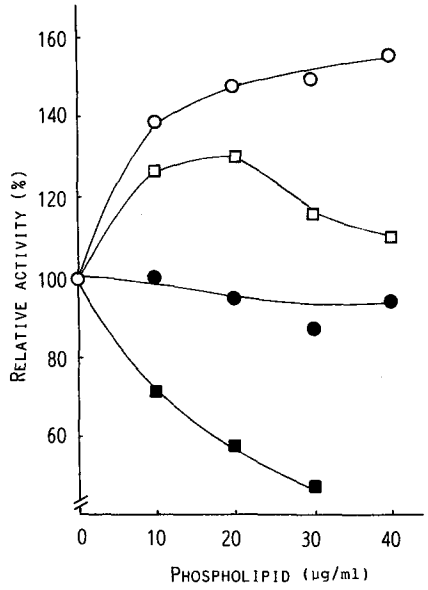

FIG. 3. Comparison between phosphatidylserines and phosphatidylcholines in stimulating gastric progesterone 5α-reductase. 5α-Reductase preparation (2 μg) was incubated with various phospholipids at the indicated concentrations: ○, dioleoyl PS; □, natural PS from bovine brain; ●, dioleoyl PC; ■, natural PC from bovine brain. The enzyme activity was 0.45 nmol of products formed/min/mg, when PS or PC was omitted from the reaction mixture.

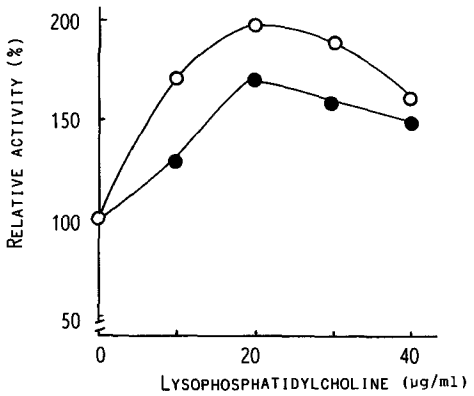

FIG. 4. Effect of lysophosphatidylcholines on gastric progesterone 5α-reductase. 5α-Reductase preparation (2 μg) was incubated with the indicated concentration of oleoyl lysoPC (○) or natural lysoPC from egg yolk (●). The enzyme activity was 0.45 nmol of products formed/min/mg, when lysoPC was omitted from the reaction mixture.

stimulation was observed with the C_{12}, C_{14} and C_{16} derivatives. While lysoPC with a saturated C_{18} fatty acid (stearoyl) brought about only limited enzyme activation, the presence of a single double bond in the acyl chain (oleoyl) greatly enhanced the stimulatory effect [Fig. 5(B)].

Similar results were obtained with lysoPE. While natural PE from bovine liver and brain did not exhibit any effect on 5α-reductase, the corresponding lysoPE compounds had marked stimulatory effects on enzyme activity [Fig. 6 (A) and (B)]. Like lysoPC, synthetic lysoPE with different fatty acyl chains activated 5α-reductase to various extents (Fig. 7). Of interest is that the presence of a single double bond in the acyl chain of lysoPE (Fig. 7) caused an enhancement of enzyme activation, as was observed for lysoPC (Fig. 5).

The effects of other lysophospholipids (lysoPI, lysoPS, lysoPG and lysoPA) on reductase activity are given in Figure 8. LysoPA (oleoyl), lysoPS (bovine brain) and lysoPG (soybean) were strongly inhibitory over a wide range of concentrations, whereas lysoPI (soybean) was weakly stimulatory in a narrow range of concentrations (10–20 μg/mL). In contrast to the stimulatory effect of PS, the corresponding lysoPS strongly inhibited 5α-reductase activity.

DISCUSSION

In our previous study (6) we demonstrated that endogenous PS had a specific stimulatory effect on progesterone 5α-reductase activity in rat liver microsomes. In contrast to these results, however,the observations of Golf and Graef (4) and Cooke and Robaire (5) indicated that the phospholipid requirement was specific for PC. It was, therefore, important to examine in detail the effect of phospholipids on gastric 5α-reductase, which we recently solubilized from gastric mucosa microsomes of guinea pig (7). After studying the effects of commercially available phospholipids on progesterone 5α-reductase activity, we found that natural PC did not exhibit any activation, whereas some shorter chain PC, such as dilauroyl PC, could partially activate the reductase. Among other phospholipids tested, both dioleoyl PS and naturally occurring PS (brain) activated the gastric enzyme to a limited extent as compared to the rat liver enzyme previously mentioned (6). Furthermore, in our preliminary experiments, endogenous PS prepared from gastric or hepatic microsomes was observed to be weakly stimulatory to gastric enzyme activity, but not to liver enzyme activity (6). On the basis of these results, it appeared conceivable that stimulatory effector(s) other than natural PS might play a role in regulating progesterone metabolism in gastric mucosa. Therefore, we examined the effects of various lysophospholipids on 5α-reductase activity. Our results demonstrate that both lysoPC and lysoPE from biological sources were most effective in their ability to activate the reductase; neither natural PC nor natural PE increased enzyme activity. Enzyme activation was observed to various extents with synthetic lysoPC and lysoPE compounds differing in acyl chain lengths; maximum stimulation was noted with C_{12}, C_{14} and C_{16} derivatives. With C_{18} derivatives, the presence of a single double bond in the acyl chain markedly enhanced enzyme stimulation. Among the synthetic phospholipids tested with various acyl chains, maximum stimulation was observed with the rather long-chain derivatives of both the lysophospholipids, unlike synthetic PC. Based on these observations, it is proposed that lysophospholipids, such as lysoPC and lysoPE, may play a physiological role in the activation of steroid 5α-reductase in gastric mucosa. It is conceivable that lysophospholipids may be generated from the corresponding phospholipids by the action of a phospholipase A_2, detected recently in the stomach mucosa associated with plasma and microsomal membranes (9–11). However, the generation of lysoPC and/or lysoPE under physiological conditions, which results in

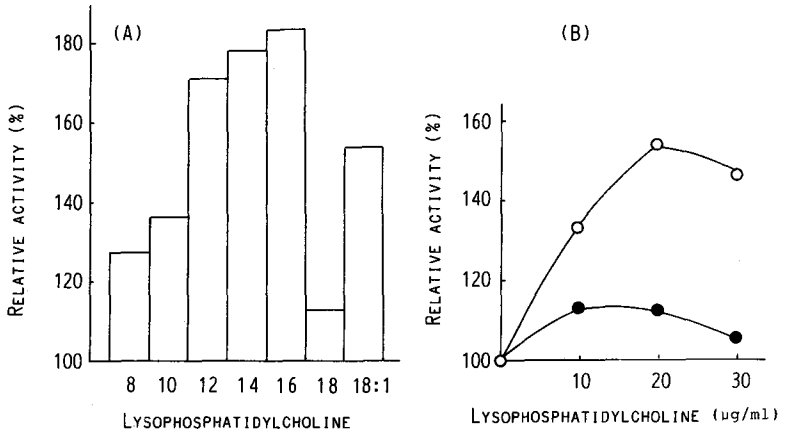

FIG. 5. Effect of synthetic lysophosphatidylcholines differing in the acyl chains on gastric progesterone 5α-reductase. (A) Effect of lysoPC with varying acyl chain lengths on 5α-reductase activity. 5α-Reductase preparation (1 μg) was incubataed with 2∼3 μg of lysoPC, where the maximum stimulation was observed. The numbers 8, 10, 12, 14, 16 and 18 represent capryloyl, decanoyl, lauroyl, myristoyl, palmitoyl and stearoyl lysoPC. 18:1 represents oleoyl lysoPC. (B) Comparison between oleoyl lysoPC (○) and stearoyl lysoPC (●) in stimulating the 5α-reductase (1 μg). The enzyme activity was 0.22 nmol of products formed/min/mg, when lysoPC was omitted from the reaction mixture.

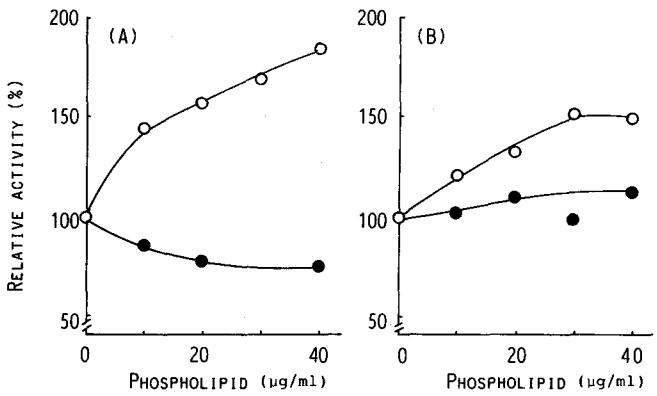

FIG. 6. Comparison between natural lysophosphatidylethanolamines and natural phosphatidylethanolamines in stimulating gastric progesterone 5α-reductase. 5α-Reductase preparation (1 μg) was incubated with the indicated concentration of lysoPE (○) or PE (●): (A) bovine brain; (B) bovine liver. The enzyme activity was 0.23 nmol of products formed/min/mg, when lysoPE or PE was omitted from the reaction mixture.

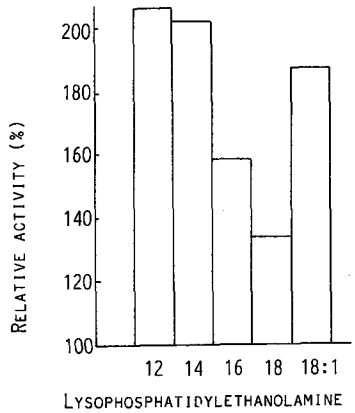

FIG. 7. Effect of synthetic lysophosphatidylethanolamines with various acyl chain lengths on gastric progesterone 5α-reductase. 5α-Reductase preparation (1.5 μg) was incubated with 2–3 μg of lysoPE, where the maximum stimulation was observed. The numbers 12, 14, 16 and 18 represent lauroyl, myristoyl, palmitoyl and stearoyl lysoPE, respectively; 18:1 represents oleoyl lysoPE. The enzyme activity was 0.32 nmol of products formed/min/mg, when lysoPE was omittd from the reaction mixture.

activation of gastric 5α-reductase, deserves further investigation.

Recently, certain lysophospholipids, lysoPC in particular, have been shown to regulate protein kinase C in a biphasic manner; stimulation at low concentration and inhibition at higher concentration (12). Likewise, the gastric 5α-reductase appears to be under dual regulation, that is, stimulation by lysoPC and lysoPE and inhibition by lysoPA, lysoPS and lysoPG. Indeed, further studies are required to determine whether the stimulation or inhibition of 5α-reductase afforded by these lysophospholipids could be functionally important in the regulation of gastric progesterone metabolism. Recently, similar results were obtained with heart acyl-CoA hydrolase (13) and erythrocyte Na^+, K^+-ATPase (14), where certain lysophospholipids exerted profound effects as inhibitors.

At present time, little is known about the mechanism by which phospholipids activate gastric 5α-reductase. Although the effect may be due to detergent action, this seems unlikely since detergents such as Triton X-100 produced a pronounced inhibition (data not shown). Also, the phospholipid requirement was rather specific for lysoPC and lysoPE in the case of gastric 5α-reductase. On the other hand, for neutral triacylglycerol hydrolase from rat heart (15), a detergent effect cannot be ruled out since

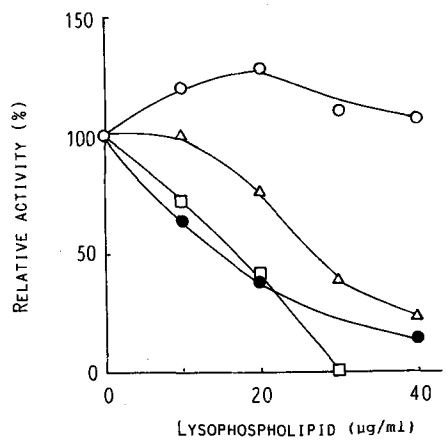

FIG. 8. Effect of various lysophospholipids on gastric progesterone 5α-reductase. 5α-Reductase preparation (1.5 μg) was incubated with the indicated concentrations of lysophospholipids: ○, lysoPI from soybean; △, lysoPG from soybean; ●, lysoPS from bovine brain; □, oleoyl lysoPA. The enzyme activity was 0.32 nmol of products formed/min/mg, when lysophospholipid was omitted from the reaction mixture.

besides lysoPE and PE, a neutral detergent stimulated hydrolase activity.

Whether lysophospholipids activate gastric 5α-reductase in cells remains to be established. It is not known whether the concentration of lysoPC or lysoPE found in gastric mucosa membrane is stimulatory. Recently, it has also been shown that a membrane-associated protein kinase in plants is stimulated by PAF, and also by both lysoPC and lysoPE (16). These results agree with our present findings, although PAF, which resembles lysoPC in molecular shape, stimulated gastric 5α-reductase to a lesser extent than did lysoPC and lysoPE. In the case of the plant protein kinase (16), a natural activator was proposed to be displaced by PAF and the lysophospholipids. Therefore, we cannot rule out the possibility that an endogenous activator structurally similar to PAF and lysoPC may exist in gastric mucosa. Much works remains to be done to pin-point the physiological activator(s) of the gastric progesterone 5α-reductase.

Steryl Esters in a Cell Suspension Culture of Celery (*Apium graveolens*)

Lynne Dyas, Mark C. Prescott, Richard P. Evershed and L. John Goad*
Department of Biochemistry, University of Liverpool, Liverpool L69 3BX, United Kingdom

A range of analytical techniques was used to investigate the composition of the steryl fatty acyl esters in a cell suspension culture of celery *(Apium graveolens)*. Gas chromatography (GC) and GC-mass spectrometry (GC-MS), using electron ionization (EI) and negative ion chemical ionization (NICI), were employed to characterize the intact steryl esters. Assignments were supported by analysis of the sterol and fatty acid moieties released from the intact molecular species by alkaline hydrolysis. A selectivity for sterol esterification was noted, with the major free sterol, stigmasterol, occurring only in a very small amount in the esterified form. Instead, the precursors to Δ^5-phytosterols, particularly cycloartenol, predominated in the ester fraction. The pentacyclic triterpene, β-amyrin, was also found as the palmitate and linoleate esters. Changes in composition and abundance of the steryl esters during the different growth phases of a celery cell suspension culture were investigated. The total amount of esterified sterols exceeded that of free sterols throughout the growth cycle. The changes observed during growth highlighted differences between the esters of precursor sterols and those of the 4-desmethylsterols, and it is postulated that the various steryl esters perform different functions in cell metabolism.
***Lipids* 26, 536–541 (1991).**

Steryl esters have been studied in numerous plant species (1–9) as well as in individual tissues and organelles (10–14). Despite this, their precise role in plants remains unclear. Suggested functions include a storage form of sterol (15,16) or a transport form, either intracellularly (17) or by translocation between tissues (15,18). Atallah and Nicholas (19) proposed that it is the liquid crystalline properties of steryl esters which determine their function, probably in association with membrane permeability. Steryl esters have also been implicated in a regulatory role in sterol biosynthesis (20,21).

Esterification of sterols has been extensively studied in animals due to the important part cholesteryl esters play, as constituents of plasma lipoproteins, and their involvement in clinical conditions such as atherosclerosis (22,23). As changes have been observed in the abundance of steryl esters at all vital stages of the plant life cycle, it is likely that they have an equally important role to play in plant metabolism. During seed germination of *Calendula officinalis* (16) and barley (24), a decrease in abundance of steryl esters occurs, accompanied by a concomitant increase in free sterols. Steryl esters accumulate again during flowering of *Calendula*, with the esterified form becoming more abundant than the free sterols in the inflorescence. The ripening of tomatoes (25) is characterized by an increase in total sterol content of the fruit, with the most marked increase being in the ester fraction (twelvefold). These changes were shown to be associated with the ripening process rather than aging, as a mutant non-ripening variety did not show similar increases at the same age. However, an increase in steryl ester abundance during senescence of tissues (15,16,26) has also been observed, with the implication that they are involved in the removal of sterols from the membranes (15).

In order to increase our understanding of the biosynthesis and metabolism of steryl esters in plants, we are investigating the changes in abundance and composition of steryl esters over the growth cycle of a single-cell suspension culture of celery *(Apium graveolens)*. This system has a growth curve exhibiting lag, logarithmic and stationary phases of growth.

Most studies concerning steryl esters have proceeded by alkaline hydrolysis of the intact molecules followed by separate analyses of the constituent sterol and acyl moieties. This method, however, loses potentially useful information on the nature of the intact esters. The use of negative ion chemical ionization gas chromatography-mass spectrometry (NICI GC-MS) has been demonstrated for the analysis of a range of intact steryl palmitates (27) and for the examination of relatively simple mixtures of steryl esters from animal and plant tissues (28). We have now used this technique to identify the steryl esters of celery, providing more precise information about individual esters, which may aid in the elucidation of their function.

EXPERIMENTAL

Growth conditions for celery. A celery cell suspension culture was provided by Dr. Hamish Collin, University of Liverpool, (Liverpool, U.K.). Cultures (60 mL) were grown in Murashige and Skoog medium (Flow Laboratories, Irvine, Scotland) supplemented with sucrose, kinetin and 2,4-dichlorophenoxyacetic acid. The cells were cultured in an orbital incubator at 20°C with constant shaking at 100 rpm and a 12-hr light/12-hr dark cycle. Cell growth was determined by cell counts and cell dry weight measurements.

Celery seedlings (White Pascal variety, Johnsons Seeds, Boston, U.K.) were grown in a greenhouse under natural night/day lighting, and harvested at 6 wk.

Extraction and fractionation of lipids. Cells were filtered from the medium through nylon, frozen in liquid nitrogen and freeze-dried. Lyophilized material was then extracted by stirring in chloroform/methanol (2:1, v/v; 30 mL per 50 mg tissue) followed by filtration. The cell residue was extracted two more times with $CHCl_3$/MeOH and the three extracts combined. Internal standards for quantification were added with the first volume of solvent, as detailed below. Combined filtrates were evaporated *in vacuo* to yield total lipids.

Total lipid extracts were applied to silica gel columns (70–230 mesh; 5 g; 5% deactivated) and eluted with

hexane (50 mL) with increasing proportions of diethyl ether. Steryl esters were eluted in 2–4% Et_2O/hexane, and free sterols were eluted in 16–32% Et_2O/hexane fractions.

Hydrolysis of steryl esters. Steryl ester mixtures (*ca.* 5 mg) were heated at 70°C for 2 hr in 2 mL 8% KOH in 80% EtOH. Free sterols were extracted into 3 vol of hexane. The aqueous fraction was acidified with aqueous 20% (v/v) H_2SO_4, and the fatty acids were extracted into $CHCl_3$. The sterols were analyzed as their trimethylsilyl ethers, and the fatty acids were converted into methyl esters by heating at 70°C in methanolic 2.5% H_2SO_4 and then extracted into hexane (29).

Analyses of lipid fractions. Gas chromatographic analyses were performed on a Hewlett-Packard 5890 GC operated in on-column mode with helium (2 mL/min) as carrier gas. A 12 m × 0.22 mm i.d. BP1-coated (0.1 μm film thickness) capillary column (S.G.E., Milton Keynes, U.K.) was employed for intact steryl ester analyses, with the oven programmed from ambient to 340°C at 4°C/min. Sterols were determined as their trimethylsilyl derivatives on a 25 m × 0.22 mm BP5-coated (0.25 μm film thickness) column, and the oven was programmed from ambient to 290°C at 6°C/min. Fatty acids (as their methyl esters) were analyzed on a 25 m × 0.32 mm i.d. Carbowax (0.3 μm film thickness) capillary column (Hewlett-Packard), with the oven programmed from ambient to 230°C at 10°C/min.

GC-MS analyses were performed on a Pye Unicam 204 GC interfaced to a VG (Altrincham, U.K.) 7070H double-focussing magnetic sector mass spectrometer, coupled to a Finnigan (Hemel Hempstead, U.K.) INCOS#2300 data system. GC columns and operating conditions were as above. Electron impact spectra were recorded at 20 eV and 3 kV accelerating voltage. GC-MS with NICI was performed with ammonia as reagent gas, as reported previously (30).

Quantification of lipids. 5α-Cholestanol (100 μg) and cholesteryl myristate (100 μg) were added to the lyophilized cells prior to extraction to act as internal standards for quantification from GC peak areas. Quantification of the co-eluting compounds β-amyrin and sitosteryl linoleates, was performed by reference to the relative intensities of the mass spectral fragment ions at *m/z* 218, arising from β-amyrin and *m/z* 396 from sitosteryl linoleate. Isofucosterol and β-amyrin, from the free sterol fraction, were quantified in a similar manner, on the basis of their characteristic fragment ion abundances at *m/z* 386 and 218, respectively.

The mean value and variance for the absolute quantities of each compound were calculated from 5 replicate analyses, and Students' t-tests (employing Bessel correction for low sample number) were performed to establish significant changes between the differently aged cultures. All changes reported in the Results section were significant below $p = 0.05$.

Nomenclature. Trivial names of sterols have been used as follows: campesterol [(24*R*)-24-methylcholest-5-en-3β-ol]; stigmasterol [(22*E*)-(24*S*)-24-ethylcholesta-5,22-dien-3β-ol]; sitosterol [(24*R*)-24-ethylcholest-5-en-3β-ol]; isofucosterol [(24*Z*)-24-ethylcholesta-5,24(24^1)-dien-3β-ol]; cycloartenol [4,4,14α-trimethyl-9,19-cyclo-5α,19β-cholest-24-en-3β-ol]; obtusifoliol [4α,14α,24-trimethyl-5α-cholesta-8,24(24^1)-dien-3β-ol]; 24-methylenecycloartanol [4,4,14α,24-tetramethyl-9,19-cyclo-5α,19β-cholest-24(24^1)-en-3β-ol]; β-amyrin [olean-12-en-3β-ol]; episterol [24-methyl-5α-cholesta-7,24(24^1)-dien-3β-ol]; 24-methylenelophenol [4α,24-dimethyl-5α-cholesta-7,24(24^1)-dien-3β-ol]; Δ7-avenasterol [(24*Z*)-24-ethyl-5α-cholesta-7,24(24^1)-dien-3β-ol]; and 24-ethylidenelophenol [(24*Z*)-4α-methyl-24-ethylcholesta-7,24(24^1)-dien-3β-ol].

Trivial names of fatty acids have been used as follows: myristic acid, 14:0 (tetradecanoic acid); palmitic acid, 16:0 (hexadecanoic acid); stearic acid, 18:0 (octadecanoic acid); oleic acid, 18:1 (*cis*-9-octadecenoic acid); linoleic acid, 18:2 (*c*9,*c*12-octadecadienoic acid); linolenic acid, 18:3 (*c*9,*c*12, *c*15-octadecatrienoic acid).

RESULTS AND DISCUSSION

Identification of the steryl esters present in a celery cell culture. A typical GC profile of the intact steryl esters isolated from a celery cell suspension culture is shown in Figure 1. Table 1 lists those compounds identified by means of electron ionization (EI) and NICI mass spectrometry and GC elution order, together with the diagnostic mass spectral ions used for compound identification. As observed previously, molecular ions (M^+) were absent from the EI spectra of fatty acyl esters of Δ^5-sterols (27,31,32); hence, NICI mass spectrometry was employed to derive information regarding the nature of the fatty acyl moieties. Under the conditions employed in this study, molecular ions (M^+) of low abundance were detected for 4α,14α-dimethyl- and 4,4,14-trimethylsteryl esters. However, in order to assign all compounds with confidence, the determination of both the EI and NICI mass spectra and also the GC elution order was required. For example, isobaric ions occurring in the EI and NICI mass spectra of obtusifoliyl and cycloartenyl linoleates introduce an ambiguity which was resolved by consideration of the GC elution order of the compounds.

Evershed *et al.* (27) noted a characteristic $[RCO_2-19]^-$ ion in the NICI mass spectra of the steryl palmitates, and again in cholesteryl stearate (30). This ion was also observed in the present study. However, the fragment ion was not apparent in the spectra of the linoleate esters,

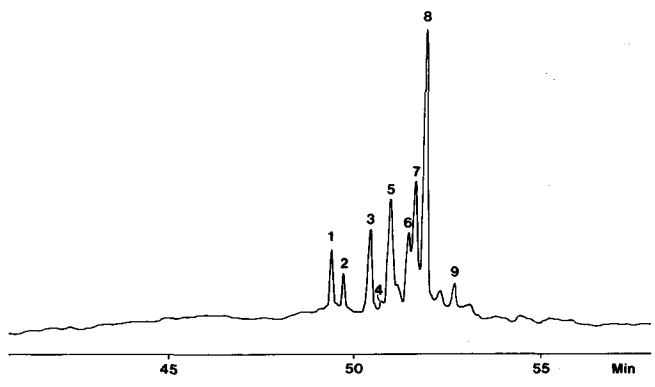

FIG. 1. A GC profile of the intact steryl esters extracted from a celery cell suspension culture. The identifications of the numbered peaks are listed by elution order in Table 1. For GC column and oven programming conditions, see Experimental.

TABLE 1

Identifications of the Intact Steryl Esters Isolated from a Cell Suspension Culture of Celery[a]

Compound	*m/z* (Relative abundance)	
	EI	NICI
β-Amyrin palmitate	189(28),203(50),218(100),393(1),408(1), 649(<1),664(<1)	237(100),236(22),255(17),407(18)
Cycloartenyl palmitate	241(26),286(5),297(11),339(7),365(9), 393(100),408(8),649(11),664(3)	237(100),236(18),255(25),407(11)
Campesteryl linoleate	213(23),255(42),367(35),382(99)	261(100),279(55),381(14)
Stigmasteryl linoleate	83(100),394(56)	261(100),279(15),393(1)
Obtusifoliyl linoleate	215(48),241(26),269(23),309(22),393(100), 409(16),673(27),688(5)	261(100),279(15),407(2)
Sitosteryl linoleate	213(14),255(35),275(36),288(44),381(30), 396(96)	261(100),279(24),395(8)
β-Amyrin linoleate	189(21),203(39),218(100),393(1),408(2)	261(100),279(52),407(4)
Cycloartenyl linoleate	241(11),286(12),297(16),339(26),365(23), 393(62),408(22),673(3),688(1)	261(100),279(15),407(6)
24-Methylenecycloartanyl linoleate	203(74),379(35),407(66),422(30)	261(100),279(9),421(11)

[a]Compounds are listed in the order of GC elution. Diagnostic ions from EI and NICI mass spectra are listed.

which suggests its occurrence is possibly confined to the esters of saturated fatty acids.

Alkaline hydrolysis of the steryl ester mixture revealed other sterol constituents (episterol, 24-methylenelophenol, Δ^7-avenasterol and 24-ethylidenelophenol) which were not apparent from the gas chromatogram (Fig. 1) or the mass spectra of the intact esters, due to their co-elution with, and similar MS behavior to, other compounds. Although the contribution of these four sterols to the total ester pool was relatively small, their presence again highlights the need for a variety of complementary analytical techniques in the analysis of the steryl esters to provide maximum compositional information.

The identification of the intact steryl esters revealed a selectivity of esterification of the various sterols. The free sterols of celery cultures consist almost exclusively of campesterol, stigmasterol, sitosterol and isofucosterol (33), whereas the steryl esters include a large proportion (*ca.* 70%) of esterified precursor sterols, particularly cycloartenyl linoleate. Nagai *et al.* (34) investigated the steryl esters of yeast (in which ergosterol is the major free sterol), and found that they were predominantly of ergosterol precursors, which were not methylated at C-24. In the same study it was shown that, in contrast to the free sterols, the steryl esters were poor substrates for S-adenosyl-L-methionine (SAM)-Δ^{24}-sterol methyltransferase. Hence, it appears that once esterified, the sterols are effectively removed from participating in biosynthetic reactions. The esterification of 4,4-dimethyl sterols at the C-3 position, as observed in the celery steryl esters, renders them unavailable for C-4 demethylation by inhibiting formation of the 3-oxosteroid intermediate. Esterification may therefore operate as a control step in phytosterol biosynthesis (21).

Also notable was the very small amount of esterified stigmasterol (<2%) even though it is the major component of the free sterol pool. Since stigmasterol is the major constituent (up to 44%) throughout the growth of the culture, its virtual absence from the steryl ester fraction implies some significant role for this sterol in cell metabolism. The need for a 24α-ethyl sterol for normal growth and cell division in celery cultures has been established, and stigmasterol was shown to be particularly active in this respect (33,35). It has also been demonstrated (36), using yeast sterol auxotrophs, that structural modifications in the sterol have an effect on membrane permeability and growth, and it was proposed that selective esterification of sterols by the cell would enable it to control the type of sterol available. Although it may appear that the results from the celery cultures agree with this hypothesis, insofar as there is an apparent discrimination against stigmasterol becoming esterified. stigmasterol does, nevertheless, occur as both the steryl glycoside and acylated steryl glycoside in this tissue (Dyas, L., unpublished data).

We have also determined the composition of free and esterified sterols of the roots and shoots of 6-week-old celery seedlings (Table 2). The roots and shoots of seedlings contained less cycloartenyl linoleate in relation to the amounts of campesteryl, stigmasteryl and, especially, sitosteryl linoleates. Although stigmasterol was esterified to both linoleic and palmitic acids in seedlings, it contributes only 4 and 16% to the esters of the shoots and roots, respectively, compared to 41 and 65% in the free sterol fractions, thus still exhibiting a degree of discrimination in the esterification process.

The NICI mass spectra of intact steryl esters from celery cultures, along with the analysis of the fatty acids resulting from their saponification, showed the presence of smaller amounts of other C_{18} fatty acids (18:0, 18:1 and 18:3) in addition to the dominant linoleate (18:2). This fatty acid complement reflected the relative proportions of total fatty acids found in celery cultures. However, a degree of selectivity was again noted; only two compounds, cycloartenol and the pentacyclic triterpene, β-amyrin, were found esterified to palmitic acid (16:0). A similar trend was observed in the celery seedling roots. The major palmitates were those of cycloartenol, obtusifoliol and β-amyrin, in contrast to the domination of

TABLE 2

Amounts (ng/mg dry weight) of Free and Esterified Sterols Isolated from 6-Week-Old Celery Seedling Roots and Shoots[a]

Compound	Root	Shoot
Free sterols		
Campesterol	200 (6.6)	60 (4.2)
Stigmasterol	1980 (65.3)	540 (41.4)
Sitosterol	710 (23.6)	550 (42.2)
Other[b]	140 (4.6)	150 (12.1)
Steryl esters		
Campesteryl palmitate	2 (0.9)	1 (2.8)
Stigmasteryl palmitate	6 (2.9)	nd[c]
Obtusifoliyl palmitate	9 (3.9)	2 (4.7)
β-Amyrin palmitate	4 (1.9)	nd
Sitosteryl palmitate	5 (2.0)	2 (4.3)
Cycloartenyl palmitate	24 (10.8)	1 (3.0)
Campesteryl linoleate	22 (9.8)	4 (7.7)
Stigmasteryl linoleate	28 (12.6)	2 (4.2)
Obtusifoliyl linoleate	11 (4.8)	1 (2.9)
β-Amyrin linoleate	9 (4.0)	nd
Sitosteryl linoleate	58 (25.7)	21 (41.2)
Cycloartenyl linoleate	15 (6.8)	1 (2.9)
Isofucosteryl linoleate	25 (11.0)	11 (22.1)
24-Methylenecycloartanyl linoleate	4 (1.9)	2 (4.3)

the linoleates by the typical Δ^5-phytosterols. Cycloartenol and β-amyrin are the initial products of 2,3-oxidosqualene cyclization, and their selective esterification to palmitic acid may prove significant when considering certain features of steryl ester biochemistry, such as the interrelationship of the sites of 2,3-oxidosqualene cyclization and sterol esterification, and the nature of the acyl donor.

Changes in abundance and composition of the steryl esters during growth. Celery cell suspension cultures exhibit a typical sigmoidal growth curve (33). Hence, cultures harvested at days 2, 7, 12 and 16 represent lag, log and early and late stationary phases of growth, respectively. Tables 3 and 4 list the amounts of free and esterified sterols extracted from each of these cultures.

At all growth stages of the cell culture, the amount of steryl esters considerably exceeded that of free sterols. In the majority of studies on plants, steryl esters rarely constitute the major sterol form, even when they appear to be metabolically significant, *e.g.* exhibiting a twelve-fold increase during the ripening of tomatoes (25). In this respect, the predominance of steryl esters in celery cultures is unusual. Whether this phenomenon is a feature of plant cell suspension cultures, or is restricted to that of celery, is unknown. However, in the celery seedlings the ratio of free-to-esterified sterols (FS/SE) is 27:1 in shoots and 14:1 in roots. Parks and co-workers (36–38) have extensively studied the esterification of sterols in yeast, and although they found that the steryl esters constituted up to 90% of total sterols during stationary phase, during logarithmic growth this figure was less than 10%. They have suggested that the conversion of free sterols to steryl esters is a result of the cessation of cell division, and excess sterols become esterified. The results obtained for the celery cultures do not, however, reveal sterol esterification following a similar pattern.

The FS/SE ratio in the celery cultures increased slightly from day 2 to day 7 (0.35:1 and 0.44:1, respectively), and more markedly to day 12 (0.60:1). The initial rise in the FS/SE ratio was due to an increase in concentration of total sterols at day 7 rather than to a decrease in the total steryl esters, which remained constant. It has been suggested that the steryl esters may serve as a storage form of sterol, which may be hydrolyzed to provide the free form in times of need, for example, prior to full development of sterol biosynthetic enzyme activity in germinating seeds (15,16,24), or when sterol biosynthesis is inhibited (39,40). This function is not apparent in this study during the growth cycle.

The amount of steryl esters in the cultures remained constant during the initial growth period, but by the

beginning of the stationary phase (12 days) they showed a marked decrease. This change in the amount of total steryl esters was due almost entirely to a decline in the amounts of the esterified precursor sterols cycloartenol (as palmitate and linoleate) and 24-methylenecycloartanol (as linoleate). It seems unlikely that the cell is hydrolyzing the cyclopropylsteryl esters to provide their free counterpart for conversion to Δ^5-sterols, because if the cell requires the latter it would apparently be more efficient to hydrolyze the appropriate Δ^5-steryl esters than undertake several biosynthetic steps from the precursors. Moreover, the culture is approaching stationary phase where growth and division is slowing down and the demand for sterols is presumably diminished.

At late stationary phase (16 days), there was an equally marked increase in the amount of total steryl esters, accounted for by both a recovery of those precursor sterols which had declined at day 12, plus augmented amounts of the other steryl esters. The amounts of campesteryl and sitosteryl linoleates remained constant throughout the growth period and increased only at this late stage, whereas stigmasteryl linoleate was not detected during logarithmic growth but became apparent at stationary phase. The elevated amounts of esters of the pentacyclic triterpene β-amyrin were particularly noticeable in the 16-day-old cultures. β-Amyrin, like cycloartenol, is formed by the cyclization of 2,3-oxidosqualene, and it has been observed (41) that in pea seeds, the cyclization into cycloartenol or β-amyrin occurs at different times during the germination and seedling development, possibly depending on the relative rates of synthesis and degradation of the respective cyclase enzymes. The relative increase of β-amyrin in the free fraction at stationary phase accompanied by a decrease in precursor sterols (cycloartenol, 24-methylenelophenol, isofucosterol) implies that the rate of sterol biosynthesis has declined at this point. The pattern of esterification at this time is thus similar to that seen in yeast (36). It seems likely therefore, that the esterified 4-desmethylsterols and precursor sterols have different roles to play in plant metabolism.

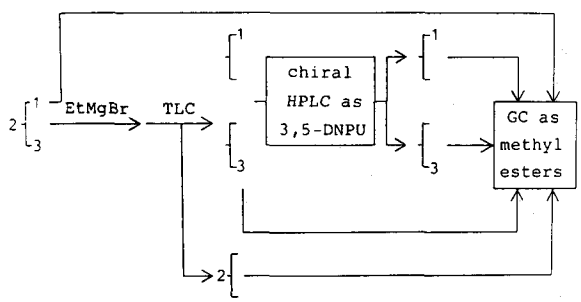
METHODS

Stereospecific Analysis of Triacyl-*sn*-glycerols by Chiral High-Performance Liquid Chromatography

Toru Takagi* and **Yasuhiro Ando**
Department of Chemistry, Faculty of Fisheries, Hokkaido University, Minato-cho, Hakodate, Japan 041

A method for the stereospecific analysis of triacyl-*sn*-glycerols by high-performance liquid chromatography (HPLC) on a chiral column is described. Triacyl-*sn*-glycerols were partially degraded with ethyl magnesium bromide, and the monoacylglycerols produced were separated as 1- and 2-monoacylglycerol fractions by thin-layer chromatography on boric acid-impregnated silica gel plates. The 1-monoacylglycerols were resolved into *sn*-1 and *sn*-3 monoacylglycerol fractions by HPLC on a chiral column (Sumichiral OA-4100) after derivatization with 3,5-dinitrophenyl isocyanate. Fatty acid methyl esters obtained from the original triacyl-*sn*-glycerols, 1- and 2-monoacylglycerol fractions, and *sn*-1 and *sn*-3 monoacylglycerol fractions were analyzed by gas chromatography on open-tubular columns. Stereospecific acyl distributions in triacyl-*sn*-glycerols were calculated from the data. The acyl distributions of several oils were obtained. The method is rapid, simple and gave reproducible results. *Lipids 26,* **542–547 (1991).**

The first stereospecific analysis of triacyl-*sn*-glycerols was reported by Brockerhoff in 1965 (1). The method involved the stereospecific cleavage with phospholipase A_2 to distinguish between the *sn*-1 and *sn*-3 positions in a triacyl-*sn*-glycerol molecule. Later, Lands and co-workers (2), Brockerhoff (3), Myher and Kuksis (4) and Christie and Moore (5) presented improved procedures for the stereospecific analysis of triacyl-*sn*-glycerols. The methods were enzymatic and involved the stereospecific lipolysis or esterification of diacylglycerols or their derivatives to discriminate between the chiralities (6,7).



The present paper presents a novel method for the stereospecific analysis of acyl distributions in triacyl-*sn*-glycerols. In this analytical approach, high-performance liquid chromatography (HPLC) of monoacylglycerol enantiomers on a chiral stationary phase is employed instead of stereospecific enzyme reactions. We previously introduced part of the methodology (8). Triacyl-*sn*-glycerols were partially hydrolyzed by ethyl magnesium bromide, and the 1-monoacylglycerol products were resolved into *sn*-1 and *sn*-3 enantiomers by HPLC as 3,5-dinitrophenylurethanes (3,5-DNPU) on a chiral column (Sumipax OA-2100, Sumitomo Chemical Co., Osaka, Japan). Stereospecific distributions of acyl groups were calculated from area percentages of the enantiomer peak. On the other hand, Laakso and Christie (9) reported the chromatographic resolution of diastereomeric 1,2-diacylglycerol derivatives prepared with a chiral reagent on a column of silica gel for the stereospecific analysis of triacyl-*sn*-glycerols. Fatty acid residues of the *sn*-1,2- and the *sn*-2,3-diacylglycerol derivatives were converted to methyl esters, and then analyzed by gas chromatography (GC). The acyl compositions at *sn*-1, *sn*-2, and *sn*-3 positions were then calculated.

We recently improved the resolution of the monoacylglycerol enantiomers by modification of the HPLC method (10). The method permits the clear separations of a 1-monoacylglycerol mixture into *sn*-1 and *sn*-3 monoacylglycerols. In the present study, this modified HPLC method was applied to the stereospecific analysis of triacyl-*sn*-glycerols. The 1-monoacylglycerol products from the partial hydrolysis of natural triacyl-*sn*-glycerols were resolved into *sn*-1 and *sn*-3 monoacylglycerol fractions by a modified HPLC method, and the methyl esters prepared from the *sn*-1 and *sn*-3 fractions were analyzed by GC. The distribution of acyl groups between the *sn*-1, *sn*-2 and *sn*-3 positions was calculated based on the results of GC analyses.

MATERIALS AND METHODS

*Triacyl-*sn*-glycerols.* Yew *(Taxus cuspidata)* seeds were collected at Hakodate, Japan. High erucic acid rapeseeds were obtained from Yonezawa Seiyu Co. (Saitama-ken, Japan). Hawaiian macadamia nuts and soybean oil were purchased at Hakodate. Rapeseed and macadamia nut oils were prepared from seeds or nuts by crushing and diethyl ether extraction. Yew seeds and flesh meats of herrings were extracted by the method of Bligh and Dyer (11). Triacyl-*sn*-glycerol samples were purified by TLC on Kiesel Gel 60G plates (Merck, Darmstadt, Germany) with n-hexane/diethyl ether (4:1, v/v) for development. 1,3-Dipalmitoyl-2-linolenoylglycerol was prepared from 1,3-dipalmitoylglycerol by esterification of the secondary hydroxy group with linolenoyl chloride. 1,3-Dioleoyl-2-stearoylglycerol was obtained from Sigma Chemical Co. (St. Louis, MO).

*Partial hydrolysis of triacyl-*sn*-glycerols.* The procedures for the analysis of triacyl-*sn*-glycerols are outlined in Scheme 1. The first step is the partial hydrolysis of triacylglycerol with ethyl magnesium bromide by a modified Brockerhoff procedures (5,6). Triacyl-*sn*-glycerols (100 mg) were dissolved in 3 mL of dry diethyl ether, and ethyl magnesium bromide in dry diethyl ether (0.33 mL of 3 M solution) was added. The mixture was shaken for 1 min, and then 0.1 mL glacial acetic acid followed by

Abbreviations: 3,5-DNPU, 3,5-dinitrophenylurethane; GC, gas chromatography; HPLC, high-performance liquid chromatography; TLC, thin-layer chromatography.

water (3.3 mL) was added to stop the reaction. The products were extracted with diethyl ether. The ether extract was washed five times with 2% aqueous sodium bicarbonate, then washed with water, and dried over anhydrous sodium sulfate. After removal of the solvent at ambient temperature, the 1- and 2-monoacylglycerol fractions were separated by preparative TLC on boric acid-impregnated silica gel plates (20 × 20 cm, 0.5 mm thickness, boric acid 10% to Kiesel Gel 60G) developed in chloroform/methanol (98:2, v/v) under nitrogen.

Enantiomer separation of 1-monoacylglycerols by HPLC. The 1-monoacylglycerol fractions (1–3 mg) were dissolved in dry toluene (500 μL) and were reacted overnight at ambient temperature with 3,5-dinitrophenyl isocyanate (10–20 mg) in the presence of dry pyridine (50 μL). The chloroform solution of the products was spotted on a Kiesel Gel 60G plate and developed with n-hexane/1,2-dichloroethane/ethanol (40:15:6, v/v/v) under nitrogen. HPLC separations of the 1-monoacylglycerol 3,5-DNPU fractions were carried out using a Shimadzu LC-6A isocratic pump (Kyoto, Japan) with a SPD-1 ultraviolet spectrophotometric detector and a C-R3A integrator from the same company. For optimum resolution, a chiral column (25 or 50 cm × 4 mm i.d.) packed with 5 μm particles of N-(*R*)-1-(α-naphthyl)ethylaminocarbonyl-(*S*)-valine chemically-bonded to γ-aminopropyl silanized silica, Sumichiral OA-4100 (Sumitomo Chemical Co.) was used. The HPLC separation was done isocratically using a mixture of n-hexane/1,2-dichloroethane/ethanol (40:12:3, v/v/v) as mobile phase at a constant flow rate. The 1-monoacylglycerol 3,5-DNPU sample was dissolved in the minimum volume of chloroform for injection. Detection was at 254 nm.

GC analysis of methyl esters. Total triacyl-*sn*-glycerols, 1- and 2-monoacylglycerols (1–2 mg), and the 3,5-DNPU derivatives of *sn*-1 and *sn*-3 monoacylglycerols (0.1–0.3 mg) were placed into 10 mL centrifuge tubes. Two mL of diethyl ether and 1 M sodium methoxide/methanol solution (25 μL) were added. The content was gently shaken for 5 min before glacial acetic acid (6 μL) was added to stop the reaction. After removing the precipitate by centrifuging for 2 min at 2000 rpm, and evaporating the solvent, the products were extracted with n-hexane and injected onto a WCOT column (50 m × 0.25 mm i.d., 0.2 μm film thickness) coated with Silar 5CP in a Shimadzu GC-6AM instrument with a FID detector and a Shimadzu C-R6A integrator. The column temperature was 190°C, and the injector and detector temperatures were 230°C. Hydrogen was the carrier gas.

RESULTS AND DISCUSSION

HPLC resolution of 1-monoacylglycerols. Enantiomer separations of 1-monoacylglycerol homologue mixtures of 3,5-DNPU derivatives by HPLC on a chiral stationary phase are accompanied by peak separations according to the number of carbon atoms and olefinic bonds of the components because of the polar nature of the chiral stationary phase (8,10). In our previous paper (10), conditions for the resolution of enantiomers were reported that allow the separation of *sn*-1 and *sn*-3 groups of peaks. This was achieved mainly by using Sumichiral OA-4100 columns instead of the OA-2100, and by using less 1,2-dichloroethane in the eluent, *i.e.*, a n-hexane/1,2-dichloroethane/ethanol mixture (10). In the present study, 1-monoacylglycerol mixtures were obtained from triacyl-*sn*-glycerols of natural fats by partial hydrolysis with ethyl magnesium bromide. The 1-monoacylglycerol mixtures were separated into *sn*-1 and *sn*-3 enantiomer groups by HPLC on the OA-4100 column. The 1-monoacylglycerols derived from vegetable oils containing palmitic, stearic, oleic, linoleic and linolenic acids were separated into *sn*-1 and *sn*-3 enantiomer groups by HPLC using a 25 cm column and n-hexane/1,2-dichloroethane/ethanol (40:12:3, v/v/v) as mobile phase at ambient temperature. Figure 1 shows the HPLC resolution of the 1-monoacylglycerols prepared from soybean oil triacyl-*sn*-glycerols. Complete resolution of racemates into enantiomer groups was achieved for the 1-monoacylglycerol derivatives from soybean oil, macadamia nut oil, and yew seed oil triacyl-*sn*-glycerols even when using micro-preparative HPLC. The time required for the separation was less than 30 min. The sample amounts were about 2 and 200 μg per injection in analytical and micro-preparative HPLC, respectively. The 1-monoacylglycerols from high erucic acid-rapeseed triacylglycerols required the 50 cm column for the clear separation of the enantiomers under similar conditions.

HPLC of fish oil 1-monoacylglycerols. In HPLC of 1-monoacylglycerols on an OA-4100 chiral column, the components eluted in the order of decreasing acyl chain-length, while a double bond in the acyl chain lengthened the retention time by the equivalent of about 2 carbon atoms (10). Thus, the retention time of an *sn*-1 18:3 monoacylglycerol derivative was similar to that of an *sn*-1 12:0 monoacylglycerol. These were the last components to emerge in HPLC of the 1-monoacylglycerol derivatives from plant oils reprsenting the *sn*-1 group. By the modified HPLC method (10), it was possible to separate these components from the first eluting components representing the *sn*-3 group, namely the *sn*-3 20:0 and 22:1 monoacylglycerol derivatives. However, when fish oils were used, complete separation of enantiomeric groups was more difficult. The first peak in the *sn*-3 group, *i.e.*, 22:1 or 24:1 monoacylglycerol derivatives, and the last peak in the *sn*-1 group, *i.e.*, 16:4 or 22:6 monoacylglycerol derivatives, overlapped on the OA-4100 column at ambient

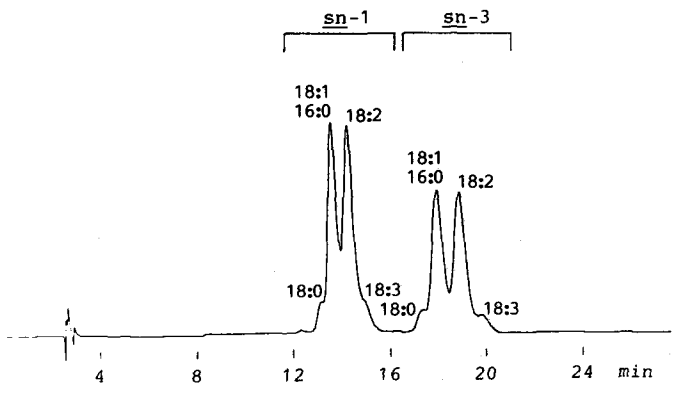

FIG. 1. Separation of 1-monoacylglycerols, formed by partial hydrolysis of soybean oil triacyl-*sn*-glycerols with ethyl magnesium bromide, as their 3,5-DNPU derivatives on a chiral column, OA-4100 (25 cm × 4 mm i.d.). Mobile phase, n-hexane/1,2-dichloroethane/ethanol (40:12:3, v/v/v). Flow rate, 1.0 mL/min; temperature, ambient; detection, 254 nm UV.

temperature. We observed that lowering the column temperature brought about a considerable improvement in enantiomer separation. Figure 2 shows a chromatogram obtained at −9°C using 50 cm column. The separation factor for the enantiomer resolution increased from about 1.4 to about 1.8 by lowering the column temperature from 20°C to −9°C. The time required for the separation of *sn*-1 and *sn*-3 monoacylglycerols from fish oils was about 200 min.

Differential losses in the conversions. Selective loss of monoacylglycerols in the preparation of 3,5-DNPU derivatives and methyl esters causes errors. To determine selective losses in the conversions, unsaturated 1-monoacylglycerols (A) were converted to 3,5-DNPU derivatives (B), and then to methyl esters (C) by the method described previously. In the present study, the following three samples were used (as A) in mixture with 1-stearoylglycerol: 1-oleoyl-, 1-linoleoyl- and 1-linolenoylglycerols (I); 1-arachidonoyl- and 1-eicosapentaenoylglycerols (II); and 1-docosahexaenoylglycerol (III). In each case, the results of HPLC of B and of GC of C were compared with the result of GC of the methyl esters obtained from A (Table 1). HPLC analysis of the 1-monoacylglycerol 3,5-DNPU was done as described in the previous paper (10). The results showed, in general, increasing losses as the unsaturation of the acyl groups increased. The apparent losses of methyl esters of unsaturated fatty acids could have been due to the short methylation time. 3,5-DNPU derivatives prepared from sample I were therefore converted to fatty acid methyl esters by transesterification in 1% sulfuric acid/methanol at 50°C overnight in a stoppered centrifuge tube. However, the fatty acid composition obtained by the latter method was close to that obtained by base-catalyzed transesterification as employed here.

Acyl compositions in sn-*1,* sn-*2 and* sn-*3 positions.* The composition (mole %) of the acyl group in each of the three positions was obtained by the following calculations using the procedure outlined in Scheme 1. The mean composition of each acyl group in the *sn*-1 and *sn*-3 positions [*sn*-1(3) position] was calculated from the GC analysis of

[c] Analyzed by GC using the present procedure.

the original triacylglycerols and those of the 1- and 2-monoacylglycerols isolated by boric acid-impregnated silica gel TLC, *i.e.,* for each component:

$$sn\text{-}1(3)\ \text{position (mole \%)} = 3 \times \text{TG} \times [\text{1-MG}/(2 \times \text{1-MG} + \text{2-MG})]$$

where TG, 1-MG and 2-MG represent the proportions (mole %) of each acyl group in the original triacylglycerols, 1-monoacylglycerols and 2-monoacylglycerols, respectively. The composition of each acyl group in the *sn*-2 position was calculated in a similar manner as above, *i.e.*:

$$sn\text{-}2\ \text{position (mole \%)} = 3 \times \text{TG} \times [\text{2-MG}/(2 \times \text{1-MG} + \text{2-MG})]$$

The amount of each acyl group in the *sn*-1 and *sn*-3 positions was calculated from the concentration of each component in the *sn*-1(3) position and GC analyses of *sn*-1 and *sn*-3 monoacylglycerols resolved by HPLC on the chiral column, *i.e.*:

$$sn\text{-}1\ \text{position (mole \%)} = 2 \times sn\text{-}1(3)\ \text{position} \times [sn\text{-}1/(sn\text{-}1 + sn\text{-}3)]$$

$$sn\text{-}3\ \text{position (mole \%)} = 2 \times sn\text{-}1(3)\ \text{position} \times [sn\text{-}3/(sn\text{-}1 + sn\text{-}3)]$$

where *sn*-1 and *sn*-3 represent the proportions (mole %) of each acyl group in *sn*-1 and *sn*-3 monoacylglycerols analyzed by GC as methyl esters, respectively. These calculations avoid cumulative errors in the result for a particular position, and give reproducible and reliable results. In contrast, direct analysis of methyl esters from *sn*-1, *sn*-2 and *sn*-3 monoacylglycerols can involve considerable experimental errors. The composition of the acyl group in each of the three positions could also be obtained based on the following relationships:

$$sn\text{-}1\ \text{position} = 3 \times \text{TG} - \text{2-MG} - sn\text{-}3$$

$$sn\text{-}2\ \text{position} = 3 \times \text{TG} - sn\text{-}1 - sn\text{-}3$$

$$sn\text{-}3\ \text{position} = 3 \times \text{TG} - sn\text{-}1 - \text{2-MG}$$

However, this approach is not recommended, since the result for each position is subject to the cumulative experimental error of the other analyses.

[c] ND, not detected.

Reproducibility of the stereospecific analysis. The reproducibility of the analytical method was checked for soybean oil triacyl-*sn*-glycerols. Table 2 shows the results. The stereospecific analyses carried out by four different persons showed good agreement. Another soybean oil triacyl-*sn*-glycerol sample was analyzed by the present method and by the Brockerhoff method as modified by Christie (6). The results are compared in Table 3. The positional distributions obtained differed little from each other.

Acyl migration in the course of analysis. Monoacylglycerols generally isomerize more rapidly than do diacylglycerols due to acyl migration. Isomerization affects the accuracy of a method. The accuracy of our method was determined by the stereospecific analysis of racemic synthetic triacyl-*sn*-glycerols (Table 4). The results showed that the *sn*-1 and *sn*-3 positions can be contaminated with 2.5–3.0% of acyl groups which have migrated from the *sn*-2 position. This would indicate that the error in the relative proportions at the *sn*-1 and *sn*-3 positions could be about 1%, when the acyl group in *sn*-2 position is 30% of the total. On the other hand, the *sn*-2 position contained 4–6% of acyl groups that migrated from the *sn*-1 and *sn*-3 positions (Table 4). However, the total acyl compositions suggest that the 1,3-dioleoyl-2-stearoylglycerol and 1,3-dipalmitoyl-2-linolenoylglycerol samples contained 1.5% 18:1 acyl and 5.1% 16:0 acyl in the *sn*-2 position, respectively. Thus, the *sn*-2 position can be contaminated with up to 3.0% of acyl groups which have migrated from the primary positions. These results demonstrate the relatively low rate of isomerization of monoacylglycerols, as compared to what has been reported for diacylglycerols

(5,12). For example, 1,3-diacylglycerols prepared by reaction with ethyl magnesium bromide contained 7–10% (or more) of acyl groups that had migrated from the *sn*-2 position (5,12). The *sn*-2 position of 1,2-diacylglycerols was contaminated with 4% of acyl groups that had migrated from the *sn*-1 and *sn*-3 positions (5,12).

The stereospecific analysis of the natural triacyl-*sn*-glycerols also supports the conclusion that acyl migration is minimal in the present method. Triacyl-*sn*-glycerols from macadaqmia nut oil, yew seed oil, high erucic acid rapeseed oil and herring oil were subjected to stereospecific analysis (Tables 5–8). Fatty acid compositions of macadamia nut and yew seed oils have been reported previously (13,14). Macadamia nut oil triacyl-*sn*-glycerols showed 20:1n-9 acyl groups at an abundance of 5.2% in the *sn*-3 position and of 1.0% in the *sn*-1 position, but these groups were not detected in the *sn*-2 position (Table 5). Yew seed oil triacyl-*sn*-glycerols showed all-*cis*-5,9,12-18:3 and 5,11,14-20:3 acyl groups at concentrations of 8.1 and 4.7%, respectively, in the *sn*-3 position, but these acyl groups were essentially absent in the other positions (Table 6). The rapeseed oil triacyl-*sn*-glycerols showed the 22:1n-9 acyl group at concentrations of 61.3% and 50.2% in the *sn*-3 and the *sn*-1 positions, respectively, but 22:1n-9 was only 0.8% abundant in *sn*-2 position (Table 7). Herring oil triacyl-*sn*-glycerols showed the 22:6n-3 acyl group at concentrations of 14.9% in the *sn*-2 position and of

2.19% in the *sn*-1 position, but 22:6n-3 was not detected in the *sn*-3 position (Table 8). Such specificity in measured positional distribution indicates the low degree of isomerization of monoacylglycerols in the procedures of stereospecific analysis employed here.

Selectivity of acyl distributions. As a general rule, seed oils containing common fatty acids show a selective placement of unsaturated fatty acids at the *sn*-2 position, while long-chain or anomalous fatty acids are selectively enriched in the *sn*-3 position (7). Table 5 shows that the 18:1n-9 group was enriched (*ca.* 71%) at the *sn*-2 position, but that 18:1n-7 was more abundant at the *sn*-1 and *sn*-3 positions. This shows that the position of the olefinic bond

is an important factor in governing acyl distributions as is the number of carbon atoms and the number of double bonds. Table 6 shows that anomalous 5-olefinic acyl groups were selectively concentrated in the *sn*-3 position as predicted (7). Their accumulation at the *sn*-3 position, in turn, resulted in a lower relative proportion of 18:1n-9 at this position. Table 7 shows the positional distributions of 18 different acyl groups in rapeseed oil triacyl-*sn*-glycerols. The characteristic distribution patterns of seven components of acyl groups in triacyl-*sn*-glycerols from seeds of nine Cruciferae, as determined by Brockerhoff's method, were reported previously (15). The data presented in Table 7 are in generally good agreement with these in as much as 18:1n-9 was enriched at the *sn*-2 position, whereas 18:1n-7 was more abundant in the *sn*-1 position. Table 8 shows the distributions of 34 acyl groups of herring oil triacyl-*sn*-glycerols. The distributions of 11 acyl groups in herring oil had previously been reported by Brockerhoff *et al.* (16). The 11 most abundant components (16) amount to about 80% of acyl groups listed in Table 8. The method presented here is especially useful for the analysis of the complex acyl group compositions of the triacyl-*sn*-glycerols of marine lipids.

Comparison with the Brockerhoff method. In the Brockerhoff method the composition at the *sn*-3 position is not determined directly. So errors can occur particularly for minor components at the *sn*-3 position, and sometimes small negative values may be obtained. Another drawback can be the preferential hyrdolysis of certain acyl groups by phospholipase A_2, which affects the data for the *sn*-2 position. The most common source of phospholipase A_2 for structural studies are snake venoms. King cobra, *Ophiophagus hannah,* venom is preferred because it had been shown not to preferentially hydrolyze 16:0, 18:0, 18:1, 18:2 and 20:0 from lecithins (17). It has therefore been used for the stereochemical analysis of triacylglycerols.

However, triacyl-*sn*-glycerols from natural sources contain a great variety of acyl groups, and there is at present insufficient evidence for the nonpreferential hydrolysis of all types of acyl groups.

The method presented here permits the stereospecific analysis of triacyl-*sn*-glycerols. The procedures used are simple and rapid, and permit measurement of distributions even of minor components when high resolution capillary GC is employed.

Evidence of Extensive Phospholipid Fatty Acid Methylation During the Assumed Selective Methylation of Plasma Free Fatty Acids by Diazomethane

Chu Lin, Edward W. Blank, Roberto L. Ceriani and Nome Baker*
John Muir Cancer and Aging Research Institute, Walnut Creek, California 94596

We compared a conventional method (Method I) for measuring plasma free fatty acid (FFA) concentrations with two more rapid procedures (Method II and Method III). Method I required total lipid extraction, separation of FFA by thin-layer chromatography, methylation, and gas-liquid chromatographic analysis of the fatty acid (FA) methyl esters. Method II was a colorimetric procedure. Method III relied upon diazomethane's presumed ability to selectively methylate FFA even in the presence of FA esters. The three methods were compared using plasma from fasted and from fed nude mice, tumor-bearing mice (MX-1 and ZR-75-1 human mammary carcinomas), and controls. Method II, was less reliable than Method I, but both gave similar mean values for plasma FFA levels in fasted mice. Both Methods I and II also showed similar lowering of plasma FFA levels after feeding previously fasted mice. Method III consistently gave values that were far greater than those obtained using Methods I and II. Moreover, highly significant differences between fasted and fed mice were obscured by direct methylation of plasma FFA with diazomethane (Method III). The excess FA methyl esters formed in Method III were derived from plasma phospholipids, but not from plasma triacylglycerols. After feeding fasted mice, plasma free palmitic acid and oleic acid levels fell (Method I); by contrast, the excess "FFA" formed by methylation of plasma phospholipid FA increased two-fold and fourteen-fold, respectively. Caution is therefore advised in the use of direct methylating agents when measuring total and individual plasma FFA levels.
***Lipids 26,* 548–552 (1991).**

Before initiating a study of essential free fatty acid (FFA) transport to tumor cells in relation to tumor growth rates *in vivo*, we evaluated several methods for measuring plasma FFA concentrations. One was a colorimetric method (1) which we used earlier (2,3). The other two methods were based upon the analysis of fatty acid methyl esters (FAME) by gas-liquid chromatography (GLC). One of these methods is simple and rapid; it is based on the direct and supposedly selective methylation of FFA with diazomethane, which is added directly to the plasma (4). The other method, taken as the primary standard method, requires prior extraction of total plasma lipids, followed by separation of the FFA fraction by thin-layer chromatography (TLC) and methylation of FFA to form free fatty acid methyl esters (FFAME). Each method was tested under conditions that can be expected to perturb the FFA pool size, namely, fasting and feeding of control and tumor-bearing (TB) mice.

Using the colorimetric method (1) we could demonstrate a rapid decrease in plasma FFA levels induced by a fat-free meal in both control and TB mice, as reported for other strains of TB and control mice (5). However, the colorimetric method was less reliable than the standard reference (TLC/GLC) method, especially at low plasma FFA levels. We were unable to corroborate the earlier observation (4) that plasma FFA can be specifically methylated by diazomethane in the presence of other plasma lipids. We found that such direct methylation consistently resulted in artificially high plasma FFA levels. The artifacts in some cases were an order of magnitude greater than the results obtained by the "standard" technique. The artificial increment was shown to be due to the methylation of several classes of phospholipid fatty acids (PLFA), but not of triacylglycerol fatty acids (TGFA). The composition of the artificially formed FAME was highly dependent upon the nutritional state of the animals and was qualitatively different from the changes in plasma FFA composition following fasting and feeding.

METHODS

Animals. Female BALB/c (nu/nu) mice (7–8 wk old) was obtained from Simonson (Gilroy, CA). They were housed in autoclaved cages with filter tops and bedding in a temperature-controlled room with a 12-hr light (daytime) and 12-hr dark cycle.

Tumor. The estrogen receptor negative transplantable human breast carcinoma, MX-1, derived from a primary breast tumor, was obtained originally from the EG & G Mason Research Institute (Worchester, MA) and, since 1983, was transplanted serially in nude mice in our laboratory. Under sterile conditions, nude mice were injected subcutaneously with 35 mm^3 pieces of MX-1 tumor suspended in cell culture medium, proximal to the right #4 mammary gland using a 16-gauge needle. Human breast carcinoma cell line ZR-75-1 was grown in Dulbecco Modified Eagle's (DME) plus RPMI 1640 media (1:1, v/v; Gibco, Grand Island, NY), 5% fetal bovine serum, and 200 ng/mL of bovine insulin. ZR-75-1 was obtained from the ascites effusion of a 63-yr-old woman with an infiltrating ductal carcinoma. The ZR-75-1 tumor line was initiated by injecting one-half of the confluent cells grown

Abbreviations: BHT, 3,5-di-*t*-butyl-4-hydroxytoluene; DME, Dulbecco modified Eagle's medium; EDTA, ethylenediaminetetraacetic acid; FAME, fatty acid methyl esters; FFA, free fatty acids; FFAME, free fatty acid methyl esters; GLC, gas-liquid chromatography; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; PL, phospholipid(s); PLFA, phospholipid fatty acids; PS, phosphatidylserine; TB, tumor-bearing; TG, triacylglycerol; TLC, thin-layer chromatography; TGFA, triacylglycerol fatty acids.

in a T-175 flask into the mid flank of an estrogen-primed nude mouse. Once the ZR-75-1 tumor was established it was serially passaged.

Diets. The mice were fed sterile, Purina laboratory chow (5068) from weaning until they were fasted for 24 hr. Animals that were fed for 20 hr following the fasting period were given fat-free pellets that contained (by weight) 64.75% sucrose, 24.0% vitamin-free casein, 3.75% salt mixture (AIN #76), 2.2% vitamin fortification mixture (ICN Nutritional Biochemicals, Cleveland, OH), 0.3% methionine, 5.0% cellulose, and 0.01% BHT (3,5-di-*t*-butyl-4-hydroxytoluene).

Experimental protocol. Six chow-fed animals (2 control, 2 bearing MX-1 tumors, and 2 bearing ZR-75-1 tumors) were fasted for 24 hr and were then fed the special fat-free diet for 20 hr. The mice were sacrificed along with another six 24-hr fasted animals (2 each of the corresponding C and TB groups). Retroorbital blood or blood following decapitation, both under ether anesthesia, was collected in tubes containing solid ethylenediaminetetraacetic acid (EDTA).

FFA analyses/Method I. Method I was taken to be the standard reference (TLC/GLC) method. Five μg of heptadecanoic acid in 0.05 mL of methanol were added to 0.1 mL of plasma. Total lipids were extracted according to Bligh and Dyer (6). The chloroform phase was concentrated and spotted on channels of a Whatman LK6D plate (Hillsboro, OR) and developed with the solvent system petroleum hydrocarbon/diethyl ether/acetic acid (80:20:1, v/v/v). A spray of 0.1% 2,7-dichlorofluorescein in ethanol was used to locate the FFA standard. A razor blade was used to scrape off the corresponding unsprayed FFA zone from the TLC plate. The scraped silica gel was stored in a 13 × 100 mm disposable glass tube with a Teflon cap. One mL ethereal diazomethane solution (4) was added to the tube, and methylation at room temperature was continued for about 10 min. A small desk-top centrifuge was used to centrifuge the reaction mixture. After removal of the supernatant, one mL of diethyl ether was added to wash the silica gel residue. The tubes were centrifuged again, and the ethereal supernatants were removed and added to the first extract. The ether extracts were evaporated to dryness under nitrogen. One-half mL each of hexane, water and methanol was added immediately to each tube. After vortexing and centrifuging, 0.4 mL of the hexane phase was transferred into a Wheaton (Millville, NJ) 2-mL glass sampling vial with cap. The hexane phase was then evaporated to dryness under nitrogen. Fifteen μL of hexane was added to the vial to dissolve the methyl esters. GLC analyses were carried out using 5 μL of this hexane solution.

FFA analyses/Method II. Method II was the colorimetric procedure of Hron and Menahan (1). Various concentrations of heptadecanoic acid were used to establish a standard curve. Chloroform/methanol (2:1, v/v) was used to wash all glass tubes prior to analyses in order to minimize blank values.

FFA analyses/Method III. Method III was the method of Pace-Asciak (4). Plasma FFA methylation was carried out with diazomethane in diethyl ether, which was added directly to plasma as described (4), except that heptadecanoic acid was used as internal standard. Diazide purchased from Aldrich (Milwaukee, WI) was used to prepare diazomethane by a method similar to that of Pace-Asciak (4), according to the instructions supplied by Aldrich. The following minor modifications were made in our later experiments in order to facilitate concentration of the FA methyl esters into convenient volumes and to insure dryness of the sample used for GLC analysis. After 800 μL of the ethereal reaction solution was evaporated to dryneses under nitrogen, two hundred μL each of methanol, water, and hexane were added to the tube. Samples were vortexed and quickly centrifuged, and the hexane phase was carefully transferred to a sampling vial. The hexane fraction was concentrated to dryness with nitrogen gas and reconstituted into a small volume for GLC injection.

Methylation of phospholipid. Phospholipid standards were purchased from Sigma Chemical Company (St. Louis, MO) and were purified by TLC using Whatman LK6D plates developed with choloroform/methanol/triethylamine/isopropanol/0.25 M KCl (30:9:18:25:6, by vol). Free fatty acids migrated almost to the solvent front. Phospholipids were detected by spraying the developed, air-dried plates with rhodamine B in ethanol. Methanol was used to elute the purified phospholipids from the silica gel. Methanol/acetyl chloride (50:1, v/v) (7), as well as diazomethane (4), were then used to determine the extent to which each phospholipid class would be transmethylated.

Instrumentation. Fatty acid analyses were performed on a Perkin-Elmer 8420 capillary gas chromatograph (Norwalk, CT) equipped with a flame-ionization detector (260°) and a 30-m Stabil wax column with a 0.32-mm internal diameter (Restek Corporation, Bellefonte, PA). The injector temperature was 260°. The initial temperature was set at 170° C and programmed at a rate of 3° C per min to a final temperature of 240° C and then held for 3 min. The total run time was 26.3 min. An electronic pressure readout of 14 psi was used for controlling the flow rate of helium as carrier gas. A split ratio of 10:1 was used for analysis. FAME retention times were determined by using a 68A methyl ester standard (Nu-Chek Prep, Elysian, MN). The weight percent response factor was the same for all 19 FAME standards analyzed under the conditions employed. A Perkin-Elmer data handling system set in the internal standard mode was used to calculate the results.

RESULTS

In Table 1 we compare the plasma FFA levels in 24-hr fasted control and TB mice measured by three different methods: Method I) the standard reference method (TLC/GLC of FFA methyl esters); Method II) The Hron and Menahan colorimetric method (1); and Method III) direct addition of diazomethane to plasma followed by GLC analysis of FA methyl esters (4). Using either the standard reference method (Method I) or the colorimetric method (Method II), we observed no differences between the mean plasma FFA concentrations of control and TB mice studied in the fasted state. This is consistent with earlier findings in fasted control and TB mice (with different tumors) (2,3,5). Therefore, the data obtained using each method for fasted mice (control and TB, combined) were averaged. As shown in Table 1, Methods I and II gave similar results, but Method III yielded values on average 2.7 times greater than those obtained using the standardized method. In each of the individual mouse

Statistical analysis: Method I *vs* Method II, n.s.; Method I *vs* Method III, $p \leq 0.01$. Mice were fasted 24 hr and then fed for 20 hr. See Table 1 legend for further experimental details.

samples, substantial artifactual formation of FAME was observed.

Evidence that Method III caused the artifactual formation of FAME from sources other than plasma FFA was obtained using plasma from another 6 mice that had been fasted for 24 hr and then fed a fat-free, sucrose-rich diet for 20 hr (Table 2). As expected, the plasma FFA levels were reduced significantly ($p \leq 0.001$) from 690 to 160 μM (Method I, Tables 1 and 2). Method II yielded far more inconsistent results, reflected in the S.E. values, than did Method I; however, the colorimetric method sufficed to demonstrate the significant effects of feeding on plasma FFA concentrations. Once again, with Method III we observed large artifactual elevations in the apparent plasma FFA levels in all 6 mice. The variation (Method III) in the fed mice was much greater than that seen in the fasted mice. Still, there was a consistent marked formation of FAME, which were not derived from FFA, in each of the 6 refed mice, just as had been found in the 6 fasted mice. Moreover, the formation of excess FAME obscured to a large extent the effects of feeding on the plasma FFA levels.

Changes in concentrations of the individual FFA moieties induced by feeding the previously fasted control mice are shown in Figure 1. These changes did not bear a consistent relationship to the formation of artifactually formed, "excess" FA moieties. This is additional evidence indicating that the "excess" FAME seen with Method III were derived from plasma lipids other than FFA. Under conditions in which each of the major peaks, except C_{20} and C_{22} polyunsaturated FFA, showed a significant fall in concentration in response to refeeding,

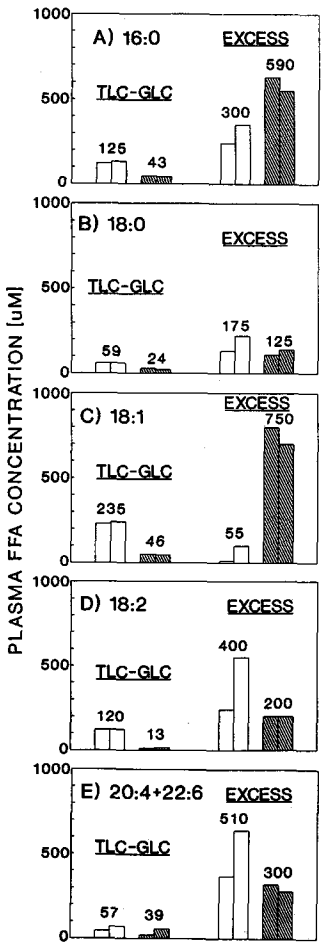

FIG. 1. Comparison of the major individual plasma FFA levels in 24-hr fasted and fasted-fed, control nude mice as measured by TLC/GLC (Method I) with the excess FA obtained by direct methylation of plasma FFA using diazomethane in diethyl ether. The plasma FFA concentration of each mouse, estimated using Method I, was substracted from the apparent FFA concentration obtained by Method III (diazomethane and GLC) to determine the excess FA formed by methylation of PLFA (see text). Data shown are those from two mice per dietary condition, each represented by a single bar, with the mean of the 2 values above them. Fasted, open bars; fasted-fed, hatched bars. Chain length and number of double bonds, separated by a colon, are indicated for each type or pair of FA.

the individual excess FA (Method I minus Method III) did not show a uniform response. Thus, the excesses of 16:0 and 18:1 both increased rather than decreased following refeeding, while excesses of 18:0, 18:2 and those of the more highly polyunsaturated FA either decreased or remained constant following refeeding.

Additional experiments were carried out to determine which of the major fatty acid ester fractions could be transmethylated under the conditions of Method III. Triglycerides (TG) did not serve as acyl donors under the latter conditions; they did not give rise to any detectable FAME. In contrast to TG, 4 classes of phospholipids (PL) were found to be acyl donors under the conditions described originally (4). When the standard phospholipids, which had been obtained commercially and then purified by TLC just before use, were treated according to Method III, the following results were obtained (values are % of total PLFA recovered as FAME): phosphatidylcholine (PC), 27%; phosphatidylethanolamine (PC), 27%; phosphatidylethanolamine (PE), 13%; phosphatidylglycerol (PG), 17%; phosphatidylserine (PS), 14%. We obtained similar results for PC, PE and PG using another supposedly specific FFA-methylating method in which acetyl chloride/methanol (1:50, v/v) was the methylating agent added directly to plasma under carefully controlled temperature and temporal conditions (7). Since PLFA is typically present in plasma lipoproteins in much higher concentrations than FFA, it seems logical to conclude that these were the sources of the excess apparent FFA found using Method III (compared to Method I).

DISCUSSION

We have compared a colorimetric method (Method II) for measuring plasma FFA levels with a standard TLC/GLC reference method (Method I). Both methods yielded the same mean plasma FFA concentrations for fasted mice and showed similar decreases in plasma FFA concentrations after carbohydrate feeding; however, the colorimetric method (1) was less reliable than the standard reference method.

We also tested two other GLC methods in which plasma FFA were methylated directly without prior extraction of total lipids and without separation of FFA by TLC. One of these (4) used diazomethane as a methylating agent (Method III). This method was selected for more detailed evaluation because it appeared to be faster and, theoretically, more specific than the other (7), which used acetyl chloride/methanol under carefully controlled conditions. Both of the latter methods (4,7) yielded plasma FFA levels far greater than those obtained using Methods I and II. The excess FAME that formed masked the effects of feeding on plasma FFA levels.

Further studies confirmed that extensive methylation of fatty acid (FA) esters (or of FFA derived from them after hydrolysis) by diazomethane had occurred; the degree of methylation was unreliable. Furthermore, the source of the FA moiety was phospholipids, not triacylglycerols. All four classes of PL tested served as effective FA donors. Whereas 16:0 and 18:1 plasma FFA concentrations fell markedly after feeding the fat-free diet to previously fasted mice, the excess 16:0 and 18:1 FAME formed by direct methylation with diazomethane (4) increased greatly. This finding indicates that one or more PL fraction(s), rich in 16:0 and 18:1, may have accumulated in the plasma during the 20-hr feeding period.

Clearly, direct methylation of plasma FFA is a risky procedure. It should only be used with great caution and validated by another more specific method. Perhaps we have inadvertently failed in some way to follow the authors' exact procedures (4,7). Nevertheless, we have reservations about the use of techniques in which total lipid extracts are injected onto the chromatographic column, which, in our experience, can ruin a column. In addition we have concerns about the potentially serious errors that may occur due to methylation of plasma esterified lipids when plasma FFA levels are low, as in fed animals, especially in the presence of hypertriglyceridemia, such as that seen in fed TB rodents. The acetyl chloride/methanol method for specific, direct methylation of plasma FFA (7) seems so sensitive to the analytical

conditions that it could conceivably give rise to a much greater degree of transesterification than that reported by the authors (3–5% of PLFA and TGFA). However, acetyl chloride is a convenient methylating reagent when used, as described by LePage and Roy (8), to measure plasma total lipid fatty acid composition, and we use that method routinely in our laboratory.

Maternal Protein Deficiency in Rat: Effects on Central Nervous System Gangliosides and Their Catabolizing Enzymes in the Offspring

V.V.T.S. Prasad[1]
Department of Biochemistry, Faculty of Science, MS University, Baroda-390002, India

Maternal protein deficiency imposed on rats a month prior to conception, and during gestation and lactation, resulted in a significant cell loss in cerebrum, cerebellum, brain stem and spinal cord of pups at weaning. The cerebellum was the most affected central nervous system (CNS) region; it contained only 25% of the normal cell number. Undernourished pups were also found to have a lower concentration of total gangliosides in cerebrum as compared to that of controls. However, the total ganglioside concentration was unaffected in the cerebellum, brain stem and spinal cord by maternal undernutrition. In all regions, undernutrition caused significant changes in the proportions of individual gangliosides; these alterations were region-specific. Sialidase, β-galactosidase, β-glucosidase, and β-hexosaminidase, which are involved in the catabolism of gangliosides, showed higher activities in all the regions of undernourished pups, suggesting that these enzymes may play a role in maintaining the porportions of various ganglioside fractions. *Lipids 26*, 553–556 (1991).

During the period of organogenesis, an organism is less equipped to cope with adverse environmental factors than it is at maturity (1). The brain is particularly vulnerable to genetic or epigenetic factors such as hormonal imbalance or nutritional deprivation during the period of cell division and during the most rapid phase of development (2). Though the development of rat central nervous system (CNS) begins around the end of the first week of gestation, growth spurt in brain development, which includes glial multiplication, axonal growth, dendritic arborization and synaptogenesis, is a postnatal event (3).

Several studies have shown that maternal protein deficiency impairs development of CNS of the offspring. Neonatal undernutrition is known to lower the concentration of CNS lipids such as cholesterol, phospholipids and galactolipids (4,5). However, reports on the effects of pre- and postnatal undernutrition on the CNS gangliosides are few and are not unequivocal (6–8). Further, there are no studies on the effects of maternal undernutrition imposed during gestation and lactation on the enzymes involved in ganglioside metabolism. The impact of maternal undernutrition imposed *in utero* and during lactation is particularly important as the gangliosides which are increasingly being implicated in differentiation, development and functions of the nervous system, accumulate at a rapid rate between 10 and 21 days of postnatal age. Hence the present experiment was designed to examine the effects of maternal undernutrition (imposed a month before conception, and during gestation and lactation) on cell number, levels of gangliosides and activities of sialidase, β-galactosidase, β-glucosidase and β-hexosaminidase in the cerebrum, cerebellum, brain stem and spinal cord of the pups at weaning.

MATERIALS AND METHODS

Experimental design and animals. Virgin female rats of the Charles Foster strain weighing 180–200 g were divided into two groups. The control group was fed a diet containing 20% casein and the undernourished group was fed a 6.5% casein diet. The 20% casein diet contained 20% casein, 20% sucrose, 7% peanut oil, 49% sago (*manihot utilissima*), 0.3% DL-methionine, 0.2% choline bitartrate, 3.5% mineral mixture and 1% vitamin mixture (9). The low protein diet contained 6.5% casein, 61.5% sago and other components similar to that of the 20% casein diet. The low protein diet of 6.5% casein was chosen because it is nutritionally similar to the diet of poor people in the area of Baroda, India. Both groups were maintained on the respective dietary regimen a month prior to conception, and during gestation and lactation. After birth, pups from different litters were culled randomly and nursed in litters of eight. Pups at 21 days of postnatal age were sacrificed by decapitation after the body weights were recorded. Intact whole brains and spinal cords were quickly dissected out on an ice-cold glass plate and the weights were recorded. Whole brains were separated into cerebrum, cerebellum and brain stem on ice-cold glass plates. Tissue samples for DNA, protein and enzyme assays were processed immediately, and samples for lipid analysis were stored until use in chloroform/methanol (1:1, v/v) at −20°C.

Biochemical analysis. DNA was extracted by the method of Schneider (10) and estimated according to the method of Burton (11). Cell numbers were calculated as described elsewhere (12). Protein was estimated according to Lowry *et al.* (13) using bovine serum albumin as the standard. Total gangliosides were isolated and purified by the method of Seyfried *et al.* (14) and ganglioside N-acetyl neuraminic acid (NANA) was assayed by the method of Warren (15) as modified by Skoza and Mohos (16). The details of these methods are described elsewhere (12). For the separation of individual gangliosides (GQ_1, GD_{1b}, DG_{1a}, GT_{1b}, and GM), 20 × 20-cm glass plates coated with silica gel G were developed by one ascending run with chloroform/methanol/water (58:38:9, v/v/v) that contained 0.02% $CaCl_2 \cdot 2H_2O$. The bands marked after exposure to iodine vapors were scraped from the plates and the ganglioside fractions were estimated as mentioned above. Since the concentrations of monosialo gangliosides such as GM_2 and GM_3 were extremely low, the bands corresponding to all monosialo gangliosides were pooled and the fraction was designated as monosialo ganglioside (GM). The bands were confirmed as gangliosides by using the resorcinol/HCl reagent on a duplicate set. The identity of the individual anglioside bands was confirmed by

simultaneously running a reference bovine brain ganglioside mixture from Sigma Chemical Company (St. Louis, MO). A typical thin-layer chromatogram of the gangliosides is shown elsewhere (12).

Enzyme assays. A 10% (w/v) homogenate was prepared by homogenizing the tissue with ice-cold glass distilled water for three min at 2000–3000 rpm, upon ice, using a Potter-Elvehjem homogenizer. The assays were carried out as described earlier (12). Statistical comparison between group means was by Student's *t*-test (17). Differences between values were considered significant for $p<0.05$.

RESULTS

Maternal undernutrition resulted in significantly lowered body, cerebrum, cerebellum, brain stem and spinal cord weights of the rat pups at 21 days of age as compared to the controls. The body weight (data not shown) of the undernourished pups was 13.5 ± 0.24 g (mean ± SE) while the control pups weighed 43.8 ± 0.28 g. The tissue weights of cerebrum, cerebellum, brain stem and spinal cord of the undernourished pups were 23, 45, 37 and 16% of the control values, respectively (Table 1). Significant reductions in DNA content (mg DNA/tissue) amounting to 16, 12, 17, and 34% respectively, were observed in the cerebrum, cerebellum, brain stem and spinal cord of undernourished pups, compared to controls. This decrease in DNA content in the CNS tissues of the undernourished pups was reflected in the lowered cell number when compared to controls. Protein concentration (mg protein/g tissue) in the undernourished pups did not show any significant changes in CNS compared to the controls.

Undernutrition also lowered the concentration (μg NANA/g tissue) of total gangliosides in cerebrum but not in cerebellum, brain stem and spinal cord (Table 2). However, total ganglioside content (μg NANA/tissue) was lowered in cerebrum, cerebellum, brain stem and spinal cord of the undernourished pups compared to controls. In addition, maternal undernutrition was also found to alter the proportions of the individual gangliosides. Polysialoganglioside, GQ_1 increased in cerebrum, cerebellum and brain stem and decreased in spinal cord of the undernourished pups compared to controls. Trisialo ganglioside, GT_{1b}, was not altered in the cerebrum, but decreased in cerebellum and brain stem, and increased in the spinal cord. By comparison, disialo ganglioside, GD_{1b}, decreased in cerebrum, increased in cerebellum and brain stem, and was unaffected in the spinal cord. In the spinal cord and brain stem, the proportion of GD_{1a} increased while declining in the cerebrum. However, the monosialo ganglioside (GM) fraction increased in cerebrum and cerebellum, and decreased in brain stem and spinal cord. Sialidase activity was higher than that found in controls in cerebrum, cerebellum, brain stem and spinal cord of the undernourished pups (Table 3). β-Glucosidase and β-galactosidase showed a higher activity, in general, in all the CNS regions studied. β-Hexosaminidase showed no significant change in the cerebrum but was higher in the cerebellum, brain stem and spinal cord of pups born of mothers fed the 6.5% casein diet.

DISCUSSION

As a low protein diet and low tissue reserves of the mother can affect the quantity of milk (18,19), pre- and postnatal undernutrition in rat pups was produced by feeding mothers a 6.5% casein diet one month prior to conception, and during gestation and lactation. Maternal protein deprivation during the period of brain development caused reductions in the cell number of cerebrum, cerebellum, brain stem and spinal cord of the pups at weaning. Cerebellum was the most affected region, containing only 25% of the normal cell number. However, the concentration of total gangliosides was lowered only in cerebrum

of the undernourished pups. The reduced concentration of total gangliosides may be related to the reported impairments in dendritic development (20) and retarded synaptogenesis (21) following undernutrition. The observed decrease in cerebral ganglioside concentration in the present study agrees well with reports of decreased concentration of forebrain gangliosides in undernourished rat pups (6) and brain gangliosides in malnourished children (22). Karlsson and Svennerholm (8) found a lowered concentration of total gangliosides in the forebrains of undernourished pups at 10 and 15 days of postnatal age but not at 21 days. This may be due to the higher amounts of protein, duration of treatment and the smaller litter size employed in their study when compared to the present study. Even reports on effects of postnatal undernutrition on rat brain gangliosides were not consistent

(5,21,23–27). The inconsistency in the results may be due to differences in the strains of rats used, variations in the methods employed to produce undernutrition, and length of treatment.

In the present study, the concentration of total gangliosides was significantly lowered only in the cerebrum due to undernutrition. Although prenatal undernutrition was found to reduce the concentration of spinal cord gangliosides in neonatal pups (12), pre- and postnatal undernutrition did not alter the concentration of the spinal cord gangliosides in the pups at weaning. However, pre- and postnatal undernutrition induced significant alterations in the proportions of individual gangliosides in all the CNS regions. The effects on the different fractions were tissue specific. Lowered proportion of GD_{1b} in cerebrum of the undernourished pups is in agreement with the reported reduction in the GD_{1a} in the forebrain of malnourished children (22). As GD_{1a} is mostly located in the dendrites (28) and as undernutrition impairs the dendritic arborization in rat pups (20), the decrease in the GD_{1a} may be attributed to deficient dentritic growth following the pre- and postnatal undernutrition. Interestingly, the proportion of monosialo ganglioside (GM) increased in cerebrum and cerebellum and decreased in myelin-rich brain stem and spinal cord of the undernourished pups at weaning. This decrease in monosialo gangliosides, which are predominant in myelin, correlates well with reported deficits in myelin due to undernutrition (29).

In agreement with the lowered concentration of cerebral gangliosides, the activities of sialidase, β-galactosidase and β-glucosidase were higher in the cerebrum of the undernourished pups than in the controls. In contrast, a decrease in brain sialidase activity was reported in 21-day-old rat pups born of mothers fed a 8% casein diet (7). Adlard and Dobbing (30) did not find any change in brain β-galactosidase activity in rat pups born of mothers fed restricted amounts of food during gestation and lactation. However, in the present study, β-galactosidase activity increased in CNS of the undernourished pups. In cerebellum, brain stem and spinal cord, although the catabolizing enzyme activities were higher, alterations were observed only in the proportions of the individual gangliosides, but not in the concentration of total gangliosides following undernutrition. However, the degree of increase in the activities varied with the enzyme and the region, suggesting a role for these enzymes in altering the proportions of the individual gangliosides.

ACKNOWLEDGMENTS

This research was supported by the University Grants Commission's special assistance program to the Department of Biochemistry, MS University, Baroda, India. The author is thankful to professor K.K. Rao for his suggestions and to R. Pillai for his help in preparing the manuscript.

[Received December 27, 1990; Revision accepted May 27, 1991]

Supplementation with Evening Primrose Oil in Atopic Dermatitis: Effect on Fatty Acids in Neutrophils and Epidermis

Liselotte Schäfer[a,*] and **Knud Kragballe**[b]

[a]Aarhus Oliefabrik A/S, Research and Development Laboratories, DK-8100 Aarhus C and [b]Marselisborg Hospital, Department of Dermatology, DK-8000 Aarhus C, Denmark

We investigated the effect of oral supplementation with evening primrose oil, containing 72% linoleic acid (18:2n-6) and 10% γ-linolenic acid (18:3n-6), on the epidermal and neutrophil phospholipid fatty acid composition in 15 patients with atopic dermatitis (AD). Three different dose levels, 4, 8 and 12 capsules per day containing 0.5 g oil, were given to three groups of patients. The only n-6 fatty acid showing a significant ($p < 0.05$) dose-related increase was dihomo-γ-linolenic acid (20:3n-6) in neutrophil phospholipids. The highest dose increased dihomo-γ-linolenic acid by 45% in neutrophil phospholipids, by 46% in lesion-free epidermal phosphatidylcholine, and by 15% in lesion-free epidermal phosphatidylethanolamine. In both lesional and lesion-free epidermis, supplementation resulted in a rise in the ratio between n-6 and monounsaturated fatty acids, reaching significance ($p < 0.05$) in lesional epidermis. This study shows that moderate and favorable fatty acid changes can be obtained in the epidermis of AD patients, when given 6 g per day of oil rich in n-6 fatty acids. The abnormal lipid and fatty acid pattern of the atopic epidermis may be involved in the pathogenesis of the disease, and should therefore be the target for future therapeutic approaches with fatty acid supplements.
***Lipids 26,* 557-560 (1991).**

The importance of using fatty acid supplements as a treatment of atopic dermatitis (AD) has been discussed for more than half a century (1). In the last ten years, oil from the seeds of evening primrose *(Oenothera biennis)* has attracted special attention due to its unusually high content (10%) of γ-linolenic acid (GLA). In a recently published meta-analysis of nine double blind trials with evening primrose oil, Morse *et al.* (2) found that the overall disease severity of AD patients, especially itching, was significantly reduced in a dose-dependent manner by oral administration of this oil. The functioning of the Δ6 desaturase, an enzyme which converts linoleic acid (LA) into GLA, was thought to be defective in AD patients (3). If this were true, a direct supply of GLA would mean a bypass of this purported metabolic blockade. In previous fatty acid supplementation trials concerning patients with skin disease, only the plasma fatty acid composition was analyzed (4-6). Supplementation trials with oils containing GLA in humans have resulted in the elevation of plasma phospholipid levels of dihomo-γ-linolenic acid (DGLA), which is the precursor of the putative anti-inflammatory substances 15-hydroxy-eicosatrienoic acid and prostaglandin E_1 (7).

Abbreviations: AA, arachidonic acid (20:4n-6); AD, atopic dermatitis; DGLA, dihomo-γ-linolenic acid (20:3n-6); FAME, fatty acid methyl ester; GLA, γ-linolenic acid (18:3n-6); LA, linoleic acid (18:2n-6); MUFA, monounsaturated fatty acids: PC, phosphatidylcholine; PE, phosphatidylethanolamine.

In two previous communications (8,9), we reported that our AD patients apparently did not have any abnormalities in fatty acid desaturation; neutrophil phospholipids and adipose tissue triglycerides showed a normal fatty acid pattern. However, the phospholipid content of the epidermis of these patients was abnormally high. Furthermore, the level of n-6 polyunsaturated fatty acids was reduced and that of monounsaturated fatty acids (MUFA) increased in the epidermal phospholipids, resulting in a highly abnormal ratio between these two fractions. The disease severity was directly related to the content of MUFA in the epidermis, and inversely related to the content of n-6 fatty acids. We interpreted these findings as being the consequence of incomplete lipid transformation combined with increased phospholipase A_2 activity in the epidermis of these AD patients.

The objective of the present study was to measure the magnitude of fatty acid changes in neutrophil and epidermal phospholipids attained by supplementation with evening primrose oil in doses commonly employed.

MATERIALS AND METHODS

Subjects and design. Fifteen adult patients with AD, 8 premenopausal women and 7 men, attending the outpatient clinic of the Department of Dermatology at Marselisborg Hospital (Aarhus, Denmark) agreed to participate in the study. The group of patients was the same as that described previously (8,9). Their age ranged from 19 to 51; the mean age was 32.3 ± 10.1 years. In 11 of the patients, eczema had commenced before the second year of life. In one patient it started at 15, and in three during adulthood. Five were smokers and four female patients used oral contraceptives. The affected body surface ranged from 3 to 70%. In 10 of the patients it ranged from 10 to 50%. None of the patients received topical or systemic treatment for 2 wk prior to the study. Subjects which were over- or underweight (more than 20% from the ideal weight), or which had diabetes or hyperlipidemia were excluded from the study. The patients were randomly assigned to three dose levels of evening primrose oil (Quest Vitamins, London, U.K.), namely 4, 8 or 12 capsules, each containing 0.5 g, per day. The fatty acid composition of the oil given as % by weight of total fatty acids was: 16:0 6.3%, 18:0 1.6%, 18:1 10.1%, 18:2n-6 71.5%, and 18:3n-6 9.9%. All patients were instructed to use only their usual emollient during the trial. Blood samples were obtained from fasted patients at week 0 and 10. Neutrophils were isolated by the Hypaque-Ficoll technique, according to Boyum (10). Skin biopsies, weighing 50-250 mg, were taken with a keratome set at 0.2 mm, and frozen immediately in liquid nitrogen, as previously described (11). Approximately two-thirds of the epidermis was removed.

Analytical procedures. Lipid extraction, separation, and analysis were carried out as previously described (8,9). Briefly, lipids were extracted from neutrophils and epidermal specimens with chloroform/methanol (2:1, v/v). Total

phospholipids were isolated from the neutrophil lipid extract by solid-phase extraction on prepacked silica cartridges. Epidermal phospholipids were isolated from the epidermal lipid extract on an aminopropyl phase, packed in a glass column. Epidermal phospholipids were further separated into classes by normal phase high-pressure liquid chromatography on a silica column in a gradient of acetonitrile/water, as previously described (9). Phospholipids were detected at 203 nm. Individual phospholipid classes were identified using external standards. Individual phospholipid fractions were collected manually and taken to dryness in a rotary evaporator at 50°C. Fatty acid methyl esters (FAME) were prepared by transesterification with sodium methoxide. FAME were analyzed on a 50 m × 0.25 mm capillary fused silica column coated with a 0.2 μm film of CP SIL88 (Chrompack, Delft, The Netherlands). The carrier gas was helium and the flow rate 2 mL/min. Injection was on-column at 90°C. The oven was programmed to rise to 210°C within 6 min and then run isothermally for 18 min. A flame-ionization detector was used, and peak areas were integrated automatically. FAME were identified by comparison with a standard mixture of known composition (68A and 68B, NuChek Prep, Elysian, MN). The relative contents of major peaks of these standards agreed within 0.2% with the values stated by the manufacturer.

Statistical analysis. All data are presented as mean ± S.D. Dose response relationships were analyzed by ANOVA. The fatty acid changes within each dosage group were analyzed by Wilcoxon's signed rank test.

RESULTS

Linoleic acid (LA) comprised 72% (by weight of total fatty acids) of the oil supplement. However, the level of LA did not show any systematic change in either neutrophil or epidermal phospholipids after 10 wk of supplementation (Tables 1 and 2). The level of GLA, comprising 10% of the oil, remained unchanged at 0.1–0.2% (by weight of total fatty acids) in epidermal and neutrophil phospholipids (data not shown). The changes in DGLA and AA in the epidermis were positive in all three dosage groups, but significant ($p < 0.05$ by Wilcoxon's signed rank test) only in subjects on the highest dose (Table 1). The total content of n-6 fatty acids tended to increase upon supplementation in all three dosage groups in both lesional and lesion-free epidermal phosphatidylcholine (PC), while that of total MUFA tended to decrease. The ratio of n-6/MUFA significantly increased at week 10 in lesional epidermis in the lowest and highest dosage group (Table 1). In phosphatidylethanolamine (PE) from lesion-free epidermis, the average changes relative to week 0 on the highest dose (12 capsules/day) were 8% in LA, 15% in DGLA, 17% in AA, 2% in total n-6 fatty acids, 4% in MUFA, and −2% in saturated fatty acids. None of these changes reached

[a]Number of capsules (0.5 g) per day; each dose was taken by five subjects.

[b]Values are mean ± S.D. and given as % weight of total fatty acids.

[c]Average of individual changes in % of initial value.

[d]Significant ($p < 0.05$) dose-related rise by ANOVA.

[e]Significantly ($p < 0.05$) different from week 0 by Wilcoxon's signed rank test.

[f]n-6 fatty acids include 18:2, 18:3, 20:3, 20:4, 22:4, and 22:5.

[g]Monounsaturated fatty acids include 14:1, 15:1, 16:1, 17:1, 18:1, 20:1n-11, and 20:1n-9.

[h]Saturated fatty acids include 14:0, 15:0, 16:0, 17:0, 18:0, 20:0, and 22:0.

statistical significance. The change in neutrophil phospholipid fatty acids upon supplementation is shown in Table 2. Here a significant dose-related rise in DGLA was found ($p < 0.05$ by ANOVA).

DISCUSSION

In previous studies on the effect of fatty acid supplementation on patients with AD, emphasis was placed on the clinical effect and on the plasma phospholipid fatty acid pattern (5,12,13). The effect of supplementation with n-6 fatty acids on epidermal phospholipids and neutrophils has, to our knowledge, not been investigated before in humans. Our data show that supplementation with evening primrose oil resulted in the elevation of DGLA in neutrophils and epidermal phopholipids, as has been shown in plasma (4). Despite the high concentration of LA and GLA in evening primrose oil, the levels of these fatty acids remained virtually unchanged. This shows that LA and GLA are rapidly desaturated and elongated when taken orally.

The effect of supplementation with evening primrose oil on the tissue phospholipid fatty acid composition has been investigated in animals. In mice macrophages, the DGLA concentration was increased 5-fold by feeding mice 25% (% by weight of total fatty acids) of GLA in the form of borage oil for three weeks (14). In another study with guinea pigs (7), using the same dose for eight weeks, a 10-, 4- and 1.3-fold elevation of GLA, DGLA and arachidonic acid (AA), respectively, and a 2-fold reduction in LA were seen in the epidermal phospholipid fraction, compared to animals fed a safflower oil-enriched diet. An analysis of the lipoxygenase products formed in the epidermis of these animals revealed that metabolites of DGLA, such as 15-hydroxy-eicosatrienoic acid and prostaglandin E_1 were synthesized. These substances have been proposed to have anti-inflammatory properties (7). Dietary GLA may therefore be a source for endogenous generation of anti-inflammatory metabolites in the epidermis which may suppress local inflammatory reactions (15). However, the highest dose of evening primrose oil normally given to patients is approximately 0.6% (% by weight of total dietary fat), corresponding to 12 × 0.5 g capsules per day. Our data show that this dose only leads to a 50% increase in DGLA in the epidermis after 10 wk of supplementation, reaching levels far less than in experimental animals. It is questionable whether the level of DGLA in human epidermis, attained by oral supplementation with evening primrose oil, would be large enough to support the synthesis of local anti-inflammatory metabolites, even if supplementation were continued for longer periods. The beneficial effect of n-6 fatty acid supplementation in AD, as reported by others (2), probably relies on other mechanisms. In a previous publication (9) we reported that the epidermis of AD patients had a lower n-6/MUFA ratio than the epidermis of healthy subjects, and that the disease severity correlated directly with the total MUFA content of the epidermal phospholipids. In essential fatty acid deficiency, which also results in dry scaling skin, an imbalance is found in the ratio between LA and MUFA (16). Although AD patients are not deficient in essential fatty acids, the characteristic dry skin could be caused by a partial substitution of polyunsaturated fatty acids by MUFA, leading to a defective structure of the epidermal water barrier. The present results show that supplementation with n-6 fatty acids results in a rise in the n-6/MUFA ratio, particularly in lesional epidermis. Subjects on the highest dose actually increased their n-6/MUFA ratio to a value of 1.68 in lesion-free epidermis. Previously we reported a value of 1.64 for healthy epidermis (9). Because this study was not controlled, we cannot relate the clinical outcome of the patients to the observed changes in the fatty acid composition of epidermal phospholipids. If and how these changes are causally related to the disease remains to be established. Because linoleic acid is an essential component of acylceramides, which constitute the epidermal water barrier (17), it would be of considerable interest to study the effect of n-6 fatty acid supplementation on the metabolism of acylceramides in the atopic epidermis.

In conclusion, this study shows that supplementation with up to 600 mg/day of evening primrose oil increases the level of n-6 fatty acids, especially DGLA, by 15–60% in neutrophil and epidermal phospholipids. Furthermore, supplementation results in a beneficial shift in the ratio between n-6 and MUFA. However, no clear evidence has yet been presented in favor of GLA as being the active component in evening primrose oil. New studies should clarify if more conventional vegetable oils containing high levels of linoleic acid, such as safflower or sunflower oil, may mediate the desired lipid changes in the epidermis, and if the dose should be further increased.

4-Desmethylsterols from the Marine Bivalve *Macoma balthica*

Andrzej Jarzebski*
Institute of Oceanology, Polish Academy of Sciences, 81-967 Sopot, Poland

4-Desmethylsterols from *Macoma balthica* L. were investigated by gas chromatography and gas chromatography/mass spectrometry after isolation by argentation and column chromatography. Twenty-three Δ^0- and Δ^5-sterols with saturated and unsaturated side chains were identified. It is suggested that sterols in *M. balthica* are derived from dietary sources. The great diversity of minor 4-desmethylsterols is likely to be due to their role as intermediates in the metabolism of dietary sterols.
***Lipids 26,* 561-563 (1991).**

The sterol composition of marine mollusks has been investigated in more detail than that of any other class of marine invertebrates (1-6). Application of modern analytical techniques has revealed that Bivalvia are unique in containing a great diversity of various Δ^5- and $\Delta^{5,22}$-sterols. Little is known about the origin of this complex mixture of sterols in bivalves.

Mollusks are an important link in the food chain in the Baltic Sea. One of these mollusks, *Macoma balthica* (a facultative filter/surface film deposit bivalve), is most abundant in the benthic fauna in the Gulf of Gdańsk. The major sterols of *M. balthica* have previously been investigated (7,8). Cholest-5-en-3β-ol (cholesterol) was the most abundant sterol; the other major *M. balthica* sterols were common constituents of bivalves (1-8). Some sterols (*e.g.* 24-methylcholesta-5,22-dien-3β-ol, 24-methylcholesta-5,24(28)-dien-3β-ol, 24-methyl-cholest-5-en-3β-ol) were typical phytoplankton sterols (4,5).

The minor sterols of *M. balthica* have previously not been characterized. In the present study, we therefore reexamined the sterols of *M. balthica* with special focus on the minor components.

MATERIALS AND METHODS

Gas chromatography was performed with a Carlo Erba (Milan, Italy) Fractovap 4100 gas chromatograph equipped with a 30 m × 0.3 mm I.D. OV-1 glass capillary column at 260°C with nitrogen as a carrier gas. Gas chromatography/mass spectrometry measurements were carried out with a Finnigan (Bremen, Germany) MAT 44S system using a OV-1 glass capillary column. ^{1}H nuclear magnetic resonance (NMR) spectra were recorded in $CDCl_3$ on a Bruker (Karlsruhe, Germany) 300-MHz spectrometer.

Argentation column chromatography was performed on silica gel 60 (0.040-0.063 mm; Merck, Darmstadt, Germany) (100 g) impregnated with silver nitrate (25 g) and activated at 100°C. Argentation thin-layer chromatography was carried out on Merck 20 × 20 cm aluminum sheets coated with silica gel impregnated with silver nitrate according to the method described by Pill *et al.* (9). Chromatograms were developed twice in chloroform/petroleum hydrocarbons (b.p. 40-60°C) (1:1, v/v).

Macoma balthica specimens (1.5 kg of wet weight) were collected from the Gulf of Gdańsk (Southern Baltic), and their lipids were extracted by the Bligh-Dyer method (10). Total sterols (690 mg, 3% of lipids) were isolated from the unsaponifiable part of the lipids as described previously (11). Re-chromatography of the total sterol fraction on a silica gel column using petroleum hydrocarbons (b.p. 40-60°C)/ethyl acetate yielded a fraction of 4-desmethylsterols (676 mg, 98.0% of total sterols), as detailed previously (12). 4-Desmethylsterols were acetylated with pyridine/acetic anhydride (1:1, v/v) for 24 hr at room temperature. The 4-desmethylsteryl acetates were chromatographed on a $AgNO_3$/silica gel gravity column (35 × 2.8 cm I.D.) with 420 mL each of 0, 2, 5, 10, 15, 20, 27.5, 35, 50 and 70% benzene in petroleum hydrocarbons (b.p. 40-60°C). Fractions (12 mL) were collected, analyzed by gas chromatography (GC) and combined as indicated to give nine fractions which were analyzed by gas chromatography/mass spectrometry (GC/MS).

RESULTS AND DISCUSSION

Total sterols isolated from *Macoma balthica* were chromatographed on a silica gel column to give fractions containing 20-isosterols (12) and 4-desmethylsterols. 4,4-Dimethylsterols and 4-methylsterols were not detected. This is important because these sterols are intermediates in the biosynthesis of cholesterol (the main *M. balthica* sterol) from simple precursors such as acetyl-CoA and mevalonic acid (13-15). The absence of 4,4-dimethylsterols and 4-methylsterols may be taken as an indication for the absence of *de novo* sterol synthesis in the bivalve studied. Therefore, sterols in *M. balthica* appear to be derived from dietary sources.

The 4-desmethylsterol fraction was acetylated in the usual manner. The acetate mixture was fractionated by argentation column chromatography. GC and GC/MS analyses of the fractions obtained by argentation column chromatography permitted the identification of the sterols, including the minor components. Sterols were identified by comparison of their retention times relative to cholesteryl acetate based on literature data (16) and by mass spectral fragmentation. The results are summarized in Table 1; the structures of the *M. balthica* sterols identified are shown in Figure 1.

The major 4-desmethylsterols, including C-24 alkylated Δ^5- and $\Delta^{5,22}$-sterols, were those previously detected in *M. balthica* (7,8). The C-24 configuration of C_{28}- and C_{29}-sterols occurring in marine invertebrates has received considerable attention in recent years. It was our intention to assign the stereochemistry at C-24 for 24-methylcholesta-5,22-dien-3β-ol, one of the major *M. balthica* sterols. Its content in the clam investigated underwent seasonal variations (17,18), which may be a further indication of the 24-methylcholesta-5,22-dien-3β-ol's exogenous origin.

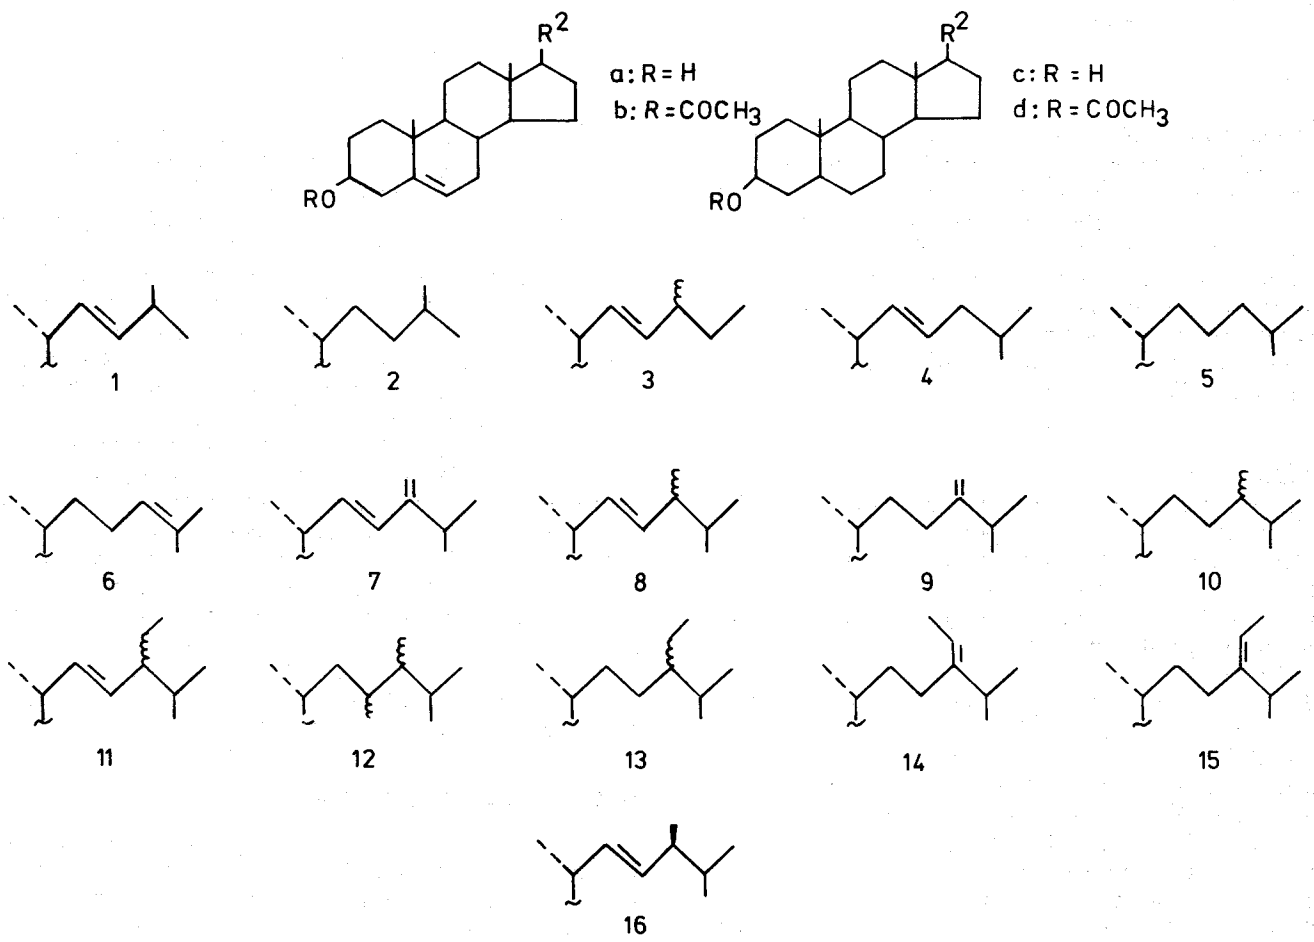

FIG. 1. 4-Desmethylsterols from *Macoma balthica*.

Fractions No. 150–160 from argentation chromatographic column contained 24-methylcholesta-5,22-dien-3β-yl acetate as the major component (identified by GC/MS) accompanied by a small quantity of acetates of: Δ^5-sterols (**5b, 10b, 13b**), other $\Delta^{5,22}$-sterols (**3b, 11b**) and some other minor sterols. Argentation thin-layer chromatography of the acetate mixture enabled us to isolate the major sterol of this group in satisfactory purity (about 95% by GC) to determine its C-24 stereochemistry. The ^{1}H NMR spectrum showed three methyl singlets at δ 0.692 (C-18), 1.018 (C-19) and 2.03 (CH_3CO); four doublets, corresponding to methyl groups, at δ 0.816 (J = 6.7 Hz, C-26 or C-27), 0.833 (J = 6.7 Hz, C-26 or C-27), 0.908 (J = 6.8 Hz, C-28) and 1.00 (J = 6.8 Hz, C-21); signals for olefinic protons at δ 5.16 (*m*, 2H, 22-H and 23-H) and 5.37 (*m*, 1H, 6-H); and a broad signal at δ 4.60 ppm (*m*, 1H, 3-H). These data are in good agreement with those reported in the literature for a (24S)-isomer (19). Therefore the structure of the sterol was assigned as (24S)-24-methylcholesta-5,22-dien-3β-ol. This sterol had first been isolated from the diatom *Phaeodactylum tricornutum* by Rubinstein and Goad (20). Later it was suggested that diatoms are the primary source of (24S)-24-methylcholesta-5,22-dien-3β-ol which is one of the prominent sterols in bivalves and other marine invertebrates (4,5). Its exclusive (no traces of 24R-isomer were observed in the ^{1}H NMR spectrum) occurrence in *M. balthica* is consistent with the hypothesis that diatoms are the main food source of this clam (21).

Among the minor components of the 4-desmethylsterol fraction from *M. balthica*, several C_{26}-C_{29} Δ^0- and Δ^5-sterols with saturated and unsaturated (Δ^{22} and/or Δ^{24}) side chains were found. In relation to other species of Bivalvia (3–6), *M. balthica* possesses relatively high content and diversity of stanols. The origin of stanols in the clam studied raises an interesting question. Stanols appear in many sediments as a result of microbiological transformation of Δ^5-sterols (22). Stanols were also found in large quantity in sediments from the Gulf of Gdańsk (Jarzebski, A., unpublished results). It is well-known that organic matter from surface sediments is an important component of the food of *M. balthica* (21). It could therefore be postulated that stanols occurring in *M. balthica* originate from sediments.

The most important source of food for *M. balthica* is phytoplankton (especially diatoms) and the organic matter derived from phytoplankton (21). The sterol composition of phytoplankton from the Gulf of Gdańsk is not

TABLE 1

4-Desmethylsterols from *Macoma balthica*

	Sterol	GC RRT[a]	%
1a	24-Norcholesta-5,22-dien-3β-ol	0.66	7.6

[a]Retention times (RRT) of acetates relative to cholesteryl acetate (RRT, 1.00) on an OV-1 capillary column (for details, see Materials and Methods).

coincident with the sterol composition of *M. balthica*. The respective species of phytoplankton contain mainly C_{28} and C_{29} Δ^5-, $\Delta^{5,22}$- and $\Delta^{5,24(28)}$-sterols (Jarzebski, A., unpublished results). It can therefore be assumed that the sterol composition of *M. balthica* is the result of transformation of exogenous sterols. The dealkylation of 24-alkylphytosterols to produce C_{27}-sterols (*e.g.* cholesterol) has been recognized as one of the possible transformations of exogenous sterols in bivalve mollusks (5,23). Adaptation of sterols from dietary sources to satisfy the sterol requirements of the bivalve involves the formation of numerous intermediates, which may explain the great diversity of 4-desmethylsterols present in *M. balthica*.

ARTICLE

Molecular Species Composition of the Major Diacyl Glycerophospholipids from Muscle, Liver, Retina and Brain of Cod (*Gadus morhua*)

M.V. Bell* and **J.R. Dick**
NERC Unit of Aquatic Biochemistry, School of Natural Sciences, University of Stirling, Stirling FK9 4LA, Scotland

The molecular species composition of phosphatidylcholine (PC), phosphatidylethanolamine (PE) and phosphatidylserine (PS) from white muscle, liver, retina and brain of cod (*Gadus morhua*) were determined by high-performance liquid chromatography of the respective 1,2-diacylglycerol 3,5-dinitrobenzoyl derivatives. A minimum of 69 diacyl species was identified. In muscle and liver saturated fatty acid/polyunsaturated fatty acid (PUFA) and monounsaturated fatty acid/PUFA molecular species were predominant, particularly 16:0/20:5 and 16:0/22:6 in PC, 16:0/22:6 and 18:1/22:6 in PE and 18:0/22:6 and 18:1/22:6 in PS. Didocosahexaenoyl species were major components of PC, PE and PS from retina, comprising 29.3, 71.8 and 59.7% of the respective totals. Didocosahexaenoyl species were also abundant in PE and PS from brain, accounting for 13.8 and 24.0% of the totals, respectively. DiPUFA species were important in muscle, totalling 21.2% in PC and 38.3% in PE. PC from all tissues had the largest amounts of species containing only saturated or monounsaturated fatty acids, accounting for 59.8% of PC from brain, including 12.8% of 18:1/24:1 plus 24:1/18:1.
***Lipids* 26, 565–573 (1991).**

The main structural glycerophosholipids from vertebrate neural tissue contain large amounts of docosahexaenoic acid (DHA; 22:6n-3). Polyunsaturated fatty acids (PUFA) are very tenaciously retained by neural tissue (1), and two or three generations of dietary deprivation are required to reduce significantly the n-3 PUFA content of brain in rat (2) and brain and retina of rhesus monkeys (3). Depletion of n-3 PUFA in brain and retina results in reduced visual and cognitive abilities in rhesus monkeys (4). However, the precise role of 22:6n-3 in neural tissue is unknown.

Early attempts to separate phospholipids from bovine rod outer segments (ROS) according to the degree of unsaturation by adsorption thin-layer chromatography (TLC) (5), and later by argentation TLC (6), showed the presence of fractions containing more than six double bonds per molecule. Positional analyses of the fatty acids in PC and PE from frog ROS showed 22:6n-3 to be on both the *sn*-1 and *sn*-2 positions of the glyceride and it was deduced that diPUFA species were present (7). The development of methods for analyzing the molecular species composition of glycerophospholipids by high-performance liquid chromatography (HPLC) directly (8) or by preparing derivatives (9–12), or by gas-liquid chromatography (GLC) of volatile derivatives (13) has revealed the fully complexity of the lipid components of membrane structures, and these techniques have now been applied to many systems. The presence of diPUFA molecular species in frog retina was confirmed by direct analysis (14), while analyses of glycerophospholipids from the brain and retina of trout showed large amounts of di22:6n-3 species, especially in phosphatidylcholine (PC), phosphatidylethanolamine (PE) and phosphatidylserine (PS) from retina and in PE and PS from brain (15). Small amounts of diPUFA species also have been found in non-neural tissues including rat erythrocyte (11), rat testes (16), fish muscle (9) and cod roe (17). Marine fish are particularly rich in n-3 PUFA (18), and this paper presents molecular species analyses of PC, PE and PS of four tissues of cod (*Gadus morhua*). The results from two neural tissues, brain and retina, are compared with those from liver and muscle.

MATERIALS AND METHODS

Cod (*Gadus morhua*) (300–600 g weight) were obtained from the Marine Station (Millport on the Firth of Clyde, Scotland), maintained in a seawater aquarium at 10–14°C on a diet of chopped squid and used within two weeks of capture. Fish were killed by decapitation, and the eyes, liver and fillet of muscle removed and frozen at −70°C until required. Brains were removed and used immediately.

Phospholipase C from *Bacillus cereus* was obtained from Boehringer Corporation (London) Ltd. (Lewes, East Sussex, England). Butylated hydroxytoluene (BHT) was from Sigma Chemical Co. (Poole, Dorset, England). 3,5-Dinitrobenzoylchloride was from Aldrich Chemical Co. (Gillingham, Dorset, England) and was recrystallized from carbon tetrachloride before use. Standard lipids were obtained from Sigma and from Nu-Chek Prep (Elysian, MN), as detailed in (15). TLC and high-performance thin-layer chromatography (HPTLC) plates were coated with silica gel 60 (Merck, Darmstadt, Germany). Analar grade glacial acetic acid, carbon tetrachloride, propan-2-ol and pyridine were purchased from BDH Ltd. (Poole, Dorset, England). All other solvents of HPLC grade were from Rathburn Chemicals (Walkerburn, Peeblesshire, Scotland).

Ultrasphere ODS and Ultrasphere octyl HPLC columns (25 × 0.46 cm, 5 micron particle size) were obtained from Altex/Beckman (Beckman Instruments U.K. Ltd., High Wycombe, Bucks, England).

Extraction and purification of lipids. All solvents, apart from those used for TLC and HPLC, contained 0.01% (w/v) BHT. Samples were stored at −20°C under nitrogen between preparative procedures.

The brains were taken from 20 cod, the meninges re-

*To whom correspondence should be addressed.

Abbreviations BHT, butylated hydroxytoluene; GLC, gas-liquid chromatography; HPLC, high-performance liquid chromatography; HPTLC, high-performance thin-layer chromatography; MUFA, monounsaturated fatty acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; PUFA, polyunsaturated fatty acid; ROS, rod outer segment; SFA, saturated fatty acid; TLC, thin-layer chromatography; VLCPUFA, very long chain PUFA. Molecular species are abbreviated as follows: *e.g.*, 16:0/22:6 PC is 1-palmitoyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine.

moved and the remaining tissue (8.3 g) homogenized in 10 volumes of chloroform/methanol (2:1, v/v) using a Polytron tissue disrupter. The retinas from 40 frozen cod eyes (5.7 g tissue) and 20 chopped frozen livers (89 g) were each homogenized in 10 volumes of chloroform/methanol (2:1, v/v), and finely shipped frozen muscle fillets (211 g) from 20 fish were homogenized in 5 volumes of solvent. After homogenization total lipid was extracted by the method of Folch *et al.* (19).

Neutral lipid was first removed from the brain and liver extracts by preparative TLC in hexane/diethyl ether/acetic acid (70:30:1, v/v/v). Phospholipids were eluted from the origin with chloroform/methanol/water (5:5:1, v/v/v), dried by rotary evaporation under vacuum at 35°C and finally under a stream of nitrogen. Phospholipid classes were separated by TLC in chloroform/methanol/water/triethylamine (30:35:6:35, by vol) (20) and the lipids detected under UV light after spraying with 0.1% (w/v) 2′,7′-dichlorofluorescein in methanol containing 0.01% (w/v) BHT. Phospholipids were eluted from the silica gel with three 40-mL washes of chloroform/methanol/water (5:5:1, v/v/v) and dried as before. 2′,7′-Dichlorofluorescein was removed from lipids by extraction with a solution of 2% (w/v) $KHCO_3$. PC and PS were further purified by TLC in chloroform/acetone/methanol/acetic acid/water (10:4:2:2:1, by vol) (21), and detected and extracted as before. All phospholipids were finally checked for purity by HPTLC in methyl acetate/propan-2-ol/chloroform/methanol/0.25% (w/v) KCl (25:25:25:10:9, by vol) (22). Lipids were detected by spraying with 3% (w/v) copper acetate in 8% (v/v) phosphoric acid and charring at 160°C for 15 min.

Fatty acid methyl esters were prepared by esterification in 2 mL of 1% (v/v) concentrated sulfuric acid in methanol at 50°C for 16 hr under nitrogen. The fatty acid composition of the phospholipids was determined by GLC of fatty acid methyl esters in a Packard 436 chromatograph fitted with a CP Wax 52CB fused silica capillary column (50 m × 0.32 mm i.d.) (Chrompack U.K. Ltd., London, England) (23), and with a CP Sil5CB fused silica capillary column (50 × 0.34 mm i.d.) (Chrompack) (24), using hydrogen as carrier gas.

Preparation of 3,5-dinitrobenzoyl derivatives. One-mg portions of phospholipid were hydrolyzed with phospholipase C using a two phase system of 1 mL diethyl ether and 1 mL 0.1M sodium borate buffer, pH 7.5, at room temperature under nitrogen for 5 hr (25). At the end of the incubations 1,2-diacylglycerols were extracted and purified by TLC in hexane/diethyl ether/acetic acid (50:50:1, v/v/v) (17). 1-Alkenyl-2-acylglycerols and 1-alkyl-2-acylglycerols were separated at this stage. Amounts of phospholipid remaining after phospholipase C digestion were less than 2% of the starting material. Diacylglycerols were derivatized in dry pyridine with 3,5-dinitrobenzoyl chloride at 60°C for 45 min under nitrogen, extracted and washed as described by Takamura *et al.* (12). The purity of the product was checked by HPTLC in hexane/diethyl ether/acetic acid (70:30:1, v/v/v).

Separation of molecular species. The 1,2-diacyl-3-dinitrobenzoyl-*sn*-glycerols were separatd by HPLC at 19–21°C on reverse phase columns using a Pye Unicam 4010 pump (Pye Unicam Ltd., Cambridge, England) and three isocratic solvent systems. An ODS column was used with methanol/propan-2-ol (95:5, v/v), flow rate 1.0 mL/min; and acetonitrile/propan-2-ol (80:20, v/v), flow rate 1.0 mL/min (12); a C8 column was used with methanol/water/acetonitrile (93:5:2, v/v/v), flow rate 1.2 mL/min (17). Peaks were detected at 254 nm with a Pye Unicam 4020 detector and quantified using a Shimadzu C-R6A recording integrator (Anachem, Luton, England).

Peaks were identified from plots of $\log_{10}$ (relative retention time, RRT) *vs.* the effective carbon number on the *sn*-1 position of the glyceride as described by Patton *et al.* (8) and Takamura *et al.* (12) using 16:0/22:6 as a reference peak. Didocosahexaenoylglycerol (Nu-Chek Prep) was also available for direct comparison of retention times. The main n-3 PUFA-containing molecular species were identified directly by GLC of the fatty acid methyl esters (17), while 18:1/20:1 plus 20:1/18:1 and 18:1/24:1 plus 24:1/18:1 had previously been synthesized (15). Each sample was chromatographed three times in each of the solvent systems and the standard deviations calculated. Where final peak areas were calculated by subtraction, the standard deviations of the contributing peaks were added to give the final error. Results are given to one decimal place for clarity. The $\log_{10}$ (RRT × 10) of all the molecular species in each solvent system are given in the appendix.

RESULTS

In muscle SFA/PUFA species were the most abundant class, comprising over 50% of PC and PS with almost equal amounts of 16:0/20:5 and 16:0/22:6 in PC and mainly 18:0/22:6 in PS (Table 1). The most abundant MUFA/PUFA species in each class and a major component of PE and PS was 18:1/22:6. DiPUFA species were also abundant in PC (21.2%) and PE (38.3%), predominantly 22:6/20:5 plus 20:5/22:6 in PC and 22:6/22:6 in PE. Another nine diPUFA species were found. Only small amounts of species containing only saturated and monounsaturated fatty acids were present of which 16:0/18:1 was the most abundant comprising 6.4% of PC.

The molecular species composition of PC, PE and PS from liver was broadly similar to that of muscle (Table 2). SFA/PUFA were the most abundant species in PC and PS, and MUFA/PUFA species in PE. In all three glycerophospholipids 16:0/22:6 was a major species comprising a quarter of the PC, and 18:1/22:6 was abundant in PE and PS. In PS, 18:0/22:6 was a major species but was much less abundant than in PS from muscle; 18:1/22:6 and 18:0/22:6 were equally abundant in PS from liver. In PS from liver 20:1/22:6 was also a major species (Table 2). In addition, liver contained up to nine diPUFA species totaling 13.1% in PE with 22:6-containing species dominant. Species containing only saturated and monounsaturated fatty acids were again of minor importance with 16:0/18:1 comprising 6.4% of PC.

Di22:6 species were most abundant in PC, PE and PS from retina accounting for 29.3, 71.8 and 59.7%, respectively (Table 3). Other diPUFA species were of minor importance. In PC, 16:0/22:6, 16:0/18:1 and 18:0/22:6 were the only other species present at greater than 5.1%. Two unknown species totaling 9.2% were also present in PC and were probably very long chain PUFA-containing species (26). In PE, 16:0/22:6, 18:1/22:6 and 18:0/22:6 at 5–6% were the only other species present at more than 2%, while in PS 18:0/22:6 was again abundant (Table 3). Species com-

[c]tr, <0.1%.

prising only SFA and MUFA totalled just 2.1% and 5.9%, respectively, in PE and PS from retina.

PC from cod brain showed the most complex composition of any of the glycerophospholipids examined; a minimum of 54 species were found, including seven unknowns which totalled 6.6% (Table 4). At least 10 species containing 24:0, 24:1 and 26:1 fatty acids totalling 16.9% were found, the most important of which was 24:1/18:1 plus 18:1/24:1 (12.8%). These species containing very long chain fatty acids were found only as trace components of PE and as less than 1% of PS. PC from brain also contained 42.9% of species containing SFA or MUFA of which 16:0/18:1 (16.9%) and 18:0/18:1 (9.5%) were the most important. The only other major species present was

[b]—, Not detected.

[c]tr, <0.1%.

16:0/22:6. PE and PS from brain were broadly similar in composition to those from muscle, liver and retina. Di22:6 was abundant in both classes, especially PS (24.0%), while 16:0/22:6, 18:1/22:6 and 18:0/22:6 were the other major species in PE, and 18:0/22:6 and 18:1/22:6 in PS.

DISCUSSION

The method used here is capable of resolving most of the molecular species present in glycerophospholipids from fish tissues. However, species containing fatty acids which are present in very small amounts (<0.5%) were not always detected, *e.g.,* 16:4n-3 and 18:3n-3. Isomers of unsaturated fatty acids are not separated, *e.g.,* n-7 and n-9 MUFA or n-3 and n-6 PUFA. Analysis by GLC showed that 22:5 was the n-3 isomer, 22:4 the n-6 isomer and 20:4 predominantly the n-6 isomer; 20:4n-3 was a very minor component in most samples. The chromatographic systems could not separate diPUFA species containing different fatty acids but the same total carbon number and double bonds. Very long chain fatty acid-containing species were also difficult to resolve, and the column and chromatography conditions

[a]Species in italics have defined *sn*-1 and *sn*-2 fatty acid distributions, otherwise it was assumed that the most saturated fatty acid was on the *sn*-1 position. Only one fatty acid combination is given for those species with two equally likely positional isomers. Bracketed species are minor components based on fatty acid composition data. The errors are given as ± 1 standard deviation rounded to the nearest decimal place (see text). The following molecular species were also detected at <0.9% in at least one of the glycerophospholipids: *20:5/20:5, 22:5/22:5, 14:0/22:6, 14:0/20:4, 14:0/22:5, 16:0/18:2, 20:1/20:5, 20:1/20:4, 20:1/22:5,* 14:0/16:0, *18:0/18:0,* 14:0/16:1, 18:0/20:1, *16:1/16:1,* 16:1/18:1, *24:1/20:5, 24:1/22:6,* 16:1/24:1, 16:0/24:1, 18:0/24:1 + (16:0/26:1), 20:1/24:1 + 18:1/26:1 + *(22:1/22:1), 24:0/20:5 + 26:1/20:5, 24:0/22:6 + 26:1/22:6.*

[b]—, Not detected.

[c]tr, <0.1%.

used could not separate the 24:0/PUFA and 26:1/PUFA pairs found in PC from brain (Table 4). The two solvent systems used with the C18 column can separate extreme positional isomers, *e.g.*, 20:5/16:0 from 16:0/20:5 but not 16:0/18:1 from 18:1/16:0. The presumption that most saturated fatty acids are located at the *sn*-1 position of the glycerol moiety is, therefore, supported by the results in all cases where the method can distinguish positional isomers.

Marine fish are particularly rich in n-3 PUFA, especially docosahexaenoic acid (18). The present results show the very unsaturated nature of the molecular species of glycerophospholipids from cod. PE was the most unsaturated glycerophospholipids in all tissues except brain, while PC was the most saturated and contained the shortest average chain length, both due to a lower proportion of 22:6n-3 containing species. PC from fish brain contains a much larger amount of SFA- and MUFA-containing species than glycerophospholipids from other fish tissues. Of particular note is the large amount of 18:1/24:1 plus 24:1/18:1, which was found in trout (9) and is even more abundant in cod. Since cod brain contains 1.0% of 22:1 fatty acid, 20:1/22:1 may be a minor component of this peak. Small amounts of other species containing very long chain fatty acids (24:0, 26:1) were also found in cod brain PC, raising the question of the special role of these molecular species in the structure and function of biomembranes in this tissue.

The increased sophistication of analytical techniques in recent years has led to the discovery of diPUFA species in an unexpectedly large number of tissues such as erythrocytes (11) and testes (16) from rat. Earlier molecular species analyses of fish muscle lecithins found appreciable amounts of diPUFA species (mainly 22:6/22:6, 20:5/22:6 and 22:5/22:6) in chum salmon *Oncorhynchus keta*, big-eyed tuna *Parathunnus obesus* and Alaska pollack *Theragra chalcogramma*, but not in carp *Cyprinus carpio* (9); the present results confirm these findings. The present study also found small amounts of diPUFA species in PC, PE and PS from cod liver and PS from cod muscle, while the large amount of di22:6 in PE from cod muscle is the greatest proportion of this molecular species yet reported in a non-neural tissue.

In bovine retina two unsaturated fatty acids were found in at least 43% of PS, 24% of PE and 24% of PC (6), and PE from frog retina contained about 50% diPUFA species, mainly 22:6n-3/22:6n-3 (14). Tissues from marine fish contain predominantly n-3 PUFA with very little n-6 PUFA, and therefore diPUFA species in fish retina are almost entirely 22:6/22:6. The amounts of di22:6 glycerophospholipids found in cod retina are the highest found in the retina of any species and are substantially higher than those found in trout retina (15). However, we found that PI from the retina of trout (15) and cod (27) does not contain diPUFA species. The molecular species of PI are usually dominated by $18:0/C_{20}$ PUFA species with 18:0/20:4n-6 a major species in the retina of fish (15,27) as in tissues from terrestrial animals (8,11,28), but 18:0/20:5n-3 is predominant in fish brain (15,27). PI is therefore much more saturated than other glycerophospholipids in retina.

Cod are visual feeders with the liver being a major depot for storage of neutral lipid, but other strategies exist for foraging and storing lipid in other species of fish. The patterns of molecular speciation of phospholipids in the tissues of cod described here therefore may not be representative of all species. Many laboratory studies with fish and other animals have shown that dietary lipid directly influences the fatty acid composition of tissue lipids (1). However, it has proved very difficult to deplete neural tissues of essential polyunsaturated fatty acids in mammals (1–3). The presence of large amounts of di22:6 glycerophospholipids in the retinas of a wide range of animal species suggests a special role for these molecules. It has been proposed that these unique lipids play a structural role by interacting with rhodopsin in the ROS membrane while also maintaining a very fluid membrane in which conformational changes can occur during the excitation cycle (29). The pigment epithelium of the eye of many teleost fish has a reflecting layer which consists of lipid spherules containing almost exclusively tridocosahexaenoylglycerol (30). This unique molecule could most easily be synthesized from a di22:6 glycerophospholipids.

Recently very long chain PUFA (VLCPUFA), with up to 36 carbons and six double bonds, of both the n-6 and n-3 series have been found in testes (31,32) and particularly in PC from retina (26). A survey of very long chain PUFA in retina from a variety of animal species found them to be present in all systems examined, including cod (26). The latter study also found extremely high levels of 22:6n-3 in cod retina and suggested a preponderance of di22:6 molecular species in this tissue (26), as was confirmed in the present study. The very long chain PUFA are esterified to the *sn*-1 position of PC with 22:6n-3 at the *sn*-2 position. Up to a third of PC from bovine ROS was found to consist of such VLCPUFA/22:6 species (29). The two unknowns found here in PC from cod retina behaved in a manner consistent with molecules containing VLCPUFA. However, the unknowns in PC from cod brain were different and did not appear to fit this pattern.

The roles of particular fatty acids in biomembrane structure has been the subject of much experimental work and debate (33,34). Molecular speciation of phospholipid classes from different tissues has shown surprising specificity indicating defined roles for some of these phospholipid species in certain membranes. However, the factors that make individual molecular species suited to particular biological roles, and the different tissue specificities of the enzymes involved in their synthesis and maintenance in the biomembrane remain to be elucidated.

[a]Species in italics have defined *sn*-1 and *sn*-2 fatty acid distributions. Only one fatty acid combination is given for those species with two equally probable positional isomers. In practice it is only possible to resolve molecular species with Log_{10} (RRT × 10) values differing by more than 0.02.

Diacetone-D-glucosyl-3-*O*-(*N,N*-diethylamido)-thiophosphates of the Lipid-Soluble Vitamins D_2, D_3 and E

Stephan D. Stamatov[a,*] and **Salo Gronowitz**[b]

[a]Department of Organic Chemical Technology, University of Plovdiv, Bulgaria and [b]Division of Organic Chemistry 1, University of Lund, Chemical Center, Sweden

The acyclic triamides of phosphorous acid, after appropriate activation, offer a number of advantages over conventional reagents when biologically active lipids are to be phosphorylated. The hexaethyltriamide of phosphorous acid activated by addition of iodine at the optimum molar ratio of 1.05:0.05 was used as phosphorylating reagent to synthesize diacetone-D-glucosyl-3-*O*-(*N,N*-diethylamido)thiophosphates of ergocalciferol, cholecalciferol and DL-α-tocopherol in a "one-pot" procedure in overall yields of 83–87%. The high selectivity of the phosphorylation at the monoester formation stage permits the direct synthesis of asymmetrical diesters. Anisochronicity was detected in the ^{13}C and ^{31}P nuclear magnetic resonance spectra of the thiophosphates synthesized. The compounds represent new types of glycophospholipid structures which, in addition to carbohydrate and a phosphagen fragment, contain a lipid-soluble vitamin.
Lipids 26, **574–577 (1991).**

Although lipid-soluble D and E vitamins are considered essential for living organisms, their physiological functions have still not been conclusively determined. As a result, the synthesis of new phospholipids from steroids and tocopherols that can be used as models has received increasing attention in recent years (1–7). The synthesis of derivatives in which a carbohydrate fragment and a lipid-soluble vitamin are structurally linked has not yet been considered. Such compounds may be of interest for biochemical and pharmacological studies.

The present paper deals with the synthesis of diacetone-D-glucosyl-3-*O*-(*N,N*-diethylamido)thiophosphate derivatives of vitamins D_2, D_3 and E. These compounds represent a new glycophospholipid structure containing a phosphagen fragment and sulfur bonded to phosphorus (Fig. 1).

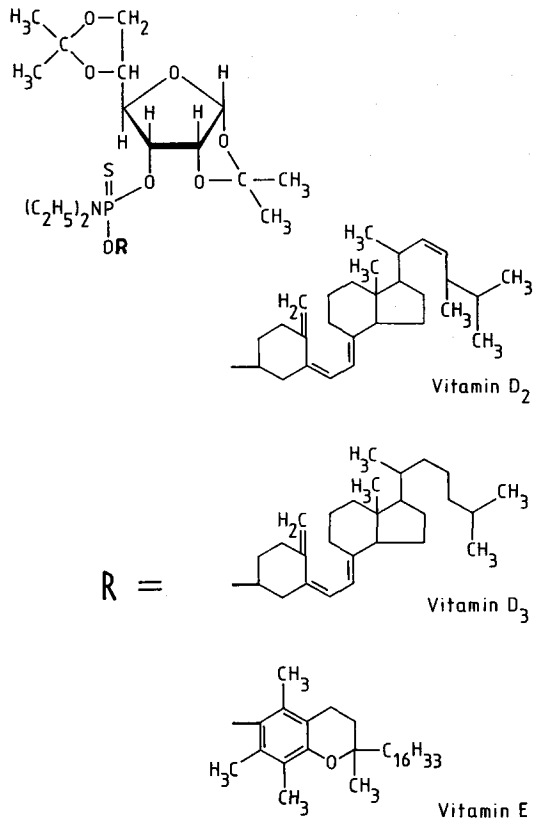

FIG. 1. Glucoamidothiophosphates of the vitamins D_2 (ergocalciferol), D_3 (cholecalciferol) and E (DL-α-tocopherol).

MATERIALS AND METHODS

Tris (*N,N*-diethyl)amide of phosphorous acid **1** (Schemes 1, 2 and 3) was prepared and freshly distilled as previously described (8). Ergocalciferol **a**, cholecalciferol **b**, DL-α-tocopherol **c** (Merck, Darmstadt, Germany), diacetone-D-glucose **d** (Fluka, Buchs, Switzerland) and all other reagents (Janssen, Stockholm, Sweden) were better than 98% pure. Benzene (Merck) was dried over sodium and freshly distilled. Reaction conditions were kept strictly anhydrous.

All processes were routinely monitored by analytical thin-layer chromatography (TLC) on pre-coated aluminum sheets of Silica Gel 60 F_{254} (Merck) using chloroform as the mobile phase. High-performance liquid chromatography (HPLC) was carried out (LDC Consta Metric III system, equipped with LKB 2142 Refractive Index Detector, Bromma, Sweden) using a Nucleosil silica gel column (500 × 10 mm) and n-heptane/ethyl acetate (8:2, v/v) as mobile phase.

^{13}C nuclear magnetic resonance (NMR) spectra were recorded on a Varian XL-300 spectrometer (Varian Assoc., Palo Alto, CA) at 75.43 MHz. ^{13}C chemical shifts are reported in ppm relative to tetramethylsilane (TMS). ^{31}P NMR spectra were recorded on the same instrument at 121.42 MHz. ^{31}P chemical shifts are reported in ppm relative to 85% phosphoric acid (external), where a positive sign is downfield from the standard. Infrared (IR) spectra were recorded on a Perkin-Elmer FT-IR 1750 (Perkin-Elmer, Norwalk, CI) spectrometer. Peak positions are reported in cm^{-1}. For **1aS–1cS** and **1adS–1cdS**, satisfactory microanalyses were obtained: C, ± 0.20; H, ± 0.11; P, ± 0.10; and S, ± 0.12.

*Ergocalciferyl-3-*0-bis(N,N-*diethylamido)thiophosphate* **(1aS)** *(representative procedure).* A mixture of iodine (0.025 g, 0.1 mmol) and the tris(*N,N*-diethyl)amide of

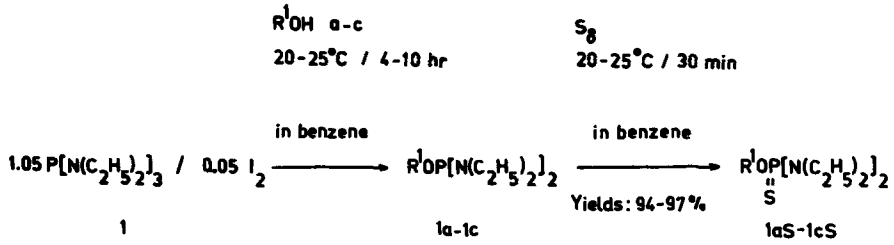
phosphorous acid (1; 0.519 g, 2.1 mmol) in benzene (50 mL) was heated at 75°C in a stream of argon until the precipitate dissolved (about 15 min). The solution was cooled to room temperature (20–25°C), ergocalciferol (**a**; 0.793 g, 2.0 mmol) was added, and the reaction mixture was kept under these conditions for 4 hr to give **1a**. Sulfur (0.067 g, 2.1 mmol) was then added, and the mixture was stirred for 30 min. The solvent was removed under vacuum and the thiophosphate **1aS** was isolated by HPLC in analytically pure form. Yield of **1aS**: 1.17 g (97%); n_D^{40} = 1.5220; R_f($CHCl_3$) 0.80; $C_{36}H_{63}N_2OPS$ (603.1). ^{13}C NMR ($CDCl_3$) δ 12.4 ppm (*s*, C-18); 17.9 (*s*, C-28); 19.9 (*s*, C-26); 20.2 (*s*, C-27); 21.4 (*s*, C-21); 72.7 (*d*, C-3, J = 4 Hz); 108.2, 112.6 (each *s*, C-19); 116.9, 118.4 (each *s*, C-7); 121.5, 122.9 (each *s*, C-6); 132.3 (*s*, C-23); 135.3, 135.4 (each *s*, C-8); 136.2 (*s*, C-22); 141.8, 143.9 (each *s*, C-5); 145.8, 149.8 (each *s*, C-10): ergocalciferyl-3-*O*-fragment; 13.9 (*m*, CH_3CH_2N); 40.4 (*m*, CH_2N). ^{31}P NMR ($CDCl_3$) δ 77.2, 77.4 ppm (each *s*). IR (KBr, film) ν 3030 (CH=); 1645 (C=C); 1023, 816 (PO-C, P-OC); 732 (P-N); 695 cm^{-1} (P=S).

Cholecalciferyl-3-O-bis(N,N-diethylamido)thiophosphate (**1bS**). The derivative **1bS** was synthesized using cholecalciferol (**b**; 0.769 g, 2.0 mmol) and then purified in the same way as described for **1aS**. Yield of **1bS**: 1.13 g (96%); n_D^{40} =1.5189; R_f($CHCl_3$) 0.78; $C_{35}H_{63}N_2OPS$ (591.1). ^{13}C NMR ($CDCl_3$) δ 12.2, 12.3 ppm (each *s*, C-18); 19.1 (*s*, C-21);22.8 (*s*, C-26); 23.1 (*s*, C-27); 72.6, 73.5 (each *d*, C-3, J=4 Hz);108.2, 112.6 (each *s*, C-19); 116.9, 118.3 (each *s*, C-7); 121.5, 122.9 (each *s*, C-6); 135.2, 135.3 (each *s*, C-8); 141.8, 143.9 (each *s*, C-5); 145.7, 149.8 (each *s*, C-10): cholecalciferyl-3-*O*-fragment; 14.4 (*m*, CH_3CH_2N); 40.3 (*m*, CH_2N). ^{31}P NMR ($CDCl_3$) δ 75.6, 75.8 ppm (each *s*). IR (KBr, film) ν 3030 (CH=); 1642 (C=C); 1023, 813 (PO-C, P-OC); 729 (P-N); 690 cm^{-1} (P=6).

DL-α-Tocopheryl-6-O-bis(N,N-diethylamido)thiophosphate (**1cS**). The compound **1cS** was synthesized using DL-α-tocopherol (**c**; 0.861 g, 2.0 mmol), at 20–25°C for 10 hr, and then purified in the same way as described for **1aS**. Yield of **1cS**: 1.20 g (94%); n_D^{20} = 1.5140; R_f ($CHCl_3$) 0.89; $C_{37}H_{69}N_2O_2PS$ (637.2). ^{13}C NMR ($CDCl_3$) δ 12.8 ppm (*s*, CH_3-5); 15.4 (*s*, CH_3-7); 15.8 (*s*, CH_3-8); 21.7 (*s*, C-4); 21.9 (*s*, C-3); 23.3 (*s*, CH_3-2); 75.4 (*s*, C-2); 144.1 (*d*, C-6, J=9 Hz); 149.3 (*s*, C-9): nucleus; 20.4 (*m*, C-13, CH_3-12); 23.3 (*s*, CH_3-4, CH_3-8): chain, DL-α-tocopheryl-6-*O*-fragment; 14.5 (*d*, CH_3CH_2N, J=4 Hz); 41.5 (*d*, CH_2N, J=4 Hz). ^{31}P NMR ($CDCl_3$) δ 72.5 ppm (*s*). IR (KBr, film) ν 1249, 840 (PO-C, P-OC_{aryl}); 730 (P-N); 690 cm^{-1} (P=S).

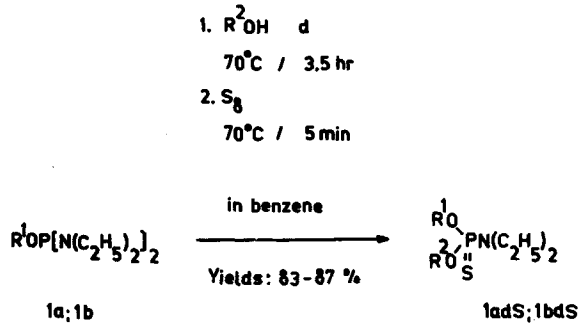
Ergocalciferyl-3-O-(diacetone-D-glucosyl-3-O-)-(N,N-diethylamido)thiophosphate (**1adS**) *(representative procedure)*. The intermediate **1a** was prepared using ergocalciferol (**a**; 0.793 g, 2.0 mmol) as described for **1aS**. Diacetone-D-glucose (**d**; 0.521 g, 2.0 mmol) was then added and the mixture was heated at 70°C for 3.5 hr. Transformation to the thiophosphate **1adS** was accomplished by reaction with sulfur (0.067 g, 2.1 mmol) at 70°C for 5 min. The solvent was removed under vacuum, and the compound was isolated by HPLC in pure form. Yield of **1adS**: 1.37 g (87%); n_D^{40} = 1.5053; R_f ($CHCl_3$) 0.52; $C_{44}H_{72}NO_7PS$ (790.2). ^{13}C NMR ($CDCl_3$) δ 12.5 ppm (*m*, C-18); 18.0 (*s*, C-28); 19.9 (*s*, C-26); 20.2 (*s*, C-27); 74.9 (*m*, C-3); 116.5, 118.1 (each *d*, C-7, J=9 Hz); 121.6, 123.0 (each *d*, C-6, J=9 Hz): ergocalciferyl-3-*O*-fragment; 26.5 (*m*, C-11, C-12); 26.9 (*m*, C-8, C-9); 79.2, 80.9 (each *d*, C-3, J=9 Hz); 83.6, 83.9 (each *s*, C-2); 105.4, 105.6 (each *s*, C-1); 109.1, 109.4 (each *s*, C-7); 112.1 (*s*, C-10): glucosyl-3-*O*-fragment; 14.3 (*m*, CH_3CH_2N); 40.4 (*m*, CH_2N). ^{31}P NMR ($CDCl_3$) δ 73.2 ppm (*m*). IR (KBr, film) ν 1636 (C=C); 1024, 818 (PO-C, P-OC); 731 (P-N); 700 cm^{-1} (P=S).

Cholecalciferyl-3-O-(diacetone-D-glucosyl-3-O-)-(N,N-diethylamido)thiophosphate, (**1bdS**). The compound **1bdS** was prepared using cholecalciferol (**b**; 0.769 g, 2.0 mmol) and diacetone-D-glucose (**d**; 0.521 g, 2.0 mmol) as described for **1adS**. Yield of **1bdS**: 1.29 g (83%); n_D^{40} = 1.4975; R_f ($CHCl_3$) 0.50; $C_{43}H_{72}NO_7PS$ (778.2). ^{13}C NMR ($CDCl_3$) δ 12.2 ppm (*m*, C-18); 19.2 (*s*, C-21); 22.8 (*s*, C-26); 23.0 (*s*, C-27); 76.0 (*m*, C-3); 116.7, 118.0 (each *s*, C-7); 135.1, 135.3 (each *s*, C-8): cholecalciferyl-3-*O*-fragment; 26.3 (*m*, C-11, C-12); 26.7 (*m*, C-8, C-9); 79.0, 80.7 (each *d*, C-3, J=9 Hz); 83.7 (*m*, C-2); 105.0, 105.1 (each *s*, C-1); 109.0, 109.2 (each *s*, C-7); 112.0, 112.1 (each *s*, C-10): glucosyl-3-*O*-fragment; 14.0 (*m*, CH_3CH_2N); 40.0 (*m*, CH_2N). ^{31}P NMR ($CDCl_3$) δ 73.1 ppm (*m*). IR (KBr, film) ν 1637 (C=C); 1025, 817 (PO-C, P-OC); 730 (P-N); 705 cm^{-1} (P=S).



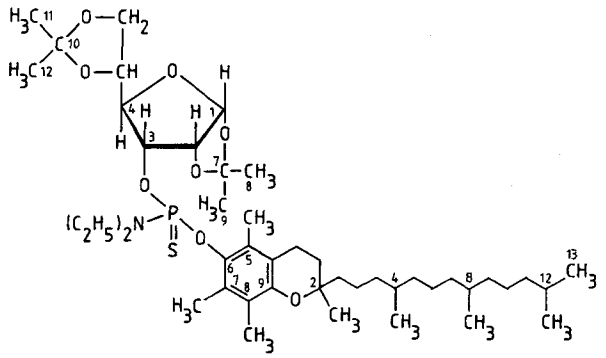
DL-α-Tocopheryl-6-O-(diacetone-D-glucosyl-3-O-)-(N,N-diethylamido)thiophosphate (**1cdS**). The thiophosphate **1cdS** was prepared by first using diacetone-D-glucose (**d**; 0.521 g, 2.0 mmol) (70°C; 15 min) and then DL-α-tocopherol (**c**; 0.861 g, 2.0 mmol) (second step: 70°C; 5 hr) in the same way as described for **1adS**. Yield of **1cdS**: 1.38 g (84%); n_D^{40} = 1.4923; R_f ($CHCl_3$) 0.44; $C_{45}H_{78}NO_8PS$ (824.3). ^{13}C NMR ($CDCl_3$) δ 11.9 ppm (*s*, CH_3-5); 14.8, 14.9 (each *s*, CH_3-7); 15.2 (*s*, CH_3-8); 74.8 (*s*, C-2); 141.7 (*d*, C-6, J=9 Hz); 148.5 (*d*, C-9, J=2 Hz): nucleus; 19.6 (*m*, C-13, CH_3-12); 22.5, 22.6 (each *s*, CH_3-4, CH_3-8): chain, DL-α-tocopheryl-6-*O*-fragment; 26.1 (*s*, C-11, C-12); 26.5 (*m*, C-8, C-9); 79.5 (*d*, C-3, J=5 Hz); 80.7 (*d*, C-4, J=8 Hz); 104.7 (*s*, C-1); 108.9 (*s*, C-7); 112.0 (*s*, C-10): glucosyl-3-*O*-fragment; 13.9 (*m*, CH_3CH_2N); 40.6 (*m*, CH_2N). ^{31}P NMR ($CDCl_3$) δ 73.1 ppm (*m*). IR (KBr, film) ν 1240, 840 (PO-C, P-OC_{aryl}); 750 (P-N); 635 cm^{-1} (P=S).

RESULTS AND DISCUSSION

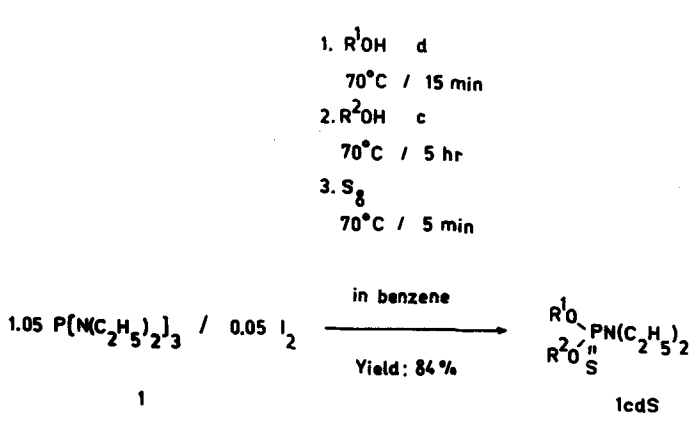


It is well known that the phosphorylation of lipids by phosphorus oxychloride, chlorophosphates and other conventional reagents can frequently be accompanied by side reactions, *e.g.*, nucleophilic substitution at the carbon with the phosphatoxyl group, molecular rearrangements, eliminations, etc. (5). Use of acyclic triamides of phosphorous acid after activation with iodine avoids these problems (5,7,8). In the present study, the tris(*N,N*-diethyl)-amide of phosphorous acid **1** (Schemes 1, 2 and 3) with iodine at an optimal molar ratio of 1.05:0.05 was used as reagent. Ergocalciferol **a**, cholecalciferol **b**, DL-α-tocopherol **c**, and diacetone-D-glucose **d** were selected as substrates (Schemes 1, 2 and 3).

The synthesis was carried out according to a method proposed recently (8). The activated phosphamide **1** was reacted with the vitamin **a-c** in stoichiometric amounts at room temperature (20–25°C) for 4 hr (10 hr for DL-α-tocopherol) to give the *bis*(*N,N*-diethylamido)phosphite **1a-1c** in close to quantitative yield. This was proven by transformation of **1a-1c** to the corresponding thiophosphate derivatives **1aS-1cS** (Scheme 1).



The high selectivity of the process at the monoester formation stage permits the next step, *viz.*, the synthesis of unsymmetrical diesters, to be performed as a "one-pot" procedure. In order to avoid extended reaction times at



SCHEME 1. For a, 1a and 1aS: R^1 = ergocalciferyl; b, 1b and 1bS: R^1 = cholecalciferyl; c, 1c and 1cS: R^1 = DL-*α*-tocopheryl.

SCHEME 2. For 1a and 1adS: R^1 = ergocalciferyl; 1b and 1bdS: R^1 = cholecalciferyl; d, 1adS and 1bdS: R^2 = diacetone-D-glucosyl.

SCHEME 3. For d and 1cdS: R^1 = diacetone-D-glucosyl; c and 1cdS: R^2 = DL-*α*-tocopheryl.

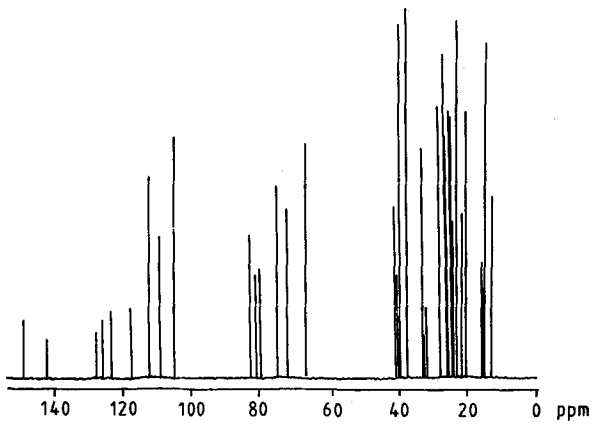


FIG. 2. Proton-decoupled 75.43 MHz ^{13}C NMR spectrum of DL-*α*-tocopheryl-6-*O*-(diacetone-D-glucosyl-3-*O*-), (*N,N*-diethylamido)thiophosphate.

room temperature, the second P-O bond was introduced by moderate heating. Thus, the consecutive treatment of the crude intermediate **1a**, **1b** with an equivalent quantity of diacetone-D-glucose **d** and sulfur at 70°C for 3.5 hr and 5 min, respectively, afforded the thiophosphate derivative **1adS**, **1bdS** in high yield (Scheme 2). An approach which used diacetone-D-glucosyl-3-*O*-*bis*-(*N,N*-diethylamido)phosphite as the initial key intermediate was not effective because transesterification occurred.

Treatment of the DL-*α*-tocopheryl-6-*O*-*bis*(*N,N*-diethylamido)phosphite **1c** with diacetone-D-glucose **d** at 70°C led to displacement of the tocopheryl radical. Thus, an alternative "one-pot" scheme with diacetone-D-glucosyl-3-*O*-*bis*(*N,N*-diethylamido)phosphite as initial key intermediate was used in the synthesis of the DL-*α*-tocopheryl-6-*O*-(diacetone-D-glucosyl-3-*O*-)-(*N,N*-diethylamido)thiophosphate **1cdS** (Scheme 3; Fig. 2).Conclusions in regard to the structures of the compounds synthesized were drawn based on spectral and microanalytical data.

The thiophosphates reported here were difficult to analyze by ^1H NMR. Individual signals were found to overlap in the extremely complex proton spectra. Thus, structure elucidation heavily relied on ^{13}C NMR data, where signal assignments were based mainly on broad band decoupling, off-resonance coherent decoupling and chemical shift comparison of the starting substrates **a-d** with their thiophosphate derivatives **1aS-1cS** and **1adS-1cdS**. Two-dimensional ^1H-^{13}C correlation NMR

techniques were also used to gather additional information on the tocopherol structures.

Multiplicities were observed for the phosphorus ester carbons C-3 and C-6. Other anisochronicities (9) detected in the ^{13}C NMR spectra (for example, **1aS**: two singlets, 108.2, 112.6 ppm, C-19; **1bS**: two singlets, 12.2, 12.3 ppm, C-18; etc.) were attributed to diastereoisomerism. The multiplicities observed in the ^{31}P NMR spectra (**1aS**: two singlets, 77.2, 77.4 ppm; **1adS**: multiplet, 73.2 ppm; **1cdS**: multiplet, 73.1 ppm; etc.) agree with the latter interpretation. The absence of anisochronicities in the ^{13}C NMR spectra of the starting substrates **a-d** is also consistent with this view. Our attempts to separate the indicated isomers by HPLC were not successful.

ACKNOWLEDGMENT

The authors thank J. Glans for recording the NMR spectra.

METHOD

Ion-Pair High-Performance Liquid Chromatography of Bile Salt Conjugates: Application to Pig Bile

Véronique Legrand-Defretin[a,*], Catherine Juste[a], Robert Henry[b] and Tristan Corring[a]

[a]Laboratoire d'Ecologie et de Physiologie du Système Digestif, C.R.J.-I.N.R.A., 78350 Jouy-en-Josas, France, and [b]Laboratoire de Chimie Organique, I.N.S.A. Bâtiment 403, 69621 Villeurbanne, France

The high-performance liquid chromatographic separation and quantitation of conjugated bile salts from pig bile is reported. Synthetic standards and bile samples were chromatographed on a C_{18} reversed phase column using acetonitrile/water/tetrabutyl ammonium phosphate as an isocratic mobile phase at a flow rate of 1 mL/min. Detection of the ion-pairs was at 214 nm. The method permits efficient separation of all conjugated pig biliary bile salts without prior modification or treatment of the samples. Analysis of 12 pig biles showed that 85% of the bile salts are conjugated to glycine. The three main conjugated bile salts were glyco-3α,6α,7α-trihydroxy-5β-cholanoic acid (GHC), glyco-3α,7α-dihydroxy-5β-cholanoic acid (GCDC), and glyco-3α,6α-dihydroxy-5β-cholanoic acid (GHDC). Glyco-3α-hydroxy-6-oxo-5β-cholanoic acid (G3α6oxo), tauro-3α,7α-dihydroxy-5β-cholanoic acid (TCDC), tauro-3α,6α,7α-trihydroxy-5β-cholanoic acid (THC), and tauro-3α,6α-dihydroxy-5β-cholanoic acid (THDC) were found to contribute each for 4 to 5% ot the total. An excellent correlation was found between the sum of conjugated bile salts quantitated by high-performance liquid chromatography (HPLC) and values obtained by conventional enzymatic assay. Simplicity, efficiency and relative rapidity of the method render it suitable for routine analyses.

Lipids 26, 578–583 (1991).

In recent years, high-performance liquid chromatography (HPLC) has been applied to the analysis of bile acids in human (1–9), rat (1,10), dog (9), rabbit (9), and hamster (11) bile. Although the pig is considered an interesting model for biomedical research (12–20), the analysis of pig bile has not been previously reported. Among the species studied, pig bile is closest to man with respect to bile salt/cholesterol and phospholipid/cholesterol ratios (12,13).

The present paper describes a reliable method for the routine analysis of biliary bile salts from pig. Among various chromatographic systems available to-date, some (2–4) are rather time-consuming because they require prior hydrolysis and derivatization, or group separation of bile salts, and thus do not offer substantial improvements over earlier gas and thin-layer chromatographic techniques. Moreover, decomposition of conjugated bile salts can occur. We therefore retained only those steps of earlier techniques that do not cause these disadvantages. They include a reversed-phase separation either under strict pH control of the mobile phase (1,5,7,11) or addition of ion-pair chromatographic reagents (6,8,9,21). The latter approach seems more appropriate for routine analysis since the problem of strict pH control is circumvented. We applied this approach (6,9) to the analysis of pig bile, which contains the unusual hyocholic, hyodeoxycholic, and 3α-hydroxy-6-oxo-5β-cholanoic conjugates, and we optimized the isocratic high-performance liquid chromatographic separation of pig biliary bile salts. Using this method, it was possible for the first time to quantitatively determine all bile salt species in pig bile.

MATERIALS AND METHODS

Equipment. The HPLC equipment used was a Beckman high-performance liquid chromatograph (Model 110-A Pump, Model SpH-125 FIX Autoinjector with a 20-μL sample loop, and a Model 160 Detector, Beckman Instruments, Palo Alto, CA) equipped with a Model CR-3A Integrator (Shimadzu, Tokyo, Japan).

Reagents. All reagents were of HPLC grade. Water was purchased from Farmitalia Carlo Erba (Milano, Italy). Acetonitrile, methanol, and ethanol were purchased from Merck (Darmstadt, Germany). Tetrabutyl ammonium phosphate 0.5 M (TBAP) was obtained from Regis Chemical (Morton Grove, IL). Sep-Pak C_{18} cartridges (Waters Associates, Milford, MA) were used to purify the bile samples.

Glycocholate (GC), taurocholate (TC), glycochenodeoxycholate (GCDC), taurochenodeoxycholate (TCDC), glycodeoxycholate (GDC), and taurodeoxycholate (TDC) were of the highest purity available from Sigma (St. Louis, MO). Taurohyocholate (THC) was kindly provided by Dr. J.Cl. Montet (INSERM U-31, Marseille, France).

Synthesis of bile salts. Glycohyocholate (GHC), glycohyodeoxycholate (GHDC), and taurohyodeoxycholate (THDC) were synthesized according to the method of Tserng *et al.* (22). Attempts to synthesize glyco-3α-hydroxy-6-oxo-5β-cholanoic acid (G3α6oxo) from 3α-hydroxy-6-oxo-5β-cholanoic acid led to a mixture of epimerization products in which the 5α-isomers predominated. Epimerization was avoided by oxidizing GHDC with Jones' reagent (23).

For this purpose, Jones' reagent (1.33 mmol in 1.23 mL) was added to a solution of GHDC (2 mmol) in acetone (50 mL) at 0°C under stirring. The mixture was left for 1 hr at 0°C, then 2 drops of isopropanol were added. The mixture was then poured into ice-water (200 mL). It was successively extracted with ethyl acetate (3 times, 150 mL each), washed with water (50 mL) and a saturated NaCl

solution (20 mL), and evaporated to dryness. A white solid residue (520 mg) was obtained which showed two main fractions (Rf 0.62 and 0.55) in thin-layer chromatography (Silicagel 60 F, Merck; eluent, chloroform/ethanol/ethyl acetate/acetic acid/water, 8:6:5:1:1, by vol, Solvent A; spray reagent, phosphomolybdic acid). The residue (520 mg) was subjected to column chromatography on silica gel 60 (100 g, 70-230 mesh, Merck). Elution with chloroform/ethanol/ethyl acetate/water (8:6:5:1, by vol) and evaporation to dryness gave G3α6oxo (57 mg) as a white and very hygroscopic solid (Rf 0.55, using Solvent A). Final purity (99%) was checked by gas chromatography after hydrolysis with cholylglycine hydrolase.

Operating conditions. An Ultrasphere IP column (particle size 5 μm, 250 × 4.6 mm i.d. Beckman Instruments) was used as a stationary phase. Loss of resolution of the column was observed with time, but the column could be regenerated by washing it successively with water, methanol, acetonitrile/tetrahydrofuran (50:50, v/v), methanol, and finally again with water. The mobile phase was prepared by mixing 65 mL water, 35 mL acetonitrile, and 1 mL TBAP 0.5 M. The flow rate was 1 mL/min. Detection was at 214 mm and 0.1 absorbance units full scale (AUFS).

Samples. Mixtures of synthetic bile salts were prepared from pure bile salts dissolved in the eluent.

Choledocal bile samples were obtained from 12 healthy castrated large white pigs (46.7 ± 1.9 kg at the beginning of the experiment, Experimental Stock Farm, Institut National de la Recherche Agronomique, La Minière, France), fed a standard diet (dry matter, 87.80%; crude protein, 14.87%; fat, 3.44% of fresh matter; energy value, 3.85 kcal/g of fresh matter). Pigs were fitted with biliary and upper duodenal fistulas to exteriorize the enterohepatic circulation according to a method previously described (24,25). A representative 24-hr sample for each of the 12 pigs was obtained by continuous 2% bile derivation over a day-night cycle. This method of bile collection does not affect the enterohepatic circulation of bile salts in pig (25). Following these collection periods, bile restitution to the duodenum was discontinued (13). Biliary collection was then followed up and 12 samples with low bile salt concentrations were collected. All bile samples were frozen at −80°C until analysis.

Bile purification was done as follows (11): 50 to 150 μL of bile were diluted with 2 mL of 0.5 M phosphate buffer (pH 7.0), and the solution was passed through a Sep-Pak C_{18} cartridge previously washed with 3 mL of methanol and 6 mL of water. The cartridge was then washed with 8 mL of water and 2 mL of 1.5% ethanol. Finally, bile salts were eluted with 5 mL of the mobile phase, and 20 μL of the solution was injected into the HPLC.

Enzymatic analysis. Total bile salt in bile was determined using 3α-hydroxysteroid dehydrogenase (Sigma) according to Turley and Dietschy (26).

Expression of results and statistical analysis. Data were expressed as means ± SEM. All relative retention times (RRT) were determined with respect to GCDC. All relations among the data (peak area *versus* amount of bile salts injected; HPLC determination *versus* enzymatic determination) were explored using correlation and linear regression analysis (least square method).

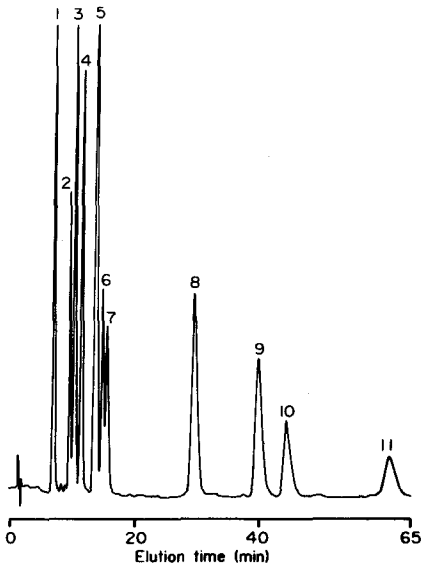

FIG. 1. Elution profile of a standard solution of pure bile salts. Chromatographic conditions: stationary phase, column Ultrasphere IP; solvent, water/acetonitrile/TBAP (65:35:1, v/v/v); flow-rate, 1 mL/min; detector wavelength, 214 nm, 0.1 AUFS. RESULTS

Separation of synthetic conjugated bile salts. A representative chromatographic tracing of purified standards to serve as reference is shown in Figure 1. Elution of the 11 bile salt conjugates tested in this study was completed in 1 hr and the separation achieved was very sharp for each. A close similarity in chromatographic behavior was observed between the glyco- and tauroconjugates. Indeed, for both glyco- and tauroconjugates the elution order was as follows: HC, HDC, C, CDC, DC. Glycine conjugates always emerged before their taurine analogues. Table 1 lists the RRT of the 11 conjugated bile salts studied.

Quantification of bile salts. The calibration curves for all bile salt conjugates are shown in Figure 2. At 214 nm, the molar absorbance of tauroconjugates on one hand, and

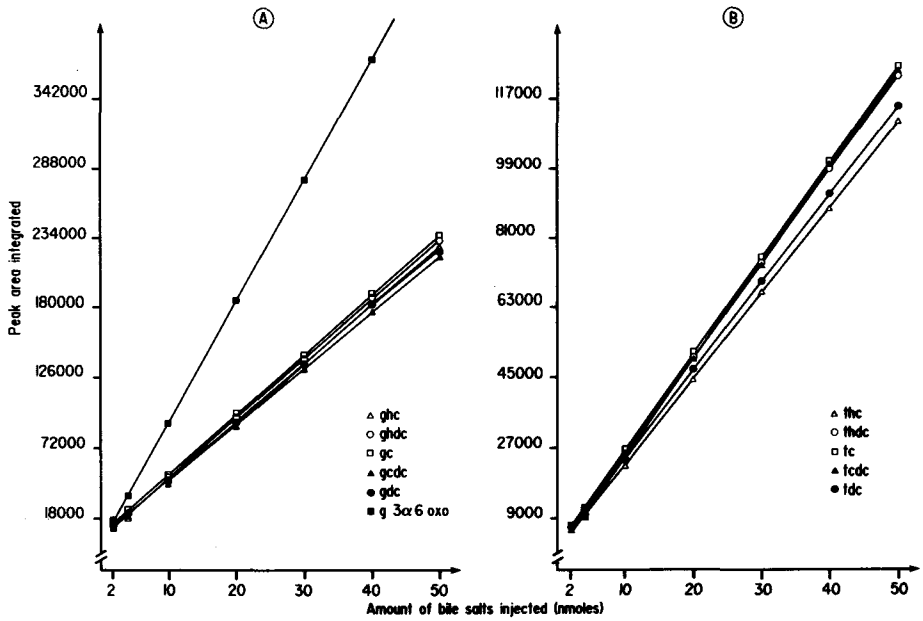

FIG. 2. Amounts of bile salt standards relative to the peak integrated areas for glycoconjugates (A) and tauroconjugates (B). Correlation coefficients of linear regression ranged from 0.963 to 0.999 for glycoconjugates and 0.995 to 0.999 for tauroconjugates. Chromatographic conditions as in Figure 1.

all glycoconjugates except G3α6oxo on the other were in the same range. Moreover, the molar extinction coefficient of a glycoconjugate was always higher than the corresponding tauroconjugate. As expected, the absorbance of the ketonic G3α6oxo was higher than of other glycoconjugates.

Within the range of concentrations tested (0.1 to 2.5 mM), all peak areas were proportional to the amount of bile salt injected into the HPLC. At 0.1 AUFS, the detection limit was 0.5 nmol for GHC, THC, GHDC, GC, GCDC, and GDC, and 1 nmol for THDC, TC, TCDC, and TDC. Correlation coefficients (r values) of linear regression ranged from 0.963 to 0.999 ($P<0.001$) and from 0.995 to 0.999 ($P<0.001$) for glycine and taurine conjugates, respectively.

To measure recoveries, standard samples of pure conjugated bile salts were added (10 nmol) to pig bile and subjected to HPLC after bile purification as described above. RRT were not affected by the conjugated bile salts present in the sample. Mean recoveries ranged from 89 to 102% (Table 2).

Biliary sample preparation. To test the recovery of bile salts after preparation of biliary samples with the Sep-Pak C_{18} cartridges, 10 bile samples were subjected to enzymatic assay of total bile salt concentration before and after the purification procedure. The mean recovery was 97 ± 1%. A special vacuum apparatus (Sep-Pak Cartridge Rak, Waters Associates) was employed to facilitate the extraction of a large number of bile samples. Ten cartridges were then run simultaneously for 20 min. This made the procedure feasible for routine analysis.

Analysis of pig bile. A representative separation of bile salts from pig bile is shown in Figure 3. Seven bile salt conjugates were identified in all chromatograms: GHC, THC, GHDC, G3α6oxo, THDC, GCDC, and TCDC. A minor unidentified peak (peak X, Fig. 3) occasionally appeared (only in chromatograms with high proportion of G3α6oxo) between TC and GCDC. Its RRT was 0.661 ± 0.001.

TABLE 2

Recovery of Bile Salts Added[a] to Pig Bile[b]

Bile salt (n)[c]	Recovery (%)
Glycohyocholate (15)	98
Taurohyocholate (10)	102

Glycocholate (15)	93
Taurohyodeoxycholate (10)	96
Taurocholate (10)	89
Glycochenodeoxycholate (15)	98
Glycodeoxycholate (15)	100
Taurochenodeoxycholate (10)	99
Taurodeoxycholate (10)	92

[a]Bile samples were supplemented with 10 nmol of each bile salt.
[b]Chromatographic conditions as in Figure 1.
[c]Number of assays.

Twelve choledocal bile samples collected from twelve pigs over a day-night cycle were analyzed according to the method developed. Table 3 shows that 85% of the bile salts found in porcine bile are conjugated to glycine. The primary bile salts, GHC and GCDC, are on average, the most abundant, comprising about 60% of the total. The dihydroxy-bile salt, GHDC, is only slightly less abundant (about 20% of the total). Respective proportions of these three main bile salts can, however, greatly differ between animals. G3α6oxo and the tauroconjugates, THC, THDC, and TCDC, each constitute about 4 to 5% of total bile salts measured (Table 3).

To check the chromatographic separation and quantita-

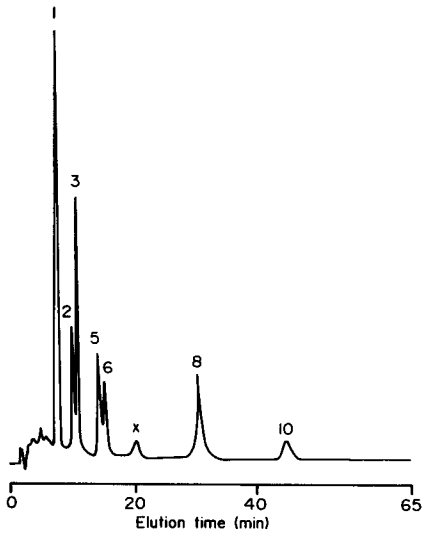

FIG. 3. Typical chromatogram of bile salts from normal pig bile. Peaks: 1 = GHC; 2 = THC; 3 = GHDC; 5 = G3α6oxo; 6 = THDC; 8 = GCDC; 10 = TCDC; X = unknown, see text. Chromatographic conditions as in Figure 1.

tion of bile salt conjugates in porcine bile, the summed value of individual bile salt concentrations obtained in HPLC was compared to enzymatically determined total bile salt concentration. This test was carried out on each of 24 samples which were collected in fistulated pigs with and without enterohepatic circulation in order to cover a wide range of bile salt concentrations. The slope and intercept of the regression line (Fig. 4) were 1.02 ± 0.01 and 0.77 ± 0.61, respectively. The correlation coefficient was 0.999 ($P<0.001$).

DISCUSSION

Addition of ion-pair chromatography reagent to the mobile phase allows better separation of ionic compounds and eliminates the problems of precise pH control in reversed phase HPLC (1,5,7,11). Thus in this study we developed a rapid, reproducible, and sensitive ion-pair technique for the simultaneous determination and quantitation of 11 bile salt conjugates. Particular attention was paid to the composition of the mobile phase (acetonitrile/water/counter-ion) in order to efficiently separate hyocholate and hyodeoxycholate conjugates. These bile salts had not been resolved before by HPLC in their conjugated forms (1,2,10).

Compared to reversed-phase chromatography (1,5,7,27), the addition of TBAP changes the elution sequence so that bile salts conjugated with glycine are eluted ahead of taurine conjugates. A reversed elution order for tauro- and glycoconjugates in reversed-phase and ion-pair HPLC systems has been observed previously (6,8,9,21), presumably due to differences in the interaction of bile salts and "ion-paired bile salts" with the stationary phase.

Disregarding the nature of conjugation, elution order of bile salt species, HDC, C, CDC, and DC, was identical with the order reported in reversed-phase chromatography (1,5,11,27). This has been discussed previously (28,29). The emergence of HC before C may be explained by the closer proximity of the 3α,6α,7α-hydroxyl groups than of the 3α,7α,12α-hydroxyl groups.

Linear regression between the amount injected and the peak area for each bile salt conjugate allows direct determination of concentrations. Due to our interest in measuring individual bile salt concentrations in pig bile (0.2 to 37.2 mM), no effort was made to extrapolate the standard curves to lower ranges of concentration. The detection limit was, however, 0.5 to 1 nmol which is within the range previously reported in ion-pair and reversed-phase HPLC (0.1 to 20 nmol, 1,5,7,11,27). To enhance detectability, more sophisticated techniques such as HPLC coupled with immobilized 3α-hydroxysteroid dehydrogenase column have been successful (10,30). Nevertheless, the expense involved limits the routine use of these techniques.

Knowledge about the profile of conjugated bile salts in pig bile remains fragmentary (14,20,31–37). The aim of the present work was to devise a rapid procedure that allows simultaneous determination and quantitation of glyco- and tauroconjugated bile salts present in pig bile. The use of a Sep-Pak cartridge allowed the direct and reproducible clean-up of bile samples without prior deproteinization. The elution profile of pig bile samples showed G3α6oxo and glyco- and tauroconjugates of the three bile salts, HC, HDC, and CDC. All these bile salts were separated in a single run while they had previously only been characterized separately by thin-layer and gas chromatography (14,31,33,34,36). Cholic and deoxycholic conjugates were not detected in pig bile, while one previous study on gallbladder porcine bile reported trace amounts of cholic acid (12). However, in the latter study, no 3α6oxo was detected. Surprisingly, pig hepatocytes in culture (20) were recently shown to synthesize small quantities of 3α,6β-dihydroxy-5β-cholanoic acid (murocholic acid, MC). With the present method, murocholic conjugates were shown to emerge with a relative retention time of 0.275 and 0.376 for glyco- and tauroconjugates, respectively, which is quite different from the relative retention times of all bile salt species identified in pig bile. 6-Epimerization of MC into HDC could prevent the secretion of MC into bile *in vivo*. One unknown bile salt, for which a reference standard was not available, appeared in very small amounts in some chromatograms. This compound may be tentatively assigned as the tauroconjugate of 3α6oxo as it fulfills the following criteria: (i) it appears only in chromatograms with high proportions of G3α6oxo; (ii) when the elution order of glyco- and tauroconjugates is juxtaposed, the unidentified peak emerges between TC and TCDC in the same manner as G3α6oxo emerges between GC and GCDC. Unfortunately, attempts to predict the RRT of T3α6oxo from a variance analysis of the RRT of the 11 standard bile salts (using the GENSTAT procedures, REGRE, FIT, and DROP) were unsuccessful. Confirmation of the identity of this compound as T3α6oxo is thus still necessary.

Quantitative determination of the bile salt spectrum for the 12 pigs clearly showed that, whatever the bile salt species, 83.7 to 86.0% of the material was conjugated with glycine. This is somewhat higher than reported in an earlier study (38). Especially high proportions of 6α-hydroxylated bile salts (GHC + THC = 38.6%, GHDC + THDC = 24.3%) were found in porcine bile. The pig is the only known species to exhibit this type of high 6α-hydroxylation activity although this pathway has been

TABLE 3

Bile Salt Composition in Pig Bile[a]

Pig	GHC (mM)	THC (mM)	GHDC (mM)	G3α6oxo (mM)	THDC (mM)	GCDC (mM)	TCDC (mM)

[a]Chromatographic conditions as in Figure 1. Choledocal bile samples were collected from 12 pigs as described in Materials and Methods.
[b,c,d]Means with a common superscript in the same row are not significantly different (P>0.05).

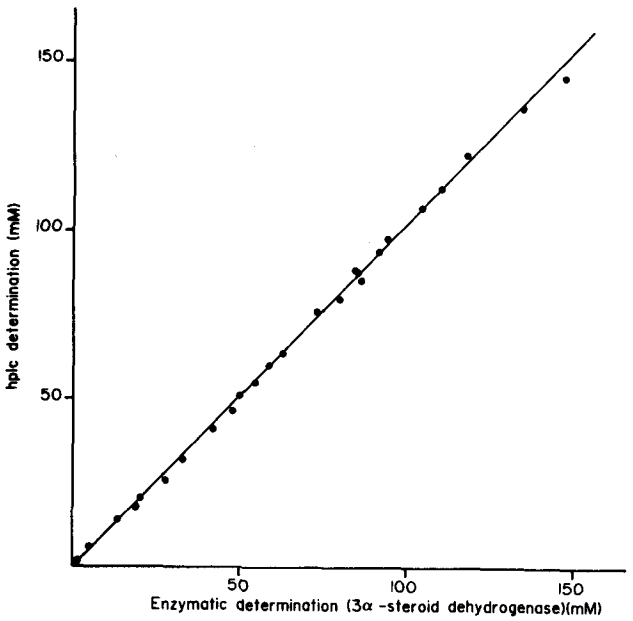

FIG. 4. Correlation between total bile salt concentrations in pig bile (n = 24) measured enzymatically and by summing the individual bile salt concentrations determined by HPLC. Slope (1.02 ± 0.01) not different from 1; intercept (0.77 ± 0.61) not different from 0; correlation coefficient r = 0.999 (P<0.001). Chromatographic conditions as in Figure 1.

shown to also exist in other species. Trace amounts of HC (<0.5%) and HDC (<1.5%) have been detected in rat bile (39). During the prenatal phase in man, 6α-hydroxylation of bile acid is a major metabolic pathway (40,41). Considerable repression of this activity then seems to occur, although certain mechanisms of derepression seem to become apparent in cases of cholestatic liver disease (42,43). The three main conjugated bile salts in porcine bile were GHC, GCDC, and GHDC. Although pigs were from the same breed and fed the same diet, appreciable differences were found in their respective proportions of GHC and GHDC. GCDC proportions were somewhat more constant. It is highly probable that the intestinal 7α-dehydroxylation of GHC in GHDC was more efficient in certain pigs. Another possible explanation might be hepatic regulation of the GHC/GHDC ratio. Although regulation through less active hepatic 7α-rehydroxylation of GHDC in GHC is not possible (34), other metabolic pathways may be involved. Indeed, GHDC may be generated by the liver, either through 6α-rehydroxylation of lithocholic acid, or through direct hepatic *de novo* synthesis, though the latter pathway still needs to be studied (37,44). The other bile salts (G3α6oxo and tauroconjugates) identified in this study each constitute less than 5.5% of total bile salts measured.

In summary, we showed that ion-pair HPLC is a simple and useful technique for the analysis of conjugated bile salts in pig bile. This method preserves the structural integrity of the conjugated bile salts since prior modification and treatment of the sample is avoided. The relative rapidity of the method renders it suitable for routine analysis. In our study it was possible to quantitatively determine the overall bile salt composition of pig bile within less than one hour using one mobile phase under isocratic conditions.

ACKNOWLEDGMENTS

The authors express their thanks to Dr. J.Cl. Montet, INSERM U-31, Marseille, France, for providing standard THC. They are grateful to A.M. Gueugneau for excellent technical assistance. Thanks are also due to G. Brachet, F. Cointepas, J. Weber, and T. Bourgeois for excellent animal management.

REVIEW

Sterol Biosynthesis Inhibitors: Their Current Status and Modes of Action[1]

E.I. Mercer
Department of Biochemistry, University College of Wales, Aberystwyth, Dyfed SY23 3DD, United Kingdom

The mechanism of each of the reactions in the post-squalene segment of the fungal and higher plant sterol biosynthetic pathway is outlined. The inhibitors of the enzymes catalyzing the reactions are described and how inhibition is brought about is explained in the areas where it is known.
Lipids 26, 584–597 (1991).

During the past twenty years, the sterol biosynthetic pathway has become of interest to agrochemical and pharmaceutical companies. The reason for this is that the primary fungitoxic effect of several classes of commercially-important fungicides has proved to be the inhibition of one or more of the enzyme catalyzing steps in sterol biosynthesis. These fungicides, now known as sterol biosynthesis inhibitors (SBI), were discovered by routine screening procedures. However, the realization that sterol biosynthesis in fungi is a prime target for fungicides, and the fear of the widespread appearance of resistance to the existing classes of SBI, has led to attempts to rationally design compounds that will inhibit other enzymes in the pathway in the hope that from amongst them will emerge new, commercially exploitable SBI.

Although inhibitors of sterol biosynthesis that act in the pre-squalene segment of the pathway are known (1), the SBI fungicides presently used in agriculture and medicine inhibit enzymes in the post-squalene segment of the fungal sterol biosynthetic pathway. The *prima facie* reason for this is that the pre-squalene segment suffers from selectivity problems which stem from the fact that it is mechanistically the same in fungi, animals and higher plants and is common to the biosynthesis of other physiologically important polyisoprenoid derivatives (*e.g.*, ubiquinone, plastoquinone, carotenoids, chlorophyll). The post-squalene segment, however, is significantly different in fungi, animals and higher plants and is common only to the polycyclic triterpenoids, of which the sterols appear to be the only class to have profound physiological importance. This is almost certainly too simplistic an explanation because it takes no account of intracellular compartmentation and the fact that some SBI exhibit marked selectivity in spite of the fact that the reaction they block (*e.g.*, 14-demethylation) is common to sterol biosynthesis in fungi, animals and higher plants. However, despite the reasons for it, whether right or wrong, the post-squalene segment of the pathway has been regarded as the most likely one to yield new SBI fungicides and therefore has been the subject of most of the recent investigations into sterol biosynthesis inhibitors in fungi and higher plants. Therefore, this review will deal exclusively with inhibitors of the post-squalene segment of the sterol biosynthetic pathway in these organisms. Other recent review literature in this area can be found in references 2–4.

POST-SQUALENE STEROL BIOSYNTHESIS

In fungi. All fungi except the Pythiaceae are able to synthesize sterols, and most fungi synthesize ergosterol as their main sterol. The conversion of squalene into ergosterol includes the following steps:

(a) oxidation of squalene to 2,3-oxidosqualene
(b) cyclization of 2,3-oxidosqualene to lanosterol
(c) methylation at C-24 to yield a 24-methylene sterol
(d) demethylation at C-14 to yield a 4,4-dimethyl-$\Delta^{8,14}$-sterol
(e) saturation of the Δ^{14}-double bond
(f) successive removal of the 4α- and 4β-methyl groups to yield a 4-demethyl-Δ^{8}-sterol
(g) isomerization of the Δ^{8}-double bond to yield a 4-demethyl-Δ^{7}-sterol
(h) introduction of a Δ^{5}-double bond to yield a 4-demethyl-$\Delta^{5,7}$-sterol
(i) introduction of a Δ^{22}-double bond
(j) saturation of the $\Delta^{24(28)}$-double bond introduced in step (c)

The sequence in which these steps occur is not the same in all ergosterol-producing fungi. In general, it may be said that i) the demethylation reactions occur before the double bond transformations in ring B and in the side chain, with that at C-14 occurring before those at C-4, where the 4α-methyl is removed first; ii) in filamentous fungi methylation at C-24 occurs before the demethylation reactions whilst the reverse is true of yeast; iii) the double bond transformations in ring B occur in the sequence $\Delta^{8}\rightarrow\Delta^{7}\rightarrow\Delta^{5,7}$; and iv) the way in which the double bond

[1]Based on a paper presented at the Symposium on Plant and Fungal Sterols: Biosynthesis, Metabolism and Function, held at the AOCS Annual Meeting, Baltimore, MD, April 1990.

Nomenclature used: Campesterol, 24α-methylcholest-5-en-3β-ol; cholesterol, cholest-5-en-3β-ol; cycloartenol, 4,4,14α-trimethyl-9β,-19-cyclo-5α-cholest-24-en-3β-ol; cycloeucalenol, 4α,14α-dimethyl-9β,-19-cyclo-5α-ergost-24(28)-en-3β-ol; desmosterol, cholesta-5,24-dien-3β-ol; dihydrobrassicasterol, 24β-methylcholest-5-en-3β-ol; ergosterol, 24β-methylcholesta-5,7,22(Z)-trien-3β-ol; fecosterol, 5α-ergosta-8,24(28)-dien-3β-ol; fucosterol, stigmasta-5,24(28E)-dien-3β-ol; lanosterol, 4,4,14α-trimethyl-5α-cholesta-8,24-dien-3β-ol; 24-methylene cholesterol, ergosta-5,24(28)-dien-3β-ol; 24-methylene cycloartanol, 4,4,14α-trimethyl-9β,19-cyclo-5α-ergost-24(28)-en-3β-ol; 24-methylene-24,25-dihydrolanosterol, 4,4,14α-trimethyl-5α-ergosta-8,24(28)-dien-3β-ol; 24-methylene lophenol, 4α-methyl-5α-ergosta-7,24(28)-3β-ol; obtusifoliol, 4α,14α-dimethyl-5α-ergosta-8,-24(28)-dien-3β-dien-ol; sitosterol, 24α-ethylcholest-5-en-3β-ol; stigmasterol, 24α-ethylcholesta-5,22(E)-dien-3β-ol; zymosterol, 5α-cholesta-8,24-dien-3β-ol.

Abbreviations: COI, cycloeucalenol obtusifoliol isomerase; Δ^{8}SI, sterol $\Delta^{8}\rightarrow\Delta^{7}$ isomerase; Δ^{14}SR, sterol Δ^{14}-reductase; DMI, demethylation inhibitor(s); FAD, flavin adenine dinucleotide; HEI, high energy intermediate(s); I_{50}, the concentration of an inhibitor required to inhibit the activity of an enzyme by 50%; LDAO, *N*-lauryl-dimethylamino-*N*-oxide; SAM, *S*-adenosylmethionine; SBI, sterol biosynthesis inhibitor(s); SMT, sterol methyltransferase(s); TS, transition state.

transformations in the side chain intermesh with those in ring B accounts for most of the sequence variations found in different fungal species.

In list of reactions involved in the post-squalene segment of the biosynthetic pathway of those fungi that do not produce ergosterol as their main sterol differs slightly from that given above (a–j) in that some extra reactions may occur and/or others may be omitted. For instance; i) fungi of the classes Chytridiomycetes and Hypochytridiomycetes synthesize cholesterol and 24-methyl and 24-ethylcholesterols; therefore they must be able to carry out a second transmethylation, introduce a Δ^5-double bond and saturate a $\Delta^{24(25)}$-double bond, but be unable to form a Δ^{22}-double bond; ii) fungi of the orders Saprolegniales and Leptomitales synthesize cholesterol, desmosterol, 24-methylene cholesterol and fucosterol and therefore must be unable to saturate a $\Delta^{24(28)}$-double bond in addition to having the peculiarities of the fungi of i); and iii) fungi of the order Uredinales have 24-ethylidene- and 24-ethyl-Δ^7-sterols as their main sterols and therefore must be able to carry out a second transmethylation, but be unable to introduce Δ^5- or Δ^{22}-double bonds (5).

In higher plants. All higher plants are able to synthesize sterols, and the predominant ones are sitosterol, stigmasterol and campesterol or dihydrobrassicasterol (6). The conversion of squalene into these sterols includes the following steps (6):

(a) oxidation of squalene to 2,3-oxidosqualene
(b) cyclization of 2,3-oxidosqualene to cycloartenol
(c) methylation at C-24 to yield 24-methylene cycloartanol (first chain methylation)
(d) demethylation at C-4 to yield a 4α,14α-dimethyl sterol (cycloeucalenol)
(e) opening of the 9β,19-cyclopropane ring to yield a 4α,14α-dimethyl-Δ^8-sterol (obtusifoliol)
(f) demethylation at C-14 to yield a 4α-methyl-$\Delta^{8,14}$-sterol
(g) saturation of the Δ^{14}-double bond introduced in step (f) to yield a 4α-methyl-Δ^8-sterol
(h) isomerization of the Δ^8-double bond to yield a 4α-methyl-Δ^7-sterol
(i) demethylation at C-4 to yield a 4-demethyl-Δ^7-sterol
(j) introduction of a Δ^5-double bond to yield a 4-demethyl-$\Delta^{5,7}$-sterol
(k) saturation of the Δ^7-double bond to yield a 4-demethyl-Δ^5-sterol
(l) methylation at C-28 to yield a 24(Z)-ethylidene sterol (second side chain methylation)
(m) saturation of $\Delta^{24(28)}$-double bond in 24-methylene- and 24-ethylidene sterols giving 24-methyl and 24-ethyl sterols, respectively
(n) introduction of a Δ^{22}-double bond

Although the sequence in which these steps occur is not the same in all higher plants, there is nevertheless a preferred sequence in most of them (6). It begins with the sequence (a)→(b)→(c)→(d)→(e)→(f)→(g)→(h), which then bifurcates. One fork, namely (h)→(i)→(j)→(k)→(m), gives the 24-methyl sterols; whilst the other, namely (h)→(l)→(i)→(j)→(k)→(m), gives the 24-ethyl sterols. It is not clear when step (n) occurs in the reaction sequences, but it is generally believed to be a late reaction (6).

A comparison of the higher plant reactions with those of fungi reveals two fundamental differences. Firstly, cycloartenol, a 9β,19-cyclopropyl sterol, is produced by the cyclization reaction rather than lanosterol, a Δ^8-sterol. This means that higher plant sterol biosynthesis has to include a reaction that is not seen in the fungal or the higher animal pathway, namely the opening up of the 9β,19-cyclopropane ring to generate the angular methyl group on C-10 and coincidentally to introduce a Δ^8-double bond. This reaction is catalyzed by the enzyme cycloeucalenol-obtusifoliol isomerase (COI). Secondly, the demethylation reactions occur in the sequence 4α, 14α, 4β, whereas in fungi the sequence is 14α, 4α, 4β (4β here refers to the biosynthetic origin or the methyl group rather than its orientation when demethylation occurs, which is 4α because the removal of the first methyl group from C-4 causes inversion of configuration).

INHIBITION OF POST SQUALENE STEROL BIOSYNTHESIS IN FUNGI AND HIGHER PLANTS

Squalene epoxidase. Squalene epoxidase (EC 1.14.99.7) catalyzes the oxidation of squalene to 2,3-oxidosqualene. It is monooxygenase and thus requires O_2 and reduced pyridine nucleotide for this purpose. The enzyme from yeasts is a microsomal flavin adenine dinucleotide (FAD)-requiring flavoprotein; that from *Candida* spp. prefers NADH (7,8), whilst that from *Saccharomyces cerevisiae* prefers NADPH (9,10). In fungi, the catalytic activity of squalene epoxidase requires the presence of a reductase which occurs with it in the membrane. The function of the reductase is to supply the squalene epoxidase with reducing equivalents from NAD(P)H. The catalytic activity of squalene epoxidase is also enhanced by a soluble protein factor(s) whose function is not clear (7,8). The *C. albicans* enzyme has been shown to be inactivated by Cu^{2+}, partially inhibited by thiol reagents and unaffected by CN^- (7). Little is known about the requirements of the higher plant enzyme.

The allylamine compounds, naftifine and terbinafine (Fig. 1), are antimycotics, now used in medicine, which are potent inhibitors of fungal squalene epoxidase (8,11–16) but are only weakly inhibitory towards the mammalian enzyme (8). They are primarily fungicidal against dermatophytes, and filamentous and dimorphic fungi, and fungistatic against some *Candida* species (17). Naftifine is used as a topical antimycotic whilst terbinafine can be used both topically and systemically. Naftifine and terbinafine are reversible, non-competitive inhibitors of squalene epoxidase (13,18). However, it is not yet clear how they bring about this inhibition. There is no evidence that they interrupt electron flow from NAD(P)H to the epoxidase; the reversible, non-competitive kinetics of inhibition effectively rule out a mechanism-based process; and their lack of an obvious structural resemblance to squalene suggests that they do not act as substrate analogues. Ryder (18) has suggested two possible inhibitory mechanisms. In one (Fig. 2) the allylamine molecule binds fairly loosely to two separate sites on the epoxidase, the naphthalene ring to the squalene binding site (A) and the side chain to a nearby lipophilic binding site (B). The enzyme is known to interact with various lipids (19) implying that it has a lipophilic binding site; moreover, the fungal and mammalian enzymes have different affinities for lipids which could explain the selec-

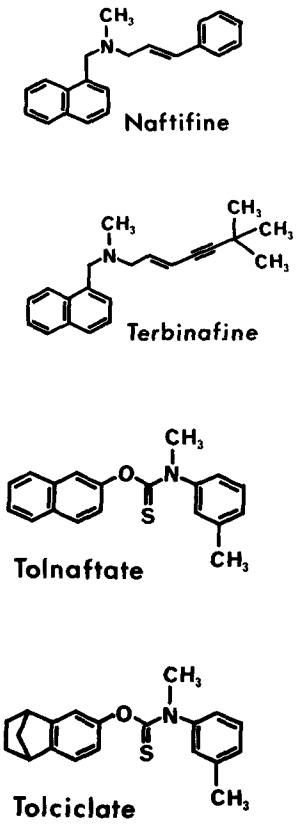

FIG. 1. Squalene epoxidase inhibitors.

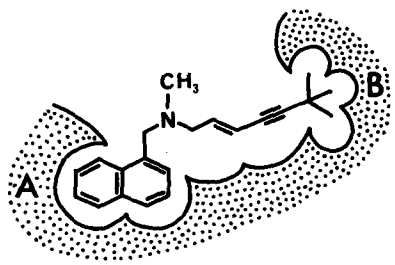

FIG. 2. Postulated mechanism of squalene epoxidase inhibition by allylamine fungicides, redrawn after Ryder (18). A is the squalene binding site and B is a lipophilic binding site on the enzyme.

tivity of the allylamines. Also in favor of this mechanism is the recent finding that naphthalene and 1-methylnaphthalene are weak inhibitors of the *Candida* squalene epoxidase (18).

The effect of the allylamines on higher plant epoxidase has not been tested but the fact that naftifine, applied to the roots of radish plants, caused a relatively weak inhibition of their growth (20) gives a *prima facie* indication that they may be only poor inhibitors of the higher plant enzyme. No fungicide of the allylamine type has been developed yet for use against fungi causing diseases of higher plants.

The thiocarbamate antifungals, tolnaftate and tolciclate (Fig. 1) have also been shown to inhibit squalene epoxidase in *Candida* spp. and *Trichophyton mentagrophytes* (21,22), but are less active than terbinafine (21).

The compounds 2,3-aza-2,3-dihydrosqualene and 1,1',2-tris-*nor*-3-trimethylammonium squalene iodide, designed as inhibitors of the 2,3-oxidosqualene cyclase (23,24), have been shown to inhibit squalene epoxidase in *Candida albicans* although they inhibited the 2,3-oxidosqualene lanosterol cyclase better (25). This fits in with the fact that, as analogues of the carbocationic high energy intermediates of the cyclization reaction, they should bind more tightly to the catalytic site of the cyclase than they would to that of the epoxidase, for which they are only substrate analogues.

2,3-Oxidosqualene cyclases. The fact that the product of 2,3-oxidosqualene cyclization is lanosterol in fungi and cycloartenol in higher plants would indicate that different enzymes catalyze the cyclization reaction in sterol biosynthesis in these organisms, namely 2,3-oxidosqualene lanosterol cyclase (EC5.4.99.7) and 2,3-oxidosqualene cycloartenol cyclase (EC 5.4.99.8), respectively. The substrate for both enzymes is the all-*trans*-stereoisomer of (3S)-2,3-oxidosqualene. For the cyclization reaction to proceed the substrate has to be folded, from its epoxy end, into a chair-boat-chair-boat sequence of potential cyclohexanoid rings. It is believed that this conformation is forced upon the substrate by the shape of the catalytic site of the cyclase during the formation of the enzyme-substrate complex. The C_8-unit at the non-epoxy end remains unfolded, and therefore does not take part in the cyclization reaction; it ultimately becomes the sterol side chain. Cyclization is apparently initiated by an electrophilic attack by a proton, probably derived from an appropriately located group at the catalytic site on the epoxy-O-C(2) bond. This leads to a wave of electron shifts from neighboring π-bonds running forward through the molecule, which ultimately results in the formation of four fused rings, three cyclohexanoid (sterol rings A, B and C) and one cyclopentanoid (sterol ring D). There is evidence (26,27) to suggest that the overall annulation process proceeds through a series of conformationally rigid carbocationic intermediates and terminates when the electron deficiency reaches C-19 (ultimately the sterol C-20), which is the start of the unfolded section of the molecule, yielding a carbocationic protosterol. This is the same for both cyclases, but has only a transient existence before undergoing a backward rearrangement by way of a series of Wagner-Meerwein shifts. There are four of these shifts for the lanosterol cyclase and five for the cycloartenol cyclase. These shifts involve the movement of H^- or H_3C^- from one carbon to an immediately adjacent carbon when the latter has an electron deficiency; they occur by way of a bridged carbocation and are permitted only when the moving and leaving groups are *trans* and coplanar.

Using the sterol numbering system, the sequence of these shifts for the lanosterol cyclase is i) 17β-H to C-20; ii) 13α-H to C-17; iii) 14β-methyl to C-13; and iv) 8α-methyl to C-14; the resulting C-8 carbocation is then stabilized by the removal of the 9β-H as proton, presumably by an appropriately placed nucleophilic group at the catalytic site.

The first four shifts in the sequence catalyzed by the cycloartenol cyclase are identical to those above, and then continue with v) 9β-H to C-8. The resulting C-9 carbocation is ultimately stabilized by the removal of a 19-H as a proton and the formation of a C-9 to C-19 bond resulting

in the 9β,19-cyclopropane ring. However, for steric reasons, the formation of this C-C bond cannot be concerted with the migration of the 9-H. This means that the final stages of the rearrangement/stabilization sequence should involve a discrete C-9 carbocationic intermediate, probably temporarily stabilized by a nucleophilic group of the cyclase, before 19-H elimination occurs.

This reaction has recently attracted a good deal of attention from designers of sterol biosynthesis inhibitors, probably because it is perceived as a potential target for fungicides, and its mechanism would allow for a rational approach to the design of such compounds. Cattel and Benveniste (*e.g.*, refs. 23,24) separately and in collaboration, have been the leaders in this field. Their aim has been to design high energy intermediate (HEI) or transition state (TS) analogues for three of the key postulated steps of the cyclization reaction sequence, namely: i) the initial step in which the attacking proton causes polarization of the epoxy-O-C(2) bond and thereby an electron deficiency, manifested as a fractional positive charge, on C-2 (A, Fig. 3); ii) the step leading to the formation of the C-20 carbocationic protosterol (B, Fig. 3); and iii) the final step in which the C-8 carbocation or C-(8,9) bridged carbocationic HEI is generated (C_1 and C_2; Fig. 3) (28).

The first compounds designed to inhibit step i) that were successful in the sterol fungal/higher plant context were structural variants of 2-aza-2,3-dihydrosqualene (Fig. 4), differing in the type (methyl, ethyl and isopropyl) and number (0–3) of alkyl substituents on the positively charged nitrogen (23,29). All except the isopropyl derivatives noncompetitively inhibited the cycloartenol cyclase of maize seedlings. It was then found that the *N*-oxide analogues of these compounds were even more effective (30,31), which was to be expected since they are nearer to the TS analogue ideal (28). 2-Aza-2,3-dihydrosqualene, its *N*-oxide, and *N*-laurel-dimethylamino-*N*-oxide (LDAO) inhibited the growth of bramble cells in suspension culture and caused them to accumulate 2,3-oxidosqualene, indicating that the cycloartenol cyclase had been inhibited (32). Squalene *N*-methyloxaziridine (33) and *N,N*-diethylazasqualene, its *N*-oxide and their bis-*N,N*-diethyl derivatives (34) inhibit the lanosterol cyclase of *S. cerevisiae*, presumably by blocking step i). Other compounds (Fig. 5) that probably inhibit the fungal/higher plant cyclases in this manner are 2,3-iminosqualene (35), AMO 1618 (36) and U-18666A (3β-[2-diethylaminoethoxy]-androst-5-en-17-one) (32,37).

To date, few inhibitors of the fungal/higher plant cyclase operating at step ii) have been discovered (Fig. 6). 20-Azadammarenol, which after protonation can be considered a HEI analogue of the C-20 protosterol, proved not to be an inhibitor of the plant cyclase (28). However, *N*-[2-(4,8-dimethyl-3(E),7-nonadienyl)phenylmethyl]-*N'*,*N'*-diethyl-1,2-ethanediamine has been found to inhibit the lanosterol cyclase of *C. albicans* (38).

In an attempt to produce a cyclase inhibitor operating at step iii), a number of *N*-substituted-8-aza-decalins have been synthesized and tested. Of these, *N*-[(1,5,9)-trimethyldecyl]-4α,10-dimethyl-8-aza-*trans*-decal-3β-ol and its 1,5,9-trimethyldeca-4,8-dienyl derivative (Fig. 7) proved to be good inhibitors of the cycloartenol cyclase of maize seedlings (28,39,40).

C-24 and C-28 S-adenosylmethionine (SAM):sterol methyltransferases (24- and 28-SMT). The methyl donor

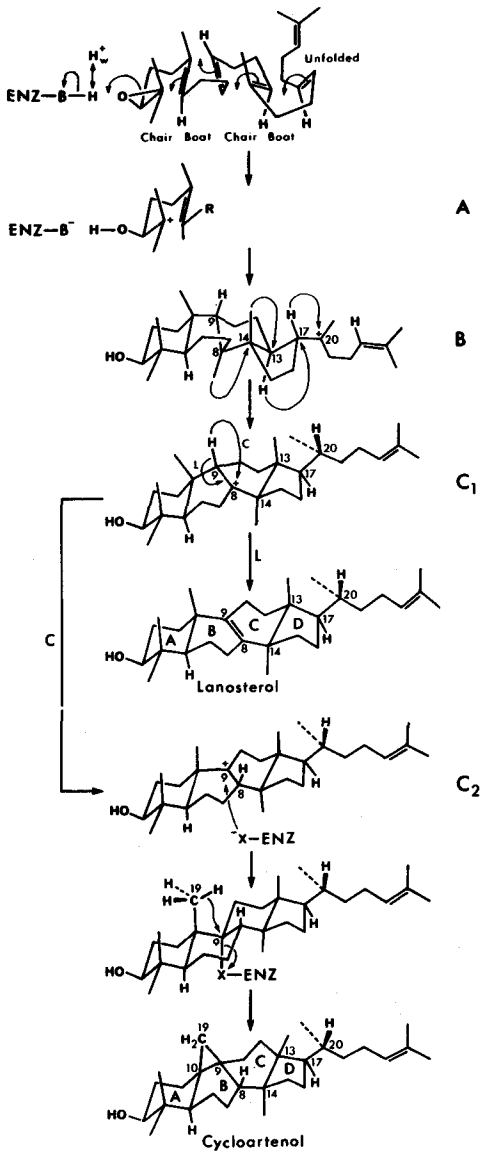

FIG. 3. Mechanism of the cyclization of 2,3-oxidosqualene to lanosterol (L) and cycloartenol (C). A, B, C_1 and C_2 are stages in the reaction sequence for which inhibitors have been designed.

for both methyltransferases is *S*-adenosylmethionine (SAM), and the acceptor sterol has to have an appropriately placed double bond, namely $\Delta^{24(25)}$ for the 24-SMT and $\Delta^{24(28)}$ for the 28-SMT. The acceptor sterols for the 24-SMT of filamentous fungi, yeast and higher plants are lanosterol, zymosterol and cycloartenol, respectively. The acceptor sterol for the 28-SMT is a 24-methylene sterol generated by the 24-SMT; this is 24-methylene lophenol in higher plants and may be 24-methylene-24,25-dihyrolanosterol in those fungi that are capable of synthesis of 24-ethylidene and 24-ethyl sterols. Although variations in the mechanism of the 24- and 28-transmethylation reactions have been observed (6,41), certain generalizations can be made, namely that: i) the 24-SMT generates a C-25 carbocationic intermediate; ii) in ergosterol-producing fungi and in 24-ethylidene/ethyl-sterol-producing organisms the 24-SMT also generates a C-24 carbocationic intermediate as a result of a 1,2-H^- shift from C-25 to

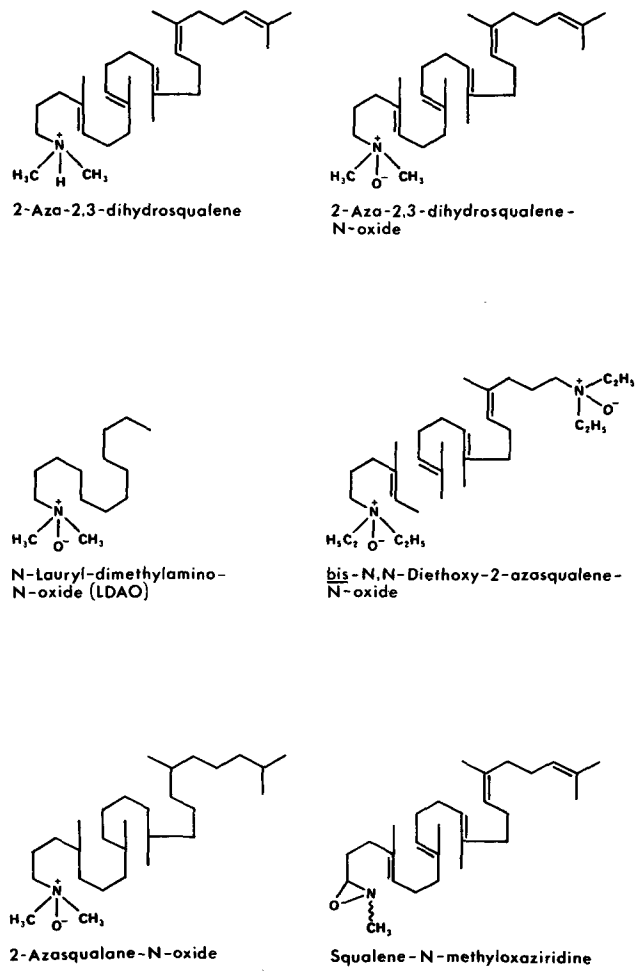

FIG. 4. Compounds designed to inhibit 2,3-oxidosqualene cyclases at stage A (see Fig. 3) of the cyclization reaction sequence.

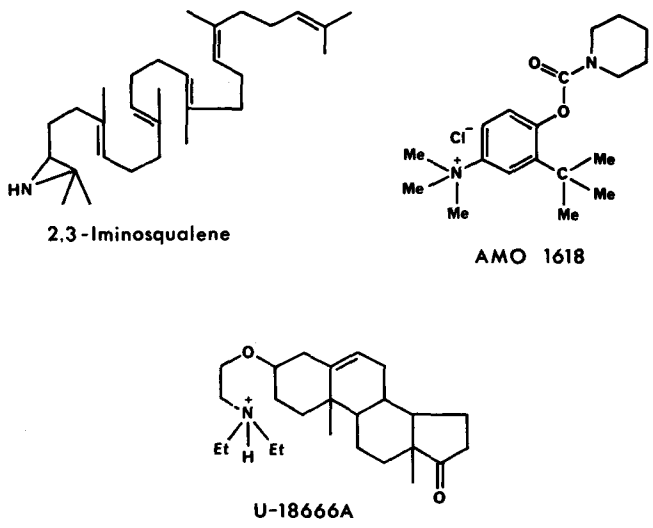

FIG. 5. Other compounds that inhibit 2,3-oxidosqualene cyclases at stage A (see Fig. 3) of the cyclization reaction sequence.

C-24; and iii) the 28-SMT generates a C-24 carbocationic intermediate. The participation of these two carbocationic intermediates in these reactions has stimulated the rational design of inhibitors of the 24- and 28-SMT. In general, these compounds are steroids with a positively charged heteroatom replacing either C-24 or C-25 in the hope that they would be satisfactory HEI analogues.

In aerobically-growing *S. cerevisiae*, 25-aza-24,25-dihydrozymosterol was shown to inhibit the 24-SMT (42), with the result that no 24-methylene- or 24-methyl-sterols were produced, and zymosterol accumulated. Tertiary amines such as this have a pK_a close to 10 and, consequently, mainly exist in the protonated state at physiological pH, thus placing a positive charge on the nitrogen atom. 23-Azacholesterol, with its N atom non-ideally placed to inhibit the 24-SMT, nevertheless did so (71% inhibition at 10 μM) in *S. cerevisiae* (43), although it was a far better inhibitor of the sterol $\Delta^{24(28)}$-reductase (100% inhibition at 1 μM). A 1 μM concentration of 23-azacholesterol in the growth medium of the *erg-2, erg-3* and *erg-5* mutants of *S. cerevisiae* also blocked the 24-SMT (44), causing zymosterol accumulation. Using a 24-SMT enzyme preparation from *S. cerevisiae*, the inhibitory power (expressed as μM I_{50} values) of a series of azasterols (Fig. 8) was found to be: 25-azacholesterol HCl (0.05) > 25-aza-24,25-dihydrozymosterol (0.08) > 25-azacholesterol = 25-azacholestanol (0.14) > (20*R*)- and (20*S*)-22,25-diazacholesterol (0.18) > 24-azacholesterol (0.22) > 25-aza-24,25-dihydrolanosterol (1.14) > 23-azacholesterol (4.8) (45). The 24-SMT of *Saprolegnia ferax* also has been shown to be inhibited by 25-azacholesterol (46), whilst that of *Gibberella fujikuroi* is inhibited by 24-epiiminolanosterol (47).

The 24- and 28-SMT present in microsomes prepared from maize embryos were shown to be inhibited by 25-azacycloartanol (48); moreover, a 1 μM concentration of this compound cause a marked decrease in 24-alkylated sterols in suspension cultures of bramble cells (48). The relative potencies of 25-azacycloartanol and an extensive range of related compounds as inhibitors (Fig. 9) of the 24-SMT of maize microsomes have been determined (49). The investigation showed that: i) the most potent inhibitors (K_i values 15–50 nM) had a sterol-like structure with a positively charged atom replacing C-25; ii) the sterol nucleus could be that of cycloartenol, lanosterol or cholesterol and the positively charged atom could be N, S or As; iii) the positive charge on the heteroatom could arise as a result of protonation at physiological pH of a neutral amine such as 25-azacycloartanol to give a tertiary ammonium group, polarization of the carbonyl group of an amide such as 24-oxo-25-azacycloartanol to give a species with a partial positive charge on the N atom, or the presence of an N-O bond which, in tertiary amines such as 24-methyl-25,26,27-trisnor-24-dimethylamino-*N*-oxide cycloartanol, has a strong permanent dipole moment (N^+-O^-); iv) compounds with a positively charged atom replacing C-24 or C-23 were also inhibitory (K_i values 90–180 nM) but were less so than those in which the positively charged atom replaced C-25; and v) compounds with a positively charged atom replacing C-20 were not significantly inhibitory. These effects have been discussed further in the literature (6,28,40).

The only other inhibitors of the 24- and 28-SMT of note are analogues of the immediate or more remote methyl

donors, SAM and *L*-methionine, respectively. Sinefungin, an antibiotic analogue of SAM isolated from *Streptomyces griseolus*, inhibits the 24-SMT of *S. cerevisiae* (50), as does *D,L*-ethionine (51).

Sterol 14-demethylase. Sterol 14-demethylation takes place in three O_2 and NADPH requiring steps, namely: i) oxidation of the 14α-methyl group to a 14α-hydroxymethyl group; ii) oxidation of the 14α-hydroxymethyl group to a 14α-formyl group; and iii) oxidative removal of the 14α-formyl group as formate along with the 15α-hydrogen atom to generate a Δ^{14}-double bond (52, and refs. therein). It is now known that a cytochrome P-450 catalyzes all three steps in *S. cerevisiae* (53,54) and rat liver (55–58). The substrate for this enzyme is lanosterol and the product is 4,4-dimethyl-5α-cholesta-8,14,24-trien-3β-ol. It has been given the abbreviated name cyt. P-450_{14DM} but, in view of the distinct possibility that a similar cytochrome P-450 exists in filamentous fungi whose substrate and product are 24-methylene-24,25-dihydrolanosterol and 4,4-dimethyl-5α-ergosta-8,14,24(28)-trien-3β-ol, respectively, a better name would be cyt. P-$450_{Lano.14DM}$, so as to differentiate it from the (as yet hypothetical) cyt. P-$450_{24Melano.14DM}$. This would also bring the nomenclature in line with the abbreviated name given to the higher plant 14-demethylase, cyt. P-$450_{Obt.14DM}$ (59), whose substrate and product are obtusifoliol and 4α-methyl-5α-ergosta-8,14,24(28)-trien-3β-ol, respectively. It would also allow the abbreviation cyt. P-450_{14DM} to be used for sterol 14-demethylases in general, regardless of their source or specificity; it is in this manner that the term cyt. P-450_{14DM} will be used in the rest of this review.

Cyt. P-450_{14DM} are located in microsomal membranes in close association with a flavoprotein enzyme whose function is to catalyze the transfer of two electrons, one at a time, from NADPH to the protoheme iron of this and other cytochrome P-450; it may thus be called NADPH:cyt. P-450 oxidoreductase. Since cytochrome P-450 are *b*-type cytochromes, their prosthetic group is protoheme, which is believed to be situated in a cleft within the apoenzyme (60). The protoheme iron has six ligands, four are the pyrrole N-atoms of the porphyrin ring, the fifth is the S-atom of an apoenzyme cysteine residue, and the sixth is oxygen during the catalytic cycle, but is probably water when the enzyme is inactive. The apoenzyme also has a lipophilic binding site to which the substrate that is to be oxidized (in this case a 14α-methyl sterol) binds non-covalently. The location of this binding site is not definitely known, but it is clear that it must be positioned sufficiently closely to the protoheme to allow the substrate, when bound to it, to react with oxygen bonded to the protoheme iron; it is therefore likely that the binding site is associated with the protoheme-containing cleft (6,61).

A cytochrome P-450 catalytic cycle begins with the binding of the substrate to the lipophilic binding site; for this to be possible the protoheme iron must be in the Fe^{3+} state. An electron, received from NADPH *via* the NADPH:cyt. P-450 oxidoreductase, then reduces the iron to the Fe^{2+} state, allowing a molecule of O_2 to become the

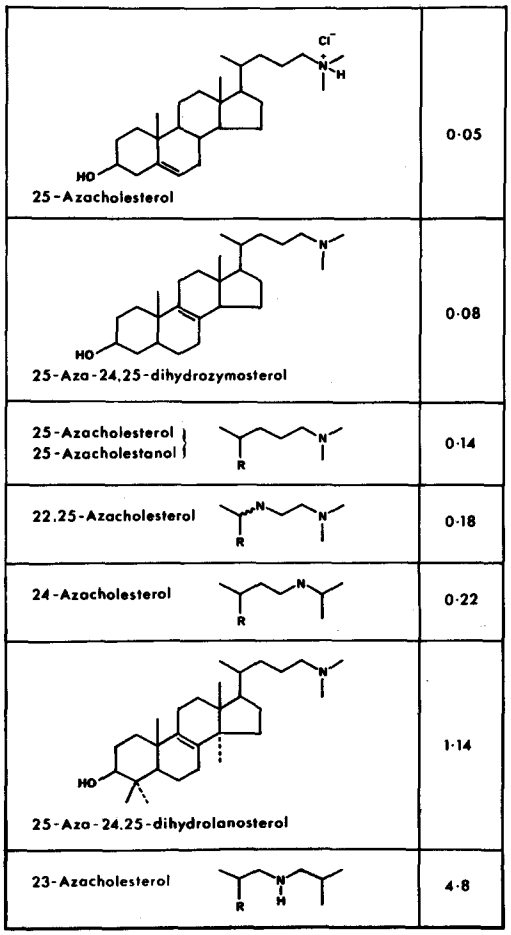

FIG. 8. Relative efficacy of various azasterols as inhibitors of the sterol 24-methyltransferase of *S. cerevisiae* (45).

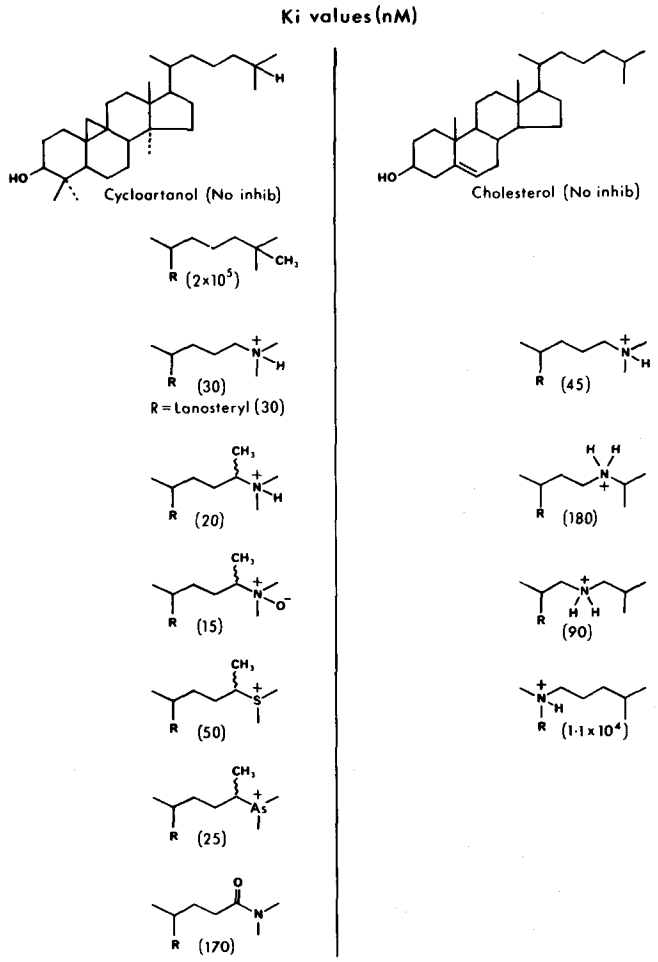

FIG. 9. Relative efficacy of various azasterols and related hetero compounds as inhibitors of the sterol 24- and 28-methyltransferases present in maize embryo microsomes (49). The compounds on the left are derivatives of cycloartanol (or, in one case, lanosterol), while those on the right are derivatives of cholesterol.

sixth ligand. There then follows a complex and poorly understood sequence of events which includes the receipt of a second electron from NADPH, cleavage of the O-O bond with loss of one atom of oxygen as water, reaction of the remaining oxygen atom (probably as an oxene) with the substrate carbon atom that is to be oxidized, and terminates with the formation of the oxidized product and reestablishment of the protoheme iron in the Fe^{3+} state. In the case of the cyt. P-450_{14DM} there must be three such cycles, with the product of the first, the 14-hydroxymethyl sterol, becoming the substrate of the second, and the product of the second, the 14α-formyl sterol, becoming the substrate of the third. In such a sequence it is presumed that only the product of the third catalytic cycle is released from the lipophilic binding site.

Inhibition of the cyt. P-450_{14DM} has been a source of great interest since it was discovered (62) that the pyrimidine fungicide triarimol (Fig. 10) inhibited the 14-demethylation step in sterol biosynthesis. Since then a considerable number of fungicides have been shown to exert their primary fungitoxic action by inhibiting the cyt. P-450_{14DM} and have consequently been called demethylation inhibiting fungicides or DMI; they have been the subject of a considerable number of reviews (63–72). Structurally, the DMI consist of an N-containing heterocyclic ring which may be 5- or 6-membered with 1, 2 or 3 N-atoms, and which is linked to a relatively large lipophilic moiety of quite varied structure—Fig. 10 shows some representative examples. It has been shown that both fungitoxicity (73) and 14-demethylase-inhibiting ability (74) reside in the *N*-heterocycle and that it is dependent upon the presence of an unsubstituted and unhindered N-atom *meta* with respect to the ring atom carrying the lipophilic moiety.

DMI inhibit the cyt. P-450_{14DM} by utilizing the non-bonded electron pair on the *meta*-N of the N-heterocycle to form a coordinate bond with the positively charged protoheme iron. The evidence for this is i) the appearance of a type 2 binding spectrum when a DMI is incubated with the cyt. P-450_{14DM} (59,61,72,75); type 2 binding spectra are produced when binding to the protoheme iron occurs (76); and ii) the ability of DMI to compete with CO for binding to the sixth coordination position of the protoheme when the iron is in the Fe^{2+} state (72).

Although the main inhibitory interaction of DMI with cyt. P-450_{14DM} is between the N-heterocycle and the pro-

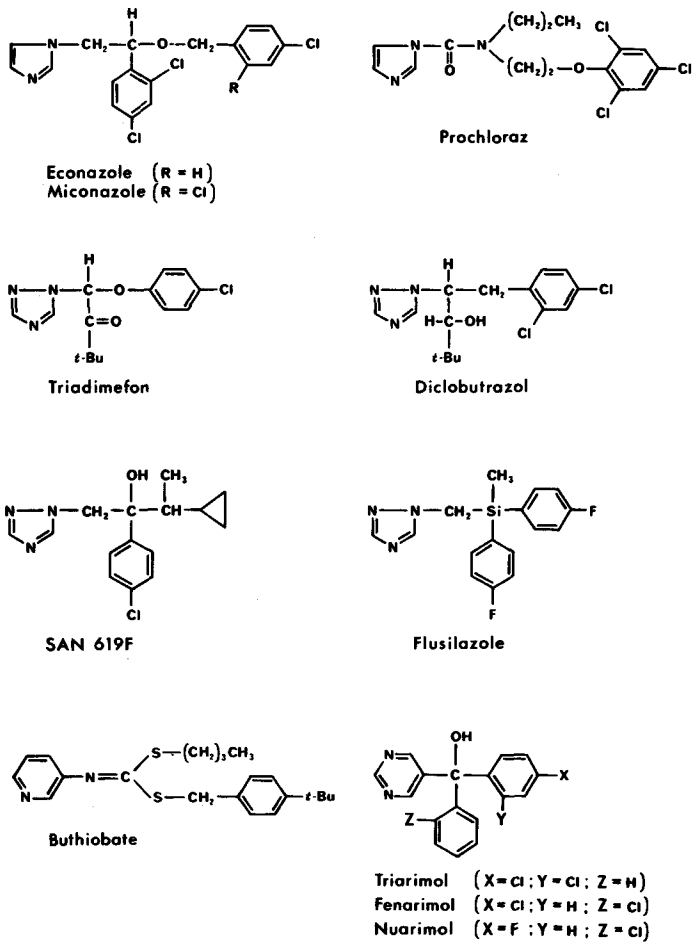

FIG. 10. Structures of some sterol 14-demethylase inhibiting (DMI) fungicides.

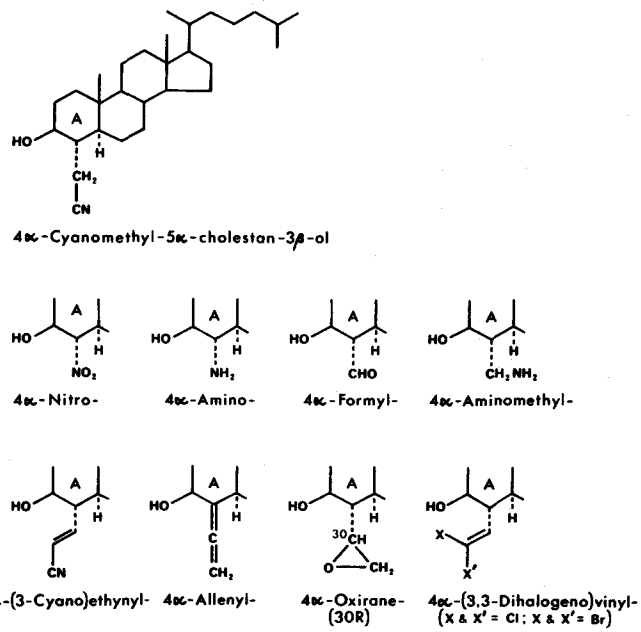

FIG. 11. Compounds designed to inhibit sterol 4-demethylation (82–84).

toheme iron, it has been assumed that some interaction also occurs between the lipophilic moiety and the lipophilic binding site and that this accounts for differences in the inhibitory power of different DMI towards the cyt. $P\text{-}450_{14DM}$ from a given organism and for differences in the inhibitory power of a given DMI towards cyt. $P\text{-}450_{14DM}$ from different organisms. However, a recent study (77) has cast some doubt upon this. It was found that the difference in the efficacy of flusilazole (Fig. 10) as an inhibitor of the cyt. $P\text{-}450_{14DM}$ of *S. cerevisiae* and rat liver diminished markedly as the two enzyme preparations were purified.

Sterol 4-demethylation. Demethylation at C-4 involves a complex of microsomal enzymes rather than a single sterol 4-demethylase. Thus, there are more opportunities for blocking the process since each of the component enzymes is available for inhibition. Despite this, inhibitors of 4-demethylation are few, and to date no fungicide has been developed which acts by inhibiting C-4 demethylation.

The enzyme complex from rat liver (78–80) and presumably that of fungi and higher plants consists of a monooxygenase, an NAD^+-dependent sterol 4-decarboxylase and an NADPH-dependent 3-ketosteroid reductase. The monooxygenase catalyzes the stepwise oxidation of the 4α-methyl group of a 4,4-dimethyl- or 4α-methyl sterol to a 4α-carboxyl group, *via* a 4α-hydroxymethyl- and a 4α-formyl group, each step requiring one molecule of O_2 and one of NADPH. It is not a cytochrome P-450 since it is not inhibited by CO. The resulting 4α-carboxy-4β-methyl- or 4α-carboxy sterol is then oxidatively decarboxylated by the NAD^+-dependent sterol 4-decarboxylase. In this reaction it is likely that the loss of the carboxyl group, as CO_2, is facilitated by the concerted removal of the 3α-H, as H^-, by NAD^+ to yield the enol of the corresponding 4-methyl-3-ketosteroid or 3-ketosteroid, respectively. This is then followed by spontaneous tautomerization of these enols to their more stable keto forms. When the enol undergoing this tautomerization has a residual methyl group at C-4, as is the case during the removal of the first of the two C-4 methyl groups, this methyl takes up the 4α position in the resulting 4-methyl-3-ketosteroid because, as such, it has the spatially more satisfactory equatorial orientation. Thus, the methyl that was 4β in the 4,4-dimethyl sterol becomes 4α in the 4-monomethyl sterol and is consequently positioned correctly for the monooxygenase at the start of the second 4-demethylation reaction sequence. In the final step of the process, the NADPH-dependent 3-ketosteroid reductase catalyzes the reduction of the 3-keto moiety to yield a 4α-methyl- or a 4-demethyl sterol.

The monooxygenase component of the rat liver 4-demethylase complex has been shown to be weakly inhibited (15%) by 1.5 mM cyanide ions (81). It is also inhibited by 4α-cyanomethyl-5α-cholestan-3β-ol (Fig. 11), a compound specifically designed for this purpose (82). This inhibition is irreversible and only occurs in the presence of NADPH. It has been suggested that inhibition is caused by the generation, as a result of catalytic action by the monooxygenase, of an electrophilic 4α-acyl cyanide which then reacts with a nucleophilic group at the active site of the enzyme. The 4α-nitro-, 4α-amino-, 4α-formyl-, 4α-

aminomethyl-, 4α-(3-cyano)ethynyl-, 4α-allenyl-, 4α-oxirane-, 4α-(3,3-dichloro)vinyl-, and 4α-(3,3-dibromo)vinyl-derivatives of 5α-cholestan-3β-ol (Fig. 11) recently have been synthesized as other possible inhibitors of the monooxygenase (83,84), but as yet no reports as to their efficacy have been published. It will be interesting to see whether any of these compounds are selectively inhibitory towards the animal, fungal or higher plant 4-demethylase complexes.

Sterol Δ^{14}-reductase, sterol $\Delta^{8}\rightarrow\Delta^{7}$-isomerase and cycloeucalenol obtusifoliol isomerase. These three enzymes are treated together because they are all inhibited, to a greater or lesser extent, by the morpholine and 3-phenylpropylamine group of fungicides (6,85) and by many of the compounds designed in recent years to inhibit one or the other (6).

The sterol Δ^{14}-reductase (Δ^{14}SR) catalyzes the reduction of the Δ^{14}-double bond that was introduced by 14-demethylation. Its preferred substrate in filamentous fungi is 4,4-dimethyl-5α-ergosta-8,14,24(28)-trien-3β-ol, whilst in yeast it is 4,4-dimethyl-5α-cholesta-8,14,24-trien-3β-ol, and in higher plants it is 4α-methyl-5α-ergosta-8,14,24(28)-trien-3β-ol; its preferred reductant in all cases is NADPH (52,86).

The sterol $\Delta^{8}\rightarrow\Delta^{7}$-isomerase ($\Delta^{8\rightarrow7}$SI) catalyzes the isomerization of the Δ^{8}-double bond that was originally present in the lanosterol in fungi and was generated by the action of COI in higher plants, to a Δ^{7}-double bond. Its preferred substrate in fungi is fecosterol, whilst that in higher plants is 4α-methyl-5α-ergosta-8,24(28)-3β-ol (6,52). There is no evidence to suggest that it needs a cofactor.

Cycloeucalenol obtusifoliol isomerase (COI), an enzyme found in higher plants but not fungi, catalyzes the opening of the 9β,19-cyclopropane ring of cycloeucalenol so as to generate the $\Delta^{8(9)}$-double bond and a β-orientated methyl group at C-10 that are found in the product of the reaction, obtusifoliol (6). Again, there is no evidence of a cofactor requirement.

The mechanism of the reactions catalyzed by these enzymes is outlined in Fig. 12 (also see refs. 6 and 85). They are all initiated by an electrophilic attack by a H^+, probably derived from an appropriately positioned group at the catalytic site of the relevant enzyme (and exchangeable with H^+ in the aqueous milieu), on a nucleophilic carbon of the sterol substrate which results in the generation of a carbocationic HEI intermediate. The formal location of the positive charge in the carbocationic HEI generated by the Δ^{14}SR, $\Delta^{8\rightarrow7}$SI and COI are relatively close to one another, being C-14, C-8 and C-9, respectively. This proximity of the positive charges and the probability that each is delocalized to some extent around the adjacent carbon atoms, thereby emphasizing the proximity, is believed to be the key to the observation that, in many cases, all three enzymes are subject to inhibition by the same compound, particularly when that compound, by accident or design, is a structural and electronic mimic of one of the HEI.

This first became apparent when the primary fungitoxic effect of the morpholine fungicides—tridemorph and fenpropimorph, and subsequently the 3-phenylpropylamine fungicide, fenpropidin (Fig. 13)—was eventually tracked down to inhibition of sterol biosynthesis at the steps catalyzed by Δ^{14}SR and $\Delta^{8\rightarrow7}$SI (87–93). During the same period, Benveniste and his co-workers (94–97) showed that tridemorph and fenpropimorph were potent inhibitors of COI in higher plants (94–97); they achieved an intellectual breakthrough in explaining the mode of action by pointing out that at physiological pH these compounds were protonated and, as such, were both structural and electronic mimics of the carbocationic HEI of all three enzymes. Consequently, they would bind to the catalytic sites of these enzymes much more tightly than the true substrates and would in this way inhibit the enzymes (6,96–100). This followed from the concept of transition state analogues as potent enzyme inhibitors (101–105). Figure 14 shows how a morpholine fungicide would bind to the catalytic sites of the three enzymes so as to mimic the relevant carbocationic HEI.

Based on this proposed mode of action, Benveniste's group synthesized a range of components derived from 8-aza-4α,10-dimethyl-*trans*-decal-3β-ol (Fig. 15, 1–7) which mimics the sterol rings A and B and has a positively charged N-atom at the equivalent of the sterol C-8, thereby mimicking the carbocationic HEI. All the derivatives have a relatively large group that can be folded or positioned to look somewhat like all or part of the rest of the sterol molecule which is attached to the N-atom. Based upon the predominant type of sterol, 9β,19-cyclopropyl-, Δ^{8}- or $\Delta^{8,14}$-, that accumulated when maize seedlings and bramble cells were grown in the presence of these compounds, the following conclusions were drawn: i) compounds **3** and **7** (the *N*-oxides) were powerful inhibitors of Δ^{14}SR; ii) compound **2** was a powerful inhibitor of $\Delta^{8\rightarrow7}$SI; and iii) compounds **4**, **5** and **6** are particularly powerful inhibitors of COI (106). An assay system for Δ^{14}SR using a microsomal preparation from maize embryos has shown that compounds **2**, **4**, **5** and **6** are particularly good inhibitors, and compound **1** is a fairly good inhibitor of this enzyme (86). Assay systems based on the maize embryo microsomal preparation have shown that compound **2** is a good inhibitor of $\Delta^{8\rightarrow7}$SI and that compounds **2**, **2A**, **2B**, **2C** and **5** are good inhibitors of COI (28,40,107). That the nature of the *N*-substituent of such compounds may play a part in determining which of the three enzymes is inhibited most strongly is shown by the finding that the 2*S*-2-methyl isomer of fenpropimorph causes a greater accumulation of 9β,19-cyclopropyl sterols than Δ^{8}-sterols in wheat caryopses, whilst the 2*R*-2-methyl isomer causes the reverse (108).

It would appear that 2-aza-2,3-dihydrosqualene, its *N*-oxide and LDAO (Fig. 4), as well as inhibiting cycloartenol cyclase, can also inhibit $\Delta^{8\rightarrow7}$SI in bramble cells (32), although it is doubtful whether they do this by mimicking the carbocationic HEI. COI has been shown to be inhibited reversibly and highly specifically by 7-oxo-24(28)-dihydroeucalenol (Fig. 16) in bramble cells (109). Again, this inhibition is probably not due to the mimicking of the carbocation HEI. It is suggested (109) that the carbonyl group at C-7 of the inhibitor could compete with the 9β,19-cyclopropyl ring of the substrate for the H^+ supplied by the enzyme. A compound that is a substrate analogue, rather than a HEI analogue, is 15-aza-24-methylene-*D*-homocholesta-8,14-dien-3β-ol (often called 15-azasterol; Fig. 16), an antimycotic (A25822B) which has been shown to inhibit Δ^{14}SR in *S. cerevisiae* (110,111) and bramble cells in suspension culture (112).

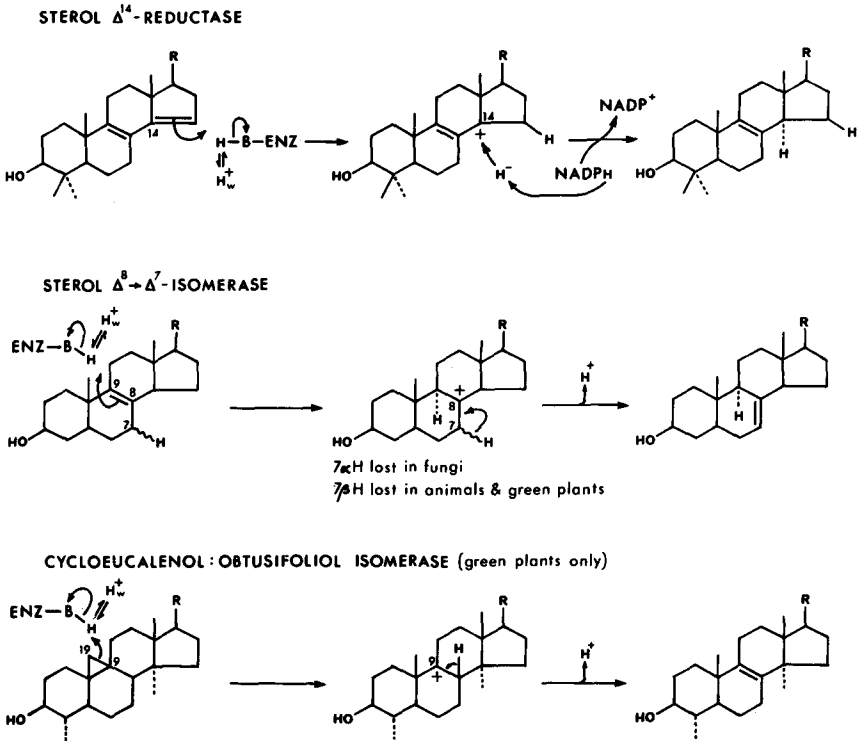

FIG. 12. Mechanism of the reactions catalyzed by the sterol Δ^{14}-reductase, the sterol $\Delta^{8}\rightarrow\Delta^{7}$-isomerase and cycloeucalenol obtusifoliol isomerase.

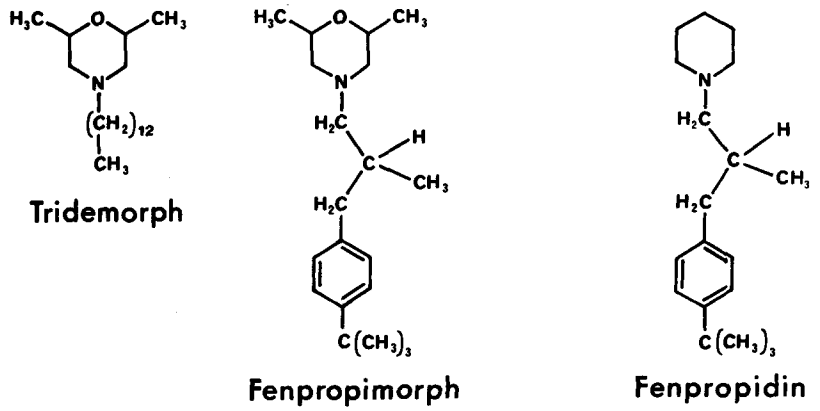

FIG. 13. Structure of some morpholine and 3-phenylpropylamine fungicides.

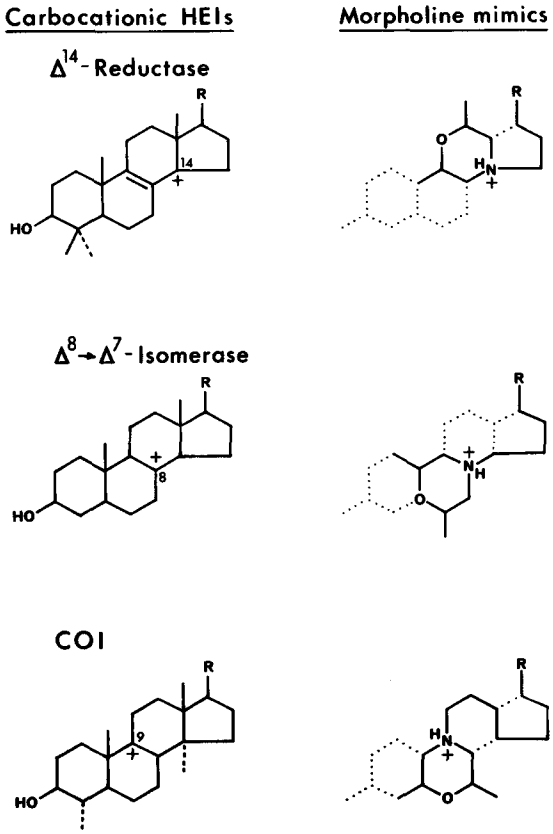
Other compounds which have been shown to inhibit Δ^{14}SR and $\Delta^{8\rightarrow7}$SI are AY-9944 and triparanol (Fig. 16). AY-9944 caused the accumulation of Δ^{8}-sterols in bramble suspension cultures (113), while triparanol did likewise in *S. cerevisiae* (114), indicating inhibition of $\Delta^{8\rightarrow7}$SI. The two compounds had a considerable effect on the sterol composition of three *Chlorella* species when present in their growth medium, which suggested inhibition of one or the other of these two enzymes, along with other possible enzymes. Their effect varied from species to species (115).

Δ^{5} *Desaturation.* Insertion of the Δ^{5}-double bond occurs at the Δ^{7}-sterol level, thereby generating a $\Delta^{5,7}$-sterol; it involves the loss of the 5α and 6α H-atoms (116–118). The overall reaction is obligatorily aerobic (119), and requires NAD(P)H (120–122), suggesting the participation of a monooxygenase. However, its mechanism is not clear and two different processes have been suggested. The first involves two steps, an initial aerobic hydroxylation at C-5 or C-6 which is followed by an anaerobic dehydration. The second involves a single step desaturation catalyzed by a sterol Δ^{5} desaturase, of the fatty acid desaturase type, which is an oxygenase sited at the terminus of an electron transport chain whose other components are a flavoprotein [NAD(P)H:cytochrome b_5 oxidoreductase], cytochrome b_5, and a cyanide-sensitive protein (52).



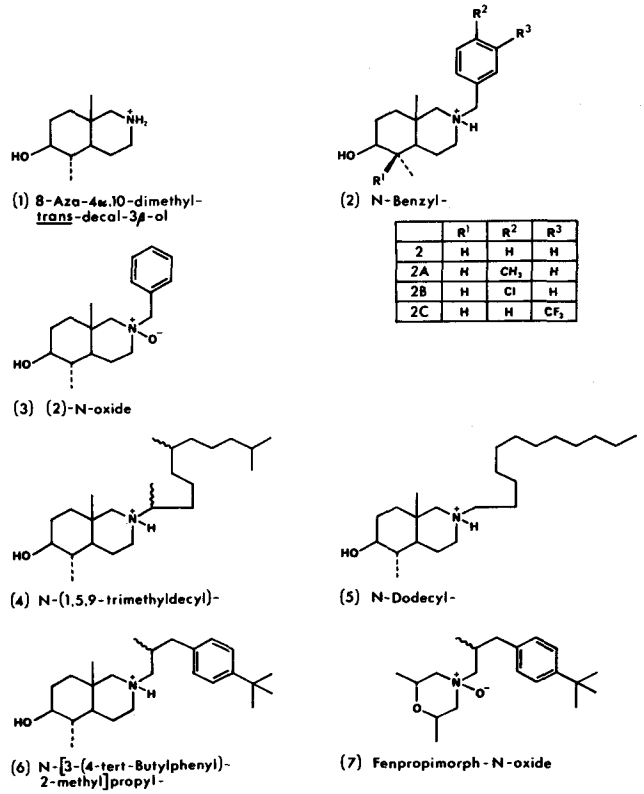


FIG. 14. Morpholine fungicides as structural and electronic mimics of the carbocationic HEI generated in the reactions catalyzed by the sterol Δ^{14}-reductase, the sterol $\Delta^{8}\rightarrow\Delta^{7}$-isomerase and cycloeucalenol obtusifoliol isomerase.

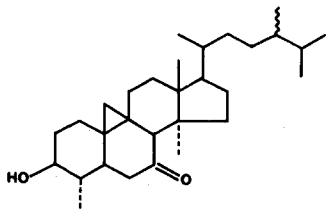
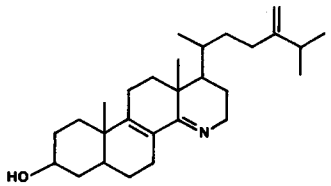
FIG. 15. Compounds based on 8-aza-4α,10-dimethyl-*trans*-decal-3β-ol which have been designed as potential inhibitors of the sterol Δ^{14}-reductase, the sterol $\Delta^{8}\rightarrow\Delta^{7}$-isomerase and cycloeucalenol obtusifoliol isomerase (28,40,86,105,106).



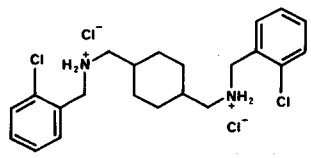
Specific inhibitors of Δ^5 desaturation have yet to be found. Cyanide but not CO has been shown to block the enzyme in *S. cerevisiae* (123). Moreover, there is an indication that 14-demethylase inhibitors may partially block it. The first hint of this was that *Ustilago maydis* accumulated 14α-methyl-5α-ergosta-8,24(28)-dien-3β,6α-diol when treated with etaconazole (124). This sterol has now been detected in other fungi treated with DMI (66,125) but, significantly, not in an *erg3* mutant (A2) of *S. cerevisiae* (125), which does not have a functional Δ^5 desaturation system. This suggests that DMI are inhibiting the Δ^5 desaturation system and, in doing so, are causing the accumulation of the 3α,6β-diol, which may or may not be a normal intermediate in the Δ^5 desaturation process.

Δ^7 *Saturation.* Little is known about the mechanism of Δ^7 saturation. It is a process that does not occur in many fungi but is a usual reaction in sterol biosynthesis in higher plants. By analogy with the animal system (126), the reaction ought to involve the *trans* addition of H-atoms at 7α and 8β, with the former arising from NADPH and the latter from the aqueous milieu (6).



The classical inhibitor of this reaction in cholesterol biosynthesis in rat liver is AY-9944 (Fig. 16; 127,128). However, this compound has been shown to be much less specific in its inhibitory actions on sterol biosynthesis in the plant kingdom (115) and, to date, there is no good, specific inhibitor of this reaction in plants or in those fungi that can carry it out.

$\Delta^{24(28)}$ *Saturation.* Saturation of the $\Delta^{24(28)}$-double bond in fungi appears to be catalyzed by a microsomal, NADPH-dependent enzyme which adds the H^- from NADPH to C-24 and H^+ from the aqueous milieu to C-28 (52). It is inhibited by 23-azacholesterol (43,44).



Δ^{22} *Desaturation.* The Δ^{22}-double bond in the fungal and higher plant sterols has the *trans* configuration and is introduced by the removal of the 22-*pro-S* and 23-*pro-S* H-atoms (116,117). Little is known about the mechanism of the reaction, but the introduction of the Δ^{22}-double bond into ergosta-5,7-dien-3β-ol in *S. cerevisiae* has been shown to be catalyzed by a cytochrome P-450 monooxygenase. This probably explains why the fungicide, triarimol (Fig. 10), an inhibitor of the cyt. $P\text{-}450_{14DM}$, was found to have an inhibitory effect on Δ^{22} desaturation in *U. maydis* (62). It is quite possible that many such DMI would be shown to inhibit Δ^{22} desaturation if they were assayed against the Δ^{22} desaturase itself. The presence of a marked inhibition of this enzyme would be missed if, as is usual, the inhibitory qualities of a DMI are assessed by its ability to: i) inhibit the cyt. $P\text{-}450_{14DM}$ in an enzyme assay procedure; or ii) alter the sterol profile of an organism grown in its presence. The reason why such a marked inhibition of the Δ^{22} desaturase would not be apparent with the latter procedure is because 14-demethylation precedes Δ^{22} desaturation in the biosynthetic pathway and so the better the compound is as a DMI, the less sterol would be available for Δ^{22} desaturation and, consequently, the less obvious the lack

of Δ^{22}-sterols in the sterol profile would be. It is, however, clear that the Δ^{22} desaturase cytochrome P-450 is distinct from cyt. $P\text{-}450_{Lano,14DM}$, because fungal mutants deficient in the Δ^{22}-desaturase are able to carry out 14-demethylation (67). Thus, a DMI which also inhibited Δ^{22} desaturation would be exhibiting the lack of specificity towards cyt. $P\text{-}450_{14DM}$ also seen in those which inhibit the cytochrome P-450-dependent *ent*-kaurene to *ent*-kaurenoic acid step in the gibberellin biosynthetic pathway.

CONCLUSIONS

During the past decade, it has been gratifying to see the elucidation of the mechanism by which some of the known sterol biosynthesis inhibitors act, and the rational approach being taken in the development of new inhibitors. The rational approach is dependent upon a sound knowledge of the mechanism of the reaction whose enzyme is to be inhibited. In this respect, inhibitor designers are fortunate because such knowledge is available for many of the reactions of sterol biosynthesis. However successful though this approach has been, its limitations are becoming apparent in that compounds designed to inhibit a particular enzyme may work well with the enzyme from one organism but not with that from another. The reason for this must be in the nature of the enzymes themselves. Although the enzymes from the organisms in question catalyze the same reaction, there must be significant differences in their catalytic sites which affect the binding of the inhibitor and, therefore, its efficacy. The consequence of this is that inhibitor designers should perhaps switch their sights from the mechanism of the reaction to the enzyme catalyzing it. They should isolate the enzyme and, using the skills of the molecular biologist, produce sufficient amounts of it to submit the protein to X-ray crystallography for three-dimensional structural analysis. From there it is a relatively small step to the elucidation of the structure of the catalytic site and the design of compounds that would bind to it. By examining the enzyme derived from different organisms, differences in the structures of the catalytic sites would become apparent and the way would be open for design of organism-selective inhibitors.

[Received May 24, 1990, and in revised form September 29, 1990; Revision accepted June 15, 1991]

Involvement of Heme Components in Sterol Metabolism of *Saccharomyces cerevisiae*[1]

R. Todd Lorenz and L.W. Parks*
Department of Microbiology, North Carolina State University, Raleigh, North Carolina 27695-7615

There is an intimate association between sterol biosynthesis in yeast and aerobicity. Besides the requirement for molecular oxygen for the epoxidation of squalene, cytochrome hemoproteins are involved in demethylation and desaturation steps. Regulatory effects of hemes on sterol formation have been demonstrated using specifically defective mutants of yeast. Heme competency participates in a mechanism whereby wild-type cells are prevented from taking exogenous sterols from the growth media. The multiple interactions of hemes and sterols appear to be associated with the variously defined functions for sterols in the yeast cells.
***Lipids* 26, 598-603 (1991).**

Yeasts are the most primitive organisms that synthesize abundant amounts of sterols. *Saccharomyces cerevisiae* is especially suitable for studies on sterol function and synthesis because of its ease of culture, well defined genetic mechanism, amenability to molecular biological manipulations, and wealth of biochemical information. Its principal sterol is ergosterol, which in common with many plant sterols has an unsaturation and an alkylation in the side chain (see Fig. 1). In this report we shall review the interactions between hemes and sterols and how these affect the physiology of the organism.

STEROL ESTERIFICATION

Sterols exist in two forms in yeast, in the free hydroxyl form, and as esters of long-chain fatty acids. Free sterols are intercalated within each leaflet of the phospholipid bilayer. The hydroxyl group is orientated toward the aqueous environment, and the ring structure and side chain are surrounded by the hydrophobic fatty acids of the phospholipids. Free sterols are deposited within all phospholipid bilayers of yeast cells such as the endoplasmic reticulum, golgi apparatus, mitochondria and the nuclear and plasma membranes. Steryl esters are extramembranous lipids which are deposited in globules within the cytoplasm. The lipid globules are closely associated with the endoplasmic reticulum and contain predominately steryl esters, triacylglycerol, and phospholipids (1-3). The free sterol and the steryl ester pools undergo a culture-cycle dependent interconversion. The free sterol pool remains relatively constant, but the steryl ester pool is very low during exponential growth and increases dramatically as the culture enters stationary phase (4). When stationary phase cells are transferred to fresh medium, the steryl esters are rapidly hydrolyzed to free sterol and fatty acids, and utilized for new membrane biogenesis (5; see Fig. 2).

We have shown that the ratio of the amount of sterol in the free and esterified form is variable (6). Using a sterol auxotroph that cannot synthesize sterols, we found that by titrating the cellular response to increasing concentra-

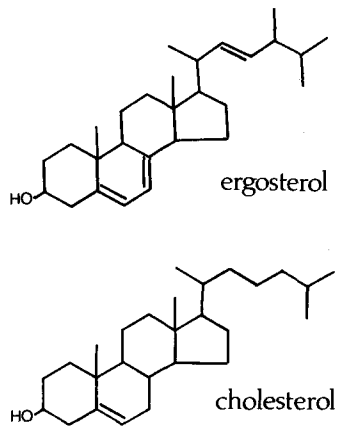

FIG. 1. Ergosterol and cholesterol.

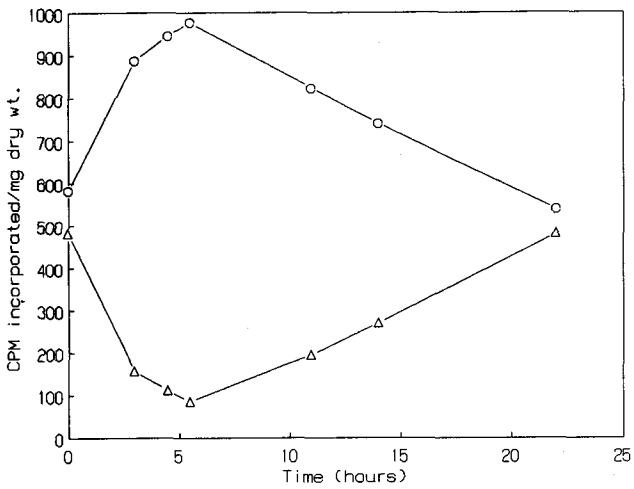

FIG. 2. Interconversion of free sterol and steryl ester during the growth cycle. A wild-type strain, X2180-1A, was pregrown to stationary phase in the presence of [^{14}C]acetate to label the lipids. Cells were then washed and inoculated into fresh media without [^{14}C]acetate. Samples were taken at the designated time points, harvested, and prepared for extraction. Free sterol (O) and steryl esters (△) were separated by thin-layer chromatography, and the accumulated radioactivity was determined by scintillation counting.

Abbreviations: ALA, δ-aminolevulinic acid; DOS, dioxidosqualene; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A.

tions of free sterol in the medium, there is a minimal cellular concentration of free sterol below which the culture cannot proliferate (6). We have defined this level of sterol as the domain function. As the amounts of exogenous sterol are increased, the cellular levels of free sterol increase until a saturating concentration of free sterol is eventually reached. This pool of free sterol of variable concentration of sterol we have defined as the bulk function. As the cellular concentration of the bulk pool increases toward saturation there is an increasingly greater portion of the accumulated sterol that can be converted to steryl ester. Above the bulk concentration, all additional sterol is deposited as ester.

The complex cycling of sterols into and out of the ester fraction provides little insight into the physiological role of sterols in cellular metabolism. We reasoned that if there were diverse functions for sterols in the organism, it was unlikely that the different functions would have the same precise requirements for the different features of the ergosterol molecule. Additionally, it seemed unlikely that there would be the same quantitative requirements. Using a sterol auxotrophic mutant of yeast, we have varied quantitatively and qualitatively the sterols that were provided to the organism to determine which features of the ergosterol molecule were required for growth.

STEROL AUXOTROPHY

By feeding different sterols and stanols to the sterol auxotroph RD5-R (*hem1, erg3, erg7*), it was found that growth could not occur when highly purified cholestanol was supplied as the sole sterol source. However, if ergosterol was supplied in trace amounts (10 ng/mL) in the presence of excess cholestanol (5 μg/mL), the growth rate was similar to that of cells grown on excess ergosterol. Cells were not able to grow on the cholestanol or microamounts of ergosterol separately (7). The role fulfilled by the microamount of ergosterol has been termed "the sparking function" (8). The cholestanol could be replaced by a wide range of sterols and stanols, but the sparking function could only be satisfied by sterols possessing C-5 unsaturation (9).

Other studies with yeast have also demonstrated growth differences from various sterols, depending on culture conditions. The sterol auxotroph GL7 (*hem3, erg7*) had higher growth rates and yields in media supplemented with cholesterol and growth-limiting amounts of ergosterol, when compared to the growth of the organism on either sterol alone (10). Sterol preferences for optimal activity of a protein kinase (11), a methyltransferase (12), and for polyphosphoinositide metabolism (13) have been reported. It has also been proposed that a sterol with a C-24 β-methyl group is required when the wild-type organism is grown under anaerobic conditions in the presence of the synthetic sterol inhibitor, 2,3-iminosqualene (14,15).

Apparently, anaerobically cultured cells have a different sterol requirement than heme mutants that are cultured aerobically. For example, GL7 does not grow on lanosterol (which lacks the C-5,6 unsaturation) aerobically, but does grow on lanosterol anaerobically (16,17). However, one factor which has been overlooked in many studies is the unsaturated fatty acid source used to supplement sterol auxotrophs. The ratios are critical, since the resulting phospholipid composition can alter the growth response to different sterols (18). This may account for discrepancies that have been seen between different systems that have been studied.

Correlating biochemical and biophysical activities with physiological functions involves a number of factors in addition to the accumulated sterol in the cell. Involved in this somewhat complicated process are the interrelationships between sterols, molecular oxygen and heme biosynthesis.

HEME INTERACTIONS

The biosynthesis of ergosterol, unsaturated fatty acids, hemes and methionine in *S. cerevisiae* is an aerobic process (19,20). Molecular oxygen is required early in the ergosterol pathway for the conversion of squalene to 2,3-oxidosqualene (21). Additionally, oxygen is necessary for coproporphyrinogen decarboxylation and protoporphyrinogen oxidation, in the yeast heme pathway (22,23). Therefore, in the absence of oxygen, hemes cannot be synthesized, and the ergosterol precursor, squalene, accumulates (24).

Cytochrome P-450 hemoproteins are required in the ergosterol pathway for the oxidative demethylation of lanosterol (25,26) and the desaturation at the C-22 position of the side chain (27). Cytochrome b_5 hemoproteins are necessary for the desaturation at the C-5 position of the sterol molecule (28,29), and for fatty acid desaturase which introduces a double bond at C-9 of palmitic and stearic acids (30,31). A siroheme is an integral component of the sulfite reductase enzyme which is necessary for methionine synthesis (32). Therefore, anaerobically cultured cells or heme mutants must be supplemented with an exogenous source of sterol, unsaturated fatty acids, and methionine for growth to occur. Hemes also play a regulatory role in sterol biosynthesis at 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase (see below). Finally, hemes participate in a process, termed "aerobic sterol exclusion," which precludes the accumulation of exogenous sterols. Thus, a defect in heme biosynthesis has broad effects on the cells; the mutants cannot synthesize methionine, unsaturated fatty acids, ergosterol, or hemes which results in respiratory deficiency.

The rate-determining enzyme of the ergosterol pathway in yeast is HMG-CoA reductase (33,34). This pathway produces all isoprenoid-containing compounds, including sterols, ubiquinone, dolichol, and isopentenylated adenosine. Regulation of enzyme activity in response to varying growth conditions or mutations in the sterol biosynthetic pathway have been described (35–38). Other reports indicate a feedback inhibition on the activity of HMG-CoA reductase by ergosterol (39,40). Unsaturated fatty acids and glucose have been reported to be inducers of HMG-CoA reductase activity (41,42). Squalene epoxidase may be another highly regulated enzyme of the ergosterol biosynthetic pathway because of the requirement for unsaturated fatty acids in the conversion of squalene to 2,3-oxidosqualene (43).

A direct effect of hemes on sterol formation was observed using mutants with defects in the cyclization of squalene (*erg7*) and in the synthesis of δ-aminolevulinic acid (*hem1*). This defect in heme biosynthesis can be remedied by the addition of δ-aminolevulinic acid (ALA)

to the medium. We observed that the organism had a five-fold increase in HMG-CoA reductase activity when the cells attained heme competency by the addition of ALA. Appropriate controls showed that it was not ALA *per se*, but the acquisition of heme competency that elicited the response. The increase in HMG-CoA reductase was dependent also on the presence of glucose as the carbon and energy source.

Attendant to the stimulation of HMG-CoA reductase activity was a marked accumulation of 2,3-oxidosqualene and, later in the incubation, 2,3,22,23-dioxidosqualene (DOS; see Fig. 3). This demonstrated that heme competency caused an enhanced diversion of cellular carbon and energy to the ergosterol biosynthetic pathway.

HMG-CoA reductase activity is derived from two isozymes with separate structural genes (*HMG1* and *HMG2*) and different controlling mechanisms (44,45). The expression of *HMG1* is enhanced by heme competency *via* the *hap1* gene product, while *HMG2* responds in a contrary manner (46). However, under the conditions of these experiments, the depletion of hemes did not affect the total activity of HMG-CoA reductase *in vitro*. Although this appears to be in conflict with our results, other factors such as differences between *in vitro* and *in vivo* enzyme activities, and compartmentalization of the isozymes may account for the excessive accumulation of sterol precursors by heme competency that we see in our experiments.

Mevinolin is an unmethylated derivative of compactin, and both are competitive inhibitors of HMG-CoA reductase (47,48). We tested the effect of mevinolin on the growth of yeast cultures. Only a slight inhibition of growth was observed with up to 75 μg/mL of mevinolin. Above 150 μg/mL of mevinolin, growth was seriously impaired (unpublished experiment). An interesting observation was made when we analyzed the free sterol and the steryl ester concentrations of the cells. The ester content was decreased dramatically in the stationary phase with low mevinolin concentrations. Only when the bulk concentration of sterols was substantially reduced was growth reduction observed. Growth ceased when the domain level of free sterol was attained.

We were surprised that such dramatic changes in sterol content elicited such minor variations in growth rate. The apparently excessive concentrations of both bulk and ester components of sterols would seem to provide little physiological advantage to the cells. This apparent overproduction may be of significance in nature where the yeast would be exposed to varying aerobic and anaerobic conditions. As mentioned earlier, there is a dependency for molecular oxygen and hemes in ergosterol formation. Yet, yeast cells can grow efficiently under anaerobic conditions. Thus it appears that the variable bulk pool and ester fractions serve as reserve components that can be mobilized when endogenous sterol synthesis is precluded by the lack of oxygen. We have shown that the bulk pool can be maintained through hydrolysis of the steryl ester fraction. Esterification as a storage mechanism is a physiologically expensive process. A considerable saving would be realized by storing as much sterol as possible in the free form. What dictates the upper limit of the bulk pool of sterol remains an interesting point for discussion.

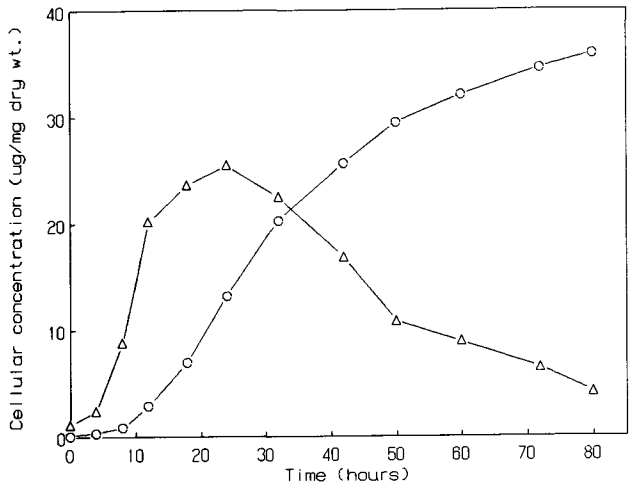

FIG. 3. Overproduction of sterol intermediates by heme competency. Strain FY3 (*hem1, erg7*) was pregrown on 5 μg/mL of cholesterol and transferred to fresh medium containing 100 μg of δ-aminolevulinic acid (ALA) per mL. Samples were taken at the designated time points, harvested, and prepared for extraction. Lipids were separated by thin-layer chromatography, eluted, and quantified by gas chromatography. When heme competency was attained by the addition of ALA to bypass the *hem1* mutation, there was a dramatic increase in the synthesis of 2,3-oxidosqualene; 2,3-oxidosqualene, (▽); DOS (○).

AEROBIC STEROL EXCLUSION

A peculiar situation exists with wild-type yeast in their inability to take up sterols from the environment under aerobic conditions. This is an interesting phenomenon, since it might be anticipated that the cells would prefer to use exogenous sterols and thus save the enormous metabolic costs of synthesizing the large amount of sterols that are found in the cell. Usually, when there is a cellular metabolite that is available in the medium, there is a preference to use the exogenous source to spare endogenous synthesis. Feed-back control and down-regulation of endogenous synthesis is a customary response to many external supplies. However, an exception to this situation exists with respect to the 28-carbon lipid, ergosterol. In the presence of exogenous sterol, aerobically grown wild-type yeast cells continue to produce large amounts of ergosterol and do not take up a significant quantity of the sterol supplied (49,50). This phenomenon has been termed aerobic sterol exclusion.

Under anaerobic conditions, heme and sterol synthesis are precluded, and sterol uptake occurs readily (14,15). Sterol auxotrophs blocked early in the heme pathway also accumulate exogenous sterol from the medium (18,51).

The mechanism and regulation of aerobic sterol exclusion was investigated using a strain of yeast, FY3, that has a defect in *hem1* (aminolevulinic acid synthetase), and a block at oxidosqualene cyclase (*erg7*). Cultures of FY3 were grown on differing concentrations of cholesterol, harvested at mid-exponential phase, and the sterols were extracted and quantified. As the exogenous concentration of cholesterol was decreased, there was a concomitant decrease in the free sterol concentration of the cell until a minimal level of 0.62 μg/mg dry wt was reached. These cells, grown on 1 μg of the cholesterol or less were termed

"sterol-depleted cells." Conversely, as the concentration of cholesterol in the medium was increased, there was an attendant increase in the cellular concentration of free sterol until a maximal level of 3.94 μg/mg dry wt was attained. Cells grown on 11 μg of cholesterol or ergosterol per mL or more did not have an increased free sterol concentration. These cells were termed "free sterol saturated" (see Fig. 4).

Parallel experiments revealed that the amount of sterol taken up from the medium was inversely proportional to the amount of cellular free sterol. This mechanism of sterol uptake regulation is thus termed "sterol-dependent."

Sterol uptake by these heme-incompetent cells was not an active uptake process for the following reasons: (i) no media components were required, (ii) sterol uptake was unaffected by inhibitors of cellular energy transformations known to affect uptake of actively transported nutrients, (iii) no pH optimum was observed, and (iv) cellular viability was not required.

Strain FY14 (*hem1, erg1::URA3, leu2, ade2, ura3*) was constructed to determine the effects of heme competency on the ability of cells to take up exogenous sterol. FY14 has an insertionally inactivated gene for squalene epoxidase, preventing the synthesis of any sterol. The *hem1* defect can be by-passed by the addition of ALA. A culture of FY14 was grown under sterol-depleting conditions (1μg/mL cholesterol) and exposed to 100 μg/mL ALA for 48 hr. Sterol uptake assays that were performed on these cells revealed that the cells were severely inhibited in regard to sterol uptake. Compared to a control culture not exposed to ALA, heme competency decreased sterol uptake by 71% (see Fig. 5). The *HAP* (heme-activating protein) gene family appears to comprise a global activation system for products involved in respiration (52). However, further experiments demonstrated that the *HAP1* and *HAP2* gene products are not likely to be involved in this exclusion process. Thus, sterol uptake is also controlled in some way by heme competency, and this mechanism of regulation is termed "sterol-independent." These two mechanisms, sterol-dependent and heme-dependent, control sterol uptake such that exogenous sterols can enter during heme incompetent situations (*e.g.*, anaerobic conditions) and are excluded during heme competency.

A mutant of the aerobic sterol exclusion system has been isolated. Strain upc20 (mutant of uptake control) is heme-competent, produces ergosterol as its endproduct sterol, and takes up about 3.2 μg of exogenous sterol per mg dry wt. Wild-type yeast only take up about 0.08 μg of exogenous sterol per mg dry wt. A most striking characteristic of upc20 is a five-fold overproduction of steryl esters, which appears to be a result of an abnormal esterification/hydrolysis partitioning cycle of sterols. Steryl esters produced in upc20 are not hydrolyzed to free steryl and fatty acids when cells are shifted to new culture medium. The sterol uptake phenotype of upc20 is genetically inseparable from the esterification phenotype. The pleiotropic mutation is known to be recessive and involves only one gene (50).

An interesting complication of aerobic sterol exclusion in the selection of sterol auxotrophs has caused considerable difficulty in preparing those mutants. Since heme competency elicits sterol-independent exclusion, mutants that are auxotrophic for sterols but prototrophic for hemes (*e.g., hem1, erg7*) have not been isolated. It

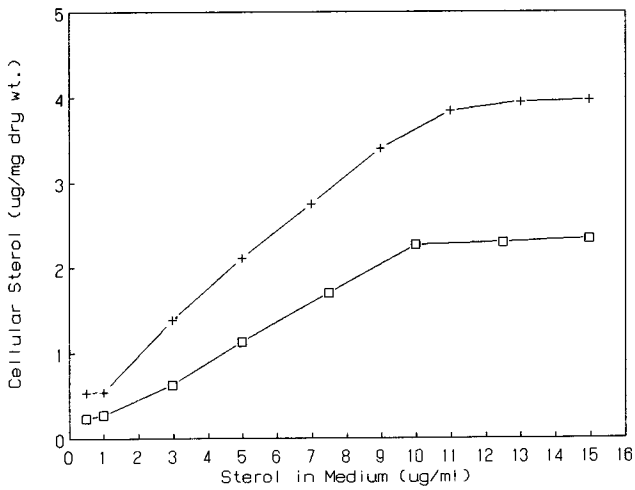

FIG. 4. Free sterol saturation curves of cholesterol and ergosterol. FY3 was grown on different concentrations of exogenous cholesterol or ergosterol and harvested at late log phase. Lipids were extracted, and the amount of sterol associated with the free sterol fraction was quantified by gas chromatography. Cells grown on 1 μg/mL or less sterol are termed "sterol-depleted" representing the domain level. Cholesterol, (+); ergosterol, (□).

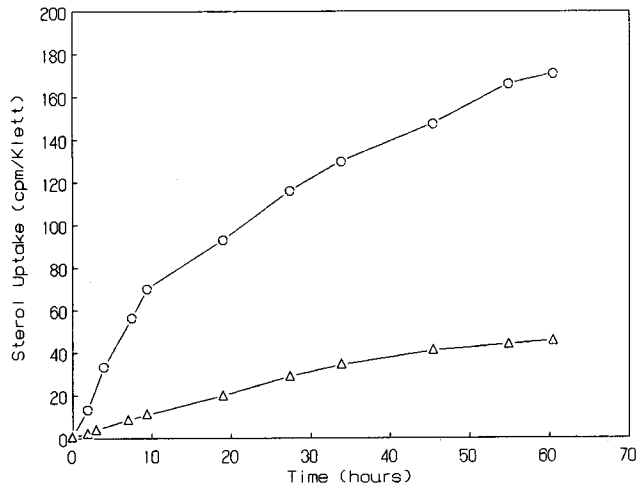

FIG. 5. Effect of heme competency on cholesterol uptake of a sterol auxotroph. Strain FY14 (*hem1, erg1::URA3*) was constructed to determine the influence of heme competency on the ability to take up exogenous sterol. FY14 was pregrown on 1 μg/mL of cholesterol, and transferred to fresh media containing ^{14}C-labelled cholesterol with and without 100 μg/mL ALA. Samples were taken at the designated time points, filtered, and washed, and the amount of radiolabelled cholesterol taken up was determined by scintillation counting. FY14 control, (○); FY14 + 100 μg/mL ALA, (△).

appears that the exclusion is so effective that sterol starvation prevents germination of the spores, even though an abundance of suitable sterol is provided in the medium. Interestingly, both sterol exclusion processes are vitiated in the upc20 strain.

The survival advantage of aerobic sterol exclusion to the yeast cell is not immediately apparent. The substantial physiological advantage to having no exclusion for a

variety of cellular components has been mentioned. It might be anticipated that aerobic sterol exclusion is indeed of survival advantage to the organism, or the process would have been eliminated by natural selection. Yeast appear to compete best in nature in hypertonic environments. Yeast flourish on fruit, in flower nectars, in salt-preserved meats and other high osmotic environments. These media also have an abundance of sterols from the plant or animal sources. We have shown that there are multiple functions for sterols in yeast and that ergosterol is indeed the preferred sterol. In sterol auxotrophs, cholesterol will allow abundant growth, but enormously higher concentrations of the animal sterol are needed for some functions in yeast (51). As the predominant sterol in yeast, ergosterol best fulfills the multiple roles. Preferences for different features of the sterol for optimal function in the different physiological roles have been demonstrated. Ergosterol must represent a consensus structure that is able to satisfy the distinctive and cumulative needs of the sterol functions for the survival of the cells. If the organism were free to take up a sterol different from ergosterol, and one that was less suitable for the specific requirements of the cell, that cell would be at a distinct disadvantage to one which was synthesizing and utilizing ergosterol. Despite the enormous metabolic expense of synthesizing sterol, fulfilling the precise requirements with ergosterol rather than an exogenous substitute sterol may offer such a physiological advantage that endogenous synthesis of ergosterol is preferred by the yeast.

Unlike most small-molecular-weight cellular constituents, like amino acids, purines, pyrimidines, vitamin cofactors, *etc.*, which have a single defined role, sterols appear to have multiple functions. This substantially complicates attempts to define the different roles. Interactions between sterols and hemes introduce another level of complexity in defining sterol functions. Nevertheless, the challenge is exciting and has practical ramifications. Most antifungal agents that are being used intercede in one fashion or another in sterol physiology. By understanding the precise physiological functions of the fungal sterols, it may be possible to design specific controlling agents for the fungi. Those antifungals, being targeted at a distinctive cellular activity, might be needed in only very low concentrations, potentially minimizing toxic effects. In addition, physiological manipulation of the fungi, such that the organism has enhanced sensitivity to antifungal agents, would lower the effective minimal inhibitory concentrations of the drug.

[Received June 9, 1990; Revision accepted June 14, 1991]

Diversity of Sterol Biosynthetic Capacity in the Caryophyllidae[1]

Thomas A. Salt[a,*], Sihua Xu[b], Glenn W. Patterson[b] and John H. Adler[c]

The order Caryophyllales, along with its two associated orders, the Polygonales and Plumbaginales, comprise the angiosperm subclass Caryophyllidae. We have now characterized the sterol compositon of 231 members of this subclass. This includes 210 species and 21 cultivars in 108 genera within the 14 families of these three orders. From these data, clear differences in biosynthetic capability and putative relationships between taxa have been established. Members of the two monofamilial orders (Polygonales and Plumbaginales) contain Δ^5-sterols in ratios typical of "main line" angiosperms. Members of families in the Caryophyllales contain Δ^5-sterols, or Δ^7-sterols or mixtures of Δ^5- and Δ^7-sterols. In the majority of species where Δ^7-sterols are the dominant sterols produced, trace amounts to almost equal amounts of Δ^5-sterols are also present. Replicate samples of many of these species have shown that the ratio of Δ^5-sterol to Δ^7-sterol in these species is stable over time and/or location. From these data, it appears that the conversion of Δ^7-sterols to Δ^5-sterols is highly regulated in the majority of species within this order. In these families, similarities in sterol composition correlate well with taxonomic relatedness. Relationships between these taxa with respect to biosynthetic capability can now be postulated.
***Lipids* 26, 604–613 (1991).**

The order Caryophyllales, along with its two associated orders, the Polygonales and Plumbaginales, comprise the angiosperm subclass Caryophyllidae. The Polygonales and Plumbaginales are both monofamilial orders (Polygonaceae and Plumbaginaceae) customarily associated, but with an uncertain taxonomic relationship to the Caryophyllales (1). Together, these two orders contain approximately 10% of the species in the subclass.

The Caryophyllales consists of 12 families (Fig. 1) with approximately 10,000 species (1) and is generally agreed (1–3) to include the following families: Phytolaccaceae, Achatocarpaceae, Nyctaginaceae, Aizoaceae, Didiereaceae, Cactaceae, Chenopodiaceae, Amaranthaceae, Portulacaceae, Basellaceae, Molluginaceae and Caryophyllaceae. In this paper, the Stegnospermataceae (frequently included in the Phytolaccaceae) and the Gyrostemonaceae (moved to the order Dilleniidae) are also presented for the comparison of sterol composition.

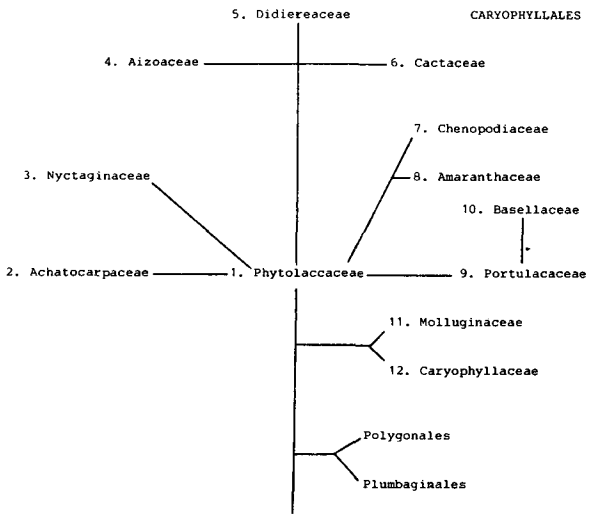

FIG. 1. Putative relationships among the families and orders of the Caryophyllidae (1).

Prior to 1980, the distribution of sterols in angiosperms was based on a sparse sampling of a few genera in many families. The majority of angiosperms are reported to produce 24-alkyl-Δ^5-sterols as the dominant 4-desmethylsterols (4–7). However, several species were reported which deviated from these "main line" angiosperms. Species in the Theaceae and Cucurbitaceae were reported to produce 24-alkyl-Δ^7-sterols as their dominant 4-desmethylsterols (4,6). While the Asteraceae and Fabaceae are considered "main line" families, at least one species in each produces exclusively 24-alkyl-Δ^7-sterols (8,9). Within the Caryophyllales, *Spinacia oleracea* (Chenopodiaceae) (9–11), *Lophocereus schottii* (Cactaceae) (12–13) and *Phytolacca americana* and *P. esculenta* (Phytolaccaceae) (14–16) were the only species reported and also contain exclusely 24-alkyl-Δ^7-sterols.

Plants exclusively producing 24-alkyl-Δ^7-sterols are widely scattered throughout the angiosperms and are considered to be "rare" except in the Cucurbitaceae and Theaceae. In 1980, realizing the relationship of the above four species, we began to characterize the sterol composition of families in the Caryophyllales to determine if other families existed which were similar to the Cucurbitaceae and Theaceae. The relationship of the Chenopodiaceae, Cactaceae and Phytolaccaceae presented the first opportunity to study sterol biosynthesis at a taxonomic level above the genus or family.

[1]Based on a paper presented at the Symposium on Plant and Fungal Sterols: Biosynthesis, Metabolism and Function, held at the AOCS Annual Meeting, Baltimore, Maryland, April 1990.

TAXONOMIC ARRANGEMENT

The taxonomic relationships between families and orders in the Caryophyllidae are presented in Figure 1. Within the Caryophyllales, the Phytolaccaceae is regarded as the basal family from which all other families are derived. The Achatocarpaceae and Nyctaginaceae are closely related and only marginally removed from the Phytolaccaceae (1). The Aizoaceae, Didiereaceae and Cactaceae are "linked" families and appear in the linear sequence. Similarly, the Chenopodiaceae and Amaranthaceae, the Portulacaceae and Basellaceae, and the Molluginaceae and Caryophyllaceae are "linked" pairs of families reflected by the linear arrangement of the order (1).

POLYGONALES AND PLUMBAGINALES

The species examined in the Polygonales and Plumbaginales all synthesize Δ^5-sterols from 87–100% of the desmethylsterols (Table 1). The 24-methylcholest-5-enol, 24-ethylcholest-5-enol and 24-ethylcholesta-5,22-dienol were isolated consistently from all species in ratios generally characteristic of "main line" angiosperms (4,6,7). Species in the Polygonales and Plumbaginales are distinctly different, with respect to their sterol composition, than the majority of species examined in the Caryophyllales below.

CARYOPHYLLALES

Phytolaccaceae and Stegnospermataceae. The Phytolaccaceae, including the Stegnospermataceae, is considered to be the most basal family in the Caryophyllales and all other families are believed to be derived from it either directly or indirectly (1). The family is presented in Table 2 in relation to the current taxonomic position of the species (20).

Species in the Phytolaccaceae, within the subfamilies Gisekioideae and Phytolaccoideae, produce predominantly Δ^7-sterols. However, these species also produce trace to considerable quantities of Δ^5-sterols. While these species are capable of producing Δ^5-sterols, Δ^7-sterols appear to be the preferred sterol species. This would suggest that a genetic block, as previously postulated for the Cucurbitaceae (6), does not exist within these species. It would appear that the conversion of Δ^7-sterols to Δ^5-sterols is, instead, regulated to produce the preferred Δ^7-sterol products. This would also amend the previous belief that if an organism is capable of producing Δ^5-sterols, then it is committed to do so (4,6).

Those species which are capable of producing Δ^5-sterols also produce Δ^0-sterols (stanols), presumably through a Δ^4-3-one intermediate, as demonstrated in a few other organisms (21,22). This may also represent a point of regulation within these species. Whether the stanols represent the final product in sterol metabolism in these species is unknown. Other organisms have been demonstrated to be capable of introducing a Δ^7-double bond into a saturated sterol nucleus (21–26). This would create a "stanol pathway" of Δ^7-sterol $\rightarrow$ Δ^5-sterol $\rightarrow$ Δ^0-sterol $\rightarrow$ Δ^7-sterol. While this has not been demonstrated in plants, it could present a mechanism by which the ratio of Δ^7 : Δ^5 : Δ^0-sterol might be maintained in these species.

N, 24-ethylcholest-22-enol.
t, Trace amount (<1%).

Metabolism appears to shift away from the Δ^7-sterols toward Δ^5-sterols and Δ^0-sterols in species within the subfamily Rivinoideae. Within the tribes Seguierieae and Rivineae, metabolism is shifted to the extent that in many species Δ^0-sterols are among the dominant sterols produced. This is in contrast to the final two subfamilies (Agdestidoideae and Lophiocarpoideae), where the Δ^5-sterols are the preferred sterol species and ratios of sterol composition approximate those of "main line" plants.

Gyrostemonaceae, Achatocarpaceae and Nyctaginaceae. The Gyrostemonaceae is a small family of 5 genera and 17 species, originally included in the Caryophyllales and later excluded (1,20). The Achatocarpaceae is the smallest family of the order with only two genera and eight species, while the Nyctaginaceae consists of 30 genera with 300 species (1). The latter two families are closely allied to the Phytolaccaceae and only marginally removed within the taxonomic relationships of the order.

The species within these three families exhibit a strong preference toward the Δ^5-sterols (Table 3). Spe-

cies in the Achatocarpaceae and Nyctaginaceae contain a sterol composition which is typical of other "main line" angiosperms. Only species in the Gyrostemonaceae exhibit a continued metabolism to the Δ^0-sterols. Based on the sterol data, it would appear that the origin of the Achatocarpaceae and Nyctaginaceae would be in or near the subfamilies Agdestioideae and Lophiocarpoideae of the basal family Phytolaccaceae.

Aizoaceae, Didiereaceae and Cactaceae. The Aizoaceae, Didiereaceae and Cactaceae are the cactus and cactus-like succulent group within the Caryophyllales (1). With the exception of *Lophocereus schottii* in the Cactaceae (12,13), these three families are similar to the previous families in exhibiting a strong preference toward Δ^5-sterol production (Tables 3 and 4). While species in the Cactaceae produce predominantly Δ^5-sterols, species in the Aizoaceae and Didiereaceae also produce substantial quantities of Δ^0-sterols. In *Drosanthemum hispidium* (Aizoaceae), Δ^0-sterols were the preferred sterol species (57%). It appears that regulation of sterol metabolism in these families is similar to that previously stated for the subfamily Rivinoideae in the basal family Phytolaccaceae.

Chenopodiaceae and Amaranthaceae. The Chenopodiaceae and Amaranthaceae have been referred to as the archetypical core of the Caryophyllales (1). The Chenopodiaceae (Table 5) is organized by the subfamily arrangement of Blackwell (33). The treatment of the genus *Chenopodium* is that of Aellen and Just (34).

Species within the Chenopodiaceae are very diverse in their sterol biosynthetic capacity. Within the subfamily Chenopodioideae, sterol metabolism ranges from those species which produce in excess of 98% Δ^7-sterols to species which produce 1:1 ratios of Δ^7-:Δ^5-sterols to species which produce in excess of 98% Δ^5-sterols. In genera where many species have been examined, percent sterol composition does not appear to be consistent at the genus level. Most species within the

genus *Chenopodium* produce more Δ^7-sterols than Δ^5-sterols. In only three species was this trend reversed. However, repeated characterization of the sterol composition of a species over time and/or location has shown that the bulk sterol composition of an individual species is stable (19,30).

In the genus *Atriplex*, some species are monoecious while others are dioecious. In the two dioecious species examined (*A. watsonii* and *A. polycarpa*), male and female plants were analyzed separately (32). While both sexes produce mixtures of Δ^7- and Δ^5-sterols, male plants produced higher proportions of Δ^5-sterols. Whether all dioecious *Atriplex* species exhibit this pattern is not known.

The species examined in the subfamily Salisoloideae all produce predominantly Δ^5-sterols in ratios comparable to "main line" angiosperms. While all species in the Chenopodiaceae are capable of producing Δ^5-sterols, further metabolism to the Δ^0-sterols appears to be limited except in two species. This would suggest that the conversion of Δ^5-sterols to Δ^0-sterols is being regulated or that Δ^0-sterols are metabolized further to some other products.

The Amaranthaceae is one of the three largest families in the order (1). The family (Tables 6 and 7) is organized according to Engler and Prontl (38). The Amaranthaceae is similar to the Chenopodiaceae with respect to the sterol composition of its member species. The majority of species in the subfamilies Deeringioideae and Amaranthoideae produce mixtures of Δ^7- and Δ^5-sterols (Table 6). In several species in the subfamily Amaranthoideae and all species in the Gomphrenoideae, sterol metabolism is shifted to favor Δ^5-sterol production.

Unlike members of the related Chenopodiaceae, all members of the Amaranthaceae further metabolize Δ^5-sterols to Δ^0-sterols. In most species, Δ^0-sterols are present in excess of 10% of the total desmethylsterol. In this respect, species in the Amaranthaceae are more similar to species in the basal family Phytolaccaceae than to species in the Chenopodiaceae. This would lend support to the belief that the Chenopodiaceae and Amaranthaceae are derived from a common ancestor and not from each other (1).

Portulacaceae and Basellaceae. The Portulacaceae consists of approximately 20 genera while the Basellaceae consists of only four genera (1). The Basellaceae is derived from the closely related Portulacaceae and is generally considered to be more advanced (1).

Members of the Portulacaceae may be divided into

two groups (Table 8). Species in the genera *Calandrinia, Claytonia, Grahamia* and *Lewisia* produce Δ^7-sterols in excess of Δ^5-sterols. In these species, substantial quantities of Δ^0-sterols are also produced. In *Montia* and *Portulaca,* sterol metabolism is shifted to favor the production of Δ^5-sterols. In two species, Δ^5-sterols presumably are further metabolized to produce substantial quantities of Δ^0-sterols, while in the remaining species Δ^0-sterols appear to be absent.

Species in the Basellaceae are believed to be derived from species in the Portulacaceae (1). It would appear appropriate that these species would have an origin in or near the first group above. While the sterol composition of species in the Basellaceae is similar to the first group in the Portulacaceae, the production of Δ^0-sterols appears to be more limited. Whether this represents an "advancement" in biosynthetic regulation in the Basellaceae is equivocal.

Molluginaceae and Caryophyllaceae. The Molluginaceae and Caryophyllaceae may represent the group with the earliest dichotomy from the Phytolaccaceae. The Molluginaceae and Caryophyllaceae are unique within the Caryophyllales in that all other families of the order produce betalains (unique and characteristic of the order), whereas the Molluginaceae and Caryophyllaceae produce anthocyanins (1). These two pigments have not been demonstrated to coexist within the same species. While the production of betalains has received taxonomic significance within this order, other unique morphological characteristics clearly support the inclusion of the Molluginaceae and Caryophyllaceae in this order.

The Caryophyllaceae is the type family of the order. The tribal arrangement of the family (Table 9) is that of Thomson (39), the subtribal arrangement of the Alsineae is that of McNeill (40).

The sterol composition of species in the Molluginaceae (Table 8) is most similar to that of species in the tribe Rivineae in the basal family Phytolaccaceae. Species in the Molluginaceae produce mixtures of Δ^7- and Δ^5-sterols or Δ^5-sterols. In both groups, Δ^5-sterols are further metabolized to the Δ^0-sterols.

The species in the Caryophyllaceae exhibit a diversity of sterol biosynthetic capacities which is unique within the angiosperms (Table 9). Species in the tribes Sclerantheae, Paronychieae, Lychnideae and Diantheae

produce Δ^7-sterols exclusively (19,41). However, these analyses were performed on packed GLC columns (41). The analyses of two additional species of *Dianthus* with capillary GLC have indicated that minor quantities of Δ^5-sterols may be present in these four tribes.

Species in the tribe Alsineae, subtribes Sabulininae and Polycarpeae, produce Δ^7-sterols with both 24α-ethyl and 24β-ethyl side chain configurations. Conformational analyses of sterol species with 360 MH_z NMR (41) have demonstrated that the $\Delta^{25(27)}$-sterols in these species possess the 24β-alkyl orientation. In *Spergula arvensis,* 24β-ethylsterols are the preferred sterol species even though 24α-ethylsterols are also produced.

The majority of species in the subtribe Stellariinae (except *Myosoton aquaticum*) produce prominantly Δ^7-sterols with lesser amounts of Δ^5-sterols. As the ratio of Δ^5-sterols to Δ^7-sterols increases, Δ^0-sterols are also produced.

SUMMARY

The Caryophyllales possesses other unique chemical features (1) and sterol chemistry may now be listed among these. Species within the families of the Caryophyllales possess a diversity of sterol metabolism which is currently unique in angiosperms.

The fossil record indicates that the Caryophyllales originated approximately 70 million years ago (1). The Caryophyllales may represent an order where evolution and attempts at regulation of sterol biosynthesis are most prominant. Alternatively, most species in this order are xerotolerant or halotolerant and many species are highly adaptable weeds found in waste places. Many species can tolerate conditions across all of these environments. If functional requirements for sterols with altered structures or stereospecificity exists in plants, the diversity of sterols in these species may facilitate tolerance to widely differing and harsh condi-

tions if sterols of differing structure are readily available. If, however, this diversity reflects the evolution of regulation within the sterol pathway, the species in the Caryophyllales could serve as a useful tool for investigating these control mechanisms.

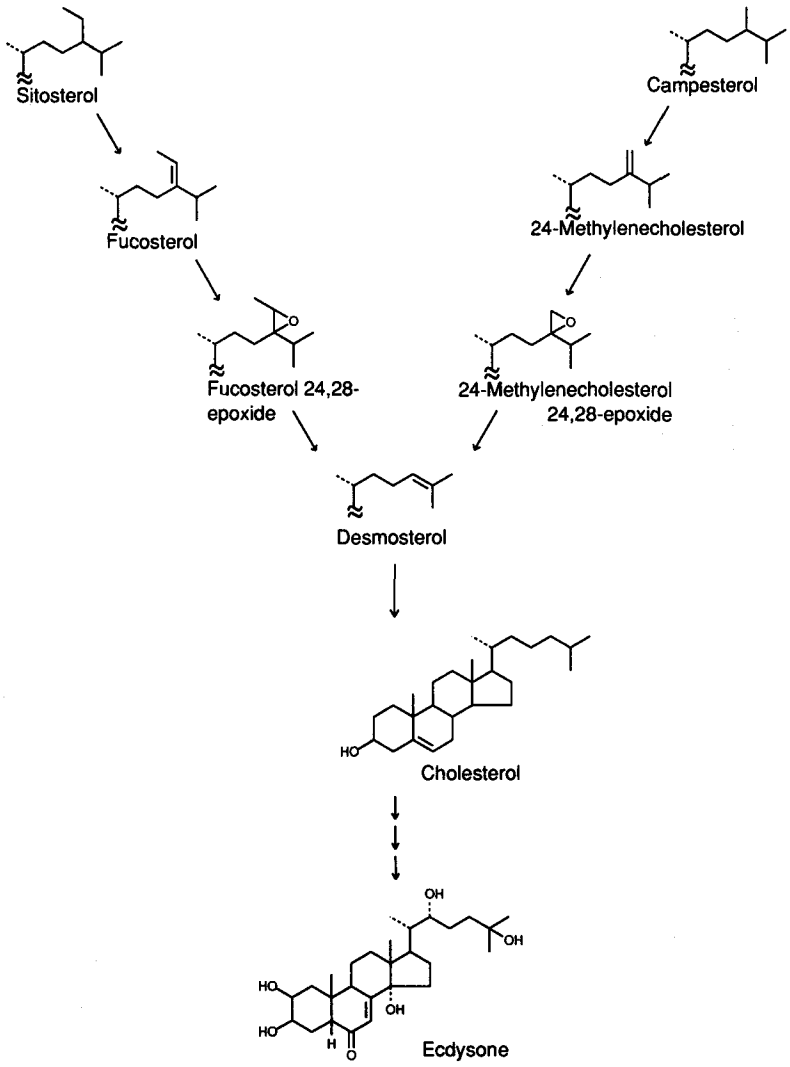
Neutral Sterol Metabolism in Insects[1]

James A. Svoboda* and **Mark F. Feldlaufer**
Insect Hormone Laboratory, Agricultural Research Service, USDA, Beltsville, Maryland 20705

Since they are unable to biosynthesize sterols, many phytophagous and omnivorous insects satisfy their cholesterol requirement by side chain dealkylation of the C-24 alkyl group of dietary C_{28} and C_{29} phytosterols. However, not all insects that can dealkylate the phytosterol side chain produce cholesterol. In addition, certain insects, *e.g.*, some Hymenoptera, Hemiptera, and Diptera, are unable to dealkylate the sterol side chain. Although C_{27} ecdysteroids (molting hormones), which are biosynthesized from cholesterol, are the major ecdysteroids in most insects, many of those species that are unable to dealkylate phytosterols utilize campesterol as a precursor for the C_{28} ecdysteroid makisterone A. The considerable diversity of steroid utilization between certain insect species makes it difficult to generalize about insect steroid biochemistry. The ability to disrupt certain unique aspects of steroid utilization and metabolism in insects might be exploited for developing new insect control technology.
***Lipids* 26, 614–618 (1991).**

SCHEME 1. Structures of ecdysteroids referred to in this review.

Insects are unable to biosynthesize the steroid nucleus (1) and require a dietary source of sterol to support normal development and reproduction (2). This presents an important area of biochemical difference between insects and many other species which might be exploited for developing new insect control technology by selectively disrupting steroid metabolism in insects. Cholesterol will generally (with few known exceptions) satisfy the dietary requirement of insects for sterol both as a membrane component and for physiological purposes such as ecdysteroid (molting hormone) biosynthesis (3). Ecdysone and 20-hydroxyecdysone (Scheme 1), the two most common ecdysteroids found in insects, are C_{27} steroids derived from cholesterol (4). Ecdysteroids are essential for every molt or morphological change that an insect undergoes. Obtaining a dietary source of cholesterol is no problem for insects that feed on animals or animal products which contain an abundance of cholesterol. However, for phytophagous insects that must subsist on a diet of plant or plant-derived material containing little or essentially no cholesterol, there would exist a major problem had these insects not evolved the ability to dealkylate C_{28} and C_{29} phytosterols to produce cholesterol (Scheme 2). Thus, it follows that a disruption of sterol metabolism at any metabolic step between the dietary phytosterol and cholesterol or between cholesterol and the molting hormone would result in mortality during early larval molts, which would be highly desirable with crop pests. It is necessary, first of all, to understand the variability of steroid metabolism among insects in order to be able to logically develop specific inhibitors of these essential biochemical pathways.



In this review, we will discuss recent research in several areas of neutral sterol metabolism in insects and the relationships of neutral sterols to ecdysteroid biosynthesis. We will not attempt to cover this area of research historically. The reader is referred to several recent reviews that treat this area of insect steroid metabolism in considerable depth (5–8). We will consider: i) certain aspects of dealkylation of C_{28} and C_{29} phytosterols; ii) sterol utilization in certain Hymenoptera; iii) some comparative studies with Hemiptera; and iv) comparative studies with Diptera.

SIDE CHAIN DEALKYLATION STUDIES

Much of the research on conversion of C_{28} and C_{29} phytosterols to cholesterol was done with sitosterol and campesterol (Scheme 2), but stigmasterol ($\Delta^{5,22E}$-24-ethyl) is also one of the most ubiquitous C-24 alkyl phytosterols. The metabolism of stigmasterol was examined in some depth recently in two separate studies. To date, the Mexican bean beetle, *Epilachna varivestis*, differs from any other insect that has been examined rigorously with respect to the metabolism of dietary C_{28} and C_{29} phytosterols. Regardless of the dietary sterol involved, whether sitosterol or stigmasterol, this insect reduces the Δ^5 bond before dealkylating the C-24 substituent, thus producing mainly cholestanol, some of which is subsequently converted to Δ^7-cholestenol (9). Three new intermediates were isolated and identified as metabolites of [^{3}H]stigmasterol and were found to accumulate in the insect tissues when azasteroid inhibitors were fed to the insects in combination with [^{3}H]stigmasterol (10). The three new insect

SCHEME 2. Generalized scheme for dealkylation and conversion of sitosterol and campesterol to cholesterol in insects.

sterols are 22-stigmastenol, 22,24-cholestadienol and 24-cholestenol. Thus, the pathway for dealkylation of stigmasterol in this species appears to be:

$$\Delta^{5,22}\text{-24-ethyl} \rightarrow \Delta^{22}\text{-24-ethyl} \rightarrow \Delta^{22,24} \rightarrow \Delta^{24} \rightarrow \Delta^{0} \rightarrow \Delta^{7}$$

The side chain metabolism proceeds in the same sequence as found in other insects that do not reduce the Δ^5 bond prior to dealkylation:

$$\Delta^{5,22}\text{-24-ethyl} \rightarrow \Delta^{5,22,24} \rightarrow \Delta^{5,24} \rightarrow \Delta^{5}$$

It is of interest to note, however, that stigmastanol is not dealkylated nearly as efficiently as stigmasterol, nor does Δ^7-stigmastenol appear to be metabolized by this insect. The Δ^5 bond must be present to obtain good metabolism of dietary sterols in the Mexican bean beetle.

The fate of [^{3}H]stigmasterol also was studied in a lepidopteran, *Spodoptera littoralis,* and stigmasterol-24,28-epoxide and stigmasta-5,22E,24(28E)-trien-3β-ol were identified for the first time from insects as intermediates in the dealkylation and conversion of stigmasterol to cholesterol (11). These two new sterols, plus cholesta-5,22E,24-trien-3β-ol, accumulated in the insect tissues when an azasteroid inhibitor was fed in combination with stigmasterol in the diet. Thus, it appears that intermediates in the conversion of stigmasterol to cholesterol in this lepidopteran occur that are analogous to fucosterol and fucosterol-24,28-epoxide in the conversion of sitosterol to cholesterol in other species (Scheme 2). The available evidence indicates that in *S. littoralis* the following pathway exists: stigmasterol → stigmasta-5,22E,24(28E)-trien-3β-ol → stigmasterol-24,28-epoxide → cholesta-5,22E,24-trien-3β-ol → desmosterol → cholesterol. Earlier indirect evidence from sitosterol metabolism studies with *Bombyx mori* is consistent with these results from *S. littoralis* (12). Later *in vitro* and *in vivo* metabolic studies with silkworms fed sitosterol provided more direct evidence for the presence of an epoxide as an intermediate in dealkylation (13,14). Additional information on the involvement of an

epoxide in dealkylation of phytosterols in several species was provided by a number of laboratories concerned with the mechanism involved (15–20). The review by Svoboda and Thompson (6) contains a detailed discussion of this mechanism.

The dealkylation of C_{28} phytosterols, such as campesterol, proceeds similarly to that of C_{29} sterols, with 24-methylene (21) and 24,28-epoxide (5) compounds serving as intermediates. However, *Heliothis zea*, which readily converts Δ^5-C_{28} and Δ^5-C_{29} phytosterols to cholesterol, utilizes $\Delta^{5,7}$-24-alkyl sterols differently (22). In metabolic studies with *H. zea* fed ergosterol ($\Delta^{5,7,22E}$-C_{28} sterol), the major insect sterol was 7-dehydrocholesterol, indicating that the side chain could be metabolized to a typical cholesterol side chain, but little saturation of the Δ^7 bond occurred in the B ring (22). In fact, less cholesterol was formed from ergosterol than when 7-dehydrocholesterol was the added dietary sterol. This is in contrast to the capability of *Tribolium confusum* to utilize 7-dehydrocholesterol, since this sterol and cholesterol occur in equilibrium in *T. confusum* regardless of the dietary sterol used (6).

STEROL UTILIZATION IN HYMENOPTERA

The honey bee, *Apis mellifera*, is one of a growing number of phytophagous insect species known to be incapable of dealkylating C_{28} and C_{29} phytosterols to produce cholesterol. Extensive studies with both C_{28} and C_{29} radiolabeled sterols, including campesterol, sitosterol, and 24-methylenecholesterol, using a well-defined diet, provided no proof of conversion of any of these 24-alkyl sterols to cholesterol (23). Regardless of the dietary sterol added, 24-methylenecholesterol was always the major sterol of the next generation. It was determined that the nurse bees have a very unusual ability to selectively transfer sterols from their own endogenous sterol pools in order to maintain a high level of 24-methylenecholesterol in the brood food and, thus, provide high levels of this sterol to the developing brood in the cells (23). Sitosterol and isofucosterol also seem to be favored by this selective transfer mechanism, although the significance of this selective sterol transfer remains unknown.

Of particular interest in recent research with the honey bee was the discovery that the C_{28} ecdysteroid, makisterone A (Scheme 1), is the major ecdysteroid identified in the pupa and ovaries of this species (24,25). This finding is consistent with what was found with several species of Hemiptera, all of which are also unable to dealkylate and convert C_{28} and C_{29} phytosterols to cholesterol, but utilize makisterone A as their molting hormone (26,27). In metabolic studies with labeled sterols, campesterol was identified as the precursor of makisterone A in the honey bee (28), although it was suspected prior to this that 24-methylenecholesterol, the major sterol of the honey bee, may have been the precursor of this ecdysteroid. The honey bee converts [^{3}H]campesterol, but not [^{3}H]24-methylenecholesterol, to makisterone A. It also converts [^{14}C]cholesterol to [^{14}C]20-hydroxyecdysone, although it does so less efficiently (28).

In comparative studies, another phytophagous hymenopteran, the alfalfa leafcutter bee, *Megachile rotundata*, was found to have 24-methylenecholesterol as a major component of its tissue sterols, with very little cholesterol occurring (0.5% of the total sterols), indicating that this solitary bee utilizes dietary sterols similarly to the honey bee (29). In this same study, the sterols of four omnivorous species of Hymenoptera, the baldfaced hornet, *Dolichovespula maculata*, the eastern yellowjacket, *Vespula maculifrons*, the Allegheny mound ant, *Formica exsectoides*, and the red imported fire ant, *Solenopsis invicta*, contained cholesterol as the major sterol, reflecting use of dietary sterols with no metabolic change, since their diet is usually high in cholesterol content (29). A very significant report of sterol utilization in a hymenopteran concerned the leaf-cutting ant, *Atta cephalotes isthmicola*. This paper described the first study in which no cholesterol could be detected in an insect (30). Apparently this phytophagous species cannot dealkylate the sterol side chain and the principal sterol of the brain and whole body was 24-methylcholesta-5,7,24(28)-trien-3β-ol. This provides the first evidence that a functional nervous system can exist in an animal without cholesterol.

STEROL UTILIZATION IN HEMIPTERA

The milkweed bug, *Oncopeltus fasciatus*, was the first phytophagous species found to be unable to dealkylate and convert 24-alkyl phytosterols to cholesterol (31). In addition, it was the first insect shown to produce makisterone A (32). Subsequent studies showed that other related Hemiptera also were able to produce makisterone A as their major ecdysteroids (26,27). This led to investigations of neutral sterol metabolism in a number of Hemiptera belonging to two different groups, the Pentatomomorpha and the Cimicomorpha. Three species of the first group, *O. fasciatus*, *Nezara viridula* and *Dysdercus cingulatus* are phytophagous and cannot dealkylate phytosterols; a fourth member of this group, *Podisus maculiventris*, is predacious and obtains adequate cholesterol from its diet (33). However, all of these species produce makisterone A as their major molting hormone (26). It is interesting to note that *P. maculiventris* is secondarily predacious but has maintained the ecdysteroid biosynthesizing capabilities of its ancestors. The three members of the Cimicomorpha group included in this study, *Rhodnius prolixus*, *Arilus cristatus*, and *Cimex lectularius*, are all blood feeders and cholesterol is their major tissue sterol, as it is normally in abundance in their diet (33). These blood feeders were found to produce only C_{27} ecdysteroids, such as ecdysone and 20-hydroxyecdysone (34). Another phytophagous true bug, *Megalotomus quinquespinosus*, although belonging to a different taxonomic group than the Hemiptera previously discussed, is likewise unable to dealkylate C_{28} and C_{29} phytosterols to form cholesterol (35). This species also produces makisterone A as its major ecdysteroid (35), thus fitting into the pattern of those phytophagous Hemiptera and other species that are unable to dealkylate but are able to utilize a dietary phytosterol unchanged, to produce makisterone A as their major ecdysteroid.

STEROL UTILIZATION IN DIPTERA

The house fly, *Musca domestica*, in studies using adequate biochemical methodology, was shown to be unable to convert [^{3}H]sitosterol to cholesterol over 25 years ago (36,37). For many years after, it was assumed that all

Diptera lacked this capability. However, eventually it was found that larvae of the yellow fever mosquito, *Aedes aegypti*, have the necessary enzymes to carry out such a conversion (38). In this study, dietary radiolabeled sitosterol, campesterol, and desmosterol were used to verify that this dealkylation capacity existed in *A. aegypti*. The 24-sterol reductase inhibitor, 25-azacholesterol, was also used in combination with [^{14}C]sitosterol to further demonstrate that a 24-reductase enzyme was present and could be inhibited, bringing about an accumulation of desmosterol with little cholesterol produced.

Until recently, the literature on phytosterol utilization in *Drosophila melanogaster* was unclear. Early growth studies with *D. melanogaster* led to the conclusion by the authors that this insect was able to dealkylate phytosterols to produce cholesterol (39). More recently, from another study, it was assumed that ergosterol was dealkylated by *D. melanogaster* (40). Neither of these studies used selective, valid biochemical or analytical techniques. Still other researchers used gas-liquid chromatography (GLC) to show metabolism of yeast sterols fed to *D. melanogaster*, but it is difficult to conclude that no cholesterol was present in the insects reared on the wild type yeast strain (41). However, in order to clarify this situation, and by using thorough metabolic studies, we were able to definitively demonstrate that neither dietary [^{14}C]sitosterol nor [^{14}C]desmosterol are converted to [^{14}C]cholesterol by *D. melanogaster* (42). It is noteworthy that *D. melanogaster* is classified among the higher Diptera as is the house fly, which it resembles with respect to sterol dealkylation.

From related research, it was concluded that several cactophilic *Drosophila* species could not dealkylate. They were fed cactus and the sterols were analyzed by GLC. From additional studies with axenic cultures, it was determined that these *Drosophila* were capable of some selective uptake of sterols (43), and demonstrated poor development when fed desmosterol as the sole added sterol (44). Since insects that dealkylate should thrive on a diet supplemented with desmosterol, this provides further proof of the inability of certain cactophilic species to dealkylate.

Recent investigations on the capability of *M. domestica* and *D. melanogaster* to utilize various dietary sterols and synthesize certain ecdysteroids were carried out in light of the fact that neither species is capable of dealkylating 24-alkyl sterols to produce cholesterol (45). These studies indicated that both species are capable of producing makisterone A from campesterol when this sterol is included at a fairly high concentration in the artificial medium. Through selective uptake, trace contaminants of cholesterol in the diet still allow both species to produce predominantly C_{27} ecdysteroids (ecdysone and 20-hydroxyecdysone). Whether the makisterone A has any physiological significance in these species is as yet unknown.

CONCLUSION

As we learn more about all aspects of steroid biochemistry in insects, the variety of ways that insects utilize and metabolize dietary neutral sterols becomes increasingly fascinating. This variability is a reflection of the ability of insects to adapt to living in virtually every conceivable ecological niche and to utilize whatever medium is available. Basic information on steroid metabolism provides important comparisons from a taxonomic standpoint, but also such indepth knowledge is necessary to enable discovery and development of specific inhibitors or other means of disrupting this important and unique area of insect biochemistry.

Metabolism of Plant Sterols by Nematodes[1]

David J. Chitwood* and **William R. Lusby**
Nematology Laboratory and Insect Neurobiology and Hormone Laboratory, USDA-ARS, Building 467, BARC-East, Beltsville, Maryland 20705

Parasitic nematodes do not biosynthesize sterols *de novo* and therefore possess a nutritional requirement for sterol, which must be obtained from their hosts. Consequently, the metabolism of phytosterols by plant-parasitic nematodes is an important process with potential for selective exploitation. The sterol compositions of several species of plant-parasitic nematodes were determined by capillary gas chromatography-mass spectrometry and compared with the sterol compositions of their hosts. Saturation of the phytosterol nucleus was the major metabolic transformation performed by the root-knot nematodes *Meloidogyne arenaria* and *M. incognita* and the corn root lesion nematode, *Pratylenchus agilis*. In addition to saturation, the corn cyst nematode, *Heterodera zeae*, dealkylated its host sterols at C-24. Because free-living nematodes can be cultured in sterol-defined artificial medium, they have been successfully used as model organisms for investigation of sterol metabolism in plant-parasitic nematodes. Major pathways of phytosterol metabolism in *Caenorhabditis elegans*, *Turbatrix aceti* and *Panagrellus redivivus* included C-24 dealkylation and 4α-methylation (a pathway unique to nematodes). *C. elegans* and *T. aceti* introduced double bonds at C-7, and *T. aceti* and *P. redivivus* saturated the sterol nucleus similarly to the plant-parasitic species examined. Several azasteroids and long-chain dimethylalkylamines inhibited growth and development of *C. elegans* and also the Δ^{24}-sterol reductase enzyme system involved in the nematode C-24 dealkylation pathway.
***Lipids* 26, 619–627 (1991).**

One of the few major biochemical differences between parasitic nematodes and their plant or vertebrate hosts is that nematodes possess a nutritional requirement for sterol because they are incapable of *de novo* sterol biosynthesis (1,2). Because higher plants synthesize 24-alkylsterols almost exclusively and because most animals predominantly contain cholesterol (3), one might expect plant-parasitic nematodes to remove the C-24 alkyl substituents of common phytosterols and thereby produce cholesterol. Not only is phytosterol dealkylation by nematodes of interest to the steroid biochemist, but this pathway offers the potential for being selectively exploited by novel nematode control agents. Therefore, we have examined various aspects of nematode sterol metabolism in depth in recent years, especially phytosterol metabolism and its disruption (4–16). The purpose of this review is to consolidate this research in which over 60 sterols have been identified in nematodes, with emphasis upon our recent work with *Pratylenchus agilis*.

Nematodes can be divided into at least three major groups according to their feeding habits: plant-parasitic nematodes, animal-parasitic nematodes, and the somewhat misnamed free-living nematodes, which in nature primarily feed upon microorganisms (17). The most significant obstacle in investigation of the biochemistry of parasitic nematodes is the present inability of biologists to readily culture parasitic nematodes throughout their entire life cycles in artificial medium. As a result, all of our research involving the metabolism of supplemented (usually radiolabeled) sterols by nematodes has been restricted to free-living nematodes. We have focused such studies upon *Caenorhabditis elegans* because it has received intensive study by molecular geneticists and developmental biologists (18). For comparative investigations of metabolic diversity in free-living nematodes, we examined *Panagrellus redivivus* and *Turbatrix aceti*. The plant-parasitic species investigated were representatives of the two most agronomically important groups of nematodes: the cyst nematodes *(Heterodera, Globodera)* and the root-knot nematodes *(Meloidogyne)*. These nematodes are sedentary endoparasites, *i.e.*, they establish themselves within plant roots and establish permanent feeding sites. We also investigated the lesion nematode *Pratylenchus agilis* because large quantities of it can be reared in sterile culture on excised corn root explants. This species is a migratory parasite that feeds both endoparasitically and ectoparasitically on corn roots (19).

STEROL IDENTIFICATION

The sterols we identified in nematodes were identical to authentic standards (when in our possession) by gas-liquid chromatography (GLC) relative retention times (RRT; Table 1) and gas-chromatography-mass spectrometry (GC-MS) (Table 2). In our previous investigations, the identification of compounds for which we lacked authentic material (Table 1, compounds 6, 7, 14, 15, 17, 18, 20, 26, 28, 30, 33, 45, 48, 50, 52–54, 56, 57, 59, 60, and 63) was accomplished by careful interpretation of data from GLC, GC-MS, ultraviolet (UV), and argentation column and thin-layer chromatography, with corroboration being obtained from MS and GLC data in the literature. Similarly, in our more recent investigations with *P. agilis*, we identified compounds 13, 34, 41, 44, 51, 55, 58, and 61 by comparison of GLC and GC-MS data with data associated with structurally related, previously identified compounds, as well as comparison with GLC and mass spectrometry (MS) data from the literature (20–28). In experiments with free-living nematodes, dietary sterols with known stereochemistry at C-24 were used: *e.g.*, sitosterol (24α-ethylcholesterol), campesterol (24α-methylcholesterol), or stigmasterol (24α-ethylcholesta-5,22(*E*)-

[a]GLC was performed on a temperature-programmed (90°C 1 min, 15°C/min increase to 250°C) DB-1 fused silica capillary column (14 m × 0.25-mm i.d., 0.25-μm film) and on an isothermally operated packed glass column containing 2.0% OV-17 stationary phase.

[b]Values in parentheses are RRT of steryl acetates relative to cholesteryl acetate. Trivial and systematic names: cholesterol, cholest-5-en-3β-ol; cholestanol, 5α-cholestan-3β-ol; desmosterol, cholesta-5,24-dien-3β-ol; lathosterol, 5α-cholest-7-en-3β-ol; fucosterol, 24(*E*)-ethylidenecholest-5-en-3β-ol; isofucosterol, 24(*Z*)-ethylidenecholest-5-en-3β-ol; isofucostanol, 24(*Z*)-ethylidene-5α-cholestan-3β-ol; obtusifoliol, 4α,14-dimethyl-24-methylene-5α-cholest-8-en-3β-ol; cycloartanol, 4,4,14-trimethyl-9β,19-cyclo-5α-cholestan-3β-ol; cycloeucalenol, 4α,14-dimethyl-24-methylene-9β,19-cyclo-5α-cholestan-3β-ol; cycloartenol, 4,4,14-trimethyl-9β,19-cyclo-5α-cholest-24-en-3β-ol.

dienol). Therefore, we assumed that nematode metabolites would have the same orientation at C-24 and have described such metabolites in Tables 3–5 as having the same 24α-orientation. Because quantities of sterols isolated from plant-parasitic nematodes or host roots were insufficient for nuclear magnetic resonance (NMR), we could not assign such orientations to the compounds in Table 6.

FREE-LIVING NEMATODES

The first question investigated was whether free-living nematodes could be useful models for investigating phytosterol dealkylation by plant-parasitic nematodes. *Caenorhabditis elegans* successfully utilized several phytosterols to satisfy its nutritional requirement for sterol (12). When this free-living species was propagated in medium containing only sitosterol (5,13), the major metabolite was 7-dehydrocholesterol (Table 3). Other metabolites included cholesterol, lathosterol, cholesta-5,7,9(11)-trienol, and most interestingly, 4α-methylcholest-8(14)-enol. Identification of these metabolites indicated that *C. elegans* not only is capable of phytosterol dealkylation but also introduces a double bond at C-7 and saturates the Δ^5-bond of $\Delta^{5,7}$-sterols. The subsequent direct 4α-methylation of lathosterol to produce 4α-methylcholest-7-enol and (after isomerization of the Δ^7-bond)

TABLE 2

Mass Spectral Data for Nematode Sterols, Analyzed as Steryl Acetate Derivatives[a]

Steryl acetate	Mass spectrum (*m/z*, intensity relative to base peak)

[a]Roots of *Zea mays* 'Pioneer 3184' from growth chambers.

[b]Host roots (greenhouse grown *Solanum melongena* 'Black Beauty') were not analyzed.

[c]Sterile root cultures of *Zea mays* 'Iochief'.

[d]Not detected.

4α-methylcholest-8(14)-enol was completely unexpected. This direct nuclear methylation of sterols is unique to nematodes; in other organisms, 4α-methylsterols are biosynthetic intermediates produced from 4,4,14α-trimethylsterols during *de novo* cholesterol biosynthesis (3). We considered the possibility that nematode 4α-methylsterols were artifacts, but in subsequent experiments with radiolabeled cholesterol, sitosterol, or desmosterol, the 4α-methylsterols isolated from *C. elegans* had the same specific activity as the dietary sterol. This result indicates that nematode 4α-methylsterols were not concentrated medium contaminants. Similarly, incubated nematode-free medium did not contain 4α-methylsterols. It remained possible that the 4α-methylsterols were the products of some external contaminant or internal symbiont, but supplementation of cultures with antimicrobial compounds (penicillin, streptomycin, and ketoconazole) failed to decrease the amount or composition of the 4α-methylsterols (Chitwood, D.J., unpublished).

Next, *C. elegans* was propagated in medium containing sitosterol plus an azasteroid, 25-azacoprostane hydrochloride (5β-cholan-24-dimethylamine hydrochloride) (5), an inhibitor of phytosterol dealkylation in insects (29). Excluding the dietary sitosterol, over 96% of the total sterol from *C. elegans* consisted of sterols with $\Delta^{24(25)}$- or $\Delta^{24(28)}$-bonds (Table 3), none of which normally occur in more than trace quantities. This accumulation of Δ^{24}-sterols and fucosterol indicated that the latter is a key intermediate in the phytosterol dealkylation pathway and that the azacoprostane was inhibiting the nematode Δ^{24}-sterol reductase enzyme system. Because growth and reproduction of *C. elegans* was strongly inhibited by 5 μg/mL of the azacoprostane·HCl, this experiment demonstrated the feasibility of using inhibitors of nematode sterol metabolism as model compounds for development of novel control agents for nematodes. Structurally related long-chain dimethylalkylamines (*e.g.*, *N,N*-dimethyldodecanamine) similarly inhibited growth, reproduction, and sterol metabolism of *C. elegans* (6).

Although inhibition of sterol metabolism by the alkyl-

amines was not as great as that with azacoprostane, the alkylamines were successfully used as metabolic probes to elucidate the pathways involved in the metabolism of other phytosterols by *C. elegans* (10). For example, treatment of stigmasterol-fed *C. elegans* with *N,N*-dimethyldodecanamine (Table 4) revealed that stigmasterol is dealkylated *via* a stigmasta-5,22,24(28)-trienol intermediate prior to reduction of the Δ^{22}-bond, which is then reduced prior to the Δ^{24}-bond. Analogous experiments with campesterol also resulted in an accumulation of Δ^{24}-sterols (Table 5). Interestingly, both control and inhibitor-treated cultures contained substantial proportions of campesterol metabolites with intact side chains but modified sterol nuclei, *i.e.*, $\Delta^{5,7}$-, Δ^{7}-, or $\Delta^{5,7,9(11)}$-bond systems, as well as $\Delta^{8(14)}$- and Δ^{7}-4α-methylcampestenols. This finding indicates that the nuclear modification enzymes in the *C. elegans* sterol metabolism pathway exclude 24-ethylsterols but may bind to 24-methylsterols. Lastly, use of stigmastanol-supplemented medium revealed that stigmastanol can be dealkylated by *C. elegans* (Table 4). Interestingly, cholesterol and 7-dehydrocholesterol were not detected, despite the fact that lathosterol was the major sterol metabolite. This finding revealed that *C. elegans* lacks the ability to introduce double bonds at C-5, a conclusion supported by additional investigations with dietary lathosterol and cholestanol (14).

Some comparative investigations with *Panagrellus redivivus* and *Turbatrix aceti* revealed that these free-living species also can dealkylate phytosterols (Tables 3, 5). The dealkylation pathway in *P. redivivus,* in contrast to *C. elegans,* does not result in the production of 7-dehydrocholesterol; instead, the major metabolite is cholestanol, with the principal 4α-methylsterol being 4α-methylcholestanol. *Turbatrix aceti* contains both pathways in that it produces both Δ^{0}- and $\Delta^{5,7}$-sterol metabolites.

PLANT-PARASITIC NEMATODES

The inability to culture plant-parasitic nematodes *in vitro* away from their plant hosts has restricted investigation of their sterol metabolic pathways to comparison of sterol compositions of host and parasite. Evidence for existence of C-24 dealkylation in plant-parasitic nematodes was initially discovered in the stem and bulb nematode, *Ditylenchus dipsaci,* which contained equal amounts of cholesterol and lathosterol and only traces of the phytosterols of its host, alfalfa callus (30). Although the major sterol of both cotton roots and the reniform nematode, *Rotylenchulus reniformis,* was 24-ethylcholesterol, cholesterol comprised 23% of the sterols of *R. reniformis* and only 0.6% of the sterols of the host roots (31). The major sterols of the tobacco cyst nematode, *Globodera tabacum solanacearum,* included 43% 24-methylcholestanol and 12% cholesterol (32). Although analysis of tobacco roots was not performed, the scarcity of stanols in higher plants led to the conclusion that this cyst nematode can hydrogenate plant sterols.

In our studies with a cyst nematode, *Heterodera zeae* (7), the major sterols of roots of its host (corn propagated in a growth chamber) were 24-ethylcholesta-5,22-dienol, 24-methylcholesterol, and 24-ethylcholesterol (Table 6). The predominant sterols of cysts (*i.e.,* adult females containing eggs) of *H. zeae* were 24-ethylcholesterol, 24-methylcholesterol, 24-ethylcholesta-5,22-dienol, and cholesterol. The abundance of cholesterol in this nematode in comparison to its host is suggestive of existence of C-24 dealkylation, although the possibility of selective uptake of cholesterol cannot be excluded. Similarly, the difference in ratios of 24-ethylcholesterol to 24-ethylcholesta-5,22-dienol in *H. zeae* and corn roots is suggestive of C-22 hydrogenation, but selective uptake remains a possibility, especially because *C. elegans* dealkylates stigmasterol before saturating the Δ^{22}-bond, as discussed previously. Another interesting finding in *H. zeae* was the detection of only a small relative percentage of stanols. Stanols of *G. tabacum solanacearum* comprised the majority of its sterols (32). The possibility that the two genera of cyst nematodes have different sterol saturation capabilities is a speculation worthy of further investigation.

Because the sterols of two different species of the same nematode genus had not been compared, we examined the sterols from the eggs of two different species of root-knot nematodes, *Meloidogyne incognita* and *M. arenaria* (15). The sterol compositions of the two species were very similar, with the principal sterols being 24-ethylcholesterol, 24-ethylcholestanol, 24-methylcholestanol, 24-methylcholesterol, and cholesterol (Table 6). The sterols of another race of *M. incognita* (race 3) were indistinguishable (15). We did not analyze sterols from the host roots (eggplant); because higher plants seldom contain more than traces of stanols, it is very likely that *M. incognita* and *M. arenaria* hydrogenate Δ^{5}-bonds. Cholesterol comprised a substantial percentage of the sterols (Table 6). Because roots of other Solanaceae contain as much as 10% cholesterol (33), it is uncertain whether *Meloidogyne* females or eggs can dealkylate phytosterols.

More recently, we have examined the sterols of mixed developmental stages of *Pratylenchus agilis* (Table 6), a nematode chosen because large quantities of vermiform stages can be obtained from sterile cultures of corn root explants. The only previous investigation of sterols in vermiform plant-parasitic nematodes was performed several years ago in *D. dipsaci* (33), as previously described. We had hoped to use *P. agilis* for studies involving dealkylation of radiolabeled phytosterols by phytoparasitic nematodes. A total of 28 sterols were identified; the major nematode sterols were 24-ethylcholest-22-enol, 24-ethylcholesta-5,22-dienol, 24-methylcholestanol, 24-ethylcholestanol, isofucostanol, and 24-ethylcholesterol (Table 6). The unexpectedly small amount of cholesterol (0.4% of the nematode sterol) indicates that *P. agilis* lacks the ability to dealkylate the sterols of corn roots. Instead, the four major metabolic products are 24-ethylcholest-22-enol, 24-methylcholestanol, 24-ethylcholestanol, and isofucostanol. As with *Meloidogyne* spp., *P. agilis* primarily saturates the phytosterol nucleus; our results indicate that *P. agilis* does not dealkylate the side chains of phytosterols.

Use of an on-column injector fitted to the gas chromatograph facilitated the identification in *P. agilis* of 9 sterols previously unidentified in nematodes: 24-methylcholest-22(*E*)-enol, 24-methylcholesta,5,24(25)-dienol, 24-ethylcholesta-5,23-dienol, 24-ethylcholesta-5,24(25)-dienol, 24-ethylcholest-24(25)-enol, 4α-methyl-24-ethylcholest-22-enol, 4α-methylisofucostanol, obtusifoliol, and cycloeucalenol. We are not aware of previous reports in *Z. mays* of 24-methylcholesta-5,24(25)-dienol, 24-ethylcholesta-

5,23-dienol, and 24-ethylcholesta-5,24(25)-dienol. Some Δ^{23}- and $\Delta^{24(25)}$-sterols have been implicated in biosynthesis of the major sterols of corn (34), although few of these have been detected previously in *Z. mays*.

Because of the uniqueness of the 4α-methylation pathway in nematodes, we were disappointed not to find any 4α-methylsterols in cysts of *H. zeae*. Small quantities of several 4α-methylsterols occurred in eggs of *Meloidogyne* spp., but the compounds identified had previously been reported in host plant seeds (23) or else were the stanol derivatives. In *P. agilis*, however, we detected very small quantities of 4α-methyl derivatives of the four major products of nematode sterol metabolism described above, *i.e.*, 4α-methyl-24-ethylcholest-22-enol, 4α,24-dimethylcholestanol, 4α-methyl-24-ethylcholestanol, and 4α-methylisofucostanol. Therefore, it is conceivable that *P. agilis* contains a slightly active 4α-methylation pathway. Whether our detection of these compounds in *P. agilis* and not other plant-parasitic nematodes has resulted from improved analytical equipment, greater analytical expertise, or existence of larger amounts of 4α-methylsterols in vermiform life stages is not known.

Compared to plant-parasitic and free-living nematodes, vertebrate-parasitic nematodes are less extensively investigated with respect to their sterol metabolism. As expected, cholesterol is the major sterol of these organisms, with digestive tract parasites also containing substantial amounts of phytosterols and stanols (8). In the only investigation of phytosterol metabolism in vertebrate-parasitic nematodes, *Ascaris* adults did not convert injected radiolabeled sitosterol to other sterols (35). Comparison of the sterol compositions of the insect-parasitic nematode *Steinernema feltiae* and its host, *Heliothis zea*, indicated that this nematode saturates Δ^5-bonds and introduces Δ^7-bonds (36), somewhat similarly to *C. elegans*, although 7-dehydrocholesterol was not detected in *S. feltiae*.

The diversity of phytosterol metabolism in nematodes is interesting. Particularly notable is the frequent abundance of phytosterols or their stanol derivatives in some plant-parasitic species. It is unknown whether these C-24 alkylsterols are utilized intact or else dealkylated by many of these nematodes prior to utilization, but the extremely low relative proportion of cholesterol in *P. agilis* indicates that this species probably utilizes phytosterols with a saturated nucleus in their intact form. Various species of nematodes are capable of saturation of Δ^5-, Δ^{22}-, and Δ^{24}-bonds, introduction of double bonds at C-7 and C-9(11), isomerization of a Δ^7-bond to a $\Delta^{8(14)}$-bond, 4α-methylation, C-24 dealkylation, and C-3 esterification. Exploration of other nematode taxa may reveal further metabolic capacities. Regardless, the fact that disruption of phytosterol metabolism has severely deleterious effects on the nematode life cycle (5,37) indicates that nematode steroid metabolism is a fruitful area for development of new approaches toward nematode control.

EXPERIMENTAL APPENDIX

Nematodes. Caenorhabditis elegans, Panagrellus redivivus, and *Turbatrix aceti* were propagated in an aqueous semidefined medium containing yeast extract, soy peptone, glucose, hemoglobin, Tween 80, and supplemented sterol (13). All of the medium components except soy peptone were extracted previously to remove endogenous sterol contaminants (5). Nematodes from late-logarithmic cultures were isolated by centrifugation, flotation on 40% sucrose, and repeated rinsing with distilled water.

The corn cyst nematode, *Heterodera zeae,* was propagated on roots of *Zea mays* 'Pioneer 3184' in growth chambers. Cysts (mature adult females containing eggs) were washed from roots and sand by collection on a sieve, floated on 40% sucrose, and rinsed thoroughly with distilled water (7). The root-knot nematodes *Meloidogyne incognita* race 2 and *M. arenaria* race 1 were propagated on eggplant (*Solanum melongena* 'Black Beauty') in a greenhouse (15). Eggs were released from egg masses, concentrated and thoroughly rinsed (38). The root lesion nematode *Pratylenchus agilis* was propagated on *Zea mays* 'Iochief' root sections on Gamborg's B5 medium formulated with 1.5% agar and 2.0% sucrose and lacking cytokinins and auxins (39). The agar was extracted previously with methanol and chloroform/methanol 2:1 (v/v, twice each) to remove the high amounts of endogenous cholesterol in commercial agar (40). The agar cultures were placed on top of a wet-strength paper tissue supported by a wire mesh screen in a funnel filled with water (*i.e.*, a modified Baermann funnel). Fifteen hours later, the mixed juvenile and adult nematodes that had settled at the bottom of the funnel were collected and cleaned as described above for the free-living species.

Sterol analysis. Lipids were extracted from lyophilized nematodes and fractionated into various lipid classes including steryl esters and free sterols by column chromatography on silica (7). The steryl ester and free sterol fractions were saponified separately, and the 4-desmethylsterols and 4-methylsterols isolated were further purified by Florisil column chromatography (15). For comparison of host and nematode sterols, uninfected roots of *Z. mays* 'Pioneer 3184' or root cultures of *Z. mays* 'Iochief' were analyzed identically as the nematodes, except the total lipid extract was saponified.

Sterols were tentatively identified by gas-liquid chromatography (GLC) on a DB-1 fused silica capillary column and an OV-17 packed glass column (15). The sterols were then acetylated, purified on Florisil columns, positively identified *via* gas chromatography-mass spectrometry (GC-MS), and, when necessary, fractionated on argentation columns (15). Instrumentation for mass spectrometry, liquid scintillation counting, and, when appropriate, UV spectrophotometry and 60 Mhz NMR spectroscopy, has been published previously (5,6,13).

ARTICLE

Cloning and Disruption of the Yeast C-8 Sterol Isomerase Gene[1]

William H. Ashman[a], Robert J. Barbuch[b], Corinne E. Ulbright[c], Harry W. Jarrett[d] and Martin Bard[a]*
[a]Department of Biology, Indiana University-Purdue University at Indianapolis, Indianapolis, Indiana 46205, [b]Merrell Dow Research Institute, Cincinnati, Ohio 45215, [c]Veterans Affairs Medical Center, Indianapolis, Indiana 46202 and [d]Department of Biochemistry, University of Tennessee Medical School, Memphis, Tennessee 38163

The yeast *ERG2* gene codes for the C-8 sterol isomerase, an enzyme required for the isomerization of the Δ8 double bond to the Δ7 position in ergosterol biosynthesis. The *ERG2* gene was cloned by complementation of a C-8 sterol isomerase mutant strain (*erg2*). The complementing region of DNA required to restore ergosterol synthesis to *erg2* was limited to a 1.0 kb *StuI-BglII* fragment. In order to determine whether the *ERG2* gene was essential for yeast viability, a *LEU2* gene was inserted into the *NdeI* site (made blunt) of this 1.0 kb fragment. Transformation of a wild type diploid strain with the *ERG2* substituted DNA resulted in the generation of viable haploids containing the *erg2* null allele (*erg2-4::Leu2*). These results suggest that the C-8 sterol isomerase activity is not essential for yeast cell viability. This disruption represents the second ergosterol biosynthetic gene in the distal portion of the pathway to be disrupted without adversely affecting cell viability.
***Lipids* 26, 628-632 (1991).**

Two distinct roles for sterol molecules in the yeast *Saccharomyces cerevisiae* have been postulated. The "bulk membrane function" is fulfilled by the major amount of sterol and is involved in the regulation of membrane fluidity, permeability, and growth rates. The "sparking function" (1,2) or "sterol synergism" (3) has been postulated based on the observation that yeast cells require nanomolar levels of ergosterol to enter the S phase of the mitotic cycle (4). Dahl *et al.* (4) demonstrated that sterol-depletion in the ergosterol-auxotroph, GL7 (*erg12-1 hem3-6*) results in arrest at the unbudded G1 state. Cell-budding and proliferation are reinitiated upon addition of nanomolar levels of ergosterol. Ergosterol was found to stimulate a protein kinase antigenically related to $pp60^{v\text{-}src}$ enabling the cell through the G1 to S transition (4). Several investigators have suggested that *erg6* or *erg3* mutants are leaky as these enzymatic modifications, the sterol transmethylase or the C-5 sterol desaturase are essential for the formation of the sparking sterol (1,2,5,6). We have previously demonstrated through cloning, gene disruption, and allele replacement studies of *ERG6* that this gene is unessential for yeast cell viability (7). If methylated sterols are essential for the sparking sterol, perhaps a non-allelic methylase can perform this function.

The cloning and disruption of *ERG2* was undertaken to determine whether this gene is essential for yeast cell viability. *ERG2* is the putative structural gene for the C-8 sterol isomerase, which is responsible for the isomerization of the B ring double bond from the 8(9) to the 7(8) position (8). This isomerization is followed by the introduction of a second double bond at C-5 to give a conjugated double bond system in the B ring. In yeast, an *erg2* mutation leads to the accumulation of sterols containing the Δ8 double bond (ergosta-8-en-3β-ol, ergosta-8,22-dien-3β-ol, and ergosta-5,8,22-trien-3β-ol). Heme and cytochrome P450 mutants unable to remove the 14α methyl group of lanosterol accumulate only Δ8-containing sterols suggesting that the C-8 sterol isomerase enzyme requires the prior removal of the 14α methyl group (9,10). Finally, the partially purified rat liver enzyme isolated by Paik *et al.* (11) was found to have a M_r of approximately 80 kdal.

In this report, we demonstrate the cloning of the *ERG2* gene, its disruption and allele replacement, which suggests that the *ERG2* gene is not essential for yeast cell viability.

MATERIALS AND METHODS

Strains. The *S. cerevisiae* strain WAO which contained the *erg2-3* mutation was the result of a cross between CG379 (kindly supplied by C. Giroux) and *pol2*, a polyene resistant strain derived from the wild-type strain A184D (12). Strains WA1 and WA6 were the result of crosses using strains CG379 and WAO. Strain WA2 was the result of transforming WA1 with a plasmid (pIU405) containing *ERG2* DNA inserted into the integrating vector, Ylp5. The yeast strains used are further described in Table 1. The *Escherichia coli* strains HB101 and MC1066 were used for amplification and selection of plasmids.

Plasmids and transformations. To clone the wildtype *ERG2* gene, a library of genomic yeast DNA fragments ligated into the shuttle vector YCp50 (13) was used. Yeast transformations were accomplished using the method of Gaber *et al.* (7). The subcloning vectors were pRS314, pRS315 and pRS316 (14). YIp5 was used for directed integration and YEp13 was the source of the LEU2 gene. Calcium chloride treated competent *E. coli* were transformed as described by Maniatis *et al.* (15).

Media. YPD (1% yeast extract, 2% peptone, and 2% dextrose), YNB (0.67% yeast nitrogen base, 2% dextrose) were prepared as described by Sherman *et al.* (16). YNB was supplemented with appropriate amino acids and nitrogenous bases and, when required, with 0.06 μg of cycloheximide or 0.8 μg of nystatin per mL. *E. coli* complete media, TY, consisted of 0.5% NaCl,

0.8% Bacto-tryptone and 0.5% Bacto-yeast extract. Ampicillin was added 50 μg per mL. *E. coli* minimal medium was made as described by Miller (17) and supplemented with ampicillin and/or appropriate amino acids.

Plasmid constructions. Standard recombinant DNA techniques were used to subclone the DNA fragments containing the *ERG2* gene from pIU402 and pIU403 (15). Frameshift mutations were introduced into various plasmids by complete digestion with the appropriate restriction endonuclease, followed by filling in of the protruding ends using the *E. coli* polymerase 1 large fragment (Klenow). The blunt ends were then ligated to recircularize the plasmid. For subcloning, gel-purified DNA was ligated into appropriately digested vectors. Disrupted constructions were generated by the one-step gene disruption method of Rothstein (18).

DNA manipulations. Large-scale plasmid DNA isolation from *E. coli* was prepared as described by Maniatis *et al.* (15); small-scale plasmid DNA was isolated from *E. coli* using the Miniprep Kit Plus (Pharmacia Inc., Piscataway, N.J.). Plasmid DNA from yeast and yeast genomic DNA were prepared as described by Sherman *et al.* (16). Hybridization probes for Southern blots were made using a random oligonucleotide primer kit from NEN (Boston, MA). The *ERG2* probe was prepared by gel purification of a 1.45 kb *Bgl*II-*Sca*I fragment and yeast genomic DNA was digested with *Xba*I. Southern analysis was carried out as described by Maniatis *et al.* (15) and the protocol using Nytran membranes supplied by Scheicher & Schuell (Keene, NH).

Sterol analysis. Nonsaponifiable sterols were extracted from stationary-phase yeast cells into n-heptane by the method of Molzahn and Woods (12) and scanned between 200 and 300 nm for absorption maxima. The gas chromatographic-mass spectral (GC-MS) analyses were done using either a Finnigan MAT Model 4600 or VG Trio-1 mass spectrometer system (Finnigan Corp., Sunnyvale, CA). The GC separations were performed on a 15 M × 0.32 mm Durabond DB-1 column with a 0.25 μm film thickness. The column oven temperature was programmed from 200–300°C at 15°C per min and the carrier gas was helium at a linear velocity of 50 cm/sec. The indicated MS ion source temperature was 120°C. The mass spectrometer was operated in the electron impact ionization mode at 70°V and was scanned from *m/z* 40 to *m/z* 600. Mass spectra were enhanced by subtraction when necessary.

RESULTS AND DISCUSSION

Isolation of the ERG2 *gene.* The *ERG2* gene was isolated using essentially the genetic transformation protocol of Gaber *et al.* (7). The gene was isolated from a yeast genomic library constructed in the shuttle vector, YCp50. Strain bearing *erg2* mutations exhibit a number of phenotypes including resistance to nystatin and sensitivity to cycloheximide and the *ERG2* gene was cloned on the basis of its ability to suppress the cycloheximide sensitivity of *erg2.* Four plasmids isolated—pIU401, pIU402, pIU403, and pIU404—suppressed the cycloheximide sensitivity of the *erg2—3* strain, WAO. This strain fails to grow on YNB medium containing 0.06 μg/mL cycloheximide, whereas *erg2-3* transformants containing plasmids pIU401–404 demonstrated wildtype growth levels on this medium. All transformants were also nystatin-sensitive.

Sterol analysis of erg2-3 *and transformants.* The sterol profile of *erg2* elucidated by Barton *et al.* (8) demonstrated that only sterols with Δ8 double bonds accumulated in this strain. No sterols with a Δ7 double bond were observed. The sterol profile of *erg2-3* grown on YNB medium contains three major sterols determined by GC-MS (Fig. 1): ergosta-5,8,22-trien-3β-ol (peak A); ergosta-8,24(28)-dien-3β-ol; and ergosta-8-en-3β-ol (peaks B and C). The sterol ratio for these three sterols are 22:15:60, respectively. These results are all consistent with our previous determination that *erg2* strains are deficient in C-8 sterol isomerase activity. The pIU401–404 transformants, however, are able to synthesize ergosterol as well as other wildtype sterols. *erg2*/pIU401 Accumulates zymosterol (peak D, 10%), ergosterol (peak E, 35%) as well as two other Δ7 sterols, ergosta-7,24(28)-dien-3β-ol and ergosta-7-3n-3β-ol (peaks F and G, both 4%). Ergosta-8,24(28)-dien-3β-ol and ergosta-8-en-3β-ol were present in the

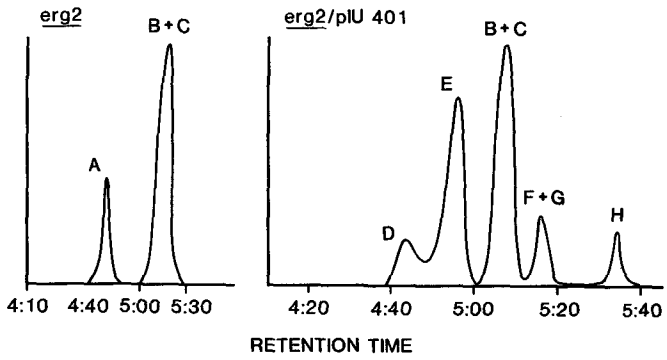

FIG. 1. Retention times (minutes) of sterols extracted from WA0 (*erg2–3*) and the same strain transformed with plasmid pIU401 (Erg$^+$). Peak A, ergosta-5,8,22-trien-3β-ol; peaks B & C, ergosta-8,24(28)-dien-3β-ol and ergosta-8-en-3β-ol, respectively; peak D, zymosterol; peak E, ergosterol; peaks F & G, ergosta-7,24(28)-dien-3β-ol and ergosta-7-en-3β-ol, respectively; and peak H, lanosterol. GC-MS was carried out using a Finnegan MAT Model 4600 or VG Trio-1.

transformed strains at 15% and 27%, respectively. Peaks not clearly separable by GC were distinguished by MS.

Subcloning and localization of the ERG2 *gene.* Plasmids pIU401 and pIU404 were identical containing inserts of 12.7 kb of genomic DNA. pIU402 and pIU403 Contained 6.4 and 6.6 kb of insert, respectively, and were identical except at their termini (Fig. 2). Plasmid pIU406 represents a subclone in which a 3.0 kb *Sac*I fragment was deleted from pIU403. Plasmid pIU407 was derived from pIU406 and contains a further 0.7 kb deletion at the left terminus of the insert. Plasmid pIU409 represents a subclone in which 3.1 kb of the pIU402 insert is deleted. All three plasmids complemented the *erg2–3* strain. pIU411 Contains a 2.7 kb *Kpn*I-*Sac*I fragment also able to complement *erg2–3*, whereas pIU412 deleted for a 1.2kb *Kpn*I-*Bgl*II fragment failed to complement the mutant strain. Two plasmids, pIU415 and pIU420, containing 1.9 kb *Stu*I-*Hind*III and 1.0 kb *Stu*I-*Bgl*II DNA frag-

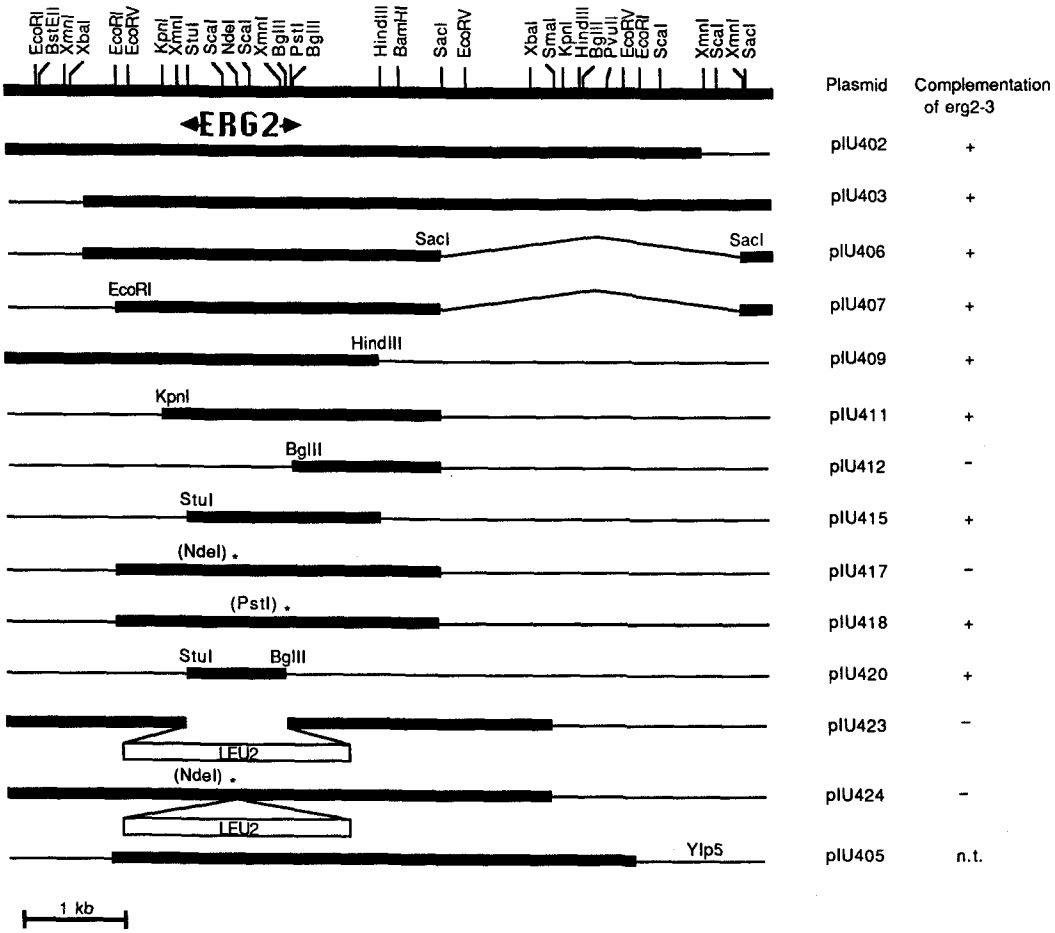

FIG. 2. Restriction endonuclease sites of the *ERG2* gene and construction of plasmid subclones. Genomic clones are pIU402 and pIU403. Subclones pIU406, pIU407, pIU409 are in YCp50; pIU405 is in YIp5. All others were constructed in the pRS vector series (14). The ability of each plasmid to complement *erg2–3* is indicated. Asterisked restriction sites indicate sites made blunt by DNA polymerase I(Klenow). n.t., not tested.

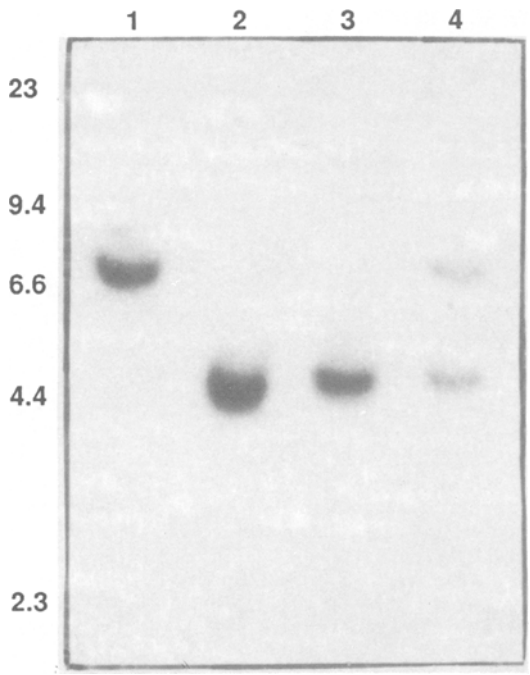

FIG. 3. Southern blot analysis of *Xbal* digested genomic DNA from haploid strains *erg2-4::LEU2* (WA10-3-1A, lane 1) and *ERG2* (WA10-3-1B, lane 2) probed with a 1.45 kb *Bgl*II-*Sac*I fragment from pIU 411. Lane 3, untransformed dipoid WA1/6 and lane 4, transformed diploid WA10, heterozygous for the disruption.

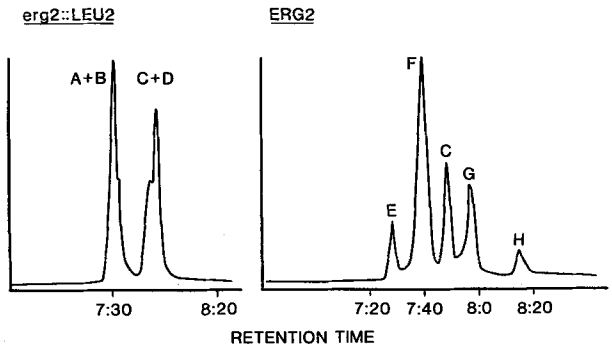

FIG. 4. Retention times (min) of sterols extracted from WA10-3-1A (*erg2-4::LEU2*) and WA10-3-1B (*ERG2*). Peaks A and B, ergosta-5,8,22-trien-3β-ol, and ergosta-8,22-dien-3β-ol, respectively; peaks C and D, ergosta-8,24(28)-dien-3β-ol, and ergosta-8-en-3β-ol, respectively; peak E, zymosterol; peak F, ergosterol; peak G, ergosta-7,24(28)-dien-3β-ol; and peak H, lanosterol.

ments, respectively, also complemented *erg2-3* (Fig. 2).

Frameshift mutagenesis of ERG2. The location of restriction endonuclease sites within the *ERG2* gene was determined through *in vitro* mutagenesis. Frameshift mutations were introduced at the *Nde*I and *Pst*I sites in pIU417 and pIU418, respectively, as described in Materials and Methods. Only pIU418 was able to complement *erg2-3*, suggesting that the *Nde*I site is within the coding region of *ERG2* (Fig. 2). The *Pst*I site is either not in the coding region, or if it is, it must be in a C-terminal portion of the gene.

Directed integration of ERG2 DNA into the yeast genome. In order to verify that the cloned DNA coded for *ERG2* and not an unlinked supressor gene, a directed integration experiment in which the 5.1 kb *EcoRI* fragment from pIU403 was subcloned into YIp5 to make the recombinant plasmid pIU405. pIU405 Was linearized by digestion with *Xba*I to enhance frequency of integration into the homologous chromosomal site. A *ura3-52* strain (WA1) was transformed with the linear plasmid to uracil prototrophy and one of the transformants (WA2) URA$^+$ ERG$^+$ mated to a *ura3-52 erg2-3* strain (WA0). The resultant diploid (WA3) was sporulated and asci were disected onto YPD agar plates. Twenty-two tetrads showed a 2 Ura$^+$ Erg$^+$: 2 Ura$^-$Erg$^-$ segregation pattern, demonstrating genetic linkage between the integrated plasmid containing the *URA3* marker and the *ERG2* locus. This indicates that the cloned DNA integrates at the *ERG2* locus, and is therefore the *ERG2* gene.

Disruption of the ERG2 *gene.* In order to determine whether the C-8 sterol isomerase gene is essential for yeast cell viability, null alleles of *ERG2* were generated. pIU423 Contained a 1.0 kb deletion of the *Stu*I-*Bgl*II region (previously shown to fully complement *erg2-3*) and in its place was inserted a 2.4 kb *Hpa*I-*Bgl*II fragment containing the *LEU2* gene isolated from YEp13. A 5.7 kb *Xba*I fragment derived from pIU423 encompassing this disrupted *erg2Δ::LEU2* allele was gel-purified and used to transform the diploid strain WA1/6 to leucine prototrophy. The recombination event to Leu$^+$ transformants involves the replacement of a wildtype *ERG2* allele with the deletion/substitution (disrupted) allele (18). The Leu$^+$ transformants were sporulated and, following asci dissection, showed a 2:0 segregation pattern with only Leu$^-$ spores growing. However, when Leu$^+$ transformants were sporulated, asci dissected, and grown anaerobically on ergosterol containing medium, the results were the same (only two viable Leu$^-$ colonies) suggesting that disruption resulted in the loss of non-*ERG2* chromosomal DNA required for viability. A second *ERG2* gene disruption was performed using plasmid pIU424. This plasmid contained the entire complementing *Stu*I-*Bgl*II 1.0 kb DNA fragment, in which the *Nde*I site was restricted, made blunt using DNA polymerase I (Klenow) followed by ligation of a 2.2kb *Hpa*I *LEU2* gene. A 6.7 kb *Xba*I fragment (derived from pIU425) encompassing this disrupted *erg2::LEU2* allele was obtained and again used to transform strain WA1/6. Leu$^+$ transformants were isolated, sporulated, and asci dissected. Among 27 tetrads, spore viability was 100%. Leu$^+$ Erg$^-$ and Leu$^-$ Erg$^+$ spores segregated 2:2 and showed complete linkage (parental ditype asci only), indicating that the disruption of *ERG2* did not result in cell inviability or a requirement for exogenous ergosterol. Southern blot analysis of genomic DNA prepared from the Leu$^+$ Erg$^-$ (Fig. 3, lane 1) and Leu$^-$ Erg$^+$ (lane 2) haploids confirmed that the former har-

bored the *erg2-4::Leu2* mutation as a result of gene disruption. Genomic DNA digested with *Xba*I and probed with a 1.45 kb *Bgl*II- *Sca*I DNA fragment gave rise to two hybridizeable bands—a non-disrupted 4.5 kb band and a 6.7 kb band (containing 2.2 kb of *LEU2* DNA). Figure 3 similarly demonstrates that the non-disrupted diploid, WA1/6 (lane 3) contains only the 4.5 kb hybridizeable band, whereas the transformed diploid WA10 (lane 4), heterozygous for the disruption, contains both the 4.5 and 6.7 hybridizeable bands.

Sterol analysis of the erg2 *disruption.* Figure 4 shows a sterol profile of a disrupted and a non-disrupted isolate from the same tetrad. WA10-3-1A (Leu^+ Erg^-) grown on YPD medium contains sterols with only Δ8 double bonds. These are peaks A and B, comprising 50% of the total sterol, ergosta-5,8,22-trien-3β-ol and ergosta-8,22-dien-3β-ol, and peaks C and D, also comprising 50% of total sterol containing ergosta8,24(28)-dien-3β-ol and ergosta-8-en-3β-ol. Within the limits of our detection (less than 1% of total sterol), we found no evidence of Δ7 sterols. Strain WA10-3-1B, a non-disrupted colony from the same tetrad (Leu^- Erg^+) gave the wildtype sterol spectrum with ergosterol (peak F, 76%) as the predominant sterol.

The molecular disruption of *ERG2* represents the second ergosterol biosynthetic gene which we found to be not essential for cell viability. Thus, it is still unclear whether there is a specific requirement for a particular sterol molecule. It is also unclear whether other non-allelic genes may be responsible for enzymes required for the formation of the sparking sterol since it is clear that the disruptions in *ERG2* and *ERG6* eliminate their participation in ergosterol formation. The yeast, *Saccharomyces cerevisiae*, exhibits flexibility with regard to lipid composition. For example, a *chol1-1 ino1-13* double mutant supplemented with inositol and choline is deficient in the synthesis of phosphatidylserine and a strain which overproduces inositol (*opi3-d*) is deficient in phosphatidylcholine synthesis (19). Similarly, viable yeast strains that are deficient in sphingolipids have been described (20). Thus, at least in *Saccharomyces cerevisiae*, there is unusual tolerance to major alterations in the phospholipid, sterol, and sphingolipid compositions.

Yeast mutant strains auxotrophic for ergosterol and blocked in mevalonate diphosphate decarboxylase (*erg19*) and farnesyl diphosphate (FPP) synthetase (*erg20*) were isolated. The main feature of the mutants blocked in FPP synthetase is their ability to excrete prenyl alcohols, such as geraniol and farnesol. The isolation of the functional *ERG20* gene allowed us to show that farnesyl diphosphate synthetase could be a rate limiting enzyme in ergosterol biosynthesis in yeast.
***Lipids* 26, 633-636 (1991).**

Saccharomyces cerevisiae cells contain 1-3% sterols depending on the growth medium. Ergosterol represents about 50% of the total sterols and is the major free sterol involved in membrane structure.

Three kinds of mutants blocked in the ergosterol pathway have been isolated and extensively studied. The first kind corresponds to mutations affecting late steps in the pathway, down stream of zymosterol; these mutants were isolated based on resistance to the polyene antibiotic nystatin and are not sterol-auxotrophic (1). The second type of mutants were isolated as requiring both ergosterol and an unsaturated fatty acid (2,3). It was shown that the pleiotropic requirements are related to deficiency in porphyrin biosynthesis; hematin enzymes are implicated in respiration, lanosterol demethylations, fatty acid desaturation and sulfate reduction. The physiological study of these mutants allowed us to isolate numerous mutant strains affected in enzymes from acetoacetyl-CoA thiolase to lanosterol C-14 demethylase. The main feature of the mutants of this third class is that they are generally temperature sensitive. Temperature sensitivity of mutants defective in early enzymes of the sterol pathway is easy to understand since the biosynthetic route provides, in addition to ergosterol, many essential molecules such as the side chain of ubiquinone, dolichol, and farnesyl groups of prenylated proteins.

We describe here the last mutations that we have isolated; *erg19* and *erg20*, affecting mevalonate diphosphate (MVAPP) decarboxylase and farnesyl diphosphate (FPP) synthetase, respectively. Furthermore, we present evidence that FPP synthetase may be a rate-limiting enzyme in sterol biosynthesis in yeast.

EXPERIMENTAL PROCEDURES

Strains and culture conditions. The strains used were derived from *Saccharomyces cerevisiae* FL100 (A.T.C.C. 28383) haploid, a mating type, or from an isogenic strain FL200 (A.T.C.C. 32119), haploid, α mating type. Culture conditions and media were those previously described (4). 5247 Was an *ura3 trp1* auxotroph. Plasmid pCC1 was a derivative of pUC 19 bearing a yeast chromosomal origin of replication (ARS), the CEN 6 DNA, the *TRP1*, and *ERG20* genes. pCC2 was a pUC 19 derivative bearing the yeast 2 μm DNA as replication origin, the *URA3*, and *ERG20* genes (5).

Enzyme preparation. A 12,000 $\times$ *g* cell-free supernatant was prepared as described (5).

MVAPP decarboxylase assay. [1,3,5-^{14}C]MVAPP was synthesized by an enzymatic method using a cell-free extract of mutant strain MN*erg19*. The standard assay mixture contained, in a total volume of 0.5 mL, 75 mM potassium phosphate buffer pH 7.4, 1.5 mM DTT, 10 mM ATP, 10 mM G6P, 1 mM NADP, 5 mM PEP, 0.25 mM CoA, 10 mM KF, 5 mM $MgCl_2$, 30 mM KCl, 2 units glucose-6-phosphate dehydrogenase, 2 units pyruvate kinase and [1-^{14}C]acetate 1 mM (2 mCi/mmol). The assay was initiated by addition of 5-mg of crude enzyme. The incubation period was 90 min at 30°C; the reaction was stopped by addition of 0.05N HCl in 75% ethanol. The mixture was warmed quickly to 60°C and kept at that temperature for 90 sec. The mixture was then cooled in ice, and the precipitate was sedimented by centrifugation. The supernatant was decanted and saved, and the precipitate was washed three times with 75% ethanol. The washings combined with the first supernatant were concentrated on a rotary evaporator at 50°C, and the residue was dissolved in a minimum amount of buffer pH 7.4. An aliquot was assayed for radioactivity by liquid scintillation counting. The remainder was applied to Silica Gel G plates and the plates were developed with n-propanol/NH_4OH/water (6:3:1, v/v/v). Distribution of the radioactivity incorporated was then determined using a Berthold 2382 thin-layer chromatography(TLC) Linear Analyzer (Berthold Analytical, Wildbad, Germany). The band containing [1,3,5-^{14}C](R)-5-mevalonate diphosphate (R_f 0.09) was scrapped into a small flask, and MVAPP was extracted by shaking with dilute aqueous ammonia; the preparation was 40 μM (6 mCi/mol). MVAPP was identified by two different methods: acid hydrolysis in 1N HCl for 10 min at 100°C led to the formation of mevalonate phosphate (MVAP) (R_f 0.15), and alkaline phosphatase hydrolysis released mevalonic acid (R_f 0.7).

[1]Based on a paper presented at the symposium on Plant and Fungal Sterols: Biosynthesis, Metabolism and Function, held at the AOCS Annual Meeting, Baltimore, MD, April 1990.

Abbreviations: DMAPP, dimethylallyl diphosphate; DTT, dithiothreitol; ERG, functional gene in ergosterol pathway; erg, gene defective in ergosterol pathway; FPP, farnesyl diphosphate; GC/MS, gas chromatography/mass spectrometry; GPP, geranyl diphosphate; HMG-CoA, hydroxymethylglutaryl-Coenzyme A; IPP, isopentenyl diphosphate; MVA, mevalonic acid; MVAP, mevalonate phosphate; MVAPP, mevalonate diphosphate; TLC, thin-layer chromatography; [], denotes plasmid-carrier state.

The assay of MVAPP decarboxylase activity was carried out in 3-mL Warburg flasks. The center well contained 0.2 mL of 40% KOH and frilled filter paper. The two side arms contained 0.1 mL of 6N HCl and 0.1 mL MVAPP (40 μM), respectively. The 0.4-mL incubation mixture in the main compartment consisted of 75 mM potassium phosphate buffer, pH 7.4, 5 mM $MgCl_2$, 10 mM KF, 1.7 mM DTT, 5 mM ATP, and about 3 mg protein. The substrate [1,3,5-^{14}C](R)-mevalonate diphosphate was added last to a concentration of 8 μM. The mixture was incubated with shaking at 30°C for 60 min, then the acid was tipped from the side arm into the main compartment and the incubation was continued for one hour. The filter papers were removed from the center well, kept overnight at room temperature and counted for radioactivity. Enzyme specific activity is expressed as nanomoles of CO_2 generated per mg protein per hour.

FPP synthetase assay. The assay was performed as previously described (5).

Phosphatases assays. The assays were performed as described by Torriani (6).

Analysis of excreted prenyl alcohols. The prenyl alcohols were analyzed by gas chromatography/mass spectrometry (GC/MS) after dichloromethane extraction, using methyl undecanoate as internal standard and a Fracto Vap 4160 (Carlo Erba, Milano, Italy) chromatograph (Carbowax 20M column) coupled to a Kratos MS25 (Kratos Analytical, Ramsey, NJ) mass spectrometer connected to a Data General Eclipse S120 computer. The compounds were identified by comparison to a library of reference spectra.

RESULTS AND DISCUSSION

Mutant isolation and general characteristics. Mutants bearing *erg19* and *erg20* mutations were isolated on the basis of resistance to the polyene antibiotic nystatin as previously described (7). Thus far we have isolated sterol auxotrophic mutant strains which belong to 14 complementation groups. Moreover, intragenic complementation was observed in the *ERG10* and *ERG12* genes, reflecting the oligomeric nature of these two proteins (Table 1).

The mutants are, in general, temperature sensitive, which means that they are unable to grow at high tempratures (36°C), even in sterol-supplemented medium. Four mutants are simple sterol auxotrophs, namely *FKerg7, FKerg17, FKerg9* and *VL134* (or *VL135*). We have shown (7) that mutant strains *FKerg7, FKerg9* and *FKerg17* bear an additional mutation (*aux30*) allowing sterol permeability, as *hem* mutations do. All other mutant strains are intrinsically permeable to exogenous sterols and do not require an additional mutation. One can assume that exogenous sterol uptake takes place as soon as the cells become sterol-requiring; the accumulation of oxidosqualene (*FKerg7* and *FKerg17*) or FPP (*FKerg9*) could neutralize the starvation signal.

The lack of sterol permeability in aerobiosis is not the reason why sterol auxotrophs must be isolated as conditional mutants. More likely, a complete enzymatic block in an early step of the sterol pathway would lead to a pleiotropic requirement not satisfied by exogenous supplementation. This has been shown by gene disruption experiments (8,9). Under standard aerobic growth conditions at 28°C the sterol auxotrophs present optimal growth at ergosterol supplementation of 2 mg/L. Under such conditions, the ergosterol level of the cells is about 0.25% of cell dry weight (*i.e.,* three-fold lower than in the wild type strain). With a high ergosterol supplementation (50 mg/L), the ergosterol level of the mutants is strongly enhanced by 6–10-fold; in spite of this high ergosterol content, enzyme activities such as acetoacetyl-CoA thiolase and HMG-CoA synthase remain induced (10).

TABLE 1

Gene-Enzyme Relation in Ergosterol Pathway in *Saccharomyces cerevisiae*

Gene	Enzyme
ERG10A, ERG10B	Acetoacetyl-CoA thiolase
ERG11, ERG13	HMG-CoA synthase
ERG12A, ERG12B	Mevalonate kinase
ERG8	MVAP kinase
ERG19	MVAPP decarboxylase
ERG20	FPP synthetase
ERG9	Squalene synthetase
ERG1, ERG18, ERG14	Squalene epoxidase
ERG7, ERG17	Oxidosqualene:lanosterol cyclase
ERG16	Lanosterol-14 demethylase

TABLE 2

MVAPP Decarboxylase and FPP Synthetase Activities in Wild Type, MN*erg19*, VL134 and VL135 Mutant Strains

Strains[c]	FPP synthetase[a] DMAPP	FPP synthetase[a] GPP	MVAPP decarboxylase[b]
WT	6.47	5.13	0.36
MN*erg19*	10.60	9.10	0.01
VL134	0.09	0.09	—[e]
VL135	ND[d]	ND	—[e]

[a]Results are expressed as nmoles [^{14}C]IPP converted per min per mg protein.

[b]Results are expressed as nmoles $^{14}CO_2$ formed per min per mg.

[c]Wild type strain and sterol auxotrophic mutants were grown in a complete medium supplemented with ergosterol (2 mg/L) at 28°C with shaking. Cells were harvested during the exponential phase.

[d]ND, not detected.

[e]Not determined.

Determination of the enzymatic lesions. Enzyme lesions were identified first by precursor accumulation and then by measurement of *in vitro* enyme actiities. Identification of *erg10* (acetoacetyl-CoA thiolase), *erg11* (HMG-CoA synthase), *erg12* (mevalonate kinase), *erg8* (MVAP kinase), *erg9* (squalene synthetase), *erg1, erg18* and *erg14* (squalene epoxidase), *erg7* and *erg17* (oxidosqualene lanosterol cyclase) and *erg16* (lanosterol demethylase) has been described previously (7,11).

Identification of defects in MVAPP decarboxylase (erg19) *and FPP synthetase* (erg20). [^{14}C]Acetate incubation in cell free extracts of MN*erg19* mutant strain showed accumulation of a compound more polar in TLC than MVAP. This compound was identified as MVAPP as described in the experimental section. Mevalonate diphosphate decarboxylase activity was measured in cell-free extracts of wild type and MN*erg19* mutant strains; no significant activity was observed in MN*erg19* extracts (Table 2).

[^{14}C]Mevalonic acid (MVA) incubation in cell-free extracts of VL134 and VL135 mutant strains showed the accumulation of a compound displaying the same strong polarity on Silica Gel G plates as dimethylallyldiphosphate (DMAPP), isopentenyl diphosphate (IPP) or MVAP. This compound was identified as DMAPP (5). Therefore, the two mutants were likely to be affected in FPP synthetase. This enzyme activity was measured in crude extracts of the wild type strain and VL134 and VL135 mutant strains using [^{14}C]IPP and either DMAPP or geranyl diphosphate (GPP) as substrates. Table 2 shows that no activity was detected in the extracts of VL135. A very low activity was detected in the extracts of VL134 with a high protein concentration. These results show that VL134 and VL135 were blocked in FPP synthetase.

Properties of mutant strains affected in FPP synthetase. Upon incubation of mevalonate with cell-free extracts of FK*erg9* (defective in squalene synthetase), VL134 and VL135, the major reaction products were FPP and DMAPP. We wondered whether the dephosphorylated forms of these sterol precursors are excreted into the culture medium during cell growth. Table 3 shows that, as expected, no prenyl alcohols were found in the culture medium of the wild type strain. By contrast, we noted the presence of isopentenol, dimethylallyl alcohol and farnesol in culture media of VL134, VL135 and FK*erg9*. The amounts of dimethylallyl alcohol and isopentenol are very high in VL134 and VL135 in agreement with the inactivation of FPP synthetase. The farnesol amount, however, is lower in VL134 and VL135 than in FK*erg9* blocked in squalene synthetase. Secondly we observed that, unlike the other strains tested, VL134 produces geraniol and linalool in addition to farnesol. These results suggest that the two mutant strains, VL134 and VL135, carry two different mutations in the FPP synthetase gene, *erg20-1* and *erg20-2*, respectively. However, the measurement of the genetic linkage between the two mutations showed less than 10^{-3} recombinants, strongly suggesting that VL134 and VL135 bear the same mutation in FPP synthetase gene. The genetic analysis of these two mutant strains detailed elsewhere (5) is summarized in Table 4. The results reveal that the two strains differ by additional mutations in the ergosterol pathway, affecting either squalene synthetase (*erg9*) or mevalonate kinase (*erg12-2*). One additional mutation is required for cell viability, for decreasing geraniol production. In the presence of both mutations, there is no geranoil formation. It is noteworthy that, by one UV light mutagenesis (10% survival) we obtained multiple mutations; this can be explained by the genetic instability of our haploid wild type strain FL100, but also by the selection procedure, which involves successive cell growths on different selective media.

We have measured phosphatase activities in cell-free extracts of wild type, FK*erg9*, VL134 and VL135 mutant strains. The results show that the specific activities of both acid and alkaline phosphatases are about 2-3-fold higher in mutant strains than in the parent strain (Table 5). Therefore, phosphatase activities may actually be involved in the dephosphorylation of FPP and GPP. As for the excretion itself, it probably proceeds by simple diffusion due to the hydrophobic nature of farnesol and geraniol.

Effect of the overexpression of FPP synthetase on the ergosterol level of yeast cells. We isolated the *ERG20* gene by complementation of the *erg20* mutation. The DNA fragment isolated from a yeast genomic library had a length of 5.7 kb. The restriction map was established and the insert could be reduced to 3 kb without loss of activity (5). The DNA fragment was identical to the yeast FPP synthetase gene isolated by hybridization of a synthetic oligonucleotide probe based on the NH_2 terminal sequence of the purified enzyme (12). This result shows that the *erg20* mutation affects the FPP synthetase structural gene. Therefore, it can be assumed that geraniol formation observed in VL134 is directly related to the properties of the modified FPP synthetase.

We constructed strains 5247 [pCC1] and 5247 [pCC2] carrying one copy or multiple copies of the *ERG20* gene, respectively, depending on the replication origins of the vectors used. Table 6 shows that in 5247 bearing pCC1 the addition of the extrachromosomal *ERG20* gene to the

FPP Synthetase Activity and Ergosterol Level of Yeast Cells

Strains	FPP synthetase specific activity[a]		Ergosterol level[b]
	DMAPP	GPP	
5247	6.4 ± 0.1 (3)	5.4 ± 0.2 (3)	0.65 ± 0.06 (3)
5247 [pCC1]	7.8 ± 0.1 (3)	6.9 ± 0.2 (3)	0.84 ± 0.07 (3)
5247 [pCC2]	23.0 ± 0.9 (3)	17.2 ± 1.1)3)	0.72 ± 0.09 (3)

[a]Specific activity is expressed as nmoles [^{14}C]IPP incorporated per min per mg protein ± S.D. (number of independent experiments).

[b]Expressed as % of mg cell dry weight ± S.D. (number of independent experiments).

chromosomal copy leads to an increase of about 25% in FPP synthetase specific activity; the ergosterol amount is correspondingly increased by 28% in comparison with the parent strain. This result strongly suggests that FPP synthetase is a rate-limiting enzyme in the sterol pathway. In 5247 [pCC2] increased more than three-fold the FPP synthetase specific activity is in comparison with the parent strain, owing to the high number of *ERG20* gene copies. However, the ergosterol level is not correspondingly increased, instead it is lowered as compared to 5247 [pCC1]. This last result can be explained by a regulatory mechanism in the sterol pathway. The high FPP synthetase activity in 5257 [pCC2] may increase the FPP pool. It is well known that mevalonate kinase activity is inhibited by an excess of FPP; squalene synthetase specific activity is 0.5 nmoles FPP converted/min/mg, and the FPP synthetase in 5247 [pCC2] produces about 7 nmoles FPP/min/mg. Further experiments need to be performed in order to evaluate the importance of mevalonate kinase feed-back regulation by FPP in the overall sterol pathway in yeast.

ACKNOWLEDGMENTS

We thank Dr. F. Lacroute for the gift of the yeast genomic library. Part of this work was supported by Grant 88G0318 from Ministère de la Recherche et de la Technologie.

We purified and characterized a membrane-associated enzyme system from radish (*Raphanus sativus* L.) that is capable of converting acetyl-CoA into 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA). The enzyme system apparently comprises acetoacetyl-CoA thiolase (EC 2.3.1.9) and HMG-CoA synthase (EC 4.1.3.5). Its activity *in vitro* can be strongly stimulated by Fe^{II}. When ferrous ions are applied chelated with ethylenediaminetetraacetate, citrate or adenosine 5'-triphosphate (ATP), the stimulation is further increased. Stimulation is due to a higher catalytic efficiency as indicated by an increase in V_{max}, whereas the affinity of the enzyme towards acetyl-CoA remains constant (K_m = 6 μM). A considerable portion of HMG-CoA lyase activity is associated with the same membranes. HMG-CoA lyase (EC 4.1.3.4) is also solubilized and partially co-purified. Its activity requires comparatively high concentrations of Mg^{2+}. The conversion of HMG-CoA to mevalonic acid is catalyzed by HMG-CoA reductase (EC 1.1.1.34) that is associated with the same membranes. By cDNA encoding the *Arabidopsis* HMG-CoA reductase, we isolated a corresponding gene from a cDNA library newly established from etiolated radish seedlings. This full-length cDNA, referred to as λcRS3, encodes a polypeptide of 583 amino acids with a molecular mass of about 63 kDa. The hydropathy profile suggests the presence of two hydrophobic membrane-spanning domains within the N-terminal 165 amino acids. The carboxy-terminal part, where the catalytic site resides, is highly conserved in all eukaryotic HMG-CoA reductase genes sequenced so far. *Lipids 26*, 637-648 (1991).

Plants are capable of synthesizing a myriad of isoprenoid derivatives which are biochemically functional in cells. The basic building block of all these compounds, despite their variety in structure and intracellular location, is derived from mevalonic acid (MVA, see refs. 1-3 for literature). The synthesis of MVA, which is generally considered the first step in isoprenoid biosynthesis, is catalyzed by the enzyme 3-hydroxy-3-methylglutaryl-coenzyme A reductase [HMGR, (*R*)-mevalonate:$NADP^+$ oxidoreductase (CoA-acylating), EC 1.1.1.34]. This particular enzyme has been the subject of a great number of studies, mainly because of its key role in the regulation of cholesterol biosynthesis (4,5). HMGR has recently become a target in the treatment of hypercholesterolemia, a prevalent risk factor of cardiovascular disease in Western societies (6-12).

In plants, HMGR is apparently regulated by various environmental factors and stimuli, including light (13-16), growth regulators and phytohormones (16-18), as well as herbicides (19). Regulation by feedback mechanisms (17), by wounding and infection with pathogens or by fungal elicitor treatment (20-25), and by Hg (26) have also been reported. The cell-free synthesis of MVA has been demonstrated in a variety of plant species and in tissue cultures (1,3). Generally, the reaction is catalyzed by a membrane-bound enzyme. Recently, the solubilization of HMGR from the membranes either by detergent treatment (3,27-29) or by partial trypsinization (30) and subsequent purification (3,27-30) was shown to be possible. The data available on plant HMGR suggest its occurrence in plastids and mitochondria, in addition to the cytoplasm. However, this model, originally based on incorporation experiments (31), is still a matter of debate (32). The model appears difficult to prove due to the low activity and the susceptibility of HMGR towards rapid inactivation *in vitro*. However, the results from inhibition studies (1,3,32-35) strongly support the existence of HMGR isozymes in plant cells. Further evidence in favor of this hypothesis can be gathered using the powerful techniques of molecular biology and immunology. Genes encoding HMGRs from several plants have been characterized (36-40); some of the latter findings will be summarized and discussed in this contribution.

Another problem to be addressed is how HMG-CoA synthesis is regulated in plants. HMG-CoA plays a pivotal role not only as a precursor of the isoprenoid pathway, but it additionally serves as a putative intermediate in the degradation of branched-chain amino acids. Until recently, surprisingly little had been known about the properties as well as the intracellular localization of the enzymes involved (cf. 2,3). The synthesis of HMG-CoA from three acetyl-CoA units comprises: i) a Claisen-type condensation that is catalyzed by acetoacetyl-coenzyme A thiolase (AACT, acetyl-coenzyme A acetyltransferase, EC 2.3.1.9); and ii) a subsequent aldol condensation catalyzed by 3-hydroxy-3-methylglutaryl-coenzyme A synthase [HMGS, (*S*)-3-hydroxy-3-methyl-glutaryl-coenzyme A:acetoacetyl-coenzyme A lyase (CoA acylating), EC 4.1.3.5]. The presence of HMGS was largely inferred from the formation of an uncharacterized HMG-derivative from acetate in a cell-free extract of flax seedlings (41), the same plant tissue from which HMG-acid had first been isolated (42). Lynen (43) determined the activity of several enzymes of the rubber biosynthetic pathway in the latex of *Hevea brasiliensis*, among them AACT and HMGS; their properties were not investigated further. The synthesis of a HMG-derivative, most likely HMG-CoA, from acetyl-CoA

Abbreviations: AACT, acetoacetyl-CoA thiolase; ATP, adenosine 5-triphosphate; Brij W-1, polyoxyethylene ether Brij W-1; CoA, coenzyme A; DTE, dithioerythritol; EDTA, ethylenediaminetetraacetate; FPLC, fast-performance liquid chromatography; HMG-CoA, 3-hydroxy-3-methylglutaryl-coenzyme A; HMGL, HMG-CoA lyase; HMGR, HMG-CoA reductase; HMGS, HMG-CoA synthase; HPLC, high-performance liquid chromatography; MVA, mevalonic acid; PAGE, polyacrylamide gel electrophoresis; SDS, sodium dodecylsulfate.

in a cell-free system of sweet potato was reported (44). This biosynthetic capacity was found in cytosolic and microsomal preparations and did not require co-factors such as ATP, Mg^{2+}, HCO_3^- or NADPH (44). An iodoacetamide-sensitive AACT activity has been identified in vesicles from mature orange fruits (45); attempts to assay HMGS and HMGR activities were not successful. Quite recently, AACT activity has been found in plastid preparations from *Parthenium argentatum* and *Phaseolus radiatus* (46). The presence of HMGS activity in osmophores of the orchid *Stanhopea anfracta* was detected by a cytochemical approach (47). Our experience with cytosolic and membrane-associated AACT/HMGS activity (3,48) support the view of a variable intracellular location of these enzymes.

Once synthesized, HMG-CoA instead of entering the isoprenoid pathway can be cleaved by HMG-CoA lyase [HMGL, (*S*)-3-hydroxy-3-methylglutaryl coenzyme A lyase, EC 4.1.3.4] in a stereochemically controlled Claisen-type retrocondensation to yield acetoacetate and acetyl-CoA (49). This important reaction contributes to the formation of ketone bodies in vertebrate cells (50,51). Indeed, Hepper and Audley (52) provided some evidence for the presence of this enzyme activity in the latex of the rubber tree. An enzyme activity that interferes with the HMGR assay in membrane preparations from *Ipomoea batatas*, most probably HMGL, was also reported (53). Skrukrud *et al.* (54) have assayed HMGL in the soluble fraction of latex collected from *Euphorbia lathyris*. The presence of HMGL in latex explains, in part, the failure to detect any significant incorporation of acetyl-CoA, HMG-acid or of HMG-CoA into triterpenoids (55). HMGL might also be involved in the MVA shunt pathway (56,57), a cyclic retroconversion of MVA to HMG-CoA and a mechanism of routing away isoprene-units from their inclusion into the isoprenoid pathway. Convincing evidence has been presented of the MVA shunt existing in plants (58,59). We have started to characterize from plant tissue the enzymes that are involved in the synthesis and metabolism of HMG-CoA (3,48). Some improvements in the purification protocols and further *in vitro*-properties of these enzyme systems are reported here.

MATERIALS AND METHODS

Chemicals. [1-^{14}C]Acetyl-CoA, (*R,S*)-[3-^{14}C]HMG-CoA, [2-^{3}H]mevalonic acid and [^{32}P]GTP were purchased from Amersham (Braunschweig, Germany); [^{35}S]ATP was from New England Nuclear (Bad Homburg, Germany). Brij W-1 (polyoxyethylene ether), HMG-CoA, acetyl-CoA and molecular weight standards were from Sigma (Deisenhofen, Germany); HS-CoA, NADPH, NADH, glucose-6-phosphate, glucose-6-phosphate dehydrogenase, and a DNA random priming kit were from Boehringer (Mannheim, Germany). Superose 6 and oligo(dT) cellulose were from Pharmacia (Freiburg, Germany); Cellufine GC 200 and GC 700 were from Amicon (Witten, Germany). Fractogel materials (anion exchange and affinity chromatography) were purchased from Merck (Darmstadt, Germany); sorbitol and DTE from Serva (Heidelberg, Germany); and scintillation vials plus cocktails from Zinsser (Frankfurt, Germany). The sources of materials used for experiments in the cloning and expression of plant HMGR have been described elsewhere (38,60). All other chemicals purchased from commercial sources were of the highest purity available.

Plant cultivation and membrane isolation. Radish (*Raphanus sativus*, var. Saxa Knacker) seedlings were grown in tap water in complete darkness for four days. Membrane fractions (P 16,000 and P 140,000) and cytosol were isolated as described (16). Membranes were resuspended in small volumes of isolation buffer "A" (28). DTE was added to the suspended membranes to a final concentration of at least 20 mM. The suspensions were kept on ice until use or immediately deep-frozen and stored at −20°C. The enzyme activities determined remained stable under these conditions.

Enzyme assays. The assay of HMGR activity has been described in detail (28).

Assay of HMG-CoA synthesis from acetyl-CoA (coupled assay of AACT and HMGS) using a crude enzyme preparation. Fifteen μL Tris/HCl [pH 7.5, 0.2 M, containing 10 mM ethylenediaminetetraacetate (EDTA)] was mixed with 25 μL of enzyme solution (in 0.2 M K_xPO_4, 10 mM EDTA, 5 mM $MgCl_2$, 20 mM DTE, supplemented with 1% w/v Brij W-1) and kept on ice. After preincubation at 30°C for 5 min the reaction was started by addition of a 10 μL mixture containing 1.25 μL [1-^{14}C]acetyl-CoA (10 μCi/mL, specific activity 52 mCi/mmol), 1.2 μL acetyl-CoA (2 mM), and 7.75 μL 0.2 M Tris/HCl, pH 7.5, containing 10 mM Na_2 EDTA. The incubation at 30°C was continued for 10 min and the reaction was terminated by addition of 150 μL of 6N HCl. After incubation at 30°C for 30 min the reaction mixture was transferred into plastic scintillation vials (5-mL) that were kept at 105°C for more than 5 hr. Under such conditions, thioesters are hydrolyzed, acetate evaporates, and HMG acid remains in the vial (51,61). In order to avoid any contamination, the samples were evaporated in a closed metal box inside a drying oven. Vapors from the box were continuously removed by pumping and the radioactive material was trapped by passage through three wash bottles containing water, 1N NaOH and paraffin. Water (250 μL) was then added to the vials, and the samples were vigorously vortexed. Quickszint 2000 (4 mL) was added, and after vortexing the samples were assayed for radioactivity by liquid scintillation counting (Packard 2000 CA, Frankfurt, Germany). For time course and kinetic studies the enzyme assay volume was increased to 150 μL. At various time points, 50 μL aliquots of the reaction mixture were withdrawn, transferred to 150 μL 6N HCl and treated further as described above. The data were computed using spline functions to calculate best fit curves (62), which allowed calculation of approximate v_o values. In kinetic studies, substrate concentrations were varied as appropriate (substrate dilution, cf. 16,28) and data were plotted as described (16,28). When the separation of AACT and HMGS activities was attempted, assays were run in duplicate, either in the presence or in the absence of 50 μM acetoacetyl-CoA. HMGS activity in fractions not containing AACT should be measurable only in the presence of acetoacetyl-CoA.

Assay of partially purified AACT/HMGS (free of HMGL). Tris/HCl (25 μL, pH 7.5, 0.2 M) was mixed with 15 μL enzyme solution (in 50 mM K_xPO_4, 0.3 M sorbitol, 5 mM EDTA, 5 mM $MgCl_2$, 3 mM DTE, 0.3% Brij W-1). After preincubation at 30°C the reaction was started by addition of 10 μL of a mixture containing 1.25 μL

[1-^{14}C]acetyl-CoA (10 μCi/mL, 52 mCi/mmol), 0.6 μL acetyl-CoA (2 mM), and 8.2 μL 0.2 M Tris/HCl pH 7.5. Further processing of the assay mixtures was as described above. When the effects of various cations on the activity of AACT/HMGS were studied, the cation tested (if required, complexed in the presence of a double concentration of EDTA) was first added to the Tris buffer, immediately followed by addition of the enzyme solution.

Assay of HMGL activity. The standard assay system in a final volume of 50 μL contained 20 μL of enzyme solution, and 20 μL of 0.2 M Tris/HCl, buffer pH 7.5–8.0, supplied with 40 mM $MgCl_2$. After preincubation for 2 min at 30°C the reaction was started by addition of 10 μL of starting mixture: 1.25 μL (*R,S*)-[3-^{14}C]HMG-CoA (*ca.* 30,000 dpm, specific activity 52 mCi/mmol), 0.6 μL unlabeled (*R,S*)-HMG-CoA (4 mM stock solution in 50 mM KH_2PO_4), and 8.15 μL of 200 mM Tris/HCl pH 7.5). The final concentration of (*R,S*)-HMG-CoA thus obtained was *ca.* 50 μM. After incubation at 30°C the reaction was stopped by addition of 150 μL 6N HCl. The mixture was transferred to minivials and kept at 115°C for a minimum of 3–4 hr. Labeled acetoacetate evaporated and nonvolatile HMG-CoA remained in the vial (51,61). Further processing of samples was as described for the AACT/HMGS assay. Because HMGL cleaves only the (*S*)-isomer of synthetic HMG-CoA (49), a maximum of 50% of the initial radiolabeled material was used up by the enzyme.

Enzyme solubilization and purification. AACT/HMGS activity was solubilized from a heavy-membrane pellet (P 16,000) by thawing of frozen samples followed by incubation at 30°C for 30 min in the presence of 2% (w/v) Brij W-1. The turbid yellow suspension was homogenized by aid of a teflon homogenizer (15 to 20 strokes) and centrifuged at 100,000 × *g* for 45 min at 15°C. In the supernatant 80–90% of the initial enzyme activity was found. The clear solution was brought to a final concentration of higher than 10 mM with DTE. A 1.5-fold volume of −20°C cold acetone was added. After incubation on ice for 10 min, the turbid solution was centrifuged for 10 min at 10,000 × *g* (2°C). The resulting pellet was washed three times with cold acetone and resuspended in a buffer system consisting of 50 mM K_xPO_4 pH 7.5, 0.3 M sorbitol, 5 mM EDTA, 5 mM $MgCl_2$ and 0.3% Brij W-1, 3 mM DTE (buffer system "D") (28). The volume of resuspension buffer was 50% of the enzyme solution used for acetone precipitation. Material that could not be redissolved by 15 strokes with a teflon homogenizer was removed by centrifugation for 5 min at 5,000 × *g*. After this step about 80% of the initial enzyme activity was found in the supernatant.

Gel filtration. Superose 6 prep grade (90 cm^3) in an HR 16/50 column (Pharmacia-LKB, Freiburg, Germany) was equilibrated overnight with buffer system "D" with a biocompatible high-performance liquid chromatography (HPLC) system (Pharmacia-LKB) at a flow rate of 0.1 mL/min. Partially purified enzyme (3.3 mL, resuspended in buffer D) was loaded on the column and elution was continued with buffer D (0.75 mL/min). The fractions collected (2.25 mL) were tested for AACT/HMGS activity as described above. The column was calibrated with standard proteins with molecular masses from 29 to 150 kDa.

Anion exchange chromatography. Fractogel EMD TMAE 650 S (11 cm^3) in a Superformance glass column (Merck, Darmstadt, Germany) was equilibrated with 50 mL of buffer D at a flow rate of 1.5 mL/min by using the same HPLC system. The three peak fractions from the gel filtration with highest apparent AACT/HMGS activity were pooled, and 6.6 mL were loaded on the column. The column was washed with the same buffer system. AACT/HMGS activity eluted with the breakthrough fraction.

Determination of molecular weight by classical gel filtration. Cellufine 200 (or 700, 130 cm^3) in a C 16/70 column (Pharmacia-LKB) was equilibrated with 200 mL of modified isolation buffer A (0.05 M K_xPO_4, 0.35 M sorbitol, 10 mM Na_2EDTA, 5 mM $MgCl_2$, 3 mM DTE), containing 0.2% Brij W-1. Solubilized enzyme (7.5 mL; see above) was loaded and the column was eluted with the same buffer system. The fractions collected (2.25 mL) were tested for AACT/HMGS activity as described above. The column was calibrated with standard proteins with a molecular mass ranging from 29 to 150 kDa.

Protein assay. Proteins were assayed by a modified Lowry assay (63) with some additional modifications, as described elsewhere (28).

Molecular cloning of radish HMGR. Total RNA from either etiolated or green (light regime: 16 hr white light, *ca.* 4500 lux, 8 hr darkness, 22–24°C) four-day-old radish seedlings was isolated as described (64), with minor modifications (28). Poly(A)$^+$ RNA was purified by oligo(dT) cellulose chromatography according to Aviv and Leder (65). RNA samples were fractionated on 1% agarose/formaldehyde gels, transferred and UV-cross-linked to Zeta-Probe membranes and hybridized for Northern blot analysis as described (28). A cDNA library from mRNA isolated from etiolated radish seedlings was constructed by the aid of a cDNA synthesis kit (Bethesda Research Laboratories, Eggenstein, Germany) according to the manufacturer's manual and cloned into the expression vector λgt11 (*Eco*RI restriction site) following established protocols (66,67). The radish cDNA library was screened by hybridization with a ^{32}P-labeled cDNA probe encoding HMGR from *Arabidopsis thaliana* (38). Repeated screening yielded seven positive clones referred to as λcRS1–7. λcRS3 comprised the entire protein-coding transcription unit of a HMGR gene of radish.

DNA sequencing and analysis. For DNA sequencing, the DNA fragments generated by digestion of the *Eco*RI insert with various restriction enzymes were subcloned into appropriate Bluescript plasmids (Stratagene, San Diego, CA). The DNA was sequenced by the dideoxy chain termination method (68) as modified by Biggen *et al.* (69) by the aid of the T7-Sequencing kit (Pharmacia-LKB). Microgen software from Beckman (München, Germany) was used to analyze DNA sequences. Hydropathy profiles were calculated according to the algorithm of Kyte and Doolittle (70).

RESULTS

Solubilization and partial purification of plant AACT/HMGS. A considerable portion of the total activity capable of converting acetyl-CoA to HMG-CoA appears to be associated with a heavy-membrane pellet (P 16,000) isolated from four-day-old etiolated radish (48) and maize seedlings (3). Since the activity found in the cytosolic fraction was shown to be salt-sensitive, concentration and

fractionation by ammonium sulfate precipitation was not possible (48). However, in radish, the same membrane fraction (P 16,000) is the major source of HMGR activity (28) and was therefore used as a source of enzymes to further study the properties of AACT/HMGS. Previously, we successfully developed a protocol for solubilizing HMGR from membranes using the detergent Brij W-1 (27,28). For the enzyme system containing AACT and HMGS we used a similar, but simplified protocol. Prolonged incubation at 37°C was detrimental to the enzyme activity, whereas HMGR appeared to be quite heat-stable (3,28). Therefore, the temperature during the incubation in the presence of 2% Brij W-1 was lowered to 30°C. By application of the protocol, as outlined in Materials and Methods, the recovery of total AACT/HMGS activity was about 90% of the initial value (Table 1).

During the attempts to purify the enzyme(s) further, we always ran enzyme assays twice—either in the presence or absence of unlabeled acetoacetyl-CoA, in addition to [1-^{14}C]acetyl-CoA. If a protein fraction exclusively would contain HMGS, but not AACT activity, only if both substrates were available should we have been able to observe the incorporation of radiolabel into HMG-CoA. We have not separated AACT from HMGS activity as yet, even though we have developed different protocols, including precipitation with polyethylenimine (3,48) and free solution IEF (3,71). As already mentioned above, the salt-sensitivity of this enzyme system, in contrast to the properties of HMGR (28), prevented the use of salt gradients higher than 200 mM for the elution of enzyme activity from various column materials. An important factor in maintaining enzyme activity during purification is to speed up the procedures, which is possible by using fast-performance liquid chromatography (FPLC). In this way we have already achieved a considerable purification factor by combination of mild detergent solubilization, gel filtration, acetone precipitation, and anion exchange chromatography (Table 1). If cation chromatography is included in the purification protocol (where AACT/HMGS is passing through the column, whereas many contaminating proteins bind) an additional purification by 1.5–2-fold is possible. It was possible to separate AACT/HMGS activity from HMGL (cf. Fig. 1). This is especially important when kinetic properties have to be determined, where any interference of HMGL with AACT/HMGS has to be excluded.

Some properties of AACT/HMGS. Recently it has been shown that both enzymes appear to cooperate closely in a way so that no intermediate acetoacetyl-CoA is released into the medium from AACT before it can bind to the active site of HMGS (3,48). During the course of these experiments we have also proved that our enzyme-assay system allows for the conversion of acetyl-CoA to HMG-CoA, which is quantitatively converted to MVA in the presence of NADPH and highly purified yeast HMGR (3,48). Recrystallization from diethyl ether of an enzymatically formed and acid-hydrolyzed product, supplied with additional unlabeled HMG-acid, resulted in greater than 90% radiochemical purity (data not shown). Complex formation between both enzymes could easily explain why any attempt to separate AACT from HMGS was unsuccessful. The apparent molecular mass of the coupled enzyme system AACT/HMGS as deduced from conventional gel filtration on Cellufine 200 and 700 was about 54 kDa (3). This value was confirmed by chromatography of a crude solubilisate from radish membranes (P 16,000) using a FPLC system with Superose 6 prep grade. Although the properties of this material do not permit a good separation of proteins with a difference in molecular mass of less than 20 kDa, some separation from HMGL activity (68–72 kDa, cf. 3) was achieved (Fig. 2).

When the enzyme system was purified by anion exchange chromatography, especially after an additional passage through small PD-10 columns to remove low-molecular-weight molecules and ions, apparent activity was drastically decreased. Reconstitution of activity required the presence of bivalent cations in addition to Mg^{2+} (3). Fe^{2+} was the most active cofactor of various cations tested. Complex formation with EDTA led to an even higher efficacy of Fe^{2+} (Fig. 3) in stimulating AACT/HMGS activity *in vitro*. This stimulation of enzyme activity, *e.g.*, a doubling of enzyme activity requiring less than 50 μM of Fe^{2+}EDTA in the assay mixture, was apparently due to a V_{max} effect (Fig. 4) without change in the affinity towards the substrate acetyl-CoA. The k_m value was calculated to be 6 μM. Since EDTA cannot shield all six coordination sites of Fe^{2+}, additional Fe^{2+} complexes were tested for their ability to stimulate the *in vitro* conversion of acetyl-CoA to HMG-CoA. The data show that concomitant with a decrease in the dissociation constants of the complexes the stimulation disappeared (Fig. 3). Fe^{2+}, either complexed with CN^-,

TABLE 1

Solubilization and Purification of Radish AACT/HMGS[a]

Fraction	Specific activity (nmol × mg^{-1} × min^{-1})	Purification factor	Yield (%)	Total protein (mg)
Homogenate	0.29	1	100	4235
P 16,000	0.32	1.11	11.8	451.8
P 16,000 + Brij	0.68	2.33	13.6	247.3
Resuspended acetone precipitate	1.40	4.80	8.1	71.8
Gel filtration (peak fraction)	28.03	96.22	17.5	7.7
Anion exchange chromatography	70.22	240.9	12.3	2.2

[a]The homogenate was prepared from four-day-old etiolated seedlings, and membranes (P 16,000) were isolated as described (15,28). The enzyme activity was solubilized by incubation in the presence of 2% (w/v) Brij W-1 for 30 min at 30°C. Substrate concentration: 30 μM [1-^{14}C]acetyl-CoA (30,000 dpm).

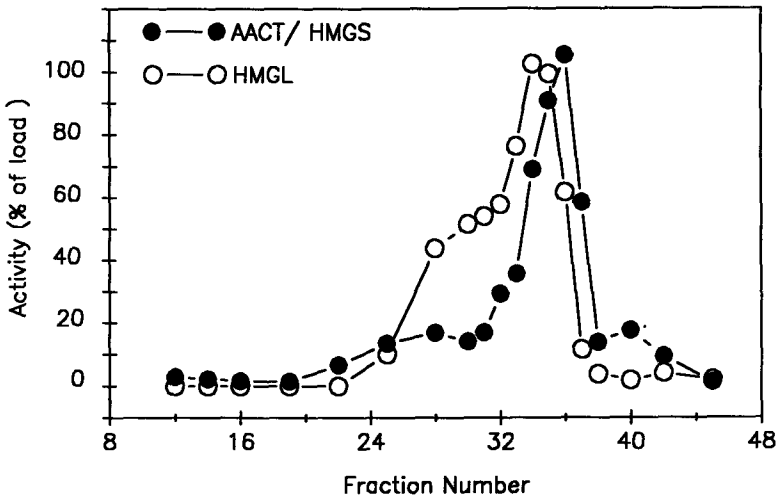

FIG. 1. Gel filtration on Superose 6 prep grade. Proteins from a heavy-membrane pellet isolated from four-day-old etiolated radish seedlings were solubilized in the presence of 2% (w/v) Brij W-1. Solubilized proteins were concentrated by acetone precipitation. The precipitate was resuspended, and insoluble proteins were removed by centrifugation. The clear solution (3.3 mL) was loaded onto the column and eluted as described in Materials and Methods. Volume activity is expressed as percent of loaded fraction. Assay conditions: a) AACT/HMGS: 5 min at 30°C, 25 μM [1-^{14}C]acetyl-CoA, 250 μM Fe^{2+} and 500 μM EDTA. Assay volume was 55 μL: 20 μL fraction, 25 μL Tris/HCl (0.2 M, pH 7.5), immediately mixed with EDTA (stock solution: 40 mM, pH 7.0) and $FeSO_4$ (stock solution: 20 mM, pH 2). The Tris/HCl-Fe-EDTA system was immediately added to the enzyme solution and after a preincubation of 2 min, 10 μL of start mix containing [^{14}C]acetyl-CoA were added. The reaction was stopped by addition of 6N HCl. b) HMGL: Similar to a), however, the Tris buffer was supplied with 30 mM Mg^{2+} instead of Fe-EDTA. Concentration of *R,S*-[3-^{14}C]HMG-CoA, 25 μM.

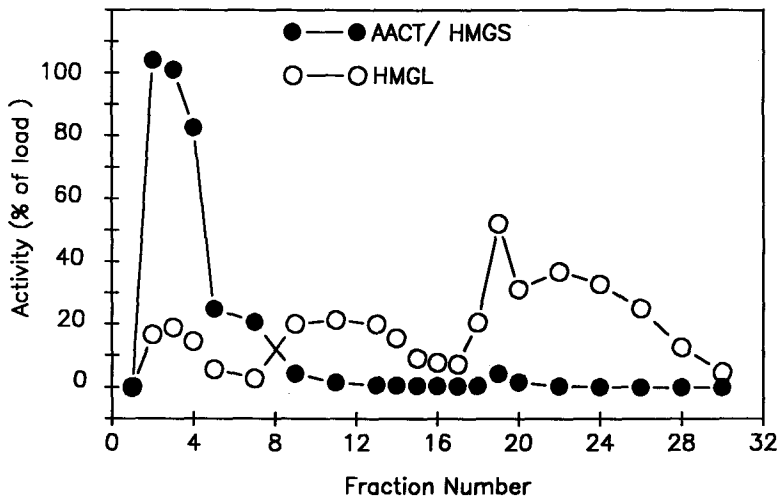

FIG. 2. Anion exchange chromatography on Merck Fractogel EMD TMAE 650. The four peak fractions from gel filtration (Fig. 1) were loaded and the column was eluted as described in Materials and Methods. The assay conditions for AACT/HMGS and HMGL, respectively, were described in the legend to Figure 1 with the exception that 25 μL of fraction was mixed with 20 μL of Tris buffer.

where all six coordination sites are occupied, or sterically shielded, as in the heme moiety of reduced cytochrome c (not shown), was inactive. When EDTA was replaced by either ATP or citrate, which may act as natural chelators of Fe^{2+} (72), the activation of AACT/HMGS was relatively efficient (Fig. 3). When ferrous ions were prevented from becoming oxidized by the presence of excess ascorbic acid (a natural reductant), an even better stimulation of *in vitro* activity occurred (Fig. 5). Hydroxyurea that is known to scavenge radicals (73), inhibited the activation by ferrous ions of gel-filtrated AACT/HMGS, but it was slightly inhibitory to the enzyme(s), even in the absence of Fe^{2+} (Table 2).

Molecular properties of radish HMGR. When HMGR

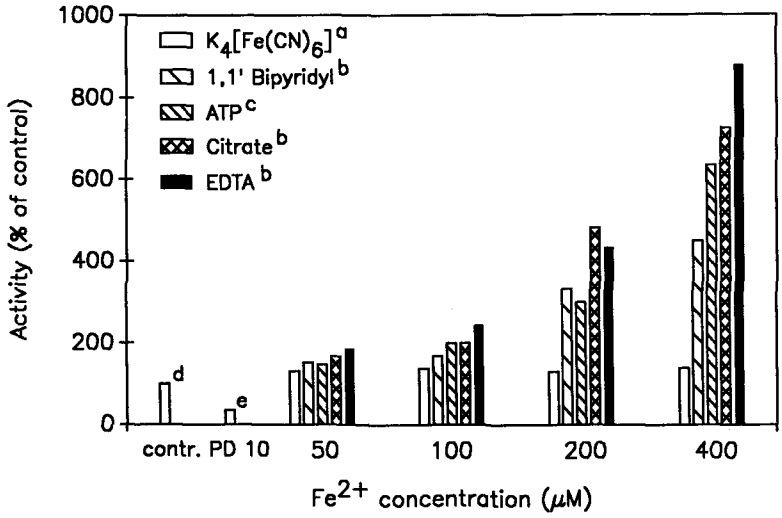

FIG. 3. Effect of ferrous ions on the *in vitro* activity of AACT/HMGS. a) Enzyme solution (15 μL) purified as summarized in Table 1 (control); or b) additionally stripped off from low molecular-weight components by a passage through a PD-10 column, was used per assay in a final volume of 50 μL (35 μL Tris buffer system, 0.2 M, pH 7.5). The sequence of mixing solutions was always kept identical (see legend to Fig. 1). After a preincubation of 2 min at 30°C, the reaction was started by addition of 10 μL start mix containing [1-^{14}C]acetyl-CoA (final concentration, 15 μM). After 5 min at 30°C, the reaction was terminated by addition of 6N HCl. a) No additional Fe^{2+} in the assay; b) concentration of chelator was two times [Fe^{2+}]; c) concentration of chelator was four times [Fe^{2+}]; d) no other reagent in the assay; e) after gel filtration (100 mM K_2PO_4). Stock solutions: Fe^{2+} in H_2O, pH 2; EDTA, $K_4[Fe(CN)_6]$, citrate, ATP in H_2O, pH 7; bipyridyl in 50% (v/v) MeOH (max. concentration in the assay: < 1%).

was detergent-solubilized from radish membranes and purified further (28), a band of 45 kDa was detected in the peak fractions from the last purification step when analyzed by SDS-PAGE. Sucrose-density centrifugation suggested a molecular weight of 180 kDa for the active, non-denatured enzyme. Thus, a tetramer of 45 kDa subunits was suggested to represent the functional entity (28). However, in the first peak fraction we also observed an additional band of less than 66 kDa, which was first interpreted as a typical contaminant appearing in SDS gels loaded with mercaptoethanol-treated protein samples (cf. 74). We have characterized a full-length cDNA clone, referred to as λcRS3 (39), from a newly established radish cDNA library. Northern blot analysis of poly(A)$^+$RNA isolated from etiolated and light-grown radish seedlings revealed a total length of 2.3 kb for the primary transcript (39). The cDNA consists of a 5′-noncoding region of 45 nucleotides, an open reading frame of 1749 bases, and a 3′-untranslated region with two potential polyadenylation signals. λcRS3 codes for a polypeptide of 583 amino acids with a molecular mass of 62,720 Da. The hydropathy profile of the amino-acid sequence (Fig. 6) suggests the presence of two membrane-spanning domains within the N-terminal 165 amino acids (residues 33 to 57, and 68 to 104) as was found for HMGR(s) from *Arabidopsis* (38), pea (40) and tomato (J.O. Narita and W. Gruissem, personal communication). These domains and the spacer region in between are highly conserved between the *Arabidopsis* and radish HMGR (Fig. 7). The linker region (residues 105 to 165) that joins the N- and C-terminal parts of radish HMGR contains a proline-rich "PEST" sequence (cf. 75), which is slightly longer than in *Arabidopsis* and is less conserved. The C-terminal part of radish HMGR (residues 165 to 571), where the catalytic site resides, is highly conserved in all plant and other eukaryotic HMGR genes sequenced so far (36–40,76–82), indicating a stringent evolutionary pressure onto this region (Fig. 8). Since proline-rich sequences serve as recognition sites for certain proteases, a cleavage product presumably has given rise to the formation of the 45 kDa fragment seen on the SDS gel, although the solubilization efficiency was not affected in the presence of protease inhibitors (28,83). For the HMGR isolated from latex of *Hevea brasiliensis*, by application of essentially the same protocol as was developed for radish, a subunit molecular mass of 44 kDa was determined by the aid of SDS-PAGE and, as deduced from native PAGE, a functional size of 176 kDa (29). The band of higher molecular mass as detected in the SDS gel loaded with purified HMGR from radish was most probably not caused by contamination, as was discussed earlier (28), but more likely represented undegraded, native HMGR protein.

DISCUSSION

Synthesis and metabolism of HMG-CoA. In mammalian systems it is well documented that regulation of HMGR is mediated by rapid processes both at the translational and the post-translational level (cf. refs. 4–6). HMGS appears to be regulated in parallel (84–92). Similar processes can be expected to occur in plant cells. A thorough study using plant tissue requires a profound knowledge of the properties of the enzymes involved in the formation of HMG-CoA.

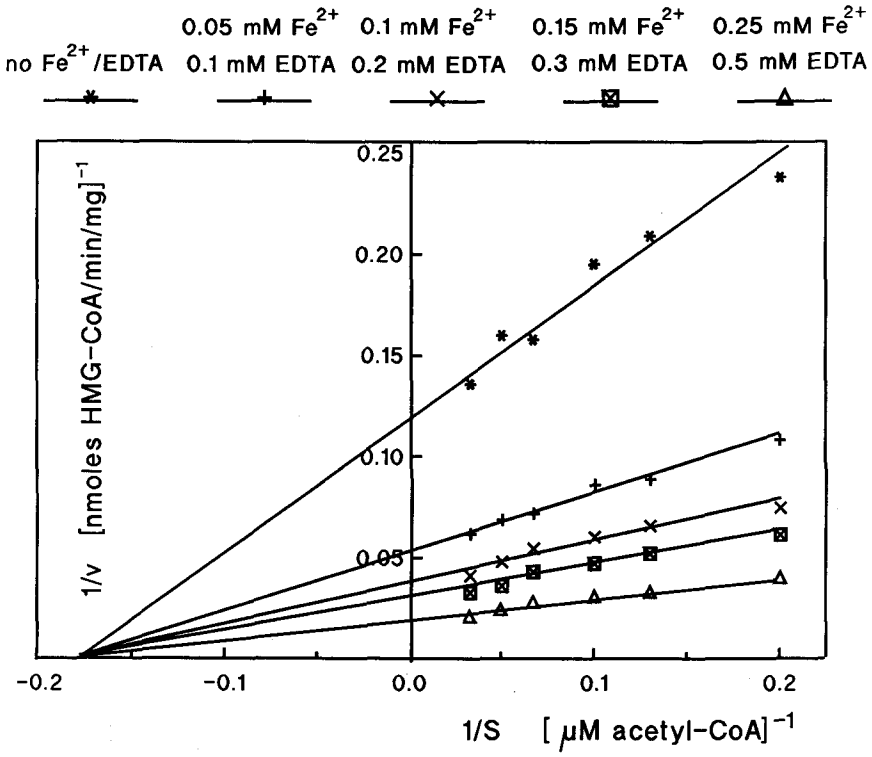

FIG. 4. Effect of ferrous ions on the apparent kinetic properties of partially purified AACT/HMGS. AACT/HMGS was purified as indicated in Table 1, followed by gel filtration on PD-10. Substrate was varied as indicated (isotope dilution). All other conditions were as described in the previous legends. The apparent K_m with respect to acetyl-CoA was calculated to be 6 μM.

TABLE 2

The Effect of Hydroxyurea on Fe^{2+}-Induced Activation of AACT/HMGS[a]

Treatment	[^{14}C]HMG-CoA synthesized[b] (dpm)	[^{14}C]HMG-CoA synthesized[c] (dpm)
Control	2,293 (100%)	12,779 (100 %)
+ 10 mM Hydroxyurea	1,839 (80.2%)	9,502 (74.4%)
+20 mM	1,607 (70.1%)	5,593 (43.8%)
+ 50 mM	1,602 (69.8%)	3,955 (30.9%)

[a]AACT/HMGS was solubilized and purified as indicated in Table 1, followed by gel filtration on a PD-10 column.

[b]Activity was determined in the absence of Fe^{2+}-EDTA.

[c]Activity was determined in the presence of 400 μM Fe^{2+} and 800 μM EDTA.

Our data (3,38) imply the formation of a tightly fitted complex between AACT and HMGS. The acetoacetyl-CoA arising from the AACT reaction was immediately transferred to the active site of the consecutive enzyme HMGS without any substantial diffusion into or exchange with the medium (3,38). We have some further evidence for this hypothesis since the antibiotic F-244 is completely inactive in our system (3). F-244 has been described as a highly specific inhibitor of HMGS both from yeast (93) and rat liver (94), with K_i values in the range of 100 nM. Through the formation of this enzyme complex, the active site of HMGS may somehow be shielded, preventing the binding of the inhibitor, but otherwise facilitating the direct transfer of acetoacetyl-CoA to enter the HMGS catalyzed reaction. In view of the numerous enzymes competing for the central intermediate acetyl-CoA (cf. 1), a directed flux of carbon units into the isoprenoid pathway makes sense. However, despite the differences in the reaction mechanisms in both condensations leading from acetyl-CoA to HMG-CoA, *viz.* Claisen *vs.* aldol condensation, it cannot be excluded that a single polypeptide catalyzes both partial reactions.

Separation of HMGL from AACT/HMGS has been achieved, *e.g.*, by means of free-solution IEF, where the enzyme appears to band at high activity with an apparent pI value of 7.0 (3,71), or by ion exchange chromatography. Considerable activity of HMGL is associated with the same heavy-membrane pellet (P 16,000) like AACT/HMGS (cf. 3,38). HMGL behaves rather unstably and loses ac-

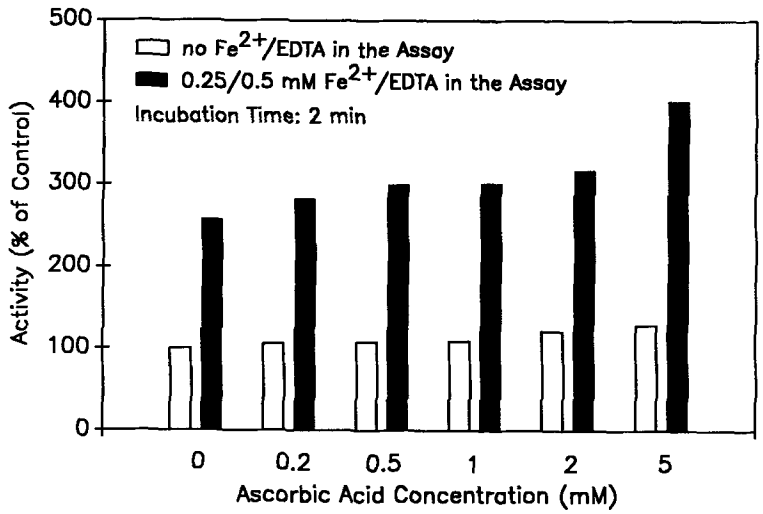

FIG. 5. Effect of ascorbic acid on the efficiency of AACT/HMGS activation by Fe^{2+}-EDTA. AACT/HMGS was purified as indicated in previous legends. The assay volume was 70 μL (30 μL of enzyme solution, 30 μL of Tris buffer system). Cofactors were freshly added to this buffer system (sequence: EDTA, ascorbate, Fe^{2+}). After preincubation at 30°C for 2 min the reaction was started by addition of 10 μL start mix (final concentration of 1-acetyl-CoA, 25 μM. Control 100%): without ascorbate (stock solution: 40 mM, pH 7.0) and Fe^{2+}-EDTA.

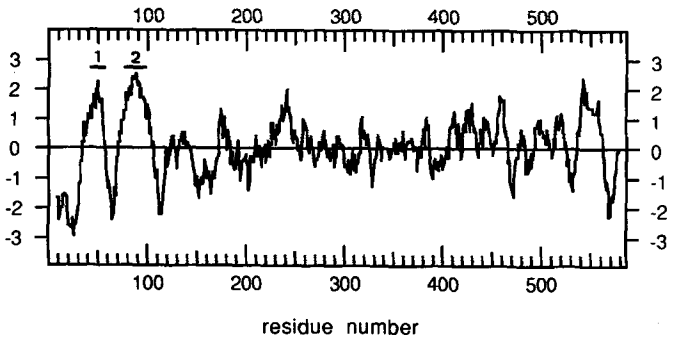

FIG. 6. Hydropathy index plot of radish HMGR. The algorithm of Kyte and Doolittle (70) was used with a window size of nine residues. Positive values indicate hydrophobic regions. Bars 1 and 2 indicate putative *trans*-membrane regions.

tivity within a few hr, even at 4°C, but can be kept active when stored frozen at −20°C. In our assay system, the radish HMGL had a pH optimum in the alkaline region (3), similar to values reported for the bovine enzyme (95,96); however, under such conditions the influence of artifact formation from the instability of thioesters cannot be excluded. For that reason, the activity of plant HMGL was routinely assayed at pH 8.0 (3). HMGL is rapidly inactivated above 30°C and requires the presence of Mg^{2+}. If rather crude fractions are examined, interference of HMGL with the HMGR assay can be excluded by incubation at 37°C in the presence of EDTA (standard conditions of the HMGR assay). Total cellular HMGL activity far exceeds that of HMGR. However, *in vivo* the interference of both enzymes competing for the same substrate might be prevented by differential compartmentalization, a subject of future research.

Gel filtration of solubilized and partially purified radish HMGL on Sephadex G-25 or G-10 to remove low molecular weight molecules resulted in inactivation (3). A series of cations have been tested for their ability to restore the initial activity. Mg^{2+}, Co^{2+}, Mn^{2+}, and Fe^{2+} were similarly effective in stimulating HMGL activity, whereas trivalent cations were inactive (3). However, it cannot be excluded that cations such as Ca^{2+} remain bound to the enzyme even after passage through a gel filtration column. Higgins *et al.* (97) compared the data obtained for several mammals and tissues as an enzyme source and assumed the enzyme to contain bound Ca^{2+}, which was not affected by chelators above pH 8.

The effects of cations have been studied in great detail for AACT/HMGS. Although required for some basal activity, Mg^{2+} alone stimulated enzyme activity *in vitro* only slightly. This was demonstrated when the enzyme system that was purified about 240-fold was additionally

FIG. 8. Amino-acid sequence alignment of the C-terminal region of plant HMGRs. RS: Radish (*HMG1*); AT: *Arabidopsis thaliana* (*HMG1*) (data from refs. 37,38,40); PSa, PSb, PSc: Pea, 3 related HMGR isozymes (data from ref. 40); Tom: tomato (*HMG1*) (data from ref. 36).

filtered through PD-10 columns previously equilibrated with 100 mM phosphate buffer without any Mg^{2+}. In previous experiments, it was shown that AACT/HMGS can be separated from HMGL by free-solution IEF, forming a peak at a rather acidic pH. The reason for this apparent acidic pI value may be due to complex formation of the enzyme system with phospholipids that are detergent-solubilized in parallel. Under such conditions AACT/HMGS lost most of its activity. A series of cations were tested for their ability to restore activity, with Fe^{2+} being the most effective (3). The even higher activity observed in the presence of a double concentration of EDTA (at pH 7.5 to 8.0) can be readily explained by stabilization of Fe^{2+} which, as a free cation, is rapidly oxidized to Fe^{3+} and does not stimulate enzyme activity. Which amino acids of the protein(s) are involved in the reaction of Fe^{2+}, presumably histidine residues (cf. 98), is not yet known.

When Fe^{2+} was added as a complex where all six coordination sites are occupied (*e.g.*, with CN^-) the enzyme

system was not activated. There remains the possibility that Fe^{2+} is involved in the formation of an organic free radical, as it is essential for ribonucleotide reductase activity (cf. 73, and literature cited therein). Addition of hydroxyurea, which is capable of scavenging such radicals, partially prevented activation of AACT/HMGS (Table 2).

Other bivalent cations such as Co^{2+}, Mn^{2+}, Sn^{2+} or Ni^{2+}, which are more stable than Fe^{2+}, were much less effective (3). When the ferrous ions were prevented from being oxidized because of the presence of ascorbic acid, activation of AACT/HMGS was increased further. Iodoacetamide capable of alkylating thiol groups did not drastically affect catalytic efficiency. A mechanism that only involves the shielding by Fe^{2+}-EDTA of reactive thiol groups from becoming oxidized seems unlikely. It was reported that Fe^{2+}-EDTA, but not unchelated ferrous and ferric ions, efficiently inhibited porcine brain lipoamidase, possibly due to interaction with the active center (99). Anaerobically induced NAD-linked glycerol dehydrogenase of *Klebsiella pneumoniae* was inactivated in the presence of O_2, Fe^{2+} and ascorbate (100). This was interpreted to mean that O_2 and ascorbate generated H_2O_2 and that H_2O_2 reacted with Fe^{2+} to produce an activated species of oxygen, which attacked the enzyme (100). In the cell Fe^{2+} possibly forms complexes with ATP or citrate (101). These complexes, capable of generating oxygen radicals, might lock plant AACT/HMGS into a conformation that results in a higher catalytic efficiency, *viz.* in an increased turnover rate, whereas the apparent affinity towards the substrate is not affected; V_{max}, but not k_m, changes. A doubling of apparent activity can already be achieved at concentrations less than 50 μM Fe^{2+}, which is well within physiological range.

Cloning and characterization of radish HMGR. Recently, by the aid of a cDNA encoding hamster HMGR (76), it has been possible to isolate a corresponding gene from *Arabidopsis thaliana* (38). The isolation of the corresponding gene from radish has been facilitated because of the close phylogenetic relationship between *Raphanus sativus* and *A. thaliana*, both belonging to the same family of *Brassicaceae*. The radish HMGR was the first enzyme that was purified from a plant source; its kinetic properties (28,83) and many aspects of regulation are already well known (15,16,19). That we have indeed cloned a radish HMGR gene has been proven through overexpression in *E. coli* of a truncated, but highly active protein referred to as HMGR45, comprising the soluble domain where the catalytic site resides (60). Because of a unique *Eco*RV restriction site close to the initial methionine codon, only the full-length radish cDNA clone (λcRS3), but not the corresponding *Arabidopsis* cDNA clone could be used for the construction of a plasmid and overexpression of a slightly truncated protein in *E. coli*, comprising nearly the entire amino-acid sequence (583 − 1) of the holoenzyme (60). The protein thus produced was, however, insoluble and catalytically inactive. This can be readily explained by the postulated presence of two membrane-spanning domains at the N-terminal end of the intact enzyme as suggested by the hydropathy profile. Incorrect folding of nascent protein chains and hydrophobic interactions within the non-bacterial protein molecule or between different molecules can lead to the formation of precipitates (inclusion bodies) without activity (cf. 102).

As far as we know, plant HMGRs contain only two membrane-spanning domains, whereas other eukaryotic HMGRs usually have seven and more (76–82). In mammalian cells the presence of the part anchored in the membrane is necessary for intact regulation (77,103,104). Soluble, truncated HMGR, lacking this moiety and reintroduced by transfection into a mutant cell line having lost HMGR is not feedback-regulated (103). In the yeast system, ultrastructural changes, formation of karmellae (105), can only be observed when HMGR arising from the *HMG1*, but not from the second *HMG2* gene, is overproduced. There is no experimental data available as yet that would ascribe a similar regulatory role to the membrane domain of plant HMGR.

Whereas animal cells apparently contain only one HMGR gene (76–78,80–82), yeast contains two related, but rather divergent genes referred to as *HMG1* and *HMG2* (79). From the cDNA library established from poly(A)$^+$RNA isolated from etiolated radish seedlings, we have isolated several positive clones (39). λcRS2, only about 1.6 kb in length, has a different restriction pattern than λcRS3, which has been completely sequenced. Thus, in radish seedlings at least two genes are actively expressed. In *Arabidopsis* two genes have been identified (38,40), which are also referred to as *HMG1* and *HMG2*. Since *HMG2* is apparently expressed at a very low level and only in certain parts of seedlings, in contrast to *HMG2*, its complete sequence has been determined from genomic, but not from cDNA clones (Enjuto, M., and Boronat, A., unpublished observations). In tomato, only a single HMGR gene had been initially isolated (36); however, a second HMGR gene also has been identified (Narita, J.O., and Gruissem, W., personal communication). Based on the presumably variable localization of HMGR isozymes in the plant cell, the presence of three HMGR genes has been postulated (1). Recently it has been shown that in the pea three closely related genes appear to be active (40).

The expression system we have used to produce radish HMGR45 in *E. coli* (60) should facilitate isolation of HMGR protein from other cDNA clones for identification of kinetic and molecular properties. Since this enzyme can be considered a promising target for plant growth regulators (1,33,34,106), such as the antibiotic mevinolin (lovastatin) and its natural and synthetic analogues (cf. 7), structural modeling requiring the crystallization of plant HMGR could be envisaged. It is possible to obtain greater than 95% pure radish HMGR45 by just two purification steps (Bach, T.J., unpublished observations).

Clear information on the differences of HMGR isozymes may finally provide us with the clue as to the intracellular location, and of the expression of the corresponding genes in space and time. Antibodies that are raised against oligopeptides comprising non-homologous parts of the isozymes could be used for immuno-cytochemical studies. The ultimate aim must be to isolate the genes coding for AACT, HMGS, HMGL and for enzymes beyond the HMGR step, to get a better understanding of how MVA biosynthesis and utilization is regulated in plants.

[Received June 12, 1990, and in revised form February 19, 1991; Revision accepted June 9, 1991]

On the Structure, Biosynthesis, Function and Phylogeny of Isoarborinol and Motiol

W. David Nes[a,*], Rosalind Y. Wong[b], Jane F. Griffin[c] and William L. Duax[c]

[a]Plant and Fungal Lipid Research, Microbial Products Research Unit, Richard B. Russell Research Center, Athens, Georgia 30613, [b]Western Regional Research Center, U.S. Department of Agriculture, Albany, California 94710 and [c]Medical Foundation of Buffalo, Buffalo, New York 14203

The solid-state conformations of the C-3 acetates of two isomeric hopanoids — 1, isoarborinol (D:C-friedo-B[1]:A[1]-3β,5α,8α,10β,13β,14α,17β,18α, 21β) and 2, motiol (D:C-friedo-B[1]:A[1]-neogammacer-7(8)-en-3β-ol[3β,5α,9α,10β,13α,14β,17-α,18β,21α])—have been determined by X-ray crystallography. The data show that whereas both molecules are planar, 1 orients into a chair-halfchair-chair-chair-halfchair conformation while 2 orients into a chair-sofa-twist-half-chair-halfchair conformation. To explain the biogenesis of 1 and 2 from squalene oxide, a step-wise mechanism is proposed which proceeds through the protosteroid cation (for 1) and dammarenyl cation (for 2). After ring enlargement from the corresponding 13(17)bond followed by concerted 1,2-migrations and loss of the 11β-H and 7β-H as protons, respectively, a 9,11-double bond (in 1) and a 7,8-double bond (in 2) is introduced into the nucleus. The mechanism is discussed in relation to the classical view of a non-stop cyclization process where, for example, squalene oxide folds in a chair-chair-chair-chair-boat conformation to give a cyclized product (motiol) presumably with the same conformational disposition as the cyclizing material. The three-dimensional geometry of 1 and 2 was found to be structurally dissimilar from sterols. For instance, 1 and 2 are shorter and volumetrically smaller molecules than cholesterol, and this may explain their diminished importance as membrane inserts compared with sterols in eukaryote evolution.
***Lipids 26,* 649–655 (1991).**

Pentacyclic triterpenoids (PT) are a class of 30-carbon isopentenoid (isoprenoid) natural products which function in a manner analogous to sterols as structural components of membranes (1–3). Pentacyclic triterpenoids, specifically the hopanoids, are thought to have predated sterols in evolution perhaps having arisen with the primal prokaryotes in the precambrian anaerobic environments *via* the cyclization of squalene (4,5). As sufficient molecular oxygen became available for the genesis of squalene oxide, several new classes of triterpenoids, *e.g.*, pentacycles (hopanoids) and tetracycles (steroids), were synthesized by prokaryotes (1,3). Apparently, the genetic information for the varied cyclases was carried into the algae (6). However, selection mechanisms evolved during eukaryote development which caused PT production to become ontogenetically delayed relative to sterol synthesis in fungi (7) and vascular plants (8) suggesting a secondary metabolite role for pentacyclic triterpenoids. In the metazoan line, selection pressures led ultimately to their eradication (9).

The utility of developmental regulation of the isopentenoid pathway is not entirely clear, especially when we are led to believe that in their molecular dimensions, rigidity and amphiphilic properties, hopanoids are structural equivalents of sterols, thus suggesting functional equivalence as well (2,4,5). In search for an explanation to this anomaly, we were guided by two rather opposing ideas: architectural parity existed between PT and sterols so that random mutations which directed altered biosynthesis in bacteria led to the production of PT mimics (sterols) which replaced PT as membrane inserts. Because of this parity (functional equivalence), as mutations in PT formation occurred, life continued so long as compensatory mutations accrued to insure the formation of PT-like compounds, *e.g.*, sterols in eukaryotes. If this was so, then PTs should readily replace sterols as membrane bulk components in prokaryotes and eukaryotes. In support of this view, mycoplasmas are known to use PTs and sterols equally well as growth-support agents (10,11). However, this is not the case in fungal sterol auxotrophs. As we have recently demonstrated, PTs fail to serve in the bulk role at certain stages of the life cycle of either of two sterol auxotrophic fungi — in growth of *Saccharomyces cerevisiae* (8) or in oosporogenesis in *Phytophthora cactorum* (ref. 8, and refs. cited therein). The other possibility is that sterols and PTs are structurally and stereochemically dissimilar. The variations, while also arising by mutation, are then actively, rather than passively retained because they serve a purpose *e.g.*, in one or another temporally expressed function during development. If this is so, then we might expect that, in contrast to what is generally thought (2,4,5), sterols (which came after PTs in evolution) are alternatives to, rather than replacements of PTs. As such, they should possess distinguishing structural characteristics which can be shown to increase their fitness compared with PTs to promote survival and speciation.

In an attempt to shed further light on PT and sterol phylogenesis, we have examined by X-ray crystallography the three-dimensional structure of two PTs which may be considered geohopanoids (4) and which occur throughout the plant kingdom (3,9).

MATERIALS AND METHODS

Crystal and refinement data. X-ray crystallography was performed at the Western Regional Research Center (Albany, CA). $C_{32}H_{52}O_2$, isoarborinol acetate and [in brackets] motiol acetate: M = 468.9, monoclinic [orthorhombic], space group $P2_1$ (C_2^2, No. 4) [$P2_12_12_1$ (D_2^4, No. 19)], a = 11.039(2) [7.587(1)], b = 7.498(1) [17.792(6)], c = 17.451(4) [20.758(4)] (Å), β = 106.63(1) [90.0]°, V = 1384 [2802] Å^3, D_c = 1.12 [1.11] g cm^{-3}, Z = 2 [4], F(000) = 520 [1040], μ(Cu-K$_\alpha$) = 4.79 [4.73] cm^{-1}, R = 0.045 [0.080], R_w = 0.051 [0.079] for 2226 [2154] unique reflections with $|F_0| \geq 3\sigma|F_0|$ in the range of $3° \leq 2\theta \leq 114°$. Tables of anisotropic thermal parameters with their estimated standard deviations (e.s.d.) for the non-hydrogen atoms, positional and thermal parameters for the hydrogen atoms, and observed-calculated structure factors have

*To whom correspondence should be addressed.

Abbreviations: PT, pentacyclic triterpenoid; ^{1}H NMR, proton nuclear magnetic resonance spectroscopy.

been deposited at the Cambridge Crystallographic Data Centre.

Data collection and structure refinement. Intensity data were collected on a Nicolet R3 diffractometer with graphite monochromatized Cu-Kα radiation (λ = 1.5418Å) by the θ-2θ scan technique with variable scan speed (4-30°) min^{-1} at room temperature. The intensity data were corrected for background, Lorentz-polarization effects (Nicolet XTL Operation Manual (1980), Nicolet Analytical Instruments, Inc., Cupertino, CA 95014, but not for absorption or secondary extinction. The crystal structures were solved by direct methods and refined by a 'blocked-cascade' full-matrix least-squares procedure with the SHELXTL (12) program package. The function minimized was $\Sigma\omega(|F_o|-|F_c|)^2$, where $\omega = [\sigma^2|F_o|^2+0.001|F_o|^2]^{-1}$. Scattering factors were from *International Tables for X-ray Crystallography* (13); those of oxygen were corrected for anomalous dispersion. Atomic parameters of all non-hydrogen atoms were refined anisotropically, and all hydrogen positions were estimated but verified in subsequent difference Fourier maps are included with invariant idealized values in the respective structure-factor calculation.

Numbering system. The numbering system for the atoms in the arborane and fernane skeletons shown in Figure 1 follows IUPAC rules whereas the carbon atoms assigned numbers in the X-ray crystallographic study are of an arbitrary system. When discussion regarding hopanoid biosynthesis and function is presented, reference is to the numbering system shown in Figure 1.

RESULTS AND DISCUSSION

Sorghum bicolor leaves were the source of isoarborinol and motiol. In the leaves, two additional isomeric hopanoids are found. The isolation and separation methods, and chromatographic and spectral properties of the four hopanoids were given in an earlier report (14). Based on a proton nuclear magnetic resonance (^{1}H NMR) study of the sorghum hopanoids, we thought the plant synthesized a series of stereoisomers. Shortly after our study appeared, two Japanese groups provided an extensive tabulation of the ^{1}H NMR chemical shifts for numerous PTs including hopanoids (15,16). The data given by us for fernenol agreed with their data but our data for sorghumol, trematol and isoarborinol agreed with their data for isoarborinol, motiol (fern-7(8)-enol) and isomotiol (fern-8(9)-enol), respectively. The X-ray crystallographic studies which we now have obtained on what we thought was sorghumol and trematol are in fact of isoarborinol and motiol, respectively. Since we based our identification of trematol from mass spectral and ^{1}H NMR data given in the literature (17), we conclude 21-epifernenol has not been found in nature, although in the 3-desoxy series there is some evidence for its occurrence in ferns (18).

The atomic coordinates for isoarborinol acetate (1) and motiol acetate (2) are shown in Table 1. The torsion angles for 1 and 2 are shown in Figure 2, and the molecular conformations of 1 and 2 with their thermal motions and numbering scheme used in the X-ray investigation are shown in Figure 3. The average bond distances and angles

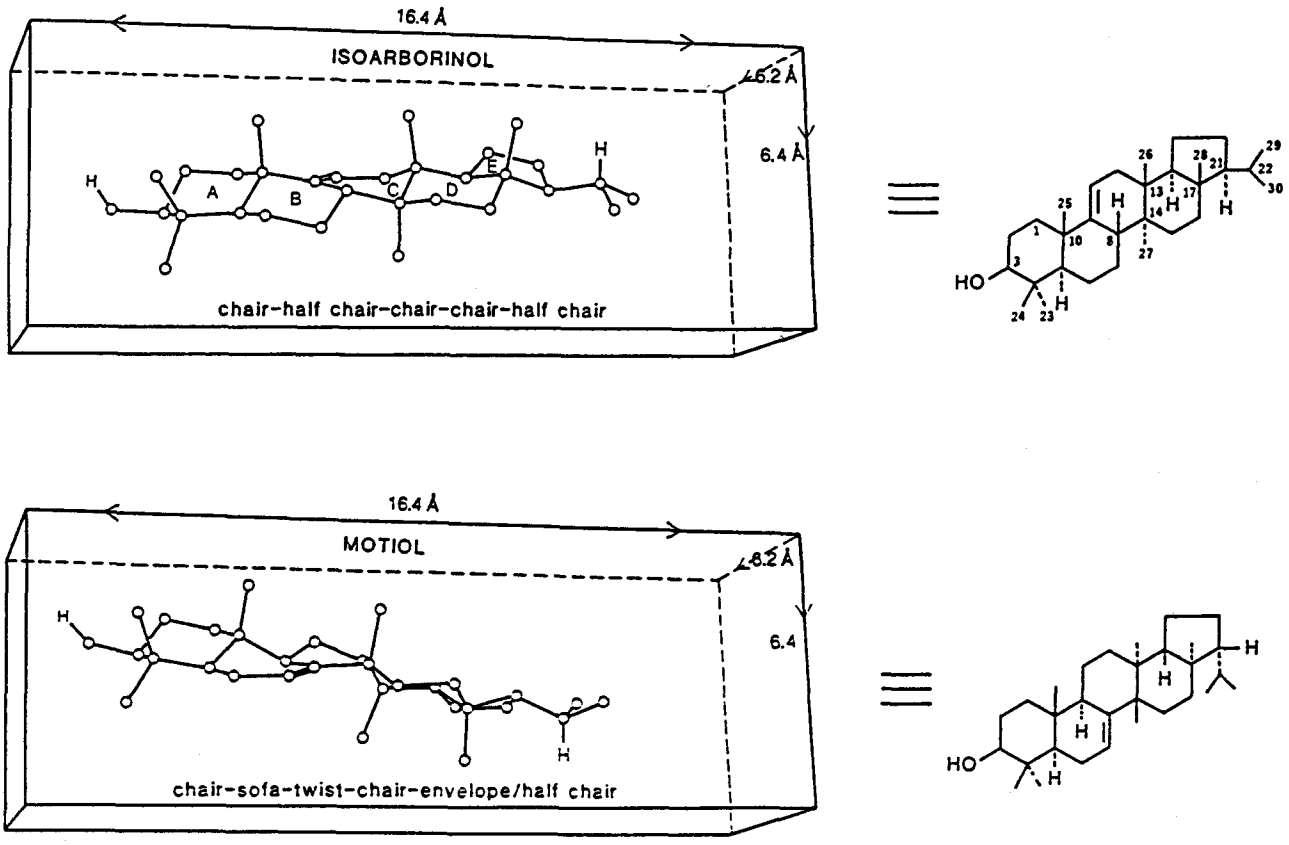

FIG. 1. Approximate molecular dimensions of isoarborinol and motiol as determined by X-ray crystallography.

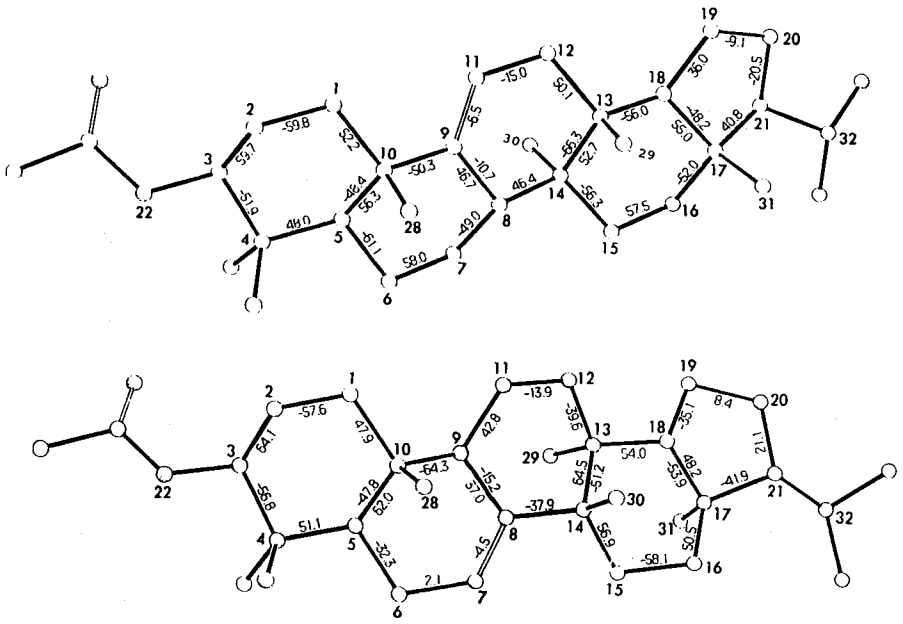

FIG. 2. Endocyclic torsion angles for isoarborinol acetate (top) and motiol acetate (bottom).

for 1 are similar with those found in the structure 2α-bromoarbinone which was earlier examined by X-ray crystallography (19). The C–C distances in the nucleus range from 1.505 to 1.582 in 1 and from 1.505 to 1.598 in 2.

From Figure 1, it can be seen that 1 and 2 possess the same all-*trans*-anti-stereochemistry in the ring systems, a similar planarity and similar approximate molecular dimensions, as the free alcohols—164. × 6.2 × 6.4 Å. Examination of the torsion angles indicated that the rings of 1 orient into a chair-halfchair-chair-chair-halfchair conformation whereas the rings of 2 orient into a chair-sofa-twist-chair-halfchair conformation. The major conformational difference between 1 and 2 comes from the difference in the torsion angles shown in Figure 4 and indicates that ring C is distorted part way toward the twist (boat) conformation in 2. This results in a slight convex bending of the skeleton towards the α-side of the molecule. As also shown in Figure 1, atoms C-13 and C-14 in both molecules are appreciably out of the mean plane through the C-ring and point toward the opposite directions. Atoms C-13 and C-14 are displaced from their mean ring plane by +0.38 and −0.35Å in 1 and −0.41 and +0.40Å in 2, respectively. Presumably, the difference of the orientation in C-13, C-14, C-29 and C-30 on the C-ring accounts for the deviation of the relative positions and conformations of the D- and E-rings in both molecules. The comparative dihedral angle data between the plane normals of all the ring units in both structures are given in Table 2. The sofa-twist-chair (B-, C- and D-rings) arrangement in 2, a migrated hopanoid, is the favored conformation of lowest energy, although the molecule remains thermodynamically unstable and may undergo acid-induced molecular rearrangements to the more stable hopanoid skeleton, as in the rearrangement of friedelin to the amyrin skeleton or of the euphoid to the dammarenoid skeleton (20,21). Alternatively, due to the all-chair system present in isoarborinol acid treatment simply moves the double bond from the C-ring into the B-ring as in the acid-induced

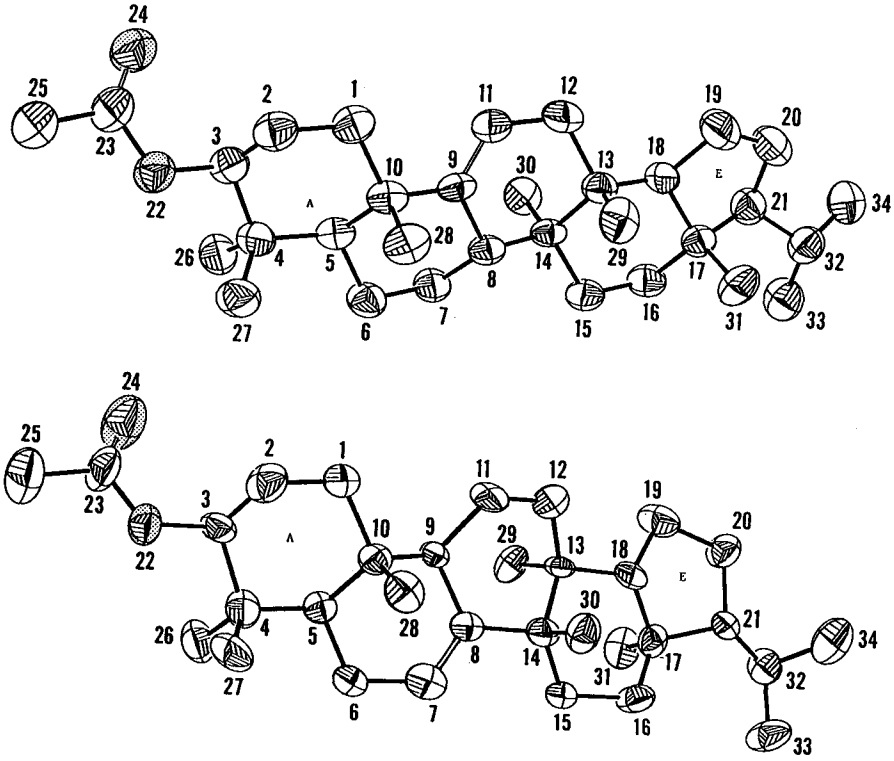

FIG. 3. Perspective view of isoarborinol acetate (top) and motiol acetate (bottom) with the crystallographic numbering system. The thermal ellipsoids are drawn at 50% probability level and the shaded ellipsoids represent oxygen (O-22 and O-24).

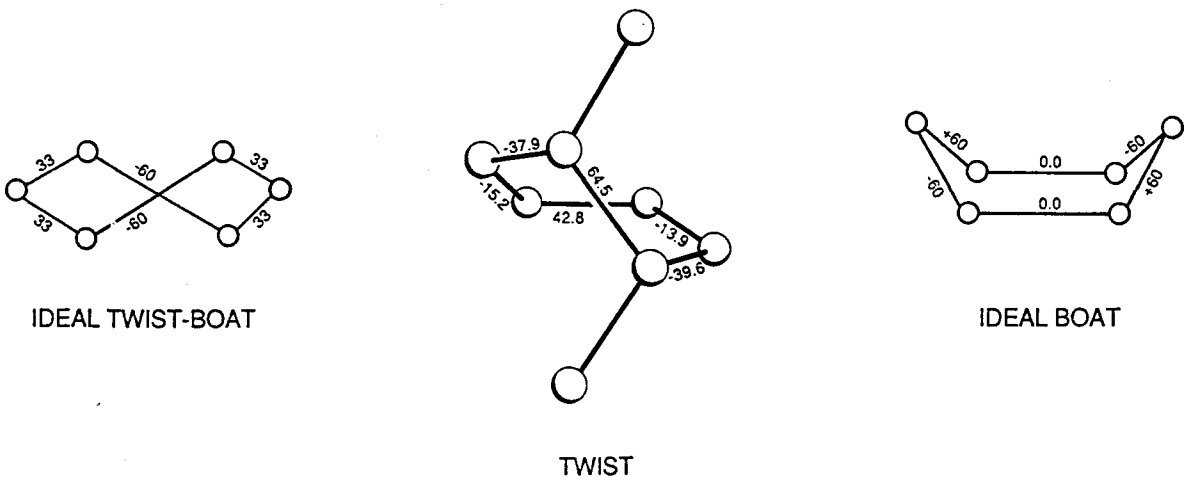

FIG. 4. Torsion angles of ideal twist-boat, ideal boat and the experimentally determined values in motiol ring C.

rearrangement of Δ^8- to Δ^7-steroids (21–23). In the usual schematic view of the molecule illustrated on the right side of Figure 1, the impression we are given is that the terminal isopropyl group in 1 and 2 may orient into different quadrants of space. In fact, certain hopanoids are known to possess 21α axial isopropyl groups (25). However, as seen in Figure 1, the terminal isopropyl group in 1 and 2 both orient into an equatorial position although C-22 in 1 is inverted compared with 2. Another interesting aspect of the geometry is that in 1 the molecule arcs up relative to the front end of the molecule while in 2 the molecule arcs down relative to the front (3-OAC) end. Here the isopropyl side chain is affected by long-range conformational transmission effects which mediate the

orientation of the geminal methyl groups, C-29 and C-30. In 1, the geminal methyls point down whereas in 2 they point up. This is due to the 1,3-diaxial interactions between H-22 and C-28. Thus inversion of the configuration at C-21 resulted in a rotational preference of the side-chain methyls. That this conformation is likely maintained in solution is supported by NMR. For example, the chemical shifts and coupling constants for H-29 and H-30 are similar in 1 and 2 (14-16).

How these stereochemical similarities could have arisen based on previously described cyclization schemes to fernenol or arborenol is not clear. For the biosynthesis of fernenol, it has been thought that prior to cyclization, squalene oxide assumes a coiling pattern which rearranges into a chair-chair-chair-chair-boat conformation (21-23,25). After proton-initiated attack at C-3, the molecule then undergoes cyclization in a one-step non-stop process to an initial stable pentacyclic structure. The resulting hopanoid cation (consisting of five rings, four cyclohexanoid, and one cyclopentanoid), presumably with the same conformational disposition as the cyclizing material, is localized in the side chain at C-22 (Fig. 5). Additional 1,2-migration proceeds in a concerted manner to give rise to migrated hopanoids, *e.g.*, motiol. Other types of hopanoids, *e.g.*, tetrahymanol, are assumed to be formed by cyclization of squalene with no intramolecular rearrangements during the course of ring annulation (26). Thus, the cyclization of hopanoids has been envisaged as a completely concerted process, a view supported by the failure to trap or otherwise detect any of the cyclizing intermediates. The family of enzymes conducting cyclizations to produce hopanoids would have to be fundamentally different from the one(s) involved in the biogenesis of related PTs, such as, lupeol, the amyroids and epifriedelanol. For this group of PTs a step-wise pathway demonstrably operates by forming a series of intermediate frozen (27) mono- or bicyclic carbonium ion entities possessing boat-like conformations that pass through a key tetracycle, the dammarenyl cation (syn.—triterpenoid cation), before elaboration of the fifth ring (28-30). Several "missing links" have recently been identified as quasi intermediates between squalene oxide, the dammarenyl cation and β-amyrin which support the step-wise mechanism (31,32).

An alternative possibility that we now offer is that the hopanoid skeleton is formed by the same mechanistic pathway that proceeds from squalene oxide to other PTs using the dammarenyl cation, as shown in Figure 6. This would allow for a conservation of genetic material in PT cyclase evolution as speculated by Ourisson and Rohmer (4). For the biogenesis of 2, cyclization would be initiated by electrophilic attack by H^+ on the epoxy oxygen while the squalene oxide is held in the chair-chair-chair-boat-"left-handed" unfolded conformation on the active site of the enzyme. This leads to the formation of the dammarenyl cation (Fig. 6). The formation of the fifth ring involves ring enlargement from the 13,17-bond (steroid numbering system) so that C-13 is joined to C-20 producing a new cation at C-17 (4 in Fig. 6). If the terminal isoprene unit is folded as a boat, attack of the Δ^{22}-pi electrons (hopanoid numbering system) onto the electron-deficient site produced at C-17 would yield a new cation (5 in Fig. 6) which should be stabilized by hyperconjugation from the six H-atoms on C-29 and C-30, acting in part as a driving force for the formation of the cyclopentanoid ring. Remote

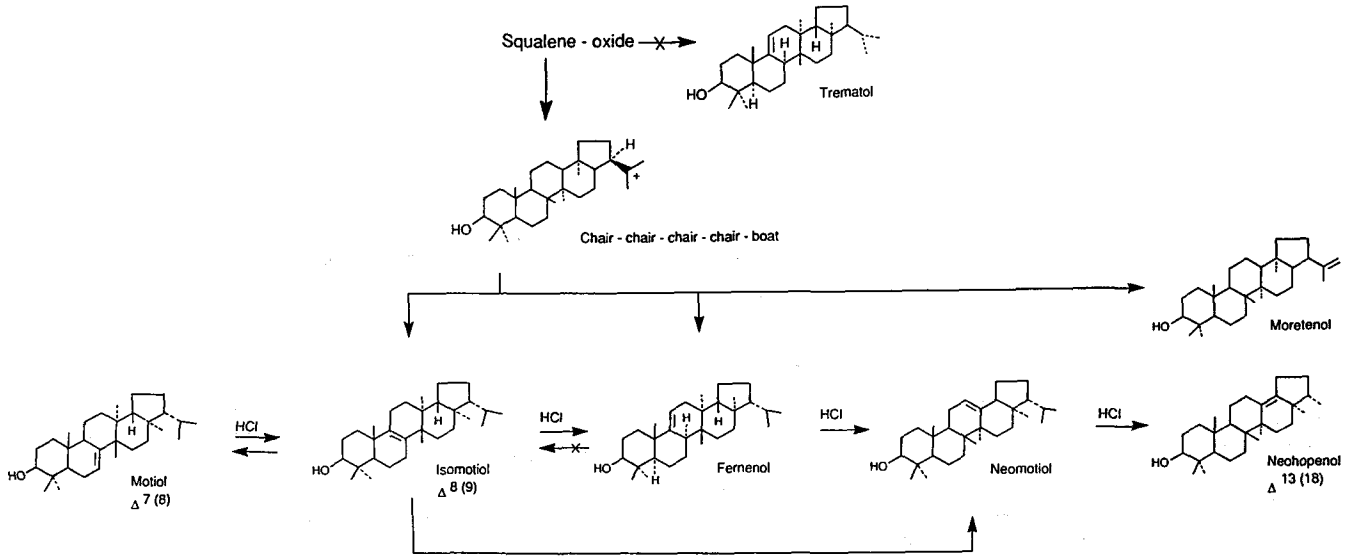

FIG. 5. Relationship of previously considered biogenetic mechanisms with acid-induced rearrangements in the formation of hopanoids (*cf.* 16,22-24,26).

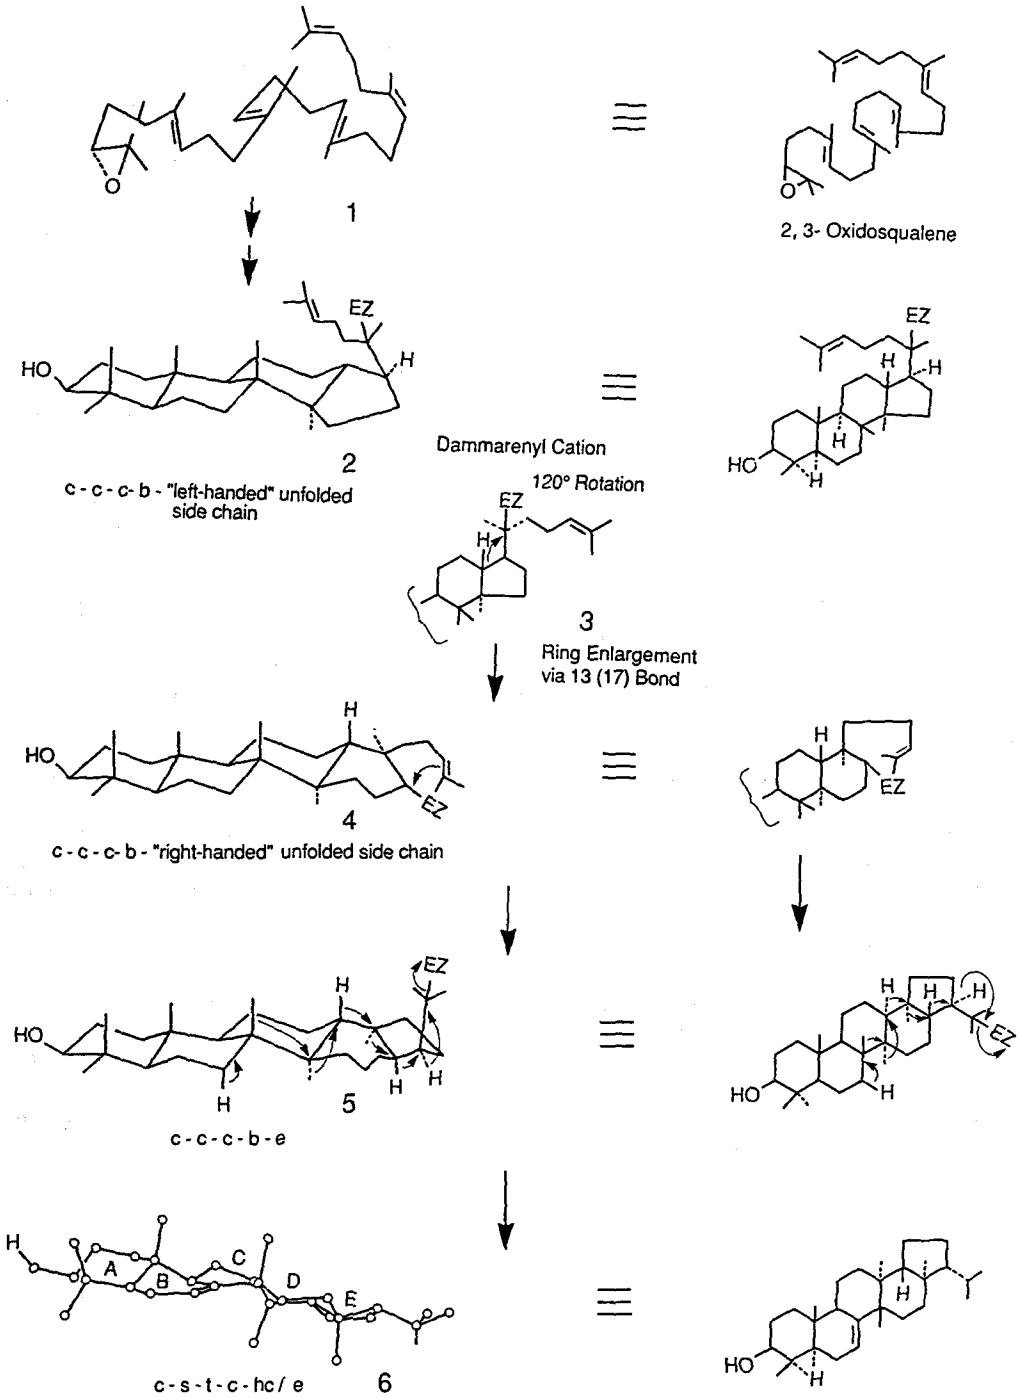

FIG. 6. Hypothetical cyclization mechanism for the conversion of squalene oxide to motiol.

deprotonation of the 7α-H atom would then induce a series of 1,2-migrations with inversion of the configuration at each of the carbons involved to produce motiol. The conformational driving force that affects the thermodynamics of inversion does not come from the all *trans*-anti arrangement of the intermediate cation 5; rather it comes from the steric compression in the boat-like D- and E-rings coupled with the eclipsed 17β-H and 21β-isopropyl group. These structural features confer the higher entropy to push for further backbone rearrangements that culminate in the migrated hopanoid structure with an *equatorial* 21α isopropyl group. Thus, as indicated by labeling studies (21) and now for conformational reasons, neohop-13(18)-enol, which assumably maintains an all-chair conformation, could not act as a legitimate precursor of fernenol, rather it is an end product of the synthetic sequence as shown in Figure 5. That boat-like cyclohexanoid rings are formed during cyclization and maintained in the cyclized product is supported by the conformation of some other PTs which possess a combination of chair

and boat rings in the completed cyclized structures. Most of the PTs were thought to be all-chair, but now some are known to possess one or more boat rings in the distal part of the molecule. The effect of introducing boat conformers is to produce a flat structure which then is maintained in solution and in the solid state. For instance, epifriedelanol is now known to obtain a flat structure by orienting into a chair-chair-chair-boat-boat conformation, rather than orienting into a bent conformer, as suggested earlier (33,34). On the assumption, for thermodynamic reasons, that chair-boat interconversions seem unlikely in the cyclized product, *i.e.*, to flip from the flat to the bent structure then in order to produce the three-dimensionally flat conformation, the original cyclization scheme to friedelin as suggested by others (29) requires modification. We have considered the possibility that elaboration of the dammarenyl cation and of the protosteroid cation, followed by ring enlargement from $\Delta^{13,17}$-bond may give rise to other triterpenoids, epifriedelanol, tetrahymanol and isoarborinol, respectively (8).

Another interesting aspect of the three-dimensional geometry of 1 and 2 is that they are somewhat shorter and volumetrically smaller than sterols. From the dimensions given in Figure 1 the length and volume for 1 and 2 are calculated to be 16.4 Å and 645 Å^3 while the corresponding data calculated for cholesterol are 19.1 Å and 853 Å^3, respectively (4). The size difference in the two groups of molecules is presumably the major reason for differences in their biological utilization rather than their conformation (flat compared with bent, *cf.* 8, for discussion) or location of angular methyl groups in the nucleus. Furthermore, we assume that the free isooctyl side chain in cholesterol contributes to the size differences due to its ability to sweep out a cone, *i.e.*, decreasing viscosity by increasing van der Waals' dispersion contacts (*cf.*, Fig. 7). Thus, this molecular feature should increase the volume of sterols compared to PTs and increase the suitability of sterols to function better than PTs as membrane components (8).

Regarding the phylogenetic arguments presented in the introduction, the results of our studies seem to support the second possibility: that is, sterols possess novel structural features which have allowed them to supersede the shorter, more rigid and volumetrically smaller PTs as architectural components of cell membrane inserts during the evolution of plant systems. PTs which continue to be synthesized by more advanced plants are produced presumably because they acquired additional new functions, *e.g.*, as components of the epicuticular wax (8). Thus we may now assume a non-conservation of architectural parity with evolutionary ascent.

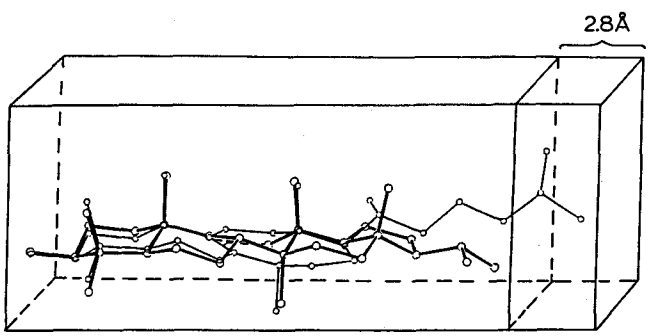

FIG. 7. Comparison of X-ray molecular dimensions of isoarborinol (this study) and 24,25-dihydrolanosterol (Griffin, J.F., and Nes, W.D., unpublished observations). Note the length of the sterol is approximately 3 Å greater than that of the pentacycle.

***Pavlova gyrans*, a unicellular alga of interest as food for oysters, was cultured axenically and examined for sterol composition. Desmethyl monohydroxy sterols, which are frequently seen in algae, made up 40% of the total sterols and were observed primarily in the free sterol fraction. The principal sterols of this group were 5-ergostenol, poriferasterol, and clionasterol, as well as some poriferast-22-enol and poriferastanol. Several "methyl" sterols with unusual structures made up 27% of the total sterols. The principal "methyl sterols" were 4α-methyl ergostanol, 4α-methyl poriferastanol, and 4α-methyl poriferast-22-enol. Methyl sterols were found primarily in the ester fraction. Also observed was a new class of dihydroxysterols composing 33% of the total sterols. These sterols are structurally related to the methyl and desmethyl sterols of *Pavlova* but contain an extra nuclear hydroxyl which can be acetylated when present on a desmethyl sterol, but which is nonreactive with acetic anhydride in 4α-methyl sterols. None of these sterols were observed in ester form but are concentrated in the acid-hydrolyzable, bound fraction. The unique nature of these sterols suggests potential taxonomic utility.**

***Lipids 26*, 656-659 (1991).**

Many marine invertebrates feed on unicellular algae, and it seems likely that the numerous exotic sterols found in these organisms might in fact be unchanged or modified dietary algal sterols (1,2). The commercial oyster, *Crassostrea virginica*, has been found to contain 39 sterols (3). Of these, only four appear to be produced by the oyster (4), although more recent work indicates that all oyster sterols are of exogenous origin (5).

Sterol composition has been found to be of interest in plant taxonomic considerations (6-8). The Prymnesiophyceae are a family of small, primarily marine protists characterized by the possession of a haptonema between two smooth flagella. Formerly, the organisms were considered a part of the chrysophyceae, until Christiansen (9) split them off into the Haptophyceae, a descriptive name. Subsequently, the name was changed to the Prymnesiophyceae (10).

Pavlova gyrans is a member of the Pavlovales in the Prymnesiophyceae and has been used for oyster culture (11, and Wikfors, G., and co-workers; manuscript in preparation). Ballantine *et al.* (12) found in the closely related species, *P. lutheri* (as *Monochrysis lutheri*), cholesterol, 24-methyl and 24-ethyl cholesterol and 22-dehydro-24-ethyl cholesterol as major sterols in cultures harvested in the exponential growth phase; however, when harvested in the stationary phase, this species contained an increased quantity of 4-methyl sterols which were present along with a C_{29} and a C_{30} dihydroxysterol. The specific structures of these sterols were not determined. In the present paper we report on the occurrence of four dihydroxysterols in stationary phase cells of *Pavlova gyrans*. Each compound was characterized by a saturated nucleus and contained two hydroxyl groups. We report here on the sterols of *P. gyrans* and *P. lutheri* and their occurrence in specific sterol fractions.

MATERIALS AND METHODS

Culture conditions. Pavlova gyrans Butcher, strain designation "93," utilized in this study, was obtained from the Milford Laboratory (Milford, CT) microalgal culture collection where it has been maintained for many years in enriched natural seawater medium, "E" formulation (13). At Milford, axenic test-tube cultures were increased in volume through a series of progressively larger flasks and finally inoculated into carboy assemblies (13). Carboy cultures were operated semi-continuously, with harvests of about one-third of the total culture volume (6 liters taken from 18 liters) on Friday of each week, followed immediately by replacement of harvested volumes with autoclave-sterilized "E" medium. Harvests and additions of growth medium were accomplished with sterile technique so that cultures remained axenic. Carboy cultures were routinely monitored for the presence of microbial contaminants at each harvest by inoculating 0.2 mL of algal culture into 5 mL of thioglycollate medium made up in 50% seawater. Direct observation with the fluorescence microscope using acridine orange confirmed that cell suspensions subjected to sterol analysis were, indeed, axenic.

Algae for sterol analysis were harvested five days after the most recent addition of medium. We consider these cells to be in the stationary phase of growth because no further increases in cell density occurred in carboy cultures after five days, and protein-nitrogen analysis of *P. gyrans* harvested on this schedule revealed that all nitrogen in the medium had been incorporated into algal biomass (Wikfors, G. H., unpublished observation). Harvested cultures were concentrated by cold centrifugation (1020 × *g* at 10°C for 20 min), and re-suspended in a minimal volume of isotonic NaCl. This concentrated algal cell suspension was volumetrically aliquotted into glass ampoules, with a small volume being retained for microscopic counting in an Improved Neubauer (Buffalo, NY) hemacytometer. Ampoules containing algal cell suspensions were then frozen in a rotating bath of cold methanol (−25°C) and lyophilized using a VirTis Unitrap 10-100 manifold-style freeze-dryer (VirTis, Gardiner, NY). Ampoule necks were melt-sealed immediately upon removal from the lyophilizer manifold, and algal samples were stored in the sealed ampoules until analyzed.

[d]Less than 1%.

[e]None detected.

[f]Apparently differ only in position or location of second hydroxyl.

[g]Structure also contains an additional hydroxyl on the nucleus.

Isolation of sterols. Lyophilized samples (7.6 g) of *P. gyrans* (#93) were extracted in chloroform/methanol (2:1, v/v) using a Soxhlet extractor (Fisher Scientific, Silver Spring, MD) for 8 hr. The crude lipid extract was partitioned by column chromatography using Unisil (100–200 mesh, Clarkson Chemical Co. Inc., Williamsport, PA). Hydrocarbons, sterol esters, free sterols, and polar sterols were eluted with 100 mL each of hexane, hexane/chloroform (50:50, v/v), chloroform, and ethanol, respectively. The polar sterol fraction was hydrolyzed in 6 N HCl/MeOH (1:5, v/v) at 80°C, for one hr; sterols were recovered by adding water and by partitioning into chloroform. The ester fraction was saponified with 7% KOH in methanol at 80°C for 1 hr, and sterols were recovered by adding water and by partitioning into diethyl ether. The ester and polar fractions from the Unisil column were further fractionated on an alumina column and eluted with 30, 40, 50, 60, and 75% diethyl ether in hexane, 100% diethyl ether, and 20% methanol/diethyl ether (v/v) to separate the methyl sterols from the desmethyl sterols.

Chromatography. Qualitative and quantitative analyses of sterols were performed by gas-liquid chromatography (GLC) on a Varian 3700 gas chromatograph with a hydrogen flame ionization detector and a 30 m × 0.25 mm i.d. SPB-1 capillary column (Supelco, Inc., Bellefonte, PA) at a column temperature of 255°C and an injector temperature of 265°C. Data were corrected for detector response with isolated dihydroxy sterols. Column flow was 1 mL/min with helium as the carrier gas. Peak area calculations were processed with a Varian 401 Chromatographic Data System. Relative retention times (RRT) of sterols are expressed relative to cholesterol.

Mass spectra of free sterols were obtained from a Finnigan-MAT Model 4512 gas chromatograph-mass spectrometer equipped with a 30 m × 0.32 mm i.d. fused silica capillary column with a 0.25 μm film of DB-1 (J&W Scientific, Folsom, CA). The column was operated at a head pressure of 13 psi of helium and the temperature was programmed, after a 2-min hold at 230°C, to 255°C at either 2 or 5°C/min. Electron impact mass spectra were measured at 70 eV and an ionization temperature of 150°C. Data were recorded and analyzed with an Incos Data Systems (Incos Finnigan Corp., San Jose, CA).

RESULTS AND DISCUSSION

Fractionation of the *P. gyrans* lipid extract into sterol esters, free sterols, and covalently-bound polar sterols permitted a more accurate description of the sterol composition of this alga than would be provided by analysis for total sterol alone. Sterols found in each fraction are summarized in Table 1. Sterol structures are seen in Figure 1. Sterols from *P. lutheri* were also analyzed, but data were obtained only for total sterols. The monohydroxy sterols identified possessed one of three types of sterol nuclei: monohydroxydesmethyl sterols (type 1 and 2 in Fig. 1), common in most living organisms, and monohydroxy-4-methyl sterols (type 3). Type 2 and type 3 sterol nuclei were also found with an extra hydroxyl in the sterol nucleus (Fig. 1). These dihydroxysterols are called pavlovols. Characterization of the dihydroxy sterols has been completed except for the location of the second hydroxyl. Work is continuing to identify the dihydroxy sterols. The monohydroxydesmethyl fraction consists principally of 5-ergostenol (1B) (Fig. 1), poriferasterol (1D), clionasterol (1E) and poriferast-22-enol (2D). Except for the last, these sterols are quite common in the algal division Chromophycota, to which *Pavlova* belongs (14,15).

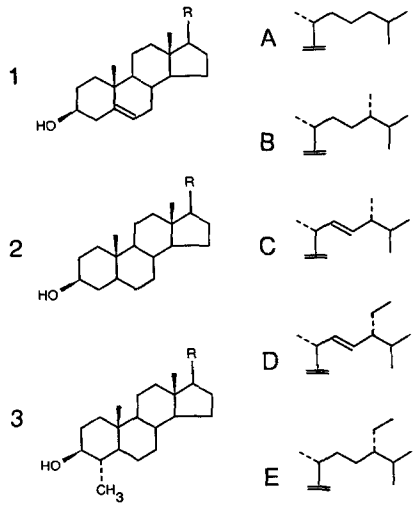

FIG. 1. Structures of sterols from *Pavlova*.

Small quantities of cholesterol (1A) and epibrassicasterol (1C) were also detected. Identifications were based on capillary gas chromatography (GC) relative retention times (Table 1) and on mass spectra, which matched those of authentic standards. Poriferasterol was identified as being 24β-ethyl (24R) by its melting point (156°C) and by ^{1}H nuclear magnetic resonance (NMR) (16–18). Other sterols in *Pavlova* are assumed to be 24β, based on the configuration at C-24 of poriferasterol and because the 24β-configuration is characteristic of most algae (6). The principal exception to the 24β configuration is epibrassicasterol which has been demonstrated to be 24α-methyl rather than 24β-methyl in all identified algae in the Chromophycota where such determinations have been made (7,8,19).

The monohydroxy-4-methyl sterols are, for the most part, unusual structures; their principal mass spectral characteristics are shown in Table 2. Each of these sterols corresponds structurally to one of the monohydroxy desmethyl sterols already identified, but with the retention of the 4-methyl group and the absence of the Δ^5-double bond. Sterols with a saturated nucleus and a 4-methyl group are quite rare, primarily occurring in marine animals where these sterols are presumed to be of dietary origin (20,21), although their nutritional role is not known. Although these sterols have also been isolated from the dinoflagellates *Heterocapsa* (22) and *Glenodinium* (23,24), they have not been found in other algal taxa. These sterols have not been reported to occur in *P. lutheri* harvested during logarithmic growth, but appear to be the methyl sterols detected by Ballantine *et al.* (12) and identified here. The quantities of sterols found in ester, free, and bound fractions are presented in Table 3. From these data it is apparent that various sterols are not distributed in each fraction in the 1:6:3 ratio found between quantities of ester, free, and polar sterols. For instance, monohydroxy-4-methyl sterols comprise 27% of total sterols but they account for nearly 90% of the ester sterols (Table 3). Dihydroxy sterols make up 33% of the total sterols but they make up over 77% of the polar sterols. Clearly, some mechanism is directing specific sterol structures preferentially toward certain

sterol fractions (ester, free, polar). Two-thirds of the total sterol in the *P. gyrans* culture examined here had a saturated nucleus. Therefore, direct algal synthesis as well as bacterial modification of sterols may be sources of marine stanols (25). Cholestanol is the principal sterol of several red algae (26) and several higher plants contain dominant saturated sterols (27,28), but in these cases the sterols were 4-desmethyl, in contrast to the 4α-methyl sterols in *Pavlova*.

Sterols have been suggested to have some chemotaxonomic value for algae because the occurrence of specific sterols in algae corresponds well with taxonomic placement (6). *P. gyrans* and *P. lutheri* belong to a newly erected algal class, the Prymnesiophyceae. Sterol compositions have been determined for this class for the orders Coccosphaerales (7,29,30) and Isochrysidales (8,17,29,30). In each of the above orders, epibrassicasterol was the principal sterol and sterols with a 9-carbon side chain were dominant. In a third order, Prymnesiales, sterols with 8-carbon side chains (mostly cholesterol) are dominant (30). In the order Pavlovales, to which *Pavlova* belongs, Ballantine *et al.* (12) have shown that sterols with

the 10-carbon side chain are dominant in both exponential and stationary cultures of *P. lutheri*. The present work confirms their findings with stationary-phase cultures of *P. lutheri*, and extends their results to include stationary-phase *P. gyrans*, in which about 90% of the sterols have a 10-carbon side chain. The order Pavlovales appears to differ sharply from the previously mentioned orders in this respect, although data on more species are needed.

Data on sterol composition must be viewed with some caution unless all sterol fractions from the organism are accounted for. The importance of including analyses for polar, bound sterols is demonstrated by the findings in this study, that they constitute 30% of the total sterol in *P. gyrans*. Several green algae showed an increase in total sterol when cultured photosynthetically *versus* heterotrophically (31), but the ratios between individual sterol components were rather constant. However, with *Emiliania huxleyi* (29) and *P. lutheri* (8), the phase of growth can markedly affect the ratio between various sterols. Compositional data between species cultured in different conditions must be evaluated with caution. However, it is apparent that sterol distributions within or between algal taxa can provide useful systematic information in support of the more traditional morphological characters (30).

ACKNOWLEDGMENTS

The contributions of Gail E. Ferris and Barry C. Smith to culturing and preparing algae for analysis are gratefully acknowledged. We thank Roland M. Waters, Insect Chemical Ecology Laboratory, U.S. Department of Agriculture, Beltsville, MD, for proton NMR spectra. Sterols of *Kalanchoe pinnata*: First Report of the Isolation of Both C-24 Epimers of 24-Alkyl-Δ^{25}-sterols from a Higher Plant

Toshihiro Akihisa[a,*], W.C.M.C. Kokke[b], Toshitake Tamura[a] and Taro Matsumoto[a]

[a]College of Science and Technology, Nihon University, Tokyo 101, Japan, and [b]Department of Synthetic Chemistry, SmithKline Beecham Pharmaceuticals, King of Prussia, Pennsylvania 19406

Eighteen sterols were isolated from the aerial parts of *Kalanchoe pinnata* (Crassulaceae) including four novel sterols, *viz.* (24*R*)-stigmasta-5,25-dien-3β-ol (24-epiclerosterol), (24*R*)-5α-stigmasta-7,25-dien-3β-ol, 5α-stigmast-24-en-3β-ol, and 25-methyl-5α-ergost-24(28)-en-3β-ol. 24-Epiclerosterol and its Δ^7-analog occur together with their 24*S*/β-epimers in the same plant making this the first report of the isolation of both C-24 epimers of Δ^{25}-unsaturated 24-alkylsterols from a non-marine organism. Iodine-catalyzed isomerization of stigmasta-5,24-dien-3β-ol (24-ethyldesmosterol), the main sterol of *K. pinnata*, yielded 24-epiclerosterol among other products.
***Lipids* 26, 660–665 (1991).**

The principal sterols of the great majority of higher plants are two 24α-ethylsterols, sitosterol (2e) (see Table 1 and Figure 1 for systematic names and structures) and stigmasterol (2g), and C-24 epimeric 24-methylsterols, campesterol (2a) and 22-dihydrobrassicasterol (2b) (1–5). There are, however, also plants which contain Δ^{25}-unsaturated 24-ethylsterols as the dominant sterols. Examples are several *Clerodendrum* species (Verbenaceae) (6,7,9,10; 8, and references cited therein), and *Kalanchoe* species (Crassulaceae) (4,5), which contain clerosterol (2n) and 22-dehydroclerosterol [(22*E*,24*S*)-stigmasta-5,22,25-trien-3β-ol, 2o]. The seeds of several cucurbitaceous plants (11–18; 19, and references cited therein) are the other examples which contain (24*S*)-5α-stigmasta-7,25-dien-3β-ol (3n) and (22*E*,24*S*)-5α-stigmasta-7,22,25-trien-3β-ol (3o), as their dominant sterols.

In this paper we report the sterol composition of the aerial parts of *Kalanchoe pinnata* (air plant; Crassulaceae). The sterols include both epimers at C-24 of stigmasta-5,25-dien-3β-ol (2m,n) and 5α-stigmasta-7,25-dien-3β-ol (3m,n). In all previous cases in which the stereochemistry at C-24 of Δ^{25}-unsaturated 24-alkylsterols of plants and their seeds has been carefully investigated (1–31), the stereochemistry at C-24 was found to be 24*S*/β The eighteen identified sterols of *K. pinnata* (Table 1) include four novel ones (1j, 1p, 2m, 3m) (*vide infra*).

MATERIALS AND METHODS

General methods. Crystallizations were from acetone/methanol. Melting points (m.p.) are uncorrected. Preparative thin-layer chromatographic (TLC) plates (silica gel) and argentation TLC plates (Silica Gel/$AgNO_3$, 4:1, w/w) were developed three times with hexane/EtOAc (6:1, v/v) and CCl_4/CH_2Cl_2 (5:1, v/v), respectively. High-performance liquid chromatography (HPLC) separations were performed using a Beckman (Altex) Ultrasphere ODS column (5μ, 25 cm × 10 mm i.d.) (Beckman Instruments, Inc., San Ramon, CA) with a refractive index detector and methanol/H_2O (98:2, v/v) as the mobile phase (flow 4 mL/min). A SCOT OV-17 glass capillary column was used for gas liquid chromatography (GLC) (30 m × 0.3 mm i.d., 260°C). Cholesterol acetate was the standard (RRT = 1.00) for the determination of relative retention times (RRT) in both HPLC and GLC. The electron ionization-mass spectrometry (EI-MS) spectra were taken on a Hitachi M-80B double focusing gas chromatography/mass spectrometry (GC/MS) (70 eV) (Hitachi Seisakusho Ltd., Tokyo, Japan). The MS data do not include peaks having *m/z* <200. The ^1H nuclear magnetic resonance (NMR) spectra (400 MHz) were recorded on a JNM GX-400 spectrometer (Japan Electron Optics Laboratory, Co., Tokyo, Japan) or on a Bruker AM400 instrument (Karlsruhe, Germany). The ^{13}C NMR spectra were recorded in $CDCl_3$ with $SiMe_4$ as internal standard; shifts (δ) are given downfield from $SiMe_4$. Acetylations were done in Ac_2O/pyridine at room temperature overnight. The aerial parts (leaves and stems) of *Kalanchoe pinnata* (Lam.)Pers. [*Bryophyllum calycinum* Salisb.; *B. pinnatum* (Lam.) Kurz.] were courteously donated by Mr. Yoshiya Satoh (Green Interia Co., Tokyo, Japan). Acetyl derivatives of 1n (32), and 2a, 2b, 2c, 2e, 2g, 2l, 2p, 3j, 3l, and 3n (19), 2d (26), 2j (33) and 2n (9) (see Table 1 for the systematic names of these sterols) were used as reference compounds. (24*E*)-Stigmasta-5,24(28)-dien-3β-ol (fucosterol, 2k) acetate was a gift from Kimitsu Chemical Industries, Co. (Tokyo, Japan).

Isolation of sterols. Leaves and stems of *K. pinnata* (15.4 kg) were air-dried and powdered (980 g) and then extracted with CH_2Cl_2 in a Soxhlet extractor. The extracted lipid (38.7 g) was saponified (5% KOH in methanol, reflux, 3 hr). The residue was partitioned between water and isopropyl ether giving neutral unsaponifiable lipids (6.9 g) which were fractionated over silica gel (200 g) using (i) hexane (1.0 L), (ii) hexane/ethyl acetate (EtOAc) (9:1, v/v; 3.0 L), (iii) hexane/EtOAc (7:3, v/v; 2.0 L), and EtOAc (1.0 L). Part of the fractions obtained from the hexane/EtOAc (9:1, v/v) eluate afforded the mixture of free sterols (750 mg). The mixture was acetylated, and the resulting acetate mixture (640 mg) was fractionated by argentation TLC. Five bands (referred to as bands 1–5 in order of polarity, beginning with the least polar) were scraped off and extracted. HPLC of the fraction from band 1 (15 mg, R_f 0.77–0.89) afforded 1j-acetate (2mg). The fraction from band 2 (184 mg, R_f 0.69–0.77) yielded 2e-acetate (74 mg) and a mixture of 2a- and 2b-acetates (13 mg) (The ratio of 2a and 2b in the mixture was estimated to be 60:40 by ^1H NMR spectroscopy.). The fraction from band 3 (136

[a]All sterols have a C-3β hydroxyl group. Sterols with a ring system 1 (Δ^0) or 3 (Δ^7) are 5α-sterols.
[b]Retention time relative to cholesterol acetate.
[c]$[M - HOAc]^+$.

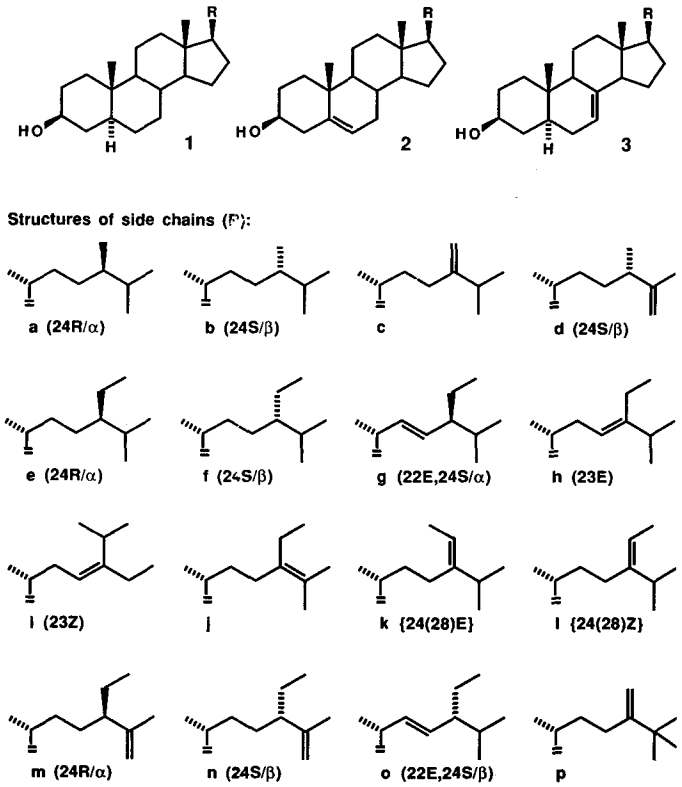

FIG. 1. Structures of sterols.

mg, R_f 0.56-0.69) was hydrolyzed, and the free sterol mixture obtained was separated by preparative TLC into two fractions, 3A and 3B. The faster moving band (fraction 3A, R_f 0.33) consisted mainly of Δ^5-sterols, and fraction 3B from the slower moving band (R_f 0.31) was composed mainly of Δ^7-sterols (18). The two fractions were acetylated and the resulting acetyl derivatives were fractionated by HPLC: fraction 3A-acetate afforded the acetates of **1n** (1 mg), **2g** (1 mg), and **2j** (76 mg); and fraction 3B-acetate gave **3j**-acetate (1 mg). The fraction from band 4 (116 mg, R_f 0.22-0.56) was hydrolyzed, and the resulting free sterol mixture was separated into two subfractions, 4A and 4B, in the same manner as described above, and subsequently acetylated. HPLC fractionation of 4A-acetate gave the acetates of **1p** (2 mg), **2d** (1 mg), **2l** (12 mg), **2m** (3 mg), and **2n** (5 mg), whereas HPLC fractionation of 4B-acetate yielded the acetates of **3l** (2 mg), **3m** (1 mg), and **3n** (1 mg). HPLC of the fraction from band 5 (17 mg, R_f 0.05-0.22) afforded the acetates of **2c** (1 mg) and **2p** (3 mg). Hydrogenation of **2m**- and **2n**-acetates in ethanol over PtO_2 at atmospheric pressure and room temperature overnight followed by HPLC purification gave an almost quantitative yield of sitosterol (**2e**) and clionasterol (**2f**) acetates, respectively.

5α-Stigmast-24-en-3β-ol (1j) acetate. MS, *m/z* (assignment, rel. int.) 456.3970 ($C_{31}H_{52}O_2$, $[M]^+$, 16, calcd. 456.3964), 441.3726 ($C_{30}H_{49}O_2$, 5), 396.3761 ($C_{29}H_{48}$, 8), 381.3568 ($C_{28}H_{45}$, 4), 358.2841 ($C_{24}H_{38}O_2$, 100), 343.2636 ($C_{23}H_{35}O_2$, 16), 315.2350 ($C_{21}H_{31}O_2$, 25), 302.2239 ($C_{20}H_{30}O_2$, 5), 298.2609 ($C_{22}H_{34}$, 4), 283.2403 ($C_{21}H_{31}$, 7), 276.2052 ($C_{18}H_{28}O_2$, 10), 275.1991 ($C_{18}H_{27}O_2$, 13), 255.2145 ($C_{19}H_{27}$, 13), 229.2008 ($C_{17}H_{25}$, 13), 216.1921 ($C_{16}H_{24}$, 15), 215.1801 ($C_{16}H_{23}$, 22), 203.1763 ($C_{15}H_{23}$, 6), 201.1666 ($C_{15}H_{21}$, 7).

25-Methylergost-24(28)-en-3β-ol (1p) acetate. MS, *m/z* (assignment, rel. int.) 456.3933 ($C_{31}H_{52}O_2$, $[M]^+$, 6), 441.3713 ($C_{30}H_{49}O_2$, 6), 381.3519 ($C_{28}H_{45}$, 5), 358.2840 ($C_{24}H_{38}O_2$, 100), 344.2672 ($C_{23}H_{36}O_2$, 8), 343.2670 ($C_{23}H_{35}O_2$, 9), 315.2310 ($C_{21}H_{31}O_2$, 27), 302.2219 ($C_{20}H_{30}O_2$, 5), 298.2662 ($C_{22}H_{34}$, 5), 285.2555 ($C_{21}H_{33}$, 6), 283.2409 ($C_{21}H_{31}$, 7), 275.1991 ($C_{18}H_{27}O_2$, 10), 255.2092 ($C_{19}H_{27}$, 13), 241.1954 ($C_{18}H_{25}$, 3), 229.1988 ($C_{17}H_{25}$, 15), 215.1822 ($C_{16}H_{23}$, 29), 213.1667 ($C_{16}H_{21}$, 10), 203.1776 ($C_{15}H_{23}$, 8), 201.1622 ($C_{15}H_{21}$, 10).

(24R)-Stigmasta-5,25-dienol (2m) acetate. MS, *m/z* (assignment, rel. int.) 394.3547 ($C_{29}H_{46}$, $[M - HOAc]^+$, 100,

calcd. 394.3596), 379.3385 ($C_{28}H_{43}$, 8), 352.3093 ($C_{26}H_{40}$, 1), 310.2676 ($C_{23}H_{34}$, 2), 296.2520 ($C_{22}H_{32}$, 2), 286.2650 ($C_{21}H_{34}$, 3), 281.2282 ($C_{21}H_{29}$, 4), 273.2565 ($C_{20}H_{33}$, 4), 255.2075 ($C_{19}H_{27}$, 7), 253.1912 ($C_{19}H_{25}$, 8), 228.1926 ($C_{17}H_{24}$, 8), 213.1640 ($C_{16}H_{21}$, 9), 211.1478 ($C_{16}H_{19}$, 3).

(24R)-5α-stigmasta-7,25-dien-3β-ol (3m) acetate. MS, *m/z* (assignment, rel. int.) 454.3797 ($C_{31}H_{50}O_2$, $[M]^+$, 34, calcd. 454.3807), 439.3577 ($C_{30}H_{47}O_2$, 22), 394.3611 ($C_{29}H_{46}$, 20), 379.3381 ($C_{28}H_{43}$, 5), 370.2883 ($C_{25}H_{38}O_2$, 2), 356.2662 ($C_{24}H_{36}O_2$, 3), 342.2515 ($C_{23}H_{34}O_2$, 5), 313.2140 ($C_{21}H_{29}O_2$, 100), 300.2120 ($C_{20}H_{28}O_2$, 5), 299.2057 ($C_{20}H_{27}O_2$, 5), 288.2100 ($C_{19}H_{28}O_2$, 9), 273.1873 ($C_{18}H_{25}O_2$, 9), 255.2092 ($C_{19}H_{27}$, 39), 253.1912 ($C_{19}H_{25}$, 9), 227.1819 ($C_{17}H_{23}$, 18), 213.1644 ($C_{16}H_{21}$, 32), 201.1617 ($C_{15}H_{21}$, 8).

Stigmasta-5,24-dienol (2j) acetate. ^1H NMR data. Assignment, δ (multiplicity, *J* in Hz): 3α-H, 4.604 (*m*); CO-CH_3, 2.028 (*s*); 4-H_2, 2.310 and 2.328 (each 1H and *m*); 6-H, 5.374 (*d* like, 5.0); 18-H_3, 0.682 (*s*); 19-H_3, 1.020 (*s*); 21-H_3, 0.970 (*d*, 6.6); 26-H_3 and 27-H_3, 1.627 and 1.631 (each *s*); 29-H_3, 0.932 (*t*, 7.7).

25-Methylergosta-5,24(28)-dien-3β-ol (2p) acetate. ^1H NMR data. Assignment, δ (multiplicity, *J* in Hz): 3α-H, 4.603 (*m*); CO-CH_3, 2.030 (*s*); 4-H_2, 2.309 and 2.328 (each 1H and *m*); 6-H, 5.372 (*d* like, 5.0); 18-H_3, 0.688 (*s*); 19-H_3, 1.021 (*s*); 21-H_3, 0.963 (*d*, 6.6); 26-H_3, 27-H_3, and 29-H_3, 1.057 (*s*); 28-H_2, 4.659 and 4.832 (each 1H and br. *s*).

(24R)-Stigmast-5-enol (2e) acetate prepared from (24R)-stigmasta-5,25-dienol (2m) acetate by hydrogenation. RRT 1.63 (GLC), 1.26 (HPLC). MS, *m/z* 396 $[M - HOAc]^+$. ^1H NMR data. Assignment, δ (multiplicity, *J* in Hz): 3α-H, 4.605 (*m*); CO-CH_3, 2.032 (*s*); 4-H_2, 2.310 and 2.328 (each 1H and *m*); 6-H, 5.375 (*d* like, 5.0); 18-H_3, 0.677 (*s*); 19-H_3, 1.020 (*s*); 21-H_3, 0.922 (*d*, 6.6); 26-H_3, 0.837 (*d*, 7.7); 27-H_3, 0.815 (*d*, 6.6); 29-H_3, 0.847 (*t*, 7.7).

(24S)-Stigmast-5-enol (2f) acetate prepared from (24S)-stigmasta-5,25-dienol (2n) acetate by hydrogenation. RRT 1.63 (GLC), 1.26 HPLC). MS, *m/z* 396 $[M - HOAc]^+$. ^1H NMR data. Assignment, δ (multiplicity, *J* in Hz). 3α-H, 4.604 (*m*); CO-CH_3, 2.031 (*s*); 4-H_2, 2.310 and 2.328 (each 1H and *m*); 6-H, 5.375 (*d* like, 4.7); 18-H_3, 0.678 (*s*); 19-H_3, 1.020 (*s*; 21-H_3, 0.926 (*d*, 6.6); 26-H_3, 0.831 (*d*, 7.1); 27-H_3, 0.812 (*d*, 6.9); 29-H_3, 0.855 (*t*, 6.6).

(24R)-5α-Stigmast-7-en-3β-ol (3e) acetate prepared from (24R)-5α-stigmasta-7,25-dien-3β-ol (3m) acetate by hydrogenation. RRT 1.94 (GLC), RRT 1.26 (HPLC). MS, *m/z* 456 $[M]^+$. ^1H NMR data. Assignment, δ (multiplicity, *J* in Hz): 3α-H, 4.696 (*tt*, 4.4, 11.5); CO-CH_3, 2.026 (*s*); 7-H, 5.147 (*dd* like, 2.7, 5.4); 18-H_3, 0.535 (*s*); 19-H_3, 0.811 (*s*); 21-H_3, 0.926 (*d*, 6.6); 26-H_3, 0.838 (*d*, 7.1); 27-H_3, 0.816 (*d*, 7.1); 29-H_3, 0.847 (*t*, 7.4).

(24S)-5α-Stigmast-7-en-3β-ol (3f) acetate prepared from (24S)-5α-stigmasta-7,25-dien-3β-ol (3n) acetate by hydrogenation. RRT 1.93 (GLC), RRT 1.26 (HPLC). MS, *m/z* 456 $[M]^+$. ^1H NMR data. Assignment, δ (multiplicity, *J* in Hz): 3α-H, 4.694 (*tt*, 4.4, 11.5); CO-CH_3, 2.026 (*s*); 7-H, 5.146 (*dd* like, 2.2, 4.4); 18-H_3, 0.533 (*s*); 19-H_3, 0.809 (*s*); 21-H_3, 0.931 (*d*, 6.6); 26-H_3, 0.832 (*d*, 7.1); 27-H_3, 0.812 (*d*, 6.6); 29-H_3, 0.855 (*t*, 7.4).

Reaction of stigmasta-5,24-dienol (2j) and (24E)-stigmasta-5,24(28)-dienol (2k) acetates with iodine. The isomerization reaction was performed in the same manner as described by Ikekawa *et al.* (34). A solution of 1.0 g fucosterol (**2k**) acetate and 70 mg iodine in 50 mL benzene was refluxed for 15 hr. After washing the solution with 1% $Na_2S_2O_3$ and water, the benzene layer was dried over anhydrous Na_2SO_4. Evaporation of the solvent gave 862 mg of crude product. Argentation TLC followed by HPLC of the product enabled the isolation of the following compounds as the acetyl derivatives (Percentages are abundances in the reaction mixture and not isolated yields.): **2h** [mp 120–121°C; RRT 1.61 (GLC) and 0.96 (HPLC); R_f 0.38; 21.6%], **2i** (mp 106–108°C; RRT 1.65 and 0.98; R_f 0.35; 17.0%), **2j** (mp 139–140°C; RRT 1.95 and 1.01; R_f 0.49; 39.8%), **2k** (mp 115–117°C; RRT 1.73 and 0.98; R_f 0.34; 13.3%), **2l** (mp 135–137°C; RRT 1.81 and 0.99; R_f 0.30, 4.3%), **2m** (mp 132–134°C; RRT 1.63 and 0.93; R_f 0.30; 1.4%), and **2n** (mp 130–131°C; RRT 1.63 and 0.91; R_f0.30; 2.6%). Isomerization products were identified by spectral comparison (MS, ^1H and ^{13}C NMR). See Table 2 for the ^{13}C NMR spectral data. The reaction of 24-ethyldesmosterol (**2j**) acetate with iodine yielded almost the same results as with **2k**-acetate described above (acetates of **2h**, 23.2%; **2i**, 12.1%; **2j**, 43.0%; **2k**, 13.4%; **2l**, 4.2%; **2m**, 1.3%; and **2n**, 2.8%). This work enabled us to isolate the acetates of **2h**, **2i**, **2j**, and **2m** in sufficient amount for ^{13}C NMR studies. They are known compounds but their ^{13}C NMR data had not yet been reported in the literature. Their spectra and those of **2l**- and **2m**-acetates were assigned by comparison with literature data (15,35,36).

RESULTS AND DISCUSSION

The abundances of all identified sterols of *K. pinnata* and the chromatographic data of their acetates are listed in Table 1. ^{13}C and ^1H NMR data of the acetates of the novel sterols **1j**, **1p**, **2m**, and **3m** are included in Tables 2 and 3 respectively. Fourteen of the eighteen compounds in Table 1 are known sterols. They were identified by comparison of their chromatographic (GLC, HPLC) and spectral data (400 MHz ^1H NMR, MS) with literature data (9,10,14–19) and with those of reference compounds.

Structure determination of the new sterols. A sample of crude (24*S*)- stigmasta-5,25-dien-34-ol (**2n**, clerosterol) acetate was obtained by reverse phase HPLC after fractionation of the acetylated *K. pinnata* sterols by argentation TLC, saponification of the acetates, separation of Δ^5- and Δ^7-sterols by silica gel TLC and re-acetylation. Purification of clerosterol (**2n**) acetate and isolation of the minor component of the crude clerosterol acetate sample was accomplished by repetitive HPLC fractionation. The eluate was divided into two subfractions (A and B), fraction A corresponding to the first half of the peak and fraction B corresponding to the second half. The residue of each of the fractions was reinjected, and, again, the peaks were divided into two fractions. This process was repeated several times until clerosterol (**2n**) acetate, which has the shorter retention time, and the acetate of the novel sterol (**2m**) which has the longer retention time, were pure by 400 MHz ^1H NMR.

The mass spectra of the acetates of **2m** and **2n** were indistinguishable and their ^1H NMR spectra very similar. There is only a 2–3 Hz difference in the shift of the 21-H_3 doublet and the 29-H_3 triplet (Table 2). Thus it appeared that **2m** and **2n** were stereoisomers.

The structure of **2n**-acetate, which had tentatively been assigned by comparison with reference compound, was confirmed by catalytic hydrogenation to give clionasterol

TABLE 2

^{12}C NMR Data (100.62 MHz, $CDCl_3$) of the Acetyl Derivatives of Some Side-Chain Unsaturated 24-Ethyl-Δ^5-sterols[a]

[a]Shifts are δ values. Internal standard TMS. Figures in parentheses denote *J* values (Hz) with the exception for the multiplet signals where the figures denote $W_{1/2}$ values (Hz).

[b]Isolated from *Kalanchoe pinnata* in this study.

[c]Semi-synthetic compound

[d]Assignment interchangeable.

(**2f**) acetate (9). Spectral similarities (*vide supra*) indicated that the structure of the minor component of the crude clerosterol (**2n**) acetate sample was (24*R*)-stigmasta-5,25-dien-3β-ol (24-epiclerosterol, **2m**) acetate. The structure of the minor component was confirmed by its catalytic hydrogenation to give sitosterol (**2e**) acetate which was identified on the basis of the ^{1}H NMR spectra. ^{13}C NMR data of **2m**- and **2n**-acetates are included in Table 2.

The repetitive HPLC peak fractionation was also used to obtain crude (24*S*)-5α-stigmasta-7,25-dien-3β-ol (**3n**) acetate, for its purification, and to obtain the minor component of that crude sample in pure form. This minor component was identified as (24*R*)-5α-stigmasta-7,25-dien-3β-ol (**3m**) acetate because of spectral similarities (^{1}H NMR, MS) between **3m**- and **3n**-acetates and because **3m**-acetate, upon catalytic hydrogenation, afforded (24*R*)-5α-stigmast-7-en-3β-ol (**3e**) acetate. The structure of the major component, **3n**-acetate, was confirmed because it yielded (24*S*)-5α-stigmast-7-en-3β-ol (**3f**) acetate upon hydrogenation.

The acetates of the novel sterols **1j** and **1p** had very similar mass spectra. Their molecular weight was 456 (acetate of a monounsaturated C_{29} sterol) and the presence of a diagnostic peak at *m/z* 315 [M − side chain 2H]$^+$ indicated that the sterols possess a saturated skeleton and a monounsaturated C_{10} side chain (37). Comparison of their ^{1}H NMR data (Table 3) with Zürcher values (38) for 5α-cholestan-3β-ol acetate (18-H_3 δ 0.650; 19-H_3 δ0.825) showed that both sterols had a normal (*i.e.*, 5α, 14α) skeleton. The diagnostic peak at *m/z* 358 (100%, [M − end of side chain]$^+$) due to a McLafferty rearrangement supported a structure with either a $\Delta^{24(25)}$ or a $\Delta^{24(28)}$ double bond (37). NMR comparison of **1j**-acetate (Table 3) and the acetate of 24-ethyldesmosterol (**2j**) (see Materials and Methods), the main sterol of *K. pinnata*, left no doubt that **1j** and **2j** had the same side chain. Thus the structure of **1j** is 5α-stigmast-24(25)-en-3β-ol.

The NMR spectrum of **1p**-acetate showed presence of two olefinic protons (δ 4.656, 1H, *s*; δ 4.829, 1H, *s*) and of a deshielded *t*-butyl singlet (δ 1.054), indicative of a *t*-butyl substituent at a double bond. In combination with the other information obtained from its mass and ^{1}H NMR spectra (*vide supra*), **1p** was shown to be 25-methyl-5α-ergost-24(28)-en-3β-ol. The proposed structure of **1p** was confirmed by NMR comparison of **1p**-acetate (Table 3) and **2p**-acetate (see Materials and Methods), a constituent of several higher plants (5,29,30,39).

Partial synthesis of both epimers at C-24 of stigmasta-5,25-dien-3β-ol (2m,n). 24-Ethyldesmosterol (**2j**) is the main sterol of *K. pinnata*. We felt that we had to address the question whether 24-epiclerosterol (**2m**) was indeed a natural product or whether it was an artefact formed during the isolation procedure from the main sterol *via* a carbonium ion intermediate. The iodine-mediated double bond isomerization of **2j**-acetate and fucosterol (**2k**) acetate has been reported to yield an equilibrium mixture of Δ^{23}, Δ^{24}, $\Delta^{24(28)}$ and Δ^{25} isomers (34). However, not all products were properly identified. We repeated this work (see Materials and Methods for details) and confirmed that essentially the same mixture was obtained starting with **2j**-acetate or **2k**-acetate. As expected, both epimers of Δ^{25}-sterols (**2m,n**) could be isolated. Δ^{23}-Sterols (**2h,i**-acetates, together ≈40%) and Δ^{24}-sterol (**2j**, ≈40%) are major components of the reaction mixtures. Thus if double bond isomerization had taken place during the isolation procedure, Δ^{23}-sterols would also have been formed. Careful analysis of the *K. pinnata* sterols did not result in the detection of Δ^{23}-sterols. Thus, no artefacts were formed during the isolation procedure.

^{1}H and ^{13}C NMR spectra of 24-ethyl-Δ^{25}-sterols. The 400 MHz ^{1}H NMR data of the two C-24 epimeric pairs of 24-ethyl-Δ^{25}-sterols (**2m,n** and **3m,n**) show that discrimination between the C-24 epimers is possible on the basis of the shift of the 21-H_3 and 29-H_3 signals (see Table 3). The 24*R*-epimers have their 21-H_3 doublet at lower field (*ca.* 3 Hz, 0.008 ppm) and their 29-H_3 triplet at higher field (2–3 Hz, 0.005–0.007 ppm) than the 24*S*-epimers. Differentiation between the epimers is also possible using the signals of C-17 and of the side-chain carbons (C-20–C-29) in the ^{13}C NMR spectra (see Table 2 for ^{13}C NMR data of **2m,n**-acetates).

Sterol side-chain biosynthesis and configuration at C-24. Some sterols of *K. pinnata* (Table 1) are sterically pure at C-24 (**2d, 2g**) whereas others occur as mixtures of epimers (**2a,b, 2m,n, 3m,n**). We have noticed this before in our detailed work on sterols of the *Cucurbitaceae* (11–19) and *Clerodendrum* species (Verbenaceae) (6–10). Apparently, *K. pinnata* is another example of a plant in which sterol biosynthesis has become complicated: different mechanisms for the formation of the same side chain seem to be operating parallel and at the same time. The Δ^{25}-sterols, **2m,n** and **3m,n**, are epimeric mixtures because different mechanisms do not necessarily result in the formation of the same epimer at C-24.

Other examples of 24-alkyl-Δ^{25}-sterols from higher plants. In cases where the configuration at C-24 has been firmly established, Δ^{25}-unsaturated 24-alkylsterols isolated from seed-bearing plants always were reported to have the 24*S*/β-stereochemistry (4–20,23–29,31). Thus, this study constitutes the first example of the isolation of 24*R*-alkyl-Δ^{25}-sterols, **2m** and **3m**, from the seed-bearing plants, and, also, the first demonstration of the co-occurrence of C-24 epimeric 24-alkyl-Δ^{25}-sterols (**2m/2n** and **3m/3n**) in a non-marine organism. Epimeric mixtures have been found in sponges (40,41). (Sponges do not do *de novo* synthesis of sterols but accumulate dietary sterols. Unless they modify dietary sterols they are thus an unlikely source of sterically pure 24-alkylsterols.) Some ferns (which are vascular plants) have been demonstrated to contain either 24*R*- or 24*S*- epimer of 24-alkyl-Δ^{25}-sterols. Thus, some polypodiaceous ferns contain (24*R*)-24-methyl-25-dehydrolophenol, 24-epicyclolaudenol, (24*R*)-24-ethyl-25-dehydrolophenol, and (24*R*)-cyclomargenol [(24*R*)-24-ethyl-9β,19-cyclo-5α-lanost-25-en-3β-ol] (42,43), whereas a dryopteridaceous fern contains polysthicol [(24*S*)-24-ethyl-9β,19-cyclo-5α-lanost-25-en-3β-ol], the 24*S*-epimer of (24*R*)-cyclomargenol (44).

Other examples of plant sterols alkylated at C-25. Sterol **1p**, a novel sterol, constituted the fourth 25-methylated 24-methylenesterol (with side chain **p**) from a natural source. The previously known sterols possessing a side chain **p** are: **2p** (5,28,29,39) isolated also in this study from *K. pinnata*, 25-methyl-5α-ergosta-7,24(28)-dien-3β-ol (**3p**) (45), and 24-methylene-25-methyllophenol (25-methylgramisterol) (46) isolated from some seed-bearing plants.

These are rare examples of sterols with quaternary carbon in the side chain. Sterols possessing an acyclic, quaternary carbon in the side chain are encountered more frequently in marine sponges (47–49).

ACKNOWLEDGMENTS

We thank Dr. M. Aimi and Miss J. Nasu (Nihon University) for mass and ^{1}H NMR spectra.

Occurrence and Levels of Ecdysteroids in Spinach[1]

Robert J. Grebenok, Perry V. Ripa and John H. Adler*
Department of Biological Sciences and Department of Chemistry, Michigan Technological University, Houghton, Michigan 49931

The dominant ecdysteroid in spinach, *Spinacia oleracea* L., is 20-hydroxyecdysone (2β,3β,14α,20R,22R,25-hexahydroxy-5β-cholest-7-en-6-one) with the presence of a smaller amount of polypodine B (2β,3β,5β,14α,20R,22R,25-heptahydroxycholest-7-en-6-one). Ecdysteroids are present in the seed embryo at 14 μg ecdysteroid/seed, and ecdysteroid levels increase in the plant during growth and development. During the onset of ecdysteroid production, the ratio of ecdysteroid to total sterol shifts from a value of one to about ten over the course of a week. Spinach may serve as a model to study ecdysteroid biosynthesis in plants.
Lipids 26, 666–668 (1991).

Since the first isolation of ecdysteroids from plants (1,2), these steroids were thought to serve as a defense against insects. Susceptibility of insects to these compounds varies depending upon the insect species and the structure of the ecdysteroid (2–4). The most commonly reported plant ecdysteroid, 20-hydroxyecdysone, when present at 50 parts per million (ppm) of an artificial diet, is effective on pink bollworm *(Pectinophora gossypiella)* causing a 95% ecdysis inhibition (3). The 20-hydroxyecdysone causes a 50% feeding inhibition for the aphid *(Schizaphis graminum)* at 650 ppm in the diet , but has no effect on feeding of corn earworm *(Heliothus zea)* at 3000 ppm in the diet (3). Alteration of the phytoecdysteroid structure from 20-hydroxyecdysone to ponasterone A by loss of the C-25 hydroxyl group produces at only 2 ppm a 95% ecdysis inhibition in pink bollworm (3). Polyphagous insects such as locust (2) are reportedly affected by dietary ecdysteroids to various degrees.

Well over one-hundred plant families have been reported to contain ecdysteroids (2,5), yet little is known about the production of phytoecdysteroids in plants. In perennials, phytoecdysteroids cycle within plant organs concurrently with the onset of developmental events, such as new shoot growth (6–10) and flowering (10). In the leaves of the perennial evergreen *Taxus cuspidata,* 20-hydroxyecdysone and ponasterone A levels increase as leaves mature during the first year's growth, and appear to be rapidly transported into newly developing leaves during the next flush of leaf growth (6). However, levels in two-year-old leaves do not decrease below a level that is physiologically effective (40 μg 20-hydroxyecdysone/g fresh weight (fr wt) and 20 μg ponasterone A/g fr wt) in altering insect development (3). In the herbaceous perennial *Rhaponticum carthamoides,* the underground parts cycle ecdysteroids to the newly developing shoots, and in autumn the ecdysteroid level of the underground parts rises (7). Similarly, in *Leuzea carthamoides* the young herbaceous shoots of spring have the highest ecdysteroid levels (8). The biosynthesis of ecdysteroids is difficult to study in perennial plants due in part to the large mass of these compounds that appear to be cycled in the plant. Annual plants, however, initially carry forward only the ecdysteroid present in the seed. In this paper we examine the occurrence, onset of production, and enhanced accumulation of ecdysteroids in the annual spinach. Spinach may serve as a model for studying phytoecdysteroid biosynthesis in seed crop plants.

EXPERIMENTAL

Spinacia oleracea (Spinach) variety Avon (Burpee #5133), used for analysis of ecdysteroid production at various developmental stages, was grown in the laboratory using 8-hr photoperiods. Seeds and leaves were extracted with ethanol for 72 hr. The material was ground, reextracted, evaporated to dryness, resuspended in 70% methanol/water and then partitioned against hexane to remove lipids and 4-desmethylsterols. The methanol/water fraction was evaporated to dryness, resuspended in water, and partitioned against butanol to remove ecdysteroids (6). The butanol fraction was evaporated to dryness, resuspended in methanol, and filtered through a 45-μm membrane. The filtrate was evaporated and analyzed at 254 nm using reverse phase high pressure liquid chromatography (RP-HPLC) on a C18 ODS, Supelco 4.6 mm × 25 cm, 5-μm particle column (Supelco, Bellefonte, PA). Elution was with methanol/water (45:55, v/v) at 1.0 mL/min at 33°C. Quantitation was based on a standard curve for 20-hydroxyecdysone. Fresh commercial spinach (226 g) was extracted as described above, to verify the presence of ecdysteroids by ^{1}H nuclear magnetic resonance spectroscopy (NMR). The butanol fraction after evaporation was resuspended in a minimal amount of methanol/ethyl acetate (1:3, v/v). The resuspended fraction was applied to a 15% deactivated neutral alumina column, and was eluted utilizing 7.5 mL of each of the following: methanol/ethyl acetate (1:3, v/v); methanol/ethyl acetate (1:1, v/v); methanol; and water. 20-Hydroxyecdysone eluted with the 1:1 methanol/ethyl acetate fraction. Polypodine B, when present, eluted with the methanol and water fractions. Thin-layer chromatography (TLC) on 0.3 mm layers of Silica Gel G (Sigma, St. Louis, MO) was utilized to identify the ecdysteroids in various column fractions. The solvent system chloroform/ethyl acetate/ethanol/acetic acid (50:25:20:5, by vol) was used which gave the following R_f values for authentic standards: 20-hydroxyecdysone, 0.20; polypodine B, 0.23; makisterone A, 0.25; and ecdysone, 0.26. Ecdysteroids were made visible on the TLC plates by spraying with a solution of 3% vanillin and 2% H_2SO_4 in ethanol and subsequent heating for 8 min at 110°C (2).

^{1}H NMR spectra were measured at 200 MHz in perdeuteropyridine at 22°C using tetramethylsilane (TMS) as internal standard. The ^{1}H NMR spectrum of 20-hydroxyecdysone isolated from spinach showed the following signals (in ppm from TMS) for protons on the

[1]Based on a paper presented at the symposium on Plant and Fungal Sterols: Biosynthesis, Metabolism and Function, held at the AOCS Annual Meeting, Baltimore, MD, April 1990.

Abbreviations: fr wt, fresh weight; NMR, nuclear magnetic resonance; ppm, parts per million; RP-HPLC, reverse phase high pressure liquid chromatography; TLC, thin-layer chromatography, TMS, tetramethylsilane.

carbons designated: 3H at C-18(s) 1.23, 3H at C-19(s) 1.08, 3H at C-21(s) 1.60, 6H at C-26,27(s,s) 1.37. The ^{1}H NMR spectrum of polypodine B isolated from spinach showed the following chemical shifts: 3H at C-18(s) 1.23, 3H at C-19(s) 1.17, 3H at C-21(s) 1.60, 6H at C-26,27(s,s) 1.37. All ^{1}H NMR values are in agreement with those of authentic standards run under identical conditions and with reported values (2,6,11,12).

The sterols were isolated from the hexane fraction. The hexane fraction was evaporated to dryness and the residue saponified with 5% KOH in ethanol/water (7:3, v/v). The sterols were extracted with diethyl ether, and the diethyl ether was subsequently washed with water to neutrality. The neutral lipids present in the diethyl ether fraction were chromatographed on 10% deactivated alumina by eluting with 7.5 mL of each of the following: hexane; hexane/toluene (1:1, v/v); toluene; diethyl ether; diethyl ether/methanol (1:1, v/v); and methanol (13). The fractions were analyzed by gas-liquid chromatography on 1% XE-60 on Chromosorb Q (100–120 mesh) at 235°C. Desmethylsterols that were separated by silica gel TLC with the solvent system benzene/ethyl acetate (9:1, v/v) were analyzed by analytical RP-HPLC on a Supelco C18 ODS column (25 cm × 4.6 mm) using acetonitrile/isopropyl alcohol (8:2, v/v; 1 mL/min) at 45°C and were detected at 210 nm. The chromatographic characteristics of the three major sterols, spinasterol, 22-dihydrospinasterol and avenasterol were in agreement with reported values (13–15).

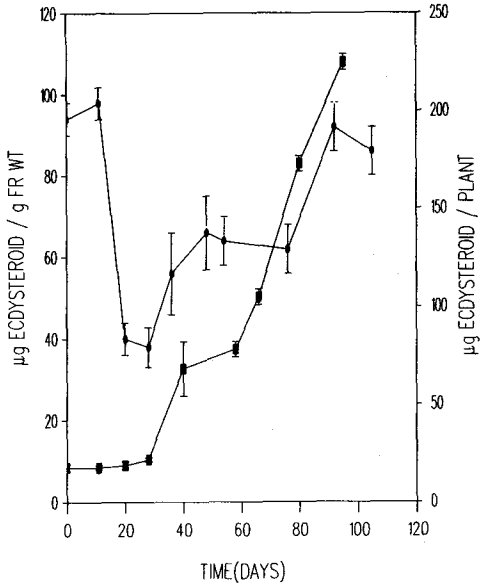

FIG. 1. Time course of ecdysteroid content in spinach plotted on a per plant and fresh weight basis. Plot of μg ecdysteroid per g fresh weight (●) and μg ecdysteroid per plant (■) from three independent analyses of spinach plants planted on different start dates. Data for day zero were from seeds on the day of planting which started the time clock for all analyses. Plants typically emerged from the soil between days 3 and 4. The bars represent the range of values from an average of the 3 data sets.

RESULTS AND DISCUSSION

20-Hydroxyecdysone (2β,3β,14α,20R,22R,25-hexahydroxy-5β-cholest-7-en-6-one) and polypodine B (2β,3β, 5β,14α, 20R,22R,25-heptahydroxycholest-7-en-6-one) from spinach were characterized by chromatography and identified by ^{1}H NMR. The data confirm previous reports on 20-hydroxyecdysone (16,17) in spinach and furthermore demonstrate the occurrence of polypodine B in this plant. Polypodine B and 20-hydroxyecdysone were present at a ratio of approximately 1:4 in mature leaves of commercially grown spinach as well as throughout the developmental stages of spinach examined in this study. The mixture(s) of 20-hydroxyecdysone and polypodine B will be referred to as ecdysteroid(s).

Laboratory-grown spinach from three different plantings was analyzed for ecdysteroid content. The levels of ecdysteroid (μg ecdysteroid/g fr wt) showed reproducible changes during growth (Fig. 1). Seeds contained approximately 90 μg ecdysteroid/g fr wt at day zero, and upon germination the level dropped to 40 μg ecdysteroid/g fr wt by day 20–27. This decrease on a μg ecdysteroid/g fr wt basis is a consequence of the gain in fresh weight as the seedling develops. During further growth, two cyclical increases in ecdysteroid levels occurred between days 27–44 and days 76–90. A relatively constant level of 20-hydroxyecdysone was found in spinach between days 44 and 76 at 65 μg ecdysteroid/g fr wt. Spinach plants at 90 days of age had reached a level of ecdysteroid sufficient to supply their seeds with ecdysteroid levels similar to those found in commercial seeds. Over the 100-day time course of our experiments, the level of ecdysteroid (μg ecdysteroid/g fr wt) maintained in the plants was sufficient to effectively control certain herbivorous insects (3). Although ecdysteroid levels (μg ecdysteroid/g fr wt) underwent cyclic changes in the course of plant growth, the amount of ecdysteroid on a per-plant basis (μg ecdysteroid/plant) showed a steady increase from day 24 onward (Fig. 1). This increase in ecdysteroid content per plant coincided with the increase observed on a μg ecdysteroid/g fr wt basis which may suggest the onset of ecdysteroid biosynthesis.

TABLE 1

Spinach Ecdysteroid and Sterol Content

Time (days)[a]	Plant mass (g fr wt)	Ecdysteroid (μg/g fr wt)	Sterol (μg/g fr wt)	Ratio ecdysteroid/ sterol
21	3.4	168	119	1.4
33	3.1	157	120	1.3
36	8.5	56	61	0.9
37	8.0	136	40	3.4
40	13	790	74	10.7
50	21	330	40	8.2

[a]All experiments were from the same day planting of *Spinacia oleracea* variety Avon, except that data for day 21 were from an independent planting.

Sterols have been shown to be the biosynthetic precursors of ecdysteroids in insects (18) and are presumed to serve a similar function in plants (19). Analyses of ecdysteroids and sterols from a single experiment are presented in Table 1. The predominant sterols were spinasterol (24α-ethylcholesta-7,22E-dien-3β-ol), 22-dihydrospinasterol (24α-ethylcholest-7-en-3β-ol) and avenasterol (24-ethylcholesta-7,24(28)Z-dien-3β-ol) which were present at 71%, 10% and 13% of total sterol content, respectively.

In Table 1, the levels of ecdysteroid and sterol are reported for the time period of the first cyclic increase in ecdysteroid content shown in Figure 1, *i.e.* for days 27–44. Throughout the time course, plant mass increased. Early in spinach development, the sterol levels at days 21 and 33 were elevated on a μg sterol/g fr wt of plant basis as compared to those at day 36 and onward. After day 36, an increase in μg ecdysteroid/g fr wt was observed. This increase in ecdysteroid levels in the plant coincides with the observed decreased sterol levels on g fr wt basis. The ecdysteroid-to-sterol ratio is maintained at approximately 1 from days 21 through 36, but dramatically increased from day 37 to 50 (Table 1). The timing of the shifts in sterol and ecdysteroid levels (Table 1) suggests a coordinated control of ecdysteroid and sterol biosynthesis and supports the presumption that plant ecdysteroids are derived from sterols. Interestingly, the levels of ecdysteroids and sterols in spinach were approximately equal (days 21–36) or the ecdysteroids were present in greater amounts than the sterols (days 37–50) during the early phase of plant growth (Table 1). Ecdysteroid-to-sterol ratios were substantially greater in this plant than those reported for insects. In insects the ecdysteroids are used hormonally and are present at a lower level than the sterols (18,19).

Spinach may be an ideal model system for the study of ecdysteroid biosynthesis in plants. The system has many advantages: the rather clear onset of phytoecdysteroid biosynthesis (Table 1); the relative lack of high background levels of ecdysteroids often present in perennial plants (6–8); the apparent regulation of ecdysteroid levels within physiologically effective dose ranges that deter some insect species (3,20); and the absence of interfering compounds in the chromatographic analysis of spinach ecdysteroids. Use of natural insect growth regulators instead of poisons is likely to take on greater significance in an environmentally aware world.

ACKNOWLEDGMENTS

The authors wish to thank Professor Huw H. Rees, Dr. Denis H. Horn and the U.S.D.A. Insect and Nematode Physiology Laboratory for generously providing authentic ecdysteroid samples.

Fatty Acid Metabolism in *Taphrina deformans* Treated with Sterol Biosynthesis Inhibitors[1]

J.D. Weete*, M. Sancholle[2], K.A. Patterson, K.S. Miller, M.Q. Huang[3], F. Campbell and M. Van den Reek
Department of Botany and Microbiology, Alabama Agricultural Experiment Station, Auburn University, Auburn, Alabama 36849

Changes in the unsaturated fatty acid content of the fungus *Taphrina deformans* as a function of growth, temperature, and sterol content were investigated. It was found that the highest growth rate was accompanied by a relatively high degree of fatty acid unsaturation (18:1 < 18:2 + 18:3) and low sterol (brassicasterol) content. Also, a substantial shift in the degree of unsaturation from mainly 18:2 + 18:3 to 18:1 occurred in the later stages (mid-linear) of culture development. Cells readily adapted from 18°C to 13°C, and exhibited a higher growth rate at the lower temperature after a period of acclimation. Growth was readily inhibited by the sterol biosynthesis inhibitors propiconazole and naftifine, which blocked brassicasterol biosynthesis at C-14 demethylation and squalene epoxidation, respectively. Growth was also inhibited by tunicamycin which did so without affecting sterol content. The shift in degree of fatty acid unsaturation did not occur in cells from cultures at reduced temperature or treated with any of the inhibitors. Since tunicamycin did not affect the sterol content, delay in the shift in the degree of fatty acid unsaturation was attributed to factors other than a reduction in sterol content.
***Lipids* 26, 669–674 (1991).**

There is a relatively large number of chemically diverse substances known collectively as sterol biosynthesis inhibitors (SBIs) that block the formation of ergosterol, or a functionally equivalent sterol, in fungi. For example, certain azoles (*e.g.* triazoles and imidazoles) prevent the conversion of lanosterol to ergosterol by inhibiting C-14 demethylation (1). Since sterols such as ergosterol are required for growth, many SBIs exhibit potent antifungal activity. We have worked with several triazoles and fungal species in this laboratory, but mainly with the propiconazole and *Taphrina deformans*, respectively. *T. deformans* proliferates by budding (as a yeast) in laboratory culture, produces C_{18} polyenoic fatty acids, and produces brassicasterol rather than ergosterol as the major sterol. Growth of this fungus is suppressed about 50% by 0.073 μg/mL propiconazole, and the sterol composition of the treated cells changes from approximately 95% brassicasterol to mainly C-14 methyl sterols such as 24-methylene-24,25-dihydrolanosterol, obtusifoliol and 14-methyl fecosterol (2,3).

This laboratory and others have reported that treatment of many fungi with certain azoles also results in altered fatty acid metabolism. This is characterized by increased free fatty acid content and changes in the relative proportions of fatty acids, *e.g.*, increased saturated fatty acids, particularly in the free fatty acid fraction at relatively high inhibitor concentrations, and an increase in the degree of fatty acid unsaturation mainly in the polar lipid fraction (1,4). We and others have interpreted these changes as adaptive or compensatory responses to inhibitor-induced alterations in sterol-related membrane fluidity, principally the reduction of ergosterol and/or increase in C-14 methyl sterols (ref. 1, and refs. cited therein). We began to question this interpretation of fungal responses to SBIs when the sterols and fatty acids in the fungus *Mucor rouxii* treated with these inhibitors were examined (5). About 80 μg/mL of propiconazole are required for 50% growth inhibition of *Mucor* compared to 0.05 to 2 μg/mL for most other fungi. Tolerance to the inhibitor was not due to inability of the inhibitors to suppress ergosterol biosynthesis because only about 2 μg/mL were required to substantially reduce ergosterol content and increase C-14 methyl sterols (5). Furthermore, the fatty acid responses observed in other fungi as described above did not accompany the change in sterol content.

In this study, we have investigated the changes in fatty acid composition in *T. deformans* as a function of culture age, temperature and inhibitor-treatment, including a non-sterol biosynthesis inhibitor to separate growth effects from sterol effects on fatty acid unsaturation. The results suggest that the inhibitor-induced changes in sterol content may not be directly responsible for the alterations in fatty acid composition observed in fungi treated with SBIs, at least not in *T. deformans*, and that the differences between control and treated cultures may be linked more closely to growth related factors than sterol content.

MATERIALS AND METHODS

Naftifine and propiconazole (Fig. 1) were gifts from Sandoz Forschungsinstitut (Vienna, Austria) and the Ciba Geigy Corporation (Greensboro, NC), respectively. Tunicamycin was purchased from Cal Biochem. (La Jolla, CA).

Fungal culture. Taphrina deformans (D1) was obtained as described previously (6) and cultured at 18°C or 13°C in 1% yeast extract/2% dextrose (YD) medium amended with inhibitors at concentrations given in the tables and figures. All cells used for inoculation, regardless of whether they were to be incubated at 18°C or 13°C, were cultivated 36 to 48 hr at 18°C. Except where growth was measured over time, cells were cultured for 48, 60 or 72 hr in 125-mL Erlenmeyer flasks containing 40 mL medium on a rotary incubator-shaker (150 or 176 cycles/min). In time-course experiments, cells were incubated with or without 0.073 μg/mL propiconazole for 72 hr in 2-L Erlenmeyer flasks containing 700 mL medium, and a

portion of the cells was removed periodically for analysis. Cells were collected by centrifugation (1000 × *g*), washed with distilled water, and placed directly into the solvent for lipid extraction or stored at −15°C prior to analysis. Two or 5-mL portions of each culture were also taken at intervals (see tables and figures) and/or at the end of the incubation time for cell dry weight determination.

The values reported here are the average of 2 to 3 replicates with 10% or less variation. The experiments, except for the one involving tunicamycin which was performed once, have been conducted at least twice with essentially the same results each time.

Lipid extraction and hydrolysis. Lipid was extracted from the cells by the procedure of Bligh and Dyer (7). A portion of the total lipid or polar lipid (see below) was heated at 90°C for 120 min in 4.0 mL of 95% ethanol containing 0.4 mL 33% KOH (8). Sterols were obtained by washing the hydrolysate three times with hexane (nonsaponifiable fraction), and fatty acids were obtained in diethyl ether after adjusting the pH of the hydrolysate to approximately 2.

Thin-layer chromatography (TLC). Polar lipids, comprised mainly of phospholipids (2,3), were separated from neutral lipids by TLC on glass plates (20 cm × 20 cm) coated with a 250 μm layer of silica gel 60 (Merck, Darmstadt, Germany) developed twice in hexane/diethyl ether/acetic acid (79:20:4, v/v/v). Silica gel at the origin, which contained the polar lipids, was scraped from the TLC plates and washed with chloroform/methanol (1:1, v/v) containing 0.5% water to recover the polar lipids.

Gas-liquid chromatography (GLC). Sterols were analyzed either as the free alcohol or acetates as described previously (2), except that a 25-m fused silica capillary column coated with SE-54 (Applied Science Laboratories, State College, PA) was used. Acetates were prepared by heating the sterols in pyridine/acetic anhydride (1:1, v/v) at 60°C for 15 min. Steryl acetates were recovered in hexane. In experiments with naftifine, the inhibitor and squalene were both present in the nonsaponifiable fraction and analyzed with the sterols. Sterols were quantified using the internal standard method with either cholesterol or 5-dihydrocholesterol, or their respective acetates, as standards. The identification of brassicasterol has been confirmed by GLC/mass spectrometry (MS) and nuclear magnetic resonance (NMR) (2,9) and 24-methylene-24,25-dihydrolanosterol has been identified by GLC/MS (2). Squalene was detected in the nonsaponifiable fraction of cells treated with naftifine, and was tentatively identified by comparison of its GLC retention time with that of an authentic standard purchased from Sigma Chemical Co. (St. Louis, MO).

Fatty acid methyl esters (FAME) were prepared from the polar lipid fraction by transesterification using 0.3% sodium methoxide in methanol (Applied Science Laboratories), or from the fatty acids obtained from the hydrolysate by heating in 5% conc. HCl in methanol for 60 min at 80°C. FAME were analyzed by GLC as described by Weete *et al.* (2).

Miscellaneous. Lipid phosphorus was measured by the method of Bartlett (10).

RESULTS

Propiconazole. The growth of *T. deformans* was progressively reduced from 7% to 37% by 0.0125 to 0.05 μg/mL propiconazole (Table 1). The reduction of brassicasterol did not follow a similar linear decline as a function of increased inhibitor concentration. Instead, there was a sharp reduction (58%) of this sterol at 0.025 μg/mL propiconazole and no further reduction at higher inhibitor concentrations (Table 1). C-14 demethylation was reduced at the lowest inhibitor concentration, and inhibition of this reaction increased progressively as a function of propiconazole concentration based on changes in 24-methylene-24,25-dihydrolanosterol from 0.3 μg/mg at 0.0125 μg/mL to 0.9 μg/mg at 0.05 μg/mL.

The principal changes in polar lipid fatty acid content in propiconazole-treated cells involved the C_{18} unsaturated fatty acids. There was progressively less 18:1 and more 18:2 and 18:3 with increasing inhibitor concentration (Table 2). For example, there was 16%, 66%, and 81% less 18:1 at inhibitor concentrations of 0.0125, 0.025 and 0.05 μg/mL, and 5.4%, 59% and 87% more 18:2 + 18:3, respectively. There was little change in the relative proportions or absolute amounts of the principal saturated fatty acids, 16:0 and 18:0. However, at higher inhibitor concentrations (0.035 to 0.05 μg/mL), there was a progressive increase in the amounts of these saturated fatty acids in the polar lipid fraction relative to cell dry weight but their relative proportions remained essentially constant (data not given).

Naftifine. The growth of *T. deformans* was progressively reduced 6% to 37% by 0.75 to 3.0 μg/mL naftifine (Fig. 2), and 10 μg/mL were required for 90% inhibition. When expressed on the basis of lipid phosphorus rather than cell dry weight, brassicasterol was only slightly reduced at 0.75 μg/mL naftifine, but it was progressively reduced by 1.5 and 3.0 μg/mL, respectively. As expected, considering the mode of action of this compound as a squalene epoxidase inhibitor (11), squalene accumulated in the cells from 0.11 to 0.35 μg/mg dry weight with increasing inhibitor concentration (data not given).

As with propiconazole, the major changes in polar lipid fatty acid composition in naftifine-treated cells involved the C_{18} unsaturated fatty acids (Fig. 2). As inhibitor concentrations increased, the polar lipid fraction contained

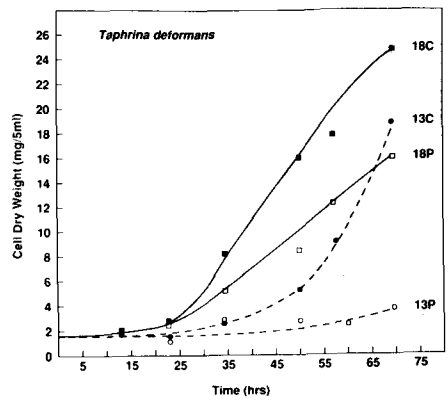

FIG. 3. Effects of propiconazole (P) on the growth of *Taphrina deformans* cultured at 13°C and 18°C (C, Control).

less 18:1 and more 18:2 + 18:3. The saturated fatty acid content remained essentially the same over the range of inhibitor concentrations used.

Effects of propiconazole and temperature on growth. There was a relatively short period of logarithmic growth in the control and inhibitor-treated cultures incubated at 18°C, and an extended linear growth phase. In this experiment, 0.073 μg/mL propiconazole resulted in about 40% growth inhibition after 60-hr incubation when the inhibitor was added at inoculation (Fig. 3). The initiation of growth was delayed slightly by the inhibitor, but the growth rate was reduced by about 30%. By contrast, control cultures incubated at 13°C had an extended log phase that spanned the incubation time (72 hr) of the experiment (Fig. 3). The growth of these cells was delayed approximately 12 hr past the time rapid cell proliferation had begun in control cultures at 18°C. Very little growth was observed in cultures containing propiconazole at 0.073 μg/mL and at 13°C.

Effects of propiconazole and temperature on fatty acid unsaturation. There was very little growth in the cultures at 18°C during the first 23.5 hr of incubation. In the

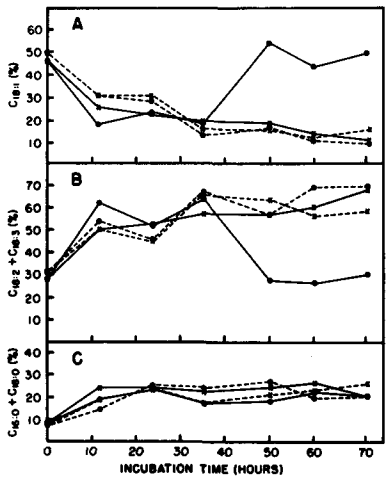

FIG. 4. Effects of propiconazole and temperature on changes in polar lipid unsaturated fatty acids as a function of time. Fatty acid content is expressed as a percentage of polar lipid fatty acids. 18°C: Control ●—●; Propiconazole-treated (0.073 mg/mL) □—□. 13°C: Control ●– – –●; Propiconazole-treated (0.073 mg/mL) □– – –□.

control culture at 13°C, growth was delayed 35 hr, and very little growth occurred in the inhibitor-treated culture at this temperature (Fig. 3). However, changes in the polar lipid fatty acid composition were detected during that time as reflected in changes in the degree of fatty acid unsaturation (Δ/mol). Cells comprising the inoculum culture contained relatively high amounts of 18:1 (45 to 50%) and low amounts of 18:2 + 18:3 (28 to 30%) (Fig. 4). There was a reciprocal shift in these fatty acids during the first 11.5 hr of incubation in all cultures resulting in an increase in the degree of unsaturation. The relatively high Δ/mol persisted during the first 35-hr incubation (Fig. 4). The degree of fatty acid unsaturation in control cells cultured at 18°C and 13°C was reduced 10% and 13%, respectively, between 11.5- and 23.5-hr incubation (Table 3). There was no difference in the Δ/mol in control and treated cells cultured at either temperature for 23.5 hr, but the degree of unsaturation of cells cultured at 13°C was only 8% lower than that of cells incubated at 18°C.

There was a second shift in the fatty acid composition of the control cells cultured at 18°C that involved an increase in the relative amount of 18:1 from 18.4% at 35 hr to 54.2% at 50 hr, and a corresponding decrease in 18:2 + 18:3 (Fig. 4), all of which occurred during the linear growth phase (Fig. 3). This shift in fatty acid composition did not occur in cells treated with propiconazole or cultured at 13°C (Fig. 4). After 35-hr incubation, the degree of fatty acid unsaturation was relatively high and similar in the inhibitor and cold temperature-treated cultures (Table 3). The Δ/mol in propiconazole-treated cells cultured at 18°C increased slowly from 1.31 to 1.60 over the 72-hr incubation period. There was little growth in inhibitor-treated cells at 13°C (Fig. 3).

When the degree of fatty acid unsaturation in cells cultured at 18°C with or without propiconazole is considered as a function of biomass accumulation rather than incubation time, it was found that attaining equal amounts of cells on a weight basis in the two treatments did not result in the same degree of fatty acid unsaturation. For example, control flasks contained 17 mg/mL dry

TABLE 3

Effects of Propiconazole and Temperature on the Degree of Unsaturation of Polar Lipid in *Taphrina deformans* as a Function of Culture Age[a]

Culture age (hr)	Δ/mol[a,b,c]

weight of cells having fatty acids with a Δ/mol of 1.13, *i.e.* after the shift from relatively high 18:2 + 18:3 to 18:1 (Table 4). When the inhibitor-treated cells reached the same biomass, which required an additional 22 hr, the Δ/mol was relatively high at 1.60.

Effects of tunicamycin on growth, sterol content and the relative proportion of total fatty acids. The growth of cells cultured in medium containing 0.02 μg/mL tunicamycin was inhibited 45% compared to controls, and there was no difference in the brassicasterol content of cells from either treatment at 1.1 μg/mg cell dry weight. As before, fatty acids from cells cultured for more than 50 hr at 18°C had a relatively low degree of unsaturation, *i.e.* Δ/mol of 1.27 with a high 18:1 content relative to 18:2 + 18:3 (Table 5). By contrast, cells from cultures

TABLE 5

Effects of Tunicamycin on the Total Fatty Acid Composition of *Taphrina deformans*[a]

Fatty acid	Control	Tunicamycin-treated
16:0	10.9	13.9
18:0	6.8	6.4
18:1	43.2	25.5
18:2	32.9	40.2
18:3	6.1	14.1
Δ/mol	1.27	1.48

[a]The cells were cultured as described in the Materials and Methods section, except that tunicamycin at 0.02 μg/mL was added to the cultures, and cells were harvested for analysis after 72-hr incubation.

containing tunicamycin did not exhibit the shift in fatty acid composition and their lipid had a relatively high degree of fatty acid unsaturation of 1.48 (Table 5).

DISCUSSION

As expected from previous studies, propiconazole is a potent inhibitor of growth (6) and lanosterol C-14 demethylation in *T. deformans* (2). At the relatively low levels of inhibitor used in this study, 24-methylene-24,25-dihydrolanosterol accumulation in the cells, rather than the depletion of brassicasterol, appeared to be a better reflection of dose-related inhibition of C-14 demethylation inhibition, and an indirect manifestation of the suppression of brassicasterol biosynthesis. This might be explained by the relatively slow turnover of brassicasterol in this fungus (Weete, J.D., unpublished data), and formation of small amounts of the sterol at the low inhibitor doses used.

Naftifine was also an effective inhibitor of *T. deformans* growth, showing approximately 10 times more activity against this fungus than several human pathogenic fungi previously tested (11), but over 40 times less potent than propiconazole. Also, the reduction in brassicasterol content of *T. deformans* confirmed naftifine as an inhibitor of sterol biosynthesis, and the accumulation of squalene indicated that squalene epoxidation is the metabolic step blocked by naftifine as observed in other fungi (11). The total amount of squalene, and C-14 methyl sterols in propiconazole-treated cells (see above), that accumulated with naftifine-treatment was greater than the amount of total sterols present in untreated cells. This has been observed in fungi treated with other SBIs (1). The increase in carbon partitioned into the isoprenoid pathway was possibly due to a reduction in feedback regulation of sterol biosynthesis that resulted from the decrease in brassicasterol synthesis.

Tunicamycin is a potent inhibitor of *T. deformans* growth with 0.02 μg/mL as the ED_{45} concentration, compared to 30 to 50 μg/mL as the minimal inhibitory concentration for several yeasts and 1 μg/mL for *Piricularia oxyzae* (12).

Under the batch culture conditions typically employed for *T. deformans,* there are two reciprocal changes in the polar lipid fatty acid fraction that involve the C_{18} unsaturated fatty acids. The first favors a greater degree of unsaturation (18:1 → 18:2 + 18:3) and occurs during logarithmic growth, and the second favors less unsaturation (18:2 + 18:3 → 18:1) and begins during mid-linear growth. Treatment of the cells with sterol biosynthesis inhibitors prevented the shift to less unsaturation. The difference in fatty acid composition between the control and inhibitor-treated cells did not appear to be due simply to differences in the stage of cell growth resulting from growth suppression. However, maintenance of the relatively high degree of unsaturation is not sufficient to overcome growth suppression, and does not appear to be a factor in the growth inhibitory action of propiconazole or probably other sterol biosynthesis inhibitors. Further evidence that fatty acid composition *per se* is not involved in growth suppression by propiconazole is that neither exogenous C_{18} unsaturated fatty acids nor palmitic acid will overcome the growth inhibitory effects of propiconazole in *T. deformans* (13). It is also unlikely that suppression of the shift to less unsaturation is the result of a direct action of the inhibitor since the two chemically distinct inhibitors (triazole *vs* allylamine) used in this study would not be expected to elicit the same response.

T. deformans readily adapts from 18°C to 13°C, and even to 8°C (data not shown), incubation temperature. In fact, after a 12-hr acclimation period, the cells have a higher growth rate at the reduced temperatures. Polar lipid from cells cultured at 13°C had a higher degree of fatty acid unsaturation than that from cells grown at 18°C after 50-hr incubation. These cells exhibit the first shift to higher relative amounts of 18:2 + 18:3 as in cells at 18°C, but rather than undergoing the shift to favor increased levels of 18:1, they maintain the high degree of unsaturation throughout the 72-hr incubation period. Ferrante *et al.* (14) have reported similar results for *Candida lipolytica, i.e.* sequential reciprocal changes in 18:1 and 18:2, first in favor of 18:2 and then 18:1, and prevention of the latter shift to maintain a relatively high degree of fatty acid unsaturation throughout the incubation period at relatively low cultivation temperatures. They also demonstrated that the high 18:2 levels were correlated with an increased maximal specific activity of 18:1-CoA desaturase.

It is well-known that relatively high levels of lipid unsaturation are associated with acclimation to cold temperature in poikilothermic organisms (15). While indeed this was true in *T. deformans,* timing of the increase in unsaturation did not correlate with the onset of growth by cells at 13°C. For example, the 18:1 → 18:2 + 18:3 shift began during the first 11.5-hr incubation, but measurable growth occurred only after about 23.5-hr incubation. Perhaps this might be explained by the fact that a certain degree of lipid unsaturation necessary for growth was not achieved until 23 hr, but it also suggests that there may be adaptive changes other than fatty acid unsaturation in the acclimation process that are required for growth of *T. deformans* at the reduced temperature.

The early proposal that alterations in fatty acid composition in fungi treated with azoles are due to changes in sterol content of the membranes was based on the following: i) One of the mechanisms of modulating membrane fluidity by poikilothermic microorganisms in response to environmental signals is by changing the acyl chain lengths and the degree of fatty acid saturation/unsaturation in membrane lipid (15), and ii) the specific sterol available to sterol-auxotrophic yeast cells influences

the fatty acids that best support growth (16). In addition, by analogy with acclimation to cold temperature, where a relatively high degree of fatty acid unsaturation is associated with reduced cultivation temperature, reduction in sterol content may alter fluidity such that a compensatory response manifested by increased fatty acid unsaturation results. However, the results of this study suggest that the high degree of fatty acid unsaturation in *Taphrina* cells treated with SBIs may be coincident with, but not the direct result of, reduced brassicasterol and/or elevated C-14 methyl sterols. Maintenance of the relatively high degree of fatty acid unsaturation could result from growth suppression *per se* rather than a decrease in sterols, as was suggested by incubating the cells with tunicamycin, an inhibitor of glycoprotein biosynthesis (12). In this case, growth was inhibited 45% with no effect on sterol content, but the 18:2 + 18:3 content remained relatively high in the inhibitor-treated cells compared to the corresponding controls. Further evidence that the sterol content of membranes and desaturase activity are not directly related is that Mucorales fungi such as *Mucor rouxii* and *Rhizopus stolonifer,* which are relatively tolerant to the triazoles with respect to growth, show inhibition of C-14 demethylation without a change in the degree of fatty acid unsaturation (5). The endoplasmic reticulum (ER) is believed to be the site of both the Δ^{12} and Δ^{15} fatty acid desaturases and enzymes in the latter stages of sterol biosynthesis, and has a relatively low sterol content. If indeed activities of the desaturases are responsive to changes in membrane fluidity, the apparent unresponsiveness to reduction in sterol content might be explained on the basis of the low levels that may occur in specific domains spatially separated from the desaturase or, perhaps more likely, the ER is geared for high sterol turnover and the sterols are rapidly removed through rapid membrane differentiation or transport. Therefore, sterols may not play an important role in fluidity modulation of the ER and hence fatty acid unsaturation as it may be influenced by membrane fluidity.

ACKNOWLEDGMENTS

This work was supported in part by AAES projects Ala 5-877 and 773, and the Ciba Geigy Corporation in Greensboro, NC. We express our gratitude to Ciba Geigy and Sandoz Forschungsinstitut for the gifts of propiconazole and naftifine, respectively. Alabama Agricultural Experiment Station Publication No. 6-871260.

A Facile Chemical Synthesis of Cholest-4-en-3-one. Carbon-13 Nuclear Magnetic Resonance Spectral Properties of Cholest-4-en-3-one and Cholest-5-en-3-one[1]

Edward J. Parish,* Hiroshi Honda, Sarawanee Chitrakorn and Peter Livant
Department of Chemistry, Auburn University, Auburn, Alabama 36849

This paper presents a simplified method for the chemical synthesis of cholest-4-en-3-one, which is a naturally occurring steroid and a salient intermediate in steroid chemistry. Pyridinium chlorochromate (PCC) in refluxing benzene has been found to be an effective and convenient reagent for the oxidation and concomitant isomerization of cholest-5-en-3β-ol (cholesterol) to cholest-4-en-3-one in high yield. Also described are the carbon-13 nuclear magnetic resonance spectral properties of cholest-4-en-3-one and of the isolated reaction intermediate cholest-5-en-3-one.
Lipids 26, 675–677 (1991).

The cholesterol derivative cholest-4-en-3-one (1) is a naturally occurring substance found in both plant and animal tissues. Its presence may result from biosynthesis or be due to autoxidation of cholesterol (1,2).

In steroid chemistry, 1 is a key intermediate in the modification of the A-ring (including alkylations at C-4) and in further chemical transformations of the steroid nucleus (2–10). Moreover, the conversion of cholest-5-en-3-β-ol (cholesterol) to 1 is an important reaction of basic steroid chemistry and in the synthesis of many cholesterol derivatives (9–12; and references herein).

As a result of our continuing interest in selective steroid oxidation reactions, we have developed a simplified method for the chemical synthesis of 1 from commercially available cholesterol. The one-step synthesis reported herein is applicable to both small- and large-scale preparations and represents an improvement in methodology over previously reported procedures.

Also described are complete carbon-13 nuclear magnetic resonance (^{13}C NMR) spectral assignments for 1 its reaction intermediate 2.

EXPERIMENTAL

General methods. Procedures for recording of melting points (m.p.) and of infrared (IR), ^1H NMR ^{13}C NMR, mass (MS), and ultraviolet (UV) spectra were those used previously (13,14). Similarly, details concerning the use of gas-liquid (GLC), thin-layer (TLC), and column chromatography have been described (13,14). Solvent systems for TLC analysis were: SS-1, 2% ethyl acetate in toluene; SS-2, 10% diethyl ether in toluene; SS-3, 10% diethyl ether in hexane (by volumes). Details concerning distortionless enhancement polarization transfer (DEPT) experiments and carbon-hydrogen (C-H) correlation have been presented (13). Commercial cholesterol (Sigma Chemical Co., St. Louis, MO) was purified by multiple recrystallization from acetone water. Samples of authentic 1 and 2 were prepared by the method of Fieser (15,16). Pyridinium chlorochromate (PCC) was obtained from Aldrich Chemical Co. (Milwaukee, WI).

General oxidation procedures. Cholest-5-en-3β-ol-(cholesterol, 3.80 g, 0.01 mol) was dissolved in benzene (100 mL) containing molecular sieves (0.5 g, type 3A). Pyridinium chlorochromate (PCC, 53.90 g, 0.25 mol) was added, and the stirred reaction mixture was gently refluxed under a nitrogen atmosphere for 5 hr. The benzene solution was decanted, and the remaining contents of the reaction flask were washed several times with diethyl ether. The combined extracts were washed with a saturated NaCl solution, dried over anhydrous magnesium sulfate and evaporated to dryness under reduced pressure. TLC analysis (SS-1) indicated the presence of essentially one component of ca. 95% purity. The residue was recrystallized from acetone/water to yield cholest-4-en-3-one (1, 3.42 g, 89%): m.p., 80.5–82°C; lit. (16), 81–82°C; IR λ_{max} was identical with that of an authentic sample (C=O, 1671 cm^{-1}); ^1H NMR 0.71 (*s*, 3H, C-18 CH_3), 1.18 (*s*, 3H, C-19 CH_3), 5.72 (*s*, 1H, C-4 H); ^{13}C NMR: (see Table 1); MS, *m/e* (rel. int.): 384 (M; 67%), 369 (M−CH_3; 7.5%), 242 (22%), 271 (M − side chain; 7.7%), 299 (6.8%), 261 (25%), 229 (39%), 124 (100%). UV λ_{max} (ethanol) 242 nm, ε = 16,500, lit. (14) 242 nm. GLC analysis indicated the presence of a single major component of 98% purity, and TLC analysis in three solvent systems (SS-1, SS-2 and SS-3) confirmed that 1 consisted of a single component. GLC and TLC chromatographic mobilities corresponded to those of the authentic compound.

When the preceding reaction was discontinued after 15 minutes at reflux, TLC analysis (SS-2) showed that the reaction product consisted of ca. 60% cholest-4-en-3-one(1) and ca. 40% cholest-5-en-3-one(2). The residue was then subjected to column chromatography using a solvent gradient of diethyl ether in toluene. The purified products were recrystallized from acetone/water to yield 1 (2.08 g, 54%), described above, and cholest-5-en-3-one (2, 1.38 g, 36%): m.p., 125–127°C; lit. (17), 125–127°C; lit. (15) 117–125°C; lit. (16) 126–127°C; IR λ_{max} was identical with that of an authentic

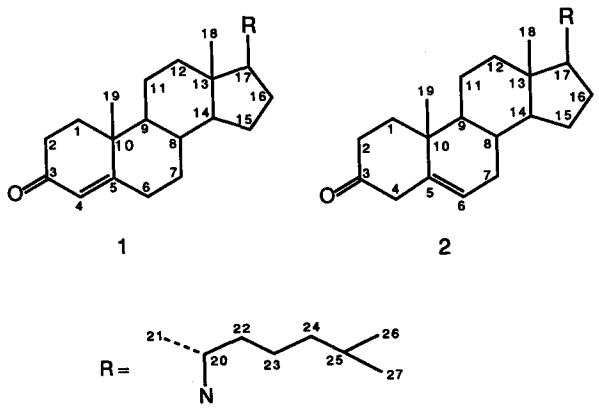
sample (C=O, 1725 cm^{-1}); ^1H NMR 0.73 (*s*, 3H, C-18 CH_3), 1.24 (*s*, 3H, C-19 CH_3), 5.37 (*m*, 1H, C-6 H); ^{13}C NMR: (see Table 1); MS, *m/e* (rel. int.): 384 (M; 100%), 369 (M−CH_3; 28%), 271 (M − side chain; 19%), 229 (55%). TLC analysis in three solvent systems (SS-1, SS-2 and SS-3) indicated the presence of a single component.

RESULTS AND DISCUSSION

The presently prevailing methods for the synthesis of cholest-4-en-3-one(1) include the Oppenauer oxidation of cholest-5-en-3β-ol (cholesterol) (18–20) and the acid-catalyzed isomerization of cholest-5-en-3-one (2) (15,16,19). The Oppenauer oxidation involves the initial formation of the corresponding β,γ-unsaturated ketone 2, *in situ*, which is immediately isomerized (in basic medium) to the α,β-unsaturated ketone 1 (19,20). Cholest-5-en-3-one (2) was originally obtained by a three-step sequence involving protection of the Δ^5 double bond of cholesterol by bromination, followed by chromate oxidation to the 5,6-dibromo-3-ketone, and finally debromination with zinc in acetic acid. The ketone 2 was then isomerized to 1 by oxalic acid in ethanol (15,16). Other methods used to prepare 1 from cholesterol include the use of trifluoromethanesulfonic anhydride/dimethyl sulfoxide, which gave 1 in 51% yield (21), and trifluoroacetic acid/dimethyl sulfoxide, which gave Δ^5-3-one (2) and Δ^4-3-one (1) a 2:1 ratio (22). In addition, the conversion of cholesterol to 1 can be achieved using cholesterol oxidase derived from microbial sources (2,23).



In the present communication, we report that pyridinium chlorochromate (PCC) in refluxing benzene can convert, in one step and in high yield, cholesterol to the corresponding Δ^4-3-ketosteroid 1. The present study (represents an extension of our previous work in which we focused on the selective oxidation of cholesterol to the unconjugated Δ^5-3-ketone 2 (17,24). Using PCC in methylene chloride, we found that the inclusion of powdered $CaCO_3$ in the reaction mixture effectively prevented isomerization of the Δ^5 double bond during reaction and aqueous work-up. Previous workers obtained a mixture of Δ^4- and Δ^5-3-ketones under their reaction conditions (25). In the present case, using PCC in refluxing benzene, the acidic properties of PCC (26) are thought to be responsible for the complete isomerization of the Δ^5 double bond during reaction to give the final Δ^4-3-ketone product. When the reaction time was shortened, isolation of the reaction intermediate 2 was possible.

Commercially available PCC has recently become widely used in organic synthesis for the oxidation of primary and secondary alcohols (27). This reagent, in methylene chloride containing pyridine (28), other aromatic amines (29), pyrazole (30), 3,5-dimethylpyrazole (31), or benzotriazole (32) was reported to effect the selective oxidation of allylic alcohols and to bring about allylic and benzylic oxidations in refluxing methylene chloride (33) and benzene (13,34). Other recent studies have found PCC useful for the oxidation of carbon-boron bonds in organoboranes to produce aldehydes (35) and ketones (36).

Carbon-13 nuclear magnetic resonance (^{13}C NMR) spectroscopy can usually provide more information concerning the structure of steroids than can proton (^1H) NMR, since most carbons produce separately resolved signals that can be assigned to specific carbon atoms (37). As an extension of our synthetic studies, we have completed the ^{13}C NMR assignments for the carbon atoms in cholest-4-en-3-one (a) and cholest-5-en-3-one (2) (Table 1, Scheme 1). The carbon assignments of 1 represent a revised and corrected interpretation of the original reported spectra (38), using improved spectroscopic methods. Supporting data for the assignments of the ^{13}C resonances in these compounds were derived from spectral assignments made previously (13,39).

A DEPT (11) experiment made it possible to distinguish the carbon resonances of secondary carbons (down signals) from those of primary and tertiary carbons (up signals). Once carbon assignments were made, a C-H correlation (13) spectrum facilitated the correct assignment of the proton chemical shifts. Among the more surprising results was the vast separation between the non-equivalent protons on C-12 of cholest-4-en-3-one (2.03 ppm and 1.16 ppm) and of cholest-5-en-3-one (2.05 ppm and 1.21 ppm). The correlation spectroscopy (COSY) spectrum (40,41) of cholest-4-en-3-one revealed a clear cross peak connecting one of the two protons on C-1 (the more upfield peak) with the methyl protons of C-19.

Distinguishing C-9, C-14, and C-17 is problematic since all three signals usually fall in the 50–57 ppm region. In cholest-4-en-3-one, the signals appeared at 53.6, 55.6 and 55.9 ppm, respectively. The 55.9 ppm peak correlated with the proton chemical shift of 1.10

SCHEME 1. Steroid structures of 1 and 2.

ppm, the 55.6 ppm peak with the 1.00 ppm shift, and the 53.6 peak with the 0.91 ppm shift. The 1.10 ppm signal exhibited a clear cross peak in the COSY spectrum with one proton on C-16, thus establishing the 55.9 ppm peak as due to C-17. Similarly, the 0.91 ppm signal showed a cross peak in the COSY spectrum connecting to the proton on C-8 at 1.53 ppm, which established the 53.6 ppm peak as being due to C-9, and, by default, the 55.6 peak as being due to C-14. In cholesterol, C-9, C-17 and C-14 appear at 50.0, 56.1 and 56.6 ppm respectively, which is very close to their positions in cholest-5-en-3-one (49.2, 56.2 and 56.6 ppm). In cholest-4-en-3-one, however, C-9 shifts downfield by 3.6 ppm to 53.6 ppm and C-14 and C-17 reverse order. Accompanying the downfield displacement of C-9 is C-8, which appears 3.5 ppm downfield of the position of C-8 in cholesterol. Other peaks displaced downfield of their positions in cholesterol are C-10 (1.8 ppm displacement) and C-2 (2.1 ppm displacement). An upfield displacement is observed for C-19 (−2.1 ppm displacement).

In summary, we describe a new and facile synthesis of 1 which expands the scope of synthetic transformations known to be accomplished by PCC. Additionally, we have presented the complete ^{13}C NMR assignments for the carbon resonances in 1 and its synthetic intermediate 2.

REVIEW

Lipoprotein(a): Nonhuman Primate Models

Kazuhiko Makino[1] and **Angelo M. Scanu***
Department of Medicine, Biochemistry and Molecular Biology, and Lipoprotein Study Unit, University of Chicago, Chicago, Illinois 60637

Lipoprotein(a) [Lp(a)] is a low density lipoprotein which has apo(a) disulfide-linked to apoB100. Apo(a) has recently been shown to have a striking homology with plasminogen, a knowledge that has stimulated a lot of interest in the mechanism of atherogenicity and thrombogenicity of this lipoprotein particle. Several studies have documented the presence of Lp(a) in nonhuman primates with particular reference to the rhesus monkeys and baboons. The Lp(a) of rhesus monkey is structurally very similar to that of humans, except for the absence of kringle V and the amino acid composition of the catalytic region. The Lp(a) of nonhuman primates, like their human counterparts, exhibit a wide range of interindividual plasma levels and also a wide size polymorphism of apo(a). Nonhuman primates appear to represent a good model for the study of the structure and biology of Lp(a).
Lipids 26, 679-683 (1991).

Lipoprotein(a) [Lp(a)], first described by Berg (1) as a genetic variant of low density lipoprotein (LDL), is considered to be an independent risk factor for atherosclerotic cardiovascular disease, (ACD) (2-5). The distinguishing feature of Lp(a) is to have apoB100 bound to apo(a) by a disulfide linkage (6,7). This protein has recently been shown to have a striking homology with plasminogen (8,9), which is a serine protease zymogen that promotes clot lysis on activation to plasmin. This knowledge has stimulated a lot of interest in the mechanism of atherogenicity and thrombogenicity of this lipoprotein particle.

Lp(a) is heterogeneous in size and density due to differences in protein/lipid mass ratio, apo(a) size polymorphism and apoB100/apo(a) molar ratio (10,11). Apo(a) size isoforms are under the control of a single gene which is localized in the long arm of chromosome 6 in proximity of the plasminogen gene (12,13). Family studies have shown a linkage between apo(a) and plasminogen genes (14).

The studies conducted thus far favor the concept that apo(a) is under a strict genetic regulation, a notion that is in keeping with the insensitivity of plasma Lp(a) to diets and hypolipidemic agents (15). However, data are emerging that post-translational events may be contributing factors in determining the plasma levels of Lp(a) (16). Most of the studies on Lp(a) have been carried out in human subjects. Lp(a) has been reported absent in the plasma of common laboratory animals (*e.g.*, dogs, rats, mice, etc.). On the other hand, several studies have documented the presence of Lp(a) in nonhuman primates. The purpose of this article is to provide an overview on these studies with particular emphasis on the Old World monkeys.

GENERAL OBSERVATIONS

Lp(a) immunoreactive materials were identified by Berg (17) in serum samples from rhesus monkey, baboon, chimpanzee and orangutan. Several reports have also identified Lp(a) in the plasma of patas monkeys (18,19), pig-tailed monkeys (19), mangabey monkeys (20) but not in common marmosets (21) which belong to the New World monkeys.[2]

Makino *et al.* (23) carried out a systematic, genealogical study on some of the immunological characteristics of Lp(a) or Lp(a)-like material in the serum samples of 77 nonhuman primates of 24 species (see Table 1). The immunological cross-reactives of Lp(a) or Lp(a)-like materials were studied by Ouchterlony's double diffusion using a rabbit anti-human Lp(a) serum (Fig. 1). Sera from great apes (orangutan and chimpanzee) exhibited a reaction of complete identity with human sera (Fig. 1D, E). Sera from Old World monkeys (savannah, patas, Assamese, rhesus, Formosan, pig-tailed, crab-eating, Japanese monkeys and hamadryas baboon) generated spurs when tested in adjacent wells against human sera, indicating that Lp(a) species of Old World monkeys are relatively deficient in antigenic determinants as compared with human Lp(a).

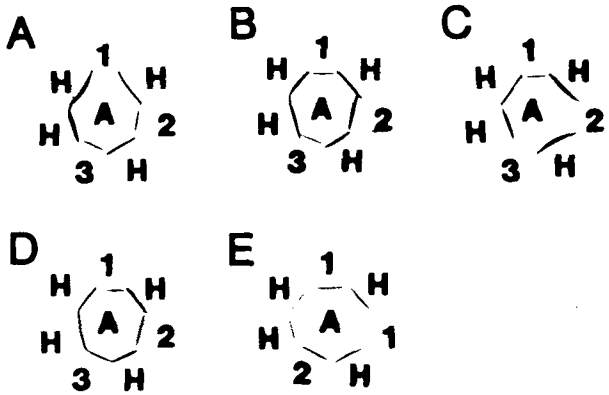

FIG. 1. Ouchterlony's double diffusion tests. The anti-human serum is in the central well (H, human serum). A: 1, Common marmoset; 2, savannah monkey; 3, patas monkey. B: 1, Assamese monkey; 2, Formosan monkey; 3, rhesus monkey. C: 1, pig-tailed monkey; 2, night monkey; 3, gibbon. D: 1, Japanese monkey; 2, crab-eating monkey; 3, chimpanzee. E: 1, Chimpanzee; 2, orangutan.

[2] A very recent study, which appeared after this article had completed the review process, reported the presence of Lp(a) in the plasma of the common marmoset (Callithrix jacchus). A single apo(a) isoform the size of apoB100 was observed and associated with variable plasma Lp(a) levels (22).

TABLE 1

Species and Numbers of Nonhuman Primates Used in the Studies and Lp(a) Detection[a]

Species		No.	Lp(a)
Prosimiae:	Prosimians:		
Lemuridae			
Lemur catta	Ring-tailed lemur	3	ND
Galagidae			
Galago crassicaudatus	Grand galago	3	ND
Lorisidae			
Nycoticebus coucang	Slow loris	1	ND
Simiae:	Simians:		
Platyrrhina	New World monkeys		
Callithricidae			
Callithrix jacchus	Common marmoset	1	ND
Sanguinus oedipus	Cotton-headed tamarin	5	ND
Cebidae			
Aotes trivirgatus	Night monkey	2	ND
Cebus capucinus	White-throated capuchin	2	ND
Cebus apella	Tufted capuchin	3	ND
Ateles geoffroyl	Central American spider monkey	2	ND
Cattarrrhina	Old World monkeys		
Cercopithecidae			
Cercopithecus aethiops	Savannah monkey	3	D
Erythorcebus patas	Patas monkey	3	D
Macaca assamensis	Assamese monkey	4	D
Macaca mulatta	Rhesus monkey	5	D
Macaca cyclopis	Formosan monkey	3	D
Macaca arctoides	Stump-tailed monkey	4	D
Macaca nemestrina	Pig-tailed monkey	4	D
Macaca radiata	Bonnet monkey	3	D
Macaca fascicularis	Crab-eating monkey	5	D
Macaca fuscata	Japanese monkey	4	D
Papio hamadryas	Hamadryas baboon	4	D
Hylobatidae	Lesser apes		
Hylobates lar	White-handed gibbon	2	D
Hylobates agilis	Agile gibbon	1	D
Pongidae	Great apes		
Pongo pygmaeus	Orang-utan	1	D
Pan troglodytes	Chimpanzee	8	D

[a]ND, not detected; D, detected.

On the other hand, Lp(a) was undetectable in sera of Prosimians (ring-tailed lemur, grand galago and slow loris) and New World monkeys (common marmoset, cotton-headed tamarin, night monkey, white-throated capuchin, tufted capuchin and Central American spider monkey) by both the double diffusion method and a sensitive ELISA. It is worth noting that the New World monkeys are believed to have diverged from the Old World monkeys about 40 million years ago, which is the same time frame that has been estimated for a divergence of the apo(a) gene from the plasminogen gene (9).

STUDIES IN THE RHESUS MONKEY

Early studies by Fless *et al.* (24) showed that plasma rhesus monkey Lp(a) is heterogenous in size and density and that such heterogeneity can also occur within individual monkeys. Those studies also showed that the concentration of Lp(a) in plasma is unaffected by diets, although some remodeling of the Lp(a) core components (*i.e.*, cholesteryl esters and triglycerides) can occur (25). From the structural standpoint, rhesus monkey Lp(a), like that of humans, represents an LDL-like particle having as a protein moiety apoB100 covalently linked to apo(a) (26,27). Tomlinson *et al.* (28) cloned and sequenced the 3′ 4.5kb region of the apo(a) cDNA from an individual rhesus monkey and found it to share 93% nucleotide homology and a predicted 90% amino acid identity with its human counterpart. The rhesus sequence was also composed of multiple, tandem repeats encoding plasminogen kringle IV-like sequences, but not a kringle V-like domain (Fig. 2).

Scanu and co-workers (29,30) recently described a rhesus monkey pedigree with members exhibiting a spontaneous hypercholesteremia associated with a low density lipoprotein receptor (LDL-R) deficiency (Fig. 3), assessed by [^{125}I]LDL binding to cultured skin fibroblasts, ligand and immunoblot analyses. By using the polymerase chain reaction in subsequent studies, they showed that the affected monkeys are heterozygous for a nonsense mutation (TGG→TAG) in position 284 of exon 6 of the LDL-R gene, potentially resulting in a truncated 283 (31) (Fig. 4). Using this *Spe I* site as a marker, this mutation was shown to

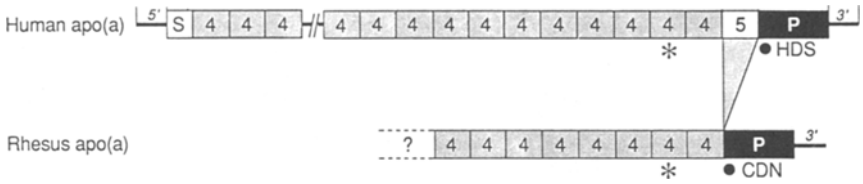

FIG. 2. Comparative representation of the structure of human and rhesus monkey apo(a). The sequence domains indicated are 5′ untranslated, signal peptide(S), plasminogen kringle IV- and V-like sequences of human and rhesus monkey apo(a), protease(P), and 3′ untranslated. Also indicated are the extra cysteine residue in kringle 36 that is a candidate for covalent linkage to apoB100 (*), the substitution of serine for the activation site arginine residue of plasminogen (●), and the catalytic triad of plasminogen (HDS) that is retained in human apo(a) and changed to CDN in rhesus monkey apo(a) (From Lawn, *et al.*; ref. 27).

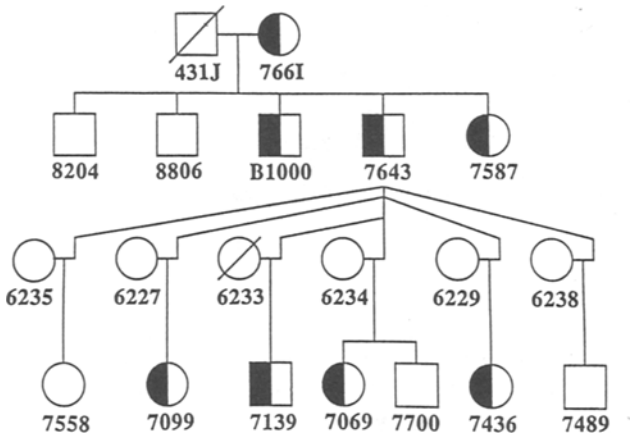

FIG. 3. Pedigree of the rhesus monkey family. Half-filled symbols indicate monkeys heterozygous for the mutation in exon 6 in the LDL-R gene as determined by the presence of an *Spe I* restriction site. Circles, females; squares, males; slashed lines, deceased animals.

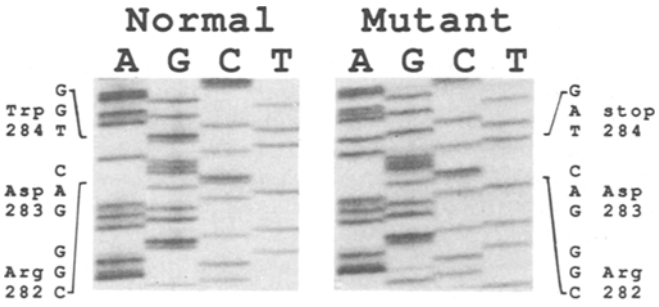

FIG. 4. Identification of the mutation in exon 6 of the rhesus monkey LDL-R gene. Exon 6 was amplified from genomic DNA of monkey 7643. PCR products were clones into M13 and sequenced. Five of thirteen clones had the sequence TGG at a position corresponding to amino acid 284 of the human protein (left). The remaining clones had a G→A transition which causes replacement of a tryptophan residue with a translation termination codon (right).

be present in all of the hypercholesteremic members of the pedigree and absent in unaffected members through three generations. Quantitative analyses of RNA obtained from liver biopsies showed that the abundance of the LDL-R RNA of the affected monkeys was also reduced by about 50% (Fig. 5).

All of the animals studied had levels of plasma Lp(a) protein ranging between 1.0 mg/dL and 57.5 mg/dL that were only weakly correlated with total plasma cholesterol, LDL cholesterol and apoB. LDL-R deficiency correlated with plasma LDL but not Lp(a). A seven-week fat challenge (16.5% lard, 0.64% cholesterol) that markedly raised the plasma LDL levels had no effect on plasma Lp(a) (30), suggesting that in the rhesus monkey the LDL receptor plays either only a limited or no functional role in the metabolism of Lp(a).

As in the human model, rhesus monkey apo(a) exhibits size polymorphism. A total of six isoforms were detected in all animals studied and classified by relating the R_f of each isoform to that of the apoB100 band. However, each animal presented either one or two isoforms (Fig. 6). About 25% of the animals studied exhibited a single fast band with an R_f of 1.13. About 5% of the animals were homozygous for the slow apo(a) isoform with an R_f of 0.80. The majority of the animals were heterozygous; the most frequent phenotypes were 0.64/1.13 and 0.80/1.13. The apo(a) isoforms with a migration faster than apoB100 (low molecular weight) had a preference for affiliation with the lighter lipoprotein particles and *vice versa*. As shown in Figure 7, animals with phenotype 1.13/1.13 had a tendency to have the highest plasma levels of Lp(a), whereas those with phenotype 0.80/0.80 had the lowest plasma concentrations. However, in spite of the same apo(a) phenotype, the plasma Lp(a) levels varied widely, supporting the concept that factors other than apo(a) phenotype participate in the regulation of these levels. In animals that were heterogeneous of the apo(a) isoforms the relation with plasma Lp(a) levels was equivocal, indicating that in the presence of heterozygosity it is difficult to assess the role that the apo(a) gene plays in the overall biology of Lp(a).

More recent studies showed the accumulation of Lp(a) in atherosclerotic arteries of rhesus monkeys with diet-induced atherosclerosis (32). Immunohistochemistry with monospecific Lp(a) antisera revealed striking accumulation of Lp(a) in atherosclerotic coronary artery lesions, whereas no Lp(a) was detected in the normal, nonatherosclerotic arteries. Analysis of paired tissue and serum samples from 17 male hyperlipoproteinemic monkeys revealed a significant correlation between the concentrations of aortic wall Lp(a) and serum Lp(a) levels. The serum cholesterol level failed to correlate with either aortic Lp(a) or serum Lp(a). These results add further evidence for the potential role of Lp(a) in the pathogenesis of atherosclerosis.

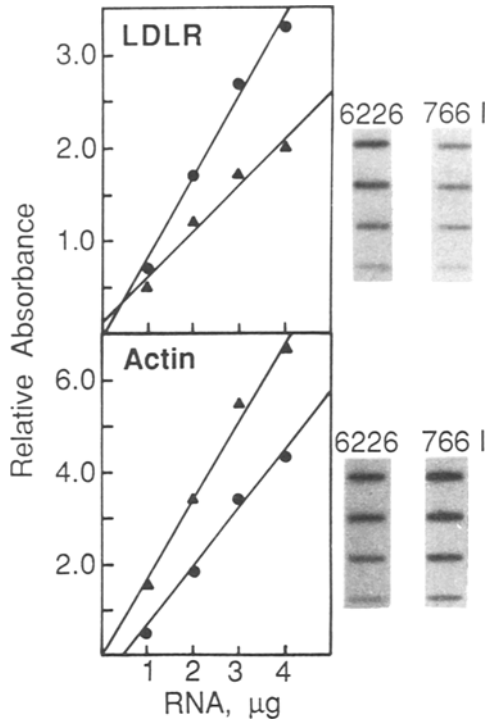

FIG. 5. Slot blot analysis of total cell RNA isolated from 766I, a hypercholesteremic monkey, and 6226, a normocholesteremic control. RNA (1, 2, 3 or 4 µg) from each monkey was applied to Zeta-Probe filter in triplicate. The filter was hybridized to a human LDL-R cDNA probe and scanned by laser densitometry. The average value for each point was calculated and the slope was determined by linear regression. One set of these data is shown at the right. The slopes are 0.50 (r=0.98) and 0.88 (r=0.99) for 766I and 6226, respectively. The filter was stripped and rehybridized with a mouse β-actin cDNA probe. Slopes of 1.77 (r=0.99) and 1.29 (r=0.99) were calculated for 766I and 6226, respectively. ●, 6226; ▲, 766I.

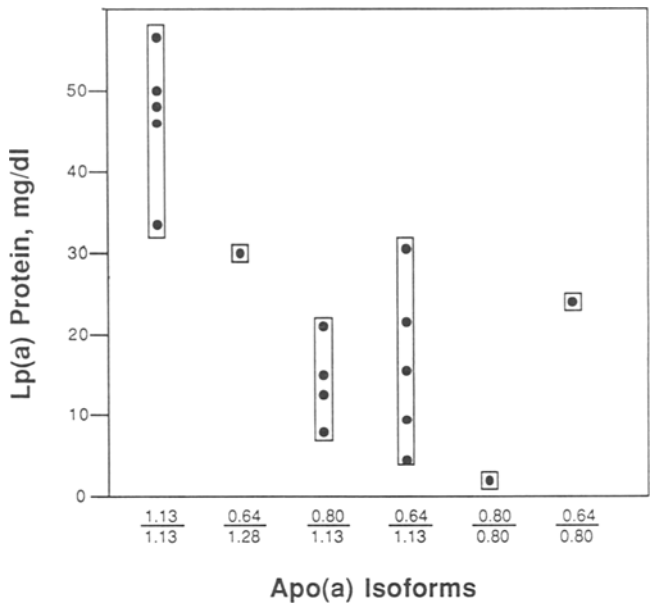

FIG. 7. Relation between apo(a) isoform phenotypes and plasma Lp(a) protein levels.

STUDIES IN THE BABOON

Studies by Rainwater and colleagues (33-38) have demonstrated that baboons possess Lp(a) that is similar to human Lp(a) and that the gene encoding apo(a) is closely linked to plasminogen (34). The mean serum level of 80 unrelated baboons was 4.7 mg/dL, with the distribution skewed toward the lower levels (35). Moreover, primary baboon hepatocytes were found to synthesize Lp(a) (36).

Baboon apo(a) exhibited at least nine isoforms distinguishable by size (36). Thirty-one different apo(a) isoform phenotypes were detected in a population of 165 unrelated baboons and found to be unaffected by changes in diet. The analysis of two large families suggested that apo(a) isoform patterns and serum Lp(a) concentrations are inherited. Putative parental alleles responsible for specific Lp(a) concentration was estimated to be 0.95 ± 0.04.

In a survey of 22 baboons, Hixson *et al.* (16) found a correlation between size of liver apo(a) transcripts (5.2∼11.2 kilobases) and size of serum apo(a) isoforms (r^2=0.996, $p<0.001$). However, the correspondence between length of the liver apo(a) messages and relative mobility of each specific isoform by gradient gel electrophoresis was not always observed, suggesting that post-transcriptional events might affect apo(a) production.

In more recent studies, twelve different size isoforms (including the null) of apo(a) were identified across the five subspecies (*Papio hamadryas hamadryas, P.h. cynocephalus, P.h. ursinus, P.h. papio* and *P.h. anubis*) and these isoforms acted as alleles (38). Significant differences in apo(a) isoform frequencies were found between subspecies. Plasma levels of Lp(a) also differed among subspecies. The genetic distances between the baboon

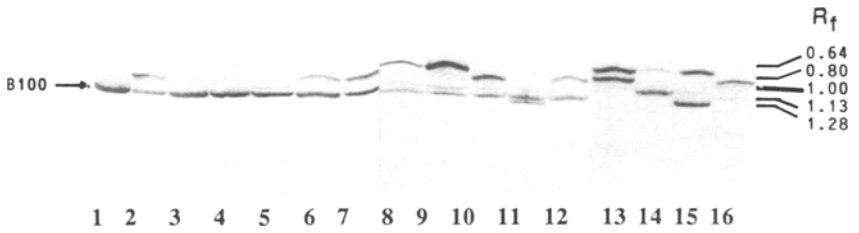

FIG. 6. Apo(a) isoform patterns of animals from a rhesus monkey pedigree with FH (see text). Some animals exhibited a single band and some two main bands. Each isoform was classified as ratio between their R_f and that of apoB100 by 2-16% polyacrylamide gel electrophoresis. 1 #766, 2 #431, 3 #1000, 4 #7643, 5 #8204, 6 #8806, 7 #7587, 8 #7099, 9 #7139, 10 #7436, 11 #7489, 12 #7558, 13 #6229, 14 #6234, 15 #6238, and 16 #7587.

subspecies based on the apo(a) isoforms were consistent with geographic relationships between the subspecies and previously assessed genetic marker information. However, the genetic distances based on apo(a) isoforms did not exhibit the same pattern of between-subspecies variation as phenotypic distances based on Lp(a) levels, suggesting that multiple genes might be involved in the determination of Lp(a) levels.

GENERAL COMMENTS

The results of the studies reviewed in the previous sections indicate that the Lp(a) of rhesus monkeys and baboons has structural properties very close to those of humans. It is apparent that like in human subjects, the plasma Lp(a) levels and apo(a) isoforms of these nonhuman primates are highly inherited traits, although this does not rule out the action of other factors, either genetic or environmental. Significant in this regard are the studies of Scanu and colleagues (29,30), showing that members of the same rhesus monkey family, although exhibiting the same fast apo(a) phenotype, had varying plasma levels of Lp(a). The studies on rhesus monkeys have also indicated that the plasma levels of Lp(a) do not closely correlate with LDL-R function, implying that the LDL receptor might have a very limited or no role in Lp(a) degradation. This conclusion is in accord with turnover studies showing a plasma residence time for Lp(a) significantly longer than that of LDL (unpublished data) and also with the dietary experiments documenting diverging effects on the plasma levels of Lp(a) and LDL.

While recognizing that nonhuman primates represent a good model for the study of the structure and biology of Lp(a), it is also important to stress that nonhuman primates offer unique features complementary to those in man. A case in point is absence of kringle V in rhesus monkey apo(a) that should permit an assessment of the functional significance of this kringle domain in Lp(a). Moreover, nonhuman primates offer the possibility of a comparatively wider experiment latitude like turnover studies, performance of serial liver biopsies, testing new pharmacological agents or potential drug toxicity. Not of lesser importance is the possibility of breeding studies to further elucidate the genetic basis of the inheritance of the apo(a) isoforms and also permit a careful analysis of the effect of development on plasma Lp(a) levels and distribution. These are just a few advantages that the nonhuman primate model offers in the study of Lp(a). An additional dimension is offered by the rhesus monkey family with FH described by Scanu and colleagues (29,30), since the members of this family provide an ideal setting for examining the potential role of the LDL receptor on Lp(a) metabolism.

Lipid and apolipoprotein (apo) A-I concentrations in different density fractions of New Zealand White (NZW) and Watanabe (WHHL) rabbit plasma were studied. Aside from the low plasma apoA-I and high density lipoprotein (HDL) cholesterol levels in WHHL rabbits, the distribution of apoA-I was also different between the two rabbits. ApoA-I was concentrated in both the HDL_2 and HDL_3 fractions of NZW rabbits but was found primarily in the HDL_3 fraction of WHHL rabbits. ApoA-I secretion in these two rabbits was further studied *in vitro* by using intestinal and hepatocyte cell cultures. ApoA-I secretion was highest from cultures of the duodenum and the proximal end of the jejunum; whereas, cell cultures of the distal end of the small intestine secreted very little apoA-I into the medium. Intestinal cell cultures from WHHL rabbits secreted less, but significant amounts of, apoA-I compared to that of NZW rabbits. ApoA-I was most concentrated in the density range of 1.12–1.21 (HDL_3) fraction in medium containing 10% fetal calf serum (FCS). Serum-free medium promoted apoA-I secretion by intestinal cell cultures that was mostly found in the d>1.21 (lipoprotein-deficient) fraction. Hepatocytes isolated from the same rabbits by collagenase perfusion secreted little apoA-I, and it was found only in the d>1.21 fraction. The addition of oleic acid into the culture medium with 10% FCS decreased the secretion of total apoA-I and HDL by intestinal cell cultures and increased the secretion of very low density lipoprotein (VLDL) and intermediate density lipoproteins (IDL). The results indicate that intestinal cells, not hepatocytes, are responsible for the secretion of apoA-I and HDL_3 in rabbits, and that the secretion may be regulated under different nutritional conditions. ***Lipids* 26, 684–688 (1991).**

HDL has been recognized as an important factor in assessing the risk of coronary artery disease (CAD) in humans (1,2). The higher the HDL cholesterol levels, the lower the risk of CAD. The major apolipoprotein in the HDL particles is apoA-I (3) which is synthesized both by the liver (4) and by the intestine (5) in humans. Under fed conditions, the intestine may contribute as much as 50% of the apoA-I circulating in plasma (6). Efforts in raising HDL cholesterol levels and lowering the low density lipoprotein (LDL) cholesterol by diet or medications have not been fruitful. Unsaturated fat that lowers LDL cholesterol levels also lowers HDL levels in humans (7). Similarly, saturated fat not only increases the levels of HDL cholesterol but also increases all the other plasma lipid levels (8). The difficulties in obtaining human hepatocyte and intestinal cell cultures further hinder the understanding of the regulation of apoA-I and HDL synthesis and secretion. By mRNA hybridization techniques, it was found that the majority of apoA-I was synthesized by the small intestine, but not the liver, in rabbits (9,10). Thus, rabbits can serve as an excellent model to study the regulation of apoA-I and HDL synthesis by intestinal cells under different nutritional conditions. Intestinal mucosa cells have been successfully isolated and cultured for a variety of studies from different animals (11–13). In this study, rabbit intestinal mucosa cells were cultured to study the secretion of apoA-I in different culture media. Furthermore, intestinal cells from WHHL rabbits (14) were also used in an attempt to understand if there are any other defects that may lead to the low plasma HDL cholesterol levels in these hypercholesterolemic rabbits.

MATERIALS AND METHODS

Materials. $Na^{125}I$ (carrier-free) was purchased from Amersham Corp., Arlington Heights, IL. Type IV collagenase was purchased from Sigma Chemical Co., St. Louis, MO. All tissue culture supplies were purchased from Grand Island Biological Co., Grand Island, NY. The Hep G2 cell line was generously provided by Dr. Barbara B. Knowles of the Wistar Institute, Philadelphia, PA.

Animals. WHHL rabbits were obtained from the National Institutes of Health, Bethesda, MD. NZW rabbits were obtained from the Institute Hills Farms of Mayo Clinic, Rochester, MN. WHHL rabbits were sacrificed at 2–3 yrs of age, and NZW rabbits were used at 6 mon to 1 yr of age.

Isolation of intestinal mucosa cells and hepatocytes. Fresh hepatocytes were isolated using the collagenase perfusion techniques as described by Attie *et al.* (15) with slight modification. Rabbits were anesthetized by ketamine hydrochloride (Ketaset; Aveco Co., Inc., Fort Dodge, IA) injection (20 mg/kg of body weight) and xylazine (Rompun; Mobay Corp., Shawnee, KS) administered (2 mg/kg of body weight) through the ear vein. An incision was made to expose the portal vein and inferior *vena cava.* A 13-gauge catheter was inserted into either vessel and secured. The liver was perfused first with preperfusion buffer (8.3 g NaCl, 0.5 g KCl, and 2.4 g HEPES per liter, pH 7.4) at a flow rate of 40 mL/min for 10 min. A collagenase perfusion buffer (3.9 g NaCl, 0.5 g KCl, 0.7 g $CaCl_2 2H_2O$, 24 g HEPES, and 1 g collagenase per liter, pH 7.1) was used afterwards for 30 min at a flow rate of 40 mL/min. The blanched liver was removed and cut into small pieces with a surgical blade. Loose hepatocytes were obtained by shaking the liver pieces vigorously in a small amount of collagenase buffer at 37°C. The viability of the hepatocytes was checked by Trypan blue exclusion under an inverted microscope. The small intestine was removed and cut into 10-cm segments starting from the ileocecal valve. A total of 34 segments were obtained. All the segments were washed in ice-cold saline and divided into four pieces. The mucosa was removed from each piece of 2.5 cm using a surgical blade and cultured in a 24-well Falcon tissue culture plate (American Scientific Products,

McGaw Park, IL) with 2 mL of medium for 12 hr. Medium (250 μL) was withdrawn at time 0, 3 hr, 7 hr, and 12 hr. For the other experiments, 10 to 20 cm of the small intestine of the duodenal, jejunal, and ileal sections were incised. The intestine was washed four times with phosphate buffered saline (PBS), and the mucosa cells were scraped off with a surgical blade. Mucosa cells were further washed three times in PBS and precipitated by low speed centrifugation (1,000 rpm) at 4°C.

Cell culture. Hepatocytes (10^6 cells) were seeded into culture dishes (100 × 15 mm) in Dulbecco's Modified Eagle's Medium with 100 units/mL penicillin, 100 μg/mL streptomycin, 0.025 M HEPES buffer, pH 7.4 (medium A), and 10% fetal calf serum (FCS). Intestinal mucosa cells collected from each segment of 10–20 cm were suspended in medium A and divided into four culture dishes (100 × 15 mm with 10 mL of medium A and 10% FCS). Hep G2 cells (16) were grown in monolayers in medium A plus 10% FCS as above. Cells were incubated in a humidified incubator with 5% CO_2 in air at 37°C. Hepatocytes and intestinal cells were cultured for 48 hr after which the culture medium was collected and filtered through a 0.2 μ filter (Millipore, Corp., Bedford, MA) to remove cellular debris. The cells were collected by scraping with a rubber policeman, washed in PBS, and precipitated by centrifugation at 4°C. The cells were then used for protein analysis by the method of Lowry *et al.* (17). Oleic acid was prepared as the bovine serum albumin (BSA) conjugate as described by Van Harken *et al.* (18).

Fractionation of lipoproteins. The culture medium was fractionated into chylomicrons plus VLDL (d<1.006), IDL plus LDL (1.006–1.063), HDL_2 (1.063–1.12), HDL_3 (1.12–1.21), and lipoprotein deficient plasma (LPDP) (d>1.21) fractions by sequential centrifugation (35,000 rpm for 48 hr). One mL of standard buffer was layered on top of 8 mL of culture medium adjusted to each density with KBr before centrifugation. The top 1-mL layer was carefully withdrawn after centrifugation and used as the respective lipoprotein class. Each lipoprotein fraction was dialyzed overnight against the standard buffer.

Radioimmunoassays. Rabbit apoA-I was purified from pooled rabbit HDL as described for the isolation of human apoA-I (19). Purified apoA-I was used to immunize adult male goats to produce high titer goat anti-rabbit apoA-I antiserum (19). The antiserum was partially purified by ammonium sulfate precipitation (35% saturation) and by using a size exclusion column (Sephadex G-25, Pharmacia, Piscataway, NJ). The rabbit apoA-I assay was performed as described for the human apoA-I assay (20). A non-ionic detergent, Tween-20, was used to detect all the immunoreactivity of the apoproteins in lipoprotein particles (21). The assays were performed in 12 × 75 mm disposable glass tubes. All dilutions were made in radioimmunoassay (RIA) buffer containing 0.1% BSA, 0.1 M sodium borate, 0.01 M NaN_3, and 0.001 M EDTA, pH 8.5. The goat anti-apoA-I antiserum was titrated so as to bind 40–50% of the [^{125}I]apoA-I (1–2 ng with 20,000–30,000 dpm). A typical assay contained 100 μL [^{125}I]apoA-I, 100 μL anti-apoA-I serum (1:4,000 dilution in RIA buffer), 100 μL sample (1:10,000 dilution in RIA buffer), and 100 μL 1% Tween-20. The non-specific binding when no antibody was used was less than 2% of the total counts. The antibody-antigen complexes were equilibrated overnight at room temperature and precipitated with an excess of streptococcal protein A (diluted 3-fold with 0.1 M Tris buffer, pH 8.0). The precipitates were washed with diluted RIA buffer (1:5 dilution with saline) and counted. The linear range of this assay is 0.3125 ng–160 ng/100 μL sample. Pooled normal rabbit plasma (Calbiochem Corp., San Diego, CA) was used as a reference in every assay to correct for daily variations.

RESULTS

The plasma of four WHHL or four NZW rabbits were combined, and the lipids and lipoprotein levels were studied (Table 1). WHHL rabbits have elevated cholesterol and triglyceride levels as compared to NZW rabbits. Most of the cholesterol is carried in the LDL fraction. A significant amount of cholesterol was also found in the VLDL (d<1.006) fraction in WHHL rabbits. Plasma apoA-I levels were significantly lower in WHHL rabbits than those of NZW rabbits as expected. Further fractionation of HDL into HDL_2 (1.063<d<1.12) and HDL_3 (1.12<d<1.21) fractions indicated that most of the apoA-I (60%) was associated with the HDL_3 fraction in both NZW and WHHL rabbits. Little apoA-I was found in the HDL_2 fraction of WHHL rabbits, whereas 24% apoA-I was found in the HDL_2 fraction of NZW rabbits. Furthermore, a significant portion of apoA-I was found in the LPDP (d>1.21) fraction of both NZW and WHHL rabbits which presumably exists as free apoA-I and is not associated with lipids. The ratio of cholesterol to triglycerides of different lipoprotein classes indicated that VLDL of WHHL rabbits is enriched in cholesterol, and HDL of the same rabbits is enriched in triglycerides as compared to those of NZW rabbits.

The difference in plasma HDL levels and in the distribution of apoA-I in HDL_2 and HDL_3 fractions between NZW and WHHL rabbits suggested that the secretion of apoA-I by the intestines of these two breeds of rabbits may be different. The small intestine of a NZW rabbit was divided into 34 segments of 10 cm each, and the mucosa cells were isolated and cultured in medium A with 10% FCS as described in Materials and Methods. The secretion of apoA-I by the mucosa cell cultures into the culture medium was followed by RIA. The results shown in Figure 1 suggest that most of the secretion of apoA-I was observed in segments proximal to the entry of the common bile duct. Very little apoA-I was found in mucosa cells derived from the ileal end of the small intestine. The intestinal mucosa cells of representative duodenal, jejunal, and ileal sections of intestine of both NZW and WHHL rabbits were cultured in a larger amount of medium (10 mL) for 48 hr to maintain the viability of the mucosa. The results shown in Table 2 suggest that duodenal mucosa cells secreted the most apoA-I/mg of cellular mucosa protein within 48 hr. Jejunal cells also secreted significant amounts of apoA-I, whereas ileal cells secreted less than half the amount secreted by either duodenal or jejunal cells. The amount of apoA-I secreted by intestinal cells of the WHHL rabbits was less than that by cells of NZW rabbits. Fractionation of the culture medium of mucosa cell cultures by density gradient centrifugation indicated that apoA-I was most concentrated in the HDL fraction (Table 3). The secretion of apoA-I by jejunal cells of a NZW rabbit was further studied in medium with and without 10% FCS. As shown in Table 4, slightly more apoA-I was

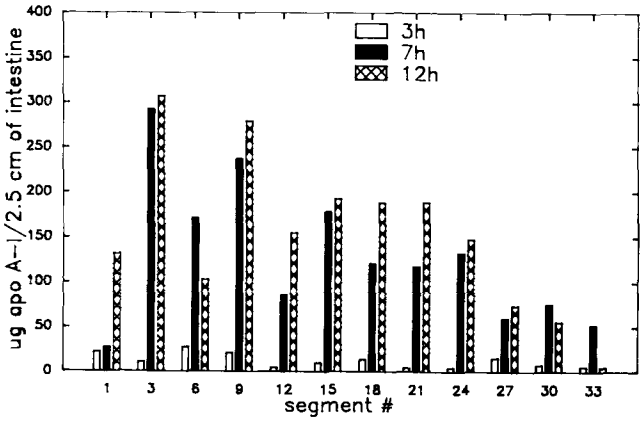

FIG. 1. Secretion of apoA-I by intestinal mucosa cells of a NZW rabbit. The small intestine of a NZW rabbit (10 mon old) was removed and divided into 34 segments numbered 1–34 consecutively from the proximal to distal ends. The mucosa cells were scraped off and cultured in 2 mL of medium A with 10% FCS. ApoA-I secretion into the medium was measured by RIA. Each value represents the average of eight determinations.

secreted by jejunal mucosa cell cultures in medium without FCS than in medium containing 10% FCS. However, apoA-I was mostly found in the lipoprotein-deficient (d>1.21) fraction in medium without FCS. Similar results were obtained with cultures from WHHL rabbits (data not shown).

Hepatocytes were isolated from a NZW rabbit by collagenase perfusion techniques and cultured in medium A with 10% FCS. Hepatocytes attached to the culture dish after 6 hr of incubation at 37°C. The remaining floating cells were then washed away with PBS. Fresh medium with and without 10% FCS was then introduced, and the incubation was continued for 48 hr. As shown in Table 4, hepatocytes secreted less than the 1% of apoA-I that was secreted by jejunal mucosa cell cultures under the same conditions. Fractionation of the medium into different lipoprotein density classes indicated that most of the apoA-I was found in the lipoprotein-deficient (d>1.21) fraction.

TABLE 4

Secretion of ApoA-I by NZW Jejunal Cell Cultures and Hepatocytes in Medium with and without 10% FCS[a]

[a] Jujunal mucosa cells and hepatocytes isolated from a NZW rabbit were cultured in medium A with and without 10% FCS for 48 hr. The medium was separated into different density ranges by ultracentrifugation. Each density fraction was dialyzed and the level of apoA-I was determined.

[b] μg/mg of total cellular protein.

[c] μg/mg of total protein in the respective density fraction.

The effect of oleic acid/BSA conjugate on the secretion of different lipoprotein classes by NZW rabbit intestinal cells and hepatocytes was studied. The results are shown in Table 5. Intestinal mucosa cells secreted only 58% of apoA-I into the medium in the presence of 0.8 mM oleate/BSA in 48 hr. ApoA-I distribution in each density class suggests that there may be a shift toward secreting more VLDL (d<1.063) and less HDL into the medium containing oleic acid by intestinal cells. The human liver cell line, Hep G2 cells, was known to secrete both VLDL and HDL and apoA-I into the culture medium (16) and was used in the same experiment for comparison. The total amount of apoA-I secreted into the culture medium after 48 hr was decreased 25% in the presence of 0.8 mM oleate/BSA.

DISCUSSION

Watanabe rabbits were developed by Watanabe (14) for the study of hypercholesterolemia and atherosclerosis. This breed of rabbit has a defect in the LDL-receptor gene that reduces their ability to clear LDL and VLDL (22). WHHL rabbits, unlike type IIa hypercholesterolemic patients, have elevated plasma triglyceride levels and low HDL cholesterol levels. From the plasma lipid analysis, it was apparent that WHHL rabbits had high cholesterol levels that were mainly associated with the LDL particles. WHHL rabbits also had low HDL cholesterol levels, and the HDL particles were relatively depleted of cholesterol and enriched triglycerides. By contrast, VLDL particles from WHHL rabbits were enriched in cholesterol but not those of NZW rabbits. The difference may be due to the long residence time of VLDL in WHHL rabbits. Plasma apoA-I levels in WHHL rabbits were only 39% of that of NZW rabbits. Further fractionation of HDL particles into HDL_2 (1.063<d<1.12) and HDL_3 (1.12<d<1.21) fractions indicated that most of the apoA-I was concentrated in the HDL_3 fractions in WHHL rabbits. It has been demonstrated that HDL_2 is formed from HDL_3 by multiple processes that may involve lipoprotein lipase, lecithin:cholesterol acyltransferase, and cholesterol ester transfer protein (23,24). The lack of HDL_2 in WHHL rabbits suggests that there may be very little lipid transfer between VLDL and HDL. Whether this is related to the low apoA-I and HDL levels and high VLDL and LDL levels in

[a] Jejunal mucosa cells isolated from a NZW rabbit and the human hepatoma cell line, Hep G2 cells, were cultured in medium containing 10% FCS with and without 0.8 mM oleate/BSA conjugate for 48 hr. The medium was separated into different density classes by ultracentrifugation. The level of apoA-I was determined in each fraction.

[b] μg/mg of total cellular protein.

[c] μg/mg of total protein in the respective fraction.

WHHL rabbits is not known. By using intestinal mucosa cell cultures and RIA for apoA-I, we demonstrated that apoA-I was secreted primarily from the intestinal cells, but not hepatocytes, of both NZW and WHHL rabbits (Table 2). Both duodenal and jejunal sections of intestinal cells secreted significant amounts of apoA-I into the culture medium, whereas ileal cells secreted very little apoA-I. Intestinal cells isolated from WHHL rabbits secreted approximately 60% the amount of apoA-I secreted by NZW rabbits. This difference may partly explain the low plasma apoA-I and HDL levels in WHHL rabbits. As expected, most of the apoA-I secreted was associated with particles in the HDL density fraction ($1.063<d<1.21$) of the culture medium. However, significant amounts of apoA-I were also found in the lipoprotein-deficient fraction ($d>1.21$) which may be nascent apoA-I particles without significant association with lipids. Use of serum-free medium further promoted the secretion of apoA-I into the $d>1.21$ fraction by jejunal mucosa cells of a NZW rabbit (Table 4). The results indicated that newly secreted apoA-I can be incorporated into lipoprotein particles in the culture medium. Hepatocytes isolated from NZW rabbits secreted a very small amount of apoA-I into the culture medium which is in accordance with other reports (9,10).

It has been demonstrated that addition of oleic acid into the culture medium of Hep G2 cells increased the secretion of VLDL (16). Similarly, the addition of oleic acid into the medium may increase the secretion of VLDL and chylomicrons by intestinal mucosa cells. In the present study, we demonstrated that oleic acid greatly decreased the secretion of apoA-I by intestinal cells. A similar decrease in apoA-I secretion into the medium containing oleic acid was found with jejunal cells from WHHL rabbits (from 96.98 μg/mg protein to 61.95 μg/mg protein). It is possible that plasma apoA-I levels may also decrease after a fatty meal that contains oleic acid. It will be of interest to study the effect of other fatty acids on the secretion of apoA-I by intestinal cells.

BW755C or Staurosporine Inhibits Collagen-Stimulated Phosphoinositide Phosphorylation in Platelets

Lisa M. Thomas and **Bruce J. Holub***
Department of Nutritional Sciences, University of Guelph, Guelph, Ontario, Canada N1G 2W1

Stimulation of platelets by collagen results in increased formation of the polyphosphoinositides, phosphatidylinositol phosphate (PtdIns*P*) and phosphatidylinositol bisphosphate (PtdInsP_2) through stimulation of phosphoinositide kinase activities. We investigated a possible regulatory role of endogenous thromboxane formation and protein kinase C (PKC) activation in the induction of phosphoinositide phosphorylation following collagen stimulation, as well as following stimulation by the thromboxane mimetic, U-46619. Human platelets were prelabeled with [^{3}H]inositol and stimulated with collagen (2 μg/mL) or U-46619 (1 μM), in the absence or presence of either the cyclo-oxygenase/lipoxygenase inhibitor, BW755C, or staurosporine, a putative inhibitor or PKC. Collagen stimulation resulted in a time-dependent increase in [^{3}H]inositol-labeled PtdIns*P* and PtdInsP_2 which was completely inhibited in the presence of BW755C. Addition of U-46619 to BW755C-treated, collagen-stimulated platelets restored the increased polyphosphoinositide formation. Stimulation of platelets with U-46619 alone also resulted in increased formation of [^{3}H]PtdIns*P* and [^{3}H]PtdInsP_2, but this was not affected by the presence of BW755C. These results suggest that the collagen-induced activation of phosphoinositide kinases was dependent upon thromboxane formation, but that U-46619-induced phosphoinositide formation was rather independent of further thromboxane production. Pretreatment of platelets with staurosporine, prior to agonist addition, completely blocked the collagen-stimulated rise in radiolabeled PtdIns*P* and the U-46619-induced PtdIns*P* and PtdInsP_2 generations, suggesting that protein kinase, possibly PKC, may play a role in the activation of phosphoinositide kinases by these agonists.
***Lipids* 26, 689–695 (1991).**

The levels of the phosphoinositides, phosphatidylinositol (PtdIns), phosphatidylinositol phosphate (PtdIns*P*) and phosphatidylinositol bisphosphate (PtdInsP_2) in resting platelets are controlled *via* phosphoinositide kinase and phosphomonoesterase activities (1). Activation of platelets by thrombin (2–5) or collagen (6,7) results initially in the hydrolysis of phosphoinositides followed subsequently by increased formation of PtdIns*P* and/or PtdInsP_2. Little information is available on the regulation of the phosphoinositide kinases in platelets. Platelet PtdIns kinase activity, *in vitro*, requires magnesium and ATP and has been shown to be inhibited in the presence of calcium (8,9). Although corresponding data in human platelets are not available, erythrocyte PtdIns*P* kinase also requires magnesium and ATP for activity and is inhibited by PtdInsP_2 (10). Stimulation of intact platelets with dibutryl cyclic AMP or cyclic AMP-elevating agents has been shown to increase polyphosphoinositide levels (11,12). Similarly, treatment of platelets with a diacylglycerol analog or phorbol ester also resulted in PtdIns*P* and PtdInsP_2 formation (13–15). This suggests that cyclic AMP-dependent protein kinase and protein kinase C (PKC) may somehow regulate phosphoinositide kinase activity. Recent evidence also suggests that the phosphoinositide kinases may be regulated by a guanine nucleotide binding protein (16–18).

Stimulation of platelets with collagen has been shown to cause changes in the levels of [^{32}P]orthophosphate-labeled phosphoinositides (5–7,19). Early collagen stimulation results in decreases in both PtdInsP_2 and PtdIns*P*, presumably due to increased phospholipase C activity, while stimulation for longer periods results in the formation of these polyphosphoinositides. The increased levels of polyphosphoinositides are considered to result from stimulated PtdIns and PtdIns*P* kinase activities (5,7). Recent evidence suggests that polyphosphoinositide phosphorylation may play important roles in mediating platelet and other cellular reactivity (20–23). Many collagen-induced responses in platelets, such as aggregation, secretion, arachidonic acid release, and calcium mobilization are dependent upon the production of endogenous thromboxane (24–27). Therefore, we investigated a possible thromboxane-dependency of the collagen-stimulated, as well as thromboxane mimetic-induced, polyphosphoinositide production in [^{3}H]inositol-labeled human platelets. In addition, we investigated a possible involvement of PKC in agonist-induced phosphoinositide formation by pretreating platelets with staurosporine, a putative PKC inhibitor, prior to collagen or thromboxane mimetic, U-46619 (9,11-dideoxy-11α,9α-epoxymethanoprostaglandin $F_{2\alpha}$), stimulation.

MATERIALS AND METHODS

Materials. The *myo*-[2-^{3}H]inositol (10–20 Ci/mmol) was purchased from Amersham Canada, Ltd. (Oakville, Ontario, Canada) and Aquasol-2 was from New England Nuclear (Lachine, Quebec, Canada). Collagen was obtained from Hormon Chemie (München, Germany) and U-46619 was from Upjohn Scientific Co. (Kalamazoo, MI). The U-46619 was evaporated under nitrogen and dissolved in ethanol for storage below 0°C. Staurosporine was donated by Dr. G. Murphy of Sandoz, Canada, Inc. (Whitby, Ontario, Canada) and was dissolved in Me_2SO for storage below 0°C. The 3-amino-1-(3-trifluoromethylphenyl)-2-pyrazoline (BW755C) was a gift from Dr. R. Ippersiel of the Wellcome Research Laboratories (Kirkland, Quebec, Canada), and was stored in powder form below 0°C. Heparin, phosphoinositide standards, and 8-anilino-1-naphthalenesulfonic acid (ANS) were from

Sigma Chemical Co. (St. Louis, MO), and bovine serum albumin (fraction V, fatty acid free) was from Boehringer Mannheim Canada (Dorval, Quebec, Canada). The method of Molnar and Lorand (28), modified by dialyzing the final material against 0.9% sodium chloride, was utilized to isolate apyrase from potatoes. Siliconized glassware or polypropylene tubes were used for the isolation and incubation of the platelets. All solvents and chemicals were of analytical grade.

Platelet isolation and labeling procedures. Platelets were isolated from healthy donors who denied taking anti-inflammatory drugs for the past 10 days. Blood was drawn into 1/6 volume of acid-citrate-dextrose anticoagulant (29) and the platelets isolated at 37°C according to the method of Mustard *et al.* (30). Platelets were labeled with [^{3}H]inositol by incubation for 2 hr at 37°C with 20–25 μCi of [^{3}H]inositol per 10 mL of the first washed platelet suspension [Tyrodes buffer containing 60 μg/mL apyrase, 50 units/mL heparin, 0.35% bovine serum albumin and 5 mM Hepes (30)]. In some experiments the volume of the first platelet suspension was decreased to 5 mL, which provided an approximate doubling of the incorporated radioactivity. In addition, the 1 mM $MgCl_2$ in the Tyrodes buffer was substituted with 2 mM $MnCl_2$ and the glucose concentration was decreased from 5.5 mM to 0.55 mM to increase the incorporation of [^{3}H]inositol into platelet phosphoinositides, as described by Culty *et al.* (31). Less than 1% of the labeled inositol was incorporated into the platelet phosphoinositides. Subsequently, the platelets were washed free of radiolabel and resuspended in a magnesium-containing Tyrodes buffer (with 5.5 mM glucose) containing 3 μg/mL apyrase and 0.35% bovine serum albumin (30). This final platelet suspension was adjusted to a concentration of 5×10^8/mL using a Coulter Counter Model ZM (Coulter Electronics of Canada Ltd., Burlington, Ontario, Canada).

Incubations. One-mL platelet suspensions were pre-incubated (with stirring) at 37°C for 1 min in an aggregometer (Payton Scientific Inc., Buffalo, NY) before incubation for 2 min with either 1 μM staurosporine (or the vehicle, Me_2SO, 0.5%, v/v) or 120 μM BW755C (or the vehicle, water). Collagen (2 μg/mL) or U-46619 (1 μM) was then added and the stirred suspensions incubated for various time periods. The platelet phosphoinositides in the resulting aggregates were extracted three times using an acidified Bligh and Dyer (32) method as described by Allan and Michell (33).

Thin-layer chromatographic separation of phosphoinositides. PtdIns*P*, PtdInsP_2 and lysophosphatidylinositol (lysoPtdIns) standards were added as carrier to the platelet lipid extracts prior to spotting on Merck pre-coated thin-layer chromatographic plates (BDH Chemicals Canada Ltd., Toronto, Ontario, Canada). The phosphoinositides were separated in a one-dimensional system described previously (8). Following detection using a 0.1% ANS solution (34) and viewing under ultraviolet light, the phosphoinositide bands were scraped into vials, 1.5 mL of water and 13.5 mL of Aquasol-2 were added, and the vials were vortexed. The radioactivity associated with the phosphoinositides was counted on a Beckman LS3801 scintillation counter (Beckman Instruments, Fullerton, CA).

Statistical analyses. For most experiments, the responses following agonist stimulation are expressed as a percentage of the unstimulated values due to the variability in the incorporation of the radioactive label into the phospholipids between individual subjects. To facilitate the statistical analysis, the radioactive data were first log transformed and analyzed using an analysis of variance, following which specific differences for preplanned comparisons between treatment means were determined using a paired Student's *t*-test (35). For some experiments, where the data is expressed as the mean (± SEM) in radioactive dpm values, statistical significance was determined using an unpaired Student's *t*-test (35).

RESULTS

Effect of BW755C on collagen-stimulated phosphoinositide metabolism. Figure 1 shows the changes in [^{3}H]inositol-labeled phosphoinositide levels following stimulation with collagen (2 μg/mL) for various time periods and the effect of a 2 min pre-incubation with the combined cyclo-oxygenase/lipoxygenase inhibitor, BW755C (120 μM) (36–38). Changes in the levels of phosphoinositides can occur through stimulation of phospholipase C and A_2, and kinase and/or phosphomonoesterase activities. Collagen stimulation for 30 seconds in the absence of BW755C (closed circles) resulted in decreases in both [^{3}H]inositol-labeled PtdIns and PtdInsP_2, consistent with phosphoinositide hydrolysis by phospholipase C. At this time period, there were no significant changes in the levels of [^{3}H]PtdIns*P* or [^{3}HlysoPtdIns. At later times of collagen stimulation (90 and 180 seconds) in the absence of BW755C, there were significant rises in the polyphosphoinositides, PtdIns*P* and PtdInsP_2, that were indicative of phosphoinositide kinase activity; however, the concurrent involvement of phospholipase C and/or phosphomonoesterase activities cannot be excluded. Pretreatment with BW755C (open circles) had no significant effect on the levels of PtdIns and PtdInsP_2 at 30 seconds of collagen stimulation, suggesting that the hydrolysis of these phosphoinositides by phospholipase C at this time period was eicosanoid-independent. However, the rises in PtdIns*P* and PtdInsP_2 at later times of stimulation with collagen were completely blocked by the presence of BW755C, suggesting the involvement of eicosanoids in this collagen-induced response. There were further decreases in PtdIns at 90 seconds and 180 seconds of collagen stimulation and an increase in lysoPtdIns at 180 seconds of collagen stimulation which were also markedly inhibited by the presence of BW755C. This suggests the involvement of eicosanoids in the further depletion of PtdIns by the action of PtdIns kinase and/or *via* the hydrolysis by phospholipase C and/or phospholipase A_2.

Effect of simultaneous stimulation of BW755C-treated platelets with collagen and U-46619. To investigate the eicosanoid-dependency of the collagen-stimulated changes in phosphoinositides, the effect of adding a thromboxane mimetic (U-46619) to platelets pre-incubated with BW755C and stimulated with collagen was determined. Platelet suspensions were first pretreated with the dual cyclo-oxygenase/lipoxygenase inhibitor, BW755C, and then were stimulated simultaneously with collagen and U-46619 for 3 min. The results are shown in Table 1. Collagen stimulation for 3 min caused a significant decrease in PtdIns and significant increases in the polyphospho-

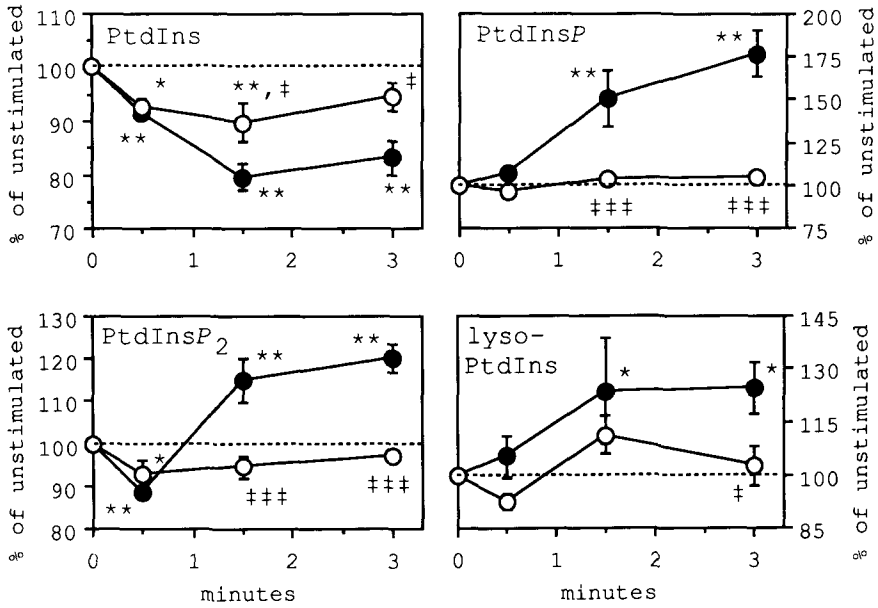

FIG. 1. Effect of BW755C on collagen-induced phosphoinositide metabolism in [^{3}H]inositol-labeled platelets. Platelet phosphoinositides were prelabeled with [^{3}H]inositol as described in Materials and Methods. One-milliliter samples of platelet suspensions (5 × 10^8/mL) were incubated at 37°C for 2 min in the absence (●) or presence (○) of 120 μM BW755C, prior to incubation with collagen (2 μg/mL) for the times indicated. Data are the mean (± S.E.M.) from three separate experiments and are expressed as the percentage of the unstimulated controls. Average unstimulated radioactivity associated with PtdIns, PtdIns*P*, PtdInsP_2 and lysoPtdIns, respectively, were 12665, 1204, 1455 and 830 dpm in the absence of BW755C and 12737, 1209, 1410 and 852 dpm, respectively, in the presence of BW755C. There was no significant effect of BW755C on the unstimulated dpm values associated with these phosphoinositides. The symbols * and ** indicate significant difference from the unstimulated value ($p < 0.05$ and $p < 0.01$, respectively); while the symbols ‡ and ‡‡‡ indicate significant difference from the collagen-stimulated value in the absence of BW755C ($p < 0.05$ and $p < 0.001$, respectively).

Effect of Simultaneous Stimulation of BW755C-Treated Platelets with Collagen and U-46619 on Phosphoinositide Metabolism[a]

Phosphoinositide	Unstimulated	Collagen		
		Alone	+ BW755C	+ BW755C, + U-46619
	[dpm ± S.E.M.]		[dpm ± S.E.M. (%)]	
PtdIns	21847 ± 293	17857 ± 741 (82)**	21605 ± 118 (99)	20433 ± 259 (94%)*
PtdIns*P*	1583 ± 121	2264 ± 49 (143)**	1702 ± 8 (108)	2725 ± 121 (172%)**
PtdInsP_2	1318 ± 90	1594 ± 53 (121)[b]	1135 ± 4 (86)	1853 ± 65 (141%)*

[a]Platelet phosphoinositides were prelabeled with [^{3}H]inositol as described in Materials and Methods. One milliliter samples of platelet suspensions (5 × 10^8/mL) were incubated at 37°C for 2 min in the presence or absence of 120 μM BW755C prior to incubation with collagen (2 μg/mL) or collagen and U-46619 (1 μM) for 3 min. Data are the mean (± S.E.M.) radioactivity of three determinations. The numbers in parentheses express the values as a percentage of the unstimulated control. The symbols, * and **, indicate significant difference from the unstimulated values ($p<0.05$ and $p<0.01$, respectively).

[b]Indicates a p-value of 0.057 as compared to the unstimulated value.

inositides, PtdIns*P* and PtdInsP_2. The presence of BW755C significantly inhibited these responses to collagen. Simultaneous addition of collagen and U-46619 to BW755C-treated platelets restored the collagen-induced degradation of PtdIns and formation of polyphosphoinositides. These results suggest that the inhibitory effect of BW755C on the collagen-stimulated phosphoinositide metabolism (Fig. 1) was due to the inhibition of thromboxane production (*via* blockade of cyclo-oxygenase activity).

Effect of BW755C on U-46619-induced phosphoinositide metabolism. The effect of incubation of platelets with U-46619 alone or incubation of BW755C-treated platelets with U-46619 is shown in Table 2. A 3-min incubation with this thromboxane mimetic resulted in a decrease in the level of PtdIns as well as increases in PtdIns*P* and PtdInsP_2, thereby suggesting that thromboxane receptor occupancy alone could induce both the depletion of PtdIns and polyphosphoinositide generation. Pretreatment with BW755C, however, did not influence the U-46619-induced

TABLE 2

Effect of BW755C on U-46619 Induced Phosphoinositide Metabolism in [^{3}H]Inositol-Labeled Platelets[a]

	(dpm)	(% of unstimulated)	
PtdIns*P*	683	183 (±23)**	99 (±3)‡‡
lysoPtdIns	586	122 (±7)**	103 (±5)‡‡

[a]Platelet phosphoinositides were prelabeled with [^{3}H]inositol as described in Materials and Methods. One-milliliter samples of platelet suspensions (5×10^8/mL) were incubated at 37°C for 2 min in the presence of 1 μM staurosporine or the vehicle, Me_2SO (0.5%, v/v) prior to incubation with collagen (2 μg/mL) for 3 min. Data are the mean (± S.E.M.) from four separate experiments and are expressed as the percentage of the unstimulated controls. The symbol ** indicates a significant difference from the unstimulated value ($p<0.01$), while the symbol ‡‡ indicates a significant difference from the collagen-stimulated value in the absence of staurosporine ($p<0.01$).

phosphoinositide metabolism, indicating that further endogenous eicosanoid production (*i.e.*, thromboxane) was without effect in platelets stimulated by U-46619 at this concentration.

Effect of staurosporine on collagen- and U-46619-induced phosphoinositide metabolism. The effects of staurosporine, a PKC inhibitor (39,40), on collagen-induced and U-46619-induced phosphoinositide metabolism are shown in Tables 3 and 4, respectively. Pretreatment of platelets with staurosporine (1 μM) for 2 min significantly blocked the collagen-induced formations of PtdIns*P* and lysoPtdIns. The data for PtdInsP_2 were too inconsistent to determine the effect of staurosporine in collagen-stimulated platelets. In U-46619-stimulated platelets, the loss in PtdIns and generation of PtdIns*P* and PtdInsP_2 were also significantly suppressed in the presence of staurosporine. These data suggest that PKC may be involved in collagen and U-46619-induced phosphoinositide metabolism, particularly the increased formations of polyphosphoinositides observed upon stimulation.

DISCUSSION

We investigated collagen- and U-46619-stimulated phosphoinositide metabolism in [^{3}H]inositol-labeled human platelets. It has been assumed that PtdIns, PtdIns*P* and PtdInsP_2 had the same specific radioactivity and that these phosphoinositides exist in a metabolically homogenous pool within platelets (41). Labeling with inositol in this study produced an average distribution of radioactivity between PtdIns, PtdIns*P* and PtdInsP_2 of 85, 7 and 8%, respectively. This is similar to the mass distribution of phosphoinositides described by Tysnes *et al.* (41).

The stimulated formations of polyphosphoinositides were studied in the presence or absence of either the cyclooxygenase/lipoxygenase inhibitor, BW755C, or staurosporine, a putative inhibitor of PKC. Caution must be exerted during the interpretation of data utilizing staurosporine since it has been demonstrated to be a non-specific inhibitor of protein kinases (42,43). However, the possible involvement of PKC in agonist-induced phospholipid alterations (40,44) and accumulation of inositol phosphates (45,46) in platelets has been investigated in the past using staurosporine. Both thrombin-induced and dioctanoylglycerol-induced phosphorylation of the 47 kDa protein, the main PKC substrate in platelets, were found to be completely inhibited by staurosporine at a concentration of 1 μM (40).

Following stimulation of [^{3}H]inositol-prelabeled human platelets with collagen, evidence for the depletion of radiolabeled PtdInsP_2 at 30 seconds was followed, at later times of stimulation, by increased formations of both

[a]Platelet phosphoinositides were prelabeled with [^{3}H]inositol as described in Materials and Methods. One-milliliter samples of platelet suspensions (5 × 10^8/mL) were incubated at 37°C for 2 min in the presence of 1 μM staurosporine or the vehicle, Me_2SO (0.5%, v/v) prior to incubation with U-46619 (1 μM) for 3 min. Data are the mean (± S.E.M.) radioactivity from three determinations, with qualitatively similar results obtained in a separate experiment. The numbers in parentheses express the values as a percentage of the unstimulated control. The symbol ** indicates a significant difference from the unstimulated value ($p<0.01$), while the symbols ‡ and ‡‡ indicate significant difference from the U-46619-stimulated value in the absence of staurosporine ($p<0.05$ and $p<0.01$, respectively).

[b]Indicates a p-value of 0.08 compared to the unstimulated value.

the polyphosphoinositides, PtdIns*P* and PtdInsP_2 (Fig. 1). This agrees with previous studies employing [^{32}P]orthophosphate-labeled platelets which showed a similar hydrolysis of PtdInsP_2 and increased polyphosphoinositide formation following collagen stimulation (6,7). However, in contrast with these investigators, we did not observe a decrease in PtdIns*P* using [^{3}H]inositol labeling, but we did observe a depletion of PtdIns. These differences may be due to the different radiotracers utilized or the time points taken for analysis of phosphoinositides. We also observed an increase in lysoPtdIns with collagen (2 μg/mL) stimulation. This agrees with previous studies employing very high levels of collagen that measured lysoPtdIns formation in [^{3}H]glycerol-labeled (47) and unlabeled (48) platelets. In addition, we recently observed a collagen-induced formation of [^{14}C]stearoyl-labeled lysoPtdIns (49). In [^{3}H]inositol-labeled platelets stimulated by U-46619, we also observed increased polyphosphoinositide formation above basal levels (Table 2) which was not observed in [^{32}P]orthophosphate-labeled platelets (50). The longer incubation period with U-46619 and/or the different radiotracer we utilized may have accounted for the differences.

In our experiments involving BW755C, we obtained opposite effects of this inhibitor in collagen- and U-46619-stimulated platelets. The collagen-induced rise in lysoPtdIns and the polyphosphoinositides, PtdIns*P* and PtdInsP_2, were found to be dependent upon endogenous eicosanoid production as was the further loss of PtdIns at later times of collagen stimulation (Fig. 1). These collagen-induced, eicosanoid-dependent changes in phosphoinositides are most likely explained as a thromboxane dependency. Platelets pre-incubated with BW755C and then simultaneously stimulated with collagen and the thromboxane mimetic, U-46619, showed a reversal of the inhibitory effect of BW755C on the collagen-stimulated phosphoinositide metabolism (Table 1). In addition, other collagen-induced responses, such as arachidonic acid release, calcium mobilization, secretion and aggregation, have been shown to be dependent upon endogenous thromboxane formation (24–27). Other investigators have demonstrated the thromboxane dependency of the collagen-stimulated loss in PtdIns (26,51) and gain in lysoPtdIns (48) in platelets treated with aspirin or indomethacin. Previously, we demonstrated that the formation of [^{14}C]stearoyl-labeled lysoPtdIns in collagen-stimulated platelets was inhibited by pretreatment with BW755C (49). We confirm these results in [^{3}H]inositol-labeled platelets and also show that the collagen-stimulated formation of PtdIns*P* and PtdInsP_2 are likely dependent upon thromboxane formation.

The failure of BW755C treatment to affect the phosphoinositide changes observed following U-46619 stimulation (Table 2) suggests that the level of thromboxane mimetic employed (1 μM) was sufficient to cause phosphoinositide phosphorylation without a dependency on further production of endogenous thromboxane. It cannot be determined from the present work whether thromboxane activates both PtdIns kinase and PtdIns*P* kinase, or only one of them. U-46619 stimulation caused a greater than two-fold increase in PtdIns*P* over PtdInsP_2 (Table 2), suggesting a greater activation of PtdIns kinase as compared to PtdIns*P* kinase. It is possible that thromboxane primarily acts on PtdIns kinase with the resulting increase in PtdIns*P* stimulating the formation of PtdInsP_2 *via* PtdIns*P* kinase.

Phorbol ester treatment of platelets has been shown to stimulate increase formation of PtdIns*P* and PtdInsP_2 with a resulting decrease in PtdIns, in [^{32}P]orthophosphate-labeled or unlabeled platelets (13,14), suggesting the stimulation of PtdIns and PtdIns*P* kinase activities by PKC. We investigated a possible involvement of PKC in agonist-stimulated phosphoinositide phosphorylation through the use of the protein kinase inhibitor, staurosporine. Pretreatment with staurosporine blocked the collagen-induced rise in PtdIns*P* (Table 3) and the U-46619-induced formation of PtdIns*P* and PtdInsP_2 (Table 4). These results suggest a role of protein kinase, possible PKC, in the collagen- and U-46619-stimulated phosphoinositide kinase activities. We recently observed a possible PKC-dependency of the collagen-stimulated release of arachidonic acid, formation of lysophospholipids, including lysoPtdIns, and production of thromboxane (52). Since thromboxane production appeared to be necessary for phosphoinositide phosphorylation in collagen-stimulated platelets (Fig. 1), we suggest that suppressed thromboxane production with staurosporine pretreatment may account for the inhibited PtdIns

kinase activity seen in staurosporine-treated, collagen-stimulated platelets. However, in U-46619-stimulated platelets, phosphoinositide phosphorylation was independent of further thromboxane formation, yet was inhibited in the presence of staurosporine. Therefore, staurosporine appears to inhibit U-46619-stimulated polyphosphoinositide formation by a mechanism not involving thromboxane formation. The ability of PKC to cause the sequestration of calcium in platelets (53) may account for the stimulated PtdIns kinase activity, since this enzyme activity appears to be inhibited, *in vitro*, in the presence of calcium (9). Alternatively, PtdIns kinase may be phosphorylated by PKC resulting in its activation. Endogenously produced thromboxane or thromboxane analog may activate PtdIns kinase through the activation of PKC (50).

Very recently, novel phosphorylated PtdIns compounds, PtdIns(3,4)P_2 and/or PtdIns(3,4,5)P_3, have been identified in platelets stimulated by either thrombin, U-46619 or phorbol 12,13-dibutyrate (54–57). It was suggested that these products resulted from stimulated PtdIns 3-kinase activity on PtdIns(4)P and PtdIns(4,5)P_2, respectively (54), or from stimulated PtdIns 4-kinase activity on PtdIns(3)P (55). The basal level of radioactivity associated with PtdIns(3)P in platelets has been reported to be <2% of the total PtdIns$P$, and PtdIns(3)P does not appear to increase upon stimulation (54–57). Therefore, the increased PtdIns$P$ formation we observed with stimulation is most likely due to PtdIns 4-kinase activity. Similarly, PtdIns(3,4)P_2 has been shown to be a minor component (<1%) of the total PtdInsP_2 in resting platelets (54–56). Although increases in PtdIns(3,4)P_2 in platelets have been observed upon stimulation, it represents a very minor component of the increase in total PtdInsP_2 (54–57). From the data of Kucera and Rittenhouse (54), it can be calculated that >93% and >98%, respectively, of the total increases in PtdInsP_2 following thrombin or phorbol ester stimulation were due to the PtdIns(4,5)P_2 isomer. Therefore, the majority of the increase in PtdInsP_2 which we report herein with collagen or U-46619 stimulation is most likely due to an increase in PtdIns(4,5)P_2.

It has been suggested that the activation of phospholipase C and the resulting decrease in PtdInsP_2 may remove the product inhibition on PtdIns$P$ kinase, thus stimulating the phosphorylation of PtdIns to PtdIns$P$ to PtdInsP_2 (58,59). Previously, it was shown that PtdIns$P$ kinase activity, *in vitro*, was inhibited by the presence of PtdInsP_2 (10,58,59). However, we find that in the presence of BW755C, the collagen-stimulated decrease in PtdInsP_2 was unaffected, while the formation of PtdIns$P$ and PtdInsP_2 at later times of stimulation were blocked. This suggests that a decrease in PtdInsP_2 may not be an efficient stimulus for phosphoinositide kinase activity in collagen-stimulated platelets. Recently, it was suggested that increased phosphoinositide kinase activity may precede or occur concurrently with activation of phospholipase C in thrombin-stimulated platelets (60).

The significance of polyphosphoinositide accumulation following collagen or U-46619 stimulation remains to be determined. However, PtdIns and PtdIns$P$ kinase activities have been associated with the platelet cytoskeleton (21) and PtdInsP_2 has been shown to interact specifically with the cytoskeletal proteins profilin and gelsolin (61,62), resulting in increased actin polymerization. Recently, PtdInsP_2 has been shown to be capable of activating PKC isolated from brain (22) and in adrenal chromaffin cells, the polyphosphoinositides may be required for secretion, independently of being substrates for the production of diacylglycerol (23). In addition, in a platelet mixed vesicle (endoplasmic plus plasma membranes), both PtdIns$P$ and PtdInsP_2 induced a rapid release of calcium which was distinguishable from that produced by inositol triphosphate (20). Increased polyphosphoinositide formation may result in the opening of a calcium channel in the plasma membrane allowing the influx of external calcium (63). The thromboxane dependent increase in PtdIns$P$ and PtdInsP_2 upon collagen stimulation may be associated with an influx of extracellular calcium, since the collagen-stimulated rise in cytoplasmic calcium is highly dependent upon thromboxane production (26,27).

In conclusion, the present work suggests an involvement of eicosanoids (presumably thromboxane) and protein kinase, possibly PKC, in the collagen-stimulated formation of polyphosphoinositides in human platelets. Furthermore, the induction of polyphosphoinositide phosphorylation using U-46619 as agonist appears to be mediated by protein kinase, possibly PKC, activation but not by the further production of thromboxane.

Decrease in Platelet Reduced Glutathione Increases Lipoxygenase Activity and Decreases Vitamin E

Institut National de la Santé et de la Recherche Médicale U.205, Chimie Biologique INSA, 69621 Villeurbanne, France

Unstimulated normal human blood platelets were treated with azodicarboxylic acid *bis*(dimethylamide) (diamide), a thiol-oxidizing agent. Oxygenated arachidonic acid (AA) metabolites, malondialdehyde (MDA), and tocopherols were then quantified by high-performance liquid chromatography (HPLC). Diamide treatment partially decreased the amount of reduced glutathione (GSH) content and induced a subsequent decrease in peroxidase activity. However, formation of 12-hydroxy-eicosatetraenoic acid (12-HETE), the end-product of lipoxygenation of AA, increased. Formation of MDA, a marker of overall lipid peroxidation, was also enhanced. Furthermore, platelet α-tocopherol, but not γ-tocopherol, significantly decreased. These results indicate that enhanced "basal" lipoxygenase activity, as a marker of specific AA oxygenation, may be linked to decreased platelet antioxidant status. *Lipids 26*, 696-699 (1991).

Platelet hyperactivity is of concern in atherosclerosis and thrombosis and has been linked to the high incidence of vascular diseases observed in pre-thrombotic states such as aging and diabetes. During agonist-induced platelet activation, arachidonic acid (AA) is liberated from membrane phospholipids and is subsequently oxygenated *via* the cyclooxygenase and lipoxygenase pathways (1). The major oxygenated end-products of the former pathway are thromboxane B_2 and 12-hydroxy-heptadecatrienoic acid (12-HHT). The latter pathway forms an unstable primary oxygenated product, 12-hydroperoxy-eicosatetraenoic acid (12-HPETE). 12-HPETE is rapidly reduced to its corresponding hydroxy derivative, 12-hydroxy-eicosatetraenoic acid (12-HETE), by a glutathione-dependent peroxidase (GSH-Px) (2) which is involved in the antioxidant defense of the cells. GSH-Px is tightly coupled to the hexose monophosphate shunt through reduced nicotinamide adenine dinucleotide phosphate (NADPH) which restores reduced glutathione (GSH) *via* the GSH-reductase. 12-HPETE is known to cause a marked stimulation of its own biosynthesis (3) as well as of the lipoxygenation and cyclooxygenation of some other polyunsaturated fatty acids (4). Its transitory accumulation may be important in pro-aggregatory prostanoid formation. However, platelets possess an efficient system of defense against lipid peroxidation. This system mainly consists of peroxide scavenger enzymes, such as GSH-Px, the glutathione redox system and vitamin E, the latter being the most important lipid-soluble antioxidant. During oxidative damage, enhanced lipid peroxidation occurred and the antioxidant system may be altered. Indeed, platelets from elderly people and from diabetic people synthesized higher amounts of oxygenated metabolites of AA. Vitamin E was decreased in such platelets (5-7).

The present study was undertaken to determine whether there is a link between increased lipoxygenase activity (leading to increased lipid peroxidation) and a decrease in vitamin E content. Unstimulated platelets were subjected to oxidative stress by using azodicarboxylic acid *bis*(dimethylamide) (diamide), a GSH-depleting agent. The effects of a moderate concentration of diamide on platelet lipid peroxidation and antioxidant status were investigated.

MATERIALS AND METHODS

Preparation of platelet suspensions. Venous blood was drawn from healthy adults who had not taken any drugs for at least ten days before venipuncture, and platelets were isolated as previously described (8). Briefly, after centrifugation of the blood at 200 × *g* for 20 min, platelet-rich plasma was acidified to pH 6.4 with 0.15 M citric acid and centrifuged at 900 × *g* for 10 min. Platelets were then resuspended into a Tyrode-HEPES buffer without external calcium (137 mM NaCl, 2.7 mM KCl, 11.9 mM $NaHCO_3$, 0.41 mM NaH_2PO_4, 1 mM $MgCl_2$, 5 mM HEPES, 5.5 mM glucose; pH 7.35). The platelet suspensions were incubated in the absence or presence of 10^{-6}M diamide for one hr at 37°C. Different parameters of the antioxidant status and of lipid peroxidation were then analyzed.

Glutathione measurement. For GSH determinations, platelet suspensions were extracted with methylene chloride in order to lyse platelets and remove diamide. After centrifugation, the upper aqueous layer was removed and assayed for total and reduced glutathione according to a modification of the method of Neuschwander-Tetri and Roll (9). For total glutathione measurement, disulfides were reduced with dithiothreitol in a first step. GSH was derivatized with *ortho*-phthaldialdehyde (OPT) and the GSH-OPT complex was quantified after reverse phase high-performance liquid chromatography (rp-HPLC) by measuring its ultraviolet (UV) absorbance at 340 nm (Fig. 1 A).

Measurement of the reduction of hydroperoxides. The ability of platelets to reduce hydroperoxides to hydroxy derivatives was investigated. The hydroperoxy derivative of AA used was 15-HPETE. 15-HPETE has been reported to inhibit 12-lipoxygenase activity (10); in addition, 15-HPETE is a physiological substrate of GSH-dependent peroxidase. Briefly, platelet suspensions were incubated with or without 10^{-6}M diamide for one hr at 37°C. The reaction was initiated by the addition of 10 μM [^{14}C]15-HPETE, which was obtained by incubating soybean lipoxygenase with [^{14}C]AA (11). The assay was terminated after one min at 37°C by extraction of the com-

Abbreviations: AA, arachidonic acid; BHT, butylated hydroxytoluene; GSH, reduced glutathione; GSH-Px, glutathione-peroxidase; (12 or 15)-HETE, (12 or 15)-hydroxy-eicosatetraenoic acid; 12-HHT, 12-hydroxy-heptadecatrienoic acid; (12 or 15)-HPETE, (12 or 15)-hydroperoxy-eicosatetraenoic acid; MDA, malondialdehyde; NADPH, reduced nicotinamide adenine dinucleotide phosphate; OPT, *ortho*-phthaldialdehyde; rp-HPLC, reverse phase high-performance liquid chromatography; TBA, thiobarbituric acid; TLC, thin-layer chromatography; UV, ultraviolet.

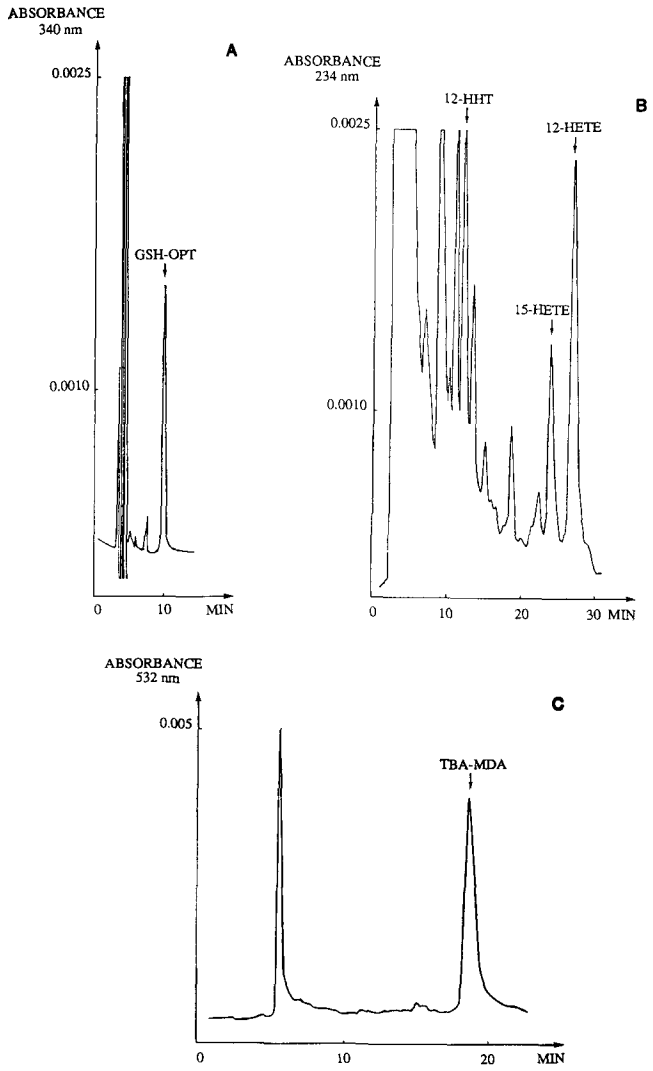

FIG. 1. Typical rp-HPLC separations of different parameters obtained from diamide-treated platelets. (A) GSH (*i.e.* GSH-OPT complex) was separated on a 25-cm column packed with Nucleosil C_{18} (5μm) and was eluted with 0.15M sodium acetate, pH 7/methanol (92.5:7.5, v/v) at a flow rate of 0.8 mL/min. (B) Monohydroxylated fatty acids (12-HHT and 12-HETE) and 15-HETE, the internal standard, were separated on a 25-cm column packed with Nucleosil C_{18} (5μm). The mobile phase, methanol/water (pH 3, with acetic acid) (75:25, v/v), was pumped at 0.7 mL/min. (C) MDA (*i.e.* TBA-MDA complex) was separated on a 15-cm column packed with Nucleosil C_{18} (5μm) and was eluted with water/methanol (80:20, v/v) at a flow rate of 1 mL/min.

pounds at pH 3 with diethyl ether. The hydroperoxy compound was separated from the hydroxy derivative by thin-layer chromatography (TLC) using the solvent mixture diethyl ether/hexane/acetic acid (85:15:0.1, v/v/v). Peroxidase activity was evaluated by determining the amount of [^{14}C]15-HETE formed in one min per 10^9 platelets using a Berthold TLC scanner (Elancourt, France). The classical measurement of GSH-Px activity according to Paglia and Valentine (12) could not be used in our model. The conventional assay was performed in the presence of an excess GSH (mM concentration) and of the recycling system, GSH-reductase and NADPH. The addition of an excess GSH to diamide-treated platelets would restore the capacity of cells to reduce hydroperoxides, *i.e.* peroxidase activity.

Basal metabolism of endogenous AA. The platelet lipids were extracted twice with chloroform/ethanol (2:1, v/v) containing 5×10^{-5}M butylated hydroxytoluene (BHT) as an antioxidant, in the presence of 15-HETE as an internal standard. After separation by TLC with the eluent mixture hexane/diethyl ether/acetic acid (60:40:1, v/v/v) (13), and extraction from the silica-gel with diethyl ether, 12-HHT and 12-HETE were analyzed by rp-HPLC and measured at 234 nm (14) (Fig. 1 B).

Malondialdehyde (MDA) determination. MDA was determined as an index of overall lipid peroxidation by rp-HPLC according to the method of Therasse and Lemonnier (15). Briefly, the platelet suspensions were incubated for one hr at 95°C at low pH with 10 mM thiobarbituric acid (TBA) in phosphate buffer (0.1 M, pH 3) and in the presence of BHT. The TBA-MDA complex was extracted with ethyl acetate and quantified by rp-HPLC at 532 nm (Fig. 1 C).

Vitamin E determination. Vitamin E determinations were done according to a previously reported method (7). The platelet suspensions were mixed with two volumes of ethanol/water (1:1, v/v) containing 1% ascorbic acid as an antioxidant and tocol as an internal standard. After extracting twice with three volumes of hexane, the vitamin E extract was analyzed by rp-HPLC and measured at 292 nm (16).

Statistics. Student's paired t-test was used to compare the different groups of data.

RESULTS

Diamide, a well-known thiol-oxidizing agent, has been reported to lower the level of GSH (17), a cofactor of the peroxidase activity associated with platelet lipoxygenase (2). Treatment of platelets with 10^{-6}M diamide for one hr at 37°C resulted in a substantial and significant decrease (28%) in the primary antioxidant, GSH (Table 1), whereas total glutathione was not significantly depressed (data not shown). In order to evaluate the ability of the cells to convert hydroperoxides to the corresponding hydroxylated fatty acids *via* the lipoxygenase cascade, *e.g.* to determine the peroxidase activity *in situ*, 15-HPETE was used as a physiological substrate and its reduction rate to 15-HETE was determined. Diamide treatment impaired the reduction of 15-HPETE to 15-HETE by one-third (Table 1) corresponding to the lower ability of cells to reduce hydroperoxides.

The effect of 10^{-6}M diamide on platelet lipid peroxidation, in the absence of agonist-specific stimulation, is shown in Table 2. The basal metabolism of platelet endogenous AA, *via* cyclooxygenase and lipoxygenase pathways, was modified after diamide treatment. The formation of the lipoxygenase end-product, 12-HETE, increased significantly in GSH-depleted platelets (40.4 pmol/10^9 in diamide-treated platelets *versus* 32.9 pmol/10^9 in controls). Simultaneous measurement of 12-HHT, a cyclooxygenase by-product of AA, revealed that its formation tended to increase under diamide treatment, although not significantly (data not shown). The overall lipid peroxidation was also affected by diamide treatment; the formation of MDA increased by 58% in GSH-depleted platelets compared to controls.

TABLE 1

Effect of 10^{-6}M Diamide on Different Parameters of Platelet Antioxidant Status

Diamide (M)	GSH[a]	[^{14}C]15-HETE formation[b] (peroxidase activity)	α-Tocopherol[c]
0	16.3 ± 4.5	9.2 ± 3.0	1.01 ± 0.08
10^{-6}	11.6 ± 3.2[d]	6.1 ± 1.9[d]	0.77 ± 0.08[d]

[a]Results are expressed in nmol/10^9platelets as means ± SEM of six determinations.

[b]Results, corresponding to the rate of reduction of [^{14}C]15-HPETE (10 μM for 1 min incubation at 37°C) by platelet peroxidase, are expressed in nmol/min/10^9 platelets as means ± SEM of eight determinations.

[c]Results are expressed in nmol/10^9 platelets as means ± SEM of six determinations.

[d]Values significantly different from control ($p<0.05$).

TABLE 2

Basal Lipid Peroxidation in Control and Diamide-Treated Platelets[a]

Diamide (M)	12-HETE	MDA
0	32.9 ± 4.9	122.7 ± 38.3
10^{-6}	40.4 ± 5.1[b]	194.8 ± 53.4[b]

[a]Results, in pmol/10^9 platelets, are means ± SEM of six determinations for 12-HETE derived from endogenous AA and of eight determinations for the TBA-MDA complex.

[b]Values significantly different from control ($p<0.01$).

The effect of 10^{-6}M diamide on platelet vitamin E content is shown in Table 1. α-Tocopherol concentration in diamide-treated platelets was significantly reduced when compared to control platelets (0.77 ± 0.08 nmol/10^9 in diamide-treated platelets *versus* 1.01 ± 0.08 nmol/10^9 in controls). No corresponding decrease in γ-tocopherol concentration was observed (0.037 ± 0.005 nmol/10^9 in diamide-treated platelets *versus* 0.038 ± 0.004 nmol/10^9 in controls).

Higher concentrations of diamide (10^{-5}M and 10^{-4}M) did not lead to either an increase in lipoxygenase activity or a further decrease in α-tocopherol concentration (data not shown).

DISCUSSION

It has been reported that the platelets from elderly populations demonstrate a moderate decrease in their vitamin E content (6,7). This has also been associated with increased peroxidation of AA (18). We have explored the mechanism of this relationship by treating normal platelets *in vitro* with diamide. The diamide induced oxidative stress by depleting the platelets of GSH.

Incubation of platelets, in the presence of 10^{-6}M diamide, for one hr at 37°C, without specific stimulation, resulted in a partial and significant decrease of GSH but not of total glutathione, suggesting that complete GSH regeneration did not occur in diamide-treated platelets under these conditions. As a result of a lesser recycling of oxidized glutathione, the hexose monophosphate shunt, which provides NADPH for the replenishment of GSH, may not have been significantly stimulated by the low concentration of diamide. In contrast, the hexose monophosphate shunt may have been involved in higher concentrations of diamide where no additional effect was noticed.

In accordance with the lowered GSH level, the peroxidase activity, evaluated by using 15-HPETE as a substrate, was depressed in diamide-treated platelets, which may have been due to the decrease of the enzyme cofactor, GSH. The 12-HPETE peroxidase is assumed to be a glutathione-dependent peroxidase requiring selenium at the active site (19,20).

The partial depletion of both the GSH level and peroxidase activity might have led to a transitory enhancement of 12-HPETE (2). 12-HPETE has been shown to markedly stimulate its own biosynthesis from the endogenous pool of non-esterified AA (3). In agreement with a presumed increase of lipoxygenase activity by 12-HPETE, we have indeed observed enhanced formation of the end-product of the lipoxygenase pathway, 12-HETE, in diamide-treated platelets. The increase of 12-HETE appears somewhat paradoxical on account of the lower ability of diamide-treated platelets to reduce hydroperoxides. However, we assume that the remaining peroxidase (around two-thirds of the total activity) is high enough to reduce the unstable 12-HPETE entirely. Moreover, the formation of a cyclooxygenase by-product of AA, 12-HHT, tended to be stimulated. This also agrees with previous results showing that platelet cyclooxygenase is less responsive to 12-HPETE than lipoxygenase (4,21). It is important to point out that the levels of the AA metabolites present in unstimulated platelets were very low (around 50 pmol/10^9 platelets) compared with the levels of AA metabolites in agonist-stimulated platelets. It corresponds with the very low amount of unesterified AA in unstimulated platelets (22,23) compared with the amount of free AA pool in activated platelets. More generally, MDA, which is formed either by the physicochemical degradation of lipid peroxides or by the cleavage of the cyclopentane ring of cyclic prostaglandin endoperoxides (24), was increased after diamide treatment, which means that 12-HPETE may not be the only peroxide responsible for the enhanced AA oxygenation. Although other peroxides might have contributed to the stimulation of oxygenases, we suggest that the transient accumulation of 12-HPETE could have been responsible for the increased oxygenase activities which are thought to be stimulated by peroxides (25).

Finally, platelet α-tocopherol, which is the most important antioxidant, was depressed after diamide treatment, whereas the much less effective γ-tocopherol (26) re-

mained unchanged. This is in good agreement with the results of Vatassery (27) who reported that diamide, in final concentrations of 2–5 mM, decreases platelet α-tocopherol by partially converting it to α-tocopherolquinone. The most probable explanation for the reduction of α-tocopherol in GSH-depleted platelets is the increased peroxide level which may have led to oxidation of vitamin E acting as a scavenger of peroxyl radicals. Such a reduction may also be considered as a marker of an elevated peroxide level in the cell.

Overall, the decreased platelet antioxidant status, of which vitamin E, GSH and peroxidase activity are some parameters, may be linked to an enhanced lipoxygenation of endogenous AA. We presume that the transient accumulation of 12-HPETE might lead to an increased formation of pro-aggregatory eicosanoids (responsible for at least part of the platelet hyperactivity).

We conclude from this study that lipoxygenase activity and α-tocopherol may be linked through a redox cascade. Although further studies are needed to demonstrate this, it is tempting to speculate that 12-HETE might be a biochemical marker of platelet lipid peroxidation in pre-thrombotic states (5,7).

Characterization of the Coronary Vascular Responses to Platelet-Activating Factor in the Isolated Perfused Heart

Weimin Hu, Patrick C. Choy and Ricky Y.K. Man*
Department of Pharmacology and Therapeutics, and Department of Biochemistry, Faculty of Medicine, University of Manitoba, Winnipeg, Manitoba, Canada R3E OW3

Platelet-activating factor (PAF) is a potent phospholipid mediator with diverse *in vivo* and *in vitro* coronary vascular effects. In the present study, the coronary vascular responses to bolus injections of PAF were compared in rat hearts perfused under constant flow and under constant pressure. Low levels of PAF (1 pmol) produced vasodilatation only, while higher PAF concentrations (100 pmol) produced initial vasodilatation which was followed by a vasoconstriction under both experimental conditions. To determine species differences in PAF action, the effect of PAF was tested on perfused guinea pig hearts. Unlike in perfused rat hearts, only a dose-dependent vasoconstrictor response was observed in perfused guinea pig hearts following a bolus injection of 1 fmol to 10 pmol of PAF. The results from repeated injections of PAF indicated that depletion of vasoactive mediators induced by PAF or receptor desensitization may explain a failure of a second injection of PAF to initiate a vasoconstrictor response. After PAF injection, the coronary vascular response to leukotriene was not altered, indicating that the reduced vasoconstrictor effect of a second injection of PAF cannot be due to a reduced ability of the smooth muscle to constrict. The study demonstrates that similar coronary vascular responses to PAF are observed in perfused rat hearts under either constant flow rate or constant pressure and that some of the variable coronary vascular responses reported may be due to the difference between animal species.
***Lipids* 26, 700-704 (1991).**

Platelet-activating factor (PAF) is a phospholipid mediator with vasoactive properties (1-3). The diverse cardiovascular effects of PAF in coronary circulation have been shown in a number of studies *in vivo* and *in vitro*. Vasoconstrictor effects of PAF were observed in guinea pig and rat hearts perfused at a constant perfusion pressure (4) and at a constant flow rate (5). In the anesthetized dog, Sybertz *et al.* (6) reported a vasoconstrictor response after an intracoronary injection of PAF while a vasodilator response, as indicated by an increase in coronary flow, was reported by Jackson *et al.* (7). These differences may be due to different experimental conditions. A biphasic response characterized by vasodilatation followed by vasoconstriction after intracoronary injection of PAF was shown in other studies (8-11). We have previously demonstrated that depending on the experimental conditions, coronary vasodilatation, vasoconstriction, or a combination of both responses can be observed following bolus injections of PAF in the isolated rat heart perfused at a constant flow rate (12).

Abbreviations: LTC_4, leukotriene C_4; PAF, platelet-activating factor.

Depending on experimental conditions, changes in vascular tone by a vasoactive compound in the perfused heart can result in changes in the flow rate if the perfusion pressure is kept constant, or in changes in perfusion pressure if the flow rate is kept constant. In the present study, we sought to demonstrate a similar response to PAF in isolated rat hearts perfused at a constant pressure as compared to using a constant flow rate. The platelets of various animal species have been reported as having different sensitivities to PAF (13). Therefore, we also investigated the effects of PAF in guinea pig hearts to determine whether a similar vasodilator and/or vasoconstrictor response could be observed following bolus injections of PAF. It has been reported that in *in vitro* studies repeated injections of PAF did not elicit a vasoconstrictor response (5,12,14). Possible explanations include desensitization of PAF receptors, depletion of vasoactive mediators induced by PAF, or loss of vascular smooth muscle response to PAF or its mediators. In the present study, we attempted to further investigate the possible mechanisms for the lack of coronary vascular response to repeated injections of PAF.

MATERIALS AND METHODS

Materials. PAF (1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine, prepared from bovine heart) and bovine serum albumin were purchased from Sigma Chemical Co. (St. Louis, MO). Leukotriene C_4 (LTC_4) was a gift from Merck Frosst Canada Inc. (Montreal, Canada). All other chemicals and reagents were obtained from Fisher Chemical of Canada (Edmonton, Canada) and Canlab Scientific (Winnipeg, Canada).

Heart perfusion. Male Sprague-Dawley rats (250-300 g) and Hartley guinea pigs (300-400 g) were killed by cervical dislocation 15 min after heparin (1000 μ/kg, i.p.) was administered. Hearts were rapidly excised and placed in ice-cold Krebs-Henseleit solution gassed with 95% O_2/5% CO_2. The Langendorff technique was used to perfuse hearts with Krebs-Henseleit solution which was maintained at 37 $\pm$ 0.5°C and gassed with 95% O_2/5% CO_2. The composition of Krebs-Henseleit solution was as follows (mM): NaCl 120, KCl 4.7, NaH_2PO_4 1.18, $MgSO_4$ 1.18, $CaCl_2$ 1.25, $NaHCO_3$ 25, and glucose 5.5. The heart was allowed to beat spontaneously and was perfused at a constant flow rate or under a constant perfusion pressure. The perfusion pressure was measured by attaching a pressure transducer (Bentley Trantec Model 800, Bentley Laboratories of Canada, Markham, Canada) to a side arm of the aortic cannula. To measure changes in flow rate under constant pressure perfusion, the flow rate was measured by a electromagnetic flow meter (Carolina Medical Electronics, King, North Carolina). Both perfusion pressure and flow rate were recorded on a Gould chart recorder and monitored with a digital display of the perfusion pressure and flow rate. The procedures to determine the coronary vascular effects of PAF in the perfused rat heart have been described previously (12).

Drug preparation and administration. Hearts were equilibrated for 20 min using Krebs-Henseleit solution. In some experiments, the flow rate was adjusted to obtain a perfusion pressure of 65–75 mm Hg during the equilibration period and was kept constant for the rest of the experiment. In experiments in which the perfusion pressure was kept constant, the pressure was set at 70 mm Hg. PAF was prepared in saline (0.9% NaCl) solution containing 0.25% bovine serum albumin. LTC_4 was diluted in saline to the appropriate concentration. All stock solutions were made fresh daily and refrigerated between experiments. All bolus injections of PAF and LTC_4 were given a volume of 0.1 mL over a one-second period, into the perfusion line 5–6 cm proximal to the aortic cannula. In some experiments, a second injection was administered 10 min after the first injection. Changes in perfusion pressure or flow rate and the time at which maximum changes occurred were recorded.

Statistical analyses. The data were analyzed by Student's t-test, or one-way analysis of variance followed by Duncan's multiple range test where appropriate. Values were expressed as means and standard deviations (S.D.). A P value less than 0.05 was considered statistically significant.

RESULTS

Comparison of the coronary vascular responses to PAF in rat hearts using constant flow or constant pressure perfusion. Comparisons of the parameters of constant flow perfusion with those of constant pressure perfusion are shown in Tables 1 and 2. There was no significant difference in the flow rates required to attain a control pressure between 65–75 mm Hg using constant flow perfusion from those used at a constant perfusion pressure of 70 mm Hg. Bolus injections of 1 pmol PAF produced only vasodilatation (a decrease in perfusion pressure and an increase in perfusion flow rate in hearts using constant flow and constant pressure perfusion, respectively). With 100 pmol PAF (bolus injection), a biphasic response characterized by an initial vasodilatation followed by a vasoconstriction was observed. These results are summarized in Tables 1 and 2. The time to reach a peak response for the initial vasodilatation and the subsequent vasoconstriction when 100 pmol PAF was administered were similar in hearts perfused under constant flow and constant pressure conditions ($P > 0.05$).

The effect of PAF in perfused guinea pig hearts. To determine the coronary vascular effect of PAF in another animal species, experiments were conducted using guinea pig hearts. The results of bolus injections of PAF in guinea pig hearts using constant flow perfusion are summarized in Table 3. An injection of PAF ranging from 1 fmol to 1 pmol resulted in only a vasoconstrictor response. No vasodilator response was observed with any of the amounts of PAF tested in perfused guinea pig hearts. The magnitude of the vasoconstriction was dose-dependent. Serial dilution was used to obtain the very small amounts of PAF used for injections. The recovery after the dilution was determined by using [^{3}H]PAF. The accuracy of

the recovery was limited by the specific radioactivity of the PAF used (81 Ci/mmol). The lowest amount of PAF that we were able to measure reliably was 1 fmol. Hence further dilution to obtain a quantity smaller than 1 fmol was not used.

The effects of repeated injections of PAF in rat hearts. After a bolus injection of 100 pmol of PAF in the perfused rat heart, a second injection of 100 pmol of PAF did not produce any significant change in the perfusion pressure as reported previously (5,12). Figure 1 shows the coronary vascular effect of PAF was transient and the perfusion pressure returned to baseline level within 10 min (67 ± 3 mm Hg before PAF injection and 69 ± 6 mm Hg 10 min after PAF injection, n = 8). The second injection of PAF was therefore given after 10 min of the first injection in the rest of this study. The coronary vascular responses to a second injection of PAF was dependent on the amount of PAF given in the first injection. These results are summarized in Table 4. When 1 pmol PAF was administered first, a second injection of 10 or 100 pmol PAF resulted in an initial vasodilatation followed by a vasoconstriction. After an initial injection of 1 pmol PAF, the vasodilatation produced by 10 pmol PAF was significantly greater while the vasoconstriction was greatly reduced (Table 4). The vasoconstriction produced by a second injection of 100 pmol PAF was also reduced when compared to that produced by an initial injection of 100 pmol PAF (22.1 ± 6.2, n = 9 and 29.1 ± 12.4, n = 11 respectively, $P > 0.5$). When 10 pmol PAF was given in the first injection, a second injection of 10 pmol PAF did not produce a significant vasoconstrictor response while a second injection of 100 pmol PAF resulted in a significant vasoconstriction (Table 4). However, the vasoconstriction produced by a second injection of 100 pmol PAF was reduced (18.8 ± 10.3, n = 6, $P < 0.05$ when compared to the effect of an initial injection of 100 pmol PAF). In contrast, if 100 pmol PAF was given in the initial injection, a second injection of PAF (100 and 10,000 pmol) did not elicit any significant vasoconstriction (Table 4).

To determine whether the tachyphylaxis after an injection of 100 pmol PAF was time-dependent, a second injection of 100 pmol PAF was given after 60, 90 or 120 min after a first injection of 100 pmol PAF in separate experiments. The vasodilatation and vasoconstriction by a second injection of 100 pmol PAF was 6.0 ± 1.7 and 0 mm Hg respectively after 60 min (n = 3), 7.7 ± 2.1 and 0.7 ± 1.2 mm Hg respectively after 90 min (n = 3), and 5.7 ± 2.1 and 0.7 ± 0.6 mm Hg, respectively, after 120 min (n = 3). These effects were not statistically different from those obtained with a second injection of 100 pmol PAF, 10 min after the first injection of 100 pmol PAF. The results indicate that there was no time-dependent recovery of the vasoconstrictor response to PAF.

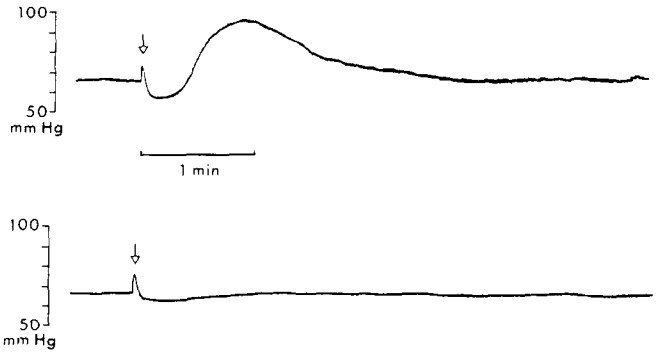

FIG. 1. Original tracings showing the changes in perfusion pressure in a perfused rat heart when 100 pmol PAF was injected first (top tracing) and 10 min later (bottom tracing). The heart was perfused using a constant flow rate as described in Materials and Methods. Arrow indicates the time when 100 pmol PAF was given as a bolus injection (a small injection artifact is displayed on the tracing). A first injection of 100 pmol PAF produced an initial vasodilatation followed by a vasoconstriction (top tracing). Perfusion pressure returned to preinjection level within approximately 5 min after the first injection of PAF. No significant change in perfusion pressure was observed when a second injection of 100 pmol PAF was administered 10 min later (bottom tracing).

The coronary vascular responses to bolus injections of PAF and LTC_4 in the same isolated perfused rat heart. To determine the response of the perfused rat heart to repeated exposure to different vasoactive compounds, PAF and LTC_4 were administered. The coronary vascular responses of the same hearts to PAF and LTC_4 are summarized in Table 5. There was no significant difference in the coronary vascular response to an injection of 100 pmol PAF in hearts with and without a previous administration of 50 pmol LTC_4. The vasoconstriction produced by 50 pmol LTC_4 was also similar in hearts with or without a previous administration of 100 pmol PAF (Table 5).

TABLE 5

The Effects of Injection Order of PAF and LTC_4 on the Perfusion Pressure of Rat Hearts[a]

Compound	Control perfusion pressure (mm Hg)	Decrease in perfusion pressure		Increase in perfusion pressure		n
		Maximum (mm Hg)	Time to peak (s)	Maximum (mm Hg)	Time to peak (s)	
First injection PAF (100 pmol)	69 ± 3	12.7 ± 12.5	13 ± 6	22.9 ± 9.0[b]	76 ± 22	
Second injection LTC_4 (50 pmol)	69 ± 6	—[c]	—[c]	41.0 ± 31.2[d]	9 ± 1	3
First injection LTC_4 (50 pmol)	69 ± 6	—[c]	—[c]	41.2 ± 26.0	17 ± 11	
Second injection PAF (100 pmol)	69 ± 4	5.0 ± 4.2	10 ± 1	29.4 ± 24.4	44 ± 21	5

[a]Hearts were perfused using a constant flow rate. Values represent mean ± S.D.

[b]No statistical difference in the increase in perfusion pressure was detected when PAF was injected first or when PAF was injected second, 10 min after a first injection of LTC_4.

[c]Denotes no detectable change.

[d]No statistical difference in the increase in perfusion pressure was detected when LTC_4 was injected first or when LTC_4 was injected second, 10 min after a first injection of PAF.

DISCUSSION

In a previous study, we have demonstrated that bolus injections of PAF resulted in coronary vasodilatation, vasoconstriction, or the combination of both responses in isolated perfused rat heart (12). Perfusion flow was kept constant in these experiments and any change in vascular resistance was reflected by a change in the perfusion pressure. Alternatively, perfusion pressure can be kept constant and changes in vascular resistance can be measured as changes in flow rate. However, changes in vascular resistance by a vasoactive compound, in particular intense vasoconstriction, could produce relative ischemia which might change the subsequent coronary vascular response. In *in vivo* studies where a small amount of PAF was administered by an intracoronary injection, the perfusion pressure or the systemic blood pressure was usually not affected and alterations in vascular resistance resulted in changes in coronary blood flow. Hearts perfused under a constant pressure would mimic more closely the situation of *in vivo* studies. In the present study, the coronary vascular responses to PAF were similar under constant flow and constant pressure perfusion. Our data therefore suggest that different modes of perfusion are not a factor in the diverse results of previous studies on the coronary vascular effects of PAF.

In the present study, PAF only elicited a vasoconstrictor response, and the vasodilator response was not observed in the perfused guinea pig heart. The lowest amount of PAF tested (1 fmol) was still capable of producing a significant vasoconstrictor response in the perfused guinea pig heart. However, our previous study showed that 10 pmol of PAF was needed to elicit a significant coronary vasoconstrictor effect in the rat heart (12). These results are consistent with the report that the guinea pig heart was more sensitive to the cardiac action of PAF than the rat heart (14-16). In this regard, rat platelets had been shown to be insensitive to PAF due to a lack of PAF receptors while platelets from other animals including rabbit, dog, guinea pig and sheep were sensitive to PAF (13,17). Our results suggest that species differences may be a contributing factor to the reported diverse coronary vascular responses to PAF.

Repeated injections of PAF did not elicit a vasoconstrictor response in the perfused heart (5,12,14). Possible explanations include desensitization of PAF receptors, depletion of vasoactive mediators produced by PAF, and loss of vascular smooth muscle response to PAF or its mediators. In the present study, we found that the vasoconstrictor response to a second injection of PAF was dependent on the amounts of PAF given in the first and second injections. If the initial injection of PAF was small (1-10 pmol), a second injection of 10 pmol PAF produced only a small vasoconstrictor response while 100 pmol PAF could still produce a significant vasoconstrictor response. However, 100 pmol PAF in the initial injection would abolish or greatly diminish the vasoconstrictor response to PAF irrespective of the amount of PAF in the second injection. This indicates that depletion of vasoactive mediator induced by the initial injection of PAF may be the mechanism for the reduced coronary vascular response to subsequent injections of PAF. Alternatively, the exposure to 100 pmol PAF in the initial injection may cause receptor desensitization. This leads to a reduction or elimination of subsequent response to PAF in the perfused rat heart. The exposure to a smaller amount of PAF may produce only partial or incomplete desensitization. Thus a reduction of the coronary vascular effect to a second injection of PAF would be expected. In contrast, repeated intracoronary injections of PAF produced similar vascular responses *in vivo* (8-11). It is therefore unlikely that receptor desensitization occurred in *in vivo* studies. Alternatively, it can be speculated that depletion of vasoactive compounds after an initial injection of PAF only occurs in perfused hearts, while these vasoactive compounds can be replenished quickly *in vivo* to enable the heart to respond to subsequent injections of PAF.

It has been suggested that the coronary vasoconstrictor effect of PAF was indirectly mediated by the release of LTC_4 (5), and leukotrienes including LTC_4 have been shown to possess vasoconstrictor properties. The role of LTC_4 in mediating the coronary vasoconstrictor effect of PAF was further confirmed by the detection and quantitation of LTC_4 in the coronary effluent after the administration of PAF in the perfused heart (5). In order to determine whether the reduced response to a second injection of PAF was due to an altered coronary vascular response to leukotrienes, the effect of LTC_4 was examined. Our results indicated that there was no change in the coronary vascular responses to PAF or LTC_4 which were injected to the same perfused rat heart irrespective of the injection order of the two compounds. In spite of a significant loss of vasoconstrictor response to a second administration of PAF after a first injection of PAF in the perfused rat heart, our data show that the heart was still capable of generating a normal vasoconstriction in the presence of LTC_4. Therefore, the mechanism for a reduction or elimination of the PAF response after an initial injection of PAF cannot be due to a failure of the coronary vascular smooth muscle to constrict in response to LTC_4.

In summary, we have shown that diverse coronary vascular responses to PAF can be observed in two animal species and that the diverse responses are not due to the different perfusion models used in the isolated heart studies. Our data indicate that depletion of vasoactive mediator induced by PAF and/or receptor desensitization could be the reason why the vasoconstrictor response fails after repeated injections of PAF into perfused hearts. However, the mechanism(s) for the desensitization of the PAF receptor or for the depletion of vasoactive mediators after exposure to PAF remains to be elucidated.

ACKNOWLEDGMENTS

We wish to thank Dr. Ford-Hutchison of Merck Frosst Canada Inc. for the supply of LTC_4. This study was supported by the Manitoba Health Research Council and the MRC of Canada. The assistance of Ms. Anne A.A. Kinnaird is greatly appreciated.

Modulation of Polyunsaturated Fatty Acid Content of Triglycerides in Rat Pre-Adipocytes in Culture

Grace R. Gavino and Victor C. Gavino*
Department of Nutrition, Université de Montréal, Montréal, Québec Canada H3C 3J7

Rat peri-renal and epididymal pre-adipocytes in culture undergoing triglyceride (TG) accumulation were incubated with oleic (18:1), linoleic (18:2), α-linolenic (18:3ω3), arachidonic (20:4) and 4,7,10,13,16,19-docosahexaenoic (22:6ω3) acids in the presence of 0.8 μM insulin. The fatty acids were incorporated in cellular TG with relative enrichments over control from 1.4-fold for 18:1 to greater than 40-fold for 18:3ω3. Greater than 80% of fatty acids taken up were incorporated into cellular TG. The balance was distributed, in decreasing amounts, into phospholipids, unidentified intracellular constituents, and ketone bodies. The P/S ratio of cellular TG was at least an order of magnitude lower than that of the external milieu for both cell types and for all treatment groups, including controls. Doubling the concentration of treatment fatty acid increased its incorporation into cellular TG. However, it did not affect the accumulation of the other fatty acids in TG. Epididymal cells consistently acquire a higher proportion of treatment fatty acids in cell TG than peri-renal cells. Pre-adipocytes with polyunsaturated fatty acids (PUFA)-enriched TG is a potential model for the study of PUFA metabolism in these types of cells.
***Lipids* 26, 705–710 (1991).**

Rat peri-renal or epididymal-derived pre-adipocytes in culture have been used as model systems for adipocytes and adipose tissue metabolism (1–3). An important aspect of adipose tissue metabolism is the control of the flux of various fatty acids as they are esterified into adipose triglyceride (TG) and released into the circulation as serum-bound non-esterified fatty acids. Adipose tissue contains a lower proportion of polyunsaturated fatty acids (PUFA) relative to other tissues and organs of the body (4–12), a phenomenon that has not yet been adequately explained. It has, however, been difficult to study PUFA metabolism in adipose tissue not only because of the low proportion of PUFA, but also because adipose TG fatty acid composition adapts slowly to the fatty acid profile in the diet (4,13). In this communication, we describe an *in vitro* method for the PUFA enrichment of accumulating TG in cultured pre-adipocytes. Pre-adipocytes with PUFA-enriched TG may serve as a useful model for the study of PUFA metabolism in these types of cells.

EXPERIMENTAL PROCEDURES

Cell culture. Pre-adipocytes were prepared from rat epididymal and peri-renal fat pads by collagenase digestion as described by Van and Roncari (1). The cells were cultured in Falcon 9.6 cm^2 6-well plates (Ingram and Bell, Montréal, Canada) as described by Wiederer and Loffler (14), using culture medium consisting of M199E (Gibco, Grand Island, NY), 10% (v/v) iron transferrin-enriched bovine calf serum (Hyclone, Logan, UT), and the antibiotics penicillin (100 U/mL) and streptomycin (0.1 mg/mL). After 2 population doublings, fat-filling of the cells was induced by replacing the culture medium with differentiation medium. The latter consisted of M199E plus penicillin and streptomycin, 1% (v/v) fetal bovine serum (Gibco), 4% (v/v) CPSR-1 (a delipidized serum replacer from Sigma, St. Louis, MO), 10 mM glucose, 0.8 μM bovine insulin (Sigma), 0.1 μM corticosterone (Boehringer, Montréal, Canada) and 0.5 mM methylisobutylxanthine (Sigma). After 48 hr, the culture medium was again replaced with differentiation medium minus methylisobutylxanthine (14), and supplemented with various concentrations of different non-esterified fatty acids (NEFA) (NuChek Prep, Elysian, MN) complexed to CPSR-1. As an antioxidant, 5 μM of 2,3-di-*tert*-butyl-4-methylphenol was added to the NEFA-supplemented differentiation medium. Differentiation was monitored by the induction of glycerol-3-phosphate dehydrogenase (G3PDH) (15). Fat-filling of the pre-adipocytes was assayed by quantitative gas-chromatographic analysis of intracellular TG (described below) and by the accumulation of visually-apparent intracellular lipid droplets in cultures stained with osmium tetroxide (16).

Fatty acid incubations. Pre-adipocytes were incubated with fatty acid-supplemented differentiation medium for 4 days. During this period, the differentiation medium was renewed every day in order to maximize the uptake of treatment fatty acids by the cells. [1-^{14}C]-Labeled fatty acids (Dupont, Montréal, Québec Canada) were used to monitor fatty acid uptake by the cells. Uptake was calculated as the disappearance of non-acid volatile radioactivity from the differentiation medium summed over the 4-day incubation period. Non-acid volatile radioactivity was determined by acidifying aliquots of differentiation medium with a tenth volume of 12N HCl followed by incubation at 37°C for 60 min before counting. This procedure completely expels CO_2 from the samples. Calculations of fatty acid uptake were corrected for the release of ketone bodies which are also non-acid volatile. Ketone body production was estimated in aliquots of differentiation medium as $HClO_4$-soluble radioactivity. Using radiolabeled fatty acids, we verified that NEFA co-precipitate completely with protein upon $HClO_4$ treatment (data not shown). Fatty acid uptake data derived from radiolabel experiments were verified by quantitative gas-chromatographic analysis of non-esterified fatty acid in the differentiation media (see below) before and after cell incubation. Total intracellular radioactivity was determined in cells that had been rinsed and digested with 0.2N NaOH in 50% aqueous methanol.

Lipid analyses. Lipids were extracted from cultured

cells, fractionated into a TG and phospholipid (PL) fraction and analyzed as fatty acid methyl esters (FAME) by gas-chromatography as described previously (17). NEFA in the culture media was extracted and derivatized to FAME with diazomethane. Quantification of lipid classes was accomplished by the internal standard method using tri-heptadecanoylglycerol for the TG fraction, 1,2-diheptadecanoyl phosphatidylcholine for the PL fraction, and heptadecanoic acid for the NEFA fraction. Internal standards were added to the samples at the time of lipid extraction. FAME were separated using a Carbowax-bonded phase 30 m fused silica capillary column (Chromatographic Specialties, Brockville, Ontario Canada). Detection was by flame ionization. The gas chromatograph was calibrated using standard FAME mixtures (NuChek). In experiments involving the extraction and quantitation of [1-^{14}C]-labeled lipids, the corresponding ^{3}H-labeled lipids were used as recovery standards.

Miscellaneous. Cell counts were performed with a hemocytometer after release with trypsin. All solvents were redistilled before use. Chemicals were reagent grade or better.

RESULTS

G3PDH has been used as a late differentiation marker for pre-adipocytes (14). Figure 1 shows that the appearance of G3PDH activity was induced by the treatment of cultured pre-adipocytes with differentiation medium which had 1% fetal calf serum plus 4% lipid-poor serum replacer CPSR-1. This proportion between the serum supplements was found to be optimal for lipid-filling in the cultured pre-adipocytes. Various other proportions of fetal calf serum and CPSR-1 serum replacer were tried and found inadequate with respect to cell survival and/or differentiation (data not shown). Figure 1 shows that insulin concentration did not influence the rate nor the extent of G3PDH induction in epididymal pre-adipocytes. Figure 1 suggests, however, that G3PDH induction in peri-renal pre-adipocytes is facilitated with a high (0.8 μM) concentration compared to a low (0.01 μM) concentration of insulin.

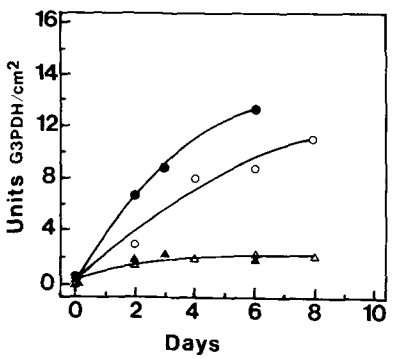

FIG. 1. Expression of glycerol-3-phosphate dehydrogenase activity during the differentiation of rat epididymal and peri-renal pre-adipocytes in culture. Batchwise enzyme assays were performed at the indicated time points for both epididymal and peri-renal cells. Each point is the mean of 2 assays. △, epididymal low insulin; ▲, epididymal high insulin; ○, peri-renal low insulin; ●, peri-renal high insulin.

Table 1 confirms the results of Figure 1 in that the cultured cells accumulate TG as is expected of differentiating pre-adipocytes. In the absence of treatment fatty acid, epididymal and peri-renal pre-adipocytes accumulated, respectively, 786 ± 99 and 3270 ± 490 nmol esterified fatty acid in TG per 9.6 cm² well. The difference in total TG accumulation is consistent with Figure 1 in that under our culture conditions, peri-renal pre-adipocytes developed more G3PDH activity and accumulated more TG than epididymal cells. Epididymal and peri-renal-derived cells that have undergone 12 population doublings and therefore have lost the ability to differentiate (14) did not accumulate TG under the same experimental conditions (data not shown).

The fatty acid treatments had no statistically significant effect on phospholipid content of either cell type (Table 1). However, the various fatty acid treatments at 50 μM concentration affected the total TG-accumulation by the cells. Depending on the treatment fatty acid, total TG-accumulation ranged from 0.7- to 1.5-fold of the corresponding controls (Table 1). Furthermore, the treatment fatty acid affected TG accumulation differently depending on the pre-adipocyte origin. In epididymal-derived pre-adipocytes, the highest TG-accumulation occurred in the 18:1 treatment group and the least in the 18:3ω3 treatment group. Peri-renal pre-adipocytes, in contrast, had the highest TG accumulation in the 18:2 treatment group and the least in the 22:6ω3 treatment group. These effects were statistically significant (Newman-Keuls procedure, 95% level).

At 50 μM, all the fatty acid treatments modulated the fatty acid profile of the accumulated TG (Table 2). For example, treatment with 22:6ω3 caused incorporation of this fatty acid into TG, whereas it was undetectable in control pre-adipocytes. The enrichment relative to control of other TG fatty acids by the corresponding exogenous treatment fatty acid ranged from 1.4 for 18:1 to more than 40 for 18:3ω3 (calculated from Table 2). Epididymal pre-adipocytes had higher proportions of treatment fatty acids in TG; however, peri-renal pre-adipocytes actually esterified more treatment fatty acids in TG based on absolute mass (calculated from Tables 1 and 2).

The fatty acid composition of accumulated TG in the control group of both peri-renal and epididymal pre-adipocytes (Table 2) did not match the fatty acid composition of the neutral lipid fraction (TG plus non-esterified fatty acids) present in the control differentiation medium (Table 3). The P/S ratio for intracellular TG was 0.018 and 0.043 for peri-renal and epididymal control pre-adipocytes, respectively, whereas it was 0.25 in the control differentiation medium. Furthermore, the change in the P/S ratio of TG in cells treated with PUFA did not increase in proportion to that in the fatty acid-supplemented differentiation medium. For example, the P/S ratio in peri-renal cells treated with 50 μM 18:3ω3 (calculated from Table 2) was 0.16 while that of the differentiation medium was 3.8 (calculated from Table 3).

In a separate series of experiments, peri-renal pre-adipocytes were incubated with either a high (80 μM) or a low (40 μM) concentration of 18:1 or 18:3ω3, respectively. The effect on total TG accumulation and fatty acid composition was determined and the results shown in Table 4. Treatment fatty acid concentrations above 100 μM resulted in a drop in the number of cells per culture

[a]Pre-adipocytes from epididymal or peri-renal adipose tissue were incubated with 50 μM of the indicated fatty acids and 0.8 μM insulin for 4 days. TG fatty acid composition is expressed as relative percentage of fatty acid (n = 3) per treatment group. Data were analyzed by one-way analysis of variance using multiple range testing (Scheffe, 95% confidence level). The statistical test results are presented in ascending, ordered sequence. Statistically homogeneous groups are connected by an underscore. Student's t-test was used in cases where the component fatty acid is detectable only in two treatment groups.

well (data not shown), indicating toxic effects. Therefore, we used 80 μM fatty acid as the "high" concentration in order to provide a margin of safety for cell survival. Table 4 shows that doubling the treatment fatty acid concentration results in a minor increase in the total amount of TG accumulated by the cells over the 4-day incubation

18:2	10.5 ± 0.9
20:4ω6	1.9 ± 1.9

[a]Neutral lipid is TG plus NEFA. The total amount of neutral lipid fatty acid in the differentiation medium was 17.1 ± 3.7 nmole/mL.

period. Furthermore, the increase in total TG was due mainly to a rise in the incorporation of the treatment fatty acid. The data show that the absolute amounts of each of the other TG-esterified fatty acids were largely unaffected (Table 4).

The uptake and distribution of 18:1 and 18:3ω3 were further investigated in peri-renal pre-adipocytes using [1-^{14}C]-labeled fatty acids. The results (Table 5) show that the uptake was similar for these two fatty acids. Doubling the concentration of treatment fatty acid from 40 to 80 μM resulted in a 2.5-fold increase in 18:1 uptake and a 1.8-fold increase in 18:3ω3 uptake. Radioactive fatty acids taken up were accounted for by the accumulation of intracellular radioactivity. Only minor amounts (less than 2%) were metabolized to ketone bodies. The combined TG and PL fraction in turn accounted for at least 90% of the total intracellular radioactivity. Lastly, the radioactivity in the TG fraction was 92 to 96% of the total radioactivity in the combined TG plus PL fractions.

DISCUSSION

The results of these experiments demonstrate the feasibility of controlling the fatty acid composition of accumulating TG in differentiating, cultured pre-adipocytes. This model, while not intended to duplicate physiological conditions, does provide a way for inducing acute and rapid changes in TG fatty acid profile of cells destined for adipogenesis, which is otherwise difficult to accomplish in intact tissue. Pre-adipocytes enriched with PUFA would be useful as a model for the study of PUFA flux in these cells.

A significant difference between the culture conditions in this study and those of others (1,14) was the serum supplement used in the differentiation-medium. In general, proliferation and differentiation of pre-adipocytes are mutually exclusive (18). The low proportion of fetal calf serum in the differentiation medium was intended to minimize the concentration of mitogens while still providing the serum components essential for pre-adipocyte differentiation (19). The use of the lipid-poor serum replacer improved cell survival, while providing a vehicle for the fatty acid treatments. However, the low total serum content of the differentiation medium limits the maximum concentration of NEFA that may be used to treat the cells, due to toxic detergent effects.

Adipocytes obtain extracellular fatty acids for incorporation into adipose TG from the action of adipose capillary bed lipoprotein lipase on circulating very low density lipoprotein (VLDL) (20). Therefore, pre-adipocytes in culture, which also express lipase activity (21,22), should be able to hydrolyze serum TG normally present in culture medium, and incorporate the liberated fatty acids in intracellular TG. At the same time, since it is

Total intracellular radioactivity[d]	17.8, 17.7	37.2 ± 0.4	19.8 ± 0.5	37.4 ± 0.3
TG[e]	17.6 ± 1.4	34.2 ± 2.7	16.8 ± 0.9	31.2 ± 1.6
PL	0.72 ± 0.07	1.4, 1.5	1.5, 1.0	1.6 ± 0.2

[a]Pre-adipocytes were treated with [1-^{14}C]fatty acid (400-600 dpm/nmole).

[b]Culture medium was acidified with HCl to expel CO_2 before counting. Uptake was calculated as the decrease in non acid-volatile radioactivity in the medium, corrected for ketone body production.

[c]Ketone bodies were assumed to be $HClO_4$-soluble radioactivity. Radioactive NEFA co-precipitates completely with serum albumin in the culture medium upon $HClO_4$-treatment.

[d]Cells were rinsed and digested with 0.2 N NaOH/50% CH_3OH before counting.

[e]Intracellular lipid was extracted from intact cells and separated into a TG and PL fraction by thin-layer chromatography.

actually NEFA that cross the adipocyte membrane for incorporation into cellular lipid (23), exogenously added NEFA should also be incorporated into cellular TG, as was indeed the case.

The insulin concentration in our cultures, 0.8 μM, is within the saturation range of the insulin response curve for adipocytes (24). Since adipocytes internalize and degrade insulin (25), 0.8 μM is appropriate for a non-circulating, non-renewing system such as a cell culture, in order to maintain an effective concentration of insulin during the periods between culture media changes. Other investigators have used similarly high concentrations of insulin in pre-adipocyte cultures (25-27).

Several studies have shown that the fatty acid composition of adipose tissue adapts, albeit slowly, to the fatty acid profile of the diet (4,13,28). However, a closer analysis of published data reveals that the proportions of PUFA found in adipose tissue were always lower than the relative content of PUFA in the diet (4,9,29-33). The pre-adipocyte model described in this communication represents an extreme case where a high-concentration of PUFA is made directly available to the cell for incorporation into TG. Even under these conditions, the cell TG acquires a P/S ratio that is at least an order of magnitude lower than that in the NEFA supplemented differentiation medium. This is likely due to *de novo* synthesis and accumulation of 16:0, which appears to be unaffected by the presence of exogenous fatty acid. Interestingly, Nelson *et al.* (34) reported that rat adipose tissue can continue to synthesize fatty acids *de novo* even when the animal is consuming a high-fat diet. Taken together, the data suggest that pre-adipocytes have an innate ability to control their TG-fatty acid profile, and in particular, to favor a low P/S relative to the extracellular milieu. The mechanisms that control TG-fatty acid profile appear to be cell-type specific as peri-renal and epididymal pre-adipocytes differ in their capacity to incorporate exogenous fatty acids. The ability of epididymal pre-adipocytes to incorporate a higher proportion of PUFA *in vitro* is consistent with the reported *in vivo* differences between the fatty acid compositions of epididymal and dorsal fat (34).

In conclusion, the data indicate that TG accumulation in pre-adipocytes is not a simple and unspecific loading process but is likely to be subject to control mechanisms that determine which fatty acids are stored and in what proportion, and which ones are released to the external milieu. The pre-adipocyte model system with NEFA treatments permits a rapid and acute method for the modulation of the fatty acid composition of accumulating TG. This model may facilitate the study of PUFA metabolism in this type of cells.

trans Fatty Acids. 4. Effects on Fatty Acid Composition of Colostrum and Milk

Jan Pettersen and **Johannes Opstvedt***
Norwegian Herring Oil and Meal Industry Research Institute, Bergen, Norway

trans **Isometric fatty acids of partially hydrogenated fish oil (PHFO) consist of *trans* 20:1 and *trans* 22:1 in addition to the *trans* isomers of 18:1, which are abundant in hydrogenated vegetable oils, such as in partially hydrogenated soybean oil (PHSBO). The effects of dietary *trans* fatty acids in PHFO and PHSBO on the fatty acid composition of milk were studied at 0 (colostrum) and 21 days *postpartum* in sows. The dietary fats were PHFO (28% *trans*), or PHSBO (36% *trans*) and lard. Sunflower seed oil (4%) was added to each diet. The fats were fed from three weeks of age throughout the lactation period of Experiment 1. In Experiment 2 PHFO or "fully" hydrogenated fish oil (HFO) (19% *trans*), in comparison with coconut oil (CF) (0% *trans*), was fed with two levels of dietary linoleic acid, 1 and 2.7%, from conception throughout the lactation period. Feeding *trans*-containing fats led to secretion of *trans* fatty acids in the milk lipids. Levels of *trans* 18:1 and *trans* 20:1 in milk lipids, as percentages of total *cis* + *trans* 18:1 and *cis* + *trans* 20:1, respectively, were about 60% of that of the dietary fats, with no significant differences between PHFO and PHSBO. The levels were similar for colostrum and milk. Feeding HFO gave relatively less *trans* 18:1 and *trans* 20:1 fatty acids in milk lipids than did PHFO and PHSBO. Only low levels of *cis* + *trans* 22:1 were found in milk lipids. Feeding *trans*-containing fat had no consistent effects on the level of polyenoic fatty acids but reduced the level of saturated fatty acids and increased the level of *cis* + *trans* monoenoic fatty acids. Increasing the dietary level of linoleic acid had no effect on the secretion of *trans* fatty acids but increased the level of linoleic acid in milk. The overall conclusion was that the effect of dietary fats containing *trans* fatty acids on the fat content and the fatty acid composition of colostrum and milk in sows were moderate to minor.**
Lipids 26, 711-717 (1991).

Increasing attention has been given to the nutritive value of human milk. As milk is the sole or main source of nutrients for an infant during the first six months of life, it is important that the nutrients in milk meet the substantial requirements of the rapidly developing infant.

The milk should contain sufficient quantities of essential fatty acids to meet the demand for synthesis of membrane tissues in the central nervous and vascular systems. The content of long-chain polyenoic fatty acids (*e.g.*, 22:6n-3) is particularly important for the development of the brain and the retina (1). Since *in vitro* studies have indicated that *trans* fatty acids may influence essential fatty acid metabolism, the effect on the fatty acid composition of human milk from ingestion of *trans*-containing partially hydrogenated fats has been of concern (2).

Although the transfer of *trans* fatty acids from diet and the adipose tissue into milk has been demonstrated in humans (3-8) and rats (9-11), no significant *trans* fatty acid effects on the content of essential fatty acids have been found. The studies used elaidic acid (*trans*-octadecenoic acid, *trans* 18:1n-9) or partially hydrogenated vegetable fats containing *trans* fatty acids with chain length of 18 carbon atoms or less. However, partially hydrogenated fish oils contain *trans* fatty acids with a chain length of 20 and 22 carbon atoms (12), and the biological effects of these acids are only poorly understood. We have previously reported the effects of dietary *trans* fatty acids in PHFO in comparison with PHSBO on brain weight, peroneal histology and nerve conduction velocity (13), and on the fatty acid profile of brain lipids and other organ lipids in sows (14) and offsprings (15). The present work was conducted to study the extent to which dietary *trans* fatty acids, and especially long-chain (*i.e.*, with 20 and 22 carbon atoms) *trans* monoenoic fatty acids, are incorporated into milk lipids under chronic dietary regimens (*i.e.*, when the contents of *trans* fatty acids have reached a steady state condition). It was further intended to find out if dietary *trans* fatty acids affect the overall fatty acid composition of milk lipids and essential fatty acid (EFA) content. Since an interrelationship between the metabolism of *trans* fatty acids and EFA has been indicated (16), the *trans* fatty acids were fed at two levels of dietary linoleic acid. Because of the many physiological similarities between pig and humans (17,18), we used pigs as models in these studies.

MATERIALS AND METHODS

General procedures. A composite sample of about 10 mL of milk was obtained from all lactating teats of each primiparous sow on day 0 (colostrum) and 21 days *postpartum*. Experiment 1 used four sows that had been fed 14 wt% of lard (control, diet 1), PHFO (partially hydrogenated capelin oil, mp 30-32°C, diet 2) or PHSBO (partially hydrogenated soybean oil, mp 40°C, diet 3) plus 4 wt% of SFO (sunflower seed oil, 65% linoleic acid) as additions to diets otherwise composed of solvent extracted soybean meal and cereals. The diets were fed from three weeks of age throughout the lactation period.

Experiment 2 used four sows that had been fed according to a 2 × 3 factorial design with 14 wt% of CF (coconut fat, diets 1.1 and 2.1), PHFO (diets 1.2 and 2.2) or HFO (fully hydrogenated fish oil, mp 50-52°C, diets 1.3 and 2.3), either without (diets 1.1, 1.2 and 1.3) or with (diets 2.1, 2.2 and 2.3) an extra 3 wt% addition of SFO to diets otherwise composed of solvent extracted soybean meal and cereals. The diets were fed from gestation at about six months of age throughout the lactation period.

Abbreviations: CF, coconut oil; EFA, essential fatty acids; GLC, gas-liquid chromatography; HFO, hydrogenated fish oil; HPLC, high-performance liquid chromatography; PHFO, partially hydrogenated fish oil; PHSBO, partially hydrogenated soybean oil; PUFA, polyunsaturated fatty acids; SFO, sunflower seed oil; VLDL, very low density lipoproteins.

In both experiments the sows were held in individual pens and offered the feed twice daily in amounts determined by their weights, stage of pregnancy and number of offspring (feeding standard). The design of the experiments and the fatty acid composition of the diets are shown in Table 1. Details of diets, feeding and management have been described earlier (13).

Chemical methods. Lipids from milk and colostrum were prepared by diethyl-ether extraction (19), and the lipid extracts were stored at −25°C pending further analysis. Total fat content was determined gravimetrically. Fatty acid composition was analyzed by capillary gas-liquid chromatography (GLC) using a 50-m fused silica capillary column (CP Sil 88, Chrompack, Middleburg, The Netherlands) as described earlier (14). The content of *trans* 16:1 was only analyzed in the dietary fats of Experiment 2 (Table 1).

Statistical methods. The statistical model used was a linear mixed model with diets as fixed, and sows as random effects. The various subgroups contained varying numbers of experimental units, making the statistical estimation and testing procedures numerically rather complex. The computer program selected among the few available at the time was General Mixed Model Analysis of Variance (BMDP P3V) (20). Estimation is Maximum Likelihood, and testing of effects uses chisquares in Likelihood Ratio Tests. Other methods used were simple, one-way analysis of variance models with varying group sizes. The pooled standard deviation, rather than the individual group standard deviations, was used in assessing the variability. Since testing of effects uses a one-way analysis of variance model, the underlying assumption that groups may vary according to location, but not in terms of spread, implies that the estimate of spread, found by MS error, comprises the total information on variability. Accordingly, in assessing differences in the group means the standard error of the different means were computed, making use of this common measure of spread for individual experimental units.

RESULTS

Experiment 1. Fat content and fatty acid composition of the milk at day 0 (colostrum) and 21 *postpartum* are shown in Table 2. Fat content of colostrum averaged 3.4 percentage units higher than that of milk. There were no major differences in fatty acid composition due to the stage of lactation. In group 1 and 2, but not in group 3, the level of linoleic acid decreased and the levels of *cis* monoenoic fatty acids increased from day 0 (colostrum) to day 21 of lactation. The effect of diets on the fatty acid composition of the milk was independent of the stage of lactation (*i.e.*, at 0 and 21 days *postpartum*).

At both sampling times, the *trans* 18:1 levels were

[f]Relative amount of sum of PUFA (P) to sum of saturated fatty acids (S). Average of eight replicates.

significantly influenced by diet. The level of *trans* 18:1 in milk from sows fed PHFO was similar to the dietary level, while that from sows fed PHSBO was only half the dietary level. In contrast, the level of *trans* 20:1 in the milk fat of PHFO-fed sows was lower than that of the dietary fat. Our analytical technique did not separate the *cis* and *trans* isomers of 16:1 and 22:1 in milk lipids.

Compared with the lard-fed sows, feeding of PHFO increased and of PHSBO reduced the level of linoleic acid in colostrum. In milk, both fat sources led to an increase in linoleic acid that was not significant. Feeding PHFO and PHSBO reduced the level of 22:5n-3 as compared with the control (lard) (significantly in colostrum). The general effects of PHFO compared with lard was an increase in polyunsaturated fatty acids (PUFA) n-6 and total PUFA at both sampling times, while PHSBO reduced PUFA in colostrum and increased PUFA in milk compared with lard. Feeding PHFO increased the level of 16:1, reduced *cis* 18:1 and increased 20:1 and 22:1 as compared with lard at both sampling times. Sows fed PHSBO had reduced levels of 16:1 and increased levels of *cis* 20:1 at both sampling times compared with lard.

Fatty acids with less than 16 carbon atoms were not determined in Expt. 1. Compared with lard, feeding partially hydrogenated fat (PHFO and PHSBO) reduced the level of 16:0 and 18:0. PHFO increased the level of 20:0 and PHSBO decreased the level of 20:0, as compared with lard.

Experiment 2. The fat content and fatty acid composition of colostrum and milk are shown in Table 3. Fat content in colostrum was at the same level as that found in Expt. 1, but higher in milk than in Expt. 1. Thus, contrary to the findings found in Expt. 1, the differences in fat content between day 0 and day 21 were negligible. Despite large differences in average fat content between dietary groups the differences were not significant due to large within diet variation. As in the findings in Expt. 1, the level of linoleic acid and saturated fatty acids decreased, while that of *cis* + *trans* monoenoic fatty acids increased from day 0 to day 21 of lactation.

[e]Not detectable.

[f]Relative amount of sum of PUFA (P) to sum of saturated fatty acids (S). Average of eight replicates.

There were no consistent differences in the content of *trans* fatty acids between colostrum and milk. Contents of *trans* fatty acids in both colostrum and milk varied significantly between diets, and only trace levels of *trans* fatty acids were found in milk from sows fed the *trans*-free control diets. As in Expt. 1, the level of *trans* 18:1 in milk of sows fed PHFO or HFO was similar to that in the dietary fat, while that of *trans* 20:1 was about half of that in the dietary fat. *trans* 16:1 and 22:1 Were not identified in milk. Increasing the dietary level of linoleic acid reduced the level of *trans* 18:1 and *trans* 20:1 in both colostrum and milk, but the reduction was only significant in milk.

The main effects of the dietary fat sources (*i.e.*, lard, PHFO and HFO) were found in the level of several fatty acids in colostrum. Compared with CF, the feeding of PHFO reduced the level of 18:2n-6, 20:4n-6, 22:4n-6, 18:3n-3 and 22:5n-3. Further, the feeding of PHFO increased the level of 16:1, *cis* 20:1 and *cis* + *trans* 22:1 as compared with CF. The differences in the fatty acid composition of milk from CF *trans* 20:1 and PHFO *trans* 20:1 fed sows were smaller than those seen in colostrum, though the levels of *cis trans* 20:1 and *cis* + *trans* 22:1 were significantly increased in PHFO as compared with CF. Compared with CF, the feeding of PHFO reduced the contents of all saturated fatty acids except 20:0 and 22:0, which were increased in both colostrum and milk. The effects of HFO compared with CF were similar, although generally less than those found with PHFO. Addition of dietary linoleic acid (18:2n-6) significantly affected the level of several fatty acids in milk at both stages of lactation. This resulted in an increase in the level of 18:2n-6, while the levels of 18:3n-3, 20:5n-3, 22:5n-3 and 16:0 were reduced.

Compared with CF, the feeding of PHFO and, to a lesser extent, of HFO, reduced the level of PUFA n-6 and PUFA n-3 in colostrum but not in milk. Feeding PHFO and HFO increased the level of monoenoic and decreased the level of saturated fatty acids as compared with CF at both sampling times.

Significant interactions between dietary fat sources and level of linoleic fatty acid in the diet, in addition to those in *trans* fatty acids (already pointed out), were also found for *cis* 20:1, 20:5n-3 and 22:5n-3 in milk. Thus, the level of *cis* 20:1 was higher when PHFO was fed at low dietary levels of linoleic acid compared with results at high levels.

DISCUSSION

Our experimental diets contained appreciable levels of *trans* isomers of 16, 18, 20 and 22 carbon monoenoic fatty acids and substantial levels of *trans* 18:1 and *trans* 20:1 were found in milk lipids from the *trans*-fed sows. In agreement with previous results in rats (10) the level of *trans* fatty acids in milk was not affected by the stage of lactation. As in earlier results with rats (2), the levels of *trans* 18:1 and *trans* 20:1 in the milk lipids were clearly related to the dietary levels.

We have previously (14,15) proposed the use of the discrimination factor (*i.e.*, the relation of the percentage *trans* isomers of the total monoene content of 18:1 or 20:1 in the synthesized lipids as compared to that of the dietary lipids) as a tool to evaluate the utilization of *trans* fatty acids for lipid synthesis. Table 4 shows the discrimination factors in colostrum and milk for the different diets in the two experiments. In Expt. 1 the discrimination factors were similar for milk and colostrum. They were also fairly similar for *trans* 18:1 and *trans* 20:1, and the differences between the two fat sources (*i.e.*, PHFO and PHSBO) were negligible. In Expt. 2 the discrimination factors were more variable. Thus, relatively more *trans* 20:1 than *trans* 18:1 were incorporated in milk lipids, regardless of dietary source and stage of lactation. Further, a relatively smaller amount *trans* 18:1 was incorporated into milk lipids from HFO as compared with PHFO, while there were apparently no differences between the two fat sources with regard to *trans* 20:1. As demonstrated earlier with regard to the level of *trans* 18:1 in milk from rats (11), there was no consistent effect on the incorporation of *trans* fatty acids as a result of dietary level of linoleic acid. On average, the discrimination factors for *trans* 18:1 in PHFO, PHSBO and HFO were 0.56, 0.68 and 0.27, respectively.

The value for PHSBO compares well with the discrimination factor of 0.66 calculated for milk by these authors from data from PHSBO-fed rats in the study of Wickwire *et al.* (11), but is lower than the discrimination factor of 0.77 calculated for milk from partially hydrogenated corn oil-fed rats in the data of Ross *et al.* (10). The value in Table 4 for PHSBO is also fairly similar to the discrimination factor of 0.61 that may be calculated for transfer of *trans* 18:1 from PHSBO into human milk (2). Our discrimination factors for milk are similar to those previously determined for blood lipids and adipose tissues in sows of Expt. 1 (14). Therefore, it appears that the incorporation of dietary *trans* monoenoic fatty acids into milk fat is 30–40% less than that of the homolog *cis* fatty acids.

The ratio of monoenes, saturated and polyunsaturated fatty acids in colostrum and milk relative to that of the dietary fats are shown in Table 5. The results show that the variation in fatty acid compostion in the diets

[a]See legend of Table 1 for explanation of abbreviations.

were moderated somewhat by the process of lactation. This is demonstrated by the milk fat from the CF fed-sows, which contained 50% saturated fatty acids as compared to 80% in the dietary fat. However, although the fatty acid composition of the dietary lipids had some influence, it seems natural to conclude from Table 5 that the lipid composition of colostrum and milk tends to remain fairly constant. This conclusion is in general agreement with those of previous studies on human milk (21). However, our results show that a restricted EFA level of the diets clearly reduced the total EFA level of colostrum and, in particular, of milk.

Milk lipids are derived from blood chylomicron and very low density lipoproteins (VLDL) (fatty acids with 16 or more carbon atoms) and from the *de novo* fatty acid synthesis in the mammary gland (fatty acids with 16 or less carbon atoms) (22).

The blood lipids are of dietary origin and from mobilized adipose tissue. The relative contribution of these two sources is dependent somewhat on species and energy status of the animals (7). *De novo* fatty acid synthesis in the mammary gland, which provided 10–12% of the total milk lipids in humans (23), would cause a dilution of total *trans*. Further, synthesis of *cis* 18:1 (24), and possibly of *cis* 20:1, in the mammary gland would reduce the ratio of *trans* to *cis* monoenes. Adipose tissue contains less *trans* fatty acids than dietary fat (14). Thus, the increasing contribution of adipose tissue to blood lipids would reduce content of *trans* fatty acids in milk fat. The reduced content of *trans* fatty acids in the milk lipids may also be due to discrimination of *trans* fatty acids in VLDL synthesis in the liver, or to reduced uptake from the blood in the mammary gland, *i.e.*, the *trans* fatty acids being transported in blood lipids other than chylomicrons and VLDL. Moreover, *trans* fatty acids may be discriminated against in the synthesis of milk lipids in the mammary gland.

From the data presented in this work, it is not possible to decide by which mechanism the reduction in the content of *trans* fatty acids in the milk occurred. It is, however, of interest to note that the discrimination factors in milk lipid synthesis were similar to those found in adipose tissues (14) because both mainly consist of triglycerides. Thus, *trans* 20:1, but not *trans* 22:1, appears to be utilized with the same efficiency as *trans* 18:1 for synthesis of triglycerides, while *trans* 18:1 is preferred to *trans* 20:1 in synthesis of phospholipids (14).

The results of Expt. 2 clearly demonstrate and confirm previous results in pigs (25), namely, that the level of linoleic acid in the milk is a linear function of dietary linoleic acid content. In agreement with previous results in rats (11), the content of *trans* fatty acids in the diets had no consistent effect on the linoleic fatty acid levels in the milk.

The tendency in the data was that the level of long chain PUFA (*i.e.*, fatty acids containing 20 carbon atoms or more) in the milk lipids was somewhat depressed when the sows received diets with high contents of *trans* fatty acids. The results agree with our previous findings in tissue lipids of sows and their offsprings (14,15), but are contrary to the results of previous studies on milk lipids in rats (11). It has been hypothesized that a depression of the activities of the Δ6 (26,27) and Δ5 (28,29) desaturation enzymes by *trans* fatty acids should reduce the rate of synthesis of higher homologues of the n-6 series of fatty acids, including 20:4n-6, from linoleic acid. However, a later study (30) did not confirm these findings.

The 22:1 monoenes, present in appreciable levels in PHFO and HFO diets and the 22:0 of HFO, were only found at low levels in milk lipids; and 24:1 was not detected. Thus, as has previously been found in tissue lipids (14,15), these fatty acids are discriminated against in the synthesis of milk lipids. Since this was the case with *cis* as well as with *trans* isomers, the reason is evidently related to chain length.

The different experimental fats used in this study varied substantially in fatty acid composition. Although some characteristics of the dietary fatty acid profiles were reflected in the milk lipids, the fatty acid composition of the milk lipids in the various groups was remarkably similar, and this is in line with previous studies in humans (21). The most consistent effect of the hydrogenated fats containing *trans*, regardless of control fat, was a reduction in the level of saturated fatty acids and a compensating increase in the level of *cis* and *trans* monoenoic fatty acids.

In conclusion, the results show that dietary *trans* 18:1 and *trans* 20:1 from PHFO and PHSBO are incorporated to a similar degree into milk lipids. The content of *trans* monoenes as a percentage of total *cis* plus *trans* monoenes

was reduced by some 40% from diet to milk. Only low levels of dietary *cis* and *trans* 22:1 were found in milk lipids from sows fed PHFO.

The fatty acid composition of the milk lipids remained remarkably constant despite a wide range in dietary fatty acid composition, though the feeding of fats containing *trans* fatty acids did lead to a reduction in the level of saturated and an increase in the level of *cis* and *trans* monoenoic fatty acids. The overall conclusion was that the effects of dietary fats containing *trans* fatty acids on the fat content and fatty acid composition of colostrum and milk in sows were moderate to minor.

Dietary Fat Composition Influences Fatty Acid Composition of Milk Fat Globule Membrane in Lactating Cows[1]

D.L. Palmquist* and **F.L. Schanbacher**
Department of Dairy Science, Ohio Agricultural Research and Development Center, The Ohio State University, Wooster, Ohio 44691

Milk fat globule membranes are derived directly from the apical plasma membrane of mammary epithelial cells. To evaluate the effect of dietary fat on mammary membranes, we determined the fatty acid composition of the milk fat globule membrane in lactating dairy cows fed diets supplemented with fats of different fatty acid composition, or infused intravenously with soy oil emulsion. A preliminary survey, using an abbreviated preparation procedure (membranes isolated at 48,000 × *g-max* for 15 min), yielded about 45% of the total membrane fatty acids that could be recovered by centrifuging at the same speed for 120 min, and showed that changes in fatty acid composition of membranes reflected dietary fatty acids to some extent. Dietary palmitic acid increased the content of 16:0 in the membranes. A high corn diet increased ruminal formation of *t*18:1, and its level increased to 12% of membrane fatty acids. Infusion of soy oil emulsion increased 18:2 membrane content, and decreased the levels of 18:1 and 20:4. All treatments decreased the ratio of unsaturated/saturated fatty acids as compared to controls, whereas the ratio of polyunsaturated/saturated fatty acids was increased by feeding a high corn diet or by infusing soy oil. The ratio of 18:2/c18:1 increased from 0.31 to 1.0 after infusing soy oil for 4 days. The fatty acids of membranes isolated upon 120-min centrifugation were slightly more saturated. The differences were not sufficiently large, however, to affect overall results significantly.
***Lipids* 26, 718–722 (1991).**

The milk fat globule membranes (MFGM) surround the fat droplets secreted by lactating mammary cells. The membranes are derived from the apical portion of the cell, surrounding and enveloping the fat globules as they are extruded from the cells. Eventually the membranes are pinched off during the apocrine secretion process (1,2). Membrane composition and cellular function has been shown to be influenced by dietary fat composition (3) in Ehrlich ascites cells (4), rat aorta (5), rat liver (6), rat hepatocyte culture (7), and rat adipocytes (8). There is little information on the effects of dietary fat on membranes of ruminant animals; however, milk fat composition is influenced by dietary fat under normal feeding conditions (9,10), and it is not unreasonable to speculate that tissue membranes may be influenced as well. Smith *et al.* (11) reported that feeding a mixture of sunflower and soybean seeds protected from ruminal biohydrogenation increased the proportion of linoleic acid in both core and membrane lipids of the milk fat globule, whereas Anderson (12) found that coconut oil similarly protected did not change fatty acid composition of milk fat globule membrane phospholipids.

In this study, we surveyed the effects of various types of fats, or diets known to influence lipid metabolism in lactating cows, on the fatty acid composition of milk fat globule membranes. Because MFGM are derived from intracellular membranes (1,2), it is likely that changes in fatty acid composition of MFGM represent similar changes in intracellular membrane composition. A preliminary study examined effects of several different diets; results were confirmed in a second experiment.

MATERIALS AND METHODS

Animals and diets. Five cows in mid-lactation (15–35 kg milk/day) were fed standard diets containing (dry matter basis) 40–50% concentrate mix, with the balance from roughages (alfalfa hay and corn silage) in a 5 × 5 Latin square design. Concentrate mixes contained no added fat or 10% added yellow grease, tallow, saturated fatty acids or calcium soap of palm fatty acids (Table 1). Additionally, two cows were fed a diet of whole shelled corn and ground, pelleted alfalfa (75:25, w/w), which is known to induce milk fat depression and to alter milk fat composition (13), and two cows were maintained on a standard diet and infused intravenously with 1900 mL/d (380 g oil) of a commercial soy emulsion (Intralipid, Baxter Healthcare Corp., Deerfield, IL). All cows except those infused with Intralipid were fed their respective diets for at least 3 wk prior to sampling milk.

Yellow grease is primarily restaurant cooking fat recycled by renderers, and tallow comes from renderers. The saturated fatty acid supplement is primarily palmitic, stearic, and oleic acids (Energy Booster 100, Milk Specialties Co., Dundee, IL); the calcium soap (Megalac, Church and Dwight Co., Inc., Princeton, NJ) is prepared from palm fatty acid distillate. Intralipid is a commercial soybean emulsion manufactured for intravenous nutritional support for humans.

Milk fat globule membrane. Milk samples for determination of milk fat globule fatty acid composition were obtained on one day from two cows on each treatment. Milk from the p.m. milking was prepared for harvesting milk fat globules essentially according to Patton and Huston (14). Fresh milk (175 mL, containing 5% sucrose) was put into each of six 250-mL polyethylene bottles and overlayed with 75 mL of phosphate-buffered saline (0.14 M NaCl in 0.01 M phosphate, pH 7.3). The milk was centrifuged at 1500 × *g* for 20 min at room temperature, and the bottles were held at 4°C overnight. The fat layer was harvested, sealed under N_2, and frozen until churning. The fat was thawed and churned while on ice by working with a spatula to release the milk fat globule membrane. This approach, rather than using a blender, was taken to limit exposure to air. In the preliminary survey, membranes

were precipitated by centrifuging for 15 min at 48,000 × *g-max* at 4°C, resuspended, washed once in phosphate-buffered saline, and recentrifuged. The washed pellet was extracted with hexane/isopropanol/HCl (60:40:1, v/v/v) as described by Radin (15), and the material in the hexane layer was methylated (16). Fatty acid analysis of feeds, MFGM, and milk fat taken from the cream before churning were as described by Sukhija and Palmquist (16). In a second study, milk was obtained on three different days from a single cow fed a standard diet, and duplicate sets of membranes were prepared by churning as above. After harvesting the pellet from the 15-min centrifugation (48,000 × *g-max*), the supernatant was recentrifuged for 2 hr at 48,000 × *g-max* to obtain a second pellet. Membrane fatty acids were analyzed as above, and additionally, were quantitated by gas-liquid chromatography (GLC), using nonadecanoic acid (19:0, Nu-Chek Prep, Elysian, MN) as internal standard (16).

Data from the first study show fatty acid composition of MFGM averaged from two animals on each treatment; no statistical manipulations were performed. In the second study, data were subjected to Least Squares Analysis of Variance (17) to determine precision of analysis, repeatability of daily sampling, and similarity of membrane composition from different isolation procedures.

RESULTS

Table 1 shows fatty acid composition of the control diet and various fat supplements. The small amount of fat in the control diet is typically highly unsaturated (65% unsaturated 18-carbon fatty acids). The fatty acid composition of the supplements was intentionally different; yellow grease provided low 16- and high unsaturated 18-carbon fatty acids; tallow provided more 16- and less unsaturated 18-carbon fatty acids. Saturated fatty acids and calcium soaps of palm fatty acid distillate were high in 16:0 and have little or no effect on rumen function. The high grain diet provided high 18:2 (from corn lipids) and is known to change ruminal biohydrogenation activity. Intralipid infusion provided a high amount of 18:2 directly to the mammary gland (18).

Data in Table 2 show daily intakes of fatty acid, milk yield, and milk fat percent to indicate the magnitude of daily fat metabolism of the lactating cows. Yield differences are primarily due to differences in lactation stage and are not intended to suggest differences among treatments in ability to support lactation.

Average fatty acid composition of milk fat obtained from cows on the different treatments is in Table 3. Dietary fat supplements decreased fatty acids of 4- to 14-carbon chain length, whereas content of 16- and 18-carbon fatty acids increased or decreased in accordance with the amount of these consumed. The content of *t*18:1 was increased 8-fold and 15-fold by feeding the yellow grease and the high corn diet, respectively. Infusing Intralipid changed 4- to 14-carbon fatty acids very little, and increased 18:2 4-fold, primarily by replacing 16:0, 18:0, and 18:1.

The fatty acid composition of MFGM is given in Table 4. No short-chain fatty acids were detected. The content of 14:0 varied from 4 to 10%; there was little variation in content of 16:0 (26 to 30%), except for the saturated fatty acid and calcium soap supplements, which increased 16:0 to 33 and 37%, respectively. Patterns of 16:1, 18:0, and *t*18:1 of MFGM followed those of milk fat. The proportion of *c*18:1 in MFGM from cows fed control or high fat diets was 27 to 33%, whereas *c*18:1 was less than 20% in high grain and Intralipid infusion treatments. Conversely, 18:2 was higher in the latter two treatments than control or fat-fed treatments. Arachidonic acid (20:4) was observed in all MFGM preparations except those from Intralipid infusion. Ratios of unsaturated/saturated fatty acids in MFGM were lower than those of controls for all treatments; the same was true for ratios of polyunsaturated/saturated fatty acids except for the high grain diet and Intralipid infusion. Calculated iodine values were highest for the latter two treatments.

In Table 5, data are shown from sampling of one cow on three different days, with sequential centrifugation of duplicate samples for 15 and 120 min. Coefficients of variation (CV, n=6) for determination of the proportion of individual fatty acids ranged from 0.6 to 103% of the mean. Only CV values of 16:0 (15.0%) and 18:2 (103%) exceeded 10%; inspection of data showed that variation was caused by a single sample. There was no difference ($P>0.05$) in fatty acid composition among days; however,

[a] $\frac{16:1 + c18:1 + 18:2 + 20:4}{14:0 + 16:0 + 18:0 + t18:1}$ [b] $\frac{18:2 + 20:4}{14:0 + 16:0 + 18:0 + t18:1}$ [c]Calculated iodine value: 100% 18:1 = 90.

several fatty acids differed significantly between 15- and 120-min isolations. These changes caused higher saturation in the 120-min pellet. The 120-min pellet contained more unidentified 14 and 16, more 18:0, *t*18:1, 22:0, and 24:0, and less 16:0, *c*18:1, 18:3, and 20:4 than the 15-min pellet.

Because individual samples in this study varied in mass, a weighted mean composition was computed as the sum of mass and weight percent of each fatty acid, and is shown in Table 5. This value is representative of the composition if the MFGM had not been separated by centrifuging sequentially for 15 and 120 min.

DISCUSSION

Ruminant diets are typically low in fat (2% in this basal diet), and the fatty acid profile of the basal diet reflects the unsaturated nature of corn oil and leaf lipids (Table 1). However, these unsaturated fatty acids are 80–90% biohydrogenated by rumen microorganisms; thus, little unsaturated fatty acid is absorbed (19). The amount of fat supplemented was within the range recommended for commercial practice (20). Yellow grease and tallow are metabolized extensively in the rumen, with conversion of C_{18} unsaturates primarily to 18:0 and *t*18:1n-7. The

calcium salt of palm fatty acid distillate is moderately (about 50%) biohydrogenated in the rumen (19). Hydrogenated fatty acids undergo little change in the rumen. After ruminal lipolysis, linoleic acid of corn oil is converted extensively to *t*18:1n-7 (21); however, if ruminal pH is low (<6), lipolysis is limited (22), and 18:2n-6 escapes ruminal biohydrogenation and is absorbed intact.

Supplementing a basal diet with fat caused increased mammary uptake of long-chain fatty acids and reduced output of fatty acids with 4–15 carbons (Table 3). Lower short-chain fatty acid output is due to feedback inhibition of *de novo* synthesis in the mammary gland (23). The content of fatty acids with 16 and 18 carbons reflected their content in the diet. The most dramatic effects on long-chain fatty acid composition are seen with feeding a high corn-low roughage diet, or infusing soybean oil intravenously. Both milk fats had very low 18:0 content. Milk fat from cows fed high corn had very low short-chain fatty acid content, also by inhibition of *de novo* synthesis (14) and a high content of *t*18:1, reflecting abnormal ruminal biohydrogenation patterns (22–24). The very high 18:2 content indicated that a large amount of this fatty acid escaped ruminal metabolism (22). Even though *c*18:1 was not increased, 16:1 was increased, suggesting conversion of 16:0 to 16:1 by Δ9 desaturase activity. Activity of the desaturase would be expected to increase because it is stimulated by insulin (25), and insulin also increases in cows fed high corn diets (13). The large amount of 18:2 in Intralipid was transferred directly to milk fat. The milk fat composition from cows infused with Intralipid is unusual in that the composition of short-chain fatty acids was changed very little from control. There seems to be a nearly 1:1 substitution of 18:2 for 16:0 + 18:0 + 18:1. This pattern is not typical of that observed with feeding of protected polyunsaturated fats (26).

The content of fatty acids with 4–12 carbons in MFGM in the preliminary study was nil or low (data not shown), indicating that the membrane fatty acids were not contaminated with milk fatty acids. The content of 14:0 was significant (Table 4). Palmitic and 18:1 were present in highest amounts, approximately 30% each, with variations reflecting chain length of diet fat source. For example, diets with commercial saturated fatty acid or calcium soap supplements contributed to higher 16:0, whereas yellow grease and tallow induced higher 18:1 levels. The sum of *t*18:1 and *c*18:1 was 30% and 18:2 was highest, except for Intralipid infusion, with the high corn diet. Intralipid infusion for only 4 days lowered the level of *c*18:1 and increased the level of 18:2 compared to control or fat-supplemented treatments. Interestingly, 20:4 was not detected in MFGM when Intralipid was infused. Plasma contents of 18:2 and 20:4 were inversely related in lambs fed a diet high in protected polyunsaturated fatty acids (27) and in sheep maintained for long periods on intravenous glucose infusions (28). Spector *et al.* (29) discussed in detail the decreased incorporation of 20:4 into cellular phospholipids in the presence of high 18:2 in cultured human umbilical vein endothelial cells. They suggested that the endothelial cell has a limited capacity to convert 18:2 to 20:4, probably by low activity of Δ6 desaturase. Further, 18:2 apparently competitively inhibits incorporation of 20:4 into *sn*-2 of phospholipids, and the effect was expressed fully within 24 hr. Clandinin *et al.* (30) found similar 16:0 and 18:0, lower 18:2, and much higher 18:3 and 20:4 in phospholipids of rat mucosal plasma membrane than we found in MFGM.

The unsaturated/saturated (U/S) index (Table 4) was computed with *t*18:1 included as a saturated fatty acid because its contribution to membrane structure would be much more similar to 18:0 than to 18:1. It is interesting that no treatment, including Intralipid infusion, induced membrane composition with a higher unsaturation index than that of the control. Tallow caused little change, whereas the index was lower for yellow grease, calcium soap, and high corn. The low index for high corn is unexpected, considering the high 18:2 content; however, the high *t*18:1 and low *c*18:1 content lowered the ratio. Alternatively, the calculated iodine values were higher than the control with high grain feeding and Intralipid infusion, and were lowest when calcium soap was fed, because *t*18:1 is included in the calculation of iodine value.

Since our initial procedure for precipitating MFGM was not standard, a confirming study evaluated yield and composition of membranes by obtaining a pellet first at 48,000 × *g-max* for 15 min, followed by recentrifugation of the supernatant for 120 min at 48,000 × *g-max* (31). We repeated the separation on duplicate samples of milk from the same cow on three different days in order to document precision of determining membrane fatty acid composition. The data in Table 5 document that precision of estimating fatty acids was good (CV < 10%), with the exceptions of 16:0 and 18:2, in which variation was due to a single sample. The analysis showed no difference by day of sampling; however, fatty acids from membranes separated by centrifuging 15 min were less saturated (less unidentified 14 and 16, 18:0, 22:0, and 24:0; more 16:1, *c*18:1, 18:3, and 20:4), than those obtained by recentrifuging the supernatant for 120 min. Quantitation showed that the distribution of total fatty acid was approximately 45:55 (w/w) in the 15- and 120-min pellets, respectively. Calculated weighted mean fatty acid composition of the total membrane, obtained by summing the product of proportion and mass of fatty acid in each fraction (Table 5, last column), was not different from the statistical mean (Table 5, first column). Further, differences between the weighted mean and the composition of membranes obtained by 15-min centrifugation were not sufficient to invalidate conclusions drawn from data in Table 4.

Patton and Keenan (2) discussed the possibility that the large amount of neutral glyceride in MFGM may be caused by association of high-melting glycerides from milk fat with the inner membrane surface. They noted that high-melting glycerides were lower in membranes prepared at 37°C from uncooled milk. Since our membranes were prepared at 0-4°C, contamination by high-melting glycerides cannot be discounted. If such were to occur, buoyancy of the glyceride should cause these membranes to precipitate more slowly, and perhaps to contain a greater proportion of saturated fatty acids. That we indeed observed higher saturation in the 120-min pellet is consistent with contamination by high-melting glycerides. Though measurable and consistent, the higher saturation had a relatively small effect on overall fatty acid composition of membranes, and did not change or confound conclusions drawn about treatment effects on membrane composition. Finally, it would be expected that any methodological artifacts would be expressed in all treatments, resulting in small effects on differences among treatments.

We have no documentation as to whether the observed differences in membrane fatty acid composition are related to differences in mammary function. With exception of Intralipid infusion, all cows were fed the experimental diets for a minimum of 3 wk. It is interesting that dramatic changes in membrane fatty acid composition were observed after only four days of Intralipid infusion, which is consistent with the high turnover of cell membranes associated with milk fat secretion (32).

Tocopherol Contents of Lipoproteins from Frozen Plasma Separated by Affinity Chromatography

Beverly A. Clevidence[a,*] and **Rachel Ballard-Barbash**[b]

[a]Lipid Nutrition Laboratory, Beltsville Human Nutrition Research Center, ARS-USDA, Beltsville, Maryland 20705 and [b]Division of Cancer Prevention and Control, National Cancer Institute, NIH, DHHS, Bethesda, Maryland 20892

We investigated whether freezing and storage of plasma altered α-tocopherol levels of whole plasma or the lipoprotein fractions derived from such plasma. Plasma from 24 men, at each of two collection periods, was frozen at −20°C for six weeks, then high-density lipoproteins (HDL) were separated from low- plus very low-density lipoproteins (LDL-VLDL) by heparin affinity chromatography. Whole plasma and the lipoprotein fractions were analyzed for α-tocopherol content and compared to counterparts from fresh plasma. Freezing and storage did not reduce α-tocopherol levels of plasma or the lipoprotein fractions. α-Tocopherol values from fresh and frozen plasma were highly correlated for both plasma (period 1, r = 0.94; period 2, r = 0.93) and the LDL-VLDL fractions (periods 1 and 2, r = 0.97). Percent distribution of α-tocopherol between the two lipoprotein fractions was comparable for lipoproteins derived from fresh and frozen plasma. Under the storage conditions used in this study, plasma can be frozen for at least six weeks prior to lipoprotein fractionation with no detectable detrimental effects on α-tocopherol content of either plasma or lipoproteins.

Lipids 26, 723–728 (1991).

α-Tocopherol is a major lipophilic antioxidant that is transported in plasma by lipoproteins. Low-density lipoproteins (LDL) and high-density lipoproteins (HDL) are the major transport vehicles for α-tocopherol in human plasma (1–3), and the amount of tocopherol carried by these lipoproteins is strongly influenced by their lipid concentrations (4). The amount of tocopherol carried by very low-density lipoproteins (VLDL) from fasting, normolipemic subjects is a minor portion of the total (1,2).

α-Tocopherol has been measured less frequently on lipoprotein fractions than on whole plasma, but recently there has been considerable interest in structural and biochemical properties of lipoproteins as they relate to lipoprotein tocopherol levels (1,2,5–8). This interest in measuring tocopherol levels of lipoproteins suggests that reliable and convenient methods for determining tocopherol levels of human lipoproteins would be useful. We recently reported that commercially available affinity columns allow quick separation of the two major α-tocopherol-containing lipoproteins from human plasma (9). Using this separation method in combination with high-performance liquid chromatography (HPLC), analysis of lipoprotein tocopherol can be carried out the day of blood collection with complete recovery of α-tocopherol in lipoprotein fractions.

Abbreviations: apoB, apolipoprotein B; HDL, high-density lipoproteins; HPLC, high-performance liquid chromatography; LDL, low-density lipoproteins; VLDL, very low-density lipoproteins.

Yet, practical considerations often require delayed sample analysis bringing into question the suitability and effect of storage conditions. While α-tocopherol appears to be stable for over a year in frozen plasma (10) or serum (11), little is known about how freezing and storage affect subsequent analysis of tocopherol from lipoprotein fractions. It is generally recommended that plasma be held in the liquid state prior to lipoprotein analysis, and that determinations be carried out promptly. However, if samples are to be held more than a few days, then freezing is recommended, in part, to prevent oxidation of unsaturated lipids (12). If lipoproteins rapidly decompose during freezing and storage of plasma, as generally (13,14) but not universally (15–17) believed, then α-tocopherol levels of lipoprotein fractions could be greatly reduced. It is also possible that redistribution of tocopherols among lipoproteins occurs during freezing and thawing, thus affecting lipoprotein tocopherol levels without altering tocopherol levels of whole plasma.

The objective of this study was to determine whether freezing and storage of plasma would alter α-tocopherol contents of lipoproteins and thus compromise results obtained following separation of the lipoproteins by affinity chromatography.

MATERIALS AND METHODS

Twenty-four subjects, 24 to 57 years of age, were chosen at random from 40 nonsmoking men participating in a controlled diet study (18). For that study, applicants with plasma α-tocopherol levels of less than 6 μg/mL or greater than 12 μg/mL were not accepted as subjects. Study protocols were approved by the Institutional Review boards of the Georgetown University School of Medicine, Washington, D.C., and the National Cancer Institute, DHHS, Bethesda, Maryland.

During two ten-week periods, men took 15 soft gelatin capsules each day with each capsule providing 1 g of fat and 1 IU of all-*rac*-α-tocopherol (0.74 d-α-tocopherol equivalents) as a preservative. During period 1, fat in the capsules was a blend of stripped lard, hormone-free beef tallow and corn oil (48:40:12, w/w/w). During period 2, the capsules contained a concentrate of refined anchovy oil (ROPUFA®, Hoffmann-La Roche, Inc., Nutley, NJ) that provided 6.5 g per day of n-3 fatty acids (eicosapentaenoic plus docosahexaenoic acids). For both periods, fat from the diet, including capsules, provided 40% of energy. The minimum intake of α-tocopherol from diet and capsules was estimated to be 18 d-α-tocopherol equivalents per day. Menus excluded vitamin E-enriched foods, such as fortified breakfast cereals, and the use of vitamin supplements was not allowed. Plasma cholesterol and triglyceride levels of subjects averaged (mean ± SEM) 173 ± 7.0 and 87 ± 6.9 mg/dL, respectively, for period 1 and 169 ± 6.7 and 60 ± 5.1 mg/dL for period 2.

Blood was drawn during the tenth week of each period after an overnight (≥12 hr) fast. Blood samples, collected

in vacuum tubes containing potassium EDTA (1.5 mg/mL final concentration), were cooled on ice and plasma promptly separated from red blood cells by low-speed centrifugation (1600 × *g* for 20 min) at 4°C. Plasma samples were protected from light at all stages of processing and analysis.

Plasma lipoproteins were fractionated as described previously (9) using heparin affinity columns (LDL Direct, Isolab Inc., Akron, OH). Whole plasma (50 μL) and eluates (200 μL) containing HDL or LDL plus VLDL (LDL-VLDL) were mixed with 1 to 2 mL of 100% methanol and centrifuged at 1600 × *g* for 10 min. Fifty μL of the methanolic extracts were assayed for α- and γ-tocopherol by HPLC using fluorescence detection (19). Each plasma sample and its corresponding lipoprotein fractions were chromatographed, in duplicate, in the order: plasma, HDL, LDL-VLDL.

Fresh samples were processed and analyzed within 10 hr of collection. Replicate plasma samples were frozen at −20°C immediately after separation from red blood cells. Samples were frozen in 0.5-mL aliquots in tightly sealed plastic vials, but no further precautions were taken against oxidation of stored samples. Following six weeks of storage, samples were thawed at room temperature, then fractionated and analyzed under the same conditions as the fresh counterparts. To assure analytical consistency across time, α-tocopherol standards were validated prior to analysis of each storage-period combination using reference standards of reconstituted serum (National Institute of Standards and Technology, Gaithersburg, MD).

An electroimmunoassay (20) for apolipoprotein B (apoB) was used to determine whether freezing and storage of plasma inhibited the binding of apoB-containing lipoproteins to heparin columns. Column eluates from a subset of eight plasma samples were diluted in electrophoresis buffer to a final concentration of 1:12 (v/v) and, for HDL only, to a final concentration of 1:6 (v/v). Fractions were analyzed, in duplicate, in 1.5% agarose gels containing 1.2% antisera to human apoB, raised in rabbits (Behring Diagnostics, La Jolla, CA). Buffers and conditions for electrophoresis have been described (9).

Data were analyzed using the SAS system (SAS Institute, Cary, NC). Correlation coefficients were determined by the Pearson product-moment method, and the paired t-test was used to compare fresh and frozen/stored samples for plasma and lipoprotein tocopherol content (21).

RESULTS

Plasma α- and γ-tocopherol levels. Frozen/stored plasma was not different from fresh plasma when compared for α- and γ-tocopherol contents (Table 1). For period 1, plasma α-tocopherol levels were 10.5 ± 0.5 mg/dL (mean ± SEM) for both fresh and frozen/stored plasma. For period 2, plasma α-tocopherol levels were 9.4 ± 0.4 and 9.5 ± 0.4 μg/mL for fresh and frozen/stored plasma, respectively. Mean levels of γ-tocopherol for fresh and frozen/stored plasma were identical for both period 1 (1.5 ± 0.1 μg/mL) and period 2 (1.4 ± 0.1 μg/mL).

Fresh and frozen/stored plasma samples were strongly correlated (Fig. 1) for both plasma α-tocopherol (period 1: $r = 0.94$, $P<0.001$; period 2: $r = 0.93$, $P<0.001$) and plasma α-tocopherol (period 1: $r = 0.93$, $P<0.001$; period 2: $r = 0.94$, $P<0.001$).

α-Tocopherol content of lipoprotein fractions. α-Tocopherol levels of lipoprotein fractions were not reduced as a function of freezing and storage of plasma (Table 1). However, the period 1 value for LDL-VLDL from fresh plasma was 9% lower than its frozen/stored counterpart (6.1 *vs* 6.7 μg/mL). This difference was not observed for LDL-VLDL at period 2 or for HDL at either period.

Correlations were strong between LDL-VLDL levels of α-tocopherol from fresh and frozen/stored plasma samples (Fig. 2 $r = 0.97$, $P<0.001$ for both periods). Correlations were weaker for HDL α-tocopherol levels of fresh and frozen/stored plasma (period 1: $r = 0.73$, $P<0.001$; period

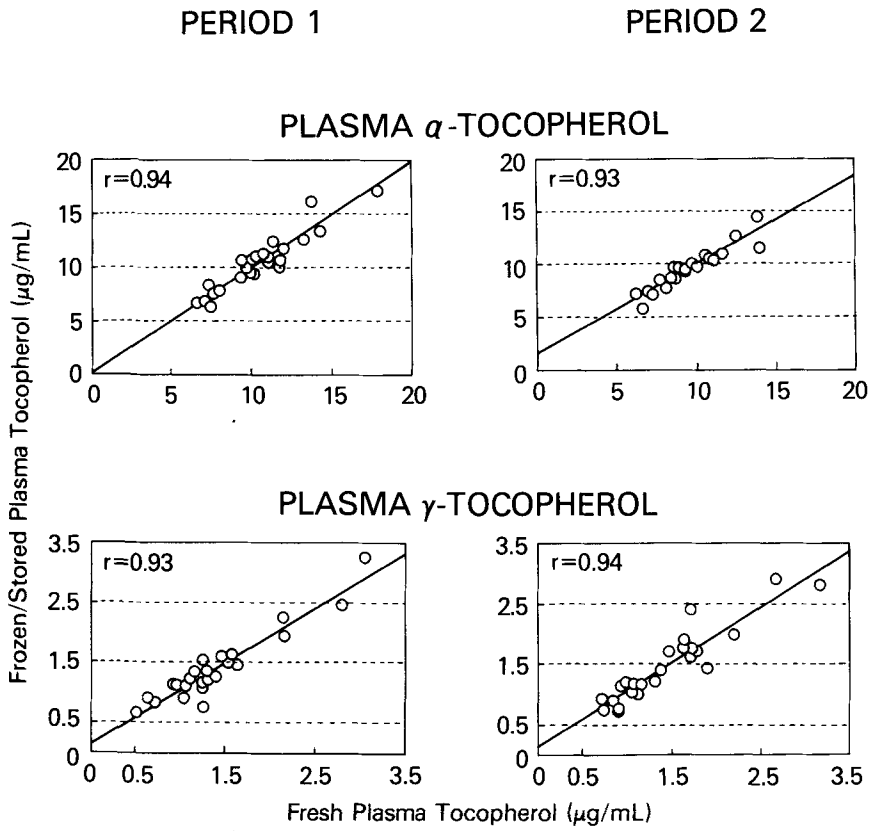

FIG. 1. Correlations of α- and γ-tocopherol levels in frozen/stored *vs* fresh plasma for two blood collection periods.

2: r = 0.81, P<0.001), due largely to the narrow range of HDL α-tocopherol values.

Distribution of α-tocopherol between LDL-VLDL and HDL. Distribution of α-tocopherol between the LDL-VLDL and the HDL fractions is shown in Table 2. With the exception of the LDL-VLDL fraction for period 1, the percentage of tocopherol carried by lipoprotein fractions did not differ for fresh and frozen/stored samples. The higher percentage distribution of α-tocopherol observed in period 1 for LDL-VLDL from frozen/stored plasma (62 *vs* 57%) was probably a function of the improved recovery (99 *vs* 95%) associated with the frozen/stored samples, as discussed below, rather than a direct effect of freezing and storage.

ApoB in column fractions. ApoB was confined exclusively to the LDL-VLDL fraction from each of the eight frozen/stored plasma samples analyzed.

DISCUSSION

As anticipated, plasma α- and γ-tocopherol were stable under the storage conditions of this study. Craft *et al.* (10) reported that α-tocopherol in heparinized plasma was stable for at least 15 months at −20°C and that purging plasma samples with nitrogen gas prior to storage had no detectable beneficial effects. Driskell *et al.* (11), using a single-donor pool of human serum, found that α-tocopherol was stable for 16 months when stored at −20°C. Furthermore, α-tocopherol levels were unaffected by 17 cycles of freezing and thawing. In the present study, all plasma samples contained EDTA as an added precaution against oxidative degradation of lipoprotein components (12) including loss of α-tocopherol (7).

The suitability of frozen plasma for determination of lipoprotein tocopherol levels appears to depend more on the stability of the lipoproteins than the stability of tocopherol. Several studies have been conducted to investigate the influence of freezing and storage of plasma on stability of lipoproteins as judged by recovery of lipoprotein cholesterol following ultracentrifugation. Two reports (13,14) concluded that lipoproteins are rapidly degraded by freezing, but others (16,17) concluded that decomposition of lipoproteins in frozen plasma was negligible for at least several months.

Frozen plasma has certain advantages over fresh plasma for lipoprotein fractionation and α-tocopherol analysis. Use of frozen replicate samples provides the opportunity to repeat chromatography and analysis of samples when recovery of α-tocopherol in lipoprotein fractions is incomplete. Storage also provides the convenience of pacing sample analysis. This can be important when large numbers of samples are to be analyzed; or, as frequently

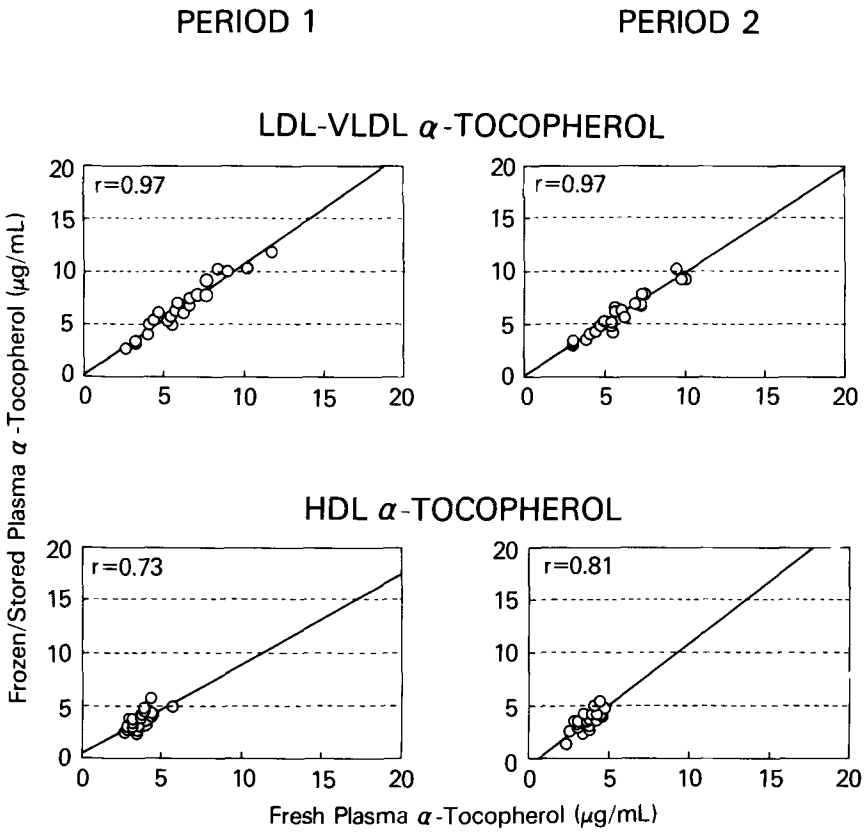

FIG. 2. Correlations of α-tocopherol levels in lipoprotein fractions separated by affinity chromatography from frozen/stored *vs* fresh plasma for two blood collection periods.

TABLE 2

Percent of Whole Plasma α-Tocopherol Recovered in LDL-VLDL and HDL Fractions Separated by Affinity Chromatography Using Fresh or Frozen/Stored Plasma[a]

	Fresh	Frozen/ stored[b]	Paired t-test	
			DIF ± SE[c]	P[d]
	Percent			
Period 1				
LDL-VLDL	57 ± 1.8	62 ± 2.0	−5 ± 1.3	<0.001
HDL	38 ± 1.7	37 ± 2.1	1 ± 1.0	NS
Recovery	95 ± 1.2	99 ± 1.2	−4 ± 1.7	0.019

required, when lipids, proteins, or other components of column fractions are to be concurrently measured. Use of frozen plasma also provides the opportunity to analyze, in one run, plasma samples collected at different times from a single donor.

In spite of such advantages, most investigators have chosen to use fresh plasma, and thus avoid the possibility that physical forces involved in freezing and thawing could alter lipoprotein integrity. In the present study, plasma that had been frozen at −20°C for six weeks was examined for evidence of lipoprotein decomposition. Ineffective binding of apoB to heparin affinity columns and loss of LDL tocopherol were not evident as might be expected if LDL particles had been substantially altered.

Freezing and storage of plasma did not appear to disrupt the binding of apoB-containing lipoproteins to affinity columns. If the affinity of apoB for the heparin ligand had been lost, then apoB should have been found in the unbound (HDL) fraction. Yet, no apoB was detected in that fraction for the eight plasma samples analyzed.

Furthermore, α-tocopherol content of lipoproteins was not decreased due to fractionating plasma that had been subjected to a single freeze-thaw cycle. Although a difference in the α-tocopherol content of LDL-VLDL was observed for period 1, the lower α-tocopherol value was from the LDL-VLDL fraction that was produced from fresh plasma. It is likely that this lower value was the result of an unexplained 5% lower recovery of LDL-VLDL from fresh plasma during period 1. That conclusion is supported by the α-tocopherol values for LDL-VLDL during period 2. There, the difference between mean α-tocopherol values for fresh and frozen/stored LDL-VLDL was negligible (-0.01 ± 0.10, $P = 0.900$). This illustrates the importance of complete recovery for accurate determination of lipoprotein tocopherol levels. Our 95% recovery from period 1, fresh plasma, was associated with a 9% decrease in the mean value for LDL-VLDL α-tocopherol as compared to frozen plasma where recovery averaged 99%. Yet, recoveries as high as 95% are generally not achieved using traditional methods of lipoprotein separation such as ultracentrifugation and gel filtration (1,2).

Because our observations were limited to a single storage temperature and to a relatively brief period of storage, they cannot be generalized to all conditions of low-temperature storage. Additionally, it is not known whether the relatively low lipid levels of the plasma samples used in this study influenced the outcome. In hypertriglyceridemic subjects VLDL can carry an unusually large proportion of α-tocopherol (3), and decay of VLDL and chylomicrons appears to be more pronounced in plasma samples with relatively high concentrations of these lipoproteins (15). Since fasting, normolipemic subjects carry only a minor proportion of α-tocopherol in VLDL (1-3), α-tocopherol contents of the LDL-VLDL fractions from this study predominately reflect α-tocopherol contents of LDL.

Measuring α-tocopherol content of LDL may prove useful for assessing the degree of protection this lipophilic antioxidant provides against certain oxidative processes. Recent studies have implicated oxidatively modified LDL as a promoter of atherosclerosis (22,23). *In vitro*, modified LDL are chemotactic for human monocytes (22) and promote lipid accumulation in macrophages (5,24). They are also toxic to cells in culture (25-27). Yet, it has been clearly demonstrated that oxidative modification of LDL, *in vitro*, is effectively inhibited by α-tocopherol (7,26,27). If these processes are operative *in vivo*, then the α-tocopherol carried by LDL could play a significant role in protecting this lipoprotein from oxidative modification.

We have previously described a rapid method for determining α-tocopherol levels of plasma lipoproteins. The present study expands the versatility of that method by demonstrating that plasma can be stored at −20°C for at least six weeks prior to lipoprotein fractionation by affinity chromatography without loss of α-tocopherol from either LDL-VLDL or HDL fractions. This simplified and convenient method for assessing α-tocopherol content of LDL may have practical application for assessing susceptibility to oxidative stresses.

Diet-Induced Type IV-Like Hyperlipidemia and Increased Body Weight Are Associated with Cholesterol Gallstones in Hamsters[1]

K.C. Hayes*, Pramod Khosla and **Andrzej Pronczuk**
Foster Biomedical Research Laboratory, Brandeis University, Waltham, Massachusetts 02254

Male Syrian hamsters (60–70 g) were fed purified diets containing 5% fat (American Fat Blend) and 15% fiber with or without 0.3% cholesterol (0.86 mg/kcal), for 12 weeks. Hamsters fed the cholesterol-supplemented challenge diet revealed a major increase in plasma triglyceride between 9 and 12 weeks, whereas plasma cholesterol (which reflected body weight dynamics) increased threefold up to nine weeks and plateaued (342 ± 22 *vs.* 122 ± 5 mg/dL). The greatest increases in cholesterol occurred in the very low density lipoprotein (VLDL) and high density lipoprotein (HDL_2) fractions. Gallstone incidence was similar (69% *vs.* 78%) for cholesterol-supplemented *vs.* control hamsters, but the type of stones differed. Of the cholesterol-supplemented hamsters with gallstones, 45% had cholesterol stones and 55% had pigment stones. Only pigment stones were seen in control hamsters. Hamsters with cholesterol stones were 25% heavier and transported most cholesterol in VLDL (33 ± 5%), approximately double that in VLDL of cholesterol-supplemented hamsters with no stones (19 ± 3%) or cholesterol-supplemented hamsters with pigment stones (21 ± 3%). Hamsters with pigment stones or no stones (regardless of diet fed) transported the majority of their cholesterol in HDL_2 (44%), whereas this figure was only 27% in hamsters that developed cholesterol stones. Thus pigment stones develop routinely in hamsters fed casein-based purified diets. Adding dietary cholesterol resulted in cholesterol gallstones only in those hamsters that gained the most weight and whose terminal VLDL/HDL cholesterol ratio exceeded 1.0, not unlike the lipoprotein profile of obese humans who develop cholesterol gallstones.
***Lipids* 26, 729–735 (1991).**

Syrian hamsters have been used extensively as an animal model for the study of gallstones because they are one of the few species in which gallstones can be readily induced by dietary manipulation (1–4). Their gallbladder bile seems to contain the requisite mucus, and biliary stasis with "sludging" appears to enhance their gallstone formation once lithogenic bile develops (5,6). Although both pigment stones and cholesterol stones occur (3–6), the dietary factors and the mechanisms responsible for these two types of stones are unresolved.

Diets with defined composition, as opposed to crude diet formulations or laboratory chow diets, allow study and identification of the specific dietary factor(s) causing lithogenesis. Recent work from this (5,6) and other investigators (3,4) describe purified diets that induce either pigment (3,5) or cholesterol gallstones (4,6).

Although it is well appreciated that cholesterol gallstones in humans are associated with abnormal cholesterol metabolism (7) and elevated plasma triglycerides (8), and that cholesterol metabolism itself is linked to the metabolism of plasma lipoproteins, minimal information exists concerning the relationship between lipoprotein metabolism and gallstone development in any species (9–12). In a recent study (6) we identified an association between an elevated very low density lipoprotein (VLDL) cholesterol pool, bile lithogenecity and cholesterol gallstones in Charles River (Lakeview, MA) hamsters fed butter fat and cholesterol.

To follow the time-course of the changes in circulating lipoproteins and gallstone development (including the type of gallstones induced), we have fed hamsters purified diets differing solely in their cholesterol content. The Sasco strain of male golden Syrian hamsters was studied because a recent report suggested that this hamster was especially sensitive to cholesterol gallstone induction (4).

MATERIALS AND METHODS

One hundred and ten male golden Syrian hamsters (*Mesocricetus auratus*) were obtained from Sasco Inc. (Omaha, NE; Sasco, golden Syrian outbred hamster derived from a closed colony from the University of Nebraska Medical Center, Eppley Cancer Institute) at a starting weight of 60–70 g. Hamsters were housed 4 per cage in a controlled environment with a 12-hr light-dark cycle (lights on at 1800 hr). All hamsters were fed a purified, cholesterol-free control diet with 5% fat (w/w). After 5 days of feeding the control diet, and just prior to feeding of the cholesterol-supplemented challenge diet (designated t=0 weeks), plasma lipids and lipoproteins were evaluated in 16 hamsters selected at random. Of the 16 hamsters, 7 were sacrificed for gallstone evaluation (no visible lesions or gallstones were observed). The data from these 16 animals constitutes the basal (t=0 week) values. The hamsters were then randomly divided into two groups. Group 1 (n=25) was continued on the control diet, whereas Group 2 (n=78) was fed the control diet supplemented with 0.3% (w/w) cholesterol (0.86 mg/kcal) for the remainder of the study. Hamsters had access to fresh food and water (provided daily) *ad libitum*. The composition of the diets (Table 1) reveals a polyunsaturated to saturated fatty acid ratio (P/S) of 0.54. The experimental design and procedures were approved by the Brandeis University Animal Use Committee.

In addition to the analysis at t=0 weeks, lipoprotein changes were also assessed at t=2, 5, 9 and 12 weeks in the cholesterol-supplemented hamsters. For this purpose, 16 hamsters were randomly selected from the pool of 78 animals. Individual hamsters were fasted overnight in wire-bottomed cages prior to being anesthetized lightly

Abbreviations: ANOVA, analysis of variance; EDTA, ethylenediaminetetraacetic acid; HDL, high density lipoprotein; HPLC, high-performance liquid chromatography; IDL, intermediate density lipoprotein; LDL, low density lipoprotein; PLSD, protected least significant difference; P/S, ratio of polyunsaturated to saturated fatty acids; VLDL, very low density lipoprotein.

TABLE 1

Composition of Purified Diets Fed to Hamsters[a]

	Control diet (cholesterol-free)	Challenge diet (cholesterol-supplemented)
	g/100g	
Casein	20	20
Glucose	18.9	18.9
Corn starch	35	34.7
Fat[b]	5	5
Cellulose	10	10
Wheat bran	5	5
Mineral mix[c]	4.6	4.6
Vitamin mix[d]	1.2	1.2
Choline chloride	0.3	0.3
Cholesterol	—	0.3

[a]Diets were fed as gel blocks, prepared by withholding 60 g corn starch (per Kg mix) from the formulation and premixing it with 800 mL of simmering water to form a gel to which the remaining ingredients were added.

[b]American fat blend (2.6 butter, 1.6 canola oil, 0.8 corn oil) had a P/S ratio of 0.54 and a P/M/S ratio of 1.0:1.0:1.9 (P, polyunsaturated; M, monounsaturated; S, saturated).

[c]Ausman-Hayes Salt Mix (BioServ Inc., Frenchtown, NJ).

[d]Hayes-Cathcart Vitamin Mix; the composition of the vitamin mix has been detailed previously (5).

for blood sample collection (2-3 mL) by cardiac puncture, into ethylenediaminetetraacetic acid (EDTA)-wetted syringes using a 25-gauge needle. (Unless sacrificed for gallstone evaluation, all hamsters recovered from the blood sampling). Lipoproteins were also analyzed at t=12 weeks in 16 animals from the control group. To allow for gallstone evaluation (at t=12 weeks), all 16 hamsters fed the cholesterol-supplemented diet (and 9 of the 16 animals fed the control diet) were exsanguinated by cardiac puncture. Gallbladders from the 9 control and 16 test hamsters were opened under an Olympus M100 dissecting microscope and all gallstones present were examined under regular and polarized light. Spherical white cholesterol gallstones (0.1-1.2 mm) and dark green-to-black pleomorphic pigment gallstones (<0.1-0.6 mm) were identified. Upon drying, representative gallstones of both cholesterol and pigment varieties were analyzed by high-performance liquid chromatography (HPLC) for their cholesterol content (13). The cholesterol content of cholesterol gallstones was routinely over 90%, whereas this figure was less than 2% for pigment gallstones. A detailed description of the two types of gallstones has been reported elsewhere (6).

Sodium azide (10%, w/v) was added to the plasma samples (10 μL/mL plasma). Throughout the study, lipoproteins were isolated from plasma pooled from 3-4 hamsters, with the exception of the analysis at t=12 weeks for the cholesterol-supplemented animals when lipoproteins were isolated from the plasma of individual hamsters. In all cases lipoproteins were isolated using stock density solutions of d=1.006 g/mL and d=1.38 g/mL by sequential ultracentrifugation (14) in Quick seal tubes®™ (Beckman, Palo Alto, CA) using a Ti 70.1 rotor at 12°C. Stock density solutions contained EDTA, gentamycin sulfate, sodium azide (15) and benzamidine (16). Five lipoprotein fractions were isolated, VLDL (d<1.006 g/mL), intermediate density lipoprotein (IDL) (1.006<d<1.019 g/mL), low density lipoprotein (LDL) (1.019< d<1.055 g/mL), HDL_2 (1.055<d<1.125 g/mL) and HDL_3 (1.125<d<1.21 g/mL). These density cuts for hamsters were determined in an initial study in which lipoproteins were isolated by discontinuous density-gradient ultracentrifugation (17) (data not shown). With the exception of VLDL and IDL, all lipoprotein fractions were dialyzed against 0.15M NaCl/1 mM EDTA, pH 7.4, at 4°C, for 24-36 hr. Lipoprotein cholesterol and triglyceride content were measured by enzymatic methods. Lipoprotein protein was measured using a modification (18) of the procedure of Lowry *et al.* (19). The sum of the cholesterol measured in each lipoprotein fraction was divided by the total plasma cholesterol to determine the percent recovery (20). The percent recovery for the lipoprotein isolations carried out at 12 weeks (n=21; 5 controls and 16 experimental) was 81% ± 2%. The final concentration of cholesterol, triglyceride and protein in each lipoprotein fraction was calculated by applying the same percent recovery.

To assess whether gallstone formation might be associated with differences in cholesterol esterification and/or changes in essential fatty acid availability, VLDL free cholesterol and individual cholesteryl esters were determined by HPLC (13). Cholesterol (free and esterified) was extracted by a double-solvent extraction procedure (isopropanol/0.75 M NaOH, 33:17, v/v and n-octane). The individual cholesteryl esters were separated on a Waters Radial-Pak Resolve™ C18 column by isocratic elution with acetonitrile/isopropanol (45:55, v/v) at 2 mL/min with a Beckman 110B solvent delivery module. The absorbance of the eluate was measured at 210 nm using a Waters model 480 LC spectrophotometer (Waters Associates, Wilmington, MA).

Plasma and lipoprotein cholesterol and triglyceride concentrations were determined enzymatically using kits (#336 and #352, respectively) obtained from Sigma Diagnostics (St. Louis, MO). Statistical analyses were carried out on a Macintosh Plus®™ computer (Apple Computer Inc., Cupertino, CA) using the Statview 512®™ software package (Brain Power, Inc., Calabasca, CA). Statistical differences between mean values for the control and cholesterol-supplemented dietary groups was assessed using Student's unpaired *t*-test. For subgroup analysis of the cholesterol-supplemented hamsters, the various parameters related to the gallstone response were analyzed by a one-factorial analysis of variance (ANOVA), and the Fisher protected least significant difference (PLSD) was used to test for statistical significance.

RESULTS

Time course of the changes in body weights, plasma lipids and lipoproteins. The time course of the changes in body weights and plasma lipid concentrations in hamsters fed the cholesterol-supplemented challenge diet over the 12 weeks of the study is shown in Figure 1. The final body weights represented a two-fold increase (p<0.001) in comparison to the body weights observed at the start of the study (68 ± 5 g). The plasma lipid values reflected body weight dynamics in that plasma cholesterol increased three-fold up to nine weeks (p<0.001), and then plateaued. By contrast, the plasma triglyceride concentration

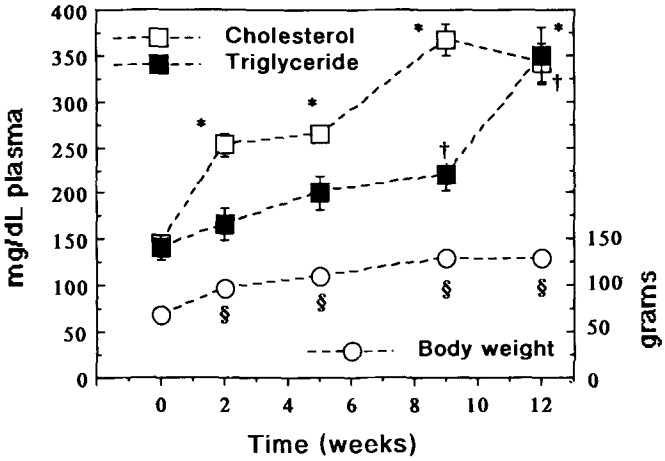

FIG. 1. Time-course of the change in body weight, plasma cholesterol and plasma triglyceride concentrations in hamsters fed the cholesterol-supplemented diet. Each point is the mean ± SEM of 16 hamsters. The data was analyzed with a one-way ANOVA followed by Fisher's PLSD to test for statistical significance ($p<0.05$). Symbols indicate values that were significantly different from the zero-time value.

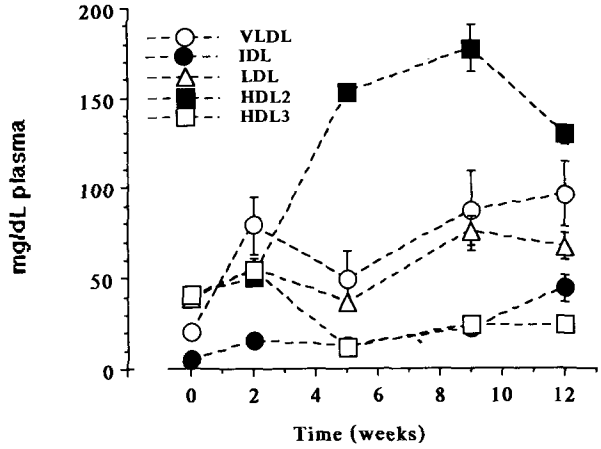

FIG. 2. Time-course of the change in lipoprotein cholesterol concentrations in hamsters fed the cholesterol-supplemented diet. Values are means ± SEM of four isolations using the plasma pooled from 3–5 animals, with the exception of the analysis at 12 weeks, which is the mean ± SEM of 16 individual hamsters. The data was analyzed with a one-way ANOVA followed by Fisher's PLSD to test for statistical significance ($p<0.05$). For VLDL and IDL, all values were significantly higher than the zero-time values. For HDL_2 the 5, 9 and 12 week values were significantly higher than the zero-time values. For LDL, the 9 and 12 week values were significantly higher than the zero-time values.

increased throughout the study, but significant increases were noted at 9 and 12 weeks ($p<0.001$).

The time-course for changes in lipoprotein cholesterol concentrations in the cholesterol-supplemented hamsters over the 12 weeks of the study is depicted in Figure 2. Fluctuating cholesterol concentrations in most of the lipoprotein fractions were apparent during the first 5 weeks, with the greatest relative increase in VLDL and HDL_2 cholesterol. After 5 weeks the cholesterol increased in all the lipoprotein fractions except HDL_3, but the most striking increase in mass occurred in HDL_2 until 9 weeks. By 12 weeks, HDL_2 cholesterol had decreased while only VLDL and IDL cholesterol revealed further increases.

Terminal weights and plasma lipid responses. Body weights, liver weights and plasma lipid levels after 12 weeks of feeding the two diets are presented in Table 2. Although body weights were comparable in the two dietary groups (125 ± 4 *vs.* 129 ± 4 g), the liver weights (as a percentage of the body weight) were significantly higher in hamsters fed the cholesterol-supplemented challenge diet ($p<0.001$). The terminal plasma cholesterol (361 ± 28 *vs.* 122 ± 5 mg/dL; $p<0.001$) and plasma triglyceride concentrations (405 ± 63 *vs.* 141 ± 13 mg/dL; $p<0.001$) were almost threefold higher in the challenge group. The final plasma cholesterol concentration in the hamsters fed the control diet was modestly, but significantly, lower than the value obtained at the start of the study (122 ± 5 *vs.* 144 ± 5 mg/dL; $p<0.003$), whereas the concentration of plasma triglyceride was similar (142 ± 12 *vs.* 141 ± 13 mg/dL).

The 12-week lipoprotein data revealed a greater lipoprotein mass in hamsters fed the challenge diet (Table 3). For both dietary groups the HDL_2 fraction transported the greatest percentage of cholesterol. The hypercholesterolemia in the experimental group was characterized by a four-fold increase in VLDL cholesterol, a seven-fold increase in IDL cholesterol, a three-fold increase in LDL cholesterol and a two-fold increase in HDL_2 cholesterol.

TABLE 2

Body Weights, Liver Weights and Plasma Lipid Concentrations in Hamsters Fed the Control and Challenge Diets for 12 Weeks[a]

	Control diet (cholesterol-free)	Challenge diet (cholesterol supplemented)
Body weight (g)	125 ± 4	129 ± 4
Liver weight (% body weight)	3.5 ± 0.5	5.6 ± 0.5
Plasma cholesterol (mg/dL)	122 ± 5	361 ± 28
Plasma triglyceride (mg/dL)	141 ± 13	405 ± 63

[a]Of the 16 hamsters fed the control diet, 9 hamsters were sacrificed for gallstone evaluation. Therefore, with the exception of the liver weights for the hamsters fed the control diet (n=9), all values are the means ± SEM of 16 animals. All parameters were significantly different between groups as determined by Student's unpaired *t*-test ($p<0.001$) with the exception of body weights.

These changes in the terminal cholesterol distribution represented a relative decrease in HDL_2 cholesterol, but relative and absolute increases in VLDL cholesterol as compared to control hamsters. The hypertriglyceridemia in the supplemented group was reflected principally in the VLDL fraction. In terms of cholesterol distribution, cholesterol-feeding almost doubled the cholesterol load in the VLDL/IDL pool (38% *vs.* 22%) while decreasing the cholesterol in HDL by 30% and leaving the LDL pool unaltered.

Gallstone incidence. No gallstones were detected in hamsters fed the cholesterol-supplemented challenge diet over the first five weeks of the study (Table 4). At nine weeks, three of five hamsters killed had early pigment stone formation only (represented by soft, mucus-rich clusters of greenish, sawdust-like material which was typically amorphic and less than 0.1 mm long). By 12

TABLE 3

Lipoprotein Lipid and Protein Concentrations in Hamsters Fed the Control or Challenge Diets for 12 Weeks[a]

	Control diet (cholesterol-free)	Challenge diet (cholesterol-supplemented)
VLDL (d < 1.006 g/mL)		
Cholesterol	22 ± 1 (17.4)[b]	96 ± 18[c] (26.2)
Triglyceride	85 ± 6	302 ± 61[d]
Protein	16 ± 1	22 ± 5
IDL (1.006 < d < 1.019 g/mL)		
Cholesterol	6 ± 0.1 (4.6)	44 ± 7[c] (12.4)
Triglyceride	13 ± 0.2	38 ± 3[d]
Protein	5 ± 0.2	16 ± 2[c]
LDL (1.019 < d < 1.055 g/mL)		
Cholesterol	23 ± 0.9 (18.3)	67 ± 7[e] (18.4)
Triglyceride	10 ± 0.3	24 ± 1[d]
Protein	14 ± 0.3	44 ± 5[e]
HDL_2 (1.055 < d < 1.125 g/mL)		
Cholesterol	57 ± 2 (45.9)	129 ± 5[e] (36.2)

Protein	114 ± 6	257 ± 9[e]
HDL_3 (1.125 < d < 1.21 g/mL)		
Cholesterol	17 ± 0.9 (13.8)	24 ± 2 (6.7)
Triglyceride	3 ± 0.3	11 ± 1[c]
Protein	50 ± 5	77 ± 4[c]
VLDL-C/HDL_2-C	0.4 ± 0.04	0.8 ± 0.2

[a]mg/dL Plasma. Values are the means ± SEM; n=5 for the control group and n=16 for the experimental group. For the control group lipoproteins were isolated from plasma pooled from 3-4 hamsters, whereas for the experimental group, lipoproteins were isolated from the plasma of individual animals.

[b]Values in parentheses represent percent distribution.

[c,d,e]Statistical significance between mean values for the two dietary groups was calculated using Student's unpaired *t*-test. p Values: [c]p<0.02; [d]p<0.05; [e]p<0.001.

TABLE 4

Gallstone Incidence in Hamsters Fed the Control and Challenge Diets

Time (weeks)	Criterion	Control diet (cholesterol-free)	Challenge diet (cholesterol supplemented)
0	Gallstone incidence[a]	0/7 [0%]	
2	Gallstone incidence		0/16 [0%]
5	Gallstone incidence		0/11 [0%]
9	Gallstone incidence		3/5 [60%][b]
12	Gallstone incidence	7/9 [78%]	11/16 [69%]
	Cholesterol stones[c]	0/7 [0%]	5/11 [45%]
	Pigment stones[c]	7/7 [100%]	6/11 [55%]
	Gallstone severity[d]		
	Cholesterol stones	0	5
	Pigment stones	3.6 ± 0.5	3.3 ± 1.5

[a]The number of hamsters with gallstones/number of hamsters examined.

[b]Only early pigment stone formation observed. Additional hamsters were not killed.

[c]The number of hamsters with cholesterol or pigment stones/number of hamsters with gallstones.

[d]Both cholesterol and pigment stones were scored microscopically on a scale of 0-5 to characterize relative size and number.

TABLE 5

Body Weights, Liver Weights, Plasma Lipid and Lipoprotein Concentrations in Subgroups of Hamsters Fed the Challenge Diet for 12 Weeks (Based on Gallstone Response)[a]

		No stones	Cholesterol stones	Pigment stones
Number of hamsters		5	5	6
Body weight (g)		120 ± 8[b]	149 ± 4[b,c]	121 ± 4[c]
Liver weight (% body wt.)		4.6 ± 1.0[d,e]	6.6 ± 1.5[d]	6.7 ± 1.0[e]
Plasma cholesterol (mg/dL)		319 ± 35	421 ± 70	346 ± 34
Plasma triglyceride (mg/dL)		338 ± 64	562 ± 173	329 ± 54
VLDL[f]	Cholesterol	64 ± 17[g] (19.8)[h]	152 ± 46[g,i] (35.3)	77 ± 19[i] (21.4)
	Triglyceride	231 ± 60	462 ± 166	228 ± 55
	Protein	25 ± 6	49 ± 13	27 ± 6
IDL	Cholesterol	39 ± 9 (13.2)	60 ± 15 (14.1)	36 ± 10 (10.5)
	Triglyceride	36 ± 4	43 ± 6	35 ± 2
	Protein	14 ± 3	21 ± 5	14 ± 4
LDL	Cholesterol	53 ± 8 (16.3)	78 ± 18 (18.4)	69 ± 4 (20.3)
	Triglyceride	23 ± 3	25 ± 3	23 ± 1
	Protein	43 ± 10	49 ± 8	41 ± 5
HDL_2	Cholesterol	136 ± 4[j] (42.4)	110 ± 6[j,k] (27.0)	139 ± 7[k] (40.6)
	Triglyceride	34 ± 3	22 ± 4	33 ± 5
	Protein	260 ± 17[l]	224 ± 12[l,m]	281 ± 12[m]
HDL_3	Cholesterol	26 ± 2 (8.1)	22 ± 5 (5.2)	25 ± 2 (7.1)
	Triglyceride	14 ± 2	10 ± 1	11 ± 1
	Protein	75 ± 7	74 ± 9	82 ± 6
VLDL-C / HDL_2-C		0.47 ± 0.12[n]	1.43 ± 0.45[n,o]	0.53 ± 0.11[o]

[a] Mean ± SEM.

[f] mg/dL Plasma.

[h] Values in parentheses represent the percent distribution of cholesterol among the lipoprotein fractions. Data from the 16 hamsters fed the Challenge diet (cholesterol-supplemented) are expressed in terms of the gallstone response. The data was analyzed by a one factorial ANOVA followed by Fishers PLSD test for significance between the subgroups. Mean values, sharing a common superscript are significantly different.

p Values: [b,c] $p<0.02$; [j,k] $p<0.03$; [d,e,n,o] $p<0.05$; [g,i,l,m] $0.05<p<0.10$.

weeks, the incidence of gallstones in the two dietary groups was comparable (78% *vs.* 69%). When the control hamsters were sacrificed, the livers in the first nine hamsters were dark red-brown and smaller than test hamster livers, and since none of these had cholesterol crystals in their bile and the only gallstones present were pigment stones, the other seven animals in this group were not killed. By contrast, hamsters fed the cholesterol-supplemented challenge diet were found to have enlarged, pale-yellow livers. Among the 69% with gallstones, either cholesterol stones (45%) or pigment stones (55% incidence) were observed. Both number and size of pigment stones in the control dietary group were similar to those in the cholesterol-supplemented group.

Lipoprotein distribution in relation to gallstone response. Since the cholesterol-supplemented group revealed three responses in terms of gallstones (no stones, cholesterol stones, or pigment stones), the data from this dietary group was re-analyzed according to gallstone subgroup (Table 5). Although all three subgroups experience elevated total plasma cholesterol and triglyceride concentrations by comparison to controls, the cholesterol-stone formers tended to have higher lipid values than the other two subgroups, and their lipoprotein profile was characterized by 20% less HDL_2 cholesterol ($p<0.03$). The HDL protein tended to be lower as well ($0.05<p<0.10$). Their VLDL cholesterol, however, tended to be higher ($0.05<p<0.10$). The combined effect of the lipoprotein differences resulted in the ratio of VLDL to HDL_2 cholesterol being essentially three-fold higher ($p<0.05$) in hamsters with cholesterol stones as compared to cholesterol-supplemented hamsters having no stones or pigment stones. The percentage of plasma cholesterol in the VLDL fraction of hamsters with cholesterol stones (35%) was almost double that of the other two subgroups. All other lipoprotein parameters between the three subgroups of hamsters were similar. Furthermore, no differences were noted in any of the measured lipoprotein parameters between hamsters with no stones and those with pigment stones. In essence, the two types of gallstones were associated with distinct VLDL and HDL_2 cholesterol distributions such that pigment stone bearers transported the majority of their lipoprotein cholesterol in the HDL_2 fraction (41%), whereas hamsters bearing cholesterol gallstones transported the majority of cholesterol in the VLDL fraction (35%).

A striking finding was that the mean body weight of cholesterol-supplemented hamsters developing cholesterol stones was 25% greater ($p<0.02$) than either of the other two subgroups having no stones or pigment stones.

VLDL cholesterol. The two-fold increase in total VLDL cholesterol observed in the subgroup of hamsters with

TABLE 6

VLDL Cholesteryl Ester Distribution in Hamsters Fed the Challenge Diet for 12 Weeks[a]

Criterion	No stones	Cholesterol stones	Pigment stones
	mg/dL plasma		
Total VLDL cholesterol	64 ± 17[b]	152 ± 46[b,c]	77 ± 19[c]
VLDL free cholesterol	15 ± 3 (23.5)[d]	44 ± 12 (28.7)	24 ± 7 (31.6)
Cholesteryl esters	49 ± 11[e] (76.5)	108 ± 20[e,f] (71.2)	53 ± 7[f] (68.4)

[a]Values are the mean ± SEM for five hamsters with no stones, five with cholesterol stones and six with pigment stones. Mean values sharing a common superscript differ significantly between groups using a one factorial ANOVA.

[d]Parentheses represents percent distribution of the total cholesterol fraction or the fatty acid cholesteryl esters, respectively.

p values: [e,f] $p<0.05$; [b,c,g–j] $0.05<p<0.10$.

cholesterol stones was reflected in the mass of cholesterol esters (Table 6), although the relative distribution between free and esterified cholesterol was similar for the three subgroups. Furthermore, the cholesteryl ester fatty acid profile was similar for the three subgroups with no difference in the 18:1/18:2 ratio.

DISCUSSION

The objective of this investigation was to define the progressive impact of dietary cholesterol on hamster plasma lipoproteins and to determine the relationship of the lipoprotein changes to the induction of cholesterol gallstones observed previously (6). In addition, we wanted to establish the time-frame of the associated lipoprotein alterations. Upon termination of our previous study we noted an elevated VLDL/HDL cholesterol ratio in hamsters with cholesterol gallstones, but the diet in that study was more severe, containing 5% butter, more glucose, and more cholesterol (0.4% or 1.14 mg/kcal). Evidence of mild essential fatty acid depletion also was deduced from plasma fatty acid profiles. Our previous hamsters (Charles River) were allegedly more resistant to gallstones than the Sasco strain used in the present experiment (4), yet with the previous cholesterol challenge diet and hamster strain we found a much higher overall incidence of cholesterol gallstones (93% *vs.* 45%) over the same experimental period (6).

In the present study an American Fat Blend (P/S ratio 0.54) that provided 2.6% dietary energy as 18:2 was fed to improve essential fatty acid status, and dietary cholesterol was reduced by 25%. Furthermore, the sequential changes in plasma lipids, including the lipoprotein profile, were measured during gallstone induction to document the time-course in lipoprotein alterations. This identified HDL_2 as the predominant lipoprotein in the normal hamster. Feeding a 0.86 mg/kcal cholesterol supplement (0.3%, w/w) initiated a rapid rise in VLDL and HDL_2 cholesterol, but the latter pool of cholesterol then declined somewhat by 12 weeks, while VLDL and IDL cholesterol continued to increase. This distribution of cholesterol was most pronounced in the subset of hamsters that developed cholesterol gallstones, a process that appeared to occur between 9 and 12 weeks in our study. By contrast, the hamsters fed the same diet that managed to resist the VLDL-cholesterol increase and maintain their HDL_2, remained free of cholesterol gallstones and were either free of all gallstones or developed only pigment stones. The animals that developed cholesterol stones also gained 25% more body weight than controls fed no cholesterol or the other two subgroups (no stones, pigment stones) also fed cholesterol. Essential fatty acid status did not appear compromised in any group. In fact, the cholesterol-stone formers had the highest percentage of 18:2 among their cholesteryl esters.

At least three implications can be inferred from these data. First, cholesterol gallstone induction in response to cholesterol feeding in hamsters appeared to be associated with an expansion of the VLDL cholesterol pool and relative decrease in HDL_2, the principal lipoprotein cholesterol pool found in normal hamsters. Previously in hamsters fed a comparable diet with a similar shift in their lipoprotein profile (6), we found that the gallbladder bile was markedly supersaturated with cholesterol (lithogenic index of 1.72 with bile acids, phospholipids and cholesterol of 79, 13 and 8 mol%, respectively) and that the liver was enlarged and cholesterol laden (2 mg *vs.* > 20 mg cholesterol/g liver) as it was herein. In the present study the plasma cholesterol (and triglyceride) concentrations tended to be higher in hamsters with cholesterol stones than in the two other subgroups that were fed cholesterol without developing cholesterol stones, supporting our previous observation that increased cholesterol transport was associated with cholesterol gallstone induction (6). However, both the plasma cholesterol and triglyceride values in all three cholesterol-fed subgroups were higher than the control values. This suggests that 0.3% cholesterol (0.86 mg/kcal) approximates the minimal threshold for initiating a cholesterol "overload", causing approximately one-third of the hamsters to exceed their ability to metabolize the increased rate of cholesterol transport. Similar to the situation in gallstone patients where

triglyceridemia could not be separated from decreased HDL levels (7), we are not able to ascertain why HDL_2 should protect against, or VLDL-C should be associated with, cholesterol supersaturation of bile in hamsters. One possibility might be that VLDL-C (as VLDL remnants) has more direct access to the biliary cholesterol pool or that HDL_2 cholesterol has preferential access to bile acid synthesis, since we previously noted an increase in biliary cholesterol (8 *vs.* 2 mol%) and a decrease in the relative concentration of bile acids (79 *vs.* 90 mol%) in hamsters with cholesterol-gallstones under similar circumstances (6). It is interesting that Syrian hamsters, as a species, like women whose gender seems to predispose to gallstones (21), have a predominant HDL_2 profile.

The second point relates to the greater body weight of hamsters with cholesterol gallstones. It is well accepted that obesity is the single most important risk factor for cholesterol stones in humans (7,8,21,22). Obese persons typically experience increased cholesterol transport rates and a lipoprotein profile (expanded VLDL and LDL pools) reflective of hypercholesterolemia and hypertriglyceridemia (7,23,24). Even in non-obese women with increased gallstone incidence, the factor most associated with gallstones was excessive caloric intake (22). If the propensity for increased body weight in hamsters bearing cholesterol gallstones eventually proves to be a reflection of increased energy flux through lipoproteins with its attendant cholesterol transport, it would suggest that at least one mechanism of lithogenesis in cholesterol-fed hamsters and humans may be comparable, *i.e.*, increased caloric consumption resulting in elevated cholesterol transport and increased flux and catabolism of VLDL cholesterol through the liver. If bile acid production is compromised, or the direct transport of free cholesterol into bile is enhanced, or phospholipid synthesis is curtailed in any way, lithogenic bile may ensue.

Although the adipose stores were not measured in these hamsters, subsequent experiments have revealed that weight increments above 100 g body weight in male hamsters are highly correlated (r=0.88) with the size of the adipose depots (unpublished observations). Thus, it would appear that the extra body weight in the cholesterol-stone formers represented fat and that this subgroup had assumed certain characteristics of the moderately obese, type-IV hyperlipidemic human characterized by elevated plasma cholesterol and triglyceride concentrations (7,8,23-26). It will be important to determine whether the propensity to gain weight by the subgroup of susceptible hamsters represents excessive food intake (behavioral) or whether this subpopulation is metabolically more energy efficient resulting in an aberrant shift in cholesterol transport and disposition (genetic).

Finally, as we noted previously (6), susceptibility and induction of pigment gallstones would appear to be independent of changes in cholesterolemia or the lipoprotein profile, as the incidence of pigment stones and the degree of pigment stone involvement (number, size, etc.) was similar in control and cholesterol-fed hamsters.

[Received February 22, 1991; Revision accepted June 9, 1991]

Metabolism of Meadowfoam Oil Fatty Acids in Mice[1]

E.A. Emken[a,*], R.O. Adlof[a] and S. Abraham[b]

[a]Food Quality and Safety Research, National Center for Agricultural Utilization Research, ARS, U.S. Department of Agriculture, Peoria, Illinois 61604, and [b]Children's Hospital Medical Center, Oakland, California 94609

Meadowfoam oil is unusual because over 95% of the fatty acids are 20- and 22-carbon aliphatic acids with *cis* double bonds located principally at the 5- and/or 13-position. Since little information is available on the metabolism of the 5*c*-20:1 and 5*c*,13*c*-22:2 fatty acids, an exploratory study in mice was conducted to investigate the metabolism of purified samples of the free fatty acids isolated from meadowfoam oil, and to determine the effect of meadowfoam oil on weight gain and tissue lipid composition. Mice fed diets containing 5% by wt of the purified 5*c*-20:1 or 5*c*,13*c*-22:2 for 6 days exhibited no apparent physiological problems. Total liver lipids from mice fed the purified fatty acid diets contained mean values of 2.0% 5*c*-20:1 and 2.1% 5*c*,13*c*-22:2; total heart lipids contained 1.7% 5*c*-20:1 and 10.7% 5*c*,13*c*-22:2. Liver total phospholipids from mice fed a 5% meadowfoam oil diet for 19 wk contained 1.4% 5*c*-20:1 and 1.9% 5*c*,13*c*-22:2. There was no evidence of desaturation, elongation or retroconversion. Weight gain for mice fed the meadowfoam oil diet for 19 wk was similar to mice fed corn oil, and was higher than for mice fed hydrogenated cottonseed oil. Considering the high 5*c*-20:1 and 5*c*,13*c*-22:2 content of the diets, the percentages of these fatty acids in mouse tissue lipids from both the short- and long-term studies were low. Weight gain was surprisingly good since the meadowfoam oil diet was essential fatty acid-deficient. Results of this initial investigation suggest that the 5*c*-20:1 and 5*c*,13*c*-22:2 fatty acids were utilized primarily for energy. In the short-term study, these fatty acids did not produce toxic effects or cause metabolic problems.

***Lipids* 26, 736–742 (1991).**

The fatty acid composition of *Limnanthes douglasii* or meadowfoam oil (MFO) was characterized in 1960 (1). The composition of the oil is unusual because over 95% of the fatty acids are 20- and 22-carbon aliphatic acids with *cis* double bonds located principally at the 5- and/or 13-position. This unique composition and the high oxidative stability of the oil has resulted in its use in cosmetics, surfactants, lubricants and waxes (2,3). No data have been reported on the metabolism of the 5*c*-20:1 and 5*c*,13*c*-22:2 fatty acids which comprise over 80% of the oil.

The health concerns caused by the physiological and metabolic data reported for rats fed high erucic acid (13*c*-22:1) rapeseed oil (4) suggest that the metabolism and physiological properties of the structurally related 5*c*,13*c*-22:2 should be evaluated before meadowfoam oil is used in food products. The structure of 5*c*-20:1 suggests the possibility that it could compromise the metabolism of arachidonic acid (5,8,11,14-20:4) or eicosapentaenoic acid (5,8,11,14,17-20:5).

The purpose of this initial evaluation of the metabolism of meadowfoam oil was to determine if the 5*c*-20:1 and 5*c*,13*c*-22:2 fatty acids (i) accumulate or influence the fatty acid composition of mouse tissue lipids, (ii) influence weight gain, (iii) alter lipogenesis, or (iv) are desaturated or elongated to other structures.

EXPERIMENTAL PROCEDURES

Materials. Alkali refined and bleached meadowfoam oil was supplied by Richard Purdy Inc. (Ukiah, CA). Hydrogenated cottonseed oil was supplied from Wilfey Food Co. (Oakland, CA). Corn oil was a gift from Best Foods (Union, NJ). Samples of 5*c*-20:1 and 5*c*,13*c*-22:2 acids were obtained by transesterification of meadowfoam oil and saponification of the methyl esters that were isolated by silver resin chromatography (5). The enriched 5*c*-20:1 fraction contained 82% 5*c*-20:1, 4% 5*c*-22:1, 11% 13*c*-22:1, and about 1% each of 9*c*-18:1, 20:0 and 22:0. The 5*c*,13*c*-22:2 fraction contained 98% 5*c*,13*c*-22:2, 0.5% 18:2, and 1.5% 20:2. The purity of the oleic acid (9*c*-18:1) and linoleic acid (9*c*,12*c*-18:2) was 99% (Nu-Chek Prep. Inc., Elysian, MN).

Diets. The experimental diets were prepared by starting with a fat-free dry base mixture. This mixture contained by weight, 60% glucose, 20% vitamin-free casein, 5% cellulose, 3.5% salt mix (AIN mineral mixture 76), 1% vitamin mixture (Vitamin Diet Fortification Mixture), 0.3% methionine, 0.2% choline and 0.01% butylated hydroxytoluene. NBC Biochemicals (Cleveland, OH) was the source of all diet components except for glucose and butylated hydroxytoluene. The final diets were formulated by adding 5% by weight of the pure fatty acid plus 5% additional glucose or 10% by weight of the meadowfoam oil, corn oil or hydrogenated cottonseed oil to the dry mixture. The mice were provided free access to the diets, and

TABLE 1

Fatty Acid Composition of Dietary Fats

Fatty acid	Meadowfoam oil (%)	Corn oil (%)	Hydrogenated cottonseed oil (%)

the portion of diet that was not consumed was discarded. The diet was replaced daily.

Meadowfoam oil study. Diets containing 10 wt% of meadowfoam oil (MFO), hydrogenated cottonseed oil (HCTO) or corn oil were fed to groups of 11–16 young adult BALB/c female mice (initial wt, *ca.* 20 g) obtained from the breeding colony at The Children's Hospital Medical Center, Oakland, CA. The fatty acid composition of the oils are summarized in Table 1. The mice were housed in groups of 3–5 per cage and the diets were fed *ad libitum*. Temperature was maintained at 22° with a 12 hr light/12 hr dark cycle. Weight gain was determined, and the mice were sacrificed after 19 wk. Organs were removed, placed in ice-cold sucrose solution and homogenized. Portions of the tissue homogenate were removed for fatty acid analysis. Liver mitochondria and microsomes were isolated by centrifugation of the liver homogenates as previously described (6). Free fatty acids were obtained by saponification with aqueous/ethanolic potassium hydroxide (7). Methyl esters were prepared either by refluxing the free fatty acid extracts with sulfuric acid/methanol or by treatment with diazomethane (8).

Purified fatty acid study. Diets containing 5 wt% of either 9*c*-18:1, 9*c*,12*c*-18:2, 5*c*-20:1 or 5*c*,13*c*-22:2 as the free fatty acid were fed to groups of 4 BALB/c weanling female mice (age 3–4 wk; wt 10–12 g). Free fatty acid was used to facilitate absorption. After 6 days, 500 microcuries of tritiated water was injected intraperitoneally and the mice were sacrificed after 15 min. The procedures used to analyze the organ lipids were the same as described for the meadowfoam oil study.

Portions of the homogenized tissues were analyzed also for tritiated fatty acids to determine fatty acid synthetase activity as described previously (9,10).

Analytical methods. Fatty acid synthetase activity was determined as described elsewhere (9,10). Extraction, methyl ester preparation, and determination of fatty acid composition by gas chromatography (GC) have been described (10).

Liver, heart, and small intestine lipid extracts from the purified fatty acid study were analyzed by both capillary and packed column GC. Mammary gland, kidney, lung, and brain lipid extracts from the purified fatty acid study and liver samples from the meadowfoam oil study were analyzed by packed column GC only (6 ft × 1/4 in DEGS column). The chromatograms shown in Figure 1 for heart lipid methyl esters illustrate the separation obtained with the 100-m SP2560 coated fused silica capillary column. The 5*c*-20:1 and 5*c*,13*c*-22:2 esters were completely resolved from other fatty acid methyl esters present in these mouse tissue lipids.

Statistical methods. A SAS statistical program was utilized (11). A paired t-test was used to analyze the differences between mean values. Linear regression analysis of 0–9 wk and 10–19 wk data was used to evaluate differences in weight gain.

RESULTS

Weight gain. The mean body weights and regression slopes for 0–9 wk and 10–19 wk are plotted in Figure 2 for mice fed corn oil (CO), hydrogenated cottonseed oil (HCTO) and meadowfoam oil (MFO) diets.

Rate of weight gain for each mouse was estimated by linear regression analysis. Individual weight gains were used to calculate regression slopes. For mice fed the CO diet, a small weight gain occurred during the first 9 wk (regression slope = 0.12 g/wk/mouse, $p = 0.07$ for a t-test of null hypothesis (H_0)). No weight gain occurred during the last 10 wk (slope = 0.04, $p = 0.38$). Overall weight gain was nearly zero (slope = −0.02, $p = 0.78$). For mice fed the MFO diet, weight gain occurred during the first 9 wk (slope = 0.15, $p < 0.01$) and then remained stable for the last 10 wk (slope = −0.01, $p = 0.19$). The mice fed the HCTO diet gained weight during the first 9 wk (slope = 0.18, $p < 0.01$) and lost weight during the last 10 wk (slope = −0.32, $p < 0.01$). Comparison of mean weight gains during the first 9 wk by analysis of variance indicated no significant difference due to diet (all $p > 0.25$). For the last 10 wk of the study, weight gains were similar ($p = 0.99$) for the mice fed the CO and MFO diets. Mean weight gains for mice fed CO and MFO diets were significantly different ($p < 0.01$) from mean weight gains for mice fed the HCTO diet.

Weight loss for the HCTO-fed mice is probably related to the linoleic acid deficiency of these diets. Although the weight loss for the MFO-fed mice was not significantly different from that of the CO-fed mice, they did develop a scruffy and sometimes scaly appearance that is typical of essential fatty acid deficiency (12).

Liver lipids. The fatty acid composition of liver total lipids from mice fed the purified fatty acid diets is listed in Table 2. The differences in the total liver lipid fatty acid composition for the mice fed the purified 9*c*-18:1, 5*c*-20:1 and 5*c*,13*c*-22:2 diets were relatively small. The most notable effect of the 5*c*-20:1 and 5*c*,13*c*-22:2 diets compared to the 18:1 diet was a 25% to 50% depression of the 18:2n-6, 20:4n-6 and 22:6n-3 percentages. A smaller decrease in 18:0 (10–30%) and a 10–30% increase in 16:0 and 16:1 also occurred. Samples from the MFO-acid-fed mice contained only 1.99% 5*c*-20:1 and 2.13% 5*c*,13*c*-22:2, which is less than the reduction in the total percentages for 20:4n-6 and 22:6n-3. These data suggest the 5*c*-20:1 and 5*c*,13*c*-22:2 acids did not merely replace other 20- and 22-carbon fatty acids, but that they also influenced the metabolism of other fatty acids. In particular, when 5*c*,13*c*-22:2 was fed, the percentage of oleic acid increased 8% (48.5% *vs* 40.6%) compared to that in mice fed the oleic acid diet, but the 5*c*-20:1 diet did not alter the percentage of oleic acid in the liver lipids. Both the 5*c*-20:1 and 5*c*,13*c*-22:2 diets substantially reduced 20:4n-6 levels. Fatty acids were not detected that could be associated with chain elongation, desaturation or retroconversion of the 5*c*-20:1 or 5*c*,13*c*-22:2 structures.

The liver mitochondrial and microsomal lipids from mice fed MFO for 19 wk contained 3.6% and 2.0% of 5*c*-20:1 and 5*c*,13*c*-22:2, respectively (Table 2). When compared to data from three mice fed the CO diet, the values for 18:2n-6 were lower in the samples from the MFO-fed mice. The difference is likely due to the low 18:2n-6 content of the MFO diet. The percentage of 20:4n-6 was reduced in the MFO-fed mice compared to that in corn oil-fed mice, but the percentage of 22:6n-3 was similar in samples from both the CO and MFO diets. The MFO diet was essential fatty acid (EFA)-deficient and produced the expected increase in 20:3n-9 as did the HCTO diet and the pure 18:1 diet (12). Since mouse liver mitochondrial and microsomal lipid fractions contain about 90%

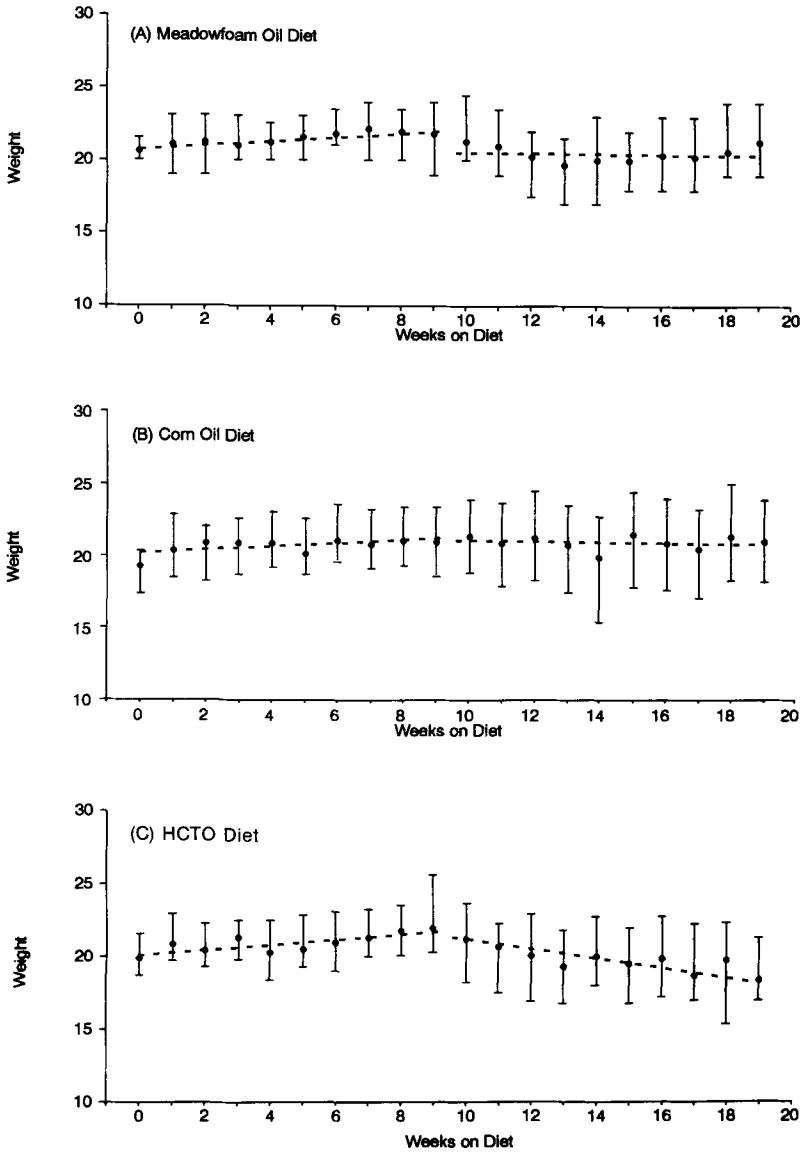

FIG. 2. Weights of mice fed triglyceride diets for 19 wk. A) Meadowfoam oil diet (n=10). B) Corn oil diet (n=10). C) Hydrogenated cottonseed oil diet (n=15). Symbols represent mean values and bars indicate range of body weights. Dashed lines represent linear regression analysis of 0–9- and 10–19-wk data.

phospholipids (13), the fatty acid data reflect the total liver phospholipid fatty acid composition.

Heart lipids. The fatty acid composition of the heart total lipids from mice fed the purified fatty acids is listed in Table 3. The influence of the purified 9*c*-18:1, 5*c*-20:1 and 5*c*,13*c*-22:2 diets on the total heart lipid fatty acid composition was different than that on the liver. The heart lipids contained 2.2% 5*c*-20:1 (mice fed 5*c*-20:1) and 8.4% 5*c*,13*c*-22:2 (mice fed 5*c*,13*c*-22:2). The percentage of 5*c*-20:1 in the liver and heart lipids were similar, but the percentage of 5*c*,13*c*-22:2 was nearly 5 times higher in heart lipids than in liver lipids. There was no evidence for fatty acids with structures that would be indicative of chain elongation, desaturation or retroconversion of 5*c*-20:1 or 5*c*,13*c*-22:2. An interesting effect of the 5*c*-20:1 diet was a 20% increase in 20:4n-6 compared to the data for 9*c*-18:1-fed mice. For the 5*c*,13*c*-22:2 *vs* 9*c*-18:1 diets, there was a 15% decrease in the 22:6n-3 percentages.

Other tissue lipids. The 5*c*-20:1 and 5*c*,13*c*-22:2 percentages in kidney, intestine, lung, brain and mammary tissues are compared to heart and liver total lipids in Table 4. These data were from mice fed the purified 5*c*-20:1 and 5*c*,13*c*-22:2 diets. The percentages for 5*c*-20:1 and 5*c*,13*c*-22:2 were the highest in intestine and mammary tissue. Brain tissue contained only traces of 5*c*-20:1 and 5*c*,13*c*-22:2. In all tissues, the percentage of 5*c*,13*c*-22:2 was significantly higher than that of 5*c*-20:1.

Fatty acid synthetase activity. The influence of dietary 5*c*-20:1 and 5*c*,13*c*-22:2 on fatty acid synthetase (FAS)

activity in mouse tissue is compared to the effect of 9*c*-18:1 and 9*c*,12*c*-18:2 in Table 5. Fatty acid synthesis in livers from mice fed the purified 5*c*-20:1 and 5*c*,13*c*-22:2 diets were similar and was intermediate between that in livers of mice fed 9*c*-18:1 and 9*c*,12*c*-18:2. Both of the fatty acids from MFO significantly depressed FAS activity compared to 9*c*-18:1. The FAS activity data for livers from mice fed 5*c*-20:1 and 5*c*,13*c*-22:2 were higher than for 18:2n-6-fed mice, but the data were not significantly different at $p < 0.05$.

[b]Micromoles of tritiated water converted to fatty acids per gram wet tissue per 15 min.

[c]p Values for comparison of 9c-18:1 diet to other diets calculated by paired t-test.

DISCUSSION

Weight gain for MFO-fed mice was no different than for CO-fed mice. The EFA-deficient nature of the MFO diet was reflected in the general scruffy appearance of the mice and the high triene-to-tetraene ratio (20:3n-9/20:4n-6 = 1.26) in the liver samples.

In the 19-wk study, absorption of the MFO long-chain acids is believed to have been good to produce weight gains that were comparable to the CO and HCTO diets during the first 9 wk of the study (Fig. 2). Total diet consumed per day was similar for each group which indicates the MFO-fed mice did not need to compensate for poor fat absorption by increasing carbohydrate intake. For the short-term pure acid study, the 9–13% levels of 5c-20:1 and 5c,13c-22:2 in the mammary gland (an adipose-like tissue) and intestinal cells indicate absorption of both acids was similar (Table 4). The acids rather than triglycerides were used in the purified fatty acid study to avoid potential problems due to poor absorption of the monoacid triglyceride.

Excessive accumulation of MFO acids in livers was not observed in either the short-term purified acid or the long-term MFO feeding studies. The levels of 5c-20:1 and 5c,13c-22:2 in liver lipids were about 2%. This percentage was lower than expected considering the high amount of these acids in the diets and the percentages in the intestine and mammary tissue. The data suggest that a substantial portion of MFO acids is efficiently oxidized to meet energy needs. The lower percentages of the MFO acids in the liver compared to the mammary gland and intestinal cells may also be a result of discrimination against the MFO acids by the phospholipid acyltransferases. Although 5c,13c-22:2 did not accumulate, livers from mice fed 5c,13c-22:2 contained substantially more total lipid. This difference in liver lipid concentration may indicate a possible metabolic problem associated with 5c,13c-22:2, but not with 5c-20:1. The lack of detectable levels of desaturation or elongation products indicates that 5c-20:1 and 5c,13c-22:2 are not rapidly desaturated or elongated. The 11% 13c-22:1 impurity in the 5c-20:1 diet was not detected in the liver lipids.

In total heart lipids, the percentage of 5c, 13c-22:2 was more than 6 times the percentage of 5c-20:1, and the 5c-20:1-to-13c-22:1 ratio was the same as in the fed diet. These data suggest that 5c,13c-22:2 has a greater tendency to accumulate in heart lipids than either 5c20:1 or 13c-22:1. The reason for accumulation of 5c,13c-22:2 is unknown, but it may be related to the same mechanism that induces accumulation of 13c-22:1 in heart lipids from rapeseed oil-fed rats (4).

Both 5c-20:1 and 5c,13c-22:2 produced similar effects on fatty acid synthesis. The values in Table 5 for these fatty acids were between the fatty acid synthetase depressed values for 18:2 and the non-depressed values for 18:1. Data suggest that the 5c bond position has some influence on the regulation of fatty acid synthesis but is 50% less effective as a fatty acid synthetase inhibitor than the 9c,12c methylene-interrupted structure.

The results show that MFO acids are absorbed, incorporated into tissue lipids, used as an energy source, do not accumulate excessively in liver microsomal and mitochondrial phospholipids, and are not converted to other fatty acid structures. Toxic effects were not observed and the gross appearance of the organs was normal. However, the presence of some, more subtle physiological effects cannot be ruled-out. Our initial data on the metabolism of MFO acids are encouraging and suggest that the use of small amounts of refined MFO as a food additive may become acceptable in the future.

ACKNOWLEDGMENTS

We wish to thank Mrs. L. Copes, National Center for Agricultural Utilization Research, Peoria, IL, for assistance with the analysis of the tissue lipids; Terry Nelson, Biometrician, Midwest Area Office, Peoria, IL, for assistance with the statistical analysis; and Dr. L.J. Faulkin and Mr. D.J. Mitchell, School of Veterinary Medicine, University of California, Davis, for assistance with the long-term diet studies.

[Received February 11, 1991; Revision accepted June 18, 1991]

Prostaglandin Synthesis and Fatty Acid Composition of Phospholipids and Triglycerides in Skeletal Muscle of Chicks Fed Combinations of Flaxseed Oil and Animal Tallow

J.M. Olomu and **V.E. Baracos***
Department of Animal Science, University of Alberta, Edmonton, Alberta, Canada T6G 2P5

Chicks were fed isocaloric and isonitrogenous diets containing 6% (w/w) added fat consisting of various proportions of animal tallow and flaxseed oil (FSO). No differences among treatments were seen in growth rate, muscular deposition of protein and lipids nor in the muscle phospholipid (PL) and triglyceride (TG) contents. Prostaglandin (PG)E_2 synthesis in isolated skeletal muscle was depressed significantly by feeding FSO or by treatment with naproxen (6-methoxy-α-methyl-2-napthaleneacetic acid), an inhibitor of PG synthesis. The changes associated with diet may be related to differences in the fatty acid composition of muscle lipids. Levels of saturated fatty acids in muscle PL and TG were relatively insensitive to dietary treatments. Monounsaturated fatty acid levels were significantly lower in the FSO-fed groups. FSO diets caused significant depression in muscle PL 20:4ω6 and almost completely inhibited 22:5ω6 incorporation. FSO diets decreased ratios of ω6/ω3 fatty acids and increased the unsaturation index of muscle PL. Muscles of chicks fed FSO showed increased levels of 18:3ω3, and of its derivatives 20:4ω3 and 22:5ω3. These results suggest that FSO inhibits PG synthesis and modifies the fatty acids of PL and TG of chick muscle. These changes may have implications for PG-dependent and/or membrane-dependent processes in muscle metabolism.
Lipids 26, 743–749 (1991).

It has been suggested that in skeletal muscle, prostaglandins (PG) are involved in the regulation of protein and amino acid metabolism (1–3), differentiation (4), and the local control of blood flow in active and reactive hyperemia (5). It is known that incubated skeletal muscle *in vitro*, as well as muscle cells in tissue culture produce PG and other metabolites of arachidonic acid, including PGE_2, $PGF_{2\alpha}$, PGI_2 and thromboxane A_2 (1). However, the physiological, pathological and nutritional factors affecting the synthesis of these metabolites in skeletal muscles have not yet been fully characterized.

A number of studies with laboratory rodents (6–8) have shown that PG synthesis in several cell types is depressed by the addition of long-chain ω3 fatty acids (mainly 20:5ω3 and 22:6ω3) in the form of fish oil to the diet. Similar results have been obtained with rats fed flaxseed (FSO) oil (9,10) which contains 18:3ω3. It would appear that the inhibitory effects of the fish oils on PG synthesis are related to characteristic changes in the fatty acid composition of tissue phospholipids (6,7,11–13). In particular, ω3 fatty acids are thought to i) competitively inhibit the synthesis of arachidonic acid (20:4ω6), the immediate precursor of PG (10–12); ii) act as an alternate substrate for PG synthesis (20:5ω3), leading to synthesis of the less potent 3-series PG; iii) activate PG catabolism (6); and iv) competitively inhibit the PG synthetase complex (20:5ω3) (11).

Dietary modification of the fatty acid composition of platelets, liver, heart, kidney, plasma and dermis has been well described (7,8,10,13). By contrast, information on the influence of dietary oils on the fatty acid composition and metabolism of skeletal muscle is limited. A number of earlier studies (*e.g.*, reference 14 and references therein) have shown that fatty acids from dietary fish oil are incorporated into muscle lipids. In these studies no distinction was made between fatty acid incorporation into phospholipids and triglycerides. Whether the effect of feeding long-chain ω3 fatty acids of marine origin can be duplicated by the feeding of 18:3ω3 found in the oils of terrestrial plants, such as flaxseed is not clear. It would depend upon the availability of 18:3ω3 for desaturation and elongation, and would presumably be species-dependent. Cunnane *et al.* (15), for example, have shown increased levels of 20:5ω3 in porcine skeletal muscle after feeding flaxseed, but longer chain derivatives such as 22:5ω3 and 22:6ω3 were not detected.

The objective of our study was to determine to which extent dietary ω3 fatty acids can be incorporated into chicken skeletal muscle triglycerides and phospholipids and how fatty acid incorporation relates to FSO feeding and tissue PG synthesis. The effects are compared with those caused by naproxen, a direct inhibitor of PG synthesis (16).

MATERIALS AND METHODS

Animals and diets. Broiler chicks of the Hubbard strain, vaccinated for Marek's disease, were obtained on the day of hatching from the Cooperative Hatchery (Edmonton, Canada). The chicks were housed in thermostatically controlled, electrically heated batteries (33–35°C) with raised mesh floors and stainless steel waterers, feeders and partitions. Birds were maintained under continuous light. Feed and water were provided for *ad libitum* consumption. Experiments were done according to the guidelines of the Canadian Council on Animal Care.

Two experiments were conducted. Birds were placed on treatments on the day of hatching. At the start of each experiment, birds were weighed individually and divided into groups of 12 (Expt. 1) or 24 birds (Expt. 2) such that the average body weight and weight range were similar

[a]18% calcium, 21% phosphorus.

[b]Vit-Min premix supplied per Kg of diet the following: Vitamin A, 400 IU; Vitamin D_3, 600 ICU; Vitamin E, 10 IU; menadione, 1 mg; riboflavin, 5 mg; calcium pantothenate, 10 mg; niacin, 20 mg; choline chloride, 100 mg; folic acid, 1 mg; Vitamin B_{12}, 10 μg; Mn, 108 mg; Zn, 72 mg.

[c]Ethoxyquin, at 0.25% of the diet, was added to the dietary fats before mixing, as an antioxidant.

for each group. Three such groups were placed on each treatment. Equal numbers of male and female chicks were used per group in Expt. 1, while male chicks only were used in Expt. 2.

The diets used were isonitrogenous (22% crude protein) and isocaloric (3164 Kcal/Kg diet) with similar amounts of calcium and phosphorus (Table 1). The diets were based on ground corn and soybean meal. The diets contained 6% added fat, consisting of 100% animal tallow (AT); 75% AT/25% flaxseed oil (FSO); 50% AT/50% FSO; and 25% AT/75% FSO (Table 1). A further experimental treatment included the administration of naproxen (6-methoxy-α-methyl-2-napthaleneacetic acid), an inhibitor of PG synthesis (16). This agent was administered in the drinking water (76 mg/L), to birds fed Diet 1, as in previous studies (2,3). Fresh flaxseed oil (cold-pressed) stored in light- and air-tight bottles was obtained from Omega Nutrition Inc. (Vancouver, Canada). Animal tallow rendered from slaughterhouse waste at 118°C was obtained from Northern Alberta Processors (Edmonton, Canada).

Diets were prepared weekly and stored at −4°C. Table 2 shows the fatty acid contents of the oils and diets studied. Diets were fed for 7 days (Expt. 1) or 21 days (Expt. 2). In Expt. 1, diets 1 to 4 (Table 1) were tested while in Expt. 2, diet 3 was not included in the tests. Records of body weight and feed consumption were kept on a weekly basis. On day 7 (Expt. 1,2) and 21 (Expt. 2), four birds were taken from each replicate and killed by cervical dislocation. One extensor digitorum communis (EDC) muscle from the wing and sartorius muscles from both thighs were dissected immediately after killing. Sartorius muscles were weighed individually and then pooled by replicate for lipid extraction (see below).

Analytical. The EDC muscle is a thin, long muscle suited to incubation studies where oxygen and nutrients are provided by superfusion (17). Freshly dissected EDC muscles were mounted at their resting length *in situ* on stainless steel supports (17) and immediately incubated in 3 mL Krebs Ringer bicarbonate medium (NaCl 119 mM; KCl 4.8 mM; $CaCl_2$ 1.0 mM; $NaHCO_3$ 25 mM; $MgSO_4$ 1.25 mM; NaH_2PO_4 1.24 mM; HEPES 2.0 mM, pH 7.4) containing 15 mM glucose and insulin (0.01 U/mL) as previously described (17). Media were continuously gassed with O_2/CO_2 (19:1, v/v) and the temperature was maintained at 35°C in a shaking water bath. Muscles were preincubated for 30 min, then transferred to fresh media and incubated for 3 hr. PGE_2 production was estimated by radioimmunoassay of the incubation medium (2,3). The antibody used showed 100% cross-reactivity with PGE_1, but no cross-reactivity with $PGF_{2\alpha}$. Since skeletal muscle does not appear to synthesize PGE_1 (18), this cross-reactivity does not interfere with the assay of PGE_2.

Total lipid was extracted from sartorius muscles and feed samples by mechanical homogenization with 20 vol of chloroform/methanol (2:1, v/v). The crude lipid extracts were washed with 0.2 vol of 0.88% NaCl, and then with 0.65 vol of chloroform/methanol/water (3:48:47, v/v/v) as described by Folch *et al.* (19). The lipid extract was evaporated to dryness at 60°C under N_2 for determination of total lipid content. Total sartorius lipids were separated by two-dimensional thin-layer chromatography on a 20 × 20 cm Redi/Pit Silica Gel GF (Fisher Scientific, Ottawa, Canada). Benzene/diethyl ether/ethanol/acetic acid (50:40:2:0.2, by vol) was the solvent in the first dimension (15–20 min) to separate the phospholipids from the monoglycerides. Hexane/diethyl ether/formic acid (80:20:2, v/v/v) was the solvent used in the second dimension (30–40 min) to completely separate cholesteryl esters and triglycerides. The fractions were visualized under ultraviolet light after spraying with 0.1% 2,4-dichloro-

[a]SAT, saturated; MUFA, monounsaturated; PUFA, polyunsaturated fatty acids; ND, not detectable. Total lipid was extracted from feed samples after mixing of the diets. No fatty acids longer than 22 carbons were detected in the feed or fat samples. Results are means of duplicate analyses.

fluorescein in methanol and identified by comparison with standards. The phospholipids and triglyceride bands were scraped off the plate directly into methylating tubes. Nonadecanoic acid (19:0) was added as internal standard and the tubes were tightly closed with Teflon-lined screw caps. Prior analysis of sartorius muscle showed that it did not contain nonadecanoic acid.

The lipid extracts were then converted to fatty acid methyl esters using a mixture of boron trifluoride (in 10% methanol), hexane and methanol (35:20:45, v/v/v). The resulting fatty acid methyl esters were separated and quantified by automated gas-liquid chromatography (Varian model 3400 equipped with autosampler and flame ionization detector, Varian Associates, Palo Alto, CA), using a 30-m fused silica capillary column (International Scientific, Folsom, CA). Helium was used as the carrier gas at a flow rate of 3.0 mL/min. The column temperature was increased from 60°C to 230°C at a rate of 30°C/min up to 160°C and then at 5°C/min up to 230°C. Conditions were chosen to separate fatty acids ranging from 12 to 24 carbons in chain length. Fatty acids were identified by comparison of retention times with those of standard fatty acid methyl esters (Sigma Chemical Co., St. Louis, MO). The results are expressed as percent distribution of fatty acid methyl esters. The amount of phospholipid and triglyceride was determined from the percent fatty acid contents, using the procedures and factors earlier proposed by Christie *et al.* (20).

Muscle protein content was determined by the Kjeldahl method (21), or using a modified Bradford method (22) in the case of EDC muscles, which were too small for Kjeldahl analysis. Bovine serum albumin served as the protein standard in the Bradford method.

Data obtained were tested by one-way and two-way analysis of variance, and differences between means were determined using Student Neuman-Keuls multiple range test. Planned comparisons were carried out using procedures of orthogonal contrast, to determine effects of duration of feeding, FSO addition to the diets, and FSO levels. Fatty acid data are presented as least squares means and the error mean square presented as the error term. The criterion for significance was a probability of 0.05.

RESULTS

Feed consumption, and body and muscle weights. Feed intake averaged 35.8 ± 1.5 (standard deviation) g/bird/day, and liveweight gain averaged 528 ± 17.8 g/bird over the 21-day study period. These variables and the wet weights of the sartorius (1.5 ± 0.1 g) and EDC (57.1 ± 3.5 mg) muscles on day 21 were not significantly affected by experimental treatments (n = 12; data not shown).

Muscle protein and lipid deposition. There were no effects of treatment on the total amount of protein and lipid deposited in the muscles studied nor on the phospholipid (PL) and triglyceride (TG) contents of the sartorius muscle (Table 3). The proportion of PL and TG in the muscle was age-dependent, irrespective of the treatment, the PL fraction being higher and the TG fraction lower at 3 wk of age ($p<0.05$).

PGE_2 synthesis. After 7 days of feeding FSO, PGE_2 synthesis in the EDC muscle was significantly depressed (Fig. 1); this inhibition was not evident at 2 or 4 days after initiating treatments (data not shown). The inhibition was proportional to the FSO content of the diet. The continuous administration of naproxen also inhibited PGE_2 production and its effect was quantitatively

[a]Values in the same row with common superscripts are not different ($p<0.05$). Values are mean ± SEM. Values are for chicks fed from hatch to 3 wk except where indicated otherwise.

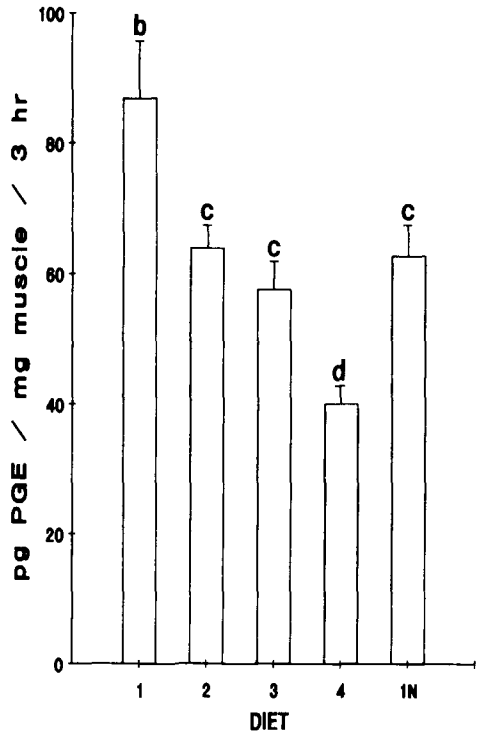

FIG. 1. PGE_2 synthesis in extensor digitorum communis muscle. Broiler chicks were fed diets described in Table 1 for a period of 7 days. One group of birds on Diet 1 received naproxen (N), an inhibitor of prostaglandin synthesis, in the drinking water (76 mg/L). At the end of the period of study birds were killed and the extensor digitorum communis muscles were incubated for the determination of PGE_2 synthesis. Values with different superscripts are different ($p<0.05$; n = 12). Values are mean ± SEM.

similar to that of the lower levels of FSO feeding. There was no further reduction in muscle PGE_2 synthesis when FSO was fed, or naproxen administered for longer periods up to 21 days.

Fatty acid composition of sartorius muscles. In order to simplify presentation of the results, only data obtained on day 21 are shown (Tables 4 and 5). Since initial statistical analysis revealed no effects of naproxen on the level of any fatty acid in PL or TG, these data were pooled with data from other birds fed diet 1.

Phospholipids. In spite of substantial differences in the levels of dietary saturated fatty acids, there were few differences seen in the levels of saturated fatty acids between groups (Table 4). Levels of several individual and total saturated fatty acids declined over the study period. Only 18:0 was significantly affected by diet, and was increased in FSO-fed chicks. Total monounsaturated fatty acids (MUFA) content decreased with increasing dietary FSO level. All of the MUFA, with the exception of 16:1ω7 were significantly decreased by the addition of FSO to the diets, and for 16:1ω7 and the three 18:1 fatty acids, these changes were progressive with continued feeding from 7 to 21 days.

There were marked alterations in the individual and total polyunsaturated fatty acid (PUFA) contents of sartorius PL when FSO was consumed. Only 18:2ω6 was not affected by diet. For many PUFA, these alterations were significantly related to the level of FSO fed, and/or progressive with time. Consumption of FSO reduced levels of 20:2ω6 and 20:3ω6. Arachidonic acid (20:4ω6) was significantly reduced within one week by the 4.5% FSO diet while feeding a 1.5% FSO diet even for 3 wk did not reduce 20:4ω6. The level of 22:4ω6 was depressed by FSO feeding and little or no 22:5ω6 was detected in birds consuming FSO. Total ω3 fatty acids increased as much as four-fold on the FSO diets, while total ω3 fatty acids decreased 40% in PL of birds fed only animal tallow. Levels of 18:3ω3 did not increase further after the first week, while levels of 20:3ω3, 20:5ω3 and 22:5ω3 continued to rise. Levels of 22:6ω3 were increased after 3 wk of feeding. As a result of these changes in PUFA levels, chicks fed FSO showed a marked increase in the index of unsaturation (sum of the product of the percentage unsaturated fatty acid and number of double bonds).

Triglycerides. Although the level of total saturated fatty acids was similar in TG and PL, levels of MUFA were higher and levels of PUFA were lower in the TG fraction (Table 5). In contrast to the PL fraction, FSO lowered levels of all saturated fatty acids except 20:0 in TG. These changes were progressive, and were related to the FSO level of the diet. Total and individual MUFA decreased with increased dietary FSO, and only 16:1ω7 was not affected by FSO. As in PL, 18:2ω6 was the principal PUFA

found in muscle TG, and comprised >85% of total PUFA in chicks fed AT only. Levels of 18:2ω6 acid were increased by FSO feeding. The levels of other ω6 fatty acids including 20:2ω6 and 20:3ω6 were reduced by FSO feeding, while levels of 20:4ω6 were low and not affected by diet. Neither 22:4ω6 or 22:5ω6 was present in TG. When FSO was fed, 18:3ω3 was deposited in the sartorius muscle TG, and its level increased progressively, and with the level of FSO fed, to as much as 48% of total PUFA. Levels of other ω3 fatty acids including 18:4ω3, 20:3ω3, 20:5ω3, 22:5ω3 and 22:6ω3 were low in TG compared with PL, but were increased by feeding FSO. As a result of these changes in PUFA, the unsaturation index of muscle TG was increased.

DISCUSSION

Muscle prostaglandin synthesis. The results of the present study indicate that PG synthesis by skeletal muscle in the rapidly growing broiler chick may be altered by dietary means on a rapid time scale. Dietary FSO decreased PG synthesis as much, or more, than an orally administered inhibitor of PG synthesis. At the concentration used here, naproxen has been shown to alter skeletal muscle protein metabolism in different pathological states (1-3). It remains to be clarified whether this would also be the case when PG synthesis is modified by dietary means. A depression in PG synthesis by feeding ω3 fatty acids is in agreement with data obtained on other tissues with other species of animals (6-8,10). Several factors may have contributed to the decrease in muscle PGE_2 production in chicks fed FSO. The depressed level of 20:4ω6, the precursor of PG of the 2 series, and enhanced levels of ω3 fatty acids of sartorius phospholipid, may help to explain the depression of PGE_2 synthesis by FSO. It has been proposed (7,10-12) that increased levels of ω3 fatty acids competitively inhibit the synthesis of 20:4ω6. The enhanced level of 20:5ω3 in the FSO groups may also have competitively inhibited the PG synthetase complex (10,23,24). Naproxen did not alter the fatty acid composition of muscle; this inhibitor's action is at the level of fatty acid cyclooxygenase (16).

[a]Values in the same row with common superscripts are not different ($p<0.05$; n=6, diet 1; n=3, diets 2,4). Significance of main effects, *, $p<0.05$; **, $p<0.01$, NS, $p>0.05$. FSO, flaxseed oil; EMS, error mean square; ND, not detectable; NS, not significant.

Fatty acid incorporation into skeletal muscle lipids. The levels of total lipid, PL and TG in skeletal muscle were not affected by composition of the diets fed in this study. PL are the main constituents of cell membranes and are relatively resistant to quantitative changes from dietary lipids (25,26). However, consistent with some results obtained on chicks (27), PL increased and TG decreased, with age in this study.

Fatty acid composition of muscle phospholipids. The fatty acid composition of PL was not strictly a reflection of that of the dietary lipids. Although levels of saturated fatty acids in the diets ranged from 18 to 30% of total fatty acids, these had little influence on the total saturated fatty acid incorporation into sartorius muscle PL. Levels of PUFA in the diets ranged from 25.5 to 52.6% of total fatty acids, yet levels of total PUFA in muscle PL varied little. Although total muscle MUFA decreased with decrease in dietary MUFA, differences in the PL MUFA were also small compared to differences in dietary total MUFA. Finally, although the ratios of saturated to unsaturated fatty acids were constant at 0.5–0.6 for all groups, the index of unsaturation was increased by FSO feeding. These observations support the hypothesis that a homeostatic mechanism prevents membranes from significant compositional changes in PL, thus preserving a relatively constant state of membrane fluidity (28). The lower level of 18:1 in the FSO groups may be due to its lower level in the FSO diets and/or a reduced rate of desaturation of endogenous 18:0 due to increased total substrate (18:2ω6, 18:3ω3) competing for desaturation.

The depressed level of 20:4ω6 in PL of the FSO groups in this study is consistent with that reported for microsomal fractions of white and dark meat of FSO-fed chickens (29). This may have been due to competition between 18:3ω3 and 18:2ω6 for Δ6 desaturation, thus limiting the synthesis of 20:4ω6 from 18:2ω6 (11,27). Our results also revealed that FSO diets reduced the deposition of 22:4ω6 and that virtually no 22:5ω6 was found after extended feeding. FSO decreased levels of ω6 fatty acids in a dose- and time-dependent fashion, and it seems likely that even greater modifications could be produced with longer feeding periods or higher levels of FSO in the

diet. Diet 2 contained 11% 18:3ω3 and did not affect PL levels of 20:4ω6 at any stage. However, the deposition of 22:4ω6 and 22:5ω6 was significantly reduced in chicks fed this diet for 3 wk. Diet 4 provided 26% 18:3ω3 and caused a reduction of 20:4ω6 within one week of feeding, but required a longer feeding period to significantly depress levels of 22:4ω6 and 22:5ω6. Studies with rats (25) showed that 18:3ω3 at levels less than 15% of dietary fat did not inhibit the conversion of 18:2ω6 to 20:4ω6 but the subsequent conversion to the C_{22} PUFA was reduced, as seen here.

Although the muscle total PL PUFA was similar for all the dietary groups, there was a dose- and time-dependent change in the ratios of ω6/ω3 and 20:4ω6/20:5ω3 with FSO feeding. The present results thus show that ω3 PUFA of the diet is incorporated into chick muscle PL. The accumulation of ω3 fatty acids in the FSO-fed chicks is not surprising since 18:3ω3, the predominant fatty acid in FSO, serves as the precursor in the synthesis of longer chain ω3 fatty acids by Δ6 and Δ5 desaturases (11,30). Other reports have not been consistent in demonstrating long-chain ω3 fatty acids in skeletal muscle. For example, 20:5ω3 was detected in rat (12) and pig (15) muscle, but not in muscle of chicks (29) and rats (31). These discrepancies may be due to the use of total muscle lipids in these studies, where the low content of this fatty acid and its derivatives in TG would tend to mask changes in PL.

Fatty acid composition of muscle triglycerides. In the TG fraction, as the level of FSO in the diet increased, total saturated fatty acids and MUFA decreased, while total PUFA increased, in direct relationship to their levels in the diets. There would appear to be a much greater incorporation of dietary fatty acids into TG than PL; for example the maximum level of 18:3ω3 in TG reached 16.8%, while in PL this fatty acid reached 2.0%. Longer-chain derivatives of the dietary fatty acids were less abundant in the TG than in the PL, also tending to reflect storage of fatty acids in the TG fraction rather than metabolism.

These studies demonstrate the inhibitory effect of 18:3ω3 from FSO on PGE_2 synthesis in the chick. Chicks metabolize 18:3ω3 to longer chain ω3 fatty acids; this in turn enriches the tissue lipids with ω3 and alters the pattern of fatty acid incorporation. Although the composition of PL was generally less influenced than that of TG, it is apparent that both fractions contain dietary fatty acids as well as elongated and desaturated derivatives. The altered fatty acid composition may have implications for muscle metabolism. For example, in related studies it has been shown that the incorporation of ω3 fatty acids into muscle lipids, by feeding fish oil, increases the responsiveness of glucose transport to insulin (32). The importance of fatty acid composition for other membrane-associated functions of muscle including substrate transport, excitation/contraction coupling, and lysosomal sequestration, and for PG-dependent processes (1–3) remains to be characterized.

Distribution Among Tissues of Intravenously Administered Sucrose Octaoleate

F.H. Mattson[1] and **R.J. Jandacek***
Miami Valley Laboratories, Procter & Gamble Company, Cincinnati, Ohio 45239-8707

The distribution of [^{14}C]oleate label in rat tissues in the 6 hr after intravenous administration of sucrose octa-[^{14}C]oleate (7.5 mg; SuO_8) was compared with that observed after administration of [^{14}C]triolein. The [^{14}C]-oleate label, whether injected as triolein emulsion, or as chylomicrons obtained from donor animals, rapidly cleared from the serum; only 10% or less remained in the serum 15 min after injection. Labeled SuO_8 disappeared less rapidly from the serum; about one-third of the dose was present after 15 min, and after 120 min 14% remained. In the liver, there was an initial greater accumulation of fatty acid label when an emulsion of either triolein or SuO_8 was given rather than the chylomicrons. The octa-ester continued to accumulate in the liver throughout the 6 hr of study, and 78% of the initial dose was present at that time. By contrast, although one-third of the triolein, as of SuO_8, was found in the liver shortly after injection, levels subsequently decreased; at 6 hr, 12% of the label remained associated with that organ. A small portion, up to 8% of the acid label, whether administered as chylomicrons or as a triolein emulsion, was found in the epididymal fat pads. Smaller amounts, usually 1% or less, of the [^{14}C]oleate label were found in fat pads following the injection of labeled SuO_8. In a separate study, the levels of acid label in the liver and spleen were monitored for 21 days following the intravenous administration of [^{14}C]SuO_8. There was an initial accumulation of approximately half of the injected lipid label in the liver and one-quarter in the spleen. By day 21, the level in the liver had decreased to one-third of that administered, while the level in spleen remained at one-quarter.
***Lipids 26,* 750–753 (1991).**

Olestra (sucrose polyester) is the now common name for the mixture of hexa-, hepta-, and octaesters that results from esterification of sucrose with long-chain fatty acids derived from edible fats. Olestra has the physical, culinary, and organoleptic properties of customary dietary fat of similar fatty acid composition. However, the biological behavior of olestra differs markedly. Unlike triglyceride, olestra is not hydrolyzed by the lipolytic enzymes of the pancreas (1). Hence, olestra is not absorbed, but rather is excreted unchanged in the feces (2,3). Olestra has also been reported to reduce the absorption of dietary cholesterol (4), presumably through entrapment of intestinal cholesterol in the non-absorbable oil phase (5), which in turn results in a decrease of plasma total cholesterol and low-density lipoprotein cholesterol (6,7). Olestra's nonabsorbability and its physical similarity with common fats have suggested its utility as a noncaloric, partial replacement for dietary fat.

Although olestra is not absorbed, it was nevertheless, of interest to determine its distribution in body tissues following intravenous (i.v.) injection. Rats were therefore injected with an emulsion of [^{14}C]oleate-labeled sucrose octaoleate (SuO_8), one of the major components of olestra. The levels of labeled lipid in serum, liver, and adipose tissue were then monitored over 6 hr, and over 21 days in liver and spleen. The fate of [^{14}C]oleate-labeled chylomicrons and emulsified [^{14}C]triolein was followed over 6 hr after i.v. administration.

MATERIALS AND METHODS

Animals. Male Sprague-Dawley rats (Charles River Laboratories, Portage, MI) were used in all studies. The rats were housed in individual stainless steel cages in a room maintained at 24 ± 3°C and at 30–70% relative humidity, using a twelve-hour light/dark cycle. The animals received rat chow (Ralston-Purina, St. Louis, MO) and tap water *ad libitum,* unless noted otherwise.

Materials. [^{14}C]Oleic acid used was homogeneous as judged by thin-layer chromatography (TLC). Triolein was prepared by base-catalyzed esterification of glycerol. Following purification by Florisil column chromatography, the isolated triolein was shown by TLC to have a purity of greater than 99%. SuO_8 was synthesized similarly; the octaester fraction from the Florisil column was better than 99% pure.

A portion of the labeled triolein was administered *per os* to rats fitted with a thoracic duct cannula (3). The lymph of these animals was collected and the chylomicrons isolated (8). The isolated chylomicrons were taken up in 0.85% NaCl to a lipid concentration of 15 mg/mL.

Emulsions of triolein and SuO_8 were prepared by the method of Rodbell and Scow (9) at a lipid concentration of 125 mg/mL. On the day of injection, 1 mL of lipid emulsion was added dropwise, while vortexing, to 7.5 mL of fresh serum obtained from rats that had been fasted for 24 hr. The final concentration of labeled lipids was 15 mg/mL. The specific activities of these preparations were: SuO_8, 6.9 μCi/g; triolein, 2.7 μCi/g; and chylomicron lipids, 1.1 μCi/g.

Experimental protocol. In the first study, the early fate of intravenously administered SuO_8 was determined. A control group received a similar emulsion of oleate-labeled triolein. The effect of the emulsifying system was examined by injecting rats with chylomicrons that were harvested from the lymph of rats fed [^{14}C]oleate. Based on the results obtained, the duration of a subsequent study was extended to encompass 21 days, but observation was limited to liver and spleen. Emulsified triolein or chylomicrons were not administered in the long-term study.

Prior to treatment, rats were fasted overnight. However, in order to minimize catabolism of the injected lipids, the "water" bottles during this period supplied 20% glucose and 0.45% NaCl (w/v). Two hours prior to i.v. injection, the rats were given 5 mL of the glucose-saline solution by stomach tube (10). Immediately prior to use, the lipid preparation was passed through a 1.2-μm Millipore filter and 0.5 mL of the filtrate was injected into the tail vein.

[1] Present address: Department of Medicine, University of California, San Diego, California 92093.

*To whom correspondence should be addressed.

The exact weight of administered emulsion was determined by weighing the syringe before and after injection. Each animal received 7.5 ± 0.2 mg of labeled lipid. With each injection, an aliquot of the material administered was taken for radiochemical assay. The animals were returned to their cages and offered water and Purina Laboratory Chow (Ralston Purina).

At the time points indicated, animals were killed by guillotine. In the initial study, the blood was collected from the carcass, allowed to clot, and the serum, which was recovered by centrifugation, was weighed. The liver was flushed *in situ* with 0.85% NaCl until pallid. Tissues were removed, rinsed, blotted dry, weighed, and stored at −4°C. To verify the success of the i.v. injection, the entire tail was severed and assayed for labeled lipid.

Tissue analysis. Serum, homogenized tissues, and the emulsions administered were extracted with $CHCl_3$/MeOH (2:1, v/v). The chloroform phase was washed with phosphate buffer, dried with Na_2SO_4, and evaporated to dryness. The lipid extract was assayed for ^{14}C label by liquid scintillation counting.

Serum was assumed to constitute 3.5% of body weight. Values for liver and spleen were obtained by analysis of the entire organ. Values given for epididymal fat pads are representative of total label accumulation, but do not indicate the absolute amounts of label in total adipose tissue.

After i.v. administration, the tails of some animals contained more than 5% of the material administered indicating faulty injection; values from these animals were not considered. In the animals used, remaining label at the injection site was typically only 1 to 2 percent of the dose injected.

Statistical methods. To compare the fit of a piecewise (two pool) linear regression model with a single (one pool) model, a piecewise mode was fitted to the log-transformed blood serum data for each treatment, assuming a common point of intersection (at 60 min for the two segments of the regression lines) (11). The fit of the piecewise model was then compared with the single linear trend model for each treatment (12). Once we had verified the piecewise model as providing the best fit, we checked the point of intersection, by estimating separately for each treatment the point of intersection of the two trend lines (13). To make comparisons between the three treatments, the average of the three estimates for the point of intersection was used to fit a single model with dummy variables to accommodate a piecewise linear regression for each treatment. F-tests of the appropriate linear combinations of the regression coefficients were used to test hypotheses corresponding to linear combinations of the parameters of the three piecewise regression lines. For each linear regression, the correlation coefficient (R) was calculated (14).

A single model (one pool), with dummy variables to accommodate a simple linear regression for each treatment, was fitted to the data for each tissue, *i.e.*, liver and fat pads without log transformation. F-tests of the appropriate regression coefficients were used to test hypotheses corresponding to the parameters of the three regression lines.

RESULTS

The percentage recoveries in serum of the intravenously administered ^{14}C-labeled lipids are given in Figure 1.

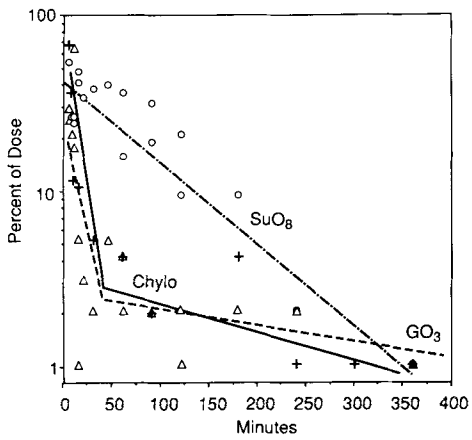

FIG. 1. Percent of ^{14}C administered in serum lipids after i.v. injection into rats at (t = 0) of sucrose octa-[^{14}C]oleate (SuO_8, O, —·—) ^{14}C-labeled triolein (GO_3, Δ, ——) or chylomicrons (Chylo, +, ——).

TABLE 1

Equations Describing the Two Pools for Chylomicrons and Remaining Serum Levels[a]

	Log % of dose	R
Pool 1		
Chyl	1.727 − 0.0382t[b]	0.79
GO_3	1.330 − 0.277t	0.58
Pool 2		
Chyl	0.520 − 0.00158t	0.62
GO_3	0.393 − 0.00084t	0.59
Time of breakpoint of pool 1 and 2:		
Chyl	33.0 min	
GO_3	34.9 min	

[a]Rate of removal from the serum was calculated from the data in Figure 1.

[b]t, time in minutes.

Statistical analyses showed the disappearance of the administered chylomicrons (Chyl) and triolein emulsion (GO_3) to fit a two-pool model. The rates of removal calculated from the data in these plots of the initial study are given in Table 1. The rates of removal for the chylomicrons and for the triolein emulsion from the pools do not differ statistically ($p > 0.1$). The pattern seen following the administration of the sucrose ester (SuO_8) was quite different, with a one-pool model sufficiently describing the data. The rate of removal of the material, log % of dose = 1.63 − 0.00451t (t = min, R = 0.94), was slower than that observed for pool 1 of the chylomicrons and triolein in serum (Table 1). Whereas only 10% or less of the label from the administered chylomicrons or triolein was present in the serum 15 min after injection, the same level was still found two hours following SuO_8 injection.

The portions of ^{14}C-labeled lipids found in the liver are shown in Figure 2. The three preparations each exhibited different patterns. Shortly after administration, approximately 12% of the label that was given as chylomicrons was present in liver. Subsequently the level, as percent of dose, decreased at a linear rate, 12.12 − 0.020t (R =

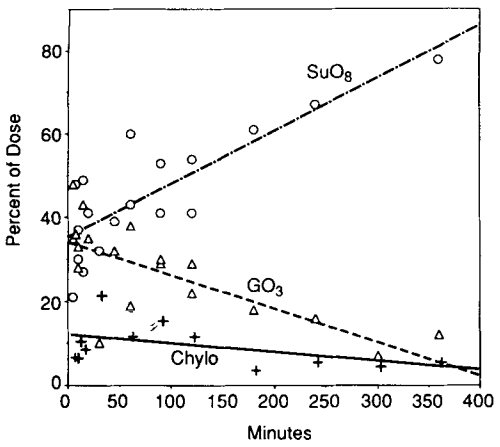

FIG. 2. Percent of ^{14}C administered found in the livers of rats after i.v. injection (at t = 0) of sucrose octa-[^{14}C]oleate (SuO_8, O, —·—), ^{14}C-labeled triolein (GO_3, Δ, ——) or chylomicrons (Chylo, +, —).

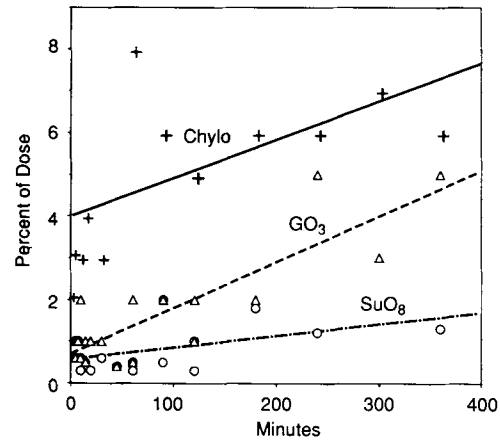

FIG. 3. Percent of ^{14}C administered in the epididymal fat pads of rats after i.v. injection (at t = 0) of sucrose octa-[^{14}C]oleate (SuO_8, O, —·—), ^{14}C-labeled triolein (GO_3, Δ, ——) or chylomicrons (Chylo, +, —).

0.48). When the labeled lipid was administered as an emulsion, whether as GO_3 or SuO_8, approximately 35% of the dose rapidly appeared in liver. The level supplied as GO_3 subsequently decreased; the rate as percent of dose was 34.44 − 0.078t (R = 0.3). When the label was administered as SuO_8, the level in the liver increased throughout the study. The rate as percent of dose was 35.31 + 0.126t (R = 0.82). Six hours after intravenous injection, 80% of the label given as SuO_8 was found in the liver, whereas that organ contained only about 10% of the label from the other lipids. The rates of change for the labeled lipid supplied by the three sources, chylomicrons, GO_3, or SuO_8, differed significantly from each other ($p < 0.05$).

Throughout the course of the experiment, less than 2% of the labeled lipid was found in the epididymal fat pads following administration of SuO_8 (Fig. 3). When the labeled fatty acid was given as triolein emulsion (GO_3), a somewhat higher level was found in the fat pads. An even larger amount, up to 8%, was found following the injection of chylomicrons (chyl). The accumulation of labeled

TABLE 2

Percentage of Sucrose Octa-[^{14}C]oleate Found in Liver and Spleen of Rats at Various Time Points After Intravenous Administration[a]

	Days after injection						
Tissue	1/4	1	2	3	7	14	21
Liver	60	51	53	58	35	49	34
Spleen	22	22	29	24	31	15	26
Liver and spleen	82	73	82	82	66	64	60
Number of animals	5	3	3	4	1	1	2

[a]At zero time each animal received i.v. (tail vein) 7.5 mg of sucrose octa-[^{14}C]oleate. Subsequently, the animals had access to Purina Laboratory Chow.

fatty acid from the three sources as a function of time as percentage of dose was: chyl, 3.90 + 0.00948t (R = 0.62); GO_3, 0.704 + 0.011t (R = 0.855); SuO_8, 0.558 + 0.0030t (R = 0.517). The rates in the GO_3 and chyl equations did not differ significantly ($p = 0.66$), but both differed from the rate of SuO_8 ($p < 0.05$). The intercepts of the GO_3 and SuO_8 equations differed from that of the chyl equation ($p < 0.0001$), but not from each other ($p = 0.70$).

In a subsequent study that was of longer duration, the tissue levels of ^{14}C-labeled lipids upon intravenous injection of the SuO_8 emulsion were followed. During the first three days following SuO_8 administration, serum, lung, and epididymal fat pads each contained less than 1% of the dose (data not shown). As shown in Table 2, initially 60% of the ^{14}C label that was administered as SuO_8 was found in liver lipids. Another 22% was recovered in the spleen. Since the mass of the spleen is typically 3 to 5% of that of the liver, the affinity of SuO_8 for spleen was greater than that for liver, when expressed as per unit mass of tissue. Over the course of the study there was a decrease in label in the liver; label in spleen was essentially unchanged. Even 21 days after injection, 60% of the dose was still present in both liver and spleen.

DISCUSSION

Following ingestion, triglycerides are partially hydrolyzed (1), and the products of digestion are absorbed (3). By contrast, SuO_8 is not hydrolyzed (1) and is not absorbed (1,3). The fate of the two lipids also differs when they are administered intravenously. Triglycerides are rapidly removed from the blood stream and distributed to various tissues and organs where they undergo a sequence of catabolic conversion. By contrast, SuO_8 disappears from the blood stream more slowly. A major portion of SuO_8 is taken up by the liver and spleen where it is retained tenaciously.

A concern in this study was that the emulsifying system used may affect the metabolic fate of SuO_8 as it affects in part the fate of triolein (15). Therefore, triolein was administered in the same emulsifying system as was SuO_8 and the redistribution was compared with that of chylomicron lipids. The disappearance of lipids from the chylomicron and triolein emulsions (Fig. 1) followed a two-pool pattern with similar rates (Table 1). The half-life of both in pool 1 was approximately 10 min, similar to values reported by others (16–18). Removal of the triolein

emulsion from serum was similar to that of chylomicrons. Since the same emulsifying system was used for SuO_8, the markedly different pattern of removal of SuO_8 from serum does not appear to be attributable to the emulsifying system employed, but rather appears to be a consequence of differing metabolic pathways.

The greater accumulation in the liver and subsequent slower release of triolein administered as emulsion, rather than as chylomicrons, has been observed by others (19-21), and this effect was attributed to the emulsified fat in the serum being taken up by the reticulo-endothelial system of the liver. In the present study (Fig. 2), as in those of others, the fatty acids from triolein initially accumulated in the respective organ and subsequently were slowly released. After several hours, the level in the liver approximated that seen following administration of the chylomicrons. The emulsified sucrose octaoleate, like the triolein emulsion, was rapidly taken up by the liver, here too probably by the reticulo-endothelial system. However, unlike the triolein, the labeled lipid in the liver subsequently increased rather than decreased. Three days following the injection of sucrose octaoleate, about 80% of the dose was recovered in liver and spleen (Table 2). By day 21, the amount of SuO_8 in liver and spleen had decreased, but only to 60% of the dose that was administered. This decrease could be due to redistribution to other tissues, secretion into the bile, or catabolism. The accompanying paper by Jandacek and Holcombe (22) shows that a major route of removal from the liver is by way of the bile with subsequent egestion in the feces. Whether other pathways are operative as well remains to be determined.

ACKNOWLEDGMENTS

We thank Peter Clarke and Robert Volpenhein for the synthesis of the oleate esters and Marcia Schulte for statistical analyses.

The Excretion and Characterization of Intravenously Administered Olestra

R.J. Jandacek* and **B.N. Holcombe**
Miami Valley Laboratories, The Procter and Gamble Company, Cincinnati, Ohio 45239-8707

Although sucrose octaoleate that is consumed is neither digested or absorbed, following intravenous injection it is found mainly in the liver. Olestra is a mixture of the hexa-, hepta-, and octaesters of sucrose. To follow the metabolic fate of intravenously administered [^{14}C]sucrose-labeled olestra, we measured its urinary elimination, and the rate of excretion of ^{14}C in the feces, and characterized the ^{14}C-labeled material that appeared in bile. The fecal excretion for days 4-14 after dosing was found to be first order with the half-life of the injected olestra being 5.0 ± 0.5 days. The ^{14}C recovered in the bile was soluble in chloroform. Two-dimensional thin-layer chromatography autoradiograms of the biliary lipid showed the pattern of the biliary ^{14}C to be essentially the same as that of the dosed olestra. Biliary excretion and subsequent fecal egestion of essentially unhydrolyzed sucrose esters is the principal route for the removal of intravenously administered olestra. Only traces of ^{14}C were found in the urine.
Lipids 26, 754–758 (1991).

Olestra, the mixture of the hexa, hepta, and octa long-chain fatty acid esters of sucrose, is not digested (1) and not absorbed (2). Investigation of the fate of the material in tissues other than the gastrointestinal tract is possible only following intravenous administration. Such a study, described in the preceding paper (3), showed that one component of olestra, sucrose octaoleate, is principally taken up and retained by the liver and spleen. To further investigate the fate of intravenously administered sucrose polyesters, we have utilized ^{14}C-labeled olestra to determine the rate of excretion and the identity of the excreted labeled material.

In three studies [^{14}C]sucrose-labeled olestra was administered intravenously to rats. We measured organ uptake and the rate of fecal excretion of ^{14}C (Studies 1 and 2), measured the elimination of urine (Study 2), and characterized the labeled material in excreted bile (Study 3).

MATERIALS AND METHODS

Animals. Young, adult male Sprague-Dawley rats (Charles River Laboratories, Portage, MI) were utilized in all studies. Body weights ranged from 163–172 g in Study 1, 110–125 g in Study 2, and 180–200 g in Study 3. Housing and feeding were the same as described previously (3). The schedule for assay of tissues and excreta is given in Table 1.

Materials. [^{14}C]Olestra was synthesized by base-catalyzed reaction of methyl oleate and [^{14}C] sucrose (uniformly labeled). The specific activity was 0.6 μCi/mg in Study 1. This level of activity proved to be sufficient for the tissue and fecal assays used in this study. The components of this material were resolved by one-dimensional thin-layer chromatography (TLC) silica gel GF, heptane/toluene/methanol, 100:94:6, v/v/v). Its composition was found to be 65% octaester and 34% combined hexa- and heptaester, based on a radio-scan of the plate. The R_f of the octaester was 0.88–1.0; the R_f values of the hexa- and heptaesters, consisting of isomer mixtures, ranged from 0.28–0.87. The distribution of mass determined by charring a plate after TLC development was consistent with the radiochemical scan.

To increase the assay sensitivity for the urinary excretion and biliary characterization required in Studies 2 and 3, olestra of higher specific activity, 8.9 μCi/mg, was obtained. The ester distribution of this olestra sample was 60% octaester and 39% combined hepta- and hexaester, as determined by the TLC method described above. The material used in Studies 2 and 3 was also analyzed by two-dimensional TLC [north, hexane/diethyl ether/acetic acid (190:10:2, v/v/v); east, same solvents (140:60:2); north, same solvents (190:10:2, v/v/v)]. An autoradiogram of the two-dimensional TLC plate was made by placing X-ray film in contact with the plate after development. The film was developed after 30 days of dark storage of plate and film. The autoradiogram was consistent with the two-dimensional olestra pattern observed on a charred TLC plate. The two-dimensional TLC procedure and autoradiography were also used in the analysis of biliary lipids by visual comparison of position and intensity of exposed areas.

Dosing regimen. After an overnight fast, the animals were anesthetized with Nembutal (0.1 mL/100 g body weight, intraperitoneal), and an incision made in a hind

TABLE 1

Design and Assay Schedule of the Three Studies of Intravenous [^{14}C]Olestra Administration to Rats

Study	Design	Assay schedule
1	14-Day measurement of fecal excretion and tissue distribution of ^{14}C.	5 Animals—necropsy and tissues at 24 hr. 4 Animals—necropsy and tissues at 7 days. 4 Animals—fecal collection days 1–14; necropsy and tissues at day 14.
2	35-Day study of excretion and tissue accumulation.	4 Animals fecal and urine samples, days 1–4, 11–15. Necropsy and tissues at day 35.
3	5-Day study of biliary excretions.	Bile collection from 3 animals for 5 days.

Abbreviations: TLC, thin-layer chromatography.

limb to expose the saphenous vein. The preparation of the dosing emulsion was according to the procedure of Rodbell and Scow (4) as described in the preceding paper (3). The emulsion was injected into the vein and the incision closed with a suture. The syringe was weighed before and after dosing to determine the mass of injected emulsion. A typical dose was 0.6 g of emulsion, and the amount of olestra administered was approximately 800 μg in Study 1. The availability of higher specific activity material allowed a reduction of dose to 450 μg in Study 2, and 300 μg in Study 3.

Collection of excreta, bile, and tissues. In Studies 1 and 2, a screen was attached beneath the cage of each animal and 24-hr collections of feces were made daily throughout Study 1, and collectively for days 1–5 and 11–15 of Study 2. Samples were stored frozen until analyzed. In Study 2, urine from the animals was collected in iced containers during the fecal collection periods.

In Study 3, after injection of the emulsion and while the animals were still anesthetized, their bile ducts were cannulated. The animals were placed in restraining cages. Bile was collected daily in containers in ice baths and then frozen until analyzed. The animals were provided chow pellets and water. At the times shown in the Table 1, the animals were killed by carbon dioxide inhalation. Livers, spleens, kidneys, lungs, and epididymal fat pads were removed and frozen until analyzed. In Study 3, the absence of bile in the cannula in one animal prevented biliary analysis, although the livers from all four animals were analyzed. Fecal samples from Study 1 were mixed with enough distilled water and then ground so as to form a pasty suspension. Samples were combusted and the trapped carbon dioxide assayed for radioactivity.

Multiple aliquots confirmed the homogeneity of the mixture. In Study 2, fecal lipids were extracted with chloroform/methanol (2:1, v/v) and aliquots of the washed chloroform were assayed for radioactivity. Radioactivity in urine was measured by direct scintillation counting of an aliquot of urine in a gelled scintillation solution.

Analysis of excreta, tissues, and bile. All tissues were homogenized and extracted with chloroform/methanol (2:1, v/v), washed with a solution of KH_2PO_4 and then dried as described in the preceding paper (3).

To determine total radioactivity, aliquots of the bile were counted directly. Another portion of the bile was extracted with chloroform/methanol (2:1, v/v) which was then washed with a solution of KH_2PO_4 (2%, wt). The chloroform and aqueous phases were each assayed for radioactivity. Following evaporation of a portion of the chloroform, the lipid residue was analyzed by two-dimensional TLC as described above. Unlabeled olestra (35 μg) was spotted on the plate at the origin directly over the bile extract before development to provide a mass that could be visualized by charring for comparison with the distribution of radioactivity on the plate.

RESULTS

Distribution of olestra in tissues. The distribution of ^{14}C in the tissues taken in Study 1 is shown in Table 2. As reported in the previous study (3), most of the radioactivity was found in the liver. The radioactivity in the spleen accounted for less than 2.5% of the dose, a fraction that is much less than was previously observed. A large decrease in the radioactivity in the livers was evident between days 1 and 7. The levels on days 7 and 14 (Study 1) and day 35 (Study 3) did not differ appreciably from each other. The radioactivity in spleen did not change with time. Less than 1% of the administered material was found in the other tissues that were analyzed. The recovery of radioactivity from all of the tissues that were examined was approximately 35% at days 7 and 14.

The concentrations of olestra in the spleen and liver were similar in this study. At 24 hr after dosing, the concentration in the spleen was 4.1 ± 0.5% of dose/g of tissue compared with 6.9 ± 0.4% of dose/g of tissue for the liver. Thus the accumulation of the olestra in the liver reflects the mass of the organ, typically 20–30 times that of the spleen, rather than a greater affinity for the liver.

Excretion. The recovery of ^{14}C in feces, urine, and bile is summarized in Table 3. A significant portion was found in bile and feces from intact animals (Studies 1 and 2); only trace amounts were in the urine (Study 2). Less than 0.1% of the activity was recovered in the feces of the bile duct-cannulated rats in Study 3.

Extraction of bile with chloroform/methanol (2:1, v/v) resulted in recovery of essentially all of the label in the chloroform phase; only trace amounts were in the aqueous phase. This extract was separated by two-dimensional TLC. Autoradiograms of this material (Fig. 1b) and of the injected olestra (Fig. 1a) were similar. The majority of the activity in the bile was associated with octa-, hepta-, and hexaesters.

DISCUSSION

The sucrose esters administered intravenously were found primarily in the liver at levels similar to those seen in the preceding study (3). Accumulation in the spleen was also evident, but to a lesser extent than previously seen (3). Even some five weeks after administration, a considerable portion was still present in those organs. The possible metabolic fate of the remainder of the intravenously administered olestra includes hydrolysis, distribution to other tissues, and excretion into bile and feces. If hydrolysis had occurred, the resulting free sucrose would have been excreted in urine. Since no more than a trace of ^{14}C was found in the urine, this pathway was not significant. The presence of only trace amounts of ^{14}C in tissues other than the liver and spleen indicates that general distribution to tissues is insignificant. The presence of appreciable levels of ^{14}C in bile and feces shows this to be the major pathway for removal. After discharge into the intestinal lumen, olestra administered intravenously, like that consumed in the diet, is not digested or absorbed, but is evacuated as a component of the feces.

From the data in Study 1 the rate constant of fecal excretion was calculated for each rat for days 4-14 from the least squares determination of the linear equations for the logarithm of the daily excretion *vs.* time. The rate constant was found to be 0.14 ± 0.01 days^{-1}. This value corresponds to a half life of 5.0 ± 0.5 days for the injected olestra. The amounts of injected ^{14}C found in the livers of the rats at 14 days (32.7%, Table 1), 21 days (34%, ref. 3), and 35 days (33.3%, Table 1) suggest a slower rate of removal. It is possible that the rate calculated from the fecal data for the initial 14 days reflects a pool that turns over rapidly, whereas a pool that turns over more slowly is indicated by the liver values.

The feces of unoperated animals from Studies 1 and 2 contained appreciable levels of ^{14}C, whereas the feces of the animals fitted with bile duct cannulas had quite low levels of activity. This low fecal activity conforms with the appreciable activity that was present in the bile of these animals.

A comparison of the TLC autoradiograms of the excreted biliary radioactivity (Fig. 1b) with the autoradiogram of the injected olestra (Fig. 1a) shows that olestra is not significantly metabolized or hydrolyzed prior to excretion in bile. Essentially all of the excreted radioactivity was found in the areas of the TLC plate corresponding to the octaester (area A), and the several isomers of the hepta- and hexaesters (area B) of olestra. The radioactivity of the administered material found in area C, whose identity is not known, did not appear in the bile. Traces of radioactivity in the bile outside of areas A and B might have resulted from a small amount of hydrolysis to more polar sucrose esters, but it is clear that the principal components of olestra, as administered, account for essentially all of the excreted radioactivity. Apparently, olestra can be suspended by bile acids and phospholipids and then excreted into the intestine. Presumably the olestra in bile was suspended in the biliary aqueous system as an emulsion rather than in solution, since its size would exclude it from the mixed micelles of the components of bile. The bile was normal in appearance, as might be predicted from the very low concentration of olestra. Since the sucrose esters excreted in the bile are similar in composition to olestra (Fig. 1), which is not absorbed, this excreted material, like dietary olestra, passes out in the feces.

The deposition of olestra in the liver seen in these studies is consistent with that reported in the accom-

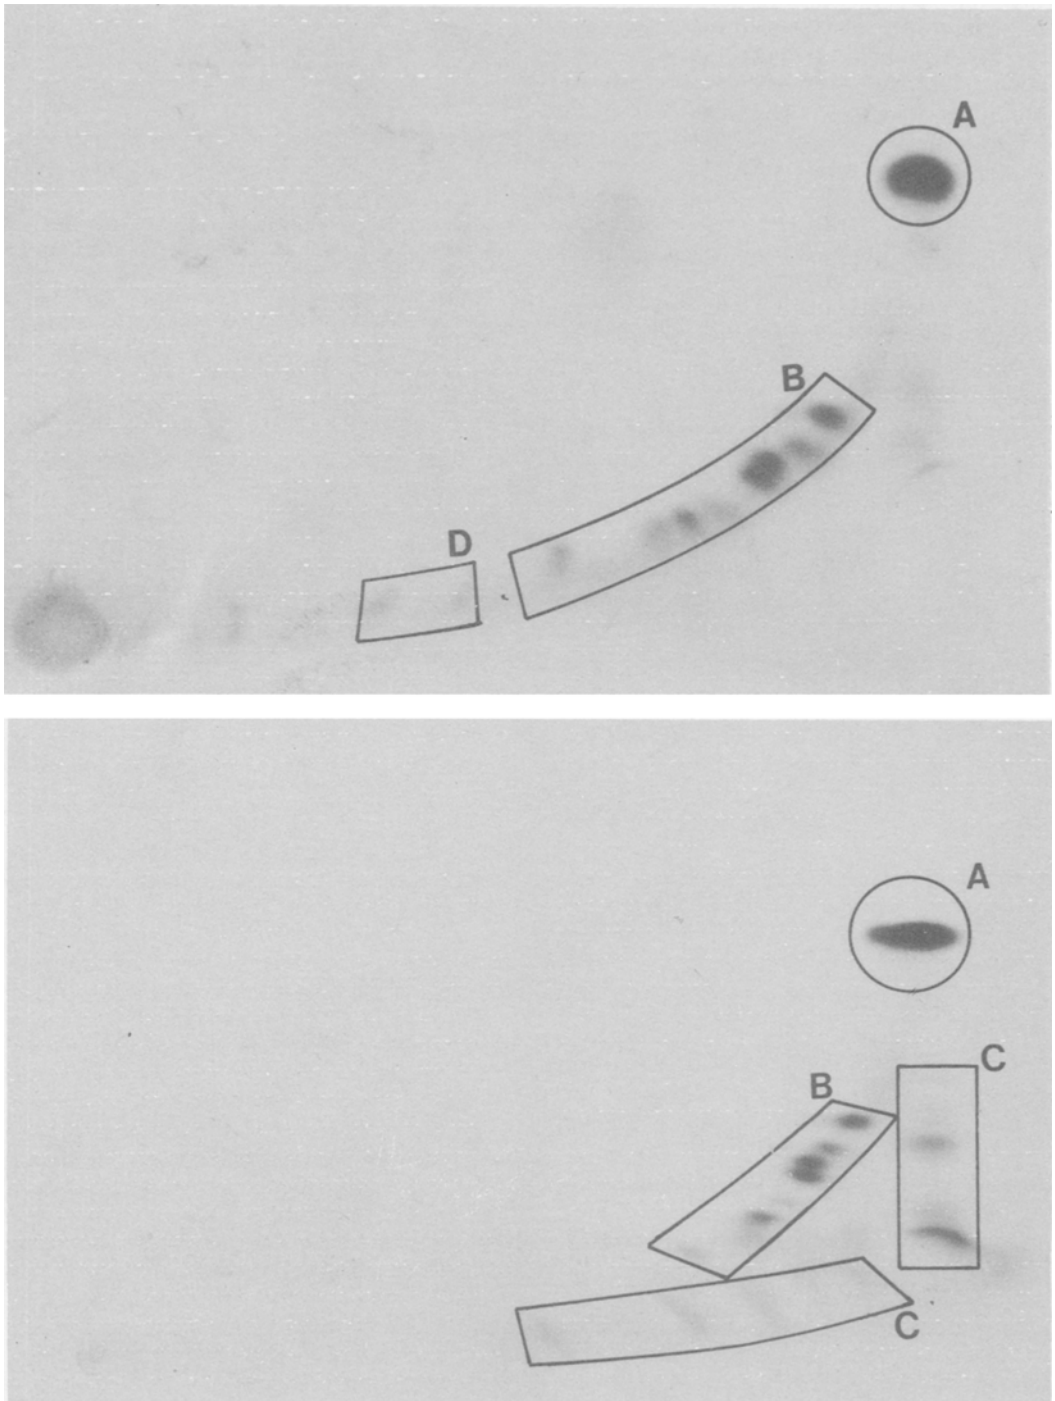

FIG. 1. Top (1a). Two-dimensional TLC autoradiogram of the [^{14}C]olestra used in Studies 2 and 3. A denotes the octaester; B, hepta- and hexaesters; C, unknown species. Bottom (1b). panying paper (3). The fraction of the injected dose found in the spleen, however, is approximately 10% of that previously found. This smaller accumulation in contrast with that seen in the previous study (3) suggests that the accumulation in the spleen was dependent on the dose of injected fat. Thus, the high level found in the spleen in the previous paper (3) resulted when 7.5 mg of sucrose octaoleate was injected, whereas the 300–800 μg of olestra administered in this study resulted in only a small accumulation in that organ. Since the olestra used in this study comprised more than 60% sucrose octaester, it seems unlikely that the different levels of accumulation in the spleen resulted from the compositional differences of the olestra and sucrose octaoleate.

Thus far it has not been possible to demonstrate the absorption of any olestra by rats (2) or humans (5). Since it is impossible to establish zero absorption of any material, the conclusion from each of those studies was necessarily that within the limits of the sensitivity of the methods that were used, absorption could not be demonstrated. The results obtained in this and the preceding paper partially resolve the fate of sucrose polyesters, even if trace amounts were absorbed. Such material would be rapidly removed from the circulation, primarily by the liver and secondarily by the spleen—probably by the reticulo-endothelial system. Subsequently, the sucrose ester would be slowly released and excreted in the bile. In the intestinal tract the biliary excreted sucrose ester, like that taken orally, would be egested in the feces.

ACKNOWLEDGMENT

We wish to thank Dr. J.E. Thompson for the preparation of the labeled material and Dorothy Bailey for chromatographic analyses.

Interaction Between Dietary Proteins and Lipids in the Regulation of Serum and Liver Lipids in the Rabbit. Effect of Fish Protein[1]

N. Bergeron, Y. Deshaies[2], C. Lavigne and H. Jacques*
Département de Nutrition Humaine et de Consommation, Faculté des Sciences de L'Agriculture et de L'Alimentation, Université Laval, Québec G1K 7P4, Canada

Purified diets varying in dietary protein, namely casein (CA), soy protein (SP), fish protein (FP), and lipid origin (corn oil (CN), coconut oil (CO)) were fed to rabbits to evaluate the effects of protein and fat source, as well as protein-lipid interactions, on serum total, lipoprotein and hepatic lipid levels. Dietary proteins and lipids exerted a separate effect on serum total cholesterol (C), very low-density lipoprotein cholesterol (VLDL-C), and low-density lipoprotein cholesterol to high density lipoprotein cholesterol (LDL-C/HDL-C) ratio. Hence, CA increased serum cholesterol compared to SP, while coconut oil enhanced serum and VLDL-C, and decreased LDL-C/HDL-C compared to corn oil. Dietary proteins interacted with dietary lipids to modulate HDL-C levels. Thus, FP maintained a high level of HDL-C regardless of lipid origin, compared to CA and SP whose HDL-C levels were decreased by corn oil, compared to coconut oil. A dietary protein-lipid interaction was also observed in the regulation of liver cholesterol levels. Coconut oil, compared to corn oil, decreased liver cholesterol in rabbits fed FP, whereas hepatic cholesterol concentration was unaltered by dietary lipid source in CA- and SP-fed rabbits. These results demonstrate that dietary proteins act synergistically with dietary lipids to regulate cholesterol metabolism in the rabbit.
***Lipids 26,* 759-764 (1991).**

The hypercholesterolemic effect of casein compared to soy protein, irrespective of the high saturated or polyunsaturated nature of the fats included in the purified diets of rabbits, is well established (1,2). Nevertheless, the origin of dietary lipids has been shown to affect the magnitude of the cholesterolemic response of rabbits to dietary proteins (3). Butter, a fat rich in saturated fatty acids, has been reported to intensify casein-induced hypercholesterolemia compared to corn oil, a fat rich in polyunsaturated fatty acids (2).

The effect of fish protein as well as the modulatory role exerted by saturated and unsaturated dietary lipids included in a fish protein diet on cholesterol metabolism are more variable and still poorly understood. While fish protein exerts a cholesterolemic action similar to that of casein when fed to the rabbit as part of a low-fat (1%) corn oil diet (2), fish protein is hypocholesterolemic compared to casein, when included in a high-fat (14%) coconut oil diet (4). In a corn oil-coconut oil diet with an intermediate lipid content (5%), fish protein exerts a cholesterolemic action intermediary to that of casein and soy protein (5). Meanwhile, regardless of the lipid content of the purified diet, fish protein, compared to casein (4,5) and soy protein (5), has consistently been shown to increase high-density lipoprotein cholesterol (HDL-C) levels in the rabbit. The variation in serum cholesterol levels induced by fish protein when included in purified diets which differ in their lipid content and origin suggests that dietary proteins and lipids may act synergistically to regulate cholesterol metabolism in the rabbit.

Numerous studies have been conducted to determine the individual effects of various dietary proteins (1,2) or lipids (6) on serum and lipoprotein cholesterol levels. However, studies that have been statistically designed to isolate the dietary protein effects from the dietary lipid effects in rabbits (3,7) and other animal models (8-10) are scarce. It is therefore not possible at present to identify with certainty which specific nutrients are responsible for serum total and lipoprotein cholesterol changes subsequent to feeding purified diets. Inasmuch as dietary proteins and lipids are normally consumed as part of a mixed diet and are thus liable to exert an overall effect on cholesterol metabolism, the present study was designed by means of a 3 × 2 factorial model, to isolate the dietary protein effect from the dietary lipid effect, and to detect the interaction between dietary proteins and lipids simultaneously present in purified diets on cholesterol metabolism in the rabbit. For this purpose, rabbits were fed casein, soy protein and fish protein in purified diets differing in their lipid sources. The latter consisted of either corn oil, rich in n-6 polyunsaturated linoleic acid (18:2n-6), or coconut oil, rich in saturated lauric acid (12:0), two dietary lipid sources known to have contrasting effects on lipid and lipoprotein metabolism (6).

MATERIALS AND METHODS

Experimental animals. Upon arrival, 53 male New Zealand white rabbits were housed individually in stainless steel cages with mesh floors, suspended over sawdust in a room maintained under constant conditions of temperature (20-24°C), lighting (12-hr cycle) and humidity (45-55%). Following a 5-day adaptation to the animal quarters where animals were maintained on a non-purified diet (NPD) (Performance blend no. 5301, Ralston Purina, Québec, Canada), rabbits were divided into 6 experimental groups balanced for initial body weight (1400 g), and gradually adapted to their experimental rations by feeding mixtures of NPD and purified diets over a 5-day period. For the duration of the 30-day study, fresh food and water were provided once daily on an *ad libitum* basis. Food

intake was measured daily while growth of animals was monitored twice a week.

Purified diets. In the present study high fat (11%), cholesterol-free, powdered purified diets, assigned to rabbits in a 3 × 2 factorial arrangement, consisted of either casein-corn oil (CA-CN), casein-coconut oil (CA-CO); soy protein-corn oil (SP-CN), soy protein-coconut oil (SP-CO); fish protein-corn oil (FP-CN) and fish protein-coconut oil (FP-CO). The composition of the corn oil and coconut oil based purified diets is detailed in Table 1. The coconut oil diets were supplemented with 1% corn oil in order to meet the essential fatty acid requirements of the rabbit (11). The nutrient content of the vitamin and mineral mix has been described in a previous study (5). Casein and soy protein were purchased from ICN Biomedicals (Cleveland, OH). Fish protein, prepared in our laboratory, was obtained by lyophilization of frozen cod fillets which were then delipidated in an industrial Soxhlet-type apparatus during 12-hr cycles, using a mixture of ethyl acetate/hexane (1:1, v/v) in order to extract both neutral and polar lipids. The delipidation procedure was done with the collaboration of the Food Research and Development Centre (St-Hyacinthe, Québec, Canada). Residual lipid content of casein (0.02%), soy protein (0.4%) and fish protein (0.2%) was verified with a Goldfish Lipid Extractor (model 35001, Labconco Corporation, Kansas City, MO). The protein content (N × 6.25) of casein (88.5%), soy protein (87.4%) and fish protein (92.0%) was assayed by the Kjeldahl method using a Kjell Foss autoanalyzer (Model 16210, Foss Co., Hillerod, Denmark). The level of protein in the purified diets was then adjusted to 20% on an isonitrogenous basis, at the expense of cornstarch. As confirmed by bomb calorimetry, the CA-CN (4.71 kcal/g), CA-CO (4.64 kcal/g), SP-CN (4.65 kcal/g), SP-CO (4.56 kcal/g), FP-CN (4.59 kcal/g) and FP-CO (4.43 kcal/g) purified diets were isocaloric providing an average of 4.60 kcal/g of feed. The American Institute of Nutrition (AIN) mineral mix, cornstarch, and cellulose (Alphacel) were purchased from ICN Biomedicals. Coconut oil was obtained from Sigma Chemical Company (St. Louis, MO) and the vitamin mix was purchased from Teklad test diets (Madison, WI). Corn oil was bought from a local food market.

Serum, lipoprotein and hepatic lipid analyses. At the end of the 30-day experimental period, 18-hr fasted rabbits were submitted to a light ketamine-xylazine anesthesia (0.4 mL/kg body weight) before extracting blood by cardiac puncture. Blood samples were allowed to clot at room temperature, followed by low-speed centrifugation to isolate serum. Livers were also removed, weighed, frozen in liquid nitrogen, and stored at −70°C until subsequent chloroform/methanol (2:1, v/v) extraction of hepatic lipids by the method of Folch *et al.* (12). All 4-mL aliquots of serum were stained with Sudan black dye (13) to later visualize the lipoprotein bands, and were submitted to a 25-hr discontinuous gradient ultracentrifugation (14) using a SW-41 swinging bucket rotor in a Beckman ultracentrifuge, model L8 M70 (Palo Alto, CA). Very low-density lipoproteins (VLDL; d< 1.006 g/mL), low-density lipoproteins (LDL; 1.006 < d < 1.063 g/mL) and high-density lipoproteins (HDL; 1.063 < d < 1.21 g/mL) thus separated were collected by aspiration and frozen at −70°C until determination of their cholesterol and triglyceride (TG) contents.

Serum, liver and lipoprotein cholesterol and TG concentrations were determined enzymatically using the CHOD-PAP and triglycerides without free glycerol kits supplied by Boehringer Mannheim (Laval, Québec, Canada) according to the methods described by Siedel *et al.* (15) and Kohlmeier (16), respectively.

Statistical analyses. Data were subjected to an analysis of variance (ANOVA) according to a 3 × 2 factorial arrangement (17) in a randomized block design using the statistical analysis system (SAS) general linear model (GLM) procedure allowing for missing cells in factorial models (18), in order to determine the main protein and lipid effects, and to identify any interaction among dietary protein and lipid sources (P × L) at a probability level inferior to 0.05. Overall dietary protein and lipid effects, as well as protein-lipid interactions detected by ANOVA, were then submitted to least square mean (LSmean) multiple comparisons (18) to identify the statistical differences (P<0.05) among the groups. All data were log transformed (18) prior to statistical analysis in order to make comparisons among homogeneous means. Values in tables and figures are however expressed as the original means ± SEM.

TABLE 1

Composition of the Purified Diets[a]

Ingredients	Corn oil diets	Coconut oil diets
	(g/100 g feed)	
Protein	20	20
Cornstarch	51	51
Corn oil	11	1
Coconut oil	—	10
Cellulose	12	12
Vitamin mix	1	1
Mineral mix	5	5

[a]Composition of the vitamin and mineral mix has been described previously (5).

RESULTS

Food intake, weight gain and gross weight gain efficiency (GWGE) (g of body weight gained/g of food ingested daily) are presented in Table 2. Although the CA-CO rabbits had a significantly (P<0.05) lower food intake than the animals of the other groups, weight gain and GWGE were similar in all dietary groups. These results indicate that all experimental rations supported normal and linear growth throughout the study period and were thus nutritionally adequate and equivalent.

Mean serum total cholesterol, VLDL-C, LDL-C and LDL-C/HDL-C are listed in Table 3. The overall analyses of variance performed on these data are reported in the top half of Table 4, while the multiple comparisons are shown on the bottom half of this table. As indicated by the P values lower than 0.05, both dietary proteins and lipids separately and significantly affected serum total cholesterol, VLDL-C, and the LDL-C/HDL-C ratio. Hence feeding FP, as well as CA, significantly (P<0.05) increased serum total cholesterol compared to SP. By comparison, VLDL-C concentrations were significantly (P<0.05) decreased by FP, in contrast to the CA and SP groups

TABLE 2

Food Intake, Weight Gain and Gross Weight Gain Efficiency (GWGE) of Rabbits Fed the Purified Diets[a]

Mean Serum Total and Lipoprotein Cholesterol Levels in Rabbits Fed the Purified Diets[a]

Dietary group	Cholesterol (mg/dL)			
	Total	VLDL	LDL	LDL-C/HDL-C
CA-CN	70 ± 10	4 ± 1	28 ± 7	1.5 ± 0.6
CA-CO	99 ± 10	10 ± 1	33 ± 7	0.8 ± 0.2
SP-CN	37 ± 2	4 ± 1	15 ± 2	1.6 ± 0.5
SP-CO	71 ± 9	8 ± 3	25 ± 8	1.0 ± 0.4
FP-CN	79 ± 14	3 ± 1	23 ± 3	0.5 ± 0.1
FP-CO	81 ± 5	2 ± 1	20 ± 3	0.5 ± 0.1

[a]Refer to Table 4 for two-way analysis of variance performed on these data. Means ± SEM. CA, casein; SP, soy protein; FP, fish protein; CN, corn oil; CO, coconut oil.

whose VLDL-C levels were similar. The lipid effect observed translated into a significant (P<0.05) enhancement in serum total cholesterol and VLDL-C in the CA and SP groups fed coconut oil, in relation to corn oil. Interestingly, this rise in serum and VLDL-C consequent to coconut oil compared to corn oil feeding was not observed in the FP group (Table 3), indicating that dietary proteins tended to act synergistically with dietary lipids to regulate serum total cholesterol (P<0.1) and VLDL-C (P<0.08) levels.

Although LDL-C levels were not affected by the type of dietary protein or lipid, the LDL-C/HDL-C ratio was significantly influenced by diet composition. Thus, FP caused a significant (P<0.05) decrease in LDL-C/HDL-C ratio compared to CA and SP, which induced similar LDL/HDL ratios. Moreover, feeding corn oil, in contrast to coconut oil, significantly (P<0.05) increased the LDL-C/HDL-C ratio in the CA and SP groups. This lipid effect was again not experienced by the FP-fed rabbits.

The significant (P<0.05) interactions illustrated in Figures 1 and 2 indicate that proteins and lipids exerted synergistic, as opposed to distinct, effects on HDL and hepatic cholesterol levels, respectively. Although corn oil, compared to coconut oil, significantly (P<0.05) decreased HDL-C in the rabbits fed CA-CN and SP-CN diets, it did not have this effect with FP; HDL-C levels remained high and unchanged in both the FP-CN- and FP-CO-fed rabbits (Fig. 1). Concomitantly, feeding the FP-CO and

Lipid	CO > CN	CO > CN	CO = CN		CO < CN	

[a]The symbols designate: =, no significant difference among the groups at P<0.05; >, significantly higher than the group to which it is compared at P<0.05. CA, casein; SP, soy protein; FP, fish protein; CN, corn oil; CO, coconut oil.

FP-CN diets resulted in a significant ($P<0.05$) rise in HDL-C, compared to the respective counterparts fed the SP-CO, SP-CN, and CA-CN diets. However, when included in coconut oil-based diets FP-CO and CA-CO exerted similar effects on HDL-C levels.

Similarly, while hepatic cholesterol levels (Fig. 2) induced by CA and SP were unaffected by the origin of dietary lipids, feeding coconut oil, compared to corn oil, resulted in a significant ($P<0.05$) decrease in liver cholesterol in the FP rabbits. The P × L interaction on hepatic cholesterol may thus be ascribed to FP. Nevertheless, when included in a corn oil diet, the liver cholesterol level of the FP-CN rabbits was intermediary to, and not significantly different from that of the CA-CN and SP-CN groups. By comparison, when incorporated into a coconut oil diet, FP-CO and SP-CO caused a significant ($P<0.05$) reduction in liver cholesterol, compared to CA-CO. A significant ($P<0.05$) increase in hepatic cholesterol concentration was observed in the rabbits fed CA, in contrast to SP, irrespective of the saturated or n-6 polyunsaturated origin of dietary lipids.

Mean serum, hepatic and lipoprotein TG levels are presented in Table 5. The overall ANOVA, along with the multiple comparisons are summarized in Table 6. Although no significant differences were observed in serum total TG levels, which remained low in all dietary groups, dietary proteins significantly ($P<0.05$) affected VLDL-TG and HDL-TG, whereas dietary lipids significantly ($P<0.05$) influenced the liver and HDL-TG concentration. Interestingly, in parallel to its cholesterol lowering effect in

VLDL, FP significantly ($P<0.05$) decreased VLDL-TG and concomitantly, significantly ($P<0.05$) raised HDL-TG, in relation to the CA and SP groups. No significant difference was observed in serum, lipoprotein and liver TG levels of the CA- and SP-fed rabbits. The significant lipid effect on HDL and hepatic TG was translated by a significant ($P<0.05$) coconut oil-induced rise in TG, compared to corn oil. VLDL-TG were however unaffected by dietary lipids. Likewise, dietary proteins did not interact with dietary lipids to regulate serum total, lipoprotein and hepatic TG levels in the rabbit.

DISCUSSION

Results from the current investigation confirm the recognized hypercholesterolemic effect of casein in relation to soy protein (1). Moreover, in agreement with previous trials (2,5), FP was shown to induce serum cholesterol levels similar to those of the CA-fed rabbits (2,5) and greater to those of the SP-fed rabbits (2). Likewise the cholesterol-raising effect of coconut oil, compared to corn oil, observed in CA and SP groups is consistent with the established hypercholesterolemic influence of saturated in contrast to polyunsaturated fatty acids (PUFA) (6,19). However, this lipid effect was not expressed in the FP groups where feeding coconut oil (FP-CO), compared to corn oil (FP-CN), failed to further enhance serum cholesterol levels. In this sense, although dietary proteins and lipids were shown to exert a separate effect on serum cholesterol in the CA- and SP-fed rabbits, as also demonstrated by Sanchez *et al.* (7), the present results suggest that dietary proteins tended to act synergistically with the lipid component of the purified diet to modulate serum cholesterol levels in rabbits fed fish protein.

Consistent with prior observations, FP, despite its similarity to CA with respect to serum total cholesterol levels (5), was shown to significantly increase HDL-C, rendering this lipoprotein the predominant serum cholesterol carrier (4,5). High HDL-C levels observed in rabbits fed both FP-CN and FP-CO diets demonstrate that dietary proteins and lipids acted synergistically and suggest that the FP effect may override the lipid effect in the regulation of HDL-C levels in the rabbit. Likewise, dietary proteins tended ($P<0.08$) to interact with dietary lipids to down-regulate VLDL-C levels, in contrast to CA and SP. Absence of significant differences in VLDL-C between CA and SP groups could be expected since changes in VLDL-C concentrations have been reported to occur only when serum cholesterolemia exceeds 600 mg/dL (20).

Since a hypercholesterolemic state has been shown to be conditional to LDL-C increase in the rabbit (20), failure to observe changes in LDL-C levels in the present study may be due to serum cholesterol levels which remained below 100 mg/dL in all dietary groups. The cornstarch content of the purified diets may be responsible for the low serum, and thus unaltered LDL cholesterol levels observed in the present investigation. Cornstarch diets, as opposed to molasses-dextrose purified diets, have recently been shown to attenuate serum total cholesterol and LDL-C response to casein feeding (21). Despite the similar LDL-C levels observed, feeding FP resulted in an average 2.5-fold decrease in LDL-C/HDL-C ratio compared to CA and SP. Furthermore, the increase in LDL-C/HDL-C ratio in CA and SP rabbits fed corn oil, as compared to coconut oil, is consistent with the established HDL-C lowering action of n-6 PUFA against saturated fatty acids (SFA) (6, 10). It is however noteworthy that FP again seemed to counteract the lipid effect to maintain low LDL-C/HDL-C ratios. These findings are in agreement with those of previous studies where FP, by raising HDL-C (4,5), has constantly been reported to decrease LDL-C/HDL-C (5) as well as aortic atherosclerosis (4) compared to CA. The present results suggest that whereas CA and SP may generate a beneficial lipoprotein profile depending on the dietary lipid source to which they are combined, FP, by increasing HDL-C, may consistently be efficient in reverse cholesterol transport in the rabbit, whether combined to saturated or polyunsaturated dietary fats.

Absence of protein-induced changes in serum TG levels is in agreement with data reported by Bauer (22). However, coconut oil, in contrast to corn oil intake has already been associated with an increase in serum TG, and a decrease in liver TG, in casein-fed rabbits (23). Since TG metabolism is also known to be influenced by dietary carbohydrate origin (21,24), discrepancies may be due to the 40% sucrose content of the purified diets used by Kritchevsky *et al.* (23), while the current diets provided 51% cornstarch. Indeed, coconut oil supplemented to a non-purified diet (NPD) containing complex carbohydrates has been shown to result in an efficient removal of TG-rich particles and unaltered TG levels in the rabbit (19).

The assembly of HDL particles is known to be closely related to VLDL metabolism (25). HDL lipid and protein constituents have been shown to result from the lipoprotein lipase (LPL)-dependent lipolysis of VLDL (25). Increased catabolism of VLDL, activated by LPL, in turn enhances HDL formation. Hence, decreased VLDL-C coupled to the concomitant rise in HDL-C consequent to FP feeding suggests that the FP-induced rise in HDL-C may result from increased VLDL catabolism either through the promoted activity of LPL, or consequent to a more efficient catabolism due to changes in VLDL composition. The similar low VLDL-TG and high HDL-TG relationship observed in FP groups provides further evidence that the FP-induced increase in HDL may depend on the activity of LPL. In CA and SP rabbits, the increase in cholesterol and TG content in both VLDL and HDL upon feeding coconut oil, as opposed to corn oil, is in agreement with the enhanced production rate of apo A-I and HDL particles demonstrated by Quig and Zilversmit (19) in coconut oil-fed rabbits.

The differential influence of dietary proteins on cholesterol metabolism has been suggested to originate from a hepatic cholesterol saturation threshold (4.64 mg liver cholesterol/g wet weight) (26) and suppressed liver receptor-mediated uptake of circulating lipoproteins (27) causing an increase in serum cholesterol in CA- as opposed to SP-fed rabbits. These findings are consistent with the current data where a direct relationship was observed between liver and serum cholesterol levels which both rose in rabbits fed CA, while they both remained low in the SP groups. Conversely, while serum cholesterolemia induced by FP and CA were similar, FP decreased liver cholesterol in the coconut oil-fed rabbits, in contrast to corn oil-fed animals, to a level below that observed in CA rabbits. These results suggest that FP acted synergistically with coconut oil to decrease cholesterolemia below the liver saturation threshold and thus prevent a serum

cholesterol rise in rabbits fed the FP-CO compared to FP-CN diets.

Although CA and SP, as well as coconut oil and corn oil, are established potent regulators of cholesterol metabolism, the present investigation has additionally shown that these nutrients act separately, as opposed to synergistically, to modulate serum, lipoprotein and liver lipid distribution in the rabbit. However, dietary proteins were shown to interact with dietary lipids to regulate liver cholesterol concentration, and maintain high HDL-C levels in FP-fed rabbits. Combining FP to other dietary lipids varying in degree of unsaturation would, however, be required to confirm the overriding effect of FP on cholesterol metabolism in the rabbit. Nevertheless, the HDL-C rise, combined with the VLDL-C decrease, currently observed in FP-fed rabbits suggests that the formation of HDL particles may be regulated by the extent of VLDL catabolism. These results emphasize the need to further investigate the activity of lipoprotein lipase as well as apoprotein C-II-induced LPL activation of TG-rich particle catabolism consequent to fish protein feeding.

ACKNOWLEDGMENT

The authors wish to gratefully acknowledge the contribution of the Food Research and Development Centre (St-Hyacinthe, Québec) in the delipidation of fish protein.

METHOD

A Simple Assay for Lipid Hydroperoxides Based on Triphenylphosphine Oxidation and High-Performance Liquid Chromatography

Takashi Nakamura* and **Hiroyuki Maeda**
Laboratory of Fisheries Technology, Faculty of Agriculture, Kyushu University, Fukuoka 812, Japan

A simple and sensitive method was developed to measure total hydroperoxides. After the reduction of hydroperoxides with triphenylphosphine (TP) in cyclohexane at 30°C, the amount of triphenylphosphine oxide (TPO) produced is determined by reverse-phase or normal-phase high-performance liquid chromatography (HPLC) in combination with an ultraviolet (UV)-detector by measuring absorption at 220 or 260 nm. TPO was shown to be generated stoichiometrically by reduction of known amounts of either cumene hydroperoxide or methyl 13-hydroperoxyoctadecadienoate. For various lipids at low levels of oxidation, the peroxide values determined by this method were in good agreement with those obtained by conventional iodometry. The detection limit of TPO in HPLC using absorption at 220 nm was less than 10 pmol. Consequently, total hydroperoxides in lipids at levels corresponding to less than a peroxide value of 1 can be estimated by the TP method on a 10-mg sample.
***Lipids 26*, 765–768 (1991).**

Lipid peroxidation in biological systems has been implicated in the pathogenesis of various degenerative diseases (1–3). Hence, there is considerable interest in the development of methods to determine very small quantities of hydroperoxides, the primary products of lipid oxidation. Among these methods, the most popular is the thiobarbituric acid (TBA) test (4–6). This test is based on the acid-catalyzed decomposition of lipid peroxides to form malondialdehyde, and its subsequent reaction with TBA to form a red chromogen. The TBA test is neither specific for hydroperoxides, nor is it positive for all lipid hydroperoxides. Spectrophotometric methods based on the oxidation of iodide ions (7–9), ferrous ions (10), sesamol dimer (11) and methylene blue (12) by hydroperoxides are also available. Nanomolar levels of hydroperoxides can be determined by these methods; however, sensitivity problems exist and the procedures remain tedious.

In recent years, methods based on high-performance liquid chromatography (HPLC) have been developed for measuring hydroperoxides. Yamada *et al.* (13) quantitatively determined hydroperoxy phospholipids in rat liver by a combination of reverse-phase HPLC and an electrochemical detector. Miyazawa *et al.* (14,15) and Yamamoto *et al.* (16) developed chemiluminescence HPLC systems for the detection of lipid hydroperoxides in biological samples at the picomolar levels. Akasaka *et al.* (17–19) utilized 1-naphthyldiphenylphosphine, 9-anthryldiphenylphosphine and diphenyl-1-pyrenylphosphine for the postcolumn fluorometric HPLC assay of lipid peroxides. These HPLC methods are excellent and can detect picomolar levels of resolved lipid hydroperoxides. However, specialized HPLC/equipment and/or tedious procedures can be involved, and poor reactivity of the latently fluorescent phosphines with lipid hydroperoxides can be encountered.

Triphenylphosphine (TP), which has long been used for the structural analysis of lipid hydroperoxides (20–22), reduces hydroperoxides quantitatively to the corresponding hydroxy compounds, while being converted to triphenylphosphine oxide (TPO). Consequently, peroxide content of lipids can be estimated by quantitatively measuring the TPO produced or the TP consumed in the reaction. Bernard and Wong (23) and Akasaka *et al.* (17) assayed the residual TP after reducing the hydroperoxides with a modest excess of TP, using gas-liquid chromatography and reverse-phase HPLC, respectively. However, at low lipid oxidation levels, the determination of trace amounts of TP consumed based on the measurements of unreacted TP can lead to substantial errors.

This paper describes a first attempt to determine total hydroperoxides in lipid samples by direct measurement of the TPO produced using reverse-phase or normal-phase HPLC and ultraviolet (UV)-detection.

MATERIALS AND METHODS

Materials. Linoleic acid (purity 99%), cumene hydroperoxide, and soybean lipoxygenase (type 1-S) were purchased from Sigma Chemical Co. (St. Louis, MO). TP (purity 98%) and TPO (purity 98%) were obtained from Kishida Chemical Co. (Osaka, Japan) and Aldrich (Milwaukee, WI), respectively. TP was purified by chromatography on a silicic acid column, using cyclohexane/benzene (85:15, v/v), to remove traces of TPO which are present as impurity in the reagent. Methyl 13-hydroperoxyoctadecadienoate (Me-13-HPO) was prepared enzymatically from linoleic acid using lipoxygenase, followed by methylation with diazomethane (24,25). The product was purified by normal-phase HPLC (μ-Porasil 7.8 i.d. × 300 mm, Waters, Milford, MA; n-hexane/2-propanol, 99:1, v/v). The purity of cumene hydroperoxide as estimated by iodometry (26) was 86.1%. Other materials such as methyl linolenate (purity 70%, Tokyo Kasei Co., Tokyo, Japan), olive oil, safflower oil, linseed oil and squid liver oil were obtained from commercial suppliers. Sardine muscle lipids were extracted from frozen sardines (*Sardinops melanosticta*) by the method of Folch *et al.* (27).

TP reaction. TP (400 nmol) in 100 μL of cyclohexane was added to lipid hydroperoxides, or oxidized lipids, in 100 μL

*To whom correspondence should be addressed at Laboratory of Fisheries Technology, Faculty of Agriculture, Kyushu University, 6-10-1, Hakozaki, Fukuoka 812, Japan.

Abbreviations: HPLC, high-performance liquid chromatography; Me-13-HPO, methyl 13-hydroperoxyoctadecadienoate; POV, peroxide value(s); TBA, thiobarbituric acid; TP, triphenylphosphine; TPO, triphenylphosphine oxide; UV, ultraviolet.

of cyclohexane in a screw-capped reaction tube. The mixture was shaken at 30°C in the dark. After the prescribed reaction period, usually 30 min, 5 to 10 μL of the mixture was analyzed by HPLC. TP reagent was freshly prepared just before use.

HPLC. Using a Hitachi HPLC system with a UV-detector, Model 4000, and a data processor, Model D-2500 (Hitachi Ltd., Tokyo, Japan), TPO and TP were separated and assayed by reverse-phase HPLC on a column of Inertsil ODS-2 (5 μm, 4.6 i.d. × 250 mm, Gasukuro Kogyo Inc., Tokyo, Japan) using CH_3CN/H_2O (90:10, 70:30, v/v, etc.) as eluent. For normal-phase HPLC, a Nova-pak Silica column (3.9 i.d. × 150 mm, Waters) and n-hexane/2-propanol (98:2, v/v) at a flow rate of 1.5 mL/min were used.

Other methods. Peroxide values (POV) were also determined iodometrically by the standard method of the Japanese Oil Chemists' Society (26). The reaction of TP with hydroperoxides was monitored by thin-layer chromatography on Silicagel 60 plates (E. Merck, Darmstadt, Germany) using n-hexane/diethyl ether/acetic acid (60:40:1, v/v/v) as developing solvent.

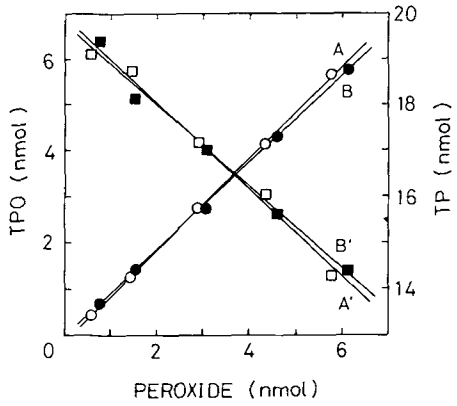

FIG. 2. Correlation between hydroperoxides used and TPO produced or TP remaining. A known amount of cumene hydroperoxide or Me-13-HPO was reduced with TP (400 nmol) at 30°C for 30 min as described in Materials and Methods. The amounts of TPO (—○— cumene hydroperoxide, —●— Me-13-HPO) and TP (—□— cumene hydroperoxide, —■— Me-13-HPO) were measured by reverse-phase HPLC using CH_3CN/H_2O (90:10, v/v) as eluent for Me-13-HPO and CH_3CN/H_2O (60:40, v/v) changing to CH_3CN at 7 min for cumene hydroperoxide.

RESULTS AND DISCUSSION

Reaction of TP with hydroperoxides. The time course of the reaction of TP with hydroperoxides was studied. TP (400 nmol) in 100 μL of cyclohexane was added to 50 μg (153 nmol) of Me-13-HPO in 100 μL of cyclohexane. The mixture was shaken at 30°C in the dark. After the prescribed reaction period, 5μL of the mixture was analyzed by reverse-phase HPLC and by measuring absorption at 260 nm. As shown in Figure 1, the reaction was complete within a short time after addition of the TP solution. The production of TPO correlated well with the molar quantity of Me-13-HPO added. No traces of Me-13-HPO were detected by thin-layer chromatography, even after a 10-min reaction.

Figure 2 shows the correlation between the amounts of hydroperoxides used and the amounts of TPO produced or TP remaining after completion of the reaction. For both the reduction of cumene hydroperoxide and Me-13-HPO, the amount of TPO produced correlated well with the amount of hydroperoxide present (correlation coefficient = 0.999 for both hydroperoxides). These results confirm that, for practical purposes, the hydroperoxides were completely reduced within 30 min, and that TP was stoichiometrically oxidized to TPO in relation to the amount of hydroperoxides present. Less than 10 pmol of TPO was detectable by HPLC based on absorption at 220 nm.

Estimation of POV in lipid samples. Peroxide content of frozen sardines stored at −20°C for a month was measured after reduction of the extracted lipids with TP and subsequent normal-phase HPLC. Figure 3 shows

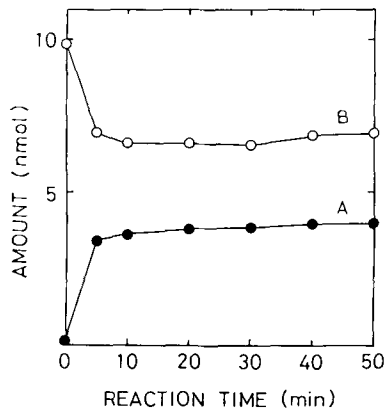

FIG. 1. Time course of the reaction of TP with hydroperoxides in cyclohexane. Me-13-HPO (153 nmol) was reduced with TP (400 nmol) in 200 μL of cyclohexane, as described in Materials and Methods. After the reaction, 5 μL of the mixture was analyzed by reverse-phase HPLC using CH_3CN/H_2O (90:10, v/v) as eluent at a flow rate of 1.5 mL/min. TPO produced (—●—) and TP remaining (—○—) were determined based on absorption at 260 nm.

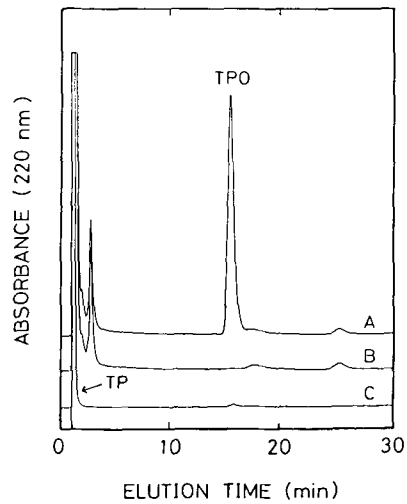

FIG. 3. HPLC of TPO produced by the lipids of sardine muscle. Lipids from sardine muscle were reduced at 30°C for 30 min as described in Materials and Methods, and analyzed by normal-phase HPLC based on absorption at 220 nm. (A): TP reaction mixture of the extracted lipids, (B): the extracted lipids. (C): TP reagent incubated under the same conditions as (A). With an injection of 483 μg of lipid, 2.08 nmol of TPO (equivalent to POV 8.61) was determined.

the elution pattern of the TPO generated; 2.08 nmol of TPO was detected by injection of 483 μg of the lipids. The POV was calculated to be 8.61.

The POV of various other oxidized lipids were estimated by the TP method and by conventional iodometric assay. Figure 4 shows the good agreement between the results obtained for various oils by the two methods. For the TP method, 10 mg of lipid was sufficient for the assay. Figure 5 shows changes in POV with oxidation time during autoxidation of methyl linolenate, as measured by the TP method and by iodometry. For low oxidation levels of the ester, POV obtained by the two methods showed good agreement. However, as autoxidation progressed, the values obtained by the TP method were lower than those obtained by iodometry. By the TP method, a maximum was reached at 68 hr. The discrepancy may be the result of differences between the reducing ability of KI in the acidic medium of $CHCl_3$/acetic acid and of TP in cyclohexane against the peroxidized products of methyl linolenate, including monocyclic and bicyclic endoperoxides and polymers.

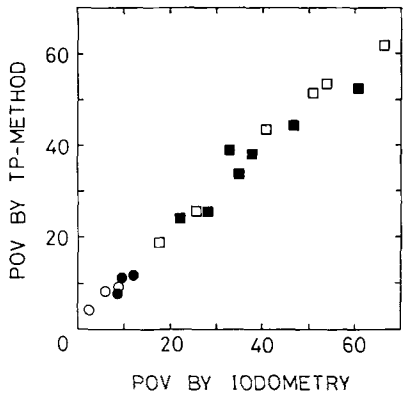

FIG. 4. Relationship between POV obtained by the TP method and by the iodometric method. Olive Oil (●), safflower oil (○), linseed oil (■) and squid liver oil (□) were oxidized in an incubator set at 40°C, and POV was estimated. The conditions for HPLC were the same as in Figure 1.

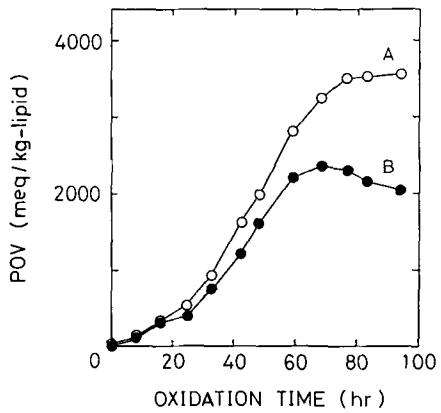

FIG. 5. Changes in POV with oxidation time during autoxidation of methyl linolenate. Methyl linolenate was oxidized at 40°C in the dark with stirring. POV was estimated by the iodometric method (—○—) and by the TP method (—●—) using reverse-phase HPLC. The conditions of HPLC were the same as in Figure 1, except that CH_3CN/H_2O (70:30, v/v) was used as eluent.

TPO in the HPLC solvents used in our experiment has absorption maxima at 220 and 265 nm. Hence, at either wave length, the TPO generated can satisfactorily be determined by HPLC. However, since lipids from biological sources can contain various substances with absorption at the UV-region, care should be taken to exclude peaks that could overlap with TPO. Generally, for lipids from biological sources which contain polar lipids, such as phospholipids, normal-phase HPLC can be used (Fig. 3). However, control experiments are essential to establish background values for HPLC analysis. By our method, the detection limit of TPO in HPLC based on absorption at 220 nm was less than 10 pmol. Consequently, total hydroperoxides in lipids corresponding to oxidation levels of less than POV 1 can be estimated by the TP method using a 10-mg sample of lipid.

ACKNOWLEDGMENTS

This work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture, Japan. Dr. M. Kitamikado provided advice and encouragement and M. Ohara offered helpful comments concerning the manuscript.

High-Performance Liquid Chromatographic Separation of Enantiomeric Alkyl Glycerol Ethers[1]

Thomas A. Foglia* and **Kazuhito Maeda**[2]
U.S.D.A., ARS, Eastern Regional Research Center, Philadelphia, Pennsylvania 19118

The resolution of a series of racemic 1-alkyl-3-trityl-*rac*-glycerols and 1-alkyl-2-benzyl-*rac*-glycerols into their enantiomers by high-performance liquid chromatography (HPLC) was investigated. Of the racemic glycerol derivatives studied, only three (1,2-*O*-isopropylidene-*rac*-glycerol, 1,2-*O*-isopropylidene-3-benzyl-*rac*-glycerol and 1-hexadecyl-2-benzyl-*rac*-glycerol) could be resolved into their enantiomers. The compounds were resolved on a silica (10 μm) column coated with cellulose tribenzoate and eluted isocratically with hexane/isopropanol as mobile phase. The effects of mobile phase composition, column temperature and flow rate on the resolution of enantiomeric pairs were investigated. Also, the effect of substituents, *i.e.*, trityl, benzyl, hydroxyl or alkyl, on the resolution of the alkyl glycerol ethers by HPLC was evaluated. *Lipids 26*, 769–773 (1991).

1-*O*-Alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (commonly referred to as platelet activating factor, PAF) and its analogs have been attracting considerable attention because of their role in initiating or mediating various biological processes (1). It also has been shown that there are distinct differences in the biological activity between the enantiomers of PAF and of its analogs (2,3). In order to prepare pure PAF enantiomers, several total synthetic methods, employing optically active starting materials, have been developed (3–6). However, such stereospecific syntheses usually require numerous steps, and overall yields are relatively low. Moreover, in some cases synthetic intermediates are labile and racemize quite readily. Thus, convenient methods for the preparation of pure enantiomeric ether lipids are urgently needed.

High-performance liquid chromatography (HPLC) technology for the chiral separation of enantiomers has undergone rapid development in recent years. Several types of chiral stationary phases (CSP) for HPLC separation are now available (7). Some of the more useful CSP are the cellulose derivatives on which various compounds have been separated successfully into pure enantiomers without prior derivatization (8–12). Moreover, even large scale chiral separations by HPLC appear feasible, since cellulose derivatized CSP columns are reported to have good stability and durability. Therefore, we considered that in preparing enantiomeric ether lipids, it may be easier to separate selected racemic intermediates into their enantiomers by HPLC, rather than to synthesize them by multistep stereospecific procedures. The enantiomeric resolution of diradylglycerols by HPLC has been reported previously (13) on other chiral liquid phases. However, such resolutions are accomplished after prior conversion of the diacylglycerols into urethane or naphthyl urea diastereomeric pairs.

In the present study, we investigated the use of HPLC for the chiral separation of glycerol ethers without derivatization. Several of the compounds are intermediates of PAF synthesis and of other biologically active ether lipids. Here we describe the enantiomer separation of some glycerol ethers by HPLC using a cellulose derivatized CSP column.

MATERIALS AND METHODS

Materials. Racemic glycerol acetonide 1 was obtained from Aldrich Chemical Co. (Milwaukee, WI). All other glycerol ether derivatives (compounds 2–12) (Fig. 1) were synthesized in our laboratory. 1-Bromohexadecane, benzyl chloride, trityl chloride, methyl iodide, and all catalysts used were obtained from Aldrich Chemical Co. n-Hexane and isopropanol used for HPLC separations were obtained from American Burdick & Jackson (Muskegon, MI).

High-performance liquid chromatography. The HPLC instrument used in this study was an HP 1090 Liquid Chromatograph (Hewlett-Packard, Avondale, PA) that included an ultraviolet detector. A Waters Differential Refractometer Model R 401 detector (Waters Associates, Milford, MA) was employed when necessary. The CSP HPLC column used was a 4.6 mm ID × 25 cm stainless steel type prepacked with 10 μm silica coated with cellulose tribenzoate (Bakerbond Chiralcel OB, J.T. Baker, Phillipsburg, NJ). An analytical silica column (Zorbax SIL, 4.6 mm ID × 25 cm, 5–6 μm, DuPont, Wilmington, DE) was used for determining purity of the glycerol ethers prepared. The integrator/recorder was a Chromatopac C-R3A System (Shimadzu, Columbia, MD). The samples were eluted isocratically with n-hexane/isopropanol varying in composition from 90:10 to 99:1 (v/v), at flow rates of 0.25 to 1 mL/min. Samples were dissolved in mobile phase (1% w/v; injection volumes for the chiral HPLC column were 20 μL). Column temperature was 25 ∼ 27°C, unless stated otherwise.

Syntheses. The glycerol ether derivatives used in this study were prepared using the procedures illustrated in Figure 1.

1-*O*-Hexadecyl-2,3-*O*-isopropylidene-*rac* glycerol 2 was synthesized by alkylation of 1 with 1-bromohexadecane in the presence of sodium hydride in dimethylformamide (4). 1-*O*-Hexadecyl-*rac*-glycerol 3 was obtained by hydrolysis of 2 with conc. HCl in methanol solution. Tritylation at the 3-position of 3 with trityl chloride in triethylamine gave 1-*O*-hexadecyl-3-*O*-trityl-*rac*-glycerol 4 (4). Benzylation at the 2-position of 4 with benzyl chloride in the presence of sodium hydride gave 1-*O*-hexadecyl-2-*O*-benzyl-3-*O*-trityl-*rac*-glycerol 5 (5). 1-*O*-Hexadecyl-2-*O*-benzyl-*rac*-

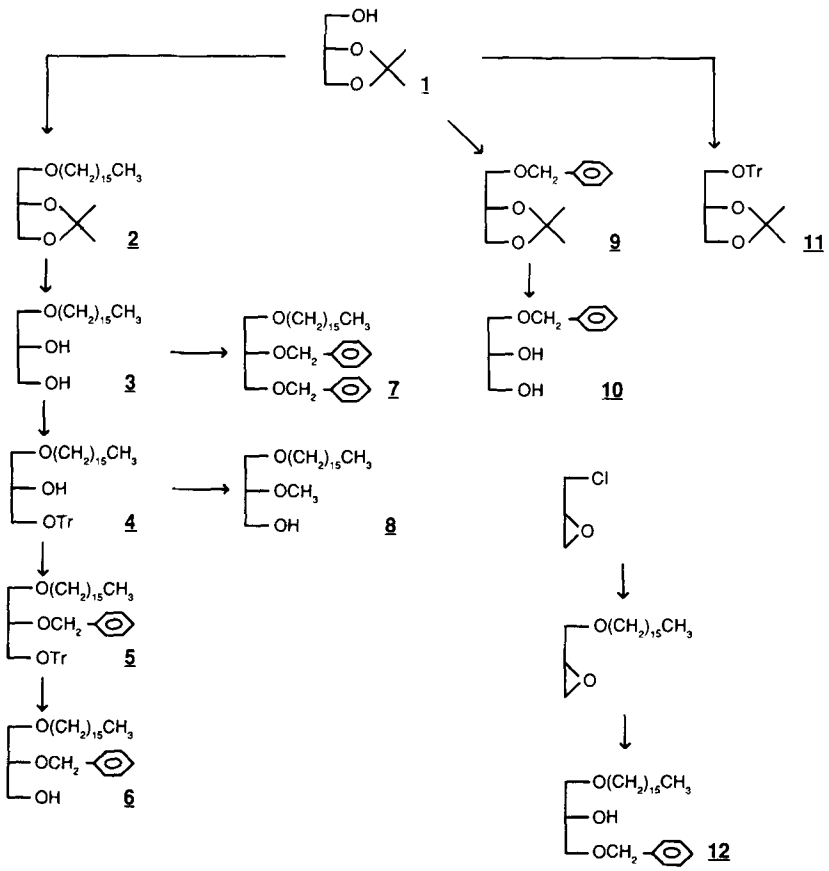

FIG. 1. Preparation of glycerol ethers.

glycerol **6** was prepared by detritylation of **5** with *p*-toluenesulfonic acid in methanol (6).

1-*O*-Hexadecyl-2-*O*-methyl-*rac*-glycerol **8** was obtained from **4** by methylation with methyl iodide in the presence of sodium hydride in dimethylformamide followed by detritylation (5). Benzylation of **3** gave 1-*O*-hexadecyl-2, 3-*O*-dibenzyl-*rac*-glycerol **7** (6).

1-*O*-Benzyl-2,3-*O*-isopropylidene-*rac*-glycerol **9** was prepared from **1** by benzylation; hydrolysis of **9** with conc. HCl in methanol at 0°C gave 1-*O*-benzyl-*rac* glycerol **10** (5). 1-*O*-Trityl-2,3-*O*-isopropylidene-*rac*-glycerol **11** was obtained by tritylation of **1** (5).

1-*O*-Hexadecyl-3-*O*-benzyl-*rac*-glycerol **12** was prepared from epichlorohydrin and 1-hexadecanol in the presence of sodium hydride in dimethylformamide, followed by selective reaction at the 3-position with benzyl alcohol in the presence of sodium hydride in dimethylformamide (6).

All glycerol ether derivatives were identified by infrared (IR) and ^{13}C nuclear magnetic resonance (NMR) spectroscopy, and purity was confirmed by HPLC with the analytical silica column (Table 1).

RESULTS AND DISCUSSION

Enantiomer separation by CSP column. Various chiral compounds have been reported to be separated into their enantiomers on the cellulose tribenzoate CSP column (Chiralcel OB). However, only three of the glycerol derivatives (**1**, **6** and **9**) which we prepared were separated into their enantiomers on the column used (Fig. 2).

Table 2 gives the chromatographic data for the enantiomeric separation of compounds **1**, **6** and **9**. Although elution times with lower polarity mobile phases were longer, better enantiomer separations were obtained. Racemic glycerol acetonide **1** was separated into its enantiomers, as previously reported (14). Good resolution (Rs 1.24) was obtained with n-hexane/isopropanol (99:1, v/v). However, **1** may not be a good intermediate for enantiomer separation since the enantiomers tend to racemize in the process. 1-*O*-Benzyl-2,3-*O*-isopropylidene-*rac*-glycerol **9** was separated into its enantiomers. However, resolution (Rs) was less than 0.8 under optimal conditions. 1-*O*-Hexadecyl-2-*O*-benzyl-*rac*-glycerol **6** was separable into its enantiomers although it has a long alkyl chain at the 1-position of the glycerol backbone. A desirable baseline resolution (Rs 1.47) was obtained with n-hexane/isopropanol (99:1, v/v) as mobile phase. The observed order of elution, R enantiomers before S enantiomers, shown in Figure 2, is in agreement with work previously reported for compound **1** (14). Moreover, the order of elution for compounds **1** and **9** was confirmed by the direct preparation of the R enantiomer of **1** and the S enantiomer of **9**.

We also checked the effect of mobile phase flow rate as well as column temperature on the enantiomer separation of **6** (Table 3). Column selectivites (α) were similar at all flow rates studied. However, enantiomer resolution (Rs)

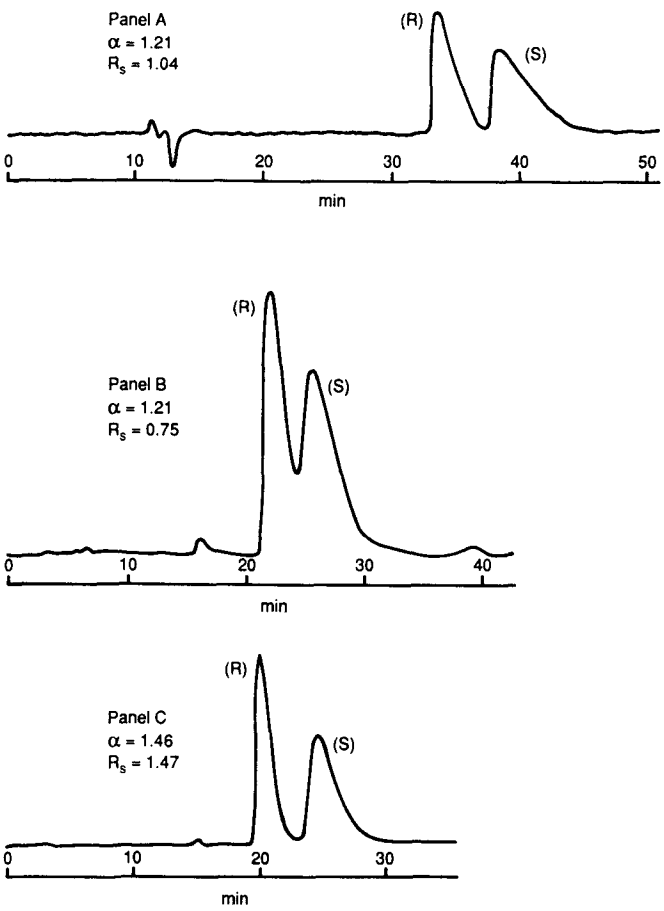

FIG. 2. Enantiomer separation of glycerol derivatives 1, 6 and 9 on Chiralcel OB column (4.6 × 250 mm). Panel A: compound 1, mobile phase, n-hexane/isopropanol (98:2, v/v); flow rate, 0.25 mL/min; RI detector. Panel B: compound 9; mobile phase n-hexane/isopropanol (99:1, v/v); flow rate, 0.5 mL/min; UV detector (254 nm). Panel C: compound 6; mobile phase, n-hexane/isopropanol (99:1, v/v) flow rate, 0.25 mL/min; UV detector (254 nm).

decreased at higher flow rates, presumably because of decreased column efficiency. No appreciable difference in Rs was observed between 25°C and 32°C. However, resolution decreased at 40°C. This may be attributed to a decrease in column efficiency at the higher column temperature. As a result of the above experiments, we concluded that in order to obtain good enantiomer separation, this particular CSP column should be used with a lower polarity solvent, at relatively low flow rate, and at, or near, room temperature (20–30°C).

Structure of glycerol ethers and separation of enantiomers. In the present study only three of the glycerol derivatives, **1**, **6** and **9** were resolved into their enantiomers. Judging from the structure of compounds **1**, **6** and **9**, the combination of a hydroxy group, a benzyl group and an isopropylidene group seems to provide chiral recognition by CSP. The structures probably interact with CSP through hydrogen bonding and π–π interaction that are also governed by steric effects. Furthermore, more than two of the three groups appear to be required for successful enantiomer separation. This seems plausible because multiple site interactions between the racemates

TABLE 3

Dependence of Enantiomer Separation of (6) on Flow Rate and Column Temperature

		α	R_s
Flow rate[a]	0.25 mL/min	1.42	1.32
Mobile phase	0.5 mL/min	1.41	1.08
	1 mL/min	1.41	0.86
Column temperature[b]	25°C	1.46	1.48
	32°C	1.39	1.51
	40°C	1.32	1.17

[a]Mobile phase, n-hexane/isopropanol (99:1, v/v); column temperature, 25°C.

[b]Mobile phase, n-hexane/isopropanol (99:1, v/v); flow rate of mobile phase, 0.25 mL/min.

and CSP would be expected to be required for good chiral recognition (14). If two of the functional groups occur in the structure, they are not necessarily effective as recognition sites, as compound **10** and **12** were not separated into enantiomers. These results support the idea that for chiral recognition to be effective, factors other than the mere presence of chemical recognition sites (11) of the analyte play a role. It appears that the morphology of cellulose tribenzoate on the silica gel, for example, is also important. Moreover, it has been reported that electron-donating substituents on the aromatic ring of a racemate (15) or the cellulose tribenzoate CSP (11) tend to improve enantiomer separations. Such substituents seem to work by changing the electron density of the aromatic ring which relates to the π-π interaction of the analyte and CSP. Accordingly, the enantiomer separation of **6** and **9** might be improved by attaching an electron-donating unit to the benzyl group.

In conclusion, of the glycerol derivatives studied, compound **6** has the best potential for preparative enantiomer separation by HPLC because of the good column selectivity (α) and resolution (Rs) obtained with this compound (Table 2). The S-isomer of **6** would be the intermediate of choice for the stereoselective synthesis of PAF.

COMMUNICATION

The Effects of Tricaine Methanesulfonate (MS-222) on Plasma Nonesterified Fatty Acids in Rainbow Trout, *Oncorhynchus mykiss*

A.J. Harrington, K.A. Russell, T.D. Singer and **J.S. Ballantyne***
Department of Zoology, University of Guelph, Guelph, Ontario, K1A 2W1 Canada

The effects of tricaine methanesulfonate (MS-222), a commonly used fish anesthetic, on plasma nonesterified fatty acid levels (NEFA) were examined in rainbow trout, *Oncorhynchus mykiss*. Total NEFA levels declined with increasing duration of exposure to MS-222. Most of the decline in total NEFA was due to decreases in saturated fatty acids (14:0, 16:0 and 18:0). The fatty acid displaying the most rapid response to exposure to MS-222 was 20:5n-3. The lower plasma NEFA levels in anesthetized fish may be explained by depressed lipolysis in the presence of the anesthetic.
***Lipids* 26, 774–775 (1991).**

The anesthetic, tricaine methanesulfonate (MS-222), is commonly used to reduce stress in fish for blood sampling and other experimental procedures. As indicated by a recent study (1), the anesthetics themselves may induce stress. Levels of a variety of blood parameters during anesthesia with MS-222 have been investigated. These include glucose and/or lactate (2–6), blood amino acid levels (6), blood hormone levels (1,3), blood cholesterol and urea (3), as well as blood electrolytes (3,7). There have been no studies of the effects of MS-222 on pathways of lipid catabolism. Studies of the effects of similar anesthetics in mammals indicate that inhibition of lipolysis occurs (8,9). Since plasma nonesterified fatty acids are the most metabolically labile form of plasma lipid in teleost fish, some understanding of the effects of MS-222 on plasma fatty acids would be useful in interpreting a variety of experimental manipulations of fish involving anesthesia with MS-222.

MATERIALS AND METHODS

Experimental animals. Rainbow trout (*Oncorhynchus mykiss, Salmo gairdneri*) with an average weight of 150–200 g were obtained from a local supplier and maintained in freshwater at 10 ± 1.0°C for three weeks prior to use. Animals were fed *ad libitum* a commercial salmonid diet (Martin Feed Mills, Ltd., Elmira, Ontario, Canada). The fatty acid composition of the diet (wt%) was 14:0, 5.9%; 14:1, 0.3%; 16:0, 12.6%; 16:1n-7, 6.3%; 18:0, 1.4%; 18:1n-9 , 13.1%; 18:2n-6, 11.2%; 18:3n-3, 1.3%; 18:4n-3, 1.4%; 20:1 isomers, 14.2%; 20:2n-6, 0.1%; 20:3n-6, 0.04%; 20:4n-6, 0.2%; 20:3n-3, 0.1%; 20:4n-3, 0.3%; 20:5n-3, 5.0%; 22:1 isomers, 20.4%; 22:5n-3, 0.6%; 22:6n-3, 4.6%; 24:0, 0.8%; 24:1, 0.3%.

Treatment of animals. Blood was drawn into unheparinized syringes from the caudal vein before killing the fish. The control group (no anesthetic) was removed and bled as quickly as possible, with an average sampling time of 30 sec. Another group of fish was exposed to MS-222 at a concentration of 100 mg/L until equilibrium was lost, a process which took approximately 30 sec. The final group of fish was exposed to the same concentration of MS-222 until cessation of respiration, taking approximately 5 min.

Determination of plasma nonesterified fatty acids. Blood was immediately centrifuged for 5 min at 28,000 × *g* in a refrigerated centrifuge (BHG Hermle Z320K, Gosheim, Germany), after which the supernatant was removed and kept at −20°C until use. Nonesterified fatty acids (NEFA) were determined as described previously (10). This method is essentially the same as that first described by Lepage and Roy (11) using acid catalyzed methylation (methanol/acetyl chloride). The assay allows quantitative identification of NEFA from small amounts of plasma. Methyl esters were redissolved in 50 μL CS_2. Two μL of CS_2 containing methyl esters was injected into the gas chromatograph (Hewlett-Packard, HP5890 series II, Hewlett-Packard, Mississauga, Ontario, Canada) fitted with a flame ionization detector. Fatty acid methyl esters were analyzed on a DB-225 megabore fused silica column (Chromatographic Specialties Inc., Brockville, Ontario, Canada). The column temperature was initially 60°C, then was increased to 200°C over 3 min, and kept at 200°C for the remaining 22 min. Fatty acid methyl esters were identified by comparison of their retention times with those of known standards. Absolute amounts of fatty acids were calculated with the aid of an internal standard, heptadecanoic acid (17:0).

Statistical analysis. Differences between the levels of individual and total NEFA between treatment groups were tested with a one-way analysis of variance (ANOVA) and those parameters with significant differences were further analyzed with Duncan's New Multiple-Range test ($P<0.05$ was considered significant) according to Steele and Torrie (12). Log transformation of data was used to meet the assumption of parametric tests.

RESULTS AND DISCUSSION

Plasma NEFA levels declined with increasing duration of exposure to MS-222 (Table 1). The longest duration of anesthesia (to the point of cessation of respiration) resulted in a significantly lower plasma fatty acid level (total fatty acids were almost 50% lower than unanesthetized controls). Most of this decline was due to decreases in the levels of saturated fatty acids (14:0, 16:0 and 18:0). Significant but quantitatively smaller decreases occurred in 20:1 and 20:5n-3. The fatty acid displaying the most rapid response to exposure to MS-222 was 20:5n-3.

[a]Absolute amounts of individual nonesterified fatty acids in plasma of rainbow trout, *Oncorhynchus mykiss*, subjected to 100 mg/L of MS-222. Values are presented as means ± SE for five determinations. Conditions were as described in Materials and Methods. For each fatty acid, values with a common superscript are not significantly different.

Significantly lower levels of this fatty acid were observed after about 30 sec (anesthesia to the point of loss of equilibrium).

The decreased plasma NEFA observed in fish exposed to MS-222 may be due either to elevated oxidation of fatty acids or a decrease in lipolysis. It has been found that stress causes an increased mobilization of lipids from the liver of fish (13). Stress, such as that associated with blood sampling of unanesthetized fish would therefore cause an increase in NEFA levels in the blood. Further studies are required to establish true "resting" plasma NEFA levels. Regardless of the origin of the high levels of plasma NEFA in unanesthetized fish, the reduction in plasma NEFA levels with increasing level of anesthetization may indicate a reduction in lipolysis rather than increased levels of utilization of fatty acids. It has been shown that blood partial pressure of oxygen (pO_2) in rainbow trout declines with MS-222 anesthesia due to impaired respiration (4). Cessation of oxygen delivery to fat catabolizing tissues would decrease fatty acid oxidation sparing blood NEFA elevating plasma NEFA. An antilipolytic effect of MS-222 may be responsible for the reduced plasma NEFA levels.

Other anesthetics including prilocaine (9), dibucaine and piperocaine (8) have been shown to reduce lipolysis in mammals. Tricaine methanesulfonate (MS-222) may have a similar effect in fish. The present study suggests that caution must be exercised in interpreting studies of hormonal effects on the metabolism of fish when MS-222 is used as an anesthetic. MS-222-induced depression of lipolysis would obscure hormonal effects on blood NEFA levels.

ARTICLE

Adenosine Triphosphate (ATP) and Other Nucleotides Stimulate the Hydrolysis of Phosphatidylethanolamine in Intact Fibroblasts

Zoltan Kiss* and **Karan S. Crilly**
The Hormel Institute, University of Minnesota, Austin, Minnesota 55912

Addition of adenosine triphosphate (ATP) to [^{14}C]ethanolamine-prelabeled NIH 3T3 fibroblasts resulted in rapid formation of [^{14}C]ethanolamine from the prelabeled cellular phosphatidylethanolamine (PtdEtn) pool. After 2-min exposure, 10 μM ATP had near maximal effects on PtdEtn hydrolysis. Several other nucleotides, including UTP, ITP, and the stable ATP analog adenosine 5′-*O*-(3-thiotriphosphate) (ATPγS), also had stimulatory effects on PtdEtn hydrolysis with a potency comparable to that observed with ATP. The same nucleotides which acted on PtdEtn hydrolysis also had similar stimulatory effects on the hydrolysis of phosphatidylcholine (PtdCho) in [^{14}C]choline-labeled cells. In isolated membranes, Mg^{2+} greatly enhanced the stimulatory effects of ATP and ATPγS, but not of other nucleotides, on the hydrolysis of PtdEtn and PtdCho. Results indicate that in isolated membranes, both ATP and ATPγS stimulate phospholipid hydrolysis by two different mechanisms, but in intact cells only one of these mechanisms appears to be responsive to externally added nucleotides.
Lipids 26, 777–780 (1991).

External adenosine triphosphate (ATP) has several purinergic receptor-mediated effects in mammalian cells (reviewed in ref. 1). Most relevant to the present studies, ATP was found to stimulate both phospholipase C-mediated degradation of phosphatidylinositol 4,5-bisphosphate (2–11), and phospholipase D-mediated hydrolysis of phosphatidylcholine (PtdCho) (12,13).

Recently, we showed that in membranes isolated from NIH 3T3 fibroblasts, ATP also stimulates phospholipase D-mediated hydrolysis of phosphatidylethanolamine (PtdEtn) (14). However, the site and the mechanism of this ATP action remained unknown. Here we show that in intact fibroblasts, externally added ATP and several other nucleotides can stimulate the hydrolysis of PtdEtn, suggesting the role of purinergic receptors in the mediation of the ATP effect. In addition, in membranes, ATP and adenosine 5′-*O*-(3-thiotriphosphate) (ATPγS), but not other nucleotides, also stimulate PtdEtn hydrolysis by a second mechanism which appears to be unrelated to the effects observed in intact cells.

EXPERIMENTAL PROCEDURES

Materials. Dowex-50W (H^+ form) and all nucleotides were purchased from Sigma Chemical Company (St. Louis, MO). [2-^{14}C]Ethanolamine (60 mCi/mmol), [*methyl*-^{14}C]-choline chloride (50 mCi/mmol) and [γ-^{32}P]ATP (3000 ci/mmol) were from Amersham Corporation (Arlington Heights, IL). Tissue culture reagents were purchased from Gibco (Grand Island, NY), and fetal calf serum was purchased from Flow Laboratories (McLean, VA).

Cell culture. NIH 3T3 cells were cultured in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal calf serum, penicillin/streptomycin (50 units/mL and 50 μg/mL, respectively), and glutamine (2 mM). For all experiments, the cells were used during the exponential phase of growth.

Measurement of phospholipid hydrolysis in cells prelabeled with ^{14}C-labeled precursors. NIH 3T3 cells were grown in humidified CO_2/air (5/95%) at 37°C and were used between passages 16–42. Cells were incubated with [2-^{14}C]ethanolamine (0.25 μCi/mL) or [*methyl*-^{14}C]-choline chloride (0.30 μCi/mL) for 48 hr, washed with fresh medium, and incubated in fresh DMEM for 3 hr. This last step reduced the amount of unincorporated ^{14}C-labeled precursors from 5,000–6,000 dpm/10^6 cells to 600–1,000 dpm/10^6 cells. Cells were harvested by gentle scraping from the dish and counted hemocytometrically. The harvested cells, usually pooled from 3–6 dishes (150 cm^2) were again washed with fresh medium. At this step, 95–98% of cells were viable, determined by the trypan blue dye exclusion assay. Aliquots of cell suspension (0.7–0.9 × 10^6 cells/mL) were incubated in a final volume of 0.3 mL at 37°C for 2–20 min. The incubation medium contained 2 mM unlabeled ethanolamine or choline, as appropriate, to suppress phosphorylation and reesterification of newly formed ^{14}C-labeled ethanolamine or choline as described earlier (15,16). Incubations were terminated by the addition of 4 mL of a mixture of chloroform/methanol (1:1, v/v). Phase separation was initiated by the addition of 3 mL of water. Fractionation of choline and ethanolamine metabolites was performed on Dowex-50W(H^+)-packed columns (Bio-Rad Econo columns—Richmond, CA; 1 mL bed volume) as described by Cook and Wakelam (17) for the choline derivatives with minor modifications. The initial flow-through (5 mL) along with a following 3- or 5-mL wash (water) contained glycerophosphoethanolamine or glycerophosphocholine, respectively. Ethanolamine phosphate and choline phosphate were eluted by 15 and 20 mL of water, respectively. Finally, ethanolamine and choline were eluted with 8 and 20 mL of 1 M HCl, respectively. Appropriate ^{14}C-labeled standards were prepared as described earlier (18). For the determination of the elution profiles of standards, 1-mL fractions were collected. The metabolites of [^{14}C]ethanolamine and [^{14}C]choline were further identified by thin-layer chromatography (TLC) (Silica Gel G), using the solvent system of 0.5% aqueous NaCl/methanol/concentrated aqueous NH_3 (50:50:5, v/v/v) (15). Phospholipids were separated as described earlier (19). For the preparation of crude membrane fractions, [^{14}C]ethanolamine-labeled cells were collected by scraping and disrupted by Dounce homogenization (A pestle, 100 strokes) in ice-cold 20 mM-

Tris/HCl, pH 7.5. After centrifuging the homogenates at 1,000 × *g* for 5 min, the resulting supernatants were further centrifuged at 16,000 × *g* for 20 min at 4°C. Membranes were incubated in the presence of nucleotides as described earlier (14). For the determination of degradation of ATP, intact cells or membranes were incubated in the presence of [γ-^{32}P]ATP (10^6 cpm; 0.01–1.0 mM) for 0–10 min. Reactions were stopped, and ATP was separated on polyethyleneimine cellulose F plates (20).

Statistical methods. The Student's t-test was used. P values of < 0.05 were considered significant.

RESULTS AND DISCUSSION

Addition of 10 μM ATP to [^{14}C]ethanolamine-labeled NIH 3T3 cells for 2 min significantly stimulated the formation of [^{14}C]ethanolamine from the prelabeled PtdEtn pool; 1 mM ATP had a similar effect (Fig. 1). However, between 2–10 min of incubation, 1 mM ATP, but not 10 μM ATP, had an additional stimulatory effect on [^{14}C]PtdEtn hydrolysis (Fig. 1). These data suggested that the effect of 10 μM ATP on PtdEtn hydrolysis was transient, partly because of its rapid degradation. Indeed, we found that about 90% of 10 μM ATP was degraded by cells within 2 min. During the same period, only about 15% of 1 mM ATP was degraded.

After labeling the cells with [^{14}C]ethanolamine for 48 hr, ^{14}C activity in PtdCho was only 2.2% of that found in PtdEtn. Even though, assuming that ethanolamine and choline comigrate on the Dowex column, degradation of PtdCho still could contribute to the above results. However, under the conditions used, there was less than 10% overlapping between the ethanolamine and choline peaks judged from the elution profiles of standards (21). In addition, the exclusive formation of [^{14}C]ethanolamine in ATP-treated cells (Fig. 1) was confirmed using the TLC method for its identification as described in Methods.

We still should note that accumulation of [^{14}C]ethanolamine both in the absence and presence of ATP occurred exponentially as a function of time (Fig. 1). This phenomenon was probably due to the delayed stimulatory action of a serum factor, because the formation of [^{14}C]ethanolamine was linear in the absence of serum (data not shown). The following experiments with intact cells were performed in the presence of serum, because it did not affect interpretation of data and results were more reproducible.

ATPγS is more resistant to hydrolysis than ATP; therefore, it is often used to elicit ATP-like biological effects. As shown in Figure 2, after 10 min incubation 1–10 μM concentrations of ATPγS appeared to be more potent than ATP in stimulating the formation of [^{14}C]ethanolamine. When the incubation time was shorter (2 min), these nucleotides were nearly equipotent stimulators of PtdEtn hydrolysis (data not shown). Taken together, the data indicate that a low (~10 μM) concentration of external ATP is capable of significantly, although transiently, stimulating PtdEtn hydrolysis in intact NIH 3T3 cells.

If the effect of ATP on PtdEtn hydrolysis is mediated by a purinergic receptor, then one would expect a similar action by other nucleotides as well, because the nucleotide specificity of purinergic receptors is relatively broad (1). Indeed, as shown in Table 1, ATPγS, ITP and UTP each stimulated the hydrolysis of PtdEtn at 100 μM, although with significant differences in potency being detected at

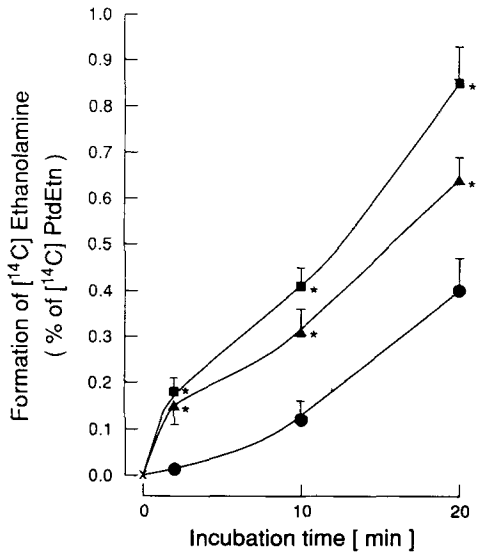

FIG. 1. Time-dependent effects of ATP on the hydrolysis of [^{14}C]-PtdEtn in NIH 3T3 cells. Cells were prelabeled with [^{14}C]-ethanolamine for 48 hr, followed by incubation of suspended cells for 2–20 min in the absence (●) or presence of 10 μM (▲) or 1000 μM ATP (■), as described in the Methods section. [^{14}C]Ethanolamine was separated by ion-exchange chromatography. The mean ^{14}C content of PtdEtn was 1.55×10^6 dpm/10^6 cells. Data are the means ± SEM of two independent experiments each performed in triplicate. Significance: $p < 0.05$ (*). Similar results were obtained in two additional experiments.

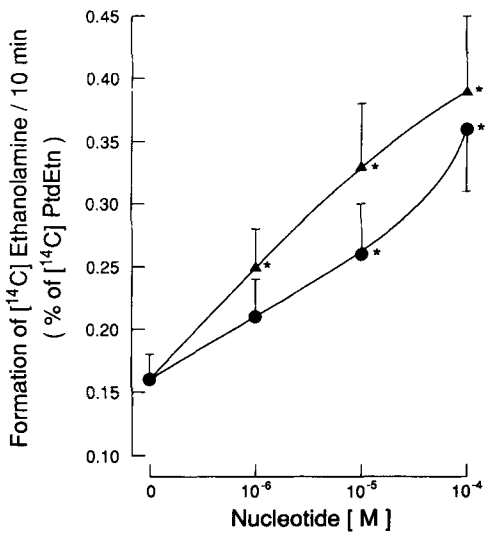

FIG. 2. Comparison of the effects of ATP and ATPγS on the hydrolysis of [^{14}C]PtdEtn in NIH 3T3 cells. Cells were prelabeled with [^{14}C]ethanolamine for 48 hr, followed by incubation of suspended cells for 10 min in the presence of varying concentrations of ATP (●) or ATPγS (▲), as described in the Methods section. The mean ^{14}C content of PtdEtn was 1.48×10^6 dpm/10^6 cells. Data are the mean ± SEM of two independent experiments each performed in triplicate. Significance: $p < 0.05$ (*). Qualitatively similar results were obtained in a third experiment.

TABLE 1

Effects of Nucleotides on Phospholipid Hydrolysis in Prelabeled NIH 3T3 Cells[a]

Nucleotide (100 μM)	Formation of [^{14}C]ethanolamine	Formation of [^{14}C]choline
	% of respective [^{14}C]phospholipid	
None	0.16 ± 0.02	0.07 ± 0.04
ATPγS	0.37 ± 0.04*	0.20 ± 0.03*
ATP	0.31 ± 0.04*	0.28 ± 0.03*

ADP	0.25 ± 0.06	0.21 ± 0.04*
AdoPP[NH]P	0.22 ± 0.06	0.11 ± 0.04
AdoPP[CH_2]P	0.20 ± 0.05	0.09 ± 0.05

[a]Cells prelabeled with [^{14}C]ethanolamine or [^{14}C]choline for 48 hr were incubated for 10 min. [^{14}C]Ethanolamine and [^{14}C]choline were separated by ion-exchange chromatography. The mean ^{14}C content of PtdEtn and PtdCho was 1.26 × 10^6 and 1.43 × 10^6 dpm/10^6 cells, respectively. Data are the mean ± SEM of two independent experiments each performed in quadruplicate.

*Significance: $p < 0.05$, according to Student's t-test. Qualitatively similar results were obtained in a third experiment.

this concentration. On the other hand, ADP, adenosine 5′[β,γ-imido)triphosphate (AdoPP[NH]P) and adenosine 5′[β,γ-methylene]triphosphate (AdoPP[CH_2]P) had only small, statistically insignificant effects on PtdEtn hydrolysis (Table 1). The same nucleotides which stimulated PtdEtn hydrolysis also stimulated the hydrolysis of PtdCho, except that in this latter case ADP also had a statistically significant effect (Table 1).

At present, we cannot exclude the possibility that at lower concentrations, the above nucleotides might exhibit greater differences in their effects on PtdEtn hydrolysis. Unfortunately, at low nucleotide concentrations the formation of [^{14}C]ethanolamine is not sufficiently stimulated over a relatively high background radioactivity (600–1,000 dpm/10^6 cells) to permit unequivocal evaluation of concentration-dependent effects. In addition, it is difficult to take into account how the rate of nucleotide hydrolysis (which differs for various nucleotides) would affect the effect of a given nucleotide on phospholipid hydrolysis. Despite these uncertainties, we can conclude that in intact fibroblasts, several phosphorylating (ATP, ATPγS) and nonphosphorylating nucleotides (UTP, ITP) can stimulate the hydrolysis of both PtdEtn and PtdCho. It also seems clear that, in these cells, nucleotide-stimulated phospholipase D similarly utilizes PtdEtn and PtdCho as substrates.

In order to investigate the mechanism of ATP action in more detail, we also compared the effects of nucleotides in plasma membrane-enriched membrane fractions isolated from [^{14}C]ethanolamine-prelabeled fibroblasts. Since most biological actions of extracellular ATP involve GTP and are affected by Mg^{2+} (1–13), we determined how these agents modified the actions of nucleotides on PtdEtn hydrolysis. As shown in Table 2, each nucleotide which enhanced phospholipid hydrolysis in intact cells also stimulated PtdEtn hydrolysis in membranes. However, while in the presence of Mg^{2+}, GTP potentiated the effect of each nucleotide, Mg^{2+} alone significantly potentiated only the effects of ATP and ATPγS on PtdEtn hydrolysis (Table 2).

It is of additional interest to note that the effects of ATP and the other nucleotides were not affected by 2 mM ethyleneglycol *bis*(2-aminoethyl)*N,N′*-tetraacetic acid used as calcium chelator, or by 10–500 μM calcium. In addition, the nucleotide effect did not require the presence of phospholipid bases (ethanolamine, choline, or L-serine). Thus, it appears that a base-exchange mechanism (22) did not mediate the effects of nucleotides on phospholipid hydrolysis. On the other hand, it was previously shown that in isolated membranes ATP stimulates the formation of phosphatidic acid from ^{32}P-labeled PtdEtn (14). Collectively, these data suggest that the effects of each

TABLE 2

Magnesium- and Guanine Nucleotide-Dependent Effects of ATP on the Hydrolysis of PtdEtn in Membranes from NIH 3T3 Cells[a]

Nucleotide	Formation of [^{14}C]ethanolamine: No $MgCl_2$, No GTPγS	No $MgCl_2$, + GTPγS	+ $MgCl_2$, No GTPγS	+ $MgCl_2$, + GTPγS
	% of [^{14}C]PtdEtn			
None	0.14 ± 0.02	0.19 ± 0.03	0.18 ± 0.03	0.23 ± 0.04

[a]Cells were prelabeled with [^{14}C]ethanolamine for 48 hr, and crude membrane fractions were isolated and then incubated (74 or 89 μg protein/sample) with $MgCl_2$ (2 mM) and/or guanosine 5′-*O*-(3-thiotriphosphate) (GTPγS) (10 μM) in the absence or presence of 250 μM nucleotides for 15 min. The mean ^{14}C content of PtdEtn was 913,000 dpm/100 μg protein. Data are the mean ± SEM of two independent experiments each performed in quadruplicate.

*Significance = $p < 0.05$; ** $p < 0.01$, according to Student's t-test.

stimulatory nucleotide on PtdEtn hydrolysis involve both a phospholipase D enzyme and a GTP-binding protein, while Mg^{2+} specifically potentiates the effects of ATP and ATPγS.

In view of the Mg^{2+}-dependent effects of ATP and ATPγS, we considered the possibility that the full actions of these nucleotides involved a protein kinase activity. However, in membranes, 1-(5-isoquinolinesulfonyl)-2-methylpiperazine (300 μM) and staurosporine (5 μM), potent inhibitors of protein kinase C and other protein kinases (23–26) failed to inhibit the stimulatory effects of 1 mM ATP on the hydrolysis of PtdEtn and PtdCho (data not shown). In NIH 3T3 cells, the protein kinase C activator 12-*O*-tetradecanoylphorbol-13-acetate (27) stimulates phospholipase D-mediated hydrolysis of both PtdEtn and PtdCho (15,18). However, addition of this compound (100 nM) to membranes in the absence or presence of ATP (0.1–1 mM) failed to significantly stimulate the hydrolysis of these phospholipids (data not shown). Thus, experimental data collected so far indicate that the stimulatory effect of ATP on phospholipid hydrolysis is not mediated by protein kinase C.

In conclusion, our data demonstrate that in NIH 3T3 fibroblasts, ATP and several other nucleotides rapidly, but only transiently, stimulate the degradation of both PtdEtn and PtdCho. These results together with our earlier observations (14) strongly suggest the involvement of a phospholipase D. However, the effect of external ATP observed in intact cells appears to represent only a portion of the previously characterized Mg^{2+}-dependent ATP effects observed in isolated membranes (14). Further work is required to clarify the mechanism and judge the importance of the Mg^{2+}-dependent and -independent effects of ATP on phospholipid metabolism.

Hypothyroidism and Thyroxin Substitution Affect the n-3 Fatty Acid Composition of Rat Liver Mitochondria

D. Raederstorff*[,a], C.A. Meier[1,b], U. Moser[a] and P. Walter[b]

[a]F. Hoffmann-La Roche Ltd., Department of Vitamin and Nutrition Research, CH-4002 Basel and [b]Department of Biochemistry, University of Basel, CH-4051 Basel, Switzerland

The effects of hypothyroidism and of daily treatment for up to 21 days with thyroxin (T4, 0.5 μg/100 g body weight) on the fatty acid composition of total lipid, phosphatidylethanolamine, and phosphatidylcholine of rat liver mitochondria were studied. The fatty acid compositions of hypothyroid and euthyroid (control) rats of similar age were compared. The n-6 and n-3 polyunsaturated fatty acids (PUFA) were affected differently by the hypothyroid state. The levels of linoleic (18:2n-6), γ-linolenic (18:3n-6) and dihomo-γ-linolenic acids (20:3n-6) were higher in hypothyroid rats than in controls, while the level of arachidonic acid (20:4n-6) was lower, which suggests an impairment of the elongase and desaturase activities. The n-3 polyunsaturated fatty acids, eicosapentaenoic (EPA, 20:5n-3) and docosapentaenoic (22:5n-3) acids, were higher in hypothyroid rats, whereas the linolenic acid (18:3n-3) content remained constant. The level of docosahexaenoic acid (DHA, 22:6n-3) was dramatically decreased in hypothyroid rats, while the levels of C_{22} n-6 fatty acids were unchanged. The differences were probably due to the competition between n-3 and n-6 PUFA for desaturases, elongases and acyltransferases. When hypothyroid rats were treated with thyroxin, the changes induced by hypothyroidism in the proportions of n-6 fatty acids were rapidly reversed, while the changes in the n-3 fatty acids were only partially reversed. After 21 days of thyroxin treatments, the DHA content was only half as high in hypothyroid rats than in euthyroid rats. These results suggest that the conversion of 18:2n-6 to 20:4n-6 is suppressed in the hypothyroid state which favors the transformation of 18:3n-3 to 20:5n-3. The marked decrease in DHA content indicates an impairment of the enzymes involved in the DHA metabolism, possibly the n-3 Δ4 desaturase or the acyltransferases. The increased levels of EPA and 22:5n-3 is consistent with the inhibition of the n-3 pathway at the Δ4 desaturase step. Observed modifications in the fatty acid composition may significantly alter eicosanoid synthesis and membrane functions in hypothyroidism.
***Lipids* 26, 781–787 (1991).**

Decreases observed in the body basal metabolic rates in hypothyroidism have been linked to decreases in mitochondrial respiration rates (1). Thyroid hormones regulate both lipogenesis and fatty acid oxidation (2). Changes which may occur in the fatty acid composition of liver and heart mitochondrial phospholipids reflect the thyroid status of experimental animals. Thyroid conditions influence cell membrane lipids (3–7) which, in turn, may modulate membrane enzymes, transporters and receptors (2,8,9), such as L-glycerol-3-phosphate dehydrogenase (10), pyruvate translocator (11), and cation permeability (12). Hoch (2) proposed that synthesis and desaturation of fatty acids regulate mitochondrial oxidation *via* altered membrane fatty acyl compositions. Numerous studies in rats have indicated a role for thyroid hormones in the regulation of hepatic fatty acid synthesis (13–21). In addition, elevated levels of linoleic acid (18:2n-6) and decreased levels of arachidonic acid (AA, 20:4n-6) have been found in the hypothyroid state (2,3,8,14–17). However, only few data are available concerning the n-3 fatty acids derived from α-linolenic acid (18:3n-3) and the possible metabolic interactions between n-6 and n-3 fatty acids in different thyroid states. The Δ6 and Δ5 desaturases, which are involved in the conversion of 18:2n-6 into 20:4n-6, were found to be decreased in hypothyroid rats compared to normal rats when n-6 fatty acids were used as substrates (22). These desaturases are also involved in the conversion of 18:3n-3 into eicosapentaenoic acid (EPA, 20:5n-3), but no data are available using n-3 fatty acids as substrates. Recently, a number of reports have indicated that n-3 fatty acids may have beneficial effects in various chronic diseases, such as atherosclerosis, heart disease and cancer, as well as in certain inflammatory diseases (23–27). These reports have stimulated interest in the metabolism of n-3 fatty acids and the interaction between n-3 and n-6 fatty acids. The n-3 and n-6 fatty acid families have antagonistic metabolic, physiological and pathological functions (Fig. 1) (28,29). Therefore, we studied the possible influence of hypothyroidism and replacement therapy with physiological doses of thyroxin (T4) on the n-3 and n-6 fatty acid composition in liver mitochondria.

MATERIALS AND METHODS

Chemicals. L-3,3′,5,5′-Tetraiodothyronine (thyroxin, T4) and solvents of analytical grade were purchased from Fluka (Buchs, Switzerland). 6-Propyl-2-thiouracil and fatty acid standards were obtained from Sigma Chemical Co. (St. Louis, MO) and Nu-Chek Prep, Inc. (Elysian, MN), respectively. Sucrose was purchased from Serva (Heidelberg, Germany) and all other reagents were obtained from Merck (Darmstadt, Germany).

Animal treatment. Thirty male Wistar rats, each weighing between 100 and 120 g, received an iodine depleted diet (Altromin No. 1042 from Altromin AG, Lage, Germany) for 30 days. Five control rats (euthyroid, Group F) were given 1 ppm potassium iodide in the drinking water and, after 30 days, 50 μL of a 0.2 mM NaOH solution orally used as vehicle for thyroxin in the experimental groups for 19 days. The remaining 25 animals were

Abbreviations: AA, arachidonic acid, 20:4n-6; DHA, docosahexaenoic acid, 22:6n-3; DPA, docosapentaenoic acid, 22:5n-3; EFA, essential fatty acid; EPA, eicosapentaenoic acid, 20:5n-3; FAME, fatty acid methyl ester; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PUFA, polyunsaturated fatty acid(s); SEM, standard error of the mean; T3, 3,3′,5-triiodothyronine; T4, 3,3′,5,5′-tetraiodothyronine, thyroxin; UI, unsaturation index.

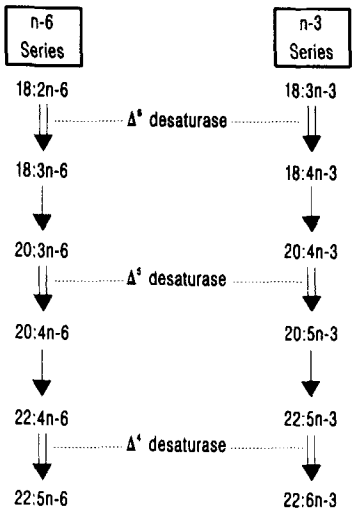

FIG. 1. Pathways for the biosynthesis of the n-6 and n-3 series of polyunsaturated fatty acids. The steps are catalyzed by either an elongation (single arrow) or a desaturation (double arrow) enzyme.

rendered hypothyroid by adding 1% $KClO_4$ to the drinking water for the 30 days. 6-Propyl-2-thiouracil (0.1%) was added to the diet for the first six days of this period. After 30 days, the hypothyroid rats were randomly assigned to five groups, each containing five animals. Group A (hypothyroid rats) received orally 50 μL of a 0.2 mM NaOH solution used as vehicle for thyroxin for 11 days. The other hypothyroid animals were orally given T4 (0.5 μg/100 g body weight) on a daily basis as sodium salt dissolved in a final concentration of 0.2 mM NaOH for various durations. Groups B, C, D and E received T4 orally for 2, 5, 9 and 21 days, respectively. The fatty acid weight percent composition of the experimental diet was: 10.4% 16:0 (palmitic acid), 3.7% 18:0 (stearic acid), 22.9% 18:1n-9 (oleic acid), 1.5% 18:1n-7 (vaccenic acid), 54.8% 18:2n-6 (linoleic acid), and 6.3% 18:3n-3 (α-linolenic acid). Heart blood was collected from the rats under short anesthesia, and the liver was quickly removed and placed into ice-cold saline buffer. The animals were sacrificed after the experimental periods.

Hormone measurement. Total L-3,3',5-triiodothyronine (T3) and free L-thyroxin (T4) levels were measured in serum using the Rapignost assay from Behring Werke (Marburg, Germany).

Preparation of mitochondria. Liver mitochondria from rats were isolated in 0.25 M mannitol/0.07 M sucrose/2 mM Hepes, pH 7.4, by the method of Johnson and Lardy (30).

Lipid analysis. Lipids were extracted from the homogenates by the method of Bligh and Dyer (31). The individual phospholipids were isolated from the lipid extracts by thin-layer chromatography on Silica Gel G 60 (Merck 5714), using the solvent chloroform/isopropanol/ethyl acetate/methanol/0.25% aqueous KCl (30:25:18:9:5, by vol). The plates were sprayed with berberine, and the bands were made visible under ultraviolet light (366 nm). The adsorbent bands corresponding to the phosphatidylethanolamine (PE) and phosphatidylcholine (PC) fractions were immediately scraped from the plates, and the lipids in the presence of the adsorbent were subjected to methanolysis by reaction with methanolic hydrogen chloride (10%) at 95°C for 25 min. Heptadecanoic acid was added as internal standard. An aliquot of the total lipid fraction was transesterified in the same way to obtain the total fatty acid composition. The fatty acid methyl esters were analyzed using a Hewlett-Packard HP 5890A gas chromatograph (Hewlett-Packard, Palo Alto, CA) equipped with a flame ionization detector. All samples were analyzed on a 50 m × 0.25 mm ID fused silica column coated with OV1. The column was temperature programmed from 55°C to 177°C at 10°C/min, then to 218°C at 1°C/min, and finally to 270°C at 4°C/min, and held at this temperature for 25 min. Peaks were identified by comparison with known standards. Quantitative data were derived from the integrator (HP 3393A) using a standard mixture of fatty acid methyl esters (FAME) to establish the response factors for the components identified. The internal standard (heptadecanoic acid) was used to convert the peak areas into μg of FAME in the samples. The results were then converted into mole percentages of the identified FAME, which represent more than 98% of the integrated area.

Statistical analysis. All results are expressed as means with their standard errors of the mean (SEM). The statistical significance of differences between means was determined by Student's *t*-test, with comparison made to the euthyroid controls (Group F).

RESULTS

Animal characteristics. The hypothyroid rats cease to grow after 10 days, and their body weight remained constant over the test period at about 170 g. The euthyroid animals grew steadily; after 30 days they weighed 74% more than the hypothyroid rats. Thyroxin treatment for 9 days and 21 days increased the weight of hypothyroid animals by 26% and 46%, respectively.

Total T3 and free T4 levels in rat serum are given in Table 1. The free T4 level increased sharply in hypothyroid rats after two days of thyroxin treatment, but leveled off at 10 pmol/L after nine days, remaining five times lower than in euthyroid animals. T3 level also increased rapidly reaching the level of euthyroid rats after two and five days of treatment, but then fell at about half the level of euthyroid animals. Neither total T3 nor free T4 in serum

could be normalized in this experiment after 21 days of thyroxin treatment.

Mitochondrial fatty acid modification. The relative fatty acid composition of total lipid, PE and PC in rat liver mitochondria is presented in Tables 2, 3 and 4. The fatty acid composition of total lipids reflects the total phospholipid content because phospholipids represent more than 85% of the liver mitochondrial lipids (32). Moreover, the two major phospholipids analyzed comprise 75% of the total phospholipids (33). The level of total saturated fatty acids in liver mitochondria was only slightly higher in hypothyroid rats than in controls. Palmitic (16:0) and stearic (18:0) acids, the major saturated fatty acids in mitochondrial lipids, were not significantly changed in total lipids. Palmitic acid was only increased in PC of hypothyroid rats. Thyroxin replacement significantly increased the proportion of 16:0 in total lipids, PC and PE. The proportion of monounsaturated fatty acids was also influenced by the thyroid state of the rats. The mitochondria from hypothyroid animals had a higher relative content of oleic (18:1n-9) and palmitoleic (16:1n-7) acids and a lower content of vaccenic acid (18:1n-7) in total lipids, PC and PE as compared to the mitochondria from controls. The level of total n-6 PUFA remained unchanged in total lipids and PE, and was slightly decreased (by 13%) in PC of hypothyroid animals. The relative contents of 18:2n-6, 18:3n-6 and 20:3n-6 were higher in the different lipid fractions of mitochondria of hypothyroid animals, while the AA content was significantly lower. T4 administration rapidly reversed the changes in n-6 PUFA in PE and total lipids. The total n-3 PUFA of total lipids (8.9%), PC (8.4%) and PE (15.2%) decreased in hypothyroid rats to 5.2%, 4.9% and 7.5%, respectively. This was due to the considerable decrease of DHA from 7.2%, 6.5%, 12.6% to 2.1%, 1.7%, 3.0% in those fractions. The precursors of DHA, *i.e.*, EPA and 22:5n-3, were significantly increased in the mitochondrial lipids of hypothyroid rats compared to euthyroid animals. The decrease in DHA was not reversed by T4 treatment.

DISCUSSION

The results show that hypothyroidism affects the phospholipid fatty acid composition of rat liver mitochondria. Moreover, thyroid hormone treatment partially reversed the changes in the phospholipid fatty acid patterns. The altered fatty acid composition in hypothyroid rats was not due to starvation and essential fatty acid deficiency because the ratio of 20:3n-9/20:4n-6 was about 10 times lower than the generally accepted normal limit of 0.4 (34). Emphasis was given to changes in the n-6 and n-3 fatty acids that are essential for humans (35,36). The proportions of n-3 and n-6 fatty acids were affected differently. The observed decrease in AA and the increase in 18:2n-6 in hypothyroid rat liver lipids confirm the previously reported alterations in AA metabolism (14–17). Microsomal Δ6 and Δ5 desaturases have been reported to be below normal in hypothyroid animals (22); these low activities may be correlated with the fatty acid composition of lipids in liver microsomes, mitochondria and nuclei (14–16,22). In the hypothyroid state, the level of 18:2n-6 may increase as a consequence of lower Δ6 desaturase

activity. The 2.8- and 6-fold increase in the 18:3n-6 content of PC and PE and the relatively small changes in the level of 20:3n-6 seem to be related to a decrease in the activity of the fatty acid elongase in hypothyroid animals. Previous investigators reported a decrease in microsomal, but not mitochondrial, fatty acid chain elongation activity in hypothyroid rats (37,38). The increase in the level of 16:1n-7 and the concomitant decrease in the 18:1n-7 level in hypothyroid animals suggest that fatty acid chain elongation is inhibited. Finally, the lower AA level in liver lipids may be a consequence of the inhibition of Δ5 desaturase. The AA content decreased less in PE than in PC, as reported by Hoch *et al.* (15). Moreover, the changes in fatty acid composition after T4 treatment were more completely reversed in PE.

T4 treatment for five days normalized the ratio of 20:4n-6/18:2n-6 which represents the overall metabolic conversion of 18:2-6 into 20:4-6 including Δ6 desaturase, elongase and Δ5 desaturase (Fig. 2). Within five days of T4 treatment, the fatty acid composition was close to normal, suggesting that the changes were due to thyroxin deficiency. In addition, T4 treatment increased the 16:0 content of mitochondrial lipids. Thyroid hormones have been shown to increase the activity and amount of fatty acid synthetase (20,39).

The decreased ratio of 20:4n-6/18:2n-6 in hypothyroid rats may have been partially compensated for by an increase in the ratio of 20:5n-3/18:3n-3. This increase in the ratio of 20:5n-3/18:3n-3 is consistent with a higher rate of overall conversion of 18:3n-3 into 20:5n-3 (Fig. 3). T4 treatment of hypothyroid rats partially reversed the ratio of 20:5n-3/18:3n-3 (Fig. 3), confirming a thyroxin deficiency effect. The n-6 and n-3 PUFAs are thought to be metabolized by the same enzyme sequence, but a competitive inhibition occurs between the two series at each step in the normal metabolism of these PUFA (40,41). Therefore, if hypothyroidism suppresses Δ5 and Δ6 desaturases, the competition between the n-3 and n-6 fatty acids may have favored the synthesis of long-chain n-3 PUFA up to 22:5n-3. The ratio of 22:6n-3/22:5n-3 was lower in hypothyroid rats than in controls consistent with an inhibition of the Δ4 desaturase of n-3 fatty acids. Previously, Hoch *et al.* (15) have documented a less marked decrease in the level of 22:6n-3 in mitochondrial lipids of hypothyroid rats. The diet fed and the strain of rat used may explain the differences in the relative changes of the fatty acid composition compared to our study. In thyroidectomized dogs the serum level of 20:5n-3 increased and the one of 22:6n-3 decreased (42). T4 replacement failed to correct the decreased level of DHA; the ratio of 22:6n-3/22:5n-3 was only slightly increased (Fig. 4). In fact, the DPA level was even further increased in hypothyroid rats after thyroxin treatment, suggesting that the Δ4 desaturase activity may be partially blocked, resulting in an accumulation of the substrate level. However, factor others than desaturation and elongation activities may influence the fatty acid composition of hypothyroid rats, such as fatty acid synthesis, esterification and oxidation, cell membrane degradation and transport of fatty acids from one site to another. Recently, Rosenthal *et al.* (43) suggested that the ratio of C_{22}/C_{20} PUFA in cells was regulated by the relative rate of retroconversion and chain length elongation, both of which may be affected by thyroid hormone levels. In addition, the n-3 PUFA also compete with 20:n-6 for acylation in the tissue phospholipids (29,40). Higher doses of thyroxin or a longer treatment period or injection may be necessary to correct the activity of the enzymes of the DHA metabolism affected by hypothyroidism. The lower PUFA content and UI in hypothyroid rats compared to controls are mainly due to a redistribution of fatty acids in favor of less unsaturated fatty acids, and to a marked decrease in the proportion

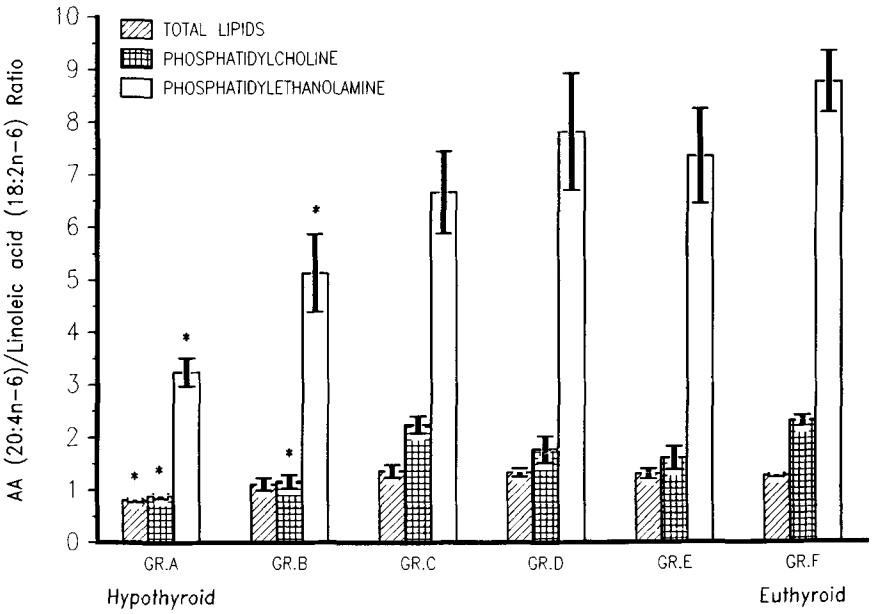

FIG. 2. Changes in the fatty acid ratio of 20:4n-6/18:2n-6 in mitochondrial lipids of hypothyroid rats given thyroxin for 2, 5, 9 and 21 days. Each bar represents the mean ± SEM (n≥4). Bars with * are significantly different from euthyroid rats ($p<0.01$).

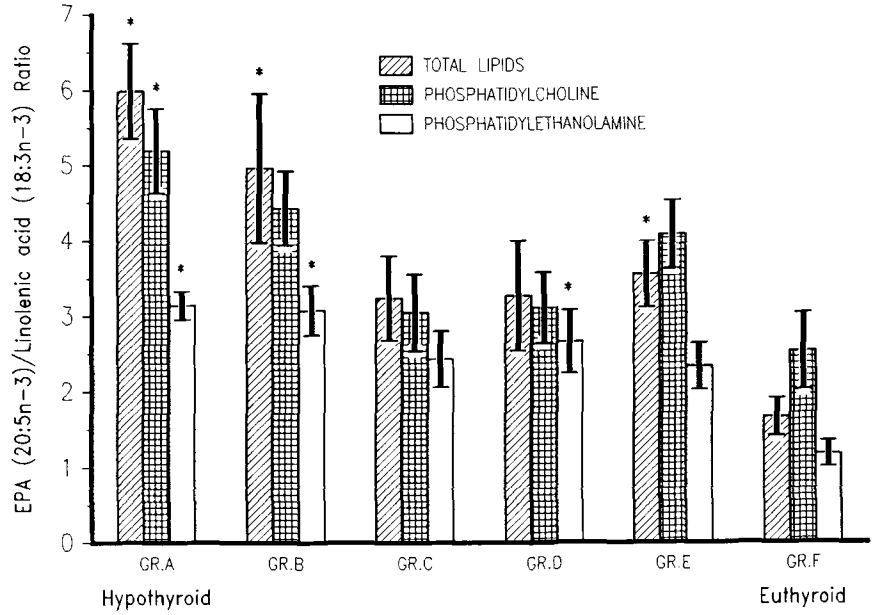

FIG. 3. Changes in the fatty acid ratio of 20:5n-3/18:3n-3 in mitochondrial lipids of hypothyroid rats given thyroxin for 2, 5, 9 and 21 days. Each bar represents the mean ± SEM (n≥4). Bars with * are significantly different from euthyroid rats ($p<0.01$).

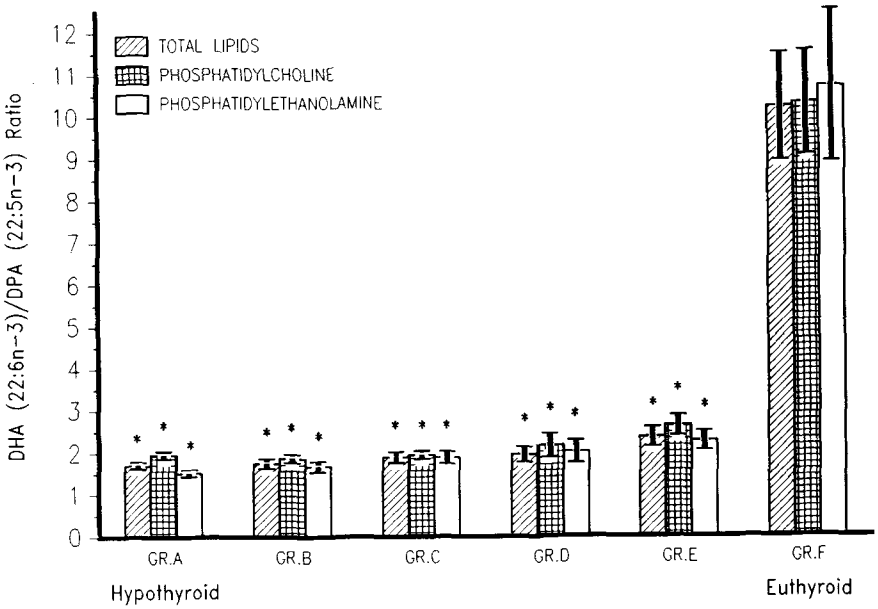

FIG. 4. Changes in fatty acid ratio of 22:6n-3/22:5n-3 in mitochondrial lipids of hypothyroid rats given thyroxin for 2, 5, 9 and 21 days. Each bar represents the mean ± SEM (n≥4). Bars with * are significantly different from euthyroid rats ($p<0.01$).

of DHA, which was not corrected by T4 replacement. The modification of the balance between n-3 and n-6 fatty acids in tissues may have significant biological implications because eicosanoids derived from the two PUFA series exert different biological activities (44–46).

Our study using hypothyroid rats and thyroid hormone replacement suggests that the biosynthesis of n-6 and n-3 PUFA is altered by thyroid hormones. However, each series seems to be affected at different steps in the biosynthesis, leading to the accumulation of different products or intermediates of desaturation and chain elongation. The decrease of the ratio of 20:4n-6/18:2n-6 confirms the previously reported impairment of the Δ5 and Δ6 desaturases by hypothyroidism, whereby the competition between n-3 and n-6 fatty acids favors the conversion of 18:3n-3 to 22:5n-3. In addition, the considerable decrease

in the ratio of 22:6n-3/22:5n-3 may be the consequence of a reduced n-3 Δ4 desaturase or of other enzymes involved in the DHA metabolism. The biosynthesis of n-6 fatty acids is inhibited at an earlier step up to the 20:4n-6 formation. T4 treatment rapidly reverses the changes in n-6 PUFA of hypothyroid rats, while changes in n-3 fatty acid levels are only slowly normalized.

ACKNOWLEDGMENTS

We are indebted to Dr. H. Maecke and the Laboratories of the Department of Nuclear Medicine, University Hospital Basel, for measuring the thyroid hormone levels in the rat sera.

Incorporation of n-3 Fatty Acids into WB-F344 Cell Phospholipids Inhibits Gap Junctional Intercellular Communication

Clare M. Hasler[a,1], **James E. Trosko**[b] and **Maurice R. Bennink**[a,*]
[a]Departments of Food Science and Human Nutrition and [b]Pediatrics and Human Development, Michigan State University, East Lansing, Michigan 48824

In this investigation, we demonstrate that rat liver epithelial (WB-F344) cells grown in medium supplemented with n-3 fatty acids (FA) results in the inhibition of gap junctional intercellular communication (GJIC). Cells incubated for 48 hr in medium containing 50 μM α-linolenate (18:3n-3) resulted in a 60% inhibition of GJIC, compared to control cells, while treatment with γ-linolenate (18:3n-6) had no effect. Supplementation with octadecatetraenoate (18:4n-3), eicosapentaenoate (20:5n-3), and docosahexaenoate (22:6n-3), inhibited GJIC by 42%, 28%, and 18%, respectively. Incubation with each of the n-3 FA markedly increased the total n-3 FA content of cellular phospholipids (PL). Growing cells in medium containing 50 μM arachidonate (20:4n-6) plus 50 μM 18:3n-3 partially attenuated the inhibition of GJIC induced by 18:3n-3. The mechanism by which n-3 FA inhibit GJIC remains to be determined.
Lipids 26, 788–792 (1991).

Previous work conducted in our laboratory (1) demonstrated that in rat liver epithelial (WB-F344) cells, the n-3 fatty acid (FA) α-linolenate (18:3n-3) was a potent inhibitor of gap junctional intercellular communication (GJIC). GJIC is a fundamental biological process thought to be critical in the maintenance of cellular homeostasis, and in the regulation of cell proliferation and differentiation (2,3). Saturated FA (laurate, 12:0; palmitate, 16:0; stearate, 18:0), unsaturated FA from the n-6 family (linoleate, 18:2n-6; arachidonate, 20:4n-6), and oleate (18:1n-9), a monounsaturated FA from the n-9 family, did not modulate GJIC. The inhibition of GJIC induced by 18:3n-3 was not due to alterations in membrane fluidity, production of intracellular free radicals, or activation of protein kinase C. We hypothesized that 18:3n-3 inhibits GJIC through alterations in the FA composition of cellular phospholipids (PL).

In the present study, we have continued our investigation into the influence of n-3 FA on GJIC by examining several metabolic desaturation/elongation products of 18:3n-3 namely octadecatetraenoate (18:4n-3), eicosapentaenoate (20:5n-3), and docosahexaenoate (22:6n-3). The results of this study demonstrate that all n-3 FA tested in our cell system inhibit GJIC. The inhibition of GJIC may be related to an elevated n-3/n-6 FA ratio subsequent to an increase in the total n-3 FA content of cell PL.

MATERIALS AND METHODS

Cell culture. WB-F344 cells (passages 10–30) were obtained from Drs. J. W. Grisham and M. S. Tsao of the University of North Carolina, Chapel Hill, NC (4). The medium consisted of a modified Eagles's medium containing Earle's balanced salt solution with a 50% increase of vitamins and essential amino acids except glutamine, a 100% increase of non-essential amino acids (Gibco Laboratories, Grand Island, NY), 1 mM sodium pyruvate, 5.5 mM glucose, 14.3 mM sodium chloride, 11.9 mM sodium bicarbonate (pH 7.3), and 50 μg/mL gentamicin (Boehringer Mannheim Biochemicals, Indianapolis, IN). The culture medium (designated D medium) was supplemented with 3% fetal bovine serum (Gibco Laboratories). Cells were grown at 37°C in a humidified incubator containing 5% CO_2/95% air. For propagation, cells were subcultured weekly by trypsinization and resuspended in fresh D medium to yield a split ratio of 1:10.

Fatty acid supplementation. γ-Linolenate (18:3n-6), 18:3n-3, 18:4n-3, 20:4n-6, 20:5n-3, and 22:6n-3 (Sigma Chemical Co., St. Louis, MO) were added to D medium as complexes with FA-free bovine serum albumin in an approximate molar ratio of 4:1 according to the method of McGee (5). Briefly, FA were dissolved in a warm, rapidly stirring solution of 20 mM sodium hydroxide, to yield a 10 mM stock FA solution. The appropriate quantity of bovine serum albumin was added to yield a final bovine serum albumin concentration of 2.5 mM. The pH of the FA-bovine serum albumin solution was quickly adjusted to 7.4, filter sterilized with a 0.45 μM filter, and stored in small aliquots under an atmosphere of N_2 at −20°C until needed. Thawed aliquots of the stock FA-bovine serum albumin solution were added directly to the culture medium to achieve the desired FA concentration.

Cells were seeded at approximately 25% of confluency in 75-cm^2 tissue culture flasks (for PL analysis) or 35-mm dishes (for measurement of cytotoxicity and GJIC) containing D medium for 24 hr. After 24 hr, cells were rinsed with phosphate-buffered saline and fresh D medium added, supplemented with various FA at a concentration of 50 μM. The cells were allowed to proliferate to confluency for an additional 48 hr period in the FA-supplemented medium. An equivalent quantity of bovine serum albumin (12.5 μM) was added to control cell cultures.

Lipid extraction and phospholipid analysis. Following the appropriate treatment, confluent WB-F344 monolayers were washed several times with phosphate-buffered saline, harvested by trypsinization, and pelleted by low-speed centrifugation (1000 × *g* for 10 min). The cell pellet was rinsed with phosphate-buffered saline and stored under N_2 in a glass centrifuge tube at −20°C prior to further analyses. Frozen cell pellets were resuspended in 3 mL of phosphate-buffered saline and total lipid was

Abbreviations: ACAS, anchored cell analysis and sorting; 20:4n-6, arachidonate, AA; 18:3n-3, α-linolenate, ALN; 22:6n-3 docosahexaenoate, DHA; 20:5n-3, eicosapentaenoate, EPA; FA, fatty acid(s); FRAP, fluorescence redistribution after photobleaching; GJIC, gap junctional intercellular communication; 18:3n-6, γ-linolenate, GLN; LDH, lactate dehydrogenase; 18:4n-3, octadecatetraenoate, ODA; PL, phospholipid(s); SEM, standard error of the mean; TPA, 12-*O*-tetradecanoyl-phorbol 13-acetate.

extracted with 12 mL of a 2:1 mixture (v/v) of chloroform and methanol (6). PL were separated from total lipids by solid phase extraction with a silica Sep-Pak cartridge (Waters Associates, Milford, MA). Neutral lipids and free FA were eluted with 20 mL chloroform followed by 20 mL chloroform/methanol (20:1, v/v). PL were eluted with 10 mL chloroform/methanol (1:1, v/v). The purity of the PL fraction was checked through the use of radiolabeled FA and thin-layer chromatography. Contamination of the PL fraction with free FA and triglycerides was negligible. The FA of total cell PL were methylated with boron trifluoride (7). FA methyl esters were analyzed by gas-liquid chromatography utilizing a Varian 3700 gas-liquid chromatograph (Sunnyvale, CA) equipped with a flame ionization detector and a Supelcowax 10 capillary column (Bellefonte, PA) 30 meters in length with an inside diameter of 0.53 mm. The oven temperature was increased from 140 to 195°C at 3° per min and then held at 195°C until the last FA methyl ester was eluted. The amount of each FA present was calculated as a percentage of total FA in the sample using a Varian CDS 111 integrator.

Assessment of gap junctional intercellular communication. GJIC was assessed with the ACAS (anchored cell analysis and sorting) 570 interactive laser cytometer (Meridian Instruments Inc., Okemos, MI) (8) *via* FRAP (fluorescence redistribution after photobleaching) analysis as previously described (9). Following the 48-hr treatment period, FA-supplemented medium was removed, and the cell monolayers were rinsed several times with phosphate-buffered saline containing calcium (0.9 mM) and magnesium (0.5 mM) (Ca/Mg phosphate-buffered saline). The cells were incubated for 10 min with the fluorescent dye 5,6-carboxyfluorescein diacetate (7 μg/mL in Ca/Mg phosphate-buffered saline) (Molecular Probes, Inc., Eugene, OR). Cells were washed several times with Ca/Mg phosphate-buffered saline following the labeling period and subjected to FRAP analysis. Five separate confluent cell areas per 35-mm plate were selected and FRAP analysis was performed on 6 labeled cells within each area. Analyses were repeated in duplicate on 3 separate occasions. The tumor-promoting phorbol ester, 12-*O*-tetradecanoyl phorbol 13-acetate (TPA), a potent inhibiter of GJIC *in vitro* (10,11), was utilized as a positive control.

Determination of cytotoxicity. Lactate dehydrogenase leakage into the culture medium was assessed as an indicator of cytotoxicity with an optimized EC 1.1.1.27 UV-test kit (Sigma Chemical Co., St. Louis, MO). Aliquots of the culture medium were analyzed for lactate dehydrogenase activity following FA treatment. Identically treated cultures were exposed briefly (10 min) to a solution of 20% Triton X-100 to solubilize cell contents and an aliquot of the culture medium removed for measurement of total lactate dehydrogenase activity. Lactate dehydrogenase activity was expressed as the amount released from treated cells as a percentage of total cellular lactate dehydrogenase.

In addition to the determination of lactate dehydrogenase release, changes in cell morphology and apparent growth rate due to FA treatment were assessed with the aid of a phase-contrast microscope on a daily basis. Analyses were not conducted on cells which had not achieved complete confluency after 48 hr of treatment.

Statistical analyses. Since dye recovery values from FRAP analysis were obtained as percentages, they were normalized using an arcsin square root transformation procedure (12). Data from all experiments are presented as means ± SEM. Data from all figures were analyzed using a one-way analysis of variance. The F-max test was utilized to assess homogeneity of variance. Statistically significant differences between individual treatment means were determined with the least significant difference test. Criterion for significance was set at $p < 0.05$ for all comparisons.

RESULTS

Effect of α- versus γ-linolenate on GJIC. In a previous investigation (1), we found that α-linolenate (9,12,15 18:3n-3) was a potent inhibitor of GJIC when incorporated into cellular PL. It was of interest therefore, to examine the effect of its positional isomer, γ-linolenate (6,9,12 18:3n-6), on GJIC. As shown in Figure 1, 18:3n-6 does not inhibit GJIC, as fluorescence recovery in cells subsequent to 18:3n-6 treatment did not differ significantly from that of control cells. However, both 18:3n-3 and TPA significantly inhibited GJIC ($p < 0.05$) in WB-F344 cells. The inhibition of GJIC by 18:3n-3 was dose-dependent (Fig. 2) with concentrations of 30, 40, and 50 μM significantly inhibiting GJIC relative to control cells.

Modulation of gap junctional intercellular communication by n-3 fatty acids. It appears that the effect of triunsaturated 18-carbon FA on GJIC is related to the position of the first double bond from the methyl end of the FA. Thus, we examined the ability of various desaturation/elongation products of 18:3n-3 (18:4n-3, 20:5n-3, 22:6n-3) to inhibit GJIC. As shown in Figure 3, each of these n-3 FA were effective inhibitors of GJIC. Interestingly, there was an inverse relationship between the ability of n-3 FA to inhibit GJIC and the degree of carbon chain unsaturation (*e.g.*, 18:3n-3 > 18:4n-3 > 20:5n-3 > 22:6n-3). This is consistent with the ability of these FA to compete with 18:2n-6 and 20:4n-6 for esterification into PL and subsequent competition with 20:4n-6 for eicosanoid

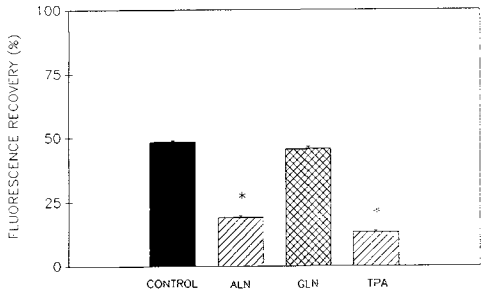

FIG. 1. Modulation of gap junctional intercellular communication (GJIC) in WB-F344 cells by α-linolenate (18:3n-3, ALN), γ-linolenate (18:3n-6, GLN), and 12-*O*-tetradecanoyl phorbol-13-acetate (TPA). Cells were allowed to grow to confluency for 48 hr in medium supplemented with 3% fetal bovine serum plus 50 μM of ALN or GLN. Control cells were treated with 12.5 μM bovine serum albumin. As a positive control, cells were treated with TPA (10 ng/mL) for 1 hr. Percent fluorescence recovery (values normalized using an arcsin transformation procedure) represents GJIC as assessed by fluorescence redistribution after photobleaching (FRAP) analysis following fatty acid or TPA treatment (see Materials and Methods). Values are expressed as means ± SEM. * = significantly less than control, $p < 0.05$, least significant difference test.

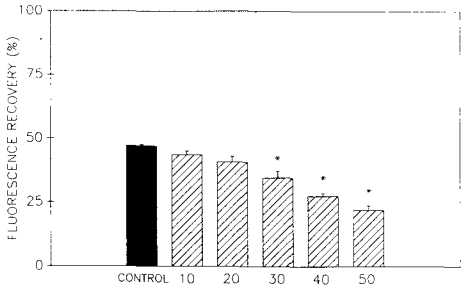

FIG. 2. Dose-dependent inhibition of GJIC in WB-F344 cells incubated with varying concentrations of ALN. Cells were allowed to grow to confluency for 48 hr in medium supplemented with 3% fetal bovine serum plus varying concentrations (10–50 μM) of ALN or 12.5 μM bovine serum albumin (control). FRAP analysis (see Materials and Methods) was performed as an assessment of GJIC 48 hr after ALN treatment. * = significantly less than control, $p < 0.05$, least significant difference test. Definitions are as in legend to Figure 1.

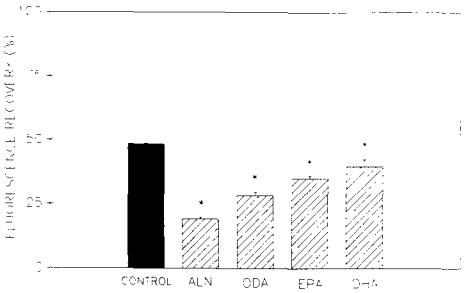

FIG. 3. Effect of n-3 FA on GJIC in WB-F344 cells. Cells were allowed to grow to confluency for 48 hr in medium supplemented with 3% fetal bovine serum plus 50 μM ALN, octadecatetraenoate (18:4n-3, ODA), eicosapentaenoate (20:5n-3, EPA), docosahexaenoate (22:6n-3, DHA), or 12.5 μM bovine serum albumin (control). GJIC was assessed *via* FRAP analysis (see Materials and Methods) at 48 hr following treatment. * = significantly less than control, $p < 0.05$, least significant difference test. Definitions are as in legend to Figure 1.

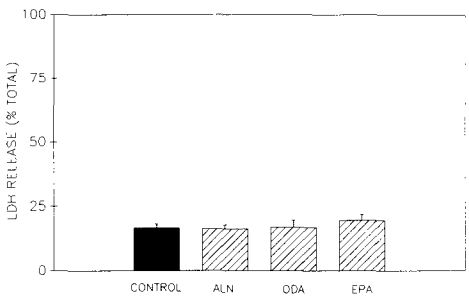

FIG. 4. Percent total lactate dehydrogenase (LDH) release in WB-F344 cells treated for 48 hr with 50 μM ALN or 12.5 μM bovine serum albumin (control). Values represent means ± SEM of triplicate replications obtained on at least two separate occasions. Definitions are as in legend to Figure 1.

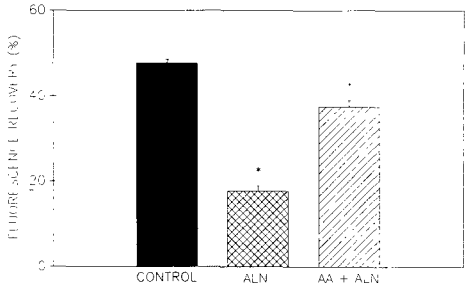

FIG. 5. Attenuating effect of arachidonate (20:4n-6, AA) on ALN-induced inhibition of GJIC in WB-F344 cells. Cells were allowed to grow to confluency in medium supplemented with 3% fetal bovine serum plus 50 μM ALN, 50 μM AA plus 50 μm ALN concurrently, or 12.5 μM bovine serum albumin (control). GJIC was assessed *via* FRAP analysis (see Materials and Methods) at 48 hr following treatment. * = significantly less than control, $p < 0.05$, least significant difference test. Definitions are as in legend to Figure 1.

synthesis (13). The inhibition of GJIC induced by n-3 FA is unlikely to be mediated by cytotoxicity as evidenced by minimal lactate dehydrogenase leakage into the culture medium (Fig. 4). Lactate dehydrogenase release following treatment with 18:3n-3, 18:4n-3, and 20:5n-3 was not significantly different from that of control cells.

Fatty acid modulation of WB-F344 cell phospholipids. Marked changes in the FA composition of total cellular PL were observed after WB-F344 cells were grown for 48 hr in FA-supplemented medium (Table 1). In general, cell PL became enriched in the FA with which they were supplemented, with the extent of enrichment varying with the particular FA employed. For example, the 22:6n-3 content of WB-F344 cell PL following treatment with this FA increased to approximately 23%, *versus* 1.9% in control cells. Conversely, the 18:3n-6 content of cell PL following 18:3n-6 treatment was only elevated to 1.2%, from less than 0.1% in control cells. In addition to the ability of WB-F344 cell PL to incorporate both n-6 and n-3 FA, there was significant elongation and desaturation of these FA. Cells treated with 18:3n-3, 18:4n-3, and 20:5n-3, produced cellular PL highly enriched with 20:5n-3 and 22:5n-3. Treatment with 18:4n-3 elevated the content of 20:5n-3 to the greatest extent (12.7%) compared to controls (0.6%), while incubation with 20:5n-3 increased the 22:5n-3 content of cell PL to 15.6%, *versus* 0.9% in control cells. Similar desaturation/elongation mechanisms were apparent in cells treated with 18:3n-6. In cells supplemented with this FA, the quantity of 20:4n-6 and 22:4n-6 in cell PL was elevated to 20.3% and 12.0%, respectively, compared to 4.6% and 1.1% in control cells. In general, all FA treatments elevated the 16:0 and 18:2n-6 content of cell PL, while reducing 16:1 and 18:1n-9.

Attenuation of α-linolenate-induced inhibition of GJIC by arachidonate. Since 18:3n-3 and 20:4n-6 are from different FA families, and compete for esterification into cell PL, or as substrates for the Δ6 or Δ5 desaturation enzymes, it was of interest to investigate the effect of co-incubating 18:3n-3 and 20:4n-6 on GJIC and the subsequent alterations in cell PL composition. As shown in Figure 5, when cells were grown to confluency in equimolar concentrations of 20:4n-6 and 18:3n-3 for 48 hr, the inhibition of GJIC induced by 18:3n-3 was partially attenuated. This treatment regimen also prevented, to some degree, some of the alterations in the FA composition of cell PL due to 18:3n-3 treatment alone (Table 2). The 20:4n-6 content of control cells, which was reduced to 2.6% following 48 hr of incubation with 50 μM 18:3n-3 (Table 1), was elevated to 18.6% when 20:4n-6 and 18:3n-3 were co-incubated. The direct elongation product of 20:4n-6 (22:4 n-6) was also elevated (11.5%) relative to control cells

(1.1%), and cells treated with 18:3n-3 alone (0.3%). In addition, 20:5n-3 and 22:5n-3, which were markedly increased following 18:3n-3 supplementation, were present at levels similar to controls when 20:4n-6 was co-incubated with 18:3n-3. Furthermore, treatment with 20:4n-6 and 18:3n-3 concurrently, minimized the amount of 18:3n-3 in cell PL (2.0% *vs* 6.8%) compared to cells treated with 18:3n-3 alone.

DISCUSSION

The results of this study demonstrate that growing cells in the presence of the n-3 FA, 18:3n-3, 18:4n-3, 20:5n-3, and 22:6n-3, results in the inhibition of GJIC in WB-F344 cells. The most effective FA in this regard was 18:3n-3, while its positional isomer, 18:3n-6, had no effect. Other investigators have examined the relationship between saturated (14,15), monounsaturated (16), and polyunsaturated FA (17,14,15,18,19) on gap junction function in a variety of cell culture systems with conflicting results. However, the influence of n-3 FA on GJIC has not been reported to date.

The exact mechanism by which n-3 FA inhibit GJIC in WB-F344 cells remains to be elucidated. In a previous report (1) we suggested that the inhibition of GJIC by 18:3n-3 was related to the reduction of 20:4n-6 in cell PL. Similarly, in the present investigation, treatment of cells with 20:5n-3 reduced the amount of 20:4n-6 in cell PL (2.8%), and significantly inhibited GJIC, further

TABLE 3

Influence of Supplemental Fatty Acid Effects on Various Cellular Parameters[a]

Parameter	Supplemental fatty acids[b]					
	Control	GLN	ALN	ODA	EPA	DHA

[c] n represents the position of the first double bond from the methyl end of the fatty acid.

supporting the concept that GJIC was inhibited due to inadequate 20:4n-6 in cell PL. However, GJIC was also significantly reduced following treatment with 18:3n-3 and 22:6n-3, even though the 20:4n-6 content of WB-F344 cell PL was not decreased.

There was a marked elevation in the total n-3 FA content of cell PL subsequent to each FA treatment which resulted in decreased GJIC. A summary of these observations is presented in Table 3. The total n-3 FA in cell PL (ODA > ALN > DHA > EPA) does not correlate well with the inhibitory influence of these FA on GJIC. However, a good relationship exists between the order of the n-3/n-6 FA ratios (ALN > ODA > DHA > EPA ≫ control) and GJIC inhibition.

The elevated n-3/n-6 ratio in cell PL subsequent to n-3 FA treatment could modulate GJIC through an alteration in eicosanoid metabolism. It is well documented that eicosanoids synthesized from n-3 FA are metabolically different than those synthesized from n-6 FA (20). Enrichment of WB-F344 cell PL with n-3 FA might inhibit GJIC by altering the amount and/or type of eicosanoid(s) produced. There is evidence to suggest that eicosanoids do influence gap junction function in a number of different biological systems, although the data are conflicting (19,21-24). Clearly, further research is necessary to determine the role of eicosanoids in gap junction formation and function.

In summary, the results of the present investigation demonstrate that when 18:3n-3, 18:4n-3, 20:5n-3, and 22:6n-3 are incorporated into WB-F344 cell PL, GJIC is inhibited. Although our present findings do not support any simple interpretation, we hypothesize that the inhibitory effect of n-3 FA on GJIC is related to an increase in the total n-3 FA content of cell PL which, in turn, increases the n-3/n-6 FA ratio. The importance of the n-3/n-6 FA ratio and eicosanoid metabolism to GJIC in WB-F344 cells remains to be determined. Future investigations should determine how altering the FA composition of specific PL subclasses in the plasma membranes modulates GJIC. In addition, it should be determined if the inhibition of GJIC by n-3 FA is related to a reduction in the number of gap junction connexins in plasma membrane and the specific connexin(s) affected.

Rapid Three-Step Purification of a Hepatic Neutral Cholesteryl Ester Hydrolase Which Is Not the Pancreatic Enzyme

Shobha Ghosh and W. McLean Grogan*
Department of Biochemistry and Molecular Biophysics, Medical College of Virginia, Virginia Commonwealth University, Richmond, Virginia 23298-0614

A rat liver cytosolic cholesteryl ester hydrolase (CEH) was purified 12,600-fold by ammonium sulfate precipitation, cation exchange chromatography and gel permeation high-performance liquid chromatography, with an overall yield of 20%. Its properties are compared to those of pancreatic CEH, with which it has sometimes been identified. Liver CEH exhibited a single silver stained band following SDS-polyacrylamide gel electrophoresis (M_r = 66 kDa), was activated by 0.5–10 mM taurocholate but was strongly inhibited by higher levels of taurocholate, which activate pancreatic CEH. Whereas bile salts are known to induce formation of a hexamer of pancreatic CEH, in the current study, 0.5 mM taurocholate dissociated a multimeric form of liver CEH to monomer. Liver CEH did not coelute with pancreatic CEH from cation exchange and chromatofocusing columns, exhibited no immunoreactivity with anti-rat pancreatic CEH IgG in Western blots, was not inhibited by anti-rat pancreatic CEH IgG and had a different amino acid composition from pancreatic CEH. In contrast to liver CEH, which is known to be activated by protein kinases A and C, pancreatic CEH was unaffected by cofactors for protein kinase A and was inhibited by cofactors for protein kinase C.

Lipids 26, 793–798 (1991).

Cholesteryl ester hydrolases occur in many tissues and are associated with different functions, depending on location. Whereas the enzyme of pancreas and intestinal mucosa plays an essential role in absorption of dietary cholesterol (1), isozymes in adrenals and gonads provide free cholesterol required for steroid hormone synthesis. Attention recently has been focused on liver cholesteryl ester hydrolase (CEH) and its involvement in cholesterol homeostasis in liver. However, little is known about the structure and function of this enzyme in liver. Although previous reports have demonstrated the presence of more than one CEH with neutral pH optima in both cytosolic and microsomal fractions of the liver (2,3), it is unclear whether a single protein is responsible for these enzyme activities. Camulli *et al.* (4) have recently described affinity purification of cytosolic neutral CEH from rat liver using anti-porcine pancreatic CEH IgG. Inasmuch as liver CEH thus purified had an identical N-terminal amino acid sequence to the rat pancreatic CEH, the authors suggested that CEH in liver and pancreas are very similar and possibly identical proteins. Based on the incomplete neutralization by anti-porcine pancreatic CEH IgG of CEH activity in liver cytosol, the authors suggested the presence of more than one CEH. Other authors report complete inhibition of liver CEH activity by monospecific anti-rat pancreatic CEH IgG and conclude that CEH activity of rat liver may be due to uptake of the enzyme originating in the pancreas (5). In contrast, using the same antibodies, Gallo *et al.* (6) were unable to show any cross-immunoreactivity between solubilized CEH from rat liver, aorta or adrenals.

The present studies describe purification of cytosolic neutral CEH from rat liver using conventional protein purification procedures and comparison of the properties of this enzyme with those of rat pancreatic CEH. The results demonstrate a liver CEH which is very different from rat pancreatic CEH.

MATERIALS AND METHODS

[1-^{14}C]Cholesteryl oleate (56.6 mCi/mmol) was purchased from New England Nuclear (Boston, MA). High-performance liquid chromatography (HPLC) grade solvents were purchased from Fischer Scientific (Columbia, MD). ATP disodium salt, adenosine 3′,5′-cyclic monophosphate (sodium salt), phosphatidylserine, diolein and sodium salts of taurocholic acid, glycocholic acid, cholic acid and deoxycholic acid were obtained from Sigma Chemical Co. (St. Louis, MO). Acrylamide, *bis*-acrylamide, SDS and TEMED were from Bio-Rad (Richmond, CA). All other chemicals used were of analytical grade.

Frozen rat livers from male Sprague-Dawley rats were purchased from Zivic Miller Laboratories, Inc. (Zelienople, PA) and used for all experiments except when effect of protein kinases was studied, in which case fresh livers were used. Tissue was homogenized with a loose teflon pestle in 20 mM Tris HCl buffer, pH 7.5, containing 5 mM 2-mercaptoethanol, 250 mM sucrose and 80 mM KCl (2 mL buffer/g tissue). The 104,000 × *g* supernatant (S104) was obtained as described previously (7). S104 from pancreas (fresh or frozen) was obtained using the same protocol except that the homogenization buffer also contained protease inhibitors, 2 mM 3-methyl propionate, 0.5 mM benzoyl arginine and 5 mM benzamidine.

CEH was assayed as described previously (7) and was purified from S104 as follows: Solid ammonium sulfate was added to S104 to produce 40% saturation and this was allowed to stir on ice for 30 min. The solution was centrifuged at 12,000 × *g* for 20 min. The supernatant was decanted and the pellet stored at −20°C until used. CEH activity was stable under these conditions for several months. The pellet was redissolved in 20 mM Tris HCl buffer, pH 7.5, containing 80 mM KCl, 0.5 mM taurocholate and 5 mM 2-mercaptoethanol (Buffer A) and ammonium sulfate was removed by passing through a Sephadex G-25 column equilibrated with Buffer A. Void volume containing the protein (60 mg) was collected and chromatographed on a Mono S (HR 10/10) cation exchange fast protein liquid chromatography (FPLC) column (Pharmacia, Piscataway, NJ) equilibrated with Buffer A

Abbreviations: cAMP, adenosine 3′,5′-cyclic monophosphate; CEH, cholesteryl ester hydrolase; FPLC, fast protein liquid chromatography; GPHPLC, gel permeation high-performance liquid chromatography; pI, isoelectric point; PKA, cAMP-dependent protein kinase; PKC, protein kinase C; S104, 104,000 × *g* supernatant; SDS-PAGE, sodium dodecylsulfate-polyacrylamide gel electrophoresis.

and eluted with a linear NaCl gradient (0–800 mM). Most of the CEH eluted at 225 mM NaCl. Fractions containing CEH activity were pooled and concentrated using Amicon Centraprep concentrators with a 30,000 molecular weight cut off. Approximately 0.8 mg of the concentrated protein was then chromatographed on gel permeation Protein pak SW 300 HPLC (GPHPLC) column (Waters, Milford, MA) equilibrated and eluted with 200 mM phosphate buffer, pH 7.5, containing 80 mM KCl, 0.5 mM taurocholate and 5 mM 2-mercaptoethanol. CEH activity was eluted in a single (1 mL) fraction corresponding to a molecular weight (M_r) of 60–70 kDa. Purity at all stages was assessed by sodium dodecylsulfate-polyacrylamide gel electrophoresis (SDS-PAGE) using 5–20% gradient gels essentially as described by Laemmli *et al.* (8). After electrophoresis, gels were silver stained using the Bio-Rad silver reagent kit. For Western blots, proteins were blotted on PVDF membranes (Millipore, Bedford, MA) using PolyBlot (American Bionetics Inc., Hayward, CA). Cross-immunoreactivity was assessed using the Immuno-Blot (GAR-HRP) assay kit from Bio-Rad. The protein band at M_r = 66 kDa was cut from the PVDF membrane and used to determine the amino acid composition. CEH inhibition by anti-rat pancreatic IgG was evaluated as described by Harrison *et al.* (5) over the same range of concentrations, with the exception that 0.5 mM taurocholate was used in the final assay buffer. Neutralization of CEH activity in pancreatic cytosol was carried out as described by Gallo *et al.* (6) using 5 mM taurocholate as the bile salt in the assay buffer.

RESULTS

Purification of cytosolic CEH. Rat liver CEH was purified to apparent homogeneity by ammonium sulfate precipitation, cation exchange FPLC and GPHPLC (Table 1). Essentially all activity was recovered from the 40% ammonium sulfate precipitate. From the cation exchange column, most CEH activity eluted with 225 mM NaCl; however, a second peak of activity eluted at 600 mM NaCl (Fig. 1). Activity in this second peak varied from preparation to preparation, but was always less than that associated with the major CEH peak. The apparent yield at this stage was essentially 100% (Table 1). In contrast, pancreatic CEH subjected to the same purification protocol exhibited an entirely different elution profile (Fig. 1).

When concentrated fractions from the cation exchange column were further fractionated by GPHPLC, CEH activity was eluted in a single fraction corresponding to M_r = 60–70 kDa. This purification procedure produced a 12,600-fold increase in specific activity with an overall yield of 20% (Table 1). Purity of the GPHPLC fraction was assessed by SDS-PAGE, which yielded a single silver-stained band, corresponding to M_r = 66 kDa (Fig. 2, lane 1). Purified CEH was unstable in storage at −20°C, however, activity was retained for at least seven days with storage in 250 mM sucrose at 4°C.

Characterization of purified CEH. Activity of fractions from GPHPLC was measured in buffers ranging from pH 4–10. As seen in Figure 3, this enzyme exhibited activity over the range pH 5–9, with optimal activity at pH 7.0–7.5. As seen in Figure 4, enzyme activity rapidly increased between 2.5 to 6.5 μM substrate and gradually increased thereafter, with further increases in substrate up to 300 μM (data not shown). Thus, typical of enzymes with insoluble substrates, this CEH did not saturate with substrate within the range of feasible substrate concentrations.

Effect of bile salts. Among various bile salts tested over the concentration range 0.25–10 mM, taurocholate was found to be most effective in stimulating activity (1.75-fold, at 0.5 mM) of liver CEH in cytosol (data not shown). Glycocholate, cholate and deoxycholate either did not stimulate or only marginally stimulated CEH (data not shown). The purified enzyme was activated by increasing taurocholate concentrations up to 1 mM, remained more or less constant in activity from 1–10 mM taurocholate and declined in activity with further

TABLE 1

Purification of Neutral Cholesteryl Ester Hydrolase from Rat Liver Cytosol[a]

Fraction	Total protein (mg)	Total activity (units/hr)	Specific activity (units/hr/mg)	Yield %	Fold
Cytosol (S104)	125	0.252	0.002	100	—
0–40% Ammonium sulfate precipitate	61.9	0.251	0.004	99.5	2
Cation exchange Mono S FPLC	0.8	0.261	0.327	103.7	164
Gel permeation HPLC SW 300 column	0.002	0.051	25.2	19.8	12,600

[a]One unit is one μmole [1-^{14}C]cholesteryl oleate hydrolyzed per hr at 37°C. Fractions from the Mono S column were assayed in Buffer A. Fractions from the gel permeation HPLC column were assayed in the elution buffer, which gave results equivalent to those of Buffer A.

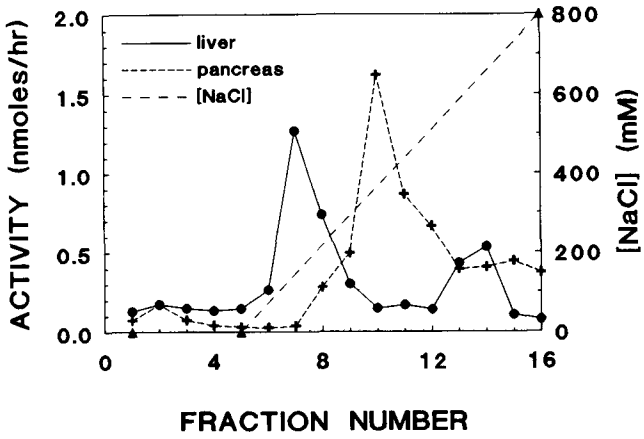

FIG. 1. Elution profile of liver and pancreatic CEH from cation exchange column. 0–40% Ammonium sulfate precipitate was desalted on Sephadex G-25, and 60 mg (or 20–25 mg for pancreas) was loaded on Mono S column. Proteins were eluted using a linear NaCl gradient. Fractions were collected every 2 min and an aliquot was assayed for CEH activity in Buffer A as described in Materials and Methods. Values represent mean of duplicates.

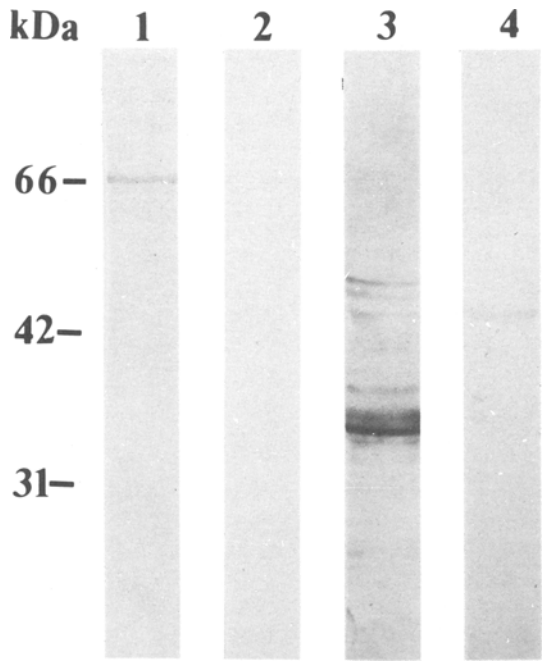

FIG. 2. SDS-polyacrylamide gel electrophoresis of rat liver and pancreatic CEH. Lane 1, silver stained purified liver CEH after GPHPLC; lane 2, immunoblot of lane 1 with anti-rat pancreatic CEH IgG; lane 3, silver-stained rat pancreatic ammonium sulfate precipitate; and lane 4, immunoblot of lane 3 with anti-rat pancreatic CEH IgG.

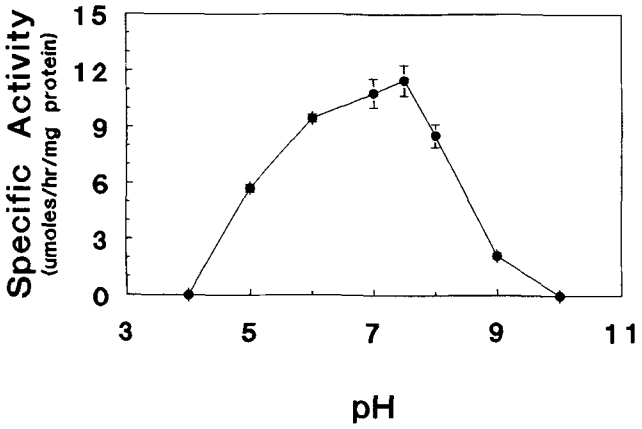

FIG. 3. pH Dependence of purified liver CEH. Fractions from GPHPLC containing purified CEH were assayed in buffers with different pH. Buffers used were: acetate, for pH 4.0, 5.0 and 6.0; phosphate, for pH 7.0, 7.5 and 8.0; and glycine-NaOH, for pH 9.0 and 10.0. All buffers contained 80 mM KCl, 5 mM 2-mercaptoethanol and 5 mM taurocholate. Values represent Mean ± S.E.M. from two experiments, each done in duplicate.

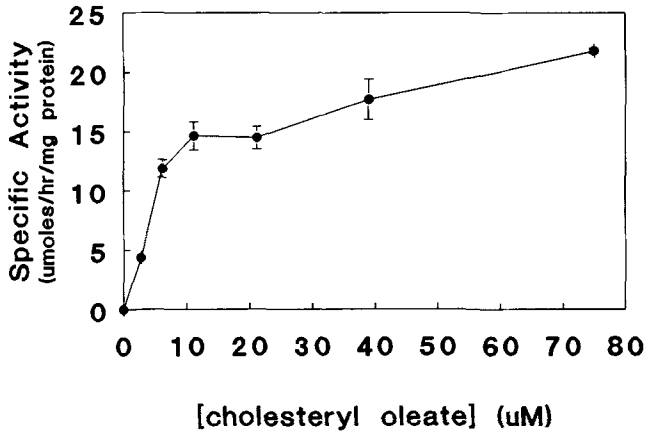

FIG. 4. Effect of cholesteryl ester concentration on catalytic activity of purified CEH. Fractions from GPHPLC were assayed as described in Materials and Methods using indicated concentrations of cholesteryl oleate. Specific radioactivity of the substrate was maintained constant at all concentrations. Values represent Mean ± S.E.M. for duplicate assays. Experiment was repeated with similar results.

increases in concentration (Fig. 5). The liver CEH is strongly inhibited by 20–40 mM taurocholate, in marked contrast to the pancreatic CEH, which is known to be activated by bile salts in this concentration range.

Inasmuch as taurocholate is known to induce formation of an active multimer of pancreatic CEH, purification of CEH was carried out both with and without taurocholate in chromatography eluents. Taurocholate had no apparent effect on elution from the cation exchange column (data not shown). However, an additional peak of activity corresponding to M_r = 400 kDa was eluted from GPHPLC when taurocholate was omitted from the eluent (Fig. 6).

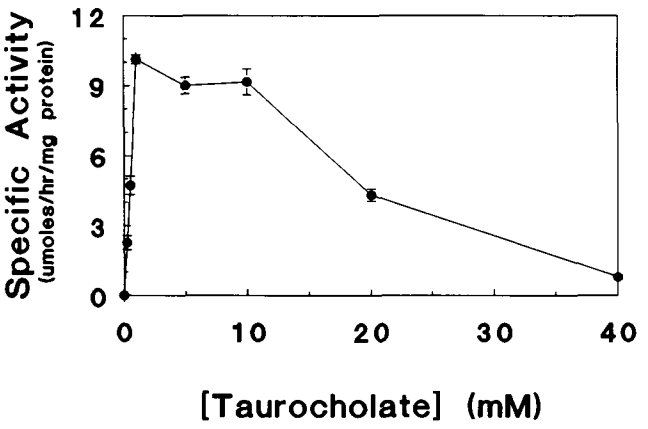

FIG. 5. Effect of varying taurocholate concentration on the activity of purified CEH. Fractions from the GPHPLC purification were assayed in the presence of indicated concentrations of taurocholate. Values represent Mean ± S.E.M. of duplicate assays. Experiment was repeated with similar results.

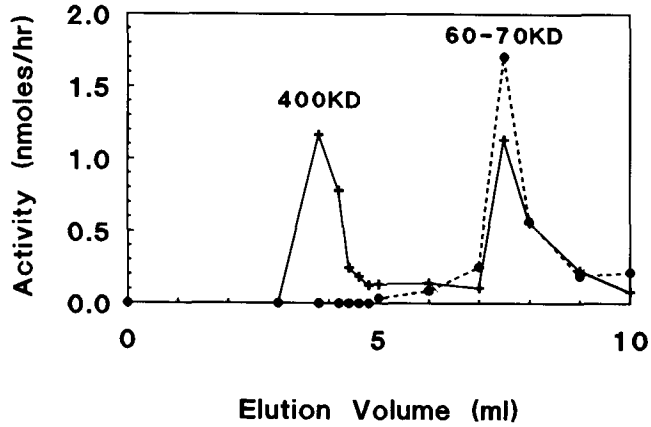

FIG. 6. Effect of taurocholate on apparent molecular weight of rat liver CEH. Pooled and concentrated fractions from cation exchange FPLC were further fractionated by GPHPLC with (—o—) and without (—+—) 0.5 mM taurocholate in the elution buffer. All fractions were equilibrated in elution buffer containing 0.5 mM taurocholate and assayed for CEH as described in Materials and Methods.

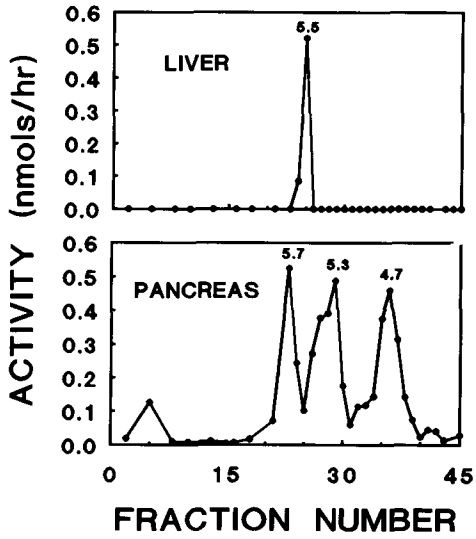

FIG. 7. Elution of liver and pancreatic CEH from Mono P (chromatofocusing) column. Column was equilibrated with 25 mM bis Tris, pH 7.1 containing 80 mM KCl, 0.5 mM taurocholate and 5 mM 2-mercaptoethanol. Proteins were eluted with Polybuffer 74 containing 80 mM KCl, 0.5 mM taurocholate and 5 mM 2-mercaptoethanol. A pH gradient of 7–4 was generated from fractions 5–45. Top panel: fraction containing CEH from GPHPLC was concentrated, brought to 1 mL with equilibration buffer and further fractionated by chromatofocusing. Mono P fractions were neutralized to pH 7.0 with Trizma base and assayed for CEH activity in Buffer A. Bottom panel: 0–40% ammonium sulfate precipitate from pancreatic S104 was desalted and fractionated by cation exchange FPLC. Active fractions were pooled, concentrated and further fractionated by chromatofocusing. CEH was assayed in Buffer A following neutralization. pI Is given for each peak of activity.

These results suggest that liver CEH disaggregates in the presence of bile salts. Whereas both 66 kDa and 400 kDa forms are apparently present in the absence of taurocholate, the activity of the 400 kDa form could not be ascertained.

Determination of isoelectric point (pI). Figure 7 shows the elution of purified rat liver CEH and partially purified rat pancreatic CEH from a FPLC chromatofocusing column. Whereas liver CEH eluted as a single peak corresponding to a pI value of 5.5 (top panel), pancreatic CEH eluted in three distinct peaks corresponding to pI values of 5.7, 5.3 and 4.7 (bottom panel). These results indicate presence of a single species of CEH in the purified fraction from liver and existence of multiple forms in pancreas, none of which are identical to the liver CEH.

N-Terminal analysis and amino acid composition. The purified CEH fraction from HPLC was analyzed by SDS-PAGE, electroblotted on PVDF membrane and proteins stained with Coomassie blue (9). The protein band at 66 kDa was cut out and subjected to protein sequencing in gas phase. Although amino acid analysis showed presence of sufficient protein for sequencing (300 pmoles), no N-terminal residue was detected, suggesting a blocked N-terminus. The amino acid composition, as shown in Table 2, is quite different from the reported compositions for two pancreatic isoenzymes.

Activation by protein kinases. The liver and pancreatic CEH isoenzymes also exhibited differential responses to cofactors for cAMP-dependent protein kinase (PKA) and protein kinase C (PKC). Previously we have demonstrated activation of liver CEH by these cofactors (7). In the current studies, concentrations of cofactors for PKA (cAMP, ATP, Mg^{2+}) which produced optimal activation of liver CEH had no effect on pancreatic CEH (data not shown). Moreover, cofactors for PKC (diacylglycerol, phosphatidylserine, ATP) produced a 33% decrease in pancreatic CEH activity (data not shown).

Immunological properties. Immunoreactivities of purified liver CEH and partially purified pancreatic CEH with anti-rat pancreatic CEH IgG were compared. The liver enzyme showed absolutely no cross-reactivity with antibody to pancreatic enzyme in Western blot analysis

[c]In trace amounts.

(Fig. 2, lane 2). In contrast, the pancreatic cytosol contained a single, strongly immunoreactive band of M_r = 45 kDa (Fig. 2, lane 4). Antibodies to pancreatic CEH had no inhibitory effect on liver CEH activity (90% activity remaining). In our hands, under similar conditions, these antibodies inhibited 88% of CEH activity in pancreatic S104, relative to normal IgG.

DISCUSSION

We have described a three-step, rapid purification of liver CEH yielding a protein associated with a 12,600-fold increase in specific activity and a single band corresponding to 66 kDa on SDS-PAGE. Relatively high yield (20%), which increases confidence that this enzyme makes a major contribution to liver CEH *in vivo*, is attributable to the simplicity and speed of this procedure, which minimizes loss of activity by this relatively unstable enzyme. Based on inhibition of liver CEH activity by antibodies to pancreatic CEH (5) and purification of rat liver CEH with antibodies to porcine pancreatic CEH (4), others have proposed that liver CEH and pancreatic CEH are either very similar or identical enzymes. The present studies provide strong evidence that a major fraction of cytosolic liver CEH is associated with the enzyme we have purified, which has very different properties from pancreatic CEH. We earlier demonstrated that this liver CEH could be distinguished from triglyceride lipase and retinyl ester hydrolase activities by differential purification and regulatory responses (10).

We have shown that this enzyme aggregates to form a multimer of M_r = 400 kDa in the absence of bile salts (Fig. 6). Tuhackova *et al.* (11) also observed aggregation of liver CEH in absence of bile salts. In contrast, Hyun *et al.* (12) and Calame *et al.* (13) have shown that at physiological concentrations of cholic acid or its conjugates, an inactive monomer of pancreatic CEH undergoes aggregation to form an active hexamer. Pancreatic and liver CEH catalytic activities are also affected differentially by bile salts. Like the pancreatic CEH, the enzyme which we have isolated is stimulated by bile salt at 0.25–10 mM. However, unlike pancreatic CEH, liver CEH is strongly inhibited by concentrations greater than 10 mM, used in several of the comparative studies (4,5). Activation by the lower concentrations (<5 mM) of taurocholate was much more pronounced with the purified liver CEH than in cytosol, suggesting that the activation may be a detergent effect rather than a specific effect on the enzyme. In contrast, as noted earlier, activation of the pancreatic CEH by bile salts involves formation of a multimeric form.

Several other properties of liver and pancreatic CEH indicate that the two enzymes are different. Unlike liver enzyme, pancreatic enzyme is apparently not regulated by reversible phosphorylation, a mode of short-term regulation of CEH in liver (7), adrenal cortex (14), testis (15), macrophages (16) and brain (17). Differential elution of the two enzymes from cation exchange columns (Fig. 1) is indicative of different surface charge distributions on the two proteins. This conclusion is further supported by different pI values for the two enzymes (Fig. 7). The amino acid compositions of the liver CEH is unlike those reported for pancreatic isoenzymes (Table 2).

Purified liver CEH did not cross-react with antibody to rat pancreatic CEH in Western blot analysis (Fig. 2, lane 2). These results are consistent with earlier observations of Gallo *et al.* (6), who showed immunological cross-reactivity between pancreatic and intestinal enzyme but no reaction with the solubilized fractions from liver, aorta or adrenals using antibodies to the rat pancreatic CEH. The anti-pancreatic CEH IgG did react with a protein in pancreatic cytosol with M_r = 45 kDa (lane 4). Although this is not one of the molecular weights previously reported for rat pancreatic CEH, this enzyme is reported to exhibit anomalous apparent molecular weights on SDS-PAGE, perhaps due to carbohydrate content (18). Moreover, the porcine pancreatic CEH has been reported to exist in several different molecular weight forms, including one of M_r = 45 kDa (19–21). It is also possible that the antibodies did not recognize higher molecular weight forms of the enzyme in their denatured state as presented in SDS-PAGE. However, that the antibodies did indeed cross-react with active pancreatic CEH was confirmed by neutralization of 88% of pancreatic enzyme activity.

In contrast to complete inhibition of liver cytosolic CEH reported by Harrison (5), antibodies to pancreatic CEH from the same source did not inhibit the liver CEH purified by us. However, it should be emphasized that 20–75 mM bile salts used by these investigators strongly inhibits the liver CEH which we have purified, as well as the isoenzymes from testis and brain (22,23).

Camulli *et al.* (4) obtained the N-terminal sequence for a liver CEH purified by immunoaffinity chromatography, which was identical to the N-terminus of rat pancreatic CEH. Since these authors used anti-porcine pancreatic CEH IgG for purification, it appears that they isolated a component of total liver CEH which is similar to the pancreatic enzyme. Using a different protocol, we have purified a liver CEH which is apparently an entirely

different protein, accounting for at least 20% of the liver cytosolic CEH. Its specific activity is two orders of magnitude higher, it does not cross-react with antibody to the pancreatic CEH and it is blocked in the N-terminus. Together, these results indicate polymorphisms for liver CEH which need to be investigated further.

ACKNOWLEDGMENTS

This work was supported by grant DK 38030 from the National Institutes of Health. Gratitude is expressed to Dr. Linda Gallo for providing antibody to the rat pancreatic CEH.

[Received September 24, 1990; Revision accepted May 7, 1991]

Effect of Chylomicron Remnants on Cholesterol Metabolism in Cultured Rabbit Hepatocytes: Very Low Density Lipoprotein and Bile Acid Production

Vladimir A. Kosykh*, Dmitri K. Novikov, Iliya N. Trakht, Eugeni A. Podrez, Alexander V. Victorov, Vadim S. Repin and **Vladimir N. Smirnov**
USSR Cardiology Research Center, Academy of Medical Sciences, Moscow 121552, USSR

The interrelationship between very low density lipoprotein (VLDL) secretion and bile acid production was studied in primary culture of rabbit hepatocytes. Chylomicron remnants (CR) were added to the cultures to study their effect on VLDL secretion and bile acid production. After 24 hr preincubation of cells with CR (10–50 μg protein/mL), intercellular neutral lipid content was increased 1.5–4-fold in a dose-dependent manner. Neutral lipid accumulation was accompanied by a 70–90% reduction of [^{14}C]acetate incorporation into cholesterol, while no stimulation of [^{14}C]oleate incorporation into cholesteryl esters was observed. Incubation of cells with CR increased secretion of free cholesterol, triacylglycerol and apoproteins B and E in VLDL. Stimulation of VLDL cholesterol secretion was accompanied by a reduction of taurocholic acid synthesis. These data demonstrate the existence of an inverse relationship between secretion of VLDL cholesterol and bile acid production under conditions of effective uptake of triacylglycerol-rich CR by hepatocytes.
Lipids 26, 799–805 (1991).

Dietary cholesterol and other lipids are transported to the liver in the form of chylomicron remnants (CR) which contain apoproteins B and E (1). These particles are bound and internalized by way of B and E receptors located on the cell surface (2–4). After hydrolysis, the components of CR are available to the cell for further use. Free fatty acids may become esterified and secreted as triacylglycerol, mainly in the form of very low density lipoproteins (VLDL). Free cholesterol can be utilized *via* a number of metabolic pathways, including the assembly and secretion of lipoproteins, the synthesis and secretion of bile acids, the secretion of biliary cholesterol, and esterification; the latter is dependent upon the activity of acyl-CoA:cholesterol acyltransferase (ACAT) (E.C. 2.3.1.26). On the other hand, plasma cholesterol levels are dependent on the flux of free cholesterol into various pathways of hepatocyte metabolism (1). Recent studies have demonstrated that the direction of cholesterol flux into and out of these pathways may depend on the lipid composition of the lipoprotein particles taken up by liver cells (5,6). Van Zuiden *et al.* (5) showed that the *in vivo* administration of triglyceride-rich chylomicrons or their remnants to perfused rat liver reduces ACAT activity and biliary cholesterol content, while secretion of VLDL cholesterol and triacylglycerol by hepatocytes increases. Other studies have demonstrated that administration of apo E- and cholesterol-rich lipoprotein fraction (d 1.02–1.06 g/mL) from hypercholesterolemic rats in isolated perfused liver produced a significant increase in ACAT activity and in hepatic VLDL secretion without significantly affecting biliary cholesterol output (6). These studies suggest that ACAT activity may regulate preferential channeling of CR cholesterol either towards VLDL cholesterol or biliary cholesterol secretion. Although the effect of CR on hepatic cholesterol metabolism has been studied in several animal models as well as in cultured cells (1,5,6), various aspects still need to be investigated further.

In the present study, we have examined the interrelationship between VLDL secretion and bile acid production in the presence of an excess of CR lipids that were delivered to hepatocytes. The effect of CR on cholesterol synthesis and cholesterol esterification was also determined. Since apo B-48 is a marker of intestinally synthesized lipoproteins in both humans and rabbits, only particles containing apo B-48 and apo E as CR were used.

MATERIALS AND METHODS

Materials. All chemicals used were reagent grade. Minimal essential medium (MEM) with Earle's salts, fetal bovine serum (FBS), MEM nonessential amino acids, kanamycin, L-glutamine, Vitrogen 100™ (purified collagen) and 35- to 100-mm culture dishes were purchased from Flow Laboratories, Inc. (Zwanenburg, The Netherlands). Collagenase 1200 units/mg and trypsin inhibitor were products of Sigma Chemical Co. (St. Louis, MO). L-[4,5-^{3}H]Leucine (spec. act. 120–190 Ci/mmol), L-[^{35}S]-Methionine (spec. act. > 1000 Ci/mmol), sodium [1-^{14}C]acetate (spec. act. 59 mCi/mmol), and sodium [1-^{14}C]oleate (spec. act. 50–60 mCi/mmol) were purchased from Amersham International (Amersham, Buckinghamshire, U.K.).

Male Chinchilla rabbits, weighing 2.5–3 kg, were used throughout and maintained on standard laboratory rabbit chow. Animals were killed between 10 and 11 a.m. for preparation of hepatocytes.

Rabbit hepatocyte preparation and culture. Rabbit liver cells were isolated by perfusion with 0.05% collagenase and 0.005% trypsin inhibitor as described in detail elsewhere (7). Cells were plated in 35-mm or 100-mm dishes coated with purified collagen at a density of 2×10^5 cells/cm^2 and were cultured in MEM supplemented with 10% FBS, 2 mM L-glutamine, kanamycin (100 μg/mL), and nonessential amino acids (1%) at 38°C in a 95% air/5% CO_2 atmosphere as described elsewhere (8). Cells were

Abbreviations: ACAT, acyl-CoA:cholesterol acyltransferase; apo, apoprotein; CR, chylomicron remnants; EDTA, ethylenediaminetetraacetic acid; FBS, fetal bovine serum; HDL, high density lipoprotein(s); HPTLC, high-performance thin-layer chromatography; LPDS, lipoprotein deficient serum; MEM, minimal essential medium; SDS, sodium dodecylsulfate; VLDL, very low density lipoprotein(s).

used for experiments after 24-hr preincubation in MEM supplemented with 10% FBS. To examine the influence of CR on various pathways of cellular lipid metabolism, the experiments were carried out as follows. After 24 hr in culture, cells were transferred in MEM supplemented with 10% lipoprotein deficient serum (LPDS) with or without CR at various concentrations; the cells were incubated at 37°C for 24 hr. After preincubation with or without CR, cells were incubated in serum-free medium, and incorporation of [^{14}C]acetate into cholesterol (at 3 hr), incorporation of [^{14}C]oleate into triacylglycerol and cholesteryl esters (at 6 hr), and secretion rates of VLDL and bile acid (at 18 hr) were measured.

Isolation of lipoproteins and LPDS. Human plasma samples were collected from normal subjects 4–5 hr after ingestion of a fatty meal (2 eggs, 200 g of cream) and were kept at 4°C overnight. The creamy layer, which contained triacylglycerol-rich lipoproteins including chylomicrons, was removed and suspended in 0.15M NaCl containing 0.01% ethylenediamine tetraacetic acid (EDTA) (pH 7). Postheparin plasma (lipoprotein lipase-rich plasma) was used to hydrolyze the triacylglycerol-rich fraction and to obtain CR. Plasma was obtained from a normal human subject 2 hr after injection of heparin (100 units/kg of body weight). The total lipoprotein fraction was incubated with postheparin plasma as described by Mahley *et al.* (9). At the end of the incubation, the solution was adjusted to a density of 1.019 with KBr, and overlayered with an equal volume of saline/EDTA. Lipoproteins were refloated overnight at 130,000 × *g* using an SW 28 rotor. After centrifugation, the top 1-mL containing CR and VLDL remnants was collected. Apo B-48 containing CR particles was isolated by immunoaffinity chromatography according to Milne *et al.* (10). Immunosorbent was prepared by covalent coupling of the anti-apo B-100 monoclonal antibodies 2G8 to Sepharose 4B (11). Preparation of monoclonal antibodies against human apo B-100 has been reported (12). These antibodies did not react with apo B-48. High density lipoproteins (HDL) (1.063<d<1.21 g/mL) and LPDS (d>1.21 g/mL) were isolated from normal plasma by preparative ultracentrifugation at 4°C after a density adjustment with solid KBr (13). HDL_2 was isolated as described previously (14). Protein concentration in the lipoprotein fraction was determined by the method of Lowry *et al.* (15). Lipoprotein total cholesterol was assayed enzymatically using the Total Cholesterol Kit (Medix; Finland). Ten μL of lipoprotein or standard solution were combined with 1 mL of cholesterol enzymatic reagent and incubated at 37°C for 20 min. The absorbance at 500 nm was measured for each sample against a reagent blank.

Analytical methods. Cells were incubated for 18 hr with leucine-free MEM supplemented with [^{14}C]leucine (10 μCi/mL) to study the secretion rates of *de novo* synthesized VLDL apoproteins. The medium was removed after incubation for analysis. VLDL fractions secreted by cells were isolated by preparative ultracentrifugation of the medium with an LP-42 Ti rotor (Beckman Instruments, Palo Alto, CA) at 130,000 × *g* for 2.5 hr at 18°C. VLDL was collected from the centrifugation tubes at d < 1.006 g/mL (50 μL from the top), and then recentrifuged. Aliquots of VLDL fractions were prepared as described by Melin *et al.* (16) and subjected to (SDS)-polyacrylamide gel electrophoresis; the gels contained 0.1% Coomassie blue. The relative quantity of VLDL apoproteins secreted by CR-treated hepatocytes as compared with control cells was estimated by scanning using an LKB 2202 Ultrascan laser densitometer. The isotope incorporation into the apoprotein band was estimated by counting the gel slices. The gels were cut into 2–3 mm slices, placed into separate vials containing 30% H_2O_2, and incubated overnight at 70°C. Radioactivity was determined in a scintillation counter.

Cells were incubated for 3 hr with MEM containing [^{14}C]acetate (5 μCi/mL, 0.1 mM) or for 6 hr with [^{14}C]oleate/albumin complex (final concentration 0.4 mM [^{14}C]oleate, approximately 10,000 cpm/nmol in MEM). Neutral lipids were extracted according to Goldstein *et al.* (17), and individual species were separated by high-performance thin-layer chromatography (HPTLC) (silica gel plates; Merck, Darmstadt, Germany) using heptane/diethyl ether/acetic acid (90:30:1, v/v/v) as developing system. Fractions corresponding to cholesterol and cholesteryl esters were scraped into counting vials, and radioactivity was assayed. Lipoprotein phospholipids were extracted according to Folch *et al.* (18) and separated on a thin layer of silica with methyl acetate/1-propanol/chloroform/methanol/0.25% KCl (25:25:25:10:9, by vol) (19). Neutral lipids and phospholipids were quantitatively determined by densitometry of HPTLC plates (20,21) with an automated Camag HPTLC/thin-layer chromatography (TLC) scanner (Muttens, Switzerland) connected to a recording integrator SP 4100 (Spectra Physics, Darmstadt, Germany). Each determination was done in parallel with a known standard mixture containing cholesterol, triolein, cholesteryl oleate, phosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol, phosphatidylserine and sphingomyelin.

After isolation of the total lipid fraction (22), bile acids were extracted according to Kempen *et al.* (23) using a reverse-phase cartridge (Sepak C-18, Waters Associates, Milford, MA). Bile acids were separated by HPTLC with the developing system chloroform/methanol/glacial acetic acid/water (15:5:1:1, by vol) using unlabeled markers. Bile acids were quantitatively determined by densitometry (564 nm) of HPTLC plates pretreated with 10% phosphomolybdenic acid. A mixture of taurocholate, taurodeoxycholate and glycocholate was used as standard.

Cells were incubated for 18 hr with [^{35}S]methionine (250 μCi/100-mm culture dish) for analysis of re-uptake of secreted lipoproteins. The medium containing labeled lipoproteins was dialyzed for 24 hr against unlabeled medium, and administered to control and CR-treated hepatocytes or to 35-mm culture dishes without cells. After 18 hr of incubation, the media were ultracentrifuged to isolate lipoproteins (d<1.21 g/mL). Following separation of apoproteins on SDS-polyacrylamide gel, the amount of ^{35}S in apo B and apo E was quantified by scintillation counting.

Results were analyzed with Student's *t*-test and expressed as mean ± SD. Values of $P < 0.05$ were considered significant.

RESULTS

As shown in Figure 1a, two major species of human apo B (apo B-48 and apo B-100) were identified in a plasma triacylglycerol-rich lipoprotein fraction after a fatty meal.

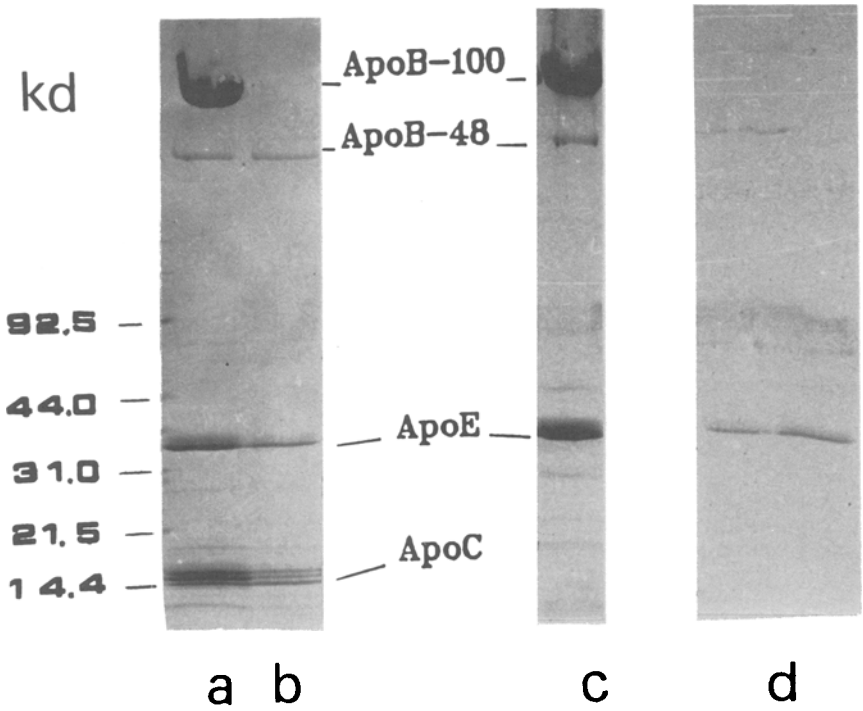

FIG. 1. Polyacrylamide gel electrophoresis of total lipoprotein fraction (a), chylomicrons (b), apo C-deficient triacylglycerol-rich lipoproteins (c), and CR (d). Delipidated apoproteins were applied to 3–20% gradient gel run in the presence of sodium dodecyl sulfate and stained by Coomassie Blue. The vertical axis indicates the molecular weights of the marker proteins.

TABLE 1

Chemical Composition (by the Weight) of Chylomicron Remnants[a]

Preparation	Protein	Triacylglycerol	Cholesterol	Cholesteryl esters	Phospholipids
1	4.1	68.2	2.6	16.3	9.4
2	8.2	61.3	2.2	20.0	8.3
3	6.5	67.7	2.8	16.1	6.9

[a]Various lipid classes were separated by HPTLC and identified by comparison to standards. Lipid concentrations were measured using densitometry. Protein was determined by the method of Lowry *et al.* (15) using bovine serum albumin as standard.

Purified apo B-48 containing chylomicron and CR were isolated by immunoaffinity chromatography (Fig. 1b and d). Lipoprotein particles containing a small quantity of apo C were produced by incubating the total lipoprotein fraction with postheparin plasma (Fig. 1c). Purified CR (Fig. 1d) were used in experiments with cells. Table 1 shows the chemical composition of CR preparations obtained from three donors. Although the protein content varied (4.1 to 8.2 weight%), the lipid composition of three CR fractions was similar.

Figure 2 shows that preincubation of cells with CR up to concentrations of 50 μg protein/mL caused a large rise in cellular neutral lipid content. Sterol synthesis at the high CR dose was decreased by approximately 70–90% (Fig. 3). In addition, incubation of cells with increasing amounts of CR increased, in a concentration-dependent manner, the amount of [^{14}C]oleate incorporated into triacylglycerol, but did not affect [^{14}C]oleate incorporation into cholesteryl esters (Fig. 4).

In these experiments, mass measurements of different classes of VLDL neutral lipids secreted by rabbit hepatocytes also were performed (Table 2). Preincubation with CR increased triacylglycerol and free cholesterol secretion in VLDL, but did not affect the release of VLDL cholesteryl esters.

To examine the effect of CR on the secretion of VLDL apoprotein by hepatocytes after preincubation of cells with CR, the media were changed and hepatocytes were further incubated with L-[4,5-^{3}H]leucine for an additional 18 hr. The VLDL fractions secreted by control and CR-treated cells were analyzed by SDS-polyacrylamide gel electrophoresis; simultaneously [4,5-^{3}H]leucine incorpora-

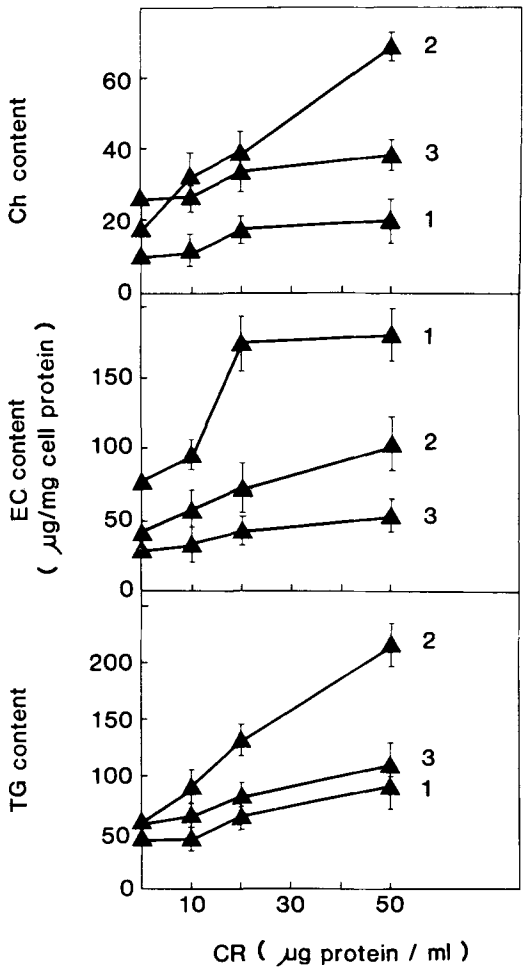

FIG. 2. Hepatocyte neutral lipid accumulation following preincubation with various concentrations of CR. Exp. 1-3 are independent experiments with cells from different rabbit livers. Ch, cholesterol; EC, cholesteryl ester; and TG, triacylglycerol. Values are means ± SD of three replicates.

tion into apo B and apo E was quantified. The results of these analyses are given in Table 3. Preincubation of the cells with CR stimulated secretion of newly synthesized apo B and apo E in the VLDL fraction approximately 1.5-2.0-fold. Analysis of the polyacrylamide electrophoretic gel by densitometry also showed increases (1.5-2.0-fold, two experiments) in VLDL apo B and apo E secretion by the cells preincubated with CR.

To examine the possibility that the results obtained may reflect alterations in the re-uptake of secreted VLDL, control and CR-treated cells were incubated with [^{35}S]methionine-labeled secreted lipoproteins. After 18-hr cultivation, the amount of [^{35}S]methionine-labeled apoprotein remaining in the medium was determined. The results shown in Table 4 demonstrate that cultured control and CR-treated hepatocytes do not actively (at least not more than 10% of total apoproteins added) take up and degrade newly secreted apo B and apo E in the culture medium. Thus, the data show that hepatocytes preincubated with CR secrete more VLDL apo B and apo E than control cells.

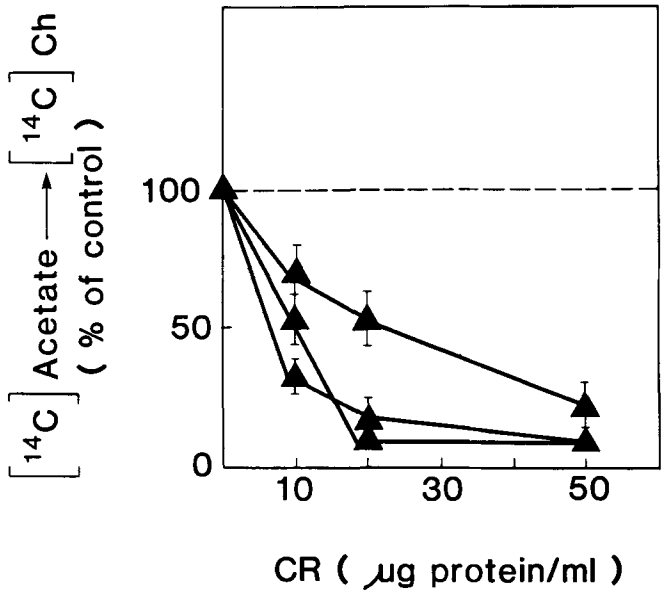

FIG. 3. Effect of CR on [^{14}C]acetate incorporation into cellular cholesterol. Each curve gives the results of one independent experiment. The results shown are based on the radioactivity ranging from 1.4×10^5 to 2.4×10^5 cpm/mg cell protein. Values are means ± SD of three replicates.

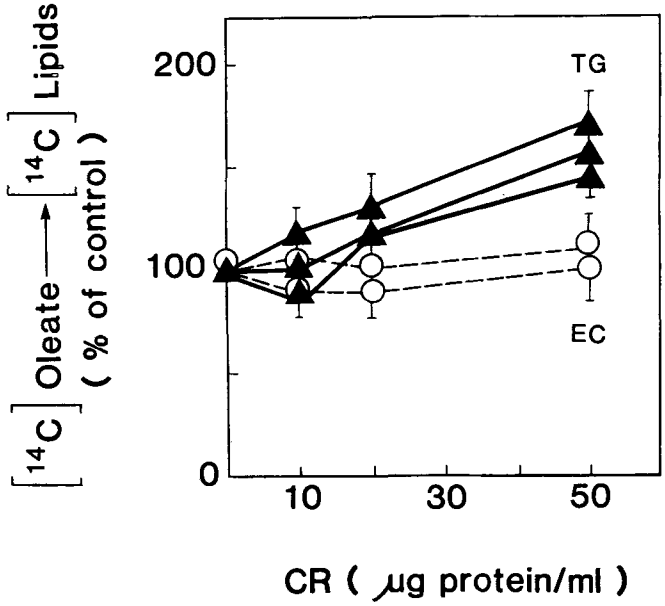

FIG. 4. Effect of CR on [^{14}C]oleate incorporation into cellular lipids. Each curve gives the results of one independent experiment. The results shown are based on the radioactivity ranging: from 5×10^3 to 5.6×10^3 cpm/mg cell protein for esterified cholesterol; and from 2.5×10^5 to 2.8×10^5 cpm/mg cell protein for triacylglycerol. Values are means ± SD of three replicates.

In the following experiments, bile acid formation was measured quantitatively by TLC. After preincubation with or without CR, hepatocytes were incubated in the serum-free medium for 18 hr. TLC analyses of the bile acids accumulated in the medium and in the cells showed

the presence of glycine and taurine conjugates of cholic acid which were identified by comparison with standards. As can be seen from Table 5, the ratio of taurocholic to glycocholic acid was about 3.5:1. During the 18-hr experiment, cultured hepatocytes produced taurocholic and glycocholic acids at a constant rate (data not shown). Addition of CR into the incubation medium suppressed taurocholic acid formation (Table 5), but did not alter the concentration of glycocholic acid. By contrast, addition of HDL_2 markedly stimulated the production of both conjugates of cholic acid in a dose-dependent manner.

DISCUSSION

During the past years, primary monolayer cultures of rat hepatocytes and the Hep G2 cell line have been used to study bile acid metabolism. However, these cells usually exhibit a low rate of bile production in culture (24–27). Recently it was reported that cultured rabbit hepatocytes, unlike rat hepatocytes, maintain a rate of bile acid synthesis similar to that found *in vivo* (28). Therefore, a primary culture of rabbit hepatocytes was used in the present study.

After incubation with CR, cell triacylglycerol and free and esterified cell cholesterol levels were increased. Such CR-induced lipid accumulation may lead to decreased synthesis of cholesterol. At the same time, free cholesterol derived from CR is not esterified, but is secreted in free form with newly synthesized VLDL. Under these conditions, the suppression of cholesterol synthesis is not sufficient to maintain cholesterol homeostasis. Therefore, the processes of apo B and apo E secretion in VLDL are also stimulated. Since each VLDL particle contains only one molecule of apo B (29), the number of VLDL particles secreted by rabbit hepatocytes increases. Our results are consistent with those of others (5,6) who have demonstrated that when exogenous cholesterol and triacylglycerol are available to hepatocytes from lipoproteins, the secretion of VLDL apoproteins and neutral lipids is enhanced. Recently Craig and Cooper (30) have reported that CR also stimulate VLDL apoprotein secretion by Hep G2 cells.

The second part of the study was devoted to the effect of CR on the production of bile acids. Previous studies with cultured rat and rabbit hepatocytes demonstrated that cholesterol availability is an important factor in stimulating the rate of bile acid production (24,31). Newly synthesized cholesterol and cholesterol of different lipoprotein fractions are used for bile acid production by hepatocytes (32,33). Our data confirm the results of Whiting *et al.* (28) that cultured rabbit hepatocytes obtained from normal liver synthesize and secrete mainly

cholic acid. However, in our study the accumulation of CR neutral lipids in hepatocytes was not accompanied by the expected stimulation of bile acid production; instead production decreased (Table 5). Two independent mechanisms may be responsible for this effect. The first is suppression of cholesterol synthesis and subsequent decrease in intracellular content of newly-synthesized cholesterol which is mainly used by rabbit hepatocytes for breakdown to bile acid (34). Our data suggest that CR cholesterol is predominantly used for VLDL production but not as precursor for bile acid synthesis. The second mechanism may be related to the direct effect of CR components on the process of bile acid synthesis. For instance, oleic acid in isolated perfused rat liver can suppress the secretion of bile acids through the inhibition of oxidation of the side chain of cholesterol leading to bile acids (35).

Our data, in corroboration with previous reports (25,26), support the idea that HDL_2 is the main source of cholesterol for the synthesis of bile acids and is capable of greatly enhancing bile acid synthesis. Recent reports (24,34) have also indicated that LDL, and cholesterol-rich VLDL added to the primary culture of hepatocytes, can stimulate the synthesis of bile acids. In contrast, triacylglycerol-rich VLDL has no effect on bile acid synthesis.

Our results demonstrate that due to the effective uptake of triacylglycerol-rich CR by hepatocytes, an inverse relationship between secretion of VLDL cholesterol and bile acid production is established. Previous studies have shown that the administration of triacylglycerol-rich CR to perfused rat liver increases VLDL cholesterol and triacylglycerol secretion, but decreases biliary cholesterol content (5). Triacylglycerol-rich CR, which are formed in the bloodstream after feeding, are unable to stimulate hepatic bile acids synthesis and secretion and biliary cholesterol output to compensate for the elevated CR cholesterol content in normal hepatocytes. Evidently, most of the CR cholesterol taken up by hepatocytes is used for VLDL assembly and secretion and, as a result, the plasma cholesterol level is increased. In contrast to this process, hepatocyte HDL_2 cholesterol uptake and subsequent stimulation of bile acids synthesis eliminate excess plasma cholesterol and maintain normal cholesterol level in the bloodstream.

Similarities in Surface Lipids of Chylomicrons from Glyceryl and Alkyl Ester Feeding: Major Components[1]

Lu-Ying Yang, Arnis Kuksis* and **John J. Myher**
Department of Biochemistry and Banting and Best Department of Medical Research, University of Toronto, Toronto, Canada M5G 1L6

This study tests the hypothesis that the rat chylomicrons are assembled and released into lymph similarly regardless of the site (rough or smooth endoplasmic reticulum) or pathway (phosphatidic acid or monoacylglycerol) of triacylglycerol biosynthesis. For this purpose we determined the lipid class, fatty acid and molecular species composition of the choline, ethanolamine, inositol and serine phospholipids of lymph chylomicrons during absorption of menhaden, mustardseed and corn oil (monoacylglycerol pathway) or the corresponding fatty acid methyl or ethyl esters (phosphatidic acid pathway). The dietary fatty acids were found to be incorporated to various extents into different phospholipid classes, the proportions of which were not affected by the nature of the dietary fat. The chylomicron phospholipids contained 80–82% choline, 8% ethanolamine and 2.5% inositol glycerophospholipids, and much smaller amounts of serine and other minor phospholipids. Administration of a meal of each dietary fat resulted in a retention of approximately 50% endogenous fatty acids in the major glycerophospholipids of the chylomicrons. A minimum of 50% of the molecular species of the choline and ethanolamine glycerophospholipids contained at least one exogenous fatty acid. No significant discrepancies were found in the fatty acid and molecular species composition of the glycerophospholipids between chylomicrons from the oil and corresponding ester feeding. It is concluded that the chylomicrons arising from the monoacylglycerol (oil feeding) and the phosphatidic acid (ester feeding) pathways of triacylglycerol biosynthesis become enveloped in surfactant monolayers containing qualitatively and quantitatively identical classes and molecular species of phospholipids.
***Lipids 26*, 806–818 (1991).**

The digestion products of glyceryl triesters and short-chain alkyl esters of fatty acids are believed to be resynthesized into triacylglycerols by the intestinal villus cells *via* two different pathways (1). The glyceryl esters have been shown to be reassembled largely *via* the monoacylglycerol (MG) pathway (2), while the alkyl esters or free fatty acids are believed to be incorporated into triacylglycerols exclusively *via* the phosphatidic acid (PA) pathway (2,3). The two pathways are known to occur at different microsomal sites and involve acyltransferases of different fatty acid and positional specificity (4,5). Furthermore, there is evidence that the triacylglycerols formed *via* the phosphatidic acid pathway in liver (6) and possibly in intestine (7) are stored and must be hydrolyzed and resynthesized before secretion. It was therefore possible that differences would be found in the chylomicron phospholipids reflecting the different membrane contacts characteristic of the two pathways of triacylglycerol formation and secretion. In previous studies (8), we have demonstrated great qualitative and quantitative similarity in the surface apoproteins of the chylomicrons. This suggested that the two pathways of triacylglycerol formation converge at some stage prior to the final assembly and secretion of the chylomicrons. We have now examined this possibility further in regards to the major surface lipid components of chylomicrons. The present study shows close similarity in the phospholipid classes and near identity in the molecular species of the choline (GPC) and ethanolamine (GPE) glycerophospholipids between chylomicrons from the oil and ester feeding. These results provide a clear indication for a common route of packaging and externalization as chylomicrons of the triacylglycerol products of both the MG and PA pathways. These findings are consistent with the results of stereospecific analyses of the triacylglycerol structure of lymph chylomicrons (9).

MATERIALS AND METHODS

Animals, surgical procedures and diets. The lymph was collected from mature rats over a period of 2–24 hr as previously described (8,10). The experimental meals were administered by stomach tube and consisted of 1–3 mL of menhaden oil and corresponding fatty acid ethyl esters as described (10). Comparable quantities of mustardseed oil and its fatty acid methyl esters (11) were used as oligounsaturated long-chain triacylglycerol controls. Corn oil or its free fatty acids were administered in 1-mL amounts.

Isolation of chylomicrons. Lymph chylomicrons were isolated by ultracentrifugation (Beckman Model L2-65B, rotor 40.3, Palo Alto, CA) at 10°C and characterized as described (8).

Isolation and quantitation of phospholipid classes. Total lipid extracts of chylomicrons were obtained with chloroform/methanol (2:1, v/v) and were resolved into neutral and polar lipids by thin-layer chromatography (TLC) as previously described (11). The phospholipids were recovered from the origin of the TLC plate and were resolved into individual phosholipid classes by TLC using acidic and basic solvent systems (12,13). The phospholipid classes were identified by reference to standards and were quantitated on the basis of the fatty acid content using 17:0 acid as an internal standard. Gel scrapings containing individual phospholipid classes were subjected to acidic methanolysis using 6% H_2SO_4 in methanol at

Abbreviations: GLC, gas-liquid chromatography; GPC, choline glycerophospholipid; GPE, ethanolamine glycerophospholipid; HDL, high density lipoprotein; HPLC, high-performance liquid chromatography; LPC, lysophosphatidylcholine; LPE, lysophosphatidylethanolamine; MG, monoacylglycerol; PA, phosphatidic acid; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; SPH, sphingomyelin, TMS, trimethylsilyl; TLC, thin-layer chromatography; VLDL, very low density lipoprotein.

80°C for 2 hrs. After addition of the internal standard, the fatty acid methyl esters were analyzed by gas-liquid chromatography (GLC) (10).

Positional analysis of fatty acids. The positional distribution of fatty acids in the glycerophospholipids was determined by digestion with phospholipase A_2 (*Crotalus adamanteus*; Sigma Chemical Co., St. Louis, MO) (14). The released fatty acids and lysophospholipids were resolved by TLC and the fatty acids determined by GLC (10,14).

Preparation of diradylglycerols and derivatization. Diradylglycerol moieties from individual phospholipid classes were obtained by hydrolysis with phospholipase C (*Bacillus cereus*) as previously described (15). The trimethylsilyl (TMS) ethers were prepared by reacting the diradylglycerols with a premixed solution of pyridine/hexamethyldisilazane/trimethylchlorosilane (12:5:2, v/v/v) for 30 min at room temperature (15). The TMS ethers of the diradylglycerol moieties of GPE were resolved into alkenylacyl, alkylacyl and diacylglycerol subfractions by normal phase high-performance liquid chromatography (HPLC) with 0.3% isopropanol in hexane (15).

Gas-liquid chromatography. Diradylglycerol TMS ethers were resolved on the basis of carbon number by means of a fused silica capillary column (8 m × 0.32 mm ID) coated with a permanently bonded SE-54 liquid phase as previously described (15). The analysis of the molecular species of the diacylglycerol moieties of GPC and GPE of chylomicrons from mustardseed oil feeding was performed isothermally at 250°C on a 10-m open tubular glass capillary column wall-coated with SP-2330 liquid phase as previously described (16). The molecular species analyses of the diradylglycerol moieties of GPC and GPE of chylomicrons from menhaden oil feeding were performed isothermally at 260°C on a fused silica capillary column (15 m × 0.32 mm ID) coated with cross-bonded RTx2330 liquid phase as described (17).

Identification and quantitation of GLC peaks. The identity of the GLC peaks of fatty acids, dimethylacetals and diradylglycerols was established relative to standards and by comparison of observed and calculated relative retention times (17). The quantitative composition of the fatty acids, dimethylacetals and molecular species of diradylglycerols was determined from the GLC peak areas obtained by flame ionization. Discrimination against higher molecular weight species resulting from the use of a split injector was corrected by means of analyses made on a nonpolar capillary column using on-column injection. Areas obtained on the polar capillary column were grouped according to carbon number (total number of acyl carbons) and renormalized to match the values obtained on the nonpolar column (17).

RESULTS

Phospholipid class composition. The relative composition of lipid classes of the chylomicrons from menhaden oil feeding averaged 8–10% phospholipids, 87–90% triacylglycerols, 1% cholesteryl esters, 0.5% free cholesterol and 0.7% free fatty acids. The smaller particles resulting from the ester feeding contained correspondingly less triacylglycerols and more phospholipids. Table 1 shows the relative proportions of phospholipid classes in the chylomicrons isolated at peak absorption of menhaden oil or the corresponding fatty acid ethyl esters. There are no significant differences in phospholipid composition between the chylomicrons from the oil and ester feeding. In both instances the major components are GPC (80–82%) and GPE (8%), with smaller amounts of other common phospholipids. In addition, the chylomicron phospholipid fraction contained several minor, previously unidentified components of lower polarity, which accounted for about 5% of total in both instances (18). This composition of the phospholipid classes differs from that of the microsomes of the intestinal villus cells by a higher proportion of GPC relative to other phospholipid classes (19,20).

TABLE 1

Relative Proportions of Phospholipid Classes in Chylomicrons from Rats Receiving Menhaden Oil or Corresponding Fatty Acid Ethyl Esters

Phospholipid classes	Chylomicrons[a]	
	Oil-fed	Ester-fed
	Mole %	
GPC	80.6 ± 1.2	82.4 ± 1.0
GPE	8.3 ± 1.7	7.8 ± 0.3
PS	0.1 ± 0.0	0.1 ± 0.0
PI	2.7 ± 0.5	2.6 ± 0.4
PA	1.1 ± 0.3	0.9 ± 0.2
SPH	0.5 ± 0.2	0.5 ± 0.1
LPC	1.6 ± 0.1	1.4 ± 0.2
Other	5.2 ± 0.5	4.2 ± 0.4

[a]Mean ± S.D. from six determinations.

Fatty acid composition of phospholipids. Figure 1 compares the fatty acid composition of GPC and GPE of chylomicrons isolated during the peak absorption of menhaden oil or its fatty acid ethyl esters. The chylomicron GPC from the oil-fed rats contains 26% 16:0, 14% 18:0, 17% 18:2, 10% 20:4 and 11% 20:5 as major components. This composition is similar to that obtained for the chylomicron GPC of the ester-fed animals. The chylomicron PE from the oil-fed animals contains 11% 16:0, 29% 18:0, 11% 18:2, 13% 20:4, 8% 20:5 and 12% 22:6 as major components, which agrees well with the fatty acid composition of the chylomicron GPE from the ester fed animals. There are marked differences, however, in the fatty acid composition between the GPC and GPE. Specifically, the GPC readily took up the 20:5, but not the 22:6 acid, while the GPE readily took up both 20:5 and 22:6 acids. The chylomicron GPC and GPE retained high proportions of 18:0, 18:2 and 20:4n-6 acids, which were largely absent from the fish oil (17). Furthermore, certain fatty acids (14:0, 16:3, 16:4, 18:4 and 20:4n-3), which occur in moderate concentrations in the fish oil, did not appear at all in the chylomicron phospholipids.

Other analyses showed that the relative proportions of the endogenous fatty acids decreased and those of exogenous (dietary) fatty acids increased with the progress of fat absorption. Thus the 18:2 content of the chylomicron GPC in the oil fed animals decreased to 18% from an initial value of 37%, while the content of 20:4 decreased to 8% from a fasting value of 11% over a period of 0–9 hr. By comparison, the contents of 20:5 and 22:6 increased from 0.7 to 13.5% and 0.6 to 2.2%, respectively, in the same period of time, with other acids showing lesser

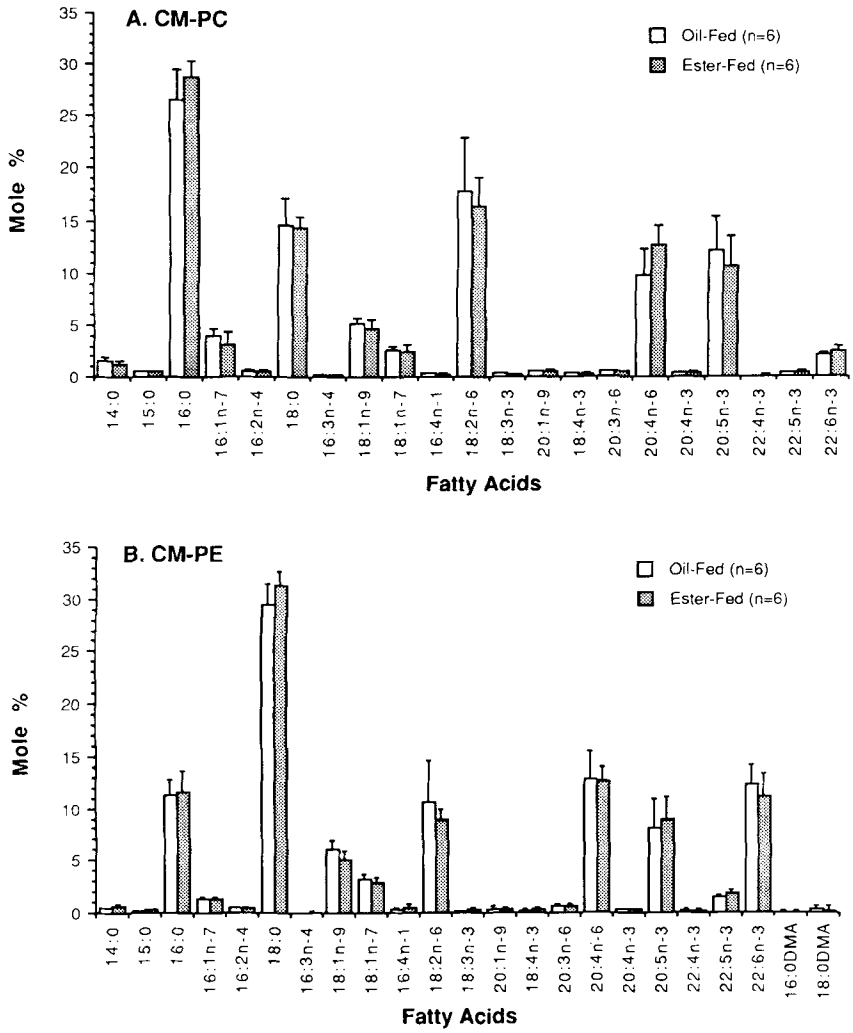

FIG. 1. Fatty acid composition of chylomicron GPC and GPE from rats receiving menhaden oil (open bars) or its fatty acid ethyl esters (hatched bars). The values are means from six determinations for each type of feeding.

differences. Similar trends took place in the composition of the fatty acids of chylomicron GPE from the oil fed animals, and in the GPC and GPE fatty acids of chylomicrons of the ester fed animals (results not shown).

Figure 2 compares the positional distribution of the fatty acids in the chylomicron GPC from the oil and ester fed animals. It confirms the usual location of saturated acids in the *sn*-1 position, a nearly equal distribution of n-9 monoenoic acids between the *sn*-1 and *sn*-2 positions, and the nearly exclusive location of the polyunsaturated fatty acids in the *sn*-2 position. There are a few exceptions among the minor acids. Thus, 14:0 was distributed about equally between the *sn*-1 and *sn*-2 positions. Also, small amounts of long-chain polyunsaturated acids were found in the *sn*-1 position. A similar pattern was seen for the chylomicron GPC from the ester fed animals. On the basis of the association of acids in the molecular species (see below) a similar positional distribution of fatty acids appeared to be present in GPE.

Figure 3 compares the fatty acid composition of PI and PS in the chylomicrons from the two types of feeding. The fatty acids of PI are characterized by a high proportion of 18:0 and 20:4n-6 acids. The fatty acids of PS are somewhat closer in composition to the fatty acids of PE than to any other phospholipid class. The chylomicrons from the oil-fed animals contain a significantly higher proportion of 18:2 in the PI and PS than the ester-fed animals which, in this case, can be attributed to incomplete clearance of the corn oil used in prefeeding. Neither of these phospholipids contains any alkenyl species, as indicated by the absence of dimethylacetals.

Figure 4 gives the fatty acid composition of chylomicron GPC and GPE from rats receiving mustardseed oil or its fatty acid methyl esters. Again, a very close similarity is

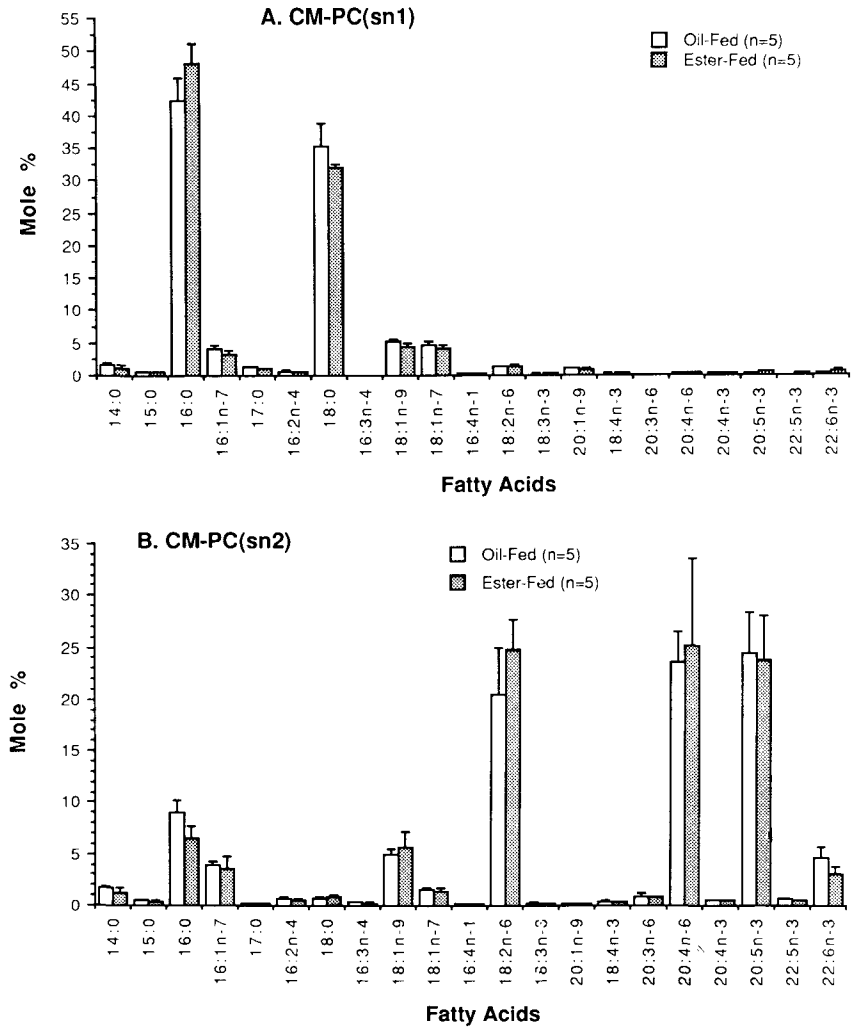

FIG. 2. Positional distribution of fatty acids in chylomicron GPC from rats receiving menhaden oil (open bars) or its fatty acid ethyl esters (hatched bars). The values are means of five determinations from each type of feeding.

found between the GPC samples isolated from the chylomicrons of the oil and the ester fed animals. Likewise, the fatty acids of the GPE are similar for the oil and ester fed animals. In contrast, the fatty acid compositions of the GPC and GPE are markedly different during the oil or ester feeding. Thus, while the GPC contained 25% 16:0, 14% 18:0, 7% 18:1, 32% 18:2 and 9% 20:4, the GPE contained 9% 16:0, 27% 18:0, 13% 18:1, 17% 18:2 and 14% 20:4. Erucic acid, 22:1n-9 (27% of total mustardseed oil), was only sparingly incorporated (less than 2%) into either GPC or GPE. In general, the chylomicron GPC and GPE from the mustardseed oil-fed animals contained the same major fatty acids as the chylomicron GPC and GPE from the fish oil-fed animals, except that those of the mustard seed oil-fed animals contained less 20:5 and 22:6.

Likewise, the fatty acid composition of chylomicron GPC from rats receiving corn oil or its free fatty acids showed only minor differences (Table 2). There was, however, a significant increase in the dietary 18:2 content of both GPC and GPE, when compared to fish oil feeding. On corn oil, the GPC contained about 40% 18:2 and GPE 28% 18:2, with the other acids occurring in their characteristic proportions. The distinct differences between the GPC and GPE were retained again. The GPE samples from corn oil feeding were investigated in detail for differences in the alkylacyl- and alkenylacyl-glycerol moieties following oil feed (see below).

Molecular species of chylomicron GPC and GPE. Figure 5A shows the polar capillary GLC profile of the diacylglycerol moieties of chylomicron GPC from fish oil feeding. A similar GLC profile was obtained for the GPC from ester feeding. The corresponding quantitative values are given in Table 3. The major molecular species of GPC are 16:0-18:2 (11-15%), 18:0-18:2 (11%), 16:0-20:4 (11-13%), 16:0-20:5 (13-15%), 18:0-20:4 (8-11%) and 18:0-20:5 (7-9%). The long-chain polyunsaturated fatty acids have been paired mainly, but not exclusively, with the 16:0 and 18:0 acids. Figure 5B shows the polar

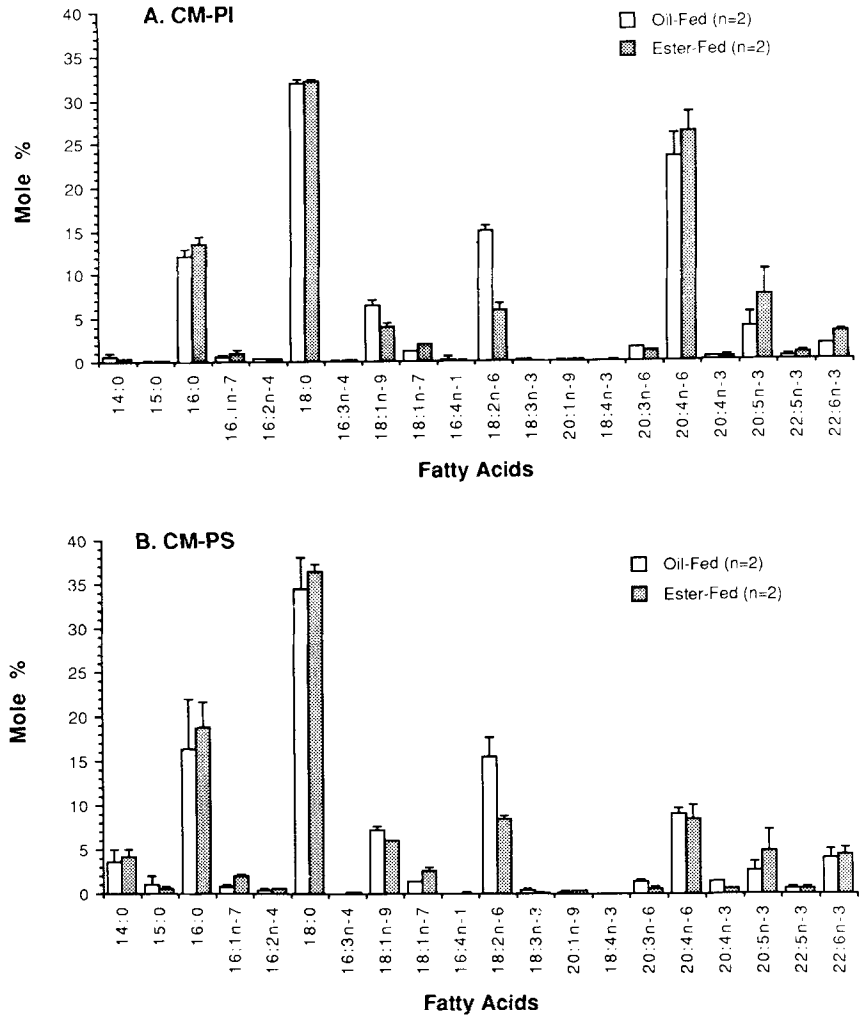

FIG. 3. Fatty acid composition of chylomicron PI and PS from rats receiving menhaden oil (open bars) or its fatty acid ethyl esters (hatched bars). The values are means of two determinations for each type of feeding.

capillary GLC profile of the diacylglycerol moieties of chylomicron GPE from fish oil feeding. Again, a similar profile was obtained for the GPE from ester feeding. The quantitative values are given in Table 3. The major species of GPE are 18:0-18:2 (9-13%), 18:0-20:4 (23-24%), 18:0-20:5 (13-16%) and 18:0-22:6 (14%), with smaller amounts of the 16:0-20:4 (4.4-5.5%), 18:0-18:1 (3-4%), 16:0-20:5 (4%) and 18:1-22:6 (1-4%). A high proportion of GPE, just like GPC, contains molecular species made up exclusively of endogenous fatty acids (18:2 and 20:4 combined with 16:0 and 18:0). There are no significant differences in the molecular species of GPC and GPE between the chylomicrons from the oil- and ester-fed animals. However, in all instances there are large differences between the GPC and GPE species.

Figure 6 depicts the polar capillary GLC profiles of the diacylglycerol moieties of chylomicron PC and PE from mustardseed oil administration. The quantitative values are given in Table 4 along with the corresponding values for the chylomicron phospholipids from the ester feeding. While the oil and ester feeding yielded similar molecular species for the corresponding GPC and GPE, the GPC and GPE differed markedly in their composition. Thus, while the GPC contained about 30% 16:0-18:2, 18% 18:0-18:2 and 6% 18:0-20:4 as major species, the GPE contained 4% 16:0-18:2, 20% 18:0-18:2 and 21% 18:0-20:4 as major species. Other differences were seen in the proportions of the minor species. Both GPC and GPE of the chylomicrons differed greatly from GPC and GPE of the microsomes of intestinal villus cells (19).

A detailed study of the ether lipid content of chylomicron GPE was undertaken only for corn oil feeding, for which microsomal GPE data are already available (19). Corn oil and free acid feeding led to closely similar fatty acid composition of chylomicron GPC and GPE (Table 2). Figure 7 shows the carbon number distribution of the alkenylacyl, alkylacyl and diacylglycerol moieties of chylomicron GPE from the

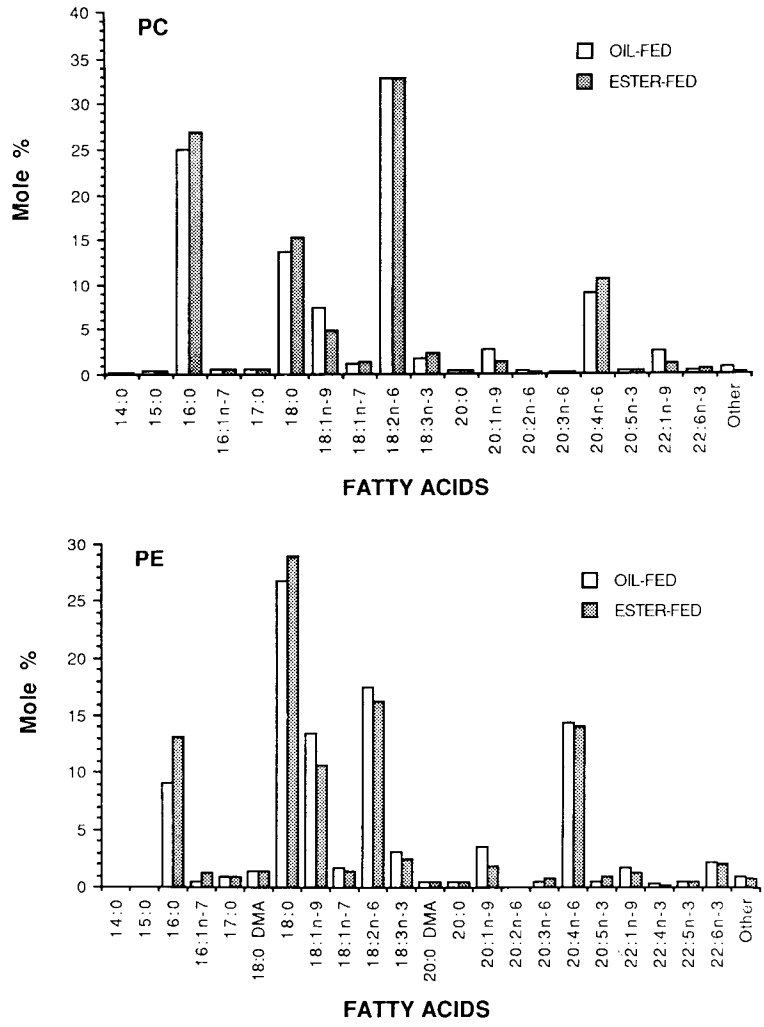

FIG. 4. Fatty acid composition of chylomicron GPC and GPE from rats receiving mustard-seed oil (open bars) or its fatty acid methyl esters (hatched bars). The values are single determinations from each type of feeding.

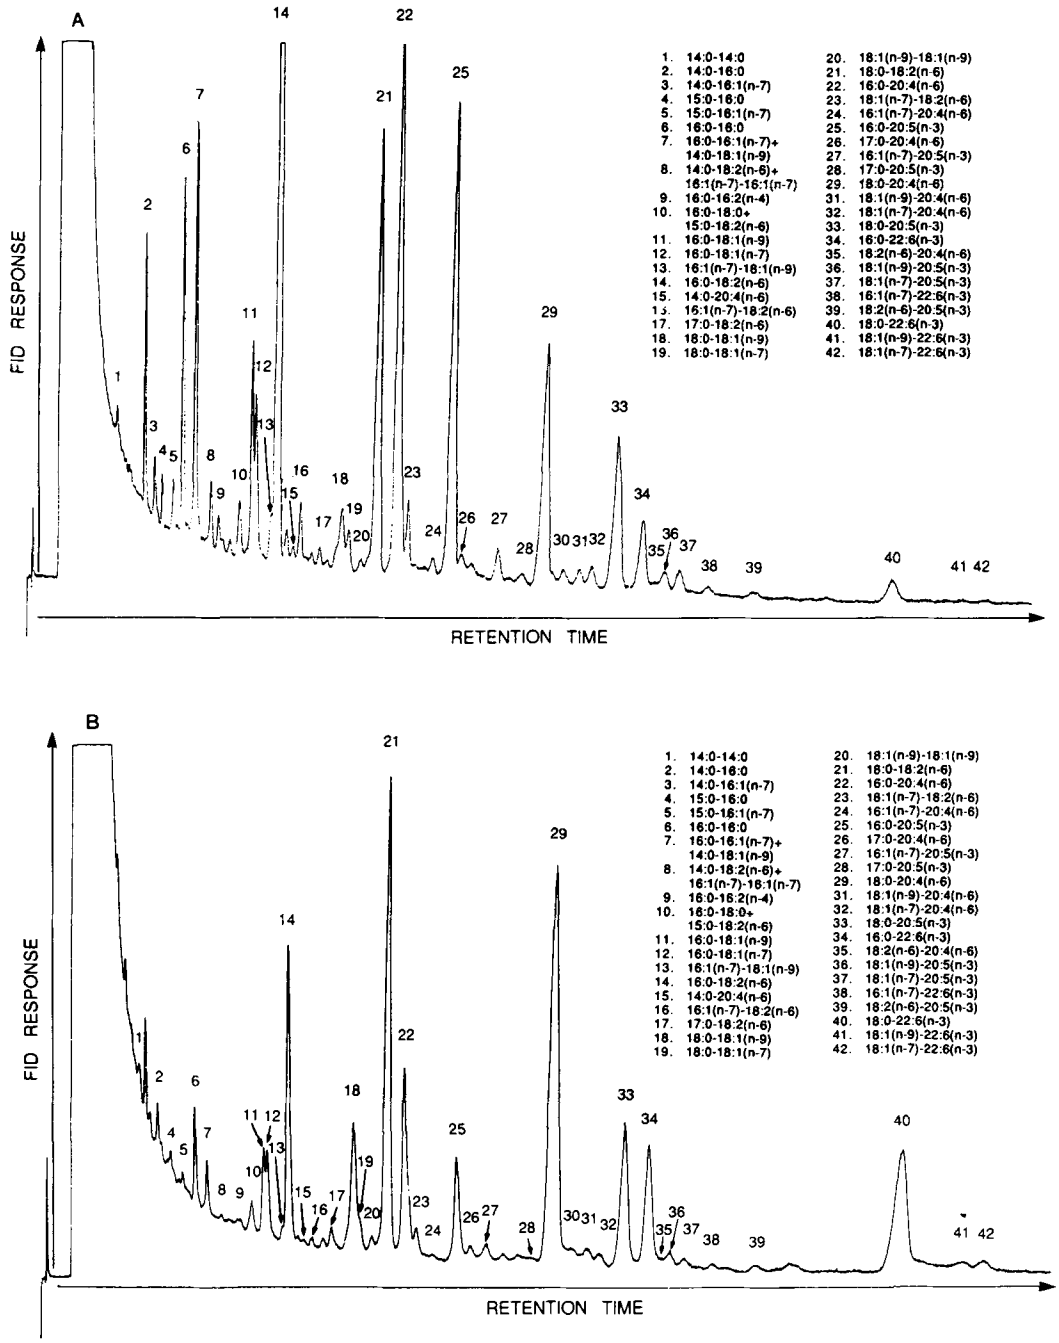

FIG. 5. Polar capillary GLC profiles of the diacylglycerol moieties of chylomicron GPC (A) and GPE (B) from rats receiving menhaden oil. Peak identification as given in Figure. GLC conditions: Column, 15 m × 0.32 mm ID fused silica capillary coated with cross-bonded RTx2330; carrier gas, H_2, 2 psi head pressure; injector split ratio, 7:1; temperature, 260°C, isothermal. Instrument and other GLC conditions are as given in text. Sample: 1 μL of 0.1% diacylglycerol TMS ethers in hexane.

corn oil fed rats as obtained by nonpolar capillary GLC after a prior resolution of the subclasses by normal phase HPLC. The GPE preparation contained 88% diacyl, 6.3% alkylacyl and 5.4% alkenylacyl subclasses. In comparison to the microsomal GPE (19), the chylomicron GPE contains less of the alkylacyl and alkenylacyl species. There are major differences in the carbon number distribution between the diacyl and alkylacyl or alkenylacyl subclasses of GPE. While the diacyl species are made up of 50% C_{36}, 21% C_{38} and 10% C_{34}, the alkenylacyl and alkylacyl species also contain large proportions of the C_{40} (25–34%), C_{42} (14%) and some C_{44} (1%) species. These dif-

ferences are best illustrated by the polar capillary GLC profiles shown in Figure 8. The corresponding quantitative values are given in Table 5. While the composition of the molecular species of the diacylglycerol GPE (Fig. 8A) is characterized by the presence of the common 16:0-18:2 (8%), 18:0-18:2 (30%) and 18:0-20:4 (19%) as major components, the molecular species of the alkylacyl GPE (Fig. 8B) are unusual in the high content of the long-chain polyunsaturated acids. Thus, alkylacyl GPE contains 20:0-18:1 (8%), 20:0-20:4 (13%), 18:0-22:4 (7%), 20:0-22:4 (5%) and 20:0-22:5 (22:6) (total of 7%), along with smaller proportions of the other long-chain polyunsaturated species. Alkenylacyl GPE (Fig. 8C) contains high proportions of the long-chain polyunsaturated species such as 16:0-22:4 (4%), 20:0-20:4 (9%), 18:0-22:4 (8%), 18:0-22:6 (7%), 18:0-22:5 (6%), 20:0-22:4 (4%), 20:0-22:6 (4%), and 20:0-22:5 (3%).

DISCUSSION

The phospholipid class composition of chylomicrons found in this study is comparable to that observed earlier

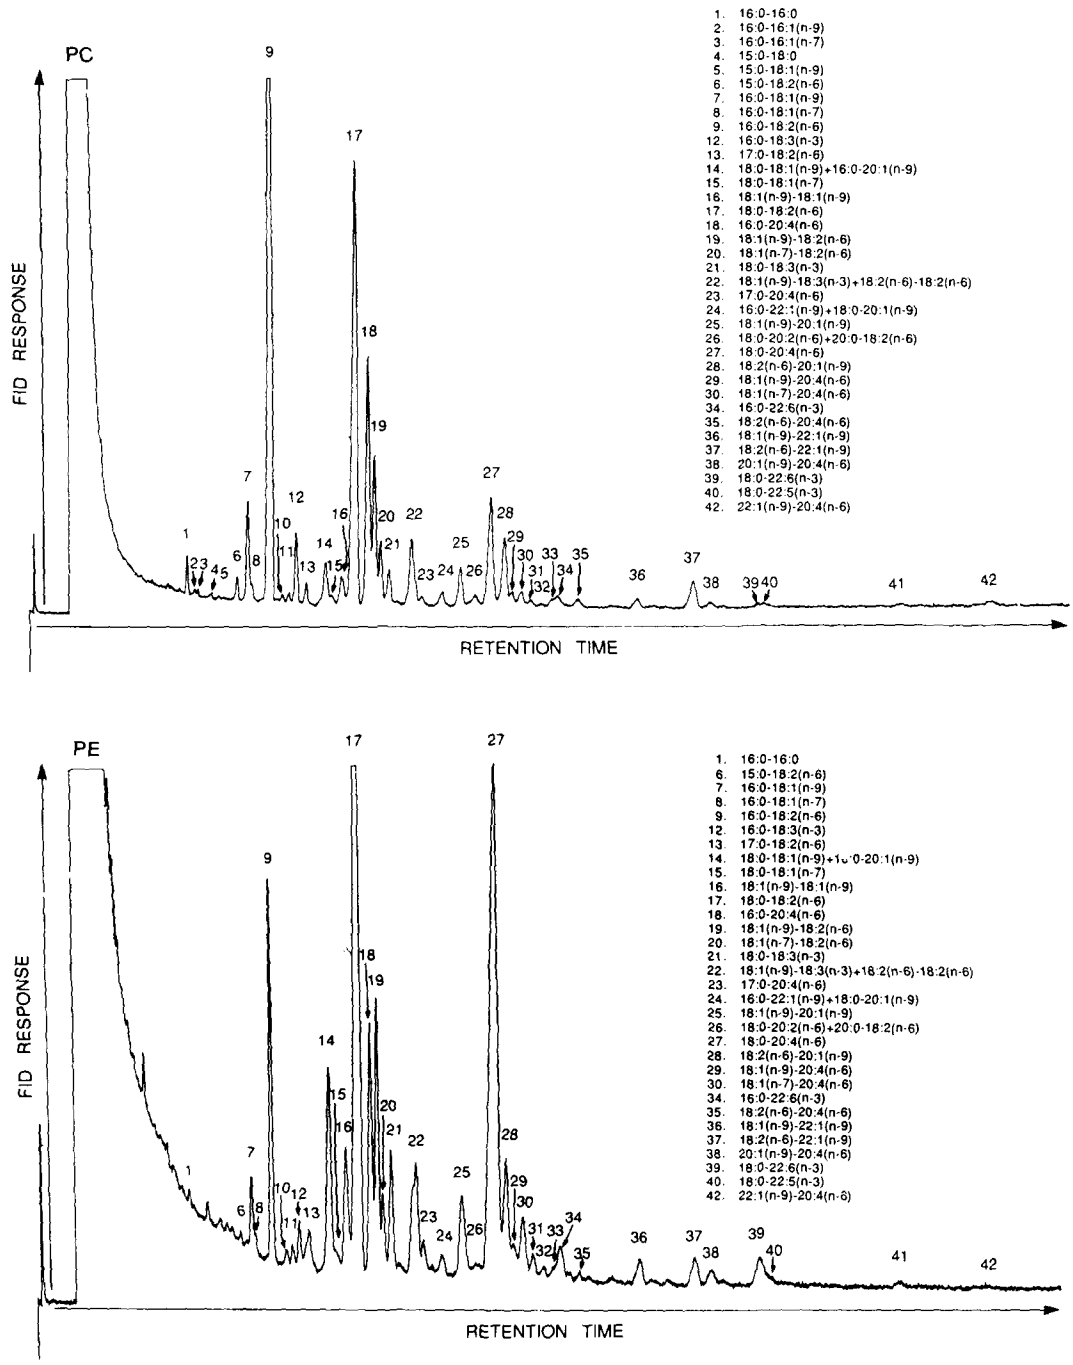

FIG. 6. Polar capillary GLC profiles of the diacylglycerol moieties of chylomicron GPC or GPE from rats receiving mustardseed oil. Peak identification as given in Figure. GLC conditions: Column, 10 m × 0.32 mm ID open tubular glass capillary wall-coated with SP-2330 liquid phase; carrier gas, H_2, 5 psi head pressure; injector split ratio, 7:1; temperature, 260°C, isothermal. Instrument and other GLC conditions are as given in text. Sample: 1 μL of 0.1% diacylglycerol TMS ethers in hexane.

during mustardseed oil feeding (11). The values for the major components are similar to those obtained by Redgrave (21), who, however, reported 6% PA. The PA levels estimated in the present study never exceeded 1%, although other minor polar lipids were isolated from all chylomicron preparations (18). The phospholipid class composition of the chylomicrons differs from that of the villus cells (20), which contain 50% GPC, 27% GPE, 6% PI, 2.7% PS and 2% SPH, and their microsomes (21), which are made up of 45% GPC, 20% GPE, 16% LPC, 8% SPH and 8% PI. Redgrave (21) also reported prechylomicrons to contain 50% GPC, 12% GPE, 11% LPC, 6% SPH, 10% PA and 7% PI. On the basis of these studies, the GPC/GPE ratio changes from 2 to 4 to 10

[a]GPE^0; 1,2-diacyl-*sn*-GPE; GPE′; 1-alkyl,2-acyl-*sn*-GPE; GPE″; 1-alkenyl, 2-acyl-*sn*GPE. GPE subclasses from the same chylomicron preparation.

when proceeding from the microsomes to prechylomicrons and chylomicrons, respectively. The microsomal GPE also contained 11–16% alkylacyl and 4–8% alkenylacyl subclasses (19), which occurred in the chylomicrons to a lesser extent (5–6% each). The phospholipids of chylomicrons are also different from those of rat plasma, which contains less GPC (63.9%) and GPE (1.3%), but much more LPC (22.7%), SPH (7.7%) and PI (4.3%) (22). These results indicate that lymph chylomicron phospholipids did not originate from microsomal phospholipids or from exchange with the plasma phospholipids that may have been filtered into the lymph.

The pathway of triacylglycerol synthesis may influence the phospholipid composition of the chylomicrons at the originial site of synthesis, or the final stage of assembly, or both. Since the synthesis takes place in the smooth (MG pathway) or rough (PA pathway) endoplasmic reticulum, depending on the nature of dietary fat, the phospholipid composition of the resulting chylomicrons would vary, assuming that the two microsomal membranes differed in their lipid composition (23). Differences in the surface phospholipids could also result if the triacylglycerols from the PA pathway were stored prior to secretion (6). Finally, the two microsomal membranes would be expected to exhibit differences in the utilization of dietary fatty acids due to differences in the enzyme specificity. The present study demonstrates great similarity in the phospholipid class and molecular species composition between the chylomicrons resulting from the oil and ester feeding. Hence these phospholipids must have been derived from the same pool of precursors during the formation and secretion of chylomicrons regardless of the metabolic origin of the triacylglycerols. This study confirms the previously demonstrated (24,25) strong dietary influence on the fatty acid and molecular species composition of GPC of lymph chylomicrons. The dietary influence is also seen in GPE, but not in PS and PI.

Previous work has shown (26–28) that chylomicron GPC originates largely from dietary and bile GPC, which are hydrolyzed to LPC in the intestinal lumen. The absorbed LPC is reacylated to GPC in the microsomes of the villus cells and incorporated into chylomicrons at one or more stages of the assembly. Scow *et al.* (26) have demonstrated that during oil feeding some 40% of the GPC of lymph chylomicrons retain the radio-label present in the lumenal (dietary plus biliary) GPC. Likewise, Parthasarathy *et al.* (27) observed that 52% of dietary GPC could be recovered from intestinal mucosa. Mansbach (28) has suggested that up to 100% of the chylomicron GPC may come from exogenous sources, depending on the dietary condition. Since the bile GPC is converted into LPC during intestinal absorption, a direct comparison is not appropriate between the molecular species of bile and chylomicron GPC. However, a comparison may be made between the ratios of 16:0 and 18:0, which are retained in the *sn*-1 position of the two types of GPC. Patton *et al.* (25) reported that based on the newly synthesized species, at least 20% of GPC is synthesized *de novo* under the condition of pure triacylglycerol feeding, which is similar to the results of the present experiment. We calculated a 16:0/18:0 ratio of 70:30 from rat bile GPC. This compares to 55:45 and 57:43 for the GPC of chylomicrons upon oil and ester feeding, respectively, which suggests that at least 15% of GPC came from *de novo* synthesis in this case as well. Under comparable conditions, the 16:0/18:0 ratio of the microsomal GPC (19) was 60:40. This indicates that neither the chylomicrons nor the microsomes correspond directly to the bile in the 16:0/18:0 ratio of the corresponding GPC. The biosynthesis and utilization of the selected molecular species of GPC for intestinal lipoprotein formation in the rat has been investigated by Arvidson and Nilsson (24) and Patton *et al.* (25). Patton *et al.* (25) have concluded that GPC incorporated into lymph HDL, VLDL and chylomicrons originate from different metabolic pools and/or different mechanisms, including *de novo* synthesis. The selectivity for chylomicron GPC species was the same in both pathways of triacylglycerol synthesis in the present study.

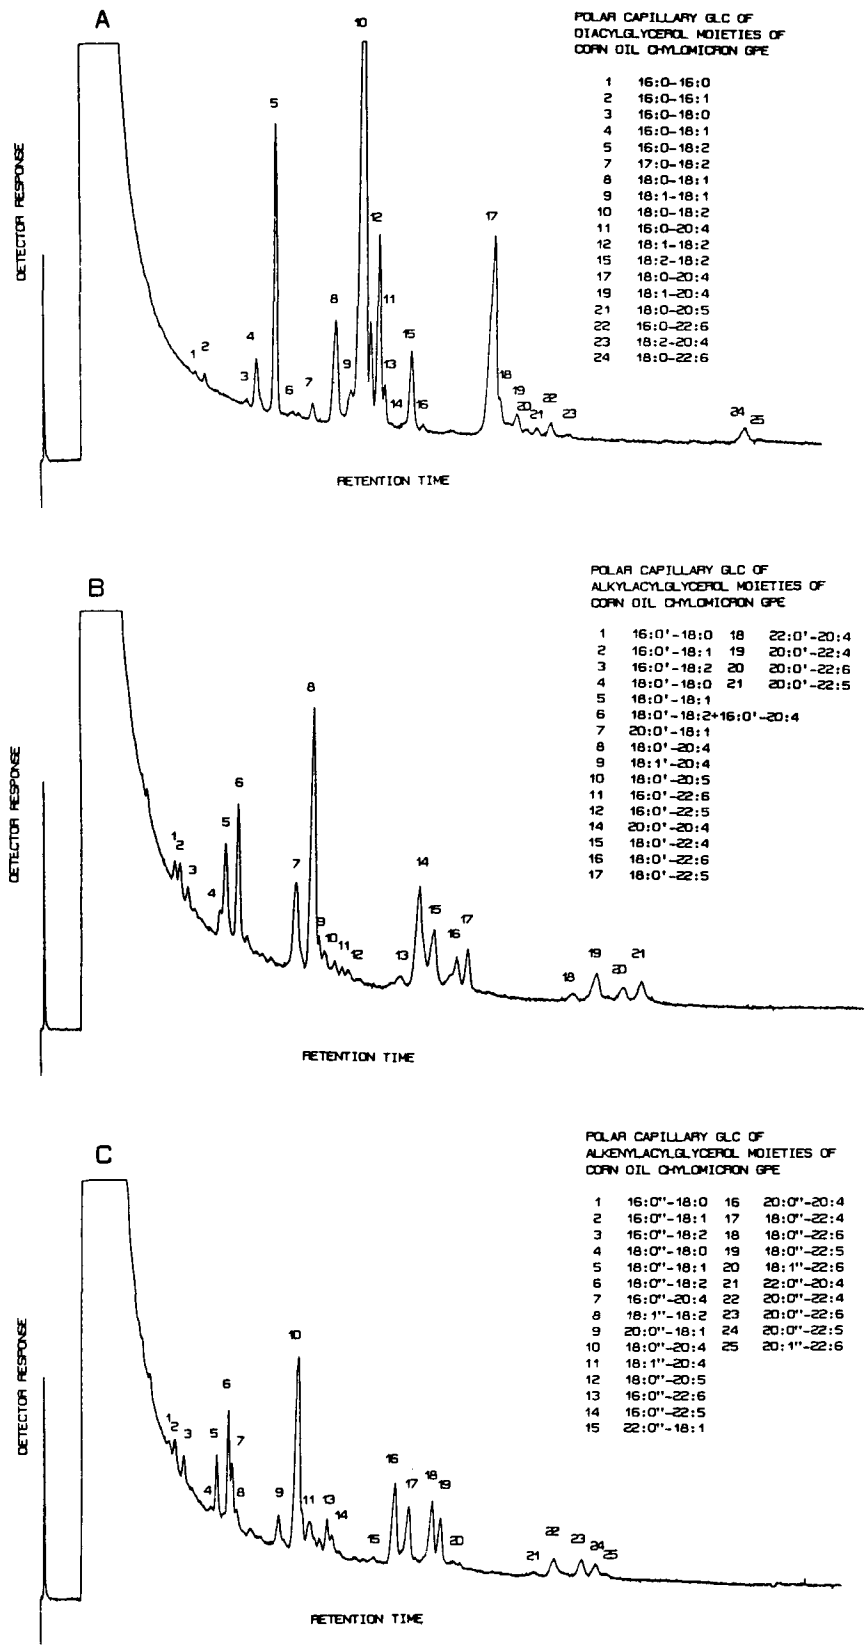

FIG. 8. Polar capillary GLC profiles of the diacyl (A), alkylacyl (B) and alkenylacyl (C) glycerol moieties of chylomicron GPC from rats receiving corn oil. Peak identification as given in Figure. GLC conditions as given in Figure 5.

Patton *et al.* (29) have demonstrated that GPC exchange can occur between chylomicrons and other lymph lipoproteins. Although the individual molecular species of GPC were noted to exchange at different rates, nearly complete equilibration of both radiolabel and mass was found after 24 hr. According to Higgins and Fieldsend (30), only a small amount of phospholipid may become associated with the triacylglycerol particles during transfer to the Golgi. The bulk of GPC would then be added just prior to the secretion of the mature chylomicrons in the Golgi, as suggested for VLDL secretion by rat liver (30-32).

The origin of chylomicron GPE has received much less experimental attention and has remained largely uncertain. The GPE values obtained for chylomicrons by Redgrave (21) and in the present studies are similar to those reported for rat bile by Kawamoto *et al.* (33), who has also detected small amounts of PS, PI and SPH in rat bile. Landin and Nilsson (34) have observed a rapid clearance of radiolabeled GPE from chylomicrons after intravenous infusion, which apparently accounts for the low level of GPE in plasma chylomicrons. Some or all of the chylomicron GPE could have come from absorption and reacylation of LPE or from *de novo* synthesis. Vance and Vance (35) have demonstrated that in hepatocytes, GPE derived from PS is preferentially used as a source of surfactant for lipoproteins, while GPE derived from ethanolamine is rejected. Also, GPE may have served as a precursor of chylomicron GPC, as the methylation pathway has been shown (36) to contribute to lipoprotein phospholipid secretion in hepatocyte cultures deficient in choline. The present work demonstrates that the mass composition of chylomicron GPE is more closely related to that of chylomicron PS than GPC in an apparent agreement with the conclusion of Vance and Vance (35), based on a study on hepatocyte VLDL. The present work also shows that chylomicron GPE contains lesser amounts of the alkylacyl and alkenylacyl species than the microsomal GPE (19).

In conclusion, this study demonstrates that the chylomicron triacylglycerols synthesized during absorption of mixed fatty acids as the glyceryl or ethyl esters possess identical surface phospholipids. This coincides with the earlier demonstrated identity in the apoprotein composition (8) and the recently shown (9) similarity in the fatty acid composition of the *sn*-1 and *sn*-3 positions of the chylomicron triacylglycerols. This work supports the idea that only a single type of chylomicrons is generated by the intestinal villus cells regardless of the nature of the dietary fat.

Compositional Changes and Apoprotein A-I Metabolism of Plasma High Density Lipoprotein in Estrogenized Chicks

B.H. Simon Cho* and **Jeong R. Park**

Department of Food Science and Division of Nutritional Science, University of Illinois, Urbana, Illinois 61801, and Harlan E. Moore Heart Research Foundation, Champaign, Illinois 61820

The effect of estrogen on compositional changes, apolipoprotein (apo) A-I metabolism and the morphology of plasma high density lipoprotein (HDL) were investigated in chicks. The administration of 17β-estradiol (25 mg/kg body weight) to growing male chicks (8-week-old) markedly reduced the concentrations of plasma HDL components, except for triglyceride (TG). At the same time, levels of TG, total cholesterol (TC) and phospholipid (PL) in plasma were greatly elevated. The respective values for TG, TC, PL and protein in HDL were 13.9, 89.3, 154.1 and 231.7 (mg/dL) in the control, and 39.0, 35.1, 113.8 and 160.0 (mg/dL) in chicks upon estrogen treatment for one day. *In vivo* kinetic studies showed that the fractional catabolic rate of HDL apo A-I was significantly higher ($p<0.05$) in estrogen-treated chicks than in control birds, indicating an increased efficiency of HDL removal in the former. The production rate of HDL apo A-I also was significantly lower ($p<0.05$) in estrogen-treated chicks. Sodium dodecyl sulfate-acrylamide gel electrophoresis followed by laser scanning densitometry of HDL apolipoproteins in estrogen-treated chicks revealed a reduction of apo A-I and the occurrence of new apolipoproteins which had been absent in HDL of untreated birds. The HDL particles showed that the mean particle size of HDL became larger upon estrogen treatment. Particles with diameters between 70 and 123 Å were predominant in HDL of control chicks, while particles with diameters between 97 and 143 Å were most abundant in HDL of estrogen-treated chicks.

***Lipids 26,* 819–823 (1991).**

High density lipoprotein (HDL) levels in plasma have received considerable attention because they have been shown to correlate inversely with the risk of coronary heart disease (1,2). The anti-atherogenic effect of HDL has been associated to its ability to remove cholesterol from peripheral tissues, a process generally referred to as reverse cholesterol transport (3,4). The concentration of plasma HDL is related to age and sex of the individual (5), to sex steroids (6,7), hypertriglyceridemia (8), obesity (9), cigarette smoking (10), dietary composition (11), alcohol intake (12), exercise (13), and hypolipidemic drug therapy (14). A significant rise in HDL is also noted when estrogen is given to humans (6,7). The elevation of plasma HDL by estrogen therapy occurs mainly in the HDL_2 subclass (15). In contrast to humans, the administration of estrogen to chickens has been shown to decrease the level of plasma HDL (16,17). Estrogen administration to chickens also causes massive hypertriglyceridemia along with a significant rise in plasma very low density lipoprotein (VLDL) levels, as has also been shown in humans (18).

Since in avian species estrogen administration causes both qualitative and quantitative changes in plasma lipoproteins, the chick is a good model for the study of estrogen effects on lipoprotein metabolism. In the present study, we have examined the turnover of HDL apolipoprotein (apo) A-I in chicks upon estrogen treatment. Plasma HDL was isolated from untreated chicks and then labeled *in vitro* with radioactive iodine. The ^{125}I-labeled HDL was reinjected into control and estrogen-treated chicks, and HDL apo A-I kinetics were studied *in vivo*. In addition, the concentrations of lipids and protein in the HDL fractions were monitored, and the size of HDL particles was determined by electron microscopy.

MATERIALS AND METHODS

Isolation of plasma high density lipoprotein (HDL). Blood samples from male crossbred 8-week-old (New Hampshire male × Colombian female) chickens were drawn *via* wing vein into glass tubes containing ethylenediaminetetraacetic acid tetra sodium salt (EDTA) (1 mg/mL blood). Plasma was separated from the blood by low speed centrifugation at 1,000 × *g* for 30 min at 4°C. Plasma was adjusted to d = 1.063 g/mL by adding NaCl/NaBr solution, and was centrifuged at 115,000 × *g* for 20 hr at 10°C in a Beckman model L5-50 Preparative Ultracentrifuge (Palo Alto, CA). After centrifugation, the top layer containing lipoproteins (d<1.063 g/mL) was removed and the infranatant fraction was recentrifuged to remove the contaminating lipoproteins of d<1.063. The infranatant fraction was then adjusted to d = 1.21 g/mL with a NaCl/NaBr solution and centrifuged for 24 hr. The top layer containing HDL was harvested and washed once by recentrifugation. The HDL isolated was dialyzed against 0.15 M NaCl containing 0.01% EDTA (pH 7.0), using 3–4 changes. The purity of the HDL preparation was examined by agarose gel electrophoresis (19). The protein content of the HDL was determined by the method of Lowry *et al.* (20) as modified later (21).

Radioiodination of HDL. The HDL preparation was labeled with ^{125}I (carrier-free from New England Nuclear, Boston, MA) by the iodine monochloride method of McFarlane (22) as modified by Fidge and Poulis (23). HDL was brought to pH 10 by dialysis against 0.4 M glycine/NaOH buffer (pH 10), and then 2 mL (10 mg protein) was added to a mixture of 50 μL of 60 mM iodine monochloride in 2 M NaCl and 50 μL of ^{125}I in dilute NaOH (100 μCi) at 4°C. The solution was mixed immediately by vortexing. Unlabeled iodine was removed by dialysis against 100 vol of 0.15 M NaCl and 0.01% EDTA solution (pH 7.4) for more than 5 hr, with batches being changed every 20–30 min. After dialysis, small aliquots of labeled HDL were removed to determine radioactivity and its distribution, and the remainder was sterilized

Abbreviations: apo, apolipoprotein; EDTA, ethylenediaminetetraacetic acid; FCR, fractional catabolic rate; HDL, high density lipoprotein; LDL, low density lipoprotein; PL, phospholipid; SDS, sodium dodecyl sulfate; TC, total cholesterol; TG, triglyceride; VLDL, very low density lipoprotein.

by passing through a 0.45 μm Millipore filter (Millipore Corp., Bedford, MA). The efficiency of iodination was 29.4%. Characterization of ^{125}I-labeled HDL showed that 97.4% of radioactivity was precipitated by 10% trichloroacetic acid, and 1.1% was extracted with chloroform/methanol (2:1, v/v). The ^{125}I-labeled HDL had the same electrophoretic mobility on agarose gel electrophoresis as unlabeled HDL.

Kinetic study. One day before the study, 8-week-old chicks were treated subcutaneously with 17β-estradiol (25 mg/kg body weight) in propylene glycol (carrier alone for control chicks). After overnight fasting, blood samples were drawn from control and estrogen-treated chicks and were used for lipoprotein isolation and chemical analysis. Labeled HDL (1-2 μCi, 1-2 mL vol) was then injected into the birds *via* a wing vein. Subsequently, 2-mL blood samples were collected in glass tubes containing EDTA (1 mg/mL blood) at 5, 15, 30, 45, 60, 90, 120, 180 and 210 min. Plasma was separated at 4°C by low speed centrifugation. Small aliquots of plasma were counted for radioactivity in a gamma-ray spectrometer. Plasma was adjusted to d = 1.063 g/mL with a NaCl/NaBr solution and centrifuged for 20 hr at 115,000 × *g* at 10°C. Lipoproteins of d<1.063 g/mL were removed by aspiration of the top 2-mL layer. The infranatant fraction was then adjusted to d = 1.21 g/mL with a NaCl/NaBr solution and centrifuged for 24 hr. The top layer containing HDL was harvested and the HDL isolated was dialyzed against a solution containing 0.15 M NaCl and 0.01% EDTA. HDL apo A-I was then separated by sodium dodecyl sulfate (SDS)-polyacrylamide gel electrophoresis as described below. Apo A-I bands from the gels were sliced and the radioactivity was determined. The radioactivity decay pattern of each sample was plotted on semilogarithmic paper, and the fractional turnover rate (FCR, K) was determined from two time points on the resulting straight line as described by Shipley and Clark (24). The turnover rate of HDL apo A-I was calculated by multiplying K by the total pool of HDL apo A-I per kilogram body weight (K × HDL apo A-I concentration × plasma volume/body weight). The plasma volume was estimated by extrapolating the plasma radioactivity decay curve back to zero time, assuming that the intercept represented total mixing of the injected ^{125}I-labeled HDL.

Sodium dodecyl sulfate (SDS)-polyacrylamide gel electrophoresis. The HDL fraction was delipidized with ice-cold diethyl ether and ethanol. The protein precipitate was washed twice with diethyl ether/ethanol (3:1, v/v), dried under a stream of N_2, and dissolved in 0.2 M phosphate buffer containing 2% SDS and 2-mercaptoethanol. HDL apo A-I was then separated by SDS-polyacrylamide gel electrophoresis using a 10% gel containing 0.1% SDS. Gels were prepared in glass tubes (0.5 cm i.d., 9 cm length) according to Laemmli (25). After electrophoresis, the gel was stained in a solution containing 0.125% Coomassie brilliant blue R-250, 25% methanol and 10% acetic acid. Gels were destained in a solution containing acetic acid (7.5%) and methanol until the background was completely clear. Molecular weights of apoproteins were estimated by plotting log molecular weight *versus* distance of migration of the reference proteins. A typical HDL apoprotein separation is shown in Figure 1. The stained apoproteins were scanned using a laser densitometer (Ultrascan 2022, LKB Instruments, Bromma, Sweden). The percent distribution of apo A-I was calculated as the integrated peak area of the apoprotein divided by the sum of the total peak areas of HDL apoproteins. The apo A-I concentration was calculated by multiplying the total HDL protein concentration by the area percent of apo A-I.

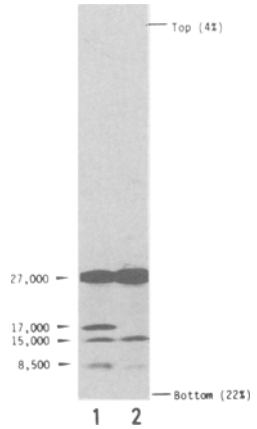

FIG. 1. SDS-polyacrylamide gel electrophoresis of HDL apoproteins of estrogen-treated (lane 1) chicks, and controls (lane 2).

Electron microscopy of HDL. Aliquots of the fresh HDL preparations from control and estrogen-treated chicks were negatively stained with 2% phosphotungstic acid (pH 6.5). The morphology and homogeneity of HDL particles were examined with a Hitachi HU-12 electron microscope (Tokyo, Japan) on carbon-coated Formvar grids.

Lipid analysis. The total and free cholesterol contents of plasma and HDL preparations from control and estrogen-treated chicks were determined using enzymatic cholesterol reagents (Wako Chemical USA, Dallas, TX). Triglyceride values were measured by the method of Foster and Dunn (26). Total phospholipid content was determined by the method of Eng and Noble (27) after digestion of lipid extracts with perchloric acid.

Statistical analysis. Data were analyzed by the difference between means, and statistical significance was based on Student t-test using the SAS program (SAS Institute Inc., Cary, NC).

RESULTS

In the present study we observed that the administration of 17β-estradiol (25 mg/kg body weight) to growing male chicks markedly reduced the plasma HDL concentration (Table 1). At the same time, levels of triglycerides (TG), total cholesterol (TC) and phospholipids (PL) in plasma were greatly elevated. The respective values for TG, TC, PL and protein in HDL were 13.9, 89.3, 154.1 and 237.1 (mg/dL) in the controls, and 39.0, 35.1, 113.8 and 160.0 (mg/dL) in chicks upon estrogen treatment for one day. The ratio of the nonpolar core mass (triglyceride and cholesteryl ester) to the polar surface components of HDL (protein, phospholipid and free cholesterol) was significantly higher ($p<0.05$) in estrogen-treated chicks than in controls (0.25 ± 0.001 *vs* 0.22 ± 0.002), suggesting that the HDL particles in the former may be larger than those

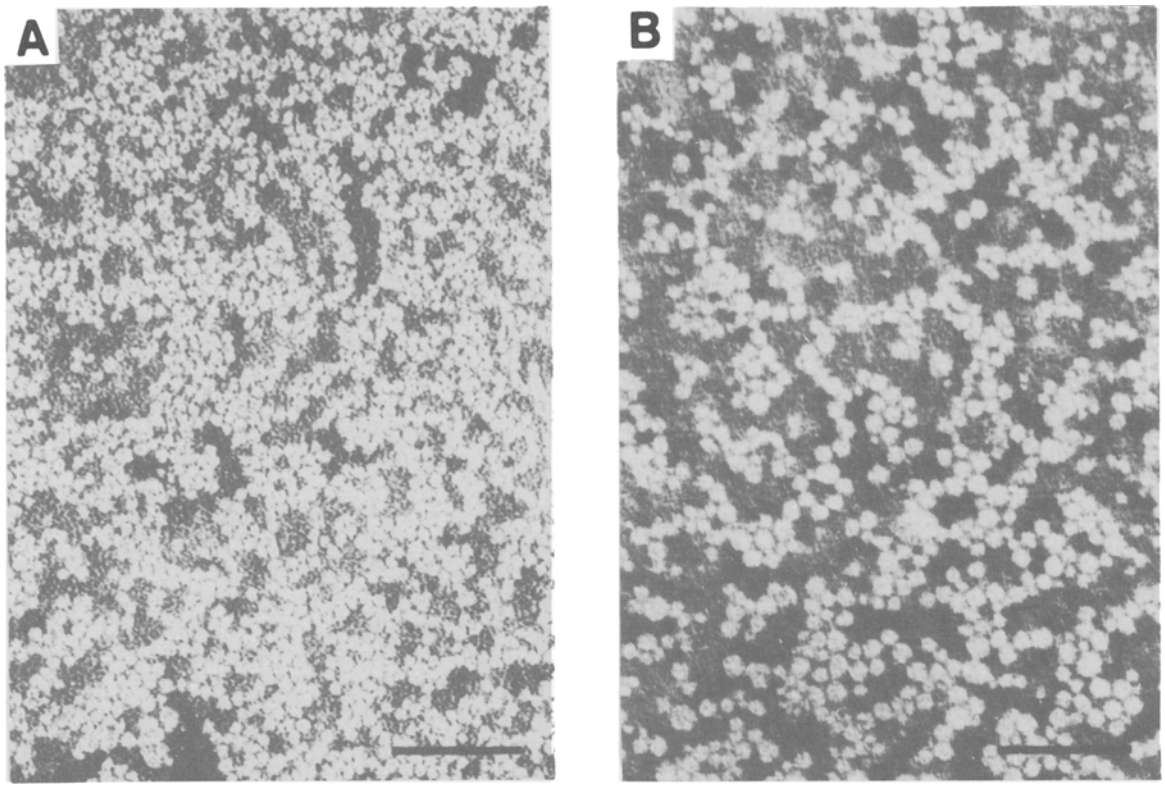

FIG. 2. Electron micrographs of plasma high density lipoproteins from control and estrogen-treated chicks. Panel A, control HDL; Panel B, estrogen-treated HDL. Final magnification is × 150,000.

in the latter. The electron microscopic appearance of HDL particles, as shown in Figure 2, is consistent with the chemical data. The mean particle size of HDL was larger in estrogen-treated chicks than in untreated birds. In control birds, HDL particles with diameters between 70 and 123 Å were predominant, whereas HDL particles with diameters between 97 and 143 Å were abundant in HDL of estrogen-treated chicks.

The separation of HDL apolipoproteins by SDS-acrylamide gel electrophoresis is shown in Figure 1. The HDL apoproteins of untreated birds were resolved into three bands and consisted mainly of apo A-I (molecular weight of 27000), accounting for 81.1% of the total HDL protein as determined by densitometric scanning. In the estrogen-treated chicks, the proportions of HDL apoproteins were significantly altered, with a marked reduction of apo A-I (58.0% of the total HDL protein). New apoproteins, presumably apo VLDL-11, with molecular weights of 8500 and 17000 were also present in HDL of estrogen-treated birds. Consequently, the amount of HDL apo A-I was significantly lower ($p<0.05$) in estrogen-treated chicks than that in controls (83.1 *vs* 174.1 mg/dL). The disappearance of radioactivity from apo A-I of plasma HDL in control and estrogen-treated chicks is shown in Figure 3. The HDL apo A-I metabolism was faster in estrogen-treated chicks than in control birds, with the fractional catabolic rate being significantly higher (Table 2). The production rate of HDL apo A-I was significantly lower

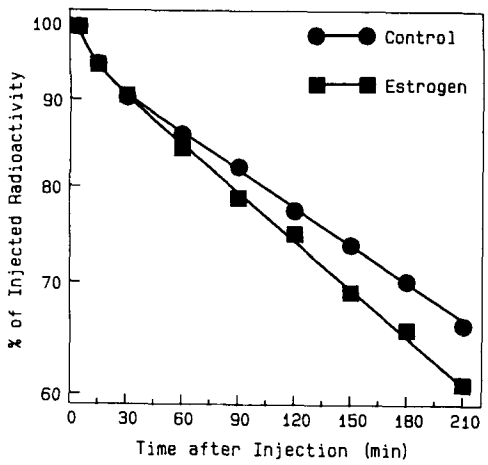

FIG. 3. Radioactivity curves of apoprotein A-I of plasma high density lipoproteins in control and estrogen-treated chicks. Points indicate the average values from 4 birds; control, ●; estrogen-treated, ■.

($p<0.05$) in estrogen-treated chicks than in controls (7.34 *vs* 12.81 mg/hr/kg body weight).

DISCUSSION

Middle-aged women have higher levels of plasma HDL (5) and a lower incidence of coronary heart disease (28) than their male counterparts. Estrogen, a female steroid hormone, has been observed to increase the plasma concentration of HDL, and especially of the HDL_2 subfraction. Estrogen has been shown to suppress hepatic lipase (15), an enzyme thought to be responsible for the catabolism of HDL_2 phospholipid (29).

However, the effect of estrogen on HDL in avian species appears to be opposite to that in humans. Estrogen-induced hyperlipidemia in chicks is characterized by the marked elevation in levels of VLDL and, to a lesser extent, low density lipoprotein (LDL), with a concomitant decrease in HDL (17). The reduction of HDL by estrogen is quite dramatic since HDL comprises almost 90% of the total lipoprotein-associated protein in untreated birds compared to the HDL level of 1–14% in estrogen-treated birds (17,30). The factors causing the decrease in HDL in birds under estrogen treatment are not clear. The decrease in HDL may be a consequence of reduced synthesis of apolipoproteins. Apolipoprotein A-I is a major apolipoprotein in HDL, and the present finding is in agreement with those of others indicating that about 90% of the protein content of HDL is composed of apo A-I in untreated birds (31). Upon estrogen administration, the apolipoprotein composition of HDL undergoes a marked reduction in apo A-I concentration in chick and turkey (30,32). This effect of estrogen in avian species is believed to be the result of decreased apo A-I synthesis causing a reduction in the levels of plasma HDL apo A-I. Since the synthesis of vitallogenin and VLDL are greatly stimulated under estrogenic influence, the synthesis of other plasma proteins, such as apo A-I, may be reduced due to competition at the level of mRNA translation (32). In a mutant strain of chicken which develops a spontaneous HDL deficiency syndrome, the principal metabolic defect has also been attributed to a major reduction in apo A-I production (33). This finding correlates well with a decrease in the concentration of apo A-I in estrogenized chickens (30). However, the reduced apo A-I production rate in the present study does not seem to agree with a previous report by others in which estrogen treatment of chickens did not alter the messenger RNA activity for apo A-I in hepatic polysomes (34). Since HDL apo A-I also originates from intestinal sources, either as nascent HDL or as the surface coat of triglyceride-richy lipoproteins of intestinal origin (35), the mRNA activity for apo A-I in the intestine may also be affected by estrogen.

In addition to reduced synthesis, a reduction in HDL apo A-I could also be due to an increase in apo A-I catabolism. The present finding clearly shows that estrogen-treated birds have a significantly increased fractional catabolic rate for apo A-I in comparison to untreated birds, indicating enhanced removal of apo A-I in estrogenized birds. The enhanced catabolism of apo A-I in estrogenized birds in conjunction with the reduced synthesis of apo A-I may then accentuate the effect of estrogen on the reduction of HDL concentration. This finding of hypercatabolism of HDL is similar to that seen in a mutant strain of chickens which have a deficiency in HDL and apo A-I (33). An increased fractional catabolic rate for triglyceride enriched HDL has also been reported in hypertriglyceridemic patients (36), and the enrichment of HDL with triglyceride may contribute to the increased HDL catabolism. Since estrogen treatment of chickens greatly elevates VLDL triglyceride, the movement of triglyceride from VLDL to HDL may be facilitated by lipid transfer protein (37) resulting in triglyceride enrichment of HDL. The present finding that the TG content of HDL in estrogen-treated chickens was nearly three times higher than that of control birds confirms the enrichment of HDL with triglyceride.

The present study indicates that the overall effects of

TABLE 2

Effect of Estrogen on Plasma Levels, and Fractional Catabolic and Turnover Rates of High Density Lipoprotein Apo A-I in Chicks[a]

Group	Body weight (g)	Plasma volume (mL)	HDL Apo A-I Content (mg/dL)	HDL Apo A-I FCR	HDL Apo A-I Turnover rate (mg/kg/hr)
Control	1423 ± 213	97.6 ± 20.3	174.12 ± 16.22	0.1086 ± 0.0097	12.81 ± 1.39
Estrogen	1570 ± 59	103.2 ± 3.1	83.10 ± 9.47[b]	0.1348 ± 0.0089[b]	7.34 ± 0.72[b]

[b]Significantly different from the control group ($p<0.01$).

estrogen on HDL metabolism are complex, and the reduction of HDL apo A-I concentration in estrogenized male chickens seems to result from decreased production and increased catabolism of this major HDL apolipoprotein.
